3 Ways To Receive
Motorola Semiconductor Technical Information

Literature Distribution Centers

Printed literature can be obtained from the Literature Distribution Centers upon request. For those items that incur a cost, the U.S. Literature Distribution Center will accept Master Card and Visa.

How to reach us:

USA / EUROPE / Locations Not Listed: Motorola Literature Distribution;
P.O. Box 5405, Denver, Colorado 80217. 303–675–2140 or 1–800–441–2447

JAPAN: Nippon Motorola Ltd.; Tatsumi–SPD–JLDC, 6F Seibu–Butsuryu–Center,
3–14–2 Tatsumi Koto–Ku, Tokyo 135, Japan. 81–3–3521–8315

Mfax™: RMFAX0@email.sps.mot.com – TOUCHTONE 602–244–6609

ASIA / PACIFIC: Motorola Semiconductors H.K. Ltd.; 8B Tai Ping Industrial Park,
51 Ting Kok Road, Tai Po, N.T., Hong Kong. 852–26629298

Mfax is a trademark of Motorola, Inc.

Mfax™ – Touch–Tone Fax

Mfax offers access to over 30,000 Motorola documents for faxing to customers worldwide. With menus and voice instruction, customers can request the documents needed, using their own touch–tone telephones from any location, 7 days a week and 24 hours a day. A number of features are offered within the Mfax system, including: product data sheets, application notes, engineering bulletins, article reprints, selector guides, Literature Order Forms, Technical Training Information, and HOT DOCS (4–digit code identifiers for currently referenced promotional or advertising material).

A fax of complete, easy–to–use instructions can be obtained by a first–time phone call into the system, entering your FAX number, and then pressing 1.

How to reach us:

Mfax: RMFAX0@email.sps.mot.com – TOUCH–TONE (602) 244–6609
or via the http://Design–NET.com home page, select the Mfax Icon.

Motorola SPS World Marketing Internet Server

Motorola SPS's Electronic Data Delivery organization has set up a World Wide Web Server to deliver Motorola SPS's technical data to the global Internet community. Technical data such as the complete Master Selection Guide along with the OEM North American price book are available on the Internet server with full search capabilities. Other data on the server includes abstracts of data books, application notes, selector guides, and textbooks. All have easy text search capability. Ordering literature from the Literature Distribution Center is available on–line. Other features of Motorola SPS's Internet server include: the availability of a searchable press release database, technical training information with on–line registration capabilities, complete on–line access to the Mfax system for ordering faxes, an on–line technical support form to send technical questions and receive answers through email, information on product groups, full search capabilities of device models, a listing of the domestic and international sales offices, and direct links to other Motorola world wide web servers. For more information on Motorola SPS's Internet server you can request **BR1307/D** from Mfax or LDC.

How to reach us:

After accessing the Internet, use the following URL:

Analog ICs

Device Data

Vol. I

This publication presents technical information for the broad line of Analog and Interface Integrated Circuit products. Complete device specifications are provided in the form of **Data Sheets** which are categorized by product type into ten chapters for easy reference. **Selector Guides** by product family are provided in the beginning of each chapter to enable quick comparisons of performance characteristics. A **Cross Reference** chapter lists Motorola nearest replacement and functional equivalent part numbers for other industry products.

One chapter is devoted showing all of the **Tape and Reel Options**. All **Packaging Information**, including surface mount packages, is provided in another chapter.

Additionally, chapters are provided with information on **Quality and Reliability Assurance** program concepts, high–reliability processing, and abstracts of available **Applications and Product Literature**.

The information in this book has been carefully checked and is believed to be accurate; however, no responsibility is assumed for inaccuracies.

Motorola reserves the right to make changes without further notice to any products herein. Motorola makes no warranty, representation or guarantee regarding the suitability of its products for any particular purpose, nor does Motorola assume any liability arising out of the application or use of any product or circuit, and specifically disclaims any and all liability, including without limitation consequential or incidental damages. “Typical” parameters can and do vary in different applications. All operating parameters, including “Typicals” must be validated for each customer application by customer’s technical experts. Motorola does not convey any license under its patent rights nor the rights of others. Motorola products are not designed, intended, or authorized for use as components in systems intended for surgical implant into the body, or other applications intended to support or sustain life, or for any other application in which the failure of the Motorola product could create a situation where personal injury or death may occur. Should Buyer purchase or use Motorola products for any such unintended or unauthorized application, Buyer shall indemnify and hold Motorola and its officers, employees, subsidiaries, affiliates, and distributors harmless against all claims, costs, damages, and expenses, and reasonable attorney fees arising out of, directly or indirectly, any claim of personal injury or death associated with such unintended or unauthorized use, even if such claim alleges that Motorola was negligent regarding the design or manufacture of the part. Motorola and Ⓜ are registered trademarks of Motorola, Inc. Motorola, Inc. is an Equal Opportunity/Affirmative Action Employer.

Data Classification

Product Preview

This heading on a data sheet indicates that the device is in the formative stages or in design (under development). The disclaimer at the bottom of the first page reads: ‘‘This document contains information on a product under development. Motorola reserves the right to change or discontinue this product without notice.’’

Advance Information

This heading on a data sheet indicates that the device is in sampling, pre–production, or first production stages. The disclaimer at the bottom of the first page reads: ‘‘This document contains information on a new product. Specifications and information herein are subject to change without notice.’’

Fully Released

A fully released data sheet contains neither a classification heading nor a disclaimer at the bottom of the first page. This document contains information on a product in full production. Guaranteed limits will not be changed without written notice to your local Motorola Semiconductor Sales Office.

Alphanumeric Index and Cross References

In Brief . . .

Motorola Analog and Interface Integrated Circuits cover a much broader range of products than the traditional op amps/ regulators/consumer–image associated with Analog suppliers. Analog circuit technology currently influences the design and architecture of equipment for all major markets. As with other integrated circuit technologies, Analog circuit design techniques and processes have been continually refined and updated to meet the needs of these diversified markets.

Operational amplifiers have utilized JFET inputs for improved performance, plus innovative design and trimming concepts have evolved for improved high performance and precision characteristics. In analog power ICs, basic voltage regulators have been refined to include higher current and voltage levels, low dropout regulators, and more precise three–terminal fixed and adjustable voltages. The power area continues to expand into switching regulators, power supply control and supervisory circuits, motor controllers, and battery charging controllers.

Analog designs also offer a wide array of line drivers, receivers and transceivers for many of the EIA, European, IEEE and IBM interface standards. Peripheral drivers for a variety of devices are also offered. In addition to these key interface functions, hard disk drive read channel circuits, 10BASE–T and Ethernet circuits are also available.

In Data Conversion, a high performance video speed flash converter is available, as well as a variety of CMOS and Sigma–Delta converters. Analog circuit technology has also provided precision low–voltage references for use in Data Conversion and other low temperature drift applications.

A host of special purpose analog devices have also been developed. These circuits find applications in telecommunications, radio, television, automotive, RF communications, and data transmission. These products have reduced the cost of RF communications, and have provided capabilities in telecommunications which make the telephone line convenient for both voice and data communications. Analog developments have also reduced the many discrete components formerly required for consumer functions to a few IC packages and have made significant contributions to the rapidly growing market for electronics in automotive applications.

The table of contents provides a perspective of the many markets served by Analog/Interface ICs and of Motorola's involvement in these areas.

Alphanumeric Index

* = See Communications Device Data (DL136).
\# = Not recommended for new designs.

Alphanumeric Index (continued)

Device Number	Function	Page
MC3405	Dual Operational Amplifier and Dual Comparator	2–129
MC3418	Continuously Variable Slope Delta Modulator/Demodulator	*

MC44603	Mixed Frequency Mode GreenLine PWM Controller	3–667
MC44604	High Safety Standby Ladder Mode GreenLine PWM Controller	3–689
MC44605	High Safety Latched Mode GreenLine PWM Controller for (Multi) Synchronized Applications	3–690
MC44817, B	PLL Tuning Circuit with 3–Wire Bus	9–367
MC44818	PLL Tuning Circuit with I2C Bus	9–374
MC44824, 25	PLL Tuning Circuit with I2C Bus	9–381
MC44826	PLL Tuning Circuit with I2C Bus	9–388
MC44827	PLL Tuning Circuit with 3–Wire Bus	9–395
MC44828	PLL Tuning Circuit with I2C Bus	9–396
MC44829	PLL Tuning Circuit with I2C Bus	9–397
MC44864	PLL Tuning Circuit with 1.3 GHz Prescaler and D/A Converters for Automatic Tuner Alignment	9–405
MC68160	Enhanced Ethernet Transceiver	7–120
MC75172B	Quad EIA–485 Line Driver with Three–State Output	7–146
MC75174B	Quad EIA–485 Line Driver with Three–State Output	7–146
MC79076	Electronic Ignition Control Chip	10–131
MCC3334	High Energy Ignition Circuit	10–15
MCCF3334	High Energy Ignition Circuit	10–15
MCCF33093	Ignition Control Flip–Chip	10–132
MCCF33094	Ignition Control Flip–Chip	10–133
MCCF33095	Integral Alternator Regulator	10–134
MCCF79076	electronic Ignition Control Chip	10–131
MCT1458, C	Internally Compensated, High Performance Dual Operational Amplifier	2–89
MCT4558C	Dual Wide Bandwidth Operational Amplifier	2–153
SAA1042	Stepper Motor Driver	4–92
SG3525A	Pulse Width Modulator Control Circuit	3–691
SG3526	Pulse Width Modulator Control Circuit	3–697
SG3527A	Pulse Width Modulator Control Circuit	3–691
SN75175	Quad EIA–485 Line Receiver	7–157
TCA0372	Dual Power Operational Amplifier	2–308
TCA3385	Telephone Ring Signal Converter	*
TCA3388	Telephone Speech Network	*
TCA5600	Universal Microprocessor Power Supply/Controller	3–705
TCF5600	Universal Microprocessor Power Supply/Controller	3–705
TCF6000	Peripheral Clamping Array	10–144
TDA1085C	Universal Motor Speed Controller	4–97
TDA1185A#	Triac Phase Angle Controller	4–107
TL062	Low Power JFET Input Operational Amplifier	2–312
TL064	Low Power JFET Input Operational Amplifier	2–312
TL071C, AC	Low Noise JFET Input Operational Amplifier	2–319
TL072C, AC	Low Noise JFET Input Operational Amplifier	2–319
TL074C, AC	Low Noise JFET Input Operational Amplifier	2–319
TL081C, AC	JFET Input Operational Amplifier	2–325
TL082C, AC	JFET Input Operational Amplifier	2–325
TL084C, AC	JFET Input Operational Amplifier	2–325
TL431, A, B Series	Programmable Precision References	5–18
TL494	Switchmode Pulse Width Modulation Control Circuit	3–716
TL594	Precision Switchmode Pulse Width Modulation Control Circuit	3–726

* = See Communications Device Data (DL136).
\# = Not recommended for new designs.

Alphanumeric Index (continued)

Device Number	Function	Page
TL780 Series	Three–Terminal Positive Fixed Voltage Regulator	3–736
UAA1016B	Zero Voltage Controller	4–116
UAA1041b	Automotive Direction Indicator	10–148
UAA2016	Zero Voltage Switch Power Controller	4–122
UC2842A	HIgh Performance Current Mode Controller	3–742
UC2842B	HIgh Performance Current Mode Controller	3–755

UC3845B	HIgh Performance Current Mode Controller	3–782
ULN2068#	Quad 1.5 A Sinking High Current Switch	7–162
ULN2803	Octal High Voltage, High Current Darlington Transistor Array	7–166
ULN2804	Octal High Voltage, High Current Darlington Transistor Array	7–166
µA78S40	Universal Switching Regulator Subsystem	3–796

Cross References

The following table represents a cross reference guide for all Analog devices that are manufactured by Motorola. Where the Motorola part number differs from the industry part number, the Motorola device is a “form, fit and function” replacement for the industry part number. However, some differences in characteristics and/or specifications may exist.

Industry Part Number	Motorola Nearest Replacement	Motorola Similar Replacement

Amplifiers and Comparators

In Brief . . .

For over two decades, Motorola has continually refined and updated integrated circuit technologies, analog circuit design techniques and processes in response to the needs of the marketplace. The enhanced performance of newer operational amplifiers and comparators has come through innovative application of these technologies, designs and processes. Some early designs are still available but are giving way to the new, higher performance operational amplifier and comparator circuits. Motorola has pioneered in JFET inputs, low temperature coefficient input stages, Miller loop compensation, all NPN output stages, dual–doublet frequency compensation and analog “in–the–package” trimming of resistors to produce superior high performance operational amplifiers and comparators, operating in many cases from a single supply with low input offset, low noise, low power, high output swing, high slew rate and high gain–bandwidth product at reasonable cost to the customer.

Present day operational amplifiers and comparators find applications in all market segments including motor controls, instrumentation, aerospace, automotive, telecommunications, medical, and consumer products.

Page

Operational Amplifiers

Motorola offers a broad line of bipolar operational amplifiers to meet a wide range of applications. From low–cost industry–standard types to high precision circuits, the span encompasses a large range of performance capabilities. These Analog integrated circuits are available as single, dual and quad monolithic devices in a variety of temperature ranges and package styles. Most devices may be obtained in unencapsulated ‘‘chip’’ form as well. For price and delivery information on chips, please contact your Motorola Sales Representative or Distributor.

High Frequency Amplifiers

A variety of high frequency circuits with features ranging from low cost simplicity to multifunction versatility marks Motorola’s line of integrated amplifiers. Devices described here are intended for industrial and communications applications. For devices especially dedicated to consumer products, i.e., TV and entertainment radio. (See the Consumer Electronics Circuits section.)

AGC Amplifiers

MC1490/MC1350 Family Wideband General Purpose Amplifiers

The MC1490 and MC1350 family are basic building blocks – AGC (Automatic Gain Controlled) RF/Video Amplifiers. These parts are recommended for applications up through 70 MHz. The best high frequency performance may be obtained by using the physically smaller SOIC version (shorter leads) – MC1350D. There are currently no other RF ICs like these, because other manufacturers have dropped their copies. Applications include variable gain video and instrumentation amplifiers, IF (Intermediate Frequency) amplifiers for radio and TV receivers, and transmitter power output control. Many uses will be found in medical instrumentation, remote monitoring, video/graphics processing, and a variety of communications equipment. The family of parts using the same basic die (identical circuit with slightly different test parameters) is listed in the following table.

Table 4. High Frequency Amplifier Specifications

Operating Temperature Range		A_V (dB)	Bandwidth @ MHz	V_{CC}/V_{EE} (Vdc)		Suffix/ Package
–40° to +85°C	0° to +70°C	Typical		Minimum	Maximum	
–	MC1350	50	45	+6.0	+18	P/626, D/751
MC1490	–	50 45 35	10 60 100			P/626

Miscellaneous Amplifiers

Motorola provides several Bipolar and CMOS special purpose amplifiers which fill specific needs. These devices range from low power CMOS programmable amplifiers and comparators to variable–gain bipolar power amplifiers.

MC3405
Dual Operational Amplifier and Dual Voltage Comparator

This device contains two Differential Input Operational Amplifiers and two Comparators; each set capable of single supply operation. This operational amplifier–comparator circuit will find its applications as a general purpose product for automotive circuits and as an industrial ''building block.''

JFET Input Operational Amplifiers

These low cost JFET input operational amplifiers combine two state–of–the–art analog technologies on a single monolithic integrated circuit. Each internally compensated operational amplifier has well matched high voltage JFET input devices for low input offset voltage. The JFET technology provides wide bandwidths and fast slew rates with low input bias currents, input offset currents, and supply currents.

These devices are available in single, dual and quad operational amplifiers which are pin–compatible with the industry standard MC1741, MC1458, and the MC3403/LM324 bipolar devices.

- Input Offset Voltage of 5.0 mV Max (LF347B)
- Low Input Bias Current: 50 pA
- Low Input Noise Voltage: 16 nV/$\sqrt{\text{Hz}}$
- Wide Gain Bandwidth: 4.0 MHz
- High Slew Rate: 13V/µs
- Low Supply Current: 1.8 mA per Amplifier
- High Input Impedance: 10^{12} Ω
- High Common Mode and Supply Voltage Rejection Ratios: 100 dB

For Typical Characteristic Performance Curves, refer to MC34001, 34002, 34004 data sheet.

NOTE: 3. Input bias currents of JFET input op amps approximately double for every 10°C rise in junction temperature. To maintain junction temperatures as close to ambient as is possible, pulse techniques are utilized during test.

MOTOROLA

LF411C
LF412C

Low Offset, Low Drift JFET Input Operational Amplifiers

Through innovative design concepts and precision matching this monolithic high speed JFET input operational amplifier family offers very low input offset voltage as well as low temperature coefficient of input offset voltage. The amplifier requires less than 3.4 mA per amplifier of supply current yet exhibits greater than 2.7 MHz of gain bandwidth product and more than 8.0 V/µs slew rate. Through the use of JFET inputs the amplifier has very low input bias currents and low input offset currents. The amplifier utilizes industry standard pinouts which afford the user the opportunity to directly upgrade circuit performance without the need for redesign.

The LF411C and LF412C are available in the industry standard plastic 8–pin DIP and SO–8 surface mount packages, and specified over the commercial temperature range.

- Low Input Offset Voltage: 2.0 mV Max (Single)
  3.0 mV Max (Dual)
- Low T.C. of Input Offset Voltage: 10 µV/°C
- Low Input Offset Current: 20 pA
- Low Input Bias Current: 60 pA
- Low Input Noise Voltage: 18 nV/$\sqrt{Hz}$
- Low Input Noise Current: 0.01 pA/$\sqrt{Hz}$
- Low Total Harmonic Distortion: 0.05%
- Low Supply Current: 2.5 mA
- High Input Resistance: 10^{12} Ω
- Wide Gain Bandwidth: 8.0 MHz
- High Slew Rate: 25 V/µs (Typ)
- Fast Settling Time: 1.6 µs (to within 0.01%)
- Internally Compensated

Low Power JFET Input Operational Amplifiers

LOW POWER
JFET INPUT
OPERATIONAL AMPLIFIERS

SEMICONDUCTOR
TECHNICAL DATA

These JFET input operational amplifiers are designed for low power applications. They feature high input impedance, low input bias current and low input offset current. Advanced design techniques allow for higher slew rates, gain bandwidth products and output swing. The LF441C device provides for the external null adjustment of input offset voltage.

These devices are specified over the commercial temperature range. All are available in plastic dual in–line and SOIC packages.

- Low Supply Current: 200 µA/Amplifier
- Low Input Bias Current: 5.0 pA
- High Gain Bandwidth: 2.0 MHz
- High Slew Rate: 6.0 V/µs
- High Input Impedance: 10^{12} Ω
- Large Output Voltage Swing: ±14 V
- Output Short Circuit Protection

MOTOROLA

LM11C, CL

Precision Operational Amplifiers

PRECISION OPERATIONAL AMPLIFIERS

SEMICONDUCTOR TECHNICAL DATA

The LM11C is a precision, low drift operational amplifier providing the best features of existing FET and Bipolar op amps. Implementation of super gain transistors allows reduction of input bias currents by an order of magnitude over earlier devices such as the LM308A. Offset voltage and drift have also been reduced. Although bandwidth and slew rate are not as great as FET devices, input offset voltage, drift and bias current are inherently lower, particularly over temperature. Power consumption is also much lower, eliminating warm–up stabilization time in critical applications.

Offset balancing is provided, with the range determined by an external low resistance potentiometer. Compensation is provided internally, but external compensation can be added for improved stability when driving capacitive loads.

The precision characteristics of the LM11C make this device ideal for applications such as charge integrators, analog memories, electrometers, active filters, light meters and logarithmic amplifiers.

- Low Input Offset Voltage: 100 µV
- Low Input Bias Current: 17 pA
- Low Input Offset Current: 0.5 pA
- Low Input Offset Voltage Drift: 1.0 µV/°C
- Long–Term Stability: 10 µV/year
- High Common Mode Rejection: 130 dB

NOTES:
1. The inputs are shunted by back–to–back diodes for over–voltage protection. Excessive current will flow if the input differential voltage is in excess of 1.0 V if no limiting resistance is used. Additionally, a 2.0 kΩ resistance in each input is suggested to prevent possible latch–up initiated by supply reversals.
2. The output is current limited when shorted to ground or any voltages less than the supplies. Continuous overloads will require package dissipation to be considered and heatsinking should be provided when necessary.
3. Devices must be derated based on package thermal resistance (see package outline dimensions).
4. These specifications apply for V_{EE} +2.0 V ≤ V_{CM} ≤ V_{CC} –1.0 V (V_{EE} +2.5 V ≤ V_{CM} ≤ V_{CC} –1.0 V for T_{low} to T_{high}) and ±2.5 V ≤ V_S ≤ ±20 V T_{low} to T_{high}: 0°C ≤ T_J ≤ +70°C for LM11C and LM11C.
5. V_{out} = ±11.5 V, all other conditions unchanged.

APPLICATIONS INFORMATION

Due to the extremely low input bias currents of this device, it may be tempting to remove the bias current compensation resistor normally associated with a summing amplifier configuration. Direct connection of the inputs to a low impedance source or ground should be avoided when supply voltages greater than approximately 3.0 V are used. The potential problem involves reversal of one supply which can cause excessive current to flow in the second supply. Possible destruction of the IC could result if the second supply is not current limited to approximately 100 mA or if bypass capacitors greater than 1.0 µF are used in the supply bus.

Disconnecting one supply will generally cause reversal due to loading of the other supply within the IC and in external circuitry. Although the problem can usually be avoided by placing clamp diodes across the power supplies of each printed circuit board, a careful design will include sufficient resistance in the input leads to limit the current to 10 mA if the input leads are pulled to either supply by internal currents. This precaution is not limited only to the LM11C.

The LM11C is capable of resolving picoampere level signals. Leakage currents external to the IC can severely impair the performance of the device. It is important that high quality insulating materials such as teflon be employed. Proper cleaning to remove fluxes and other residues from printed circuit boards, sockets and the device package are necessary to minimize surface leakage.

When operating in high humidity environments or temperatures near 0°C, a surface coating is suggested to set up a moisture barrier.

Leakage effects on printed circuit boards can be reduced by encircling the inputs (both sides of pc board) with a conductive guard ring connected to a low impedance potential nearly the same as that of the inputs.

Guard ring electrical connections for common operational amplifier configurations are illustrated in Figure 14. Electrostatic shielding is suggested in high impedance circuits.

Error voltages in external circuitry can be generated by thermocouple effects. Dissimilar metals along with temperature gradients can set up an error voltage ranging in the hundreds of microvolts. Some of the best thermocouples are junctions of dissimilar metals made up of IC package pins and printed circuit boards. Problems can be avoided by keeping low level circuitry away from heat generating elements.

The LM11C is internally compensated, but external compensation can be added to improve stability, particularly when driving capacitive loads.

Figure 14. Guard Ring Electrical Connections for Common Amplifier Configurations

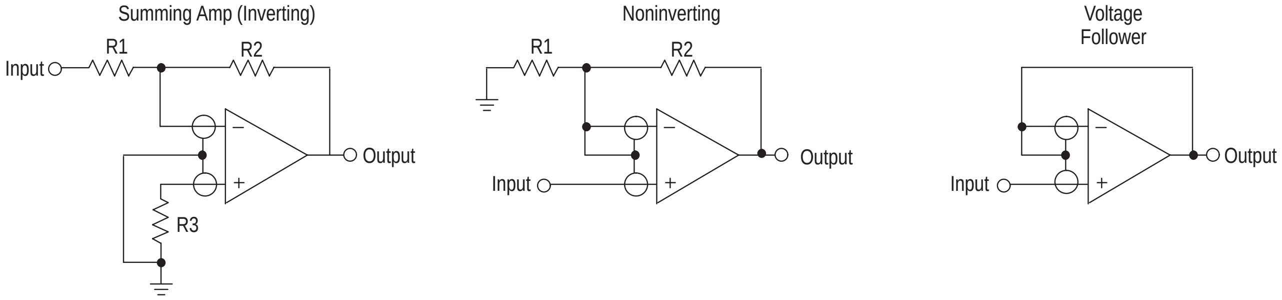

Figure 15. Input Protection for Summing (Inverting) Amplifier

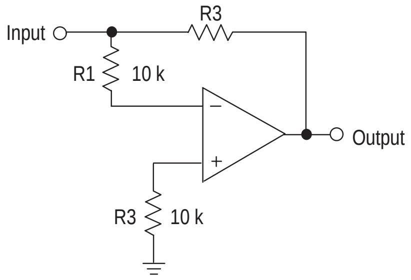
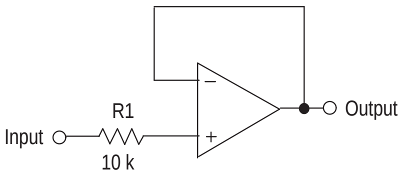


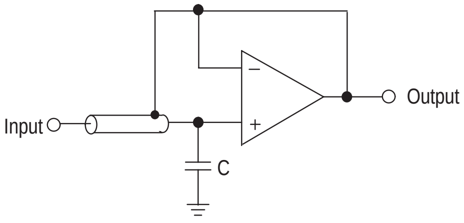
Current is limited by R1 in the event the input is connected to a low impedance source outside the common mode range of the device. Current is controlled by R2 if one supply reverses. R1 and R2 do not affect normal operation.

Figure 16. Input Protection for a Voltage Follower

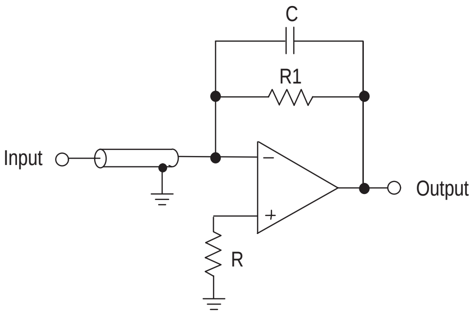


Input current is limited by R1 when the input exceeds supply voltage, power supply is turned off, or output is shorted.

Figure 17. Cable Bootstrapping and Input Shields

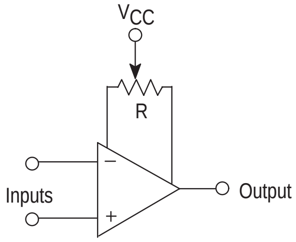


An input shield bootstrapped in a voltage follower reduces input capacitance, leakage, and spurious voltages from cable flexing. A small capacitor from the input to ground will prevent any instability.



In a summing amplifier the input is at virtual ground. Therefore the shield can be grounded. A small feedback capacitor will insure stability.

Figure 18. Adjusting Input Offset Voltage with Balance Potentiometer



Minimum Adjustment Range (mV)	R (Ω)
±0.4	1.0 k
±1.0	3.0 k
±2.0	10 k
±5.0	100 k

Input offset voltage adjustment range is a function of the Balance Potentiometer Resistance as indicated by the table above. The potentiometer is connected between the two “Balance” pins.

LM308A

Precision Operational Amplifier

The LM308A operational amplifier provides high input impedance, low input offset and temperature drift, and low noise. These characteristics are made possible by use of a special Super Beta processing technology. This amplifier is particularly useful for applications where high accuracy and low drift performance are essential. In addition high speed performance may be improved by employing feedforward compensation techniques to maximize slew rate without compromising other performance criteria.

The LM308A offers extremely low input offset voltage and drift specifications allowing usage in even the most critical applications without external offset nulling.

- Operation from a Wide Range of Power Supply Voltages
- Low Input Bias and Offset Currents
- Low Input Offset Voltage and Guaranteed Offset Voltage Drift Performance
- High Input Impedance

SUGGESTED DESIGN APPLICATIONS

INPUT GUARDING

Special care must be taken in the assembly of printed circuit boards to take full advantage of the low input currents of the LM308A amplifier. Boards must be thoroughly cleaned with alcohol and blown dry with compressed air. After cleaning, the boards should be coated with epoxy or silicone rubber to prevent contamination.

Even with properly cleaned and coated boards, leakage currents may cause trouble at +125°C, particularly since the input pins are adjacent to pins that are at supply potentials. This leakage can be significantly reduced by using guarding to lower the voltage difference between the inputs and adjacent metal runs. The guard, which is a conductive ring surrounding the inputs, is connected to a low–impedance point that is at approximately the same voltage as the inputs. Leakage currents from high voltage pins are then absorbed by the guard.

LM311
LM211

Highly Flexible Voltage Comparators

The ability to operate from a single power supply of 5.0 V to 30 V or ±15 V split supplies, as commonly used with operational amplifiers, makes the LM211/LM311 a truly versatile comparator. Moreover, the inputs of the device can be isolated from system ground while the output can drive loads referenced either to ground, the V_{CC} or the V_{EE} supply. This flexibility makes it possible to drive DTL, RTL, TTL, or MOS logic. The output can also switch voltages to 50 V at currents to 50 mA. Thus the LM211/LM311 can be used to drive relays, lamps or solenoids.

NOTES:
1. Offset voltage, offset current and bias current specifications apply for a supply voltage range from a single 5.0 V supply up to ±15 V supplies.
2. This rating applies for ±15 V supplies. The positive input voltage limit is 30 V above the negative supply. The negative input voltage limit is equal to the negative supply voltage or 30 V below the positive supply, whichever is less.
3. The offset voltages and offset currents given are the maximum values required to drive the output within a volt of either supply with a 1.0 mA load. Thus, these parameters define an error band and take into account the ”worst case” effects of voltage gain and input impedance.
4. The response time specified is for a 100 mV input step with 5.0 mV overdrive.
5. Do not short the strobe pin to ground; it should be current driven at 3.0 mA to 5.0 mA.

APPLICATIONS INFORMATION

Figure 15. Improved Method of Adding Hysteresis Without Applying Positive Feedback to the Inputs

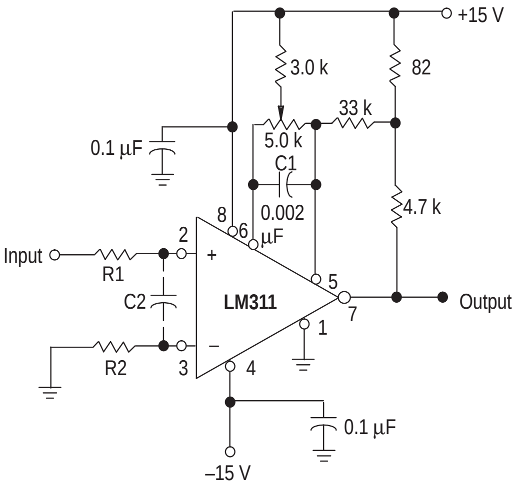

Figure 16. Conventional Technique for Adding Hysteresis

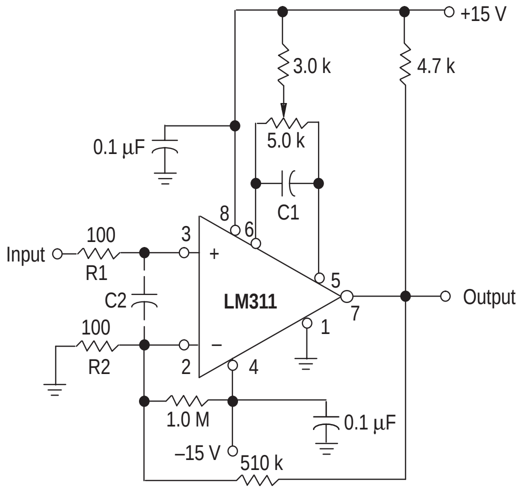

TECHNIQUES FOR AVOIDING OSCILLATIONS IN COMPARATOR APPLICATIONS

When a high speed comparator such as the LM211 is used with high speed input signals and low source impedances, the output response will normally be fast and stable, providing the power supplies have been bypassed (with 0.1 µF disc capacitors), and that the output signal is routed well away from the inputs (Pins 2 and 3) and also away from Pins 5 and 6.

However, when the input signal is a voltage ramp or a slow sine wave, or if the signal source impedance is high (1.0 kΩ to 100 kΩ), the comparator may burst into oscillation near the crossing–point. This is due to the high gain and wide bandwidth of comparators like the LM211 series. To avoid oscillation or instability in such a usage, several precautions are recommended, as shown in Figure 15.

The trim pins (Pins 5 and 6) act as unwanted auxiliary inputs. If these pins are not connected to a trim–pot, they should be shorted together. If they are connected to a trim–pot, a 0.01 µF capacitor (C1) between Pins 5 and 6 will minimize the susceptibility to AC coupling. A smaller capacitor is used if Pin 5 is used for positive feedback as in Figure 15. For the fastest response time, tie both balance pins to V_{CC}.

Certain sources will produce a cleaner comparator output waveform if a 100 pF to 1000 pF capacitor (C2) is connected directly across the input pins. When the signal source is applied through a resistive network, R1, it is usually advantageous to choose R2 of the same value, both for DC and for dynamic (AC) considerations. Carbon, tin–oxide, and metal–film resistors have all been used with good results in comparator input circuitry, but inductive wirewound resistors should be avoided.

When comparator circuits use input resistors (e.g., summing resistors), their value and placement are particularly important. In all cases the body of the resistor should be close to the device or socket. In other words, there should be a very short lead length or printed–circuit foil run between comparator and resistor to radiate or pick up signals. The same applies to capacitors, pots, etc. For example, if R1 = 10 kΩ, as little as 5 inches of lead between the resistors and the input pins can result in oscillations that are very hard to dampen. Twisting these input leads tightly is the best alternative to placing resistors close to the comparator.

Since feedback to almost any pin of a comparator can result in oscillation, the printed–circuit layout should be engineered thoughtfully. Preferably there should be a groundplane under the LM211 circuitry (e.g., one side of a double layer printed circuit board). Ground, positive supply or negative supply foil should extend between the output and the inputs to act as a guard. The foil connections for the inputs should be as small and compact as possible, and should be essentially surrounded by ground foil on all sides to guard against capacitive coupling from any fast high–level signals (such as the output). If Pins 5 and 6 are not used, they should be shorted together. If they are connected to a trim–pot, the trim–pot should be located no more than a few inches away from the LM211, and a 0.01 µF capacitor should be installed across Pins 5 and 6. If this capacitor cannot be used, a shielding printed–circuit foil may be advisable between Pins 6 and 7. The power supply bypass capacitors should be located within a couple inches of the LM211.

A standard procedure is to add hysteresis to a comparator to prevent oscillation, and to avoid excessive noise on the output. In the circuit of Figure 16, the feedback resistor of 510 kΩ from the output to the positive input will cause about 3.0 mV of hysteresis. However, if R2 is larger than 100 Ω, such as 50 kΩ, it would not be practical to simply increase the value of the positive feedback resistor proportionally above 510 kΩ to maintain the same amount of hysteresis.

When both inputs of the LM211 are connected to active signals, or if a high–impedance signal is driving the positive input of the LM211 so that positive feedback would be disruptive, the circuit of Figure 15 is ideal. The positive feedback is applied to Pin 5 (one of the offset adjustment pins). This will be sufficient to cause 1.0 mV to 2.0 mV hysteresis and sharp transitions with input triangle waves from a few Hz to hundreds of kHz. The positive–feedback signal across the 82 Ω resistor swings 240 mV below the positive supply. This signal is centered around the nominal voltage at Pin 5, so this feedback does not add to the offset voltage of the comparator. As much as 8.0 mV of offset voltage can be trimmed out, using the 5.0 kΩ pot and 3.0 kΩ resistor as shown.

MOTOROLA

LM324, LM324A, LM224, LM2902, LM2902V

Quad Low Power Operational Amplifiers

The LM324 series are low–cost, quad operational amplifiers with true differential inputs. They have several distinct advantages over standard operational amplifier types in single supply applications. The quad amplifier can operate at supply voltages as low as 3.0 V or as high as 32 V with quiescent currents about one–fifth of those associated with the MC1741 (on a per amplifier basis). The common mode input range includes the negative supply, thereby eliminating the necessity for external biasing components in many applications. The output voltage range also includes the negative power supply voltage.

- Short Circuited Protected Outputs
- True Differential Input Stage
- Single Supply Operation: 3.0 V to 32 V
- Low Input Bias Currents: 100 nA Maximum (LM324A)
- Four Amplifiers Per Package
- Internally Compensated
- Common Mode Range Extends to Negative Supply
- Industry Standard Pinouts
- ESD Clamps on the Inputs Increase Ruggedness without Affecting Device Operation

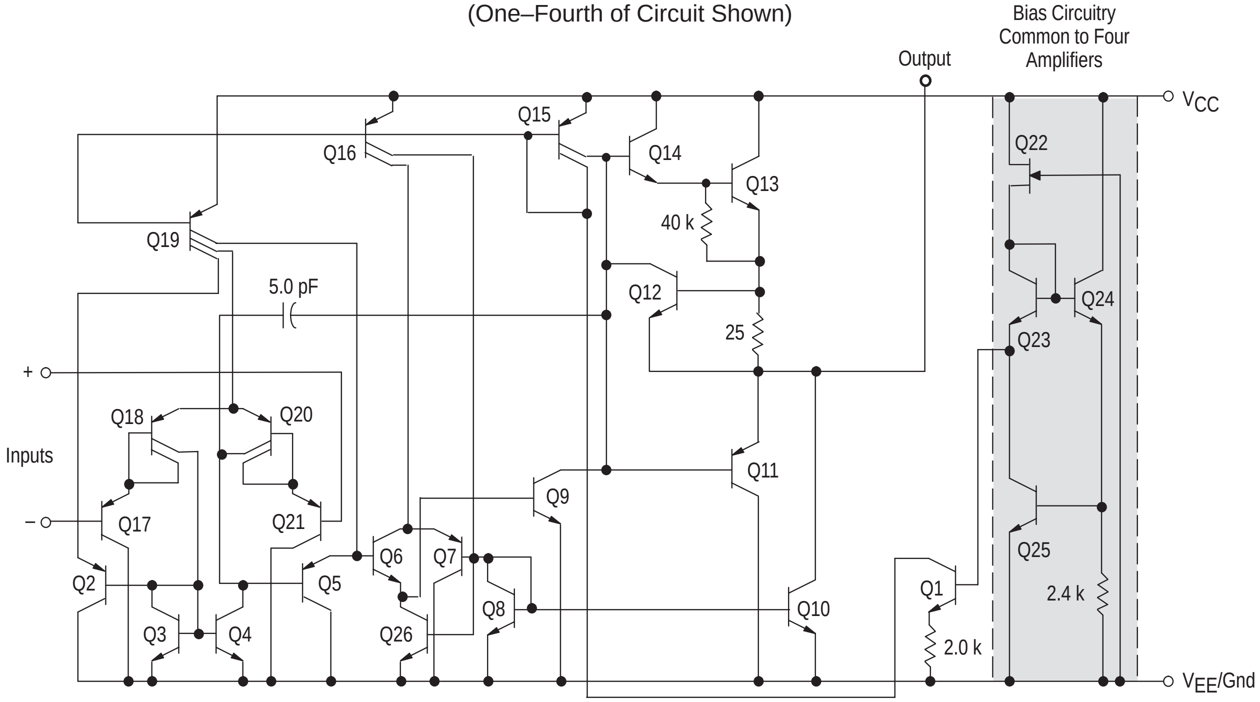
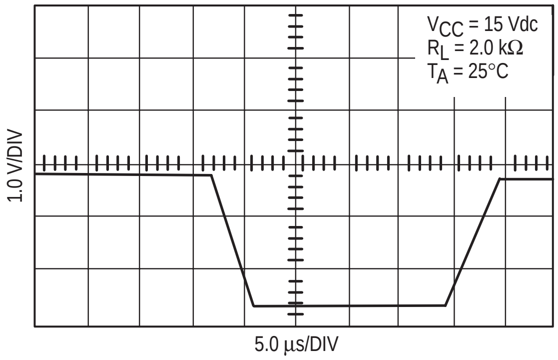
Representative Circuit Diagram
(One–Fourth of Circuit Shown)



CIRCUIT DESCRIPTION

The LM324 series is made using four internally compensated, two–stage operational amplifiers. The first stage of each consists of differential input devices Q20 and Q18 with input buffer transistors Q21 and Q17 and the differential to single ended converter Q3 and Q4. The first stage performs not only the first stage gain function but also performs the level shifting and transconductance reduction functions. By reducing the transconductance, a smaller compensation capacitor (only 5.0 pF) can be employed, thus saving chip area. The transconductance reduction is accomplished by splitting the collectors of Q20 and Q18. Another feature of this input stage is that the input common mode range can include the negative supply or ground, in single supply operation, without saturating either the input devices or the differential to single–ended converter. The second stage consists of a standard current source load amplifier stage.

Large Signal Voltage Follower Response



Each amplifier is biased from an internal–voltage regulator which has a low temperature coefficient thus giving each amplifier good temperature characteristics as well as excellent power supply rejection.

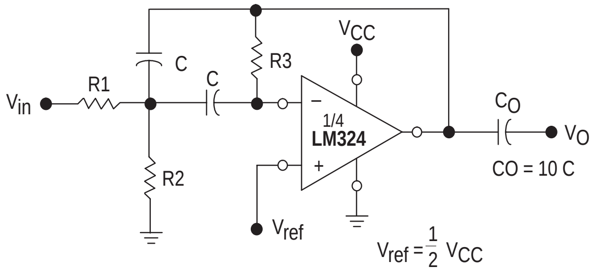
$$f = \frac{R1 + R_C}{4\, C R_f\, R1} \quad \text{if} \quad R3 = \frac{R2\, R1}{R2 + R1}$$

Figure 13. Multiple Feedback Bandpass Filter



Given: f_o = center frequency
$A(f_o)$ = gain at center frequency

Choose value f_o, C

Then: $R3 = \frac{Q}{\pi f_o C}$

$R1 = \frac{R3}{2\, A(f_o)}$

$R2 = \frac{R1\, R3}{4Q^2\, R1 - R3}$

For less than 10% error from operational amplifier, $\frac{Q_o f_o}{BW} < 0.1$

where f_o and BW are expressed in Hz.

If source impedance varies, filter may be preceded with voltage follower buffer to stabilize filter parameters.

$R2 = R3 = R4$

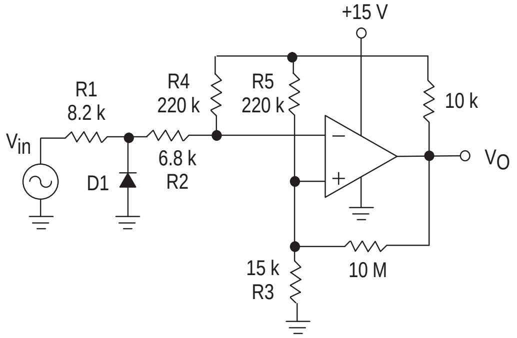
$R1 \approx R2\ //\ R3\ //\ R4$

APPLICATIONS INFORMATION

These quad comparators feature high gain, wide bandwidth characteristics. This gives the device oscillation tendencies if the outputs are capacitively coupled to the inputs via stray capacitance. This oscillation manifests itself during output transitions (V_{OL} to V_{OH}). To alleviate this situation input resistors < 10 kΩ should be used. The addition of positive feedback (< 10 mV) is also recommended. It is good design practice to ground all unused input pins.

Differential input voltages may be larger than supply voltages without damaging the comparator’s inputs. Voltages more negative than –300 mV should not be used.

Figure 9. Zero Crossing Detector (Single Supply)



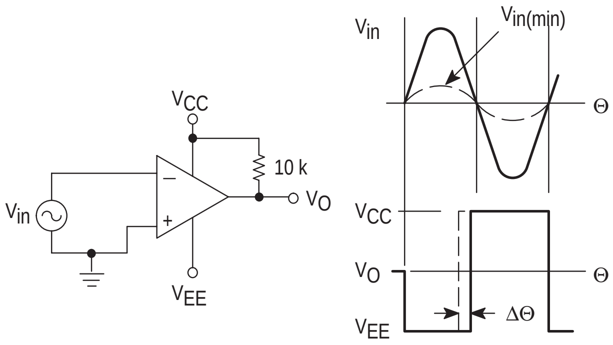
D1 prevents input from going negative by more than 0.6 V.

$R1 + R2 = R3$

$R3 \le \dfrac{R5}{10}$ for small error in zero crossing

Figure 10. Zero Crossing Detector (Split Supplies)

$V_{in(min)} \approx 0.4$ V peak for 1% phase distortion (ΔΘ).



MOTOROLA

LM348

Differential Input Operational Amplifier

The LM348 is a true quad MC1741. Integrated on a single monolithic chip are four independent, low power operational amplifiers which have been designed to provide operating characteristics identical to those of the industry standard MC1741, and can be applied with no change in circuit performance. In addition, the total supply current for all four amplifiers is comparable to the supply current of a single MC1741. Other features include input offset currents and input bias currents which are much less than the MC1741 industry standard.

The LM348 can be used in applications where amplifier matching or high packing density is important. Other applications include high impedance buffer amplifiers and active filter amplifiers.

- Each Amplifier is Functionally Equivalent to the MC1741
- Low Input Offset and Input Bias Currents
- Class AB Output Stage Eliminates Crossover Distortion
- Pin Compatible with MC3403 and LM324
- True Differential Inputs
- Internally Frequency Compensated
- Short Circuit Protection
- Low Power Supply Current (0.6 mA/Amplifier)

MOTOROLA

LM358, LM258, LM2904, LM2904V

Dual Low Power Operational Amplifiers

Utilizing the circuit designs perfected for recently introduced Quad Operational Amplifiers, these dual operational amplifiers feature 1) low power drain, 2) a common mode input voltage range extending to ground/V_{EE}, 3) single supply or split supply operation and 4) pinouts compatible with the popular MC1558 dual operational amplifier. The LM158 series is equivalent to one–half of an LM124.

These amplifiers have several distinct advantages over standard operational amplifier types in single supply applications. They can operate at supply voltages as low as 3.0 V or as high as 32 V, with quiescent currents about one–fifth of those associated with the MC1741 (on a per amplifier basis). The common mode input range includes the negative supply, thereby eliminating the necessity for external biasing components in many applications. The output voltage range also includes the negative power supply voltage.

- Short Circuit Protected Outputs
- True Differential Input Stage
- Single Supply Operation: 3.0 V to 32 V
- Low Input Bias Currents
- Internally Compensated
- Common Mode Range Extends to Negative Supply
- Single and Split Supply Operation
- Similar Performance to the Popular MC1558
- ESD Clamps on the Inputs Increase Ruggedness of the Device without Affecting Operation

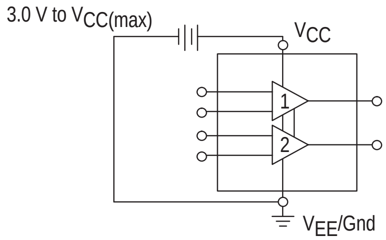
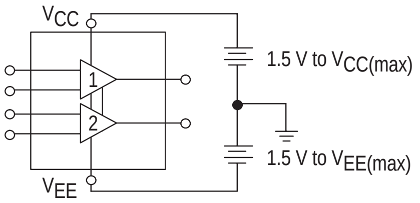
2. The input common mode voltage or either input signal voltage should not be allowed to go negative by more than 0.3 V. The upper end of the common mode voltage range is V_{CC} –1.7 V.

3. Short circuits from the output to V_{CC} can cause excessive heating and eventual destruction. Destructive dissipation can result from simultaneous shorts on all amplifiers.

Single Supply

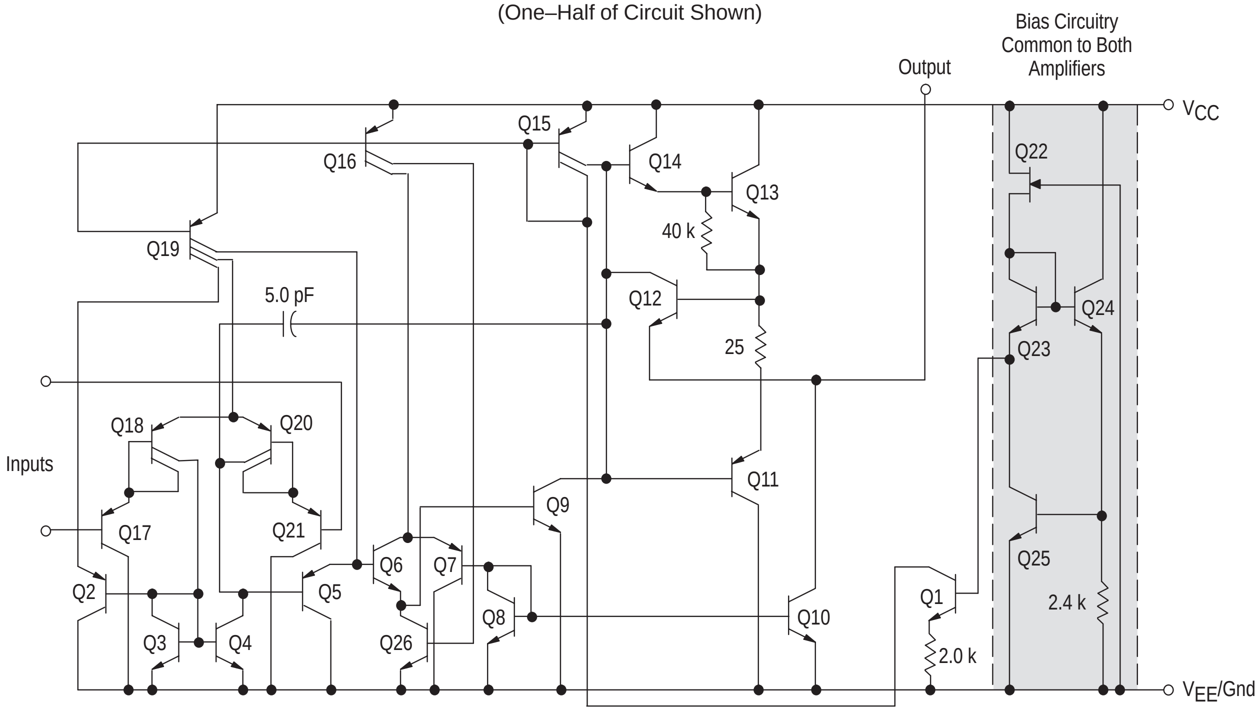


Split Supplies



Representative Schematic Diagram

(One–Half of Circuit Shown)



CIRCUIT DESCRIPTION

The LM258 series is made using two internally compensated, two–stage operational amplifiers. The first stage of each consists of differential input devices Q20 and Q18 with input buffer transistors Q21 and Q17 and the differential to single ended converter Q3 and Q4. The first stage performs not only the first stage gain function but also performs the level shifting and transconductance reduction functions. By reducing the transconductance, a smaller compensation capacitor (only 5.0 pF) can be employed, thus saving chip area. The transconductance reduction is accomplished by splitting the collectors of Q20 and Q18. Another feature of this input stage is that the input common mode range can include the negative supply or ground, in single supply operation, without saturating either the input devices or the differential to single–ended converter. The second stage consists of a standard current source load amplifier stage.

Each amplifier is biased from an internal–voltage regulator which has a low temperature coefficient thus giving each amplifier good temperature characteristics as well as excellent power supply rejection.

Low Offset Voltage Dual Comparators

SINGLE SUPPLY, LOW POWER DUAL COMPARATORS

SEMICONDUCTOR TECHNICAL DATA

The LM393 series are dual independent precision voltage comparators capable of single or split supply operation. These devices are designed to permit a common mode range–to–ground level with single supply operation. Input offset voltage specifications as low as 2.0 mV make this device an excellent selection for many applications in consumer automotive, and industrial electronics.

- Wide Single–Supply Range: 2.0 Vdc to 36 Vdc
- Split–Supply Range: ±1.0 Vdc to ±18 Vdc
- Very Low Current Drain Independent of Supply Voltage: 0.4 mA
- Low Input Bias Current: 25 nA
- Low Input Offset Current: 5.0 nA
- Low Input Offset Voltage: 2.0 mV (max) LM393A
  5.0 mV (max) LM293/393
- Input Common Mode Range to Ground Level
- Differential Input Voltage Range Equal to Power Supply Voltage
- Output Voltage Compatible with DTL, ECL, TTL, MOS, and CMOS Logic Levels

*T_{low} = 0°C, T_{high} = +70°C for LM393/393A

NOTES:
1. The maximum output current may be as high as 20 mA, independent of the magnitude of V_{CC}, output short circuits to V_{CC} can cause excessive heating and eventual destruction.
2. At output switch point, $V_O \simeq$ 1.4 Vdc, R_S = 0 Ω with V_{CC} from 5.0 Vdc to 30 Vdc, and over the full input common mode range (0 V to V_{CC} = –1.5 V).
3. Due to the PNP transistor inputs, bias current will flow out of the inputs. This current is essentially constant, independent of the output state, there fore, no loading changes will exist on the input lines.
4. Input common mode of either input should not be permitted to go more than 0.3 V negative of ground or minus supply. The upper limit of common mode range is V_{CC} –1.5 V.
5. Response time is specified with a 100 mV step and 5.0 mV of overdrive. With larger magnitudes of overdrive faster response times are obtainable.
6. The comparator will exhibit proper output state if one of the inputs becomes greater than V_{CC}, the other input must remain within the common mode range. The low input state must not be less than –0.3 V of ground or minus supply.

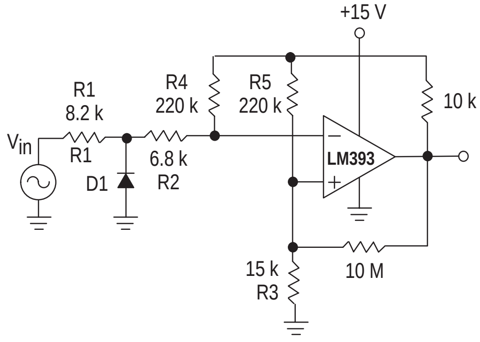
APPLICATIONS INFORMATION

These dual comparators feature high gain, wide bandwidth characteristics. This gives the device oscillation tendencies if the outputs are capacitively coupled to the inputs via stray capacitance. This oscillation manifests itself during output transitions (V_{OL} to V_{OH}). To alleviate this situation, input resistors < 10 kΩ should be used.

The addition of positive feedback (< 10 mV) is also recommended. It is good design practice to ground all unused pins.

Differential input voltages may be larger than supply voltage without damaging the comparator's inputs. Voltages more negative than –0.3 V should not be used.

Figure 7. Zero Crossing Detector (Single Supply)

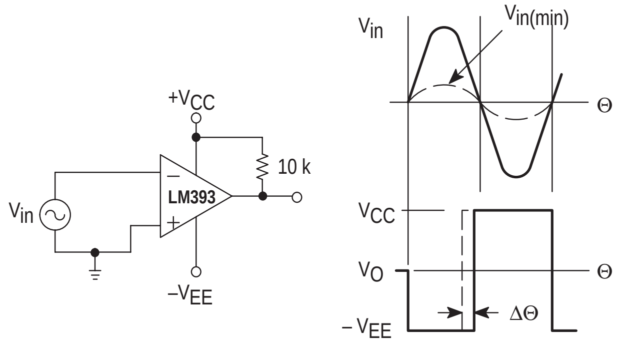


D1 prevents input from going negative by more than 0.6 V.

$$R1 + R2 = R3$$

$$R3 \leq \frac{R5}{10} \text{ for small error in zero crossing.}$$

Figure 8. Zero Crossing Detector (Split Supply)



$V_{in(min)} \approx$ 0.4 V peak for 1% phase distortion (ΔΘ).

Figure 9. Free–Running Square–Wave Oscillator

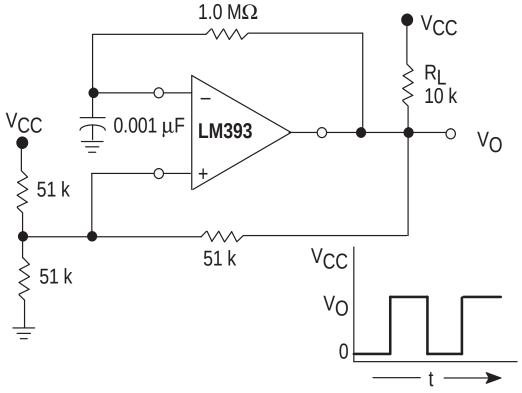


Figure 10. Time Delay Generator

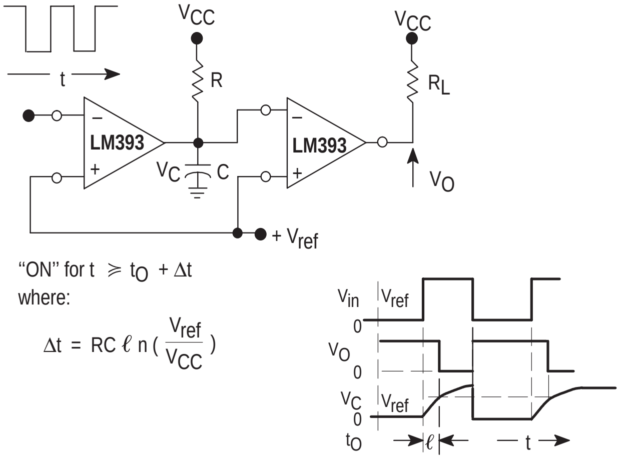
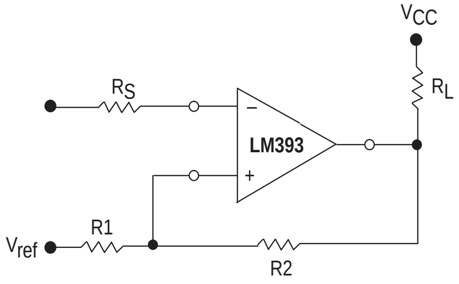


"ON" for t $\geqslant t_O + \Delta t$
where:

$$\Delta t = RC\,\ell n\left(\frac{V_{ref}}{V_{CC}}\right)$$

Figure 11. Comparator with Hysteresis



$$R_S = R1 \,||\, R2$$

$$V_{th1} = V_{ref} + \frac{(V_{CC} - V_{ref})\ R1}{R1 + R2 + R_L}$$

$$V_{th2} = V_{ref} - \frac{(V_{ref} - V_{O}\ \text{Low})\ R1}{R1 + R2}$$

MOTOROLA

LM833

Dual Low Noise, Audio Amplifier

The LM833 is a standard low–cost monolithic dual general–purpose operational amplifier employing Bipolar technology with innovative high–performance concepts for audio systems applications. With high frequency PNP transistors, the LM833 offers low voltage noise (4.5 nV/$\sqrt{Hz}$), 15 MHz gain bandwidth product, 7.0 V/µs slew rate, 0.3 mV input offset voltage with 2.0 µV/°C temperature coefficient of input offset voltage. The LM833 output stage exhibits no deadband crossover distortion, large output voltage swing, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source/sink AC frequency response.

The LM833 is specified over the automotive temperature range and is available in the plastic DIP and SO–8 packages (P and D suffixes). For an improved performance dual/quad version, see the MC33079 family.

- Low Voltage Noise: 4.5 nV/$\sqrt{Hz}$
- High Gain Bandwidth Product: 15 MHz
- High Slew Rate: 7.0 V/µs
- Low Input Offset Voltage: 0.3 mV
- Low T.C. of Input Offset Voltage: 2.0 µV/°C
- Low Distortion: 0.002%
- Excellent Frequency Stability
- Dual Supply Operation

MOTOROLA

Internally Compensated, High Performance Dual Operational Amplifier

The MCT1458, C was designed for use as a summing amplifier, integrator, or amplifier with operating characteristics as a function of the external feedback components.

- No Frequency Compensation Required
- Short Circuit Protection
- Wide Common Mode and Differential Voltage Ranges
- Low Power Consumption
- No Latch–Up

This MCT–prefixed device is intended to be a possible replacement for the similar device with the MC–prefix. Because the MCT device originates from different source material, there may be subtle differences in typical parameter values or characteristic curves. Due to the diversity of potential applications, Motorola can not assure identical performance in all circuits. Motorola recommends that the customer qualify the MCT–prefixed device in each potential application.

Secondary Winding = 2 turns, #22 AWG wire,
Coefficient of Coupling ≈ 1.0

DESCRIPTION OF SPEECH COMPRESSOR

The amplifier drives the base of a PNP transistor operating common–emitter with a voltage gain of approximately 20. The control R1 varies the quiescent Q point of this transistor so that varying amounts of signal exceed the level V_r. Diode D1 rectifies the positive peaks of Q1's output only when these peaks are greater than $V_r \simeq 7.0$ V. The resulting output is filtered by C_X, R_X.

R_X controls the charging time constant or attack time. C_X is involved in both charge and discharge. R2 (the 150 kΩ and input resistance of the emitter–follower Q2) controls the decay time. Making the decay long and attack short is accomplished by making R_X small and R2 large. (A Darlington emitter–follower may be needed if extremely slow decay times are required.)

The emitter–follower Q2 drives the AGC Pin 5 of the MC1490P and reduces the gain. R3 controls the slope of signal compression.

Table 1. Distortion versus Frequency

Frequency	Distortion		Distortion	
	10 mV e_i	100 mV e_i	10 mV e_i	100 mV e_i
100 Hz	3.5%	12%	15%	27%
300 Hz	2%	10%	6%	20%
1.0 kHz	1.5%	8%	3%	9%
10 kHz	1.5%	8%	1%	3%
100 kHz	1.5%	8%	1%	3%
	Notes 1 and 2		Notes 3 and 4	

Notes:
(1) Decay = 300 ms
Attack = 20 ms
(2) C_X = 7.5 µF
R_X = 0 (Short)
(3) Decay = 20 ms
Attack = 3.0 ms
(4) C_X = 0.68 µF

MOTOROLA

MC1776C

Micropower Programmable Operational Amplifier

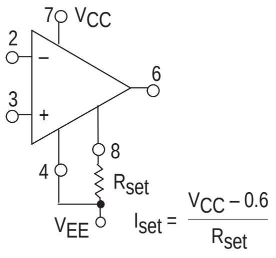
This extremely versatile operational amplifier features low power consumption and high input impedance. In addition, the quiescent currents within the device may be programmed by the choice of an external resistor value or current source applied to the I_{set} input. This allows the amplifier's characteristics to be optimized for input current and power consumption despite wide variations in operating power supply voltages.

- ±1.2 V to ±18 V Operation
- Wide Programming Range
- Offset Null Capability
- No Frequency Compensation Required
- Low Input Bias Currents
- Short Circuit Protection

Resistive Programming

(See Figure 1)

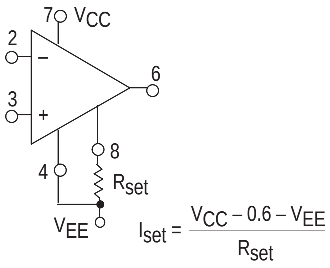
R_{set} to Ground



$$I_{set} = \frac{V_{CC} - 0.6}{R_{set}}$$

R_{set} to Negative Supply

(Recommended for supply voltage less than ±6.0 V)



$$I_{set} = \frac{V_{CC} - 0.6 - V_{EE}}{R_{set}}$$

Typical R_{set} Values		
V_{CC}, V_{EE}	I_{set} = 1.5 μA	I_{set} = 15 μA
±6.0 V	3.6 MΩ	360 kΩ
±10 V	6.2 MΩ	620 kΩ
±12 V	7.5 MΩ	750 kΩ
±15 V	10 MΩ	1.0 MΩ

Typical R_{set} Values		
V_{CC}, V_{EE}	I_{set} = 1.5 μA	I_{set} = 15 μA
±1.5 V	1.6 MΩ	160 kΩ
±3.0 V	3.6 MΩ	360 kΩ
±6.0 V	7.5 MΩ	750 kΩ
±15 V	20 MΩ	2.0 MΩ

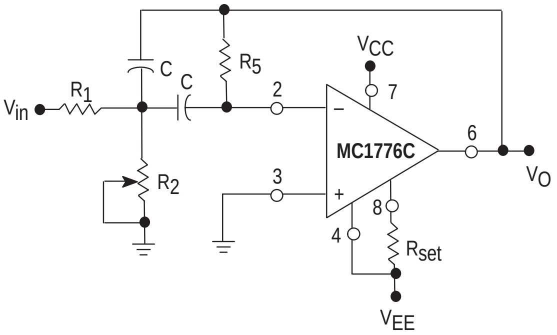
$$f_0 = \frac{1}{2\pi\ RC} \quad \text{(for } f_0 = 1.0\text{ kHz)}$$

R= 16 kΩ
C = 0.01 µF

Figure 14. Multiple Feedback Bandpass Filter



For a given:
fo = center frequency
A (fo) = Gain at center frequency
Q = quality factor

Choose a value for C, then

$$R_5 = \frac{Q}{\pi f_0 C}$$

$$R_1 = \frac{R5}{2A\ (f_0)}$$

$$R_2 = \frac{R1,R5}{4Q^2\ R1–R5}$$

To obtain less than 10% error from the operational amplifier:

$$\frac{Q_O\ f_0}{GBW} \leq 0.1$$

where f_0 and GBW are expressed in Hz. GBW is available from Figure 6 as a function of Set Current, I_{set}.

MC3301, LM2900, LM3900

Quad Single Supply Operational Amplifiers

These internally compensated Norton operational amplifiers are designed specifically for single positive power supply applications found in industrial control systems and automotive electronics. Each device contains four independent amplifiers – making it ideal for applications such as active filters, multi–channel amplifiers, tachometers, oscillators and other similar usage.

- Single Supply Operation
- Internally Compensated
- Wide Unity Gain Bandwidth: 4.0 MHz Typical
- Low Input Bias Current: 50 nA Typical
- High Open Loop Gain: 1000 V/V Minimum
- Large Output Voltage Swing: (V_{CC} – 1) V_{pp}

= 0°C for LM3900 = +70°C for LM3900

2. Open loop voltage gain is defined as voltage gain from the inverting input to the output.
3. Sink current is specified for analog operation. When the device is used as a comparator (non–analog operation) where the inverting input is overdriven, the sink current (low level output current) capability is typically 5.0 mA.
4. This specification indicates the current gain of the current mirror which is used as the noninverting input.
5. Input V_{BE} match between the noninverting and inverting inputs occurs for a mirror current (noninverting input current) of approximately 10 µA.
6. Clamp transistors are included to prevent the input voltages from swinging below ground more than approximately –0.3 V. The negative input currents that may result from large signal overdrive with capacitive input coupling must be limited externally to values of approximately 1.0 mA. If more than one of the input terminals are simultaneously driven negative, maximum currents are reduced. Common mode biasing can be used to prevent negative input voltages.
7. When used as a noninverting amplifier, the minimum output voltage is the V_{BE} of the inverting input transistor.

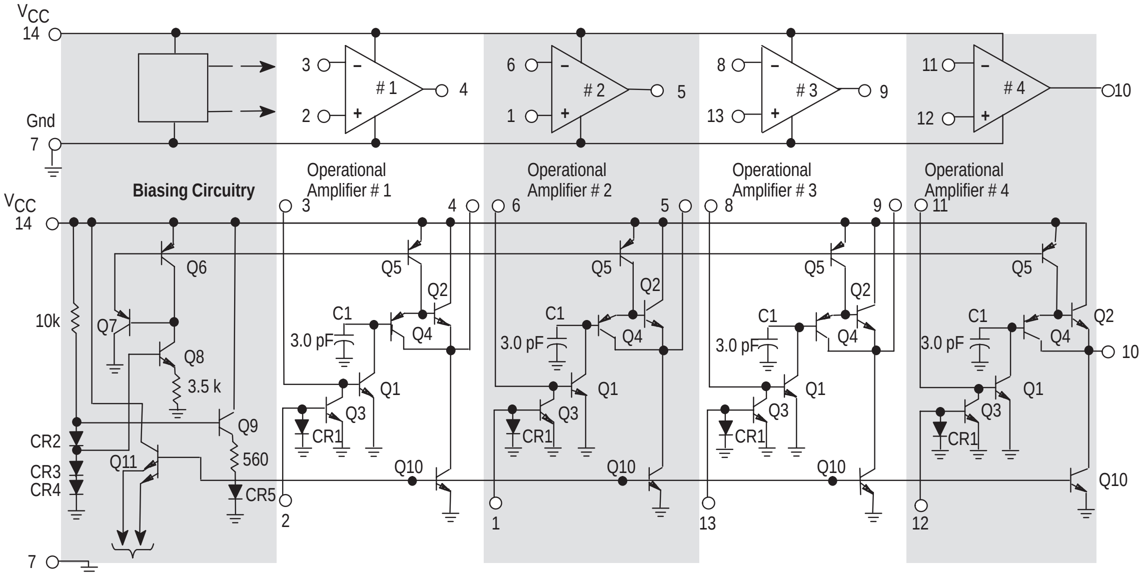
OPERATION AND APPLICATIONS

Basic Amplifier

The basic amplifier is the common emitter stage shown in Figures 7 and 8. The active load I_1 is buffered from the input transistor by a PNP transistor, Q4, and from the output by an NPN transistor, Q2. Q2 is biased Class A by the current source I_2. The magnitude of I_2 (specified I_{sink}) is a limiting factor in capacitively coupled analog operation at the output. The sink of the device can be forced to exceed the specified level by keeping the output DC voltage above ≈ 1.0 V resulting in an increase in the distortion appearing at the output. Closed loop stability is maintained by an on–the–chip 3–pF capacitor shown in Figure 10 on the following page. No external compensation is required.

Figure 7. Block Diagram



Multiple emitter (8) transistor – one emitter connected to each input.

A noninverting input obtained by adding a current mirror as shown in Figure 9. Essentially all current which enters the noninverting input, I_{in}^+, flows through the diode CR1. The voltage drop across CR1 corresponds to this input current magnitude and this same voltage is applied to a matched device, Q3. Thus Q3 is biased to conduct an emitter current equal to I_{in}^+. Since the alpha current gain of Q3 ≈ 1, its collector current is approximately equal to I_{in}^+ also. In operation this current flows through an external feedback resistor which generates the output voltage signal. For inverting applications, the noninverting input is often used to set the DC quiescent level at the output. Techniques for doing this are discussed in the “Normal Design Procedure” section.

Figure 8. A Basic Gain Stage

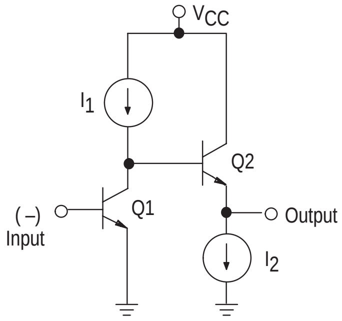


Figure 9. Obtaining A Noninverting Input

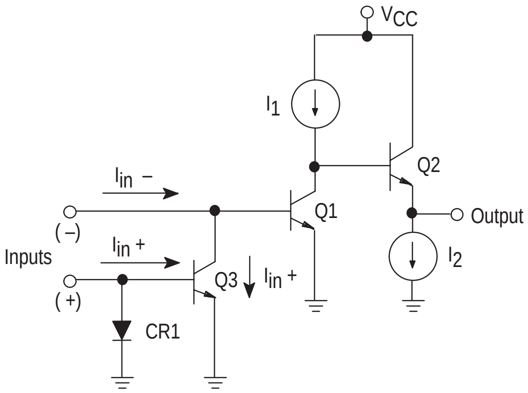

Biasing Circuitry

The circuitry common to all four amplifiers is shown in Figure 11. The purpose of this circuitry is to provide biasing voltage for the PNP and NPN current sources used in the amplifiers.

The voltage drops across diodes CR2, CR3 and CR4 are used as references. The voltage across resistor R1 is the sum of the drops across CR4 and CR3 minus the V_{BE} of Q8. The PNP current sources (Q5, etc.) are set to the magnitude V_{BE}/R1 by transistor Q6. Transistor Q7 reduces base current loading. The voltage across resistor R_2 is the sum of the voltage drops across CR2, CR3 and CR4, minus the V_{BE} drops of transistor Q9 and diode CR5; thus the current set is established by CR5 in all the NPN current sources (Q10, etc.). This technique results in current source magnitudes which are relatively independent of the supply voltage. Q11 (Figure 7) provides circuit protection from signals that are negative with respect to ground.

NORMAL DESIGN PROCEDURE

1. Output Q–Point Biasing
   A. A number of techniques may be devised to bias the quiescent output voltage to an acceptable level. However, in terms of loop gain considerations it is usually desirable to use the noninverting input to effect the biasing, as shown in Figures 12 and 13. The high impedance of the collector of the noninverting "current mirror" transistor helps to achieve the maximum loop gain for any particular configuration. It is desirable that the noninverting input current be in the 10 µA to 200 µA range.

   B. V_{CC} Reference Voltage (see Figures 12 and 13) The noninverting input is normally returned to the V_{CC} voltage (which should be well filtered) through a resistor (R_r) allowing the input current, (I_{in}^+) to be within the range of 10 µA to 200 µA.

   Choosing the feedback resistor (R_f) to be equal to $^1/_2$ R_r will now bias the amplifier output DC level to approximately $V_{CC}/2$. This allows the maximum dynamic range of the output voltage.

   C. Reference Voltage other than V_{CC} (see Figure 14) The biasing resistor (R_r) may be returned to a voltage(V_r) other than V_{CC}. By setting $R_f = R_r$, (still keeping I_{in} +between 10 µA and 200 µA) the output DC level will be equal to V_r. The expression for determining V_{Odc} is:

$$V_{Odc} = \frac{(A_i)(V_r)(R_f)}{R_r} + \left(1 - \frac{R_f}{R_r} A_i\right) \phi$$

   where ϕ is the V_{BE} drop of the input transistors (approximately 0.6 Vdc @ +25°C and assumed equal). A_i is the current mirror gain.

Figure 12. Inverting Amplifier

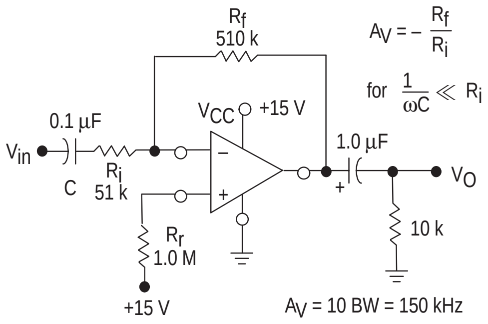

Figure 13. Noninverting Amplifier

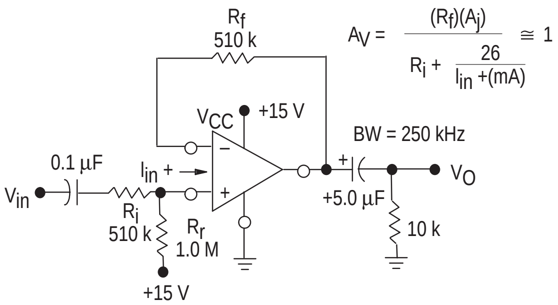


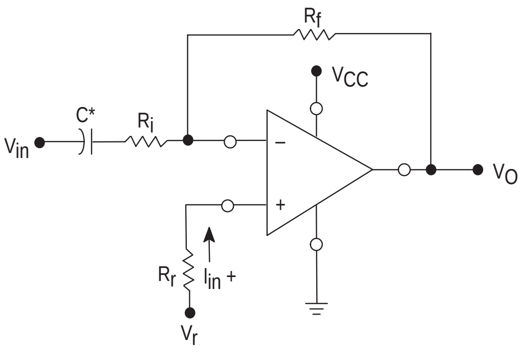
2. Gain Determination
   A. Inverting Amplifier

The amplifier is normally used in the inverting mode. The input may be capacitively coupled to avoid upsetting the DC bias and the output is normally capacitively coupled to eliminate the DC voltage across the load. Note that when the output is capacitively coupled to the load, the value of I_{sink} becomes a limitation with respect to the load driving capabilities of the device if it is direct coupled. In this configuration, the AC gain is determined by the ratio of R_f to R_i, in the same manner as for a conventional operational amplifier:

$$A_V = \frac{R_f}{R_i}$$

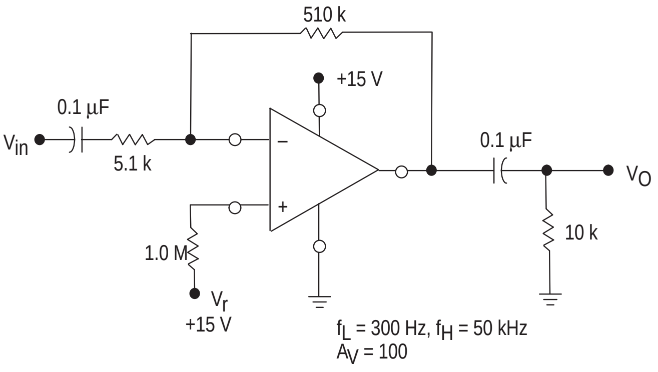
The lower corner frequency is determined by the coupling capacitors to the input and load resistors. The upper corner frequency will usually be determined by the amplifier internal compensation. The amplifier unity gain bandwidth is typically 400 kHz with 20 dB of closed loop gain or 40 kHz with 40 dB of closed loop gain. The exception to this occurs at low gains where the input resistor selected is large. The pole formed by the amplifier input capacitance, stray capacitance and the input resistor may occur before the closed loop gain intercepts the open loop response curve. The inverting input capacity is typically 3.0 pF.

Figure 14. Inverting Amplifier with Arbitrary Reference



*Select for low frequency response.

Figure 15. Inverting Amplifier with A_V = 100 and V_r = V_{CC}



B. Noninverting Amplifier

These devices may be used in the noninverting mode (see Figure 13). The amplifier gain in this configuration is subject to the current mirror gain. In addition, the resistance of the input diode must be included in the value of the input resistor. This resistance is approximately $\frac{26}{I_{in}+}$ Ω, where I_{in}+is input current in milliamperes. The noninverting AC gain expression is given by:

$$A_V = \frac{(R_f)(A_i)}{R_i + \frac{26}{I_{in} + (mA)}}$$

The bandwidth of the noninverting configuration for a given R_f value is essentially independent of the gain chosen. For R_f = 510 kΩ the bandwidth will be in excess of 200 kHz for noninverting of 1, 10, or 100. This is a result of the loop gain remaining constant for these gains since the the input resistor is effectively isolated from the feedback loop.

NOTES:
1. R is used to bias the zener.
2. If the zener TC is positive, and equal in magnitude to the negative TC of the input to the operational amplifier (≈2.0 mV/°C), the output is zero–TC. A 7.0 V zener will give approximately zero–TC.

MOTOROLA

MC3403
MC3303

Quad Low Power Operational Amplifiers

QUAD DIFFERENTIAL INPUT OPERATIONAL AMPLIFIERS

SEMICONDUCTOR
TECHNICAL DATA

The MC3403 is a low cost, quad operational amplifier with true differential inputs. The device has electrical characteristics similar to the popular MC1741C. However, the MC3403 has several distinct advantages over standard operational amplifier types in single supply applications. The quad amplifier can operate at supply voltages as low as 3.0 V or as high as 36 V with quiescent currents about one third of those associated with the MC1741C (on a per amplifier basis). The common mode input range includes the negative supply, thereby eliminating the necessity for external biasing components in many applications. The output voltage range also includes the negative power supply voltage.

- Short Circuit Protected Outputs
- Class AB Output Stage for Minimal Crossover Distortion
- True Differential Input Stage
- Single Supply Operation: 3.0 V to 36 V
- Split Supply Operation: ±1.5 V to ±18 V
- Low Input Bias Currents: 500 nA Max
- Four Amplifiers Per Package
- Internally Compensated
- Similar Performance to Popular MC1741C
- Industry Standard Pinouts
- ESD Diodes Added for Increased Ruggedness

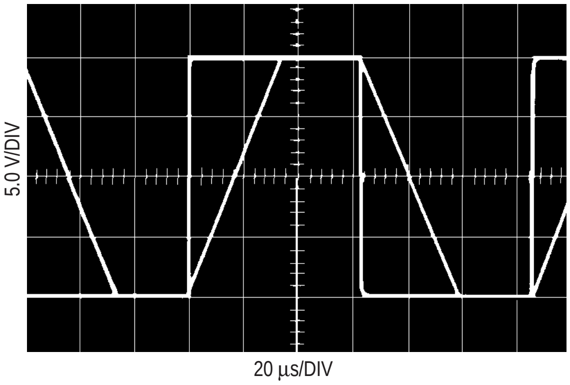
CIRCUIT DESCRIPTION

Inverter Pulse Response



The MC3403/3303 is made using four internally compensated, two–stage operational amplifiers. The first stage of each consists of differential input device Q24 and Q22 with input buffer transistors Q25 and Q21 and the differential to single ended converter Q3 and Q4. The first stage performs not only the first stage gain function but also performs the level shifting and transconductance reduction functions. By reducing the transconductance, a smaller compensation capacitor (only 5.0 pF) can be employed, thus saving chip area. The transconductance reduction is accomplished by splitting the collectors of Q24 and Q22. Another feature of this input stage is that the input common mode range can include the negative supply or ground, in single supply operation, without saturating either the input devices or the differential to single–ended converter. The second stage consists of a standard current source load amplifier stage.

The output stage is unique because it allows the output to swing to ground in single supply operation and yet does not exhibit any crossover distortion in split supply operation. This is possible because Class AB operation is utilized.

Each amplifier is biased from an internal voltage regulator which has a low temperature coefficient, thus giving each amplifier good temperature characteristics as well as excellent power supply rejection.

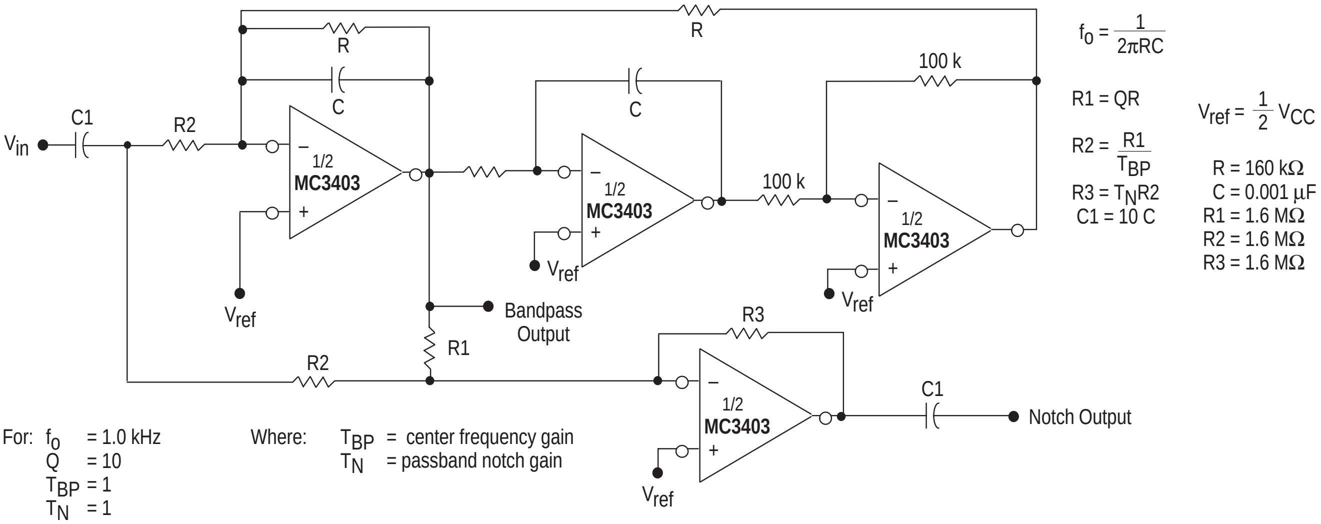
$V_{inH} = \frac{R1}{R1 + R2}(V_{OH} - V_{ref}) + V_{ref}$

$V_h = \frac{R1}{R1 + R2}(V_{OH} - V_{OL})$

Figure 11. Bi–Quad Filter



$f_o = \frac{1}{2\pi RC}$

$R1 = QR$

$R2 = \frac{R1}{T_{BP}}$

$R3 = T_N R2$

$C1 = 10\,C$

$V_{ref} = \frac{1}{2} V_{CC}$

$R = 160\ k\Omega$

$C = 0.001\ \mu F$

$R1 = 1.6\ M\Omega$

$R2 = 1.6\ M\Omega$

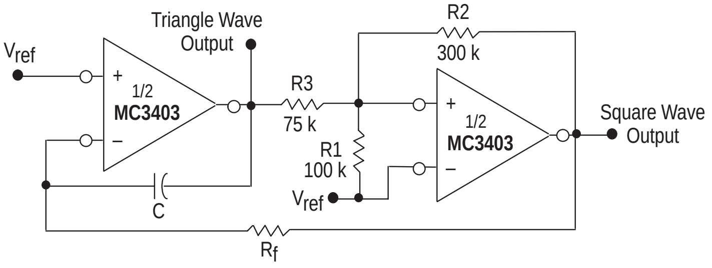
$R3 = 1.6\ M\Omega$

For: $f_o = 1.0$ kHz
$Q = 10$
$T_{BP} = 1$
$T_N = 1$

Where: T_{BP} = center frequency gain
T_N = passband notch gain

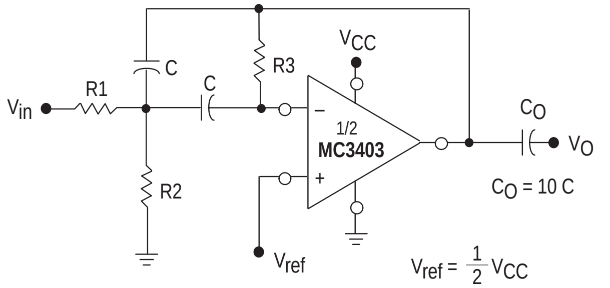
Figure 12. Function Generator

$V_{ref} = \frac{1}{2} V_{CC}$



$f = \frac{R1 + R_C}{4\,CR_f\,R1}$ if $R3 = \frac{R2\,R1}{R2 + R1}$

Figure 13. Multiple Feedback Bandpass Filter



$V_{ref} = \frac{1}{2} V_{CC}$

Given: f_o = center frequency
$A(f_o)$ = gain at center frequency

Choose value f_o, C

Then: $R3 = \frac{Q}{\pi f_o C}$ $R1 = \frac{R3}{2\,A(f_o)}$ $R2 = \frac{R1\,R5}{4Q^2\,R1 - R5}$

For less than 10% error from operational amplifier $\frac{O_o f_o}{BW} < 0.1$ where f_o and BW are expressed in Hz.

If source impedance varies, filter may be preceded with voltage follower buffer to stabilize filter parameters.

MOTOROLA

MC3405

Dual Operational Amplifier and Dual Comparator

DUAL OPERATIONAL AMPLIFIER / DUAL VOLTAGE COMPARATOR

SEMICONDUCTOR TECHNICAL DATA

The MC3405 contains two differential–input operational amplifiers and two comparators, each set capable of single supply operation. This operational amplifier–comparator circuit fulfills its applications as a general purpose product for automotive and consumer circuits as well as an industrial building block.

The MC3405 is specified over the commercial operating temperature range of 0° to +70°C.

- Operational Amplifier Equivalent in Performance to MC3403
- Comparator Similar in Performance to LM339
- Single Supply Operation: 3.0 V to 36 V
- Split Supply Operation: ±1.5 V to ±18 V
- Low Supply Current Drain
- Operational Amplifier is Internally Frequency Compensated
- Comparator TTL and CMOS Compatible

Dual, Low Power Operational Amplifiers

Utilizing the circuit designs perfected for the quad operational amplifiers, these dual operational amplifiers feature: 1) low power drain, 2) a common mode input voltage range extending to ground/V_{EE}, and 3) Single Supply or Split Supply operation.

These amplifiers have several distinct advantages over standard operational amplifier types in single supply applications. They can operate at supply voltages as low as 3.0 V or as high as 36 V with quiescent currents about one–fifth of those associated with the MC1741C (on a per amplifier basis). The common mode input range includes the negative supply, thereby eliminating the necessity for external biasing components in many applications. The output voltage range also includes the negative power supply voltage.

- Short Circuit Protected Outputs
- True Differential Input Stage
- Single Supply Operation: 3.0 V to 36 V
- Low Input Bias Currents
- Internally Compensated
- Common Mode Range Extends to Negative Supply
- Class AB Output Stage for Minimum Crossover Distortion
- Single and Split Supply Operations Available
- Similar Performance to the Popular MC1458

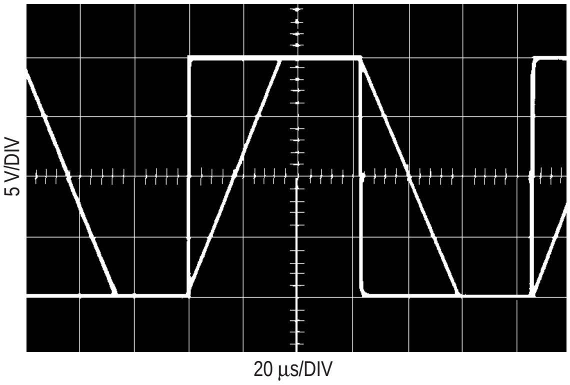
Inverter Pulse Response



CIRCUIT DESCRIPTION

The MC3458/3358 is made using two internally compensated, two–stage operational amplifiers. The first stage of each consists of differential input devices Q24 and Q22 with input buffer transistors Q25 and Q21 and the differential to single ended converter Q3 and Q4. The first stage performs not only the first stage gain function but also performs the level shifting and transconductance reduction functions. By reducing the transconductance, a smaller compensation capacitor (only 5.0 pF) can be employed, thus saving chip area. The transconductance reduction is accomplished by splitting the collectors of Q24 and Q22. Another feature of this input stage is that the input Common Mode range can include the negative supply or ground, in single supply operation, without saturating either the input devices or the differential to single–ended converter. The second stage consists of a standard current source load amplifier stage.

The output stage is unique because it allows the output to swing to ground in single supply operation and yet does not exhibit any crossover distortion in split supply operation. This is possible because Class AB operation is utilized.

Each amplifier is biased from an internal voltage regulator which has a low temperature coefficient thus giving each amplifier good temperature characteristics as well as excellent power supply rejection.

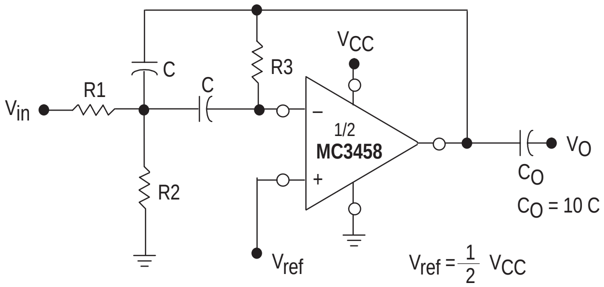
$$f = \frac{R1 + R_C}{4\,CR_f\,R1} \qquad \text{if,} \quad R3 = \frac{R2\,R1}{R2 + R1}$$

Figure 13. Multiple Feedback Bandpass Filter



Given: f_0 = center frequency
$A(f_0)$ = gain at center frequency

Choose value f_0, C.

Then: $R3 = \frac{Q}{\pi f_0 C}$ $\quad R1 = \frac{R3}{2\,A(f_0)}$ $\quad R2 = \frac{R1\,R5}{4Q^2\,R1 - R3}$

For less than 10% error from operational amplifier $\frac{Q_0\,f_0}{BW} < 0.1$

where, f_0 and BW are expressed in Hz.

If source impedance varies, filter may be preceded with voltage follower buffer to stabilize filter parameters.

MOTOROLA

MC3476

Low Cost Programmable Operational Amplifier

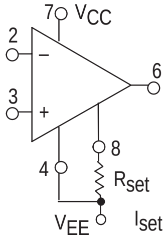
The MC3476 is a low cost selection of the popular industry standard MC1776 programmable operational amplifier. This extremely versatile operational amplifier features low power consumption and high input impedance. In addition, the quiescent currents within the device may be programmed by the choice of an external resistor value or current source applied to the I_{set} input. This allows the amplifier's characteristics to be optimized for input current and power consumption despite wide variations in operating power supply voltages.

- ±6.0 V to ±18 V Operation
- Wide Programming Range
- Offset Null Capability
- No Frequency Compensation Required
- Low Input Bias Currents
- Short Circuit Protection

Resistive Programming

(See Figure 1)

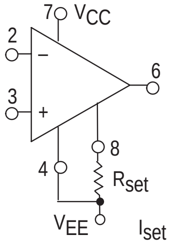
R_{set} to Ground



$$I_{set} = \frac{V_{CC} - 0.6}{R_{set}}$$

R_{set} to Negative Supply

(Recommended for supply voltage less than ±6.0 V)



$$I_{set} = \frac{V_{CC} - 0.6 - V_{EE}}{R_{set}}$$

Typical R_{set} Values		
V_{CC}, V_{EE}	I_{set} = 1.5 μA	I_{set} = 15 μA
±6.0 V	3.6 MΩ	360 kΩ
±10 V	6.2 MΩ	620 kΩ
±12 V	7.5 MΩ	750 kΩ
±15 V	10 MΩ	1.0 MΩ

Typical R_{set} Values		
V_{CC}, V_{EE}	I_{set} = 1.5 μA	I_{set} = 15 μA
+1.5 V	1.6 MΩ	160 kΩ
+3.0 V	3.6 MΩ	360 kΩ
+6.0 V	7.5 MΩ	750 kΩ
+15 V	20 MΩ	2.0 MΩ

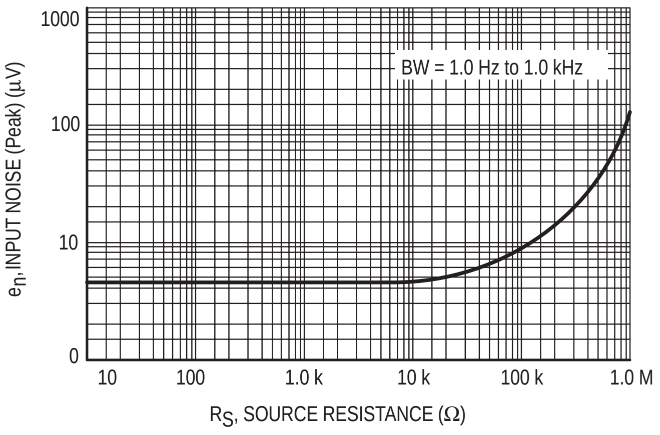

Figure 2. RMS Noise versus Source Resistance

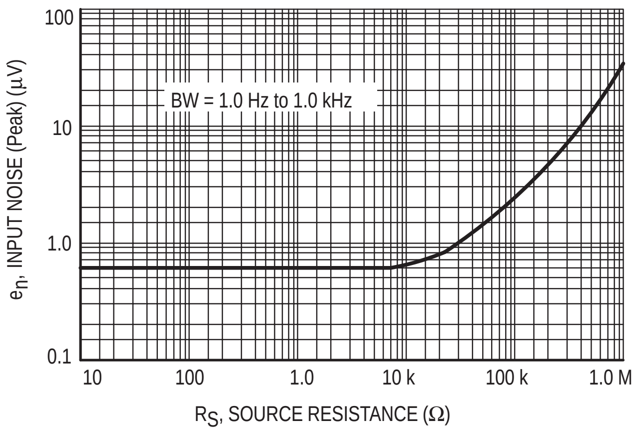

Figure 3. Output Noise versus Source Resistance

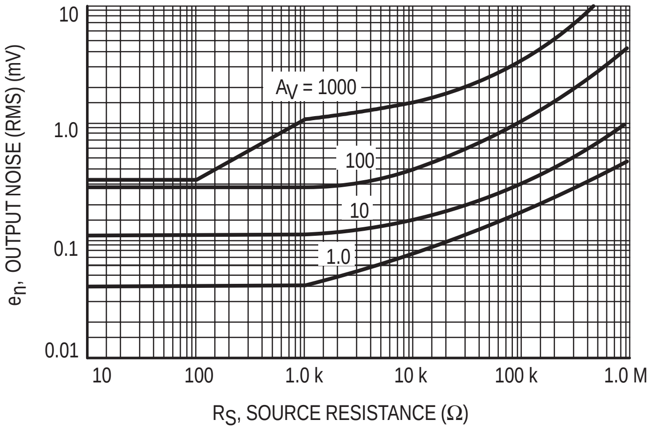

Figure 4. Spectral Noise Density

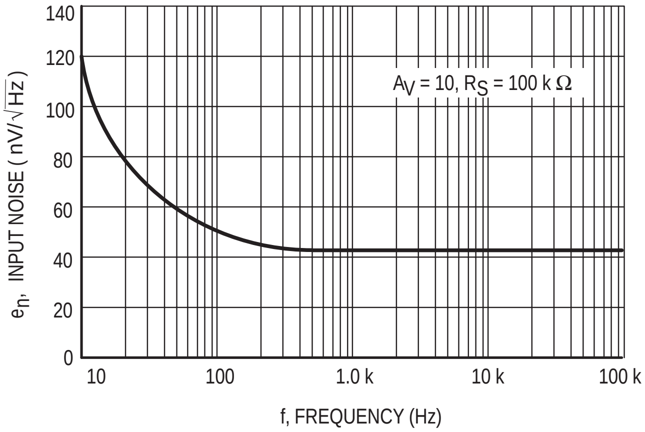

Figure 5. Burst Noise Test Circuit

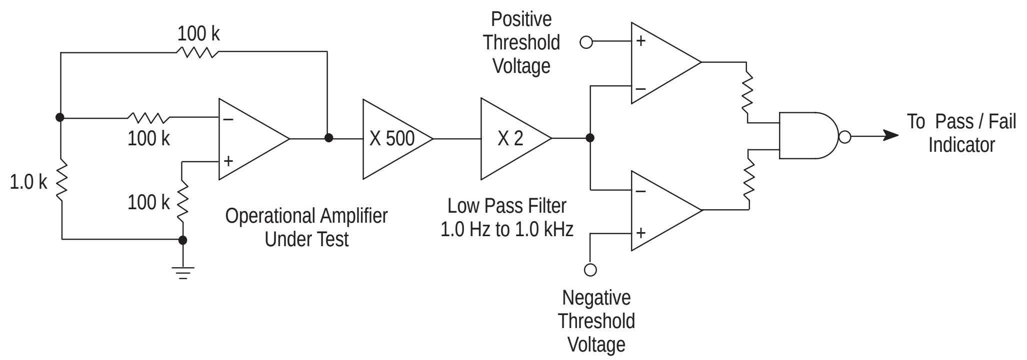

Unlike conventional peak reading or RMS meters, this system was especially designed to provide the quick response time essential to burst (popcorn) noise testing.

The test time employed is 10 sec and the 20 μV peak limit refers to the operational amplifier input thus eliminating errors in the closed loop gain factor of the operational amplifier.

MOTOROLA

MCT4558C

Dual Wide Bandwidth Operational Amplifier

The MCT4558C combines all of the outstanding features of the MC1458 and, in addition, offers three times the unity gain bandwidth of the industry standard.

- 2.0 MHz Unity Gain Bandwidth Guaranteed
- Internally Compensated
- Short Circuit Protection
- Gain and Phase Match Between Amplifiers
- Low Power Consumption

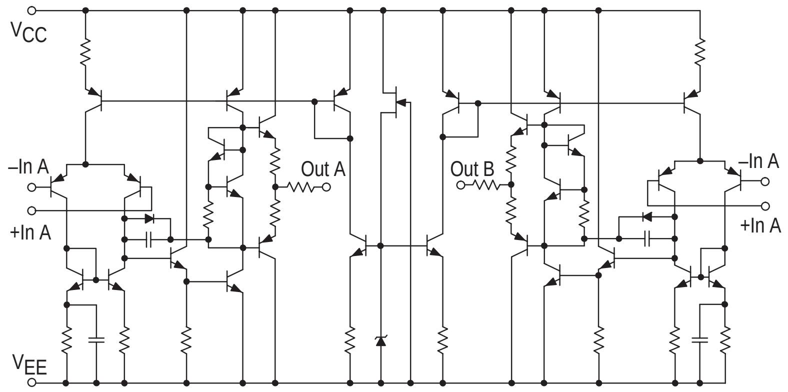
This MCT–prefixed device is intended to be a possible replacement for the similar device with the MC–prefix. Because the MCT device originates from different source material, there may be subtle differences in typical parameter values or characteristic curves. Due to the diversity of potential applications, Motorola can not assure identical performance in all circuits. Motorola recommends that the customer qualify the MCT–prefixed device in each potential application.

MAXIMUM RATINGS (T_A = +25°C, unless otherwise noted.)

Rating	Symbol	Value	Unit
Power Supply Voltages	V_{CC} V_{EE}	+18 –18	Vdc
Input Differential Voltage	V_{ID}	±30	V
Input Common Mode Voltage (Note 1)	V_{ICM}	±15	V
Output Short Circuit Duration (Note 2)	t_{SC}	Continuous	
Ambient Temperature Range	T_A	0 to +70	°C
Storage Temperature Range	T_{stg}	–55 to +125	°C
Junction Temperature	T_J	150	°C

NOTES: 1. For supply voltages less than ±15 V, the absolute maximum input voltage is equal to the supply voltage.
2. Short circuit may be to ground or either supply.

Representative Schematic Diagram



This device contains 29 active transistors.

CAUTION: These devices do not have internal ESD protection circuitry and are rated as CLASS 1 devices per the ESD test method in Mil–Std–833D. They should be handled using standard ESD prevention methods to avoid damage to the device.

MOTOROLA

MC4741C

Differential Input Operational Amplifier

The MC4741C is a true quad MC1741. Integrated on a single monolithic chip are four independent, low power operational amplifiers which have been designed to provide operating characteristics identical to those of the industry standard MC1741, and can be applied with no change in circuit performance.

The MC4741C can be used in applications where amplifier matching or high packing density is important. Other applications include high impedance buffer amplifiers and active filter amplifiers.

- Each Amplifier is Functionally Equivalent to the MC1741
- Class AB Output Stage Eliminates Crossover Distortion
- True Differential Inputs
- Internally Frequency Compensated
- Short Circuit Protection
- Low Power Supply Current (0.6 mA/Amplifier)

MOTOROLA

MC33076

Dual High Output Current, Low Power, Low Noise Bipolar Operational Amplifier

The MC33076 operational amplifier employs bipolar technology with innovative high performance concepts for audio and industrial applications. This device uses high frequency PNP input transistors to improve frequency response. In addition, the amplifier provides high output current drive capability while minimizing the drain current. The all NPN output stage exhibits no deadband crossover distortion, large output voltage swing, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source and sink AC frequency performance.

The MC33076 is tested over the automotive temperature range and is available in an 8–pin SOIC package (D suffix) and in both the standard 8 pin DIP and 16–pin DIP packages for high power applications.

- 100 Ω Output Drive Capability
- Large Output Voltage Swing
- Low Total Harmonic Distortion
- High Gain Bandwidth: 7.4 MHz
- High Slew Rate: 2.6 V/µs
- Dual Supply Operation: ±2.0 V to ±18 V
- High Output Current: ISC = 250 mA typ
- Similar Performance to MC33178

APPLICATIONS INFORMATION

The MC33076 dual operational amplifier is available in the standard 8–pin plastic dual–in–line (DIP) and surface mount packages, and also in a 16–pin batwing power package. To enhance the power dissipation capability of the power package, Pins 4, 5, 12, and 13 are tied together on the leadframe, giving it an ambient thermal resistance of 52°C/W typically, in still air. The junction–to–ambient thermal resistance ($R_{\theta JA}$) can be decreased further by using a copper padb on the printed circuit board (as shown in Figure 26) to draw the heat away from the package. *Care must be taken not to exceed the maximum junction temperature or damage to the device may occur.*

MOTOROLA

MC33077

Dual, Low Noise Operational Amplifier

DUAL, LOW NOISE OPERATIONAL AMPLIFIER

SEMICONDUCTOR TECHNICAL DATA

The MC33077 is a precision high quality, high frequency, low noise monolithic dual operational amplifier employing innovative bipolar design techniques. Precision matching coupled with a unique analog resistor trim technique is used to obtain low input offset voltages. Dual–doublet frequency compensation techniques are used to enhance the gain bandwidth product of the amplifier. In addition, the MC33077 offers low input noise voltage, low temperature coefficient of input offset voltage, high slew rate, high AC and DC open loop voltage gain and low supply current drain. The all NPN transistor output stage exhibits no deadband cross–over distortion, large output voltage swing, excellent phase and gain margins, low open loop output impedance and symmetrical source and sink AC frequency performance.

The MC33077 is tested over the automotive temperature range and is available in plastic DIP and SO–8 packages (P and D suffixes).

- Low Voltage Noise: $4.4\ \text{nV}/\sqrt{\text{Hz}}$ @ 1.0 kHz
- Low Input Offset Voltage: 0.2 mV
- Low TC of Input Offset Voltage: 2.0 µV/°C
- High Gain Bandwidth Product: 37 MHz @ 100 kHz
- High AC Voltage Gain: 370 @ 100 kHz
  1850 @ 20 kHz
- Unity Gain Stable: with Capacitance Loads to 500 pF
- High Slew Rate: 11 V/µs
- Low Total Harmonic Distortion: 0.007%
- Large Output Voltage Swing: +14 V to –14.7 V
- High DC Open Loop Voltage Gain: 400 k (112 dB)
- High Common Mode Rejection: 107 dB
- Low Power Supply Drain Current: 3.5 mA
- Dual Supply Operation: ±2.5 V to ±18 V

APPLICATIONS INFORMATION

The MC33077 is designed primarily for its low noise, low offset voltage, high gain bandwidth product and large output swing characteristics. Its outstanding high frequency gain/phase performance make it a very attractive amplifier for high quality preamps, instrumentation amps, active filters and other applications requiring precision quality characteristics.

The MC33077 utilizes high frequency lateral PNP input transistors in a low noise bipolar differential stage driving a compensated Miller integration amplifier. Dual–doublet frequency compensation techniques are used to enhance the gain bandwidth product. The output stage uses an all NPN transistor design which provides greater output voltage swing and improved frequency performance over more conventional stages by using both PNP and NPN transistors (Class AB). This combination produces an amplifier with superior characteristics.

Through precision component matching and innovative current mirror design, a lower than normal temperature coefficient of input offset voltage (2.0 μV/°C as opposed to 10 μV/°C), as well as low input offset voltage, is accomplished.

The minimum common mode input range is from 1.5 V below the positive rail (V_{CC}) to 1.5 V above the negative rail (V_{EE}). The inputs will typically common mode to within 1.0 V of both negative and positive rails though degradation in offset voltage and gain will be experienced as the common mode voltage nears either supply rail. In practice, though not recommended, the input voltage may exceed V_{CC} by approximately 30 V and decrease below the V_{EE} by approximately 0.6 V without causing permanent damage to the device. If the input voltage on either or both inputs is less than approximately 0.6 V, excessive current may flow, if not limited, causing permanent damage to the device.

The amplifier will not latch with input source currents up to 20 mA, though in practice, source currents should be limited to 5.0 mA to avoid any parametric damage to the device. If both inputs exceed V_{CC}, the output will be in the high state and phase reversal may occur. No phase reversal will occur if the voltage on one input is within the common mode range and the voltage on the other input exceeds V_{CC}. Phase reversal may occur if the input voltage on either or both inputs is less than 1.0 V above the negative rail. Phase reversal will be experienced if the voltage on either or both inputs is less than V_{EE}.

Through the use of dual–doublet frequency compensation techniques, the gain bandwidth product has been greatly enhanced over other amplifiers using the conventional single pole compensation. The phase and gain error of the amplifier remains low to higher frequencies for fixed amplifier gain configurations.

With the all NPN output stage, there is minimal swing loss to the supply rails, producing superior output swing, no crossover distortion and improved output phase symmetry with output voltage excursions (output phase symmetry being the amplifiers ability to maintain a constant phase relation independent of its output voltage swing). Output phase symmetry degradation in the more conventional PNP and NPN transistor output stage was primarily due to the inherent cut–off frequency mismatch of the PNP and NPN transistors used (typically 10 MHz and 300 MHz, respectively), causing considerable phase change to occur as the output voltage changes. By eliminating the PNP in the output, such phase change has been avoided and a very significant improvement in output phase symmetry as well as output swing has been accomplished.

The output swing improvement is most noticeable when operation is with lower supply voltages (typically 30% with ± 5.0 V supplies). With a 10 k load, the output of the amplifier can typically swing to within 1.0 V of the positive rail (V_{CC}), and to within 0.3 V of the negative rail (V_{EE}), producing a 28.7 V_{pp} signal from ±15 V supplies. Output voltage swing can be further improved by using an output pull–up resistor referenced to the V_{CC}. Where output signals are referenced to the positive supply rail, the pull–up resistor will pull the output to V_{CC} during the positive swing, and during the negative swing, the NPN output transistor collector will pull the output very near V_{EE}. This configuration will produce the maximum attainable output signal from given supply voltages. The value of load resistance used should be much less than any feedback resistance to avoid excess loading and allow easy pull–up of the output.

Output impedance of the amplifier is typically less than 50 Ω at frequencies less than the unity gain crossover frequency (see Figure 18). The amplifier is unity gain stable with output capacitance loads up to 500 pF at full output swing over the –55° to +125°C temperature range. Output phase symmetry is excellent with typically 4°C total phase change over a 20 V output excursion at 25°C with a 2.0 kΩ and 100 pF load. With a 2.0 kΩ resistive load and no capacitance loading, the total phase change is approximately one degree for the same 20 V output excursion. With a 2.0 kΩ and 500 pF load at 125°C, the total phase change is typically only 10°C for a 20 V output excursion (see Figure 27).

As with all amplifiers, care should be exercised to insure that one does not create a pole at the input of the amplifier which is near the closed loop corner frequency. This becomes a greater concern when using high frequency amplifiers since it is very easy to create such a pole with relatively small values of resistance on the inputs. If this does occur, the amplifier's phase will degrade severely causing the amplifier to become unstable. Effective source resistances, acting in conjunction with the input capacitance of the amplifier, should be kept to a minimum to avoid creating such a pole at the input (see Figure 31). There is minimal effect on stability where the created input pole is much greater than the closed loop corner frequency. Where amplifier stability is affected as a result of a negative feedback resistor in conjunction with the amplifier's input capacitance, creating a pole near the closed loop corner frequency, lead capacitor compensation techniques (lead capacitor in parallel with the feedback resistor) can be employed to improve stability. The feedback resistor and lead capacitor RC time constant should be larger than that of the uncompensated input pole frequency. Having a high resistance connected to the noninverting input of the amplifier can create a like instability problem. Compensation for this condition can be accomplished by adding a lead capacitor in parallel with the noninverting input resistor of such a value as to make the RC time constant larger than the RC time constant of the uncompensated input resistor acting in conjunction with the amplifiers input capacitance.

For optimum frequency performance and stability, careful component placement and printed circuit board layout should be exercised. For example, long unshielded input or output leads may result in unwanted input output coupling. In order to reduce the input capacitance, the body of resistors connected to the input pins should be physically close to the input pins. This not only minimizes the input pole creation for optimum frequency response, but also minimizes extraneous signal "pickup" at this node. Power supplies should be decoupled with adequate capacitance as close as possible to the device supply pin.

In addition to amplifier stability considerations, input source resistance values should be low to take full advantage of the low noise characteristics of the amplifier. Thermal noise (Johnson Noise) of a resistor is generated by thermally–charged carriers randomly moving within the resistor creating a voltage. The rms thermal noise voltage in a resistor can be calculated from:

$$E_{nr} = \sqrt{4k\,TR \times BW}$$

where:

k = Boltzmann's Constant (1.38×10^{-23} joules/k)
T = Kelvin temperature
R = Resistance in ohms
BW = Upper and lower frequency limit in Hertz.

By way of reference, a 1.0 kΩ resistor at 25°C will produce a 4.0 $nV/\sqrt{Hz}$ of rms noise voltage. If this resistor is connected to the input of the amplifier, the noise voltage will be gained–up in accordance to the amplifier's gain configuration. For this reason, the selection of input source resistance for low noise circuit applications warrants serious consideration. The total noise of the amplifier, as referred to its inputs, is typically only 4.4 $nV/\sqrt{Hz}$ at 1.0 kHz.

The output of any one amplifier is current limited and thus protected from a direct short to ground, However, under such conditions, it is important not to allow the amplifier to exceed the maximum junction temperature rating. Typically for ±15 V supplies, any one output can be shorted continuously to ground without exceeding the temperature rating.

MC33079

Dual/Quad Low Noise Operational Amplifiers

The MC33078/9 series is a family of high quality monolithic amplifiers employing Bipolar technology with innovative high performance concepts for quality audio and data signal processing applications. This family incorporates the use of high frequency PNP input transistors to produce amplifiers exhibiting low input voltage noise with high gain bandwidth product and slew rate. The all NPN output stage exhibits no deadband crossover distortion, large output voltage swing, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source and sink AC frequency performance.

The MC33078/9 family offers both dual and quad amplifier versions, tested over the automotive temperature range and available in the plastic DIP and SOIC packages (P and D suffixes).

- Dual Supply Operation: ±5.0 V to ±18 V
- Low Voltage Noise: 4.5 nV/$\sqrt{\text{Hz}}$
- Low Input Offset Voltage: 0.15 mV
- Low T.C. of Input Offset Voltage: 2.0 µV/°C
- Low Total Harmonic Distortion: 0.002%
- High Gain Bandwidth Product: 16 MHz
- High Slew Rate: 7.0 V/µs
- High Open Loop AC Gain: 800 @ 20 kHz
- Excellent Frequency Stability
- Large Output Voltage Swing: +14.1 V/ –14.6 V
- ESD Diodes Provided on the Inputs

MOTOROLA

Sleep-Mode™ Two-State, Micropower Operational Amplifier

The MC33102 dual operational amplifier is an innovative design concept employing Sleep–Mode technology. Sleep–Mode amplifiers have two separate states, a sleepmode and an awakemode. In sleepmode, the amplifier is active and waiting for an input signal. When a signal is applied causing the amplifier to source or sink 160 µA (typically) to the load, it will automatically switch to the awakemode which offers higher slew rate, gain bandwidth, and drive capability.

- Two States: “Sleepmode” (Micropower) and “Awakemode” (High Performance)
- Switches from Sleepmode to Awakemode in 4.0 µs when Output Current Exceeds the Threshold Current (R_L = 600 Ω)
- Independent Sleepmode Function for Each Op Amp
- Standard Pinouts – No Additional Pins or Components Required
- Sleepmode State – Can Be Used in the Low Current Idle State as a Fully Functional Micropower Amplifier
- Automatic Return to Sleepmode when Output Current Drops Below Threshold
- No Deadband/Crossover Distortion; as Low as 1.0 Hz in the Awakemode
- Drop–in Replacement for Many Other Dual Op Amps
- ESD Clamps on Inputs Increase Reliability without Affecting Device Operation

TYPICAL SLEEPMODE/AWAKEMODE PERFORMANCE

Characteristic	Sleepmode (Typical)	Awakemode (Typical)	Unit
Low Current Drain	45	750	µA
Low Input Offset Voltage	0.15	0.15	mV
High Output Current Capability	0.15	50	mA
Low T.C. of Input Offset Voltage	1.0	1.0	µV/°C
High Gain Bandwidth (@ 20 kHz)	0.33	4.6	MHz
High Slew Rate	0.16	1.7	V/µs
Low Noise (@ 1.0 kHz)	28	9.0	$nV/\sqrt{Hz}$

MAXIMUM RATINGS

Ratings	Symbol	Value	Unit
Supply Voltage (V_{CC} to V_{EE})	V_S	+36	V

CIRCUIT INFORMATION

The MC33102 was designed primarily for applications where high performance (which requires higher current drain) is required only part of the time. The two–state feature of this op amp enables it to conserve power during idle times, yet be powered up and ready for an input signal. Possible applications include laptop computers, automotive, cordless phones, baby monitors, and battery operated test equipment. Although most applications will require low power consumption, this device can be used in any application where better efficiency and higher performance is needed.

The Sleep–Mode™ amplifier has two states; a sleepmode and an awakemode. In the sleepmode state, the amplifier is active and functions as a typical micropower op amp. When a signal is applied to the amplifier causing it to source or sink sufficient current (see Figure 13), the amplifier will automatically switch to the awakemode. See Figures 20 and 21 for transition times with 600 Ω and 10 kΩ loads.

The awakemode uses higher drain current to provide a high slew rate, gain bandwidth, and output current capability. In the awakemode, this amplifier can drive 27 Vpp into a 600 Ω load with $V_S = \pm 15$ V.

An internal delay circuit is used to prevent the amplifier from returning to the sleepmode at every zero crossing. This delay circuit also eliminates the crossover distortion commonly found in micropower amplifiers. This amplifier can process frequencies as low as 1.0 Hz without the amplifier returning to sleepmode, depending on the load.

The first stage PNP differential amplifier provides low noise performance in both the sleep and awake modes, and an all NPN output stage provides symmetrical source and sink AC frequency response.

APPLICATIONS INFORMATION

The MC33102 will begin to function at power supply voltages as low as $V_S = \pm 1.0$ V at room temperature. (At this voltage, the output voltage swing will be limited to a few hundred millivolts.) The input voltages must range between V_{CC} and V_{EE} supply voltages as shown in the maximum rating table. Specifically, **allowing the input to go more negative than 0.3 V below V_{EE} may cause product damage.** Also, exceeding the input common mode voltage range on either input may cause phase reversal, even if the inputs are between V_{CC} and V_{EE}.

When power is initially applied, the part may start to operate in the awakemode. This is because of the currents generated due to charging of internal capacitors. When this occurs and the sleepmode state is desired, the user will have to wait approximately 1.5 seconds before the device will switch back to the sleepmode. To prevent this from occurring, ramp the power supplies from 1.0 V to full supply. Notice that the device is more prone to switch into the awakemode when V_{EE} is adjusted than with a similar change in V_{CC}.

The amplifier is designed to switch from sleepmode to awakemode whenever the output current exceeds a preset current threshold (I_{TH}) of approximately 160 µA. As a result, the output switching threshold voltage (V_{ST}) is controlled by the output loading resistance (R_L). This loading can be a load resistor, feedback resistors, or both. Then:

$$V_{ST} = (160\ \mu A) \times R_L$$

Large valued load resistors require a large output voltage to switch, but reduce unwanted transitions to the awakemode. For instance, in cases where the amplifier is connected with a large closed loop gain (A_{CL}), the input offset voltage (V_{IO}) is multiplied by the gain at the output and could produce an output voltage exceeding V_{ST} with no input signal applied.

Small values of R_L allow rapid transition to the awakemode because most of the transition time is consumed slewing in the sleepmode until V_{ST} is reached (see Figures 20, 21). The output switching threshold voltage V_{ST} is higher for larger values of R_L, requiring the amplifier to slew longer in the slower sleepmode state before switching to the awakemode.

The transition time (t_{tr1}) required to switch from sleep to awake mode is:

$$t_{tr1} = t_D = I_{TH} (R_L/SR_{sleepmode})$$

Where: t_D = Amplifier delay (<1.0 μs)
I_{TH} = Output threshold current for more transition (160 μA)
R_L = Load resistance
$SR_{sleepmode}$ = Sleepmode slew rate (0.16 V/μs)

Although typically 160 μA, I_{TH} varies with supply voltage and temperature. In general, any current loading on the output which causes a current greater than I_{TH} to flow will switch the amplifier into the awakemode. This includes transition currents such as those generated by charging load capacitances. In fact, the maximum capacitance that can be driven while attempting to remain in the sleepmode is approximately 1000 pF.

$$\begin{aligned} C_{L(max)} &= I_{TH}/SR_{sleepmode} \\ &= 160\ \mu A/(0.16\ V/\mu s) \\ &= 1000\ pF \end{aligned}$$

Any electrical noise seen at the output of the MC33102 may also cause the device to transition to the awakemode. To minimize this problem, a resistor may be added in series with the output of the device (inserted as close to the device as possible) to isolate the op amp from both parasitic and load capacitance.

The awakemode to sleepmode transition time is controlled by an internal delay circuit, which is necessary to prevent the amplifier from going to sleep during every zero crossing. This time is a function of supply voltage and temperature as shown in Figure 22.

Gain bandwidth product (GBW) in both modes is an important system design consideration when using a sleepmode amplifier. The amplifier has been designed to obtain the maximum GBW in both modes. “Smooth” AC transitions between modes with no noticeable change in the amplitude of the output voltage waveform will occur as long as the closed loop gains (A_{CL}) in both modes are substantially equal at the frequency of operation. For smooth AC transitions:

$$(A_{CLsleepmode})\ (BW) < GBW_{sleepmode}$$

Where: $A_{CLsleepmode}$ = Closed loop gain in the sleepmode
BW = The required system bandwidth or operating frequency

TESTING INFORMATION

To determine if the MC33102 is in the awakemode or the sleepmode, the power supply currents (I_D+ and I_D–) must be measured. When the magnitude of **either** power supply current exceeds 400 μA, the device is in the awakemode. When the magnitudes of both supply currents are less than 400 μA, the device is in the sleepmode. Since the total supply current is typically ten times higher in the awakemode than the sleepmode, the two states are easily distinguishable.

The measured value of I_D+ equals the I_D of both devices (for a dual op amp) plus the output source current of device A and the output source current of device B. Similarly, the measured value of I_D– is equal to the I_D– of both devices plus the output sink current of each device. I_{out} is the sum of the currents caused by both the feedback loop and load resistance. The total I_{out} needs to be subtracted from the measured I_D to obtain the correct I_D of the dual op amp.

An accurate way to measure the awakemode I_{out} current on automatic test equipment is to remove the I_{out} current on both Channel A and B. Then measure the I_D values before the device goes back to the sleepmode state. The transition will take typically 1.5 seconds with ±15 V power supplies.

The large signal sleepmode testing in the characterization was accomplished with a 1.0 MΩ load resistor which ensured the device would remain in sleepmode despite large voltage swings.

Low Power, Single Supply Operational Amplifiers

Quality bipolar fabrication with innovative design concepts are employed for the MC33171/72/74 series of monolithic operational amplifiers. These devices operate at 180 µA per amplifier and offer 1.8 MHz of gain bandwidth product and 2.1 V/µs slew rate without the use of JFET device technology. Although this series can be operated from split supplies, it is particularly suited for single supply operation, since the common mode input voltage includes ground potential (V_{EE}). With a Darlington input stage, these devices exhibit high input resistance, low input offset voltage and high gain. The all NPN output stage, characterized by no deadband crossover distortion and large output voltage swing, provides high capacitance drive capability, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source/sink AC frequency response.

The MC33171/72/74 are specified over the industrial/ automotive temperature ranges. The complete series of single, dual and quad operational amplifiers are available in plastic as well as the surface mount packages.

- Low Supply Current: 180 µA (Per Amplifier)
- Wide Supply Operating Range: 3.0 V to 44 V or ±1.5 V to ±22 V
- Wide Input Common Mode Range, Including Ground (V_{EE})
- Wide Bandwidth: 1.8 MHz
- High Slew Rate: 2.1 V/µs
- Low Input Offset Voltage: 2.0 mV
- Large Output Voltage Swing: –14.2 V to +14.2 V (with ±15 V Supplies)
- Large Capacitance Drive Capability: 0 pF to 500 pF
- Low Total Harmonic Distortion: 0.03%
- Excellent Phase Margin: 60°C
- Excellent Gain Margin: 15 dB
- Output Short Circuit Protection
- ESD Diodes Provide Input Protection for Dual and Quad

APPLICATIONS INFORMATION – CIRCUIT DESCRIPTION/PERFORMANCE FEATURES

Although the bandwidth, slew rate, and settling time of the MC33171/72/74 amplifier family is similar to low power op amp products utilizing JFET input devices, these amplifiers offer additional advantages as a result of the PNP transistor differential inputs and an all NPN transistor output stage.

Because the input common mode voltage range of this input stage includes the V_{EE} potential, single supply operation is feasible to as low as 3.0 V with the common mode input voltage at ground potential.

The input stage also allows differential input voltages up to ±44 V, provided the maximum input voltage range is not exceeded. Specifically, the input voltages must range between V_{CC} and V_{EE} supply voltages as shown by the maximum rating table. In practice, although *not recommended,* the input voltages can exceed the V_{CC} voltage by approximately 3.0 V and decrease below the V_{EE} voltage by 0.3 V without causing product damage, although output phase reversal may occur. It is also possible to source up to 5.0 mA of current from V_{EE} through either inputs' clamping diode without damage or latching, but phase reversal may again occur. If at least one input is within the common mode input voltage range and the other input is within the maximum input voltage range, no phase reversal will occur. If both inputs exceed the upper common mode input voltage limit, the output will be forced to its lowest voltage state.

Since the input capacitance associated with the small geometry input device is substantially lower (0.8 pF) than that of a typical JFET (3.0 pF), the frequency response for a given input source resistance is greatly enhanced. This becomes evident in D–to–A current to voltage conversion applications where the feedback resistance can form a pole with the input capacitance of the op amp. This input pole creates a 2nd Order system with the single pole op amp and is therefore detrimental to its settling time. In this context, lower input capacitance is desirable especially for higher values of feedback resistances (lower current DACs). This input pole can be compensated for by creating a feedback zero with a capacitance across the feedback resistance, if necessary, to reduce overshoot. For 10 kΩ of feedback resistance, the MC33171/72/74 family can typically settle to within 1/2 LSB of 8 bits in 4.2 µs, and within 1/2 LSB of 12 bits in 4.8 µs for a 10 V step. In a standard inverting unity gain fast settling configuration, the symmetrical slew rate is typically ± 2.1 V/µs. In the classic noninverting unity gain configuration the typical output positive slew rate is also 2.1 V/µs, and the corresponding negative slew rate will usually exceed the positive slew rate as a function of the fall time of the input waveform.

The all NPN output stage, shown in its basic form on the equivalent circuit schematic, offers unique advantages over the more conventional NPN/PNP transistor Class AB output stage. A 10 kΩ load resistance can typically swing within 0.8 V of the positive rail (V_{CC}) and negative rail (V_{EE}), providing a 28.4 Vpp swing from ±15 V supplies. This large output swing becomes most noticeable at lower supply voltages.

The positive swing is limited by the saturation voltage of the current source transistor Q7, the V_{BE} of the NPN pull–up transistor Q17, and the voltage drop associated with the short circuit resistance, R5. For sink currents less than 0.4 mA, the negative swing is limited by the saturation voltage of the pull–down transistor Q15, and the voltage drop across R4 and R5. For small valued sink currents, the above voltage drops are negligible, allowing the negative swing voltage to approach within millivolts of V_{EE}. For sink currents (> 0.4 mA), diode D3 clamps the voltage across R4. Thus the negative swing is limited by the saturation voltage of Q15, plus the forward diode drop of D3 (≈V_{EE} +1.0 V). Therefore an unprecedented peak–to–peak output voltage swing is possible for a given supply voltage as indicated by the output swing specifications.

If the load resistance is referenced to V_{CC} instead of ground for single supply applications, the maximum possible output swing can be achieved for a given supply voltage. For light load currents, the load resistance will pull the output to V_{CC} during the positive swing and the output will pull the load resistance near ground during the negative swing. The load resistance value should be much less than that of the feedback resistance to maximize pull–up capability.

Because the PNP output emitter–follower transistor has been eliminated, the MC33171/72/74 family offers a 15 mA minimum current sink capability, typically to an output voltage of (V_{EE} +1.8 V). In single supply applications the output can directly source or sink base current from a common emitter NPN transistor for current switching applications.

In addition, the all NPN transistor output stage is inherently faster than PNP types, contributing to the bipolar amplifier's improved gain bandwidth product. The associated high frequency low output impedance (200 Ω typ @ 1.0 MHz) allows capacitive drive capability from 0 pF to 400 pF without oscillation in the noninverting unity gain configuration. The 60°C phase margin and 15 dB gain margin, as well as the general gain and phase characteristics, are virtually independent of the source/sink output swing conditions. This allows easier system phase compensation, since output swing will not be a phase consideration. The AC characteristics of the MC33171/72/74 family also allow excellent active filter capability, especially for low voltage single supply applications.

Although the single supply specification is defined at 5.0 V, these amplifiers are functional to at least 3.0 V @ 25°C. However slight changes in parametrics such as bandwidth, slew rate, and DC gain may occur.

If power to this integrated circuit is applied in reverse polarity, or if the IC is installed backwards in a socket, large unlimited current surges will occur through the device that may result in device destruction.

As usual with most high frequency amplifiers, proper lead dress, component placement and PC board layout should be exercised for optimum frequency performance. For example, long unshielded input or output leads may result in unwanted input/output coupling. In order to preserve the relatively low input capacitance associated with these amplifiers, resistors connected to the inputs should be immediately adjacent to the input pin to minimize additional stray input capacitance. This not only minimizes the input pole for optimum frequency response, but also minimizes extraneous "pick up" at this node. Supply decoupling with adequate capacitance immediately adjacent to the supply pin is also important, particularly over temperature, since many types of decoupling capacitors exhibit great impedance changes over temperature.

The output of any one amplifier is current limited and thus protected from a direct short to ground. However, under such conditions, it is important not to allow the device to exceed the maximum junction temperature rating. Typically for ±15 V supplies, any one output can be shorted continuously to ground without exceeding the maximum temperature rating.

MC33179

High Output Current Low Power, Low Noise Bipolar Operational Amplifiers

The MC33178/9 series is a family of high quality monolithic amplifiers employing Bipolar technology with innovative high performance concepts for quality audio and data signal processing applications. This device family incorporates the use of high frequency PNP input transistors to produce amplifiers exhibiting low input offset voltage, noise and distortion. In addition, the amplifier provides high output current drive capability while consuming only 420 µA of drain current per amplifier. The NPN output stage used, exhibits no deadband crossover distortion, large output voltage swing, excellent phase and gain margins, low open–loop high frequency output impedance, symmetrical source and sink AC frequency performance.

The MC33178/9 family offers both dual and quad amplifier versions, tested over the vehicular temperature range, and are available in DIP and SOIC packages.

- 600 Ω Output Drive Capability
- Large Output Voltage Swing
- Low Offset Voltage: 0.15 mV (Mean)
- Low T.C. of Input Offset Voltage: 2.0 µV/°C
- Low Total Harmonic Distortion: 0.0024% (@ 1.0 kHz w/600 Ω Load)
- High Gain Bandwidth: 5.0 MHz
- High Slew Rate: 2.0 V/µs
- Dual Supply Operation: ±2.0 V to ±18 V
- ESD Clamps on the Inputs Increase Ruggedness without Affecting Device Performance

APPLICATION INFORMATION

This unique device uses a boosted output stage to combine a high output current with a drain current lower than similar bipolar input op amps. Its 60° phase margin and 15 dB gain margin ensure stability with up to 1000 pF of load capacitance (see Figure 23). The ability to drive a minimum 600 Ω load makes it particularly suitable for telecom applications. Note that in the sample circuit in Figure 33 both A2 and A3 are driving equivalent loads of approximately 600 Ω.

The low input offset voltage and moderately high slew rate and gain bandwidth product make it attractive for a variety of other applications. For example, although it is not single supply (the common mode input range does not include ground), it is specified at +5.0 V with a typical common mode rejection of 110 dB. This makes it an excellent choice for use with digital circuits. The high common mode rejection, which is stable over temperature, coupled with a low noise figure and low distortion, is an ideal op amp for audio circuits.

The output stage of the op amp is current limited and therefore has a certain amount of protection in the event of a short circuit. However, because of its high current output, it is especially important not to allow the device to exceed the maximum junction temperature, particularly with the MC33179 (quad op amp). Shorting more than one amplifier could easily exceed the junction temperature to the extent of causing permanent damage.

Stability

As usual with most high frequency amplifiers, proper lead dress, component placement, and PC board layout should be exercised for optimum frequency performance. For example, long unshielded input or output leads may result in unwanted input/output coupling. In order to preserve the relatively low input capacitance associated with these amplifiers, resistors connected to the inputs should be immediately adjacent to the input pin to minimize additional stray input capacitance. This not only minimizes the input pole frequency for optimum frequency response, but also minimizes extraneous “pick up” at this node. Supplying decoupling with adequate capacitance immediately adjacent to the supply pin is also important, particularly over temperature, since many types of decoupling capacitors exhibit great impedance changes over temperature.

Additional stability problems can be caused by high load capacitances and/or a high source resistance. Simple compensation schemes can be used to alleviate these effects.

If a high source of resistance is used (R1 > 1.0 kΩ), a compensation capacitor equal to or greater than the input capacitance of the op amp (10 pF) placed across the feedback resistor (see Figure 34) can be used to neutralize that pole and prevent outer loop oscillation. Since the closed loop transient response will be a function of that capacitance, it is important to choose the optimum value for that capacitor. This can be determined by the following Equation:

$$C_C = (1 + [R1/R2])^2 \times C_L (Z_O/R_2) \qquad (1)$$

where: Z_O is the output impedance of the op amp.

For moderately high capacitive loads (500 pF < C_L < 1500 pF) the addition of a compensation resistor on the order of 20 Ω between the output and the feedback loop will help to decrease miller loop oscillation (see Figure 35). For high capacitive loads (C_L > 1500 pF), a combined compensation scheme should be used (see Figure 36). Both the compensation resistor and the compensation capacitor affect the transient response and can be calculated for optimum performance. The value of C_C can be calculated using Equation (1). The Equation to calculate R_C is as follows:

$$R_C = Z_O \times R1/R2 \qquad (2)$$

Rail-to-Rail Operational Amplifiers

The MC33201/2/4 family of operational amplifiers provide rail–to–rail operation on both the input and output. The inputs can be driven as high as 200 mV beyond the supply rails without phase reversal on the outputs, and the output can swing within 50 mV of each rail. This rail–to–rail operation enables the user to make full use of the supply voltage range available. It is designed to work at very low supply voltages (± 0.9 V) yet can operate with a supply of up to +12 V and ground. Output current boosting techniques provide a high output current capability while keeping the drain current of the amplifier to a minimum. Also, the combination of low noise and distortion with a high slew rate and drive capability make this an ideal amplifier for audio applications.

- Low Voltage, Single Supply Operation (+1.8 V and Ground to +12 V and Ground)
- Input Voltage Range Includes both Supply Rails
- Output Voltage Swings within 50 mV of both Rails
- No Phase Reversal on the Output for Over–driven Input Signals
- High Output Current (I_{SC} = 80 mA, Typ)
- Low Supply Current (I_D = 0.9 mA, Typ)
- 600 Ω Output Drive Capability
- Extended Operating Temperature Ranges (–40° to +105°C and –55° to +125°C)
- Typical Gain Bandwidth Product = 2.2 MHz
- Offered in New TSSOP Package Including Standard SOIC and DIP Packages

Power Supply Current per Amplifier (I_D)	1.125	1.125	1.125	mA

Specifications at V_{CC} = 3.3 V are guaranteed by the 2.0 V and 5.0 V tests. V_{EE} = Gnd.

MAXIMUM RATINGS

Rating	Symbol	Value	Unit
Supply Voltage (V_{CC} to V_{EE})	V_S	+13	V
Input Differential Voltage Range	V_{IDR}	(Note 1)	V
Common Mode Input Voltage Range (Note 2)	V_{CM}	V_{CC} + 0.5 V to V_{EE} – 0.5 V	V
Output Short Circuit Duration	t_s	(Note 3)	sec
Maximum Junction Temperature	T_J	+150	°C
Storage Temperature	T_{stg}	– 65 to +150	°C
Maximum Power Dissipation	P_D	(Note 3)	mW

NOTES: 1. The differential input voltage of each amplifier is limited by two internal parallel back–to–back diodes. For additional differential input voltage range, use current limiting resistors in series with the input pins.

2. The input common mode voltage range is limited by internal diodes connected from the inputs to both supply rails. Therefore, the voltage on either input must not exceed either supply rail by more than 500 mV.

3. Power dissipation must be considered to ensure maximum junction temperature (T_J) is not exceeded. (See Figure 2)

General Information

The MC33201/2/4 family of operational amplifiers are unique in their ability to swing rail–to–rail on both the input and the output with a completely bipolar design. This offers low noise, high output current capability and a wide common mode input voltage range even with low supply voltages. Operation is guaranteed over an extended temperature range and at supply voltages of 2.0 V, 3.3 V and 5.0 V and ground.

Since the common mode input voltage range extends from V_{CC} to V_{EE}, it can be operated with either single or split voltage supplies. The MC33201/2/4 are guaranteed not to latch or phase reverse over the entire common mode range, however, the inputs should not be allowed to exceed maximum ratings.

Circuit Information

Rail–to–rail performance is achieved at the input of the amplifiers by using parallel NPN–PNP differential input stages. When the inputs are within 800 mV of the negative rail, the PNP stage is on. When the inputs are more than 800 mV greater than V_{EE}, the NPN stage is on. This switching of input pairs will cause a reversal of input bias currents (see Figure 6). Also, slight differences in offset voltage may be noted between the NPN and PNP pairs. Cross–coupling techniques have been used to keep this change to a minimum.

In addition to its rail–to–rail performance, the output stage is current boosted to provide 80 mA of output current, enabling the op amp to drive 600 Ω loads. Because of this high output current capability, care should be taken not to exceed the 150°C maximum junction temperature.

Advance Information

Rail-To-Rail Operational Amplifiers with Enable Feature

The MC33206/7 family of operational amplifiers provide rail–to–rail operation on both the input and output. The inputs can be driven as high as 200 mV beyond the supply rails without phase reversal on the outputs and the output can swing within 50 mV of each rail. This rail–to–rail operation enables the user to make full use of the supply voltage range available. It is designed to work at very low supply voltages (±0.9 V) yet can operate with a single supply of up to 12 V and ground. Output current boosting techniques provide a high output current capability while keeping the drain current of the amplifier to a minimum.

The MC33206/7 has an enable mode that can be controlled externally. The typical supply current in the standby mode is <1.0 µA (V_{Enable} = Gnd). The addition of an enable function makes this amplifier an ideal choice for power sensitive applications, battery powered equipment (instrumentation and monitoring), portable telecommunication, and sample–and–hold applications.

- Standby Mode (I_D ≤1.0 µA, Typ)
- Low Voltage, Single Supply Operation
  (1.8 V and Ground to 12 V and Ground)
- Rail–to–Rail Input Common Mode Voltage Range
- Output Voltage Swings within 50 mV of both Rails
- No Phase Reversal on the Output for Over–Driven Input Signals
- High Output Current (I_{SC} = 80 mA, Typ)
- Low Supply Current (I_D = 0.9 mA, Typ)
- 600 Ω Output Drive Capability
- Typical Gain Bandwidth Product = 2.2 MHz

MAXIMUM RATINGS

Rating	Symbol	Value	Unit
Supply Voltage (V_{CC} to V_{EE})	V_S	13	V
ESD Protection Voltage at any Pin Human Body Model	V_{ESD}	2,000	V
Voltage at any Device Pin	V_{DP}	$V_S \pm 0.5$	V
Input Differential Voltage Range	V_{IDR}	(Note 1)	V
Common Mode Input Voltage Range (Note 2)	V_{CM}	$V_{CC} + 0.5$ to $V_{EE} – 0.5$	V
Output Short Circuit Duration (Note 3)	t_s	(Note 3)	sec
Maximum Junction Temperature	T_J	+150	°C
Storage Temperature Range	T_{stg}	–65 to +150	°C
Maximum Power Dissipation	P_D	(Note 3)	mW

NOTES:
1. The differential input voltage of each amplifier is limited by two internal parallel back–to–back diodes. For additional differential input voltage range, use current limiting resistors in series with the input pins.
2. The common–mode input voltage range of each amplifier is limited by diodes connected from the inputs to both power supply rails. Therefore, the voltage on either input must not exceed either supply rail by more than 500 mV.
3. Power dissipation must be considered to ensure maximum junction temperature (T_J) is not exceeded.
4. ESD data available upon request.

GENERAL INFORMATION

The MC33206/7 family of operational amplifiers are unique in their ability to swing rail–to–rail on both the input and the output with a completely bipolar design. This offers low noise, high output current capability and a wide common mode input voltage range even with low supply voltages. Operation is guaranteed over an extended temperature range and at supply voltages of 2.0 V, 3.3 V and 5.0 V and ground.

Since the common mode input voltage range extends from V_{CC} to V_{EE}, it can be operated with either single or split voltage supplies. The MC33206/7 are guaranteed not to latch or phase reverse over the entire common mode range, however, the inputs should not be allowed to exceed maximum ratings.

CIRCUIT INFORMATION

Rail–to–rail performance is achieved at the input of the amplifiers by using parallel NPN–PNP differential input stages. When the inputs are within 800 mV of the negative rail, the PNP stage is on. When the inputs are more than 800 mV greater than V_{EE}, the NPN stage is on. This switching of input pairs will cause a reversal of input bias currents (see Figure 6). Also, slight differences in offset voltage may be noted between the NPN and PNP pairs. Cross–coupling techniques have been used to keep this change to a minimum.

In addition to its rail–to–rail performance, the output stage is current boosted to provide 80 mA of output current, enabling the op amp to drive 600 Ω loads. Because of this high output current capability, care should be taken not to exceed the 150°C maximum junction temperature.

Enable Function

The MC33206/07 enable pins allow the user to externally control the device. (Refer to the Pin Diagram on the first page of this data sheet for enable pin connections.) If the enable pins are pulled low (Gnd) each amplifier (MC33206) and amplifier pair (MC33207) will be disabled. When the enable pins are at a logic high ($V_{Enable} \geq V_{EE} = 1.8$ V) the amplifiers will turn "on". Refer to the data sheet characteristics for the required levels needed to change logical state.

The time to change states (from device "on" to "off" and "off" to "on") is defined as the time delay. The Circuit in Figure 27 is used to measure t_{on} and t_{off}. Typical t_{on} and t_{off} measurements are shown in Figures 28 and 29. When the device is turned off (V_{Enable} = Gnd) an internal regulator is shut off disabling the amplifier.

Figure 27. Test Circuit for t_{on} and t_{off}

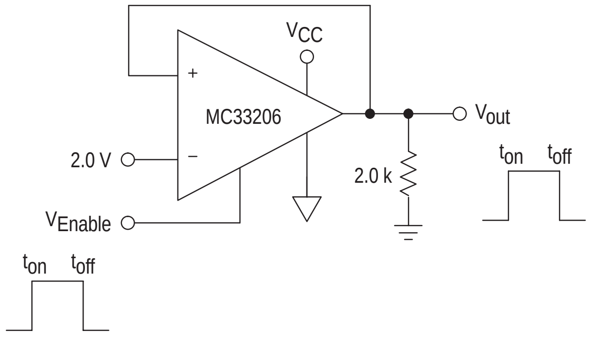

Figure 28. t_{on} Response

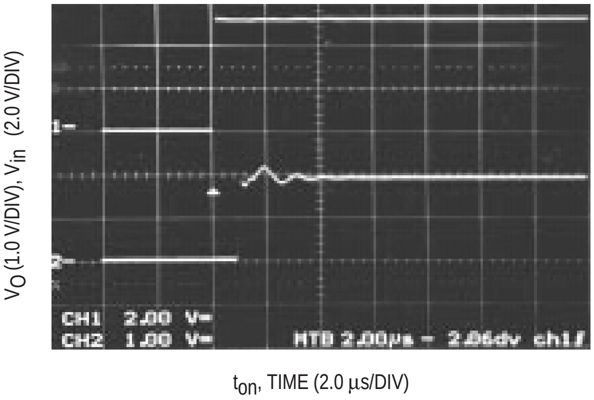

Figure 29. t_{off} Response

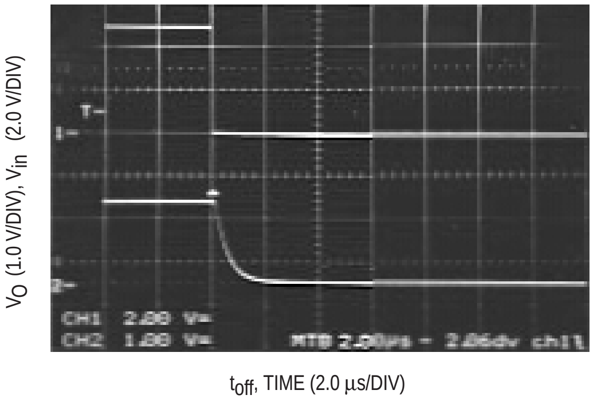


Low Voltage Operation

The MC33206/07 will operate at supply voltages down to 1.8 V and ground. Since this device is a rail–to–rail on both the input and output, one can be assured of continued operation in battery applications when battery voltages drop to low voltage levels. This is called End of Discharge (see Figure 30). Now, the user can select a minimum quantity of batteries best suited for the particular design depending on the type of battery chosen. This will minimize part count in many designs.

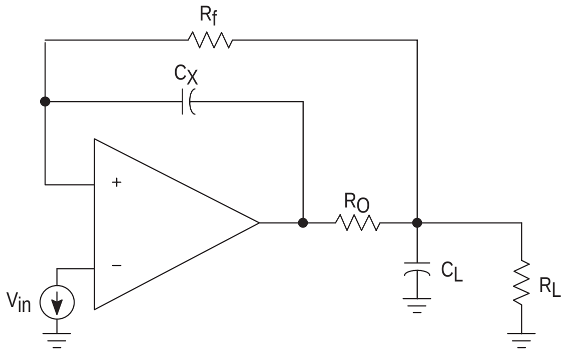
Figure 30. Typical Battery Characteristics

Type	Operating Voltage	End of Discharge
Alkaline	1.5 V	0.9 V
NiCd	1.2 V	1.0 V
NiMh	1.2 V	1.0 V
Silver Oxide	1.6 V	1.3 V
Lithium Ion	3.6 V	2.5 V

Compensating for Output Capacitance

The combination of device output impedance and increasing capacitive loading will cause phase delay (reducing the phase margin) in any amplifier (Figure 22). If the loading is excessive, the resulting response can be circuit oscillation. In other words, an amplifier can become unstable when the phase becomes greater than 180 degrees before the open loop gain drops to unity gain. Figures 18 and 19 show this situation as frequency increases for a given load. The MC33206/7 can typically drive up to 300 pF loads at unity gain without oscillating.

Figure 31. Capacitive Loads Compensation



There are several ways to compensate for this phenomena. Adding series resistance to the output is one way, but not an ideal solution. A dc voltage error will occur at the output. A better design solution to compensate for higher capacitive loads would be to use the circuit in Figure 31. This design helps to counteract the loss of phase margin by taking the high frequency output signal and feeding it back into the amplifier inverting input. This technique helps to overcome oscillation due to a highly capacitive load. Keep in mind that compensation will have the affect of lowering the Gain Bandwidth Product (GPW). The values of C_X and R0, are determined experimentally. Typical C_X and C_L will be the same value.

SPICE Model

If a SPICE Macromodel is desired for the MC33206/07, the user can define the characteristics from the following information. Obtain the SPICE Macromodel for the MC33204 Rail–to–Rail Operational Amplifier (device is the same as the MC33207). For the Enable feature of the MC33207, simulate it as a bipolar switch. The Macromodel does not include an input capacitance between the inverting and noninverting inputs. This capacitor is called C_{in}. Add 3.0 to 5.0 pF if stability analysis is required.

MOTOROLA

MC33272A
MC33274A

Single Supply, High Slew Rate Low Input Offset Voltage, Bipolar Operational Amplifiers

The MC33272/74 series of monolithic operational amplifiers are quality fabricated with innovative Bipolar design concepts. This dual and quad operational amplifier series incorporates Bipolar inputs along with a patented Zip–R–Trim element for input offset voltage reduction. The MC33272/74 series of operational amplifiers exhibits low input offset voltage and high gain bandwidth product. Dual–doublet frequency compensation is used to increase the slew rate while maintaining low input noise characteristics. Its all NPN output stage exhibits no deadband crossover distortion, large output voltage swing, and an excellent phase and gain margin. It also provides a low open loop high frequency output impedance with symmetrical source and sink AC frequency performance.

The MC33272/74 series is specified over –40° to +85°C and are available in plastic DIP and SOIC surface mount packages.

- Input Offset Voltage Trimmed to 100 µV (Typ)
- Low Input Bias Current: 300 nA
- Low Input Offset Current: 3.0 nA
- High Input Resistance: 16 MΩ
- Low Noise: 18 nV/ $\sqrt{\text{Hz}}$ @ 1.0 kHz
- High Gain Bandwidth Product: 24 MHz @ 100 kHz
- High Slew Rate: 10 V/µs
- Power Bandwidth: 160 kHz
- Excellent Frequency Stability
- Unity Gain Stable: w/Capacitance Loads to 500 pF
- Large Output Voltage Swing: +14.1 V/ –14.6 V
- Low Total Harmonic Distortion: 0.003%
- Power Supply Drain Current: 2.15 mA per Amplifier
- Single or Split Supply Operation: +3.0 V to +36 V or ±1.5 V to ±18 V
- ESD Diodes Provide Added Protection to the Inputs

MC33282
MC33284

Low Input Offset, High Slew Rate, Wide Bandwidth, JFET Input Operational Amplifiers

The MC33282/284 series of high performance operational amplifiers are quality fabricated with innovative bipolar and JFET design concepts. This dual and quad amplifier series incorporates JFET inputs along with a patented Zip–R–Trim® element for input offset voltage reduction. These devices exhibit low input offset voltage, low input bias current, high gain bandwidth and high slew rate. Dual–doublet frequency compensation is incorporated to produce high quality phase/gain performance. In addition, the MC33282/284 series exhibit low input noise characteristics for JFET input amplifiers. Its all NPN output stage exhibits no deadband crossover distortion and a large output voltage swing. They also provide a low open loop high frequency output impedance with symmetrical source and sink AC frequency performance.

The MC33282/284 series are specified over –40° to +85°C and are available in plastic DIP and SOIC surface mount packages.

- Low Input Offset Voltage: Trimmed to 200 μV
- Low Input Bias Current: 30 pA
- Low Input Offset Current: 6.0 pA
- High Input Resistance: 10^{12} Ω
- Low Noise: 18 nV $\sqrt{\text{Hz}}$ @ 1.0 kHz
- High Gain Bandwidth Products: 35 MHz @ 100 kHz
- High Slew Rate: 15 V/μs
- Power Bandwidth: 175 kHz
- Unity Gain Stable: w/Capacitance Loads to 300 pF
- Large Output Voltage Swing: +14.1 V/–14.6 V
- Low Total Harmonic Distortion: 0.003%
- Power Supply Drain Current: 2.15 mA per Amplifier
- Dual Supply Operation: ±2.5 V to ±18 V (Max)

MOTOROLA

MC33304

Low Voltage Rail-To-Rail Sleep-Mode™ Operational Amplifier

The MC33304 is a monolithic bipolar operational amplifier. This low voltage rail–to–rail amplifier has both a rail–to–rail input and output stage, with high output current capability. This amplifier also employs Sleep–Mode technology. In sleepmode, the micropower amplifier is active and waiting for an input signal. When a signal is applied, causing the amplifier to source or sink ≥200 µA (typically) to the load, it will automatically switch to the awakemode (supplying up to 70 mA to the load). When the output current drops below 90 µA, the amplifier automatically returns to the sleepmode.

Excellent performance can be achieved as an audio amplifier. This is due to the amplifier's low noise and low distortion. A delay circuit is incorporated to prevent crossover distortion.

- Ideal for Battery Applications
- Full Output Signal (No Distortion) for Battery Applications Down to ±0.9 VDC.
- Single Supply Operation (+1.8 to +12 V)
- Rail–To–Rail Performance on Both the Input and Output
- Output Voltages Swings Typically within 100 mV of Both Rails (R_L = 1.0 mΩ)
- Two States: "Sleepmode" (Micropower, I_D = 110 µA/Amp) and "Awakemode" (High Performance, I_D = 1200 µA/Amp)
- Automatic Return to Sleepmode when Output Current Drops Below Threshold, Allowing a Fully Functional Micropower Amplifier
- Independent Sleepmode Function for Each Amplifier
- No Phase Reversal on the Output for Overdriven Input Signals
- High Output Current (70 mA typically)
- 600 Ω Drive Capability
- Standard Pinouts; No Additional Pins or Components Required
- Drop–In Replacement for Many Other Quad Operational Amplifiers
- Similar to MC33201, MC33202 and MC33204 Family
- The MC33304 Amplifier is Offered in the Plastic DIP or SOIC Package (P and D Suffixes)

TYPICAL DC ELECTRICAL CHARACTERISTICS (T_A = 25°C)

Characteristic	V_{CC} = 2.0 V	V_{CC} = 3.3 V	V_{CC} = 5.0 V	Unit
Input Offset Voltage $V_{IO(max)}$ MC33304	±10	±10	±10	mV
Output Voltage Swing

NOTES:
1. The differential input voltage of each amplifier is limited by two internal diodes. The diodes are connected across the inputs in parallel and opposite to each other. For more differential input voltage range, use current limiting resistors in series with the input pins.
2. The common–mode input voltage range of each amplifier is limited by diodes connected from the inputs to both power supply rails. Therefore, the voltage on either input must not exceed supply rail by more than ±500 mV.
3. Simultaneous short circuits of two or more amplifiers to the positive or negative rail can exceed the power dissipation ratings and cause eventual failure of the device.
4. Rail–to–rail performance is achieved at the input of the amplifier by using parallel NPN–PNP differential stages. When the inputs are near the negative rail ($V_{EE} < V_{CM} <$ 800 mV), the PNP stage is on. When the inputs are above 800 mV (i.e. 800 mV $< V_{CM} < V_{CC}$), the NPN stage is on. This switching of the input pairs will cause a reversal of input bias current. Slight changes in the input offset voltage will be noted between the NPN and PNP pairs. Cross–coupling techniques have been used to keep this change to a minimum.
5. Power dissipation must be considered to ensure maximum junction (T_J) is not exceeded. (See Figure 2)
6. When connected as a voltage follower and used in transient conditions, a current limiting resistor may be needed between the output and the inverting input. This is because of the back to back diodes clamped across the inputs. The value of this resistor should be between 1.0 kΩ and 10 kΩ. If the amplifier does not become slew rate limited and is processing low frequency waveforms, then no resistor would be necessary. (The output could be tied directly to the negative input.)

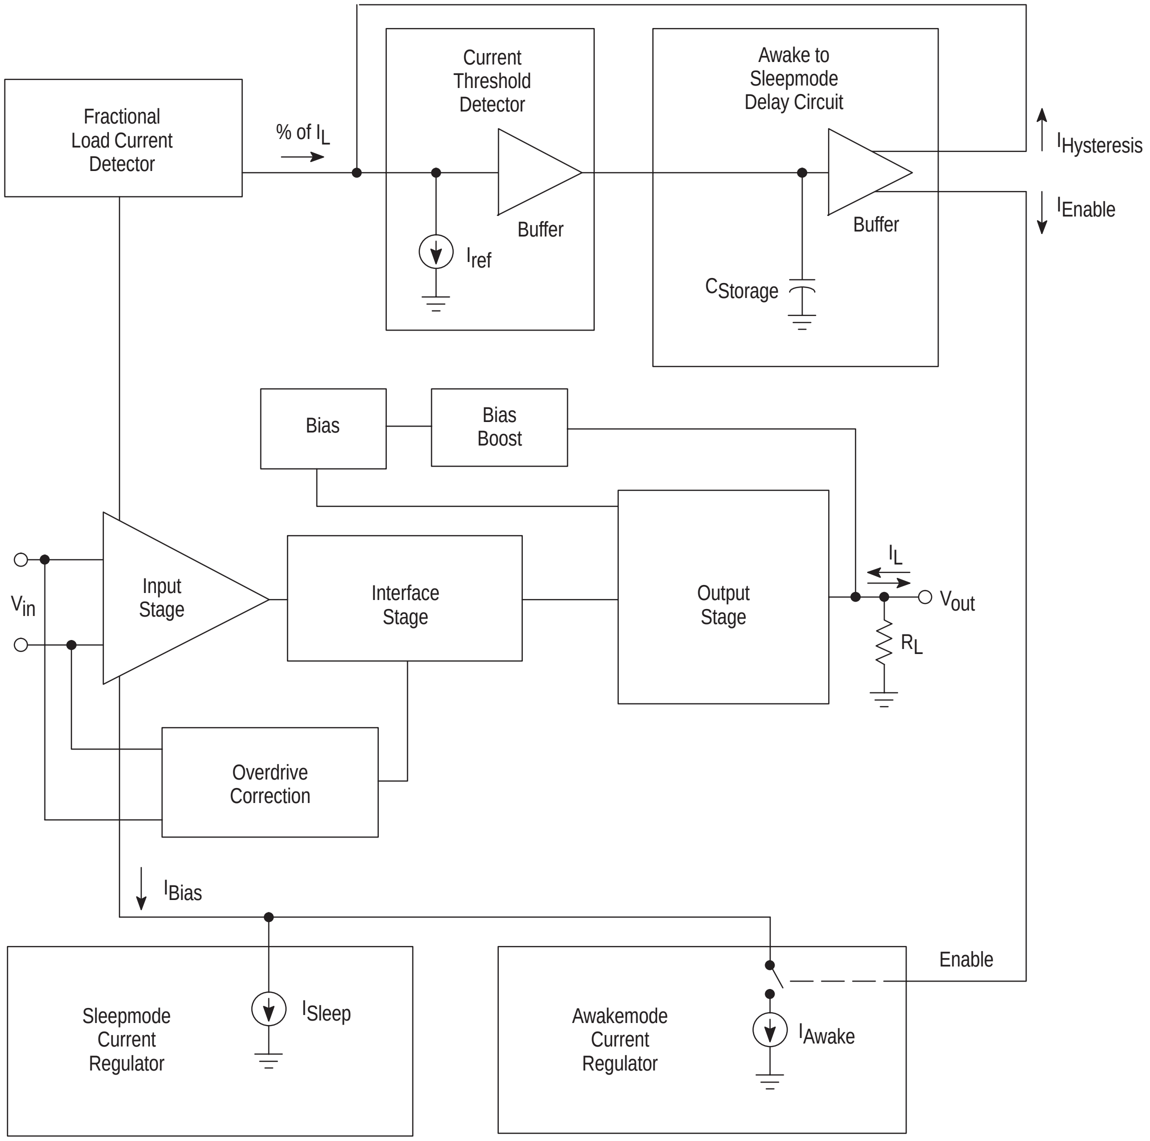
NOTES:
1. The differential input voltage of each amplifier is limited by two internal diodes. The diodes are connected across the inputs in parallel and opposite to each other. For more differential input voltage range, use current limiting resistors in series with the input pins.
2. The common–mode input voltage range of each amplifier is limited by diodes connected from the inputs to both power supply rails. Therefore, the voltage on either input must not exceed supply rail by more than ±500 mV.
3. Simultaneous short circuits of two or more amplifiers to the positive or negative rail can exceed the power dissipation ratings and cause eventual failure of the device.
4. Rail–to–rail performance is achieved at the input of the amplifier by using parallel NPN–PNP differential stages. When the inputs are near the negative rail ($V_{EE} < V_{CM} <$ 800 mV), the PNP stage is on. When the inputs are above 800 mV (i.e. 800 mV $< V_{CM} < V_{CC}$), the NPN stage is on. This switching of the input pairs will cause a reversal of input bias current. Slight changes in the input offset voltage will be noted between the NPN and PNP pairs. Cross–coupling techniques have been used to keep this change to a minimum.
5. Power dissipation must be considered to ensure maximum junction (T_J) is not exceeded. (See Figure 2)
6. When connected as a voltage follower and used in transient conditions, a current limiting resistor may be needed between the output and the inverting input. This is because of the back to back diodes clamped across the inputs. The value of this resistor should be between 1.0 kΩ and 10 kΩ. If the amplifier does not become slew rate limited and is processing low frequency waveforms, then no resistor would be necessary. (The output could be tied directly to the negative input.)

Figure 1. Equivalent Circuit Block Diagram (Each Amplifier)



There are 515 active components for the entire quad device.

DEVICE DESCRIPTION

The MC33304 will begin to function at power supply voltages as low as $V_S = \pm 0.8$ V. The device has the ability to swing rail–to–rail on both the input and the output. Since the common mode input voltage range extends from V_{CC} to V_{EE}, it can be operated with either single or split voltage supplies. The MC33304 is guaranteed not to latch up or phase reverse over the entire common mode range. However, the output could go into phase reversal state if input voltage is set higher than $+V_{CC}$ or $-V_{EE}$.

When power is initially applied, the part may start to operate in the awakemode. This occurs because of bias currents being generated from the charging of the internal capacitors. When this occurs, the user will have to wait approximately 1.5 seconds before the device will switch back to the sleepmode.

The amplifier is designed to switch from sleepmode to awakemode whenever the output current exceeds a preset current threshold (I_{TH}) of approximately 200 μA. As a result, the output switching threshold voltage (V_{ST}) is controlled by the output loading resistance (R_L). Large valued load resistors require a large output voltage to switch, but reduce unwanted transitions to the awakemode.

Most of the transition time is consumed slewing in the sleepmode until V_{ST} is reached, therefore, small values of R_L allow rapid transition to the awakemode. The output switching threshold voltage (V_{ST}) is higher for the larger values of R_L, requiring the amplifier to slew longer in the slower sleepmode state before switching to the awakemode.

Although typically 200 μA, I_{TH} varies with supply voltage, temperature and the load resistance. Generally, any current loading on the ouput which causes a current greater than I_{TH} to flow will switch the amplifier into the awakemode. This includes transition currents like those generated by charging load capacitances. In fact, the maximum capacitance that can be driven while attempting to remain in the sleepmode is approximately 300 pF.

The awakemode to sleepmode transition time is controlled by an internal delay circuit, which is necessary to prevent the amplifier from going to sleep during every zero crossing of the output waveform. This delay circuit also eliminates the crossover distortion commonly found in micropower amplifiers.

The MC33304 rail–to–rail sleepmode operational amplifier is unique in its ability to swing rail–to–rail on both the input and output using a bipolar design. This offers a low noise and wide common mode input voltage range. Since the common mode input voltage range extends from V_{CC} to V_{EE}, it can be operated with either single or split voltage supplies.

Rail–to–rail performance is achieved at the input of the amplifiers by using parallel NPN–PNP differential input stages. When the inputs are within 800 mV of the negative rail, the PNP stage is on. When the inputs are more than 800 mV above V_{EE}, the NPN stage is on. This switching of input pairs will cause a reversal of input bias currents. Also, slight differences in offset voltage may be noted between the NPN and PNP pairs. Cross–coupling techniques have been used to keep this change to a minimum.

In addition to the rail–to–rail performance, the output stage is current boosted to provide enough output current to drive 600 Ω loads. Because of this high current capability, care should be taken not to exceed the 150°C maximum junction temperature specification.

JFET Input Operational Amplifiers

These low cost JFET input operational amplifiers combine two state–of–the–art analog technologies on a single monolithic integrated circuit. Each internally compensated operational amplifier has well matched high voltage JFET input devices for low input offset voltage. The BIFET technology provides wide bandwidths and fast slew rates with low input bias currents, input offset currents, and supply currents.

The Motorola BIFET family offers single, dual and quad operational amplifiers which are pin–compatible with the industry standard MC1741, MC1458, and the MC3403/LM324 bipolar devices. The MC34001/34002/34004 series are specified from 0° to +70°C.

- Input Offset Voltage Options of 5.0 mV and 10 mV Maximum
- Low Input Bias Current: 40 pA
- Low Input Offset Current: 10 pA
- Wide Gain Bandwidth: 4.0 MHz
- High Slew Rate: 13 V/µs
- Low Supply Current: 1.4 mA per Amplifier
- High Input Impedance: $10^{12}\ \Omega$
- High Common Mode and Supply Voltage Rejection Ratios: 100 dB
- Industry Standard Pinouts

MC33071,2,4,A

High Slew Rate, Wide Bandwidth, Single Supply Operational Amplifiers

Quality bipolar fabrication with innovative design concepts are employed for the MC33071/72/74, MC34071/72/74 series of monolithic operational amplifiers. This series of operational amplifiers offer 4.5 MHz of gain bandwidth product, 13 V/µs slew rate and fast setting time without the use of JFET device technology. Although this series can be operated from split supplies, it is particularly suited for single supply operation, since the common mode input voltage range includes ground potential (V_{EE}). With A Darlington input stage, this series exhibits high input resistance, low input offset voltage and high gain. The all NPN output stage, characterized by no deadband crossover distortion and large output voltage swing, provides high capacitance drive capability, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source/sink AC frequency response.

The MC33071/72/74, MC34071/72/73 series of devices are available in standard or prime performance (A Suffix) grades and are specified over the commercial, industrial/vehicular or military temperature ranges. The complete series of single, dual and quad operational amplifiers are available in plastic DIP and SOIC surface mount packages.

- Wide Bandwidth: 4.5 MHz
- High Slew Rate: 13 V/µs
- Fast Settling Time: 1.1 µs to 0.1%
- Wide Single Supply Operation: 3.0 V to 44 V
- Wide Input Common Mode Voltage Range: Includes Ground (V_{EE})
- Low Input Offset Voltage: 3.0 mV Maximum (A Suffix)
- Large Output Voltage Swing: –14.7 V to +14 V (with ±15 V Supplies)
- Large Capacitance Drive Capability: 0 pF to 10,000 pF
- Low Total Harmonic Distortion: 0.02%
- Excellent Phase Margin: 60°
- Excellent Gain Margin: 12 dB
- Output Short Circuit Protection
- ESD Diodes/Clamps Provide Input Protection for Dual and Quad

APPLICATIONS INFORMATION
CIRCUIT DESCRIPTION/PERFORMANCE FEATURES

Although the bandwidth, slew rate, and settling time of the MC34071 amplifier series are similar to op amp products utilizing JFET input devices, these amplifiers offer other additional distinct advantages as a result of the PNP transistor differential input stage and an all NPN transistor output stage.

Since the input common mode voltage range of this input stage includes the V_{EE} potential, single supply operation is feasible to as low as 3.0 V with the common mode input voltage at ground potential.

The input stage also allows differential input voltages up to ±44 V, provided the maximum input voltage range is not exceeded. Specifically, the input voltages must range between V_{EE} and V_{CC} supply voltages as shown by the maximum rating table. In practice, although not recommended, the input voltages can exceed the V_{CC} voltage by approximately 3.0 V and decrease below the V_{EE} voltage by 0.3 V without causing product damage, although output phase reversal may occur. It is also possible to source up to approximately 5.0 mA of current from V_{EE} through either inputs clamping diode without damage or latching, although phase reversal may again occur.

If one or both inputs exceed the upper common mode voltage limit, the amplifier output is readily predictable and may be in a low or high state depending on the existing input bias conditions.

Since the input capacitance associated with the small geometry input device is substantially lower (2.5 pF) than the typical JFET input gate capacitance (5.0 pF), better frequency response for a given input source resistance can be achieved using the MC34071 series of amplifiers. This performance feature becomes evident, for example, in fast settling D–to–A current to voltage conversion applications where the feedback resistance can form an input pole with the input capacitance of the op amp. This input pole creates a 2nd order system with the single pole op amp and is therefore detrimental to its settling time. In this context, lower input capacitance is desirable especially for higher values of feedback resistances (lower current DACs). This input pole can be compensated for by creating a feedback zero with a capacitance across the feedback resistance, if necessary, to reduce overshoot. For 2.0 kΩ of feedback resistance, the MC34071 series can settle to within 1/2 LSB of 8 bits in 1.0 µs, and within 1/2 LSB of 12–bits in 2.2 µs for a 10 V step. In a inverting unity gain fast settling configuration, the symmetrical slew rate is ±13 V/µs. In the classic noninverting unity gain configuration, the output positive slew rate is +10 V/µs, and the corresponding negative slew rate will exceed the positive slew rate as a function of the fall time of the input waveform.

Since the bipolar input device matching characteristics are superior to that of JFETs, a low untrimmed maximum offset voltage of 3.0 mV prime and 5.0 mV downgrade can be economically offered with high frequency performance characteristics. This combination is ideal for low cost precision, high speed quad op amp applications.

The all NPN output stage, shown in its basic form on the equivalent circuit schematic, offers unique advantages over the more conventional NPN/PNP transistor Class AB output stage. A 10 kΩ load resistance can swing within 1.0 V of the positive rail (V_{CC}), and within 0.3 V of the negative rail (V_{EE}), providing a 28.7 V_{pp} swing from ±15 V supplies. This large output swing becomes most noticeable at lower supply voltages.

The positive swing is limited by the saturation voltage of the current source transistor Q_7, and V_{BE} of the NPN pull up transistor Q_{17}, and the voltage drop associated with the short circuit resistance, R_7. The negative swing is limited by the saturation voltage of the pull–down transistor Q_{16}, the voltage drop I_LR_6, and the voltage drop associated with resistance R_7, where I_L is the sink load current. For small valued sink currents, the above voltage drops are negligible, allowing the negative swing voltage to approach within millivolts of V_{EE}. For large valued sink currents (>5.0 mA), diode D3 clamps the voltage across R_6, thus limiting the negative swing to the saturation voltage of Q_{16}, plus the forward diode drop of D3 ($\approx V_{EE}$ +1.0 V). Thus for a given supply voltage, unprecedented peak–to–peak output voltage swing is possible as indicated by the output swing specifications.

If the load resistance is referenced to V_{CC} instead of ground for single supply applications, the maximum possible output swing can be achieved for a given supply voltage. For light load currents, the load resistance will pull the output to V_{CC} during the positive swing and the output will pull the load resistance near ground during the negative swing. The load resistance value should be much less than that of the feedback resistance to maximize pull up capability.

Because the PNP output emitter–follower transistor has been eliminated, the MC34071 series offers a 20 mA minimum current sink capability, typically to an output voltage of (V_{EE} +1.8 V). In single supply applications the output can directly source or sink base current from a common emitter NPN transistor for fast high current switching applications.

In addition, the all NPN transistor output stage is inherently fast, contributing to the bipolar amplifier's high gain bandwidth product and fast settling capability. The associated high frequency low output impedance (30 Ω typ @ 1.0 MHz) allows capacitive drive capability from 0 pF to 10,000 pF without oscillation in the unity closed loop gain configuration. The 60° phase margin and 12 dB gain margin as well as the general gain and phase characteristics are virtually independent of the source/sink output swing conditions. This allows easier system phase compensation, since output swing will not be a phase consideration. The high frequency characteristics of the MC34071 series also allow excellent high frequency active filter capability, especially for low voltage single supply applications.

Although the single supply specifications is defined at 5.0 V, these amplifiers are functional to 3.0 V @ 25°C although slight changes in parametrics such as bandwidth, slew rate, and DC gain may occur.

If power to this integrated circuit is applied in reverse polarity or if the IC is installed backwards in a socket, large unlimited current surges will occur through the device that may result in device destruction.

Special static precautions are not necessary for these bipolar amplifiers since there are no MOS transistors on the die.

As with most high frequency amplifiers, proper lead dress, component placement, and PC board layout should be exercised for optimum frequency performance. For example, long unshielded input or output leads may result in unwanted input–output coupling. In order to preserve the relatively low input capacitance associated with these amplifiers, resistors connected to the inputs should be immediately adjacent to the input pin to minimize additional stray input capacitance. This not only minimizes the input pole for optimum frequency response, but also minimizes extraneous “pick up” at this node. Supply decoupling with adequate capacitance immediately adjacent to the supply pin is also important, particularly over temperature, since many types of decoupling capacitors exhibit great impedance changes over temperature.

The output of any one amplifier is current limited and thus protected from a direct short to ground. However, under such conditions, it is important not to allow the device to exceed the maximum junction temperature rating. Typically for ±15 V supplies, any one output can be shorted continuously to ground without exceeding the maximum temperature rating.

(Typical Single Supply Applications V_{CC} = 5.0 V)

MOTOROLA

High Slew Rate, Wide Bandwidth, JFET Input Operational Amplifiers

These devices are a new generation of high speed JFET input monolithic operational amplifiers. Innovative design concepts along with JFET technology provide wide gain bandwidth product and high slew rate. Well–matched JFET input devices and advanced trim techniques ensure low input offset errors and bias currents. The all NPN output stage features large output voltage swing, no deadband crossover distortion, high capacitive drive capability, excellent phase and gain margins, low open loop output impedance, and symmetrical source/sink AC frequency response.

This series of devices is available in fully compensated or decompensated ($A_{VCL} \leq 2$) and is specified over a commercial temperature range. They are pin compatible with existing Industry standard operational amplifiers, and allow the designer to easily upgrade the performance of existing designs.

- Wide Gain Bandwidth: 8.0 MHz for Fully Compensated Devices
  16 MHz for Decompensated Devices
- High Slew Rate: 25 V/μs for Fully Compensated Devices
  50 V/μs for Decompensated Devices
- High Input Impedance: $10^{12}\Omega$
- Input Offset Voltage: 0.5 mV Maximum (Single Amplifier)
- Large Output Voltage Swing: –14.7 V to +14 V for $V_{CC}/V_{EE} = \pm15$ V
- Low Open Loop Output Impedance: 30 Ω @ 1.0 MHz
- Low THD Distortion: 0.01%
- Excellent Phase/Gain Margins: 55°/7.6 dB for Fully Compensated Devices

APPLICATIONS INFORMATION

The bandwidth and slew rate of the MC34080 series is nearly double that of currently available general purpose JFET op–amps. This improvement in AC performance is due to the P–channel JFET differential input stage driving a compensated miller integration amplifier in conjunction with an all NPN output stage.

The all NPN output stage offers unique advantages over the more conventional NPN/PNP transistor Class AB output stage. With a 10 k load resistance, the op amp can typically swing within 1.0 V of the positive rail (V_{CC}), and within 0.3 V of the negative rail (V_{EE}), providing a 28.7 p–p swing from ±15 V supplies. This large output swing becomes most noticeable at lower supply voltages. If the load resistance is referenced to V_{CC} instead of ground, the maximum possible output swing can be achieved for a given supply voltage. For light load currents, the load resistance will pull the output to V_{CC} during the positive swing and the NPN output transistor will pull the output very near V_{EE} during the negative swing. The load resistance value should be much less than that of the feedback resistance to maximize pull–up capability.

The all NPN transistor output stage is also inherently fast, contributing to the operation amplifier's high gain–bandwidth product and fast settling time. The associated high frequency output impedance is 50 Ω (typical) at 8.0 MHz. This allows driving capacitive loads from 0 pF to 300 pF without oscillations over the military temperature range, and over the full range of output swing. The 55°C phase margin and 7.6 dB gain margin as well as the general gain and phase characteristics are virtually independent of the sink/source output swing conditions. The high frequency characteristics of the MC34080 series is especially useful for active filter applications.

The common mode input range is from 2.0 V below the positive rail (V_{CC}) to 4.0 V above the negative rail (V_{EE}). The amplifier remains active if the inputs are biased at the positive rail. This may be useful for some applications in that single supply operation is possible with a single negative supply. However, a degradation of offset voltage and voltage gain may result.

Phase reversal does not occur if either the inverting or noninverting input (or both) exceeds the positive common mode limit. If either input (or both) exceeds the negative common mode limit, the output will be in the high state. The input stage also allows a differential up to ±44 V, provided the maximum input voltage range is not exceeded. The supply voltage operating range is from ±5.0 V to ±22 V.

For optimum frequency performance and stability, careful component placement and printed circuit board layout should be exercised. For example, long unshielded input or output leads may result in unwanted input–output coupling. In order to reduce the input capacitance, resistors connected to the input pins should be physically close to these pins. This not only minimizes the input pole for optimum frequency response, but also minimizes extraneous "pickup" at this node.

Supply decoupling with adequate capacitance close to the supply pin is also important, particularly over temperature, since many types of decoupling capacitors exhibit large impedance changes over temperature.

Primarily due to the JFET inputs of the op amp, the input offset voltage may change due to temperature cycling and board soldering. After 20 temperature cycles (– 55° to 165°C), the typical standard deviation for input offset voltage is 559 µV in the plastic packages. With respect to board soldering (260°C, 10 seconds), the typical standard deviation for input offset voltage is 525 µV in the plastic package. Socketed devices should be used over a minimal temperature range for optimum input offset voltage performance.

MC34181,2,4
MC33181,2,4

Low Power, High Slew Rate, Wide Bandwidth, JFET Input Operational Amplifiers

Quality bipolar fabrication with innovative design concepts are employed for the MC33181/2/4, MC34181/2/4 series of monolithic operational amplifiers. This JFET input series of operational amplifiers operates at 210 µA per amplifier and offers 4.0 MHz of gain bandwidth product and 10 V/µs slew rate. Precision matching and an innovative trim technique of the single and dual versions provide low input offset voltages. With a JFET input stage, this series exhibits high input resistance, low input offset voltage and high gain. The all NPN output stage, characterized by no deadband crossover distortion and large output voltage swing, provides high capacitance drive capability, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source/sink AC frequency response.

The MC33181/2/4, MC34181/2/4 series of devices are specified over the commercial or industrial/vehicular temperature ranges. The complete series of single, dual and quad operational amplifiers are available in the plastic DIP as well as the SOIC surface mount packages.

- Low Supply Current: 210 µA (Per Amplifier)
- Wide Supply Operating Range: ±1.5 V to ±18 V
- Wide Bandwidth: 4.0 MHz
- High Slew Rate: 10 V/µs
- Low Input Offset Voltage: 2.0 mV
- Large Output Voltage Swing: –14 V to +14 V (with ±15 V Supplies)
- Large Capacitance Drive Capability: 0 pF to 500 pF
- Low Total Harmonic Distortion: 0.04%
- Excellent Phase Margin: 67°
- Excellent Gain Margin: 6.7 dB
- Output Short Circuit Protection
- Offered in New TSSOP Package Including the Standard SOIC and DIP Packages

MOTOROLA

TCA0372

Advance Information

Dual Power Operational Amplifier

The TCA0372 is a monolithic circuit intended for use as a power operational amplifier in a wide range of applications, including servo amplifiers and power supplies. No deadband crossover distortion provides better performance for driving coils.

- Output Current to 1.0 A
- Slew Rate of 1.3 V/µs
- Wide Bandwidth of 1.1 MHz
- Internal Thermal Shutdown
- Single or Split Supply Operation
- Excellent Gain and Phase Margins
- Common Mode Input Includes Ground
- Zero Deadband Crossover Distortion

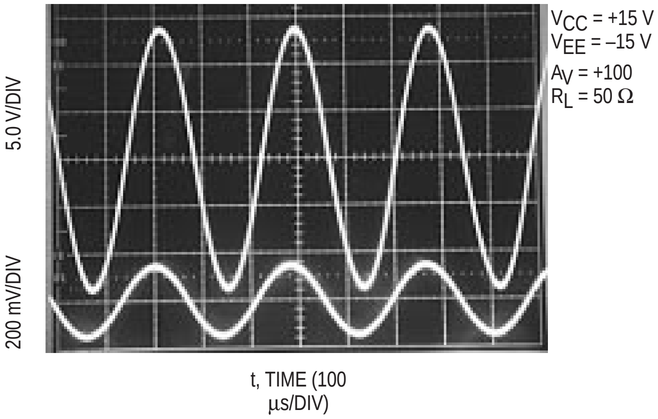

Figure 8. Bidirectional DC Motor Control with Microprocessor–Compatible Inputs

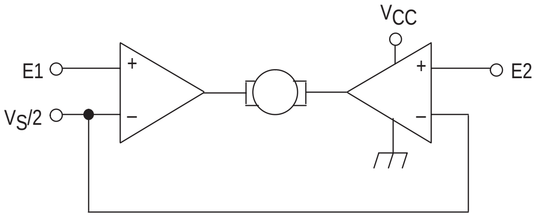
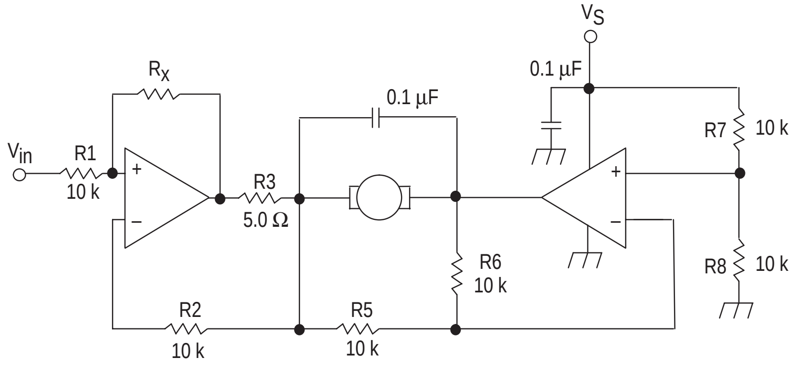


V_S = Logic Supply Voltage
Must Have $V_{CC} > V_S$
E1, E2 = Logic Inputs

Figure 9. Bidirectional Speed Control of DC Motors



For circuit stability, ensure that $R_X > \frac{2R3 \cdot R1}{R_M}$ where, R_M = internal resistance of motor.

The voltage available at the terminals of the motor is: $V_M = 2\left(V_1 - \frac{V_S}{2}\right) + |R_o| \cdot I_M$

where, $|R_o| = \frac{2R3 \cdot R1}{R_X}$ and I_M is the motor current.

THERMAL INFORMATION

The maximum power consumption an integrated circuit can tolerate at a given operating ambient temperature can be found from the equation:

$$P_{D(TA)} = \frac{T_{J(max)} - T_A}{R_{\theta JA}\ (typ)}$$

where, $P_{D(TA)}$ = power dissipation allowable at a given operating ambient temperature.

This must be greater than the sum of the products of the supply voltages and supply currents at the worst case operating condition.

$T_{J(max)}$ = Maximum operating junction temperature as listed in the maximum ratings section.
T_A = Maximum desired operating ambient temperature.
$R_{\theta JA(typ)}$ = Typical thermal resistance junction–to–ambient.

Low Power JFET Input Operational Amplifiers

These JFET input operational amplifiers are designed for low power applications. They feature high input impedance, low input bias current and low input offset current. Advanced design techniques allow for higher slew rates, gain bandwidth products and output swing.

The commercial and vehicular devices are available in Plastic dual in–line and SOIC packages.

- Low Supply Current: 200 µA/Amplifier
- Low Input Bias Current: 5.0 pA
- High Gain Bandwidth: 2.0 MHz
- High Slew Rate: 6.0 V/µs
- High Input Impedance: 10^{12} Ω
- Large Output Voltage Swing: ±14 V
- Output Short Circuit Protection

Low Noise, JFET Input Operational Amplifiers

These low noise JFET input operational amplifiers combine two state–of–the–art analog technologies on a single monolithic integrated circuit. Each internally compensated operational amplifier has well matched high voltage JFET input device for low input offset voltage. The BIFET technology provides wide bandwidths and fast slew rates with low input bias currents, input offset currents, and supply currents. Moreover, the devices exhibit low noise and low harmonic distortion, making them ideal for use in high fidelity audio amplifier applications.

These devices are available in single, dual and quad operational amplifiers which are pin–compatible with the industry standard MC1741, MC1458, and the MC3403/LM324 bipolar products.

- Low Input Noise Voltage: 18 nV/$\sqrt{Hz}$ Typ
- Low Harmonic Distortion: 0.01% Typ
- Low Input Bias and Offset Currents
- High Input Impedance: 10^{12} Ω Typ
- High Slew Rate: 13 V/µs Typ
- Wide Gain Bandwidth: 4.0 MHz Typ
- Low Supply Current: 1.4 mA per Amp

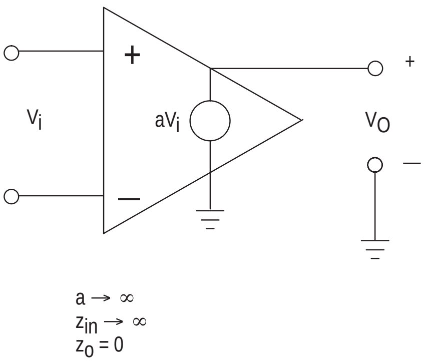
Addendum
Operational Amplifier Application Information

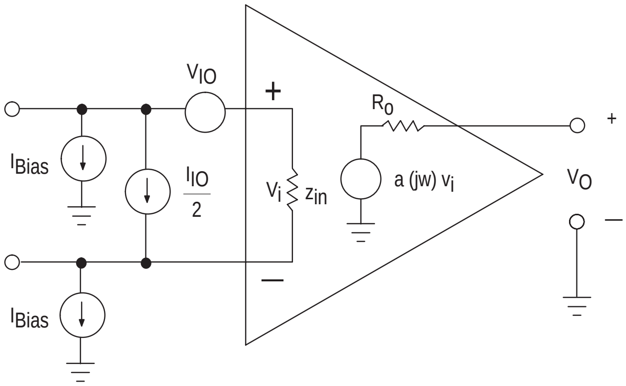
The Ideal Operational Amplifier

An ideal op amp has infinite input impedance, infinite gain, and zero output impedance. Its output is proportional to the differential voltage between the inputs. In reality, slight mismatches between the inputs create an error voltage and current, the input impedance is finite, requiring a small bias current, and gain and operating frequency are limited.

Ideal Op Amp



Equivalent Circuit for Actual Op Amp



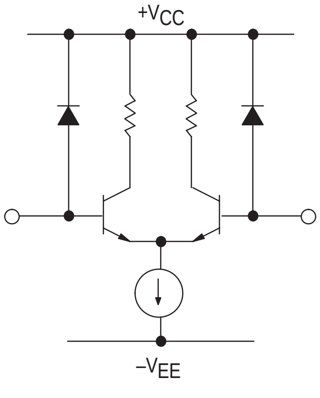
ESD Protection

Newer Motorola devices are equipped with either electrostatic discharge (ESD) diodes or CEO clamps on the inputs to increase their reliability. ESD diodes are connected with the anode attached to the input and the cathode to V_{CC}. During normal operation, the diode should be transparent to the user. However, if the input exceeds V_{CC} by more than a diode drop, the ESD diode will be forward biased and will provide a current path from the input to V_{CC}. Unless the current is limited externally the device could be damaged from overheating.

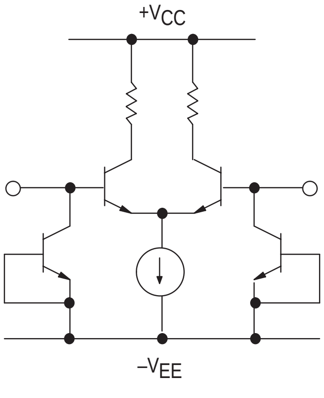
An alternate scheme uses a CEO transistor clamp with the collector connected to the input and the emitter and base connected to V_{EE}. This ESD protection method is totally transparent to the user. Although it is not recommended that the inputs be allowed to exceed V_{CC}, the CEO clamp will not affect device operation. The inputs should never exceed V_{EE}, with or without ESD protection. Single supply op amps are particularly sensitive to damage in a reverse bias condition.

If ESD protection is used on an amplifier, the ESD scheme used will be identified in the data sheet.

ESD Diodes



CEO Clamps



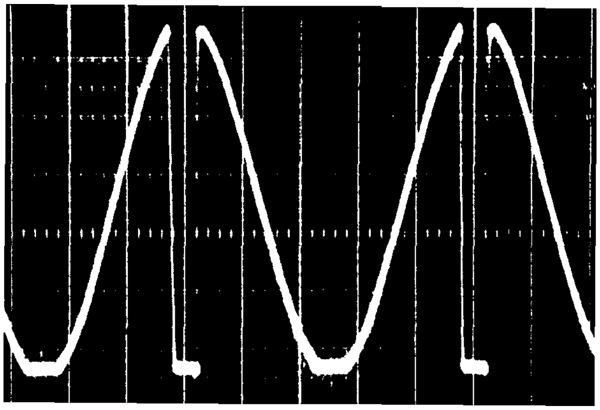
JFET Inputs versus Bipolar Inputs

Although JFET input op amps are generally associated with high speed, there are now bipolar input op amps with comparable slew rates. JFETS do offer higher input impedance and lower input bias current than a typical bipolar input. But for the lowest noise and offset voltage, a bipolar input op amp is a better choice. A bipolar input is also required for true single supply operation. Any op amp can be operated with one supply. But the common mode input voltage range of a single supply op amp includes ground.

Phase Reversal

Most op amp data sheets describe both a maximum input voltage and a minimum common mode input voltage range for the device. The input voltage limit given in the Maximum Ratings Table is considered to be the highest voltage that can be applied without damaging the device. It does not guarantee the device will function normally or within the given electrical specifications. The input common mode voltage range (V_{ICR}), on the other hand, provides the maximum input voltage (for the conditions listed) for normal operation. Exceeding the input common mode range may cause the device to exceed the electrical specifications, latch or go into phase reversal. (As shown in figure at right.)

In a latch condition, the op amp output goes to one of the supply rails, and will remain in that state until the power is removed and reapplied with the error condition corrected. In phase reversal, a normal output low would be seen as an output high, but phase reversal will self correct once the input drops below a certain level. The input voltage required for phase reversal to occur varies, but it is usually seen if the input voltage approaches or exceeds the supply voltage. As you can see in the figure the output is clipping on the negative peaks, and phase reversing on the positive peaks. But as the input drops on the negative going part of the waveform, the output returns the the correct state without powering down the device.



Thermal Considerations

Thermal resistance (θ_{JA}) information is given on most packages in the back of the data book. Low power op amps can handle a short circuit current condition indefinitely. Since some of the higher current drive op amps can deliver a hundred milliamps to an amp in a short circuit condition, extra care is needed to ensure that the maximum junction temperature of the part is not exceeded.

$T_J = T_A + P_D Q_{JA}$

T_J = Junction Temperature (Should not exceed 150°C)

T_A = Ambient Temperature

P_D = Power Dissipation

Q_A = Package Thermal Impedance

Stability and Compensation

Most op amps are internally compensated, enabling them to be used in a unity gain configuration. Uncompensated or decompensated amplifiers have a higher slew rate if no external compensation capacitor is used, but must either be used in a gain of 2 or more or with positive feedback to ensure stable operation. When externally compensating an amplifier, use a capacitor equal or greater than the value recommended in the data sheet. Since the external loop affects the stability of the op amp, the amplifier needs to be evaluated in the circuit and over temperature to determine the minimum amount of compensation required.

Insufficient compensation will cause a high frequency oscillation — higher than the unity gain frequency of the device. This high frequency oscillation is indicative of an instability in the Miller loop, internal to the device. Lower frequency oscillation (below the unity gain frequency of the amplifier) is generally caused by an instability in the outer loop.

The two primary causes of low frequency oscillation are capacitive loading on the output and high differential source resistance. Capacitive loading, which can be either distributed capacitance or an actual load capacitor, can be a problem with as little as 100 pF. Sensitivity to load capacitance varies from op amp to op amp and is not always given in the data sheets. To compensate for capacitive loading, add a small resistor in series with the output. Depending on the load and the external loop, 10 Ω to 100 Ω is generally sufficient (see Figure A). For high capacitive loading, (C_L>1500 pF) a capacitor in the feedback loop may also be necessary (see Figure B).

Keeping the differential source resistance low not only limits the noise generated in the circuit, but avoids stability problems as well. Most op amps are stable with a source resistance of up to 2 kΩ, but will vary from op amp to op amp. The differential source resistance (which includes any feedback resistance) combines with the input capacitance of the op amp to create a low frequency pole. The higher the resistance, the more likely you are to have an oscillation problem. Adding a small capacitor in parallel with the feedback resistor may solve the problem (see Figure C). The capacitor should be greater than the input capacitance of the op amp which is typically about 10 pF.

Figure B. Compensation Circuit for High Capacitive Loads

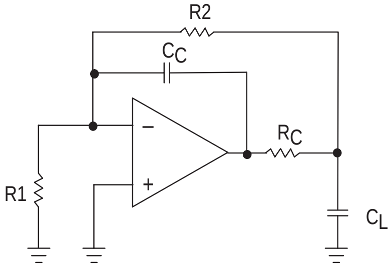

Figure C. Compensation for High Source Impedance

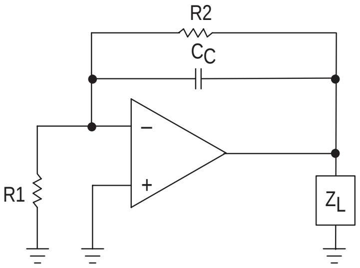


Layout Considerations

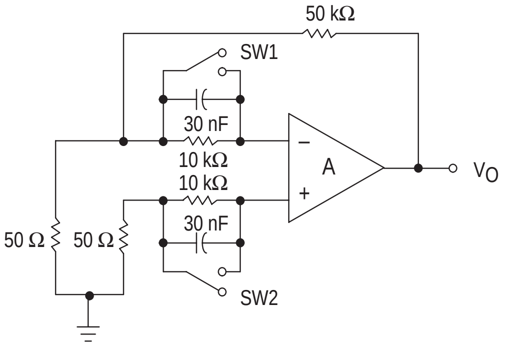
Higher frequency op amps may require special attention to layout. Since most layout problems are not reflected in computer simulations, it is worth it to follow proper layout rules consistently. Some suggestions:

- *Always* bypass the supply pins with at least 0.01 µF to ground, whether or not it is a high frequency application. Some amplifiers have a much lower power supply rejection with respect to the negative supply than to the positive supply due to the internal compensation. A larger bypass capacitor from V_{EE} to ground may be used to prevent high frequency transients from appearing on the output. Generally 10 µF to 20 µF is sufficient.
- Make sure you have a good ground plane.
- Keep AC and DC grounds separate.
- Don't use proto boards or wire wrap for high frequency circuits.
- Use appropriate external components — avoid electrolytics in high frequency paths.
- Keep high frequency paths short (including the leads on discrete components).
- Ground the inputs of unused op amps.

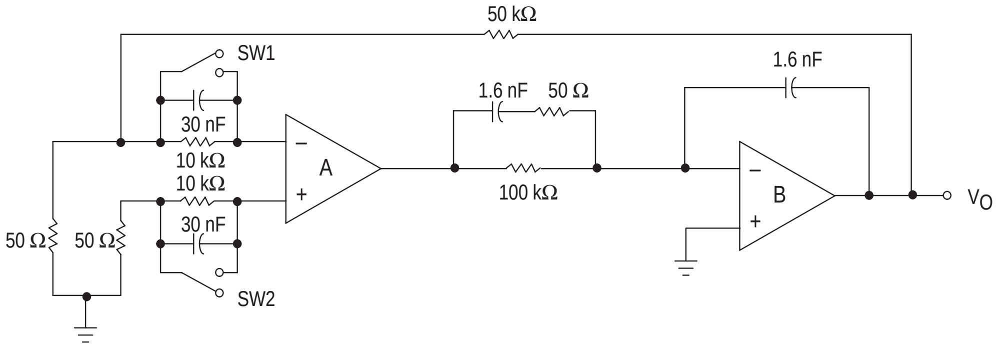
Test Information

The following circuit can be used to test V_{IO}, I_{IO}, and I_{IB}. Op Amp A is the device under test, and Op Amp B is a buffer amplifier which reduces CMRR errors and improves the accuracy of the measurement. The 30 nF capacitors across the 10k Ω source resistors are for stability and may not be needed.

A) Without Buffer Amplifier



B) With Buffer Amplifier



V_{IO} can be measured directly with SW1 and SW2 closed.

To determine I_{IB-}:

- Measure V_{IO} with both switches close,
- Open SW1 only; Measure V_{IO1}

To determine I_{IB+}:

- Close SW1 and open SW2; Measure V_{IO2}

  I_{IO} equals the difference between I_{IB+} and I_{IB-}

GLOSSARY

Input Offset Voltage (V_{IO}) — The voltage which must be applied between the inputs of an op amp to obtain a zero output voltage. For an ideal op amp, V_{IO} would be zero. Some vendors abbreviate it V_{OS}.

Input Bias Current (I_{IB}) — The current flowing in or out of both inputs of an op amp. JFET input op amps provide the lowest input bias current; typically in the picoamp range. A bipolar input op amp is typically in nanoamps. I_{IB} is highly sensitive to slight process variations and can vary an order of magnitude.

Input Offset Current (I_{IO}) — Ideally, the bias currents on the two inputs are equal. The input offset current is the difference between the two currents when the output is at zero volts. Sometimes abbreviated I_{OS}. This should not be confused with the output short circuit current (I_{SC}).

Input Common Mode Voltage Range (V_{ICR}) — The maximum input voltage range for normal operation within given specifications. Exceeding the input common mode range generally will not damage the inputs if the maximum ratings are not exceeded. However, V_{IO} may not meet the specification given in the data sheet, and phase reversal may occur as the input voltage approaches V_{CC} or V_{EE}. Sometimes abbreviated V_{CM}.

Common Mode Rejection Ratio (CMR or CMRR) — CMRR is defined as the ratio of the common mode gain to the differential mode gain. It is also equal to the ratio of the input common mode voltage to the peak–to–peak change in V_{IO}. Measures the ability of an op amp to reject a signal present at both inputs simultaneously. May be given in dB or volts per volt.

Power Supply Rejection Ratio (PSR or PSRR) — The ratio of the change in V_{IO} to the change in power supply voltage. Measures the immunity of the amplifier to changes in power supply voltage.

Output Short Circuit Current (I_{SC}) — The maximum current an amplifier can deliver into a short circuit. Care must be exercised to ensure the maximum junction temperature of the device is not exceeded to prevent damage to the device.

Supply Current (I_D or I_{CC}) — The operating current required with no load and with the output at zero volts.

Slew Rate (SR) — The rate of change of the output voltage in response to a large amplitude pulse applied to the input. The slew rate determines the power bandwidth of the device.

Gain Bandwidth Product (GBW) — The product of the closed–loop gain times the frequency response at a given frequency. For an op amp with a single pole roll–off, the gain bandwidth product is equal to the unity gain frequency.

Phase Margin (ϕ_M) — 180° minus the phase shift at the unity gain frequency of the device. The phase margin must be positive for unconditionally stable operation. Phase margin (and stability) are affected by the external circuit, particularly the capacitive loading on the output and the differential source resistance on the input.

Channel Separation (CS) — A measurement of the immunity of one op amp to a signal present on another amplifier in a dual or quad.

Power Bandwidth (BWP) — The frequency at which the output starts to clip or distort at maximum peak–to–peak input voltage.

Power Supply Circuits

In Brief . . .

In most electronic systems, some form of voltage regulation is required. In the past, the task of voltage regulator design was tediously accomplished with discrete devices, and the results were quite often complex and costly. Today, with bipolar monolithic regulators, this task has been significantly simplified. The designer now has a wide choice of fixed, low V_{Diff} and adjustable type voltage regulators. These devices incorporate many built–in protection features, making them virtually immune to the catastrophic failures encountered in older discrete designs.

The switching power supply continues to increase in popularity and is one of the fastest growing markets in the world of power conversion. They offer the designer several important advantages over linear series–pass regulators. These advantages include significant advancements in the areas of size and weight reduction, improved efficiency, and the ability to perform voltage step–up, step–down, and voltage–inverting functions. Motorola offers a diverse portfolio of full featured switching regulator control circuits which meet the needs of today's modern compact electronic equipment.

Power supplies, MPU/MCU–based systems, industrial controls, computer systems and many other product applications are requiring power supervisory functions which monitor voltages to ensure proper system operation. Motorola offers a wide range of power supervisory circuits that fulfill these needs in a cost effective and efficient manner. MOSFET drivers are also provided to enhance the drive capabilities of first generation switching regulators or systems designed with CMOS/TTL logic devices. These drivers can also be used in dc–to–dc converters, motor controllers or virtually any other application requiring high speed operation of power MOSFETs.

Linear Voltage Regulators

Fixed Output

These low cost monolithic circuits provide positive and/or negative regulation at currents from 100 mA to 3.0 A. They are ideal for on–card regulation employing current limiting and thermal shutdown. Low V_{Diff} devices are offered for battery powered systems.

Although designed primarily as fixed voltage regulators, these devices can be used with external components to obtain adjustable voltages and currents.

Adjustable Output

Motorola offers a broad line of adjustable output voltage regulators with a variety of output current capabilities. Adjustable voltage regulators provide users the capability of stocking a single integrated circuit offering a wide range of output voltages for industrial and communications applications. The three–terminal devices require only two external resistors to set the output voltage.

Micropower Voltage Regulators for Portable Applications

80 mA Micropower Voltage Regulator

MC78LC00H, N

T_A = –30° to +80°C, Case 1213, 1212

The MC78LC00 series voltage regulators are specifically designed for use as a power source for video instruments, handheld communication equipment, and battery powered equipment.

The MC78LC00 series features an ultra–low quiescent of 1.1 µA and a high accuracy output voltage. Each device contains a voltage reference, an error amplifier, a driver transistor and resistors for setting the output voltage. These devices are available in either SOT–89, 3 pin, or SOT–23, 5 pin, surface mount packages.

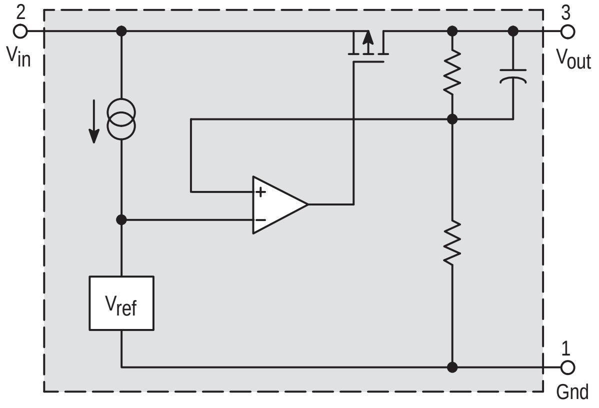
MC78LC00 Series Features:

- Low Quiescent Current of 1.1 µA Typical
- Low Dropout Voltage (30 mV Typical)
- Excellent Line Regulation (0.1%)
- High Accuracy Output Voltage (±2.5%)
- Wide Output Voltage Range (2.0 V to 6.0 V)
- Output Current for Low Power (80 mA Typical)
- Two Surface Mount Packages (SOT–89, 3 Pin, or SOT–23, 5 Pin)

ORDERING INFORMATION

Device	Output Voltage	Operating Temperature Range	Package
MC78LC30HT1 MC78LC33HT1 MC78LC40HT1 MC78LC50HT1	3.0 3.3 4.0 5.0	T_A = –30° to +80°C	SOT–89
MC78LC30NTR MC78LC33NTR MC78LC40NTR MC78LC50NTR	3.0 3.3 4.0 5.0		SOT–23

Other voltages from 2.0 to 6.0 V, in 0.1 V increments, are available upon request. Consult your local Motorola sales office for information.



120 mA Micropower Voltage Regulator

MC78FC00H

T_A = –30° to +80°C, Case 1213

The MC78FC00 series voltage regulators are specifically designed for use as a power source for video instruments, handheld communication equipment, and battery powered equipment.

The MC78FC00 series voltage regulator ICs feature a high accuracy output voltage and ultra–low quiescent current. Each device contains a voltage reference unit, an error amplifier, a driver transistor, and resistors for setting output voltage, and a current limit circuit. These devices are available in SOT–89 surface mount packages, and allow construction of an efficient, constant voltage power supply circuit.

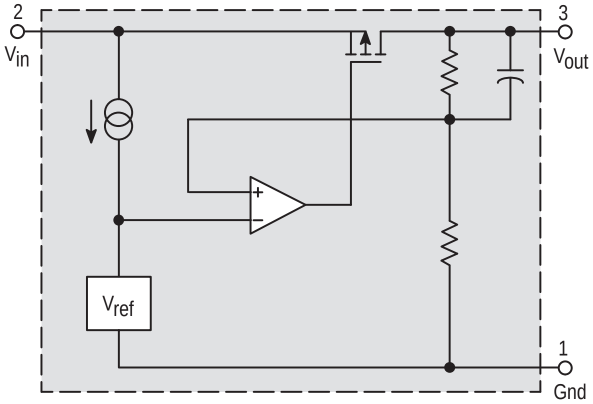
MC78FC00 Series Features:

- Ultra–Low Quiescent Current of 1.1 µA Typical
- Ultra–Low Dropout Voltage (0.5 V Typical)
- Large Output Current (120 mA Typical)
- Excellent Line Regulation (0.1%)
- Wide Operating Voltage Range (2.0 V to 10 V)
- High Accuracy Output Voltage (±2.5%)
- Wide Output Voltage Range (2.0 V to 6.0 V)
- Surface Mount Package (SOT–89)

ORDERING INFORMATION

Device	Output Voltage	Operating Temperature Range	Package
MC78FC30HT1	3.0	T_A = –30° to +80°C	SOT–89
MC78FC33HT1	3.3		
MC78FC40HT1	4.0		
MC78FC50HT1	5.0		

Other voltages from 2.0 to 6.0 V, in 0.1 V increments, are available upon request. Consult your local Motorola sales office for information.



Micropower Voltage Regulator for External Power Transistor

MC78BC00N

T_A = –30° to +80°C, Case 1212

The MC78BC00 voltage regulators are specifically designed to be used with an external power transistor to deliver high current with high voltage accuracy and low quiescent current.

The MC78BC00 series are devices suitable for constructing regulators with ultra–low dropout voltage and output current in the range of several tens of mA to hundreds of mA. These devices have a chip enable function, which minimizes the standby mode current drain. Each of these devices contains a voltage reference unit, an error amplifier, a driver transistor and resistors. These devices are available in the SOT–23, 5 pin surface mount packages.

These devices are ideally suited for battery powered equipment, and power sources for hand–held audio instruments, communication equipment and domestic appliances.

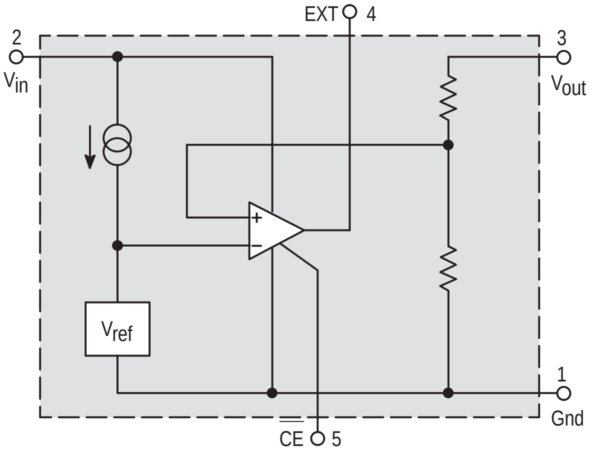
MC78BC00 Series Features:

- Ultra–Low Supply Current (50 µA)
- Standby Mode (0.2 µA)
- Ultra–Low Dropout Voltage (0.1 V with External Transistor and I_O = 100 mA)
- Excellent Line Regulation (Typically 0.1%/V)
- High Accuracy Output Voltage (±2.5%)

ORDERING INFORMATION

Device	Output Voltage	Operating Temperature Range	Package
MC78BC30NTR	3.0	T_A = –30° to +80°C	SOT–23
MC78BC33NTR	3.3		
MC78BC40NTR	4.0		
MC78BC50NTR	5.0		

Other voltages from 2.0 to 6.0 V, in 0.1 V increments, are available upon request. Consult your local Motorola sales office for information.



Micropower Voltage Regulators for Portable Applications (continued)

Micropower Voltage Regulators with On/Off Control

MC33264D, DM

T_A = –40° to +85°C, Case 751, 846A

The MC33264 series are micropower low dropout voltage regulators available in SO–8 and Micro–8 surface mount packages and a wide range of output voltages. These devices feature a very low quiescent current (100 µA in the ON mode; 0.1 µA in the OFF mode), and are capable of supplying output currents up to 100 mA. Internal current and thermal limiting protection is provided.

Additionally, the MC33264 has either active HIGH or active LOW control (Pins 2 and 3) that allows a logic level signal to turn–off or turn–on the regulator output.

Due to the low input–to–output voltage differential and bias current specifications, these devices are ideally suited for battery powered computer, consumer, and industrial equipment where an extension of useful battery life is desirable.

MC33264 Features:

- Low Quiescent Current (0.3 µA in OFF Mode; 95 µA in ON Mode)
- Low Input–to–Output Voltage Differential of 47 mV at 10 mA, and 131 mV at 50 mA
- Multiple Output Voltages Available
- Extremely Tight Line and Load Regulation
- Stable with Output Capacitance of Only
  0.33 µF for 5.0 V, 6.0 V and 4.75 V Output Voltages
  0.22 µF for 2.8 V, 3.0 V and 3.3 V Output Voltages
- Internal Current and Thermal Limiting
- Logic Level ON/OFF Control
- Functionally Equivalent to TK115XXMC and LP2980

ORDERING INFORMATION

* These ICs are intended for powering cellular phone GaAs power amplifiers and can be used for other portable applications as well.

Microprocessor Voltage Regulator and Supervisory Circuit

MC34160P, DW

T_A = 0° to +70°C, Case 648C, 751G

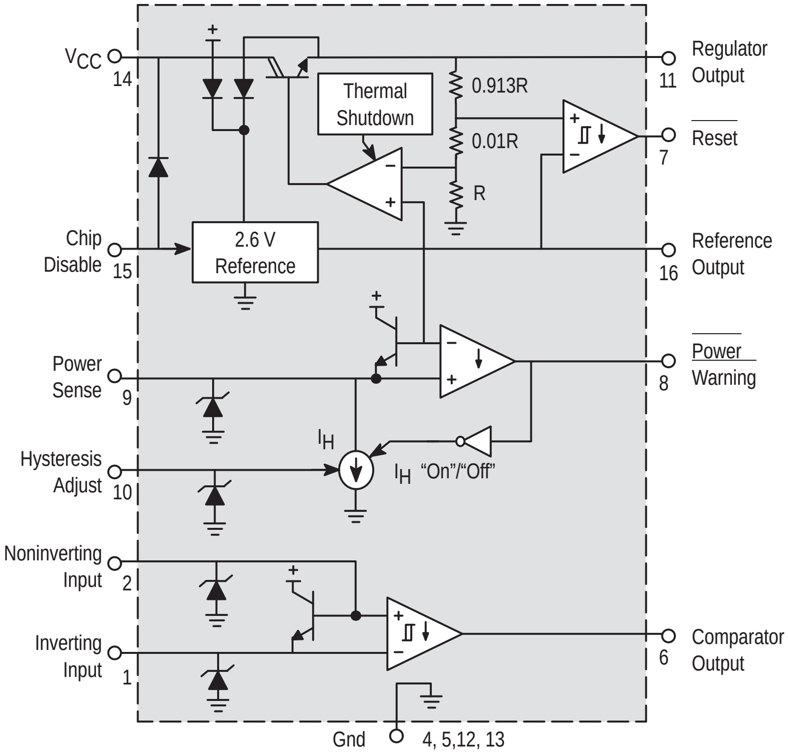
MC33160P, DW

T_A = –40° to +85°C, Case 648C, 751G

The MC34160 series is a voltage regulator and supervisory circuit containing many of the necessary monitoring functions required in microprocessor based systems. It is specifically designed for appliance and industrial applications offering the designer a cost effective solution with minimal external components. These integrated circuits feature a 5.0 V, 100 mA regulator with short circuit current limiting, pinned out 2.6 V bandgap reference, low voltage reset comparator, power warning comparator with programmable hysteresis, and an uncommitted comparator ideally suited for microprocessor line synchronization.

Additional features include a chip disable input for low standby current, and internal thermal shutdown for over temperature protection.

These devices are contained in a 16 pin dual–in–line heat tab plastic package for improved thermal conduction.



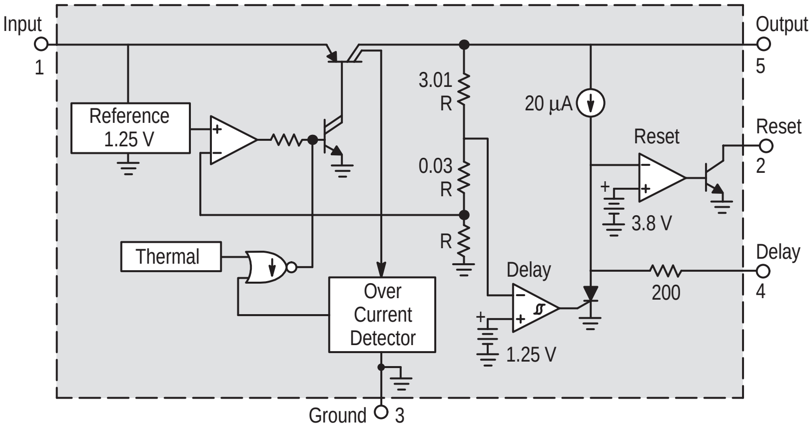
Low Dropout Regulator

MC33267T, TV

T_J = –40° to +105°C, Case 314D, 314B

The MC33267 is a positive fixed 5.0 V regulator that is specifically designed to maintain proper voltage regulation with an extremely low input–to–output voltage differential. This device is capable of supplying output currents in excess of 500 mA and contains internal current limiting and thermal shutdown protection. Also featured is an on–chip power–up reset circuit that is ideally suited for use in microprocessor based systems. Whenever the regulator output voltage is below nominal, the reset output is held low. A programmable time delay is initiated after the regulator has reached its nominal level and upon timeout, the reset output is released.

Due to the low dropout voltage specifications, the MC33267 is ideally suited for use in battery powered industrial and consumer equipment where an extension of useful battery life is desirable. This device is contained in an economical five lead TO–220 type package.



Voltage Regulator/Supervisory (continued)

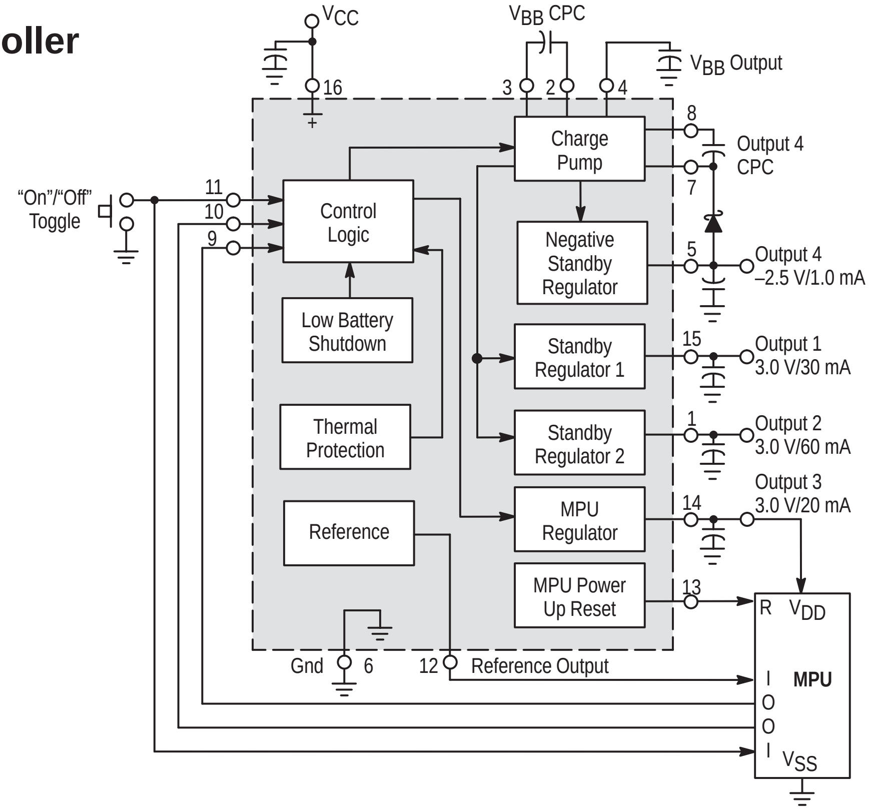
Power Management Controller

MC33128D

T_A = –30° to +60°C, Case 751B

The MC33128 is a power management controller specifically designed for use in battery powered cellular telephone and pager applications. This device contains all of the active functions required to interface the user to the system electronics via a microprocessor. This integrated circuit consists of a low dropout voltage regulator with power–up reset for MPU power, two low dropout voltage regulators for independant powering of analog and digital circuitry, and a negative charge pump voltage regulator for full depletion of gallium arsenide MESFETs.

Also included are protective system shutdown features consisting of a battery latch that is activated upon battery insertion, low battery voltage shutdown, and a thermal over temperature detector. This device is available in a 16–pin narrow body surface mount plastic package.



GaAs Power Amplifier Support IC

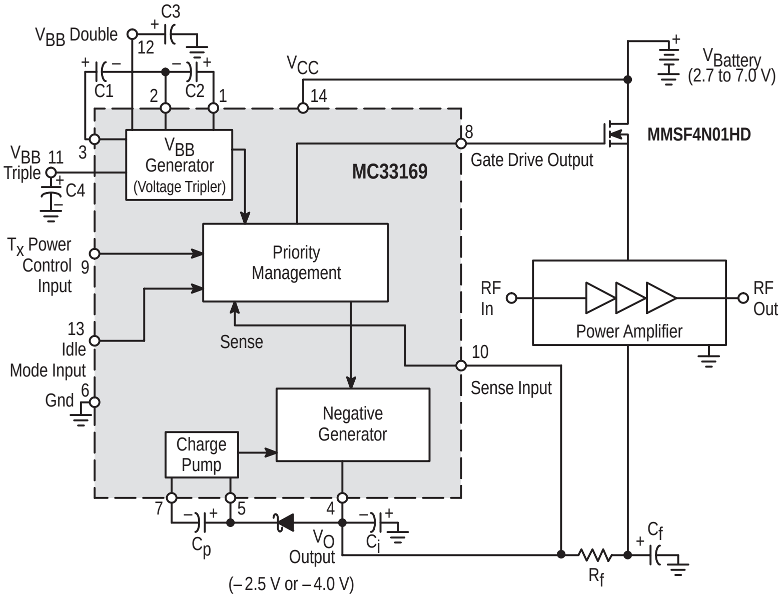
MC33169DTB

T_A = –40° to +85°C, Case 948G

The MC33169 is a support IC for GaAs Power Amplifier Enhanced FETs used in hand portable telephones such as GSM, PCN and DECT. This device provides negative voltages for full depletion of Enhanced MESFETs as well as a priority management system of drain switching, ensuring that the negative voltage is always present before turning "on" the Power Amplifier. Additional features include an idle mode input and a direct drive of the N–Channel drain switch transistor.

This product is available in two versions, –2.5 and –4.0 V. The –4.0 V version is intended for supplying RF modules for GSM and DCS1800 applications, whereas the –2.5 V version is dedicated for DECT and PHS systems.

- Negative Regulated Output for Full Depletion of GaAs MESFETs
- Drain Switch Priority Management Circuit
- CMOS Compatible Inputs
- Idle Mode Input (Standby Mode) for Very Low Current Consumption
- Output Signal Directly Drives N–Channel FET
- Low Startup and Operating Current



SCSI Regulator

Table 5. SCSI Regulator

Device	V_{out} (V)		I_{sink} (mA)	V_{in} (V)		Reg_{line} (%)	Reg_{load} (%)	T_J (°C)	Suffix/ Package
	Min	Max		Min	Max				
MC34268	2.81	2.89	800	3.9	20	0.3	0.5	150	D/751, DT

SCSI–2 Active Terminator Regulator

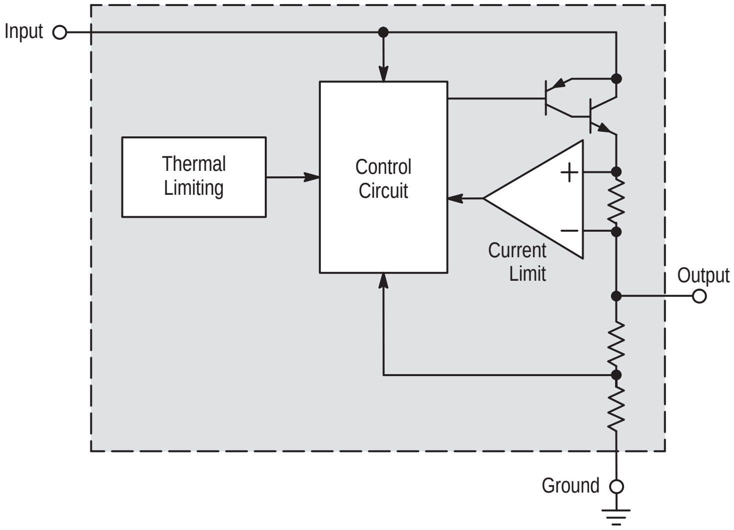
MC34268D, DT

T_J = 0° to +125°C, Case 751, 369A

The MC34268 is a medium current, low dropout positive voltage regulator specifically designed for use in SCSI–2 active termination circuits. This device offers the circuit designer an economical solution for precision voltage regulation, while keeping power losses to a minimum. The regulator consists of a 1.0 V dropout composite PNP/NPN pass transistor, current limiting, and thermal limiting. These devices are packaged in the 8–pin SOP–8 and 3–pin DPAK surface mount power packages.

Applications include active SCSI–2 terminators and post regulation of switching power supplies.

- 2.85 V Output Voltage for SCSI–2 Active Termination
- 1.0 V Dropout
- Output Current in Excess of 800 mA
- Thermal Protection
- Short Circuit Protection
- Output Trimmed to 1.4% Tolerance
- No Minimum Load Required
- Space Saving DPAK and SOP–8 Surface Mount Power Packages



Switching Regulator Control Circuits

These devices contain the primary building blocks which are required to implement a variety of switching power supplies. The product offerings fall into three major categories consisting of single–ended and double–ended controllers, plus single–ended ICs with on–chip power switch transistors. These circuits operate in voltage, current or resonant modes and are designed to drive many of the standard switching topologies. The single–ended configurations include buck, boost, flyback and forward converters. The double–ended devices control push–pull, half bridge and full bridge configurations.

Table 6. Single–Ended Controllers

These single–ended voltage and current mode controllers are designed for use in buck, boost, flyback, and forward converters. They are cost effective in applications that range from 0.1 to 200 W power output.

CMOS Micropower DC–to–DC Converters

Variable Frequency Micropower DC–to–DC Converter

MC33463H

T_A = –30° to +80°C, Case 1213

The MC33463 series are micropower switching voltage regulators, specifically designed for handheld and laptop applications, to provide regulated output voltages using a minimum of external parts. A wide choice of output voltages are available. These devices feature a very low quiescent bias current of 4.0 μA typical.

The MC33463H–XXLT1 series features a highly accurate voltage reference, an oscillator, a variable frequency modulation (VFM) controller, a driver transistor (Lx), an error amplifier and feedback resistive divider.

The MC33463H–XXLT1 is identical to the MC33463H–XXKT1, except that a drive pin (EXT) for an external transistor is provided.

Due to the low bias current specifications, these devices are ideally suited for battery powered computer, consumer, and industrial equipment where an extension of useful battery life is desirable.

MC33463 Series Features:

- Low Quiescent Bias Current of 4.0 μA
- High Output Voltage Accuracy of ±2.5%
- Low Startup Voltage of 0.9 V at 1.0 mA
- Surface Mount Package

ORDERING INFORMATION

Device	Output Voltage	Type	Operating Temperature Range	Package (Tape/Reel)

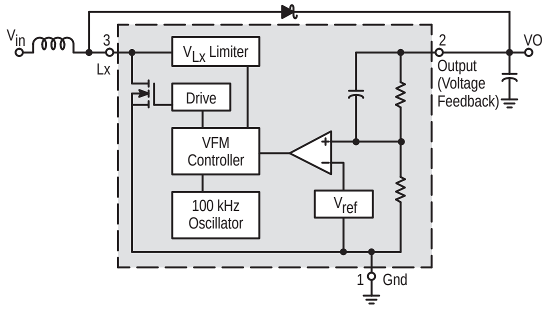
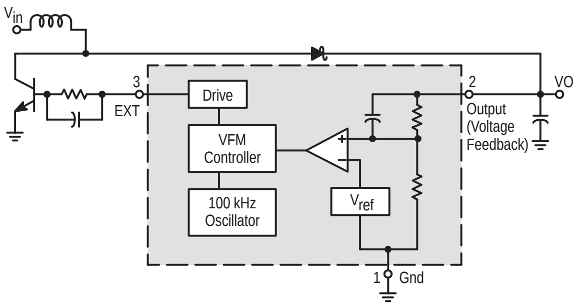
MC33463H–XXKT1



MC33463H–XXLT1



Fixed Frequency PWM Micropower DC–to–DC Converter

MC33466H

T_A = –30° to +80°C, Case 1213

The MC33466 series are micropower switching voltage regulators, specifically designed for handheld and laptop applications, to provide regulated output voltages using a minimum of external parts. A wide choice of output voltages are available. These devices feature a very low quiescent bias current of 15 µA typical.

The MC33466H–XXJT1 series features a highly accurate voltage reference, an oscillator, a pulse width modulation (PWM) controller, a driver transistor (Lx), an error amplifier and feedback resistive divider.

The MC33466H–XXLT1 is identical to the MC33466H–XXJT1, except that a drive pin (EXT) for an external transistor is provided.

Due to the low bias current specifications, these devices are ideally suited for battery powered computer, consumer, and industrial equipment where an extension of useful battery life is desirable.

MC33466 Series Features:

- Low Quiescent Bias Current of 15 µA
- High Output Voltage Accuracy of ±2.5%
- Low Startup Voltage of 0.9 V at 1.0 mA
- Soft–Start = 500 µs
- Surface Mount Package

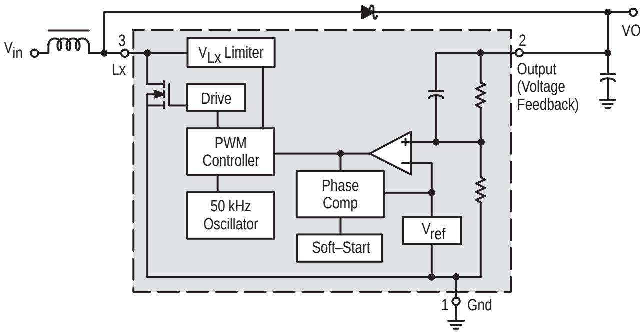
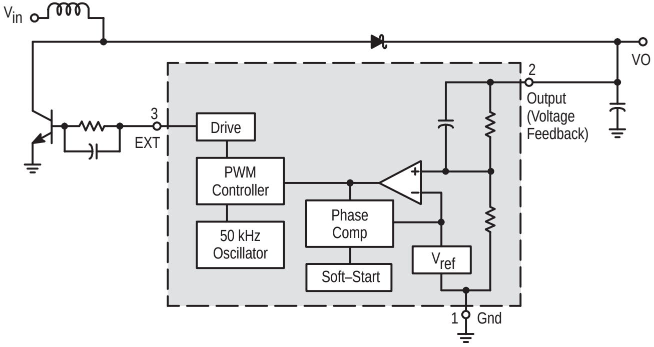
MC33466H–XXJT1



MC33466H–XXLT1



Single–Ended GreenLine™ Controllers

Mixed Frequency Mode GreenLine™ PWM Controller:

Fixed Frequency, Variable Frequency, Standby Mode

MC44603P, DW

T_A = –25° to +85°C, Case 648, 751G

The MC44603 is an enhanced high performance controller that is specifically designed for off–line and dc–to–dc converter applications. This device has the unique ability of automatically changing operating modes if the converter output is overloaded, unloaded, or shorted, offering the designer additional protection for increased system reliability. The MC44603 has several distinguishing features when compared to conventional SMPS controllers. These features consist of a foldback facility for overload protection, a standby mode when the converter output is slightly loaded, a demagnetization detection for reduced switching stresses on transistor and diodes, and a high current totem pole output ideally suited for driving a power MOSFET. It can also be used for driving a bipolar transistor in low power converters (< 150 W). It is optimized to operate in discontinuous mode but can also operate in continuous mode. Its advanced design allows use in current mode or voltage mode control applications.

Current or Voltage Mode Controller

- Operation up to 250 kHz Output Switching Frequency
- Inherent Feed Forward Compensation
- Latching PWM for Cycle–by–Cycle Current Limiting
- Oscillator with Precise Frequency Control

High Flexibility

- Externally Programmable Reference Current
- Secondary or Primary Sensing
- Synchronization Facility
- High Current Totem Pole Output
- Undervoltage Lockout with Hysteresis

Safety/Protection Features

- Overvoltage Protection Against Open Current and Open Voltage Loop
- Protection Against Short Circuit on Oscillator Pin
- Fully Programmable Foldback
- Soft–Start Feature
- Accurate Maximum Duty Cycle Setting
- Demagnetization (Zero Current Detection) Protection
- Internally Trimmed Reference

GreenLine Controller: Low Power Consumption in Standby Mode

- Low Startup and Operating Current
- Fully Programmable Standby Mode
- Controlled Frequency Reduction in Standby Mode
- Low dV/dT for Low EMI Radiations

High Safety Standby Ladder Mode GreenLine™ PWM Controller

MC44604P

T_A = –25° to +85°C, Case 648

The MC44604 is an enhanced high performance controller that is specifically designed for off–line and dc–to–dc converter applications.

The MC44604 is a modification of the MC44603. The MC44604 offers enhanced safety and reliable power management in its protection features (foldback, overvoltage detection, soft–start, accurate demagnetization detection). Its high current totem pole output is also ideally suited for driving a power MOSFET but can also be used for driving a bipolar transistor in low power converters (< 150 W).

In addition, the MC44604 offers a new efficient way to reduce the standby operating power by means of a patented standby ladder mode operation of the converter significantly reducing the converter consumption in standby mode.

Current or Voltage Mode Controller

- Operation Up to 250 kHz Output Switching Frequency
- Inherent Feed Forward Compensation
- Latching PWM for Cycle–by–Cycle Current Limiting
- Oscillator with Precise Frequency Control

High Flexibility

- Externally Programmable Reference Current
- Secondary or Primary Sensing
- High Current Totem Pole Output
- Undervoltage Lockout with Hysteresis

Safety/Protection Features

- Overvoltage Protection Facility Against Open Loop
- Protection Against Short Circuit on Oscillator Pin
- Fully Programmable Foldback
- Soft–Start Feature
- Accurate Maximum Duty Cycle Setting
- Demagnetization (Zero Current Detection) Protection
- Internally Trimmed Reference

GreenLine™ Controller:

- Low Startup and Operating Current
- Patented Standby Ladder Mode for Low Standby Losses
- Low dV/dT for Low EMI

High Safety Latched Mode GreenLine™ PWM Controller for (Multi)Synchronized Applications

MC44605P

T_A = –25° to +85°C, Case 648

The MC44605 is a high performance current mode controller that is specifically designed for off–line converters. The MC44605 has several distinguishing features that make it particularly suitable for multisynchronized monitor applications.

The MC44605 synchronization arrangement enables operation from 16 kHz up to 130 kHz. This product was optimized to operate with universal ac mains voltage from 80 V to 280 V, and its high current totem pole output makes it ideally suited for driving a power MOSFET.

The MC44605 protections provide well controlled, safe power management. Safety enhancements detect four different fault conditions and provide protection through a disabling latch.

Current or Voltage Mode Controller

- Current Mode Operation Up to 250 kHz Output Switching Frequency
- Inherent Feed Forward Compensation
- Latching PWM for Cycle–by–Cycle Current Limiting
- Oscillator with Precise Frequency Control
- Externally Programmable Reference Current
- Secondary or Primary Sensing (Availability of Error Amplifier Output)
- Synchronization Facility
- High Current Totem Pole Output
- Undervoltage Lockout with Hysteresis
- Low Output dV/dT for Low EMI
- Low Startup and Operating Current

Safety/Protection Features

- Soft–Start Feature
- Demagnetization (Zero Current Detection) Protection
- Overvoltage Protection Facility Against Open Loop
- EHT Overvoltage Protection (E.H.T.OVP): Protection Against Excessive Amplitude Synchronization Pulses
- Winding Short Circuit Detection (W.S.C.D.)
- Limitation of the Maximum Input Power (M.P.L.): Calculation of Input Power for Overload Protection
- Over Heating Detection (O.H.D.): to Prevent the Power Switch from Excessive Heating

Latched Disabling Mode

- When one of the following faults is detected: EHT overvoltage, Winding Short Circuit (WSCD), excessive input power (M.P.L.), power switch over heating (O.H.D.), a counter is activated
- If the counter is activated for a time that is long enough, the circuit gets definitively disabled. The latch can only be reset by removing and then re–applying power

Very High Voltage Switching Regulator

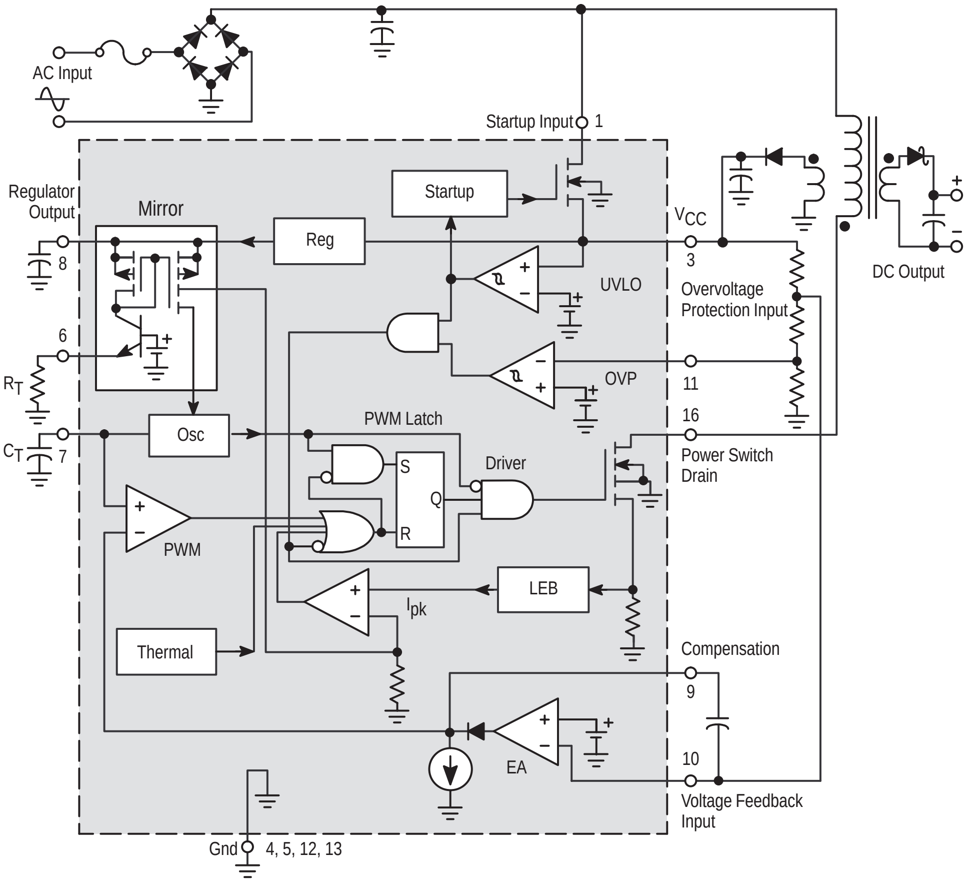
MC33362DW, P

T_J = –25° to +125°C, Case 751N, 658E

The MC33362 is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 120 VAC line source. This integrated circuit features an on–chip 500 V/2.0 A SenseFET power switch, 250 V active off–line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle–by–cycle current limiting, input undervoltage lockout with hysteresis, output overvoltage protection, and thermal shutdown. This device is available in a 16–lead dual–in–line and wide body surface mount packages.

- On–Chip 500 V, 2.0 A SenseFET Power Switch
- Rectified 120 VAC Line Source Operation
- On–Chip 250 V Active Off–Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle–By–Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Output Overvoltage Protection Comparator
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown

20 W Off–Line Converter



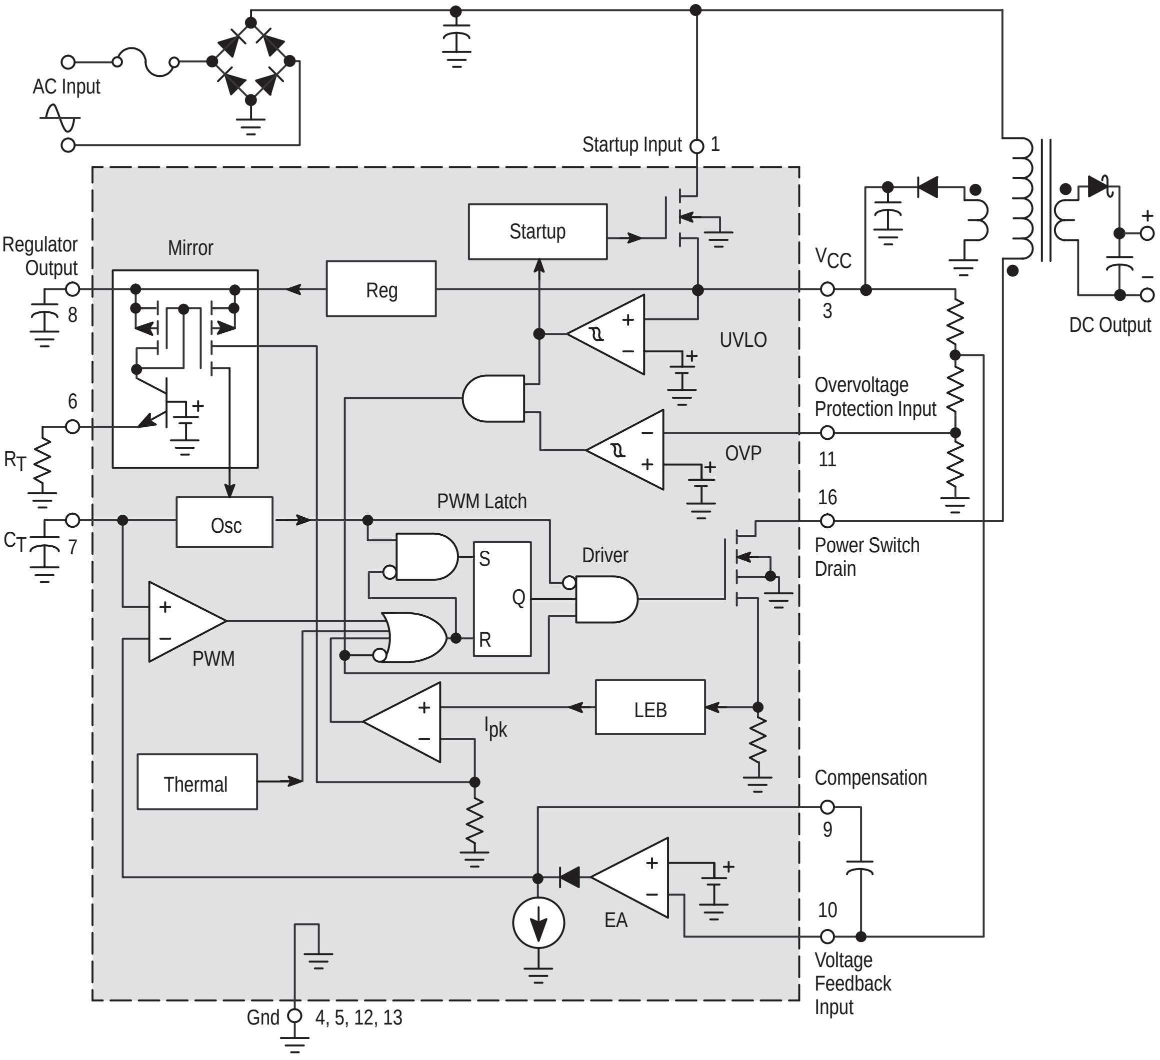
Very High Voltage Switching Regulator

MC33363DW, P, MC33363ADW, P

T_J = –25° to +125°C, Case 751N, 648E

The MC33363 is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 240 Vac line source. This integrated circuit features an on–chip 700 V/1.0 A (1.5 A in MC33363A) SenseFET power switch, 450 V active off–line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle–by–cycle current limiting, input undervoltage lockout with hysteresis, output overvoltage protection, and thermal shutdown. This device is available in a 16–lead wide body surface mount package.

- On–Chip 700 V, 1.0 A SenseFET Power Switch
- On–Chip 700 V, 1.5 A SenseFET Power Switch in MC33363A
- Rectified 240 Vac Line Source Operation
- On–Chip 450 V Active Off–Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle–By–Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Output Overvoltage Protection Comparator
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown



Critical Conduction SMPS Controller

MC33364D, D1, D2

T_J = –25° to +125°C, Case 751, 751B

The MC33364 series are variable frequency SMPS controllers that operate in the critical conduction mode. They are optimized for low power, high density power supplies requiring minimum board area, reduced component count, and low power dissipation. Each narrow body SOIC package provides a small footprint. Integration of the high voltage startup saves approximately 0.7 W of power compared to resistor bootstrapped circuits.

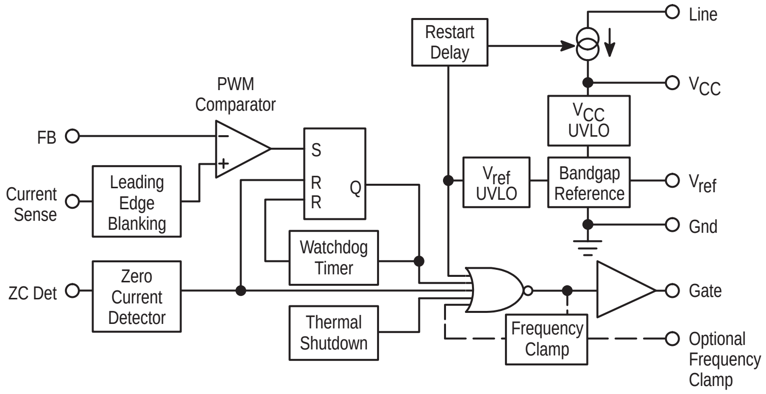
Each MC33364 features an on–board reference, UVLO function, a watchdog timer to initiate output switching, a zero current detector to ensure critical conduction operation, a current sensing comparator, leading edge blanking, and a CMOS driver. Protection features include the ability to shut down switching, and cycle–by–cycle current limiting.

The MC33364D1 is available in a surface mount SO–8 package. It has an internal 144 kHz frequency clamp. For loads which have a low power operating condition, the frequency clamp limits the maximum operating frequency, preventing excessive switching losses and EMI radiation.

The MC33364D2 is available in the SO–8 package without an internal frequency clamp.

The MC33364D is available in the SO–16 package. It has an internal 144 kHz frequency clamp which is pinned out, so that the designer can adjust the clamp frequency by connecting appropriate values of resistance and capacitance.

- Lossless Off–Line Startup
- Leading Edge Blanking for Noise Immunity
- Watchdog Timer to Initiate Switching
- Minimum Number of Support Components
- Shutdown Capability
- Over Temperature Protection
- Optional Frequency Clamp



Special Switching Regulator Controllers

These high performance dual channel controllers are optimized for off–line, ac–to–dc power supplies and dc–to–dc converters in the flyback topology. They also have undervoltage lockout voltages which are optimized for off–line and lower voltage dc–to–dc converters, respectively. Applications include desktop computers, peripherals, televisions, games, and various consumer appliances.

Table 11. Dual Channel Controllers

I_O (mA) Max	Minimum Operating Voltage Range (V)	Operating Mode	Reference (V)	Maximum Useful Oscillator Frequency (kHz)	Device	T_A (°C)	Suffix/ Package

Power Factor Controllers

MC34262D, P

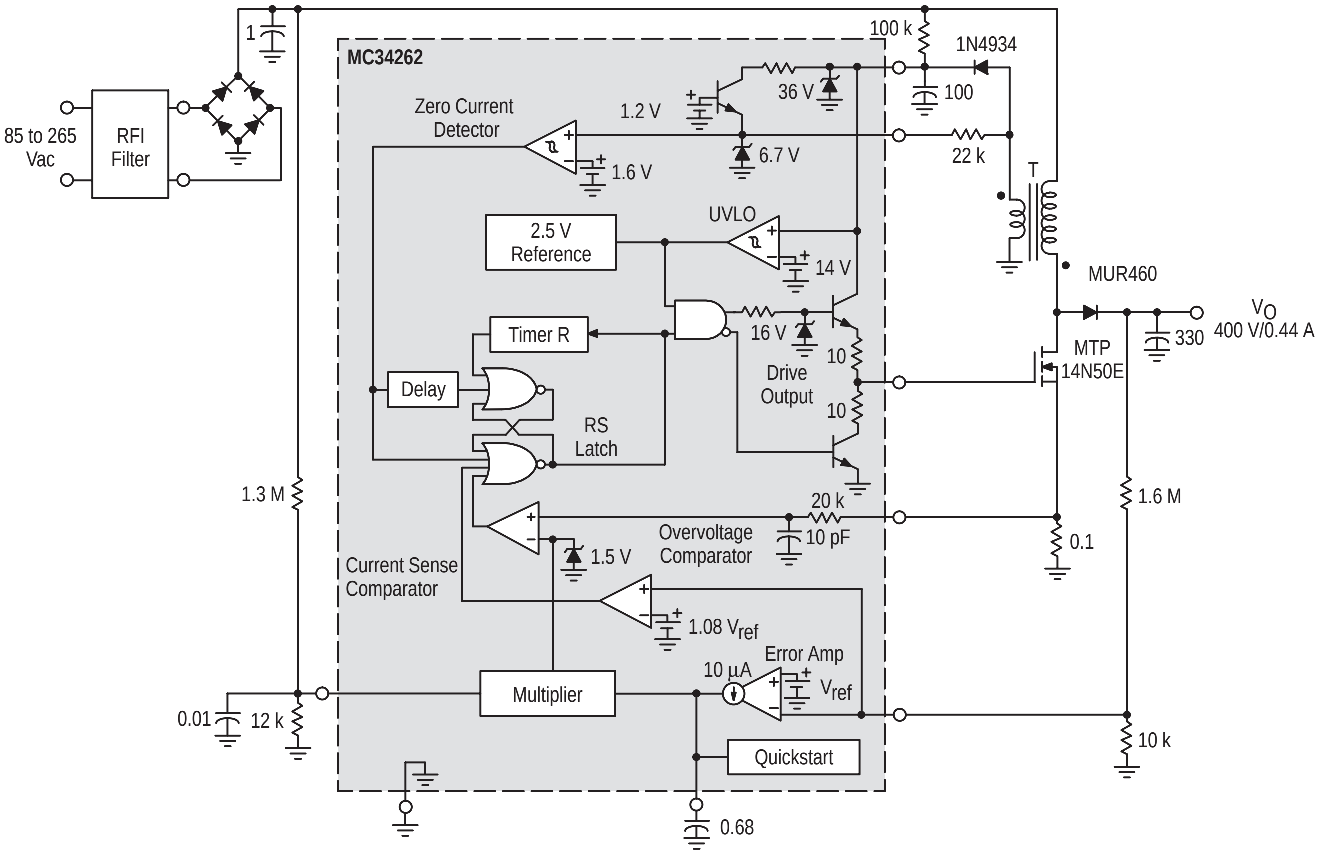
T_A = 0° to +85°C, Case 751, 626

MC33262D, P

T_A = –40° to +105°C, Case 751, 626

The MC34262, MC33262 series are active power factor controllers specifically designed for use as a preconverter in electronic ballast and in off–line power converter applications. These integrated circuits feature an internal startup timer for stand alone applications, a one quadrant multiplier for near unity power factor, zero current detector to ensure critical conduction operation, transconductance error amplifier, quickstart circuit for enhanced startup, trimmed internal bandgap reference, current sensing comparator, and a totem pole output ideally suited for driving a power MOSFET.

Also included are protective features consisting of an overvoltage comparator to eliminate runaway output voltage due to load removal, input undervoltage lockout with hysteresis, cycle–by–cycle current limiting, multiplier output clamp that limits maximum peak switch current, an RS latch for single pulse metering, and a drive output high state clamp for MOSFET gate protection. These devices are available in dual–in–line and surface mount plastic packages.



Power Factor Controllers (continued)

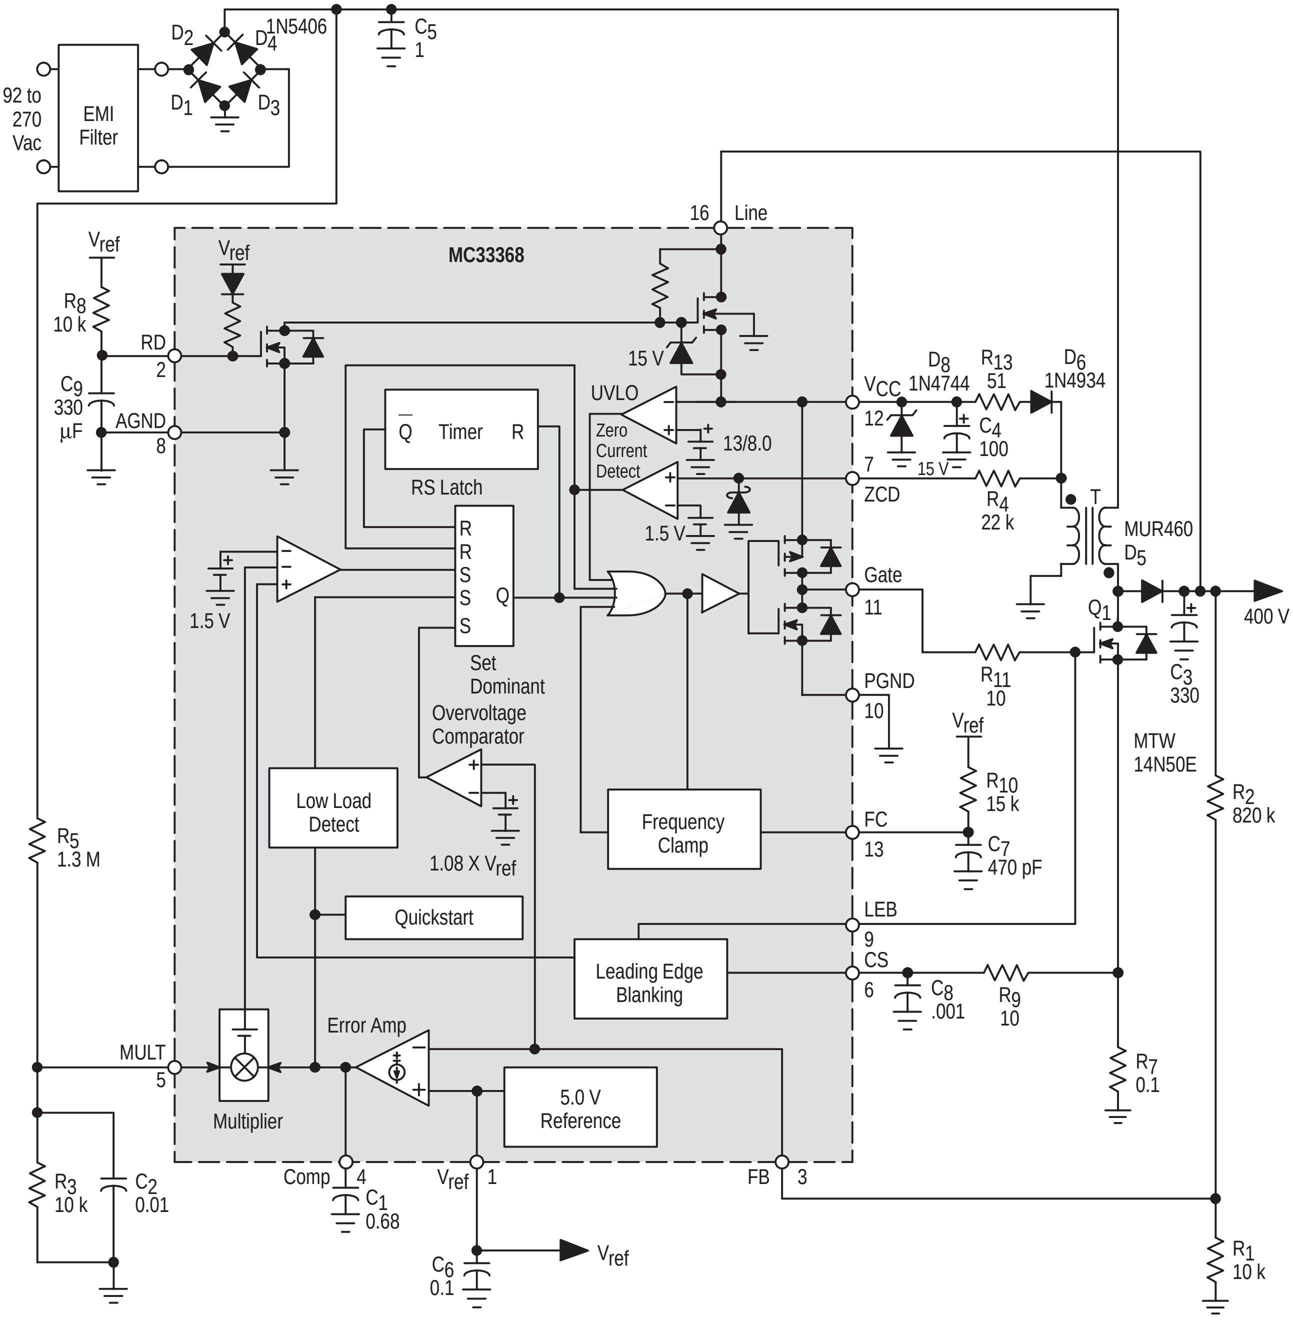
MC33368D

T_J = –25° to +125°C, Case 751K

The MC33368 is an active power factor controller that functions as a boost preconverter in off–line power supply applications. MC33368 is optimized for low power, high density power supplies requiring minimum board area, reduced component count, and low power dissipation. The narrow body SOIC package provides a small footprint. Integration of the high voltage startup saves approximately 0.7 W of power compared to resistor bootstrapped circuits.

The MC33368 features a watchdog timer to initiate output switching, a one quadrant multiplier to force the line current to follow the instantaneous line voltage, a zero current detector to ensure critical conduction operation, a transconductance error amplifier, a current sensing comparator, a 5.0 V reference, an undervoltage lockout (UVLO) circuit which monitors the V_{CC} supply voltage, and a CMOS driver for driving MOSFETs. The MC33368 also includes a programmable output switching frequency clamp. Protection features include an output overvoltage comparator to minimize overshoot, a restart delay timer, and cycle–by–cycle current limiting.

- Lossless Off–Line Startup
- Output Overvoltage Comparator
- Leading Edge Blanking (LEB) for Noise Immunity
- Watchdog Timer to Initiate Switching
- Restart Delay Timer



Supervisory Circuits

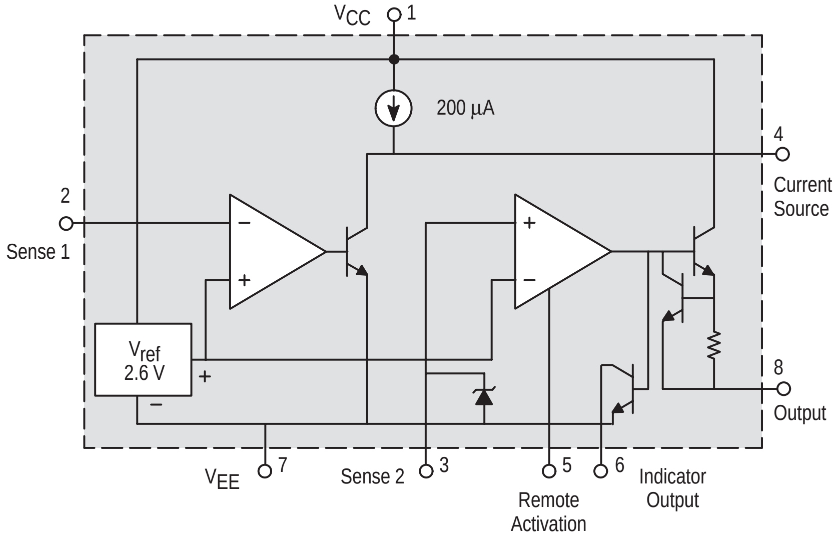
A variety of Power Supervisory Circuits are offered. Overvoltage sensing circuits which drive ‘‘Crowbar’’ SCRs are provided in several configurations from a low cost three–terminal version to 8–pin devices which provide pin–programmable trip voltages or additional features, such as an indicator output drive and remote activation capability. An over/undervoltage protection circuit is also offered.

Overvoltage Crowbar Sensing Circuit

MC3423P1, D

T_A = 0° to +70°C, Case 626, 751

This device can protect sensitive circuitry from power supply transients or regulator failure when used with an external ‘‘Crowbar’’ SCR. The device senses voltage and compares it to an internal 2.6 V reference. Overvoltage trip is adjustable by means of an external resistive voltage divider. A minimum duration before trip is programmable with an external capacitor. Other features include a 300 mA high current output for driving the gate of a ‘‘Crowbar’’ SCR, an open–collector indicator output and remote activation capability.

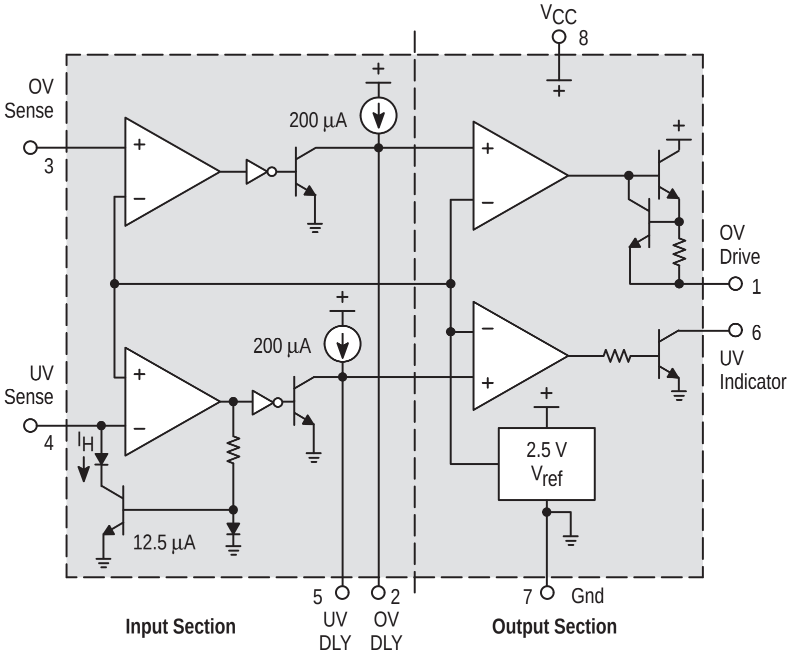


Over/Undervoltage Protection Circuit

MC3425P1

T_A = 0° to +70°C, Case 626

The MC3425 is a power supply supervisory circuit containing all the necessary functions required to monitor over and undervoltage fault conditions. This device features dedicated over and undervoltage sensing channels with independently programmable time delays. The overvoltage channel has a high current drive output for use in conjunction with an external SCR ‘‘Crowbar’’ for shutdown. The undervoltage channel input comparator has hysteresis which is externally programmable, and an open–collector output for fault indication.



CMOS Micropower Undervoltage Sensing Circuits

MC33464H, N

T_A = –30° to +80°C, Case 1213, 1212

The MC33464 series are micropower undervoltage sensing circuits that are specifically designed for use with battery powered microprocessor based systems, where extended battery life is required. A choice of several threshold voltages from 0.9 V to 4.5 V are available. These devices feature a very low quiescent bias current of 0.8 μA typical.

The MC33464 series features a highly accurate voltage reference, a comparator with precise thresholds and built–in hysteresis to prevent erratic reset operation, a choice of output configurations between open drain or complementary MOS, and guaranteed operation below 1.0 V with extremely low standby current. These devices are available in either SOT–89 3–pin or SOT–23 5–pin surface mount packages.

Applications include direct monitoring of the MPU/logic power supply used in portable, appliance, automotive and industrial equipment.

MC33464 Features:

- Extremely Low Standby Current of 0.8 μA at V_{in} = 1.5 V
- Wide Input Voltage Range (0.7 V to 10 V)
- Monitors Power Supply Voltages from 1.1 V to 5.0 V
- High Accuracy Detector Threshold (±2.5%)
- Two Reset Output Types (Open Drain or Complementary Drive)
- Two Surface Mount Packages (SOT–89 or SOT–23 5–Pin)

ORDERING INFORMATION

Device	Threshold Voltage	Type	Operating Temperature Range	Package (Qty/Reel)

CMOS Micropower Undervoltage Sensing Circuits with Output Delay

MC33465N

T_A = –30° to +80°C, Case 1212

The MC33465 series are micropower undervoltage sensing circuits that are specifically designed for use with battery powered microprocessor based systems, where extended battery life is required. A choice of several threshold voltages from 0.9 V to 4.5 V are available. This device features a very low quiescent bias current of 1.0 µA typical.

The MC33465 series features a highly accurate voltage reference, a comparator with precise thresholds and built–in hysteresis to prevent erratic reset operation, a choice of output configurations between open drain or complementary MOS, a time delayed output, which can be programmed by the system designer, and guaranteed operation below 1.0 V with extremely low standby current. This device is available in a SOT–23 5–pin surface mount packages.

Applications include direct monitoring of the MPU/logic power supply used in portable, appliance, automotive and industrial equipment.

MC33465 Features:

- Extremely Low Standby Current of 1.0 µA at V_{in} = 3.5 V
- Wide Input Voltage Range (0.7 V to 10 V)
- Monitors Power Supply Voltages from 1.1 V to 5.0 V
- High Accuracy Detector Threshold (±2.5%)
- Two Reset Output Types (Open Drain or Complementary Drive)
- Programmable Output Delay by External Capacitor (100 ms typ. with 0.15 µF)
- Surface Mount Package (SOT–23 5–Pin)
- Convenient Tape and Reel (3000 per Reel)

T_A = 0° to +70°C, Case 29, 751, 846A

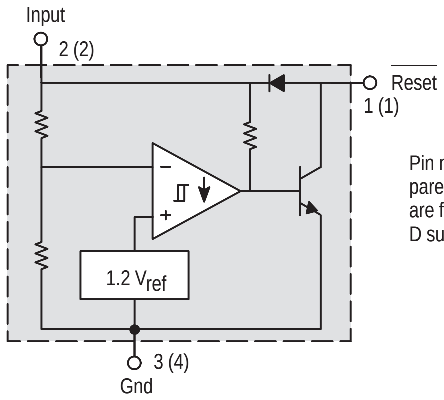
MC33164P–3, P–5, D–3, D–5, DM–3, DM–5
T_A = –40° to +85°C, Case 29, 751, 846A

The MC34064 and MC34164 are two families of undervoltage sensing circuits specifically designed for use as reset controllers in microprocessor–based systems. They offer the designer an economical solution for low voltage detection with a single external resistor. Both parts feature a trimmed bandgap reference, and a comparator with precise thresholds and built–in hysteresis to prevent erratic reset operation.

The two families of undervoltage sensing circuits taken together, cover the needs of the most commonly specified power supplies used in MCU/MPU systems. Key parameter specifications of the MC34164 family were chosen to complement the MC34064 series. The table summarizes critical parameters of both families. The MC34064 fulfills the needs of a 5.0 V ± 5% system and features a tighter hysteresis specification. The MC34164 series covers 5.0 V ± 10% and 3.0 V ± 5% power supplies with significantly lower power consumption, making them ideal for applications where extended battery life is required such as consumer products or hand held equipment.



Pin numbers in parenthesis are for the D suffix package.

Applications include direct monitoring of the 5.0 V MPU/logic power supply used in appliance, automotive, consumer, and industrial equipment.

The MC34164 is specifically designed for battery powered applications where low bias current (1/25th of the MC34064's) is an important characteristic.

Table 14. Undervoltage Sense/Reset Controller Features

MC34X64 devices are specified to operate from 0° to +70°C, and MC33X64 devices operate from –40° to +85°C.

Device	Standard Power Supply Supported	Typical Threshold Voltage (V)	Typical Hysteresis Voltage (V)	Minimum Output Sink Current (mA)	Power Supply Input Voltage Range (V)	Maximum Quiescent Input Current	Suffix/ Package
MC34064/MC33064	5.0 V ± 5%	4.6	0.02	10	1.0 to 10	500 µA @ V_{in} = 5.0 V	P–5/29

Universal Voltage Monitor

MC34161P, D

T_A = 0° to +70°C, Case 626, 751

MC33161P, D

T_A = –40° to +85°C, Case 626, 751

The MC34161, MC33161 series are universal voltage monitors intended for use in a wide variety of voltage sensing applications. These devices offer the circuit designer an economical solution for positive and negative voltage detection. The circuit consists of two comparator channels each with hysteresis, a unique Mode Select Input for channel programming, a pinned out 2.54 V reference, and two open collector outputs capable of sinking in excess of 10 mA. Each comparator channel can be configured as either inverting or noninverting by the Mode Select Input. This allows over, under, and window detection of positive and negative voltages. The minimum supply voltage needed for these devices to be fully functional is 2.0 V for positive voltage sensing and 4.0 V for negative voltage sensing.

Applications include direct monitoring of positive and negative voltages used in appliance, automotive, consumer, and industrial equipment.

- Unique Mode Select Input Allows Channel Programming
- Over, Under, and Window Voltage Detection
- Positive and Negative Voltage Detection
- Fully Functional at 2.0 V for Positive Voltage Sensing and 4.0 V for Negative Voltage Sensing
- Pinned Out 2.54 V Reference with Current Limit Protection
- Low Standby Current
- Open Collector Outputs for Enhanced Device Flexibility

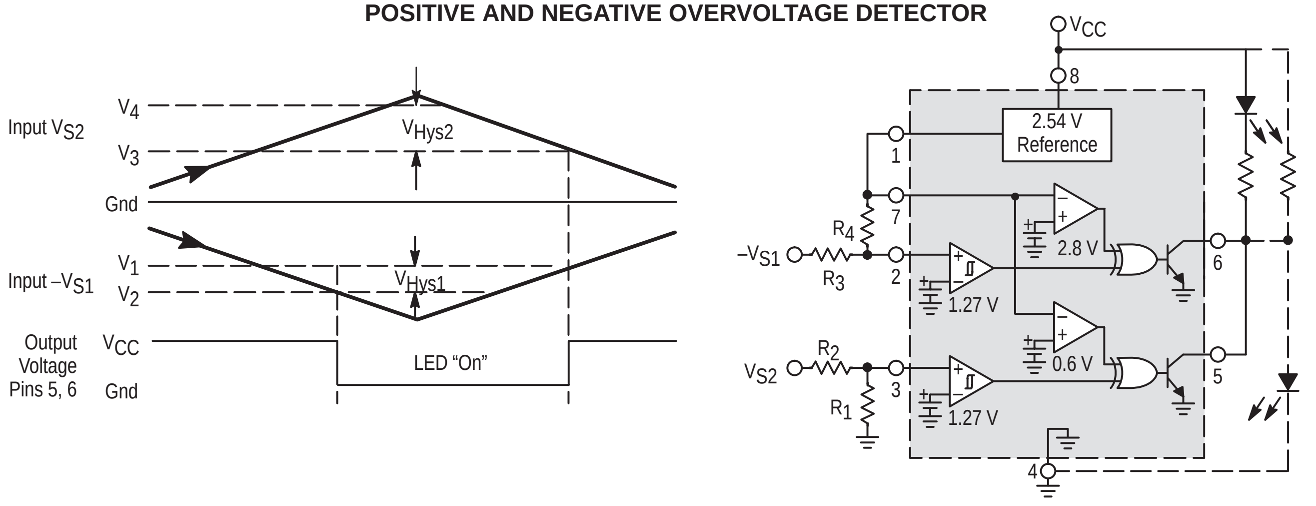
POSITIVE AND NEGATIVE OVERVOLTAGE DETECTOR



Battery Management Circuits

Battery Charger ICs

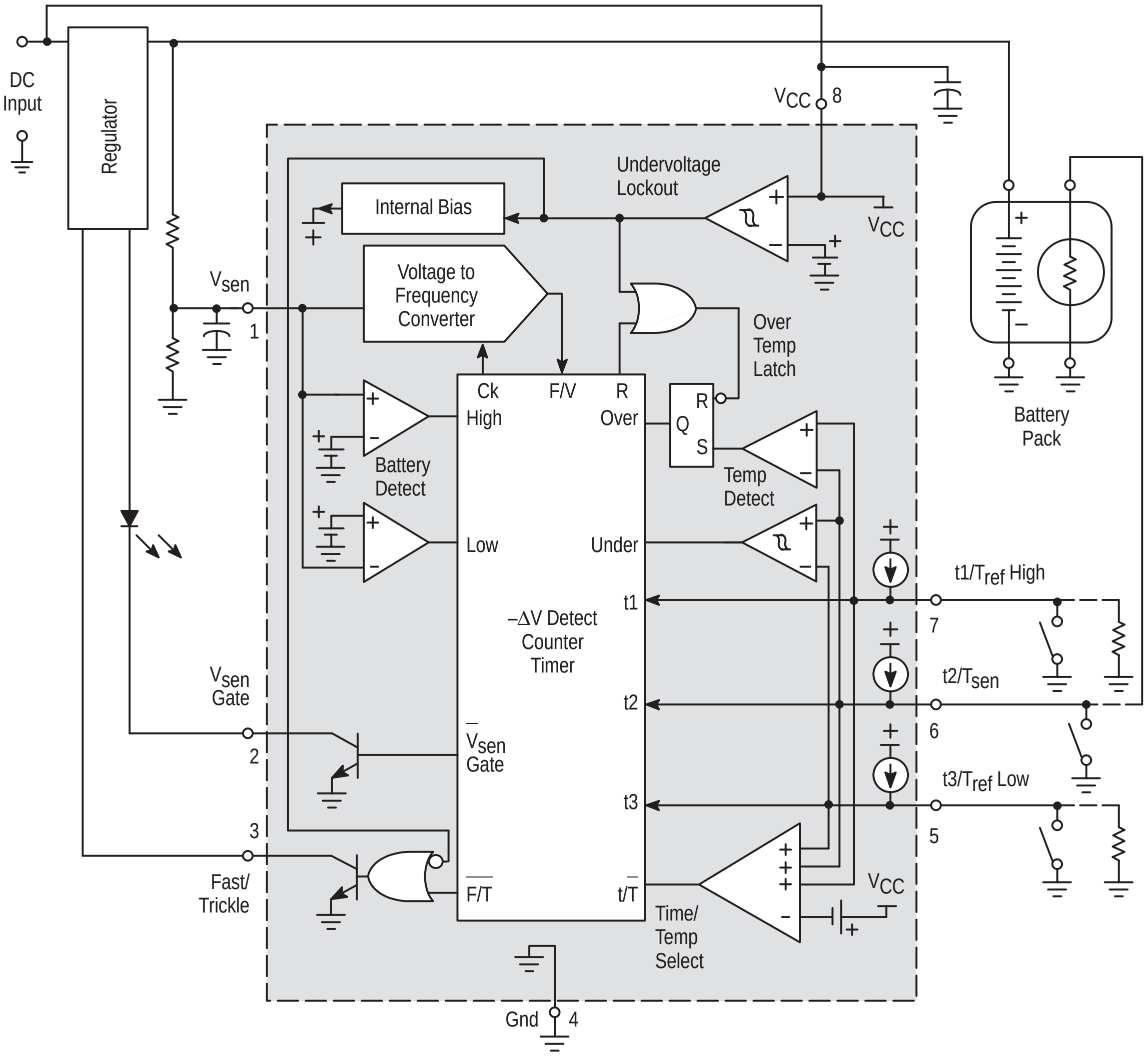
Battery Fast Charge Controller

MC33340P, D

T_A = –25° to +85°C, Case 626, 751

The MC33340 is a monolithic control IC that is specifically designed as a fast charge controller for Nickel Cadmium (NiCd) and Nickel Metal Hydride (NiMH) batteries. This device features negative slope voltage detection as the primary means for fast charge termination. Accurate detection is ensured by an output that momentarily interrupts the charge current for precise voltage sampling. An additional secondary backup termination method can be selected that consists of either a programmable time or temperature limit. Protective features include battery over and undervoltage detection, latched over temperature detection, and power supply input undervoltage lockout with hysteresis. Provisions for entering a rapid test mode are available for enhanced end product testing. This device is available in an economical 8–lead surface mount package.

- Negative Slope Voltage Detection
- Accurate Zero Current Battery Voltage Sensing
- Programmable 1 to 4 Hour Fast Charge Time Limit
- Programmable Over/Under Temperature Detection
- Battery Over and Undervoltage Fast Charge Protection
- Rapid System Test Mode
- Power Supply Input Undervoltage Lockout with Hysteresis
- Operating Voltage Range of 3.0 V to 18 V



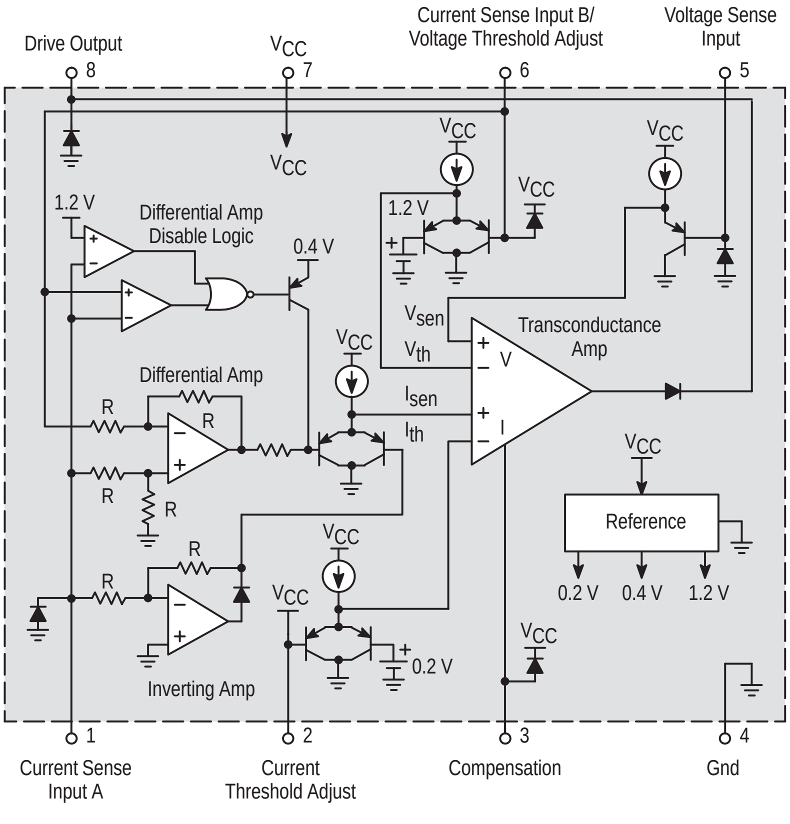
Power Supply
Battery Charger
Regulation Control Circuit

MC33341P, D

T_A = –40° to +85°C, Case 626, 751

The MC33341 is a monolithic regulation control circuit that is specifically designed to close the voltage and current feedback loops in power supply and battery charger applications. This device features the unique ability to perform source high–side, load high–side, source low–side, and load low–side current sensing, each with either an internally fixed or externally adjustable threshold. The various current sensing modes are accomplished by a means of selectively using the internal differential amplifier, inverting amplifier, or a direct input path. Positive voltage sensing is performed by an internal voltage amplifier. The voltage amplifier threshold is internally fixed and can be externally adjusted in all low–side current sensing applications. An active high drive output is provided to directly interface with economical optoisolators for isolated output power systems. This device is available in 8–lead dual–in–line and surface mount packages.

- Differential Amplifier for High–Side Source and Load Current Sensing
- Inverting Amplifier for Source Return Low–Side Current Sensing
- Noninverting Input Path for Load Low–Side Current Sensing
- Fixed or Adjustable Current Threshold in all Current Sensing Modes
- Positive Voltage Sensing in all Current Sensing Modes
- Fixed Voltage Threshold in all Current Sensing Modes
- Adjustable Voltage Threshold in all Low–Side Current Sensing Modes
- Output Driver Directly Interfaces with Economical Optoisolators
- Operating Voltage Range of 2.3 V to 18 V



Battery Pack ICs

Lithium Battery Protection Circuit for One to Four Cell Battery Packs

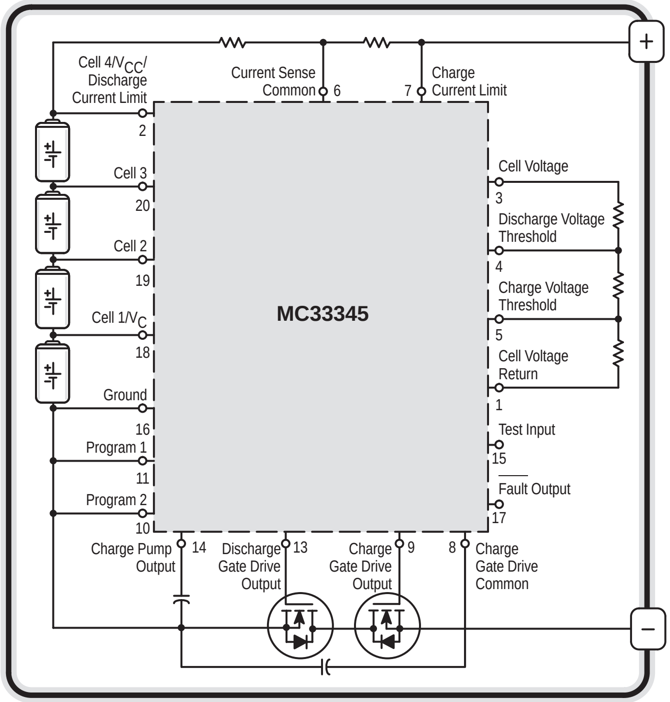
MC33345DW, DTB

T_A = –25° to +85°C, Case 751D, 948E

The MC33345 is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of one to four cell rechargeable battery packs. Cell protection features consist of independently programmable charge and discharge limits for both voltage and current with a delayed current shutdown, cell voltage balancing with on–chip balancing resistors, and a virtually zero current sleepmode state when the cells are discharged. Additional features include an on–chip charge pump for reduced MOSFET losses while charging or discharging a low cell voltage battery pack, and the programmability for a one to four cell battery pack. This protection circuit requires a minimum number of external components and is targeted for inclusion within the battery pack. The MC33345 is available in standard and low profile 20 lead surface mount packages.

- Independently Programmable Charge and Discharge Limits for Both Voltage and Current
- Charge and Discharge Current Limit Detection with Delayed Shutdown
- Cell Voltage Balancing
- On–Chip Balancing Resistors
- Virtually Zero Current Sleepmode State when Cells are Discharged
- Charge Pump for Reduced Losses with a Low Cell Voltage Battery Pack
- Programmable for One, Two, Three or Four Cell Applications
- Minimum External Components for Inclusion within the Battery Pack
- Available in Low Profile Surface Mount Packages

Typical Four Cell Smart Battery Pack



Battery Pack ICs (continued)

Lithium Battery Protection Circuit for Three or Four Cell Battery Packs

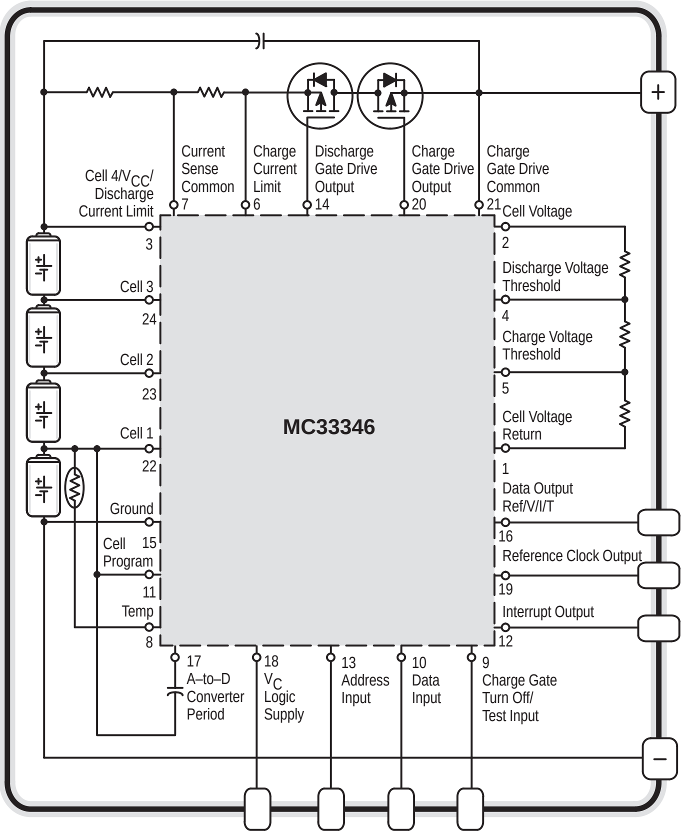
MC33346DW, DTB

T_A = –40° to +85°C, Case 751E, 948H

The MC33346 is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of three or four cell rechargeable battery packs. Cell protection features consist of independently programmable charge and discharge limits for both voltage and current with a delayed current shutdown, cell voltage balancing with on–chip balancing resistors, and virtually zero current sleepmode state when the cells are discharged. Additional features consists of a six wire microcontroller interface bus that can selectively provide a pulse output that represents the internal reference voltage, cell voltage, cell current and temperature, as well as control the states of four internal balancing and two external MOSFET switches. A microcontroller time reference output is available for gas gauge implementation. This protection circuit requires a minimum number of external components and is targeted for inclusion within the battery pack. The MC33346 is available in standard and low profile 24 lead surface mount packages.

- Independently Programmable Charge and Discharge Limits for Both Voltage and Current
- Delayed Current Shutdown
- Cell Voltage Balancing with On–Chip Resistors
- Six Wire Microcontroller Interface Bus
- Data Output for Reference, Voltage, Current, and Temperature
- Microcontroller Time Reference Output for Gas Gauging
- Virtually Zero Current Sleepmode State when Cells are Discharged
- Programmable for Three or Four Cell Applications
- Minimum External Components for Inclusion within the Battery Pack
- Available in Low Profile Surface Mount Packages

Typical Four Cell Smart Battery Pack



Lithium Battery Protection Circuit for One or Two Cell Battery Packs

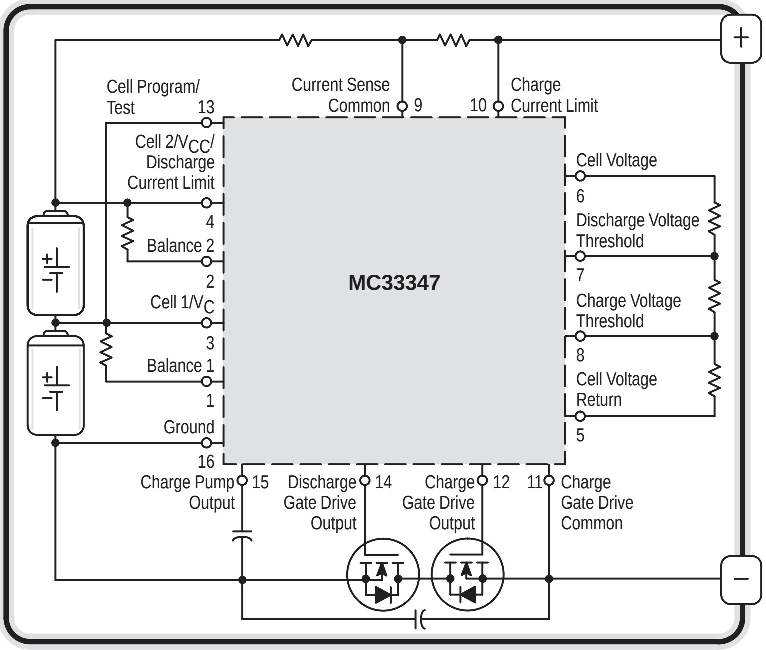
MC33347D, DTB

T_A = –25° to +85°C, Case 751B, 948F

The MC33347 is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of one or two cell rechargeable battery packs. Cell protection features consist of independently programmable charge and discharge limits for both voltage and current with a delayed current shutdown, continuous cell voltage balancing with the choice of on–chip or external balancing resistors, and a virtually zero current sleepmode state when the cells are discharged. Additional features include an on–chip charge pump for reduced MOSFET losses while charging or discharging a low cell voltage battery pack, and the programmability for one or two cell battery pack. This protection circuit requires a minimum number of external components and is targeted for inclusion within the battery pack. This MC33347 is avaialble in standard and low profile 16 lead surface mount packages.

- Independently Programmable Charge and Discharge Limits for Both Voltage and Current
- Charge and Discharge Current Limit Detection with Delayed Shutdown
- Continuous Cell Voltage Balancing
- On–Chip or External Balancing Resistors
- Virtually Zero Current Sleepmode State when Cells are Discharged
- Charge Pump for Reduced Losses with a Low Cell Voltage Battery Pack
- Programmable for One or Two Cell Applications
- Minimum External Components for Inclusion within the Battery Pack
- Available in Low Profile Surface Mount Packages

Typical Two Cell Smart Battery Pack



Battery Pack ICs (continued)

Lithium Battery Protection Circuit for One Cell Battery Packs

MC33348D, DM

T_A = –25° to +85°C, Case 751, 846A

The MC33348 is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of one cell rechargeable battery pack. Cell protection features consist of internally trimmed charge and discharge voltage limits, discharge current limit detection with a delayed shutdown, and a virtually zero current sleepmode state when the cell is discharged. An additional feature includes an on–chip charge pump for reduced MOSFET losses while charging or discharging a low cell voltage battery pack. This protection circuit requires a minimum number of external components and is targeted for inclusion within the battery pack. This MC33348 is available in standard and micro 8 lead surface mount packages.

- Internally Trimmed Charge and Discharge Voltage Limits
- Discharge Current Limit Detection with Delayed Shutdown
- Virtually Zero Current Sleepmode State when Cells are Discharged
- Charge Pump for Reduced Losses with a Low Cell Voltage Battery Pack
- Dedicated for One Cell Applications
- Minimum Components for Inclusion within the Battery Pack
- Available in Low Profile Surface Mount Packages

Typical One Cell Smart Battery Pack

MOSFET/IGBT Drivers

High Speed Dual Drivers

(Inverting)

MC34151P, D

T_A = 0° to +70°C, Case 626, 751

MC33151P, D

T_A = –40° to +85°C, Case 626, 751

(Noninverting)

MC34152P, D

T_A = 0° to +70°C, Case 626, 751

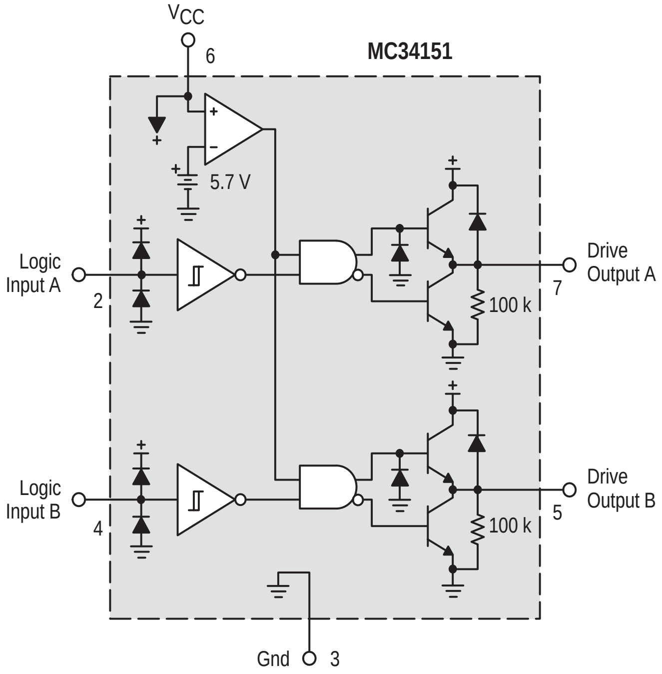
MC33152P, D

T_A = –40° to +85°C, Case 626, 751

These two series of high speed dual MOSFET driver ICs are specifically designed for applications requiring low current digital circuitry to drive large capacitive loads at high slew rates. Both series feature a unique undervoltage lockout function which puts the outputs in a defined low state in an undervoltage condition. In addition, the low “on” state resistance of these bipolar drivers allows significantly higher output currents at lower supply voltages than with competing drivers using CMOS technology.

The MC34151 series is pin–compatible with the MMH0026 and DS0026 dual MOS clock drivers, and can be used as drop–in replacements to upgrade system performance. The MC34152 noninverting series is a mirror image of the inverting MC34151 series.

These devices can enhance the drive capabilities of first generation switching regulators or systems designed with CMOS/TTL logic devices. They can be used in dc–to–dc converters, motor controllers, capacitor charge pump converters, or virtually any other application requiring high speed operation of power MOSFETs.



Single IGBT Driver

MC33153P, D

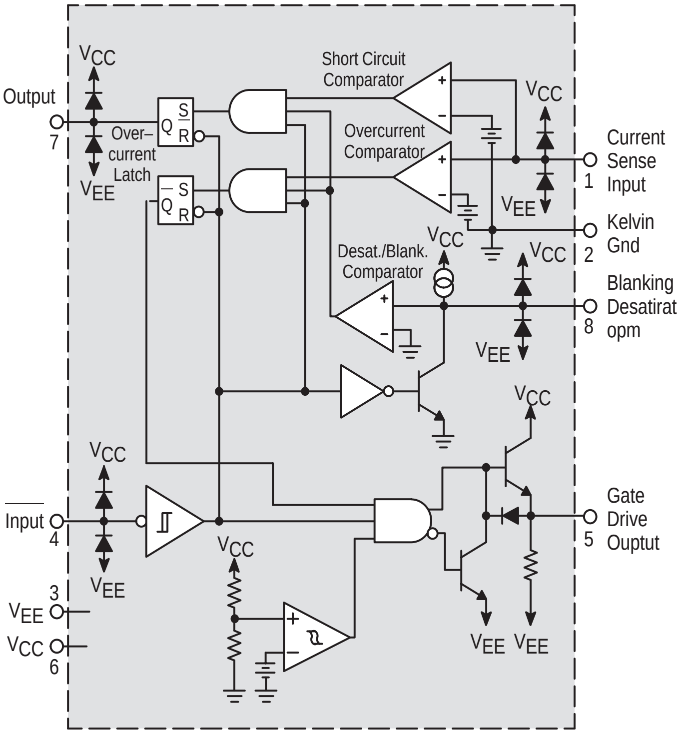
T_A = –40° to +105°C, Case 626, 751

The MC33153 is specifically designed to drive the gate of an IGBT used for ac induction motors. It can be used with discrete IGBTs and IBGT modules up to 100 A.

Typical applications are ac induction motor control, brushless dc motor control, and uninterruptable power supplies.

These devices are available in dual–in–line and surface mount packages and include the following features:

- High Current Output Stage : 1.0 A Source – 2.0 A Sink
- Protection Circuits for Both Conventional and SenseIGBTs
- Current Source for Blanking Timing
- Protection Against Overcurrent and Short Circuit
- Undervoltage Lockout Optimized for IGBT’s
- Negative Gate Drive Capability



MOSFET/IGBT Drivers (continued)

Single IGBT Gate Driver

MC33154D, P

T_A = –40° to +85°C, Case 626, 751

The MC33154 is specifically designed as an IGBT driver for high power applications including ac induction motor control, brushless dc motor control and uninterruptible power supplies.

The MC33154 is similar to the MC33153, except that the output drive is in–phase with the logic input, the output source current drive is four times higher and the supply voltage rating is higher.

Although designed for driving discrete and module IGBTs, this device offers a cost effective solution for driving power MOSFETs and Bipolar Transistors.

These devices are available in dual–in–line and surface mount packages and include the following features:

- High Current Output Stage: 4.0 A Source/2.0 A Sink
- Protection Circuits for Both Conventional and Sense IGBTs
- Programmable Fault Blanking Time
- Protection against Overcurrent and Short Circuit
- Undervoltage Lockout Optimzed for IGBTs
- Negative Gate Drive Capability
- Cost Effectively Drives Power MOSFETs and Bipolar Transistors

LM317

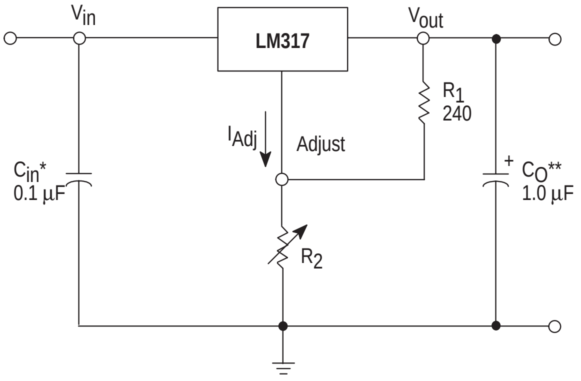
Three-Terminal Adjustable Output Positive Voltage Regulator

The LM317 is an adjustable 3–terminal positive voltage regulator capable of supplying in excess of 1.5 A over an output voltage range of 1.2 V to 37 V. This voltage regulator is exceptionally easy to use and requires only two external resistors to set the output voltage. Further, it employs internal current limiting, thermal shutdown and safe area compensation, making it essentially blow–out proof.

The LM317 serves a wide variety of applications including local, on card regulation. This device can also be used to make a programmable output regulator, or by connecting a fixed resistor between the adjustment and output, the LM317 can be used as a precision current regulator.

- Output Current in Excess of 1.5 A
- Output Adjustable between 1.2 V and 37 V
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting Constant with Temperature
- Output Transistor Safe–Area Compensation
- Floating Operation for High Voltage Applications
- Available in Surface Mount D^{2}PAK, and Standard 3–Lead Transistor Package
- Eliminates Stocking many Fixed Voltages

Standard Application



* C_{in} is required if regulator is located an appreciable distance from power supply filter.
** C_O is not needed for stability, however, it does improve transient response.

$$V_{out} = 1.25\ V\left(1+\frac{R_2}{R_1}\right)+I_{Adj}\,R_2$$

Since I_{Adj} is controlled to less than 100 µA, the error associated with this term is negligible in most applications.

NOTES:
1. T_{low} to T_{high} = 0° to +125°C, for LM317T, D2T. T_{low} to T_{high} = –40° to +125°C, for LM317BT, BD2T.
2. I_{max} = 1.5 A, P_{max} = 20 W
3. Load and line regulation are specified at constant junction temperature. Changes in V_O due to heating effects must be taken into account separately. Pulse testing with low duty cycle is used.
4. C_{Adj}, when used, is connected between the adjustment pin and ground.
5. Since Long–Term Stability cannot be measured on each device before shipment, this specification is an engineering estimate of average stability from lot to lot.
6. Power dissipation within an IC voltage regulator produces a temperature gradient on the die, affecting individual IC components on the die. These effects can be minimized by proper integrated circuit design and layout techniques. Thermal Regulation is the effect of these temperature gradients on the output voltage and is expressed in percentage of output change per watt of power change in a specified time.

APPLICATIONS INFORMATION

Basic Circuit Operation

The LM317 is a 3–terminal floating regulator. In operation, the LM317 develops and maintains a nominal 1.25 V reference (V_{ref}) between its output and adjustment terminals. This reference voltage is converted to a programming current (I_{PROG}) by R_1 (see Figure 17), and this constant current flows through R_2 to ground.

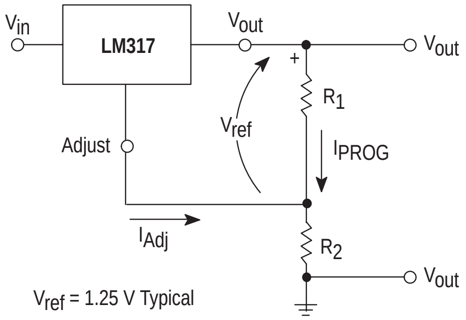
The regulated output voltage is given by:

$$V_{out} = V_{ref}\left(1 + \frac{R_2}{R_1}\right) + I_{Adj} R_2$$

Since the current from the adjustment terminal (I_{Adj}) represents an error term in the equation, the LM317 was designed to control I_{Adj} to less than 100 µA and keep it constant. To do this, all quiescent operating current is returned to the output terminal. This imposes the requirement for a minimum load current. If the load current is less than this minimum, the output voltage will rise.

Since the LM317 is a floating regulator, it is only the voltage differential across the circuit which is important to performance, and operation at high voltages with respect to ground is possible.

Figure 17. Basic Circuit Configuration



Load Regulation

The LM317 is capable of providing extremely good load regulation, but a few precautions are needed to obtain maximum performance. For best performance, the programming resistor (R_1) should be connected as close to the regulator as possible to minimize line drops which effectively appear in series with the reference, thereby degrading regulation. The ground end of R_2 can be returned near the load ground to provide remote ground sensing and improve load regulation.

External Capacitors

A 0.1 µF disc or 1.0 µF tantalum input bypass capacitor (C_{in}) is recommended to reduce the sensitivity to input line impedance.

The adjustment terminal may be bypassed to ground to improve ripple rejection. This capacitor (C_{Adj}) prevents ripple from being amplified as the output voltage is increased. A 10 µF capacitor should improve ripple rejection about 15 dB at 120 Hz in a 10 V application.

Although the LM317 is stable with no output capacitance, like any feedback circuit, certain values of external capacitance can cause excessive ringing. An output capacitance (C_O) in the form of a 1.0 µF tantalum or 25 µF aluminum electrolytic capacitor on the output swamps this effect and insures stability.

Protection Diodes

When external capacitors are used with any IC regulator it is sometimes necessary to add protection diodes to prevent the capacitors from discharging through low current points into the regulator.

Figure 18 shows the LM317 with the recommended protection diodes for output voltages in excess of 25 V or high capacitance values (C_O > 25 µF, C_{Adj} > 10 µF). Diode D_1 prevents C_O from discharging thru the IC during an input short circuit. Diode D_2 protects against capacitor C_{Adj} discharging through the IC during an output short circuit. The combination of diodes D_1 and D_2 prevents C_{Adj} from discharging through the IC during an input short circuit.

Figure 18. Voltage Regulator with Protection Diodes

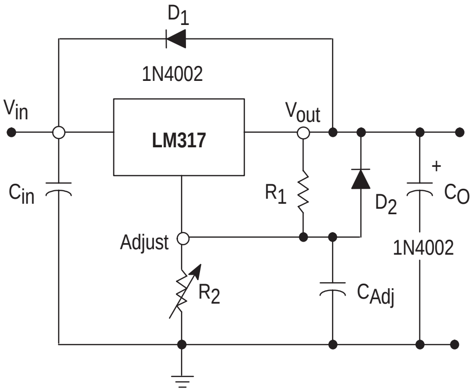


Figure 19. D²PAK Thermal Resistance and Maximum Power Dissipation versus P.C.B. Copper Length

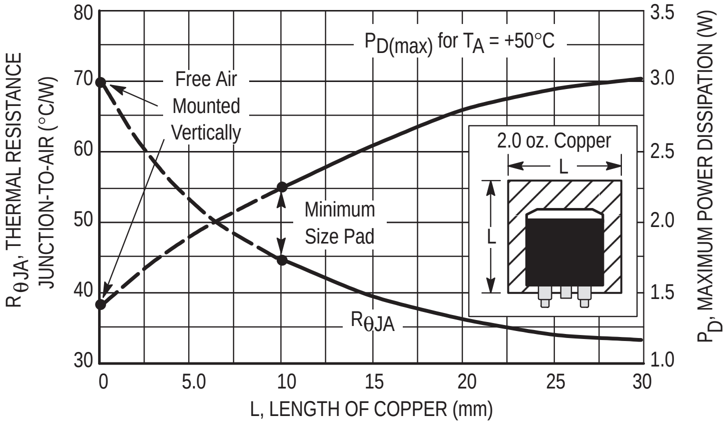

Figure 20. “Laboratory” Power Supply with Adjustable Current Limit and Output Voltage

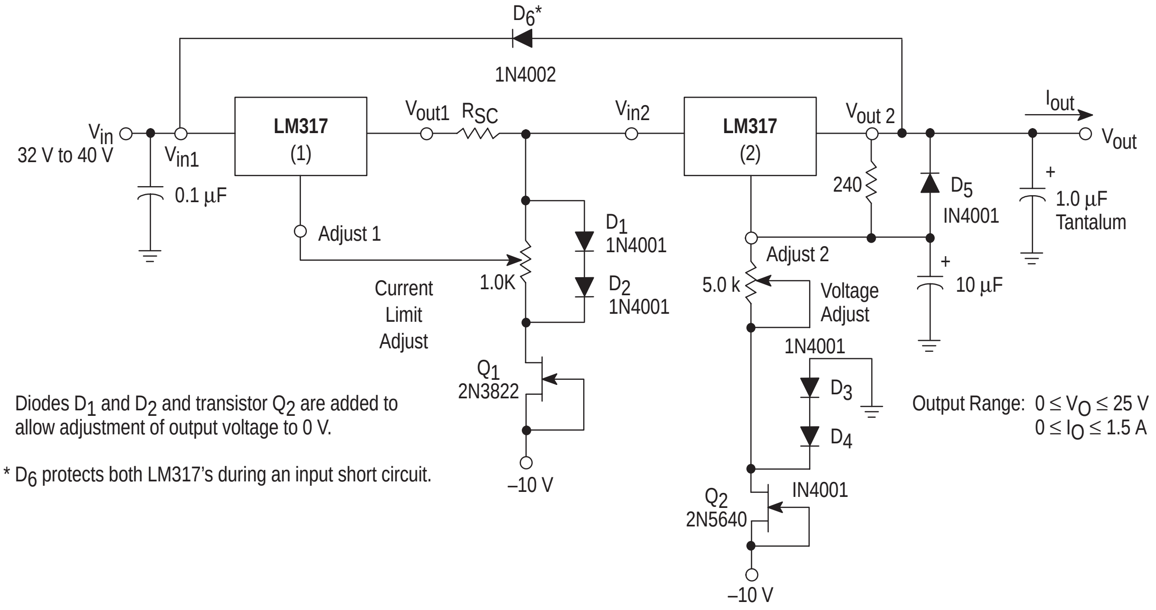
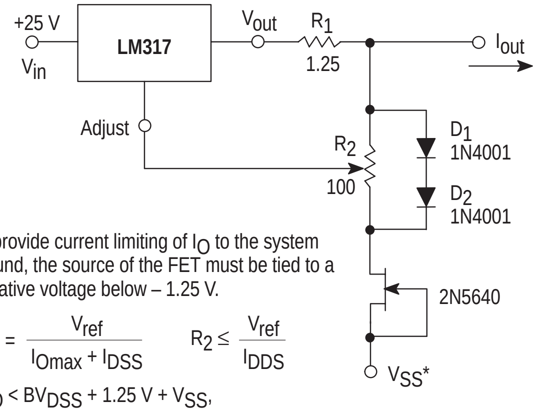


Diodes D_1 and D_2 and transistor Q_2 are added to allow adjustment of output voltage to 0 V.

* D_6 protects both LM317’s during an input short circuit.

Figure 21. Adjustable Current Limiter

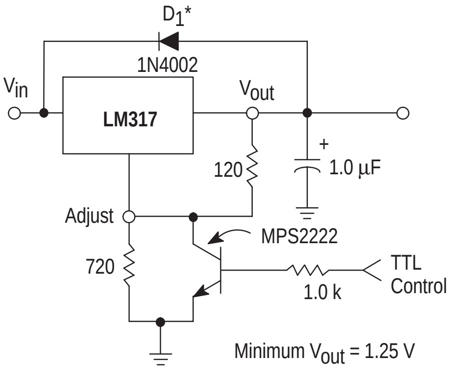


* To provide current limiting of I_O to the system ground, the source of the FET must be tied to a negative voltage below – 1.25 V.

$R_1 = \frac{V_{ref}}{I_{Omax} + I_{DSS}}$ $R_2 \le \frac{V_{ref}}{I_{DDS}}$

$V_O < BV_{DSS} + 1.25\ V + V_{SS}$,
$I_{Lmin} - I_{DSS} < I_O < 1.5$ A.
As shown $0 < I_O < 1.0$ A.

Figure 22. 5.0 V Electronic Shutdown Regulator



* D_1 protects the device during an input short circuit.

Figure 23. Slow Turn–On Regulator

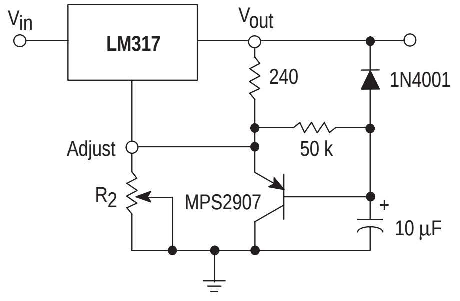


Figure 24. Current Regulator

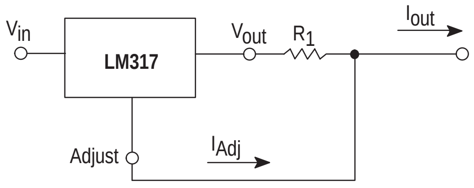


$$I_{out} = \left(\frac{V_{ref}}{R_1}\right) + I_{Adj}$$

$$= \frac{1.25\ V}{R_1}$$

$10\ mA \le I_{out} \le 1.5$ A

MOTOROLA

LM317L

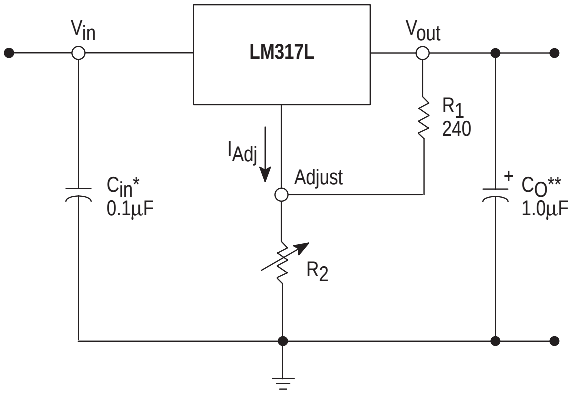
Three-Terminal Adjustable Output Positive Voltage Regulator

The LM317L is an adjustable 3–terminal positive voltage regulator capable of supplying in excess of 100 mA over an output voltage range of 1.2 V to 37 V. This voltage regulator is exceptionally easy to use and requires only two external resistors to set the output voltage. Further, it employs internal current limiting, thermal shutdown and safe area compensation, making them essentially blow–out proof.

The LM317L serves a wide variety of applications including local, on card regulation. This device can also be used to make a programmable output regulator, or by connecting a fixed resistor between the adjustment and output, the LM317L can be used as a precision current regulator.

- Output Current in Excess of 100 mA
- Output Adjustable Between 1.2 V and 37 V
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting
- Output Transistor Safe–Area Compensation
- Floating Operation for High Voltage Applications
- Standard 3–Lead Transistor Package
- Eliminates Stocking Many Fixed Voltages

Simplified Application



* C_{in} is required if regulator is located an appreciable distance from power supply filter.

** C_O is not needed for stability, however, it does improve transient response.

$$V_{out} = 1.25\ V\left(1 + \frac{R_2}{R_1}\right) + I_{Adj}\,R_2$$

Since I_{Adj} is controlled to less than 100 µA, the error associated with this term is negligible in most applications.

APPLICATIONS INFORMATION

Basic Circuit Operation

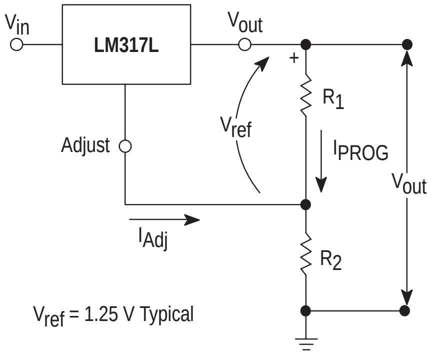
The LM317L is a 3–terminal floating regulator. In operation, the LM317L develops and maintains a nominal 1.25 V reference (V_{ref}) between its output and adjustment terminals. This reference voltage is converted to a programming current (I_{PROG}) by R_1 (see Figure 13), and this constant current flows through R_2 to ground. The regulated output voltage is given by:

$$V_{out} = V_{ref} \left(1 + \frac{R_2}{R_1}\right) + I_{Adj} R_2$$

Since the current from the adjustment terminal (I_{Adj}) represents an error term in the equation, the LM317L was designed to control I_{Adj} to less than 100 µA and keep it constant. To do this, all quiescent operating current is returned to the output terminal. This imposes the requirement for a minimum load current. If the load current is less than this minimum, the output voltage will rise.

Since the LM317L is a floating regulator, it is only the voltage differential across the circuit which is important to performance, and operation at high voltages with respect to ground is possible.

Figure 17. Basic Circuit Configuration



Load Regulation

The LM317L is capable of providing extremely good load regulation, but a few precautions are needed to obtain maximum performance. For best performance, the programming resistor (R1) should be connected as close to the regulator as possible to minimize line drops which effectively appear in series with the reference, thereby degrading regulation. The ground end of R2 can be returned near the load ground to provide remote ground sensing and improve load regulation.

External Capacitors

A 0.1 µF disc or 1.0 µF tantalum input bypass capacitor (C_{in}) is recommended to reduce the sensitivity to input line impedance.

The adjustment terminal may be bypassed to ground to improve ripple rejection. This capacitor (C_{Adj}) prevents ripple from being amplified as the output voltage is increased. A 10 µF capacitor should improve ripple rejection about 15 dB at 120 Hz in a 10 V application.

Although the LM317L is stable with no output capacitance, like any feedback circuit, certain values of external capacitance can cause excessive ringing. An output capacitance (C_O) in the form of a 1.0 µF tantalum or 25 µF aluminum electrolytic capacitor on the output swamps this effect and insures stability.

Protection Diodes

When external capacitors are used with any IC regulator it is sometimes necessary to add protection diodes to prevent the capacitors from discharging through low current points into the regulator.

Figure 14 shows the LM317L with the recommended protection diodes for output voltages in excess of 25 V or high capacitance values (C_O > 10 µF, C_{Adj} > 5.0 µF). Diode D_1 prevents C_O from discharging thru the IC during an input short circuit. Diode D_2 protects against capacitor C_{Adj} discharging through the IC during an output short circuit. The combination of diodes D_1 and D_2 prevents C_{Adj} from discharging through the IC during an input short circuit.

$5.0\ mA < I_{out} < 100\ mA$

MOTOROLA

LM317M

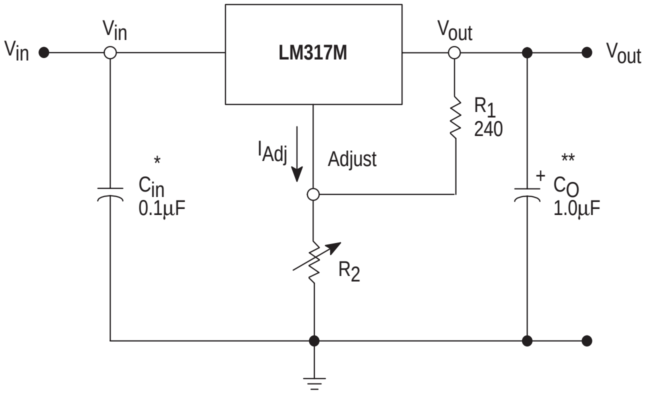
Three-Terminal Adjustable Output Positive Voltage Regulator

The LM317M is an adjustable three–terminal positive voltage regulator capable of supplying in excess of 500 mA over an output voltage range of 1.2 V to 37 V. This voltage regulator is exceptionally easy to use and requires only two external resistors to set the output voltage. Further, it employs internal current limiting, thermal shutdown and safe area compensation, making it essentially blow–out proof.

The LM317M serves a wide variety of applications including local, on–card regulation. This device also makes an especially simple adjustable switching regulator, a programmable output regulator, or by connecting a fixed resistor between the adjustment and output, the LM317M can be used as a precision current regulator.

- Output Current in Excess of 500 mA
- Output Adjustable between 1.2 V and 37 V
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting
- Output Transistor Safe–Area Compensation
- Floating Operation for High Voltage Applications
- Eliminates Stocking Many Fixed Voltages

Simplified Application



* = C_{in} is required if regulator is located an appreciable distance from power supply filter.
** = C_O is not needed for stability, however, it does improve transient response.

$$V_{out} = 1.25\ \text{V}\left(1 + \frac{R_2}{R_1}\right) + I_{Adj}\,R_2$$

Since I_{Adj} is controlled to less than 100 µA, the error associated with this term is negligible in most applications.

APPLICATIONS INFORMATION

Basic Circuit Operation

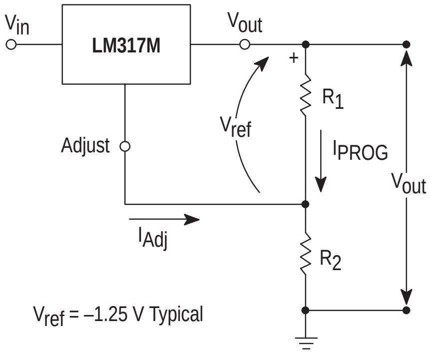
The LM317M is a three–terminal floating regulator. In operation, the LM317M develops and maintains a nominal 1.25 V reference (V_{ref}) between its output and adjustment terminals. This reference voltage is converted to a programming current (I_{PROG}) by R_1 (see Figure 17), and this constant current flows through R_2 to ground. The regulated output voltage is given by:

$$V_{out} = V_{ref}\left(1 + \frac{R_2}{R_1}\right) + I_{Adj}\,R_2$$

Since the current from the terminal (I_{Adj}) represents an error term in the equation, the LM317M was designed to control I_{Adj} to less than 100 μA and keep it constant. To do this, all quiescent operating current is returned to the output terminal. This imposes the requirement for a minimum load current. If the load current is less than this minimum, the output voltage will rise.

Since the LM317M is a floating regulator, it is only the voltage differential across the circuit which is important to performance, and operation at high voltages with respect to ground is possible.

Figure 17. Basic Circuit Configuration



Load Regulation

The LM317M is capable of providing extremely good load regulation, but a few precautions are needed to obtain maximum performance. For best performance, the programming resistor (R_1) should be connected as close to the regulator as possible to minimize line drops which effectively appear in series with the reference, thereby degrading regulation. The ground end of R_2 can be returned near the load ground to provide remote ground sensing and improve load regulation.

External Capacitors

A 0.1 μF disc or 1.0 μF tantalum input bypass capacitor (C_{in}) is recommended to reduce the sensitivity to input line impedance.

The adjustment terminal may be bypassed to ground to improve ripple rejection. This capacitor (C_{Adj}) prevents ripple from being amplified as the output voltage is increased. A 10 μF capacitor should improve ripple rejection about 15 dB at 120 Hz in a 10 V application.

Although the LM317M is stable with no output capacitance, like any feedback circuit, certain values of external capacitance can cause excessive ringing. An output capacitance (C_O) in the form of a 1.0 μF tantalum or 25 μF aluminum electrolytic capacitor on the output swamps this effect and insures stability.

Protection Diodes

When external capacitors are used with any IC regulator it is sometimes necessary to add protection diodes to prevent the capacitors from discharging through low current points into the regulator.

Figure 18 shows the LM317M with the recommended protection diodes for output voltages in excess of 25 V or high capacitance values (C_O > 25 μF, C_{Adj} > 5.0 μF). Diode D_1 prevents C_O from discharging thru the IC during an input short circuit. Diode D_2 protects against capacitor C_{Adj} discharging through the IC during an output short circuit. The combination of diodes D_1 and D_2 prevents C_{Adj} from discharging through the IC during an input short circuit.

LM323, A

Positive Voltage Regulators

The LM323,A are monolithic integrated circuits which supply a fixed positive 5.0 V output with a load driving capability in excess of 3.0 A. These three–terminal regulators employ internal current limiting, thermal shutdown, and safe–area compensation. The A–suffix is an improved device with superior electrical characteristics and a 2% output voltage tolerance. These regulators are offered with a 0° to +125°C temperature range in a low cost plastic power package.

Although designed primarily as a fixed voltage regulator, these devices can be used with external components to obtain adjustable voltages and currents. These devices can be used with a series pass transistor to supply up to 15 A at 5.0 V.

- Output Current in Excess of 3.0 A
- Available with 2% Output Voltage Tolerance
- No External Components Required
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting
- Output Transistor Safe–Area Compensation
- Thermal Regulation and Ripple Rejection Have Specified Limits

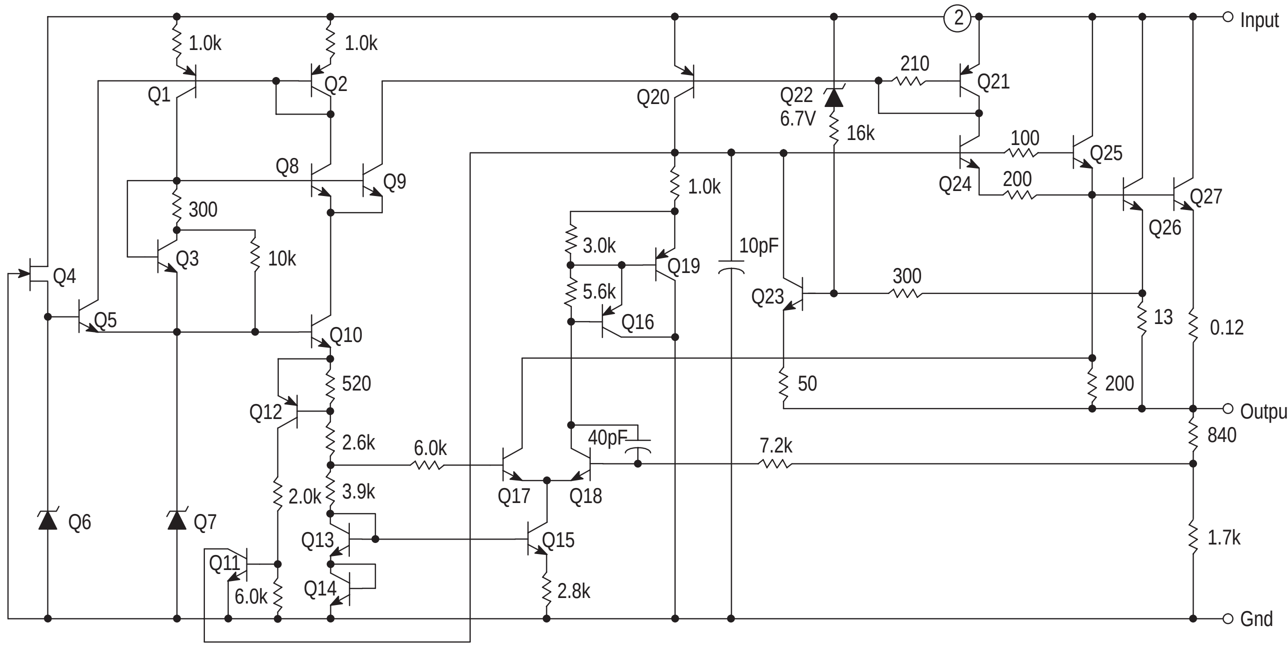
Representative Schematic Diagram



VOLTAGE REGULATOR PERFORMANCE

The performance of a voltage regulator is specified by its immunity to changes in load, input voltage, power dissipation, and temperature. Line and load regulation are tested with a pulse of short duration (< 100 µs) and are strictly a function of electrical gain. However, pulse widths of longer duration (> 1.0 ms) are sufficient to affect temperature gradients across the die. These temperature gradients can cause a change in the output voltage, in addition to changes by line and load regulation. Longer pulse widths and thermal gradients make it desirable to specify thermal regulation.

Thermal regulation is defined as the change in output voltage caused by a change in dissipated power for a specified time, and is expressed as a percentage output voltage change per watt. The change in dissipated power can be caused by a change in either input voltage or the load current. Thermal regulation is a function of IC layout and die attach techniques, and usually occurs within 10 ms of a change in power dissipation. After 10 ms, additional changes in the output voltage are due to the temperature coefficient of the device.

Figure 1 shows the line and thermal regulation response of a typical LM323A to a 20 W input pulse. The variation of the output voltage due to line regulation is labeled À and the thermal regulation component is labeled Á. Figure 2 shows the load and thermal regulation response of a typical LM323A to a 20 W load pulse. The output voltage variation due to load regulation is labeled À and the thermal regulation component is labeled Á.

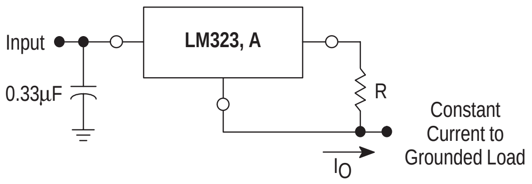
APPLICATIONS INFORMATION

Design Considerations

The LM323,A series of fixed voltage regulators are designed with Thermal Overload Protection that shuts down the circuit when subjected to an excessive power overload condition, Internal Short Circuit Protection that limits the maximum current the circuit will pass, and Output Transistor Safe–Area Compensation that reduces the output short circuit current as the voltage across the pass transistor is increased.

In many low current applications, compensation capacitors are not required. However, it is recommended that the regulator input be bypassed with a capacitor if the regulator is connected to the power supply filter with long wire lengths, or if the output load capacitance is large. An input bypass capacitor should be selected to provide good high–frequency characteristics to insure stable operation under all load conditions. A 0.33 µF or larger tantalum, mylar, or other capacitor having low internal impedance at high frequencies should be chosen. The bypass capacitor should be mounted with the shortest possible leads directly across the regulator's input terminals. Normally good construction techniques should be used to minimize ground loops and lead resistance drops since the regulator has no external sense lead.

Figure 13. Current Regulator



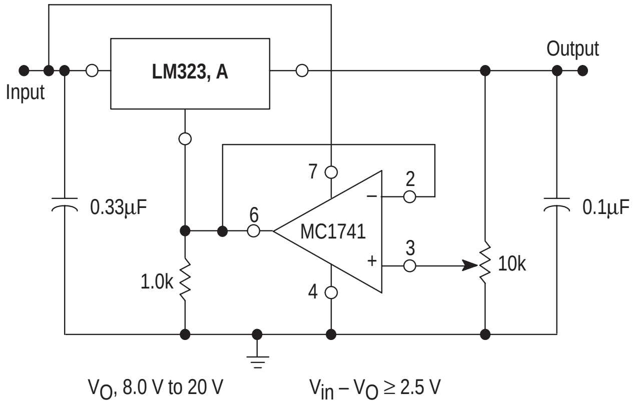
The LM323,A regulator can also be used as a current source when connected as above. Resistor R determines the current as follows:

$$I_O = \frac{5.0\ V}{R} + I_B$$

$\Delta I_B \cong$ 0.7 mA over line, load and temperature changes
$I_B \cong$ 3.5 mA

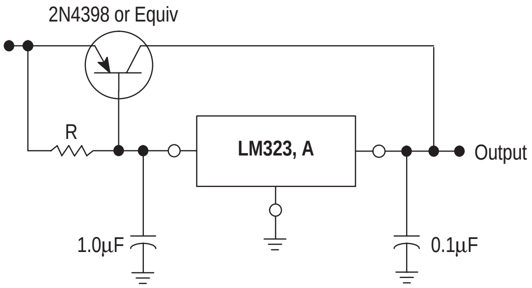
For example, a 2.0 A current source would require R to be a 2.5 Ω, 15 W resistor and the output voltage compliance would be the input voltage less 7.5 V.

Figure 14. Adjustable Output Regulator



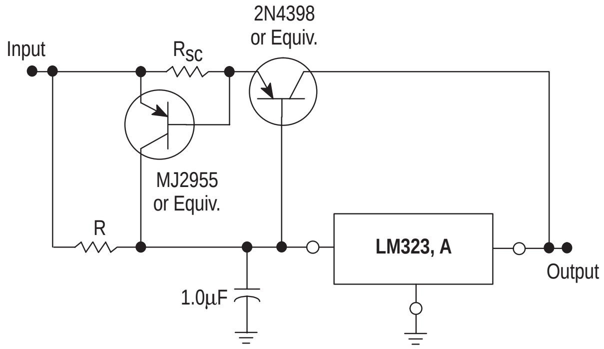
The addition of an operational amplifier allows adjustment to higher or intermediate values while retaining regulation characteristics. The minimum voltage obtainable with this arrangement is 3.0 V greater than the regulator voltage.

Figure 15. Current Boost Regulator



The LM323, A series can be current boosted with a PNP transistor. The 2N4398 provides current to 15 A. Resistor R in conjuction with the V_{BE} of the PNP determines when the pass transistor begins conducting; this circuit is not short circuit proof. Input–output differential voltage minimum is increased by the V_{BE} of the pass transistor.

Figure 16. Current Boost with Short Circuit Protection



The circuit of Figure 16 can be modified to provide supply protection against short circuits by adding a short circuit sense resistor, R_{SC}, and an additional PNP transistor. The current sensing PNP must be able to handle the short circuit current of the three–terminal regulator. Therefore, an 8.0 A power transistor is specified.

MOTOROLA

LM337

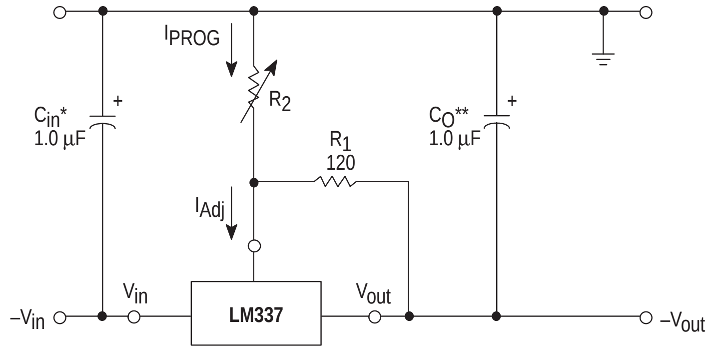
Three-Terminal Adjustable Output Negative Voltage Regulator

The LM337 is an adjustable 3–terminal negative voltage regulator capable of supplying in excess of 1.5 A over an output voltage range of –1.2 V to –37 V. This voltage regulator is exceptionally easy to use and requires only two external resistors to set the output voltage. Further, it employs internal current limiting, thermal shutdown and safe area compensation, making it essentially blow–out proof.

The LM337 serves a wide variety of applications including local, on card regulation. This device can also be used to make a programmable output regulator, or by connecting a fixed resistor between the adjustment and output, the LM337 can be used as a precision current regulator.

- Output Current in Excess of 1.5 A
- Output Adjustable between –1.2 V and –37 V
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting Constant with Temperature
- Output Transistor Safe–Area Compensation
- Floating Operation for High Voltage Applications
- Eliminates Stocking many Fixed Voltages
- Available in Surface Mount D^2PAK and Standard 3–Lead Transistor Package

Standard Application



*C_{in} is required if regulator is located more than 4 inches from power supply filter. A 1.0 µF solid tantalum or 10 µF aluminum electrolytic is recommended.

**C_O is necessary for stability. A 1.0 µF solid tantalum or 10 µF aluminum electrolytic is recommeded.

NOTES:
1. T_{low} to T_{high} = 0° to +125°C, for LM337T, D2T. T_{low} to T_{high} = –40° to +125°C, for LM337BT, BD2T.
2. I_{max} = 1.5 A, P_{max} = 20 W
3. Load and line regulation are specified at constant junction temperature. Change in V_O because of heating effects is covered under the Thermal Regulation specification. Pulse testing with a low duty cycle is used.
4. C_{Adj}, when used, is connected between the adjustment pin and ground.
5. Since Long Term Stability cannot be measured on each device before shipment, this specification is an engineering estimate of average stability from lot to lot.
6. Power dissipation within an IC voltage regulator produces a temperature gradient on the die, affecting individual IC components on the die. These effects can be minimized by proper integrated circuit design and layout techniques. Thermal Regulation is the effect of these temperature gradients on the output voltage and is expressed in percentage of output change per watt of power change in a specified time.

APPLICATIONS INFORMATION

Basic Circuit Operation

The LM337 is a 3–terminal floating regulator. In operation, the LM337 develops and maintains a nominal –1.25 V reference (V_{ref}) between its output and adjustment terminals. This reference voltage is converted to a programming current (I_{PROG}) by R_1 (see Figure 17), and this constant current flows through R_2 from ground.

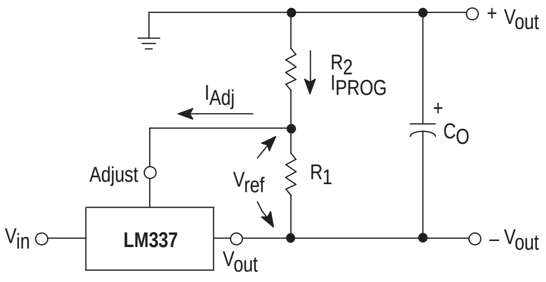
The regulated output voltage is given by:

$$V_{out} = V_{ref}\left(1 + \frac{R_2}{R_1}\right) + I_{Adj}\, R_2$$

Since the current into the adjustment terminal (I_{Adj}) represents an error term in the equation, the LM337 was designed to control I_{Adj} to less than 100 µA and keep it constant. To do this, all quiescent operating current is returned to the output terminal. This imposes the requirement for a minimum load current. If the load current is less than this minimum, the output voltage will rise.

Since the LM337 is a floating regulator, it is only the voltage differential across the circuit which is important to performance, and operation at high voltages with respect to ground is possible.

Figure 17. Basic Circuit Configuration



V_{ref} = –1.25 V Typical

Load Regulation

The LM337 is capable of providing extremely good load regulation, but a few precautions are needed to obtain maximum performance. For best performance, the programming resistor (R_1) should be connected as close to the regulator as possible to minimize line drops which effectively appear in series with the reference, thereby degrading regulation. The ground end of R_2 can be returned near the load ground to provide remote ground sensing and improve load regulation.

External Capacitors

A 1.0 µF tantalum input bypass capacitor (C_{in}) is recommended to reduce the sensitivity to input line impedance.

The adjustment terminal may be bypassed to ground to improve ripple rejection. This capacitor (C_{Adj}) prevents ripple from being amplified as the output voltage is increased. A 10 µF capacitor should improve ripple rejection about 15 dB at 120 Hz in a 10 V application.

An output capacitance (C_O) in the form of a 1.0 µF tantalum or 10 µF aluminum electrolytic capacitor is required for stability.

Protection Diodes

When external capacitors are used with any IC regulator it is sometimes necessary to add protection diodes to prevent the capacitors from discharging through low current points into the regulator.

Figure 18 shows the LM337 with the recommended protection diodes for output voltages in excess of –25 V or high capacitance values (C_O > 25 µF, C_{Adj} > 10 µF). Diode D_1 prevents C_O from discharging thru the IC during an input short circuit. Diode D_2 protects against capacitor C_{Adj} discharging through the IC during an output short circuit. The combination of diodes D_1 and D_2 prevents C_{Adj} from the discharging through the IC during an input short circuit.

APPLICATIONS INFORMATION

Basic Circuit Operation

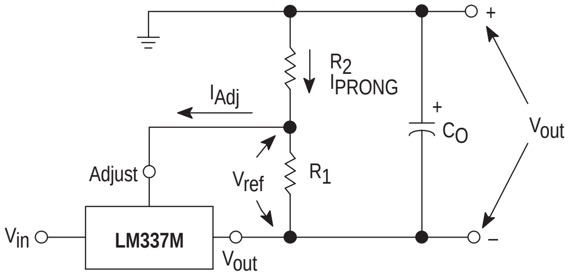
The LM337M is a three–terminal floating regulator. In operation, the LM337M develops and maintains a nominal –1.25 V reference (V_{ref}) between its output and adjustment terminals. This reference voltage is converted to a programming current (I_{PROG}) by R_1 (see Figure 17), and this constant current flows through R_2 to ground. The regulated output voltage is given by:

$$V_{out} = V_{ref} \left(1 + \frac{R_2}{R_1}\right) + I_{Adj} R_2$$

Since the current into the adjustment terminal (I_{Adj}) represents an error term in the equation, the LM337M was designed to control I_{Adj} to less than 100 µA and keep it constant. To do this, all quiescent operating current is returned to the output terminal. This imposes the requirement for a minimum load current. If the load current is less than this minimum, the output voltage will rise.

Since the LM337M is a floating regulator, it is only the voltage differential across the circuit which is important to performance, and operation at high voltages with respect to ground is possible.

Figure 17. Basic Circuit Configuration



V_{ref} = –1.25 V Typically

Load Regulation

The LM337M is capable of providing extremely good load regulation, but a few precautions are needed to obtain maximum performance. For best performance, the programming resistor (R_1) should be connected as close to the regulator as possible to minimize line drops which effectively appear in series with the reference, thereby degrading regulation. The ground end of R_2 can be returned near the load ground to provide remote ground sensing and improve load regulation.

External Capacitors

A 1.0 µF tantalum input bypass capacitor (C_{in}) is recommended to reduce the sensitivity to input line impedance.

The adjustment terminal may be bypassed to ground to improve ripple rejection. This capacitor (C_{Adj}) prevents ripple from being amplified as the output voltage is increased. A 10 µF capacitor should improve ripple rejection about 15 dB at 120 Hz in a 10 V application.

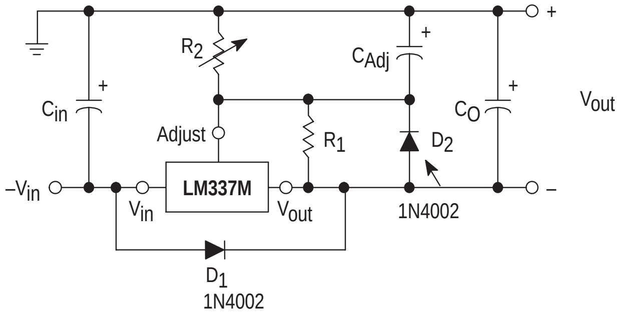
An output capacitance (C_O) in the form of a 1.0 µF tantalum or 10 µF aluminum electrolytic capacitor is required for stability.

Protection Diodes

When external capacitors are used with any IC regulator it is sometimes necessary to add protection diodes to prevent the capacitors from discharging through low current points into the regulator.

Figure 18 shows the LM337M with the recommended protection diodes for output voltages in excess of –25 V or high capacitance values (C_O > 25 µF, C_{Adj} > 10 µF). Diode D_1 prevents C_O from discharging thru the IC during an input short circuit. Diode D_2 protects against capacitor C_{Adj} discharging through the IC during an output short circuit. The combination of diodes D_1 and D_2 prevents C_{Adj} from discharging through the IC during an input short circuit.

Figure 18. Voltage Regulator with Protection Diodes



LM340, A Series

Three-Terminal Positive Fixed Voltage Regulators

This family of fixed voltage regulators are monolithic integrated circuits capable of driving loads in excess of 1.0 A. These three–terminal regulators employ internal current limiting, thermal shutdown, and safe–area compensation. Devices are available with improved specifications, including a 2% output voltage tolerance, on A–suffix 5.0, 12 and 15 V device types.

Although designed primarily as a fixed voltage regulator, these devices can be used with external components to obtain adjustable voltages and currents. This series of devices can be used with a series–pass transistor to boost output current capability at the nominal output voltage.

- Output Current in Excess of 1.0 A
- No External Components Required
- Output Voltage Offered in 2% and 4% Tolerance*
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting
- Output Transistor Safe–Area Compensation

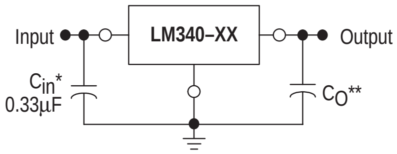
LM340AT–15	15 V ± 2%		
LM340T–18	18 V ± 4%		
LM340T–24	24 V ± 4%		

* 2% regulators are available in 5, 12 and 15 V devices.

Simplified Application



A common ground is required between the input and the output voltages. The input voltage must remain typically 1.7 V above the output voltage even during the low point on the input ripple voltage.

XX these two digits of the type number indicate voltage.
* C_{in} is required if regulator is located an appreciable distance from power supply filter.
** C_O is not needed for stability; however, it does improve transient response. If needed, use a 0.1 µF ceramic disc.

Short Circuit Current Limit (T_J = +25°C)	I_{SC}	–	2.0	–	A
Output Noise Voltage (T_A = +25°C) 10 Hz ≤ f ≤ 100 kHz	V_n	–	40	–	µV
Average Temperature Coefficient of Output Voltage I_O = 5.0 mA	TCV_O	–	±0.6	–	mV/°C
Peak Output Current (T_J = +25°C)	I_O	–	2.4	–	A
Input Voltage to Maintain Line Regulation (T_J = +25°C) I_O = 1.0 A		7.3	–	–	Vdc

NOTES: 1. T_{low} to T_{high} = 0° to +125°C
2. Load and line regulation are specified at constant junction temperature. Changes in V_O due to heating effects must be taken into account separately. Pulse testing with low duty cycle is used.

DEFINITIONS

Line Regulation – The change in output voltage for a change in the input voltage. The measurement is made under conditions of low dissipation or by using pulse techniques such that the average chip temperature is not significantly affected.

Load Regulation – The change in output voltage for a change in load current at constant chip temperature.

Maximum Power Dissipation – The maximum total device dissipation for which the regulator will operate within specifications.

Quiescent Current – That part of the input current that is not delivered to the load.

Output Noise Voltage – The rms AC voltage at the output, with constant load and no input ripple, measured over a specified frequency range.

LM340A–5.0

ELECTRICAL CHARACTERISTICS (V_{in} = 10 V, I_O = 1.0 A, T_J = T_{low} to T_{high} [Note 1], unless otherwise noted.)

VOLTAGE REGULATOR PERFORMANCE

The performance of a voltage regulator is specified by its immunity to changes in load, input voltage, power dissipation, and temperature. Line and load regulation are tested with a pulse of short duration (< 100 μs) and are strictly a function of electrical gain. However, pulse widths of longer duration (> 1.0 ms) are sufficient to affect temperature gradients across the die. These temperature gradients can cause a change in the output voltage, in addition to changes caused by line and load regulation. Longer pulse widths and thermal gradients make it desirable to specify thermal regulation.

Thermal regulation is defined as the change in output voltage caused by a change in dissipated power for a specified time, and is expressed as a percentage output voltage change per watt. The change in dissipated power can be caused by a change in either input voltage or the load current. Thermal regulation is a function of IC layout and die attach techniques, and usually occurs within 10 ms of a change in power dissipation. After 10 ms, additional changes in the output voltage are due to the temperature coefficient of the device.

Figure 1 shows the line and thermal regulation response of a typical LM340AT–5.0 to a 10 W input pulse. The variation of the output voltage due to line regulation is labeled À and the thermal regulation component is labeled Á. Figure 2 shows the load and thermal regulation response of a typical LM340AT–5.0 to a 15 W load pulse. The output voltage variation due to load regulation is labeled À and the thermal regulation component is labeled Á.

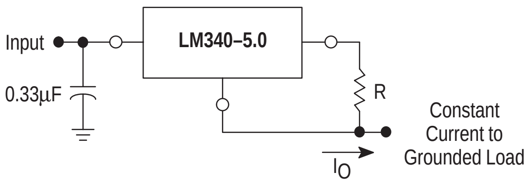
APPLICATIONS INFORMATION

Design Considerations

The LM340, A series of fixed voltage regulators are designed with Thermal Overload Protection that shuts down the circuit when subjected to an excessive power overload condition, Internal Short Circuit Protection that limits the maximum current the circuit will pass, and Output Transistor Safe–Area Compensation that reduces the output short circuit current as the voltage across the pass transistor is increased.

In many low current applications, compensation capacitors are not required. However, it is recommended that the regulator input be bypassed with a capacitor if the regulator is connected to the power supply filter with long wire lengths, or if the output load capacitance is large. An input bypass capacitor should be selected to provide good high–frequency characteristics to insure stable operation under all load conditions. A 0.33 µF or larger tantalum, mylar, or other capacitor having low internal impedance at high frequencies should be chosen. The bypass capacitor should be mounted with the shortest possible leads directly across the regulators input terminals. Normally good construction techniques should be used to minimize ground loops and lead resistance drops since the regulator has no external sense lead.

Figure 14. Current Regulator



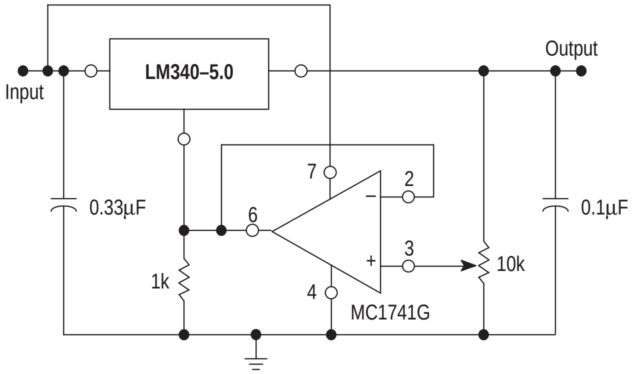
These regulators can also be used as a current source when connected as above. In order to minimize dissipation the LM340–5.0 is chosen in this application. Resistor R determines the current as follows:

$$I_O = \frac{5.0\ V}{R} + I_Q$$

$I_Q \cong$ 1.5 mA over line and load changes

For example, a 1 A current source would require R to be a 5 Ω, 10 W resistor and the output voltage compliance would be the input voltage less 7.0 V.

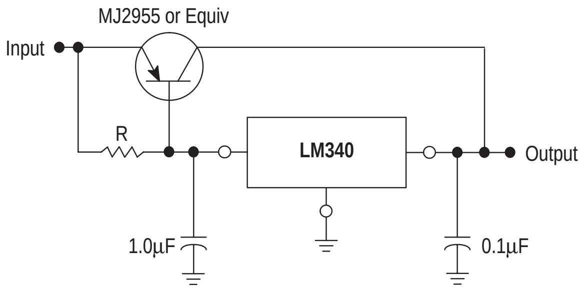
Figure 15. Adjustable Output Regulator



V_{out}, 7.0 V to 20 V
$V_{in} - V_O \geq 2.0$ V

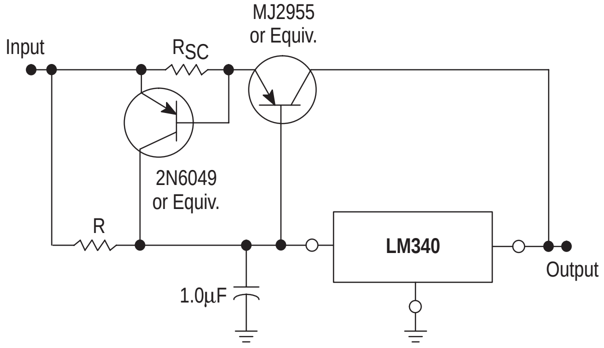
The addition of an operational amplifier allows adjustment to higher or intermediate values while retaining regulation characteristics. The minimum voltage obtainable with this arrangement is 2.0 V greater than the regulator voltage.

Figure 16. Current Boost Regulator



The LM340, A series can be current boosted with a PNP transistor. The MJ2955 provides current to 5.0 A. Resistor R in conjuction with the V_{BE} of the PNP determines when the pass transistor begins conducting; this circuit is not short circuit proof. Input–output differential voltage minimum is increased by V_{BE} of the pass transistor.

Figure 17. Short Circuit Protection



The circuit of Figure 17 can be modified to provide supply protection against short circuits by adding a short circuit sense resistor, R_{SC}, and an additional PNP transistor. The current sensing PNP must be able to handle the short circuit current of the three–terminal regulator. Therefore, 4.0 A plastic power transistor is specified.

MOTOROLA

LM350

Three-Terminal Adjustable Output Positive Voltage Regulator

THREE–TERMINAL ADJUSTABLE POSITIVE VOLTAGE REGULATOR

SEMICONDUCTOR TECHNICAL DATA

The LM350 is an adjustable three–terminal positive voltage regulator capable of supplying in excess of 3.0 A over an output voltage range of 1.2 V to 33 V. This voltage regulator is exceptionally easy to use and requires only two external resistors to set the output voltage. Further, it employs internal current limiting, thermal shutdown and safe area compensation, making it essentially blow–out proof.

The LM350 serves a wide variety of applications including local, on card regulation. This device also makes an especially simple adjustable switching regulator, a programmable output regulator, or by connecting a fixed resistor between the adjustment and output, the LM350 can be used as a precision current regulator.

- Guaranteed 3.0 A Output Current
- Output Adjustable between 1.2 V and 33 V
- Load Regulation Typically 0.1%
- Line Regulation Typically 0.005%/V
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting Constant with Temperature
- Output Transistor Safe Area Compensation
- Floating Operation for High Voltage Applications
- Standard 3–lead Transistor Package
- Eliminates Stocking Many Fixed Voltages

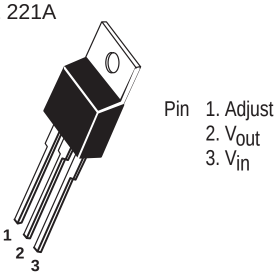
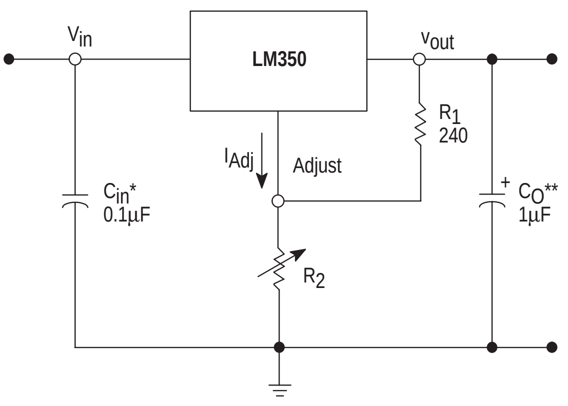
PLASTIC PACKAGE
CASE 221A



Heatsink surface is connected to Pin 2.

Simplified Application



* = C_{in} is required if regulator is located an appreciable distance from power supply filter.
** = C_O is not needed for stability, however, it does improve transient response.

$$V_{out} = 1.25\ V\left(1+\frac{R_2}{R_1}\right)+I_{Adj}\,R_2$$

Since I_{Adj} is controlled to less than 100 µA, the error associated with this term is negligible in most applications.

APPLICATIONS INFORMATION

Basic Circuit Operation

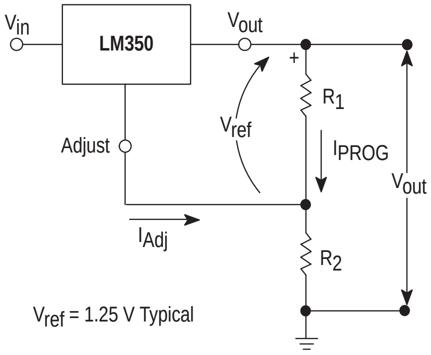
The LM350 is a three–terminal floating regulator. In operation, the LM350 develops and maintains a nominal 1.25 V reference (V_{ref}) between its output and adjustment terminals. This reference voltage is converted to a programming current (I_{PROG}) by R_1 (see Figure 17), and this constant current flows through R_2 to ground. The regulated output voltage is given by:

$$V_{out} = V_{ref}\,(1 + \frac{R_2}{R_1}) + I_{Adj}\,R_2$$

Since the current from the terminal (I_{Adj}) represents an error term in the equation, the LM350 was designed to control I_{Adj} to less than 100 µA and keep it constant. To do this, all quiescent operating current is returned to the output terminal. This imposes the requirement for a minimum load current. If the load current is less than this minimum, the output voltage will rise.

Since the LM350 is a floating regulator, it is only the voltage differential across the circuit which is important to performance, and operation at high voltages with respect to ground is possible.

Figure 17. Basic Circuit Configuration



Load Regulation

The LM350 is capable of providing extremely good load regulation, but a few precautions are needed to obtain maximum performance. For best performance, the programming resistor (R_1) should be connected as close to the regulator as possible to minimize line drops which effectively appear in series with the reference, thereby degrading regulation. The ground end of R_2 can be returned near the load ground to provide remote ground sensing and improve load regulation.

External Capacitors

A 0.1 µF disc or 1 µF tantalum input bypass capacitor (C_{in}) is recommended to reduce the sensitivity to input line impedance.

The adjustment terminal may be bypassed to ground to improve ripple rejection. This capacitor (C_{Adj}) prevents ripple from being amplified as the output voltage is increased. A 10 µF capacitor should improve ripple rejection about 15 dB at 120 Hz in a 10 V application.

Although the LM350 is stable with no output capacitance, like any feedback circuit, certain values of external capacitance can cause excessive ringing. An output capacitance (C_O) in the form of a 1 µF tantalum or 25 µF aluminum electrolytic capacitor on the output swamps this effect and insures stability.

Protection Diodes

When external capacitors are used with any IC regulator, it is sometimes necessary to add protection diodes to prevent the capacitors from discharging through low current points into the regulator.

Figure 18 shows the LM350 with the recommended protection diodes for output voltages in excess of 25 V or high capacitance values (C_O > 25 µF, C_{Adj} > 10 µF). Diode D_1 prevents C_O from discharging thru the IC during an input short circuit. Diode D_2 protects against capacitor C_{Adj} discharging through the IC during an output short circuit. The combination of diodes D_1 and D_2 prevents C_{Adj} from discharging through the IC during an input short circuit.

Figure 18. Voltage Regulator with Protection Diodes

LM2575

Advance Information

Easy Switcher™ 1.0 A Step-Down Voltage Regulator

The LM2575 series of regulators are monolithic integrated circuits ideally suited for easy and convenient design of a step–down switching regulator (buck converter). All circuits of this series are capable of driving a 1.0 A load with excellent line and load regulation. These devices are available in fixed output voltages of 3.3 V, 5.0 V, 12 V, 15 V, and an adjustable output version.

These regulators were designed to minimize the number of external components to simplify the power supply design. Standard series of inductors optimised for use with the LM2575 are offered by several different inductor manufacturers.

Since the LM2575 converter is a switch–mode power supply, its efficiency is significantly higher in comparison with popular three–terminal linear regulators, especially with higher input voltages. In many cases, the power dissipated by the LM2575 regulator is so low, that no heatsink is required or its size could be reduced dramatically.

The LM2575 features include a guaranteed ±4% tolerance on output voltage within specified input voltages and output load conditions, and ±10% on the oscillator frequency (±2% over 0°C to 125°C). External shutdown is included, featuring 80 µA typical standby current. The output switch includes cycle–by–cycle current limiting, as well as thermal shutdown for full protection under fault conditions.

Features

- 3.3 V, 5.0 V, 12 V, 15 V, and Adjustable Output Versions
- Adjustable Version Output Voltage Range of 1.23 V to 37 V ±4% Maximum Over Line and Load Conditions
- Guaranteed 1.0 A Output Current
- Wide Input Voltage Range: 4.75 V to 40 V
- Requires Only 4 External Components
- 52 kHz Fixed Frequency Internal Oscillator
- TTL Shutdown Capability, Low Power Standby Mode
- High Efficiency
- Uses Readily Available Standard Inductors
- Thermal Shutdown and Current Limit Protection

Applications

- Simple and High–Efficiency Step–Down (Buck) Regulators
- Efficient Pre–Regulator for Linear Regulators
- On–Card Switching Regulators
- Positive to Negative Converters (Buck–Boost)
- Negative Step–Up Converters
- Power Supply for Battery Chargers

NOTES:
3. The oscillator frequency reduces to approximately 18 kHz in the event of an output short or an overload which causes the regulated output voltage to drop approximately 40% from the nominal output voltage. This self protection feature lowers the average dissipation of the IC by lowering the minimum duty cycle from 5% down to approximately 2%.
4. Output (Pin 2) sourcing current. No diode, inductor or capacitor connected to output pin.
5. Feedback (Pin 4) removed from output and connected to 0 V.
6. Feedback (Pin 4) removed from output and connected to +12 V for the Adjustable, 3.3 V, and 5.0 V versions, and +25 V for the 12 V and 15 V versions, to force the output transistor “off”.
7. V_{in} = 40 V.

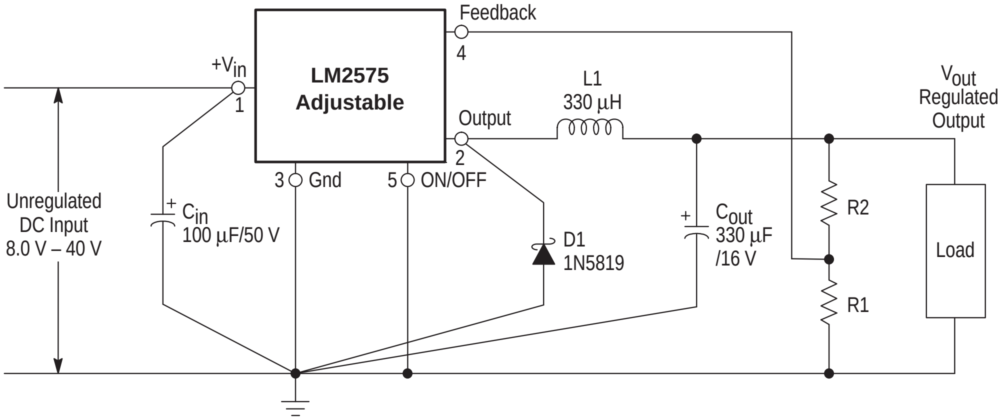
Adjustable Output Voltage Versions



$$V_{out} = V_{ref}\left(1 + \frac{R2}{R1}\right)$$

$$R2 = R1\left(\frac{V_{out}}{V_{ref}} - 1\right)$$

Where V_{ref} = 1.23 V, R1 between 1.0 kΩ and 5.0 kΩ

PCB LAYOUT GUIDELINES

As in any switching regulator, the layout of the printed circuit board is very important. Rapidly switching currents associated with wiring inductance, stray capacitance and parasitic inductance of the printed circuit board traces can generate voltage transients which can generate electromagnetic interferences (EMI) and affect the desired operation. As indicated in the Figure 14, to minimize inductance and ground loops, the length of the leads indicated by heavy lines should be kept as short as possible. For best results, single–point grounding (as indicated) or ground plane construction should be used.

On the other hand, the PCB area connected to the Pin 2 (emitter of the internal switch) of the LM2575 should be kept to a minimum in order to minimize coupling to sensitive circuitry.

Another sensitive part of the circuit is the feedback. It is important to keep the sensitive feedback wiring short. To assure this, physically locate the programming resistors near to the regulator, when using the adjustable version of the LM2575 regulator.

PIN FUNCTION DESCRIPTION

Pin	Symbol	Description (Refer to Figure 1)
1	V_{in}	This pin is the positive input supply for the LM2575 step–down switching regulator. In order to minimize voltage transients and to supply the switching currents needed by the regulator, a suitable input bypass capacitor must be present (C_{in} in Figure 1).
2	Output	This is the emitter of the internal switch. The saturation voltage V_{sat} of this output switch is typically 1.0 V. It should be kept in mind that the PCB area connected to this pin should be kept to a minimum in order to minimize coupling to sensitive circuitry.
3	Gnd	Circuit ground pin. See the information about the printed circuit board layout.
4	Feedback	This pin senses regulated output voltage to complete the feedback loop. The signal is divided by the internal resistor divider network R2, R1 and applied to the non–inverting input of the internal error amplifier. In the Adjustable version of the LM2575 switching regulator this pin is the direct input of the error amplifier and the resistor network R2, R1 is connected externally to allow programming of the output voltage.
5	$\overline{\text{ON}}$/OFF	It allows the switching regulator circuit to be shut down using logic level signals, thus dropping the total input supply current to approximately 80 µA. The input threshold voltage is typically 1.4 V. Applying a voltage above this value (up to $+V_{in}$) shuts the regulator off. If the voltage applied to this pin is lower than 1.4 V or if this pin is connected to ground, the regulator will be in the “on” condition.

DESIGN PROCEDURE

Buck Converter Basics

The LM2575 is a “Buck” or Step–Down Converter which is the most elementary forward–mode converter. Its basic schematic can be seen in Figure 15.

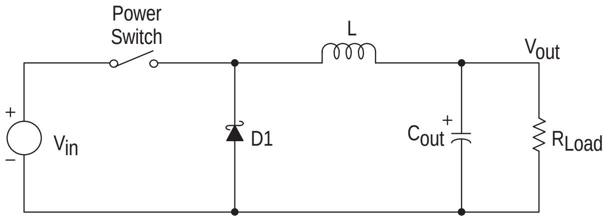
The operation of this regulator topology has two distinct time periods. The first one occurs when the series switch is on, the input voltage is connected to the input of the inductor.

The output of the inductor is the output voltage, and the rectifier (or catch diode) is reverse biased. During this period, since there is a constant voltage source connected across the inductor, the inductor current begins to linearly ramp upwards, as described by the following equation:

$$I_{L(on)} = \frac{\left(V_{in} - V_{out}\right) t_{on}}{L}$$

During this “on” period, energy is stored within the core material in the form of magnetic flux. If the inductor is properly designed, there is sufficient energy stored to carry the requirements of the load during the “off” period.

Figure 15. Basic Buck Converter



The next period is the “off” period of the power switch. When the power switch turns off, the voltage across the inductor reverses its polarity and is clamped at one diode voltage drop below ground by catch dioded. Current now flows through the catch diode thus maintaining the load current loop. This removes the stored energy from the inductor. The inductor current during this time is:

$$I_{L(off)} = \frac{\left(V_{out} - V_D\right) t_{off}}{L}$$

This period ends when the power switch is once again turned on. Regulation of the converter is accomplished by varying the duty cycle of the power switch. It is possible to describe the duty cycle as follows:

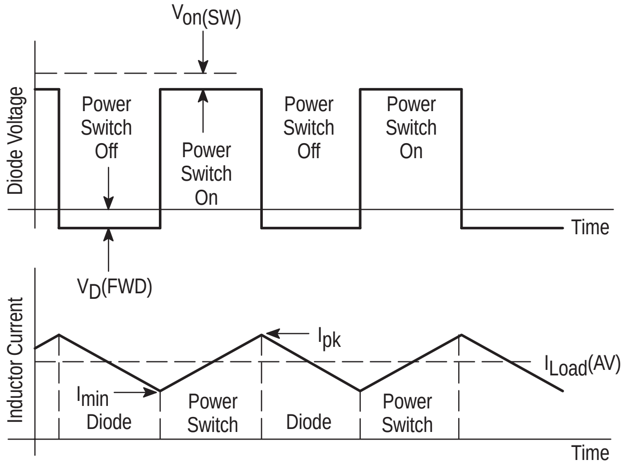
$d = \frac{t_{on}}{T}$, where T is the period of switching.

For the buck converter with ideal components, the duty cycle can also be described as:

$$d = \frac{V_{out}}{V_{in}}$$

Figure 16 shows the buck converter idealized waveforms of the catch diode voltage and the inductor current.

Figure 16. Buck Converter Idealized Waveforms



Procedure (Fixed Output Voltage Version) In order to simplify the switching regulator design, a step–by–step design procedure and example is provided.

Procedure	Example
Given Parameters: V_{out} = Regulated Output Voltage (3.3 V, 5.0 V, 12 V or 15 V) $V_{in(max)}$ = Maximum DC Input Voltage $I_{Load(max)}$ = Maximum Load Current	**Given Parameters:** V_{out} = 5.0 V $V_{in(max)}$ = 20 V $I_{Load(max)}$ = 0.8 A
1. Controller IC Selection According to the required input voltage, output voltage and current, select the appropriate type of the controller IC output voltage version.	**1. Controller IC Selection** According to the required input voltage, output voltage, current polarity and current value, use the LM2575–5 controller IC
2. Input Capacitor Selection (C_{in}) To prevent large voltage transients from appearing at the input and for stable operation of the converter, an aluminium or tantalum electrolytic bypass capacitor is needed between the input pin $+V_{in}$ and ground pin Gnd. This capacitor should be located close to the IC using short leads. This capacitor should have a low ESR (Equivalent Series Resistance) value.	**2. Input Capacitor Selection (C_{in})** A 47 µF, 25 V aluminium electrolytic capacitor located near to the input and ground pins provides sufficient bypassing.
3. Catch Diode Selection (D1) **A.** Since the diode maximum peak current exceeds the regulator maximum load current the catch diode current rating must be at least 1.2 times greater than the maximum load current. For a robust design the diode should have a current rating equal to the maximum current limit of the LM2575 to be able to withstand a continuous output short **B.** The reverse voltage rating of the diode should be at least 1.25 times the maximum input voltage.	**3. Catch Diode Selection (D1)** **A.** For this example the current rating of the diode is 1.0 A. **B.** Use a 30 V 1N5818 Schottky diode, or any of the suggested fast recovery diodes shown in the Table 4.
4. Inductor Selection (L1) **A.** According to the required working conditions, select the correct inductor value using the selection guide from Figures 17 to 21. **B.** From the appropriate inductor selection guide, identify the inductance region intersected by the Maximum Input Voltage line and the Maximum Load Current line. Each region is identified by an inductance value and an inductor code. **C.** Select an appropriate inductor from the several different manufacturers part numbers listed in Table 1 or Table 2. When using Table 2 for selecting the right inductor the designer must realize that the inductor current rating must be higher than the maximum peak current flowing through the inductor. This maximum peak current can be calculated as follows: $I_{p(max)} = I_{Load(max)} + \frac{\left(V_{in}-V_{out}\right) t_{on}}{2L}$ where t_{on} is the “on” time of the power switch and $t_{on} = \frac{V_{out}}{V_{in}} \times \frac{1}{f_{osc}}$ For additional information about the inductor, see the inductor section in the “External Components” section of this data sheet.	**4. Inductor Selection (L1)** **A.** Use the inductor selection guide shown in Figures 17 to 21. **B.** From the selection guide, the inductance area intersected by the 20 V line and 0.8 A line is L330. **C.** Inductor value required is 330 µH. From the Table 1 or Table 2, choose an inductor from any of the listed manufacturers.

Procedure (Fixed Output Voltage Version) (continued) In order to simplify the switching regulator design, a step–by–step design procedure and example is provided.

Procedure	Example
5. Output Capacitor Selection (C_{out}) **A.** Since the LM2575 is a forward–mode switching regulator with voltage mode control, its open loop 2–pole–2–zero frequency characteristic has the dominant pole–pair determined by the output capacitor and inductor values. For stable operation and an acceptable ripple voltage, (approximately 1% of the output voltage) a value between 100 µF and 470 µF is recommended. **B.** Due to the fact that the higher voltage electrolytic capacitors generally have lower ESR (Equivalent Series Resistance) numbers, the output capacitor's voltage rating should be at least 1.5 times greater than the output voltage. For a 5.0 V regulator, a rating at least 8V is appropriate, and a 10 V or 16 V rating is recommended.	**5. Output Capacitor Selection (C_{out})** **A.** C_{out} = 100 µF to 470 µF standard aluminium electrolytic. **B.** Capacitor voltage rating = 16 V.

Procedure (Adjustable Output Version: LM2575–Adj)

Procedure	Example
Given Parameters: V_{out} = Regulated Output Voltage $V_{in(max)}$ = Maximum DC Input Voltage $I_{Load(max)}$ = Maximum Load Current	**Given Parameters:** V_{out} = 8.0 V $V_{in(max)}$ = 12 V $I_{Load(max)}$ = 1.0 A
1. Programming Output Voltage To select the right programming resistor R1 and R2 value (see Figure 14) use the following formula: $V_{out} = V_{ref}\left(1 + \frac{R2}{R1}\right)$ where V_{ref} = 1.23 V Resistor R1 can be between 1.0 k and 5.0 kΩ. (For best temperature coefficient and stability with time, use 1% metal film resistors). $R2 = R1\left(\frac{V_{out}}{V_{ref}} - 1\right)$	**1. Programming Output Voltage** (selecting R1 and R2) Select R1 and R2: $V_{out} = 1.23\left(1 + \frac{R2}{R1}\right)$ Select R1 = 1.8 kΩ $R2 = R1\left(\frac{V_{out}}{V_{ref}} - 1\right) = 1.8\ k\left(\frac{8.0\ V}{1.23\ V} - 1\right)$ R2 = 9.91 kΩ, choose a 9.88 k metal film resistor.
2. Input Capacitor Selection (C_{in}) To prevent large voltage transients from appearing at the input and for stable operation of the converter, an aluminium or tantalum electrolytic bypass capacitor is needed between the input pin $+V_{in}$ and ground pin Gnd This capacitor should be located close to the IC using short leads. This capacitor should have a low ESR (Equivalent Series Resistance) value**.** For additional information see input capacitor section in the "External Components" section of this data sheet.	**2. Input Capacitor Selection (C_{in})** A 100 µF aluminium electrolytic capacitor located near the input and ground pin provides sufficient bypassing.
3. Catch Diode Selection (D1) **A.** Since the diode maximum peak current exceeds the regulator maximum load current the catch diode current rating must be at least 1.2 times greater than the maximum load current. For a robust design, the diode should have a current rating equal to the maximum current limit of the LM2575 to be able to withstand a continuous output short. **B.** The reverse voltage rating of the diode should be at least 1.25 times the maximum input voltage.	**3. Catch Diode Selection (D1)** **A.** For this example, a 3.0 A current rating is adequate. **B.** Use a 20 V 1N5820 or MBR320 Schottky diode or any suggested fast recovery diode in the Table 4.

Procedure (Adjustable Output Version: LM2575–Adj) (continued)

Procedure	Example
4. Inductor Selection (L1)	**4. Inductor Selection (L1)**
A. Use the following formula to calculate the inductor Volt x microsecond [V x µs] constant: $E \times T = \left(V_{in} - V_{out}\right) \frac{V_{out}}{V_{on}} \times \frac{10^6}{F[Hz]}\ [V \times \mu s]$	**A.** Calculate E x T [V x µs] constant: $E \times T = (12 - 8.0) \times \frac{8.0}{12} \times \frac{1000}{52} = 51\ [V \times \mu s]$
B. Match the calculated E x T value with the corresponding number on the vertical axis of the Inductor Value Selection Guide shown in Figure 21. This E x T constant is a measure of the energy handling capability of an inductor and is dependent upon the type of core, the core area, the number of turns, and the duty cycle.	**B.** E x T = 51 [V x µs]
C. Next step is to identify the inductance region intersected by the E x T value and the maximum load current value on the horizontal axis shown in Figure 21.	**C.** $I_{Load(max)}$ = 1.0 A Inductance Region = L220
D. From the inductor code, identify the inductor value. Then select an appropriate inductor from the Table 1 or Table 2. The inductor chosen must be rated for a switching frequency of 52 kHz and for a current rating of 1.15 x I_{load}. The inductor current rating can also be determined by calculating the inductor peak current: $I_{p(max)} = I_{Load(max)} + \frac{\left(V_{in} - V_{out}\right) t_{on}}{2L}$ where t_{on} is the “on” time of the power switch and $t_{on} = \frac{V_{out}}{V_{in}} \times \frac{1}{f_{osc}}$ For additional information about the inductor, see the inductor section in the “External Components” section of this data sheet.	**D.** Proper inductor value = 220 µH Choose the inductor from the Table 1 or Table 2.
5. Output Capacitor Selection (C_{out})	**5. Output Capacitor Selection (C_{out})**
A. Since the LM2575 is a forward–mode switching regulator with voltage mode control, its open loop 2–pole–2–zero frequency characteristic has the dominant pole–pair determined by the output capacitor and inductor values. For stable operation, the capacitor must satisfy the following requirement: $C_{out} \geq 7.785 \frac{V_{in(max)}}{V_{out} \times L\ [\mu H]}\ [\mu F]$	**A.** $C_{out} \geq 7.785 \frac{12}{8.220} = 53\ \mu F$ To achieve an acceptable ripple voltage, select C_{out} = 100 µF electrolytic capacitor.
B. Capacitor values between 10 µF and 2000 µF will satisfy the loop requirements for stable operation. To achieve an acceptable output ripple voltage and transient response, the output capacitor may need to be several times larger than the above formula yields.	
C. Due to the fact that the higher voltage electrolytic capacitors generally have lower ESR (Equivalent Series Resistance) numbers, the output capacitor’s voltage rating should be at least 1.5 times greater than the output voltage. For a 5.0 V regulator, a rating of at least 8V is appropriate, and a 10 V or 16 V rating is recommended.

EXTERNAL COMPONENTS

Input Capacitor (C_{in})

The Input Capacitor Should Have a Low ESR

For stable operation of the switch mode converter a low ESR (Equivalent Series Resistance) aluminium or solid tantalum bypass capacitor is needed between the input pin and the ground pin to prevent large voltage transients from appearing at the input. It must be located near the regulator and use short leads. With most electrolytic capacitors, the capacitance value decreases and the ESR increases with lower temperatures. For reliable operation in temperatures below –25°C larger values of the input capacitor may be needed. Also paralleling a ceramic or solid tantalum capacitor will increase the regulator stability at cold temperatures.

RMS Current Rating of C_{in}

The important parameter of the input capacitor is the RMS current rating. Capacitors that are physically large and have large surface area will typically have higher RMS current ratings. For a given capacitor value, a higher voltage electrolytic capacitor will be physically larger than a lower voltage capacitor, and thus be able to dissipate more heat to the surrounding air, and therefore will have a higher RMS current rating. The consequence of operating an electrolytic capacitor above the RMS current rating is a shortened operating life. In order to assure maximum capacitor operating lifetime, the capacitor's RMS ripple current rating should be:

$$I_{rms} > 1.2 \times d \times I_{Load}$$

where d is the duty cycle, for a buck regulator

$$d = \frac{t_{on}}{T} = \frac{V_{out}}{V_{in}}$$

and $d = \frac{t_{on}}{T} = \frac{|V_{out}|}{|V_{out}| + V_{in}}$ for a buck–boost regulator.

Output Capacitor (C_{out})

For low output ripple voltage and good stability, low ESR output capacitors are recommended. An output capacitor has two main functions: it filters the output and provides regulator loop stability. The ESR of the output capacitor and the peak–to–peak value of the inductor ripple current are the main factors contributing to the output ripple voltage value.Standard aluminium electrolytics could be adequate for some applications but for quality design low ESR types are recommended.

An aluminium electrolytic capacitor's ESR value is related to many factors such as the capacitance value, the voltage rating, the physical size and the type of construction. In most cases, the higher voltage electrolytic capacitors have lower ESR value. Often capacitors with much higher voltage ratings may be needed to provide low ESR values that are required for low output ripple voltage.

The Output Capacitor Requires an ESR Value That Has an Upper and Lower Limit

As mentioned above, a low ESR value is needed for low output ripple voltage, typically 1% to 2% of the output voltage. But if the selected capacitor's ESR is extremely low (below 0.05 Ω), there is a possibility of an unstable feedback loop, resulting in oscillation at the output. This situation can occur when a tantalum capacitor, that can have a very low ESR, is used as the only output capacitor.

At Low Temperatures, Put in Parallel Aluminium Electrolytic Capacitors with Tantalum Capacitors

Electrolytic capacitors are not recommended for temperatures below –25°C. The ESR rises dramatically at cold temperatures and typically rises 3 times at –25°C and as much as 10 times at –40°C. Solid tantalum capacitors have much better ESR spec at cold temperatures and are recommended for temperatures below –25°C. They can be also used in parallel with aluminium electrolytics. The value of the tantalum capacitor should be about 10% or 20% of the total capacitance. The output capacitor should have at least 50% higher RMS ripple current rating at 52 kHz than the peak–to–peak inductor ripple current.

Catch Diode

Locate the Catch Diode Close to the LM2575

The LM2575 is a step–down buck converter; it requires a fast diode to provide a return path for the inductor current when the switch turns off. This diode must be located close to the LM2575 using short leads and short printed circuit traces to avoid EMI problems.

Use a Schottky or a Soft Switching Ultra–Fast Recovery Diode

Since the rectifier diodes are very significant source of losses within switching power supplies, choosing the rectifier that best fits into the converter design is an important process. Schottky diodes provide the best performance because of their fast switching speed and low forward voltage drop.

They provide the best efficiency especially in low output voltage applications (5.0 V and lower). Another choice could be Fast–Recovery, or Ultra–Fast Recovery diodes. It has to be noted, that some types of these diodes with an abrupt turnoff characteristic may cause instability or EMI troubles.

A fast–recovery diode with soft recovery characteristics can better fulfill a quality, low noise design requirements. Table 4 provides a list of suitable diodes for the LM2575 regulator. Standard 50/60 Hz rectifier diodes such as the 1N4001 series or 1N5400 series are **NOT** suitable.

Inductor

The magnetic components are the cornerstone of all switching power supply designs. The style of the core and the winding technique used in the magnetic component's design has a great influence on the reliability of the overall power supply.

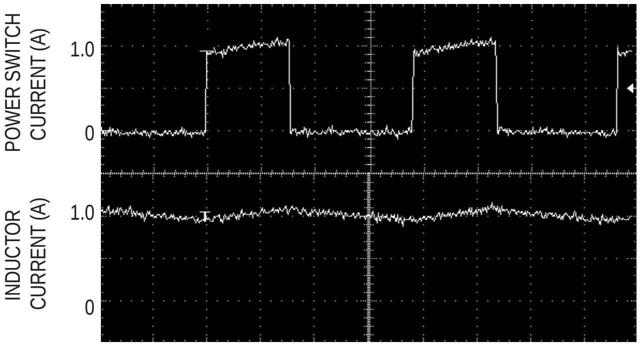
Using an improper or poorly designed inductor can cause high voltage spikes generated by the rate of transitions in current within the switching power supply, and the possibility of core saturation can arise during an abnormal operational mode. Voltage spikes can cause the semiconductors to enter avalanche breakdown and the part can instantly fail if enough energy is applied. It can also cause significant RFI (Radio Frequency Interference) and EMI (Electro–Magnetic Interference) problems.

Continuous and Discontinuous Mode of Operation

The LM2575 step–down converter can operate in both the continuous and the discontinuous modes of operation. The regulator works in the continuous mode when loads are relatively heavy, the current flows through the inductor continuously and never falls to zero. Under light load conditions, the circuit will be forced to the discontinuous mode when inductor current falls to zero for certain period of time (see Figure 22 and Figure 23). Each mode has distinctively different operating characteristics, which can affect the regulator performance and requirements. In many cases the preferred mode of operation is the continuous mode. It offers greater output power, lower peak currents in the switch, inductor and diode, and can have a lower output ripple voltage. On the other hand it does require larger inductor values to keep the inductor current flowing continuously, especially at low output load currents and/or high input voltages.

To simplify the inductor selection process, an inductor selection guide for the LM2575 regulator was added to this data sheet (Figures 17 through 21). This guide assumes that the regulator is operating in the continuous mode, and selects an inductor that will allow a peak–to–peak inductor ripple current to be a certain percentage of the maximum design load current. This percentage is allowed to change as different design load currents are selected. For light loads (less than approximately 200 mA) it may be desirable to operate the regulator in the discontinuous mode, because the inductor value and size can be kept relatively low. Consequently, the percentage of inductor peak–to–peak current increases. This discontinuous mode of operation is perfectly acceptable for this type of switching converter. Any buck regulator will be forced to enter discontinuous mode if the load current is light enough.

Figure 22. Continuous Mode Switching Current Waveforms



HORTIZONTAL TIME BASE: 5.0 µs/DIV

Selecting the Right Inductor Style

Some important considerations when selecting a core type are core material, cost, the output power of the power supply, the physical volume the inductor must fit within, and the amount of EMI (Electro–Magnetic Interference) shielding that the core must provide. The inductor selection guide covers different styles of inductors, such as pot core, E–core, toroid and bobbin core, as well as different core materials such as ferrites and powdered iron from different manufacturers.

For high quality design regulators the toroid core seems to be the best choice. Since the magnetic flux is completely contained within the core, it generates less EMI, reducing noise problems in sensitive circuits. The least expensive is the bobbin core type, which consists of wire wound on a ferrite rod core. This type of inductor generates more EMI due to the fact that its core is open, and the magnetic flux is not completely contained within the core.

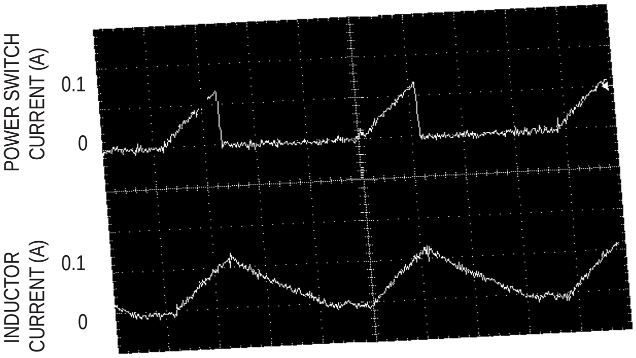
When multiple switching regulators are located on the same printed circuit board, open core magnetics can cause interference between two or more of the regulator circuits, especially at high currents due to mutual coupling. A toroid, pot core or E–core (closed magnetic structure) should be used in such applications.

Do Not Operate an Inductor Beyond its Maximum Rated Current

Exceeding an inductor's maximum current rating may cause the inductor to overheat because of the copper wire losses, or the core may saturate. Core saturation occurs when the flux density is too high and consequently the cross sectional area of the core can no longer support additional lines of magnetic flux.

This causes the permeability of the core to drop, the inductance value decreases rapidly and the inductor begins to look mainly resistive. It has only the dc resistance of the winding. This can cause the switch current to rise very rapidly and force the LM2575 internal switch into cycle–by–cycle current limit, thus reducing the dc output load current. This can also result in overheating of the inductor and/or the LM2575. Different inductor types have different saturation characteristics, and this should be kept in mind when selecting an inductor.

Figure 23. Discontinuous Mode Switching Current Waveforms



HORTIZONTAL TIME BASE: 5.0 µs/DIV

GENERAL RECOMMENDATIONS

Output Voltage Ripple and Transients

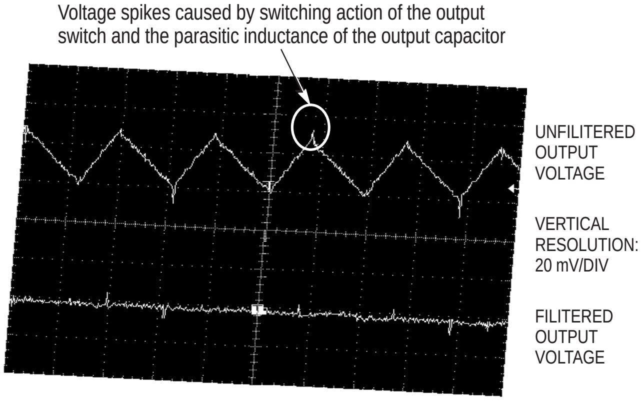
Source of the Output Ripple

Since the LM2575 is a switch mode power supply regulator, its output voltage, if left unfiltered, will contain a sawtooth ripple voltage at the switching frequency. The output ripple voltage value ranges from 0.5% to 3% of the output voltage. It is caused mainly by the inductor sawtooth ripple current multiplied by the ESR of the output capacitor.

Short Voltage Spikes and How to Reduce Them

The regulator output voltage may also contain short voltage spikes at the peaks of the sawtooth waveform (see Figure 24). These voltage spikes are present because of the fast switching action of the output switch, and the parasitic inductance of the output filter capacitor. There are some other important factors such as wiring inductance, stray capacitance, as well as the scope probe used to evaluate these transients, all these contribute to the amplitude of these spikes. To minimise these voltage spikes, low inductance capacitors should be used, and their lead lengths must be kept short. The importance of quality printed circuit board layout design should also be highlighted.

Figure 24. Output Ripple Voltage Waveforms



HORTIZONTAL TIME BASE: 10 µs/DIV

Minimizing the Output Ripple

In order to minimise the output ripple voltage it is possible to enlarge the inductance value of the inductor L1 and/or to use a larger value output capacitor. There is also another way to smooth the output by means of an additional LC filter (20 µH, 100 µF), that can be added to the output (see Figure 33) to further reduce the amount of output ripple and transients. With such a filter it is possible to reduce the output ripple voltage transients 10 times or more. Figure 24 shows the difference between filtered and unfiltered output waveforms of the regulator shown in Figure 33.

The upper waveform is from the normal unfiltered output of the converter, while the lower waveform shows the output ripple voltage filtered by an additional LC filter.

Heatsinking and Thermal Considerations

The Through–Hole Package TO–220

The LM2575 is available in two packages, a 5–pin TO–220(T, TV) and a 5–pin surface mount D^{2}PAK(D2T). There are many applications that require no heatsink to keep the LM2575 junction temperature within the allowed operating range. The TO–220 package can be used without a heatsink for ambient temperatures up to approximately 50°C (depending on the output voltage and load current). Higher ambient temperatures require some heatsinking, either to the printed circuit (PC) board or an external heatsink.

The Surface Mount Package D^{2}PAK and its Heatsinking

The other type of package, the surface mount D^{2}PAK, is designed to be soldered to the copper on the PC board. The copper and the board are the heatsink for this package and the other heat producing components, such as the catch diode and inductor. The PC board copper area that the package is soldered to should be at least 0.4 in^2 (or 100 mm^2) and ideally should have 2 or more square inches (1300 mm^2) of 0.0028 inch copper. Additional increasing of copper area beyond approximately 3.0 in^2 (2000 mm^2) will not improve heat dissipation significantly. If further thermal improvements are needed, double sided or multilayer PC boards with large copper areas should be considered.

Thermal Analysis and Design

The following procedure must be performed to determine whether or not a heatsink will be required. First determine:

1. $P_{D(max)}$ maximum regulator power dissipation in the application.
2. $T_{A(max)}$ maximum ambient temperature in the application.
3. $T_{J(max)}$ maximum allowed junction temperature (125°C for the LM2575). For a conservative design, the maximum junction temperature should not exceed 110°C to assure safe operation. For every additional 10°C temperature rise that the junction must withstand, the estimated operating lifetime of the component is halved.
4. $R_{\theta JC}$ package thermal resistance junction–case.
5. $R_{\theta JA}$ package thermal resistance junction–ambient.

(Refer to Absolute Maximum Ratings in this data sheet or $R_{\theta JC}$ and $R_{\theta JA}$ values).

The following formula is to calculate the total power dissipated by the LM2575:

$$P_D = (V_{in} \times I_Q) + d \times I_{Load} \times V_{sat}$$

where d is the duty cycle and for buck converter

$$d = \frac{t_{on}}{T} = \frac{V_O}{V_{in}},$$

I_Q (quiescent current) and V_{sat} can be found in the LM2575 data sheet,

V_{in} is minimum input voltage applied,

V_O is the regulator output voltage,

I_{Load} is the load current.

The dynamic switching losses during turn–on and turn–off can be neglected if proper type catch diode is used.

Packages Not on a Heatsink (Free–Standing)

For a free–standing application when no heatsink is used, the junction temperature can be determined by the following expression:

$$T_J = (R_{\theta JA})(P_D) + T_A$$

where $(R_{\theta JA})(P_D)$ represents the junction temperature rise caused by the dissipated power and T_A is the maximum ambient temperature.

Packages on a Heatsink

If the actual operating junction temperature is greater than the selected safe operating junction temperature determined in step 3, than a heatsink is required. The junction temperature will be calculated as follows:

$$T_J = P_D\,(R_{\theta JA} + R_{\theta CS} + R_{\theta SA}) + T_A$$

where $R_{\theta JC}$ is the thermal resistance junction–case,
$R_{\theta CS}$ is the thermal resistance case–heatsink,
$R_{\theta SA}$ is the thermal resistance heatsink–ambient.

If the actual operating temperature is greater than the selected safe operating junction temperature, then a larger heatsink is required.

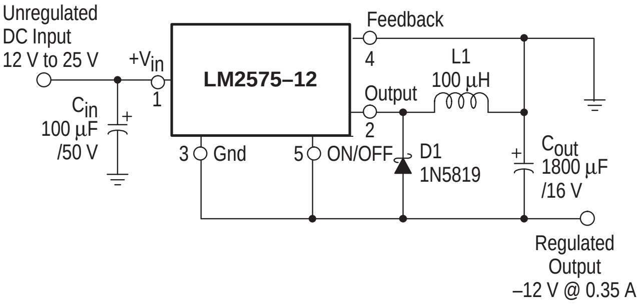
Some Aspects That can Influence Thermal Design

It should be noted that the package thermal resistance and the junction temperature rise numbers are all approximate, and there are many factors that will affect these numbers, such as PC board size, shape, thickness, physical position, location, board temperature, as well as whether the surrounding air is moving or still.

Other factors are trace width, total printed circuit copper area, copper thickness, single– or double–sided, multilayer board, the amount of solder on the board or even colour of the traces.

The size, quantity and spacing of other components on the board can also influence its effectiveness to dissipate the heat.

Figure 25. Inverting Buck–Boost Regulator Using the LM2575–12 Develops –12 V @ 0.35 A



ADDITIONAL APPLICATIONS

Inverting Regulator

An inverting buck–boost regulator using the LM2575–12 is shown in Figure 25. This circuit converts a positive input voltage to a negative output voltage with a common ground by bootstrapping the regulators ground to the negative output voltage. By grounding the feedback pin, the regulator senses the inverted output voltage and regulates it.

In this example the LM2575–12 is used to generate a –12 V output. The maximum input voltage in this case cannot exceed +28 V because the maximum voltage appearing across the regulator is the absolute sum of the input and output voltages and this must be limited to a maximum of 40 V.

This circuit configuration is able to deliver approximately 0.35 A to the output when the input voltage is 12 V or higher. At lighter loads the minimum input voltage required drops to approximately 4.7 V, because the buck–boost regulator topology can produce an output voltage that, in its absolute value, is either greater or less than the input voltage.

Since the switch currents in this buck–boost configuration are higher than in the standard buck converter topology, the available output current is lower.

This type of buck–boost inverting regulator can also require a larger amount of startup input current, even for light loads. This may overload an input power source with a current limit less than 1.5 A.

Such an amount of input startup current is needed for at least 2.0 ms or more. The actual time depends on the output voltage and size of the output capacitor.

Because of the relatively high startup currents required by this inverting regulator topology, the use of a delayed startup or an undervoltage lockout circuit is recommended.

Using a delayed startup arrangement, the input capacitor can charge up to a higher voltage before the switch–mode regulator begins to operate.

The high input current needed for startup is now partially supplied by the input capacitor C_{in}.

Design Recommendations:

The inverting regulator operates in a different manner than the buck converter and so a different design procedure has to be used to select the inductor L1 or the output capacitor C_{out}.

The output capacitor values must be larger than is normally required for buck converter designs. Low input voltages or high output currents require a large value output capacitor (in the range of thousands of µF).

The recommended range of inductor values for the inverting converter design is between 68 µH and 220 µH. To select an inductor with an appropriate current rating, the inductor peak current has to be calculated.

The following formula is used to obtain the peak inductor current:

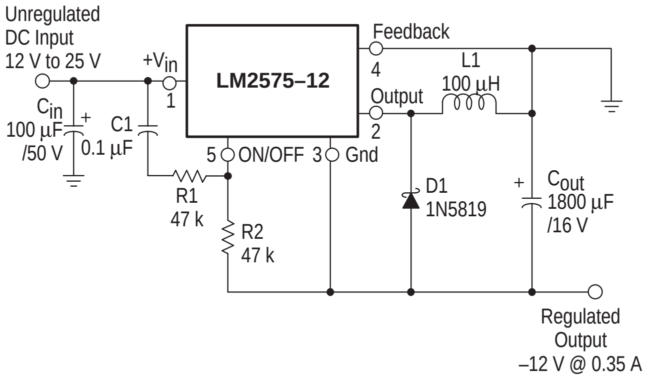
$$I_{peak} \approx \frac{I_{Load}\,(V_{in} + |V_O|)}{V_{in}} + \frac{V_{in} \times t_{on}}{2L_1}$$

where $t_{on} = \frac{|V_O|}{V_{in} + |V_O|} \times \frac{1}{f_{osc}}$, and $f_{osc} = 52$ kHz.

Under normal continuous inductor current operating conditions, the worst case occurs when V_{in} is minimal.

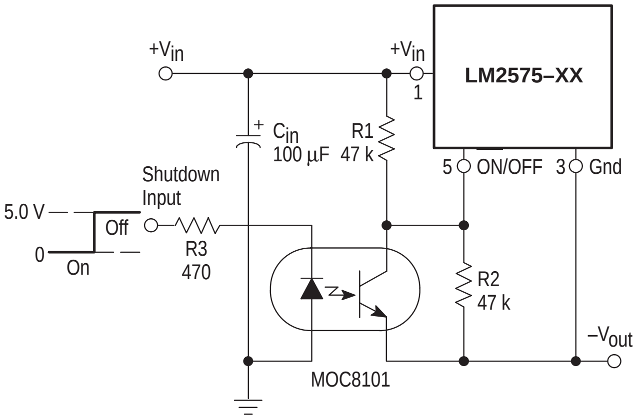
Note that the voltage appearing across the regulator is the absolute sum of the input and output voltage, and must not exceed 40 V.

Figure 26. Inverting Buck–Boost Regulator with Delayed Startup



It has been already mentioned above, that in some situations, the delayed startup or the undervoltage lockout features could be very useful. A delayed startup circuit applied to a buck–boost converter is shown in Figure 26. Figure 31 in the "Undervoltage Lockout" section describes an undervoltage lockout feature for the same converter topology.

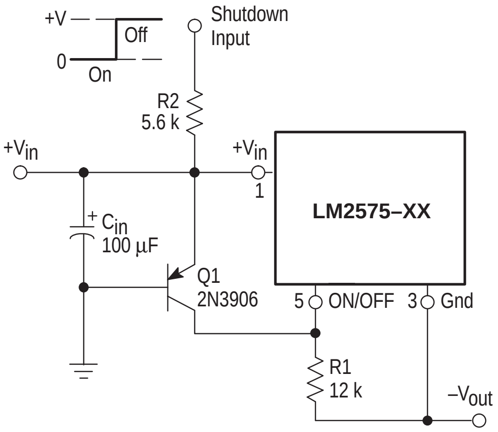
Figure 27. Inverting Buck–Boost Regulator Shut Down Circuit Using an Optocoupler



NOTE: This picture does not show the complete circuit.

With the inverting configuration, the use of the $\overline{\text{ON}}$/OFF pin requires some level shifting techniques. This is caused by the fact, that the ground pin of the converter IC is no longer at ground. Now, the $\overline{\text{ON}}$/OFF pin threshold voltage (1.4 V approximately) has to be related to the negative output voltage level. There are many different possible shut down methods, two of them are shown in Figures 27 and 28.

Figure 28. Inverting Buck–Boost Regulator Shut Down Circuit Using a PNP Transistor



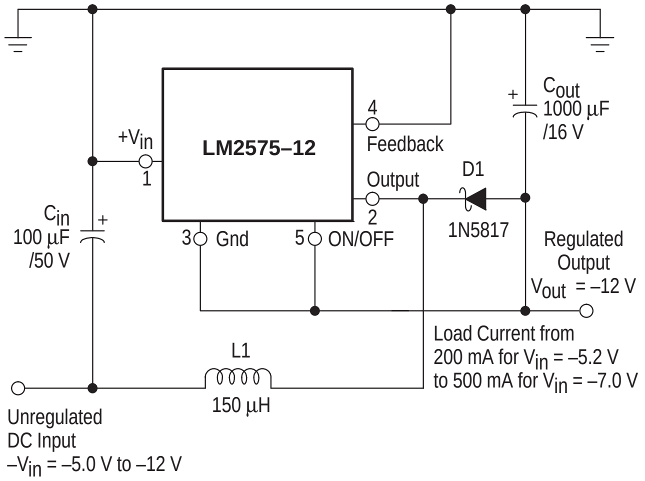
NOTE: This picture does not show the complete circuit.

Negative Boost Regulator

This example is a variation of the buck–boost topology and is called a negative boost regulator. This regulator experiences relatively high switch current, especially at low input voltages. The internal switch current limiting results in lower output load current capability.

The circuit in Figure 29 shows the negative boost configuration. The input voltage in this application ranges from –5.0 V to –12 V and provides a regulated –12 V output. If the input voltage is greater than –12 V, the output will rise above –12 V accordingly, but will not damage the regulator.

Figure 29. Negative Boost Regulator



Design Recommendations:

The same design rules as for the previous inverting buck–boost converter can be applied. The output capacitor C_{out} must be chosen larger than would be required for a standard buck converter. Low input voltages or high output currents require a large value output capacitor (in the range of thousands of µF). The recommended range of inductor values for the negative boost regulator is the same as for inverting converter design.

Another important point is that these negative boost converters cannot provide current limiting load protection in the event of a short in the output so some other means, such as a fuse, may be necessary to provide the load protection.

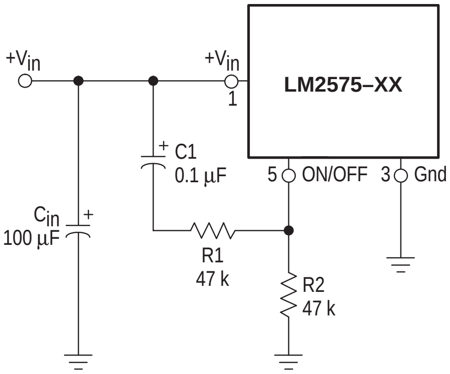
Delayed Startup

There are some applications, like the inverting regulator already mentioned above, which require a higher amount of startup current. In such cases, if the input power source is limited, this delayed startup feature becomes very useful.

To provide a time delay between the time the input voltage is applied and the time when the output voltage comes up, the circuit in Figure 30 can be used. As the input voltage is applied, the capacitor C1 charges up, and the voltage across the resistor R2 falls down. When the voltage on the ON/OFF pin falls below the threshold value 1.4 V, the regulator starts up. Resistor R1 is included to limit the maximum voltage applied to the ON/OFF pin, reduces the power supply noise sensitivity, and also limits the capacitor C1 discharge current, but its use is not mandatory.

When a high 50 Hz or 60 Hz (100 Hz or 120 Hz respectively) ripple voltage exists, a long delay time can cause some problems by coupling the ripple into the ON/OFF pin, the regulator could be switched periodically on and off with the line (or double) frequency.

Figure 30. Delayed Startup Circuitry



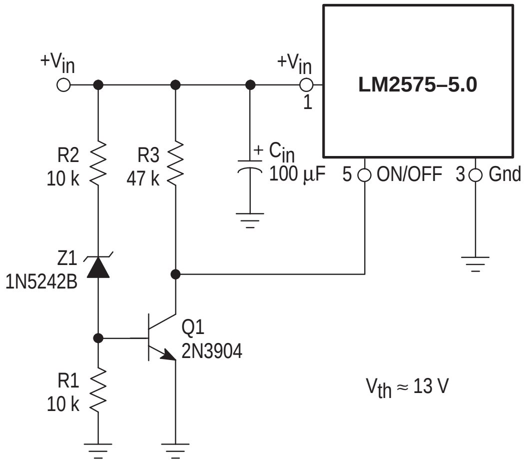
NOTE: This picture does not show the complete circuit.

Undervoltage Lockout

Some applications require the regulator to remain off until the input voltage reaches a certain threshold level. Figure 31 shows an undervoltage lockout circuit applied to a buck regulator. A version of this circuit for buck–boost converter is shown in Figure 32. Resistor R3 pulls the $\overline{\text{ON}}$/OFF pin high and keeps the regulator off until the input voltage reaches a predetermined threshold level, which is determined by the following expression:

$$V_{th} \approx V_{Z1} + \left(1 + \frac{R2}{R1}\right) V_{BE}\ (Q1)$$

Figure 31. Undervoltage Lockout Circuit for Buck Converter



NOTE: This picture does not show the complete circuit.

NOTE: This picture does not show the complete circuit.

Adjustable Output, Low–Ripple Power Supply

A 1.0 A output current capability power supply that features an adjustable output voltage is shown in Figure 33.

This regulator delivers 1.0 A into 1.2 V to 35 V output. The input voltage ranges from roughly 8.0 V to 40 V. In order to achieve a 10 or more times reduction of output ripple, an additional L–C filter is included in this circuit.

MOTOROLA

LM2931 Series

Low Dropout Voltage Regulators

LOW DROPOUT VOLTAGE REGULATORS

The LM2931 series consists of positive fixed and adjustable output voltage regulators that are specifically designed to maintain proper regulation with an extremely low input–to–output voltage differential. These devices are capable of supplying output currents in excess of 100 mA and feature a low bias current of 0.4 mA at 10 mA output.

Designed primarily to survive in the harsh automotive environment, these devices will protect all external load circuitry from input fault conditions caused by reverse battery connection, two battery jump starts, and excessive line transients during load dump. This series also includes internal current limiting, thermal shutdown, and additionally, is able to withstand temporary power–up with mirror–image insertion.

Due to the low dropout voltage and bias current specifications, the LM2931 series is ideally suited for battery powered industrial and consumer equipment where an extension of useful battery life is desirable. The ‘C’ suffix adjustable output regulators feature an output inhibit pin which is extremely useful in microprocessor–based systems.

- Input–to–Output Voltage Differential of < 0.6 V @ 100 mA
- Output Current in Excess of 100 mA
- Low Bias Current
- 60 V Load Dump Protection
- –50 V Reverse Transient Protection
- Internal Current Limiting with Thermal Shutdown
- Temporary Mirror–Image Protection
- Ideally Suited for Battery Powered Equipment
- Economical 5–Lead TO–220 Package with Two Optional Leadforms
- Available in Surface Mount SOP–8, D^{2}PAK and DPAK Packages

APPLICATIONS INFORMATION

The LM2931 series regulators are designed with many protection features making them essentially blow–out proof. These features include internal current limiting, thermal shutdown, overvoltage and reverse polarity input protection, and the capability to withstand temporary power–up with mirror–image insertion. Typical application circuits for the fixed and adjustable output device are shown in Figures 17 and 18.

The input bypass capacitor C_{in} is recommended if the regulator is located an appreciable distance (≥ 4″) from the supply input filter. This will reduce the circuit's sensitivity to the input line impedance at high frequencies.

This regulator series is not internally compensated and thus requires an external output capacitor for stability. The capacitance value required is dependent upon the load current, output voltage for the adjustable regulator, and the type of capacitor selected. The least stable condition is encountered at maximum load current and minimum output voltage. Figure 22 shows that for operation in the "Stable" region, under the conditions specified, the magnitude of the output capacitor impedance $|Z_O|$ must not exceed 0.4 Ω. This limit must be observed over the entire operating temperature range of the regulator circuit.

With economical electrolytic capacitors, cold temperature operation can pose a serious stability problem. As the electrolyte freezes, around –30°C, the capacitance will decrease and the equivalent series resistance (ESR) will increase drastically, causing the circuit to oscillate. Quality electrolytic capacitors with extended temperature ranges of –40° to +85°C and –55° to +105°C are readily available. Solid tantalum capacitors may be a better choice if small size is a requirement, however, the maximum $|Z_O|$ limit over temperature must be observed.

Note that in the stable region, the output noise voltage is linearly proportional to $|Z_O|$. In effect, C_O dictates the high frequency roll–off point of the circuit. Operation in the area titled "Marginally Stable" will cause the output of the regulator to exhibit random bursts of oscillation that decay in an under–damped fashion. Continuous oscillation occurs when operating in the area titled "Unstable". It is suggested that oven testing of the entire circuit be performed with maximum load, minimum input voltage, and minimum ambient temperature.

Figure 17. Fixed Output Regulator

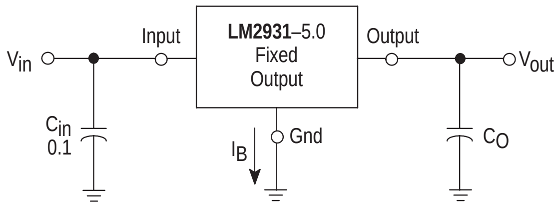

Figure 18. Adjustable Output Regulator

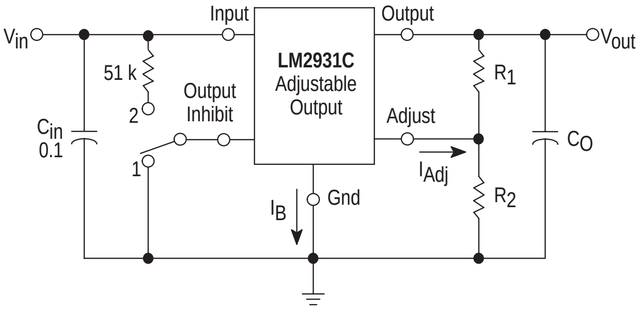
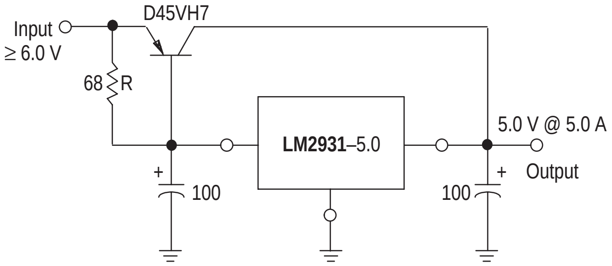


Switch Position 1 = Output “On”, 2 = Output “Off”

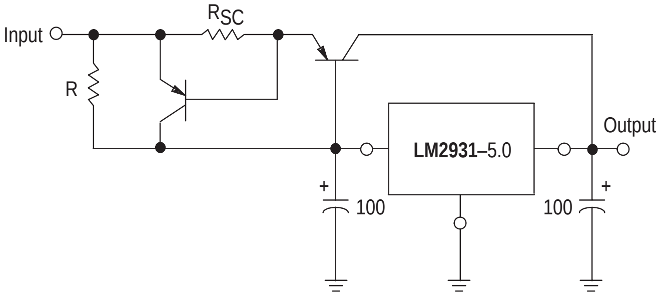
$$V_{out} = V_{ref}\left(1 + \frac{R_2}{R_1}\right) + I_{Adj}\,R_2 \qquad 22.5\ k \geq \frac{R_1\,R_2}{R_1 + R_2}$$

Figure 19. (5.0 A) Low Differential Voltage Regulator



The LM2931 series can be current boosted with a PNP transistor. The D45VH7, on a heatsink, will provide an output current of 5.0 A with an input to output voltage differential of approximately 1.0 V. Resistor R in conjunction with the V_{BE} of the PNP determines when the pass transistor begins conducting. This circuit is not short circuit proof.

Figure 20. Current Boost Regulator with Short Circuit Projection



The circuit of Figure 19 can be modified to provide supply protection against short circuits by adding the current sense resistor R_{SC} and an additional PNP transistor. The current sensing PNP must be capable of handling the short circuit current of the LM2931. Safe operating area of both transistors must be considered under worst case conditions.

DEFINITIONS

Dropout Voltage – The input/output voltage differential at which the regulator output no longer maintains regulation against further reductions in input voltage. Measured when the output decreases 100 mV from nominal value at 14 V input, dropout voltage is affected by junction temperature and load current.

Line Regulation – The change in output voltage for a change in the input voltage. The measurement is made under conditions of low dissipation or by using pulse techniques such that the average chip temperature is not significantly affected.

Load Regulation – The change in output voltage for a change in load current at constant chip temperature.

Maximum Power Dissipation – The maximum total device dissipation for which the regulator will operate within specifications.

Bias Current – That part of the input current that is not delivered to the load.

Output Noise Voltage – The rms AC voltage at the output, with constant load and no input ripple, measured over a specified frequency range.

Long–Term Stabliity – Output voltage stability under accelerated life test conditions with the maximum rated voltage listed in the devices electrical characteristics and maximum power dissipation.

MOTOROLA

LM2935

Low Dropout Dual Voltage Regulator

The LM2935 is a dual positive 5.0 V low dropout voltage regulator, designed for standby power systems. The main output is capable of supplying 750 mA for microprocessor power, and can be turned “on” and “off” by the switch/reset input. The other output is dedicated for standby operation of volatile memory, and is capable of supplying up to 10 mA loads. The total device features a low quiescent current of 3.0 mA or less when supplying 10 mA from the standby output.

This part was designed for harsh automotive environments and is therefore immune to many input supply voltage problems such as reverse battery (–12 V), double battery (+24 V), and load dump transients (+60 V).

- Two Regulated 5.0 V Outputs
- Main Output Current in Excess of 750 mA
- On/Off Control of Main Output
- Standby Output Current in Excess of 10 mA
- Low Input/Output Differential of Less than 0.6 V at 500 mA
- Short Circuit Current Limiting
- Internal Thermal Shutdown
- Low Voltage Indicator Output
- Designed for Automotive Environment Including
  - Reverse Battery Protection
  - Double Battery Protection
  - Load Dump Protection
  - Reverse Transient Protection
- Economical 5–Lead TO–220 Package with Two Optional Leadforms
- Also Available in Surface Mount D^{2}PAK Package

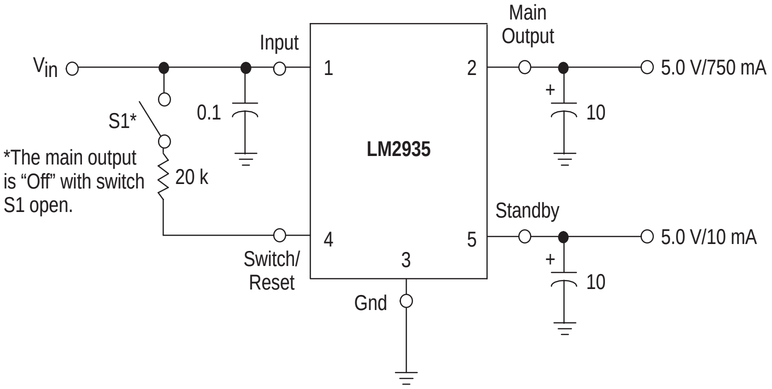
Typical Application Circuit



An input bypass capacitor is recommended if the regulator is located more than 4″ from the supply input filter. The LM2935 is not internally compensated and thus requires an external output capacitor for stability. A minimum capacitance of 10 µF is recommended. The actual capacitance value is dependent upon load current, temperature, and the capacitor’s equivalent series resistance (ESR). The least stable condition is encountered at maximum load current and minimum ambient temperature.

This device contains 29 active transistors.

MOTOROLA

LP2950
LP2951

Micropower Voltage Regulators

The LP2950 and LP2951 are micropower voltage regulators that are specifically designed to maintain proper regulation with an extremely low input–to–output voltage differential. These devices feature a very low quiescent bias current of 75 µA and are capable of supplying output currents in excess of 100 mA. Internal current and thermal limiting protection is provided.

The LP2951 has three additional features. The first is the $\overline{\text{Error}}$ Output that can be used to signal external circuitry of an out of regulation condition, or as a microprocessor power–on reset. The second feature allows the output voltage to be preset to 5.0 V, 3.3 V or 3.0 V output (depending on the version) or programmed from 1.25 V to 29 V. It consists of a pinned out resistor divider along with direct access to the Error Amplifier feedback input. The third feature is a Shutdown input that allows a logic level signal to turn–off or turn–on the regulator output.

Due to the low input–to–output voltage differential and bias current specifications, these devices are ideally suited for battery powered computer, consumer, and industrial equipment where an extension of useful battery life is desirable. The LP2950 is available in the three pin case 29 and DPAK packages, and the LP2951 is available in the eight pin dual–in–line, SO–8 and Micro–8 surface mount packages. The ‘A’ suffix devices feature an initial output voltage tolerance ±0.5%.

LP2950 and LP2951 Features:

- Low Quiescent Bias Current of 75 µA
- Low Input–to–Output Voltage Differential of 50 mV at 100 µA and 380 mV at 100 mA
- 5.0 V, 3.3 V or 3.0 V ±0.5% Allows Use as a Regulator or Reference
- Extremely Tight Line and Load Regulation
- Requires Only a 1.0 µF Output Capacitor for Stability
- Internal Current and Thermal Limiting

LP2951 Additional Features:

- $\overline{\text{Error}}$ Output Signals an Out of Regulation Condition
- Output Programmable from 1.25 V to 29 V
- Logic Level Shutdown Input

NOTES: 1. Low duty pulse techniques are used during test to maintain junction temperature as close to ambient as possible.
2. $V_{O(nom)}$ is the part number voltage option.
3. Noise tests on the LP2951 are made with a 0.01 µF capacitor connected across Pins 7 and 1.

DEFINITIONS

Dropout Voltage – The input/output voltage differential at which the regulator output no longer maintains regulation against further reductions in input voltage. Measured when the output drops 100 mV below its nominal value (which is measured at 1.0 V differential), dropout voltage is affected by junction temperature, load current and minimum input supply requirements.

Line Regulation – The change in output voltage for a change in input voltage. The measurement is made under conditions of low dissipation or by using pulse techniques such that average chip temperature is not significantly affected.

Load Regulation – The change in output voltage for a change in load current at constant chip temperature.

Maximum Power Dissipation – The maximum total device dissipation for which the regulator will operate within specifications.

Bias Current – Current which is used to operate the regulator chip and is not delivered to the load.

Output Noise Voltage – The rms ac voltage at the output, with constant load and no input ripple, measured over a specified frequency range.

Leakage Current – Current drawn through a bipolar transistor collector–base junction, under a specified collector voltage, when the transistor is "off".

Upper Threshold Voltage – Voltage applied to the comparator input terminal, below the reference voltage which is applied to the other comparator input terminal, which causes the comparator output to change state from a logic "0" to "1".

Lower Threshold Voltage – Voltage applied to the comparator input terminal, below the reference voltage which is applied to the other comparator input terminal, which causes the comparator output to change state from a logic "1" to "0".

Hysteresis – The difference between Lower Threshold voltage and Upper Threshold voltage.

APPLICATIONS INFORMATION

Introduction

The LP2950/LP2951 regulators are designed with internal current limiting and thermal shutdown making them user–friendly. Typical application circuits for the LP2950 and LP2951 are shown in Figures 17 through 25.

These regulators are not internally compensated and thus require a 1.0 µF (or greater) capacitance between the LP2950/LP2951 output terminal and ground for stability. Most types of aluminum, tantalum or multilayer ceramic will perform adequately. Solid tantalums or appropriate multilayer ceramic capacitors are recommended for operation below 25°C.

At lower values of output current, less output capacitance is required for output stability. The capacitor can be reduced to 0.33 µF for currents less than 10 mA, or 0.1 µF for currents below 1.0 mA. Using the 8–pin versions at voltages less than 5.0 V operates the error amplifier at lower values of gain, so that more output capacitance is needed for stability. For the worst case operating condition of a 100 mA load at 1.23 V output (Output Pin 1 connected to the feedback Pin 7) a minimum capacitance of 3.3 µF is recommended.

The LP2950 will remain stable and in regulation when operated with no output load. When setting the output voltage of the LP2951 with external resistors, the resistance values should be chosen to draw a minimum of 1.0 µA.

A bypass capacitor is recommended across the LP2950/LP2951 input to ground if more than 4 inches of wire connects the input to either a battery or power supply filter capacitor.

Input capacitance at the LP2951 Feedback Pin 7 can create a pole, causing instability if high value external resistors are used to set the output voltage. Adding a 100 pF capacitor between the Output Pin 1 and the Feedback Pin 7 and increasing the output filter capacitor to at least 3.3 µF will stabilize the feedback loop.

Error Detection Comparator

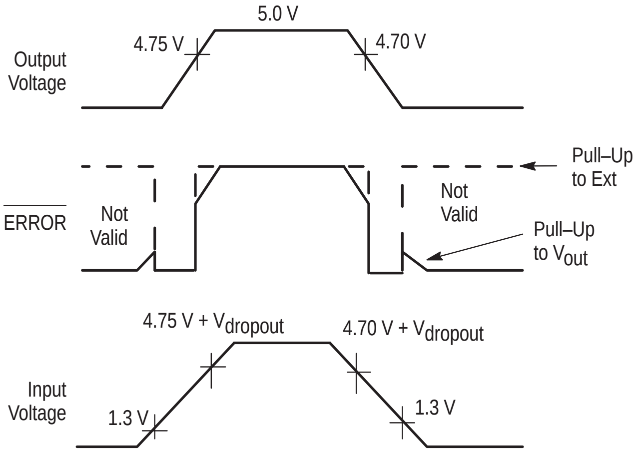
The comparator switches to a positive logic low whenever the LP2951 output voltage falls more than approximately 5.0% out of regulation. This value is the comparator's designed–in offset voltage of 60 mV divided by the 1.235 V internal reference. As shown in the representative block diagram. This trip level remains 5.0% below normal regardless of the value of regulated output voltage. For example, the error flag trip level is 4.75 V for a normal 5.0 V regulated output, or 9.50 V for a 10 V output voltage.

Figure 1 is a timing diagram which shows the ERROR signal and the regulated output voltage as the input voltage to the LP2951 is ramped up and down. The ERROR signal becomes valid (low) at about 1.3 V input. It goes high when the input reaches about 5.0 V (V_{out} exceeds about 4.75 V). Since the LP2951's dropout voltage is dependent upon the load current (refer to the curve in the Typical Performance Characteristics), the input voltage trip point will vary with load current. The output voltage trip point does not vary with load.

The error comparator output is an open collector which requires an external pull–up resistor. This resistor may be returned to the output or some other voltage within the system. The resistance value should be chosen to be consistent with the 400 µA sink capability of the error comparator. A value between 100 k and 1.0 MΩ is suggested. No pull–up resistance is required if this output is unused.

When operated in the shutdown mode, the error comparator output will go high if it has been pulled up to an external supply. To avoid this invalid response, the error comparator output should be pulled up to V_{out} (see Figure 15).

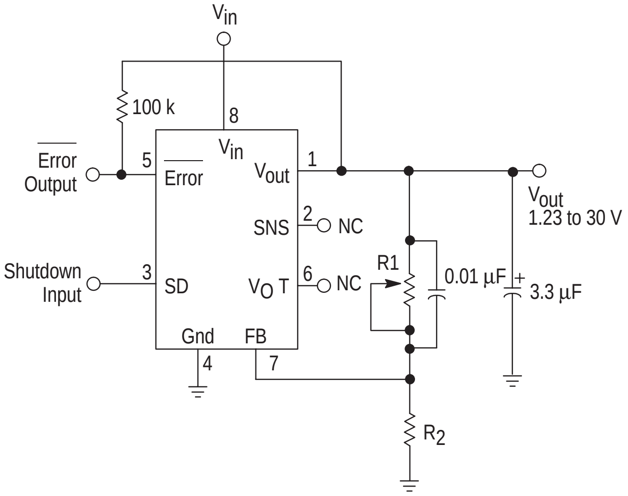
Figure 15. ERROR Output Timing



Programming the Output Voltage (LP2951)

The LP2951CX may be pin–strapped for 5.0 V using its internal voltage divider by tying Pin 1 (output) to Pin 2 (sense) and Pin 7 (feedback) to Pin 6 (5.0 V tap). Alternatively, it may be programmed for any output voltage between its 1.235 reference voltage and its 30 V maximum rating. An external pair of resistors is required, as shown in Figure 16.

Figure 16. Adjustable Regulator



The complete equation for the output voltage is:

$$V_{out} = V_{ref}\ (1 + R1/R2) + I_{FB}\ R1$$

where V_{ref} is the nominal 1.235 V reference voltage and I_{FB} is the feedback pin bias current, nominally −20 nA. The minimum recommended load current of 1.0 µA forces an upper limit of 1.2 MΩ on the value of R2, if the regulator must work with no load. I_{FB} will produce a 2% typical error in V_{out} which may be eliminated at room temperature by adjusting R1. For better accuracy, choosing R2 = 100 k reduces this error to 0.17% while increasing the resistor program current to 12 µA. Since the LP2951 typically draws 75 µA at no load with Pin 2 open circuited, the extra 12 µA of current drawn is often a worthwhile tradeoff for eliminating the need to set output voltage in test.

Output Noise

In many applications it is desirable to reduce the noise present at the output. Reducing the regulator bandwidth by increasing the size of the output capacitor is the only method for reducing noise on the 3 lead LP2950. However, increasing the capacitor from 1.0 µF to 220 µF only decreases the noise from 430 µV to 160 µVrms for a 100 kHz bandwidth at the 5.0 V output.

Noise can be reduced fourfold by a bypass capacitor across R1, since it reduces the high frequency gain from 4 to unity. Pick

$$C_{Bypass} \approx \frac{1}{2\pi R1 \times 200\ Hz}$$

or about 0.01 µF. When doing this, the output capacitor must be increased to 3.3 µF to maintain stability. These changes reduce the output noise from 430 µV to 126 µVrms for a 100 kHz bandwidth at 5.0 V output. With bypass capacitor added, noise no longer scales with output voltage so that improvements are more dramatic at higher output voltages.

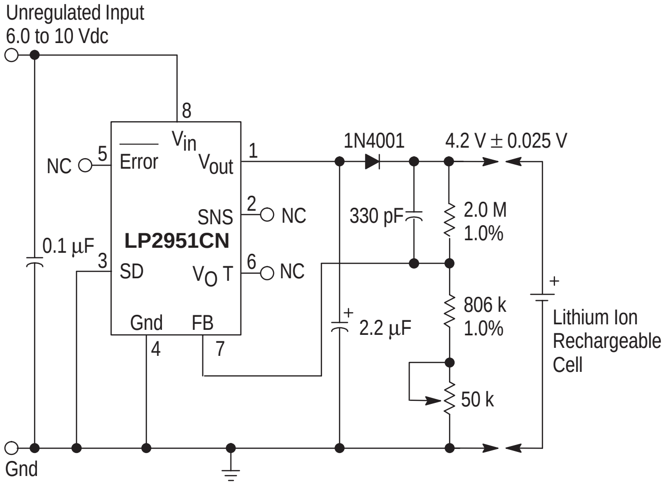

Figure 19. Low Drift Current Sink

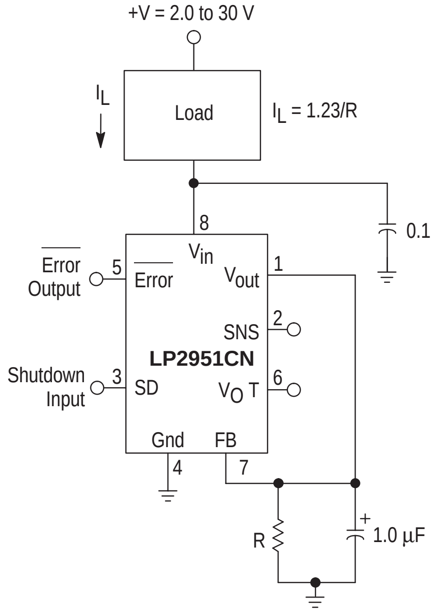

Figure 20. Latch Off When Error Flag Occurs

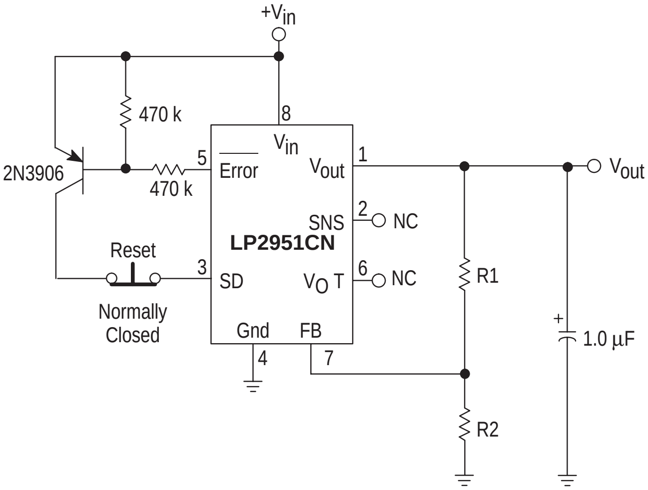

Error flag occurs when V_{in} is too low to maintain V_{out}, or if V_{out} is reduced by excessive load current.

Figure 21. 5.0 V Regulator with 2.5 V Sleep Function

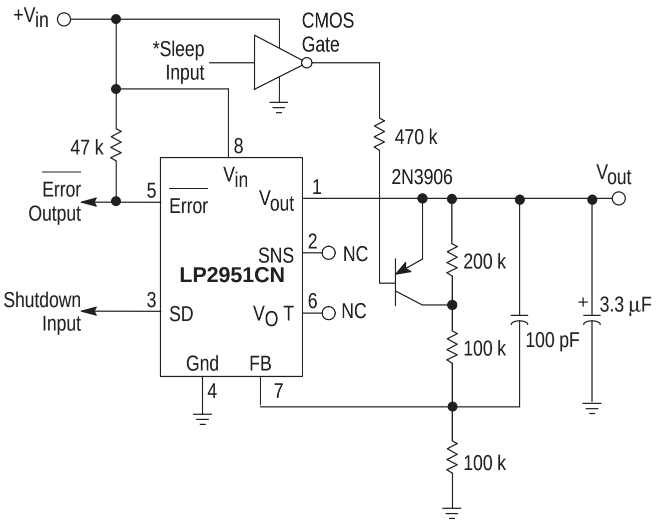

Figure 22. Regulator with Early Warning and Auxiliary Output

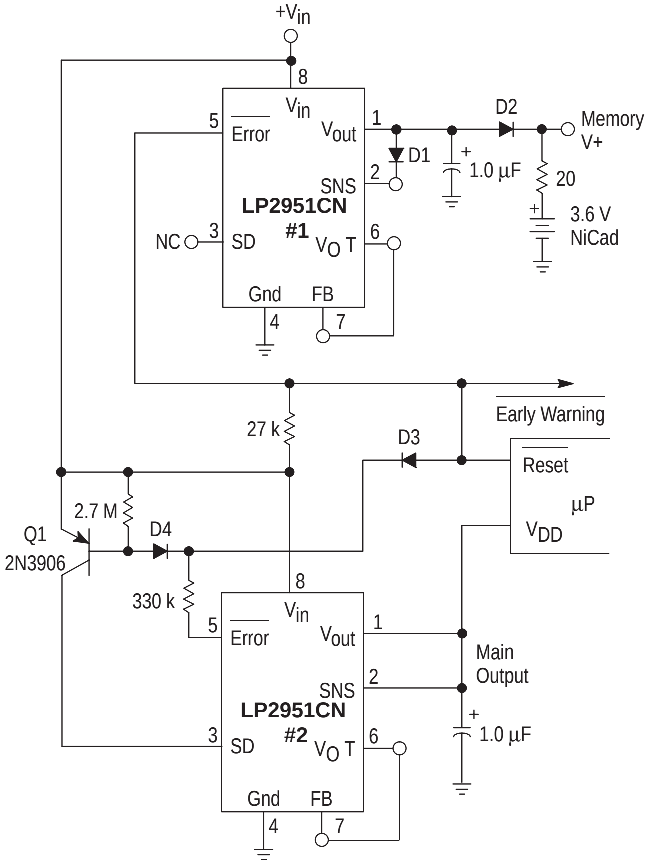

All diodes are 1N4148.

Early Warning flag on low input voltage.

Main output latches off at lower input voltages.

Battery backup on auxiliary output.

Operation: Regulator #1's V_{out} is programmed one diode drop above 5.0 V. Its error flag becomes active when $V_{in} \leq 5.7$ V. When V_{in} drops below 5.3 V, the error flag of regulator #2 becomes active and via Q1 latches the main output "off". When V_{in} again exceeds 5.7 V, regulator #1 is back in regulation and the early warning signal rises, unlatching regulator #2 via D3.

MC1723C

Voltage Regulator

The MC1723C is a positive or negative voltage regulator designed to deliver load current to 150 mAdc. Output current capability can be increased to several amperes through use of one or more external pass transistors. MC1723C is specified for operation over the commercial temperature range (0° to +70°C).

- Output Voltage Adjustable from 2.0 Vdc to 37 Vdc
- Output Current to 150 mAdc Without External Pass Transistors
- 0.01% Line and 0.03% Load Regulation
- Adjustable Short Circuit Protection

MC3423

Overvoltage Crowbar Sensing Circuit

This overvoltage protection circuit (OVP) protects sensitive electronic circuitry from overvoltage transients or regulator failures when used in conjunction with an external "crowbar" SCR. The device senses the overvoltage condition and quickly "crowbars" or short circuits the supply, forcing the supply into current limiting or opening the fuse or circuit breaker.

The protection voltage threshold is adjustable and the MC3423 can be programmed for minimum duration of overvoltage condition before tripping, thus supplying noise immunity.

The MC3423 is essentially a "two terminal" system, therefore it can be used with either positive or negative supplies.

APPLICATION INFORMATION

Basic Circuit Configuration

The basic circuit configuration of the MC3423 OVP is shown in Figure 3 for supply voltages from 4.5 V to 36 V, and in Figure 4 for trip voltages above 36 V. The threshold or trip voltage at which the MC3423 will trigger and supply gate drive to the crowbar SCR, Q1, is determined by the selection of R1 and R2. Their values can be determined by the equation given in Figures 3 and 4, or by the graph shown in Figure 8. The minimum value of the gate current limiting resistor, R_G, is given in Figure 9. Using this value of R_G, the SCR, Q1, will receive the greatest gate current possible without damaging the MC3423. If lower output currents are required, R_G can be increased in value. The switch, S1, shown in Figure 3 may be used to reset the crowbar. Otherwise, the power supply, across which the SCR is connected, must be shut down to reset the crowbar. If a non current–limited supply is used, a fuse or circuit breaker, F1, should be used to protect the SCR and/or the load.

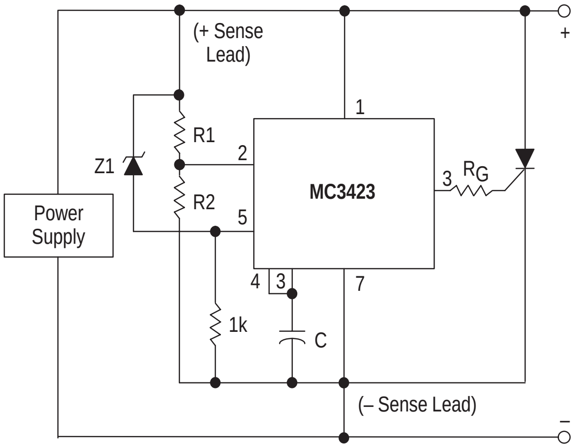
The circuit configurations shown in Figures 3 and 4 will have a typical propogation delay of 1.0 µs. If faster operation is desired, Pin 3 may be connected to Pin 2 with Pin 4 left floating. This will result in decreasing the propogation delay to approximately 0.5 µs at the expense of a slightly increased TC for the trip voltage value.

Configuration for Programmable Minimum Duration of Overvoltage Condition Before Tripping

In many instances, the MC3423 OVP will be used in a noise environment. To prevent false tripping of the OVP circuit by noise which would not normally harm the load, MC3423 has a programmable delay feature. To implement this feature, the circuit configuration of Figure 5 is used. In this configuration, a capacitor is connected from Pin 3 to V_{EE}. The value of this capacitor determines the minimum duration of the overvoltage condition which is necessary to trip the OVP. The value of C can be found from Figure 10. The circuit operates in the following manner: When V_{CC} rises above the trip point set by R1 and R2, an internal current source (Pin 4) begins charging the capacitor, C, connected to Pin 3. If the overvoltage condition disappears before this occurs, the capacitor is discharged at a rate ≅ 10 times faster than the charging rate, resetting the timing feature until the next overvoltage condition occurs.

Occasionally, it is desired that immediate crowbarring of the supply occur when a high overvoltage condition occurs, while retaining the false tripping immunity of Figure 5. In this case, the circuit of Figure 6 can be used. The circuit will operate as previously described for small overvoltages, but will immediately trip if the power supply voltage exceeds V_{Z1} + 1.4 V.

Figure 6. Configuration for Programmable Duration of Overvoltage Condition Before Trip/With Immediate Trip at High Overvoltages



Additional Features

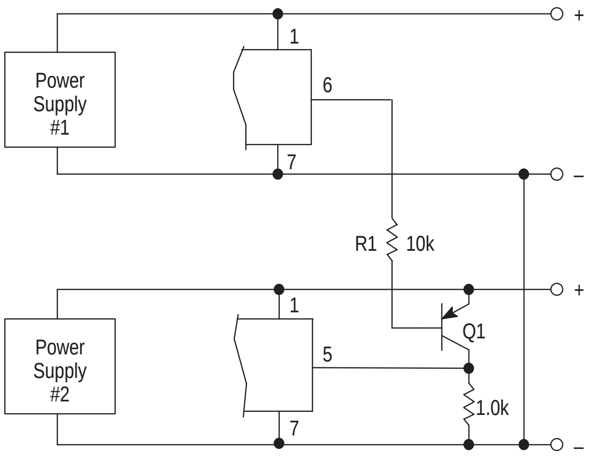
1. Activation Indication Output

An additional output for use as an indicator of OVP activation is provided by the MC3423. This output is an open collector transistor which saturates when the OVP is activated. In addition, it can be used to clock an edge triggered flip–flop whose output inhibits or shuts down the power supply when the OVP trips. This reduces or eliminates the heatsinking requirements for the crowbar SCR.

2. Remote Activation Input

Another feature of the MC3423 is its remote activation input, Pin 5. If the voltage on this CMOS/TTL compatible input is held below 0.8 V, the MC3423 operates normally. However, if it is raised to a voltage above 2.0 V, the OVP output is activated independent of whether or not an overvoltage condition is present. It should be noted that Pin 5 has an internal pull–up current source. This feature can be used to accomplish an orderly and sequenced shutdown of system power supplies during a system fault condition. In addition, the activation indication output of one MC3423 can be used to activate another MC3423 if a single transistor inverter is used to interface the former's indication output to the latter's remote activation input, as shown in Figure 7. In this circuit, the indication output (Pin 6) of the MC3423 on power supply 1 is used to activate the MC3423 associated with power supply 2. Q1 is any small PNP with adequate voltage rating.

Figure 7. Circuit Configuration for Activating One MC3423 from Another



Note that both supplies have their negative output leads tied together (i.e., both are positive supplies). If their positive leads are common (two negative supplies) the emitter of Q1 would be moved to the positive lead of supply 1 and R1 would therefore have to be resized to deliver the appropriate drive to Q1.

Crowbar SCR Considerations

Referring to Figure 11, it can be seen that the crowbar SCR, when activated, is subject to a large current surge from the output capacitance, C_{out}. This capacitance consists of the power supply output caps, the load's decoupling caps, and in the case of Figure 11A, the supply's input filter caps. This surge current is illustrated in Figure 12, and can cause SCR failure or degradation by any one of three mechanisms: di/dt, absolute peak surge, or I^2t. The interrelationship of these failure methods and the breadth of the applications make specification of the SCR by the semiconductor manufacturer difficult and expensive. Therefore, the designer must empirically determine the SCR and circuit elements which result in reliable and effective OVP operation. However, an understanding of the factors which influence the SCR's di/dt and surge capabilities simplifies this task.

di/dt

As the gate region of the SCR is driven on, its area of conduction takes a finite amount of time to grow, starting as a very small region and gradually spreading. Since the anode current flows through this turned–on gate region, very high current densities can occur in the gate region if high anode currents appear quickly (di/dt). This can result in immediate destruction of the SCR or gradual degradation of its forward blocking voltage capabilities – depending on the severity of the occasion.

Figure 12. Crowbar SCR Surge Current Waveform

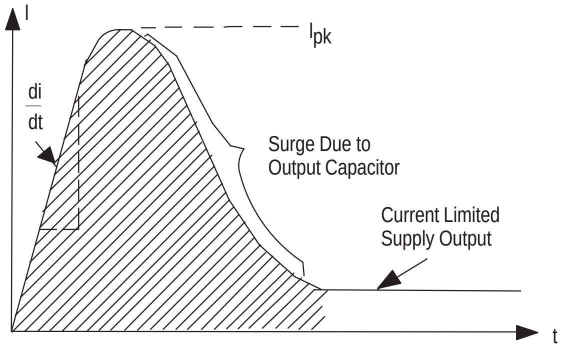

Figure 13. Circuit Elements Affecting SCR Surge and di/dt

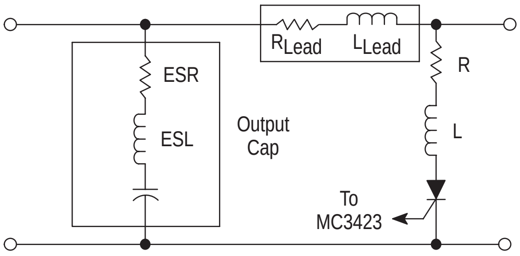

R & L EMPIRICALLY DETERMINED!

The usual design compromise then is to use a garden variety fuse (3AG or 3AB style) which cannot be relied on to blow before the thyristor does, and trust that if the SCR does fail, it will fail short circuit. In the majority of the designs, this will be the case, though this is difficult to guarantee. Of course, a sufficiently high surge will cause an open. These comments also apply to the fuse in Figure 11B.

The value of di/dt that an SCR can safely handle is influenced by its construction and the characteristics of the gate drive signal. A center–gate–fire SCR has more di/dt capability than a corner–gate–fire type, and heavily overdriving (3 to 5 times I_{GT}) the SCR gate with a fast < 1.0 µs rise time signal will maximize its di/dt capability. A typical maximum number in phase control SCRs of less than 50 A(RMS) rating might be 200 A/µs, assuming a gate current of five times I_{GT} and < 1.0 µs rise time. If having done this, a di/dt problem is seen to still exist, the designer can also decrease the di/dt of the current waveform by adding inductance in series with the SCR, as shown in Figure 13. Of course, this reduces the circuit's ability to rapidly reduce the DC bus voltage and a tradeoff must be made between speedy voltage reduction and di/dt.

Surge Current

If the peak current and/or the duration of the surge is excessive, immediate destruction due to device overheating will result. The surge capability of the SCR is directly proportional to its die area. If the surge current cannot be reduced (by adding series resistance – see Figure 13) to a safe level which is consistent with the systems requirements for speedy bus voltage reduction, the designer must use a higher current SCR. This may result in the average current capability of the SCR exceeding the steady state current requirements imposed by the DC power supply.

A WORD ABOUT FUSING

Before leaving the subject of the crowbar SCR, a few words about fuse protection are in order. Referring back to Figure 11A, it will be seen that a fuse is necessary if the power supply to be protected is not output current limited. This fuse is not meant to prevent SCR failure but rather to prevent a fire!

In order to protect the SCR, the fuse would have to possess an I^2t rating less than that of the SCR and yet have a high enough continuous current rating to survive normal supply output currents. In addition, it must be capable of successfully clearing the high short circuit currents from the supply. Such a fuse as this is quite expensive, and may not even be available.

CIRCUIT DESCRIPTION

The MC3425 is a power supply supervisory circuit containing all the necessary functions required to monitor over and undervoltage fault conditions. The block diagram is shown below in Figure 15. The Overvoltage (O.V.) and Undervoltage (U.V.) Input Comparators are both referenced to an internal 2.5 V regulator. The U.V. Input Comparator has a feedback activated 12.5 µA current sink (I_H) which is used for programming the input hysteresis voltage (V_H). The source resistance feeding this input (R_H) determines the amount of hysteresis voltage by $V_H = I_H R_H = 12.5 \times 10^{-6} R_H$.

Separate Delay pins (O.V. DLY, U.V. DLY.) are provided for each channel to independently delay the Drive and Indicator outputs, thus providing greater input noise immunity. The two Delay pins are essentially the outputs of the respective input comparators, and provide a constant current source, $I_{DLY(source)}$, of typically 200 µA when the noninverting input voltage is greater than the inverting input level. A capacitor connected from these Delay pins to ground, will establish a predictable delay time (t_{DLY}) for the Drive and Indicator outputs. The Delay pins are internally connected to the noninverting inputs of the O.V. and U.V. Output Comparators, which are referenced to the internal 2.5 V regulator. Therefore, delay time (t_{DLY}) is based on the constant current source, $I_{DLY(source)}$, charging the external delay capacitor (C_{DLY}) to 2.5 V.

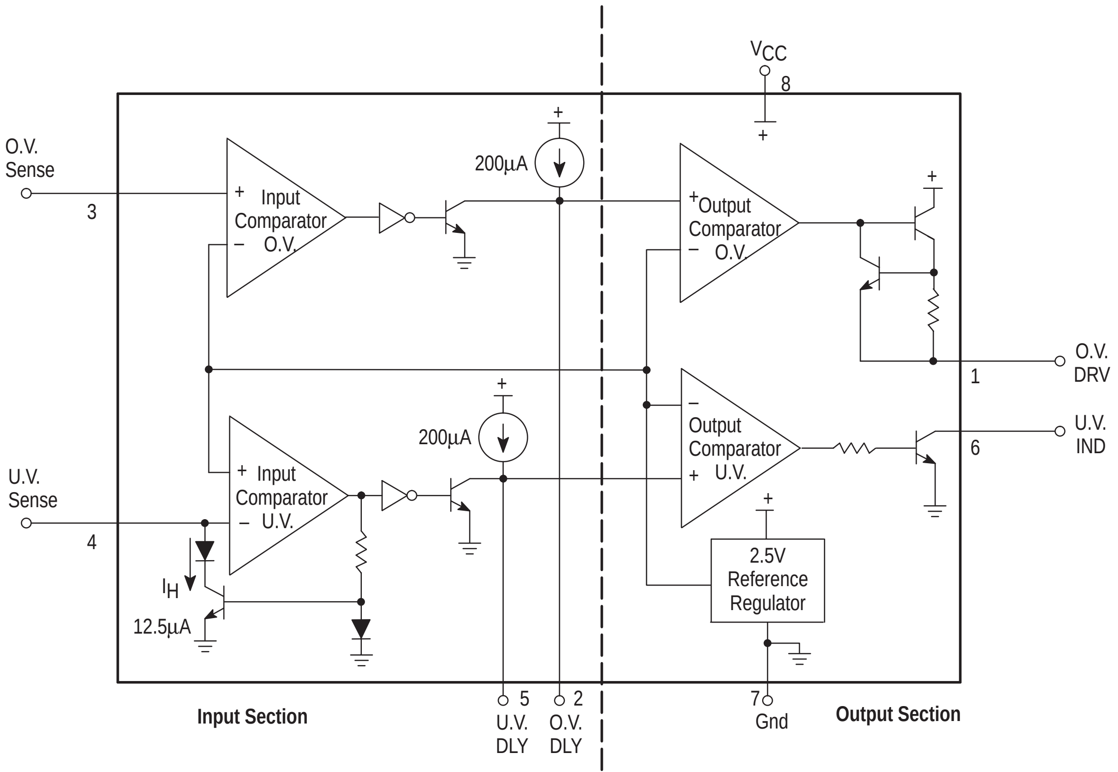
$$t_{DLY} = \frac{V_{ref}\, C_{DLY}}{I_{DLY(source)}} = \frac{2.5\, C_{DLY}}{200\ \mu A} = 12500\, C_{DLY}$$

Figure 5 provides C_{DLY} values for a wide range of time delays. The Delay pins are pulled low when the respective input comparator's noninverting input is less than the inverting input. The sink current, $I_{DLY(sink)}$, capability of the Delay pins is ≥ 1.8 mA and is much greater than the typical 200 µA source current, thus enabling a relatively fast delay capacitor discharge time.

The Overvoltage Drive Output is a current–limited emitter–follower capable of sourcing 300 mA at a turn–on slew rate at 2.0 A/µs, ideal for driving "Crowbar" SCR's. The Undervoltage Indicator Output is an open–collector, NPN transistor, capable of sinking 30 mA to provide sufficient drive for LED's, small relays or shut–down circuitry. These current capabilities apply to both channels operating simultaneously, providing device power dissipation limits are not exceeded.

The MC3425 has an internal 2.5 V bandgap reference regulator with an accuracy of ± 4.0% for the basic device.

Figure 15. Representative Block Diagram



Note: All voltages and currents are nominal.

CROWBAR SCR CONSIDERATIONS

Referring to Figure 16, it can be seen that the crowbar SCR, when activated, is subject to a large current surge from the output capacitance, C_{out}. This capacitance consists of the power supply output capacitors, the load's decoupling capacitors, and in the case of Figure 16A, the supply's input filter capacitors. This surge current is illustrated in Figure 17, and can cause SCR failure or degradation by any one of three mechanisms: di/dt, absolute peak surge, or I^2t. The interrelationship of these failure methods and the breadth of the applications make specification of the SCR by the semiconductor manufacturer difficult and expensive. Therefore, the designer must empirically determine the SCR and circuit elements which result in reliable and effective OVP operation. However, an understanding of the factors which influence the SCR's di/dt and surge capabilities simplifies this task.

1. di/dt

As the gate region of the SCR is driven on, its area of conduction takes a finite amount of time to grow, starting as a very small region and gradually spreading. Since the anode current flows through this turned–on gate region, very high current densities can occur in the gate region if high anode currents appear quickly (di/dt). This can result in immediate destruction of the SCR or gradual degradation of its forward blocking voltage capabilities – depending on the severity of the occasion.

The value of di/dt that an SCR can safely handle is influenced by its construction and the characteristics of the gate drive signal. A center–gate–fire SCR has more di/dt capability than a corner–gate–fire type, and heavily overdriving (3 to 5 times I_{GT}) the SCR gate with a fast < 1.0 µs rise time signal will maximize its di/dt capability. A typical maximum number in phase control SCRs of less than 50 A(RMS) rating might be 200 A/µs, assuming a gate current of five times I_{GT} and < 1.0 µs rise time. If having done this, a di/dt problem is seen to still exist, the designer can also decrease the di/dt of the current waveform by adding inductance in series with the SCR, as shown in Figure 18. Of course, this reduces the circuit's ability to rapidly reduce the dc bus voltage and a tradeoff must be made between speedy voltage reduction and di/dt.

2. Surge Current

If the peak current and/or the duration of the surge is excessive, immediate destruction due to device overheating will result. The surge capability of the SCR is directly proportional to its die area. If the surge current cannot be reduced (by adding series resistance – see Figure 18) to a safe level which is consistent with the system's requirements for speedy bus voltage reduction, the designer must use a higher current SCR. This may result in the average current capability of the SCR exceeding the steady state current requirements imposed by the DC power supply.

R & L EMPIRICALLY DETERMINED!

UNDERVOLTAGE SENSING

An undervoltage sense circuit with hysteresis may be designed, as shown in Figure 11, using the following equations:

$$R1 = \frac{V_{CCU} - V_{CC1}}{12.5\ \mu A}$$

$$R2 = \frac{2.5\ R1}{V_{CC1} - 2.5}$$

where: V_{CCU} is the designed upper trip point (output indicator goes off)
V_{CC1} is the lower trip point (output indicator goes on)

A WORD ABOUT FUSING

Before leaving the subject of the crowbar SCR, a few words about fuse protection are in order. Referring back to Figure 16A, it will be seen that a fuse is necessary if the power supply to be protected is not output current limited. This fuse is not meant to prevent SCR failure but rather to prevent a fire!

In order to protect the SCR, the fuse would have to possess an I^2t rating less than that of the SCR and yet have a high enough continuous current rating to survive normal supply output currents. In addition, it must be capable of successfully clearing the high short circuit currents from the supply. Such a fuse as this is quite expensive, and may not even be available.

The usual design compromise then is to use a garden variety fuse (3AG or 3AB style) which cannot be relied on to blow before the thyristor does, and trust that if the SCR does fail, it will fail short circuit. In the majority of the designs, this will be the case, though this is difficult to guarantee. Of course, a sufficiently high surge will cause an open. These comments also apply to the fuse in Figure 16B.

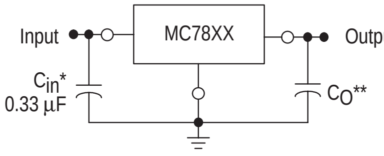
STANDARD APPLICATION



A common ground is required between the input and the output voltages. The input voltage must remain typically 2.0 V above the output voltage even during the low point on the input ripple voltage.

XX, These two digits of the type number indicate nominal voltage.

* C_{in} is required if regulator is located an appreciable distance from power supply filter.

** C_O is not needed for stability; however, it does improve transient response. Values of less than 0.1 µF could cause instability.

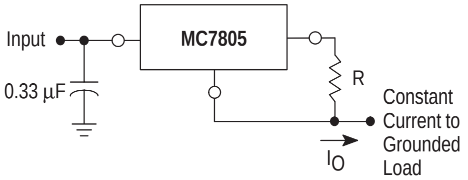
APPLICATIONS INFORMATION

Design Considerations

The MC7800 Series of fixed voltage regulators are designed with Thermal Overload Protection that shuts down the circuit when subjected to an excessive power overload condition, Internal Short Circuit Protection that limits the maximum current the circuit will pass, and Output Transistor Safe–Area Compensation that reduces the output short circuit current as the voltage across the pass transistor is increased.

In many low current applications, compensation capacitors are not required. However, it is recommended that the regulator input be bypassed with a capacitor if the regulator is connected to the power supply filter with long wire lengths, or if the output load capacitance is large. An input bypass capacitor should be selected to provide good high–frequency characteristics to insure stable operation under all load conditions. A 0.33 µF or larger tantalum, mylar, or other capacitor having low internal impedance at high frequencies should be chosen. The bypass capacitor should be mounted with the shortest possible leads directly across the regulators input terminals. Normally good construction techniques should be used to minimize ground loops and lead resistance drops since the regulator has no external sense lead.

Figure 7. Current Regulator



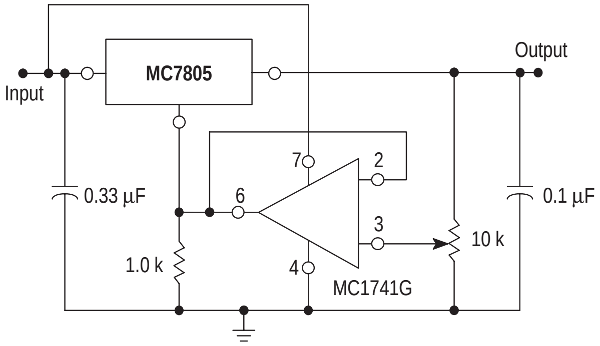
The MC7800 regulators can also be used as a current source when connected as above. In order to minimize dissipation the MC7805C is chosen in this application. Resistor R determines the current as follows:

$$I_O = \frac{5.0\ V}{R} + I_B$$

$I_B \cong$ 3.2 mA over line and load changes.

For example, a 1.0 A current source would require R to be a 5.0 Ω, 10 W resistor and the output voltage compliance would be the input voltage less 7.0 V.

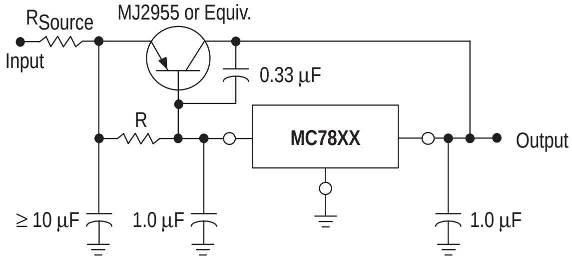
Figure 8. Adjustable Output Regulator



V_O = 7.0 V to 20 V
$V_{IN} = V_O \geq 2.0$ V

The addition of an operational amplifier allows adjustment to higher or intermediate values while retaining regulation characteristics. The minimum voltage obtainable with this arrangement is 2.0 V greater than the regulator voltage.

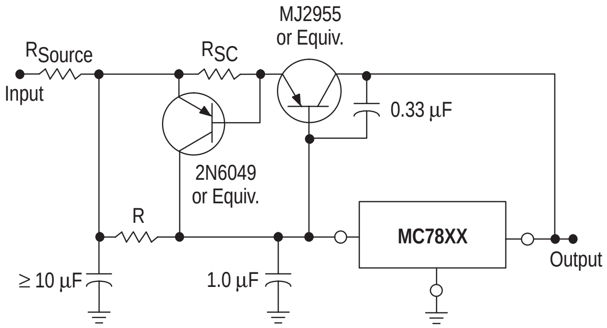
Figure 9. Current Boost Regulator



XX = 2 digits of type number indicating voltage.

The MC7800 series can be current boosted with a PNP transistor. The MJ2955 provides current to 5.0 A. Resistor R in conjunction with the V_{BE} of the PNP determines when the pass transistor begins conducting; this circuit is not short circuit proof. Input/output differential voltage minimum is increased by V_{BE} of the pass transistor.

Figure 10. Short Circuit Protection



XX = 2 digits of type number indicating voltage.

The circuit of Figure 9 can be modified to provide supply protection against short circuits by adding a short circuit sense resistor, R_{SC}, and an additional PNP transistor. The current sensing PNP must be able to handle the short circuit current of the three–terminal regulator. Therefore, a four–ampere plastic power transistor is specified.

DEFINITIONS

Line Regulation – The change in output voltage for a change in the input voltage. The measurement is made under conditions of low dissipation or by using pulse techniques such that the average chip temperature is not significantly affected.

Load Regulation – The change in output voltage for a change in load current at constant chip temperature.

Maximum Power Dissipation – The maximum total device dissipation for which the regulator will operate within specifications.

Quiescent Current – That part of the input current that is not delivered to the load.

Output Noise Voltage – The rms AC voltage at the output, with constant load and no input ripple, measured over a specified frequency range.

Long Term Stability – Output voltage stability under accelerated life test conditions with the maximum rated voltage listed in the devices' electrical characteristics and maximum power dissipation.

MOTOROLA

MC78L00, A Series

Three-Terminal Low Current Positive Voltage Regulators

The MC78L00, A Series of positive voltage regulators are inexpensive, easy–to–use devices suitable for a multitude of applications that require a regulated supply of up to 100 mA. Like their higher powered MC7800 and MC78M00 Series cousins, these regulators feature internal current limiting and thermal shutdown making them remarkably rugged. No external components are required with the MC78L00 devices in many applications.

These devices offer a substantial performance advantage over the traditional zener diode–resistor combination, as output impedance and quiescent current are substantially reduced.

- Wide Range of Available, Fixed Output Voltages
- Low Cost
- Internal Short Circuit Current Limiting
- Internal Thermal Overload Protection
- No External Components Required
- Complementary Negative Regulators Offered (MC79L00 Series)
- Available in either ±5% (AC) or ±10% (C) Selections

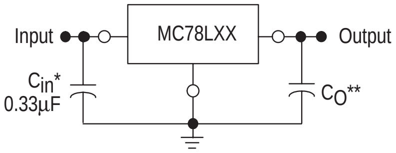
* SOP–8 is an internally modified SO–8 package. Pins 2, 3, 6, and 7 are electrically common to the die attach flag. This internal lead frame modification decreases package thermal resistance and increases power dissipation capability when appropriately mounted on a printed circuit board. SOP–8 conforms to all external dimensions of the standard SO–8 package.

Standard Application



A common ground is required between the input and the output voltages. The input voltage must remain typically 2.0 V above the output voltage even during the low point on the input ripple voltage.

*C_{in} is required if regulator is located an appreciable distance from power supply filter.

**C_O is not needed for stability; however, it does improve transient response.

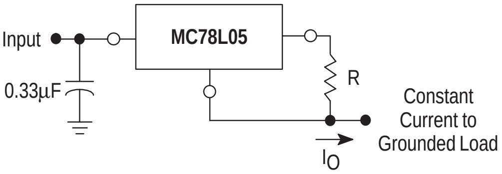
APPLICATIONS INFORMATION

Design Considerations

The MC78L00 Series of fixed voltage regulators are designed with Thermal Overload Protection that shuts down the circuit when subjected to an excessive power overload condition. Internal Short Circuit Protection limits the maximum current the circuit will pass.

In many low current applications, compensation capacitors are not required. However, it is recommended that the regulator input be bypassed with a capacitor if the regulator is connected to the power supply filter with long wire lengths, or if the output load capacitance is large. The input bypass capacitor should be selected to provide good high–frequency characteristics to insure stable operation under all load conditions. A 0.33 µF or larger tantalum, mylar, or other capacitor having low internal impedance at high frequencies should be chosen.The bypass capacitor should be mounted with the shortest possible leads directly across the regulators input terminals. Good construction techniques should be used to minimize ground loops and lead resistance drops since the regulator has no external sense lead. Bypassing the output is also recommended.

Figure 7. Current Regulator



The MC78L00 regulators can also be used as a current source when connected as above. In order to minimize dissipation the MC78L05C is chosen in this application. Resistor R determines the current as follows:

$$I_O = \frac{5.0\ V}{R} + I_B$$

I_{IB} = 3.8 mA over line and load changes

For example, a 100 mA current source would require R to be a 50 Ω, 1/2 W resistor and the output voltage compliance would be the input voltage less 7 V.

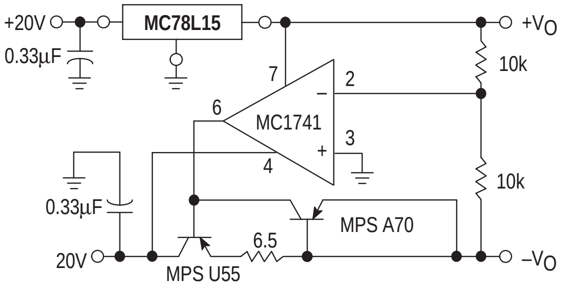

Figure 9. Positive and Negative Regulator

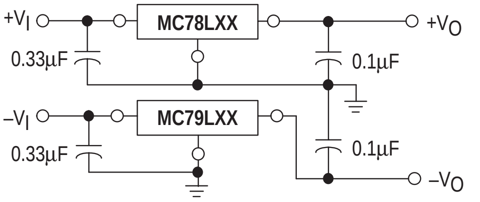


MOTOROLA

MC78M00 Series

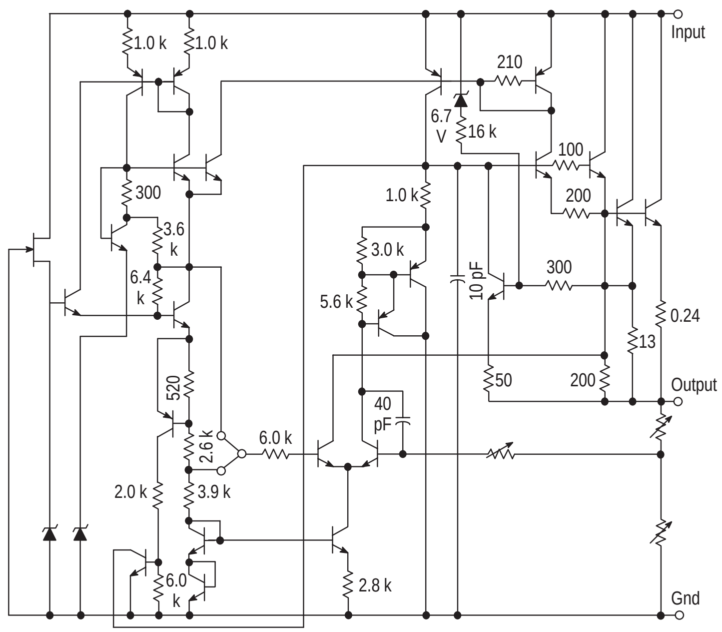
Three-Terminal Medium Current Positive Voltage Regulators

The MC78M00 Series positive voltage regulators are identical to the popular MC7800 Series devices, except that they are specified for only half the output current. Like the MC7800 devices, the MC78M00 three–terminal regulators are intended for local, on–card voltage regulation.

Internal current limiting, thermal shutdown circuitry and safe–area compensation for the internal pass transistor combine to make these devices remarkably rugged under most operating conditions. Maximum output current, with adequate heatsinking is 500 mA.

- No External Components Required
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting
- Output Transistor Safe–Area Compensation

Representative Schematic Diagram



This device contains 28 active transistors.

DEFINITIONS

Line Regulation – The change in output voltage for a change in the input voltage. The measurement is made under conditions of low dissipation or by using pulse techniques such that the average chip temperature is not significantly affected.

Load Regulation – The change in output voltage for a change in load current at constant chip temperature.

Maximum Power Dissipation – The maximum total device dissipation for which the regulator will operate within specifications.

Input Bias Current – That part of the input current that is not delivered to the load.

Output Noise Voltage – The rms AC voltage at the output, with constant load and no input ripple, measured over a specified frequency range.

Long Term Stability – Output voltage stability under accelerated life test conditions with the maximum rated voltage listed in the devices' electrical characteristics and maximum power dissipation.

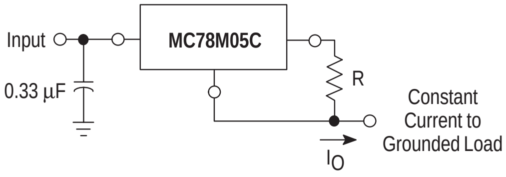
APPLICATIONS INFORMATION

Design Considerations

The MC78M00 Series of fixed voltage regulators are designed with Thermal Overload Protection that shuts down the circuit when subjected to an excessive power overload condition, Internal Short Circuit Protection that limits the maximum current the circuit will pass, and Output Transistor Safe–Area Compensation that reduces the output short circuit current as the voltage across the pass transistor is increased.

In many low current applications, compensation capacitors are not required. However, it is recommended that the regulator input be bypassed with a capacitor if the regulator is connected to the power supply filter with long wire lengths, or if the output load capacitance is large. An input bypass capacitor should be selected to provide good high frequency characteristics to insure stable operation under all load conditions. A 0.33 μF or larger tantalum, mylar, or other capacitor having low internal impedance at high frequencies should be chosen. The bypass capacitor should be mounted with the shortest possible leads directly across the regulator's input terminals. Normally good construction techniques should be used to minimize ground loops and lead resistance drops since the regulator has no external sense lead.

Figure 9. Current Regulator



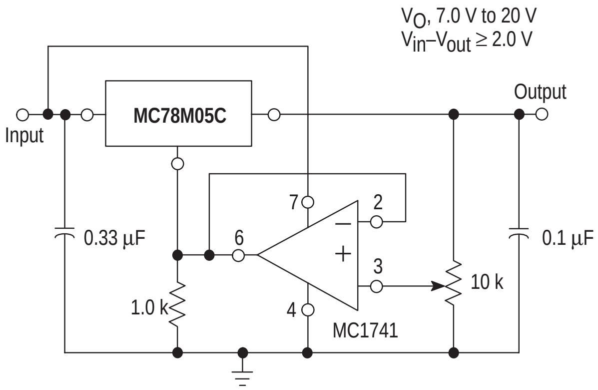
The MC78M00 regulators can also be used as a current source when connected as above. In order to minimize dissipation the MC78M05C is chosen in this application. Resistor R determines the current as follows:

$$I_O = \frac{5.0\ V}{R} + I_{IB}$$

I_{IB} = 1.5 mA over line and load changes.

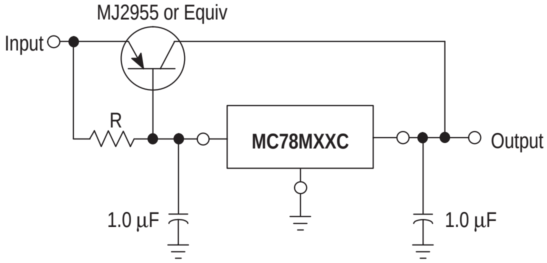
For example, a 500 mA current source would require R to be a 5.0 Ω, 10 W resistor and the output voltage compliance would be the input voltage less 7 V.

Figure 10. Adjustable Output Regulator



The addition of an operational amplifier allows adjustment to higher or intermediate values while retaining regulation characteristics. The minimum voltage obtainable with this arrangement is 2.0 V greater than the regulator voltage.

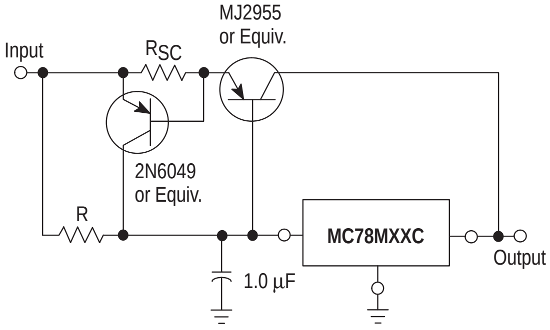
Figure 11. Current Boost Regulator



XX = 2 digits of type number indicating voltage.

The MC78M00 series can be current boosted with a PNP transistor. The MJ2955 provides current to 5.0 A. Resistor R in conjunction with the V_{BE} of the PNP determines when the pass transistor begins conducting; this circuit is not short circuit proof. Input–output differential voltage minimum is increased by V_{BE} of the pass transistor.

Figure 12. Current Boost with Short Circuit Protection



XX = 2 digits of type number indicating voltage.

The circuit of Figure 10 can be modified to provide supply protection against short circuits by adding a short circuit sense resistor, R_{SC}, and an additional PNP transistor. The current sensing PNP must be able to handle the short circuit current of the three–terminal regulator .Therefore, a 4 A plastic power transistor is specified.

MOTOROLA

MC78T00
Series

Three-Ampere Positive Voltage Regulators

This family of fixed voltage regulators are monolithic integrated circuits capable of driving loads in excess of 3.0 A. These three–terminal regulators employ internal current limiting, thermal shutdown, and safe–area compensation. Devices are available with improved specifications, including a 2% output voltage tolerance, on AC–suffix 5.0, 12 and 15 V device types.

Although designed primarily as a fixed voltage regulator, these devices can be used with external components to obtain adjustable voltages and currents. This series of devices can be used with a series–pass transistor to supply up to 15 A at the nominal output voltage.

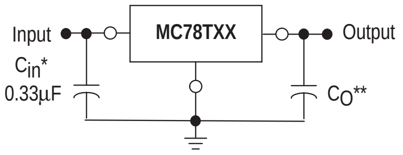
- Output Current in Excess of 3.0 A
- Power Dissipation: 25 W
- No External Components Required
- Output Voltage Offered in 2% and 4% Tolerance*
- Thermal Regulation is Specified
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting
- Output Transistor Safe–Area Compensation

MAXIMUM RATINGS (T_A = +25°C, unless otherwise noted.)

Rating	Symbol	Value	Unit
Input Voltage (5.0 V – 12 V) (15 V)	V_I	35 40	Vdc
Power Dissipation and Thermal Characteristics Plastic Package (Note 1) T_A = +25°C Thermal Resistance, Junction–to–Air T_C = +25°C Thermal Resistance, Junction–to–Case	 P_D $R_{\theta JA}$ P_D $R_{\theta JC}$	 Internally Limited 65 Internally Limited 2.5	 °C/W °C/W
Storage Junction Temperature	T_{stg}	+150	°C
Operating Junction Temperature Range (MC78T00C, AC)	T_J	0 to +125	°C

NOTES: 1. Although power dissipation is internally limited, specifications apply only for $P_O \le P_{max}$, P_{max} = 25 W.

Simplified Application



A common ground is required between the input and the output voltages. The input voltage must remain typically 2.2 V above the output voltage even during the low point on the input ripple voltage.

XX these two digits of the type number indicate voltage.

* C_{in} is required if regulator is located an appreciable distance from power supply filter. (See Applications Information for details.)

** C_O is not needed for stability; however, it does improve transient response.

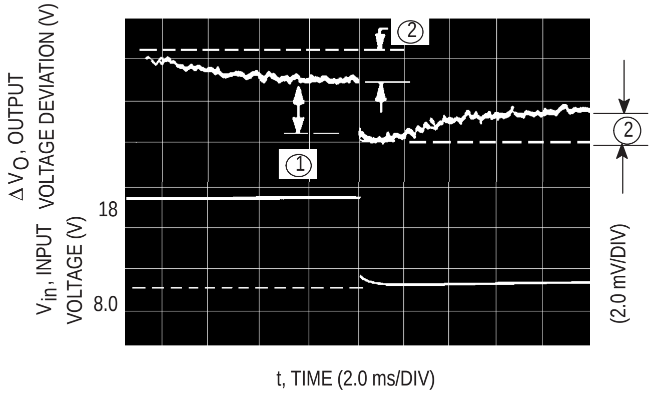
VOLTAGE REGULATOR PERFORMANCE

The performance of a voltage regulator is specified by its immunity to changes in load, input voltage, power dissipation, and temperature. Line and load regulation are tested with a pulse of short duration (< 100µs) and are strictly a function of electrical gain. However, pulse widths of longer duration (> 1.0 ms) are sufficient to affect temperature gradients across the die. These temperature gradients can cause a change in the output voltage, in addition to changes caused by line and load regulation. Longer pulse widths and thermal gradients make it desirable to specify thermal regulation.

Thermal regulation is defined as the change in output voltage caused by a change in dissipated power for a specified time, and is expressed as a percentage output voltage change per watt. The change in dissipated power can be caused by a change in either the input voltage or the load current. Thermal regulation is a function of IC layout and die attach techniques, and usually occurs within 10 ms of a change in power dissipation. After 10 ms, additional changes in the output voltage are due to the temperature coefficient of the device.

Figure 1 shows the line and thermal regulation response of a typical MC78T05AC to a 20 W input pulse. The variation of the output voltage due to line regulation is labeled ① and the thermal regulation component is labeled ②. Figure 2 shows the load and thermal regulation response of a typical MC78T05AC to a 20 W load pulse. The output voltage variation due to load regulation is labeled ① and the thermal regulation component is labeled ②.

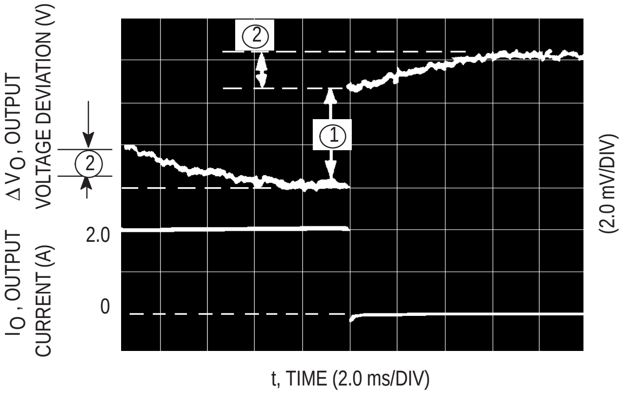
Figure 1. MC78T05AC Line and Thermal Regulation



V_{out} = 5.0 V
V_{in} = 8.0 V → 18 V → 8.0 V
I_{out} = 2.0 A

① = Reg_{line} = 2.4 mV
② = Reg_{therm} = 0.0015%V_O/W

Figure 2. MC78T05AC Load and Thermal Regulation



V_{out} = 5.0 V
V_{in} = 15
I_{out} = 0 A → 2.0 A → 0 A

① = Reg_{line} = 4.4 mV
② = Reg_{therm} = 0.0015%V_O/W

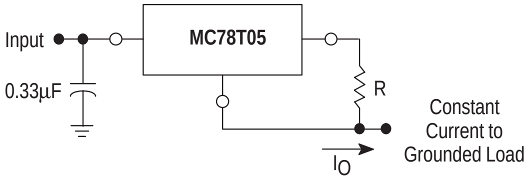
APPLICATIONS INFORMATION

Design Considerations

The MC78T00 Series of fixed voltage regulators are designed with Thermal Overload Protection that shuts down the circuit when subjected to an excessive power overload condition, Internal Short Circuit Protection that limits the maximum current the circuit will pass, and Output Transistor Safe–Area Compensation that reduces the output short circuit current as the voltage across the pass transistor is increased.

In many low current applications, compensation capacitors are not required. However, it is recommended that the regulator input be bypassed with a capacitor if the regulator is connected to the power supply filter with long wire lengths, or if the output load capacitance is large. An input bypass capacitor should be selected to provide good high frequency characteristics to insure stable operation under all load conditions. A 0.33 µF or larger tantalum, mylar, or other capacitor having low internal impedance at high frequencies should be chosen. The bypass capacitor should be mounted with the shortest possible leads directly across the regulator's input terminals. Normally good construction techniques should be used to minimize ground loops and lead resistance drops since the regulator has no external sense lead.

Figure 14. Current Regulator



The MC78T05 regulator can also be used as a current source when connected as above. In order to minimize dissipation the MC78T05 is chosen in this application. Resistor R determines the current as follows:

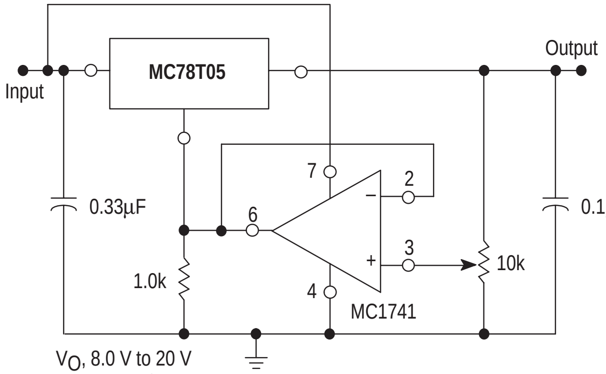
$$I_O = \frac{5.0\ V}{R} + I_B$$

$\Delta I_B \cong$ 0.7 mA over line, load and Temperature changes

$I_B \cong$ 3.5 mA

For example, a 2.0 A current source would require R to be a 2.5 Ω, 10 W resistor and the output voltage compliance would be the input voltage less 7.0 V.

Figure 15. Adjustable Output Regulator

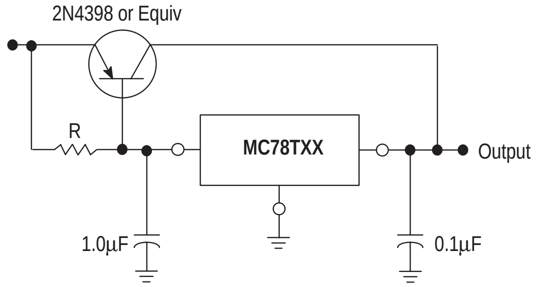


V_O, 8.0 V to 20 V

$V_{in} - V_O \geq 2.5$ V

The addition of an operational amplifier allows adjustment to higher or intermediate values while retaining regulation characteristics. The minimum voltage obtainable with this arrangement is 3.0 V greater than the regulator voltage.

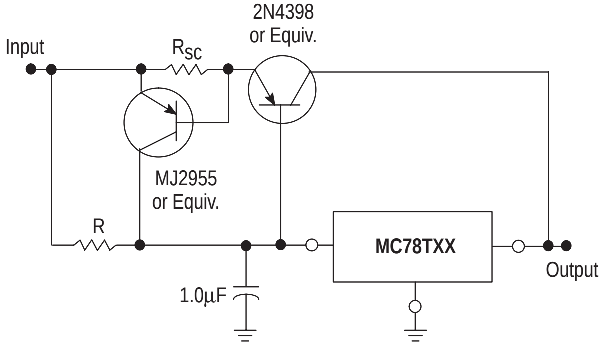
Figure 16. Current Boost Regulator



XX = 2 digits of type number indicating voltage.

The MC78T00 series can be current boosted with a PNP transistor. The 2N4398 provides current to 15 A. Resistor R in conjuction with the V_{BE} of the PNP determines when the pass transistor begins conducting; this circuit is not short circuit proof. Input–output differential voltage minimum is increased by the V_{BE} of the pass transistor.

Figure 17. Current Boost With Short Circuit Protection



XX = 2 digits of type number indicating voltage.

The circuit of Figure 17 can be modified to provide supply protection against short circuits by adding a short circuit sense resistor, R_{SC}, and an additional PNP transistor. The current sensing PNP must be able to handle the short circuit current of the three–terminal regulator. Therefore, an eight–ampere power transistor is specified.

Micropower Voltage Regulator

The MC78BC00 voltage regulators are specifically designed to be used with an external power transistor to deliver high current with high voltage accuracy and low quiescent current.

The MC78BC00 series are devices suitable for constructing regulators with ultra–low dropout voltage and output current in the range of several tens of mA to hundreds of mA. These devices have a chip enable function, which minimizes the standby mode current drain. Each of these devices contains a voltage reference unit, an error amplifier, a driver transistor and resistors. These devices are available in the SOT–23, 5 pin surface mount packages.

These devices are ideally suited for battery powered equipment, and power sources for hand–held audio instruments, communication equipment and domestic appliances.

MC78BC00 Series Features:

- Ultra–Low Supply Current (50 µA)
- Standby Mode (0.2 µA)
- Ultra–Low Dropout Voltage (0.1 V with External Transistor and I_O = 100 mA)
- Excellent Line Regulation (Typically 0.1%/V)
- High Accuracy Output Voltage (±2.5%)

ORDERING INFORMATION

Device	Output Voltage	Operating Temperature Range	Package
MC78BC30NTR	3.0	T_A = –30° to +80°C	SOT–23
MC78BC33NTR	3.3		
MC78BC40NTR	4.0		
MC78BC50NTR	5.0		

Other voltages from 2.0 to 6.0 V, in 0.1 V increments, are available upon request. Consult your local Motorola sales office for information.

Micropower Voltage Regulator

The MC78FC00 series voltage regulators are specifically designed for use as a power source for video instruments, handheld communication equipment, and battery powered equipment.

The MC78FC00 series voltage regulator ICs feature a high accuracy output voltage and ultra–low quiescent current. Each device contains a voltage reference unit, an error amplifier, a driver transistor, and resistors for setting output voltage, and a current limit circuit. These devices are available in SOT–89 surface mount packages, and allow construction of an efficient, constant voltage power supply circuit.

MC78FC00 Series Features:

- Ultra–Low Quiescent Current of 1.1 µA Typical
- Ultra–Low Dropout Voltage (0.5 V Typical)
- Large Output Current (120 mA Typical)
- Excellent Line Regulation (0.1%)
- Wide Operating Voltage Range (2.0 V to 10 V)
- High Accuracy Output Voltage (±2.5%)
- Wide Output Voltage Range (2.0 V to 6.0 V)
- Surface Mount Package (SOT–89)

Micropower Voltage Regulator

The MC78LC00 series voltage regulators are specifically designed for use as a power source for video instruments, handheld communication equipment, and battery powered equipment.

The MC78LC00 series features an ultra–low quiescent of 1.1 µA and a high accuracy output voltage. Each device contains a voltage reference, an error amplifier, a driver transistor and resistors for setting the output voltage. These devices are available in either SOT–89, 3 pin, or SOT–23, 5 pin, surface mount packages.

MC78LC00 Series Features:

- Low Quiescent Current of 1.1 µA Typical
- Low Dropout Voltage (30 mV Typical)
- Excellent Line Regulation (0.1%)
- High Accuracy Output Voltage (±2.5%)
- Wide Output Voltage Range (2.0 V to 6.0 V)
- Output Current for Low Power (80 mA Typical)
- Two Surface Mount Packages (SOT–89, 3 Pin, or SOT–23, 5 Pin)

MC7900 Series

Three-Terminal Negative Voltage Regulators

The MC7900 series of fixed output negative voltage regulators are intended as complements to the popular MC7800 series devices. These negative regulators are available in the same seven–voltage options as the MC7800 devices. In addition, one extra voltage option commonly employed in MECL systems is also available in the negative MC7900 series.

Available in fixed output voltage options from –5.0 V to –24 V, these regulators employ current limiting, thermal shutdown, and safe–area compensation – making them remarkably rugged under most operating conditions. With adequate heatsinking they can deliver output currents in excess of 1.0 A.

- No External Components Required
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting
- Output Transistor Safe–Area Compensation
- Available in 2% Voltage Tolerance (See Ordering Information)

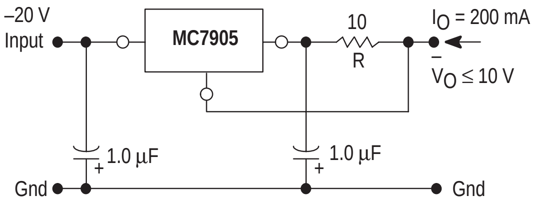
APPLICATIONS INFORMATION

Design Considerations

The MC7900 Series of fixed voltage regulators are designed with Thermal overload Protection that shuts down the circuit when subjected to an excessive power overload condition. Internal Short Circuit Protection that limits the maximum current the circuit will pass, and Output Transistor Safe–Area Compensation that reduces the output short circuit current as the voltage across the pass transistor is increased.

In many low current applications, compensation capacitors are not required. However, it is recommended that the regulator input be bypassed with a capacitor if the regulator is connected to the power supply filter with long wire lengths, or if the output load capacitance is large. An input bypass capacitor should be selected to provide good high–frequency characteristics to insure stable operation under all load conditions. A 0.33 µF or larger tantalum, mylar, or other capacitor having low internal impedance at high frequencies should be chosen. The capacitor chosen should have an equivalent series resistance of less than 0.7 Ω. The bypass capacitor should be mounted with the shortest possible leads directly across the regulators input terminals. Normally good construction techniques should be used to minimize ground loops and lead resistance drops since the regulator has no external sense lead. Bypassing the output is also recommended.

Figure 7. Current Regulator



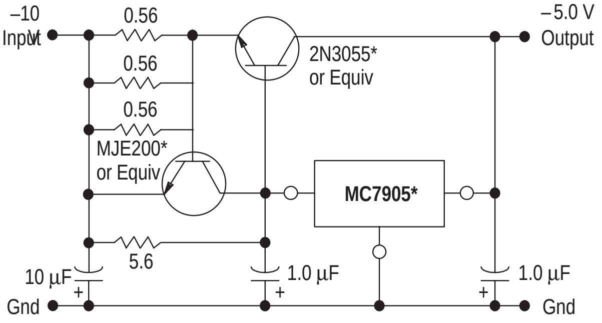
The MC7905, –5.0 V regulator can be used as a constant current source when connected as above. The output current is the sum of resistor R current and quiescent bias current as follows.

$$I_O = \frac{5.0\ V}{R} + I_B$$

The quiescent current for this regulator is typically 4.3 mA. The 5.0 V regulator was chosen to minimize dissipation and to allow the output voltage to operate to within 6.0 V below the input voltage.

Figure 8. Current Boost Regulator

(–5.0 V @ 4.0 A, with 5.0 A Current Limiting)

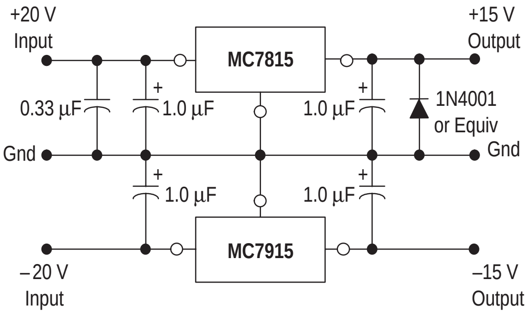


*Mounted on heatsink.

When a boost transistor is used, short circuit currents are equal to the sum of the series pass and regulator limits, which are measured at 3.2 A and 1.8 A respectively in this case. Series pass limiting is approximately equal to 0.6 V/R_{SC}. Operation beyond this point to the peak current capability of the MC7905C is possible if the regulator is mounted on a heatsink; otherwise thermal shutdown will occur when the additional load current is picked up by the regulator.

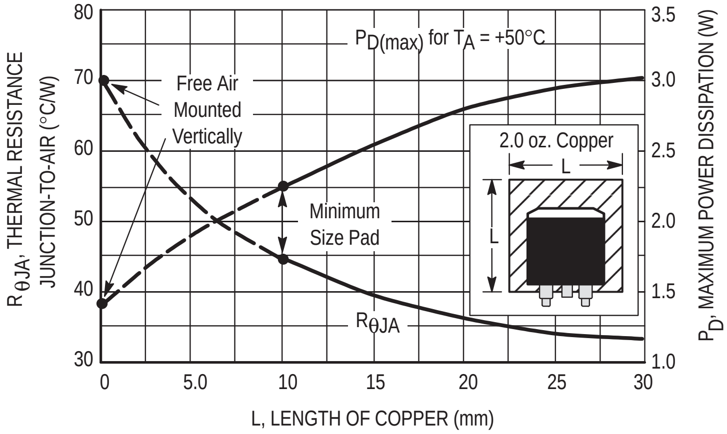
Figure 9. Operational Amplifier Supply

(±15 @ 1.0 A)



The MC7815 and MC7915 positive and negative regulators may be connected as shown to obtain a dual power supply for operational amplifiers. A clamp diode should be used at the output of the MC7815 to prevent potential latch–up problems whenever the output of the positive regulator (MC7815) is drawn below ground with an output current greater than 200 mA.

Figure 10. D^2PAK Thermal Resistance and Maximum Power Dissipation versus P.C.B. Copper Length



DEFINITIONS

Line Regulation – The change in output voltage for a change in the input voltage. The measurement is made under conditions of low dissipation or by using pulse techniques such that the average chip temperature is not significantly affected.

Load Regulation – The change in output voltage for a change in load current at constant chip temperature.

Maximum Power Dissipation – The maximum total device dissipation for which the regulator will operate within specifications.

Input Bias Current – That part of the input current that is not delivered to the load.

Output Noise Voltage – The rms AC voltage at the output, with constant load and no input ripple, measured over a specified frequency range.

Long Term Stability – Output voltage stability under accelerated life test conditions with the maximum rated voltage listed in the devices' electrical characteristics and maximum power dissipation.

MOTOROLA

MC79L00, A Series

Three-Terminal Low Current Negative Voltage Regulators

The MC79L00, A Series negative voltage regulators are inexpensive, easy–to–use devices suitable for numerous applications requiring up to100 mA. Like the higher powered MC7900 Series negative regulators, this series features thermal shutdown and current limiting, making them remarkably rugged. In most applications, no external components are required for operation.

The MC79L00 devices are useful for on–card regulation or any other application where a regulated negative voltage at a modest current level is needed. These regulators offer substantial advantage over the common resistor/zener diode approach.

- No External Components Required
- Internal Short Circuit Current Limiting
- Internal Thermal Overload Protection
- Low Cost
- Complementary Positive Regulators Offered (MC78L00 Series)
- Available in Either ±5% (AC) or ±10% (C) Selections

MOTOROLA

MC79M00 Series

Three-Terminal Negative Voltage Regulators

The MC79M00 series of fixed output negative voltage regulators are intended as complements to the popular MC78M00 series devices.

Available in fixed output voltage options of –5.0, –8.0, –12 and –15 V, these regulators employ current limiting, thermal shutdown, and safe–area compensation – making them remarkably rugged under most operating conditions. With adequate heatsinking they can deliver output currents in excess of 0.5 A.

- No External Components Required
- Internal Thermal Overload Protection
- Internal Short Circuit Current Limiting
- Output Transistor Safe–Area Compensation
- Also Available in Surface Mount DPAK (DT) Package

MC33128

Power Management Controller

POWER MANAGEMENT CONTROLLER

SEMICONDUCTOR TECHNICAL DATA

The MC33128 is a power management controller specifically designed for use in battery powered cellular telephone and pager applications. This device contains all of the active functions required to interface the user to the system electronics via a microprocessor. This integrated circuit consists of a low dropout voltage regulator with power–up reset for MPU power, two low dropout voltage regulators for independant powering of analog and digital circuitry, and a negative charge pump voltage regulator for full depletion of gallium arsenide MESFETs.

Also included are protective system shutdown features consisting of a battery latch that is activated upon battery insertion, low battery voltage shutdown, and a thermal over temperature detector. This device is available in a 16–pin narrow body surface mount plastic package.

- Three Positive Regulated Outputs Featuring Low Dropout Voltage
- Negative Regulated Output for Full Depletion of GaAs MESFETs
- MPU Power Up Reset
- Battery Latch
- Low Battery Shutdown
- Pinned–Out Reference for MPU A/D Converter
- Low Start–Up and Operating Current
- Thermal Protection

OPERATING DESCRIPTION

The MC33128 is a complete power management controller that is designed to interface the user to the system electronics via a microprocessor.

Outputs

Three low dropout voltage regulators are provided at outputs 1, 2 and 3. Outputs 1 and 2 were contemplated for independent powering of the systems analog and digital circuitry. This significantly reduces the possibility of digitally generated noise and spurious signals from coupling into the RF and analog circuits. The low dropout characteristic of Outputs 1 and 2 is achieved by applying a boosted battery voltage, V_{BB}, to their respective driver transistors. This allows the output pass transistors to be driven into saturation when the battery voltage approaches 3.0 V. The V_{BB} Output appears at Pin 4 and can be used to provide gate bias for enhancing external N channel MOSFET switches. Excessive loading of the V_{BB} output will result in an increase in dropout voltage.

Output 4 is derived from a voltage inverting charge pump circuit and is intended to provide the negative gate bias required for full depletion of RF gallium arsenide MESFETs. In personal communication system applications such as cellular telephone, negative gate bias is usually required by the antenna switch and power amplifier circuit blocks with a typical combined current of less than 1.0 mA. Output 4 can supply in excess of 2.0 mA, but there will be an increase in dropout voltage of Outputs 1, 2 and 3.

Outputs 1, 2, 4, V_{BB} Generator and Thermal Protection are all enabled and disabled in unison by the Battery Saver Input, Pin 9. The microprocessor can be programmed to significantly extend the system battery operating time by periodically enabling the receiver circuitry.

Output 3 provides power to the microprocessor, flash EPROM and the system display. These blocks are enabled by the Power Up Input, Pin 11, and disabled by the Power Down Input, Pin 10. By having separate power up and power down inputs, the microprocessor can store any pending information before turning the system and then itself OFF. This allows a controlled or graceful shutdown. Note that the power down request is initiated by pressing the toggle switch while the system is “ON”. This action generates a microprocessor non–maskable interrupt that initiates the graceful shutdown.

Battery Voltage Detection

Reverse biasing and eventual failure of the lowest capacity cell in the battery pack can occur if the system is accidentally left on for an extended time period. To prevent this condition the following circuit blocks were incorporated.

A means for low battery detection is accomplished by using the Reference Output, Pin 12, in conjunction with the microprocessor’s analog to digital converter input. A microprocessor output (LBO) can be designated to flash a display enunciator when a low battery condition exists. The Reference Output is 1.5 V ±2.7% and is capable of sourcing in excess of 10 mA.

The Power Up Reset Output, Pin 13, is designed to hold the microprocessor reset input low until the voltage at Output 3 rises above 2.66 V. This feature prevents the microprocessor from hanging or writing invalid information into its memory during power up. Notice that the output of the MPU Power Up Reset comparator also drives the base of transistor Q_{PD}. If Output 3 should fall below 2.6 V, due to an overload or a low battery condition, the comparator will drive Q_{PD} “ON”, causing its collector to pull high on the Power Down Input, immediately forcing the system into standby mode. Externally pulling down on Pin 13, base of Q_{PD}, will also force the system into standby mode.

A redundant Low Battery Shutdown circuit is included. This circuit directly monitors the battery voltage and also forces the system into standby mode when the battery voltage falls below 2.4 V. To test the functionality of this circuit, the high state signal generated by transistor Q_{PD} must be clamped low, to prevent resetting the ON/OFF Latch. An external short or a pull–down, capable of sinking 2.0 mA at less than 0.8 V, must be connected to Pin 10.

A Battery Latch circuit is designed into the IC to prevent the system from turning on when the batteries are inserted into the finished product. This feature is useful for the end customer as well as the equipment manufacturer. Upon initial application of battery voltage, the lower comparator (0.7 V threshold) forces the Battery Latch into a reset state with its “Q” output low. This in turn triggers a reset of the ON/OFF Latch via the OR gate and also locks out the set signal present at the upper input of the AND gate. As the voltage at Pin 11 rises above (V_{CC} – 1.5 V), the set signal disappears, leaving the state of the ON/OFF Latch unchanged (reset). When the voltage at Pin 11 rises above (V_{CC} –1.0 V), the upper comparator forces the Battery Latch into a set state causing its “Q” output to go high. This allows the AND gate and the ON/OFF Latch to receive a set signal from Pin 11. The initial Battery Latch lockout time is controlled by the internal 20 kΩ resistor and the external 0.1 μF capacitor.

Figure 5. MC33128 Block Diagram

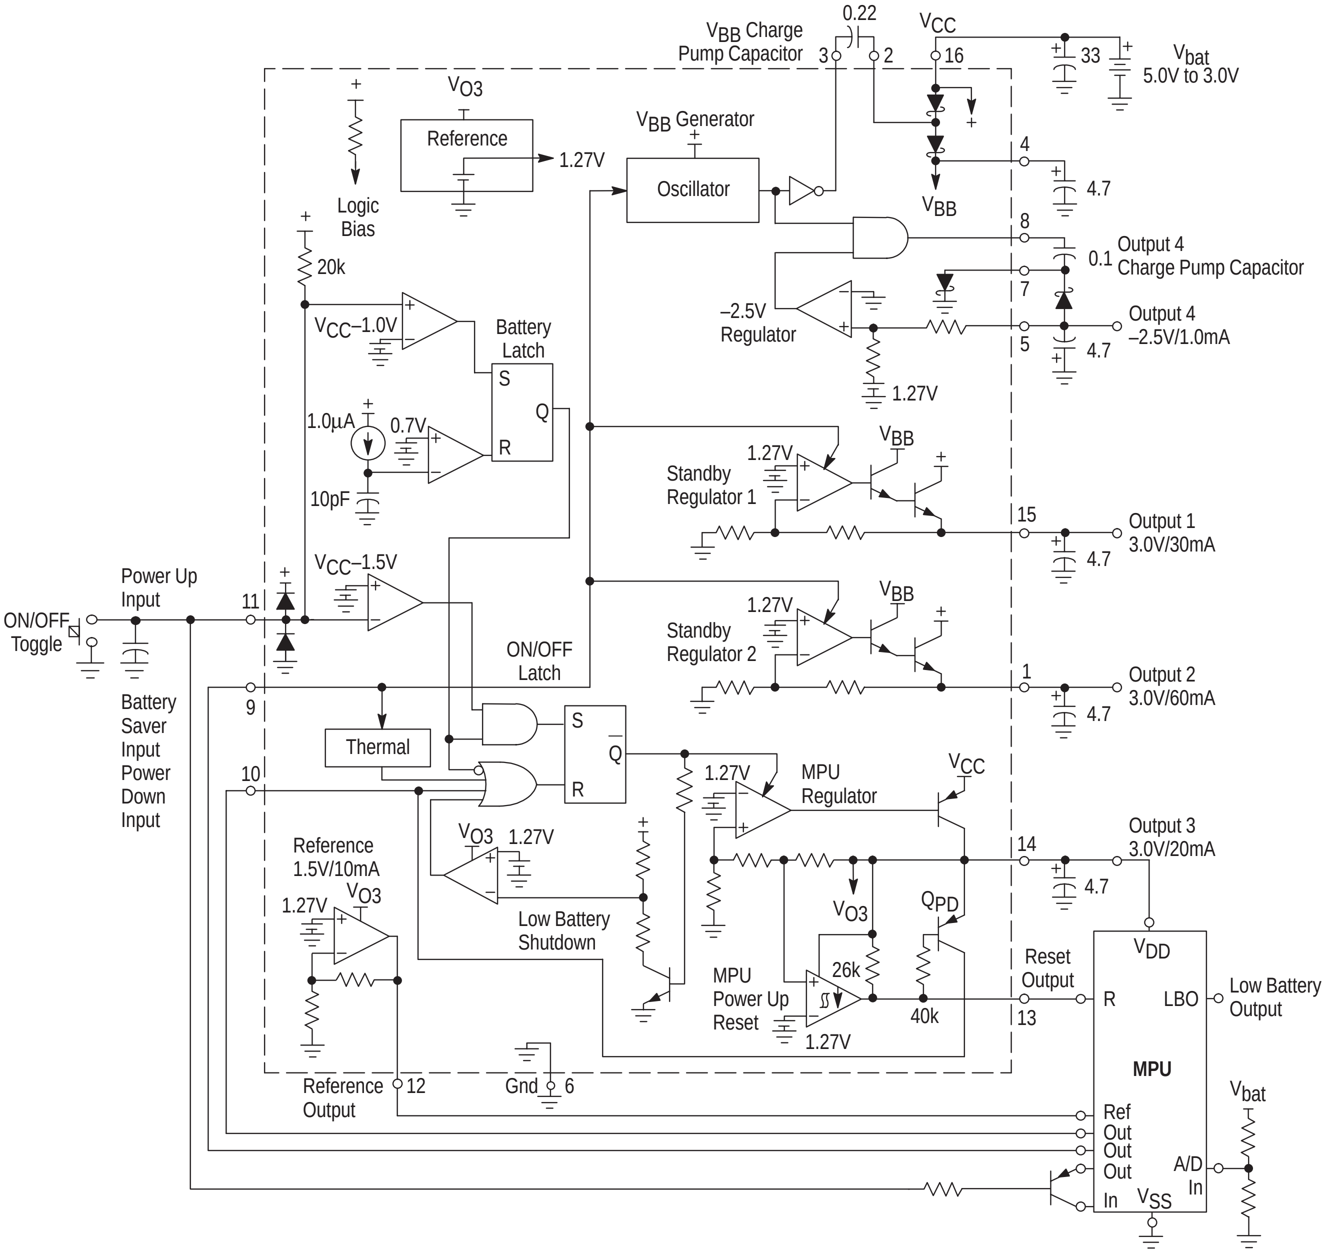

Figure 6. Voltage Tripler and Switch Driver

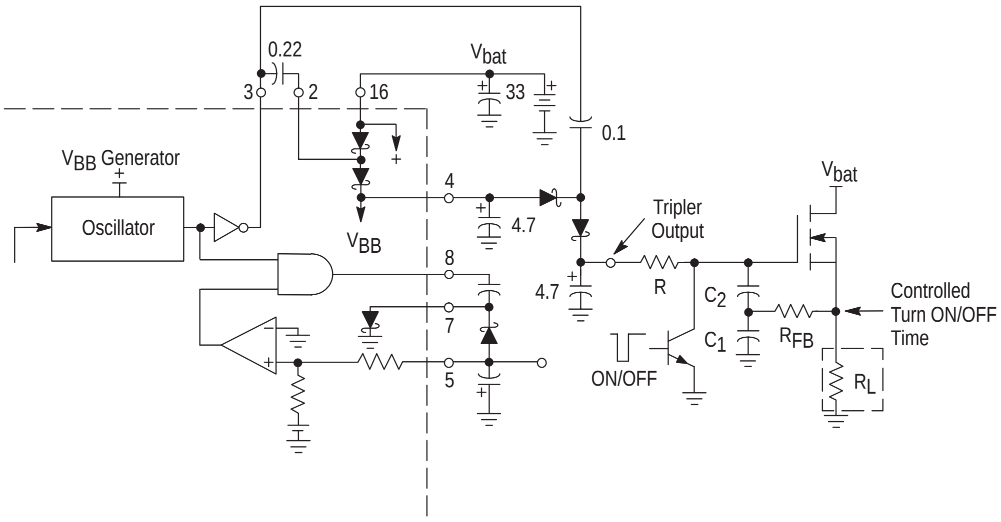
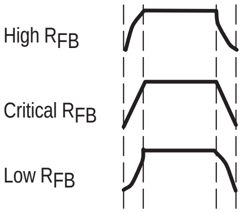


Tripler Output Voltage

Load Current (mA)	V_{CC} = 3.15 V	V_{CC} = 4.5 V
0	7.96	12.01
0.5	7.48	11.54
1.0	7.24	11.29
1.5	6.99	11.04
2.0	6.62	10.69

Load Turn ON/OFF Time



External Switch

A low threshold N–channel MOSFET can be used to switch the transmitting power amplifier (R_L) ON and OFF. To ensure that all of the available battery voltage appears across the load, the MOSFET must be fully enhanced over the system's required operating voltage range. With the addition of two Schottky diodes and two capacitors, the V_{BB} Generator can be made to function as a voltage tripler. The table in Figure 6 shows the output voltage characteristics of the tripler circuit.

In order to minimize adjacent channel splatter, the RF power amplifier must be turned ON and OFF in a controlled (soft) manner. The applied voltage rise and fall time, as well as the rate of change in rise and fall time, must be tailored to the amplifiers characteristics. The circuit consisting of resistors R, R_{FB}, and capacitors C_1 and C_2 is a simple solution allowing the system designer a means to control the ON and OFF time as well as the waveshape. Feedback resistor R_{FB} controls the waveshape. Capacitors C_1 and C_2 are usually of equal value.

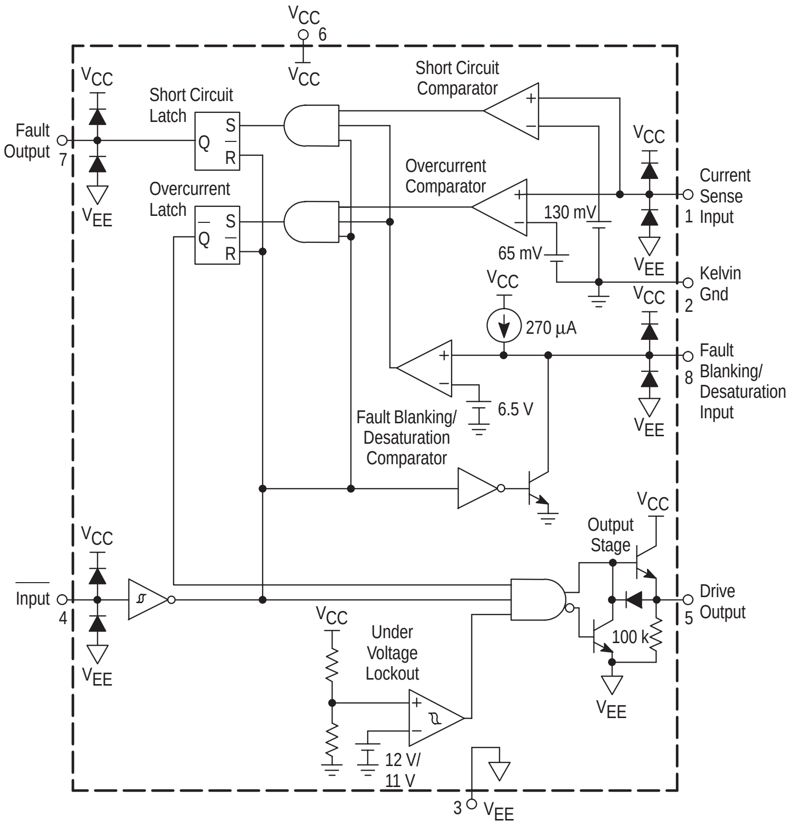
MOTOROLA

Single IGBT Gate Driver

The MC33153 is specifcally designed as an IGBT driver for high power applications that include ac induction motor control, brushless dc motor control and uninterruptable power supplies. Although designed for driving discrete and module IGBTs, this device offers a cost effective solution for driving power MOSFETs and Bipolar Transistors. Device protection features include the choice of desaturation or overcurrent sensing and undervoltage detection. These devices are available in dual–in–line and surface mount packages and include the following features:

- High Current Output Stage: 1.0 A Source/2.0 A Sink
- Protection Circuits for Both Conventional and Sense IGBT's
- Programmable Fault Blanking Time
- Protection against Overcurrent and Short Circuit
- Undervoltage Lockout Optimzed for IGBT's
- Negative Gate Drive Capability
- Cost Effectively Drives Power MOSFETs and Bipolar Transistors

Representative Block Diagram



This device contains 133 active transistors.

OPERATING DESCRIPTION

GATE DRIVE

Controlling Switching Times

The most important design aspect of an IGBT gate drive is optimization of the switching characteristics. The switching characteristics are especially important in motor control applications in which PWM transistors are used in a bridge configuration. In these applications, the gate drive circuit components should be selected to optimize turn–on, turn–off and off–state impedance. A single resistor may be used to control both turn–on and turn–off as shown in Figure 30. However, the resistor value selected must be a compromise in turn–on abruptness and turn–off losses. Using a single resistor is normally suitable only for very low frequency PWM. An optimized gate drive output stage is shown in Figure 31. This circuit allows turn–on and turn–off to be optimized separately. The turn–on resistor, R_{on}, provides control over the IGBT turn–on speed. In motor control circuits, the resistor sets the turn–on di/dt that controls how fast the free–wheel diode is cleared. The interaction of the IGBT and free–wheeling diode determines the turn–on dv/dt. Excessive turn–on dv/dt is a common problem in half–bridge circuits. The turn–off resistor, R_{off}, controls the turn–off speed and ensures that the IGBT remains off under commutation stresses. Turn–off is critical to obtain low switching losses. While IGBTs exhibit a fixed minimum loss due to minority carrier recombination, a slow gate drive will dominate the turn–off losses. This is particularly true for fast IGBTs. It is also possible to turn–off an IGBT too fast. Excessive turn–off speed will result in large overshoot voltages. Normally, the turn–off resistor is a small fraction of the turn–on resistor.

The MC33153 contains a bipolar totem pole output stage that is capable of sourcing 1.0 amp and sinking 2.0 amps peak. This output also contains a pull down resistor to ensure that the IGBT is off whenever there is insufficient V_{CC} to the MC33153.

In a PWM inverter, IGBTs are used in a half–bridge configuration. Thus, at least one device is always off. While the IGBT is in the off–state, it will be subjected to changes in voltage caused by the other devices. This is particularly a problem when the opposite transistor turns on.

When the lower device is turned on, clearing the upper diode, the turn–on dv/dt of the lower device appears across the collector emitter of the upper device. To eliminate shoot–through currents, it is necessary to provide a low sink impedance to the device that is in the off–state. In most applications the turn–off resistor can be made small enough to hold off the device that is under commutation without causing excessively fast turn–off speeds.

Figure 30. Using a Single Gate Resistor

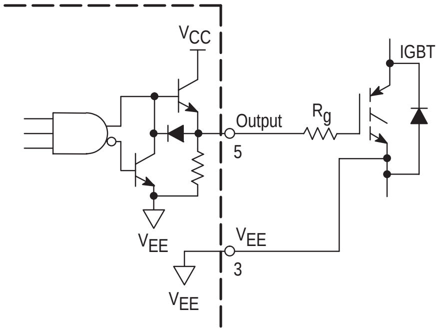

Figure 31. Using Separate Resistors for Turn–On and Turn–Off

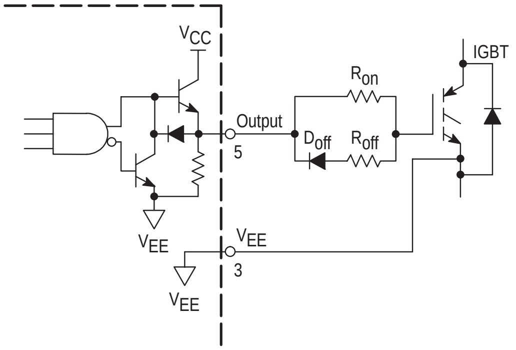


A negative bias voltage can be used to drive the IGBT into the off–state. This is a practice carried over from bipolar Darlington drives and is generally not required for IGBTs. However, a negative bias will reduce the possibility of shoot–through. The MC33153 has separate pins for V_{EE} and Kelvin Ground. This permits operation using a +15/–5.0 V supply.

INTERFACING WITH OPTOISOLATORS

Isolated Input

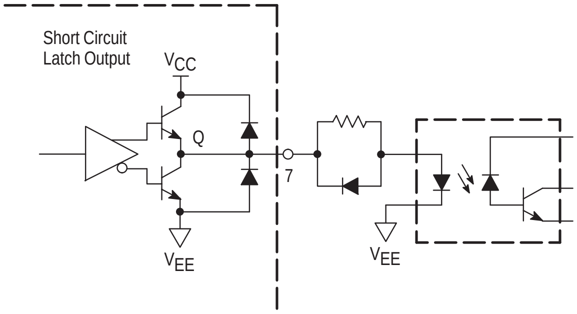
The MC33153 may be used with an optically isolated input. The optoisolator can be used to provide level shifting, and if desired, isolation from ac line voltages. An optoisolator with a very high dv/dt capability should be used, such as the Hewlett Packard HCPL4053. The IGBT gate turn–on resistor should be set large enough to ensure that the opto's dv/dt capability is not exceeded. Like most optoisolators, the HCPL4053 has an active low open–collector output. Thus, when the LED is on, the output will be low. The MC33153 has an inverting input pin to interface directly with an optoisolator using a pull up resistor. The input may also be interfaced directly to 5.0 V CMOS logic or a microcontroller.

Optoisolator Output Fault

The MC33153 has an active high fault output. The fault output may be easily interfaced to an optoisolator. While it is important that all faults are properly reported, it is equally important that no false signals are propagated. Again, a high dv/dt optoisolator should be used.

The LED drive provides a resistor programmable current of 10 to 20 mA when on, and provides a low impedance path when off. An active high output, resistor, and small signal diode provide an excellent LED driver. This circuit is shown in Figure 32.

Figure 32. Output Fault Optoisolator



UNDERVOLTAGE LOCKOUT

It is desirable to protect an IGBT from insufficient gate voltage. IGBTs require 15 V on the gate to achieve the rated on–voltage. At gate voltages below 13 V, the on–voltage increases dramatically, especially at higher currents. At very low gate voltages, below 10 V, the IGBT may operate in the linear region and quickly overheat. Many PWM motor drives use a bootstrap supply for the upper gate drive. The UVLO provides protection for the IGBT in case the bootstrap capacitor discharges.

The MC33153 will typically start up at about 12 V. The UVLO circuit has about 1.0 V of hysteresis and will disable the output if the supply voltage falls below about 11V.

PROTECTION CIRCUITRY

Desaturation Protection

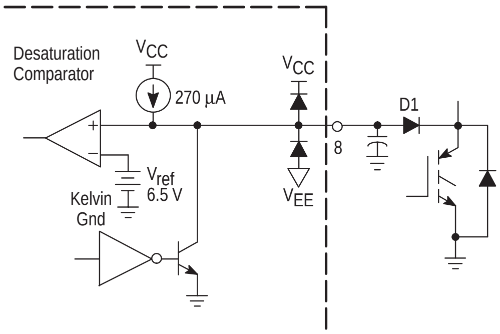
Bipolar Power circuits have commonly used what is known as “Desaturation Detection”. This involves monitoring the collector voltage and turning off the device if this voltage rises above a certain limit. A bipolar transistor will only conduct a certain amount of current for a given base drive. When the base is overdriven, the device is in saturation. When the collector current rises above the knee, the device pulls out of saturation. The maximum current the device will conduct in the linear region is a function of the base current and the dc current gain (h_{FE}) of the transistor.

The output characteristics of an IGBT are similar to a Bipolar device. However, the output current is a function of gate voltage instead of current. The maximum current depends on the gate voltage and the device type. IGBTs tend to have a very high transconductance and a much higher current density under a short circuit than a bipolar device. Motor control IGBTs are designed for a lower current density under shorted conditions and a longer short circuit survival time.

The best method for detecting desaturation is the use of a high voltage clamp diode and a comparator. The MC33153 has a Fault Blanking/Desaturation Comparator which senses the collector voltage and provides an output indicating when the device is not fully saturated. Diode D1 is an external high voltage diode with a rated voltage comparable to the power device. When the IGBT is “on” and saturated, D1 will pull down the voltage on the Fault Blanking/Desaturation Input. When the IGBT pulls out of saturation or is “off”, the current source will pull up the input and trip the comparator. The comparator threshold is 6.5 V, allowing a maximum on–voltage of about 5.8 V.

A fault exists when the gate input is high and V_{CE} is greater than the maximum allowable $V_{CE(sat)}$. The output of the Desaturation Comparator is ANDed with the gate input signal and fed into the Short Circuit and Overcurrent Latches. The Overcurrent Latch will turn–off the IGBT for the remainder of the cycle when a fault is detected. When input goes high, both latches are reset. The reference voltage is tied to the Kelvin Ground instead of the V_{EE} to make the threshold independent of negative gate bias. Note that for proper operation of the Desaturation Comparator and the Fault Output, the Current Sense Input must be biased above the Overcurrent and Short Circuit Comparator thresholds. This can be accomplished by connecting Pin 1 to V_{CC}.

Figure 33. Desaturation Detection



The MC33153 also features a programmable fault blanking time. During turn–on, the IGBT must clear the opposing free–wheeling diode. The collector voltage will remain high until the diode is cleared. Once the diode has been cleared, the voltage will come down quickly to the $V_{CE(sat)}$ of the device. Following turn–on, there is normally considerable ringing on the collector due to the C_{OSS} capacitance of the IGBTs and the parasitic wiring inductance. The fault signal from the Desaturation Comparator must be blanked sufficiently to allow the diode to be cleared and the ringing to settle out.

The blanking function uses an NPN transistor to clamp the comparator input when the gate input is low. When the input is switched high, the clamp transistor will turn “off”, allowing the internal current source to charge the blanking capacitor. The time required for the blanking capacitor to charge up from the on–voltage of the internal NPN transistor to the trip voltage of the comparator is the blanking time.

If a short circuit occurs after the IGBT is turned on and saturated, the delay time will be the time required for the current source to charge up the blanking capacitor from the $V_{CE(sat)}$ level of the IGBT to the trip voltage of the comparator. Fault blanking can be disabled by leaving Pin 8 unconnected.

Sense IGBT Protection

Another approach to protecting the IGBTs is to sense the emitter current using a current shunt or Sense IGBTs. This method has the advantage of being able to use high gain IGBTs which do not have any inherent short circuit capability. Current sense IGBTs work as well as current sense MOSFETs in most circumstances. However, the basic problem of working with very low sense voltages still exists. Sense IGBTs sense current through the channel and are therefore linear with respect to the collector current. Because IGBTs have a very low incremental on–resistance, sense IGBTs behave much like low–on resistance current sense MOSFETs. The output voltage of a properly terminated sense IGBT is very low, normally less than 100 mV.

The sense IGBT approach requires fault blanking to prevent false tripping during turn–on. The sense IGBT also requires that the sense signal is ignored while the gate is low. This is because the mirror output normally produces large transient voltages during both turn–on and turn–off due to the collector to mirror capacitance. With non–sensing types of IGBTs, a low resistance current shunt (5.0 to 50 mΩ) can be used to sense the emitter current. When the output is an actual short circuit, the inductance will be very low. Since the blanking circuit provides a fixed minimum on–time, the peak current under a short circuit can be very high. A short circuit discern function is implemented by the second comparator which has a higher trip voltage. The short circuit signal is latched and appears at the Fault Output. When a short circuit is detected, the IGBT should be turned–off for several milliseconds allowing it to cool down before it is turned back on. The sense circuit is very similar to the desaturation circuit. It is possible to build a combination circuit that provides protection for both Short Circuit capable IGBTs and Sense IGBTs.

APPLICATION INFORMATION

Figure 34 shows a basic IGBT driver application. When driven from an optoisolator, an input pull up resistor is required. This resistor value should be set to bias the output transistor at the desired current. A decoupling capacitor should be placed close to the IC to minimize switching noise.

A bootstrap diode may be used for a floating supply. If the protection features are not required, then both the Fault Blanking/Desaturation and Current Sense Inputs should both be connected to the Kelvin Ground (Pin 2). When used with a single supply, the Kelvin Ground and V_{EE} pins should be connected together. Separate gate resistors are recommended to optimize the turn–on and turn–off drive.

Figure 34. Basic Application

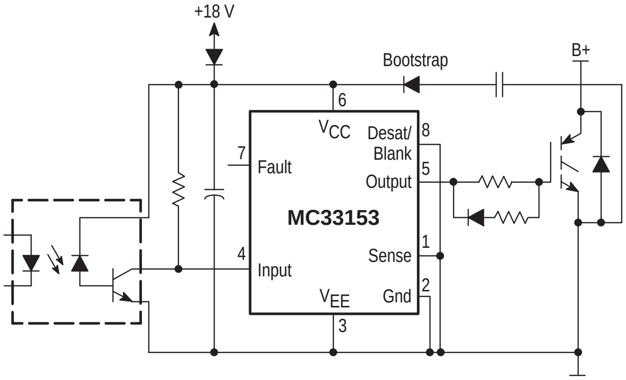


Figure 35. Dual Supply Application

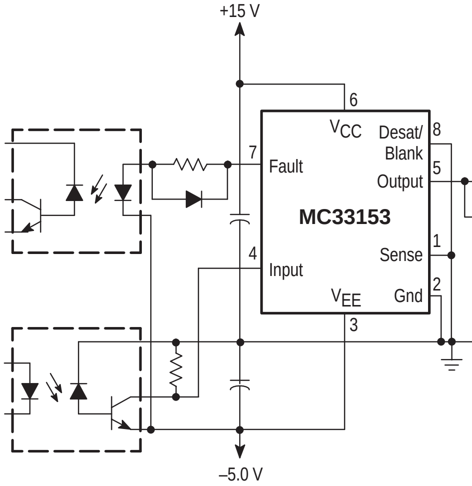
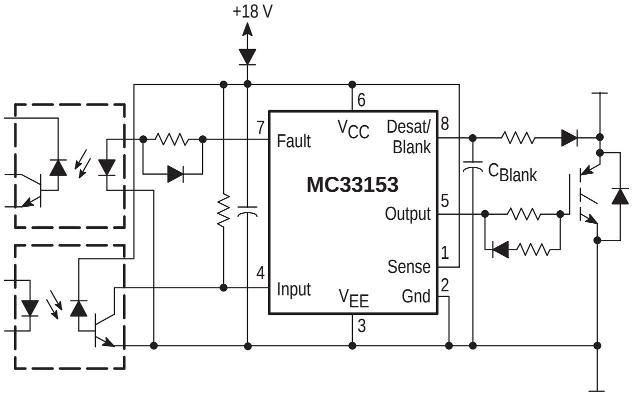


When used in a dual supply application as in Figure 35, the Kelvin Ground should be connected to the emitter of the IGBT. If the protection features are not used, then both the Fault Blanking/Desaturation and the Current Sense Inputs should be connected to Ground. The input optoisolator should always be referenced to V_{EE}.

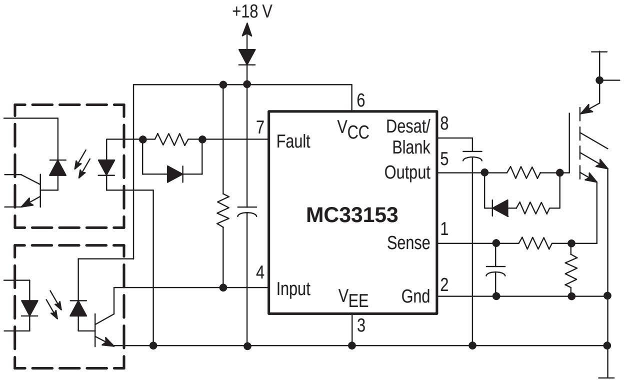
If desaturation protection is desired, a high voltage diode is connected to the Fault Blanking/Desaturation pin. The blanking capacitor should be connected from the Desaturation pin to the V_{EE} pin. If a dual supply is used, the blanking capacitor should be connected to the Kelvin Ground. The Current Sense Input should be tied high because the two comparator outputs are ANDed together. Although the reverse voltage on collector of the IGBT is clamped to the emitter by the free–wheeling diode, there is normally considerable inductance within the package itself. A small resistor in series with the diode can be used to protect the IC from reverse voltage transients.

Figure 36. Desaturation Application



When using sense IGBTs or a sense resistor, the sense voltage is applied to the Current Sense Input. The sense trip voltages are referenced to the Kelvin Ground pin. The sense voltage is very small, typically about 65 mV, and sensitive to noise. Therefore, the sense and ground return conductors should be routed as a differential pair. An RC filter is useful in filtering any high frequency noise. A blanking capacitor is connected from the blanking pin to V_{EE}. The stray capacitance on the blanking pin provides a very small level of blanking if left open. The blanking pin should not be grounded when using current sensing, that would disable the sense. The blanking pin should never be tied high, that would short out the clamp transistor.

Figure 37. Sense IGBT Application



MOTOROLA

MC33154

Product Preview

Single IGBT Gate Driver

The MC33154 is specifically designed as an IGBT driver for high power applications including ac induction motor control, brushless dc motor control and uninterruptible power supplies.

The MC33154 is similar to the MC33153, except that the output drive is in–phase with the logic input, the output source current drive is four times higher and the supply voltage rating is higher.

Although designed for driving discrete and module IGBTs, this device offers a cost effective solution for driving power MOSFETs and Bipolar Transistors.

These devices are available in dual–in–line and surface mount packages and include the following features:

- High Current Output Stage: 4.0 A Source/2.0 A Sink
- Protection Circuits for Both Conventional and Sense IGBTs
- Programmable Fault Blanking Time
- Protection against Overcurrent and Short Circuit
- Undervoltage Lockout Optimzed for IGBTs
- Negative Gate Drive Capability
- Cost Effectively Drives Power MOSFETs and Bipolar Transistors

Advance Information

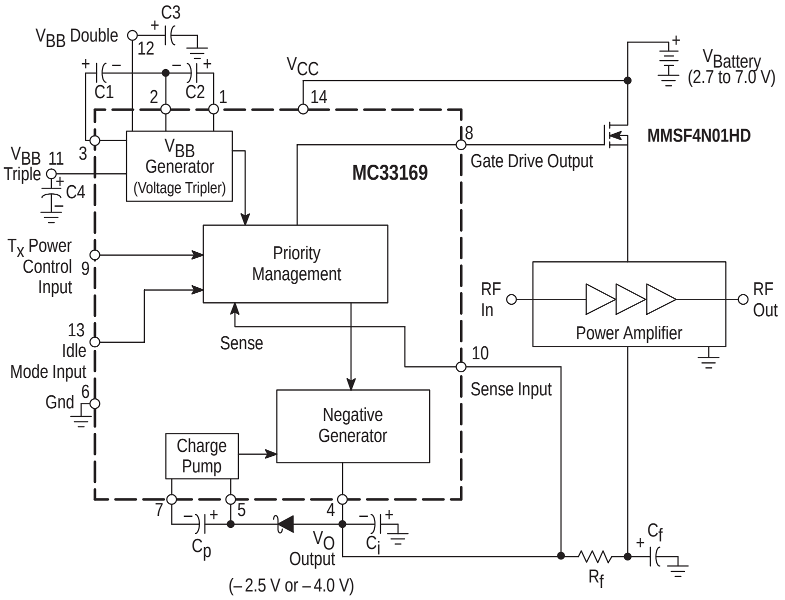
GaAs Power Amplifier Support IC

The MC33169 is a support IC for GaAs Power Amplifier Enhanced FETs used in hand portable telephones such as GSM, PCN and DECT. This device provides negative voltages for full depletion of Enhanced MESFETs as well as a priority management system of drain switching, ensuring that the negative voltage is always present before turning “on” the Power Amplifier. Additional features include an idle mode input and a direct drive of the N–Channel drain switch transistor.

This product is available in two versions, –2.5 and –4.0 V. The –4.0 V version is intended for supplying RF modules for GSM and DCS1800 applications, whereas the –2.5 V version is dedicated for DECT and PHS systems.

- Negative Regulated Output for Full Depletion of GaAs MESFETs
- Drain Switch Priority Management Circuit
- CMOS Compatible Inputs
- Idle Mode Input (Standby Mode) for Very Low Current Consumption
- Output Signal Directly Drives N–Channel FET
- Low Startup and Operating Current

Simplified Block Diagram



This device contains 148 active transistors.

PIN FUNCTION DESCRIPTION

Pin	Name	Description
1	C2 Input	This is the positive pin for the charge pump capacitor in the voltage doubler.
2	C1/C2	This is the negative pin for the charge pump capacitors.
3	C1 Input	This is the positive pin for the charge pump capacitor in the voltage tripler.
4	V_O Output	It delivers a regulated negative voltage of –4.0 V or –2.5 V depending on the product version. It can source an output current in excess of 5.0 mA.
5	V_O Charge Pump Capacitor +	This is the positive pin for the capacitor in the inverting charge pump.
6	Gnd	This pin is Ground for both signal and power circuitry.
7	V_O Charge Pump Capacitor –	This is the negative pin for the capacitor in the inverting charge pump.
8	Gate Drive Output	This is the output of the gate amplifier which directly drives the gate of an N–Channel MOSFET. It can sink and source peak currents up to 3.0 mA.
9	T_x Power Control Input	The input signal applied on this pin controls the N–Channel switching MOSFET in follower mode and therefore, linearly controls the RF output voltage.
10	Sense Input Pin	It senses the negative voltage directly on the Power Amplifier. It is also the input pin of an internal Undervoltage Lockout circuit which blocks the switching of the N–Channel MOSFET if the sensed voltage is more positive than –3.0 V (–4.0 V version) or –2.0 V (–2.5 V version).
11	V_{BB} Triple	This is the positive pin of the output filter capacitor in the voltage tripler. The triple voltage at that pin is used internally to supply the inverting charge pump and the gate amplifier.
12	V_{BB} Double	This is the positive pin of the output filter capacitor in the voltage doubler.
13	Idle Mode Input	This pin is used to set the circuit in Low Power Consumption Standby mode. It is CMOS compatible, i.e. a voltage lower than 0.5 V applied on this pin makes the device go into Standby mode in which the current consumption is lower than 1.0 µA. The MC33169 is then awakened by a voltage higher than 2.0 V applied on that pin.
14	V_{CC}	This is the supply input pin for the MC33169, V_{CC} voltage ranges from 2.7 V to 7.2 V.

OPERATING DESCRIPTION

The MC33169 is a power amplifier support IC that is designed to properly switch “on” or “off” a MESFET Power Amplifier either manually or by microprocessor. Controlling the power drain of the RF Amplifier extends operating battery life in many portable systems.

Outputs

The IC is designed to provide a –4.0 V or –2.5 V bias to the gate of the RF Ampllifier MESFET devices prior to application of a positive battery voltage to the drain. The negative output voltage can provide up to 5.0 mA of current. The positive voltage control requires an external N–Channel logic level MOSFET, connected as a source follower. The Gate Drive Output, Pin 8, can source or sink 3.0 mA to the external MOSFET. The low drive current slows the MOSFET switching speed, thereby minimizing voltage glitches on the V_{CC} line which could cause disturbances to other circuitry.

Inputs

A Sense Input, Pin 10, protects the Power Amplifier load by monitoring the level of the negative output voltage. If the negative voltage magnitude falls below a preset level, 3.2 V typical for the –4.0 V version or 2.3 V for the –2.5 V version, an undervoltage lockout circuit disables the external MOSFET gate drive.

The T_X Power Control Input controls the N–Channel external switching MOSFET in source follower mode, which allows linear control of the RF Output voltage level.

The Idle mode input is CMOS compatible, allowing the RF Amplifier to be placed in a standby mode, drawing less than 1.0 µA from the power source.

MC33264

Advance Information

Micropower Voltage Regulators with On/Off Control

LOW DROPOUT MICROPOWER VOLTAGE REGULATORS WITH ON/OFF CONTROL

SEMICONDUCTOR TECHNICAL DATA

The MC33264 series are micropower low dropout voltage regulators available in SO–8 and Micro–8 surface mount packages and a wide range of output voltages. These devices feature a very low quiescent current (100 µA in the ON mode; 0.1 µA in the OFF mode), and are capable of supplying output currents up to 100 mA. Internal current and thermal limiting protection is provided.

Additionally, the MC33264 has either active HIGH or active LOW control (Pins 2 and 3) that allows a logic level signal to turn–off or turn–on the regulator output.

Due to the low input–to–output voltage differential and bias current specifications, these devices are ideally suited for battery powered computer, consumer, and industrial equipment where an extension of useful battery life is desirable.

MC33264 Features:

- Low Quiescent Current (0.3 µA in OFF Mode; 95 µA in ON Mode)
- Low Input–to–Output Voltage Differential of 47 mV at 10 mA, and 131 mV at 50 mA
- Multiple Output Voltages Available
- Extremely Tight Line and Load Regulation
- Stable with Output Capacitance of Only
  0.33 µF for 5.0 V, 6.0 V and 4.75 V Output Voltages
  0.22 µF for 2.8 V, 3.0 V and 3.3 V Output Voltages
- Internal Current and Thermal Limiting
- Logic Level ON/OFF Control
- Functionally Equivalent to TK115XXMC and LP2980

DEFINITIONS

Dropout Voltage – The input/output voltage differential at which the regulator output no longer maintains regulation against further reductions in input voltage. Measured when the output drops 100 mV below its nominal value (which is measured at 1.0 V differential), dropout voltage is affected by junction temperature, load current and minimum input supply requirements.

Line Regulation – The change in output voltage for a change in input voltage. The measurement is made under conditions of low dissipation or by using pulse techniques such that average chip temperature is not significantly affected.

Load Regulation – The change in output voltage for a change in load current at constant chip temperature.

Maximum Power Dissipation – The maximum total device dissipation for which the regulator will operate within specifications.

Quiescent Current – Current which is used to operate the regulator chip and is not delivered to the load.

Output Noise Voltage – The rms ac voltage at the output, with constant load and no input ripple, measured over a specified frequency range.

APPLICATION INFORMATION

Introduction

The MC33264 regulators are designed with internal current limiting and thermal shutdown making them user–friendly. These regulators require only 0.33 µF (or greater) capacitance between the output terminal and ground for stability for 2.8 V, 3.0 V, and 3.3 V output voltage options. Output voltage options of 5.0 V, 6.0 V and 4.75 V require only 0.22 µF for stability. The output capacitor must be mounted as close to the MC33264 as possible. If the output capacitor must be mounted further than two centimeters away from the MC33264, then a larger value of output capacitor may be required for stability. A value of 0.68 µF or larger is recommended. Most types of aluminum, tantalum or multilayer ceramic will perform adequately. Solid tantalums or appropriate multilayer ceramic capacitors are recommended for operation below 25°C.

A bypass capacitor is recommended across the MC33264 input to ground if more than 4.0 inches of wire connects the input to either a battery or power supply filter capacitor.

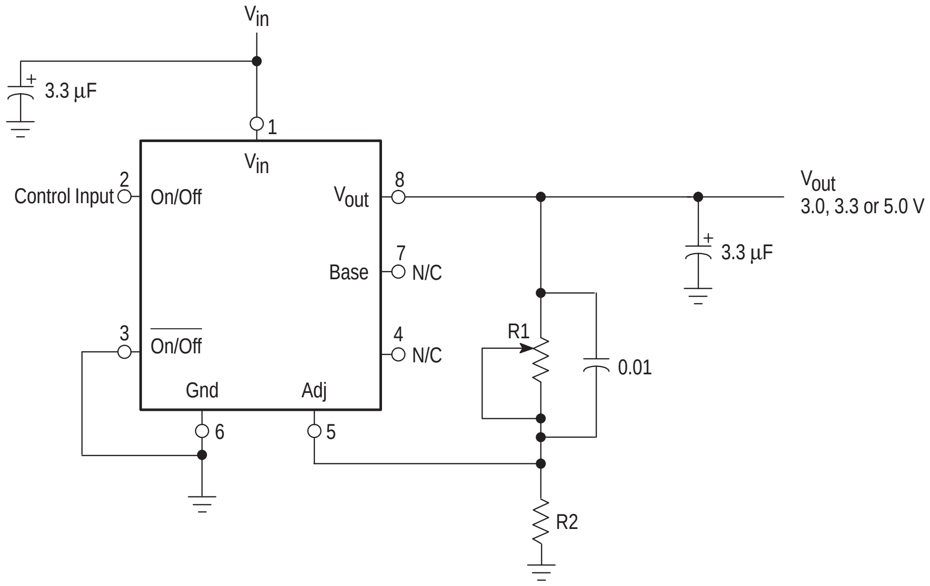
On/Off Control

On/Off control of the regulator may be accomplished in either of two ways. Pin 3 may be tied to circuit ground and a positive logic control applied to Pin 2. The regulator will be turned on by a positive (>2.4 V) level, typically 5.0 V with respect to ground, sourcing a typical current of 6.0 µA. The regulator will turn off if the control input is a logic “0” (<0.5 V). Alternatively, Pin 2 may be tied to the regulator input voltage and a negative logic control applied to Pin 3. The regulator will be turned on when the control voltage is less than V_{in} – 2.4 V, sinking a typical current of 18 µA when V_{in} = 6.0 V. The regulator is off when the control input is open or greater than V_{in} – 0.2 V.

Programming The Output Voltage

The MC33264 output voltage is automatically set using its internal voltage divider. Alternatively, it may be programmed within a typical ±15% range of its preset output voltage. An external pair of resistors is required, as shown in Figure 7.

Figure 7. Regulator Output Voltage Trim



The complete equation for the output voltage is:

$$V_{out} = V_{ref}\left(1 + \frac{R1}{R2}\right) + I_{FB}\ R1$$

where V_{ref} is the nominal 1.235 V reference voltage and I_{FB} is the feedback pin bias current, nominally –20 nA. The minimum recommended load current of 1.0 µA forces an upper limit of 1.2 MΩ on the value of R2, if the regulator must work with no load. I_{FB} will produce a 2% typical error in V_{out} which may be eliminated at room temperature by adjusting R1. For better accuracy, choosing R2 = 100 K reduces this error to 0.17% while increasing the resistor program current to 12 µA.

Output Noise

In many applications it is desirable to reduce the noise present at the output. Reducing the regulator bandwidth by increasing the size of the output capacitor is the only method for reducing noise.

Noise can be reduced fourfold by a bypass capacitor across R1, since it reduces the high frequency gain from 4 to unity for the MC33264D–5.0. Pick

$$C_{BYPASS} = \frac{1}{2\pi\ R1\ x\ 200\ Hz}$$

or about 0.01 µF. When doing this, the output capacitor must be increased to 3.3 µF to maintain stability. These changes reduce the output noise from 430 µV to 100 Vrms for a 100 kHz bandwidth for the 5.0 V output device. With the bypass capacitor added, noise no longer scales with output voltage so that improvements are more dramatic at higher output voltages.

MOTOROLA

MC33267

Low Dropout Regulator

The MC33267 is a positive fixed 5.0 V regulator that is specifically designed to maintain proper voltage regulation with an extremely low input–to–output voltage differential. This device is capable of supplying output currents in excess of 500 mA and contains internal current limiting and thermal shutdown protection. Also featured is an on–chip power–up reset circuit that is ideally suited for use in microprocessor based systems. Whenever the regulator output voltage is below nominal, the reset output is held low. A programmable time delay is initiated after the regulator has reached its nominal level and upon timeout, the reset output is released.

Due to the low dropout voltage specifications, the MC33267 is ideally suited for use in battery powered industrial and consumer equipment where an extension of useful battery life is desirable. This device is contained in an economical five lead TO–220 type package.

- Low Input–to–Output Voltage Differential
- Output Current in Excess of 500 mA
- On–Chip Power–Up Reset Circuit with Programmable Delay
- Internal Current Limiting with Thermal Shutdown
- Economical Five Lead TO–220 Type Packages

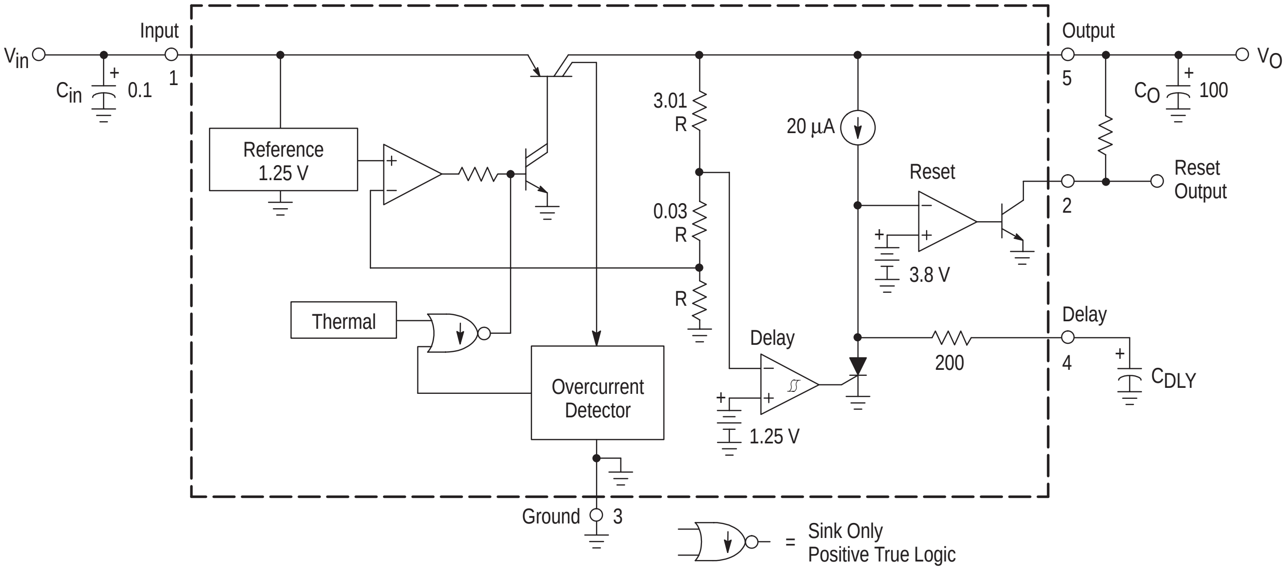
NOTE: 2. Low duty cycle pulse techniques are used during test to maintain junction temperature as close to ambient as possible.

Figure 1. Typical Application Circuit



APPLICATION CIRCUIT INFORMATION

The MC33267 is a low dropout, positive fixed 5.0 V, 500 mA regulator. Protection features include output current limiting and thermal shutdown. System protection consists of an on–chip power–up microprocessor reset circuit.

A typical applications circuit is shown in Figure 1. The input bypass capacitor (C_{in}) is recommended if the regulator is located an appreciable distance (≥ 4″) from the supply input filter. This will reduce the circuit's sensitivity to the input line impedance at high frequencies.

These regulators are not internally compensated and thus require an external output capacitor (C_O) for stability. The recommended capacitance is 100 µF with an equivalent series resistance (ESR) of less than 0.3 Ω. A minimum capacitance of 33 µF with a maximum ESR of 3.0 Ω can be used in applications where space is a premium, however, these limits must be observed over the entire operating temperature range of the regulator circuit.

With economical electrolytic capacitors, cold temperature operation can pose a serious stability problem. As the electrolyte freezes, around – 30°C, the capacitance will decrease and the ESR will increase drastically, causing the circuit to oscillate. Quality electrolytic capacitors with extended temperature ranges of – 40°C to + 85°C and – 55°C to +105°C are readily available. It is suggested that oven testing of the entire circuit be performed with maximum load, minimum input voltage, and minimum ambient temperature.

Figure 2 shows the reset circuit timing relationship. Note that whenever the regulator's output is less than 4.9 V, the delay capacitor (C_{DLY}) is immediately discharged, and the reset output is held in a low state. As the regulator's output voltage increases beyond 4.97 V, the delay comparator will allow the 20 µA current source to charge C_{DLY}. The reset output will go to a high state when C_{DLY} crosses the 3.8 V threshold of the reset comparator. The reset delay time is controlled by the value selected for C_{DLY}. The required system reset time is governed by the microprocessor and usually a reset signal which lasts several machine cycles is sufficient.

MC33269

Advance Information

Low Dropout Positive Fixed and Adjustable Voltage Regulators

The MC33269 series are low dropout, medium current, fixed and adjustable, positive voltage regulators specifically designed for use in low input voltage applications. These devices offer the circuit designer an economical solution for precision voltage regulation, while keeping power losses to a minimum.

The regulator consists of a 1.0 V dropout composite PNP–NPN pass transistor, current limiting, and thermal shutdown.

- 3.3 V, 5.0 V, 12 V and Adjustable Versions
- Space Saving DPAK and SOP–8 Power Package
- 1.0 V Dropout
- Output Current in Excess of 800 mA
- Thermal Protection
- Short Circuit Protection
- Output Trimmed to 1.0% Tolerance
- No Minimum Load Requirement for Fixed Voltage Output Devices

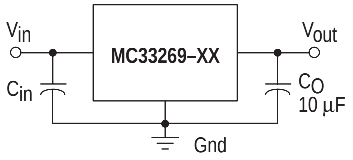
APPLICATIONS INFORMATION

Figures 9 through 13 are typical application circuits. The output current capability of the regulator is in excess of 800 mA, with a typical dropout voltage of less than 1.0 V. Internal protective features include current and thermal limiting.

The MC33269 is not internally compensated and thus requires an external output capacitor for stability. The capacitor should be at least 10 μF with an equivalent series resistance (ESR) of less than 10 Ω over the anticipated operating temperature range. With economical electrolytic capacitors, cold temperature operation can pose a problem. As temperature decreases, the capacitance also decreases and the ESR increases, which could cause the circuit to oscillate. Solid tantalum capacitors may be a better choice if small size is a requirement. Also capacitance and ESR of a solid tantalum capacitor is more stable over temperature. An input bypass capacitor is recommended to improve transient response or if the regulator is connected to the supply input filter with long wire lengths. This will reduce the circuit's sensitivity to the input line impedance at high frequencies. A 0.33 μF or larger tantalum, mylar, ceramic, or other capacitor having low internal impedance at high frequencies should be chosen. The bypass capacitor should be mounted with shortest possible lead or track length directly across the regulator's input terminals. **Applications should be tested over all operating conditions to insure stability.**

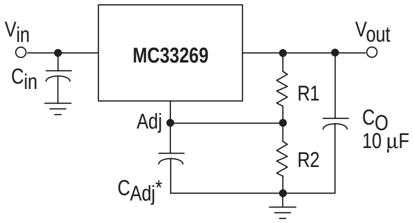
Internal thermal limiting circuitry is provided to protect the integrated circuit in the event that the maximum junction temperature is exceeded. When activated, typically at 170°C, the output is disabled. There is no hysteresis built into the thermal limiting circuit. As a result, if the device is overheating, the output will appear to be oscillating. This feature is provided to prevent catastrophic failures from accidental device overheating. **It is not intended to be used as a substitute for proper heatsinking.**

Figure 9. Typical Fixed Output Application



An input capacitor is not necessary for stability, however it will improve the overall performance.

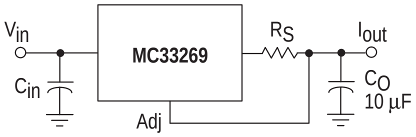
Figure 10. Typical Adjustable Output Application



$$V_{out} = 1.25 \left(1 + \frac{R2}{R1}\right) + I_{Adj}\, R2$$

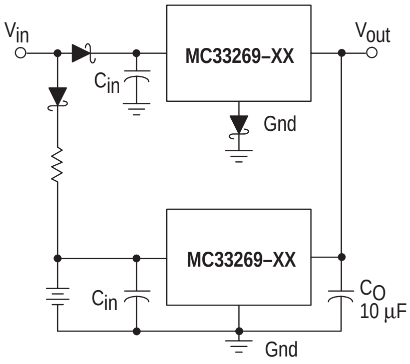
*C_{Adj} is optional, however it will improve the ripple rejection. The MC34269 develops a 1.25 V reference voltage between the output and the adjust terminal. Resistor R1, operates with constant current to flow through it and resistor R2. This current should be set such that the Adjust Pin current causes negligible drop across resistor R2. The total current with minimum load should be greater than 8.0 mA.

Figure 11. Current Regulator



$$I_{out} = \frac{1.25}{R_S}$$

Figure 12. Battery Backed–Up Power Supply



The Schottky diode in series with the ground leg of the upper regulator shifts its output voltage higher by the forward voltage drop of the diode. This will cause the lower device to remain off until the input voltage is removed.

Battery Fast Charge Controller

The MC33340 is a monolithic control IC that is specifically designed as a fast charge controller for Nickel Cadmium (NiCd) and Nickel Metal Hydride (NiMH) batteries. This device features negative slope voltage detection as the primary means for fast charge termination. Accurate detection is ensured by an output that momentarily interrupts the charge current for precise voltage sampling. An additional secondary backup termination method can be selected that consists of either a programmable time or temperature limit. Protective features include battery over and undervoltage detection, latched over temperature detection, and power supply input undervoltage lockout with hysteresis. Provisions for entering a rapid test mode are available to enhance end product testing. This device is available in an economical 8–lead surface mount package.

- Negative Slope Voltage Detection
- Accurate Zero Current Battery Voltage Sensing
- Programmable 1 to 4 Hour Fast Charge Time Limit
- Programmable Over/Under Temperature Detection
- Battery Over and Undervoltage Fast Charge Protection
- Rapid System Test Mode
- Power Supply Input Undervoltage Lockout with Hysteresis
- Operating Voltage Range of 3.0 V to 18 V

INTRODUCTION

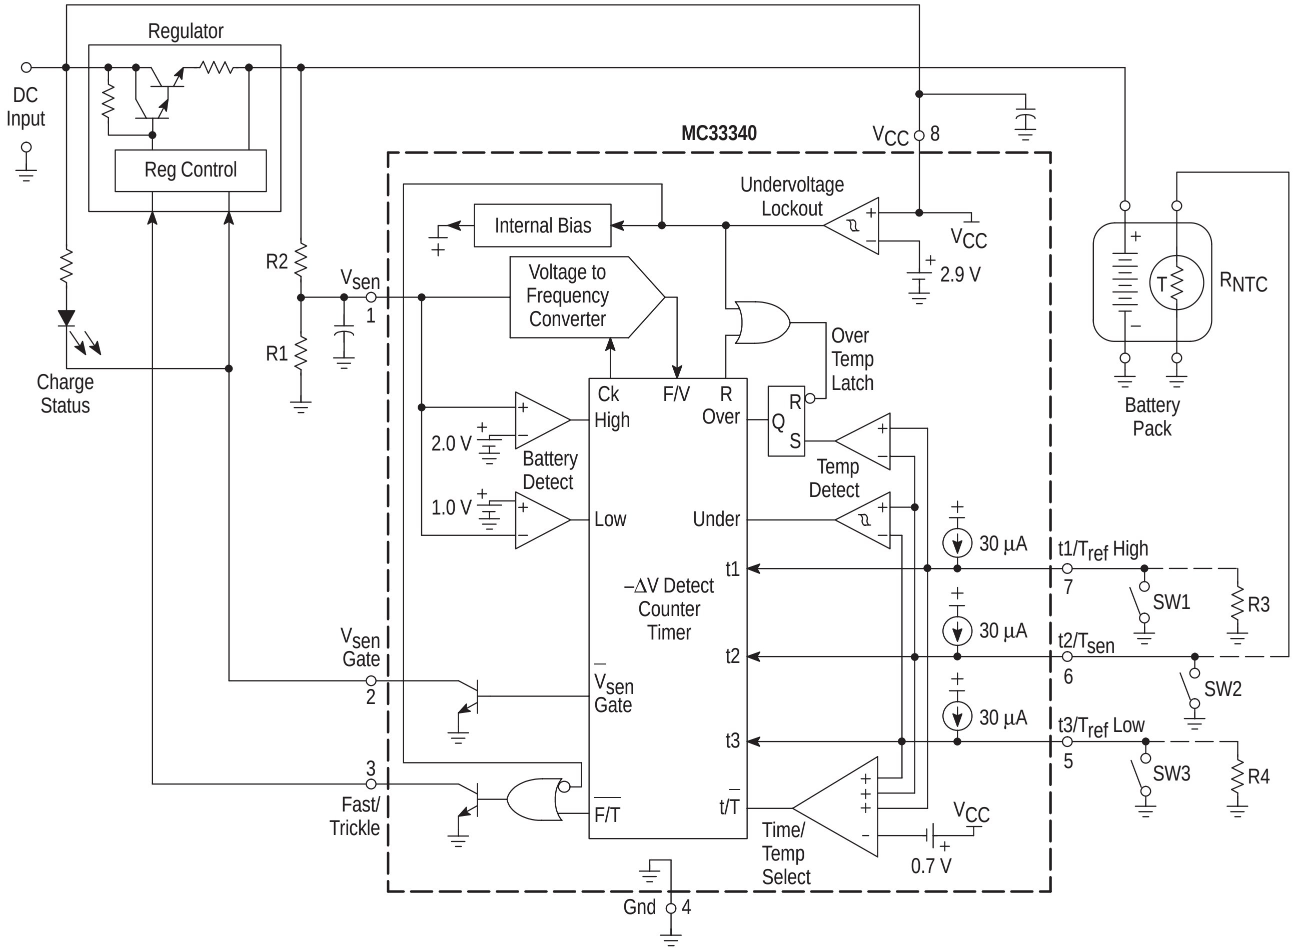
Nickel Cadmium and Nickel Metal Hydride batteries require precise charge termination control to maximize cell capacity and operating time while preventing overcharging. Overcharging can result in a reduction of battery life as well as physical harm to the end user. Since most portable applications require the batteries to be charged rapidly, a primary and usually a secondary or redundant charge sensing technique is employed into the charging system. It is also desirable to disable rapid charging if the battery voltage or temperature is either too high or too low. In order to address these issues, an economical and flexible fast charge controller was developed.

The MC33340 contains many of the building blocks and protection features that are employed in modern high performance battery charger controllers that are specifically designed for Nickel Cadmium and Nickel Metal Hydride batteries. The device is designed to interface with either primary or secondary side regulators for easy implementation of a complete charging system. A representative block diagram in a typical charging application is shown in Figure 7.

The battery voltage is monitored by the V_{sen} input that internally connects to a voltage to frequency converter and counter for detection of a negative slope in battery voltage. A timer with three programming inputs is available to provide backup charge termination. Alternatively, these inputs can be used to monitor the battery pack temperature and to set the over and under temperature limits also for backup charge termination.

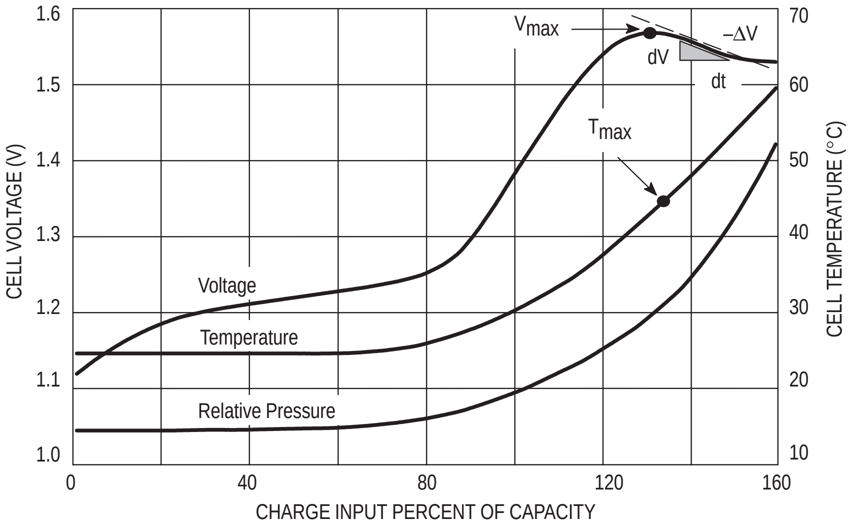
Two active low open collector outputs are provided to interface this controller with the external charging circuit. The first output furnishes a gating pulse that momentarily interrupts the charge current. This allows an accurate method of sampling the battery voltage by eliminating voltage drops that are associated with high charge currents and wiring resistances. Also, any noise voltages generated by the charging circuitry are eliminated. The second output is designed to switch the charging source between fast and trickle modes based upon the results of voltage, time, or temperature. These outputs normally connect directly to a linear or switching regulator control circuit in non–isolated primary or secondary side applications. Both outputs can be used to drive optoisolators in primary side applications that require galvanic isolation. Figure 8 shows the typical charge characteristics for NiCd and NiMh batteries.

Figure 7. Typical Battery Charging Application



$$R2 = R1\left(\frac{V_{Batt}}{V_{sen}} - 1\right)$$

Figure 8. Typical Charge Characteristics for NiCd and NiMh Batteries



OPERATING DESCRIPTION

The MC33340 starts up in the fast charge mode when power is applied to V_{CC}. A change to the trickle mode can occur as a result of three possible conditions. The first is if the V_{sen} input voltage is above 2.0 V or below 1.0 V. Above 2.0 V indicates that the battery pack is open or disconnected, while below 1.0 V indicates the possibility of a shorted or defective cell. The second condition is if a negative slope in battery voltage is detected after a minimum of 160 seconds of fast charging. This indicates that the battery pack is fully charged. The third condition is either due to the battery pack being out of a programmed temperature range, or that the preset timer period has been exceeded.

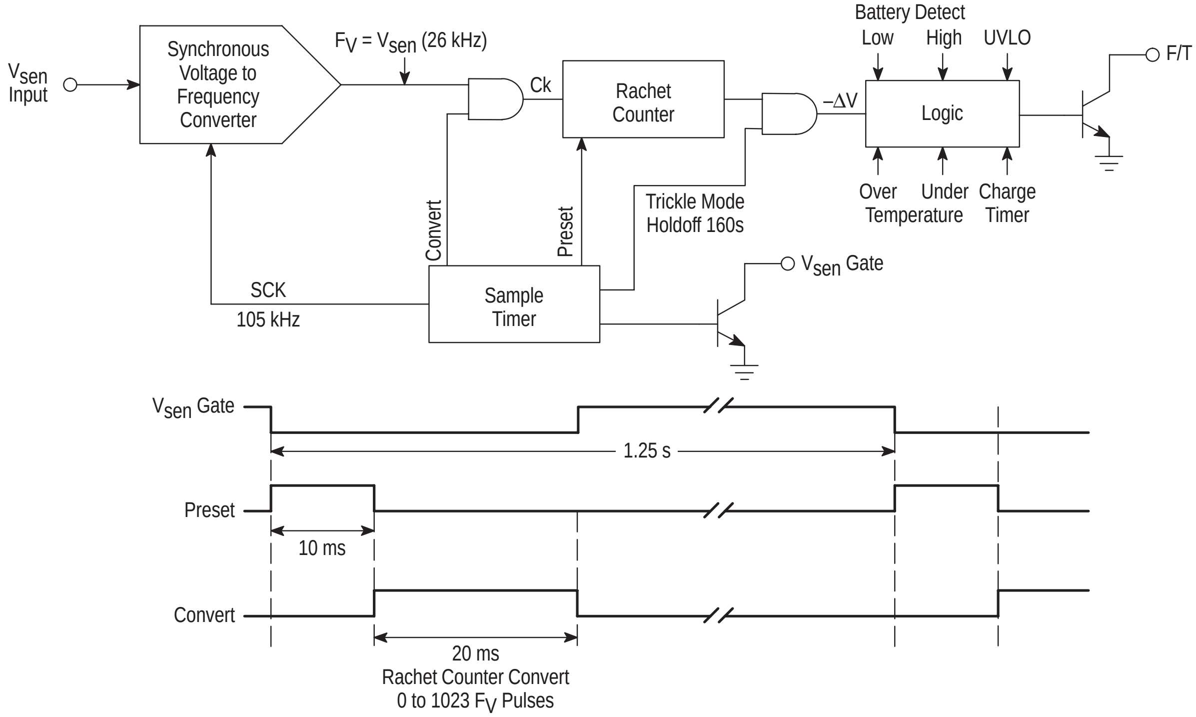
There are three conditions that will cause the controller to return from trickle to fast charge mode. The first is if the V_{sen} input voltage moved to within the 1.0 to 2.0 V range from initially being either too high or too low. The second is if the battery pack temperature moved to within the programmed temperature range, but only from initially being too cold. Third is by cycling V_{CC} off and then back on causing the internal logic to reset. A concise description of the major circuit blocks is given below.

Negative Slope Voltage Detection

A representative block diagram of the negative slope voltage detector is shown in Figure 9. It includes a Synchronous Voltage to Frequency Converter, a Sample Timer, and a Ratchet Counter. The V_{sen} pin is the input for the Voltage to Frequency Converter (VFC), and it connects to the rechargeable battery pack terminals through a resistive voltage divider. The input has an impedance of approximately 3.0 MΩ and a maximum voltage range of –1.0 V to V_{CC} + 0.6 V or 0 V to 10 V, whichever is lower. The 10 V upper limit is set by an internal zener clamp that provides protection in the event of an electrostatic discharge. The VFC is a charge–balanced synchronous type which generates output pulses at a rate of $F_V = V_{sen}$ (26 kHz).

The Sample Timer circuit provides a 105 kHz system clock signal (SCK) to the VFC. This signal synchronizes the F_V output to the other Sample Timer outputs used within the detector. At 1.25 second intervals the V_{sen} Gate output goes low for a 30 ms period. This output is used to momentarily interrupt the external charging power source so that a precise voltage measurement can be taken. As the V_{sen} Gate goes low, the internal Preset control line is driven high for 10 ms. During this time, the battery voltage at the V_{sen} input is allowed to stabilize and the previous F_V count is preloaded. At the Preset high–to–low transition, the Convert line goes high for 20 ms. This gates the F_V pulses into the ratchet counter for a comparison to the preloaded count. Since the Convert time is derived from the same clock that controls the VFC, the number of F_V pulses is independent of the clock frequency. If the new sample has more counts than were preloaded, it becomes the new peak count and the cycle is repeated 1.25 seconds later. If the new sample has two fewer counts, a less than peak voltage event has occurred, and a register is initialized. If two successive less than peak voltage events occur, the –ΔV ‘AND’ gate output goes high and the Fast/Trickle output is latched in a low state, signifying that the battery pack has reached full charge status. Negative slope voltage detection can only occur after 160 seconds have elapsed in the fast charge mode. The trickle mode holdoff time is implemented to ignore any initial drop in voltage that may occur when charging batteries that have been stored for an extended time period. The negative slope voltage detector has a maximum resolution of 2.0 V divided by 1023, or 1.955 mV per count with an uncertainty of ±1.0 count. In order to obtain maximum sensing accuracy, the R2/R1 voltage divider must be adjusted so that the V_{sen} input voltage is slightly less than 2.0 V when the battery pack is fully charged. Voltage variations due to temperature and cell manufacturing must be considered.

Figure 9. Negative Slope Voltage Detector



Fast Charge Timer

A programmable backup charge timer is available for fast charge termination. The timer is activated by the Time/Temp Select comparator, and is programmed from the t1/T_{ref} High, t2/T_{sen}, and t3/T_{ref} Low inputs. If one or more of these inputs is allowed to go above V_{CC} – 0.7 V or is left open, the comparator output will switch high, indicating that the timer feature is desired. The three inputs allow one of seven possible fast charge time limits to be selected. The programmable time limits, rounded to the nearest whole minute, are shown in Figure 10.

Over/Under Temperature Detection

A backup over/under temperature detector is available and can be used in place of the timer for fast charge termination. The timer is disabled by the Time/Temp Select comparator when each of the three programming inputs are held below V_{CC} – 0.7 V.

Temperature sensing is accomplished by placing a negative temperature coefficient (NTC) thermistor in thermal contact with the battery pack. The thermistor connects to the t2/T_{sen} input which has a 30 μA current source pull–up for developing a temperature dependent voltage. The temperature limits are set by a resistor that connects from the t1/T_{ref} High and the t3/T_{ref} Low inputs to ground. Since all three inputs contain matched 30 μA current source pull–ups, the required programming resistor values are identical to that of the thermistor at the desired over and under trip temperature. The temperature window detector is composed of two comparators with a common input that connects to the t2/T_{sen} input.

The lower comparator senses the presence of an under temperature condition. When the lower temperature limit is exceeded, the charger is switched to the trickle mode. The comparator has 44 mV of hysteresis to prevent erratic switching between the fast and trickle modes as the lower temperature limit is crossed. The amount of temperature rise to overcome the hysteresis is determined by the thermistor's rate of resistance change or sensitivity at the under temperature trip point. The required resistance change is:

$$\Delta R(T_{Low} \rightarrow T_{High}) = \frac{V_{H(T)}}{I_{in}} = \frac{44\ \text{mV}}{30\ \mu\text{A}} = 1.46\ \text{k}$$

The resistance change approximates a thermal hysteresis of 2°C with a 10 kΩ thermistor operating at 0°C. The under temperature fast charge inhibit feature can be disabled by biasing the t3/T_{ref} Low input to a voltage that is greater than that present at t2/T_{sen}, and less than V_{CC} – 0.7 V. Under extremely cold conditions, it is possible that the thermistor resistance can become too high, allowing the t2/T_{sen} input to go above V_{CC} – 0.7 V, and activate the timer. This condition can be prevented by placing a resistor in parallel with the thermistor. Note that the time/temperature threshold of V_{CC} – 0.7 V is a typical value at room temperature. Refer to the Electrical Characteristics table and to Figure 3 for additional information.

The upper comparator senses the presence of an over temperature condition. When the upper temperature limit is exceeded, the comparator output sets the Over Temperature Latch and the charger is switched to trickle mode. Once the latch is set, the charger cannot be returned to fast charge, even after the temperature falls below the limit. This feature prevents the battery pack from being continuously temperature cycled and overcharged. The latch can be reset by removing and reconnecting the battery pack or by cycling the power supply voltage.

If the charger does not require either the time or temperature backup features, they can both be easily disabled. This is accomplished by biasing the t3/T_{ref} Low input to a voltage greater than t2/T_{sen}, and by grounding the t1/T_{ref} High input. Under these conditions, the Time/Temp Select comparator output is low, indicating that the temperature mode is selected, and that the t2/T_{sen} input is biased within the limits of an artificial temperature window.

Operating Logic

The order of events in the charging process is controlled by the logic circuitry. Each event is dependent upon the input conditions and the chosen method of charge termination. A table summary containing all of the possible operating modes is shown in Figure 11.

Figure 10. Fast Charge Backup Termination Time/Temperature Limit

Backup Termination Mode	Programming Inputs			Time Limit Fast Charge (Minutes)

Temperature	0 V to V_{CC} – 0.7 V	0 V to V_{CC} – 0.7 V	0 V to V_{CC} – 0.7 V	Timer Disabled

Figure 11. Controller Operating Mode Table

Input Condition	Controller Operation
V_{sen} Input Voltage: >1.0 V and <2.0 V	The divided down battery pack voltage is within the fast charge voltage range. The charger switches from trickle to fast charge mode as V_{sen} enters this voltage range, and the reset signal that was applied to the timer and the over temperature latch is now released.
>1.0 V and <2.0 V with two consecutive –ΔV events detected after 160 s	The battery pack has reached full charge and the charger switches from fast to a latched trickle mode. A reset signal must be applied and then released for the charger to switch back to the fast mode. The reset signal is applied when either V_{sen} <1.0 V or >2.0 V, or V_{CC} <2.8 V. A signal is released when both V_{sen} >1.0 V and <2.0 V, and V_{CC} >3.0 V.
<1.0 V or >2.0 V	The divided down battery pack voltage is outside of the fast charge voltage range. The charger switches from fast to trickle mode, and a reset signal is applied to the timer and over temperature latch.
Timer Backup: Within time limit	The timer has not exceeded the programmed limit. The charger will be in fast charge mode if V_{sen} and V_{CC} are within their respective operating limits.
Beyond time limit	The timer has exceeded the programmed limit. The charger switches from fast to a latched trickle mode.
Temperature Backup: Within limits	The battery pack temperature is within the programmed limits. The charger will be in fast charge mode if V_{sen} and V_{CC} are within their respective operating limits.
Below lower limit	The battery pack temperature is below the programmed lower limit. The charger will stay in trickle mode until the lower temperature limit is exceeded. When exceeded, the charger will switch from trickle to fast charge mode.
Above upper limit	The battery pack temperature has exceeded the programmed upper limit. The charger switches from fast to a latched trickle mode. A reset signal must be applied and then released for the charger to switch back to the fast charge mode. A reset signal is applied when either V_{sen} <1.0 V or >2.0 V, or V_{CC} <2.8 V, and is released when both V_{sen} >1.0 V and <2.0 V, and V_{CC} >3.0 V.
Power Supply Voltage: V_{CC} >3.0 V and <18 V	This is the nominal power supply operating voltage range. The charger will be in fast charge mode if V_{sen}, and temperature backup or timer backup are within their respective operating limits.
V_{CC} >0.6 V and <2.8 V	The undervoltage lockout comparator will be activated and the charger will be in trickle mode. A reset signal is applied to the timer and over temperature latch.

Testing

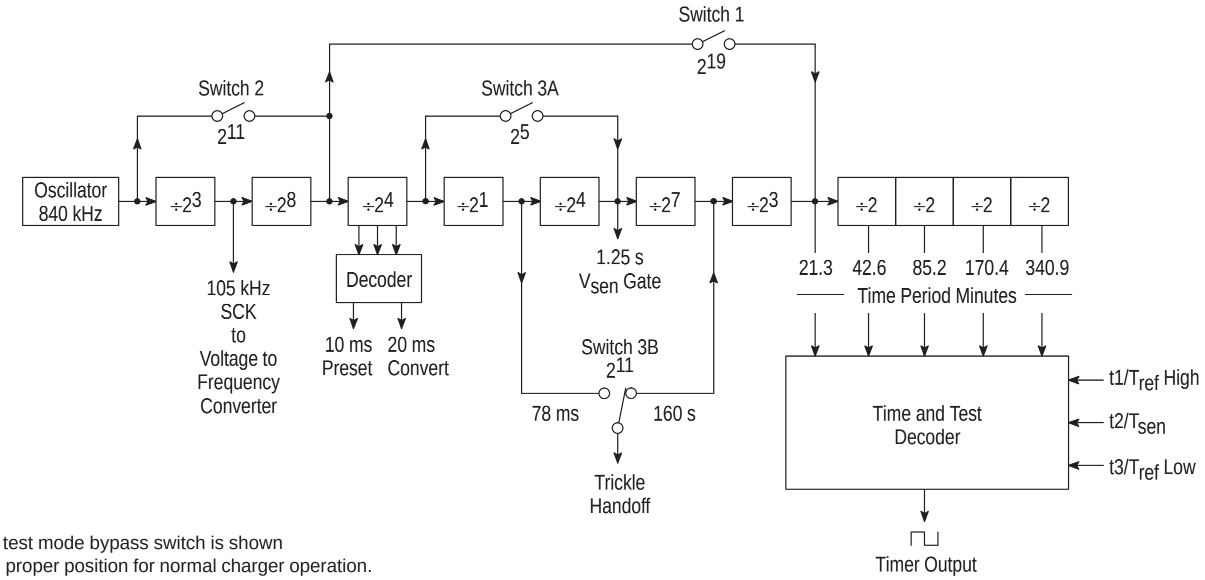
Under normal operating conditions, it would take 256 minutes to verify the operation of the 34 stage ripple counter used in the timer. In order to significantly reduce the test time, three digital switches were added to the circuitry and are used to bypass selected divider stages. Entering each of the test modes without requiring additional package pins or affecting normal device operation proved to be challenging. Refer to the timer functional block diagram in Figure 12.

Switch 1 bypasses 19 divider stages to provide a 524,288 times speedup of the clock. This switch is enabled when the V_{sen} input falls below 1.0 V. Verification of the programmed fast charge time limit is accomplished by measuring the propagation delay from when the V_{sen} input falls below 1.0 V, to when the F/T output changes from a high–to–low state. The 64, 96, 128, 160, 192, 224 and 256 minute timeouts will now correspond to 7.3, 11, 14.6, 18.3, 22, 25.6 and 29.3 ms delays. It is possible to enter this test mode during operation if the equivalent battery pack voltage was to fall below 1.0 V. This will not present a problem since the device would normally switch from fast to trickle mode under these conditions, and the relatively short variable time delay would be transparent to the user.

Switch 2 bypasses 11 divider stages to provide a 2048 times speedup of the clock. This switch is necessary for testing the 19 stages that were bypassed when switch 1 was enabled. Switch 2 is enabled when the V_{sen} input falls below 1.0 V and the $t1/T_{ref}$ Low input is biased at –100 mV. Verification of the 19 stages is accomplished by measuring a nominal propagation delay of 308 ms from when the V_{sen} input falls below 1.0 V, to when the F/T output changes from a high–to–low state.

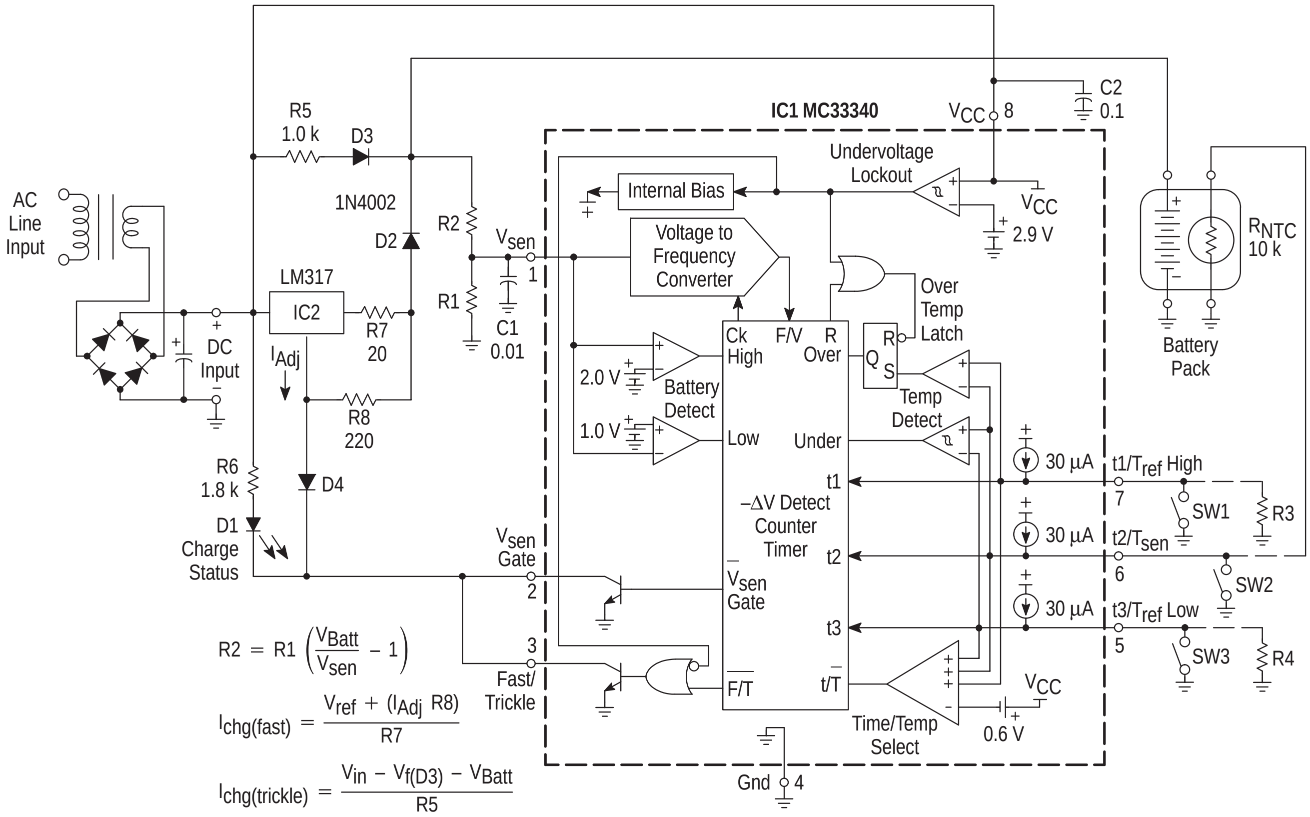
Switch 3 is a dual switch consisting of sections “A” and “B”. Section “A” bypasses 5 divider stages to provide a 32 times speedup of the V_{sen} gate signal that is used in sampling the battery voltage. This speedup allows faster test verification of two successive –ΔV events. Section “B” bypasses 11 divider stages to provide a 2048 speedup of the trickle mode holdoff timer. Switches 3A and 3B are both activated when the $t1/T_{ref}$ Low input is biased at –100 mV with respect to Pin 4. Activation results in a reduction of the V_{sen} gate sample rate from 1.25 s to 39 ms, and a trickle mode holdoff time of 160 s to 68 ms.

Figure 12. Timer Functional Block Diagram



Each test mode bypass switch is shown
in the proper position for normal charger operation.

Figure 13. Line Isolated Linear Regulator Charger



$$R2 = R1\left(\frac{V_{Batt}}{V_{sen}} - 1\right)$$

$$I_{chg(fast)} = \frac{V_{ref} + (I_{Adj}\ R8)}{R7}$$

$$I_{chg(trickle)} = \frac{V_{in} - V_{f(D3)} - V_{Batt}}{R5}$$

This application combines the MC33340 with an adjustable three terminal regulator to form an isolated secondary side battery charger. Regulator IC2 operates as a constant current source with R7 setting the fast charge level. The trickle charge level is set by R5. The R2/R1 divider should be adjusted so that the V_{sen} input is less than 2.0 V when the batteries are fully charged. The printed circuit board shown below will accept the several TO–220 style heatsinks for IC2 and are all manufactured by AAVID Engineering Inc.

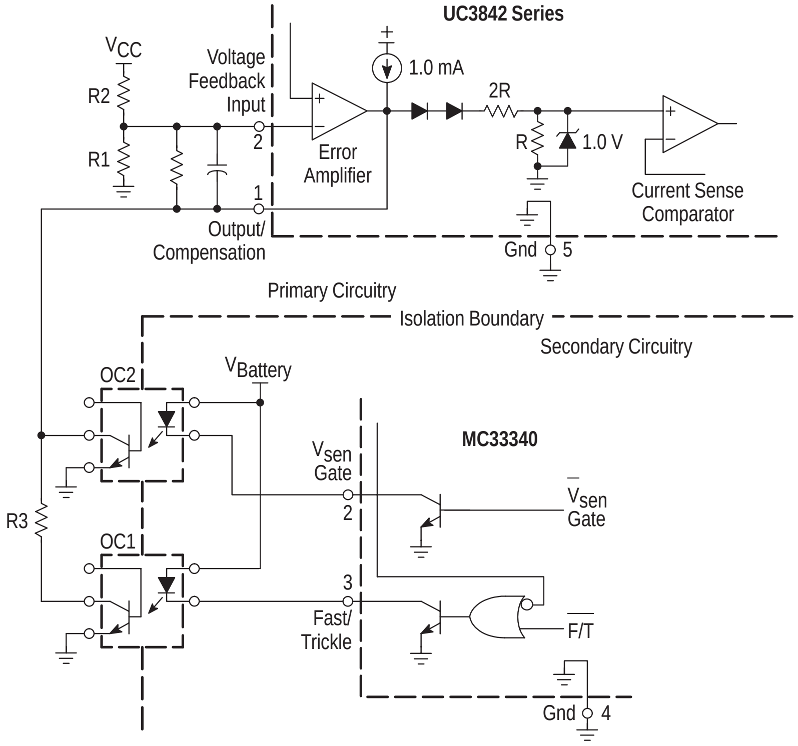
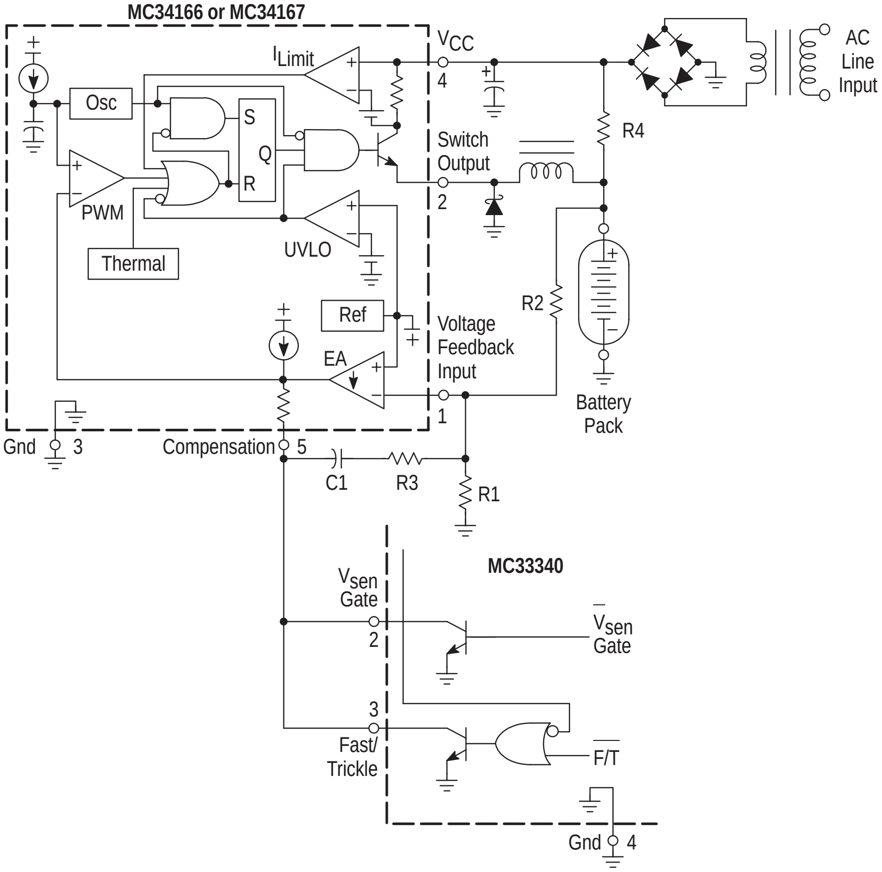
Figure 15. Line Isolated Switch Mode Charger



The MC33340 can be combined with any of the devices in the UC3842 family of current mode controllers to form a switch mode battery charger. In this example, optocouplers OC1 and OC2 are used to provide isolated control signals to the UC3842. During battery voltage sensing, OC2 momentarily grounds the Output/Compensation pin, effectively turning off the charger. When fast charge termination is reached, OC1 turns on, and grounds the lower side of R3. This reduces the peak switch current threshold of the Current Sense Comparator to a programmed trickle current level. For additional converter design information, refer to the UC3842 and UC3844 device family data sheets.

Figure 16. Switch Mode Fast Charger



The MC33340 can be used to control the MC34166 or MC34167 power switching regulators to produce an economical and efficient fast charger. These devices are capable of operating continuously in current limit with an input voltage range of 7.5 to 40 V. The typical charging current for the MC34166 and MC34167 is 4.3 A and 6.5 A respectively. Resistors R2 and R1 are used to set the battery pack fast charge float voltage. If precise float voltage control is not required, components R1, R2, R3 and C1 can be deleted, and Pin 1 must be grounded. The trickle current level is set by resistor R4. It is recommended that a redundant charge termination method be employed for end user protection. This is especially true for fast charger systems. For additional converter design information, refer to the MC34166 and MC34167 data sheets.

Power Supply Battery Charger Regulation Control Circuit

The MC33341 is a monolithic regulation control circuit that is specifically designed to close the voltage and current feedback loops in power supply and battery charger applications. This device features the unique ability to perform source high–side, load high–side, source low–side and load low–side current sensing, each with either an internally fixed or externally adjustable threshold. The various current sensing modes are accomplished by a means of selectively using the internal differential amplifier, inverting amplifier, or a direct input path. Positive voltage sensing is performed by an internal voltage amplifier. The voltage amplifier threshold is internally fixed and can be externally adjusted in all low–side current sensing applications. An active high drive output is provided to directly interface with economical optoisolators for isolated output power systems. This device is available in 8–lead dual–in–line and surface mount packages.

- Differential Amplifier for High–Side Source and Load Current Sensing
- Inverting Amplifier for Source Return Low–Side Current Sensing
- Non–Inverting Input Path for Load Low–Side Current Sensing
- Fixed or Adjustable Current Threshold in All Current Sensing Modes
- Positive Voltage Sensing in All Current Sensing Modes
- Fixed Voltage Threshold in All Current Sensing Modes
- Adjustable Voltage Threshold in All Low–Side Current Sensing Modes
- Output Driver Directly Interfaces with Economical Optoisolators
- Operating Voltage Range of 2.3 V to 18 V

PIN FUNCTION DESCRIPTION

Pin	Name	Description
1	Current Sense Input A	This multi–mode current sensing input can be used for either source high–side, load high–side, source–return low–side, or load low–side sensing. It is common to a Differential Amplifier, Inverting Amplifier, and a Noninverting input path. Each of these sensing paths indirectly connect to the current sense input of the Transconductance Amplifier. This input is connected to the high potential side of a current sense resistor when used in source high–side, load high–side, or load low–side current sensing modes. In source return low–side current sensing mode, this pin connects to the low potential side of a current sense resistor.
2	Current Threshold Adjust	The current sense threshold can be externally adjusted over a range of 0 V to 200 mV with respect to Pin 4, or internally fixed at 200 mV by connecting Pin 2 to V_{CC}.
3	Compensation	This pin is connected to a high impedance node within the transconductance amplifier and is made available for loop compensation. It can also be used as an input to directly control the Drive Output. An active low at this pin will force the Drive Output into a high state.
4	Ground	This pin is the regulation control IC ground. The control threshold voltages are with respect to this pin.
5	Voltage Sense Input	This is the voltage sensing input of the Transconductance Amplifier. It is normally connected to the power supply/battery charger output through a resistor divider. The input threshold is controlled by Pin 6.
6	Current Sense Input B/ Voltage Threshold Adjust	This is a dual function input that is used for either high–side current sensing, or as a voltage threshold adjustment for Pin 5. This input is connected to the low potential side of a current sense resistor when used in source high–side or load high–side current sensing modes. In all low–side current sensing modes, Pin 6 is available as a voltage threshold adjustment for Pin 5. The threshold can be externally adjusted over a range of 0 V to 1.2 V with respect to Pin 4, or internally fixed at 1.2 V by connecting Pin 6 to V_{CC}.
7	V_{CC}	This is the positive supply voltage for the regulation control IC. The typical operating voltage range is 2.3 V to 18 V with respect to Pin 4.
8	Drive Output	This is a source–only output that normally connects to a linear or switching regulator control circuit. This output is capable of 15 mA, allowing it to directly drive an optoisolator in primary side control applications where galvanic isolation is required.

INTRODUCTION

Power supplies and battery chargers require precise control of output voltage and current in order to prevent catastrophic damage to the system load. Many present day power sources contain a wide assortment of building blocks and glue devices to perform the required sensing for proper regulation. Typical feedback loop circuits may consist of a voltage and current amplifier, level shifting circuitry, summing circuitry and a reference. The MC33341 contains all of these basic functions in a manner that is easily adaptable to many of the various power source–load configurations.

OPERATING DESCRIPTION

The MC33341 is an analog regulation control circuit that is specifically designed to simultaneously close the voltage and current feedback loops in power supply and battery charger applications. This device can control the feedback loop in either constant–voltage or constant–current mode with automatic crossover. A concise description of the integrated circuit blocks is given below. Refer to the block diagram in Figure 13.

Transconductance Amplifier

A quad input transconductance amplifier is used to control the feedback loop. This amplifier has separate voltage and current channels, each with a sense and a threshold input. Within a given channel, if the sense input level exceeds that of the threshold input, the amplifier output is driven high. The channel with the largest difference between the sense and threshold inputs will set the output source current of the amplifier and thus dominate control of the feedback loop. The amplifier output appears at Pin 8 and is a source–only type that is capable of 15 mA.

A high impedance node within the transconductance amplifier is made available at Pin 3 for loop compensation. This pin can sink and source up to 10 µA of current. System stability is achieved by connecting a capacitor from Pin 3 to ground. The Compensation Pin signal is out of phase with respect to the Drive Output. By actively clamping Pin 3 low, the Drive Output is forced into a high state. This, in effect, will shutdown the power supply or battery charger, by forcing the output voltage and current regulation threshold down towards zero.

Voltage Sensing

The voltage that appears across the load is monitored by the noninverting V_{sen} input of the transconductance amplifier. This voltage is resistively scaled down and connected to Pin 5. The threshold at which voltage regulation occurs is set by the level present at the inverting V_{th} input of the transconductance amplifier. This level is controlled by Pin 6. In source high–side and load high–side current sensing modes, Pin 6 must be connected to the low potential side of current sense resistor R_S. Under these conditions, the voltage regulation threshold is internally fixed at 1.2 V. In source return low–side and load low–side current sensing modes, Pin 6 is available, and can be used to lower the regulation threshold of Pin 5. This threshold can be externally adjusted over a range of 0 V to 1.2 V with respect to the IC ground at Pin 4.

Current Sensing

Current sensing is accomplished by monitoring the voltage that appears across sense resistor R_S, level shifting it with respect to Pin 4 if required, and applying it to the noninverting I_{sen} input of the transconductance amplifier. In order to allow for maximum circuit flexibility, there are three methods of current sensing, each with different internal paths.

In source high–side (Figures 13 and 14) and load high–side (Figures 17 and 18) current sensing, the Differential Amplifier is active with a gain of 1.0. Pin 1 connects to the high potential side of current sense resistor R_S while Pin 6 connects to the low side. Logic circuitry is provided to disable the Differential Amplifier output whenever low–side current sensing is required. This circuit clamps the Differential Amplifier output high which disconnects it from the I_{sen} input of the Transconductance Amplifier. This happens if Pin 1 is less than 1.2 V or if Pin 1 is less than Pin 6.

With source return low–side current sensing (Figures 15 and 16), the Inverting Amplifier is active with a gain of –1.0. Pin 1 connects to the low potential side of current sense resistor R_S while Pin 4 connects to the high side. Note that a negative voltage appears across R_S with respect to Pin 4.

In load low–side current sensing (Figures 19 and 20) a Noninverting input path is active with a gain of 1.0. Pin 1 connects to the high potential side of current sense resistor R_S while Pin 4 connects to the low side. The Noninverting input path lies from Pin 1, through the Inverting Amplifier input and feedback resistors R, to the cathode of the output diode. With load low–side current sensing, Pin 1 will be more positive than Pin 4, forcing the Inverting Amplifier output low. This causes the diode to be reverse biased, thus preventing the output stage of the amplifier from loading the input signal that is flowing through the feedback resistors.

The regulation threshold in all of the current sensing modes is internally fixed at 200 mV with Pin 2 connected to V_{CC}. Pin 2 can be used to externally adjust the threshold over a range of 0 to 200 mV with respect to the IC ground at Pin 4.

Reference

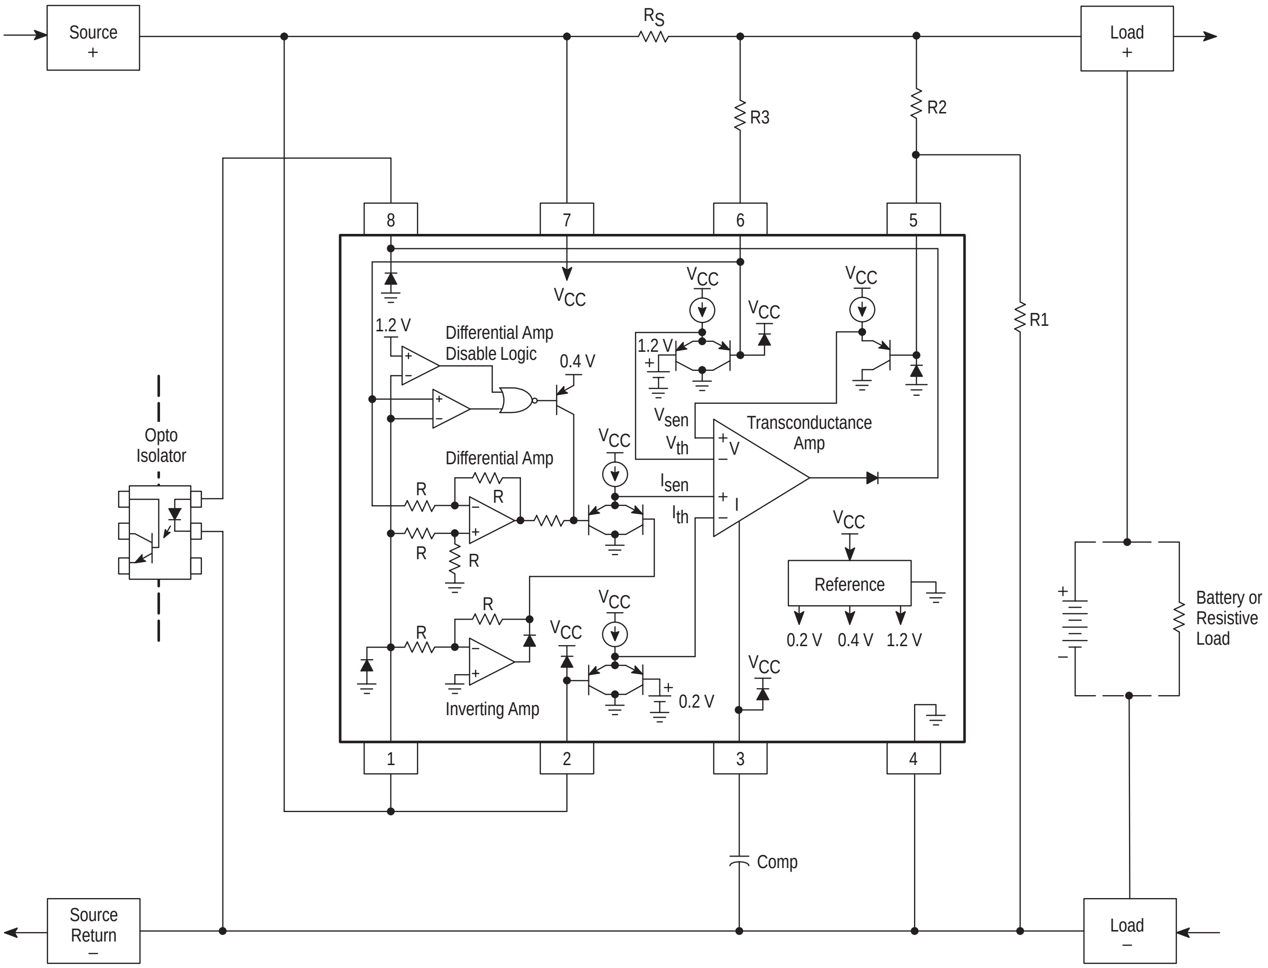
An internal band gap reference is used to set the 1.2 V voltage threshold and 200 mV current threshold. The reference is initially trimmed to a ±1.0% tolerance at T_A = 25°C and is guaranteed to be within ±2.0% over an ambient operating temperature range of –25° to 85°C.

Applications

Each of the application circuits illustrate the flexibility of this device. The circuits shown in Figures 13 through 20 contain an optoisolator connected from the Drive Output at Pin 8 to ground. This configuration is shown for ease of understanding and would normally be used to provide an isolated control signal to a primary side switching regulator controller. In non–isolated, primary or secondary side applications, a load resistor can be placed from Pin 8 to ground. This resistor will convert the Drive Output current to a voltage for direct control of a regulator.

In applications where excessively high peak currents are possible from the source or load, the load induced voltage drop across R_S could exceed 1.6 V. Depending upon the current sensing configuration used, this will result in forward biasing of either the internal V_{CC} clamp diode, Pin 6, or the device substrate, Pin 1. Under these conditions, input series resistor R3 is required. The peak input current should be limited to 20 mA. Excessively large values for R3 will degrade the current sensing accuracy. Figure 21 shows a method of bounding the voltage drop across R_S without sacrificing current sensing accuracy.

Figure 13. Source High–Side Current Sensing with Internally Fixed Voltage and Current Thresholds



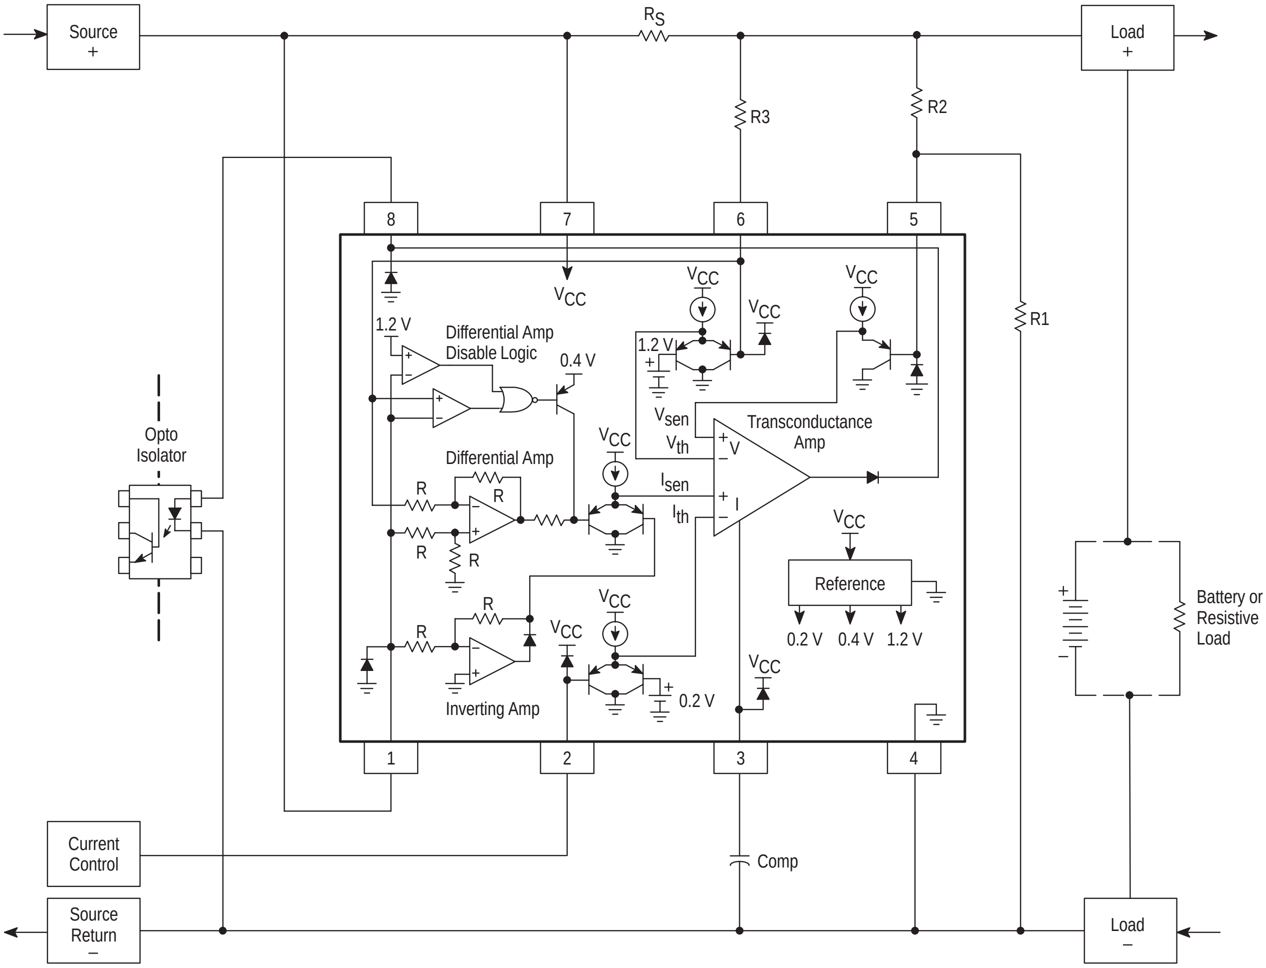
The above figure shows the MC33341 configured for source high–side current sensing allowing a common ground path between Load – and Source Return –. The Differential Amplifier inputs, Pins 1 and 6, are used to sense the load induced voltage drop that appears across resistor R_S. The internal voltage and current regulation thresholds are selected by the respective external connections of Pins 2 and 6. Resistor R3 is required in applications where a high peak level of reverse current is possible if the source inputs are shorted. The resistor value should be chosen to limit the input current of the internal V_{CC} clamp diode to less than 20 mA. Excessively large values for R3 will degrade the current sensing accuracy.

$$V_{reg} = V_{th(V)}\left(\frac{R2}{R1} + 1\right) = 1.2\left(\frac{R2}{R1} + 1\right)$$

$$I_{reg} = \frac{V_{th(I\ HS)}}{R_S} = \frac{0.2}{R_S}$$

$$R3 = \frac{\left(I_{pk}\,R_S\right) - 0.6}{0.02}$$

Figure 14. Source High–Side Current Sensing with Externally Adjustable Current and Internally Fixed Voltage Thresholds



The above figure shows the MC33341 configured for source high–side current sensing with an externally adjustable current threshold. Operation of this circuit is similar to that of Figure 13. The current regulation threshold can be adjusted over a range of 0 V to 200 mV with respect to Pin 4.

$$V_{reg} = V_{th(V)}\left(\frac{R2}{R1} + 1\right)$$

$$I_{reg} = \frac{V_{th(Pin\ 2)}}{R_S}$$

$$R3 = \frac{\left(I_{pk}\,R_S\right) - 0.6}{0.02}$$

$$= 1.2\left(\frac{R2}{R1} + 1\right)$$

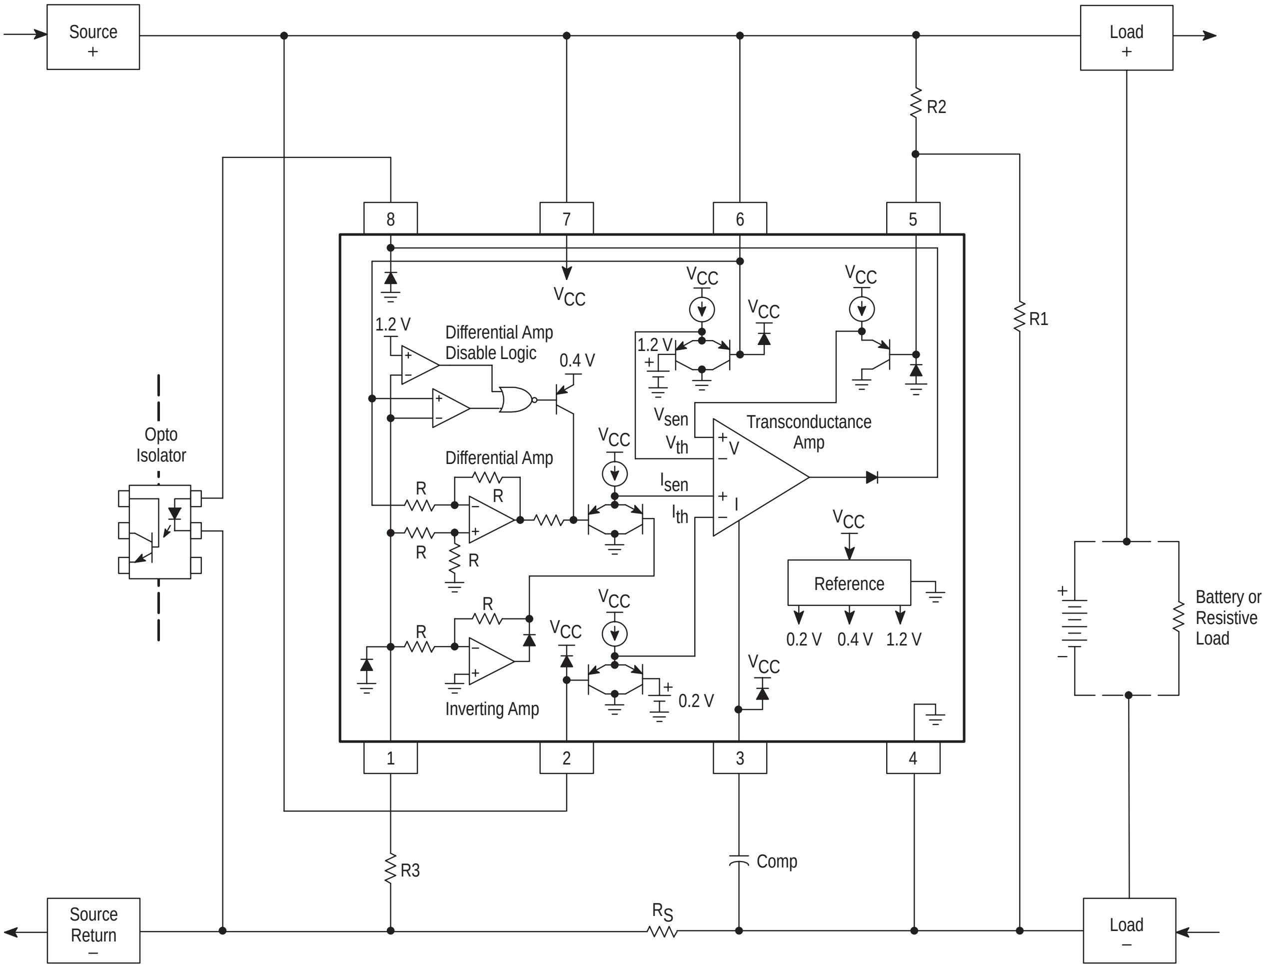


Figure 15. Source Return Low–Side Current Sensing with Internally Fixed Current and Voltage Thresholds

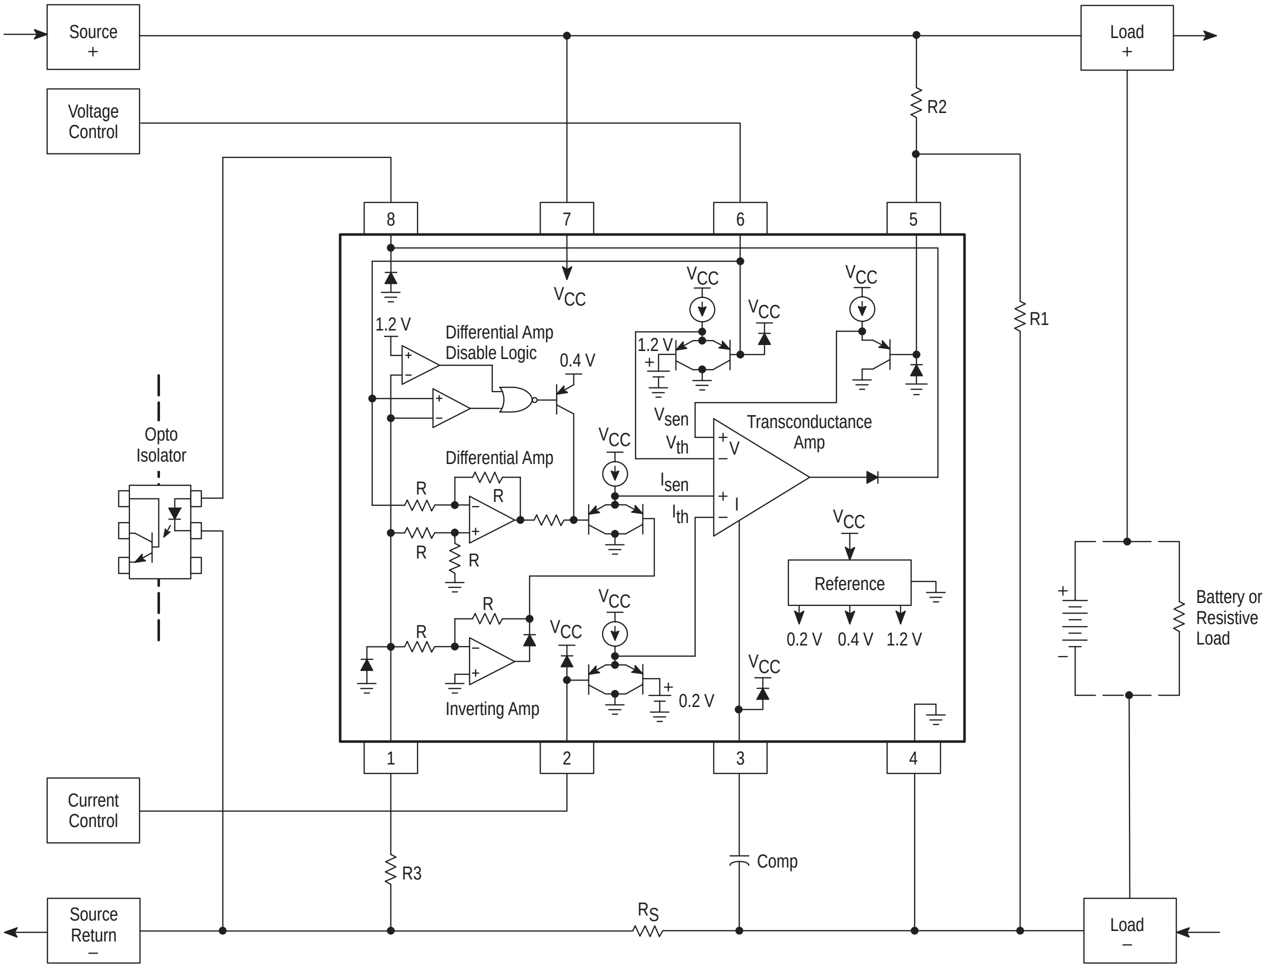
The above figure shows the MC33341 configured for source return low–side current sensing allowing a common power path between Source + and Load +. This configuration is especially suited for negative output applications where a common ground path, Source + to Load +, is desired. The Inverting Amplifier inputs, Pins 1 and 4, are used to sense the load induced voltage drop that appears across resistor R_S. The internal voltage and current regulation thresholds are selected by the respective external connections of Pins 2 and 6. Resistor R3 is required in applications where high peak levels of inrush current are possible. The resistor value should be chosen to limit the negative substrate current to less than 20 mA. Excessively large values for R3 will degrade the current sensing accuracy.

$$V_{reg} = V_{th(V)}\left(\frac{R2}{R1} + 1\right) \qquad I_{reg} = \frac{V_{th(I\ LS-)}}{R_S} \qquad R3 = \frac{\left(I_{pk}\ R_S\right) - 0.6}{0.02}$$

$$= 1.2\left(\frac{R2}{R1} + 1\right) \qquad = \frac{-0.2}{R_S}$$

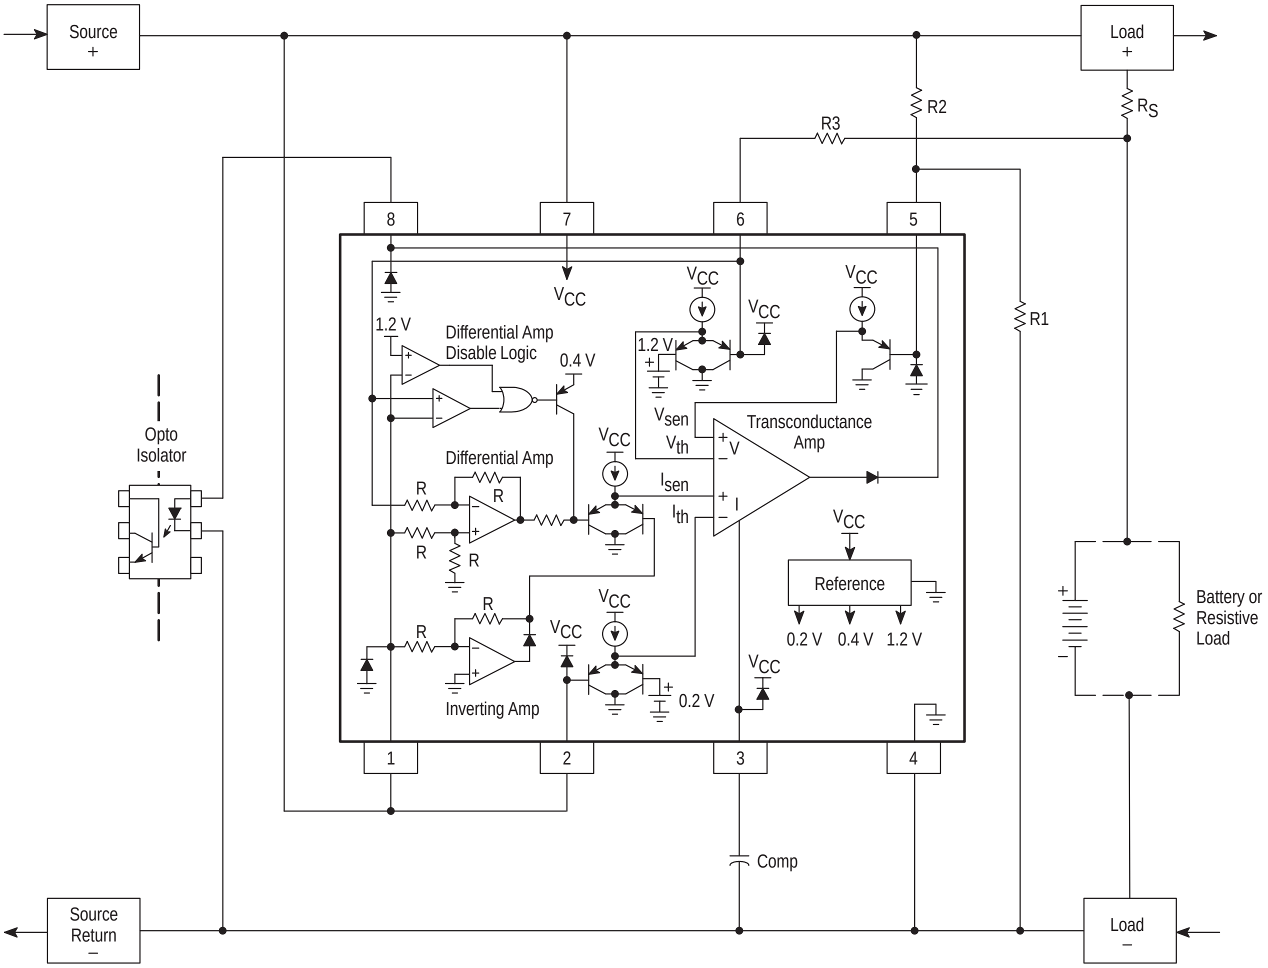
Figure 16. Source Return Low–Side Current Sensing with Externally Adjustable Current and Voltage Thresholds



The above figure shows the MC33341 configured for source return low–side current sensing with externally adjustable voltage and current thresholds. Operation of this circuit is similar to that of Figure 15. The respective voltage and current regulation threshold can be adjusted over a range of 0 to 1.6 V and 0 V to 200 mV with respect to Pin 4.

$$V_{reg} = V_{th(Pin\ 6)}\left(\frac{R2}{R1} + 1\right) \qquad I_{reg} = -\frac{V_{th(Pin\ 2)}}{R_S} \qquad R3 = \frac{\left(I_{pk}\,R_S\right) - 0.6}{0.02}$$

Figure 17. Load High–Side Current Sensing with Internally Fixed Current and Voltage Thresholds



The above figure shows the MC33341 configured for load high–side current sensing allowing common paths for both power and ground, between the source and load. The Differential Amplifier inputs, Pins 1 and 6, are used to sense the load induced voltage drop that appears across resistor R_S. The internal voltage and current regulation thresholds are selected by the respective external connections of Pins 2 and 6. Resistor R3 is required in applications where high peak levels of load current are possible from the battery or load bypass capacitor. The resistor value should be chosen to limit the input current of the internal V_{CC} clamp diode to less than 20 mA. Excessively large values for R3 ill degrade the current sensing accuracy.

$$V_{reg} = V_{th(V)}\left(\frac{R2}{R1} + 1\right)$$

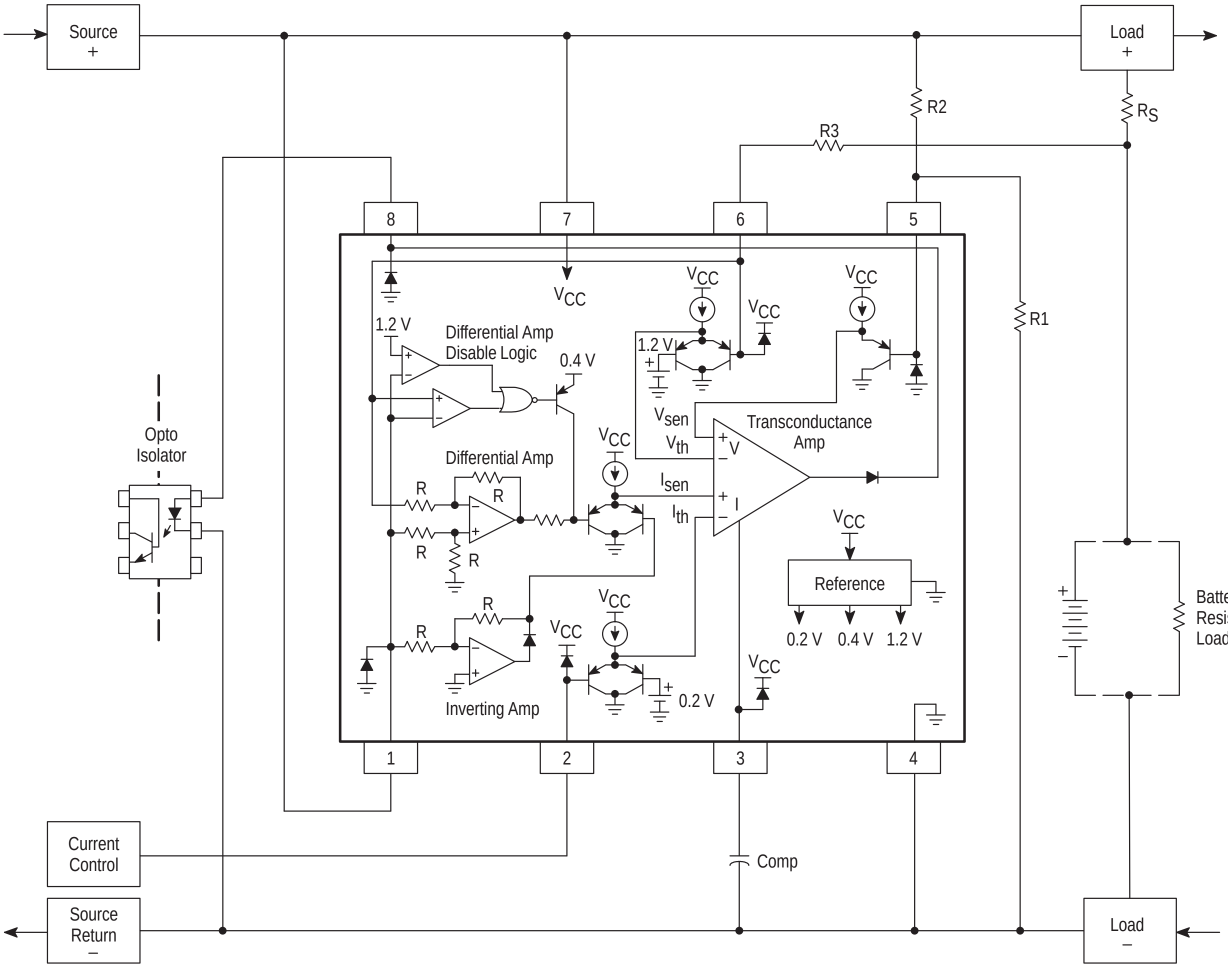
$$= 1.2\left(\frac{R2}{R1} + 1\right)$$

$$I_{reg} = \frac{V_{th(I\ HS)}}{R_S}$$

$$= \frac{0.2}{R_S}$$

$$R3 = \frac{\left(I_{pk}\ R_S\right) - 0.6}{0.02}$$

Figure 18. Load High–Side Current Sensing with Externally Adjustable Current and Internally Fixed Voltage Thresholds



The above figure shows the MC33341 configured for load high–side current sensing with an externally adjustable current threshold. Operation of this circuit is similar to that of Figure 17. The current regulation threshold can be adjusted over a range of 0 V to 200 mV with respect to Pin 4.

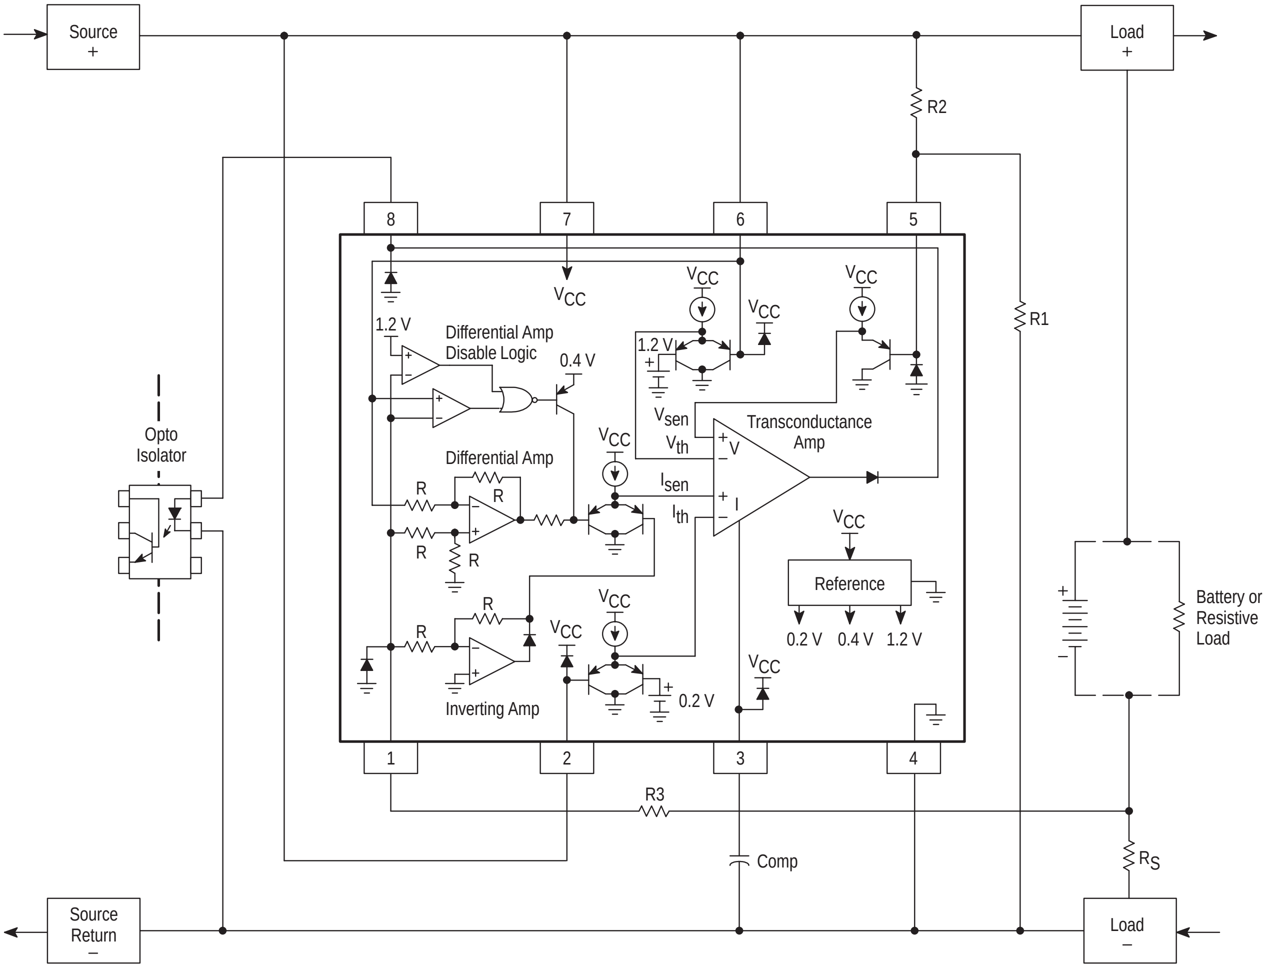
$$V_{reg} = V_{th(V)}\left(\frac{R2}{R1} + 1\right)$$

$$= 1.2\left(\frac{R2}{R1} + 1\right)$$

$$I_{reg} = \frac{V_{th(Pin\ 2)}}{R_S}$$

$$R3 = \frac{\left(I_{pk}\,R_S\right) - 0.6}{0.02}$$

Figure 19. Load Low–Side Current Sensing with Internally Fixed Current and Voltage Thresholds



The above figure shows the MC33341 configured for load low–side current sensing allowing common paths for both power and ground, between the source and load. The Noninverting input paths, Pins 1 and 4, are used to sense the load induced voltage drop that appears across resistor R_S. The internal voltage and current regulation thresholds are selected by the respective external connections of Pins 2 and 6. Resistor R3 is required in applications where high peak levels of load current are possible from the battery or load bypass capacitor. The resistor value should be chosen to limit the negative substratecurrent to less than 20 mA. Excessively large values for R3 will degrade the current sensing accuracy.

$$V_{reg} = V_{th(V)}\left(\frac{R2}{R1} + 1\right)$$

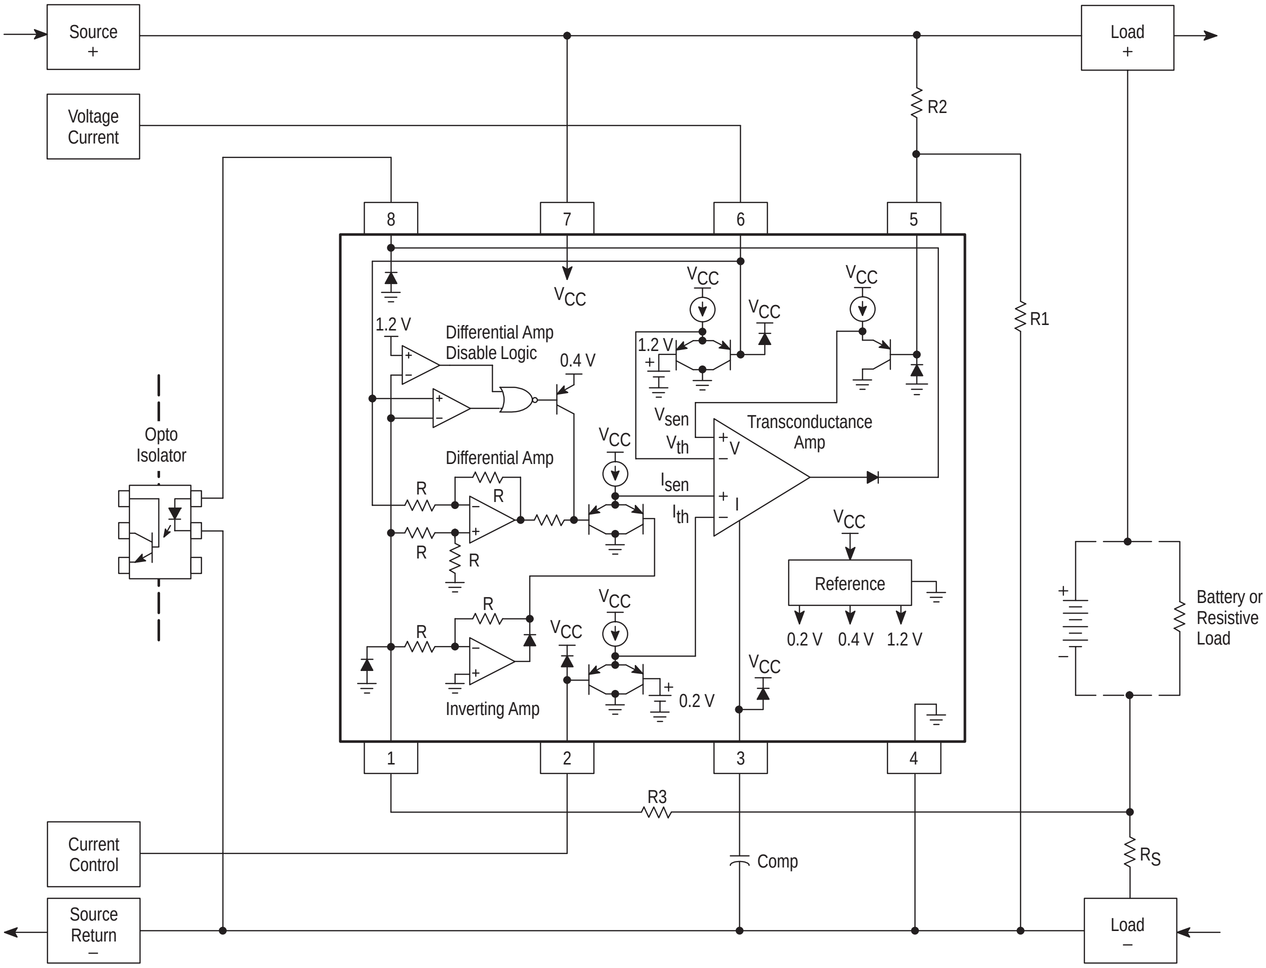
$$= 1.2\left(\frac{R2}{R1} + 1\right)$$

$$I_{reg} = \frac{V_{th(I\,LS+)}}{R_S}$$

$$= \frac{0.2}{R_S}$$

$$R3 = \frac{\left(I_{pk}\,R_S\right) - 0.6}{0.02}$$

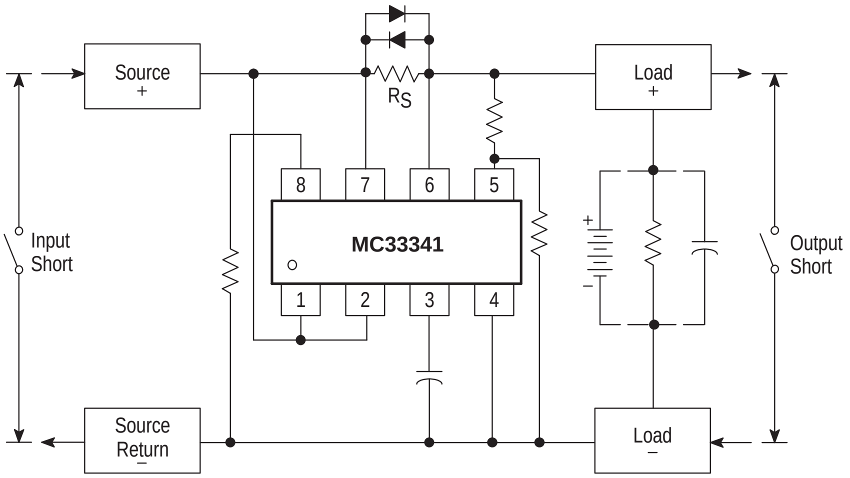
Figure 20. Load Low–Side Current Sensing with Externally Adjustable Current and Voltage Thresholds



The above figure shows the MC33341 configured for load low–side current sensing with an externally adjustable voltage and current threshold. Operation of this circuit is similar to that of Figure 19. The respective voltage and current regulation threshold can be adjusted over a range of 0 to 1.2 V and 0 V to 200 mV, with respect to Pin 4.

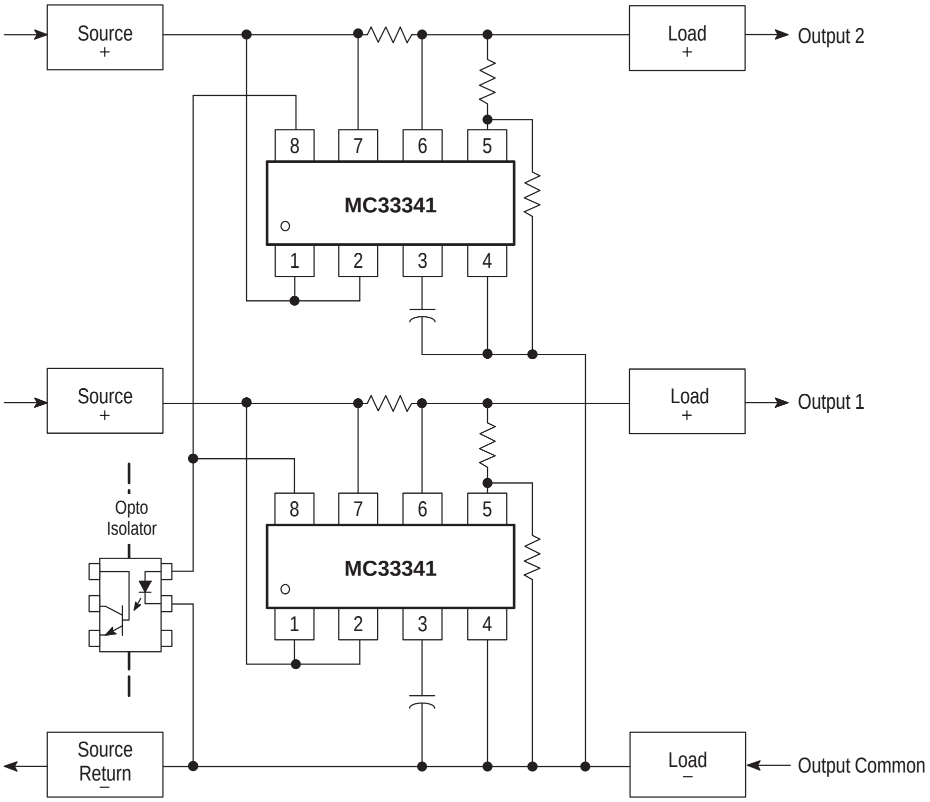
$$V_{reg} = V_{th(Pin\ 6)}\left(\frac{R2}{R1} + 1\right) \qquad I_{reg} = \frac{V_{th(Pin\ 2)}}{R_S} \qquad R3 = \frac{\left(I_{pk}\,R_S\right) - 0.6}{0.02}$$

Figure 21. Current Sense Resistor Bounding



NOTE: An excessive load induced voltage across R_S can occur if either the source input or load output is shorted. This voltage can easily be bounded with the addition of the diodes shown without degrading the current sensing accuracy. This bounding technique can be used in any of the MC33341 applications where high peak currents are anticipated.

Figure 22. Multiple Output Current and Voltage Regulation



NOTE: Multiple outputs can be controlled by summing the error signal into a common optoisolator. The converter output with the largest voltage or current error will dominate control of the feedback loop.

Lithium Battery Protection Circuit for One to Four Cell Battery Packs

The MC33345 is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of one to four cell rechargeable battery packs. Cell protection features consist of independently programmable charge and discharge limits for both voltage and current with a delayed current shutdown, cell voltage balancing with on–chip balancing resistors, and a virtually zero current sleepmode state when the cells are discharged. Additional features include an on–chip charge pump for reduced MOSFET losses while charging or discharging a low cell voltage battery pack, and the programmability for a one to four cell battery pack. This protection circuit requires a minimum number of external components and is targeted for inclusion within the battery pack. The MC33345 is available in standard and low profile 20 lead surface mount packages.

- Independently Programmable Charge and Discharge Limits for Both Voltage and Current
- Charge and Discharge Current Limit Detection with Delayed Shutdown
- Cell Voltage Balancing
- On–Chip Balancing Resistors
- Virtually Zero Current Sleepmode State when Cells are Discharged
- Charge Pump for Reduced Losses with a Low Cell Voltage Battery Pack
- Programmable for One, Two, Three or Four Cell Applications
- Minimum External Components for Inclusion within the Battery Pack
- Available in Low Profile Surface Mount Packages

PIN FUNCTION DESCRIPTION

Pin	Symbol	Description
1	Cell Voltage Return	The bottom side of a three resistor divider string connects to this pin. The Cell Selector internally switches this point to the negative terminal of the cell that is to be monitored.
2	Cell 4/V_{CC}/ Discharge Current Limit	This is a multifunction pin that connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 4 and to provide positive supply voltage for the protection IC. This pin is also used to monitor the voltage drop across the discharge current limit resistor and it provides a discharge path for the internal balancing of Cell 4.
3	Cell Voltage	The top side of a three resistor divider string connects to this pin. The Cell Selector internally switches this point to the positive terminal of the cell that is to be monitored.
4	Discharge Voltage Threshold	The upper tap of a three resistor divider string connects to this pin. The Cell Voltage Detector compares the divided down cell voltage to an internal reference. If the comparator detects that the cell voltage has fallen below the programmed level, discharge switch Q2 is disabled, and the protection circuit enters into a low current sleepmode state. This prevents further discharging of the battery pack.
5	Charge Voltage Threshold	The lower tap of a three resistor divider string connects to this pin. The Cell Voltage Detector compares the divided down cell voltage to an internal reference. If the comparator detects that the cell voltage has risen above the programmed level, charge switch Q1 is disabled, preventing further charging of the battery pack. A 2.0 µA current source pull–up is internally applied to this pin creating input hysteresis.
6	Current Sense Common	This pin is a common point that is used to monitor the voltage drop across the charge and discharge current limit resistors.
7	Charge Current Limit	This pin is used to monitor the voltage drop across the charge current limit resistor.
8	Charge Gate Drive Common	This pin provides a gate turn–off path for charge switch Q1. The charge switch source and the battery pack negative terminal connect to this point.
9	Charge Gate Drive Output	This output connects to the gate of charge switch Q1 allowing it to enable or disable battery pack charging.
10	Program 2	This pin is used in conjunction with Pin 11 to program the number of cells.
11	Program 1	This pin is used in conjunction with Pin 10 to program the number of cells.
12	No Connection	This pin is not internally connected.
13	Discharge Gate Drive Output	This output connects to the gate of discharge switch Q2 allowing it to enable or disable battery pack discharging.
14	Charge Pump Output	This is the charge pump output. A reservoir capacitor is connected from this pin to ground.
15	Test Input	This input is used to facilitate circuit testing and is normally not connected. It has an internal 2.0 k pull–up resistor.
16	Ground	This is the protection IC ground and all voltage ratings are with respect to this pin.
17	Fault Output	This is on open drain output that is active low when a charging fault limit has been exceeded. The limits sensed are both charge voltage and current.
18	Cell 1/V_C	This is a multifunction pin that connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 1 and the negative terminal of Cell 2. This pin also provides logic biasing and a discharge path for the internal balancing of Cell 1.
19	Cell 2	This pin connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 2 and the negative terminal of Cell 3. This pin also provides a discharge path for the internal balancing of Cell 2.
20	Cell 3	This pin connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 3 and the negative terminal of Cell 4. This pin also provides a discharge path for the internal balancing of Cell 3.

INTRODUCTION

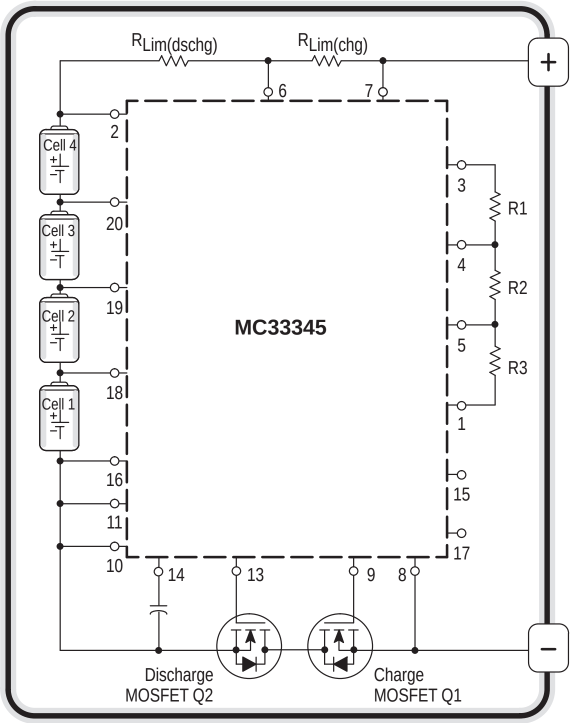
The insatiable demand for smaller lightweight portable electronic equipment has dramatically increased the requirements of battery performance. Batteries are expected to have higher energy densities, superior cycle life, be safe in operation and environmentally friendly. To address these high expectations, battery manufacturers have invested heavily in developing rechargeable lithium–based cells. Today's most attractive chemistries include lithium–polymer, lithium–ion, and lithium–metal. Each of these chemistries require electronic protection in order to constrain cell operation to within the manufacturers limits.

Rechargeable lithium–based cells require precise charge and discharge termination limits for both voltage and current in order to maximize cell capacity, cycle life, and to protect the end user from a catastrophic event. The termination limits are not as well defined as with older non–lithium chemistries. These limits are dependent upon a manufacturer's particular lithium chemistry, construction technique, and intended application. Battery pack assemblers may also choose to enhance cell capacity at the expense of cycle life. In order to address these requirements the MC33345 was developed. This device features programmable voltage and current limits, cell voltage balancing, low operating current, a virtually zero current sleepmode state, and requires few external components to implement a complete one to four cell smart battery pack.

OPERATING DESCRIPTION

The MC33345 is specifically designed to be placed in the battery pack where it is continuously powered from either one, two, three, or four lithium cells. In order to maintain cell operation within specified limits, the protection circuit senses both cell voltage and current, and correspondingly controls the state of two N–channel MOSFET switches. These switches, Q1 and Q2, are placed in series with the negative terminal of Cell 1 and the negative terminal of the battery pack.

Figure 1. Simplified Four Cell Smart Battery Pack



This configuration allows the protection circuit to interrupt the appropriate charge or discharge path FET in the event that a programmed voltage or current limit for any cell has been exceeded.

A functional description of the protection circuit blocks follows. Refer to the detailed block diagram shown in Figure 6.

Voltage Sensing

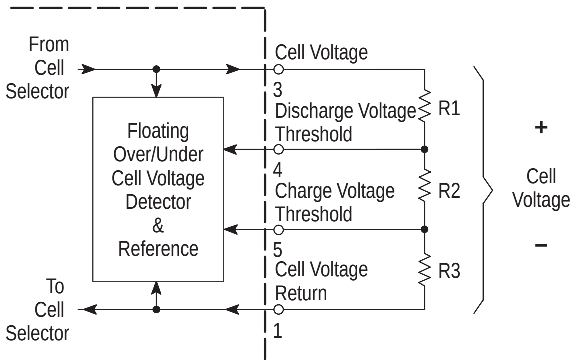
Individual cell voltage sensing is accomplished by the use of the Cell Selector in conjunction with the Floating Over/Under Voltage Detector and Reference block. The Cell Selector applies the voltage of each cell across an external resistor divider string that connects from Pins 3 to 1. The voltage at each of the tap points is sequentially polled and compared to an internal reference. If a limit has been exceeded, the result is stored in the Over/Under Data Latch and Control Logic block. The Cell Selector is gated on for an 8.0 ms period at a one second repetition rate. This low duty cycle sampling technique reduces the average load current that the divider presents across each cell, thus extending the useful battery pack capacity. The cells are sensed in the following sequence:

Figure 2. Cell Sensing Sequence

Polling Sequence	Time (ms)	Cell Sensed	Tested Limit
1	1.0	Cell 4	Overvoltage
2	1.0	Cell 3	Overvoltage
3	1.0	Cell 2	Overvoltage
4	1.0	Cell 1	Overvoltage
5	1.0	Cell 4	Undervoltage
6	1.0	Cell 3	Undervoltage
7	1.0	Cell 2	Undervoltage
8	1.0	Cell 1	Undervoltage

By incorporating this polling technique with a single floating comparator and voltage divider, a significant reduction of circuitry and trim elements is achieved. This results in a smaller die size, lower cost, and reduced operating current.

Figure 3. Cell Voltage Limit Programming



The cell charge and discharge voltage limits are controlled by the values selected for the resistor divider string and the 1.23 V input threshold of Pins 4 and 5. As the battery pack reaches full charge, the Cell Voltage Detector will sense an overvoltage fault condition on the first cell that exceeds the programmed overvoltage limit. The fault information is stored in a data latch and charge MOSFET Q1 is turned off, disconnecting the battery pack from the charging source. An internal 2.0 μA current source pull–up is then applied to Pin 5 creating an input hysteresis voltage. As a result of an overvoltage fault, the battery pack is available for discharging only.

The overvoltage fault is reset by applying a load to the battery pack. As the voltage across each cell falls below the input hysteresis level, charge MOSFET Q1 will turn on. The battery pack will now be available for charging or discharging. The over voltage limit and hysteresis voltage are given by:

$$V_{OV} = V_{th\,(Pin\,5)}\left(\frac{R1 + R2 + R3}{R3}\right)$$

$$V_{H} = I_{H\,(Pin\,5)}(R1 + R2)$$

As the load eventually depletes the battery pack charge, the Cell Voltage Detector will sense an undervoltage fault condition on the first cell that falls below the programmed undervoltage limit. After an undervoltage cell is detected, discharge MOSFET Q2 is turned off, disconnecting the battery pack from the load. The protection circuit will now enter a low current sleepmode state drawing just 5.0 nA typically, thus preventing any further cell discharging. As a result of the undervoltage fault, the battery pack is available for charging only. The undervoltage limit is given by:

$$V_{UV} = V_{th\,(Pin\,4)}\left(\frac{R1 + R2 + R3}{R2 + R3}\right)$$

The undervoltage fault is reset by applying charge current to the battery pack. When the voltage on Pin 16 exceeds Pin 8 by 0.6 V, discharge MOSFET Q2 will turned on. The battery pack will now be available for charging or discharging.

Since the thresholds of Pins 4 and 5 are equal, the above equations can be rewritten to directly solve for specific resistor values as shown in the example below.

Let the desired limits be:

V_{OV} = 4.2 V, V_H = 0.4 V, and V_{UV} = 2.5 V

With nominal values for:

V_{th} = 1.23 V, and I_H = 2.0 μA

$$R3 = \frac{\left(\frac{V_H}{I_H}\right)}{\left(\frac{V_{OV}}{V_{th}} - 1\right)} = \frac{\left(\frac{0.4}{2.0 \times 10^{-6}}\right)}{\left(\frac{4.2}{1.23} - 1\right)} = 82{,}828\ \Omega$$

$$R2 = R3\left(\frac{V_{OV}}{V_{UV}} - 1\right) = 82{,}828\ \left(\frac{4.2}{2.5} - 1\right) = 56{,}323\ \Omega$$

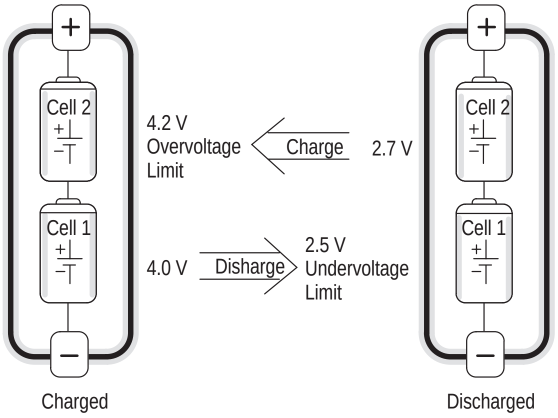
$$R1 = \left(\frac{V_H}{I_H}\right) - R2 = \left(\frac{0.4}{2.0 \times 10^{-6}}\right) - 56{,}323 = 143{,}677\ \Omega$$

Note that the Cell Selector has a typical total series resistance of 200 Ω. This will have a minimal effect on the programmed limits if the total divider resistance is in excess of 100 kΩ.

Cell Voltage Balancing

With series connected cells, successive charge and discharge cycles can result in a significant difference in cell voltage with a corresponding degradation of battery pack capacity. Figure 4 illustrates the operation of an unbalanced two cell pack. As the cells become unbalanced, the full battery pack capacity is not realized. This is due to the requirement that charging must terminate when Cell 2 reaches the overvoltage limit, and discharging must terminate when Cell 1 reaches the undervoltage limit. By employing a method of keeping the cell voltages equal, both cells can be charged and discharged to their specified limits, thus attaining the maximum possible capacity .

Figure 4. Unbalanced Battery Pack Operation



The MC33345 contains a Cell Voltage Balancing Logic circuit that controls four N–channel MOSFETs. The circuit samples the voltage of each cell during the polling period. If all of the cells are below the programmed overvoltage fault limit, no cell balancing takes place. If one or more cells reach the overvoltage fault limit, a specific latch is set for each cell. At the end of the polling period, charge MOSFET Q1 is turned off and the latches are interrogated. If all of the latches were set, no cell balancing takes place. If one, two, or three latches were set, the required cell balancing MOSFETs are then activated. The overvoltage cells are discharged to the programmed level of $V_{OV} – V_H$. As each cell attains this level, the discharge MOSFETs successively turn off. Upon completion of cell balancing, charge MOSFET Q1 is turned on. Cell voltage balancing is active during charge and discharge, but disabled during the low current sleepmode state.

Cell Programming and Test

The protection circuit can be programmed for operation with either one, two, three, or four cell battery packs. Programming inputs 1 and 2 are used to set up the internal logic for the number of cells to be monitored. If less than four cells are required, the input for each empty cell position must be connected to V_{CC}. This process starts with Cell 4 decending down to Cell 2 if required. Refer to the Cell Programming table shown below and the specific application figure.

Figure 5. Cell Sensing Sequence

Number of Cells	Program 1 (Pin 11)	Program 2 (Pin 10)	Application Figure
1	Ground	Cell 1/V_C	16
2	Cell 1/V_C	Ground	15
3	Cell 1/V_C	Cell 1/V_C	14
4	Ground	Ground	13

A test option is provided to speed up device and battery pack testing. By connecting Pin 15 to ground, the internal logic is held in a reset state and both MOSFET switches are turned on. Upon release, the Control Logic becomes active and the cells are polled within 8.0 ms.

Current Sensing

Charge and discharge current limit protection can be selectively added to the battery pack with the addition of a sense resistor. The resistors are placed in series with the positive terminal of the battery pack and the cells. Refer to Figure 1.

As the battery pack charges, Pins 6 and 7 sense the voltage drop across $R_{Lim(chg)}$. A charge current limit fault is detected if the voltage at Pin 7 exceeds Pin 6 by 18 mV for the entire delay period of 1.0 second. The fault information is stored in a data latch and charge MOSFET Q1 is turned off, disconnecting the battery pack from the charging source. As a result of the charge current fault, the battery pack is available for discharging only. The charge current limit is given by:

$$I_{Lim(chg)} = \frac{V_{th(chg)}}{R_{Lim(chg)}} = \frac{18\ \text{mV}}{R_{Lim(chg)}}$$

The charge current fault is reset by either disconnecting the battery pack from the charger, or by connecting a load to the battery pack. When the voltage on Pin 16 no longer exceeds Pin 8 by approximately 2.0 V, the Sense Enable circuit will turn on charge MOSFET Q1. Charge current sensing can be disabled by connecting Pin 7 to Pin 6.

The discharge current limiting operates in a similar manner. As the battery pack discharges, Pins 2 and 6 sense the voltage drop across $R_{Lim(dschg)}$. A discharge current limit fault is detected if the voltage at Pin 2 is less than Pin 6 by 50 mV for more than 3.0 ms. The fault information is stored in a data latch and discharge MOSFET Q2 is turned off, disconnecting the battery pack from the load. As a result of the discharge current fault, the battery pack is available for charging only. The discharge current limit is given by:

$$I_{Lim(dschg)} = \frac{V_{th(dschg)}}{R_{Lim(dschg)}} = \frac{50\ \text{mV}}{R_{Lim(dschg)}}$$

The discharge current fault is reset by either disconnecting the load from the battery pack, or by connecting the battery pack to the charger. When the voltage on Pin 8 no longer exceeds Pin 16 by approximately 2.0 V, the Sense Enable circuit will turn on discharge MOSFET Q2. Discharge current sensing can be disabled by connecting Pin 2 to Pin 6.

The charge and discharge current protection circuits contain a built in response delay of 1.0 s and 3.0 ms respectively. This helps to prevent fault activation when the battery pack is subjected to pulsed currents during charging or discharging.

Charge Pump and MOSFET Switches

The MC33345 contains an on chip Charge Pump to ensure that the MOSFET switches are fully enhanced for reduced power losses. An external reservoir capacitor normally connects from the Charge Pump output to ground, Pins 14 and 16. The capacitor value is not critical and is usually within the range of 10 nF to 100 nF. The Charge Pump output is regulated at 10.2 V allowing the use of economical logic level MOSFETs in one and two cell applications. The main requirement in selecting a particular type of MOSFET switch is to consider the desired on–resistance at the lowest anticipated operating voltage of the battery pack. A table of small outline surface mount devices is given in Figure 6. When using extremely low threshold MOSFETs, it may be desirable to disable the Charge Pump so that the maximum gate to source voltage is not exceeded. This is accomplished by connecting Pin 14 to Pin 19 with two, three, or four cell battery packs.

Battery Pack Application

Upon assembly of the battery pack, it is imperative that Cell 1 be connected first so that V_C is properly biased. The remaining cells can then be connected in any order. This assembly method prevents forward biasing the protection IC substrate which can result in overheating and non–functionality.

Each of the application figures show a capacitor labeled C_{ESD}. This capacitor provides a path around the MOSFET switches in the event of an electrostatic discharge.

Figure 6. Small Outline Surface Mount MOSFET Switches

Device Type	On–Resistance (Ω) versus Gate to Source Voltage (V)

PROTECTION CIRCUIT OPERATING MODE TABLE

Input Conditions Cell Status	Circuit Operation Battery Pack Status	Outputs			
		MOSFET Switches		Function	
		Charge Q1	Discharge Q2	Charge Pump	Cell Balancing (See Note)
CELL CHARGING/DISCHARGING					
Storage or Nominal Operation: No current or voltage faults	Both Charge MOSFET Q1 and Discharge MOSFET Q2 are on. The battery pack is available for charging or discharging.	On	On	Active	Active
CELL CHARGING FAULT/RESET					
Charge Current Limit Fault: $V_{Pin\ 7} \geq (V_{Pin\ 6} + 18\ mV)$ for 1.0 s	Charge MOSFET Q1 is latched off and the cells are disconnected from the charging source. Q1 will remain in the off state as long as $V_{Pin\ 16}$ exceeds $V_{Pin\ 11}$ by ≈ 2.0 V. The battery pack is available for discharging.	On to Off	On	Active	Active
Charge Current Limit Reset: $V_{Pin\ 16} - V_{Pin\ 8} < 2.0\ V$	The Sense Enable circuit will reset and turn on charge MOSFET Q1 when $V_{Pin\ 16}$ no longer exceeds $V_{Pin\ 11}$ by ≈ 2.0 V. This can be accomplished by either disconnecting the charger from the battery pack, or by connecting a load to the battery pack.	Off to On	On	Active	Active
Charge Voltage Limit Fault: $V_{Pin\ 5} \geq 1.23\ V$ for 1.0 s	Charge MOSFET Q1 is latched off and the cells are disconnected from the charging source. An internal current source pull–up of 2.0 µA is applied to Pin 8 creating an input hysteresis voltage of V_H with divider resistors R1 and R2. The battery pack is available for discharging.	On to Off	On	Active	Active
Charge Voltage Limit Reset: $V_{Pin\ 5} < 1.23\ V$ for 1.0 s	Charge MOSFET Q1 will turn on when the voltage across each cell falls sufficiently to overcome the input hysteresis voltage. This can be accomplished by applying a load to the battery pack.	Off to On	On	Active	Active
CELL DISCHARGING FAULT/RESET					
Discharge Current Limit Fault: $V_{Pin\ 6} \leq (V_{Pin\ 2} - 50\ mV)$ for 3.0 ms	Discharge MOSFET Q2 is latched off and the cells are disconnected from the load. Q2 will remain in the off state as long as $V_{Pin\ 11}$ exceeds $V_{Pin\ 16}$ by ≈ 2.0 V. The battery pack is available for charging.	On	On to Off	Active	Active
Discharge Current Limit Reset: $V_{Pin\ 8} - V_{Pin\ 16} < 2.0\ V$	The Sense Enable circuit will reset and turn on discharge MOSFET Q2 when $V_{Pin\ 11}$ no longer exceeds $V_{Pin\ 16}$ by ≈ 2.0 V. This can be accomplished by either disconnecting the load from the battery pack, or by connecting the battery pack to the charger.	On	Off to On	Active	Active
Discharge Voltage Limit Fault: $V_{Pin\ 4} \leq 1.23\ V$ for 1.0 s	Discharge MOSFET Q2 is latched off, the cells are disconnected from the load, and the protection circuit enters a low current sleepmode state. The battery pack is available for charging.	On	On to Off	Disabled	Disabled
Discharge Voltage Limit Reset: $V_{Pin\ 16} > (V_{Pin\ 8} + 0.6\ V)$	The Sense Enable circuit will reset and turn on discharge MOSFET Q2 when $V_{Pin\ 16}$ exceeds $V_{Pin\ 8}$ by 0.6 V. This can be accomplished by connecting the battery pack to the charger.	On	Off to On	Active	Active
FAULTY CELL					
Simultaneous Charge and Discharge Voltage Limit Faults: $V_{Pin\ 5} \geq 1.23\ V$ for 1.0 s and $V_{Pin\ 4} \leq 1.23\ V$ for 1.0 s	This condition can happen if there is a defective cell in the battery pack. The protection circuit will remain in the sleepmode state until the battery pack is connected to a charger. If Cell 2, 3, or 4 is faulty and a charger is connected, the protection circuit will cycle in and out of sleepmode. If Cell 1 is faulty (<1.5 V), the protection circuit logic will not function and the battery pack cannot be charged.	Cycles Cell 1 Good Disabled Cell 1 Faulty	Cycles Cell 1 Good Disabled Cell 1 Faulty	Cycles Cell 1 Good Disabled Cell 1 Faulty	Cycles Cell 1 Good Disabled Cell 1 Faulty

NOTE: Cell balancing is not active when programmed for one cell operation.

Lithium Battery Protection Circuit for Three or Four Cell Battery Packs

LITHIUM BATTERY PROTECTION CIRCUIT FOR THREE OR FOUR CELL SMART BATTERY PACKS

The MC33346 is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of three or four cell rechargeable battery packs. Cell protection features consist of independently programmable charge and discharge limits for both voltage and current with a delayed current shutdown, cell voltage balancing with on–chip balancing resistors, and virtually zero current sleepmode state when the cells are discharged. Additional features consists of a six wire microcontroller interface bus that can selectively provide a pulse output that represents the internal reference voltage, cell voltage, cell current and temperature, as well as control the states of four internal balancing and two external MOSFET switches. A microcontroller time reference output is available for gas gauge implementation. This protection circuit requires a minimum number of external components and is targeted for inclusion within the battery pack. The MC33346 is available in standard and low profile 24 lead surface mount packages.

Lithium Battery Protection Circuit for One or Two Cell Battery Packs

The MC33347 is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of one or two cell rechargeable battery packs. Cell protection features consist of independently programmable charge and discharge limits for both voltage and current with a delayed current shutdown, continuous cell voltage balancing with the choice of on–chip or external balancing resistors, and a virtually zero current sleepmode state when the cells are discharged. Additional features include an on–chip charge pump for reduced MOSFET losses while charging or discharging a low cell voltage battery pack, and the programmability for one or two cell battery pack. This protection circuit requires a minimum number of external components and is targeted for inclusion within the battery pack. This MC33347 is avaialble in standard and low profile 16 lead surface mount packages.

- Independently Programmable Charge and Discharge Limits for Both Voltage and Current
- Charge and Discharge Current Limit Detection with Delayed Shutdown
- Continuous Cell Voltage Balancing
- On–Chip or External Balancing Resistors
- Virtually Zero Current Sleepmode State when Cells are Discharged
- Charge Pump for Reduced Losses with a Low Cell Voltage Battery Pack
- Programmable for One or Two Cell Applications

PIN FUNCTION DESCRIPTION

Pin	Symbol	Description
1	Balance 1	This is the drain connection to an internal MOSFET. An external resistor is placed from this pin to the positive terminal of Cell 1 for increased cell balancing capability. This allows most of the additional power to be dissipated off–chip.
2	Balance 2	This is the drain connection to an internal MOSFET. An external resistor is placed from this pin to the positive terminal of Cell 2 for increased cell balancing capability. This allows most of the additional power to be dissipated off–chip.
3	Cell 1/V_C	This is a multifunction pin that connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 1 and the negative terminal of Cell 2. This pin also provides logic biasing and a discharge path for the internal balancing of Cell 1.
4	Cell 2/V_{CC}/ Discharge Current Limit	This is a multifunction pin that connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 2 and to provide positive supply voltage for the protection IC. This pin is also used to monitor the voltage drop across the discharge current limit resistor and it provides a discharge path for the internal balancing of Cell 2.
5	Cell Voltage Return	The bottom side of a three resistor divider string connects to this pin. The Cell Selector internally switches this point to the negative terminal of the cell that is to be monitored.
6	Cell Voltage	The top side of a three resistor divider string connects to this pin. The Cell Selector internally switches this point to the positive terminal of the cell that is to be monitored.
7	Discharge Voltage Threshold	The upper tap of a three resistor divider string connects to this pin. The Cell Voltage Detector compares the divided down cell voltage to an internal reference. If the comparator detects that the cell voltage has fallen below the programmed level for three consecutive samples, discharge switch Q2 is disabled, and the protection circuit enters into a low current sleepmode state. This prevents further discharging of the battery pack.
8	Charge Voltage Threshold	The lower tap of a three resistor divider string connects to this pin. The Cell Voltage Detector compares the divided down cell voltage to an internal reference. If the comparator detects that the cell voltage has risen above the programmed level, charge switch Q1 is disabled, preventing further charging of the battery pack. A 2.0 µA current source pull–up is internally applied to this pin creating input hysteresis.
9	Current Sense Common	This pin is a common point that is used to monitor the voltage drop across the charge and discharge current limit resistors.
10	Charge Current Limit	This pin is used to monitor the voltage drop across the charge current limit resistor.
11	Charge Gate Drive Common	This pin provides a gate turn–off path for charge switch Q1. The charge switch source and the battery pack negative terminal connect to this point.
12	Charge Gate Drive Output	This output connects to the gate of charge switch Q1 allowing it to enable or disable battery pack charging.
13	Cell Program/Test	This is a multifunction input that is used to program the number of cells and to facilitate circuit testing. This input is connected to Pin 3 for two cell operation, and to Pin 16 for one cell operation.
14	Discharge Gate Drive Output	This output connects to the gate of discharge switch Q2 allowing it to enable or disable battery pack discharging.
15	Charge Pump Output	This is the charge pump output. A reservoir capacitor is connected from this pin to ground.
16	Ground	This is the protection IC ground and all voltage ratings are with respect to this pin.

INTRODUCTION

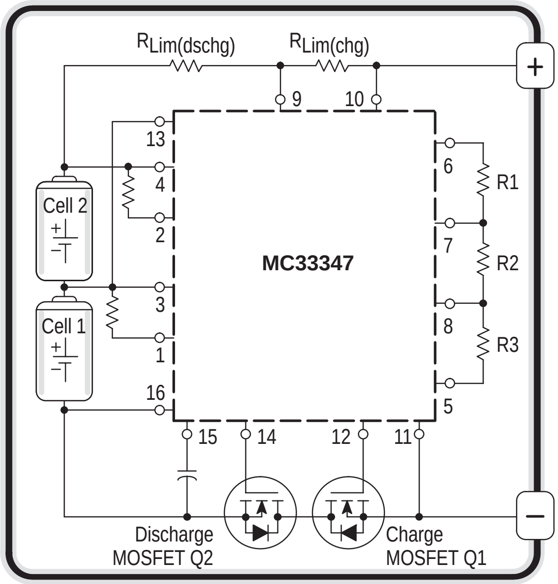
The insatiable demand for smaller lightweight portable electronic equipment has dramatically increased the requirements of battery performance. Batteries are expected to have higher energy densities, superior cycle life, be safe in operation and environmentally friendly. To address these high expectations, battery manufacturers have invested heavily in developing rechargeable lithium–based cells. Today's most attractive chemistries include lithium–polymer, lithium–ion, and lithium–metal. Each of these chemistries require electronic protection in order to constrain cell operation to within the manufacturers limits.

Rechargeable lithium–based cells require precise charge and discharge termination limits for both voltage and current in order to maximize cell capacity, cycle life, and to protect the end user from a catastrophic event. The termination limits are not as well defined as with older non–lithium chemistries. These limits are dependent upon a manufacturer's particular lithium chemistry, construction technique, and intended application. Battery pack assemblers may also choose to enhance cell capacity at the expense of cycle life. In order to address these requirements the MC33347 was developed. This device features programmable voltage and current limits, cell voltage balancing, low operating current, a virtually zero current sleepmode state, and requires few external components to implement a complete one or two cell smart battery pack.

OPERATING DESCRIPTION

The MC33347 is specifically designed to be placed in the battery pack where it is continuously powered from either one or two lithium cells. In order to maintain cell operation within specified limits, the protection circuit senses both cell voltage and current, and correspondingly controls the state of two N–channel MOSFET switches. These switches, Q1 and Q2, are placed in series with the negative terminal of Cell 1 and the negative terminal of the battery pack. This configuration allows the protection circuit to interrupt the appropriate charge or discharge path FET in the event that a programmed voltage or current limit for either cell has been exceeded.

Figure 1. Simplified Two Cell Smart Battery Pack



A functional description of the protection circuit blocks follows. Refer to the detailed block diagram shown in Figures 7 and 8.

Voltage Sensing

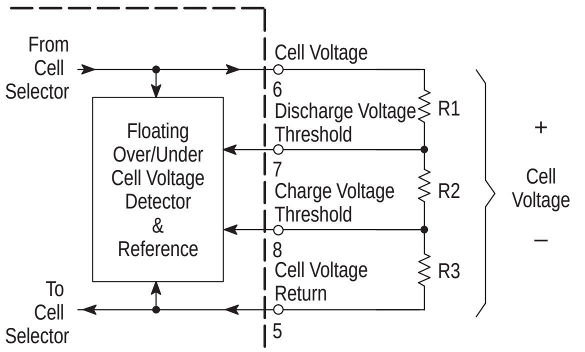
Individual cell voltage sensing is accomplished by the use of the Cell Selector in conjunction with the Floating Over/Under Voltage Detector and Reference block. The Cell Selector applies the voltage of each cell across an external resistor divider string that connects from Pins 6 to 5. The voltage at each of the tap points is sequentially polled and compared to an internal reference. If a limit has been exceeded, the result is stored in the Over/Under Data Latch and Control Logic block. The Cell Selector is gated on for a 1.0 ms period at a one second repetition rate. This low duty cycle sampling technique reduces the average load current that the divider presents across each cell, thus extending the useful battery pack capacity. The cells are sensed in the following sequence:

Figure 2. Cell Sensing Sequence

Polling Sequence	Time (ms)	Cell Sensed	Tested Limit
1	0.25	Cell 2	Overvoltage
2	0.25	Cell 1	Overvoltage
3	0.25	Cell 2	Undervoltage
4	0.25	Cell 1	Undervoltage

By incorporating this polling technique with a single floating comparator and voltage divider, a significant reduction of circuitry and trim elements is achieved. This results in a smaller die size, lower cost, and reduced operating current.

Figure 3. Cell Voltage Limit Programming



The cell charge and discharge voltage limits are controlled by the values selected for the resistor divider string and the 1.23 V input threshold of Pins 7 and 8. As the battery pack reaches full charge, the Cell Voltage Detector will sense an overvoltage fault condition on the first cell that exceeds the programmed overvoltage limit. The fault information is stored in a data latch and charge MOSFET Q1 is turned off, disconnecting the battery pack from the charging source. An internal 2.0 μA current source pull–up is then applied to Pin 8 creating an input hysteresis voltage. As a result of an overvoltage fault, the battery pack is available for discharging only.

The overvoltage fault is reset by applying a load to the battery pack. As the voltage across each cell falls below the input hysteresis level, charge MOSFET Q1 will turn on. The battery pack will now be available for charging or discharging. The over voltage limit and hysteresis voltage are given by:

$$V_{OV} = V_{th\ (Pin\ 8)}\left(\frac{R1 + R2 + R3}{R3}\right)$$

$$V_H = I_{H\ (Pin\ 8)}(R1 + R2)$$

As the load eventually depletes the battery pack charge, the Cell Voltage Detector will sense an undervoltage fault condition on the first cell that falls below the programmed undervoltage limit. After three consecutive faults are detected, discharge MOSFET Q2 is turned off, disconnecting the battery pack from the load. The protection circuit will now enter a low current sleepmode state drawing just 15 nA, thus preventing any further cell discharging. As a result of the undervoltage fault, the battery pack is available for charging only. The undervoltage limit is given by:

$$V_{UV} = V_{th\ (Pin\ 7)}\left(\frac{R1 + R2 + R3}{R2 + R3}\right)$$

The undervoltage logic is designed to automatically reset if less than three consecutive faults appear. This helps to prevent a premature disconnection of the load during high current pulses when the battery pack charge is close to being depleted.

The undervoltage fault is reset by applying charge current to the battery pack. When the voltage on Pin 16 exceeds Pin 11 by 0.6 V, discharge MOSFET Q2 will turned on. The battery pack will now be available for charging or discharging.

Since the thresholds of Pin 7 and 8 are equal, the above equations can be rewritten to directly solve for specific resistor values as shown in the example below.

Let the desired limits be:

V_{OV} = 4.2 V, V_H = 0.4 V, and V_{UV} = 2.5 V

With nominal values for:

V_{th} = 1.23 V, and I_H = 2.0 µA

$$R3 = \frac{\left(\frac{V_H}{I_H}\right)}{\left(\frac{V_{OV}}{V_{th}} - 1\right)} = \frac{\left(\frac{0.4}{2.0 \times 10^{-6}}\right)}{\left(\frac{4.2}{1.23} - 1\right)} = 82{,}828\ \Omega$$

$$R2 = R3\left(\frac{V_{OV}}{V_{UV}} - 1\right) = 82{,}828\left(\frac{4.2}{2.5} - 1\right) = 56{,}323\ \Omega$$

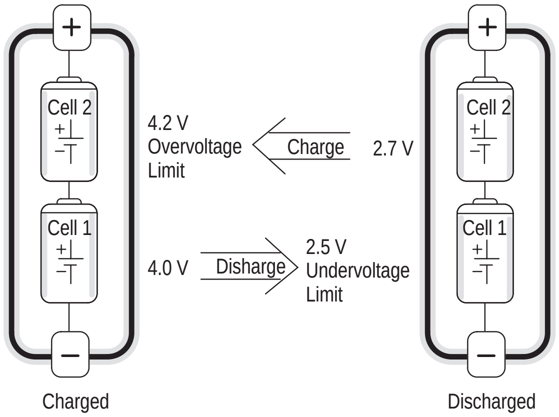
$$R1 = \left(\frac{V_H}{I_H}\right) - R2 = \left(\frac{0.4}{2.0 \times 10^{-6}}\right) - 56{,}323 = 143{,}677\ \Omega$$

Note that the Cell Selector has a maximum total series resistance of 200 Ω. This will have a minimal effect on the programmed limits if the total divider resistance is in excess of 100 kΩ.

Cell Voltage Balancing

With series connected cells, successive charge and discharge cycles can result in a significant difference in cell voltage with a corresponding degradation of battery pack capacity. Figure 4 illustrates the operation of an unbalanced pack. As the cells become unbalanced, the full battery pack capacity is not realized. This is due to the requirement that charging must terminate when Cell 2 reaches the overvoltage limit, and discharging must terminate when Cell 1 reaches the undervoltage limit. By employing a method of keeping the cell voltages equal, both cells can be charged and discharged to their specified limits, thus attaining the maximum possible capacity.

Figure 4. Unbalanced Battery Pack Operation



The MC33347 contains a Cell Voltage Balancing Amplifier that controls four N–channel MOSFETs. The amplifier samples the cell voltages during the polling period. If the detected cell voltage difference exceeds 1.0 %, the MOSFET that connects across the higher voltage cell is turned on. The excess charge will eventually be bled off through the internal 80 Ω resistor with a typical balancing current that ranges from 40 mA to 80 mA. If higher balancing currents are desired, Pins 1 and 2 provide a means for paralleling a lower value external resistor for in excess of 500 mA. The use of an external resistor allows a reduction of on–chip power dissipation. Cell voltage balancing is active during charge and discharge, but disabled during the low current sleepmode state.

Cell Programming and Test

The protection circuit can be programmed for operation with either one or two cell battery packs. The Cell Programming/Test input, Pin 13, is used to control the Cell Selector and to enable or disable the Cell Voltage Balancing Amplifier. For one cell operation, Pin 13 is connected to Pin 16, and Pin 4 is connected to Pin 3 and the positive terminal of Cell 1, refer to Figure 8. For two cell operation, Pin 13, is connected to Pin 3 and the positive terminal of Cell 1, and Pin 4 is connected to the positive terminal of Cell 2, refer to Figure 7.

A test option is provided to speed up device and battery pack testing. By biasing Pin 13 above Pin 3 by 2.0 V, the internal logic is held in a reset state and both MOSFET switches are turned on. Upon release, the logic becomes active and the cells are polled within 2.0 ms.

Current Sensing

Charge and discharge current limit protection can be selectively added to the battery pack with the addition of a sense resistor. The resistors are placed in series with the positive terminal of the battery pack and the cells. Refer to Figure 1.

As the battery pack charges, Pins 9 and 10 sense the voltage drop across $R_{Lim(chg)}$. A charge current limit fault is detected if the voltage at Pin 10 exceeds Pin 9 by 18 mV. The fault information is stored in a data latch and charge MOSFET Q1 is turned off, disconnecting the battery pack from the charging source. As a result of the charge current fault, the battery pack is available for discharging only. The charge current limit is given by:

$$I_{Lim(chg)} = \frac{V_{th(chg)}}{R_{Lim(chg)}} = \frac{18\ mV}{R_{Lim(chg)}}$$

The charge current fault is reset by either disconnecting the battery pack from the charger, or by connecting a load to the battery pack. When the voltage on Pin 16 no longer exceeds Pin 11 by approximately 2.0 V, the Sense Enable circuit will turn on charge MOSFET Q1. Charge current sensing can be disabled by connecting Pin 10 to Pin 9.

The discharge current limiting operates in a similar manner. As the battery pack discharges, Pins 4 and 9 sense the voltage drop across $R_{Lim(dschg)}$. A discharge current limit fault is detected if the voltage at Pin 4 is less than Pin 9 by 50 mV. The fault information is stored in a data latch and discharge MOSFET Q2 is turned off, disconnecting the battery pack from the load. As a result of the discharge current fault, the battery pack is available for charging only. The discharge current limit is given by:

$$I_{Lim(dschg)} = \frac{V_{th(dschg)}}{R_{Lim(dschg)}} = \frac{50\ mV}{R_{Lim(dschg)}}$$

The discharge current fault is reset by either disconnecting the load from the battery pack, or by connecting the battery pack to the charger. When the voltage on Pin 11 no longer exceeds Pin 16 by approximately 2.0 V, the Sense Enable circuit will turn on discharge MOSFET Q2. Discharge current sensing can be disabled by connecting Pin 4 to Pin 9.

The charge and discharge current protection circuits contain a built in response delay of 3.0 ms. This helps to prevent fault activation when the battery pack is subjected to pulsed currents during charging or discharging. An additional current sense delay can selectively be added as shown in Figure 5.

Charge Pump and MOSFET Switches

The MC33347 contains an on chip Charge Pump to ensure that the MOSFET switches are fully enhanced for reduced power losses. An external reservoir capacitor normally connects from the Charge Pump output to ground, Pins 15 and 16. The capacitor value is not critical and is usually within the range of 10 nF to 100 nF. The Charge Pump output is regulated at 10.2 V allowing the use of economical logic level MOSFETs in one and two cell applications. The main requirement in selecting a particular type of MOSFET switch is to consider the desired on–resistance at the lowest anticipated operating voltage of the battery pack. A table of small outline surface mount devices is given in Figure 6. When using extremely low threshold MOSFETs, it may be desirable to disable the Charge Pump so that the maximum gate to source voltage is not exceeded. This is accomplished by connecting Pin 15 to Pin 4. Application Figures 7 and 8 show a capacitor labeled C_{ESD}. This capacitor provides a path around the MOSFET switches in the event of an electrostatic discharge.

PROTECTION CIRCUIT OPERATING MODE TABLE

Input Conditions Cell Status	Circuit Operation Battery Pack Status	Outputs			
		MOSFET Switches		Function	
		Charge Q1	Discharge Q2	Charge Pump	Cell Balancing (See Note)
CELL CHARGING/DISCHARGING					
Storage or Nominal Operation: No current or voltage faults	Both Charge MOSFET Q1 and Discharge MOSFET Q2 are on. The battery pack is available for charging or discharging.	On	On	Active	Active
CELL CHARGING FAULT/RESET					
Charge Current Limit Fault: $V_{Pin\ 10} \geq (V_{Pin\ 9} + 18\ mV)$ for 3.0 ms	Charge MOSFET Q1 is latched off and the cells are disconnected from the charging source. Q1 will remain in the off state as long as $V_{Pin\ 16}$ exceeds $V_{Pin\ 11}$ by ≈ 2.0 V. The battery pack is available for discharging.	On to Off	On	Active	Active
Charge Current Limit Reset: $V_{Pin\ 16} - V_{Pin\ 11} < 2.0\ V$	The Sense Enable circuit will reset and turn on charge MOSFET Q1 when $V_{Pin\ 16}$ no longer exceeds $V_{Pin\ 11}$ by ≈ 2.0 V. This can be accomplished by either disconnecting the charger from the battery pack, or by connecting a load to the battery pack.	Off to On	On	Active	Active
Charge Voltage Limit Fault: $V_{Pin\ 8} \geq 1.23\ V$ for 1.0 s	Charge MOSFET Q1 is latched off and the cells are disconnected from the charging source. An internal current source pull–up of 2.0 μA is applied to Pin 8 creating an input hysteresis voltage of V_H with divider resistors R1 and R2. The battery pack is available for discharging.	On to Off	On	Active	Active
Charge Voltage Limit Reset: $V_{Pin\ 8} < 1.23\ V$ for 1.0 s	Charge MOSFET Q1 will turn on when the voltage across each cell falls sufficiently to overcome the input hysteresis voltage. This can be accomplished by applying a load to the battery pack.	Off to On	On	Active	Active
CELL DISCHARGING FAULT/RESET					
Discharge Current Limit Fault: $V_{Pin\ 4} \leq (V_{Pin\ 9} - 50\ mV)$ for 3.0 ms	Discharge MOSFET Q2 is latched off and the cells are disconnected from the load. Q2 will remain in the off state as long as $V_{Pin\ 11}$ exceeds $V_{Pin\ 16}$ by ≈ 2.0 V. The battery pack is available for charging.	On	On to Off	Active	Active
Discharge Current Limit Reset: $V_{Pin\ 11} - V_{Pin\ 16} < 2.0\ V$	The Sense Enable circuit will reset and turn on discharge MOSFET Q2 when $V_{Pin\ 11}$ no longer exceeds $V_{Pin\ 16}$ by ≈ 2.0 V. This can be accomplished by either disconnecting the load from the battery pack, or by connecting the battery pack to the charger.	On	Off to On	Active	Active
Discharge Voltage Limit Fault: $V_{Pin\ 7} \leq 1.23\ V$ for three consecutive 1.0 s samples	Discharge MOSFET Q2 is latched off, the cells are disconnected from the load, and the protection circuit enters a low current sleepmode state. The battery pack is available for charging.	On	On to Off	Disabled	Disabled
Discharge Voltage Limit Reset: $V_{Pin\ 16} > (V_{Pin\ 11} + 0.6\ V)$	The Sense Enable circuit will reset and turn on discharge MOSFET Q2 when $V_{Pin\ 16}$ exceeds $V_{Pin\ 11}$ by 0.6 V. This can be accomplished by connecting the battery pack to the charger.	On	Off to On	Active	Active
FAULTY CELL					
Simultaneous Charge and Discharge Voltage Limit Faults: $V_{Pin\ 8} \geq 1.23\ V$ for 1.0 s and $V_{Pin\ 7} \leq 1.23\ V$ for three consecutive 1.0 s samples	This condition can happen if there is a defective cell in the battery pack. The protection circuit will remain in the sleepmode state until the battery pack is connected to a charger. If Cell 2 is faulty and a charger is connected, the protection circuit will cycle in and out of sleepmode. If Cell 1 is faulty (<1.5 V), the protection circuit logic will not function and the battery pack cannot be charged.	Cycles Cell 1 Good Disabled Cell 1 Faulty	Cycles Cell 1 Good Disabled Cell 1 Faulty	Cycles Cell 1 Good Disabled Cell 1 Faulty	Cycles Cell 1 Good Disabled Cell 1 Faulty

NOTE: Cell balancing is not active when programmed for one cell operation.

Lithium Battery Protection Circuit for One Cell Battery Packs

The MC33348 is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of one cell rechargeable battery pack. Cell protection features consist of internally trimmed charge and discharge voltage limits, discharge current limit detection with a delayed shutdown, and a virtually zero current sleepmode state when the cell is discharged. An additional feature includes an on–chip charge pump for reduced MOSFET losses while charging or discharging a low cell voltage battery pack. This protection circuit requires a minimum number of external components and is targeted for inclusion within the battery pack. This MC33348 is available in standard and micro 8 lead surface mount packages.

- Internally Trimmed Charge and Discharge Voltage Limits
- Discharge Current Limit Detection with Delayed Shutdown
- Virtually Zero Current Sleepmode State when Cells are Discharged
- Charge Pump for Reduced Losses with a Low Cell Voltage Battery Pack
- Dedicated for One Cell Applications
- Minimum Components for Inclusion within the Battery Pack
- Available in Low Profile Surface Mount Packages

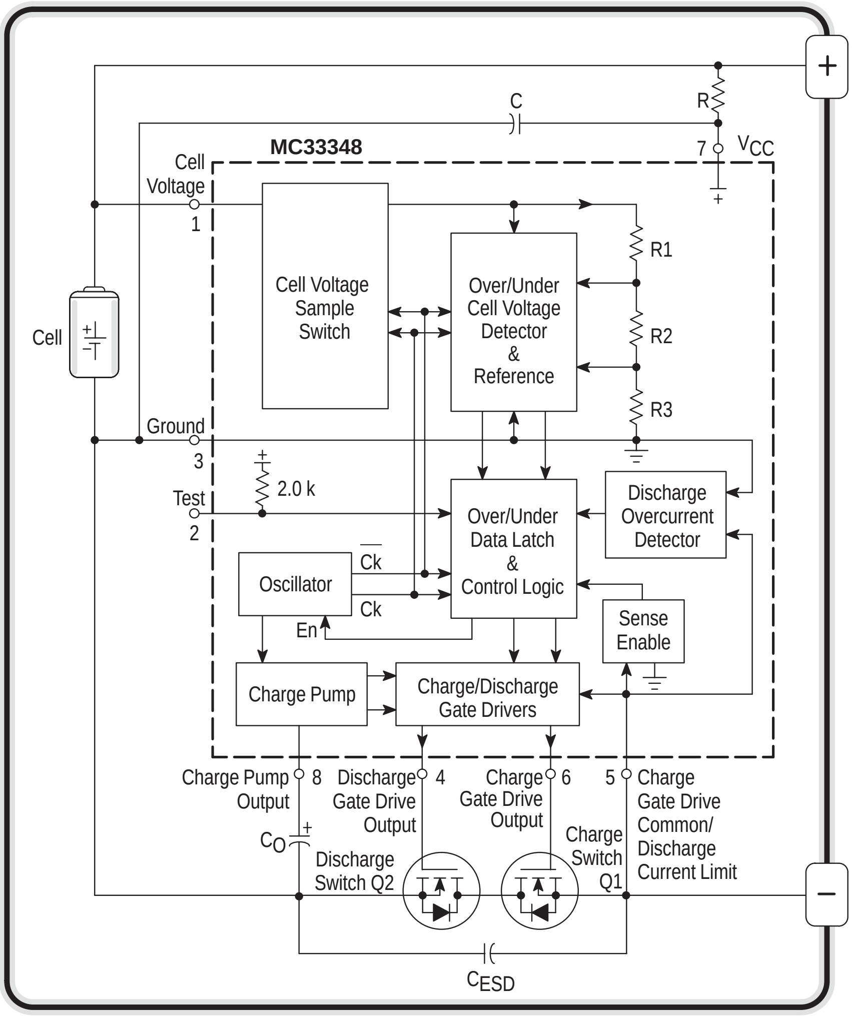
PROTECTION CIRCUIT OPERATING MODE TABLE

Input Conditions Cell Status	Circuit Operation Battery Pack Status	Outputs		
		MOSFET Switches		Function
		Charge Q1	Discharge Q2	Charge Pump
CELL CHARGING/DISCHARGING				
Storage or Nominal Operation: No current or voltage faults	Both Charge MOSFET Q1 and Discharge MOSFET Q2 are on. The battery pack is available for charging or discharging.	On	On	Active
CELL CHARGING FAULT/RESET				
Charge Voltage Limit Fault: $V_{Pin\ 1} \geq V_{th(OV)}$ for 1.0 s	Charge MOSFET Q1 is latched off and the cell is disconnected from the charging source. An internal current source pull–up is applied to divider resistors R1 and R2 creating a hysteresis voltage of V_H. The battery pack is available for discharging. Discharge current limit protection is disabled.	On to Off	On	Active
Charge Voltage Limit Reset: $V_{Pin\ 1} < (V_{th(OV)} - V_H)$ for 1.0 s	Charge MOSFET Q1 will turn on when the voltage across the cell falls sufficiently to overcome hysteresis voltage V_H. This can be accomplished by applying a load to the battery pack. Discharge current limit protection is enabled.	Off to On	On	Active
CELL DISCHARGING FAULT/RESET				
Discharge Current Limit Fault: $V_{Pin\ 5} \geq (V_{Pin\ 1} + 400\ mV)$ for 3.0 ms and $V_{Pin\ 1} < (V_{th(OV)} - V_H)$ for 1.0 ms	Discharge MOSFET Q2 is latched off and the cell is disconnected from the load. Q2 will remain in the off state as long as $V_{Pin\ 5}$ exceeds $V_{Pin\ 3}$ by ≈ 2.0 V. The battery pack is available for charging.	On	On to Off	Active
Discharge Current Limit Reset: $V_{Pin\ 5} - V_{Pin\ 3} < 2.0\ V$	The Sense Enable circuit will reset and turn on discharge MOSFET Q2 when $V_{Pin\ 3}$ no longer exceeds $V_{Pin\ 5}$ by ≈ 2.0 V. This can be accomplished by either disconnecting the load from the battery pack, or by connecting the battery pack to the charger.	On	Off to On	Active
Discharge Voltage Limit Fault: $V_{Pin\ 1} \leq V_{th(UV)}$ for three consecutive 1.0 s samples	Discharge MOSFET Q2 is latched off, the cells are disconnected from the load, and the protection circuit enters a low current sleepmode state. The battery pack is available for charging.	On	On to Off	Disabled
Discharge Voltage Limit Reset: $V_{Pin\ 3} > (V_{Pin\ 5} + 0.6\ V)$	The Sense Enable circuit will reset and turn on discharge MOSFET Q2 when $V_{Pin\ 3}$ exceeds $V_{Pin\ 5}$ by 0.6 V. This can be accomplished by connecting the battery pack to the charger.	On	Off to On	Active
FAULTY CELL				
Discharge Voltage Limit Fault: $V_{Pin\ 1} \leq 1.5\ V$	This condition can happen if the cell is a defective (<1.5 V). The protection circuit logic will not function and the battery pack cannot be charged.	Disabled	Disabled	Disabled

Figure 7. One Cell Smart Battery Pack



PIN FUNCTION DESCRIPTION

Pin	Symbol	Description
1	Cell Voltage	This input is connected to the positive terminal of the cell for voltage monitoring. Internally, the Cell Voltage Sample Switch applies this voltage to a resistor divider where it is compared by the Cell Voltage Detector to an internal reference.
2	Test	This pin is normally not connected and is used in testing the protection IC. An active low at this input resets the internal logic and turns on both MOSFET switches. Upon release, the logic becomes active and the cell voltage is sampled within 1.0 ms.
3	Ground	This is the protection IC ground and all voltage ratings are with respect to this pin.
4	Discharge Gate Drive Output	This output connects to the gate of discharge switch Q2 allowing it to enable or disable battery pack discharging.
5	Charge Gate Drive Common/Discharge Current Limit	This is a multifunction pin that is used to monitor cell discharge current and to provide a gate turn–off path for charge switch Q1. A discharge current limit fault is set when the battery pack load causes the combined voltage drop of charge switch Q1 and discharge switch Q2 to exceed the discharge current limit threshold voltage, $V_{th(dschg)}$, with respect to Pin 3.
6	Charge Gate Drive Output	This output connects to the gate of charge switch Q1 allowing it to enable or disable battery pack charging.
7	V_{CC}	This pin is the positive supply voltage for the protection IC.
8	Charge Pump Output	This is the charge pump output. A reservoir capacitor is connected from this pin to ground.

INTRODUCTION

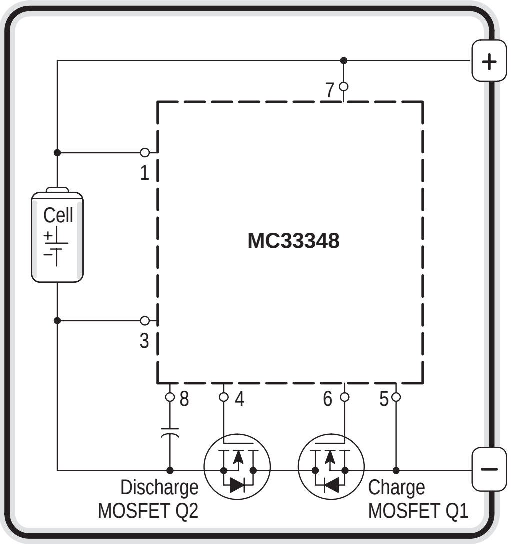
The insatiable demand for smaller lightweight portable electronic equipment has dramatically increased the requirements of battery performance. Batteries are expected to have higher energy densities, superior cycle life, be safe in operation and environmentally friendly. To address these high expectations, battery manufacturers have invested heavily in developing rechargeable lithium–based cells. Today's most attractive chemistries include lithium–polymer, lithium–ion, and lithium–metal. Each of these chemistries require electronic protection in order to constrain cell operation to within the manufacturers limits.

Rechargeable lithium–based cells require precise charge and discharge termination limits for both voltage and current in order to maximize cell capacity, cycle life, and to protect the end user from a catastrophic event. The termination limits are not as well defined as with older non–lithium chemistries. These limits are dependent upon a manufacturer's particular lithium chemistry, construction technique, and intended application. Battery pack assemblers may also choose to enhance cell capacity at the expense of cycle life. In order to address these requirements, six versions of the MC33348 protection circuit were developed. These devices feature charge overvoltage protection, discharge current limit protection with delayed shutdown, low operating current, a virtually zero current sleepmode state, and requires few external components to implement a complete one cell smart battery pack.

Operating Description

The MC33348 is specifically designed to be placed in the battery pack where it is continuously powered from a single lithium cell. In order to maintain cell operation within specified limits, the protection circuit senses both cell voltage and discharge current, and correspondingly controls the state of two N–channel MOSFET switches. These switches, Q1 and Q2, are placed in series with the negative terminal of the Cell and the negative terminal of the battery pack. This configuration allows the protection circuit to interrupt the appropriate charge or discharge path FET in the event that either a voltage threshold or the discharge current limit for the cell has been exceeded.

Figure 8. Simplified One Cell Smart Battery Pack



A functional description of the protection circuit blocks follows. Refer to the detailed block diagram shown in Figure 7.

Voltage Sensing

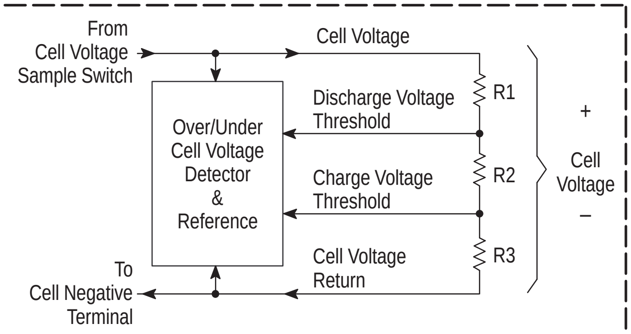
Voltage sensing is accomplished by the use of the Cell Voltage Sample Switch in conjunction with the Over/Under Voltage Detector and Reference block. The Sample Switch applies the cell voltage to the top resistor of an internal divider string. The voltage at each of the tap points is sequentially polled and compared to an internal reference. If a limit has been exceeded, the result is stored in the Over/Under Data Latch and Control Logic block. The Cell Voltage Sample Switch is gated on for a 1.0 ms period at a one second repetition rate. This low duty cycle sampling technique reduces the average load current that the divider presents across the cell, thus extending the useful battery pack capacity. The cell voltage limits are tested in the following sequence:

Figure 9. Cell Sensing Sequence

Polling Sequence	Time (ms)	Tested Limit
1	0.5	Overvoltage
2	0.5	Undervoltage

By incorporating this polling technique with a single comparator and voltage divider, a significant reduction of circuitry and trim elements is achieved. This results in a smaller die size, lower cost, and reduced operating current.

Figure 10. Cell Voltage Limit Sampling



The cell charge and discharge voltage limits are controlled by the values selected for the internal resistor divider string and the comparator input threshold. As the battery pack reaches full charge, the Cell Voltage Detector will sense an overvoltage fault condition when the cell exceeds the designed overvoltage limit. The fault information is stored in a data latch and charge MOSFET Q1 is turned off, disconnecting the battery pack from the charging source. An internal current source pull–up is then applied to lower tap of the divider, creating a hysteresis voltage. As a result of an overvoltage fault, the battery pack is available for discharging only.

The overvoltage fault is reset by applying a load to the battery pack. As the voltage across the cell falls below the hysteresis level, charge MOSFET Q1 will turn on. The battery pack will now be available for charging or discharging.

As the load eventually depletes the battery pack charge, the Cell Voltage Detector will sense an undervoltage fault condition when the cell falls below the designed undervoltage limit. After three consecutive faults are detected, discharge MOSFET Q2 is turned off, disconnecting the battery pack from the load. The protection circuit will now enter a low current sleepmode state drawing less than 10 nA, thus preventing any further cell discharging. As a result of the undervoltage fault, the battery pack is available for charging only. The typical cutoff thresholds and hysteresis voltage are shown in Figure 11.

Figure 11. Cutoff and Hysteresis Limits

Device Suffix	Charging Cutoff (V)	Hysteresis (mV)	Disharging Cutoff (V)
–1, –2	4.20	300	2.25
–3, –4	4.25	300	2.28
–5, –6	4.35	300	2.30

The undervoltage logic is designed to automatically reset if less than three consecutive faults appear. This helps to prevent a premature disconnection of the load during high current pulses when the battery pack charge is close to being depleted.

The undervoltage fault is reset by applying charge current to the battery pack. When the voltage on Pin 3 exceeds Pin 5 by 0.6 V, discharge MOSFET Q2 will turned on. The battery pack will now be available for charging or discharging.

Current Sensing

Discharge current limit protection is internally provided by the MC33348. As the battery pack discharges, Pins 8 and 5 sense the voltage drop across MOSFETs Q1 and Q2. A discharge current limit fault is detected if the voltage at Pin 5 is greater than Pin 3 by 400 mV for –1, –3 and –5 suffix devices, or 200 mV for –2, –4 and –6 suffix devices. The fault information is stored in a data latch and discharge MOSFET Q2 is turned off, disconnecting the battery pack from the load. As a result of the discharge current fault, the battery pack is available for charging only. The discharge current limit is given by:

$$I_{Lim(dschg)} = \frac{V_{th(dschg)}}{R_{Lim(dschg)}} = \frac{V_{th(dschg)}}{R_{DS(on)Q1} + R_{DS(on)Q2}}$$

The discharge current fault is reset by either disconnecting the load from the battery pack, or by connecting the battery pack to the charger. When the voltage on Pin 5 no longer exceeds Pin 3 by approximately 2.0 V, the Sense Enable circuit will turn on discharge MOSFET Q2.

Figure 12. Additional Current Limit Delay

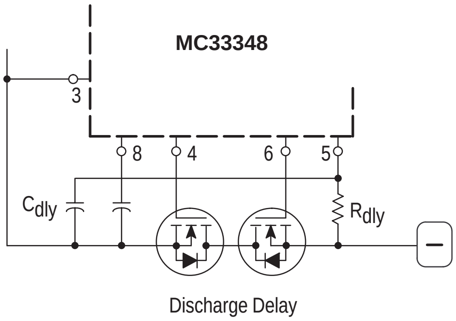


Figure 13. V_{CC} Decoupling

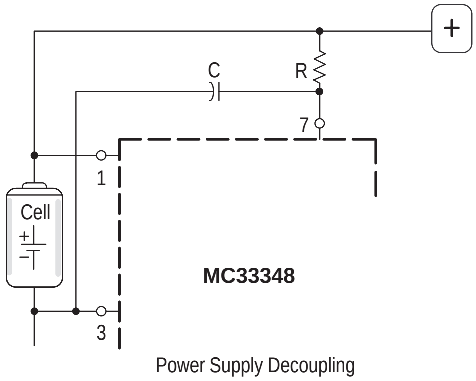

As previously stated in the voltage sensing operating description, charge MOSFET Q1 is held off during an overvoltage fault condition. When this condition is present, the discharge current limit protection function is internally disabled. This is required, since the voltage across Q1, in the off state, would exceed the current sense threshold. This would cause Q2 to turn off as well, preventing both charging and discharging of the cell. Discharge current limit protection is enabled whenever an overvoltage fault is not present.

The discharge current protection circuit contain a built in response delay of 3.0 ms. This helps to prevent fault activation when the battery pack is subjected to pulsed currents during discharging. An additional current sense delay can be added as shown in Figure 12. If the battery pack is subjected to extremely high discharge current pulses or is shorted, the V_{CC} pin must be decoupled from the cell. This is required so that the protection circuit will have sufficient operating voltage during the load transient, to ensure turn off of discharge MOSFET Q2. Figure 13 shows the placement of decoupling components.

Charge Pump and MOSFET Switches

The MC33348 contains an on chip Charge Pump to ensure that the MOSFET switches are fully enhanced for reduced power losses. An external reservoir capacitor normally connects from the Charge Pump output to ground, Pins 8 and 3. The capacitor value is not critical and is usually within the range of 10 nF to 100 nF. The Charge Pump output is regulated at 10.2 V allowing the use of economical logic level MOSFETs. The main requirement in selecting a particular type of MOSFET switch is to consider the desired on–resistance at the lowest anticipated operating voltage of the battery pack. A table of small outline surface mount devices is given in Figure 14. When using extremely low threshold MOSFETs, it may be desirable to disable the Charge Pump so that the maximum gate to source voltage is not exceeded. This is accomplished by connecting Pin 8 to Pin 7. Application Figure 7 show a capacitor labeled C_{ESD}. This capacitor provides a path around the MOSFET switches in the event of an electrostatic discharge.

Testing

A test pin is provided in order to speed up device and battery pack testing. By grounding Pin 2, the internal logic is held in a reset state and both MOSFET switches are turned on. Upon release, the logic becomes active and the cell voltage is polled within 1.0 ms.

Figure 14. Small Outline Surface Mount MOSFET Switches

Device Type	On–Resistance (Ω) versus Gate to Source Voltage (V)

Advance Information

High Voltage Switching Regulator

HIGH VOLTAGE OFF–LINE SWITCHING REGULATOR

SEMICONDUCTOR TECHNICAL DATA

The MC33362 is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 120 VAC line source. This integrated circuit features an on–chip 500 V/2.0 A SenseFET power switch, 250 V active off–line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle–by–cycle current limiting, input undervoltage lockout with hysteresis, output overvoltage protection, and thermal shutdown. This device is available in a 16–lead dual–in–line and wide body surface mount packages.

- On–Chip 500 V, 2.0 A SenseFET Power Switch
- Rectified 120 VAC Line Source Operation
- On–Chip 250 V Active Off–Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle–By–Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Output Overvoltage Protection Comparator
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown

PIN FUNCTION DESCRIPTION

Pin	Function	Description
1	Startup Input	This pin connects directly to the rectified ac line voltage source. Internally Pin 1 is tied to the drain of a high voltage startup MOSFET. During startup, the MOSFET supplies internal bias, and charges an external capacitor that connects from the V_{CC} pin to ground.
2	–	This pin has been omitted for increased spacing between the rectified AC line voltage on Pin 1 and the V_{CC} potential on Pin 3.
3	V_{CC}	This is the positive supply voltage input. During startup, power is supplied to this input from Pin 1. When V_{CC} reaches the UVLO upper threshold, the startup MOSFET turns off and power is supplied from an auxiliary transformer winding.
4, 5, 12, 13	Ground	These pins are the control circuit grounds. They are part of the IC lead frame and provide a thermal path from the die to the printed circuit board.
6	R_T	Resistor R_T connects from this pin to ground. The value selected will program the Current Limit Comparator threshold and affect the Oscillator frequency.
7	C_T	Capacitor C_T connects from this pin to ground. The value selected, in conjunction with resistor R_T, programs the Oscillator frequency.
8	Regulator Output	This 6.5 V output is available for biasing external circuitry. It requires an external bypass capacitor of at least 1.0 µF for stability.
9	Compensation	This pin is the Error Amplifier output and is made available for loop compensation. It can be used as an input to directly control the PWM Comparator.
10	Voltage Feedback Input	This is the inverting input of the Error Amplifier. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output.
11	Overvoltage Protection Input	This input provides runaway output voltage protection due to an external component or connection failure in the control loop feedback signal path. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output.
14, 15	–	These pins have been omitted for increased spacing between the high voltages present on the Power Switch Drain, and the ground potential on Pins 12 and 13.
16	Power Switch Drain	This pin is designed to directly drive the converter transformer and is capable of switching a maximum of 500 V and 2.0 A.

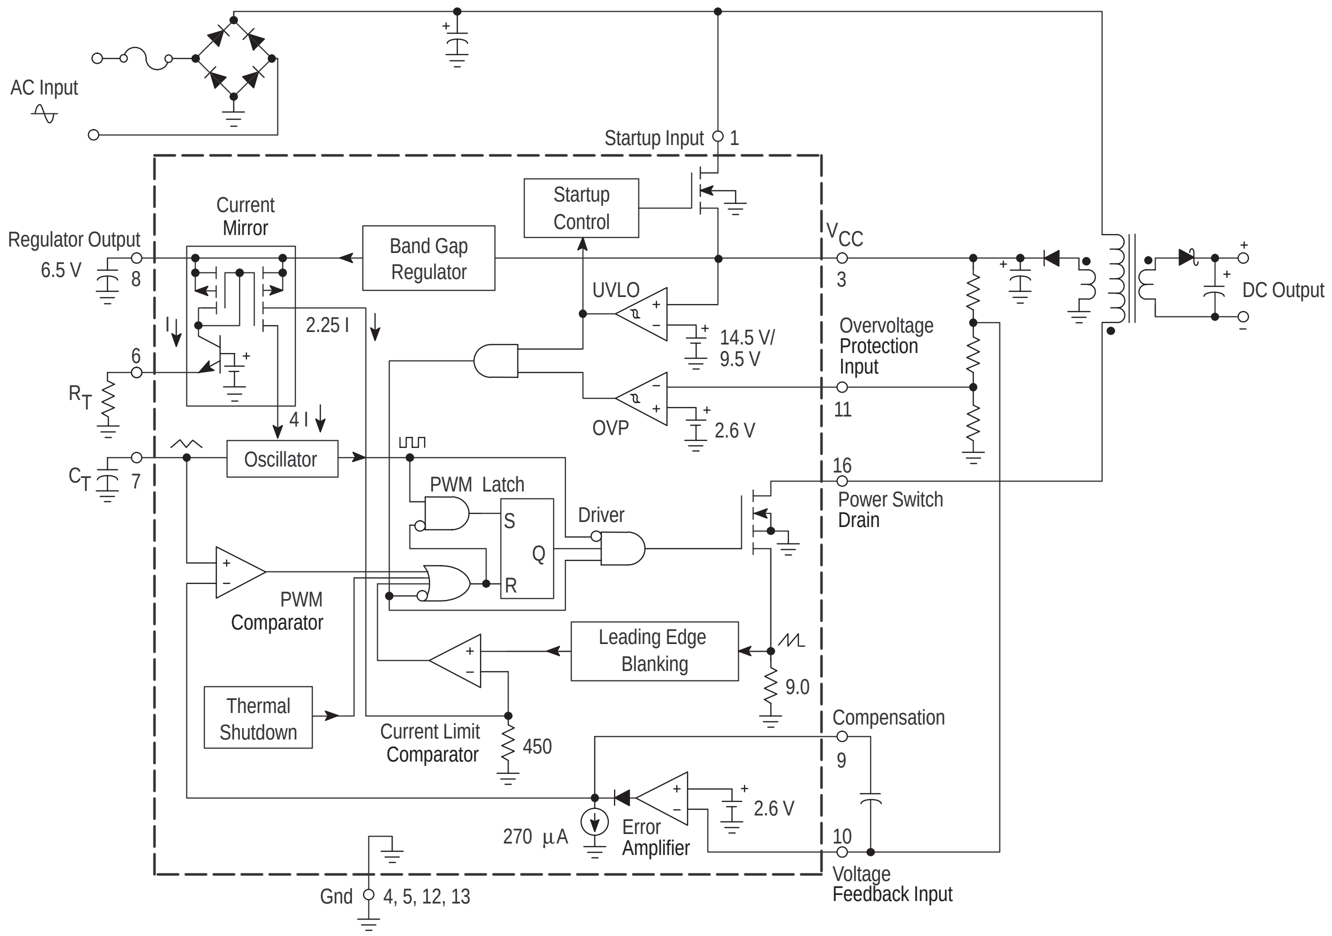

Figure 18. Timing Diagram

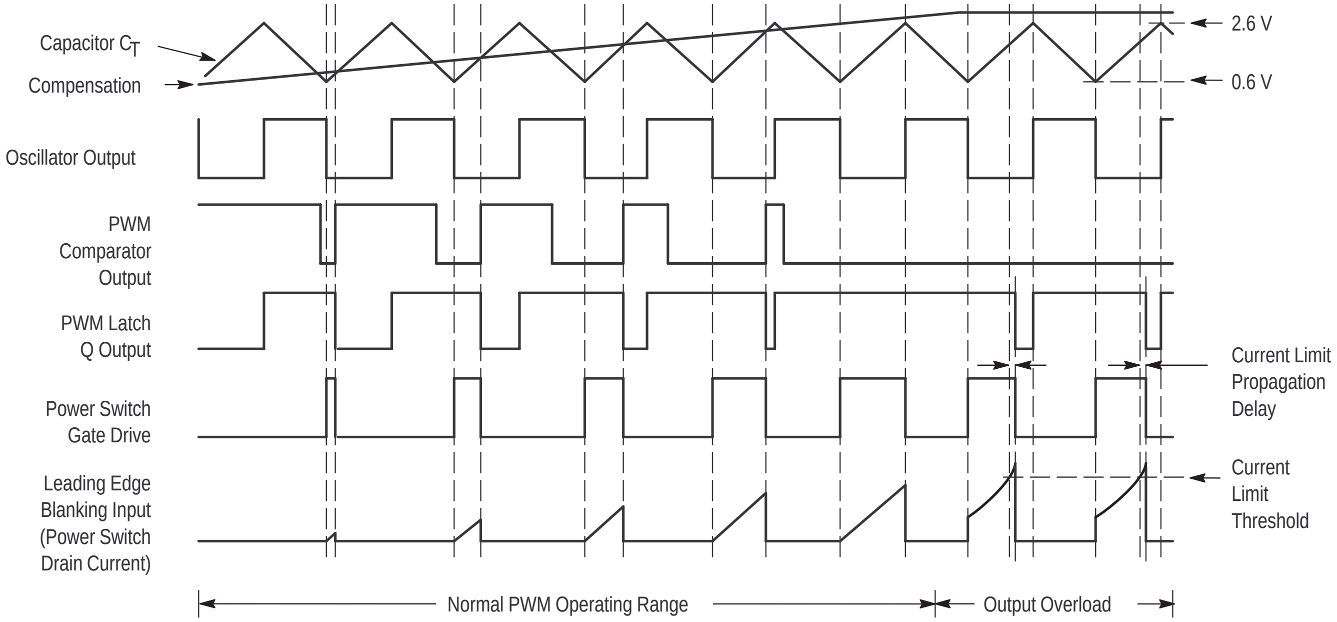


OPERATING DESCRIPTION

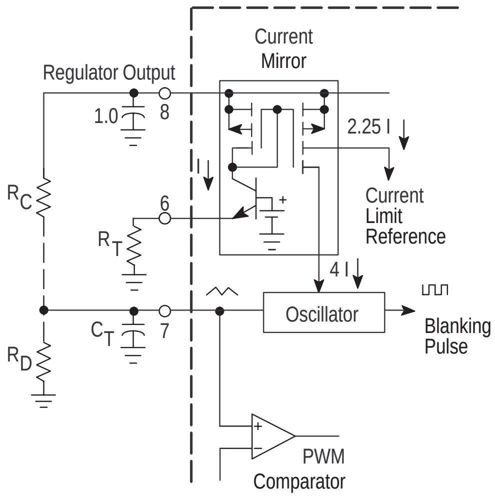
Introduction

The MC33362 represents a new higher level of integration by providing all the active high voltage power, control, and protection circuitry required for implementation of a flyback or forward converter on a single monolithic chip. This device is designed for direct operation from a rectified 120 VAC line source and requires a minimum number of external components to implement a complete converter. A description of each of the functional blocks is given below, and the representative block and timing diagrams are shown in Figures 17 and 18.

Oscillator and Current Mirror

The oscillator frequency is controlled by the values selected for the timing components R_T and C_T. Resistor R_T programs the oscillator charge/discharge current via the Current Mirror 4 I output, Figure 3. Capacitor C_T is charged and discharged by an equal magnitude internal current source and sink. This generates a symmetrical 50 percent duty cycle waveform at Pin 7, with a peak and valley threshold of 2.6 V and 0.6 V respectively. During the discharge of C_T, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gate Driver high. This causes the Power Switch gate drive to be held in a low state, thus producing a well controlled amount of output deadtime. The amount of deadtime is relatively constant with respect to the oscillator frequency when operating below 1.0 MHz. The maximum Power Switch duty cycle at Pin 16 can be modified from the internal 50% limit by providing an additional charge or discharge current path to C_T, Figure 19. In order to increase the maximum duty cycle, a discharge current resistor R_D is connected from Pin 7 to ground. To decrease the maximum duty cycle, a charge current resistor R_C is connected from Pin 7 to the Regulator Output. Figure 4 shows an obtainable range of maximum output duty cycle versus the ratio of either R_C or R_D with respect to R_T.

Figure 19. Maximum Duty Cycle Modification



The formula for the charge/discharge current along with the oscillator frequency are given below. The frequency formula is a first order approximation and is accurate for C_T values greater than 500 pF. For smaller values of C_T, refer to Figure 1. Note that resistor R_T also programs the Current Limit Comparator threshold.

$$I_{chg/dscg} = \frac{5.4}{R_T} \qquad f \approx \frac{I_{chg/dscg}}{4C_T}$$

PWM Comparator and Latch

The pulse width modulator consists of a comparator with the oscillator ramp voltage applied to the non–inverting input, while the error amplifier output is applied into the inverting input. The Oscillator applies a set pulse to the PWM Latch while C_T is discharging, and upon reaching the valley voltage, Power Switch conduction is initiated. When C_T charges to a voltage that exceeds the error amplifier output, the PWM Latch is reset, thus terminating Power Switch conduction for the duration of the oscillator ramp–up period. This PWM Comparator/Latch combination prevents multiple output pulses during a given oscillator clock cycle. The timing diagram shown in Figure 18 illustrates the Power Switch duty cycle behavior versus the Compensation voltage.

Current Limit Comparator and Power Switch

The MC33362 uses cycle–by–cycle current limiting as a means of protecting the output switch transistor from overstress. Each on–cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch current buildup during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the oscillator ramp–up period.

The Power Switch is constructed as a SenseFET allowing a virtually lossless method of monitoring the drain current. It consists of a total of 3770 cells, of which 50 are connected to a 9.0 Ω ground–referenced sense resistor. The Current Sense Comparator detects if the voltage across the sense resistor exceeds the reference level that is present at the inverting input. If exceeded, the comparator quickly resets the PWM Latch, thus protecting the Power Switch. The current limit reference level is generated by the 2.25 I output of the Current Mirror. This current causes a reference voltage to appear across the 450 Ω resistor. This voltage level, as well as the Oscillator charge/discharge current are both set by resistor R_T. Therefore when selecting the values for R_T and C_T, R_T must be chosen first to set the Power Switch peak drain current, while C_T is chosen second to set the desired Oscillator frequency. A graph of the Power Switch peak drain current versus R_T is shown in Figure 2 with the related formula below.

$$I_{pk} = 12.3\left(\frac{R_T}{1000}\right)^{-1.115}$$

The Power Switch is designed to directly drive the converter transformer and is capable of switching a maximum of 500 V and 2.0 A. Proper device voltage snubbing and heatsinking are required for reliable operation.

A Leading Edge Blanking circuit was placed in the current sensing signal path. This circuit prevents a premature reset of the PWM Latch. The premature reset is generated each time the Power Switch is driven into conduction. It appears as a narrow voltage spike across the current sense resistor, and is due to the MOSFET gate to source capacitance, transformer interwinding capacitance, and output rectifier recovery time. The Leading Edge Blanking circuit has a dynamic behavior in that it masks the current signal until the Power Switch turn–on transition is completed. The current limit propagation delay time is typically 233 ns. This time is measured from when an overcurrent appears at the Power Switch drain, to the beginning of turn–off.

Error Amplifier

An fully compensated Error Amplifier with access to the inverting input and output is provided for primary side voltage sensing, Figure 17. It features a typical dc voltage gain of 82 dB, and a unity gain bandwidth of 1.0 MHz with 78 degrees of phase margin, Figure 5. The noninverting input is internally biased at 2.6 V ±3.1% and is not pinned out. The Error Amplifier output is pinned out for external loop compensation and as a means for directly driving the PWM Comparator. The output was designed with a limited sink current capability of 270 µA, allowing it to be easily overridden with a pull–up resistor. This is desirable in applications that require secondary side voltage sensing, Figure 20. In this application, the Voltage Feedback Input is connected to the Regulator Output. This disables the Error Amplifier by placing its output into the sink state, allowing the optocoupler transistor to directly control the PWM Comparator.

Overvoltage Protection

An Overvoltage Protection Comparator is included to eliminate the possibility of runaway output voltage. This condition can occur if the control loop feedback signal path is broken due to an external component or connection failure. The comparator is normally used to monitor the primary side V_{CC} voltage. When the 2.6 V threshold is exceeded, it will immediately turn off the Power Switch, and protect the load from a severe overvoltage condition. This input can also be driven from external circuitry to inhibit converter operation.

Undervoltage Lockout

An Undervoltage Lockout comparator has been incorporated to guarantee that the integrated circuit has sufficient voltage to be fully functional before the output stage is enabled. The UVLO comparator monitors the V_{CC} voltage at Pin 3 and when it exceeds 14.5 V, the reset signal is removed from the PWM Latch allowing operation of the Power Switch. To prevent erratic switching as the threshold is crossed, 5.0 V of hysteresis is provided.

Startup Control

An internal Startup Control circuit with a high voltage enhancement mode MOSFET is included within the MC33362. This circuitry allows for increased converter efficiency by eliminating the external startup resistor, and its associated power dissipation, commonly used in most off–line converters that utilize a UC3842 type of controller. Rectified ac line voltage is applied to the Startup Input, Pin 1. This causes the MOSFET to enhance and supply internal bias as well as charge current to the V_{CC} bypass capacitor that connects from Pin 3 to ground. When V_{CC} reaches the UVLO upper threshold of 14.5 V, the IC commences operation and the startup MOSFET is turned off. Operating bias is now derived from the auxiliary transformer winding, and all of the device power is efficiently converted down from the rectified ac line.

The startup MOSFET will provide an initial peak current of 55 mA, Figure 10, which decreases rapidly as V_{CC} and the die temperature rise. The steady state current will self limit in the range of 12 mA with V_{CC} shorted to ground. The startup MOSFET is rated at a maximum of 250 V with V_{CC} shorted to ground, and 400 V when charging a V_{CC} capacitor of 1000 µF or less.

Regulator

A low current 6.5 V regulated output is available for biasing the Error Amplifier and any additional control system circuitry. It is capable of up to 10 mA and has short–circuit protection. This output requires an external bypass capacitor of at least 1.0 µF for stability.

Thermal Shutdown and Package

Internal thermal circuitry is provided to protect the Power Switch in the event that the maximum junction temperature is exceeded. When activated, typically at 155°C, the Latch is forced into a ‘reset’ state, disabling the Power Switch. The Latch is allowed to ‘set’ when the Power Switch temperature falls below 145°C. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a substitute for proper heatsinking.

The MC33362 is contained in a heatsinkable plastic dual–in–line package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figures 15 and 16 show a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction to air thermal resistance. The examples are for a symmetrical layout on a single–sided board with two ounce per square foot of copper. Figure 22 shows a practical example of a printed circuit board layout that utilizes the copper foil as a heat dissipater. Note that a jumper was added to the layout from Pins 8 to 10 in order to enhance the copper area near the device for improved thermal conductivity. The application circuit requires two ounce copper foil in order to obtain 20 watts of continuous output power at room temperature.

MC33363

Advance Information

High Voltage Switching Regulator

The MC33363 is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 240 Vac line source. This integrated circuit features an on–chip 700 V/1.0 A SenseFET power switch, 450 V active off–line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle–by–cycle current limiting, input undervoltage lockout with hysteresis, output overvoltage protection, and thermal shutdown. This device is available in a 16–lead dual–in–line and wide body surface mount packages.

- On–Chip 700 V, 1.0 A SenseFET Power Switch
- Rectified 240 Vac Line Source Operation
- On–Chip 450 V Active Off–Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle–By–Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Output Overvoltage Protection Comparator
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown

PIN FUNCTION DESCRIPTION

Pin	Function	Description
1	Startup Input	This pin connects directly to the rectified ac line voltage source. Internally Pin 1 is tied to the drain of a high voltage startup MOSFET. During startup, the MOSFET supplies internal bias, and charges an external capacitor that connects from the V_{CC} pin to ground.
2	–	This pin has been omitted for increased spacing between the rectified ac line voltage on Pin 1 and the V_{CC} potential on Pin 3.
3	V_{CC}	This is the positive supply voltage input. During startup, power is supplied to this input from Pin 1. When V_{CC} reaches the UVLO upper threshold, the startup MOSFET turns off and power is supplied from an auxiliary transformer winding.
4, 5, 12, 13	Ground	These pins are the control circuit grounds. They are part of the IC lead frame and provide a thermal path from the die to the printed circuit board.
6	R_T	Resistor R_T connects from this pin to ground. The value selected will program the Current Limit Comparator threshold and affect the Oscillator frequency.
7	C_T	Capacitor C_T connects from this pin to ground. The value selected, in conjunction with resistor R_T, programs the Oscillator frequency.
8	Regulator Output	This 6.5 V output is available for biasing external circuitry. It requires an external bypass capacitor of at least 1.0 µF for stability.
9	Compensation	This pin is the Error Amplifier output and is made available for loop compensation. It can be used as an input to directly control the PWM Comparator.
10	Voltage Feedback Input	This is the inverting input of the Error Amplifier. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output.
11	Overvoltage Protection Input	This input provides runaway output voltage protection due to an external component or connection failure in the control loop feedback signal path. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output.
14, 15	–	These pins have been omitted for increased spacing between the high voltages present on the Power Switch Drain, and the ground potential on Pins 12 and 13.
16	Power Switch Drain	This pin is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A.

OPERATING DESCRIPTION

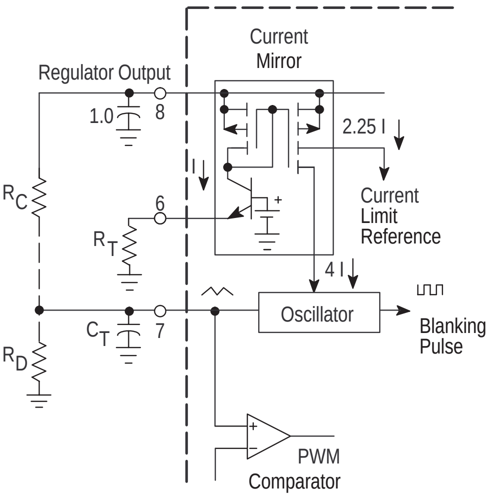
Introduction

The MC33363 represents a new higher level of integration by providing all the active high voltage power, control, and protection circuitry required for implementation of a flyback or forward converter on a single monolithic chip. This device is designed for direct operation from a rectified 240 Vac line source and requires a minimum number of external components to implement a complete converter. A description of each of the functional blocks is given below, and the representative block and timing diagrams are shown in Figures 17 and 18.

Oscillator and Current Mirror

The oscillator frequency is controlled by the values selected for the timing components R_T and C_T. Resistor R_T programs the oscillator charge/discharge current via the Current Mirror 4 I output, Figure 3. Capacitor C_T is charged and discharged by an equal magnitude internal current source and sink. This generates a symmetrical 50 percent duty cycle waveform at Pin 7, with a peak and valley threshold of 2.6 V and 0.6 V respectively. During the discharge of C_T, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gate Driver high. This causes the Power Switch gate drive to be held in a low state, thus producing a well controlled amount of output deadtime. The amount of deadtime is relatively constant with respect to the oscillator frequency when operating below 1.0 MHz. The maximum Power Switch duty cycle at Pin 16 can be modified from the internal 50% limit by providing an additional charge or discharge current path to C_T, Figure 19. In order to increase the maximum duty cycle, a discharge current resistor R_D is connected from Pin 7 to ground. To decrease the maximum duty cycle, a charge current resistor R_C is connected from Pin 7 to the Regulator Output. Figure 4 shows an obtainable range of maximum output duty cycle versus the ratio of either R_C or R_D with respect to R_T.

Figure 19. Maximum Duty Cycle Modification



The formula for the charge/discharge current along with the oscillator frequency are given below. The frequency formula is a first order approximation and is accurate for C_T values greater than 500 pF. For smaller values of C_T, refer to Figure 1. Note that resistor R_T also programs the Current Limit Comparator threshold.

$$I_{chg/dscg} = \frac{5.4}{R_T} \qquad f \approx \frac{I_{chg/dscg}}{4C_T}$$

PWM Comparator and Latch

The pulse width modulator consists of a comparator with the oscillator ramp voltage applied to the non–inverting input, while the error amplifier output is applied into the inverting input. The Oscillator applies a set pulse to the PWM Latch while C_T is discharging, and upon reaching the valley voltage, Power Switch conduction is initiated. When C_T charges to a voltage that exceeds the error amplifier output, the PWM Latch is reset, thus terminating Power Switch conduction for the duration of the oscillator ramp–up period. This PWM Comparator/Latch combination prevents multiple output pulses during a given oscillator clock cycle. The timing diagram shown in Figure 18 illustrates the Power Switch duty cycle behavior versus the Compensation voltage.

Current Limit Comparator and Power Switch

The MC33363 uses cycle–by–cycle current limiting as a means of protecting the output switch transistor from overstress. Each on–cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch current buildup during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the oscillator ramp–up period.

The Power Switch is constructed as a SenseFET allowing a virtually lossless method of monitoring the drain current. It consists of a total of 1780 cells, of which 46 are connected to a 9.0 Ω ground–referenced sense resistor. The Current Sense Comparator detects if the voltage across the sense resistor exceeds the reference level that is present at the inverting input. If exceeded, the comparator quickly resets the PWM Latch, thus protecting the Power Switch. The current limit reference level is generated by the 2.25 I output of the Current Mirror. This current causes a reference voltage to appear across the 450 Ω resistor. This voltage level, as well as the Oscillator charge/discharge current are both set by resistor R_T. Therefore when selecting the values for R_T and C_T, R_T must be chosen first to set the Power Switch peak drain current, while C_T is chosen second to set the desired Oscillator frequency. A graph of the Power Switch peak drain current versus R_T is shown in Figure 2 with the related formula below.

$$I_{pk} = 8.8\left(\frac{R_T}{1000}\right)^{-1.077}$$

The Power Switch is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A. Proper device voltage snubbing and heatsinking are required for reliable operation.

A Leading Edge Blanking circuit was placed in the current sensing signal path. This circuit prevents a premature reset of the PWM Latch. The premature reset is generated each time the Power Switch is driven into conduction. It appears as a narrow voltage spike across the current sense resistor, and is due to the MOSFET gate to source capacitance, transformer interwinding capacitance, and output rectifier recovery time. The Leading Edge Blanking circuit has a dynamic behavior in that it masks the current signal until the Power Switch turn–on transition is completed. The current limit propagation delay time is typically 233 ns. This time is measured from when an overcurrent appears at the Power Switch drain, to the beginning of turn–off.

Error Amplifier

An fully compensated Error Amplifier with access to the inverting input and output is provided for primary side voltage sensing, Figure 17. It features a typical dc voltage gain of 82 dB, and a unity gain bandwidth of 1.0 MHz with 78 degrees of phase margin, Figure 5. The noninverting input is internally biased at 2.6 V ±3.1% and is not pinned out. The Error Amplifier output is pinned out for external loop compensation and as a means for directly driving the PWM Comparator. The output was designed with a limited sink current capability of 270 µA, allowing it to be easily overridden with a pull–up resistor. This is desirable in applications that require secondary side voltage sensing, Figure 20. In this application, the Voltage Feedback Input is connected to the Regulator Output. This disables the Error Amplifier by placing its output into the sink state, allowing the optocoupler transistor to directly control the PWM Comparator.

Overvoltage Protection

An Overvoltage Protection Comparator is included to eliminate the possibility of runaway output voltage. This condition can occur if the control loop feedback signal path is broken due to an external component or connection failure. The comparator is normally used to monitor the primary side V_{CC} voltage. When the 2.6 V threshold is exceeded, it will immediately turn off the Power Switch, and protect the load from a severe overvoltage condition. This input can also be driven from external circuitry to inhibit converter operation.

Undervoltage Lockout

An Undervoltage Lockout comparator has been incorporated to guarantee that the integrated circuit has sufficient voltage to be fully functional before the output stage is enabled. The UVLO comparator monitors the V_{CC} voltage at Pin 3 and when it exceeds 14.5 V, the reset signal is removed from the PWM Latch allowing operation of the Power Switch. To prevent erratic switching as the threshold is crossed, 5.0 V of hysteresis is provided.

Startup Control

An internal Startup Control circuit with a high voltage enhancement mode MOSFET is included within the MC33363. This circuitry allows for increased converter efficiency by eliminating the external startup resistor, and its associated power dissipation, commonly used in most off–line converters that utilize a UC3842 type of controller. Rectified ac line voltage is applied to the Startup Input, Pin 1. This causes the MOSFET to enhance and supply internal bias as well as charge current to the V_{CC} bypass capacitor that connects from Pin 3 to ground. When V_{CC} reaches the UVLO upper threshold of 15.2 V, the IC commences operation and the startup MOSFET is turned off. Operating bias is now derived from the auxiliary transformer winding, and all of the device power is efficiently converted down from the rectified ac line.

The startup MOSFET will provide an initial peak current of 20 mA, Figure 10, which decreases rapidly as V_{CC} and the die temperature rise. The steady state current will self limit in the range of 8.0 mA with V_{CC} shorted to ground. The startup MOSFET is rated at a maximum of 400 V with V_{CC} shorted to ground, and 500 V when charging a V_{CC} capacitor of 1000 µF or less.

Regulator

A low current 6.5 V regulated output is available for biasing the Error Amplifier and any additional control system circuitry. It is capable of up to 10 mA and has short–circuit protection. This output requires an external bypass capacitor of at least 1.0 µF for stability.

Thermal Shutdown and Package

Internal thermal circuitry is provided to protect the Power Switch in the event that the maximum junction temperature is exceeded. When activated, typically at 155°C, the Latch is forced into a ‘reset’ state, disabling the Power Switch. The Latch is allowed to ‘set’ when the Power Switch temperature falls below 145°C. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a substitute for proper heatsinking.

The MC33363 is contained in a heatsinkable plastic dual–in–line package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figures 15 and 16 show a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction to air thermal resistance. The examples are for a symmetrical layout on a single–sided board with two ounce per square foot of copper. Figure 22 shows a practical example of a printed circuit board layout that utilizes the copper foil as a heat dissipater. Note that a jumper was added to the layout from Pins 8 to 10 in order to enhance the copper area near the device for improved thermal conductivity. The application circuit requires two ounce copper foil in order to obtain 8.0 watts of continuous output power at room temperature.

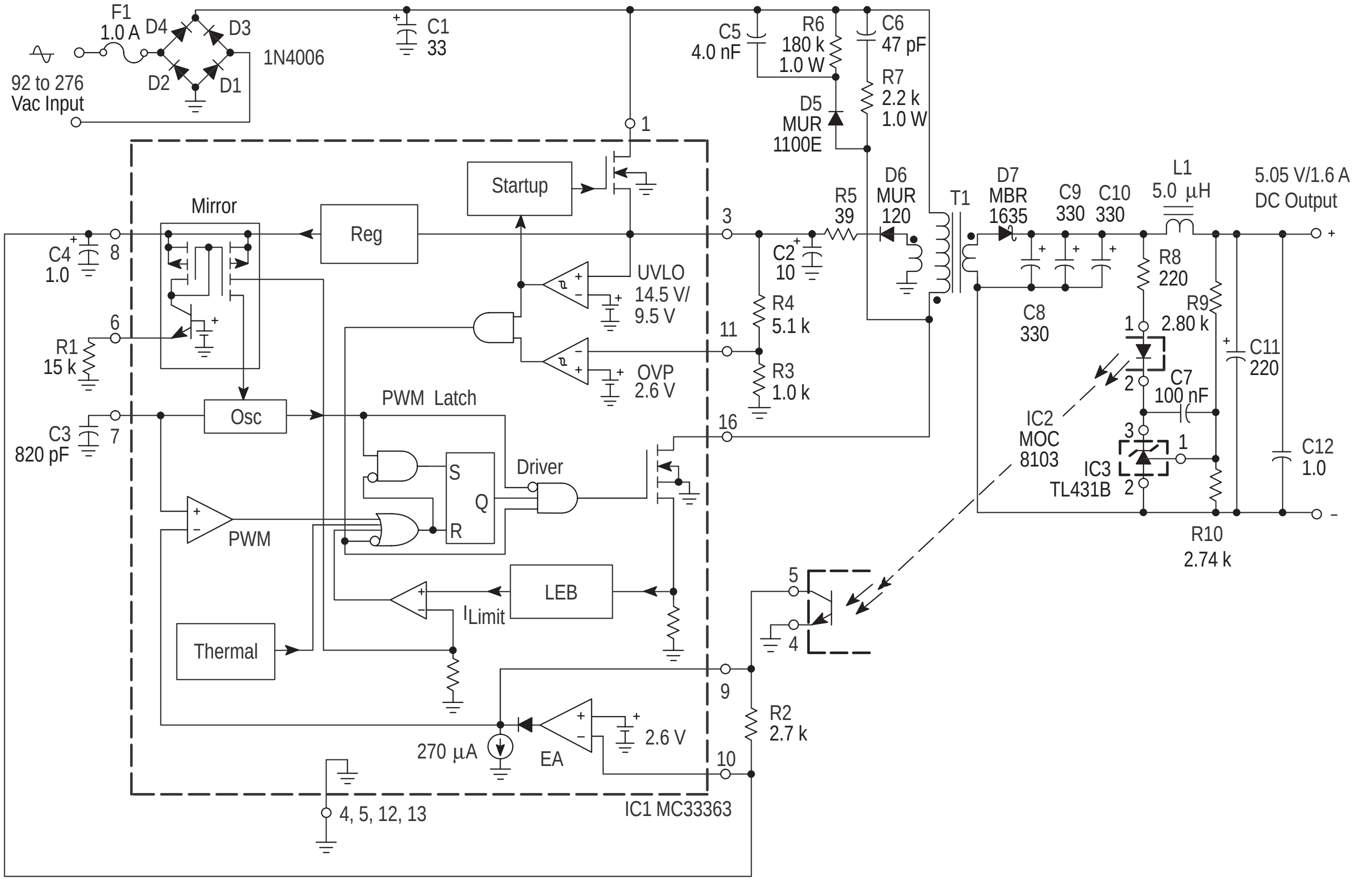

Figure 21. Converter Test Data

Test	Conditions	Results
Line Regulation	V_{in} = 92 Vac to 276 Vac, I_O 1.6 A	Δ = 1.0 mV
Load Regulation	V_{in} = 115 Vac, I_O = 0.4 A to 1.6 A	Δ = 4.0 mV
	V_{in} = 230 Vac, I_O = 0.4 A to 1.6 A	Δ = 4.0 mV
Output Ripple	V_{in} = 115 Vac, I_O = 1.6 A	Triangular = 2.0 mVpp, Spike = 12 mVpp
	V_{in} = 230 Vac, I_O = 1.6 A	Triangular = 2.0 mVpp, Spike = 12 mVpp
Efficiency	V_{in} = 115 Vac, I_O = 1.6 A	78.6%*
	V_{in} = 230 Vac, I_O = 1.6 A	75.6%

This data was taken with the components listed below mounted on the printed circuit board shown in Figure 22.

* With MBR2535CTL, 79.8% efficiency. PCB layout modification is required to use this rectifier.

For high efficiency and small circuit board size, the Sanyo Os–Con capacitors are recommended for C8, C9, C10 and C11.

C8, C9, C10 = Sanyo Os–Con #6SA330M, 330 µF 6.3 V.

C11 = Sanyo Os–Con #10SA220M, 220 µF 10 V.

L1 = Coilcraft S5088–A, 5.0 µH, 0.11 Ω.

T1 = Coilcraft S5502–A
Primary: 77 turns of # 28 AWG, Pin 1 = start, Pin 8 = finish.
Two layers 0.002″ Mylar tape.
Secondary: 5 turns of # 22 AWG, 2 strands bifiliar wound, Pin 5 = start, Pin 4 = finish.
Two layers 0.002″ Mylar tape.
Auxiliary: 13 turns of # 28 AWG wound in center of bobbin, Pin 2 = start, Pin 7 = finish.
Two layers 0.002″ Mylar tape.
Gap: 0.006″ total for a primary inductance (L_P) of 1.0 mH.
Core and Bobbin: Coilcraft PT1950, E187, 3F3 material.

High Voltage Switching Regulator

The MC33363A is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 240 Vac line source. This integrated circuit features an on–chip 700 V/1.5 A SenseFET power switch, 450 V active off–line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle–by–cycle current limiting, input undervoltage lockout with hysteresis, output overvoltage protection, and thermal shutdown. This device is available in a 16–lead dual–in–line and wide body surface mount packages.

- Enhanced Power Capability Over MC33363
- On–Chip 700 V, 1.5 A SenseFET Power Switch
- Rectified 240 Vac Line Source Operation
- On–Chip 450 V Active Off–Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle–By–Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Output Overvoltage Protection Comparator
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown

Critical Conduction SMPS Controller

The MC33364 series are variable frequency SMPS controllers that operate in the critical conduction mode. They are optimized for low power, high density power supplies requiring minimum board area, reduced component count, and low power dissipation. Each narrow body SOIC package provides a small footprint. Integration of the high voltage startup saves approximately 0.7 W of power compared to resistor bootstrapped circuits.

Each MC33364 features an on–board reference, UVLO function, a watchdog timer to initiate output switching, a zero current detector to ensure critical conduction operation, a current sensing comparator, leading edge blanking, and a CMOS driver. Protection features include the ability to shut down switching, and cycle–by–cycle current limiting.

The MC33364D1 is available in a surface mount SO–8 package. It has an internal 144 kHz frequency clamp. For loads which have a low power operating condition, the frequency clamp limits the maximum operating frequency, preventing excessive switching losses and EMI radiation.

The MC33364D2 is available in the SO–8 package without an internal frequency clamp.

The MC33364D is available in the SO–16 package. It has an internal 144 kHz frequency clamp which is pinned out, so that the designer can adjust the clamp frequency by connecting appropriate values of resistance and capacitance.

- Lossless Off–Line Startup
- Leading Edge Blanking for Noise Immunity
- Watchdog Timer to Initiate Switching
- Minimum Number of Support Components
- Shutdown Capability
- Over Temperature Protection
- Optional Frequency Clamp

Advance Information

High Voltage GreenLine™ Power Factor Controller

The MC33368 is an active power factor controller that functions as a boost preconverter in off–line power supply applications. MC33368 is optimized for low power, high density power supplies requiring a minimum board area, reduced component count and low power dissipation. The narrow body SOIC package provides a small footprint. Integration of the high voltage startup saves approximately 0.7 W of power compared to resistor bootstrapped circuits.

The MC33368 features a watchdog timer to initiate output switching, a one quadrant multiplier to force the line current to follow the instantaneous line voltage a zero current detector to ensure critical conduction operation, a transconductance error amplifier, a current sensing comparator, a 5.0 V reference, an undervoltage lockout (UVLO) circuit which monitors the V_{CC} supply voltage and a CMOS driver for driving MOSFETs. The MC33368 also includes a programmable output switching frequency clamp. Protection features include an output overvoltage comparator to minimize overshoot, a restart delay timer and cycle–by–cycle current limiting.

- Lossless Off–Line Startup
- Output Overvoltage Comparator
- Leading Edge Blanking (LEB) for Noise Immunity
- Watchdog Timer to Initiate Switching
- Restart Delay Timer

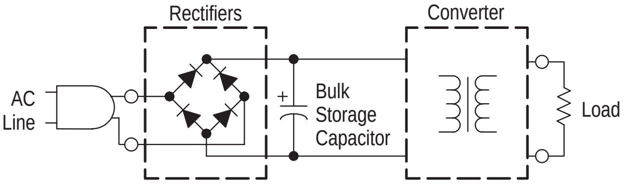
FUNCTIONAL DESCRIPTION

INTRODUCTION

With the goal of exceeding the requirements of legislation on line current harmonic content, there is an ever increasing demand for an economical method of obtaining a unity power factor. This data sheet describes a monolithic control IC that was specifically designed for power factor control with minimal external components. It offers the designer a simple cost effective solution to obtain the benefits of active power factor correction.

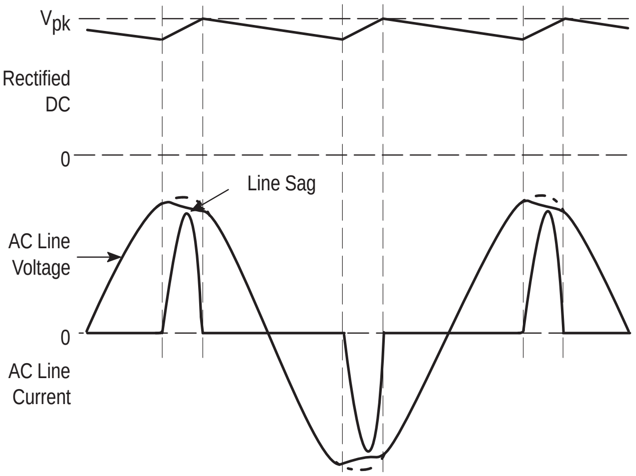
Most electronic ballasts and switching power supplies use a bridge rectifier and a bulk storage capacitor to derive raw dc voltage from the utility ac line, Figure 13.

Figure 13. Uncorrected Power Factor Circuit



This simple rectifying circuit draws power from the line when the instantaneous ac voltage exceeds the capacitor voltage. This occurs near the line voltage peak and results in a high charge current spike, Figure 14. Since power is only taken near the line voltage peaks, the resulting spikes of current are extremely nonsinusoidal with a high content of harmonics. This results in a poor power factor condition where the apparent input power is much higher than the real power. Power factor ratios of 0.5 to 0.7 are common.

Figure 14. Uncorrected Power Factor Input Waveforms



Power factor correction can be achieved with the use of either a passive or active input circuit. Passive circuits usually contain a combination of large capacitors, inductors, and rectifiers that operate at the ac line frequency. Active circuits incorporate some form of a high frequency switching converter for the power processing with the boost converter being the most popular topology. Since active input circuits operate at a frequency much higher than that of the ac line, they are smaller, lighter in weight, and more efficient than a passive circuit that yields similar results. With proper control of the preconverter, almost any complex load can be made to appear resistive to the ac line, thus significantly reducing the harmonic current content.

Operating Description

The MC33368 contains many of the building blocks and protection features that are employed in modern high performance current mode power supply controllers. Referring to the block diagram in Figure 15, note that a multiplier has been added to the current sense loop and that this device does not contain an oscillator. A description of each of the functional blocks is given below.

Error Amplifier

An Error Amplifier with access to the inverting input and output is provided. The amplifier is a transconductance type, meaning that it has high output impedance with controlled voltage–to–current gain ($g_m \approx 50$ μmhos). The noninverting input is internally biased at 5.0 V ±2.0%. The output voltage of the power factor converter is typically divided down and monitored by the inverting input. The maximum input bias current is –1.0 μA which can cause an output voltage error that is equal to the product of the input bias current and the value of the upper divider resistor R2. The Error Amplifier output is internally connected to the Multiplier and is pinned out (Pin 4) for external loop compensation. Typically, the bandwidth is set below 20 Hz so that the amplifier's output voltage is relatively constant over a given ac line cycle. In effect, the error amplifier monitors the average output voltage of the converter over several line cycles resulting in a fixed Drive Output on–time. The amplifier output stage can sink and source 11.5 μA of current and is capable of swinging from 1.7 to 5.0 V, assuring that the Multiplier can be driven over its entire dynamic range.

Note that by using a transconductance type amplifier, the input is allowed to move independently with respect to the output, since the compensation capacitor is connected to ground. This allows dual usage of the Voltage Feedback pin by the Error Amplifier and Overvoltage Comparator.

Overvoltage Comparator

An Overvoltage Comparator is incorporated to eliminate the possibility of runaway output voltage. This condition can occur during initial startup, sudden load removal, or during output arcing and is the result of the low bandwidth that must be used in the Error Amplifier control loop. The Overvoltage Comparator monitors the peak output voltage of the converter, and when exceeded, immediately terminates MOSFET switching. The comparator threshold is internally set to 1.08 V_{ref}. In order to prevent false tripping during normal operation, the value of the output filter capacitor C3 must be large enough to keep the peak–to–peak ripple less than 16% of the average dc output.

Multiplier

A single quadrant, two input multiplier is the critical element that enables this device to control power factor. The ac haversines are monitored at Pin 5 with respect to ground while the Error Amplifier output at Pin 4 is monitored with respect to the Voltage Feedback Input threshold. A graph of the Multiplier transfer curve is shown in Figure 1. Note that both inputs are extremely linear over a wide dynamic range, 0 to 3.2 V for Pin 5 and 2.5 to 4.0 V for Pin 4. The Multiplier output controls the Current Sense Comparator threshold as the ac voltage traverses sinusoidally from zero to peak line. This has the effect of forcing the MOSFET on–time to track the input line voltage, thus making the preconverter load appear to be resistive.

$$\text{Pin 6 Threshold} \approx 0.55 \left(V_{Pin\ 4} - V_{Pin\ 3}\right) V_{Pin\ 5}$$

Zero Current Detector

The MC33368 operates as a critical conduction current mode controller, whereby output switch conduction is initiated by the Zero Current Detector and terminated when the peak inductor current reaches the threshold level established by the Multiplier output. The Zero Current Detector initiates the next on–time by setting the R_S Latch at the instant the inductor current reaches zero. This critical conduction mode of operation has two significant benefits. First, since the MOSFET cannot turn–on until the inductor current reaches zero, the output rectifier's reverse recovery time becomes less critical allowing the use of an inexpensive rectifier. Second, since there are no deadtime gaps between cycles, the ac line current is continuous thus limiting the peak switch to twice the average input current

The Zero Current Detector indirectly senses the inductor current by monitoring when the auxiliary winding voltage falls below 1.2 V. To prevent false tripping, 200 mV of hysteresis is provided. The Zero Current Detector input is internally protected by two clamps. The upper 10 V clamp prevents input overvoltage breakdown while the lower –0.7 V clamp prevents substrate injection. An external resistor must be used in series with the auxiliary winding to limit the current through the clamps to 5.0 mA or less.

Current Sense Comparator and RS Latch

The Current Sense Comparator R_S Latch configuration used ensures that only a single pulse appears at the Drive Output during a given cycle. The inductor current is converted to a voltage by inserting a ground–referenced sense resistor R7 in series with the source of output switch. This voltage is monitored by the Current Sense Input and compared to a level derived from the Multiplier output. The peak inductor current under normal operating conditions is controlled by the threshold voltage of Pin 6 where:

$$I_{pk} = \frac{\text{Pin 6 Threshold}}{R7}$$

Abnormal operating conditions occur when the preconverter is running at extremely low line or if output voltage sensing is lost. Under these conditions, the Current Sense Comparator threshold will be internally clamped to 1.5 V. Therefore, the maximum peak switch current is:

$$I_{pk(max)} = \frac{1.5\ V}{R7}$$

With the component values shown in Figure 15, the Current Sense Comparator threshold, at the peak of the haversine, varies from 110 mV at 90 Vac to 100 mV at 268 Vac. The Current Sense Input to Drive Output propagation delay is typically 200 ns.

Timer

A watchdog timer function was added to the IC to eliminate the need for an external oscillator when used in stand alone applications. The Timer provides a means to automatically start or restart the preconverter if the Drive Output has been off for more than 385 µs after the inductor current reaches zero.

Undervoltage Lockout and Quickstart

The MC33368 has a 5.0 V internal reference brought out to Pin 1 and capable of sourcing 10 mA typically. It also contains an Undervoltage Lockout (UVLO) circuit which suppresses the Gate output at Pin 11 if the V_{CC} supply voltage drops below 8.5 V typical.

A Quickstart circuit has been incorporated to optimize converter startup. During initial startup, compensation capacitor C1 will be discharged, holding the Error Amplifier output below the Multiplier's threshold. This will prevent Drive Output switching and delay bootstraping of capacitor C4 by diode D6. If Pin 4 does not reach the multiplier threshold before C4 discharges below the lower SMPS UVLO threshold, the converter will hiccup and experience a significant startup delay. The Quickstart circuit is designed to precharge C1 to 1.7 V. This level is slightly below the Pin 4 Multiplier threshold, allowing immediate Drive Output switching.

Restart Delay

A restart delay pin is provided to allow hiccup mode fault protection in case of a short circuit condition and to prevent the SMPS from repeatedly trying to restart after the input line voltage has been removed. When power is first applied, there is no startup delay, but subsequent cycling of the V_{CC} voltage will result in delay times that are programmed by an external resistor and capacitor. The Restart Delay, Pin 2, is a high impedance, so that an external capacitor can provide delay times as long as several seconds.

If the SMPS output is short circuited, the transformer winding, which provides the V_{CC} voltage to the control IC and the MC33368, will be unable to sustain V_{CC} to the control circuits. The restart delay capacitor at Pin 2 of the MC33368 prevents the high voltage startup transistor within the IC from maintaining the voltage on C4. After V_{CC} drops below the UVLO threshold in the SMPS, the SMPS switching transistors are held off for the time programmed by the values of the restart capacitor (C9) and resistor (R8). In this manner, the SMPS switching transistors are operated at very low duty cycles, preventing their destruction. If the short circuit fault is removed, the power supply system will turn on by itself in a normal startup mode after the restart delay has timed out.

Output Switching Frequency Clamp

In normal operation, the MC33368 operates the boost inductor in the critical mode. That is, the inductor current ramps to a peak value, ramps down to zero, then immediately begins ramping positive again. The peak current is programmed by the multiplier output within the IC. As the input voltage haversine declines to near zero, the output switch on–time becomes constant, rather than going to zero because of the small integrated dc voltage at Pin 5 caused by C2, R3 and R5. Because of this, the average line current does not exactly follow the line voltage near the zero crossings. The Output Switching Frequency Clamp remedies this situation to improve power factor and minimize EMI generated in this operating region. The values of R10 and C7 program a minimum off–time in the frequency clamp which overrides the zero current detect signal, forcing a minimum off–time. This allows discontinuous conduction operation of the boost inductor in the zero crossing region, and the average line current more nearly follows the voltage. The Output Switching Frequency Clamp function can be disabled by connecting the FC input, Pin 13, to the V_{CC} supply Pin 12.

Output

The IC contains a CMOS output driver that was specifically designed for direct drive of power MOSFETs. The Drive Output is capable of up to ±1500 mA peak current with a typical rise and fall time of 50 ns with a 1.0 nF load. Additional internal circuitry has been added to keep the Drive Output in a sinking mode whenever the Undervoltage Lockout is active. This characteristic eliminates the need for an external gate pull–down resistor. The totem–pole output has been optimized to minimize cross–conduction current during high speed operation.

Table 1. Design Equations

Calculation	Formula	Notes
Converter Output Power	$P_O = V_O I_O$	Calculate the maximum required output power.
Peak Indicator Current	$I_{L(pk)} = \frac{2\sqrt{2}\ P_O}{\eta\ Vac_{(LL)}}$	Calculated at the minimum required ac line voltage for output regulation. Let the efficiency η = 0.92 for low line operation.
Inductance	$L_P = \frac{t\left(\frac{V_O}{\sqrt{2}} - Vac_{(LL)}\right)\eta\ Vac_{(LL)}{}^2}{\sqrt{2}\ V_O P_O}$	Let the switching cycle t = 40 µs for universal input (85 to 265 Vac) operation and 20 µs for fixed input (92 to 138 Vac, or 184 to 276 Vac) operation.
Switch On–Time	$t_{(on)} = \frac{2\ P_O L_P}{\eta\ Vac^2}$	In theory, the on–time $t_{(on)}$ is constant. In practice, $t_{(on)}$ tends to increase at the ac line zero crossings due to the charge on capacitor C5. Let Vac = $Vac_{(LL)}$ for initial $t_{(on)}$ and $t_{(off)}$ calculations.
Switch Off–Time	$t_{(off)} = \frac{t_{(on)}}{\frac{V_O}{\sqrt{2}\ Vac\ \lvert \mathrm{Sin}\ \theta \rvert} - 1}$	The off–time $t_{(off)}$ is greatest at the peak of the ac line voltage and approaches zero at the ac line zero crossings. Theta (0) represents the angle of the ac line voltage.
Minimum Switch Off–Time	$t_{(off)_{min}} = \frac{L_P I_{L(pk)}}{V_O}$	The off–time is at a minimum at ac line crossings. This equation is used to calculate $t_{(off)}$ as Theta approaches zero.
Delay Time	$t_d = -\ R10\ C7\ \ln\left(\frac{V_{CC} - 2}{V_{CC}}\right)$	The delay time is used to override the minimum off–time at the ac line zero crossings by programming the Frequency Clamp with C7 and R10.
Switching Frequency	$f = \frac{1}{t_{(on)} + t_{(off)}}$	The minimum switching frequency occurs at the peak of the ac line voltage. As the ac line voltage traverses from peak to zero, $t_{(off)}$ approaches zero producing an increase in switching frequency.
Peak Switch Current	$R7 = \frac{V_{CS}}{I_{L(pk)}}$	Set the current sense threshold V_{CS} to 1.0 V for universal input (85 to 265 Vac) operation and to 0.5 V for fixed input (92 to 138 Vac, or 184 to 276 Vac) operation. Note that V_{CS} must be less than 1.4 V.
Multiplier Input Voltage	$V_M = \frac{Vac\ \sqrt{2}}{\left(\frac{R5}{R3} + 1\right)}$	Set the mulltiplier input voltage V_M to 3.0 V at high line. Empirically adjust V_M for the lowest distortion over the ac line voltage range while guaranteeing startup at minimum line.
Converter Output Voltage	$V_O = V_{ref}\left(\frac{R2}{R1} + 1\right) - I_{IB}\ R1$	The I_{IB} R1 error term can be minimized with a divider current in excess of 100 µA.
Converter Output Peak–to–Peak Ripple Voltage	$\Delta V_{O(pp)} = I_{L(pk)}\sqrt{\left(\frac{1}{2\ \pi\ f_{ac}\ C3}\right)^2 + ESR^2}$	The calculated peak–to–peak ripple must be less than 16% of the average dc output voltage to prevent false tripping of the Overvoltage Comparator. Refer to the Overvoltage Comparator Text. ESR is the equivalent series resistance of C3.
Error Amplifier Bandwidth	$BW = \frac{g_m}{2\ \pi\ C1}$	The bandwidth is typically set to 20 Hz. When operating at high ac line, the value of C1 may need to be increased.

NOTE: The following converter characteristics must be chosen:

V_O = Desired output voltage.
I_O = Desired output current.
Vac = AC RMS operating line voltage.
$Vac_{(LL)}$ = AC RMS minimum required operating line voltage for output regulation.
ΔV_O = Converter output peak–to–peak ripple voltage.

Variable Frequency Micropower DC-to-DC Converter

The MC33463 series are micropower switching voltage regulators, specifically designed for handheld and laptop applications, to provide regulated output voltages using a minimum of external parts. A wide choice of output voltages are available. These devices feature a very low quiescent bias current of 4.0 µA typical.

The MC33463H–XXLT1 series features a highly accurate voltage reference, an oscillator, a variable frequency modulation (VFM) controller, a driver transistor (Lx), an error amplifier and feedback resistive divider.

The MC33463H–XXLT1 is identical to the MC33463H–XXKT1, except that a drive pin (EXT) for an external transistor is provided.

Due to the low bias current specifications, these devices are ideally suited for battery powered computer, consumer, and industrial equipment where an extension of useful battery life is desirable.

MC33463 Series Features:

- Low Quiescent Bias Current of 4.0 µA
- High Output Voltage Accuracy of ±2.5%
- Low Startup Voltage of 0.9 V at 1.0 mA
- Surface Mount Package

Micropower Undervoltage Sensing Circuits

The MC33464 series are micropower undervoltage sensing circuits that are specifically designed for use with battery powered microprocessor based systems, where extended battery life is required. A choice of several threshold voltages from 0.9 V to 4.5 V are available. These devices feature a very low quiescent bias current of 0.8 µA typical.

The MC33464 series features a highly accurate voltage reference, a comparator with precise thresholds and built–in hysteresis to prevent erratic reset operation, a choice of output configurations between open drain or complementary MOS, and guaranteed operation below 1.0 V with extremely low standby current. These devices are available in either SOT–89 3–pin or SOT–23 5–pin surface mount packages.

Applications include direct monitoring of the MPU/logic power supply used in portable, appliance, automotive and industrial equipment.

MC33464 Features:

- Extremely Low Standby Current of 0.8 µA at V_{in} = 1.5 V
- Wide Input Voltage Range (0.7 V to 10 V)
- Monitors Power Supply Voltages from 1.1 V to 5.0 V
- High Accuracy Detector Threshold (±2.5%)
- Two $\overline{\text{Reset}}$ Output Types (Open Drain or Complementary Drive)
- Two Surface Mount Packages (SOT–89 or SOT–23 5–Pin)

MICROPOWER UNDERVOLTAGE SENSING CIRCUITS WITH OUTPUT DELAY

SEMICONDUCTOR TECHNICAL DATA

The MC33465 series are micropower undervoltage sensing circuits that are specifically designed for use with battery powered microprocessor based systems, where extended battery life is required. A choice of several threshold voltages from 0.9 V to 4.5 V are available. This device features a very low quiescent bias current of 1.0 µA typical.

The MC33465 series features a highly accurate voltage reference, a comparator with precise thresholds and built–in hysteresis to prevent erratic reset operation, a choice of output configurations between open drain or complementary MOS, a time delayed output, which can be programmed by the system designer, and guaranteed operation below 1.0 V with extremely low standby current. This device is available in a SOT–23 5–pin surface mount packages.

Applications include direct monitoring of the MPU/logic power supply used in portable, appliance, automotive and industrial equipment.

MC33465 Features:

- Extremely Low Standby Current of 1.0 µA at V_{in} = 3.5 V
- Wide Input Voltage Range (0.7 V to 10 V)
- Monitors Power Supply Voltages from 1.1 V to 5.0 V
- High Accuracy Detector Threshold (±2.5%)
- Two Reset Output Types (Open Drain or Complementary Drive)
- Programmable Output Delay by External Capacitor (100 ms typ. with 0.15 µF)
- Surface Mount Package (SOT–23 5–Pin)
- Convenient Tape and Reel (3000 per Reel)

MC33023

High Speed Single-Ended PWM Controller

The MC34023 series are high speed, fixed frequency, single–ended pulse width modulator controllers optimized for high frequency operation. They are specifically designed for Off–Line and DC–to–DC converter applications offering the designer a cost–effective solution with minimal external components. These integrated circuits feature an oscillator, a temperature compensated reference, a wide bandwidth error amplifier, a high speed current sensing comparator, and a high current totem pole output ideally suited for driving a power MOSFET.

Also included are protective features consisting of input and reference undervoltage lockouts each with hysteresis, cycle–by–cycle current limiting, and a latch for single pulse metering.

The flexibility of this series allows it to be easily configured for either current mode or voltage mode control.

- 50 ns Propagation Delay to Output
- High Current Totem Pole Output
- Wide Bandwidth Error Amplifier
- Fully–Latched Logic with Double Pulse Suppression
- Latching PWM for Cycle–By–Cycle Current Limiting
- Soft–Start Control with Latched Overcurrent Reset
- Input Undervoltage Lockout with Hysteresis
- Low Start–Up Current (500 µA Typ)
- Internally Trimmed Reference with Undervoltage Lockout
- 90% Maximum Duty Cycle (Externally Adjustable)
- Precision Trimmed Oscillator
- Voltage or Current Mode Operation to 1.0 MHz
- Functionally Similar to the UC3823

OPERATING DESCRIPTION

The MC33023 and MC34023 series are high speed, fixed frequency, single–ended pulse width modulator controllers optimized for high frequency operation. They are specifically designed for Off–Line and DC–to–DC converter applications offering the designer a cost effective solution with minimal external components. A representative block diagram is shown in Figure 18.

Oscillator

The oscillator frequency is programmed by the values selected for the timing components R_T and C_T. The R_T pin is set to a temperature compensated 3.0 V. By selecting the value of R_T, the charge current is set through a current mirror for the timing capacitor C_T. This charge current runs continuously through C_T. The discharge current is ratioed to be 10 times the charge current, which yields the maximum duty cycle of 90%. C_T is charged to 2.8 V and discharged to 1.0 V. During the discharge of C_T, the oscillator generates an internal blanking pulse that resets the PWM Latch and, inhibits the outputs. The threshold voltage on the oscillator comparator is trimmed to guarantee an oscillator accuracy of 5.0% at 25°C.

Additional dead time can be added by externally increasing the charge current to C_T as shown in Figure 23. This changes the charge to discharge ratio of C_T which is set internally to $I_{charge}/10\ I_{charge}$. The new charge to discharge ratio will be:

$$\%\ \text{Deadtime} = \frac{I_{additional} + I_{charge}}{10\ (I_{charge})}$$

A bidirectional clock pin is provided for synchronization or for master/slave operation. As a master, the clock pin provides a positive output pulse during the discharge of C_T. As a slave, the clock pin is an input that resets the PWM latch and blanks the drive output, but does not discharge C_T. Therefore, the oscillator is not synchronized by driving the clock pin alone. Figures 27, 28 and 29 provide suggested synchronization.

Error Amplifier

A fully compensated Error Amplifier is provided. It features a typical DC voltage gain of 95 dB and a gain bandwidth product of 8.3 MHz with 75 degrees of phase margin (Figure 3). Typical application circuits will have the noninverting input tied to the reference. The inverting input will typically be connected to a feedback voltage generated from the output of the switching power supply. Both inputs have a common mode voltage (V_{CM}) input range of 1.5 V to 5.5 V. The Error Amplifier Output is provided for external loop compensation.

Soft–Start Latch

Soft–Start is accomplished in conjunction with an external capacitor. The Soft–Start capacitor is charged by an internal 9.0 µA current source. This capacitor clamps the output of the error amplifier to less than its normal output voltage, thus limiting the duty cycle. The time it takes for a capacitor to reach full charge is given by:

$$t \approx (4.5 \bullet 10^5)\ C_{Soft\text{-}Start}$$

A Soft–Start latch is incorporated to prevent erratic operation of this circuitry. Two conditions can cause the Soft–Start circuit to latch so that the Soft–Start capacitor stays discharged. The first condition is activation of an undervoltage lockout of either V_{CC} or V_{ref}. The second condition is when current sense input exceeds 1.4 V. Since this latch is “set dominant”, it cannot be reset until either of these signals is removed and, the voltage at $C_{Soft–Start}$ is less than 0.5 V.

PWM Comparator and Latch

A PWM circuit typically compares an error voltage with a ramp signal. The outcome of this comparison determines the state of the output. In voltage mode operation the ramp signal is the voltage ramp of the timing capacitor. In current mode operation the ramp signal is the voltage ramp induced in a current sensing element. The ramp input of the PWM comparator is pinned out so that the user can decide which mode of operation best suits the application requirements. The ramp input has a 1.25 V offset such that whenever the voltage at this pin exceeds the error amplifier output voltage minus 1.25 V, the PWM comparator will cause the PWM latch to set, disabling the outputs. Once the PWM latch is set, only a blanking pulse by the oscillator can reset it, thus initiating the next cycle.

Current Limiting and Shutdown

A pin is provided to perform current limiting and shutdown operations. Two comparators are connected to the input of this pin. The reference voltage for the current limit comparator is not set internally. A pin is provided so the user can set the voltage. When the voltage at the current limit input pin exceeds the externally set voltage, the PWM latch is set, disabling the output. In this way cycle–by–cycle current limiting is accomplished. If a current limit resistor is used in series with the power devices, the value of the resistor is found by:

$$R_{Sense} = \frac{I_{Limit\ Reference\ Voltage}}{I_{pk\ (switch)}}$$

If the voltage at this pin exceeds 1.4 V, the second comparator is activated. This comparator sets a latch which, in turn, causes the soft start capacitor to be discharged. In this way a “hiccup” mode of recovery is possible in the case of output short circuits. If a current limit resistor is used in series with the output devices, the peak current at which the controller will enter a “hiccup” mode is given by:

$$I_{shutdown} = \frac{1.4\ V}{R_{Sense}}$$

Undervoltage Lockout

There are two undervoltage lockout circuits within the IC. The first senses V_{CC} and the second V_{ref}. During power–up, V_{CC} must exceed 9.2 V and V_{ref} must exceed 4.2 V before the outputs can be enabled and the Soft–Start latch released. If V_{CC} falls below 8.4 V or V_{ref} falls below 3.6 V, the outputs are disabled and the Soft–Start latch is activated. When the UVLO is active, the part is in a low current standby mode allowing the IC to have an off–line bootstrap start–up circuit. Typical start–up current is 500 µA.

Output

The MC34023 has a high current totem pole output specifically designed for direct drive of power MOSFETs. It is capable of up to ± 2.0 A peak drive current with a typical rise and fall time of 30 ns driving a 1.0 nF load.

Separate pins for V_C and Power Ground are provided. With proper implementation, a significant reduction of switching transient noise imposed on the control circuitry is possible. The separate V_C supply input also allows the designer added flexibility in tailoring the drive voltage independent of V_{CC}.

Reference

A 5.1 V bandgap reference is pinned out and is trimmed to an initial accuracy of ±1.0% at 25°C. This reference has short circuit protection and can source in excess of 10 mA for powering additional control system circuitry.

Design Considerations

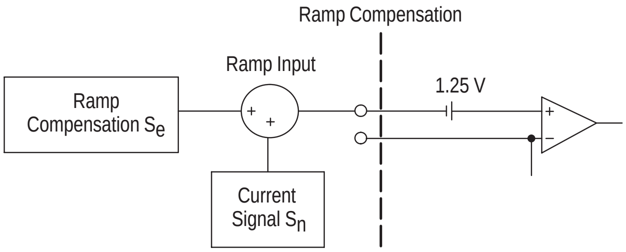
Do not attempt to construct the converter on wire–wrap or plug–in prototype boards. With high frequency, high power, switching power supplies it is imperative to have separate current loops for the signal paths and for the power paths. The printed circuit layout should contain a ground plane with low current signal and high current switch and output grounds returning on separate paths back to the input filter capacitor. Shown in Figure 35 is a printed circuit layout of the application circuit. Note how the power and ground traces are run. All bypass capacitors and snubbers should be connected as close as possible to the specific part in question. The PC board lead lengths must be less than 0.5 inches for effective bypassing for snubbing.

Instabilities

In current mode control, an instability can be encountered at any given duty cycle. The instability is caused by the current feedback loop. It has been shown that the instability is caused by a double pole at half the switching frequency. If an external ramp (S_e) is added to the on–time ramp (S_n) of the current–sense waveform, stability can be achieved.

One must be careful not to add too much ramp compensation. If too much is added the system will start to perform like a voltage mode regulator. All benefits of current mode control will be lost. Figure 25 is an example of one way in which external ramp compensation can be implemented.

Figure 20. Ramp Compensation



A simple equation can be used to calculate the amount of external ramp slope necessary to add that will achieve stability in the current loop. For the following equations, the calculated values for the application circuit in Figure 34 are also shown.

$$S_e = \frac{V_O}{L}\left(\frac{N_S}{N_P}\right)(R_S)A_i$$

where: V_O = DC output voltage
N_P, N_S = number of power transformer primary or secondary turns
A_i = gain of the current sense network (see Figures 23 and 24)
L = output inductor
R_S = current sense resistance

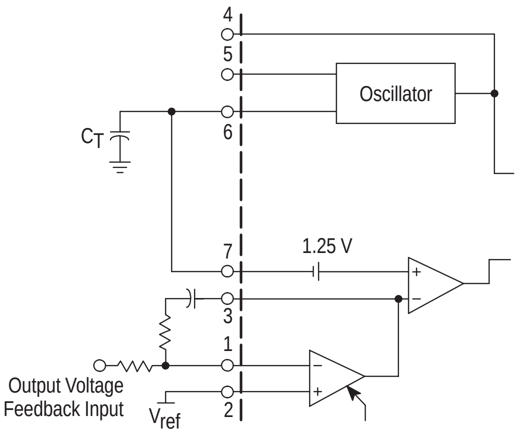
For the application circuit: $S_e = \frac{5}{1.8\ \mu}\left(\frac{2}{8}\right)(0.3)(0.55)$

$= 0.115$ V/ms

PIN FUNCTION DESCRIPTION

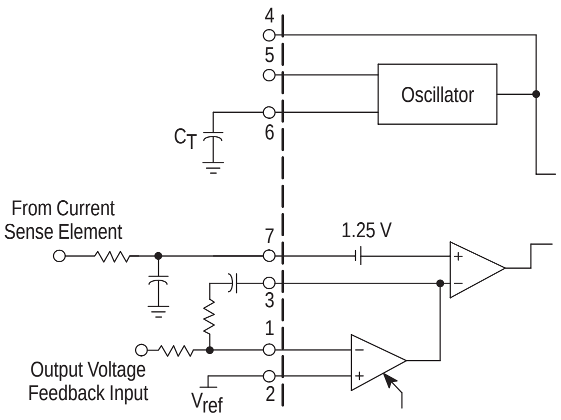
Pin		
DIP/SOIC	Function	Description
1	Error Amp Inverting Input	This pin is usually used for feedback from the output of the power supply.
2	Error Amp Noninverting Input	This pin is used to provide a reference in which an error signal can be produced on the output of the error amp. Usually this is connected to V_{ref}, however an external reference can also be used.
3	Error Amp Output	This pin is provided for compensating the error amp for poles and zeros encountered in the power supply system, mostly the output LC filter.
4	Clock	This is a bidirectional pin used for synchronization.
5	R_T	The value of R_T sets the charge current through timing Capacitor, C_T.
6	C_T	In conjunction with R_T, the timing Capacitor sets the switching frequency.
7	Ramp Input	For voltage mode operation this pin is connected to C_T. For current mode operation this pin is connected through a filter to the current sensing element.
8	Soft–Start	A capacitor at this pin sets the Soft–Start time.
9	Current Limit/ Shutdown	This pin has two functions. First, it provides cycle–by–cycle current limiting. Second, if the current is excessive, this pin will reinitiate a Soft–Start cycle.
10	Ground	This pin is the ground for the control circuitry.
11	Current Limit Reference Input	This pin voltage sets the threshold for cycle–by–cycle current limiting.
12	Power Ground	This is a separate power ground return that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry.
13	V_C	This is a separate power source connection for the outputs that is connected back to the power source input. With a separate power source connection, it can reduce the effects of switching transient noise on the control circuitry.
14	Output	This is a high current totem pole output.
15	V_{CC}	This pin is the positive supply of the control IC.
16	V_{ref}	This is a 5.1 V reference. It is usually connected to the noninverting input of the error amplifier.

Figure 21. Voltage Mode Operation



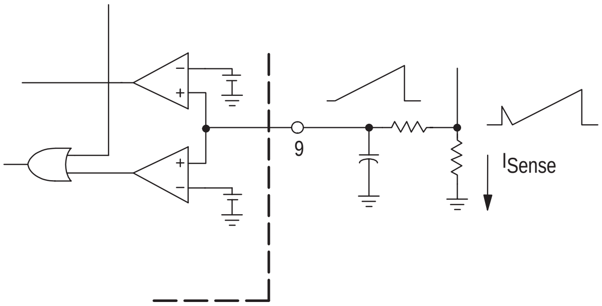
In voltage mode operation, the control range on the output of the Error Amplifier from 0% to 90% duty cycle is from 2.25 V to 4.05 V.

Figure 22. Current Mode Operation



In current mode control, an RC filter should be placed at the ramp input to filter the leading edge spike caused by turn–on of a power MOSFET.

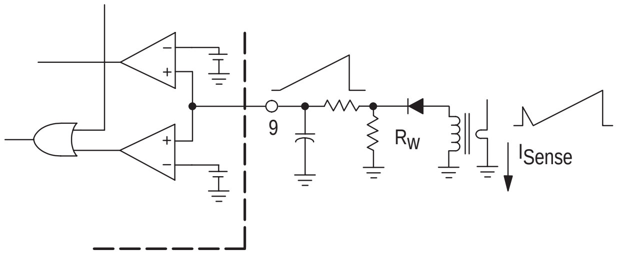
Figure 23. Resistive Current Sensing



The addition of an RC filter will eliminate instability caused by the leading edge spike on the current waveform. This sense signal can also be used at the ramp input pin for current mode control. For ramp compensation it is necessary to know the gain of the current feedback loop. If a transformer is used, the gain can be calculated by:

$$A_i = \frac{R_{Sense}}{\text{turns ratio}}$$

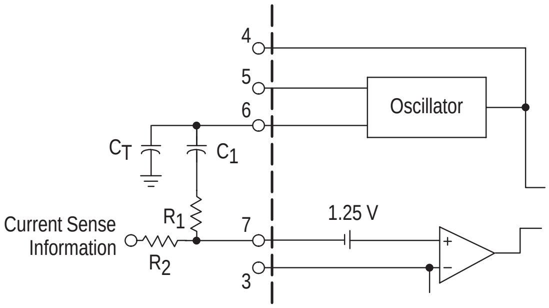
Figure 24. Primary Side Current Sensing



The addition of an RC filter will eliminate instability caused by the leading edge spike on the current waveform. This sense signal can also be used at the ramp input pin for current mode control. For ramp compensation it is necessary to know the gain of the current feedback loop. The gain can be calculated by:

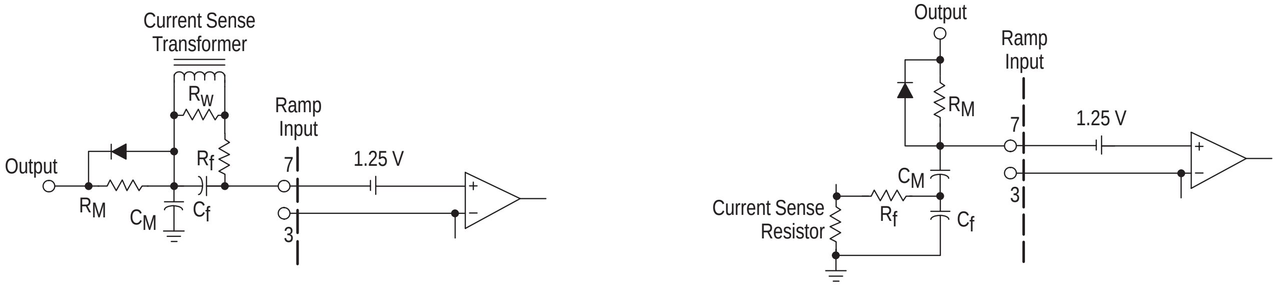
$$A_i = \frac{R_w}{\text{turns ratio}}$$

Figure 25A. Slope Compensation (Noise Sensitive)



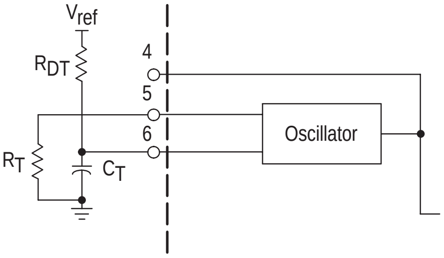
This method of slope compensation is easy to implement, however, it is noise sensitive. Capacitor C_1 provides AC coupling. The oscillator signal is added to the current signal by a voltage divider consisting of resistors R_1 and R_2.

Figure 25B. Slope Compensation (Noise Immune)



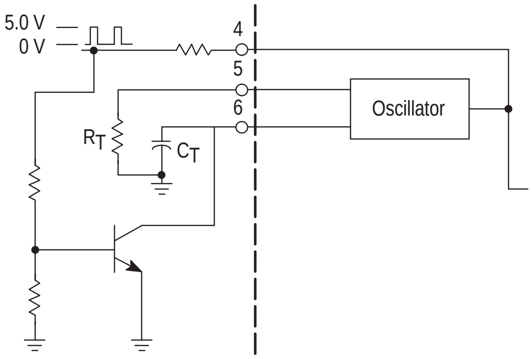
When only one output is used, this method of slope compensation can be used and it is relatively noise immune. Resistor R_M and capacitor C_M provide the added slope necessary. By choosing R_M and C_M with a larger time constant than the switching frequency, you can assume that its charge is linear. First choose C_M, then R_M can be adjusted to achieve the required slope. The diode provides a reset pulse at the ramp input at the end of every cycle. The charge current I_M can be calculated by $I_M = C_M S_e$. Then R_M can be calculated by $R_M = V_{CC}/I_M$.

Figure 26. Dead Time Addition



Additional dead time can be added by the addition of a dead time resistor from V_{ref} to C_T. See text on Oscillator section for more information.

Figure 27. External Clock Synchronization



The sync pulse fed into the clock pin must be at least 3.9 V. R_T and C_T need to be set 10% slower than the sync frequency. This circuit is also used in Voltage Mode operation for master/slave operation. The clock signal would be coming from the master which is set at the desired operating frequency, while the slave is set 10% slower.

Figure 28. Current Mode Master/Slave Operation Over Short Distances

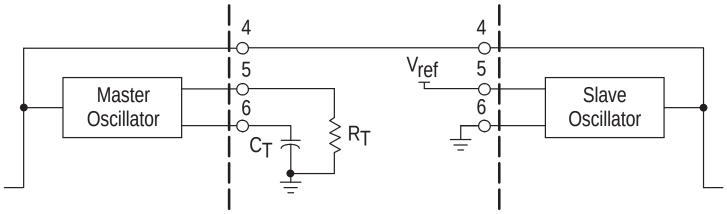


Figure 29. Synchronization Over Long Distances

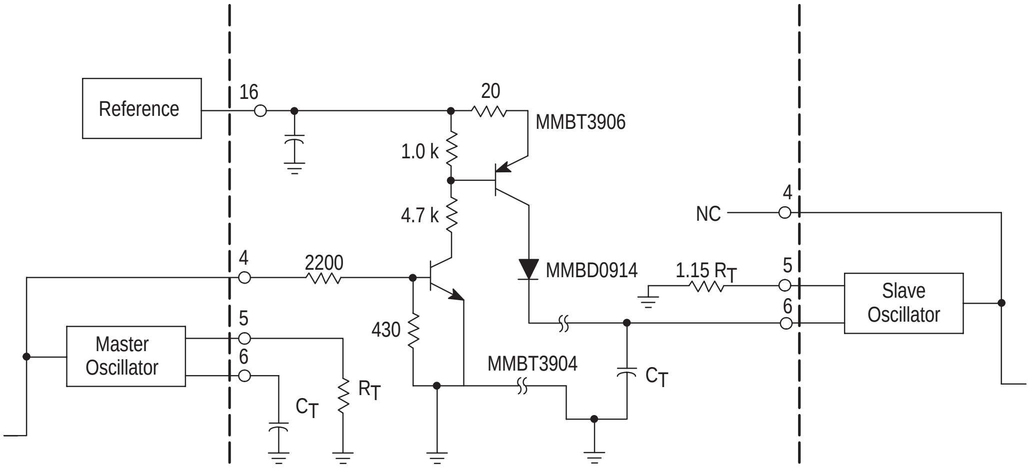

Figure 30. Buffered Maximum Clamp Level

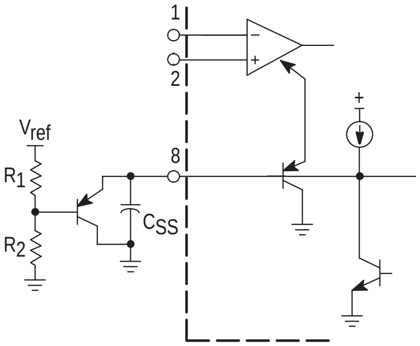
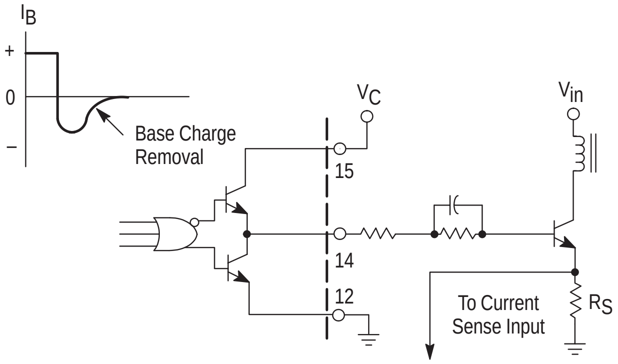


In voltage mode operation, the maximum duty cycle can be clamped. By the addition of a PNP transistor to buffer the clamp voltage, the Soft–Start current is not affected by R_1.

The new equation for Soft–Start is $t \approx \frac{V_{clamp} + 0.6}{9.0\ \mu A}(C_{SS})$

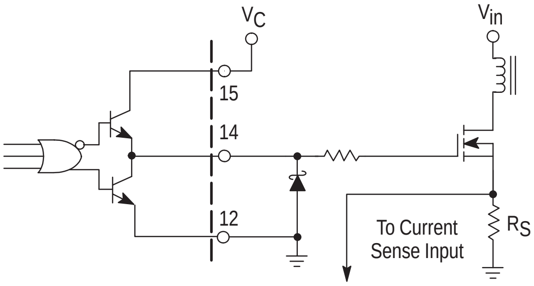
In current mode operation, this circuit will limit the maximum voltage allowed at the ramp input to end a cycle.

Figure 31. Bipolar Transistor Drive



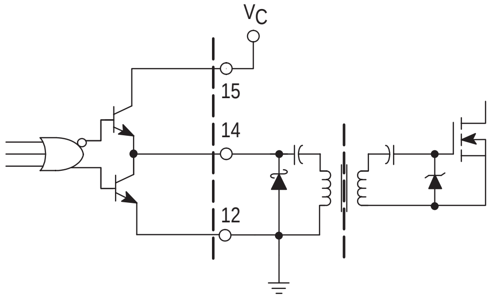
The totem pole output can furnish negative base current for enhanced transistor turn–off, with the addition of the capacitor in series with the base.

Figure 32. MOSFET Parasitic Oscillations



A series gate resistor may be needed to dampen high frequency parasitic oscillation caused by the MOSFET’s input capacitance and any series wiring inductance in the gate–source circuit. The series resistor will also decrease the MOSFET switching speed. A Schottky diode can reduce the driver’s power dissipation due to excessive ringing, by preventing the output pin from being driven below ground. The Schottky diode also prevents substrate injection when the output pin is driven below ground.

Figure 33. Isolated MOSFET Drive



The totem pole output can easily drive pulse transformers. A Schottky diode is recommended when driving inductive loads at high frequencies. The diode can reduce the driver’s power dissipation due to excessive ringing, by preventing the output pin from being driven below ground.

MOTOROLA

MC34025
MC33025

High Speed Double-Ended PWM Controller

The MC34025 series are high speed, fixed frequency, double–ended pulse width modulator controllers optimized for high frequency operation. They are specifically designed for Off–Line and DC–to–DC converter applications offering the designer a cost effective solution with minimal external components. These integrated circuits feature an oscillator, a temperature compensated reference, a wide bandwidth error amplifier, a high speed current sensing comparator, steering flip–flop, and dual high current totem pole outputs ideally suited for driving power MOSFETs.

Also included are protective features consisting of input and reference undervoltage lockouts each with hysteresis, cycle–by–cycle current limiting, and a latch for single pulse metering.

The flexibility of this series allows it to be easily configured for either current mode or voltage mode control.

- 50 ns Propagation Delay to Outputs
- Dual High Current Totem Pole Outputs
- Wide Bandwidth Error Amplifier
- Fully–Latched Logic with Double Pulse Suppression
- Latching PWM for Cycle–By–Cycle Current Limiting
- Soft–Start Control with Latched Overcurrent Reset
- Input Undervoltage Lockout with Hysteresis
- Low Start–Up Current (500 µA Typ)
- Internally Trimmed Reference with Undervoltage Lockout
- 90% Maximum Duty Cycle (Externally Adjustable)
- Precision Trimmed Oscillator
- Voltage or Current Mode Operation to 1.0 MHz
- Functionally Similar to the UC3825

OPERATING DESCRIPTION

The MC33025 and MC34025 series are high speed, fixed frequency, double–ended pulse width modulator controllers optimized for high frequency operation. They are specifically designed for Off–Line and DC–to–DC converter applications offering the designer a cost effective solution with minimal external components. A representative block diagram is shown in Figure 18.

Oscillator

The oscillator frequency is programmed by the values selected for the timing components R_T and C_T. The R_T pin is set to a temperature compensated 3.0 V. By selecting the value of R_T, the charge current is set through a current mirror for the timing capacitor C_T. This charge current runs continuously through C_T. The discharge current is ratioed to be 10 times the charge current, which yields the maximum duty cycle of 90%. C_T is charged to 2.8 V and discharged to 1.0 V. During the discharge of C_T, the oscillator generates an internal blanking pulse that resets the PWM Latch, inhibits the outputs, and toggles the steering flip–flop. The threshold voltages on the oscillator comparator is trimmed to guarantee an oscillator accuracy of 5.0% at 25°C.

Additional dead time can be added by externally increasing the charge current to C_T as shown in Figure 23. This changes the charge to discharge ratio of C_T which is set internally to $I_{charge}/10\ I_{charge}$. The new charge to discharge ratio will be:

$$\%\ \text{Deadtime} = \frac{I_{additional} + I_{charge}}{10\ (I_{charge})}$$

A bidirectional clock pin is provided for synchronization or for master/slave operation. As a master, the clock pin provides a positive output pulse during the discharge of C_T. As a slave, the clock pin is an input that resets the PWM latch and blanks the drive output, but does not discharge C_T. Therefore, the oscillator is not synchronized by driving the clock pin alone. Figures 29 and 30 provide suggested synchronization.

Error Amplifier

A fully compensated Error Amplifier is provided. It features a typical DC voltage gain of 95 dB and a gain bandwidth product of 8.3 MHz with 75 degrees of phase margin (Figure 3). Typical application circuits will have the noninverting input tied to the reference. The inverting input will typically be connected to a feedback voltage generated from the output of the switching power supply. Both inputs have a Common Mode Voltage (V_{CM}) input range of 1.5 V to 5.5 V. The Error Amplifier Output is provided for external loop compensation.

Soft–Start Latch

Soft–Start is accomplished in conjunction with an external capacitor. The soft start capacitor is charged by an internal 9.0 µA current source. This capacitor clamps the output of the error amplifier to less than its normal output voltage, thus limiting the duty cycle.

The time it takes for a capacitor to reach full charge is given by:

$$t \approx (4.5 \bullet 10^5)\ C_{Soft\text{-}Start}$$

A Soft–Start latch is incorporated to prevent erratic operation of this circuitry. Two conditions can cause the Soft–Start circuit to latch so that the Soft–Start capacitor stays discharged. The first condition is activation of an undervoltage lockout of either V_{CC} or V_{ref}. The second condition is when current sense input exceeds 1.4 V. Since this latch is "set dominant", it cannot be reset until either of these signals is removed, and the voltage at $C_{Soft–Start}$ is less than 0.5 V.

PWM Comparator and Latch

A PWM circuit typically compares an error voltage with a ramp signal. The outcome of this comparison determines the state of the output. In voltage mode operation the ramp signal is the voltage ramp of the timing capacitor. In current mode operation the ramp signal is the voltage ramp induced in a current sensing element. The ramp input of the PWM comparator is pinned out so that the user can decide which mode of operation best suits the application requirements. The ramp input has a 1.25 V offset such that whenever the voltage at this pin exceeds the Error Amplifier Output voltage minus 1.25 V, the PWM comparator will cause the PWM latch to set, disabling the outputs. Once the PWM latch is set, only a blanking pulse by the oscillator can reset it, thus initiating the next cycle.

A toggle flip flop connected to the output of the PWM latch controls which output is active. The flip flop is pulsed by an OR gate that gets its inputs from the oscillator clock and the output of the PWM latch. A pulse from either one will cause the flip flop to enable the other output.

Current Limiting and Shutdown

A pin is provided to perform current limiting and shutdown operations. Two comparators are connected to the input of this pin. When the voltage at this pin exceeds 1.0 V, one of the comparators is activated. The output of this comparator sets the PWM latch, which disables the output. In this way cycle–by–cycle current limiting is accomplished. If a current limit resistor is used in series with the power devices, the value of the resistor is found by:

$$R_{Sense} = \frac{1.0\ V}{I_{pk\ (switch)}}$$

If the voltage at this pin exceeds 1.4 V, the second comparator is activated. This comparator sets a latch which, in turn, causes the Soft–Start capacitor to be discharged. In this way a "hiccup" mode of recovery is possible in the case of output short circuits. If a current limit resistor is used in series with the output devices, the peak current at which the controller will enter a "hiccup" mode is given by:

$$I_{shutdown} = \frac{1.4\ V}{R_{Sense}}$$

Undervoltage Lockout

There are two undervoltage lockout circuits within the IC. The first senses V_{CC} and the second V_{ref}. During power–up, V_{CC} must exceed 9.2 V and V_{ref} must exceed 4.2 V before the outputs can be enabled and the Soft–Start latch released. If V_{CC} falls below 8.4 V or V_{ref} falls below 3.6 V, the outputs are disabled and the Soft–Start latch is activated. When the UVLO is active, the part is in a low current standby mode allowing the IC to have an off–line bootstrap start–up circuit. Typical start–up current is 500 μA.

Output

The MC34025 has two high current totem pole outputs specifically designed for direct drive of power MOSFETs. They are capable of up to ±2.0 A peak drive current with a typical rise and fall time of 30 ns driving a 1.0 nF load.

Separate pins for V_C and Power Ground are provided. With proper implementation, a significant reduction of switching transient noise imposed on the control circuitry is possible. The separate V_C supply input also allows the designer added flexibility in tailoring the drive voltage independent of V_{CC}.

Reference

A 5.1 V bandgap reference is pinned out and is trimmed to an initial accuracy of ±1.0% at 25°C. This reference has short circuit protection and can source in excess of 10 mA for powering additional control system circuitry.

Design Considerations

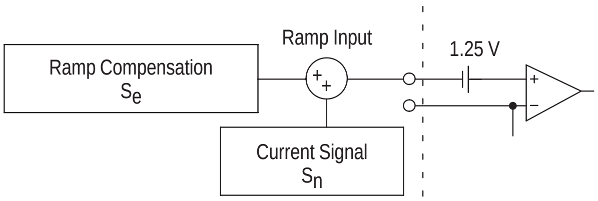
Do not attempt to construct the converter on wire–wrap or plug–in prototype boards. With high frequency, high power, switching power supplies it is imperative to have separate current loops for the signal paths and for the power paths. The printed circuit layout should contain a ground plane with low current signal and high current switch and output grounds returning on separate paths back to the input filter capacitor. All bypass capacitors and snubbers should be connected as close as possible to the specific part in question. The PC board lead lengths must be less than 0.5 inches for effective bypassing or snubbing.

Instabilities

In current mode control, an instability can be encountered at any given duty cycle. The instability is caused by the current feedback loop. It has been shown that the instability is caused by a double pole at half the switching frequency. If an external ramp (S_e) is added to the on–time ramp (S_n) of the current–sense waveform, stability can be achieved (see Figure 20).

One must be careful not to add too much ramp compensation. If too much is added, the system will start to perform like a voltage mode regulator. All benefits of current mode control will be lost. Figures 28A and 28B show examples of two different ways in which external ramp compensation can be implemented.

Figure 20. Ramp Compensation



A simple equation can be used to calculate the amount of external ramp necessary to add that will achieve stability in the current loop. For the following equations, the calculated values for the application circuit in Figure 36 are also shown.

$$S_e = \frac{V_O}{L}\left(\frac{N_S}{N_P}\right)(R_S)A_i$$

where: V_O = DC output voltage
N_P, N_S = number of power transformer primary or secondary turns
A_i = gain of the current sense network (see Figures 25, 26 and 27)
L = output inductor
R_S = current sense resistance

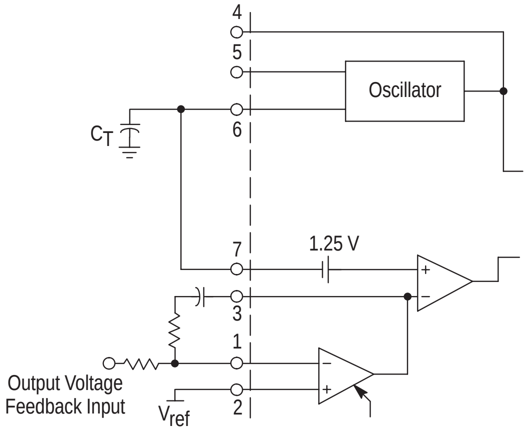
For the application circuit: $S_e = \frac{5}{1.8\ \mu}\left(\frac{4}{16}\right)(0.3)(0.55)$

$= 0.115\ V/\mu s$

PIN FUNCTION DESCRIPTION

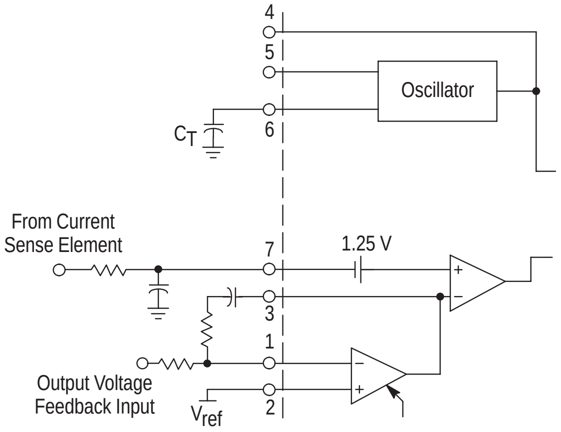
Pin No.		
DIP/SOIC	Function	Description
1	Error Amp Inverting Input	This pin is usually used for feedback from the output of the power supply.
2	Error Amp Noninverting Input	This pin is used to provide a reference in which an error signal can be produced on the output of the error amp. Usually this is connected to V_{ref}, however an external reference can also be used.
3	Error Amp Output	This pin is provided for compensating the error amp for poles and zeros encountered in the power supply system, mostly the output LC filter.
4	Clock	This is a bidirectional pin used for synchronization.
5	R_T	The value of R_T sets the charge current through timing Capacitor, C_T.
6	C_T	In conjunction with R_T, the timing Capacitor sets the switching frequency. Because this part is a push–pull output, each output runs at one–half the frequency set at this pin.
7	Ramp Input	For voltage mode operation this pin is connected to C_T. For current mode operation this pin is connected through a filter to the current sensing element.
8	Soft–Start	A capacitor at this pin sets the Soft–Start time.
9	Current Limit/Shutdown	This pin has two functions. First, it provides cycle–by–cycle current limiting. Second, if the current is excessive, this pin will reinitiate a Soft–Start cycle.
10	Ground	This pin is the ground for the control circuitry.
11	Output A	This is a high current totem pole output.
12	Power Ground	This is a separate power ground return that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry.
13	V_C	This is a separate power source connection for the outputs that is connected back to the power source input. With a separate power source connection, it can reduce the effects of switching transient noise on the control circuitry.
14	Output B	This is a high current totem pole output.
15	V_{CC}	This pin is the positive supply of the control IC.
16	V_{ref}	This is a 5.1 V reference. It is usually connected to the noninverting input of the error amplifier.

Figure 21. Voltage Mode Operation



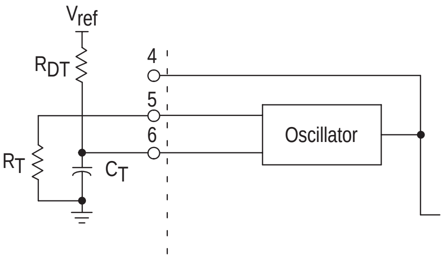
In voltage mode operation, the control range on the output of the Error Amplifier from 0% to 90% duty cycle is from 2.25 V to 4.05 V.

Figure 22. Current Mode Operation



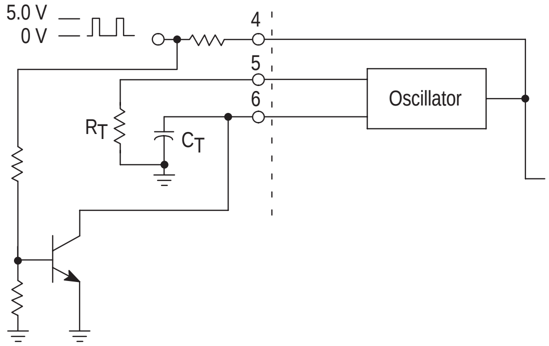
In current mode control, an RC filter should be placed at the ramp input to filter the leading edge spike caused by turn–on of a power MOSFET.

Figure 23. Dead Time Addition



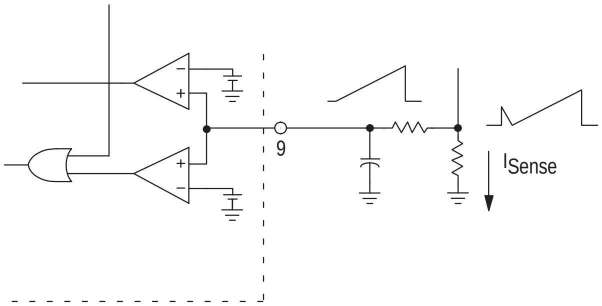
Additional dead time can be added by the addition of a dead time resistor from V_{ref} to C_T. See text on oscillator section for more information.

Figure 24. External Clock Synchronization



The sync pulse fed into the clock pin must be at least 3.9 V. R_T and C_T need to be set 10% slower than the sync frequency. This circuit is also used in voltage mode operation for master/slave operation. The clock signal would be coming from the master which is set at the desired operating frequency, while the slave is set 10% slower.

Figure 25. Resistive Current Sensing



The addition of an RC filter will eliminate instability caused by the leading edge spike on the current waveform. This sense signal can also be used at the ramp input pin for current mode control. For ramp compensation it is necessary to know the gain of the current feedback loop. If a transformer is used, the gain can be calculated by:

$$A_i = \frac{R_{Sense}}{\text{turns ratio}}$$

Figure 26. Primary Side Current Sensing

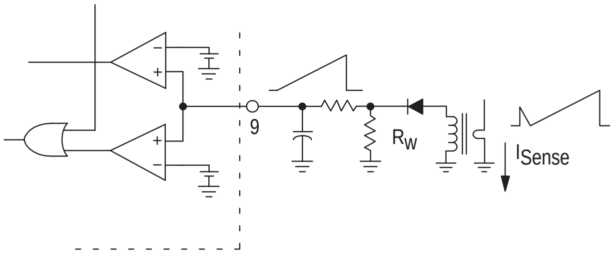


Figure 27. Primary or Secondary Side Current Sensing

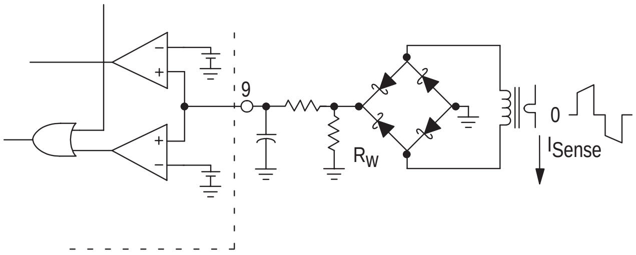
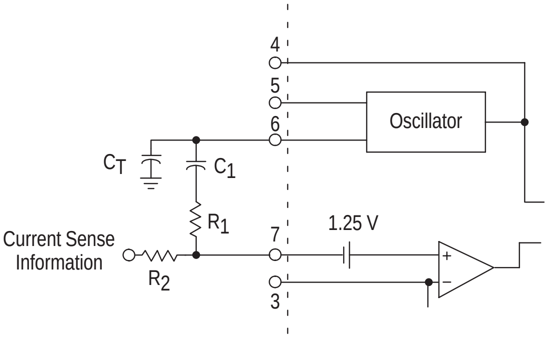


The addition of an RC filter will eliminate instability caused by the leading edge spike on the current waveform. This sense signal can also be used at the ramp input pin for current mode control. For ramp compensation it is necessary to know the gain of the current feedback loop. The gain can be calculated by:

$$A_i = \frac{R_w}{\text{turns ratio}}$$

Figure 28A. Slope Compensation (Noise Sensitive)



This method of slope compensation is easy to implement, however, it is noise sensitive. Capacitor C_1 provides AC coupling. The oscillator signal is added to the current signal by a voltage divider consisting of resistors R_1 and R_2.

Figure 28B. Slope Compensation (Noise Immune)

When only one output is used, this method of slope compensation can be used and it is relatively noise immune. Resistor R_M and capacitor C_M provide the added slope necessary. By choosing R_M and C_M with a larger time constant than the switching frequency, you can assume that its charge is linear. First choose C_M, then R_M can be adjusted to achieve the required slope. The diode provides a reset pulse at the ramp input at the end of every cycle. The charge current I_M can be calculated by $I_M = C_M S_e$. Then R_M can be calculated by $R_M = V_{CC}/I_M$.

Figure 29. Current Mode Master/Slave Operation Over Short Distances

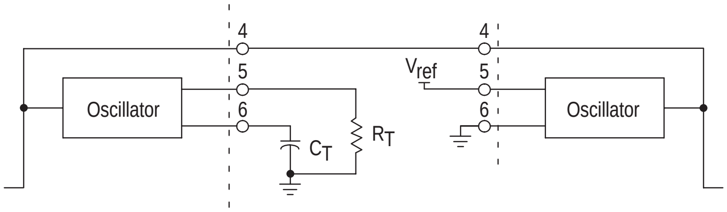


Figure 30. Synchronization Over Long Distances

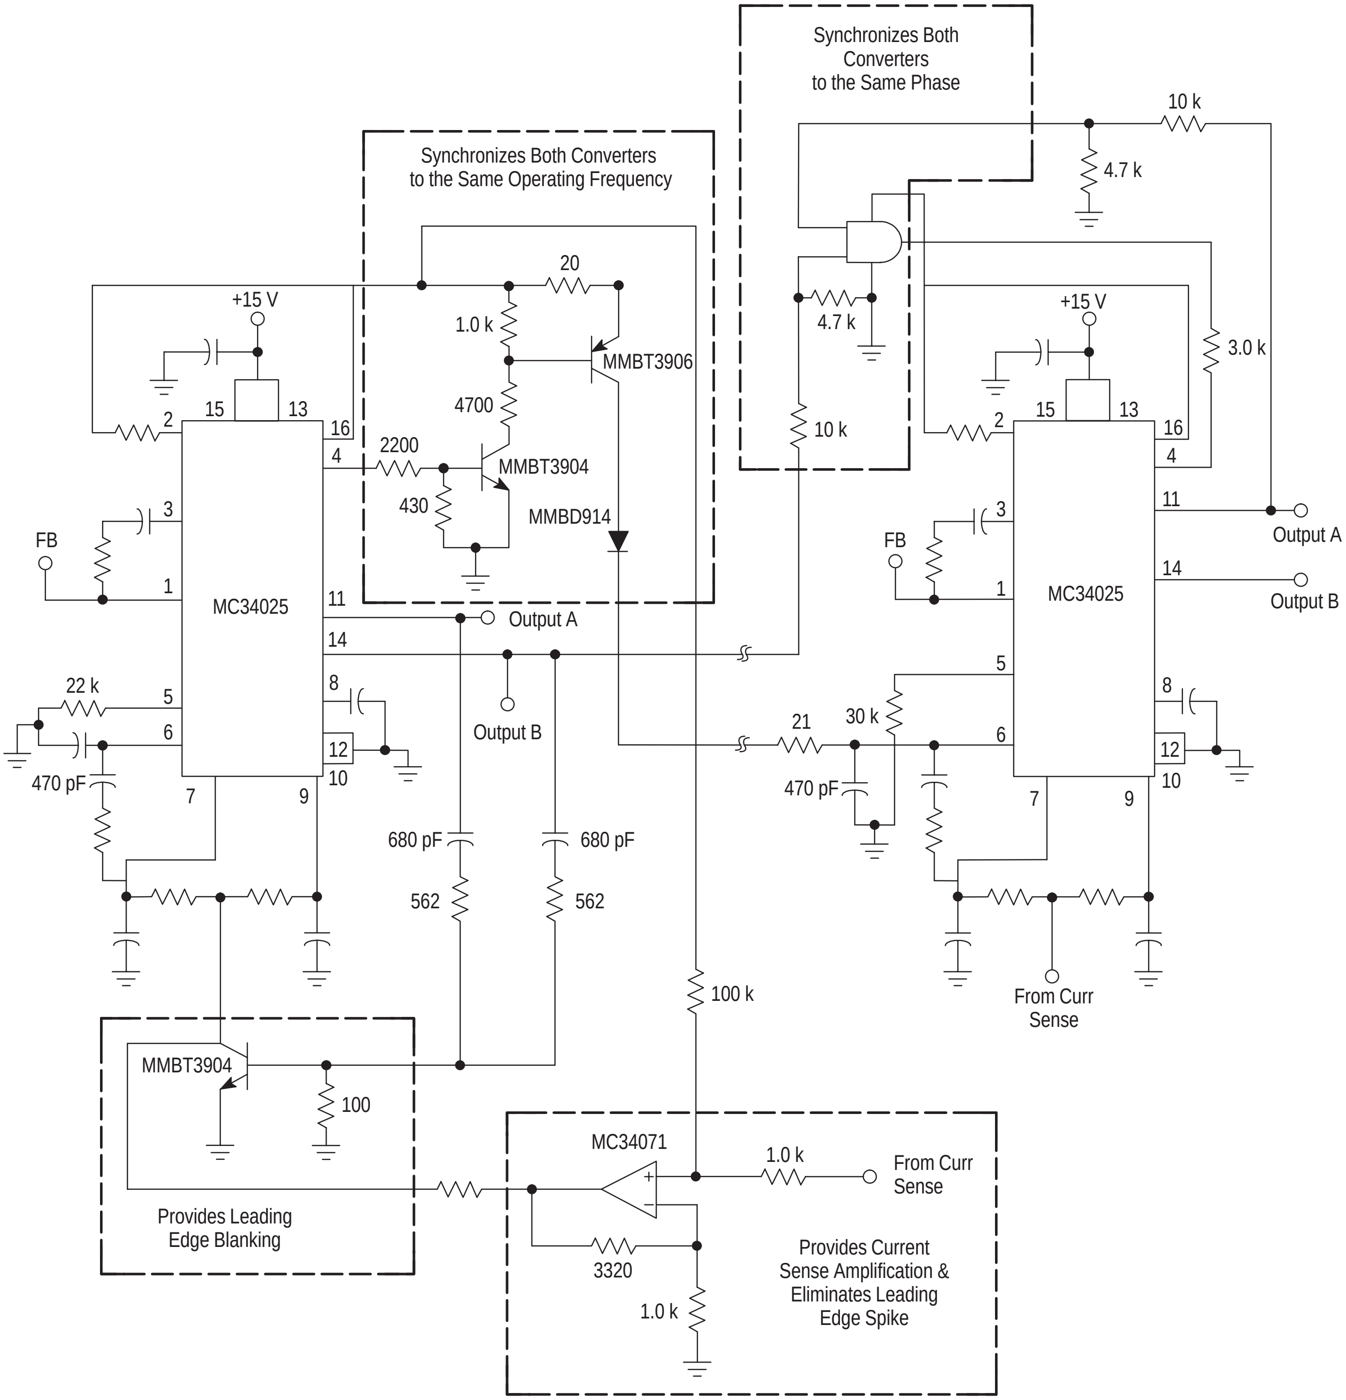

Figure 31. Buffered Maximum Clamp Level

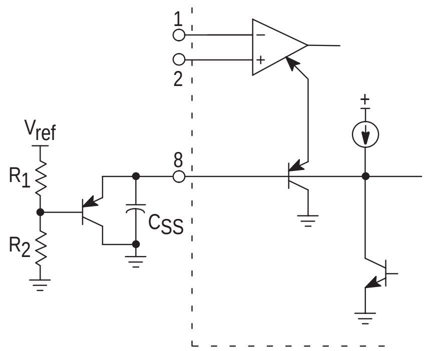
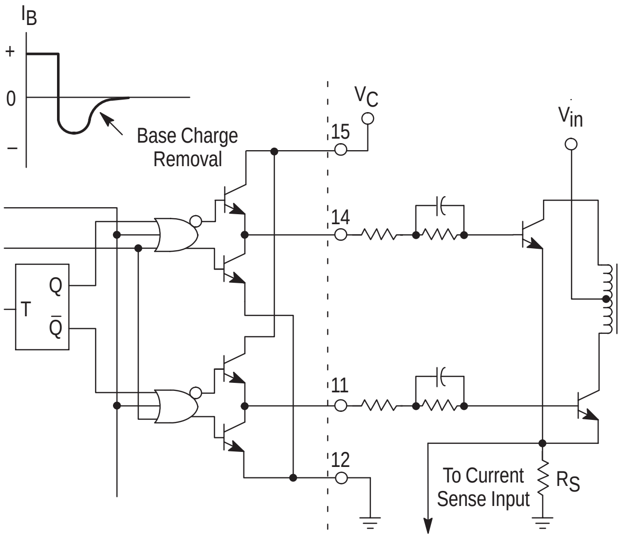


In voltage mode operation, the maximum duty cycle can be clamped. By the addition of a PNP transistor to buffer the clamp voltage, the Soft–Start current is not affected by R_1.

The new equation for Soft–Start is $t \approx \frac{V_{clamp} + 0.6}{9.0\ \mu A} \left(C_{SS}\right)$

In current mode operation, this circuit will limit the maximum voltage allowed at the ramp input to end a cycle.

Figure 32. Bipolar Transistor Drive



The totem pole output can furnish negative base current for enhanced transistor turn–off, with the addition of the capacitor in series with the base.

Figure 33. Isolated MOSFET Drive

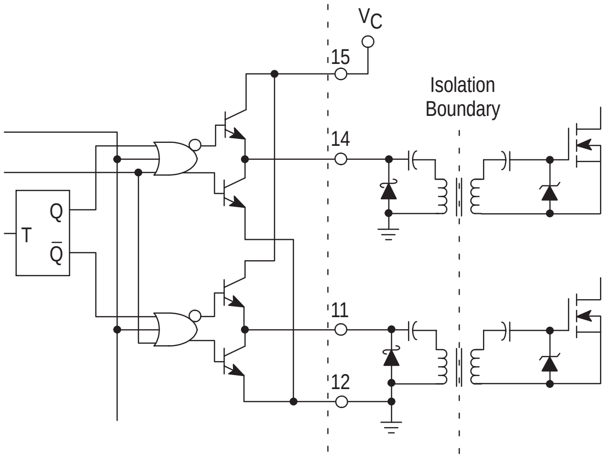


Figure 34. Direct Transformer Drive

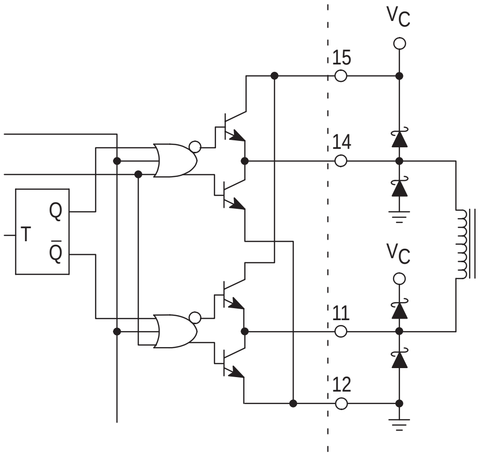
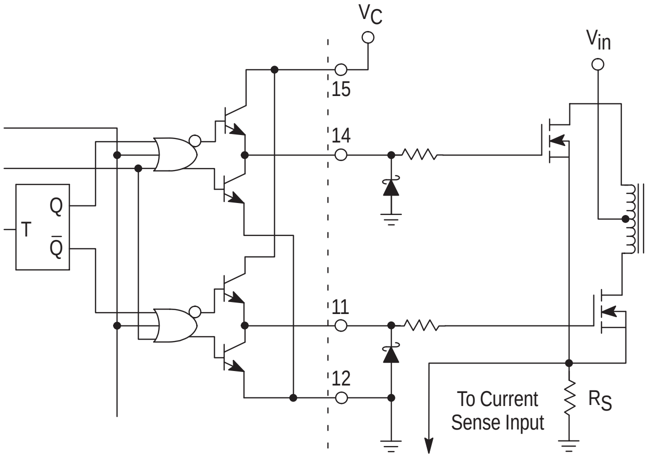


The totem pole output can easily drive pulse transformers. A Schottky diode is recommended when driving inductive loads at high frequencies. The diode can reduce the driver’s power dissipation due to excessive ringing, by preventing the output pin from being driven below ground.

Figure 35. MOSFET Parasitic Oscillations



A series gate resistor may be needed to damp high frequency parasitic oscillation caused by a MOSFET’s input capacitance and any series wiring inductance in the gate–source circuit. The series resistor will also decrease the MOSFET’s switching speed. A Schottky diode can reduce the driver’s power dissipation due to excessive ringing, by preventing the output pin from being driven below ground. The Schottky diode also prevents substrate injection when the output pin is driven below ground.

This device contains 46 active transistors.

Description

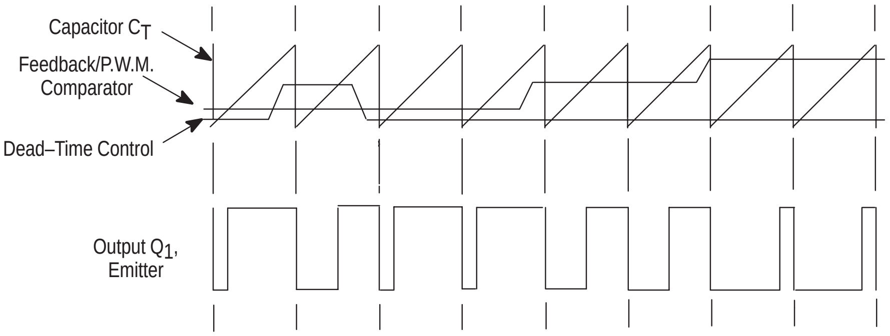
The MC34060A is a fixed–frequency pulse width modulation control circuit, incorporating the primary building blocks required for the control of a switching power supply (see Figure 1). An internal–linear sawtooth oscillator is frequency–programmable by two external components, R_T and C_T. The approximate oscillator frequency is determined by:

$$f_{osc} \cong \frac{1.2}{R_T \bullet C_T}$$

For more information refer to Figure 3.

Output pulse width modulation is accomplished by comparison of the positive sawtooth waveform across capacitor C_T to either of two control signals. The output is enabled only during that portion of time when the sawtooth voltage is greater than the control signals. Therefore, an increase in control–signal amplitude causes a corresponding linear decrease of output pulse width. (Refer to the Timing Diagram shown in Figure 2.)

Figure 2. Timing Diagram



APPLICATIONS INFORMATION

The control signals are external inputs that can be fed into the dead–time control, the error amplifier inputs, or the feed–back input. The dead–time control comparator has an effective 120 mV input offset which limits the minimum output dead time to approximately the first 4% of the sawtooth–cycle time. This would result in a maximum duty cycle of 96%. Additional dead time may be imposed on the output by setting the dead time–control input to a fixed voltage, ranging between 0 V to 3.3 V.

The pulse width modulator comparator provides a means for the error amplifiers to adjust the output pulse width from the maximum percent on–time, established by the dead time control input, down to zero, as the voltage at the feedback pin varies from 0.5 V to 3.5 V. Both error amplifiers have a common mode input range from –0.3 V to (V_{CC} –2.0 V), and may be used to sense power supply output voltage and current. The error–amplifier outputs are active high and are ORed together at the noninverting input of the pulse–width modulator comparator. With this configuration, the amplifier that demands minimum output on time, dominates control of the loop.

The MC34060A has an internal 5.0 V reference capable of sourcing up to 10 mA of load currents for external bias circuits. The reference has an internal accuracy of ±5% with a typical thermal drift of less than 50 mV over an operating temperature range of 0° to +70°C.

DC-to-DC Converter Control Circuits

DC–to–DC CONVERTER CONTROL CIRCUITS

SEMICONDUCTOR TECHNICAL DATA

The MC34063A Series is a monolithic control circuit containing the primary functions required for DC–to–DC converters. These devices consist of an internal temperature compensated reference, comparator, controlled duty cycle oscillator with an active current limit circuit, driver and high current output switch. This series was specifically designed to be incorporated in Step–Down and Step–Up and Voltage–Inverting applications with a minimum number of external components. Refer to Application Notes AN920A/D and AN954/D for additional design information.

- Operation from 3.0 V to 40 V Input
- Low Standby Current
- Current Limiting
- Output Switch Current to 1.5 A
- Output Voltage Adjustable
- Frequency Operation to 100 kHz
- Precision 2% Reference

Collector Off–State Current (V_{CE} = 40 V)	$I_{C(off)}$	–	0.01	100	µA

NOTES: 3. T_{low} = 0°C for MC34063A, –40°C for MC33063A, AV T_{high} = +70°C for MC34063A, +85°C for MC33063A, +125°C for MC33063AV
4. Low duty cycle pulse techniques are used during test to maintain junction temperature as close to ambient temperature as possible.
5. If the output switch is driven into hard saturation (non–Darlington configuration) at low switch currents (≤ 300 mA) and high driver currents (≥ 30 mA), it may take up to 2.0 µs for it to come out of saturation. This condition will shorten the off time at frequencies ≥ 30 kHz, and is magnified at high temperatures. This condition does not occur with a Darlington configuration, since the output switch cannot saturate. If a non–Darlington configuration is used, the following output drive condition is recommended:

$$\text{Forced } \beta \text{ of output switch} : \frac{I_C \text{ output}}{I_C \text{ driver} - 7.0 \text{ mA}^*} \geq 10$$

*The 100 Ω resistor in the emitter of the driver device requires about 7.0 mA before the output switch conducts.

$L_{(min)}$	$\left(\frac{(V_{in(min)} - V_{sat})}{I_{pk(switch)}}\right) t_{on(max)}$	$\left(\frac{(V_{in(min)} - V_{sat} - V_{out})}{I_{pk(switch)}}\right) t_{on(max)}$	$\left(\frac{(V_{in(min)} - V_{sat})}{I_{pk(switch)}}\right) t_{on(max)}$
C_O	$9\ \frac{I_{out}t_{on}}{V_{ripple(pp)}}$	$\frac{I_{pk(switch)}(t_{on} + t_{off})}{8V_{ripple(pp)}}$	$9\ \frac{I_{out}t_{on}}{V_{ripple(pp)}}$

V_{sat} = Saturation voltage of the output switch.
V_F = Forward voltage drop of the output rectifier.

The following power supply characteristics must be chosen:

V_{in} – Nominal input voltage.
V_{out} – Desired output voltage, $|V_{out}| = 1.25\left(1 + \frac{R2}{R1}\right)$
I_{out} – Desired output current.
f_{min} – Minimum desired output switching frequency at the selected values of V_{in} and I_O.
$V_{ripple(pp)}$ – Desired peak–to–peak output ripple voltage. In practice, the calculated capacitor value will need to be increased due to its equivalent series resistance and board layout. The ripple voltage should be kept to a low value since it will directly affect the line and load regulation.

NOTE: For further information refer to Application Note AN920A/D and AN954/D.

MOTOROLA

MC34064
MC33064

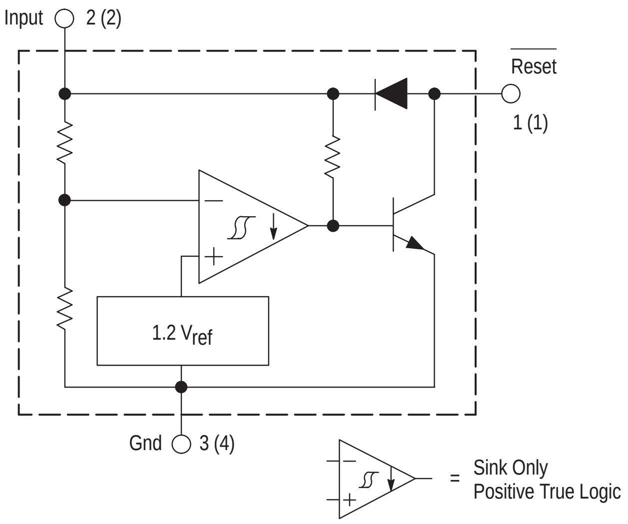
Undervoltage Sensing Circuit

The MC34064 is an undervoltage sensing circuit specifically designed for use as a reset controller in microprocessor-based systems. It offers the designer an economical solution for low voltage detection with a single external resistor. The MC34064 features a trimmed-in-package bandgap reference, and a comparator with precise thresholds and built-in hysteresis to prevent erratic reset operation. The open collector reset output is capable of sinking in excess of 10 mA, and operation is guaranteed down to 1.0 V input with low standby current. These devices are packaged in 3-pin TO-226AA, 8-pin SO–8 and Micro–8 surface mount packages.

Applications include direct monitoring of the 5.0 V MPU/logic power supply used in appliance, automotive, consumer and industrial equipment.

- Trimmed-In-Package Temperature Compensated Reference
- Comparator Threshold of 4.6 V at 25°C
- Precise Comparator Thresholds Guaranteed Over Temperature
- Comparator Hysteresis Prevents Erratic Reset
- Reset Output Capable of Sinking in Excess of 10 mA
- Internal Clamp Diode for Discharging Delay Capacitor
- Guaranteed Reset Operation with 1.0 V Input
- Low Standby Current
- Economical TO–226AA, SO–8 and Micro–8 Surface Mount Packages

Representative Block Diagram



Pin numbers adjacent to terminals are for the 3–pin TO–226AA package.
Pin numbers in parenthesis are for the 8–lead packages.

This device contains 21 active transistors.

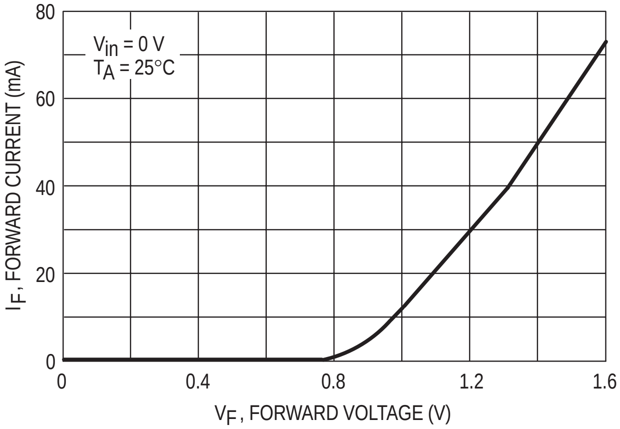

Figure 8. Low Voltage Microprocessor Reset

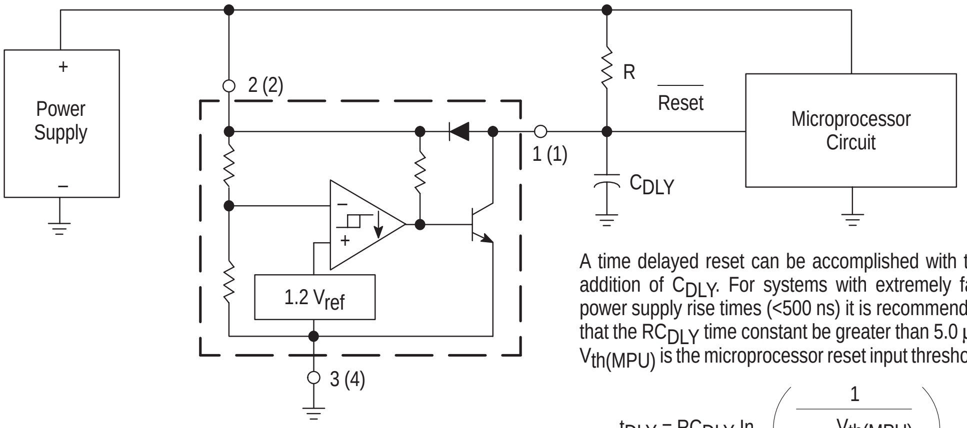
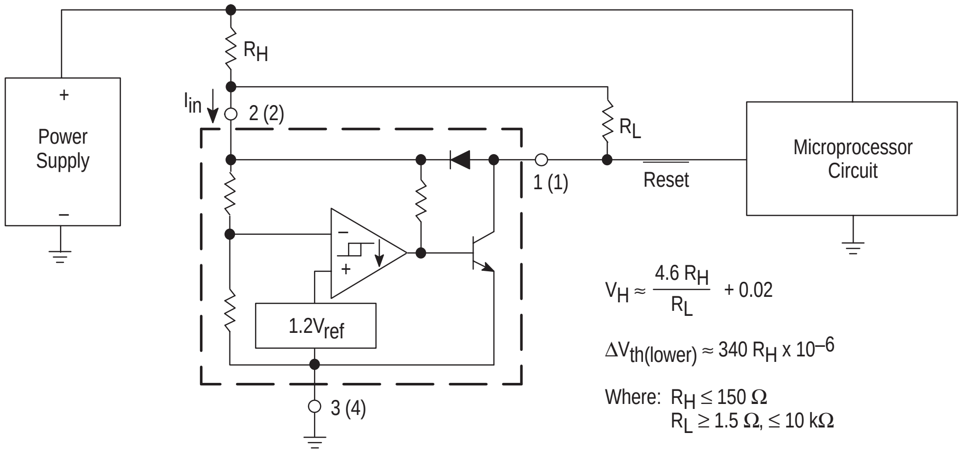


A time delayed reset can be accomplished with the addition of C_{DLY}. For systems with extremely fast power supply rise times (<500 ns) it is recommended that the RC_{DLY} time constant be greater than 5.0 µs. $V_{th(MPU)}$ is the microprocessor reset input threshold.

$$t_{DLY} = RC_{DLY} \ln \left(\frac{1}{1 - \frac{V_{th(MPU)}}{V_{in}}} \right)$$

Figure 9. Low Voltage Microprocessor Reset with Additional Hysteresis



$$V_H \approx \frac{4.6\,R_H}{R_L} + 0.02$$

$$\Delta V_{th(lower)} \approx 340\,R_H \times 10^{-6}$$

Where: $R_H \leq 150\ \Omega$
$R_L \geq 1.5\ \Omega, \leq 10\ k\Omega$

Test Data			
V_H (mV)	ΔV_{th} (mV)	R_H (Ω)	R_L (kΩ)
20	0	0	0
51	3.4	10	1.5
40	6.8	20	4.7
81	6.8	20	1.5
71	10	30	2.7
112	10	30	1.5
100	16	47	2.7
164	16	47	1.5
190	34	100	2.7
327	34	100	1.5
276	51	150	2.7
480	51	150	1.5

Comparator hysteresis can be increased with the addition of resistor R_H. The hysteresis equation has been simplified and does not account for the change of input current I_{in} as V_{CC} crosses the comparator threshold (Figure 4). An increase of the lower threshold $\Delta V_{th(lower)}$ will be observed due to I_{in} which is typically 340 µA at 4.59 V. The equations are accurate to ±10% with R_H less than 150 Ω and R_L between 1.5 kΩ and 10 kΩ.

MC34065
MC33065

High Performance Dual Channel Current Mode Controller

The MC34065 is a high performance, fixed frequency, dual current mode controllers. It is specifically designed for off–line and dc–to–dc converter applications offering the designer a cost effective solution with minimal external components. This integrated circuit feature a unique oscillator for precise duty cycle limit and frequency control, a temperature compensated reference, two high gain error amplifiers, two current sensing comparators, Drive Output 2 Enable pin, and two high current totem pole outputs ideally suited for driving power MOSFETs.

Also included are protective features consisting of input and reference undervoltage lockouts each with hysteresis, cycle–by–cycle current limiting, and a latch for single pulse metering of each output.

The MC34065 and MC33065 are available in dual–in–line and surface mount packages.

- Unique Oscillator for Precise Duty Cycle Limit and Frequency Control
- Current Mode Operation to 500 kHz
- Automatic Feed Forward Compensation
- Separate Latching PWMs for Cycle–By–Cycle Current Limiting
- Internally Trimmed Reference with Undervoltage Lockout
- Drive Output 2 Enable Pin
- Two High Current Totem Pole Outputs
- Input Undervoltage Lockout with Hysteresis
- Low Startup and Operating Current

PIN FUNCTION DESCRIPTION

Pin	Function	Description
1	Sync Input	A narrow rectangular waveform applied to this input will synchronize the oscillator. A dc voltage within the range of 2.4 V to 5.5 V will inhibit the oscillator.
2	C_T	Timing capacitor C_T connects from this pin to ground setting the free–running oscillator frequency range.
3	R_T	Resistor R_T connects from this pin to ground precisely setting the charge current for C_T. R_T must be between 4.0 k and 16 k.
4	Voltage Feedback 1	This pin is the inverting input of Error Amplifier 1. It is normally connected to the switching power supply output through a resistor divider.
5	Compensation 1	This pin is the output of Error Amplifier 1 and is made available for loop compensation.
6	Current Sense 1	A voltage proportional to the inductor current is connected to this input. PWM 1 uses this information to terminate conduction of output switch Q1.
7	Drive Output 1	This pin directly drives the gate of a power MOSFET Q1. Peak currents up to 1.0 A are sourced and sunk by this pin.
8	Gnd	This pin is the control circuitry ground return and is connected back to the source ground.
9	Drive Gnd	This pin is a separate power ground return that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry.
10	Drive Output 2	This pin directly drives the gate of a power MOSFET Q2. Peak currents up to 1.0 A are sourced and sunk by this pin.
11	Current Sense 2	A voltage proportional to inductor current is connected to this input. PWM 2 uses this information to terminate conduction of output switch Q2.
12	Compensation 2	This pin is the output of Error Amplifier 2 and is made available for loop compensation.
13	Voltage Feedback 2	This pin is the inverting input of Error Amplifier 2. It is normally connected to the switching power supply output through a resistor divider.
14	Drive Output 2 Enable	A logic low at this input disables Drive Output 2.
15	V_{ref}	This is the 5.0 V reference output. It can provide bias for any additional system circuitry.
16	V_{CC}	This pin is the positive supply of the control IC. The minimum operating voltage range after startup is 11 V to 15.5 V.

OPERATING DESCRIPTION

The MC34065 series are high performance, fixed frequency, dual channel current mode controllers specifically designed for Off–Line and dc–to–dc converter applications. These devices offer the designer a cost effective solution with minimal external components where independent regulation of two power converters is required. The Representative Block Diagram is shown in Figure 15. Each channel contains a high gain error amplifier, current sensing comparator, pulse width modulator latch, and totem pole output driver. The oscillator, reference regulator, and undervoltage lock–out circuits are common to both channels.

Oscillator

The unique oscillator configuration employed features precise frequency and duty cycle control. The frequency is programmed by the values selected for the timing components R_T and C_T. Capacitor C_T is charged and discharged by an equal magnitude internal current source and sink, generating a symmetrical 50 percent duty cycle waveform at Pin 2. The oscillator peak and valley thresholds are 3.5 V and 1.6 V respectively. The source/sink current magnitude is controlled by resistor R_T. For proper operation over temperature it must be in the range of 4.0 kΩ to 16 kΩ as shown in Figure 1.

As C_T charges and discharges, an internal blanking pulse is generated that alternately drives the center inputs of the upper and lower NOR gates high. This, in conjunction with a precise amount of delay time introduced into each channel, produces well defined non–overlapping output duty cycles. Output 2 is enabled while C_T is charging, and Output 1 is enabled during the discharge. Figure 2 shows the Maximum Output Duty Cycle versus Oscillator Frequency. Note that even at 500 kHz, each output is capable of approximately 44% on–time, making this controller suitable for high frequency power conversion applications.

In many noise sensitive applications it may be desirable to frequency–lock the converter to an external system clock. This can be accomplished by applying a clock signal as shown in Figure 17. For reliable locking, the free–running oscillator frequency should be set about 10% less than the clock frequency. Referring to the timing diagram shown in Figure 16, the rising edge of the clock signal applied to the Sync input, terminates charging of C_T and Drive Output 2 conduction. By tailoring the clock waveform symmetry, accurate duty cycle clamping of either output can be achieved. A circuit method for this, and multi–unit synchronization, is shown in Figure 18.

Error Amplifier

Each channel contains a fully–compensated Error Amplifier with access to the inverting input and output. The amplifier features a typical dc voltage gain of 100 dB, and a unity gain bandwidth of 1.0 MHz with 71° of phase margin (Figure 5). The noninverting input is internally biased at 2.5 V and is not pinned out. The converter output voltage is typically divided down and monitored by the inverting input through a resistor divider. The maximum input bias current is –1.0 µA which will cause an output voltage error that is equal to the product of the input bias current and the equivalent input divider source resistance.

The Error Amp output (Pin 5, 12) is provided for external loop compensation. The output voltage is offset by two diode drops (≈1.4 V) and divided by three before it connects to the inverting input of the Current Sense Comparator. This guarantees that no pulses appear at the Drive Output (Pin 7, 10) when the error amplifier output is at its lowest state (V_{OL}). This occurs when the power supply is operating and the load is removed, or at the beginning of a soft–start interval (Figures 20, 21).

The minimum allowable Error Amp feedback resistance is limited by the amplifier's source current (0.5 mA) and the output voltage (V_{OH}) required to reach the comparator's 0.5 V clamp level with the inverting input at ground. This condition happens during initial system startup or when the sensed output is shorted:

$$R_{f(min)} \approx \frac{3.0\ (0.5\ V)\ +\ 1.4\ V}{0.5\ mA} = 5800\ \Omega$$

Current Sense Comparator and PWM Latch

The MC34065 operates as a current mode controller, whereby output switch conduction is initiated by the oscillator and terminated when the peak inductor current reaches the threshold level established by the Error Amplifier output. Thus the error signal controls the peak inductor current on a cycle–by–cycle basis. The Current Sense Comparator–PWM Latch configuration used ensures that only a single pulse appears at the Drive Output during any given oscillator cycle. The inductor current is converted to a voltage by inserting a ground–referenced sense resistor R_S in series with the source of output switch Q1. This voltage is monitored by the Current Sense Input (Pin 6, 11) and compared to a level derived from the Error Amp output. The peak inductor current under normal operating conditions is controlled by the voltage at Pin 5, 12 where:

$$I_{pk} = \frac{V_{(Pin\ 5,\ 12)} - 1.4\ V}{3\ R_S}$$

Abnormal operating conditions occur when the power supply output is overloaded or if output voltage sensing is lost. Under these conditions, the Current Sense Comparator threshold will be internally clamped to 0.5 V. Therefore the maximum peak switch current is:

$$I_{pk(max)} = \frac{0.5\ V}{R_S}$$

When designing a high power switching regulator it may be desirable to reduce the internal clamp voltage in order to keep the power dissipation of R_S to a reasonable level. A simple method to adjust this voltage is shown in Figure 19. The two external diodes are used to compensate the internal diodes, yielding a constant clamp voltage over temperature. Erratic operation due to noise pickup can result if there is an excessive reduction of the $I_{pk(max)}$ clamp voltage.

A narrow spike on the leading edge of the current waveform can usually be observed and may cause the power supply to exhibit an instability when the output is lightly loaded. This spike is due to the power transformer interwinding capacitance and output rectifier recovery time. The addition of an RC filter on the Current Sense input with a time constant that approximates the spike duration will usually eliminate the instability, refer to Figure 24.

Figure 15. Representative Block Diagram

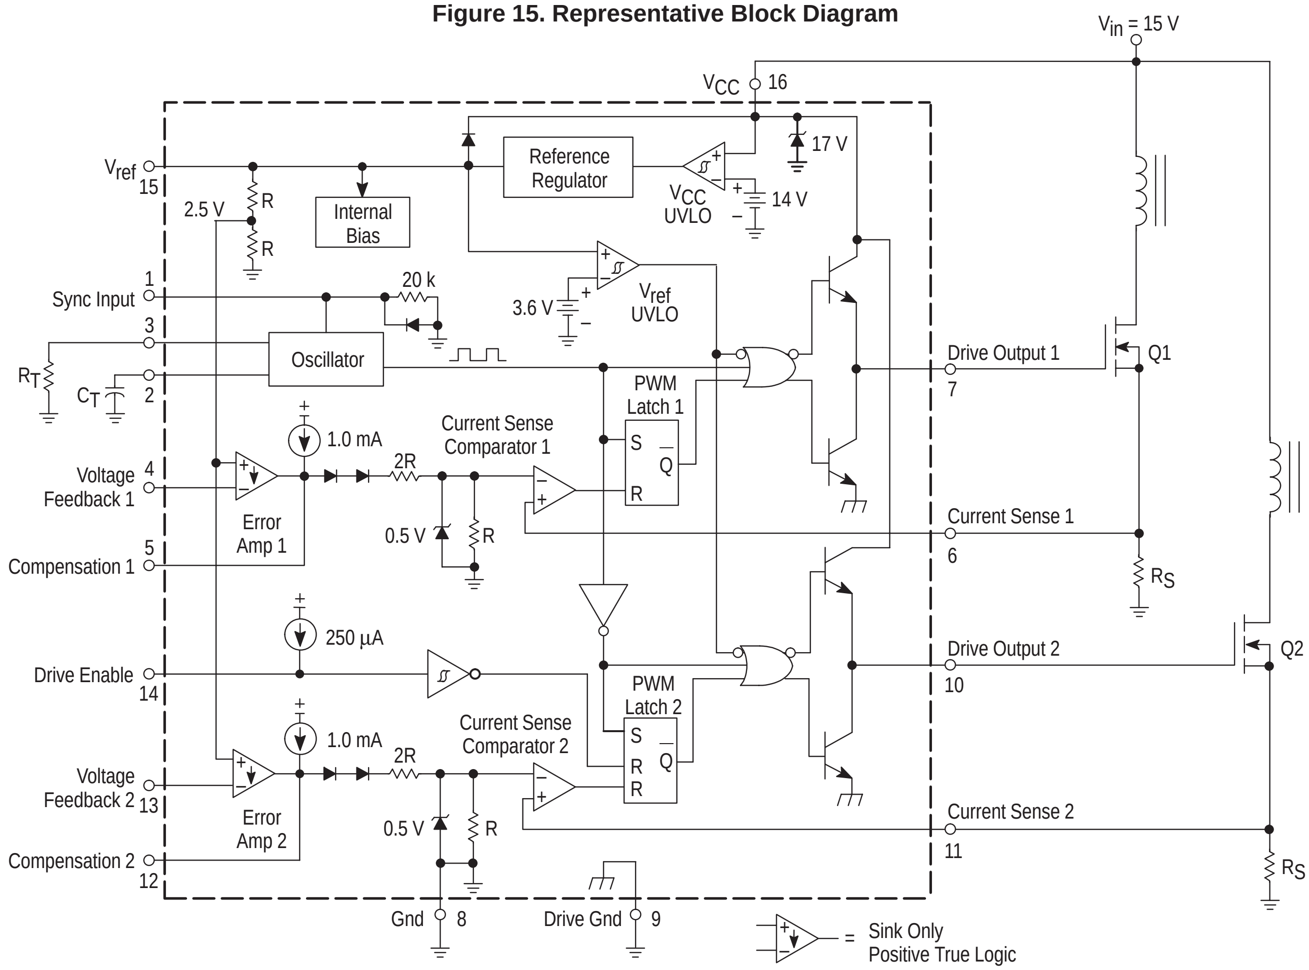

Figure 16. Timing Diagram

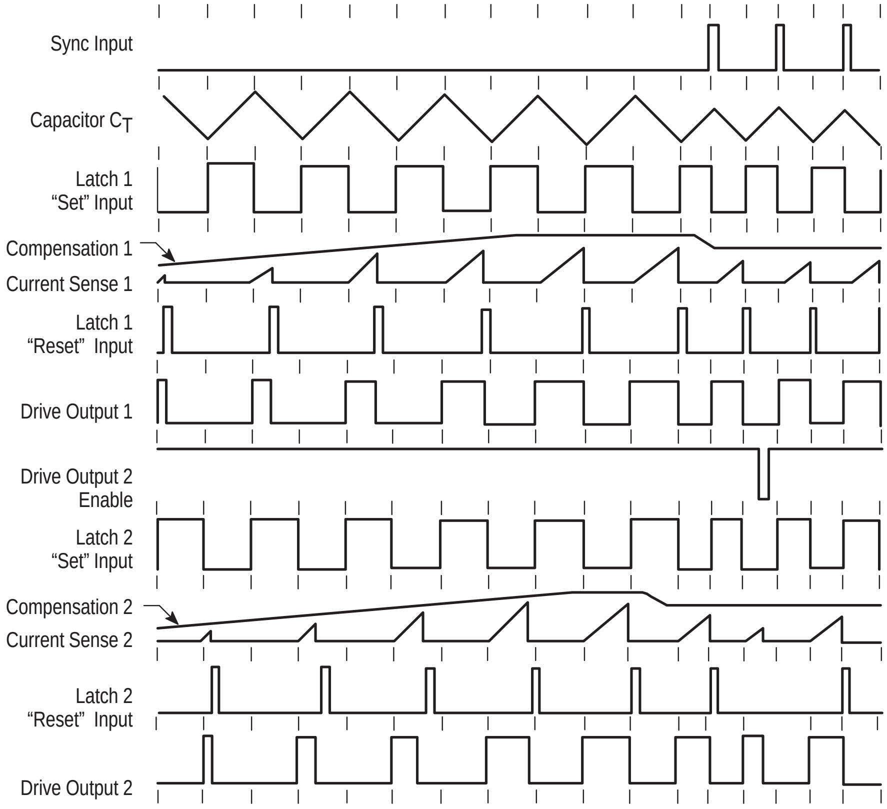


Undervoltage Lockout

Two Undervoltage Lockout comparators have been incorporated to guarantee that the IC is fully functional before the output stages are enabled. The positive power supply terminal (V_{CC}) and the reference output (V_{ref}) are each monitored by separate comparators. Each has built–in hysteresis to prevent erratic output behavior as their respective thresholds are crossed. The V_{CC} comparator upper and lower thresholds are 14 V and 10 V respectively. The hysteresis and low startup current makes these devices ideally suited to off–line converter applications where efficient bootstrap startup techniques are required (Figure 28). The V_{ref} comparator disables the Drive Outputs until the internal circuitry is functional. This comparator has upper and lower thresholds of 3.6 V and 3.4 V. A 17 V zener is connected as a shunt regulator from V_{CC} to ground. Its purpose is to protect the IC and power MOSFET gate from excessive voltage that can occur during system startup. The guaranteed minimum operating voltage after turn–on is 11 V.

Drive Outputs and Drive Ground

Each channel contains a single totem–pole output stage that is specifically designed for direct drive of power MOSFETs. The Drive Outputs are capable of up to ±1.0 A peak current with a typical rise and fall time of 28 ns with a 1.0 nF load. Internal circuitry has been added to keep the outputs in a sinking mode whenever an Undervoltage Lockout is active. This characteristic eliminates the need for an external pull–down resistor. Cross–conduction current in the totem–pole output stage has been minimized for high speed operation, as shown in Figure 13. The average added power due to cross–conduction with V_{CC} = 15 V is only 60 mW at 500 kHz.

Although the Drive Outputs were optimized for MOSFETs, they can easily supply the negative base current required by bipolar NPN transistors for enhanced turn–off (Figure 25). The outputs do not contain internal current limiting, therefore an external series resistor may be required to prevent the peak output current from exceeding the 1.0 A maximum rating. The sink saturation (V_{OL}) is less than 0.4 V at 100 mA.

A separate Drive Ground pin is provided and, with proper implementation, will significantly reduce the level of switching transient noise imposed on the control circuitry. This becomes particularly useful when reducing the $I_{pk(max)}$ clamp level. Figure 23 shows the proper ground connections required for current sensing power MOSFET applications.

Drive Output 2 Enable Pin

This input is used to enable Drive Output 2. Drive Output 1 can be used to control circuitry that must run continuously such as volatile memory and the system clock, or a remote controlled receiver, while Drive Output 2 controls the high power circuitry that is occasionally turned off.

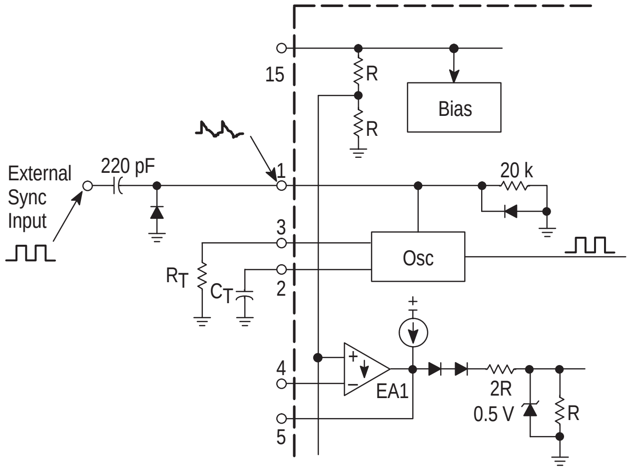
Reference

The 5.0 V bandgap reference is trimmed to ±2.0% tolerance at T_J = 25°C. The reference has short circuit protection and is capable of providing in excess of 30 mA for powering any additional control system circuitry.

Design Considerations

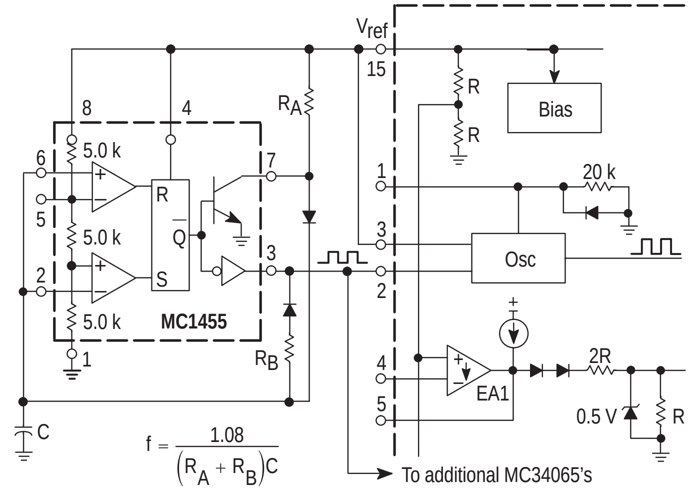
Do not attempt to construct the converter on wire–wrap or plug–in prototype boards. High frequency circuit layout techniques are imperative to prevent pulse–width jitter. This is usually caused by excessive noise pick–up imposed on the Current Sense or Voltage Feedback inputs. Noise immunity can be improved by lowering circuit impedances at these points. The printed circuit layout should contain a ground plane with low current signal and high current switch and output grounds returning on separate paths back to the input filter capacitor. Ceramic bypass capacitors (0.1 µF) connected directly to V_{CC} and V_{ref} may be required depending upon circuit layout. This provides a low impedance path for filtering the high frequency noise. All high current loops should be kept as short as possible using heavy copper runs to minimize radiated EMI. The Error Amp compensation circuitry and the converter output voltage–divider should be located close to the IC and as far as possible from the power switch and other noise generating components.

Figure 17. External Clock Synchronization



The external diode clamp is required if the negative Sync current is greater than –5.0 mA.

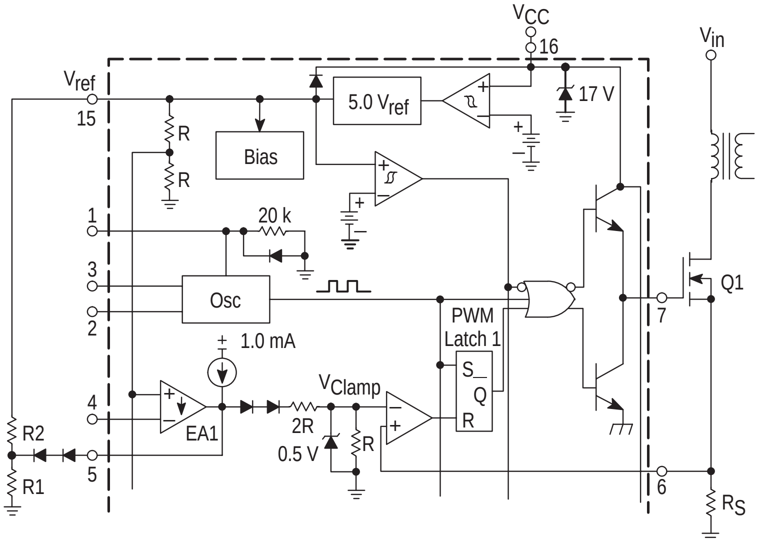
Figure 18. External Duty Cycle Clamp and Multi–Unit Synchronization



$$f = \frac{1.08}{(R_A + R_B)C}$$

$$D_{max}\ \text{Drive Output 1} = \frac{R_B}{R_A + R_B} \qquad D_{max}\ \text{Drive Output 2} = \frac{R_A}{R_A + R_B}$$

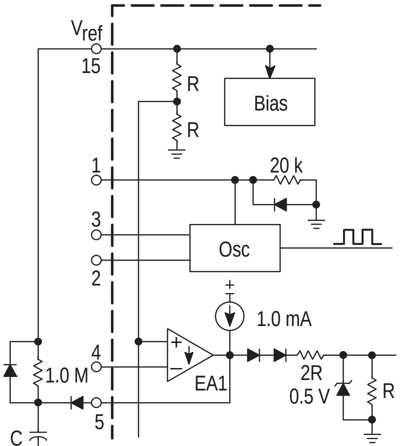
Figure 19. Adjustable Reduction of Clamp Level



$$V_{Clamp} \approx \frac{1.67}{\left(\frac{R2}{R1} + 1\right)} + 0.33 \times 10^{-3}\left(\frac{R1R2}{R1 + R2}\right) \qquad I_{pk(max)} \approx \frac{V_{Clamp}}{R_S}$$

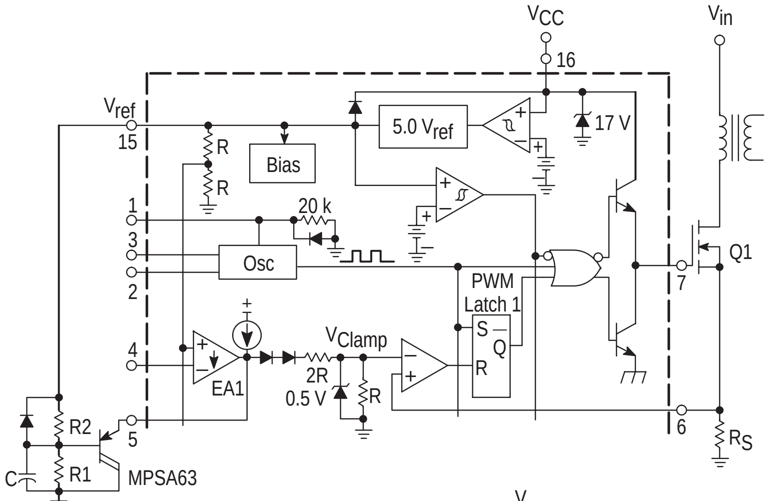
Where: $0 \le V_{Clamp} \le 0.5$ V

Figure 20. Soft–Start Circuit



$t_{Soft–Start} \approx 2100\ C$ in µF

Figure 21. Adjustable Reduction of Clamp Level with Soft–Start



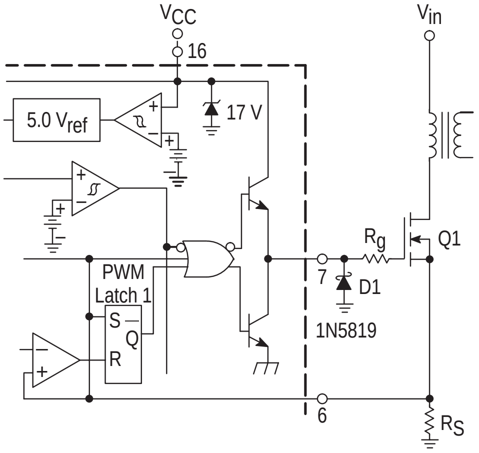
Where: $0 \le V_{Clamp} \le 0.5\ V$

$$I_{pk(max)} \approx \frac{V_{Clamp}}{R_S}$$

$$V_{Clamp} \approx \frac{1.67}{\left(\frac{R2}{R1} + 1\right)}$$

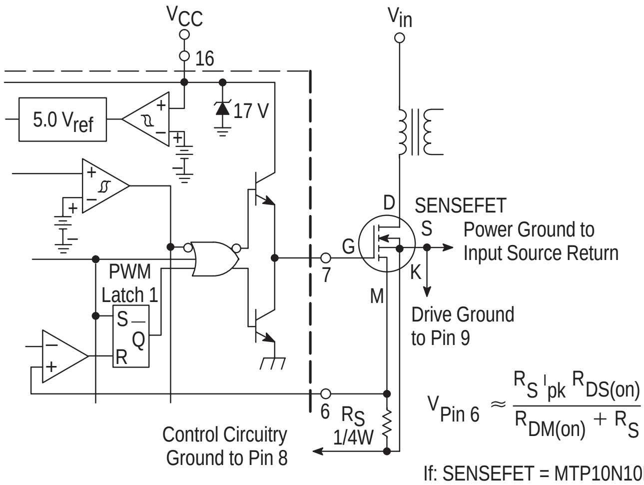
$$t_{Soft\text{–}Start} = \ln\left(\frac{1}{1 - \frac{V_C}{3\ V_{Clamp}}}\right) C\ \frac{R1R2}{R1 + R2}$$

Figure 22. MOSFET Parasitic Oscillations



Series gate resistor R_g may be needed to damp high frequency parasitic oscillations caused by the MOSFET input capacitance and any series wiring inductance in the gate–source circuit. R_g will decrease the MOSFET switching speed. Schottky diode D1 is required if circuit ringing drives the output pin below ground.

Figure 23. Current Sensing Power MOSFET

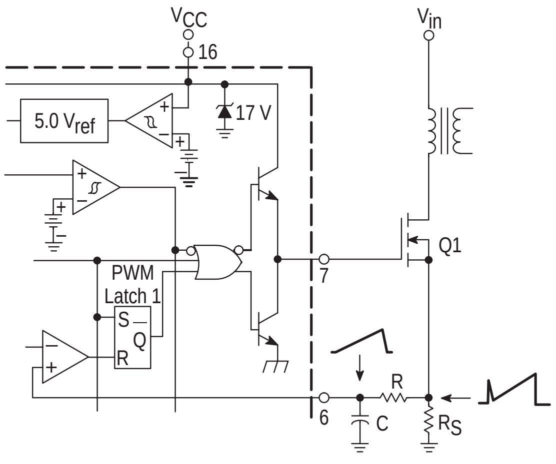


$$V_{Pin\ 6} \approx \frac{R_S\ I_{pk}\ R_{DS(on)}}{R_{DM(on)} + R_S}$$

If: SENSEFET = MTP10N10M
R_S = 200
Then: $V_{Pin\ 6} = 0.075\ I_{pk}$

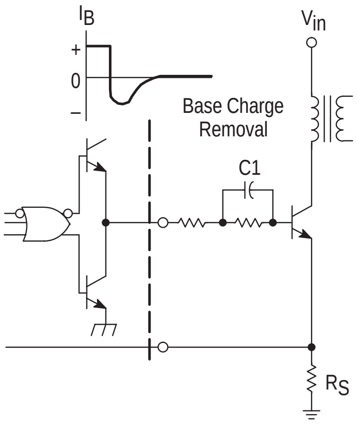
Virtually lossless current sensing can be achieved with the implementation of a SENSEFET power switch. For proper operation during over current conditions, a reduction of the $I_{pk(max)}$ clamp level must be implemented. Refer to Figures 19 and 21.

Figure 24. Current Waveform Spike Suppression



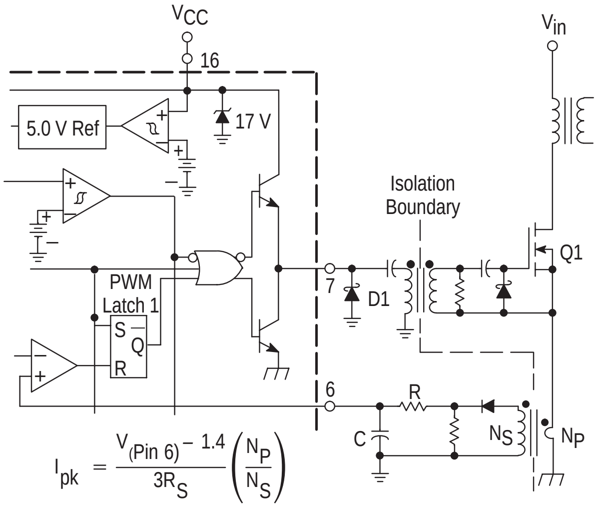
The addition of the RC filter will eliminate instability caused by the leading edge spike on the current waveform.

Figure 25. Bipolar Transistor Drive



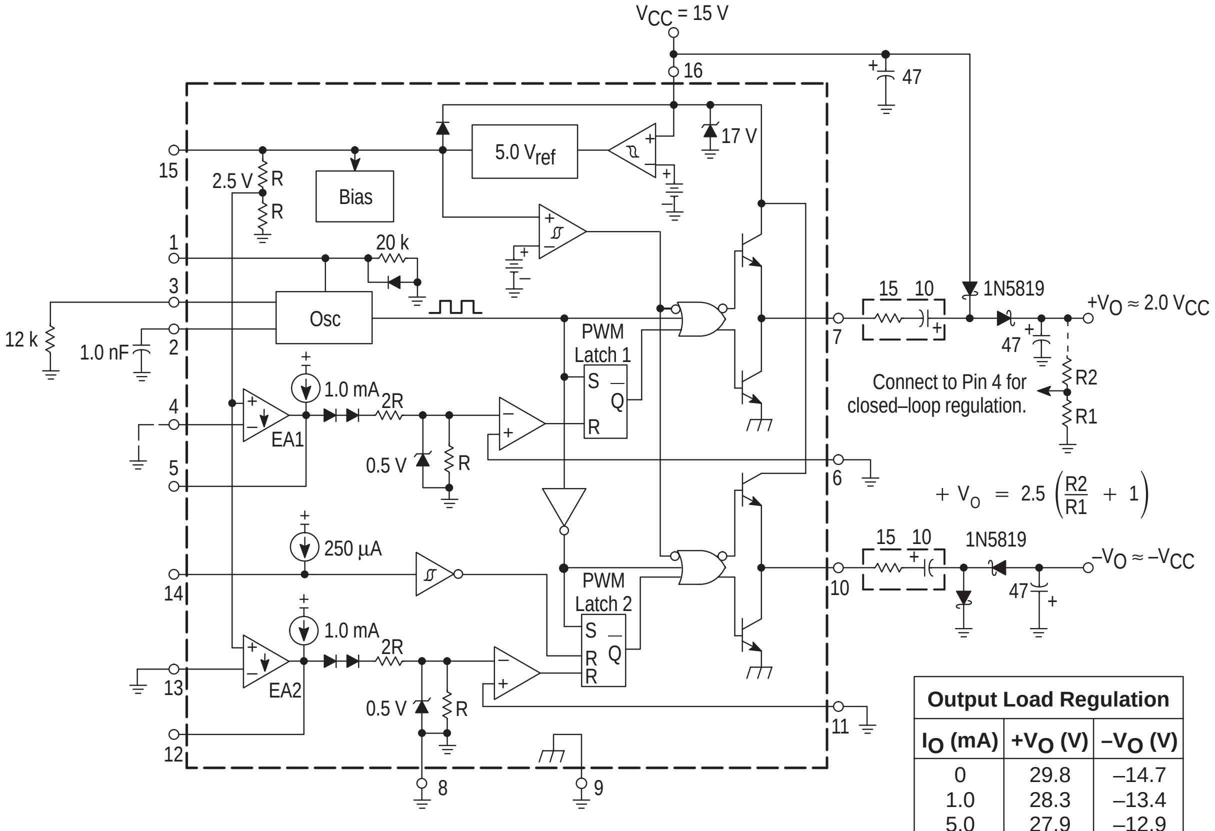
The totem–pole outputs can furnish negative base current for enhanced transistor turn–off, with the addition of capacitor C1.

Figure 26. Isolated MOSFET Drive



$$I_{pk} = \frac{V_{(Pin\ 6)} - 1.4}{3R_S}\left(\frac{N_P}{N_S}\right)$$

Figure 27. Dual Charge Pump Converter



$$+V_O = 2.5\left(\frac{R2}{R1} + 1\right)$$

Output Load Regulation

I_O (mA)	$+V_O$ (V)	$-V_O$ (V)
0	29.8	–14.7
1.0	28.3	–13.4
5.0	27.9	–12.9
10	27.5	–12.5
50	24.4	–9.5

The capacitor’s equivalent series resistance must limit the Drive Output current to 1.0 A. An additional series resistor may be required when using tantalum or other low ESR capacitors. The positive output can provide excellent line and load regulation by connecting the R2/R1 resistor divider as shown.

HIGH PERFORMANCE DUAL CHANNEL CURRENT MODE CONTROLLERS

SEMICONDUCTOR TECHNICAL DATA

The MC34065–H,L series are high performance, fixed frequency, dual current mode controllers. They are specifically designed for off–line and dc–to–dc converter applications offering the designer a cost effective solution with minimal external components. These integrated circuits feature a unique oscillator for precise duty cycle limit and frequency control, a temperature compensated reference, two high gain error amplifiers, two current sensing comparators, Drive Output 2 Enable pin, and two high current totem pole outputs ideally suited for driving power MOSFETs.

Also included are protective features consisting of input and reference undervoltage lockouts each with hysteresis, cycle–by–cycle current limiting, and a latch for single pulse metering of each output. These devices are available in dual–in–line and surface mount packages.

The MC34065–H has UVLO thresholds of 14 V (on) and 10 V (off), ideally suited for off–line converters. The MC34065–L is tailored for lower voltage applications having UVLO thresholds of 8.4 V (on) and 7.8 V (off).

- Unique Oscillator for Precise Duty Cycle Limit and Frequency Control
- Current Mode Operation to 500 kHz
- Automatic Feed Forward Compensation
- Separate Latching PWMs for Cycle–By–Cycle Current Limiting
- Internally Trimmed Reference with Undervoltage Lockout
- Drive Output 2 Enable Pin
- Two High Current Totem Pole Outputs
- Input Undervoltage Lockout with Hysteresis
- Low Startup and Operating Current

OPERATING DESCRIPTION

The MC34065–H,L series are high performance, fixed frequency, dual channel current mode controllers specifically designed for Off–Line and dc–to–dc converter applications. These devices offer the designer a cost effective solution with minimal external components where independent regulation of two power converters is required. The Representative Block Diagram is shown in Figure 15. Each channel contains a high gain error amplifier, current sensing comparator, pulse width modulator latch, and totem pole output driver. The oscillator, reference regulator, and undervoltage lock–out circuits are common to both channels.

Oscillator

The unique oscillator configuration employed features precise frequency and duty cycle control. The frequency is programmed by the values selected for the timing components R_T and C_T. Capacitor C_T is charged and discharged by an equal magnitude internal current source and sink, generating a symmetrical 50 percent duty cycle waveform at Pin 2. The oscillator peak and valley thresholds are 3.5 V and 1.6 V respectively. The source/sink current magnitude is controlled by resistor R_T. For proper operation over temperature it must be in the range of 4.0 kΩ to 16 kΩ as shown in Figure 1.

As C_T charges and discharges, an internal blanking pulse is generated that alternately drives the center inputs of the upper and lower NOR gates high. This, in conjunction with a precise amount of delay time introduced into each channel, produces well defined non–overlapping output duty cycles. Output 2 is enabled while C_T is charging, and Output 1 is enabled during the discharge. Figure 2 shows the Maximum Output Duty Cycle versus Oscillator Frequency. Note that even at 500 kHz, each output is capable of approximately 44% on–time, making this controller suitable for high frequency power conversion applications.

In many noise sensitive applications it may be desirable to frequency–lock the converter to an external system clock. This can be accomplished by applying a clock signal as shown in Figure 17. For reliable locking, the free–running oscillator frequency should be set about 10% less than the clock frequency. Referring to the timing diagram shown in Figure 16, the rising edge of the clock signal applied to the Sync input, terminates charging of C_T and Drive Output 2 conduction. By tailoring the clock waveform symmetry, accurate duty cycle clamping of either output can be achieved. A circuit method for this, and multi–unit synchronization, is shown in Figure 18.

Error Amplifier

Each channel contains a fully–compensated Error Amplifier with access to the inverting input and output. The amplifier features a typical dc voltage gain of 100 dB, and a unity gain bandwidth of 1.0 MHz with 71° of phase margin (Figure 5). The noninverting input is internally biased at 2.5 V and is not pinned out. The converter output voltage is typically divided down and monitored by the inverting input through a resistor divider. The maximum input bias current is –1.0 µA which will cause an output voltage error that is equal to the product of the input bias current and the equivalent input divider source resistance.

The Error Amp output (Pin 5, 12) is provided for external loop compensation. The output voltage is offset by two diode drops (≈1.4 V) and divided by three before it connects to the inverting input of the Current Sense Comparator. This guarantees that no pulses appear at the Drive Output (Pin 7, 10) when the error amplifier output is at its lowest state (V_{OL}). This occurs when the power supply is operating and the load is removed, or at the beginning of a soft–start interval (Figures 20, 21).

The minimum allowable Error Amp feedback resistance is limited by the amplifier's source current (0.5 mA) and the output voltage (V_{OH}) required to reach the comparator's 1.0 V clamp level with the inverting input at ground. This condition happens during initial system startup or when the sensed output is shorted:

$$R_{f(min)} \approx \frac{3.0\ (1.0\ V)\ +\ 1.4\ V}{0.5\ mA} = 8800\ \Omega$$

Current Sense Comparator and PWM Latch

The MC34065 operates as a current mode controller, whereby output switch conduction is initiated by the oscillator and terminated when the peak inductor current reaches the threshold level established by the Error Amplifier output. Thus the error signal controls the peak inductor current on a cycle–by–cycle basis. The Current Sense Comparator–PWM Latch configuration used ensures that only a single pulse appears at the Drive Output during any given oscillator cycle. The inductor current is converted to a voltage by inserting a ground–referenced sense resistor R_S in series with the source of output switch Q1. This voltage is monitored by the Current Sense Input (Pin 6, 11) and compared to a level derived from the Error Amp output. The peak inductor current under normal operating conditions is controlled by the voltage at Pin 5, 12 where:

$$I_{pk} = \frac{V_{(Pin\ 5,\ 12)} - 1.4\ V}{3\ R_S}$$

Abnormal operating conditions occur when the power supply output is overloaded or if output voltage sensing is lost. Under these conditions, the Current Sense Comparator threshold will be internally clamped to 1.0 V. Therefore the maximum peak switch current is:

$$I_{pk(max)} = \frac{1.0\ V}{R_S}$$

When designing a high power switching regulator it may be desirable to reduce the internal clamp voltage in order to keep the power dissipation of R_S to a reasonable level. A simple method to adjust this voltage is shown in Figure 19. The two external diodes are used to compensate the internal diodes, yielding a constant clamp voltage over temperature. Erratic operation due to noise pickup can result if there is an excessive reduction of the $I_{pk(max)}$ clamp voltage.

A narrow spike on the leading edge of the current waveform can usually be observed and may cause the power supply to exhibit an instability when the output is lightly loaded. This spike is due to the power transformer interwinding capacitance and output rectifier recovery time. The addition of an RC filter on the Current Sense input with a time constant that approximates the spike duration will usually eliminate the instability, refer to Figure 24.

Undervoltage Lockout

Two Undervoltage Lockout comparators have been incorporated to guarantee that the IC is fully functional before the output stages are enabled. The positive power supply terminal (V_{CC}) and the reference output (V_{ref}) are each monitored by separate comparators. Each has built–in hysteresis to prevent erratic output behavior as their respective thresholds are crossed. The V_{CC} comparator upper and lower thresholds are 14 V/10 V for –H suffix, and 8.4 V/7.6 V for –L suffix. The V_{ref} comparator upper and lower thresholds are 3.6 V/3.4 V respectively. The large hysteresis and low startup current of the –H suffix version makes it ideally suited in off–line converter applications where efficient bootstrap startup techniques are required (Figure 28). The –L suffix version is intended for lower voltage dc–to–dc converter applications. The minimum operating voltage for the –H suffix is 11 V and 8.2 V for the –L suffix.

Drive Outputs and Drive Ground

Each section contains a single totem–pole output stage that is specifically designed for direct drive of power MOSFETs. The Drive Outputs are capable of up to ±400 mA peak current with a typical rise and fall time of 50 ns with a 1.0 nF load. Additional internal circuitry has been added to keep the outputs in a sinking mode whenever an Undervoltage Lockout is active. This characteristic eliminates the need for an external pull–down resistor. The totem–pole output has been optimized to minimize cross–conduction current in high speed operation. The addition of two 10 Ω resistors, one in series with the source output transistor and one in series with the sink output transistor, reduces the cross–conduction current to minimal levels, as shown in Figure 13.

Although the Drive Outputs were optimized for MOSFETs, they can easily supply the negative base current required by bipolar NPN transistors for enhanced turn–off (Figure 25).

Figure 15. Representative Block Diagram

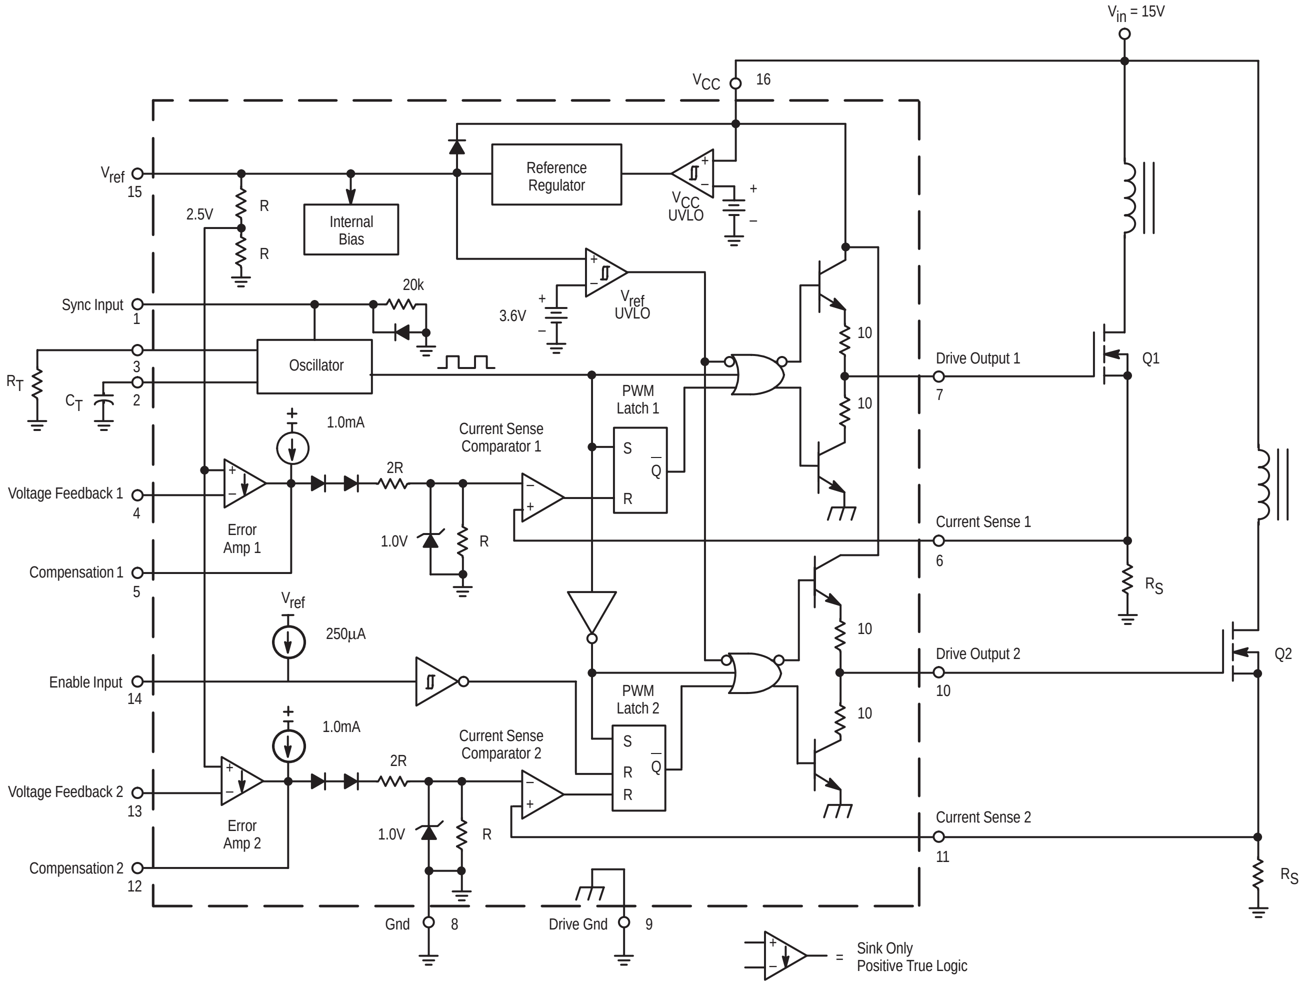

Figure 16. Timing Diagram

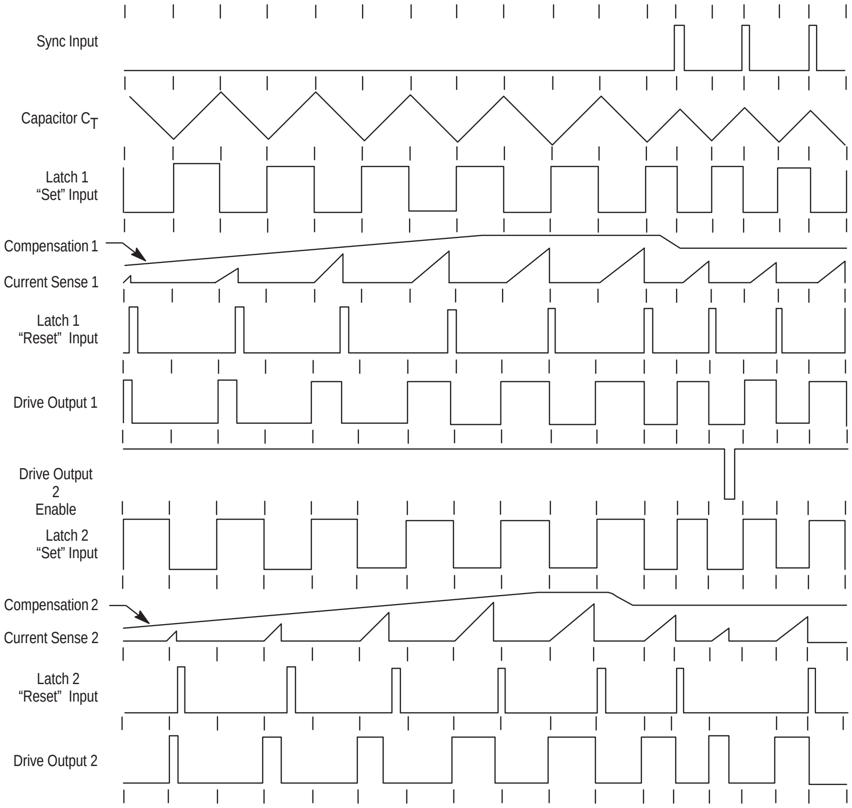


The outputs do not contain internal current limiting, therefore an external series resistor may be required to prevent the peak output current from exceeding the ±400 mA maximum rating. The sink saturation (V_{OL}) is less than 0.75 V at 50 mA.

A separate Drive Ground pin is provided and, with proper implementation, will significantly reduce the level of switching transient noise imposed on the control circuitry. This becomes particularly useful when reducing the $I_{pk(max)}$ clamp level. Figure 23 shows the proper ground connections required for current sensing power MOSFET applications.

Drive Output 2 Enable Pin

This input is used to enable Drive Output 2. Drive Output 1 can be used to control circuitry that must run continuously such as volatile memory and the system clock, or a remote controlled receiver, while Drive Output 2 controls the high power circuitry that is occasionally turned off.

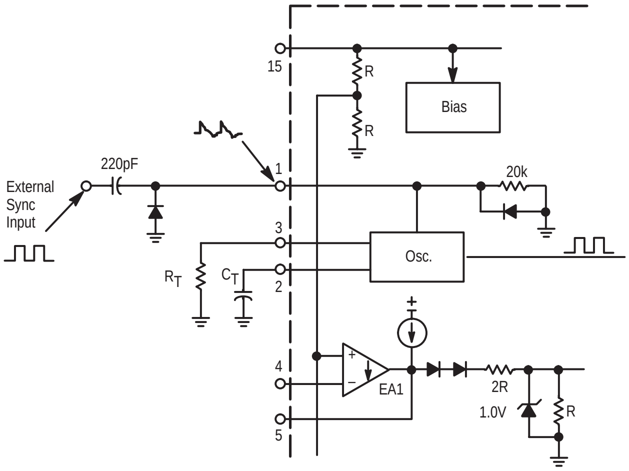
Reference

The 5.0 V bandgap reference is trimmed to ±2.0% tolerance at T_J = 25°C. The reference has short circuit protection and is capable of providing in excess of 30 mA for powering any additional control system circuitry.

Design Considerations

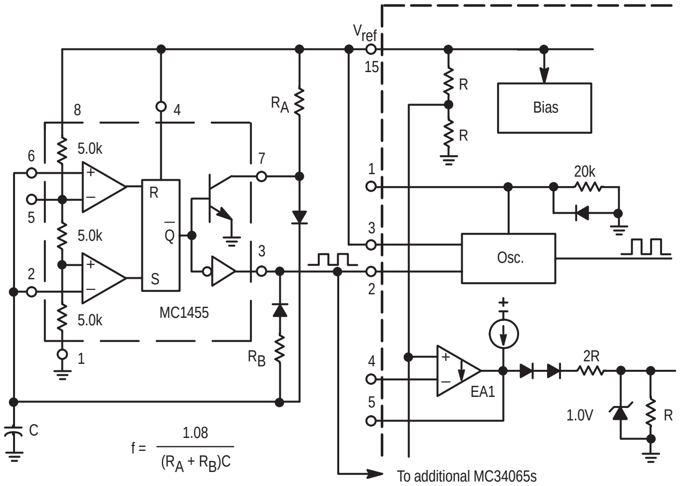
Do not attempt to construct the converter on wire–wrap or plug–in prototype boards. High frequency circuit layout techniques are imperative to prevent pulse–width jitter. This is usually caused by excessive noise pick–up imposed on the Current Sense or Voltage Feedback inputs. Noise immunity can be improved by lowering circuit impedances at these points. The printed circuit layout should contain a ground plane with low current signal and high current switch and output grounds returning on separate paths back to the input filter capacitor. Ceramic bypass capacitors (0.1 μF) connected directly to V_{CC} and V_{ref} may be required depending upon circuit layout. This provides a low impedance path for filtering the high frequency noise. All high current loops should be kept as short as possible using heavy copper runs to minimize radiated EMI. The Error Amp compensation circuitry and the converter output voltage–divider should be located close to the IC and as far as possible from the power switch and other noise generating components.

Figure 17. External Clock Synchronization



The external diode clamp is required if the negative Sync current is greater than –5.0 mA.

Figure 18. External Duty Cycle Clamp and Multi–Unit Synchronization



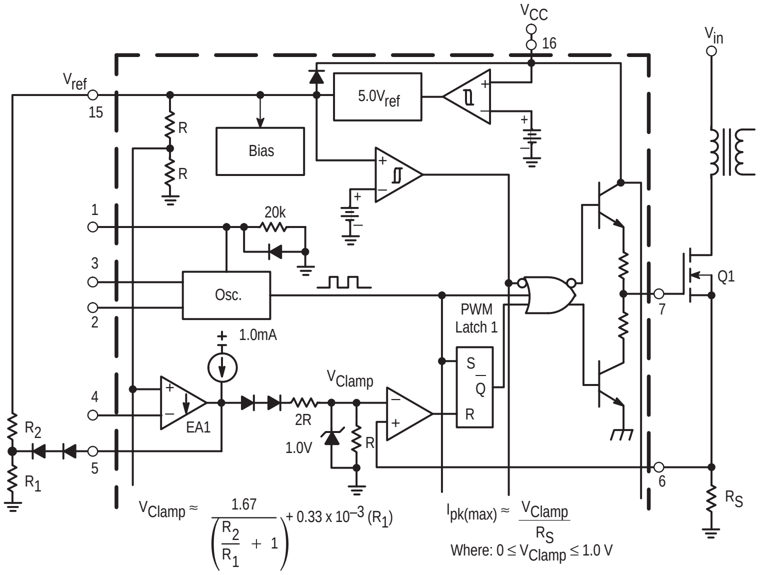
$$f = \frac{1.08}{(R_A + R_B)C}$$

$$D_{max}\ \text{Drive Output 1} = \frac{R_B}{R_A + R_B} \qquad D_{max}\ \text{Drive Output 2} = \frac{R_A}{R_A + R_B}$$

PIN FUNCTION DESCRIPTION

Pin	Function	Description
1	Sync Input	A narrow rectangular waveform applied to this input will synchronize the oscillator. A dc voltage within the range of 2.4 V to 5.5 V will inhibit the oscillator.
2	C_T	Timing capacitor C_T connects from this pin to ground setting the free–running oscillator frequency range.
3	R_T	Resistor R_T connects from this pin to ground precisely setting the charge current for C_T. R_T must be between 4.0 k and 16 k.
4	Voltage Feedback 1	This pin is the inverting input of Error Amplifier 1. It is normally connected to the switching power supply output through a resistor divider.
5	Compensation 1	This pin is the output of Error Amplifier 1 and is made available for loop compensation.
6	Current Sense 1	A voltage proportional to the inductor current is connected to this input. PWM 1 uses this information to terminate conduction of output switch Q1.
7	Drive Output 1	This pin directly drives the gate of a power MOSFET Q1. Peak currents up to 400 mA are sourced and sunk by this pin.
8	Gnd	This pin is the control circuitry ground return and is connected back to the source ground.
9	Drive Gnd	This pin is a separate power ground return that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry.
10	Drive Output 2	This pin directly drives the gate of a power MOSFET Q2. Peak currents up to 400 mA are sourced and sunk by this pin.
11	Current Sense 2	A voltage proportional to inductor current is connected to this input. PWM 2 uses this information to terminate conduction of output switch Q2.
12	Compensation 2	This pin is the output of Error Amplifier 2 and is made available for loop compensation.
13	Voltage Feedback 2	This pin is the inverting input of Error Amplifier 2. It is normally connected to the switching power supply output through a resistor divider.
14	Drive Output 2 Enable	A logic low at this input disables Drive Output 2.
15	V_{ref}	This is the 5.0 V reference output. It can provide bias for any additional system circuitry.
16	V_{CC}	This pin is the positive supply of the control IC. The minimum operating voltage range after startup is 11 V to 15.5 V for the –H suffix, 8.2 V to 9.5 V for the –L suffix.

Figure 19. Adjustable Reduction of Clamp Level

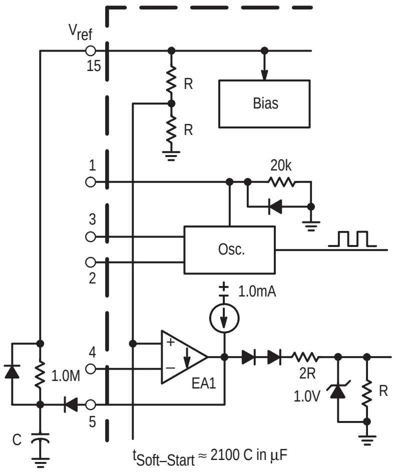


$$V_{Clamp} \approx \frac{1.67}{\left(\frac{R_2}{R_1} + 1\right)} + 0.33 \times 10^{-3}\,(R_1)$$

$$I_{pk(max)} \approx \frac{V_{Clamp}}{R_S}$$

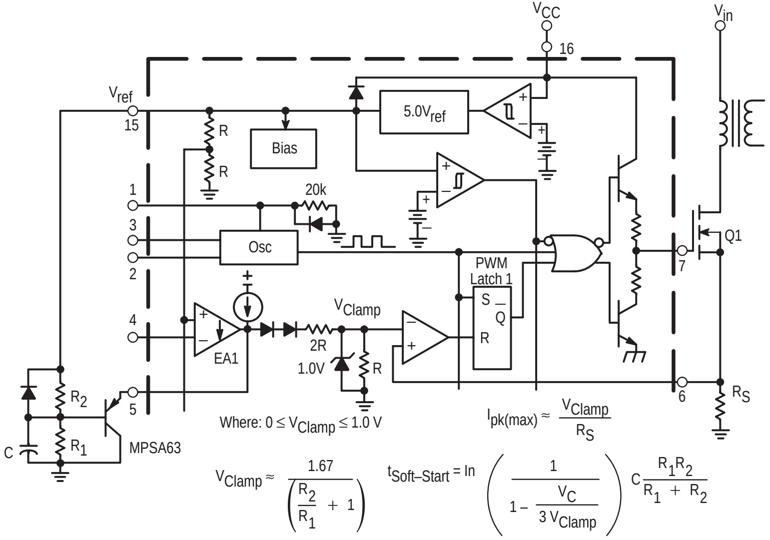
Where: $0 \le V_{Clamp} \le 1.0$ V

Figure 20. Soft–Start Circuit



$t_{Soft–Start} \approx 2100$ C in µF

Figure 21. Adjustable Reduction of Clamp Level with Soft–Start

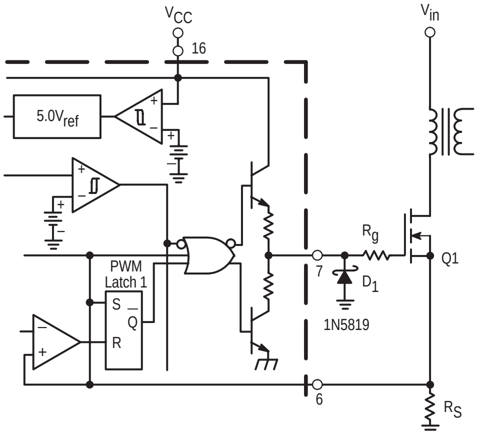


Where: $0 \le V_{Clamp} \le 1.0$ V

$$I_{pk(max)} \approx \frac{V_{Clamp}}{R_S}$$

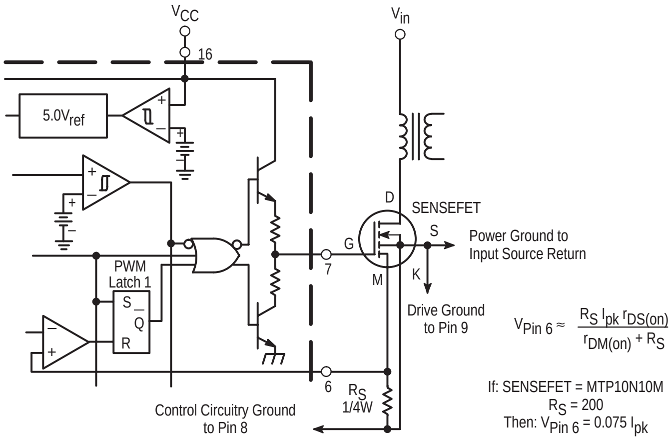
$$V_{Clamp} \approx \frac{1.67}{\left(\frac{R_2}{R_1} + 1\right)} \qquad t_{Soft–Start} = \ln\left(\frac{1}{1 - \frac{V_C}{3\,V_{Clamp}}}\right) C\,\frac{R_1R_2}{R_1 + R_2}$$

Figure 22. MOSFET Parasitic Oscillations



Series gate resistor R_g may be needed to damp high frequency parasitic oscillations caused by the MOSFET input capacitance and any series wiring inductance in the gate–source circuit. R_g will decrease the MOSFET switching speed. Schottky diode D_1 is required if circuit ringing drives the output pin below ground.

Figure 23. Current Sensing Power MOSFET

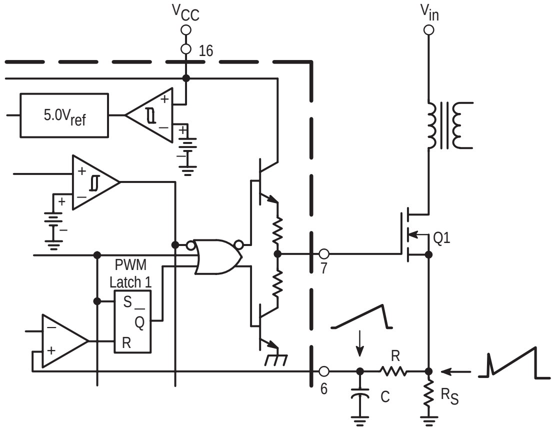


$$V_{Pin\ 6} \approx \frac{R_S\, I_{pk}\, r_{DS(on)}}{r_{DM(on)} + R_S}$$

If: SENSEFET = MTP10N10M
$R_S = 200$
Then: $V_{Pin\ 6} = 0.075\ I_{pk}$

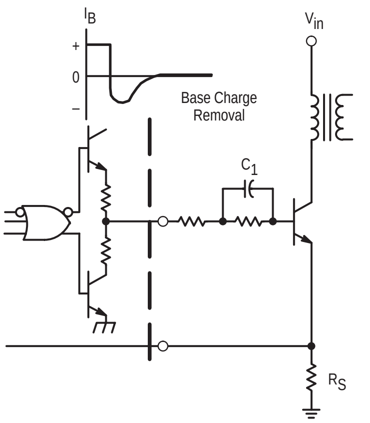
Virtually lossless current sensing can be achieved with the implementation of a SENSEFET power switch. For proper operation during over current conditions, a reduction of the $I_{pk(max)}$ clamp level must be implemented. Refer to Figures 19 and 21.

Figure 24. Current Waveform Spike Suppression



The addition of the RC filter will eliminate instability caused by the leading edge spike on the current waveform.

Figure 25. Bipolar Transistor Drive



The totem–pole outputs can furnish negative base current for enhanced transistor turn–off, with the addition of capacitor C_1.

Figure 26. Isolated MOSFET Drive

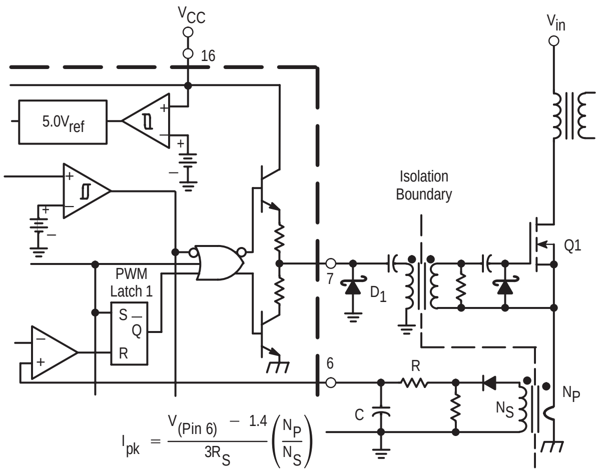


Figure 27. Dual Charge Pump Converter

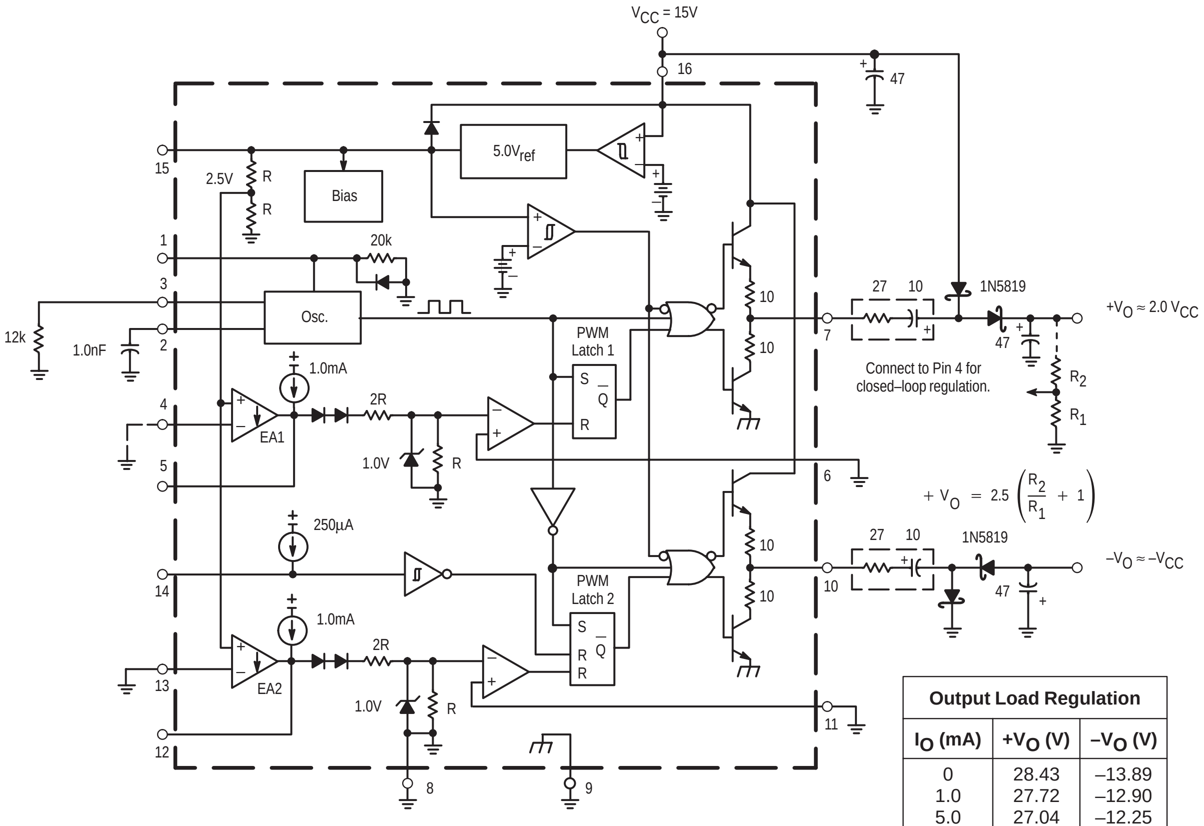

Output Load Regulation		
I_O (mA)	$+V_O$ (V)	$–V_O$ (V)
0	28.43	–13.89
1.0	27.72	–12.90
5.0	27.04	–12.25
10	26.20	–11.44
50	20.52	–5.80

The capacitor's equivalent series resistance must limit the Drive Output current to 400 mA. An additional series resistor may be required when using tantalum or other low ESR capacitors. The positive output can provide excellent line and load regulation by connecting the R_2/R_1 resistor divider as shown.

MC33066

High Performance Resonant Mode Controllers

The MC34066/MC33066 are high performance resonant mode controllers designed for off–line and dc–to–dc converter applications that utilize frequency modulated constant on–time or constant off–time control. These integrated circuits feature a variable frequency oscillator with programmable deadtime, precision retriggerable one–shot timer, temperature compensated reference, high gain wide–bandwidth error amplifier with a precision output clamp, steering flip–flop, and dual high current totem pole outputs ideally suited for driving power MOSFETs.

Also included are protective features consisting of a high speed fault comparator and latch, programmable soft–start circuitry, input undervoltage lockout with selectable thresholds, and reference undervoltage lockout.

These devices are available in dual–in–line and surface mount packages.

- Variable Frequency Oscillator with a Control Range Exceeding 1000:1
- Programmable Oscillator Deadtime Allows Constant Off–Time Operation
- Precision Retriggerable One–Shot Timer
- Internally Trimmed Bandgap Reference
- 5.0 MHz Error Amplifier with Precision Output Clamp
- Dual High Current Totem Pole Outputs
- Selectable Undervoltage Lockout Thresholds with Hysteresis
- Enable Input
- Programmable Soft–Start Circuitry
- Low Startup Current for Off–Line Operation

OPERATING DESCRIPTION

Introduction

As power supply designers have strived to increase power conversion efficiency and reduce passive component size, high frequency resonant mode power converters have emerged as attractive alternatives to conventional square–wave control. When compared to square–wave converters, resonant mode control offers several benefits including lower switching losses, higher efficiency, lower EMI emission, and smaller size. This integrated circuit has been developed to support new trends in power supply design. The MC34066 Resonant Mode Controller is a high performance bipolar IC dedicated to variable frequency power control at frequencies exceeding 1.0 MHz. This integrated circuit provides the features, performance and flexibility for a wide variety of resonant mode power supply applications.

The primary purpose of the control chip is to supply precise pulses to the gates of external power MOSFETs at a repetition rate regulated by a feedback control loop. The MC34066 can be operated in any of three modes as follows: 1) fixed on–time, variable frequency; 2) fixed off–time, variable frequency; and 3) combinations of 1 and 2 that change from fixed on–time to fixed off–time as the frequency increases. Additional features of the IC ensure that system startup and fault conditions are administered in a safe, controlled manner.

A simplified block diagram of the IC is shown on the first page of this data sheet, which identifies the main functional blocks and the block–to–block interconnects. Figure 1 is a detailed functional diagram which accurately represents the internal circuitry. The various functions can be divided into two sections. The first section includes the primary control path which produces precise output pulses at the desired frequency Oscillator, a One–Shot, a pulse Steering Flip–Flop, a pair of power MOSFET Drivers, and a wide bandwidth Error Amplifier. The second section provides several peripheral support functions including a voltage reference, undervoltage lockout, Soft–Start circuit, and a fault detector.

Primary Control Path

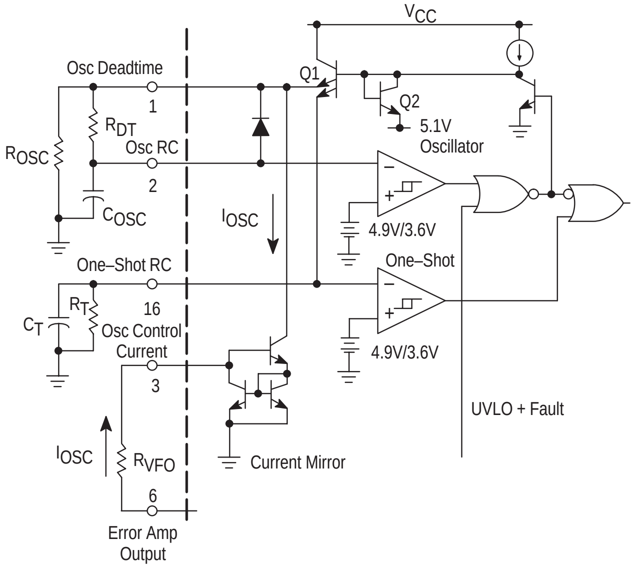
The output pulse width and repetition rate are regulated through the interaction of the variable frequency Oscillator, One–Shot timer and Error Amplifier. The Oscillator triggers the One–Shot which generates a pulse that is alternately steered to a pair of totem–pole output drivers by a toggle Flip–Flop. The Error Amplifier monitors the output of the regulator and modulates the frequency of the Oscillator. High–speed Schottky logic is used throughout the primary control channel to minimize delays and enhance high frequency characteristics.

Oscillator

The characteristics of the variable frequency Oscillator are crucial for precise controller performance at high operating frequencies. In addition to triggering the One–Shot timer and initiating the output pulse, the Oscillator also determines the initial voltage for the One–Shot capacitor and defines the minimum deadtime between output pulses. The Oscillator is designed to operate at frequencies exceeding 1.0 MHz. The Error Amplifier can control the oscillator frequency over a 1000:1 frequency range, and both the minimum and maximum frequencies are easily and accurately programmed by the proper selection of external components. The Oscillator also includes an adjustable deadtime feature for applications requiring additional time between output pulses.

The functional diagram of the Oscillator and One–Shot timer is shown in Figure 2. The oscillator capacitor C_{OSC} is initially charged by transistor Q1 through the optional deadtime resistor R_{DT}. When C_{OSC} exceeds the 4.9 V upper threshold of the oscillator comparator, the base of Q1 is pulled low allowing C_{OSC} to discharge through the external resistors and the internal Current Mirror. When the voltage on C_{OSC} falls below the comparator's 3.6 V lower threshold, Q1 turns on and again charges C_{OSC}.

Figure 2. Oscillator and One–Shot Timer



If R_{DT} is 0 Ω, C_{OSC} charges from 3.6 V to 5.1 V in less than 50 ns. The high slew rate of C_{OSC} and the propagation delay of the comparator make it difficult to control the peak voltage. This accuracy issue is overcome by clamping the base of Q1 through diode Q2 to a voltage reference. The peak voltage of the oscillator waveform is thereby precisely set at 5.1 V.

The frequency of the Oscillator is modulated by varying the current I_{OSC} flowing through R_{VFO} into the Osc Control Current pin. The control current drives a unity gain Current Mirror which pulls an identical current from the C_{OSC} capacitor. As I_{OSC} increases, C_{OSC} discharges faster thus decreasing the Oscillator period and increasing the frequency. The maximum frequency occurs when the Error Amplifier output is at the upper clamp level, nominally 2.5 V above the voltage at the Osc Control Current pin. The minimum discharge time for C_{OSC}, which corresponds to the maximum oscillator frequency, is given by Equation 1.

$$t_{dchg(min)} = (R_{DT} + R_{OSC})C_{OSC}\ln\left[\frac{\frac{2.5\mathrm{ROSC}}{\mathrm{RVFO}} + 5.1}{\frac{2.5\mathrm{ROSC}}{\mathrm{RVFO}} + 3.6}\right] \quad (1)$$

The minimum oscillator frequency will result when the I_{OSC} current is zero, and C_{OSC} is discharged through the external resistors R_{OSC} and R_{DT}. This occurs when the Error Amplifier output voltage is less than the two diode drops required to bias the input of the Current Mirror. The maximum oscillator discharge time is given by Equation 2.

$$t_{dchg(max)} = (R_{DT} + R_{OSC})\ C_{OSC}\ln\left(\frac{5.1}{3.6}\right) \quad (2)$$

The outputs of the control IC are off whenever the oscillator capacitor C_{OSC} is being charged by transistor Q1. The minimum time between output pulses (deadtime) can be programmed by controlling the charge time of C_{OSC}. Resistor R_{DT} reduces the current delivered by Q1 to C_{OSC}, thus increasing the charge time and output deadtime. Varying R_{DT} from 0 Ω to 1000 Ω will increase the output deadtime from 80 ns to 680 ns with C_{OSC} equal to 300 pF. The general expression for the oscillator charge time is give by Equation 3.

$$t_{chg(max)} = R_{DT}\ C_{OSC}\ \ln\left(\frac{5.1–3.6}{5.1–4.9}\right) + 80\ \mathrm{ns} \quad (3)$$

The minimum and maximum oscillator frequencies are programmed by the proper selection of resistor R_{OSC} and R_{VFO}. After selecting R_{DT} for the desired deadtime, the minimum frequency is programmed by R_{OSC} using Equations 2 and 3 in Equation 4:

$$\frac{1}{f_{OSC(min)}} = t_{dchg(max)} + t_{chg} \quad (4)$$

The maximum oscillator frequency is set by resistor R_{VFO} in a similar fashion using Equations 1 and 3 in Equation 5:

$$\frac{1}{f_{OSC(max)}} = t_{dchg(min)} + t_{chg} \quad (5)$$

The value chosen for resistor R_{DT} will affect the peak voltage of the oscillator waveform. As R_{DT} is increased from zero, the time required to charge C_{OSC} becomes large with respect to the propagation delay through the oscillator comparator. Consequently, the overshoot of the upper threshold is reduced and the peak voltage on the oscillator waveform drops from 5.1 V to 4.9 V. The best frequency accuracy is achieved when R_{DT} is zero ohms.

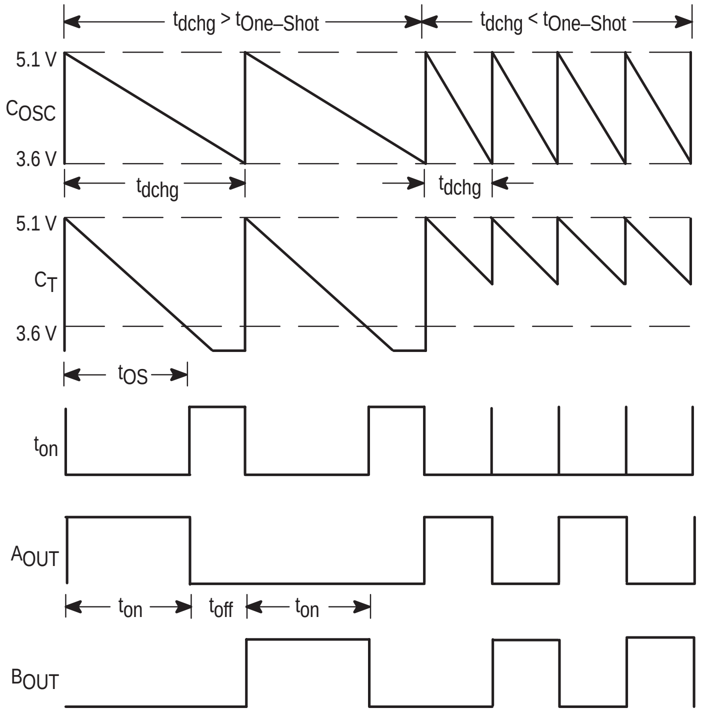
One–Shot Timer

The One–Shot capacitor C_T is charged concurrently with the oscillator capacitor by transistor Q1, as shown in Figure 2. The One–Shot period begins when the oscillator comparator turns off Q1, allowing C_T to discharge. The period ends when resistor R_T discharges C_T to the threshold of the One–Shot comparator. Discharging C_T from an initial voltage of 5.1 V to a threshold voltage of 3.6 V results in the One–Shot period given by Equation 6.

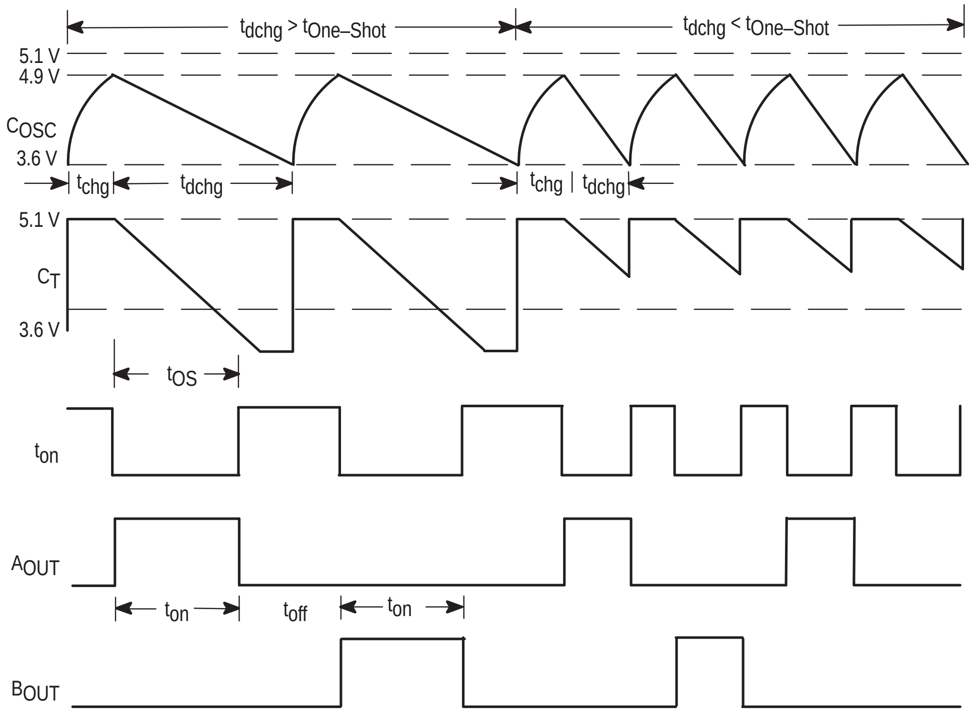
$$t_{OS} = R_T\ C_T\ \ln\left(\frac{5.1}{3.6}\right) = 0.348\ R_T\ C_T \quad (6)$$

Figure 3. Timing Waveforms

$R_{DT} = 0$



$R_{DT} = 1.0\ k$



Errors in the threshold voltage and propagation delays through the output drivers will affect the One–Shot period. To guarantee accuracy, the output pulse of the control ship is trimmed to within 5% of 1.5 µs with nominal values of R_T and C_T.

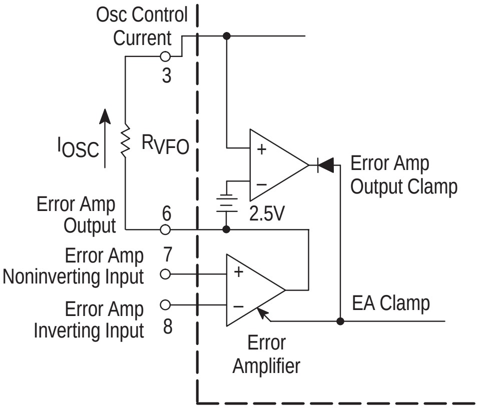
The outputs of the Oscillator and One–Shot comparators are OR'd together to produce the pulse t_{on}, which drives the Flip–Flop and output drivers. The output pulse t_{on} is initiated by the Oscillator, but either the oscillator comparator or the One–Shot comparator can terminate the pulse. When the oscillator discharge time exceeds the one–shot period, the complete one–shot period is delivered to the output section. If the oscillator discharge time is less than the one–shot period, then the oscillator comparator terminates the pulse prematurely and retriggers the One–Shot. The waveforms on the left side of Figure 3 correspond to nonretriggered operation with constant on–time and variable off–times. The right side of Figure 3 represents retriggered operation with variable on–time and constant off–time.

Error Amplifier

A fully accessible high performance Error Amplifier is provided for feedback control of the power supply system. The Error Amplifier is internally compensated and features dc open loop gain greater than 70 dB, input offset voltage less than 10 mV and guaranteed minimum gain–bandwidth product of 2.5 MHz. The input common mode range extends from 1.5 V to 5.1 V, which includes the reference voltage. For common mode voltages below 1.5 V, the Error Amplifier output is forced low providing minimum oscillator frequency.

The Oscillator Control Current pin is biased by the Error Amplifier output voltage through R_{VFO} as illustrated in Figure 4. The output swing of the Error Amplifier is restricted by a clamp circuit to limit the maximum oscillator frequency. The clamp circuit limits the voltage across R_{VFO} to 2.5 V, thus limiting I_{OSC} to 2.5 V/R_{VFO}. Oscillator accuracy is improved by trimming the clamp voltage to obtain the $f_{OSC(high)}$ specification of 1.0 MHz with nominal value external components.

Figure 4. Error Amplifier and Clamp

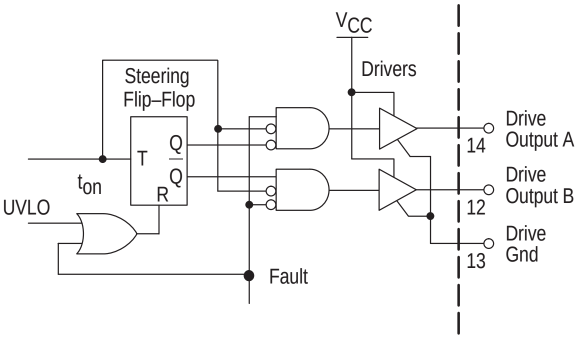


Output Section

The pulse, t_{on}, generated by the Oscillator and One–Shot timer is gated to dual totem pole output drives by the Steering Flip–Flop shown in Figure 5. Positive transitions of t_{on} toggle the Flip–Flop, which causes the pulses to alternate between Output A and Output B. The flip–flop is reset by the undervoltage lockout circuit during startup to guarantee that the first pulse appears at Output A.

The totem–pole output drives are ideally suited for driving power MOSFETs and are capable of sourcing and sinking 1.5 A. Rise and fall times are typically 20 ns when driving a 1.0 nF load. High source/sink capability in a totem–pole driver normally increases the risk of high cross conduction current during output transitions. The MC34066 utilizes a unique design that virtually eliminates cross conduction, thus controlling the chip power dissipation at high frequencies. A separate ground terminal is provided for the output drivers to isolate the sensitive analog circuitry from large transient currents.

Figure 5. Steering Flip–Flop and Output Drivers



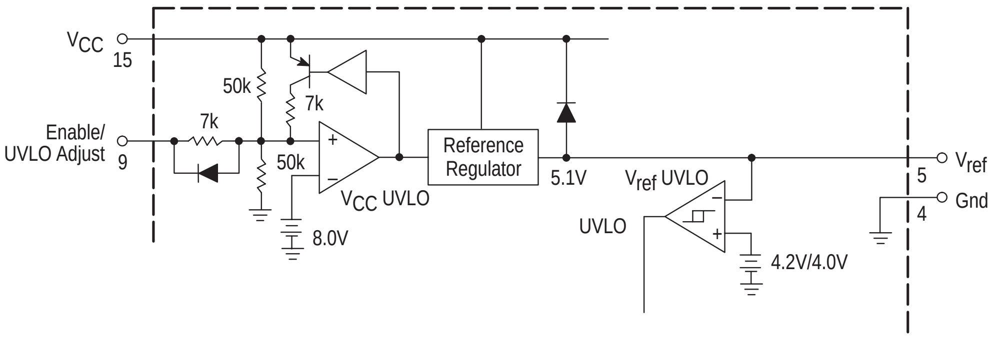
PERIPHERAL SUPPORT FUNCTIONS

The MC34066 Resonant Controller provides a number of support and protection functions including a precision voltage reference, undervoltage lockout comparators, soft–start circuitry, and a fault detector. These peripheral circuits ensure that the power supply can be turned on and off in a safe, controlled manner and that the system will be quickly disabled when a fault condition occurs.

Undervoltage Lockout and Voltage Reference

Separate undervoltage lockout comparators sense the input V_{CC} voltage and the regulated reference voltage as illustrated in Figure 6. When V_{CC} increases to the upper threshold voltage, the V_{CC} UVLO comparator enables the Reference Regulator. After the V_{ref} output of the Reference Regulator rises to 4.2 V, the V_{ref} UVLO comparator switches the UVLO signal to a logic zero state enabling the primary control path. Reducing V_{CC} to the lower threshold voltage causes the V_{CC} UVLO comparator to disable the Reference Regulator. The V_{ref} UVLO comparator then switches the UVLO output to a logic one state disabling the controller.

Figure 6. Undervoltage Lockout and Reference



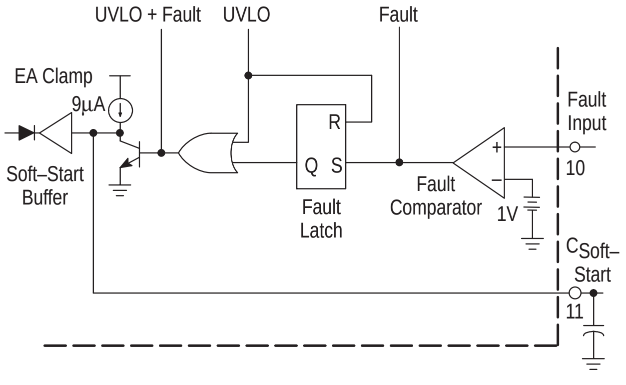
The Enable/UVLO Adjust terminal allows the power supply designer to select the V_{CC} UVLO threshold voltages. When this pin is open, the comparator switches the controller on at 16 V and off at 9.0 V. If this pin is connected to the V_{CC} terminal, the upper and lower thresholds are reduced to 9.0 V and 8.6 V, respectively. Forcing the Enable/UVLO Adjust pin low will pull the V_{CC} UVLO comparator input low (through an internal diode) turning off the controller.

The Reference Regulator provides a precise 5.1 V reference to internal circuitry and can deliver up to 10 mA to external loads. The reference is trimmed to better than 2% initial accuracy and includes active short circuit protection.

Fault Detector

The high–speed Fault Comparator and Latch illustrated in Figure 7 can protect a power supply from destruction under fault conditions. The Fault Input pin connects to the input of the Fault Comparator. If this input exceeds the 1.0 V threshold of the comparator, the Fault Latch is set and two logic signals simultaneously disable the primary control path. The signal labeled Fault at the output of the Fault Comparator is connected directly to the output drivers. This direct path reduces the propagation delay from the Fault Input to the A and B outputs to typically 70 ns. The Fault Latch output is OR'd with UVLO output from the V_{ref} UVLO comparator to produce the logic output labeled UVLO + Fault. This signal disables the Oscillator and One–Shot by forcing both the C_{OSC} and C_T capacitors to be continually charged.

Figure 7. Fault Detector and Soft–Start



The Fault Latch is reset during startup by a logic one at the UVLO output of the V_{ref} UVLO comparator. The latch can also be reset after startup by pulling the Enable/UVLO Adjust pin momentarily low to disable the Reference Regulator.

Soft–Start Circuit

The Soft–Start circuit shown in Figure 7 forces the variable frequency Oscillator to start at the minimum frequency and ramp upward until regulated by the feedback control loop. The external capacitor at the $C_{Soft–Start}$ terminal is initially discharged by the UVLO + Fault signal. The low voltage on the capacitor pass through the Soft–Start Buffer to hold the Error Amplifier output low. After UVLO + Fault switches to a logic zero, the soft–start capacitor is charged by a 9.0 µA current source. The buffer allows the Error Amplifier output to follow the soft–start capacitor until it is regulated by the Error Amplifier inputs (or reaches the 2.5 V clamp). The soft–start function is generally applicable to controllers operating below resonance and can be disabled by simply opening the $C_{Soft–Start}$ terminal.

APPLICATIONS

The MC34066 can be used for the control of series, parallel or higher order half/full bridge resonant converters. The IC is designed to provide control in discontinuous conduction mode (DCM) or continuous conduction mode (CCM) or a combination of the two. For example, in a parallel resonant converter (PRC) operating in the DCM, the IC is programmed to operate in fixed on–time, variable frequency mode of operation. For a PRC operating in the CCM, the IC can be programmed to operate in the variable frequency mode with a fixed off–time.

When operating with a wide input voltage range, such as a universal input power supply, a PRC can operate in the DCM for high input voltage and in the CCM for low input voltage. In this particular case, on–time is programmed corresponding to DCM. The deadtime of the chip is programmed to provide the desired off–time in the CCM. The frequency range is chosen to cover the complete frequency range from the DCM to the CCM. When programmed as such, the controller will operate in the fixed on–time, variable frequency mode at low frequencies. At the frequency which causes the Oscillator to retrigger the One–Shot, the control law changes to variable frequency with fixed off–time. At higher frequencies the supply will operate in the CCM with this control law.

Although the IC is designed and optimized for double ended push–pull type converters, it can also be used for single ended applications, such as forward and flyback resonant converters.

MOTOROLA

MC34067
MC33067

High Performance Resonant Mode Controllers

HIGH PERFORMANCE ZERO VOLTAGE SWITCH RESONANT MODE CONTROLLERS

SEMICONDUCTOR TECHNICAL DATA

The MC34067/MC33067 are high performance zero voltage switch resonant mode controllers designed for off–line and dc–to–dc converter applications that utilize frequency modulated constant off–time or constant deadtime control. These integrated circuits feature a variable frequency oscillator, a precise retriggerable one–shot timer, temperature compensated reference, high gain wide bandwidth error amplifier, steering flip–flop, and dual high current totem pole outputs ideally suited for driving power MOSFETs.

Also included are protective features consisting of a high speed fault comparator and latch, programmable soft–start circuitry, input undervoltage lockout with selectable thresholds, and reference undervoltage lockout.

These devices are available in dual–in–line and surface mount packages.

- Zero Voltage Switch Resonant Mode Operation
- Variable Frequency Oscillator with a Control Range Exceeding 1000:1
- Precision One–Shot Timer for Controlled Off–Time
- Internally Trimmed Bandgap Reference
- 4.0 MHz Error Amplifier
- Dual High Current Totem Pole Outputs
- Selectable Undervoltage Lockout Thresholds with Hysteresis
- Enable Input
- Programmable Soft–Start Circuitry
- Low Startup Current for Off–Line Operation

OPERATING DESCRIPTION

Introduction

As power supply designers have strived to increase power conversion efficiency and reduce passive component size, high frequency resonant mode power converters have emerged as attractive alternatives to conventional pulse–width modulated control. When compared to pulse–width modulated converters, resonant mode control offers several benefits including lower switching losses, higher efficiency, lower EMI emission, and smaller size. A new integrated circuit has been developed to support this trend in power supply design. The MC34067 Resonant Mode Controller is a high performance bipolar IC dedicated to variable frequency power control at frequencies exceeding 1.0 MHz. This integrated circuit provides the features and performance specifically for zero voltage switching resonant mode power supply applications.

The primary purpose of the control chip is to provide a fixed off–time to the gates of external power MOSFETs at a repetition rate regulated by a feedback control loop. Additional features of the IC ensure that system startup and fault conditions are administered in a safe, controlled manner.

A simplified block diagram of the IC is shown on the front page, which identifies the main functional blocks and the block–to–block interconnects. Figure 13 is a detailed functional diagram which accurately represents the internal circuitry. The various functions can be divided into two sections. The first section includes the primary control path which produces precise output pulses at the desired frequency. Included in this section are a variable frequency Oscillator, a One–Shot, a pulse Steering Flip–Flop, a pair of power MOSFET Drivers, and a wide bandwidth Error Amplifier. The second section provides several peripheral support functions including a voltage reference, undervoltage lockout, Soft–Start circuit, and a fault detector.

Primary Control Path

The output pulse width and repetition rate are regulated through the interaction of the variable frequency Oscillator, One–Shot timer and Error Amplifier. The Oscillator triggers the One–Shot which generates a pulse that is alternately steered to a pair of totem pole output drivers by a toggle Flip–Flop. The Error Amplifier monitors the output of the regulator and modulates the frequency of the Oscillator. High speed Schottky logic is used throughout the primary control channel to minimize delays and enhance high frequency characteristics.

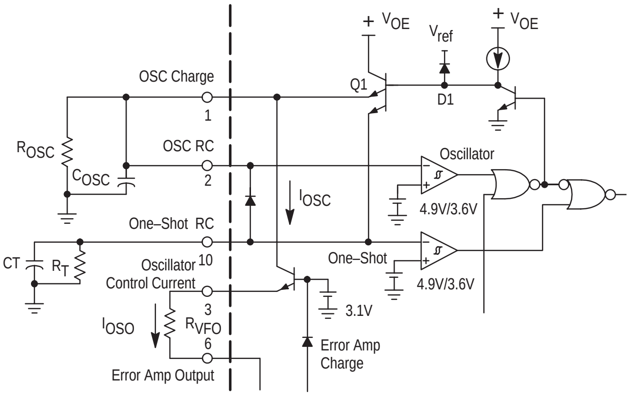
Oscillator

The characteristics of the variable frequency Oscillator are crucial for precise controller performance at high operating frequencies. In addition to triggering the One–Shot timer and initiating the output deadtime, the oscillator also determines the initial voltage for the one–shot capacitor. The Oscillator is designed to operate at frequencies exceeding 1.0 MHz. The Error Amplifier can control the oscillator frequency over a 1000:1 frequency range, and both the minimum and maximum frequencies are easily and accurately programmed by the proper selection of external components.

The functional diagram of the Oscillator and One–Shot timer is shown in Figure 14. The oscillator capacitor (C_{OSC}) is initially charged by transistor Q1. When C_{OSC} exceeds the 4.9 V upper threshold of the oscillator comparator, the base of Q1 is pulled low allowing C_{OSC} to discharge through the external resistor, (R_{OSC}), and the oscillator control current, (I_{OSC}). When the voltage on C_{OSC} falls below the comparator's 3.6 V lower threshold, Q1 turns on and again charges C_{OSC}.

C_{OSC} charges from 3.6 V to 5.1 V in less than 50 ns. The high slew rate of C_{OSC} and the propagation delay of the comparator make it difficult to control the peak voltage. This accuracy issue is overcome by clamping the base of Q1 through a diode to a voltage reference. The peak voltage of the oscillator waveform is thereby precisely set at 5.1 V.

Figure 14. Oscillator and One–Shot Timer



The frequency of the Oscillator is modulated by varying the current flowing out of the Oscillator Control Current (I_{OSC}) pin. The I_{OSC} pin is the output of a voltage regulator. The input of the voltage regulator is tied to the variable frequency oscillator. The discharge current of the Oscillator increases by increasing the current out of the I_{OSC} pin. Resistor R_{VFO} is used in conjunction with the Error Amp output to change the I_{OSC} current. Maximum frequency occurs when the Error Amplifier output is at its low state with a saturation voltage of 0.1 V at 1.0 mA.

The minimum oscillator frequency will result when the I_{OSC} current is zero, and C_{OSC} is discharged through the external resistor (R_{OSC}). This occurs when the Error Amplifier output is at its high state of 2.5 V. The minimum and maximum oscillator frequencies are programmed by the proper selection of resistor R_{OSC} and R_{VFO}. The minimum frequency is programmed by R_{OSC} using Equation 1:

$$R_{OSC} = \frac{\dfrac{1}{f_{(min)}} - t_{PD}}{C_{OSC}\ \ell n\left(\dfrac{5.1}{3.6}\right)} = \frac{t_{(max)} - 70\ \text{ns}}{0.348\ C_{OSC}} \qquad (1)$$

where t_{PD} is the internal propagation delay.

The maximum oscillator frequency is set by the current through resistor R_{VFO}. The current required to discharge C_{OSC} at the maximum oscillator frequency can be calculated by Equation 2:

$$I_{(max)} = C_{OSC} \frac{5.1 - 3.6}{\frac{1}{f_{(max)}}} = 1.5 C_{OSC} f_{(max)} \qquad (2)$$

The discharge current through R_{OSC} must also be known and can be calculated by Equation 3:

$$I_{R_{OSC}} = \frac{5.1 - 3.6}{R_{OSC}} \varepsilon^{\left(-\frac{\frac{1}{f_{(min)}}}{R_{OSC}C_{OSC}}\right)} = \frac{1.5}{R_{OSC}} \varepsilon^{\left(-\frac{1}{f_{(min)} R_{OSC} C_{OSC}}\right)} \qquad (3)$$

Resistor R_{VFO} can now be calculated by Equation 4:

$$R_{VFO} = \frac{2.5 - V_{EAsat}}{I_{(max)} - I_{R_{OSC}}} \qquad (4)$$

One–Shot Timer

The One–Shot is designed to disable both outputs simultaneously providing a deadtime before either output is enabled. The One–Shot capacitor (C_T) is charged concurrently with the oscillator capacitor by transistor Q1, as shown in Figure 14. The one–shot period begins when the oscillator comparator turns off Q1, allowing C_T to discharge. The period ends when resistor R_T discharges C_T to the threshold of the One–Shot comparator. The lower threshold of the One–Shot is 3.6 V. By choosing C_T, R_T can by solved by Equation 5:

$$R_T = \frac{t_{OS}}{C_T \ \ell n \left(\frac{5.1}{3.6}\right)} = \frac{t_{OS}}{0.348 \ C_T} \qquad (5)$$

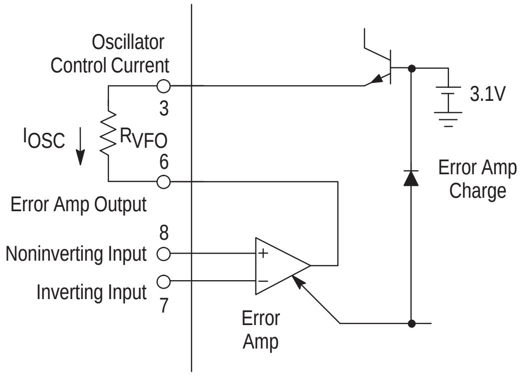
Errors in the threshold voltage and propagation delays through the output drivers will affect the One–Shot period. To guarantee accuracy, the output pulse of the control chip is trimmed to within 5% of 250 ns with nominal values of R_T and C_T.

The outputs of the Oscillator and One–Shot comparators are OR'd together to produce the pulse t_{OS}, which drives the Flip–Flop and output drivers. The output pulse (t_{OS}) is initiated by the Oscillator and terminated by the One–Shot comparator. With zero–voltage resonant mode converters, the oscillator discharge time should never be set less than the one–shot period.

Error Amplifier

A fully accessible high performance Error Amplifier is provided for feedback control of the power supply system. The Error Amplifier is internally compensated and features dc open loop gain greater than 70 dB, input offset voltage of less than 10 mV and a guaranteed minimum gain–bandwidth product of 2.5 MHz. The input common mode range extends from 1.5 V to 5.1 V, which includes the reference voltage.

Figure 15. Error Amplifier and Clamp

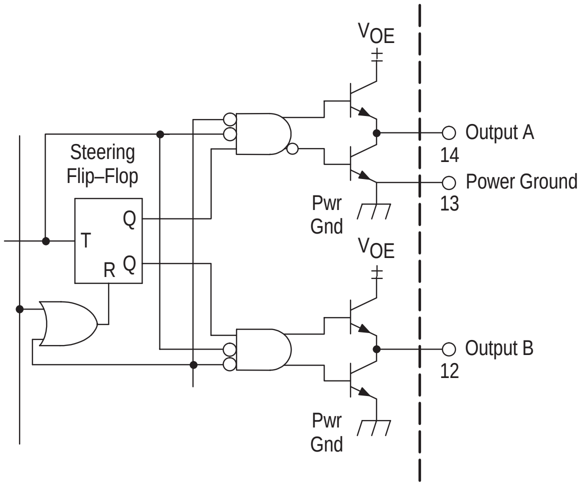


When the Error Amplifier output is coupled to the I_{OSC} pin by R_{VFO}, as illustrated in Figure 15, it provides the Oscillator Control Current, I_{OSC}. The output swing of the Error Amplifier is restricted by a clamp circuit to improve its transient recovery time.

Output Section

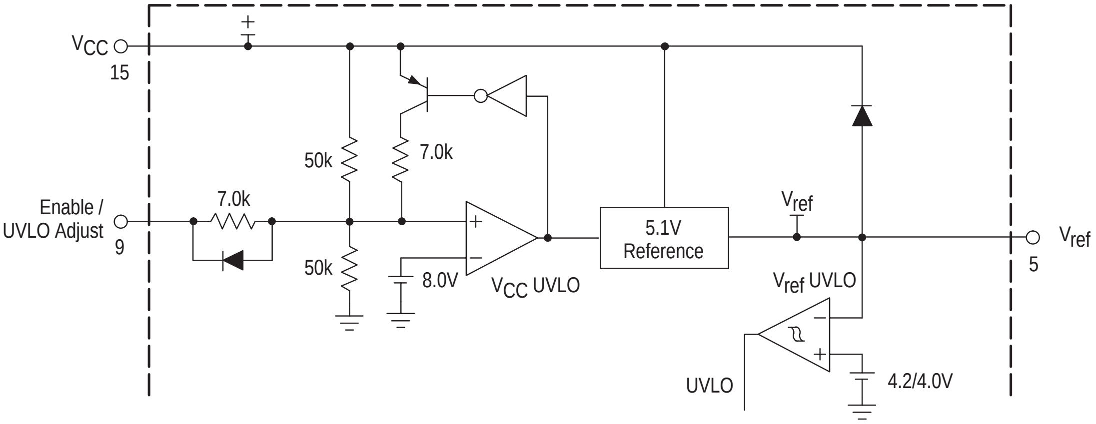
The pulse(t_{OS}), generated by the Oscillator and One–Shot timer is gated to dual totem–pole output drives by the Steering Flip–Flop shown in Figure 16. Positive transitions of t_{OS} toggle the Flip–Flop, which causes the pulses to alternate between Output A and Output B. The flip–flop is reset by the undervoltage lockout circuit during startup to guarantee that the first pulse appears at Output A.

Figure 16. Steering Flip–Flop and Output Drivers



The totem–pole output drivers are ideally suited for driving power MOSFETs and are capable of sourcing and sinking 1.5 A. Rise and fall times are typically 20 ns when driving a 1.0 nF load. High source/sink capability in a totem–pole driver normally increases the risk of high cross conduction current during output transitions. The MC34067 utilizes a unique design that virtually eliminates cross conduction, thus controlling the chip power dissipation at high frequencies. A separate power ground pin is provided to isolate the sensitive analog circuitry from large transient currents.

Figure 17. Undervoltage Lockout and Reference



PERIPHERAL SUPPORT FUNCTIONS

The MC34067 Resonant Controller provides a number of support and protection functions including a precision voltage reference, undervoltage lockout comparators, soft–start circuitry, and a fault detector. These peripheral circuits ensure that the power supply can be turned on and off in a controlled manner and that the system will be quickly disabled when a fault condition occurs.

Undervoltage Lockout and Voltage Reference

Separate undervoltage lockout comparators sense the input V_{CC} voltage and the regulated reference voltage as illustrated in Figure 17. When V_{CC} increases to the upper threshold voltage, the V_{CC} UVLO comparator enables the Reference Regulator. After the V_{ref} output of the Reference Regulator rises to 4.2 V, the V_{ref} UVLO comparator switches the UVLO signal to a logic zero state enabling the primary control path. Reducing V_{CC} to the lower threshold voltage causes the V_{CC} UVLO comparator to disable the Reference Regulator. The V_{ref} UVLO comparator then switches the UVLO output to a logic one state disabling the controller.

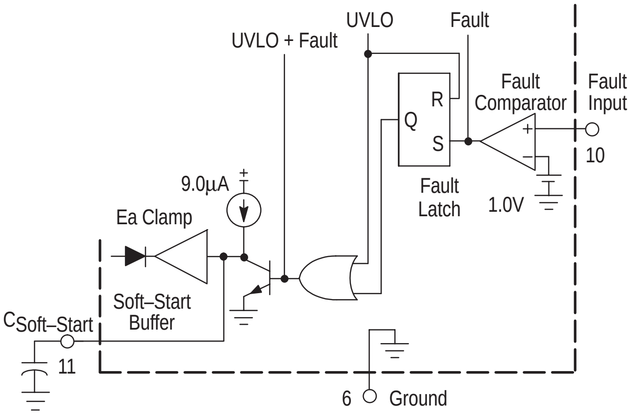
The Enable/UVLO Adjust pin allows the power supply designer to select the V_{CC} UVLO threshold voltages. When this pin is open, the comparator switches the controller on at 16 V and off at 9.0 V. If this pin is connected to the V_{CC} terminal, the upper and lower thresholds are reduced to 9.0 V and 8.6 V, respectively. Forcing the Enable/UVLO Adjust pin low will pull the V_{CC} UVLO comparator input low (through an internal diode) turning off the controller.

The Reference Regulator provides a precise 5.1 V reference to internal circuitry and can deliver up to 10 mA to external loads. The reference is trimmed to better than 2% initial accuracy and includes active short circuit protection.

Fault Detector

The high speed Fault Comparator and Latch illustrated in Figure 18 can protect a power supply from destruction under fault conditions. The Fault Input pin connects to the input of the Fault Comparator. If this input exceeds the 1.0 V threshold of the comparator, the Fault Latch is set and two logic signals simultaneously disable the primary control path. The signal labeled “Fault” at the output of the Fault Comparator is connected directly to the output drivers. This direct path reduces the propagation delay from the Fault Input to the A and B outputs to typically 70 ns. The Fault Latch output is OR’d with the UVLO output from the V_{ref} UVLO comparator to produce the logic output labeled “UVLO+Fault”. This signal disables the Oscillator and One–Shot by forcing both the C_{OSC} and C_T capacitors to be continually charged.

Figure 18. Fault Detector and Soft–Start



The Fault Latch is reset during startup by a logic “1” at the UVLO output of the V_{ref} UVLO comparator. The latch can also be reset after startup by pulling the Enable/UVLO Adjust pin momentarily low to disable the Reference Regulator.

Soft–Start Circuit

The Soft–Start circuit shown in Figure 18 forces the variable frequency Oscillator to start at the maximum frequency and ramp downward until regulated by the feedback control loop. The external capacitor at the $C_{Soft–Start}$ terminal is initially discharged by the UVLO+Fault signal. The low voltage on the capacitor passes through the Soft–Start Buffer to hold the Error Amplifier output low. After UVLO+Fault switches to a logic zero, the soft–start capacitor is charged by a 9.0 µA current source. The buffer allows the Error Amplifier output to follow the soft–start capacitor until it is regulated by the Error Amplifier inputs. The soft–start function is generally applicable to controllers operating below resonance and can be disabled by simply opening the $C_{Soft–Start}$ terminal.

APPLICATIONS INFORMATION

The MC34067 is specifically designed for zero voltage switching (ZVS) quasi–resonant converter (QRC) applications. The IC is optimized for double–ended push–pull or bridge type converters operating in continuous conduction mode. Operation of this type of ZVS with resonant properties is similar to standard push–pull or bridge circuits in that the energy is transferred during the transistor on–time. The difference is that a series resonant tank is usually introduced to shape the voltage across the power transistor prior to turn–on. The resonant tank in this topology is not used to deliver energy to the output as is the case with zero current switch topologies. When the power transistor is enabled the voltage across it should already be zero, yielding minimal switching loss. Figure 19 shows a timing diagram for a half–bridge ZVS QRC. An application circuit is shown in Figure 20. The circuit built is a dc to dc half–bridge converter delivering 75 W to the output from a 48 V source.

When building a zero voltage switch (ZVS) circuit, the objective is to waveshape the power transistor's voltage waveform so that the voltage across the transistor is zero when the device is turned on. The purpose of the control IC is to allow a resonant tank to waveshape the voltage across the power transistor while still maintaining regulation. This is accomplished by maintaining a fixed deadtime and by varying the frequency; thus the effective duty cycle is changed.

Primary side resonance can be used with ZVS circuits. In the application circuit, the elements that make the resonant tank are the primary leakage inductance of the transformer (L_L) and the average output capacitance (C_{OSS}) of a power MOSFET (C_R). The desired resonant frequency for the application circuit is calculated by Equation 6:

$$f_r = \frac{1}{2\pi\sqrt{L_L\,2C_R}} \qquad (6)$$

In the application circuit, the operating voltage is low and the value of C_{OSS} versus Drain Voltage is known. Because the C_{OSS} of a MOSFET changes with drain voltage, the value of the C_R is approximated as the average C_{OSS} of the MOSFET. For the application circuit the average C_{OSS} can be calculated by Equation 7:

$$C_R = \sqrt{2} * C_{OSS} \text{ measured at } \frac{1}{2} V_{in} \qquad (7)$$

The MOSFET chosen fixes C_R and that L_L is adjusted to achieve the desired resonant frequency.

However, the desired resonant frequency is less critical than the leakage inductance. Figure 19 shows the primary current ramping toward its peak value during the resonant transition. During this time, there is circulating current flowing through the secondary inductance, which effectively makes the primary inductance appear shorted. Therefore, the current through the primary will ramp to its peak value at a rate controlled by the leakage inductance and the applied voltage. Energy is not transferred to the secondary during this stage, because the primary current has not overcome the circulating current in the secondary. The larger the leakage inductance, the longer it takes for the primary current to slew. The practical effect of this is to lower the duty cycle, thus reducing the operating range.

The maximum duty cycle is controlled by the leakage inductance, not by the MC34067. The One–Shot in the MC34067 only assures that the power switch is turned on under a zero voltage condition. Adjust the one–shot period so that the output switch is activated while the primary current is slewing but before the current changes polarity. The resonant stage should then be designed to be as long as the time for the primary current to go to zero amps.

MOTOROLA

MC34129
MC33129

High Performance Current Mode Controllers

The MC34129/MC33129 are high performance current mode switching regulators specifically designed for use in low power digital telephone applications. These integrated circuits feature a unique internal fault timer that provides automatic restart for overload recovery. For enhanced system efficiency, a start/run comparator is included to implement bootstrapped operation of V_{CC}. Other functions contained are a temperature compensated reference, reference amplifier, fully accessible error amplifier, sawtooth oscillator with sync input, pulse width modulator comparator, and a high current totem pole driver ideally suited for driving a power MOSFET.

Also included are protective features consisting of soft–start, undervoltage lockout, cycle–by–cycle current limiting, adjustable deadtime, and a latch for single pulse metering.

Although these devices are primarily intended for use in digital telephone systems, they can be used cost effectively in many other applications.

- Current Mode Operation to 300 kHz
- Automatic Feed Forward Compensation
- Latching PWM for Cycle–by–Cycle Current Limiting
- Continuous Retry after Fault Timeout
- Soft–Start with Maximum Peak Switch Current Clamp
- Internally Trimmed 2% Bandgap Reference
- High Current Totem Pole Driver
- Input Undervoltage Lockout
- Low Startup and Operating Current
- Direct Interface with Motorola SENSEFET Products

PIN FUNCTION DESCRIPTION

Pin	Function	Description
1	Drive Output	This output directly drives the gate of a power MOSFET. Peak currents up to 1.0 A are sourced and sinked by this pin.
2	Drive Ground	This pin is a separate power ground return that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry.
3	Ramp Input	A voltage proportional to the inductor current is connected to this input. The PWM uses this information to terminate output switch conduction.
4	Sync/Inhibit Input	A rectangular waveform applied to this input will synchronize the Oscillator and limit the maximum Drive Output duty cycle. A dc voltage within the range of 2.0 V to V_{CC} will inhibit the controller.
5	R_T/C_T	The free–running Oscillator frequency and maximum Drive Output duty cycle are programmed by connecting resistor R_T to V_{ref} 2.5 V and capacitor C_T to Ground. Operation to 300 kHz is possible.
6	V_{ref} 2.50 V	This output is derived from V_{ref} 1.25 V. It provides charging current for capacitor C_T through resistor R_T.
7	Ground	This pin is the control circuitry ground return and is connected back to the source ground.
8	V_{ref} 1.25 V	This output furnishes a voltage reference for the Error Amplifier noninverting input.
9	Error Amp Noninverting Input	This is the noninverting input of the Error Amplifier. It is normally connected to the 1.25 V reference.
10	Error Amp Inverting Input	This is the inverting input of the Error Amplifier. It is normally connected to the switching power supply output through a resistor divider.
11	Feedback/PWM Input	This pin is available for loop compensation. It is connected to the Error Amplifier and Soft–Start Buffer outputs, and the Pulse Width Modulator input.
12	$C_{Soft–Start}$	A capacitor $C_{Soft–Start}$ is connected from this pin to Ground for a controlled ramp–up of peak inductor current during startup.
13	Start/Run Output	This output controls the state of an external bootstrap transistor. During the start mode, operating bias is supplied by the transistor from V_{in}. In the run mode, the transistor is switched off and bias is supplied by an auxiliary power transformer winding.
14	V_{CC}	This pin is the positive supply of the control IC. The controller is functional over a minimum V_{CC} range of 4.2 V to 12 V.

OPERATING DESCRIPTION

The MC34129 series are high performance current mode switching regulator controllers specifically designed for use in low power telecommunication applications. Implementation will allow remote digital telephones and terminals to shed their power cords and derive operating power directly from the twisted pair used for data transmission. Although these devices are primarily intended for use in digital telephone systems, they can be used cost effectively in a wide range of converter applications. A representative block diagram is shown in Figure 18.

Oscillator

The oscillator frequency is programmed by the values selected for the timing components R_T and C_T. Capacitor C_T is charged from the 2.5 V reference through resistor R_T to approximately 1.25 V and discharged by an internal current sink to ground. During the discharge of C_T, the oscillator generates an internal blanking pulse that holds the lower input of the NOR gate high. This causes the Drive Output to be in a low state, thus producing a controlled amount of output deadtime. Figure 1 shows Oscillator Frequency versus R_T and Figure 2 Output Deadtime versus Frequency, both for given values of C_T. Note that many values of R_T and C_T will give the same oscillator frequency but only one combination will yield a specific output deadtime at a give frequency. In many noise sensitive applications it may be desirable to frequency–lock one or more switching regulators to an external system clock. This can be accomplished by applying the clock signal to the Synch/Inhibit Input. For reliable locking, the free–running oscillator frequency should be about 10% less than the clock frequency. Referring to the timing diagram shown Figure 19, the rising edge of the clock signal applied to the Sync/Inhibit Input, terminates charging of C_T and Drive Output conduction. By tailoring the clock waveform, accurate duty cycle clamping of the Drive Output can be achieved. A circuit method is shown in Figure 20. The Sync/Inhibit Input may also be used as a means for system shutdown by applying a dc voltage that is within the range of 2.0 V to V_{CC}.

PWM Comparator and Latch

The MC34129 operates as a current mode controller whereby output switch conduction is initiated by the oscillator and terminated when the peak inductor current reaches a threshold level established by the output of the Error Amp or Soft–Start Buffer (Pin 11). Thus the error signal controls the peak inductor current on a cycle–by–cycle basis. The PWM Comparator–Latch configuration used, ensures that only a single pulse appears at the Drive Output during any given oscillator cycle. The inductor current is converted to a voltage by inserting the ground–referenced resistor R_S in series with the source of output switch Q_1. The Ramp Input adds an offset of 275 mV to this voltage to guarantee that no pulses appear at the Drive Output when Pin 11 is at its lowest state. This occurs at the beginning of the soft–start interval or when the power supply is operating and the load is removed. The peak inductor current under normal operating conditions is controlled by the voltage at Pin 11 where:

$$I_{pk} = \frac{V_{(Pin\ 11)} - 0.275\ V}{R_S}$$

Abnormal operating conditions occur when the power supply output is overloaded or if output voltage sensing is lost. Under these conditions, the voltage at Pin 11 will be internally clamped to 1.95 V by the output of the Soft–Start Buffer. Therefore the maximum peak switch current is:

$$I_{pk(max)} = \frac{1.95\ V - 0.275}{R_S} = \frac{1.675\ V}{R_S}$$

When designing a high power switching regulator it becomes desirable to reduce the internal clamp voltage in order to keep the power dissipation of R_S to a reasonable level. A simple method which adjusts this voltage in discrete increments is shown in Figure 22. This method is possible because the Ramp Input bias current is always negative (typically –120 μA). A positive temperature coefficient equal to that of the diode string will be exhibited by $I_{pk(max)}$. An adjustable method that is more precise and temperature stable is shown in Figure 23. Erratic operation due to noise pickup can result if there is an excessive reduction of the clamp voltage. In this situation, high frequency circuit layout techniques are imperative.

A narrow spike on the leading edge of the current waveform can usually be observed and may cause the power supply to exhibit an instability when the output is lightly loaded. This spike is due to the power transformer interwinding capacitance and output rectifier recovery time. The addition of an RC filter on the Ramp Input with a time constant that approximates the spike duration will usually eliminate the instability; refer to Figure 25.

Error Amp and Soft–Start Buffer

A fully–compensated Error Amplifier with access to both inputs and output is provided for maximum design flexibility. The Error Amplifier output is common with that of the Soft–Start Buffer. These outputs are open–collector (sink only) and are ORed together at the inverting input of the PWM Comparator. With this configuration, the amplifier that demands lower peak inductor current dominates control of the loop. Soft–Start is mandatory for stable startup when power is provided through a high source impedance such as the long twisted pair used in telecommunications. It effectively removes the load from the output of the switching power supply upon initial startup. The Soft–Start Buffer is configured as a unity gain follower with the noninverting input connected to Pin 12. An internal 1.0 μA current source charges the soft–start capacitor ($C_{Soft–Start}$) to an internally clamped level of 1.95 V. The rate of change of peak inductor current, during startup, is programmed by the capacitor value selected. Either the Fault Timer or the Undervoltage Lockout can discharge the soft–start capacitor.

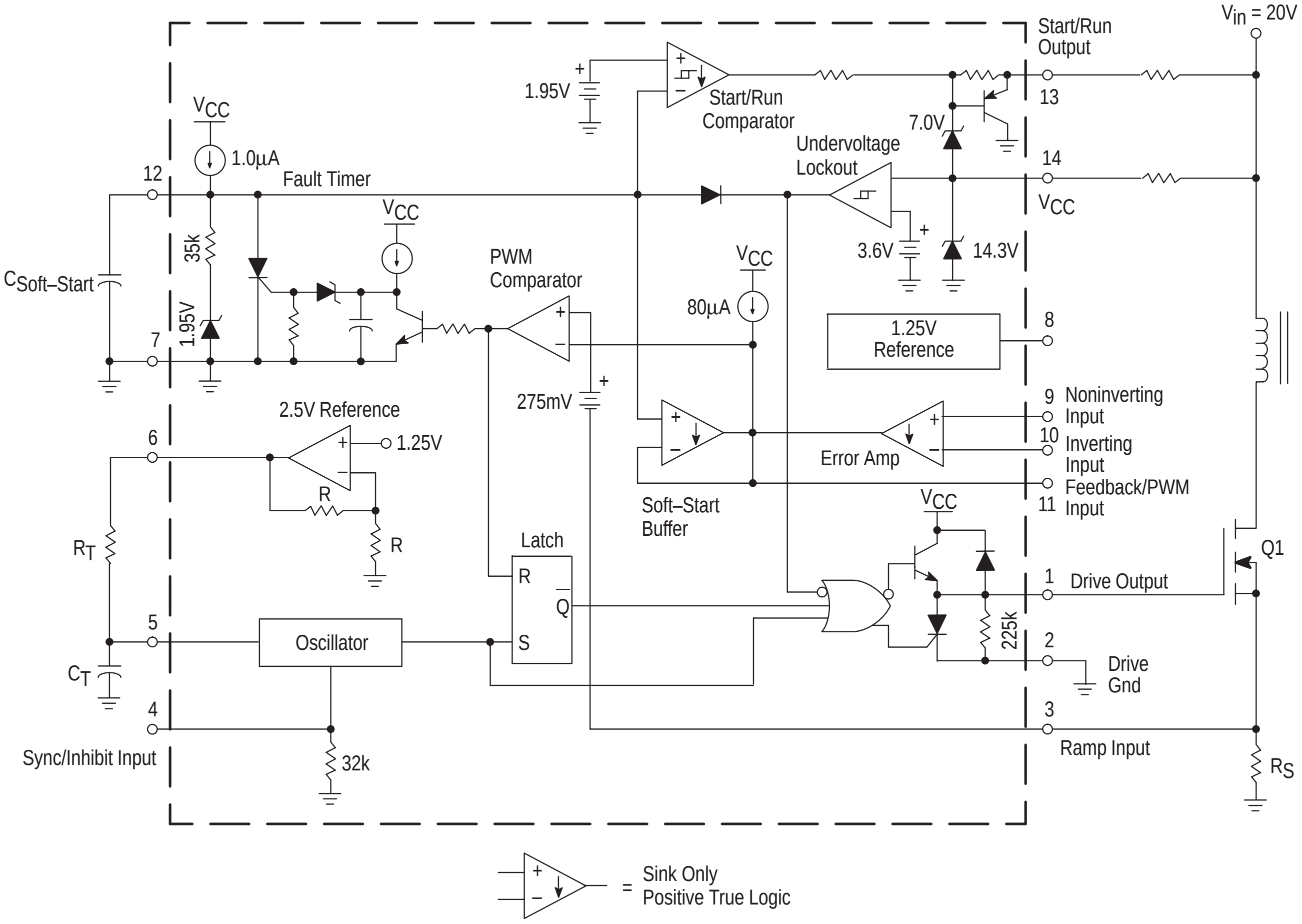

Figure 18. Representative Block Diagram

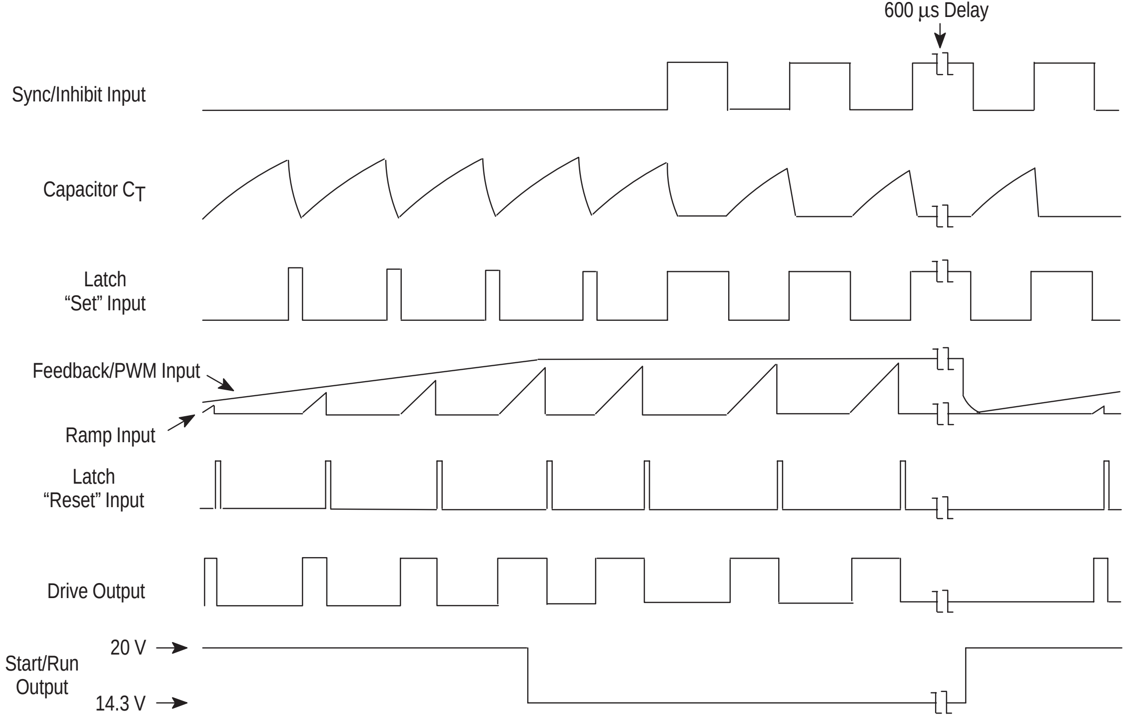

Figure 19. Timing Diagram

Fault Timer

This unique circuit prevents sustained operating in a lockout condition. This can occur with conventional switching control ICs when operating from a power source with a high series impedance. If the power required by the load is greater than that available from the source, the input voltage will collapse, causing the lockout condition. The Fault Timer provides automatic recovery when this condition is detected. Under normal operating conditions, the output of the PWM Comparator will reset the Latch and discharge the internal Fault Timer capacitor on a cycle–by–cycle basis. Under operating conditions where the required power into the load is greater than that available from the source (V_{in}), the Ramp Input voltage (plus offset) will not reach the comparator threshold level (Pin 11), and the output of the PWM Comparator will remain low. If this condition persists for more that 600 µs, the Fault Timer will active, discharging $C_{Soft–Start}$ and initiating a soft–start cycle. The power supply will operate in a skip cycle or hiccup mode until either the load power or source impedance is reduced. The minimum fault timeout is 200 µs, which limits the useful switching frequency to a minimum of 5.0 kHz.

Start/Run Comparator

A bootstrap startup circuit is included to improve system efficiency when operating from a high input voltage. The output of the Start/Run Comparator controls the state of an external transistor. A typical application is shown in Figure 21. While $C_{Soft–Start}$ is charging, startup bias is supplied to V_{CC} (Pin 14) from V_{in} through transistor Q2. When $C_{Soft–Start}$ reaches the 1.95 V clamp level, the Start–Run output switches low (V_{CC} = 50 mV), turning off Q2. Operating bias is now derived from the auxiliary bootstrap winding of the transformer, and all drive power is efficiently converted down from V_{in}. The start time must be long enough for the power supply output to reach regulation. This will ensure that there is sufficient bias voltage at the auxiliary bootstrap winding for sustained operation.

$$t_{Start} = \frac{1.95VC_{Soft–Start}}{1.0\ \mu A} = 1.95\ C_{Soft–Start} \text{ in } \mu F$$

The Start/Run Comparator has 350 mV of hysteresis. The output off–state is clamped to V_{CC} + 7.6 V by the internal zener and PNP transistor base–emitter junction.

Drive Output and Drive Ground

The MC34129 contains a single totem–pole output stage that was specifically designed for direct drive of power MOSFETs. It is capable of up to ±1.0 A peak drive current and has a typical fall time of 30 ns with a 500 pF load. The totem–pole stage consists of an NPN transistor for turn–on drive and a high speed SCR for turn–off. The SCR design requires less average supply current (I_{CC}) when compared to conventional switching control ICs that use an all NPN totem–pole. The SCR accomplishes this during turn–off of the MOSFET, by utilizing the gate charge as regenerative on–bias, whereas the conventional all transistor design requires continuous base current. Conversion efficiency in low power applications is greatly enhanced with this reduction of I_{CC}. The SCR's low–state holding current (I_H) is typically 225 µA. An internal 225 kΩ pull–down resistor is included to shunt the Drive Output off–state leakage to ground when the Undervoltage Lockout is active. A separate Drive Ground is provided to reduce the effects of switching transient noise imposed on the Ramp Input. This feature becomes particularly useful when the $I_{pk(max)}$ clamp level is reduced. Figure 24 shows the proper implementation of the MC34129 with a current sensing power MOSFET.

Undervoltage Lockout

The Undervoltage Lockout comparator holds the Drive Output and $C_{Soft–Start}$ pins in the low state when V_{CC} is less than 3.6 V. This ensures that the MC34129 is fully functional before the output stage is enabled and a soft–start cycle begins. A built–in hysteresis of 350 mV prevents erratic output behavior as V_{CC} crosses the comparator threshold voltage. A 14.3 V zener is connected as a shunt regulator from V_{CC} to ground. Its purpose is to protect the MOSFET gate from excessive drove voltage during system startup. An external 9.1 V zener is required when driving low threshold MOSFETs. Refer to Figure 21. The minimum operating voltage range of the IC is 4.2 V to 12 V.

References

The 1.25 V bandgap reference is trimmed to ±2.0% tolerance at T_A = 25°C. It is intended to be used in conjunction with the Error Amp. The 2.50 V reference is derived from the 1.25 V reference by an internal op amp with a fixed gain of 2.0. It has an output tolerance of ±5.0% at T_A = 25°C and its primary purpose is to supply charging current to the oscillator timing capacitor.

MC33151

High Speed Dual MOSFET Drivers

The MC34151/MC33151 are dual inverting high speed drivers specifically designed for applications that require low current digital circuitry to drive large capacitive loads with high slew rates. These devices feature low input current making them CMOS and LSTTL logic compatible, input hysteresis for fast output switching that is independent of input transition time, and two high current totem pole outputs ideally suited for driving power MOSFETs. Also included is an undervoltage lockout with hysteresis to prevent erratic system operation at low supply voltages.

Typical applications include switching power supplies, dc to dc converters, capacitor charge pump voltage doublers/inverters, and motor controllers.

These devices are available in dual–in–line and surface mount packages.

- Two Independent Channels with 1.5 A Totem Pole Output
- Output Rise and Fall Times of 15 ns with 1000 pF Load
- CMOS/LSTTL Compatible Inputs with Hysteresis
- Undervoltage Lockout with Hysteresis
- Low Standby Current
- Efficient High Frequency Operation
- Enhanced System Performance with Common Switching Regulator Control ICs
- Pin Out Equivalent to DS0026 and MMH0026

APPLICATIONS INFORMATION

Description

The MC34151 is a dual inverting high speed driver specifically designed to interface low current digital circuitry with power MOSFETs. This device is constructed with Schottky clamped Bipolar Analog technology which offers a high degree of performance and ruggedness in hostile industrial environments.

Input Stage

The Logic Inputs have 170 mV of hysteresis with the input threshold centered at 1.67 V. The input thresholds are insensitive to V_{CC} making this device directly compatible with CMOS and LSTTL logic families over its entire operating voltage range. Input hysteresis provides fast output switching that is independent of the input signal transition time, preventing output oscillations as the input thresholds are crossed. The inputs are designed to accept a signal amplitude ranging from ground to V_{CC}. This allows the output of one channel to directly drive the input of a second channel for master–slave operation. Each input has a 30 kΩ pull–down resistor so that an unconnected open input will cause the associated Drive Output to be in a known high state.

Output Stage

Each totem pole Drive Output is capable of sourcing and sinking up to 1.5 A with a typical 'on' resistance of 2.4 Ω at 1.0 A. The low 'on' resistance allows high output currents to be attained at a lower V_{CC} than with comparative CMOS drivers. Each output has a 100 kΩ pull–down resistor to keep the MOSFET gate low when V_{CC} is less than 1.4 V. No over current or thermal protection has been designed into the device, so output shorting to V_{CC} or ground must be avoided.

Parasitic inductance in series with the load will cause the driver outputs to ring above V_{CC} during the turn–on transition, and below ground during the turn–off transition. With CMOS drivers, this mode of operation can cause a destructive output latch–up condition. The MC34151 is immune to output latch–up. The Drive Outputs contain an internal diode to V_{CC} for clamping positive voltage transients. When operating with V_{CC} at 18 V, proper power supply bypassing must be observed to prevent the output ringing from exceeding the maximum 20 V device rating. Negative output transients are clamped by the internal NPN pull–up transistor. Since full supply voltage is applied across the NPN pull–up during the negative output transient, power dissipation at high frequencies can become excessive. Figures 19, 20, and 21 show a method of using external Schottky diode clamps to reduce driver power dissipation.

Undervoltage Lockout

An undervoltage lockout with hysteresis prevents erratic system operation at low supply voltages. The UVLO forces the Drive Outputs into a low state as V_{CC} rises from 1.4 V to the 5.8 V upper threshold. The lower UVLO threshold is 5.3 V, yielding about 500 mV of hysteresis.

Power Dissipation

Circuit performance and long term reliability are enhanced with reduced die temperature. Die temperature increase is directly related to the power that the integrated circuit must dissipate and the total thermal resistance from the junction to ambient. The formula for calculating the junction temperature with the package in free air is:

$T_J = T_A + P_D\,(R_{\theta JA})$

where: T_J = Junction Temperature
T_A = Ambient Temperature
P_D = Power Dissipation
$R_{\theta JA}$ = Thermal Resistance Junction to Ambient

There are three basic components that make up total power to be dissipated when driving a capacitive load with respect to ground. They are:

$P_D = P_Q + P_C + P_T$

where: P_Q = Quiescent Power Dissipation
P_C = Capacitive Load Power Dissipation
P_T = Transition Power Dissipation

The quiescent power supply current depends on the supply voltage and duty cycle as shown in Figure 16. The device's quiescent power dissipation is:

$$P_Q = V_{CC}\left(I_{CCL}\,(1–D) + I_{CCH}\,(D)\right)$$

where: I_{CCL} = Supply Current with Low State Drive Outputs
I_{CCH} = Supply Current with High State Drive Outputs
D = Output Duty Cycle

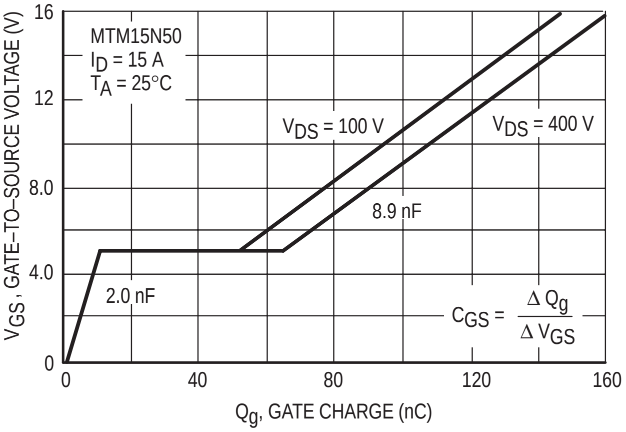
The capacitive load power dissipation is directly related to the load capacitance value, frequency, and Drive Output voltage swing. The capacitive load power dissipation per driver is:

$P_C = V_{CC}\,(V_{OH} – V_{OL})\,C_L\,f$

where: V_{OH} = High State Drive Output Voltage
V_{OL} = Low State Drive Output Voltage
C_L = Load Capacitance
f = frequency

When driving a MOSFET, the calculation of capacitive load power P_C is somewhat complicated by the changing gate to source capacitance C_{GS} as the device switches. To aid in this calculation, power MOSFET manufacturers provide gate charge information on their data sheets. Figure 17 shows a curve of gate voltage versus gate charge for the Motorola MTM15N50. Note that there are three distinct slopes to the curve representing different input capacitance values. To completely switch the MOSFET 'on', the gate must be brought to 10 V with respect to the source. The graph shows that a gate charge Q_g of 110 nC is required when operating the MOSFET with a drain to source voltage V_{DS} of 400 V.

Figure 17. Gate–To–Source Voltage versus Gate Charge



The capacitive load power dissipation is directly related to the required gate charge, and operating frequency. The capacitive load power dissipation per driver is:

$P_{C(MOSFET)} = V_C\,Q_g\,f$

The flat region from 10 nC to 55 nC is caused by the drain–to–gate Miller capacitance, occuring while the MOSFET is in the linear region dissipating substantial amounts of power. The high output current capability of the MC34151 is able to quickly deliver the required gate charge for fast power efficient MOSFET switching. By operating the MC34151 at a higher V_{CC}, additional charge can be provided to bring the gate above 10 V. This will reduce the 'on' resistance of the MOSFET at the expense of higher driver dissipation at a given operating frequency.

The transition power dissipation is due to extremely short simultaneous conduction of internal circuit nodes when the Drive Outputs change state. The transition power dissipation per driver is approximately:

$P_T \approx V_{CC}\,(1.08\,V_{CC}\,C_L\,f – 8 \times 10^{–4})$
P_T must be greater than zero.

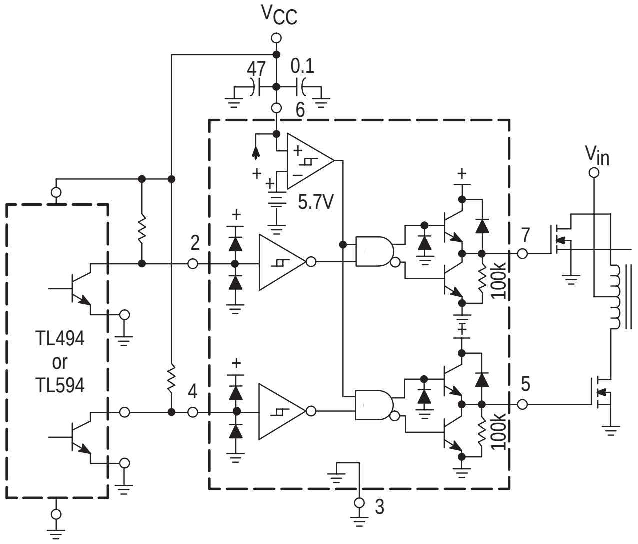
Switching time characterization of the MC34151 is performed with fixed capacitive loads. Figure 13 shows that for small capacitance loads, the switching speed is limited by transistor turn–on/off time and the slew rate of the internal nodes. For large capacitance loads, the switching speed is limited by the maximum output current capability of the integrated circuit.

LAYOUT CONSIDERATIONS

High frequency printed circuit layout techniques are imperative to prevent excessive output ringing and overshoot. **Do not attempt to construct the driver circuit on wire–wrap or plug–in prototype boards.** When driving large capacitive loads, the printed circuit board must contain a low inductance ground plane to minimize the voltage spikes induced by the high ground ripple currents. All high current loops should be kept as short as possible using heavy copper runs to provide a low impedance high frequency path. For optimum drive performance, it is recommended that the initial circuit design contains dual power supply bypass capacitors connected with short leads as close to the V_{CC} pin and ground as the layout will permit. Suggested capacitors are a low inductance 0.1 µF ceramic in parallel with a 4.7 µF tantalum. Additional bypass capacitors may be required depending upon Drive Output loading and circuit layout.

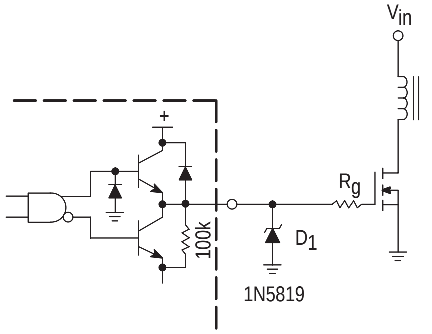
Proper printed circuit board layout is extremely critical and cannot be over emphasized.

Figure 18. Enhanced System Performance with Common Switching Regulators



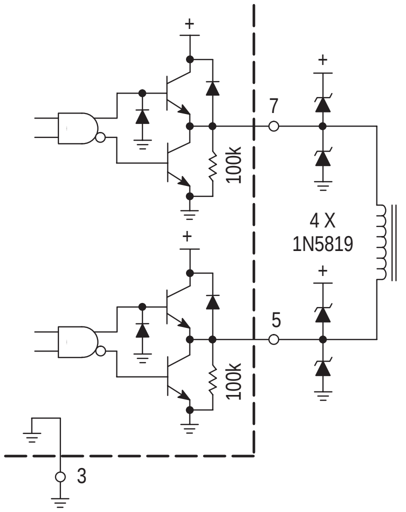
The MC34151 greatly enhances the drive capabilities of common switching regulators and CMOS/TTL logic devices.

Figure 19. MOSFET Parasitic Oscillations



Series gate resistor R_g may be needed to damp high frequency parasitic oscillations caused by the MOSFET input capacitance and any series wiring inductance in the gate–source circuit. R_g will decrease the MOSFET switching speed. Schottky diode D_1 can reduce the driver's power dissipation due to excessive ringing, by preventing the output pin from being driven below ground.

Figure 20. Direct Transformer Drive



Output Schottky diodes are recommended when driving inductive loads at high frequencies. The diodes reduce the driver's power dissipation by preventing the output pins from being driven above V_{CC} and below ground.

Figure 21. Isolated MOSFET Drive

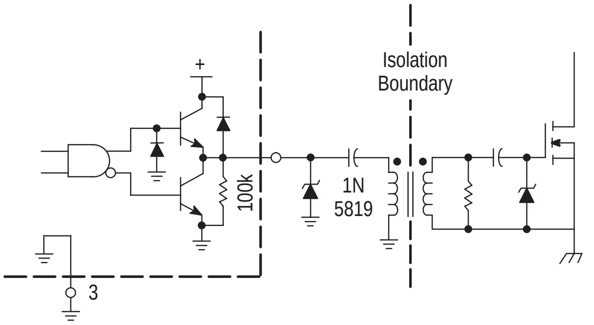


Figure 22. Controlled MOSFET Drive

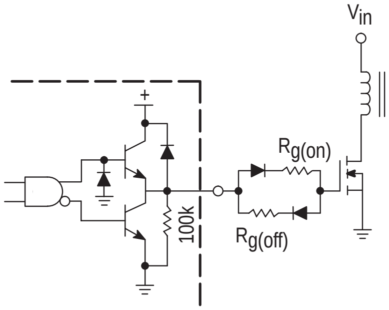
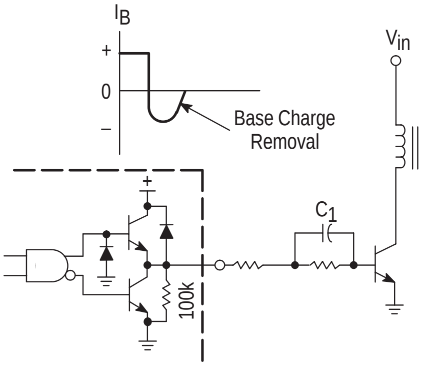


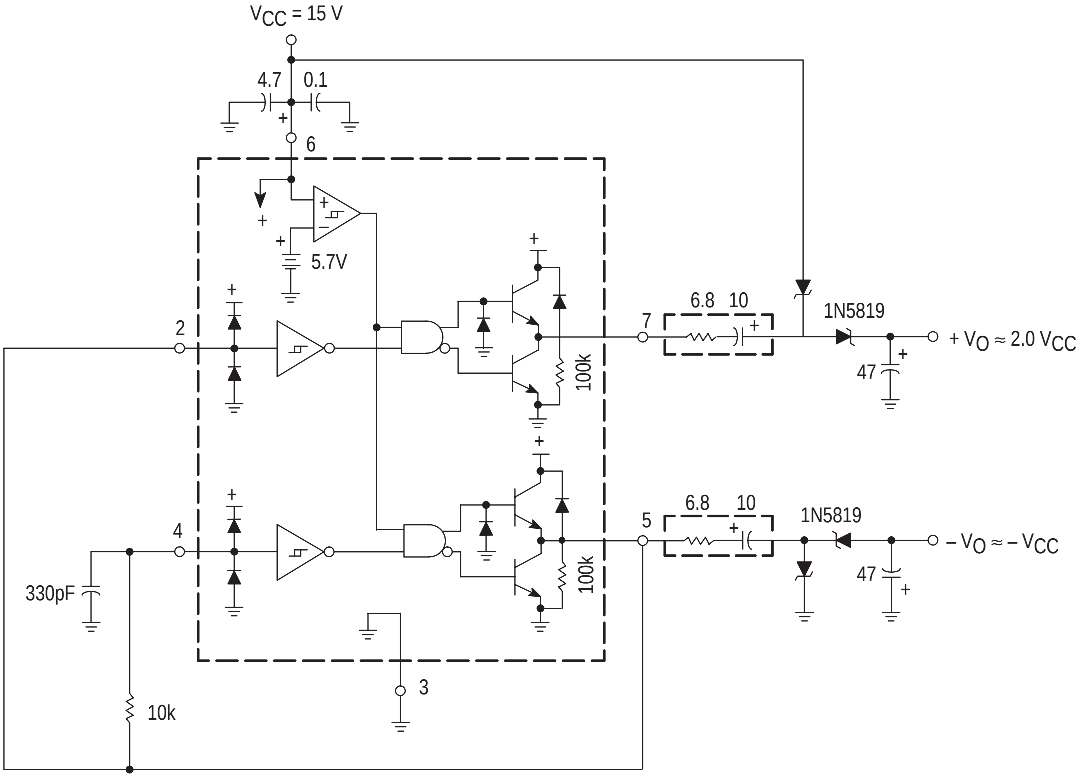
In noise sensitive applications, both conducted and radiated EMI can be reduced significantly by controlling the MOSFET's turn–on and turn–off times.

Figure 23. Bipolar Transistor Drive



The totem–pole outputs can furnish negative base current for enhanced transistor turn–off, with the addition of capacitor C_1.

Figure 24. Dual Charge Pump Converter



The capacitor's equivalent series resistance limits the Drive Output Current to 1.5 A. An additional series resistor may be required when using tantalum or other low ESR capacitors.

High Speed Dual MOSFET Drivers

The MC34152/MC33152 are dual noninverting high speed drivers specifically designed for applications that require low current digital signals to drive large capacitive loads with high slew rates. These devices feature low input current making them CMOS/LSTTL logic compatible, input hysteresis for fast output switching that is independent of input transition time, and two high current totem pole outputs ideally suited for driving power MOSFETs. Also included is an undervoltage lockout with hysteresis to prevent system erratic operation at low supply voltages.

Typical applications include switching power supplies, dc–to–dc converters, capacitor charge pump voltage doublers/inverters, and motor controllers.

This device is available in dual–in–line and surface mount packages.

- Two Independent Channels with 1.5 A Totem Pole Outputs
- Output Rise and Fall Times of 15 ns with 1000 pF Load
- CMOS/LSTTL Compatible Inputs with Hysteresis
- Undervoltage Lockout with Hysteresis
- Low Standby Current
- Efficient High Frequency Operation
- Enhanced System Performance with Common Switching Regulator Control ICs

APPLICATIONS INFORMATION

Description

The MC34152 is a dual noninverting high speed driver specifically designed to interface low current digital circuitry with power MOSFETs. This device is constructed with Schottky clamped Bipolar Analog technology which offers a high degree of performance and ruggedness in hostile industrial environments.

Input Stage

The Logic Inputs have 170 mV of hysteresis with the input threshold centered at 1.67 V. The input thresholds are insensitive to V_{CC} making this device directly compatible with CMOS and LSTTL logic families over its entire operating voltage range. Input hysteresis provides fast output switching that is independent of the input signal transition time, preventing output oscillations as the input thresholds are crossed. The inputs are designed to accept a signal amplitude ranging from ground to V_{CC}. This allows the output of one channel to directly drive the input of a second channel for master–slave operation. Each input has a 30 kΩ pull–down resistor so that an unconnected open input will cause the associated Drive Output to be in a known low state.

Output Stage

Each totem pole Drive Output is capable of sourcing and sinking up to 1.5 A with a typical 'on' resistance of 2.4 Ω at 1.0 A. The low 'on' resistance allows high output currents to be attained at a lower V_{CC} than with comparative CMOS drivers. Each output has a 100 kΩ pull–down resistor to keep the MOSFET gate low when V_{CC} is less than 1.4 V. No over current or thermal protection has been designed into the device, so output shorting to V_{CC} or ground must be avoided.

Parasitic inductance in series with the load will cause the driver outputs to ring above V_{CC} during the turn–on transition, and below ground during the turn–off transition. With CMOS drivers, this mode of operation can cause a destructive output latch–up condition. The MC34152 is immune to output latch–up. The Drive Outputs contain an internal diode to V_{CC} for clamping positive voltage transients. When operating with V_{CC} at 18 V, proper power supply bypassing must be observed to prevent the output ringing from exceeding the maximum 20 V device rating. Negative output transients are clamped by the internal NPN pull–up transistor. Since full supply voltage is applied across the NPN pull–up during the negative output transient, power dissipation at high frequencies can become excessive. Figures 19, 20, and 21 show a method of using external Schottky diode clamps to reduce driver power dissipation.

Undervoltage Lockout

An undervoltage lockout with hysteresis prevents erratic system operation at low supply voltages. The UVLO forces the Drive Outputs into a low state as V_{CC} rises from 1.4 V to the 5.8 V upper threshold. The lower UVLO threshold is 5.3 V, yielding about 500 mV of hysteresis.

Power Dissipation

Circuit performance and long term reliability are enhanced with reduced die temperature. Die temperature increase is directly related to the power that the integrated circuit must dissipate and the total thermal resistance from the junction to ambient. The formula for calculating the junction temperature with the package in free air is:

$$T_J = T_A + P_D (R_{\theta JA})$$

where: T_J = Junction Temperature
T_A = Ambient Temperature
P_D = Power Dissipation
$R_{\theta JA}$ = Thermal Resistance Junction to Ambient

There are three basic components that make up total power to be dissipated when driving a capacitive load with respect to ground. They are:

$$P_D = P_Q + P_C + P^T$$

where: P_Q = Quiescent Power Dissipation
P_C = Capacitive Load Power Dissipation
P_T = Transition Power Dissipation

The quiescent power supply current depends on the supply voltage and duty cycle as shown in Figure 16. The device's quiescent power dissipation is:

$$P_Q = V_{CC} (I_{CCL} [1–D] + I_{CCH} [D])$$

where: I_{CCL} = Supply Current with Low State Drive Outputs
I_{CCH} = Supply Current with High State Drive Outputs
D = Output Duty Cycle

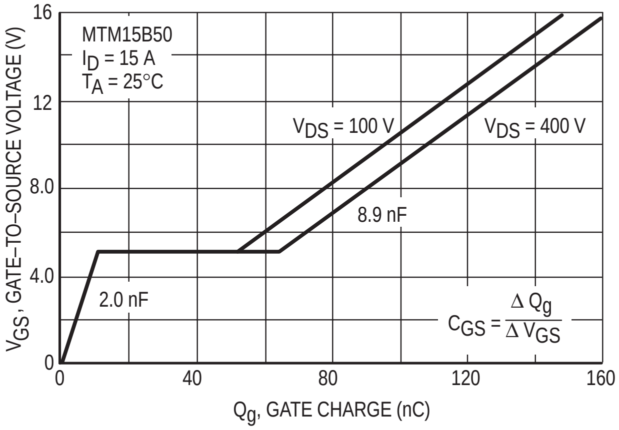
The capacitive load power dissipation is directly related to the load capacitance value, frequency, and Drive Output voltage swing. The capacitive load power dissipation per driver is:

$$P_C = V_{CC} (V_{OH} – V_{OL}) C_L f$$

where: V_{OH} = High State Drive Output Voltage
V_{OL} = Low State Drive Output Voltage
C_L = Load Capacitance
f = Frequency

When driving a MOSFET, the calculation of capacitive load power P_C is somewhat complicated by the changing gate to source capacitance C_{GS} as the device switches. To aid in this calculation, power MOSFET manufacturers provide gate charge information on their data sheets. Figure 17 shows a curve of gate voltage versus gate charge for the Motorola MTM15N50. Note that there are three distinct slopes to the curve representing different input capacitance values. To completely switch the MOSFET 'on,' the gate must be brought to 10 V with respect to the source. The graph shows that a gate charge Q_g of 110 nC is required when operating the MOSFET with a drain to source voltage V_{DS} of 400 V.

Figure 17. Gate–to–Source Voltage versus Gate charge



The capacitive load power dissipation is directly related to the required gate charge, and operating frequency. The capacitive load power dissipation per driver is:

$$P_{C(MOSFET)} = V_{CC}\ Q_g\ f$$

The flat region from 10 nC to 55 nC is caused by the drain–to–gate Miller capacitance, occurring while the MOSFET is in the linear region dissipating substantial amounts of power. The high output current capability of the MC34152 is able to quickly deliver the required gate charge for fast power efficient MOSFET switching. By operating the MC34152 at a higher V_{CC}, additional charge can be provided to bring the gate above 10 V. This will reduce the 'on' resistance of the MOSFET at the expense of higher driver dissipation at a given operating frequency.

The transition power dissipation is due to extremely short simultaneous conduction of internal circuit nodes when the Drive Outputs change state. The transition power dissipation per driver is approximately:

$$P_T \approx V_{CC} (1.08\ V_{CC}\ C_L\ f – 8 \times 10^{–4})$$

P_T must be greater than zero.

Switching time characterization of the MC34152 is performed with fixed capacitive loads. Figure 13 shows that for small capacitance loads, the switching speed is limited by transistor turn–on/off time and the slew rate of the internal nodes. For large capacitance loads, the switching speed is limited by the maximum output current capability of the integrated circuit.

LAYOUT CONSIDERATIONS

High frequency printed circuit layout techniques are imperative to prevent excessive output ringing and overshoot. **Do not attempt to construct the driver circuit on wire–wrap or plug–in prototype boards.** When driving large capacitive loads, the printed circuit board must contain a low inductance ground plane to minimize the voltage spikes induced by the high ground ripple currents. All high current loops should be kept as short as possible using heavy copper runs to provide a low impedance high frequency path. For optimum drive performance, it is recommended that the initial circuit design contains dual power supply bypass capacitors connected with short leads as close to the V_{CC} pin and ground as the layout will permit. Suggested capacitors are a low inductance 0.1 µF ceramic in parallel with a 4.7 µF tantalum. Additional bypass capacitors may be required depending upon Drive Output loading and circuit layout.

Proper printed circuit board layout is extremely critical and cannot be over emphasized.

MC33160

Microprocessor Voltage Regulator and Supervisory Circuit

The MC34160 Series is a voltage regulator and supervisory circuit containing many of the necessary monitoring functions required in microprocessor based systems. It is specifically designed for appliance and industrial applications, offering the designer a cost effective solution with minimal external components. These integrated circuits feature a 5.0 V/100 mA regulator with short circuit current limiting, pinned out 2.6 V bandgap reference, low voltage reset comparator, power warning comparator with programmable hysteresis, and an uncommitted comparator ideally suited for microprocessor line synchronization.

Additional features include a chip disable input for low standby current, and internal thermal shutdown for over temperature protection.

These devices are contained in a 16 pin dual–in–line heat tab plastic package for improved thermal conduction.

- 5.0 V Regulator Output Current in Excess of 100 mA
- Internal Short Circuit Current Limiting
- Pinned Out 2.6 V Reference
- Low Voltage Reset Comparator
- Power Warning Comparator with Programmable Hysteresis
- Uncommitted Comparator
- Low Standby Current
- Internal Thermal Shutdown Protection
- Heat Tab Power Package

PIN FUNCTION DESCRIPTION

Pin	Function	Description
1	Comparator Inverting Input	This is the Uncommitted Comparator Inverting input. It is typically connected to a resistor divider to monitor a voltage.
2	Comparator Noninverting Input	This is the Uncommitted Comparator Noninverting input. It is typically connected to a reference voltage.
3	N.C.	No connection. This pin is not internally connected.
4, 5, 12, 13	Gnd	These pins are the control circuit grounds and are connected to the source and load ground returns. They are part of the IC lead frame and can be used for heatsinking.
6	Comparator Output	This is the Uncommitted Comparator output. It is an open collector sink–only output requiring a pull–up resistor.
7	Reset	This is the Reset Comparator output. It is an open collector sink–only output requiring a pull–up resistor.
8	Power Warning	This is the Power Warning Comparator output. It is an open collector sink–only output requiring a pull–up resistor.
9	Power Sense	This is the Power Warning Comparator noninverting input. It is typically connected to a resistor divider to monitor the input power source voltage.
10	Hysteresis Adjust	The Power Warning Comparator hysteresis is programmed by a resistor connected from this pin to ground.
11	Regulator Output	This is the 5.0 V Regulator output.
14	V_{CC}	This pin is the positive supply input of the control IC.
15	Chip Disable	This input is used to switch the IC into a standby mode turning off all outputs.
16	V_{ref}	This is the 2.6 V Reference output. It is intended to be used in conjunction with the Power Warning and Uncommitted comparators.

OPERATING DESCRIPTION

The MC34160 series is a monolithic voltage regulator and supervisory circuit containing many of the necessary monitoring functions required in microprocessor based systems. It is specifically designed for appliance and industrial applications, offering the designer a cost effective solution with minimal external components. These devices are specified for operation over an input voltage of 7.0 V to 40 V, and with a junction temperature of –40° to +150°C. A typical microprocessor application is shown in Figure 10.

Regulator

The 5.0 V regulator is designed to source in excess of 100 mA output current and is short circuit protected. The output has a guaranteed tolerance of ±5.0% over line, load, and temperature. Internal thermal shutdown circuitry is included to limit the maximum junction temperature to a safe level. When activated, typically at 170°C, the regulator output turns off.

In specific situations a combination of input and output bypass capacitors may be required for regulator stability. If the regulator is located an appreciable distance (≥ 4″) from the supply filter, an input bypass capacitor (C_{in}) of 0.33 μF or greater is suggested. Output capacitance values of less than 5.0 nF may cause regulator instability at light load (≤ 1.0 mA) and cold temperature. An output bypass capacitor of 0.1 μF or greater is recommended to ensure stability under all load conditions. The capacitors selected must provide good high frequency characteristics.

Good construction techniques should be used to minimize ground loops and lead resistance drops since the regulator does not have external sense inputs.

Reference

The 2.6 V bandgap reference is short circuit protected and has a guaranteed output tolerance of ±5.0% over line, load, and temperature. It is intended to be used in conjunction with the Power Warning and Uncommitted comparator. The reference can source in excess of 2.0 mA and sink a maximum of 10 µA. For additional current sinking capability, an external load resistor to ground must be used.

Reference biasing is internally derived from either V_{CC} or V_O, allowing proper operation if either drops below nominal.

Chip Disable

This input is used to switch the IC into a standby mode. When activated, internal biasing for the entire die is removed causing all outputs to turn off. This reduces the power supply current (I_{CC}) to less than 0.3 mA.

Comparators

Three separate comparators are incorporated for voltage monitoring. Their outputs can provide diagnostic information to the microprocessor, preventing system malfunctions.

The Reset Comparator Inverting Input is internally connected to the 2.6 V reference while the Noninverting Input monitors V_O. The Reset Output is active low when V_O falls approximately 180 mV below its regulated voltage. To prevent erratic operation when crossing the comparator threshold, 70 mV of hysteresis is provided.

The Power Warning Comparator is typically used to detect an impending loss of system power. The Inverting Input is internally connected to the reference, fixing the threshold at 2.6 V. The input power source V_{in} is monitored by the Noninverting Input through the R_1/R_2 divider (Figure 10). This input features an adjustable 10 µA to 50 µA current sink I_H that is programmed by the value selected for resistor R_H. A default current of 6.5 µA is provided if R_H is omitted. When the comparator input falls below 2.6 V, the current sink is activated. This produces hysteresis if V_{in} is monitored through a series resistor (R_1). The comparator thresholds are defined as follows:

$$V_{th(lower)} = V_{ref}\left(1 + \frac{R1}{R_2}\right) - I_{IB}\,R_1$$

$$V_{th(upper)} = V_{ref}\left(1 + \frac{R1}{R_2}\right) + I_H\,R_1$$

The nominal hysteresis current I_H equals 1.2 V/R_H (Figure 4).

The Uncommitted Comparator can be used to synchronize the microprocessor with the ac line signal for timing functions, or for synchronous load switching. It can also be connected as a line loss detector as shown in Figure 11. The comparator contains 200 mV of hysteresis preventing erractic output behavior when crossing the input threshold.

The Power Warning and Uncommitted Comparators each have a transistor base–emitter connected across their inputs. The base input normally connects to a voltage reference while the emitter input connects to the voltage to be monitored. The transistor limits the negative excursion on the emitter input to – 0.7 V below the base input by supply current from V_{CC}. This clamp current will prevent forward biasing the IC substrate. Zener diodes are connected to the comparator inputs to enhance the ICs electrostatic discharge capability. Resistors R_1 and R_{in} must limit the input current to a maximum of ±2.0 mA.

Each comparator output consists of an open collector NPN transistor capable of sinking 2.0 mA with a saturation voltage less than 0.4 V, and standing off 40 V with minimal leakage. Internal bias for the Reset and Power Warning Comparators is derived from either V_{CC} or the regulator output to ensure functionality when either is below nominal.

Heat Tab Package

The MC34160 is contained in a 16 lead plastic dual–in–line package in which the die is mounted on a special Heat Tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the surrounding air. The pictorial in Figure 8 shows a simple but effective method of utilizing the printed circuit board medium as a heat dissipator by soldering these tabs to an adequate area of copper foil. This permits the use of standard board layout and mounting practices while having the ability to more than halve the junction to air thermal resistance. The example and graph are for a symmetrical layout on a single sided board with one ounce per square foot copper.

Universal Voltage Monitors

The MC34161/MC33161 are universal voltage monitors intended for use in a wide variety of voltage sensing applications. These devices offer the circuit designer an economical solution for positive and negative voltage detection. The circuit consists of two comparator channels each with hysteresis, a unique Mode Select Input for channel programming, a pinned out 2.54 V reference, and two open collector outputs capable of sinking in excess of 10 mA. Each comparator channel can be configured as either inverting or noninverting by the Mode Select Input. This allows over, under, and window detection of positive and negative voltages. The minimum supply voltage needed for these devices to be fully functional is 2.0 V for positive voltage sensing and 4.0 V for negative voltage sensing.

Applications include direct monitoring of positive and negative voltages used in appliance, automotive, consumer, and industrial equipment.

- Unique Mode Select Input Allows Channel Programming
- Over, Under, and Window Voltage Detection
- Positive and Negative Voltage Detection
- Fully Functional at 2.0 V for Positve Voltage Sensing and 4.0 V for Negative Voltage Sensing
- Pinned Out 2.54 V Reference with Current Limit Protection
- Low Standby Current
- Open Collector Outputs for Enhanced Device Flexibility

FUNCTIONAL DESCRIPTION

Introduction

To be competitive in today's electronic equipment market, new circuits must be designed to increase system reliability with minimal incremental cost. The circuit designer can take a significant step toward attaining these goals by implementing economical circuitry that continuously monitors critical circuit voltages and provides a fault signal in the event of an out–of–tolerance condition. The MC34161, MC33161 series are universal voltage monitors intended for use in a wide variety of voltage sensing applications. The main objectives of this series was to configure a device that can be used in as many voltage sensing applications as possible while minimizing cost. The flexibility objective is achieved by the utilization of a unique Mode Select input that is used in conjunction with traditional circuit building blocks. The cost objective is achieved by processing the device on a standard Bipolar Analog flow, and by limiting the package to eight pins. The device consists of two comparator channels each with hysteresis, a mode select input for channel programming, a pinned out reference, and two open collector outputs. Each comparator channel can be configured as either inverting or noninverting by the Mode Select input. This allows a single device to perform over, under, and window detection of positive and negative voltages. A detailed description of each section of the device is given below with the representative block diagram shown in Figure 13.

Input Comparators

The input comparators of each channel are identical, each having an upper threshold voltage of 1.27 V ±2.0% with 25 mV of hysteresis. The hysteresis is provided to enhance output switching by preventing oscillations as the comparator thresholds are crossed. The comparators have an input bias current of 60 nA at their threshold which approximates a 21.2 MΩ resistor to ground. This high impedance minimizes loading of the external voltage divider for well defined trip points. For all positive voltage sensing applications, both comparator channels are fully functional at a V_{CC} of 2.0 V. In order to provide enhanced device ruggedness for hostile industrial environments, additional circuitry was designed into the inputs to prevent device latch–up as well as to suppress electrostatic discharges (ESD).

Reference

The 2.54 V reference is pinned out to provide a means for the input comparators to sense negative voltages, as well as a means to program the Mode Select input for window detection applications. The reference is capable of sourcing in excess of 2.0 mA output current and has built–in short circuit protection. The output voltage has a guaranteed tolerance of ±2.4% at room temperature.

The 2.54 V reference is derived by gaining up the internal 1.27 V reference by a factor of two. With a power supply voltage of 4.0 V, the 2.54 V reference is in full regulation, allowing the device to accurately sense negative voltages.

Mode Select Circuit

The key feature that allows this device to be flexible is the Mode Select input. This input allows the user to program each of the channels for various types of voltage sensing applications. Figure 14 shows that the Mode Select input has three defined states. These states determine whether Channel 1 and/or Channel 2 operate in the inverting or noninverting mode. The Mode Select thresholds are shown in Figure 5. The input circuitry forms a tristate switch with thresholds at 0.63 V and V_{ref} + 0.23 V. The mode select input current is 10 µA when connected to the reference output, and 42 µA when connected to a V_{CC} of 5.0 V, refer to Figure 6.

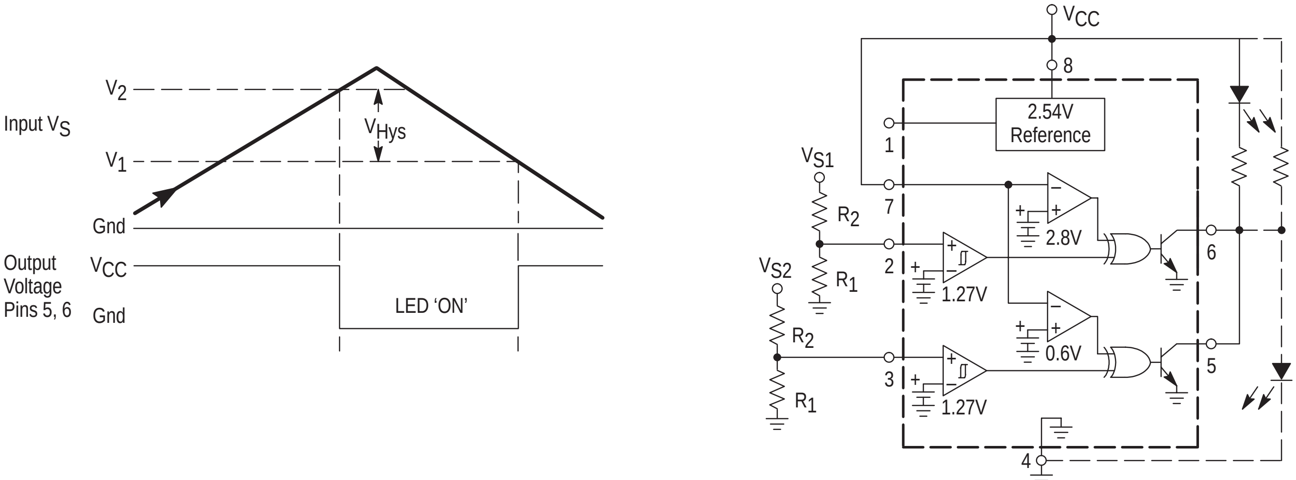
Output Stage

The output stage uses a positive feedback base boost circuit for enhanced sink saturation, while maintaining a relatively low device standby current. Figure 10 shows that the sink saturation voltage is about 0.2 V at 8.0 mA over temperature. By combining the low output saturation characteristics with low voltage comparator operation, this device is capable of sensing positive voltages at a V_{CC} of 1.0 V. These characteristics are important in undervoltage sensing applications where the output must stay in a low state as V_{CC} approaches ground. Figure 4 shows the Output Voltage versus Supply Voltage in an undervoltage sensing application. Note that as V_{CC} drops below the programmed 4.5 V trip point, the output stays in a well defined active low state until V_{CC} drops below 1.0 V.

APPLICATIONS

The following circuit figures illustrate the flexibility of this device. Included are voltage sensing applications for over, under, and window detectors, as well as three unique configurations. Many of the voltage detection circuits are shown with the open collector outputs of each channel connected together driving a light emitting diode (LED). This 'ORed' connection is shown for ease of explanation and it is only required for window detection applications. Note that many of the voltage detection circuits are shown with a dashed line output connection. This connection gives the inverse function of the solid line connection. For example, the solid line output connection of Figure 15 has the LED 'ON' when input voltage V_S is above trip voltage V_2, for overvoltage detection. The dashed line output connection has the LED 'ON' when V_S is below trip voltage V_2, for undervoltage detection.

Figure 15. Dual Postive Overvoltage Detector



The above figure shows the MC34161 configured as a dual positive overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when V_{S1} or V_{S2} exceeds V_2. With the dashed line output connection, the circuit becomes a dual positive undervoltage detector. As the input voltage decreases from the peak towards ground, the LED will turn 'ON' when V_{S1} or V_{S2} falls below V_1.

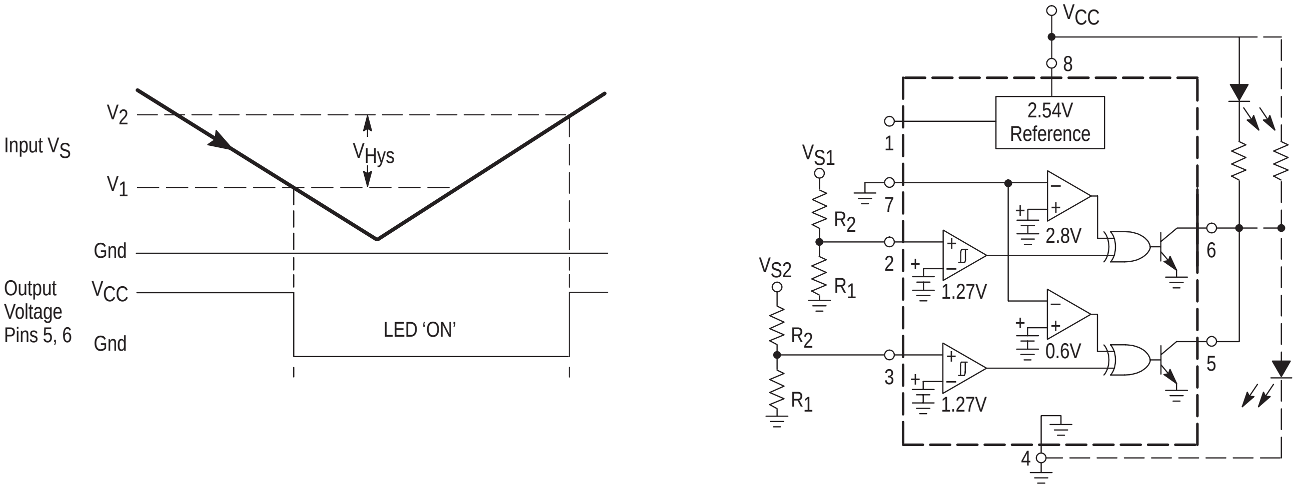
For known resistor values, the voltage trip points are:

$$V_1 = (V_{th} - V_H)\left(\frac{R_2}{R_1} + 1\right) \qquad V_2 = V_{th}\left(\frac{R_2}{R_1} + 1\right)$$

For a specific trip voltage, the required resistor ratio is:

$$\frac{R_2}{R_1} = \frac{V_1}{V_{th} - V_H} - 1 \qquad \frac{R_2}{R_1} = \frac{V_2}{V_{th}} - 1$$

Figure 16. Dual Postive Undervoltage Detector



The above figure shows the MC34161 configured as a dual positive undervoltage detector. As the input voltage decreases towards ground, the LED will turn 'ON' when V_{S1} or V_{S2} falls below V_1. With the dashed line output connection, the circuit becomes a dual positive overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when V_{S1} or V_{S2} exceeds V_2.

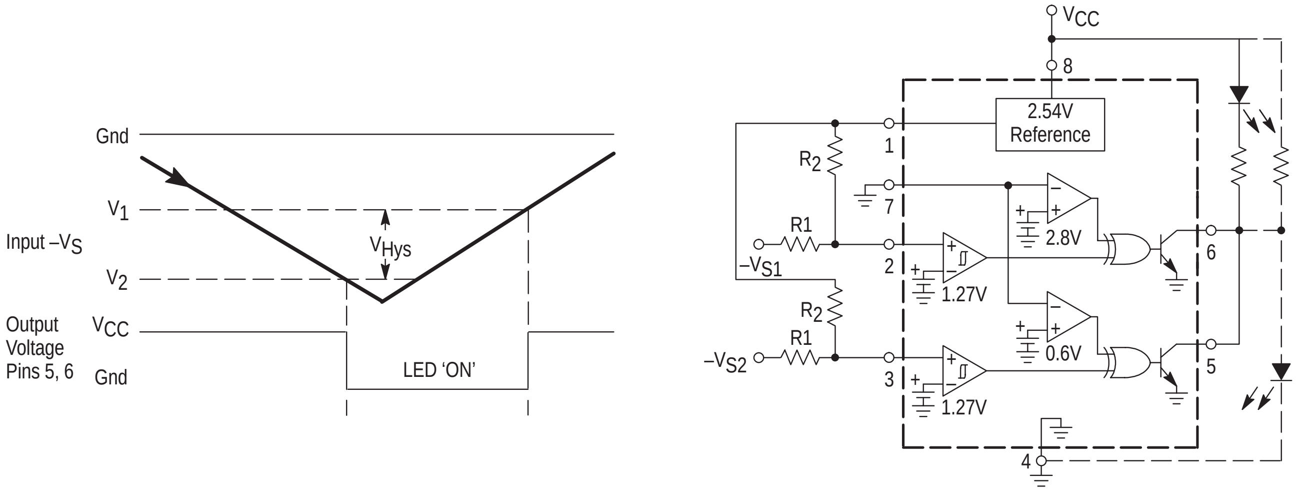
For known resistor values, the voltage trip points are:

$$V_1 = (V_{th} - V_H)\left(\frac{R_2}{R_1} + 1\right) \qquad V_2 = V_{th}\left(\frac{R_2}{R_1} + 1\right)$$

For a specific trip voltage, the required resistor ratio is:

$$\frac{R_2}{R_1} = \frac{V_1}{V_{th} - V_H} - 1 \qquad \frac{R_2}{R_1} = \frac{V_2}{V_{th}} - 1$$

Figure 17. Dual Negative Overvoltage Detector



The above figure shows the MC34161 configured as a dual negative overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when $-V_{S1}$ or $-V_{S2}$ exceeds V_2. With the dashed line output connection, the circuit becomes a dual negative undervoltage detector. As the input voltage decreases from the peak towards ground, the LED will turn 'ON' when $-V_{S1}$ or $-V_{S2}$ falls below V_1.

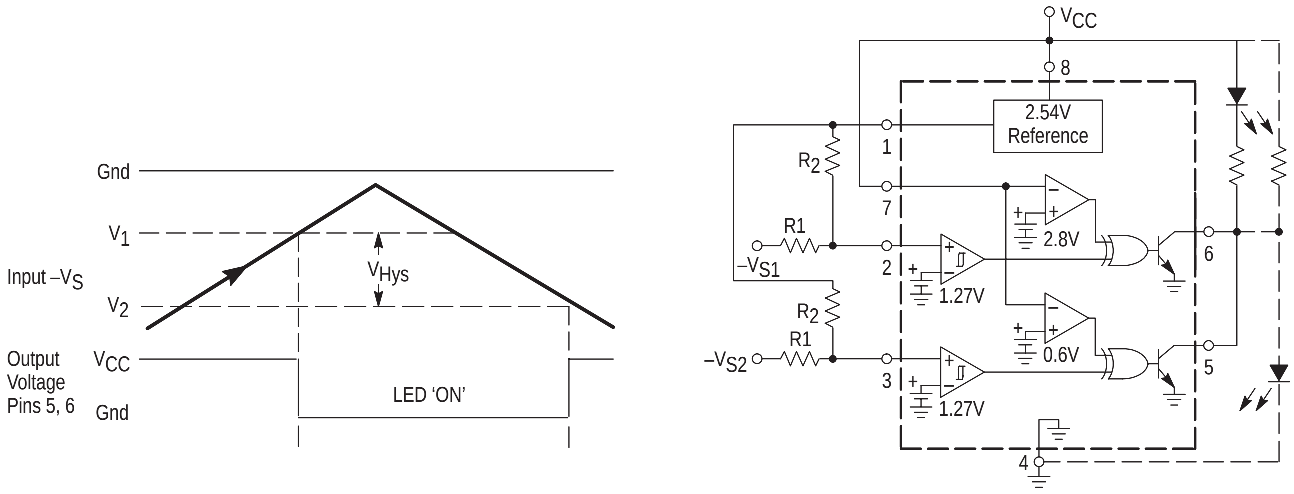
For known resistor values, the voltage trip points are:

$$V_1 = \frac{R_1}{R_2}(V_{th} - V_{ref}) + V_{th} \qquad V_2 = \frac{R_1}{R_2}(V_{th} - V_H - V_{ref}) + V_{th} - V_H$$

For a specific trip voltage, the required resistor ratio is:

$$\frac{R_1}{R_2} = \frac{V_1 - V_{th}}{V_{th} - V_{ref}} \qquad \frac{R_1}{R_2} = \frac{V_2 - V_{th} + V_H}{V_{th} - V_H - V_{ref}}$$

Figure 18. Dual Negative Undervoltage Detector



The above figure shows the MC34161 configured as a dual negative undervoltage detector. As the input voltage decreases towards ground, the LED will turn 'ON' when $-V_{S1}$ or $-V_{S2}$ falls below V_1. With the dashed line output connection, the circuit becomes a dual negative overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when $-V_{S1}$ or $-V_{S2}$ exceeds V_2.

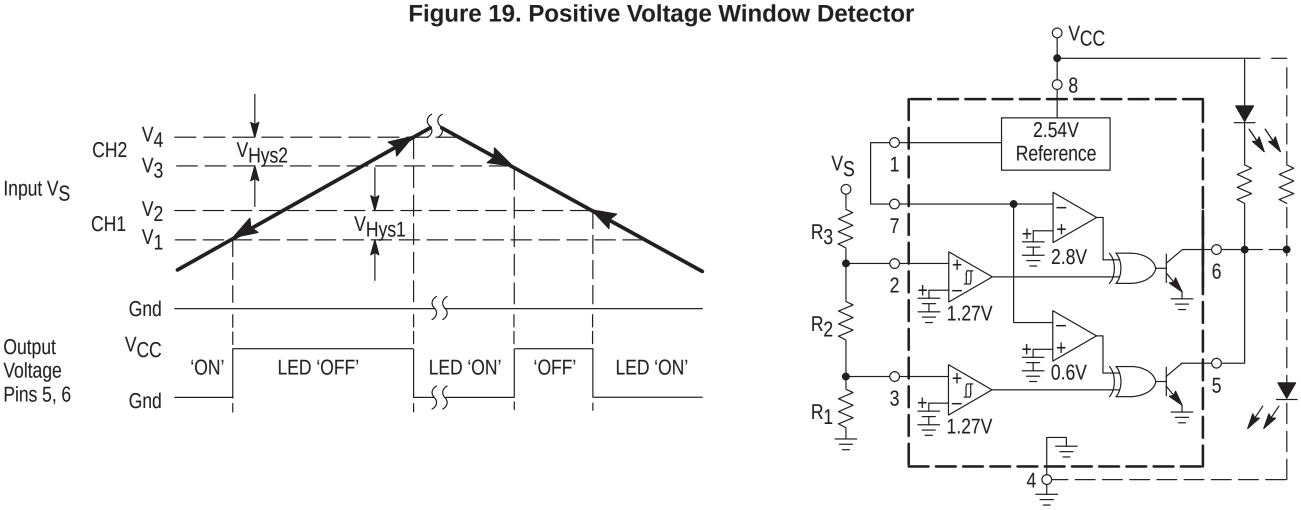
For known resistor values, the voltage trip points are:

$$V_1 = \frac{R_1}{R_2}(V_{th} - V_{ref}) + V_{th} \qquad V_2 = \frac{R_1}{R_2}(V_{th} - V_H - V_{ref}) + V_{th} - V_H$$

For a specific trip voltage, the required resistor ratio is:

$$\frac{R_1}{R_2} = \frac{V_1 - V_{th}}{V_{th} - V_{ref}} \qquad \frac{R_1}{R_2} = \frac{V_2 - V_{th} + V_H}{V_{th} - V_H - V_{ref}}$$

Figure 19. Positive Voltage Window Detector



The above figure shows the MC34161 configured as a positive voltage window detector. This is accomplished by connecting channel 1 as an undervoltage detector, and channel 2 as an overvoltage detector. When the input voltage V_S falls out of the window established by V_1 and V_4, the LED will turn ‘ON’. As the input voltage falls within the window, V_S increasing from ground and exceeding V_2, or V_S decreasing from the peak towards ground and falling below V_3, the LED will turn ‘OFF’. With the dashed line output connection, the LED will turn ‘ON’ when the input voltage V_S is within the window.

For known resistor values, the voltage trip points are:

$$V_1 = (V_{th1} - V_{H1})\left(\frac{R_3}{R_1 + R_2} + 1\right) \qquad V_3 = (V_{th2} - V_{H2})\left(\frac{R_2 + R_3}{R_1} + 1\right)$$

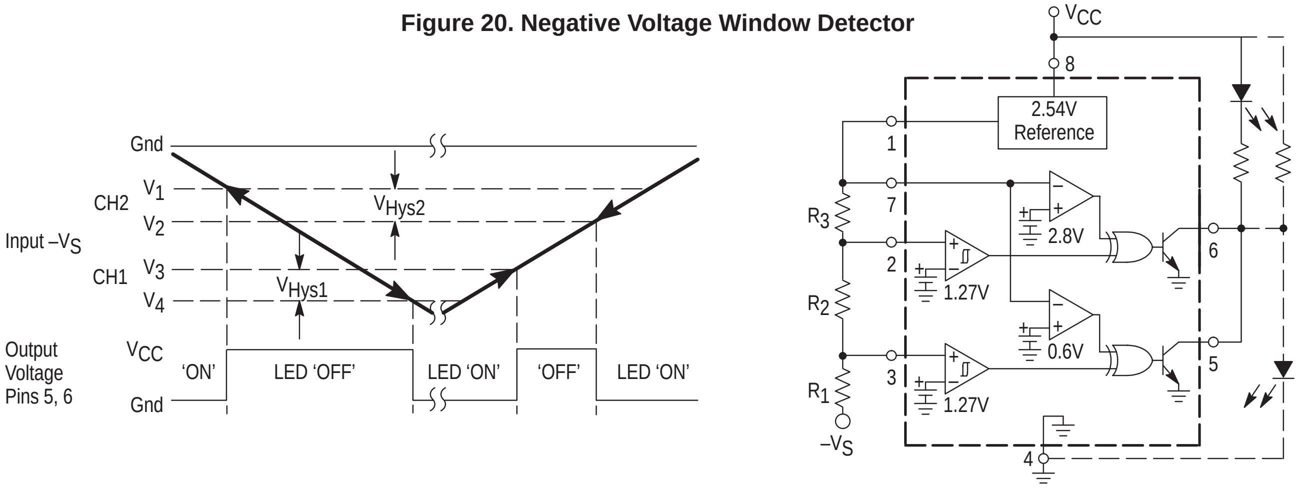
$$V_2 = V_{th1}\left(\frac{R_3}{R_1 + R_2} + 1\right) \qquad V_4 = V_{th2}\left(\frac{R_2 + R_3}{R_1} + 1\right)$$

For a specific trip voltage, the required resistor ratio is:

$$\frac{R_2}{R_1} = \frac{V_3(V_{th2} - V_{H2})}{V_1(V_{th1} - V_{H1})} - 1 \qquad \frac{R_3}{R_1} = \frac{V_3(V_1 - V_{th1} + V_{H1})}{V_1(V_{th2} - V_{H2})}$$

$$\frac{R_2}{R_1} = \frac{V_4 \text{ x } V_{th2}}{V_2 \text{ x } V_{th1}} - 1 \qquad \frac{R_3}{R_1} = \frac{V_4(V_2 - V_{th1})}{V_2 \text{ x } V_{th2}}$$

Figure 20. Negative Voltage Window Detector



The above figure shows the MC34161 configured as a negative voltage window detector. When the input voltage $-V_S$ falls out of the window established by V_1 and V_4, the LED will turn ‘ON’. As the input voltage falls within the window, $-V_S$ increasing from ground and exceeding V_2, or $-V_S$ decreasing from the peak towards ground and falling below V_3, the LED will turn ‘OFF’. With the dashed line output connection, the LED will turn ‘ON’ when the input voltage $-V_S$ is within the window.

For known resistor values, the voltage trip points are:

$$V_1 = \frac{R_1(V_{th2} - V_{ref})}{R_2 + R_3} + V_{th2}$$

$$V_2 = \frac{R_1(V_{th2} - V_{H2} - V_{ref})}{R_2 + R_3} + V_{th2} - V_{H2}$$

$$V_3 = \frac{(R_1 + R_2)(V_{th1} - V_{ref})}{R_3} + V_{th1}$$

$$V_4 = \frac{(R_1 + R_2)(V_{th1} - V_{H1} - V_{ref})}{R_3} + V_{th1} - V_{H1}$$

For a specific trip voltage, the required resistor ratio is:

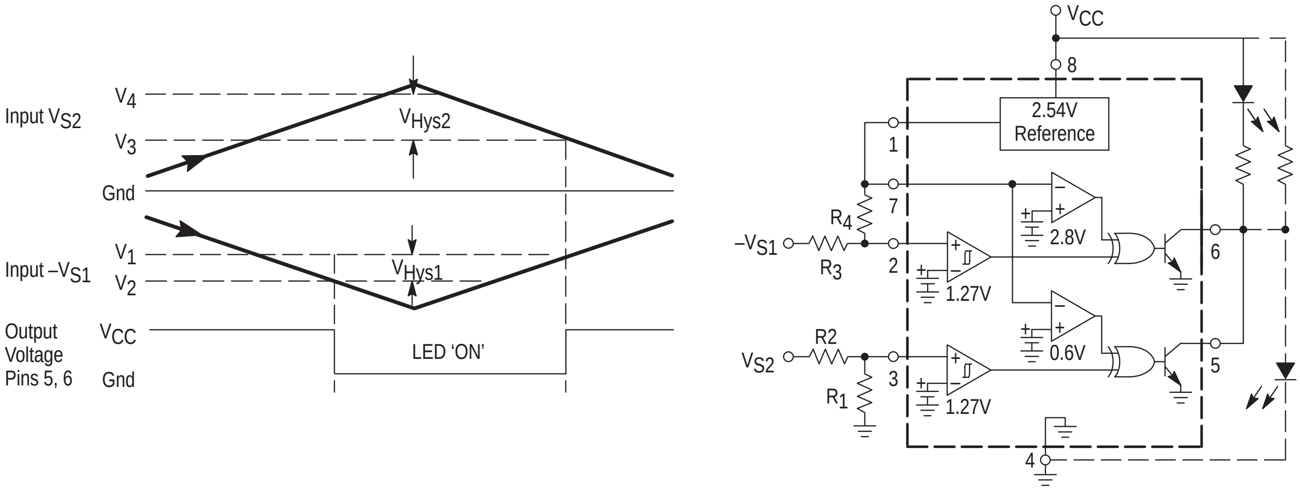
$$\frac{R_1}{R_2 + R_3} = \frac{V_1 - V_{th2}}{V_{th2} - V_{ref}}$$

$$\frac{R_1}{R_2 + R_3} = \frac{V_2 - V_{th2} + V_{H2}}{V_{th2} - V_{H2} - V_{ref}}$$

$$\frac{R_3}{R_1 + R_2} = \frac{V_{th1} - V_{ref}}{V_3 - V_{th1}}$$

$$\frac{R_3}{R_1 + R_2} = \frac{V_{th1} - V_{H1} - V_{ref}}{V_4 + V_{H1} - V_{th1}}$$

Figure 21. Positive and Negative Overvoltage Detector



The above figure shows the MC34161 configured as a positive and negative overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when either $-V_{S1}$ exceeds V_2, or V_{S2} exceeds V_4. With the dashed line output connection, the circuit becomes a positive and negative undervoltage detector. As the input voltage decreases from the peak towards ground, the LED will turn 'ON' when either V_{S2} falls below V_3, or $-V_{S1}$ falls below V_1.

For known resistor values, the voltage trip points are:

$$V_1 = \frac{R_3}{R_4}(V_{th1} - V_{ref}) + V_{th1} \qquad V_3 = (V_{th2} - V_{H2})\left(\frac{R_2}{R_1} + 1\right)$$

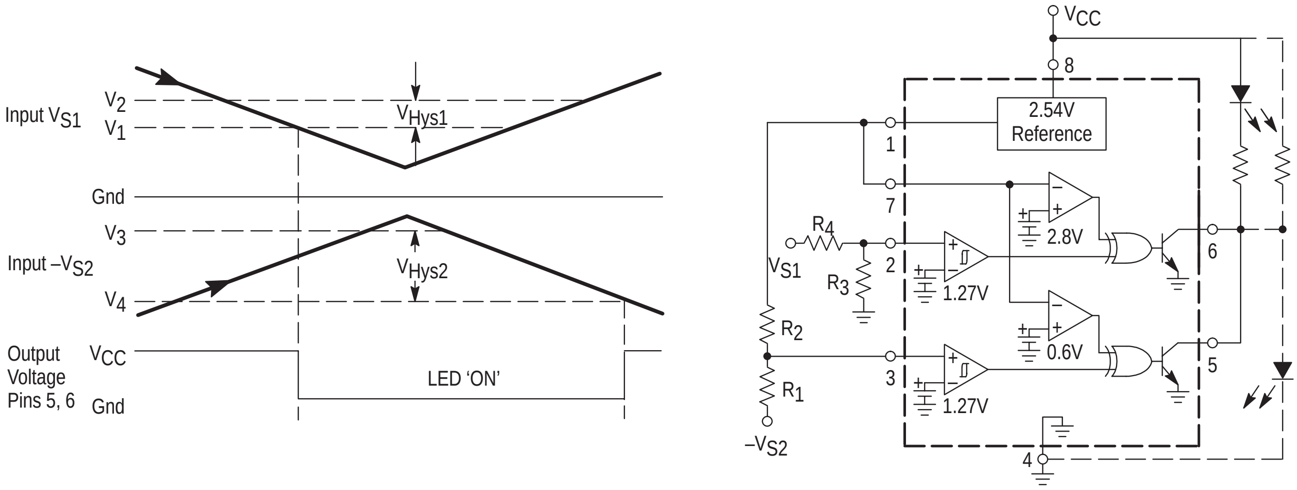
$$V_2 = \frac{R_3}{R_4}(V_{th1} - V_{H1} - V_{ref}) + V_{th1} - V_{H1} \qquad V_4 = V_{th2}\left(\frac{R_2}{R_1} + 1\right)$$

For a specific trip voltage, the required resistor ratio is:

$$\frac{R_3}{R_4} = \frac{(V_1 - V_{th1})}{(V_{th1} - V_{ref})} \qquad \frac{R_2}{R_1} = \frac{V_4}{V_{th2}} - 1$$

$$\frac{R_3}{R_4} = \frac{(V_2 - V_{th1} + V_{H1})}{(V_{th1} - V_{H1} - V_{ref})} \qquad \frac{R_2}{R_1} = \frac{V_3}{V_{th2} - V_{H2}} - 1$$

Figure 22. Positive and Negative Undervoltage Detector



The above figure shows the MC34161 configured as a positive and negative undervoltage detector. As the input voltage decreases toward ground, the LED will turn 'ON' when either V_{S1} falls below V_1, or $-V_{S2}$ falls below V_3. With the dashed line output connection, the circuit becomes a positive and negative overvoltage detector. As the input voltage increases from the ground, the LED will turn 'ON' when either V_{S1} exceeds V_2, or $-V_{S1}$ exceeds V_1.

For known resistor values, the voltage trip points are:

$$V_1 = (V_{th1} - V_{H1})\left(\frac{R_4}{R_3} + 1\right) \qquad V_3 = \frac{R_1}{R_2}(V_{th} - V_{ref}) + V_{th2}$$

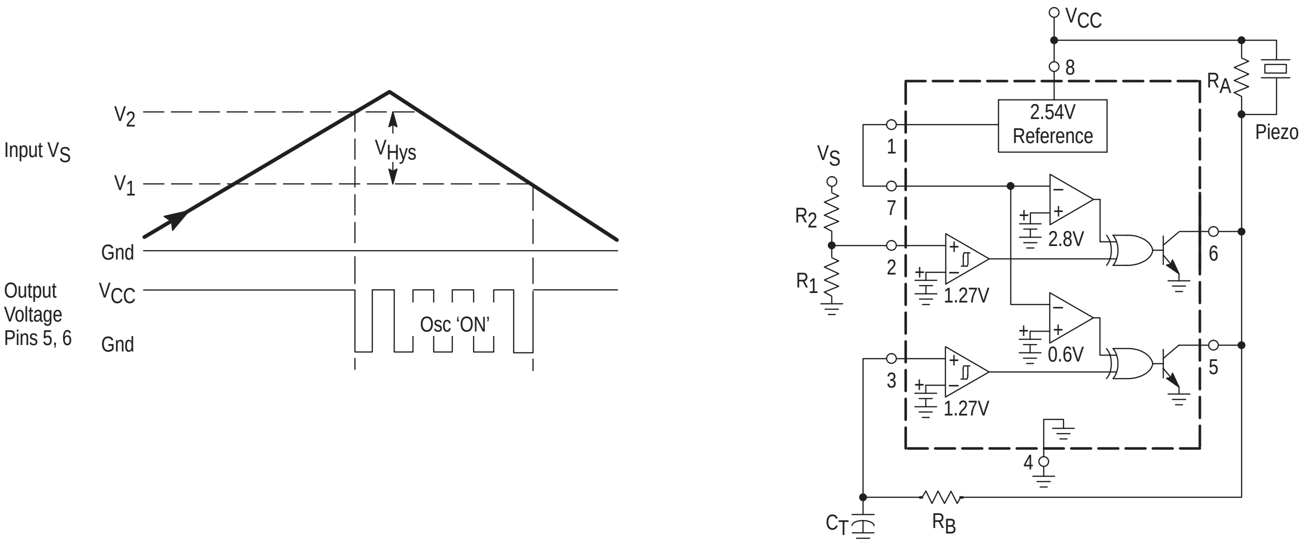
$$V_2 = V_{th1}\left(\frac{R_4}{R_3} + 1\right) \qquad V_4 = \frac{R_1}{R_2}(V_{th} - V_{H2} - V_{ref}) + V_{th2} - V_{H2}$$

For a specific trip voltage, the required resistor ratio is:

$$\frac{R_4}{R_3} = \frac{V_2}{V_{th1}} - 1 \qquad \frac{R_1}{R_2} = \frac{V_4 + V_{H2} - V_{th2}}{V_{th2} - V_{H2} - V_{ref}}$$

$$\frac{R_4}{R_3} = \frac{V_1}{V_{th1} - V_{H1}} - 1 \qquad \frac{R_1}{R_2} = \frac{V_3 - V_{th2}}{V_{th2} - V_{ref}}$$

Figure 23. Overvoltage Detector with Audio Alarm



The above figure shows the MC34161 configured as an overvoltage detector with an audio alarm. Channel 1 monitors input voltage V_S while channel 2 is connected as a simple RC oscillator. As the input voltage increases from ground, the output of channel 1 allows the oscillator to turn ‘ON’ when V_S exceeds V_2.

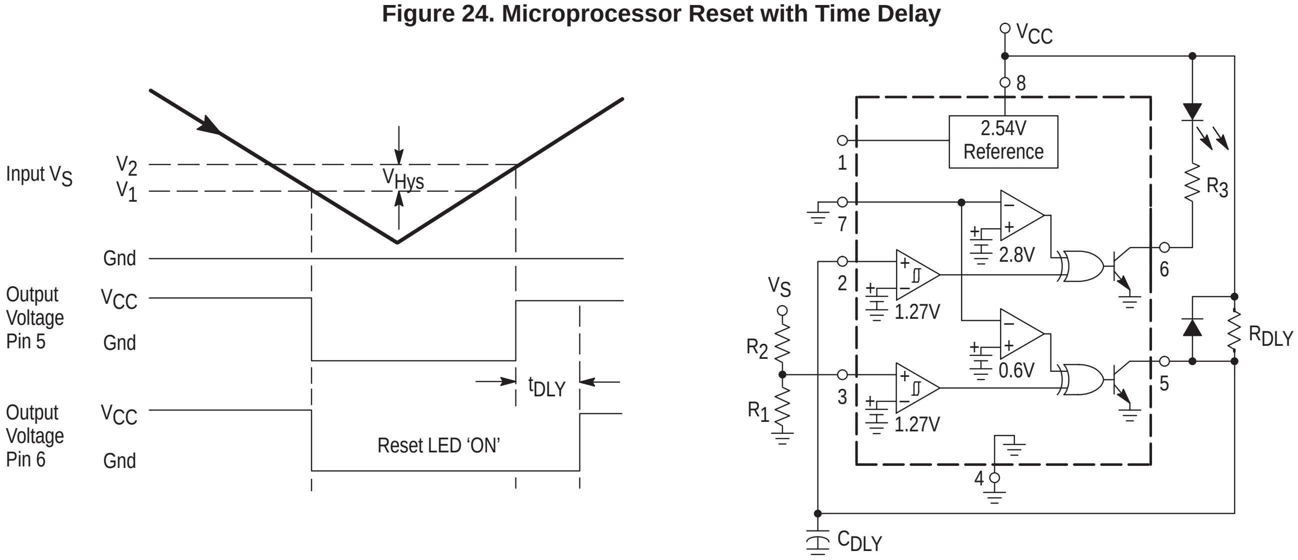
For known resistor values, the voltage trip points are:

$$V_1 = (V_{th} - V_H)\left(\frac{R_2}{R_1} + 1\right) \quad V_2 = V_{th}\left(\frac{R_2}{R_1} + 1\right)$$

For a specific trip voltage, the required resistor ratio is:

$$\frac{R_2}{R_1} = \frac{V_1}{V_{th} - V_H} - 1 \qquad \frac{R_2}{R_1} = \frac{V_2}{V_{th}} - 1$$

Figure 24. Microprocessor Reset with Time Delay



The above figure shows the MC34161 configured as a microprocessor reset with a time delay. Channel 2 monitors input voltage V_S while channel 1 performs the time delay function. As the input voltage decreases towards ground, the output of channel 2 quickly discharges C_{DLY} when V_S falls below V_1. As the input voltage increases from ground, the output of channel 2 allows R_{DLY} to charge C_{DLY} when V_S exceeds V_2.

For known resistor values, the voltage trip points are:

$$V_1 = (V_{th} - V_H)\left(\frac{R_2}{R_1} + 1\right) \quad V_2 = V_{th}\left(\frac{R_2}{R_1} + 1\right)$$

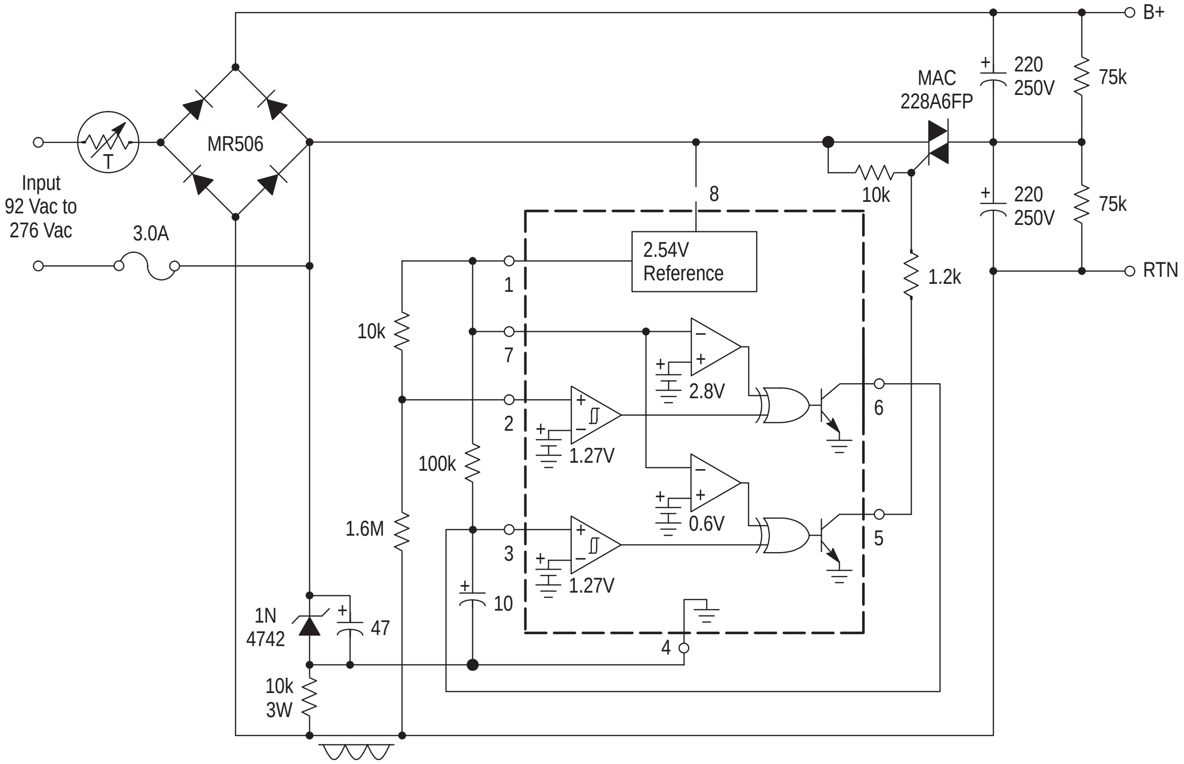
For a specific trip voltage, the required resistor ratio is:

$$\frac{R_2}{R_1} = \frac{V_1}{V_{th} - V_H} - 1 \qquad \frac{R_2}{R_1} = \frac{V_2}{V_{th}} - 1$$

For known R_{DLY} C_{DLY} values, the reset time delay is:

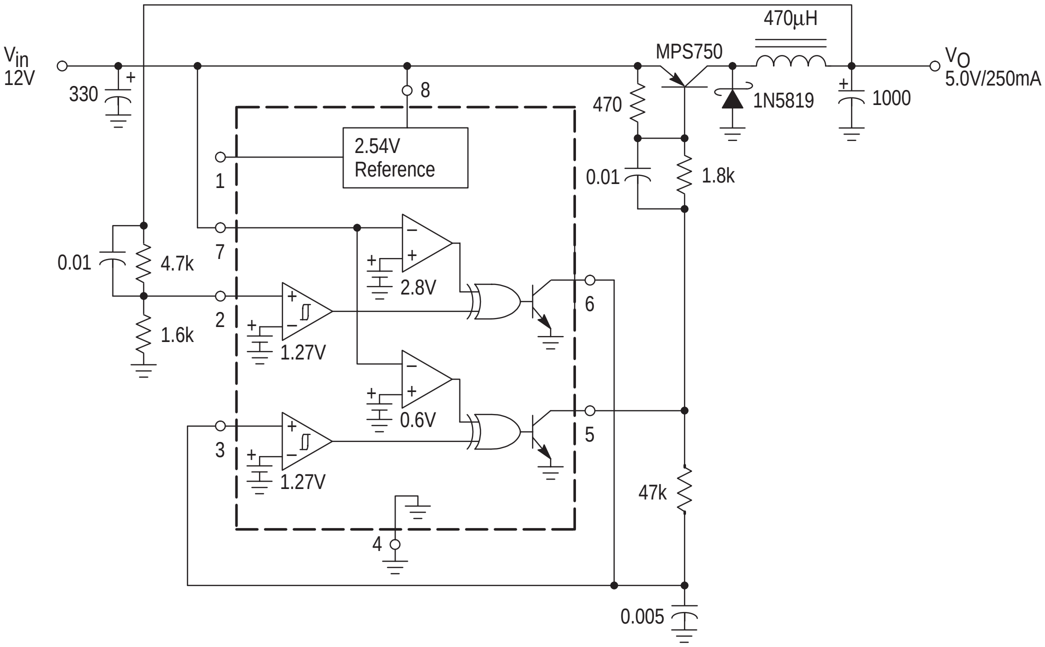
$$t_{DLY} = R_{DLY}C_{DLY} \ln\left(\frac{1}{1 - \frac{V_{th}}{V_{CC}}}\right)$$

Figure 25. Automatic AC Line Voltage Selector



The above circuit shows the MC34161 configured as an automatic line voltage selector. The IC controls the triac, enabling the circuit to function as a fullwave voltage doubler or a fullwave bridge. Channel 1 senses the negative half cycles of the AC line voltage. If the line voltage is less than150 V, the circuit will switch from bridge mode to voltage doubling mode after a preset time delay. The delay is controlled by the 100 kΩ resistor and the 10 μF capacitor. If the line voltage is greater than 150 V, the circuit will immediately return to fullwave bridge mode.

Figure 26. Step–Down Converter



Test	Conditions	Results
Line Regulation	V_{in} = 9.5 V to 24 V, I_O = 250 mA	40 mV = ±0.1%
Load Regulation	V_{in} = 12 V, I_O = 0.25 mA to 250 mA	2.0 mV = ±0.2%
Output Ripple	V_{in} = 12 V, I_O = 250 mA	50 mVpp
Efficiency	V_{in} = 12 V, I_O = 250 mA	87.8%

The above figure shows the MC34161 configured as a step–down converter. Channel 1 monitors the output voltage while Channel 2 performs the oscillator function. Upon initial power–up, the converters output voltage will be below nominal, and the output of Channel 1 will allow the oscillator to run. The external switch transistor will eventually pump–up the output capacitor until its voltage exceeds the input threshold of Channel 1. The output of Channel 1 will then switch low and disable the oscillator. The oscillator will commence operation when the output voltage falls below the lower threshold of Channel 1.

Power Switching Regulators

The MC34163 series are monolithic power switching regulators that contain the primary functions required for dc–to–dc converters. This series is specifically designed to be incorporated in step–up, step–down, and voltage–inverting applications with a minimum number of external components.

These devices consist of two high gain voltage feedback comparators, temperature compensated reference, controlled duty cycle oscillator, driver with bootstrap capability for increased efficiency, and a high current output switch. Protective features consist of cycle–by–cycle current limiting, and internal thermal shutdown. Also included is a low voltage indicator output designed to interface with microprocessor based systems.

These devices are contained in a 16 pin dual–in–line heat tab plastic package for improved thermal conduction.

- Output Switch Current in Excess of 3.0 A
- Operation from 2.5 V to 40 V Input
- Low Standby Current
- Precision 2% Reference
- Controlled Duty Cycle Oscillator
- Driver with Bootstrap Capability for Increased Efficiency
- Cycle–by–Cycle Current Limiting
- Internal Thermal Shutdown Protection
- Low Voltage Indicator Output for Direct Microprocessor Interface
- Heat Tab Power Package

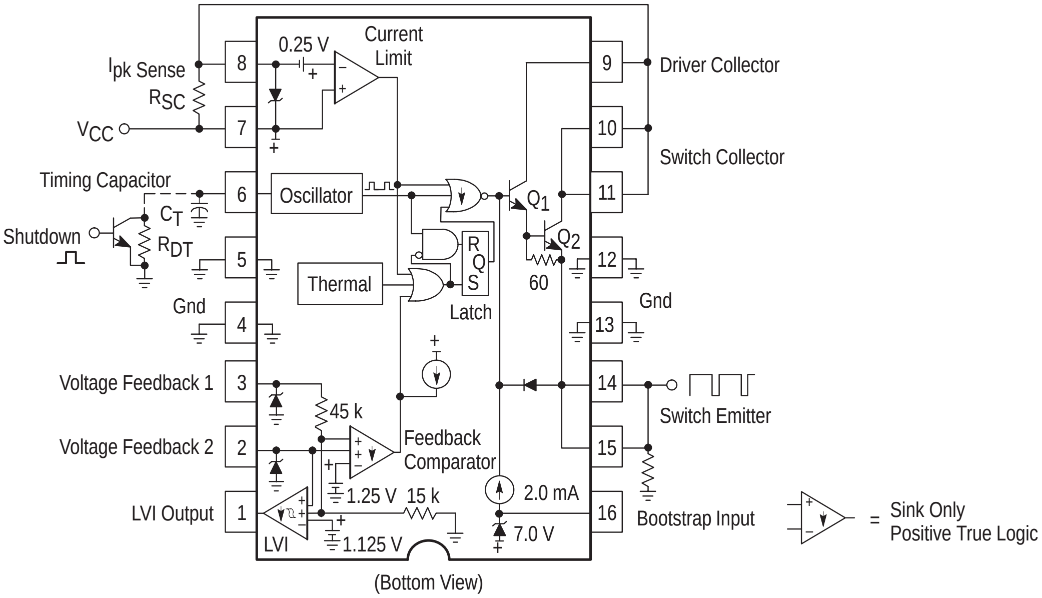

Figure 19. Typical Operating Waveforms

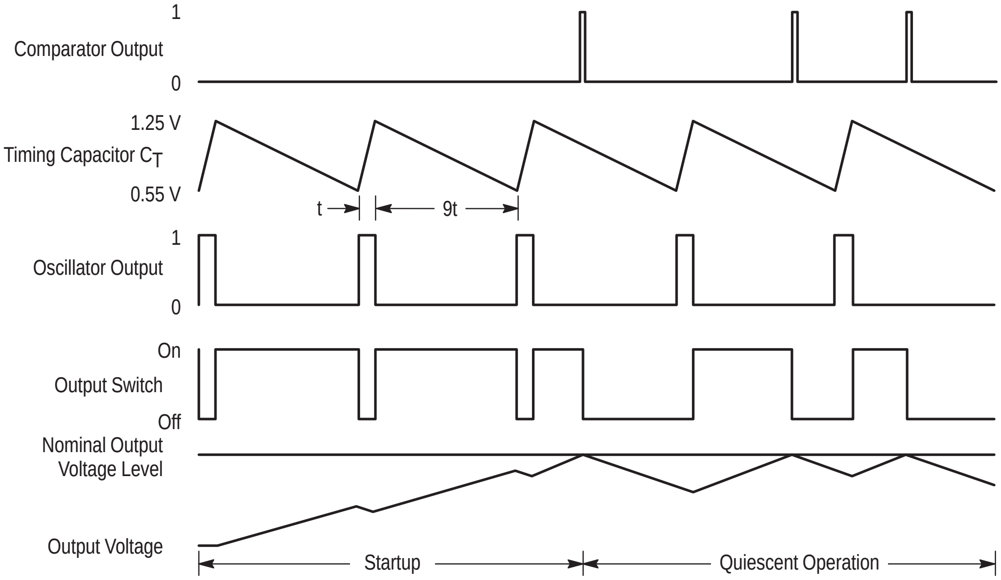

INTRODUCTION

The MC34163 series are monolithic power switching regulators optimized for dc–to–dc converter applications. The combination of features in this series enables the system designer to directly implement step–up, step–down, and voltage–inverting converters with a minimum number of external components. Potential applications include cost sensitive consumer products as well as equipment for the automotive, computer, and industrial markets. A Representative Block Diagram is shown in Figure 18.

OPERATING DESCRIPTION

The MC34163 operates as a fixed on–time, variable off–time voltage mode ripple regulator. In general, this mode of operation is somewhat analogous to a capacitor charge pump and does not require dominant pole loop compensation for converter stability. The Typical Operating Waveforms are shown in Figure 19. The output voltage waveform shown is for a step–down converter with the ripple and phasing exaggerated for clarity. During initial converter startup, the feedback comparator senses that the output voltage level is below nominal. This causes the output switch to turn on and off at a frequency and duty cycle controlled by the oscillator, thus pumping up the output filter capacitor. When the output voltage level reaches nominal, the feedback comparator sets the latch, immediately terminating switch conduction. The feedback comparator will inhibit the switch until the load current causes the output voltage to fall below nominal. Under these conditions, output switch conduction can be inhibited for a partial oscillator cycle, a partial cycle plus a complete cycle, multiple cycles, or a partial cycle plus multiple cycles.

Oscillator

The oscillator frequency and on–time of the output switch are programmed by the value selected for timing capacitor C_T. Capacitor C_T is charged and discharged by a 9 to 1 ratio internal current source and sink, generating a negative going sawtooth waveform at Pin 6. As C_T charges, an internal pulse is generated at the oscillator output. This pulse is connected to the NOR gate center input, preventing output switch conduction, and to the AND gate upper input, allowing the latch to be reset if the comparator output is low. Thus, the output switch is always disabled during ramp–up and can be enabled by the comparator output only at the start of ramp–down. The oscillator peak and valley thresholds are 1.25 V and 0.55 V, respectively, with a charge current of 225 µA and a discharge current of 25 µA, yielding a maximum on–time duty cycle of 90%. A reduction of the maximum duty cycle may be required for specific converter configurations. This can be accomplished with the addition of an external deadtime resistor (R_{DT}) placed across C_T. The resistor increases the discharge current which reduces the on–time of the output switch. A graph of the Output Switch On–Off Time versus Oscillator Timing Capacitance for various values of R_{DT} is shown in Figure 1. Note that the maximum output duty cycle, $t_{on}/t_{on} + t_{off}$, remains constant for values of C_T greater than 0.2 nF. The converter output can be inhibited by clamping C_T to ground with an external NPN small–signal transistor.

Feedback and Low Voltage Indicator Comparators

Output voltage control is established by the Feedback comparator. The inverting input is internally biased at 1.25 V and is not pinned out. The converter output voltage is typically divided down with two external resistors and monitored by the high impedance noninverting input at Pin 2. The maximum input bias current is ±0.4 µA, which can cause an output voltage error that is equal to the product of the input bias current and the upper divider resistance value. For applications that require 5.0 V, the converter output can be directly connected to the noninverting input at Pin 3. The high impedance input, Pin 2, must be grounded to prevent noise pickup. The internal resistor divider is set for a nominal voltage of 5.05 V. The additional 50 mV compensates for a 1.0% voltage drop in the cable and connector from the converter output to the load. The Feedback comparator's output state is controlled by the highest voltage applied to either of the two noninverting inputs.

The Low Voltage Indicator (LVI) comparator is designed for use as a reset controller in microprocessor–based systems. The inverting input is internally biased at 1.125 V, which sets the noninverting input thresholds to 90% of nominal. The LVI comparator has 15 mV of hysteresis to prevent erratic reset operation. The Open Collector output is capable of sinking in excess of 6.0 mA (see Figure 10). An external resistor (R_{LVI}) and capacitor (C_{DLY}) can be used to program a reset delay time (t_{DLY}) by the formula shown below, where $V_{th(MPU)}$ is the microprocessor reset input threshold. Refer to Figure 20.

$$t_{DLY} = R_{LVI}\, C_{DLY} \ln \left(\frac{1}{1 - \frac{V_{th(MPU)}}{V_{out}}} \right)$$

Current Limit Comparator, Latch and Thermal Shutdown

With a voltage mode ripple converter operating under normal conditions, output switch conduction is initiated by the oscillator and terminated by the Voltage Feedback comparator. Abnormal operating conditions occur when the converter output is overloaded or when feedback voltage sensing is lost. Under these conditions, the Current Limit comparator will protect the Output Switch.

The switch current is converted to a voltage by inserting a fractional ohm resistor, R_{SC}, in series with V_{CC} and output switch transistor Q_2. The voltage drop across R_{SC} is monitored by the Current Sense comparator. If the voltage drop exceeds 250 mV with respect to V_{CC}, the comparator will set the latch and terminate output switch conduction on a cycle–by–cycle basis. This Comparator/Latch configuration ensures that the Output Switch has only a single on–time during a given oscillator cycle. The calculation for a value of R_{SC} is:

$$R_{SC} = \frac{0.25\ V}{I_{pk\,(Switch)}}$$

Figures 11 and 12 show that the Current Sense comparator threshold is tightly controlled over temperature and has a typical input bias current of 1.0 µA. The propagation delay from the comparator input to the Output Switch is typically 200 ns. The parasitic inductance associated with R_{SC} and the circuit layout should be minimized. This will prevent unwanted voltage spikes that may falsely trip the Current Limit comparator.

Internal thermal shutdown circuitry is provided to protect the IC in the event that the maximum junction temperature is exceeded. When activated, typically at 170°C, the Latch is forced into the "Set" state, disabling the Output Switch. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a replacement for proper heatsinking.

Driver and Output Switch

To aid in system design flexibility and conversion efficiency, the driver current source and collector, and output switch collector and emitter are pinned out separately. This allows the designer the option of driving the output switch into saturation with a selected force gain or driving it near saturation when connected as a Darlington. The output switch has a typical current gain of 70 at 2.5 A and is designed to switch a maximum of 40 V collector to emitter, with up to 3.4 A peak collector current. The minimum value for R_{SC} is:

$$R_{SC(min)} = \frac{0.25\,V}{3.4\ A} = 0.0735\ \Omega$$

When configured for step–down or voltage–inverting applications, as in Figures 20 and 24, the inductor will forward bias the output rectifier when the switch turns off. Rectifiers with a high forward voltage drop or long turn–on delay time should not be used. If the emitter is allowed to go sufficiently negative, collector current will flow, causing additional device heating and reduced conversion efficiency.

Figure 9 shows that by clamping the emitter to 0.5 V, the collector current will be in the range 10 µA over temperature. A 1N5822 or equivalent Schottky barrier rectifier is recommended to fulfill these requirements.

A bootstrap input is provided to reduce the output switch saturation voltage in step–down and voltage–inverting converter applications. This input is connected through a series resistor and capacitor to the switch emitter and is used to raise the internal 2.0 mA bias current source above V_{CC}. An internal zener limits the bootstrap input voltage to V_{CC} +7.0 V. The capacitor's equivalent series resistance must limit the zener current to less than 100 mA. An additional series resistor may be required when using tantalum or other low ESR capacitors. The equation below is used to calculate a minimum value bootstrap capacitor based on a minimum zener voltage and an upper limit current source.

$$C_{B(min)} = I\,\frac{\Delta t}{\Delta V} = 4.0\ mA\ \frac{t_{on}}{4.0\,V} = 0.001\,t_{on}$$

Parametric operation of the MC34163 is guaranteed over a supply voltage range of 2.5 V to 40 V. When operating below 3.0 V, the Bootstrap Input should be connected to V_{CC}. Figure 15 shows that functional operation down to 1.7 V at room temperature is possible.

Package

The MC34163 is contained in a heatsinkable 16–lead plastic dual–in–line package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figures 16 and 17 show a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction–to–air thermal resistance. These examples are for a symmetrical layout on a single–sided board with two ounce per square foot of copper.

APPLICATIONS

The following converter applications show the simplicity and flexibility of this circuit architecture. Three main converter topologies are demonstrated with actual test data shown below each of the circuit diagrams.

C_T	$\frac{32.143 \cdot 10^{-6}}{f}$	$\frac{32.143 \cdot 10^{-6}}{f}$	$\frac{32.143 \cdot 10^{-6}}{f}$
$I_{L(avg)}$	I_{out}	$I_{out}\left(\frac{t_{on}}{t_{off}} + 1\right)$	$I_{out}\left(\frac{t_{on}}{t_{off}} + 1\right)$
I_{pk} (Switch)	$I_{L(avg)} + \frac{\Delta I_L}{2}$	$I_{L(avg)} + \frac{\Delta I_L}{2}$	$I_{L(avg)} + \frac{\Delta I_L}{2}$
R_{SC}	$\frac{0.25}{I_{pk}\ (\text{Switch})}$	$\frac{0.25}{I_{pk}\ (\text{Switch})}$	$\frac{0.25}{I_{pk}\ (\text{Switch})}$
L	$\left(\frac{V_{in} - V_{sat} - V_{out}}{\Delta I_L}\right) t_{on}$	$\left(\frac{V_{in} - V_{sat}}{\Delta I_L}\right) t_{on}$	$\left(\frac{V_{in} - V_{sat}}{\Delta I_L}\right) t_{on}$
$V_{ripple(pp)}$	$\Delta I_L \sqrt{\left(\frac{1}{8 f C_O}\right)^2 + (ESR)^2}$	$\approx \frac{t_{on}\, I_{out}}{C_O}$	$\approx \frac{t_{on}\, I_{out}}{C_O}$
V_{out}	$V_{ref}\left(\frac{R_2}{R_1} + 1\right)$	$V_{ref}\left(\frac{R_2}{R_1} + 1\right)$	$V_{ref}\left(\frac{R_2}{R_1} + 1\right)$

The following Converter Characteristics must be chosen:

V_{in} – Nominal operating input voltage.
V_{out} – Desired output voltage.
I_{out} – Desired output current.
ΔI_L – Desired peak–to–peak inductor ripple current. For maximum output current it is suggested that ΔI_L be chosen to be less than 10% of the average inductor current $I_{L(avg)}$. This will help prevent $I_{pk\ (Switch)}$ from reaching the current limit threshold set by R_{SC}. If the design goal is to use a minimum inductance value, let $\Delta I_L = 2(I_{L(avg)})$. This will proportionally reduce converter output current capability.
f – Maximum output switch frequency.
$V_{ripple(pp)}$ – Desired peak–to–peak output ripple voltage. For best performance the ripple voltage should be kept to a low value since it will directly affect line and load regulation. Capacitor C_O should be a low equivalent series resistance (ESR) electrolytic designed for switching regulator applications.

NOTES:
1. V_{sat} – Saturation voltage of the output switch, refer to Figures 7 and 8.
2. V_F – Output rectifier forward voltage drop. Typical value for 1N5822 Schottky barrier rectifier is 0.5 V.
3. The calculated t_{on}/t_{off} must not exceed the minimum guaranteed oscillator charge to discharge ratio of 8, at the minimum operating input voltage.

MC34164
MC33164

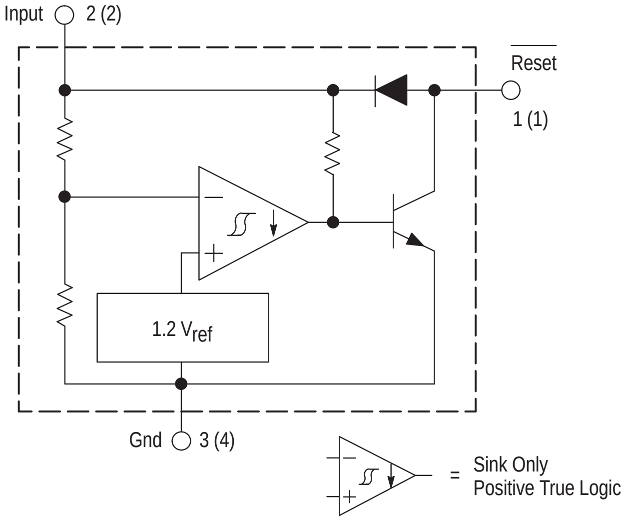
Micropower Undervoltage Sensing Circuits

The MC34164 series are undervoltage sensing circuits specifically designed for use as reset controllers in portable microprocessor based systems where extended battery life is required. These devices offer the designer an economical solution for low voltage detection with a single external resistor. The MC34164 series features a bandgap reference, a comparator with precise thresholds and built–in hysteresis to prevent erratic reset operation, an open collector reset output capable of sinking in excess of 6.0 mA, and guaranteed operation down to 1.0 V input with extremely low standby current. These devices are packaged in 3–pin TO–226AA, 8–pin SO–8 and Micro–8 surface mount packages.

Applications include direct monitoring of the 3.0 or 5.0 V MPU/logic power supply used in appliance, automotive, consumer, and industrial equipment.

- Temperature Compensated Reference
- Monitors 3.0 V (MC34164–3) or 5.0 V (MC34164–5) Power Supplies
- Precise Comparator Thresholds Guaranteed Over Temperature
- Comparator Hysteresis Prevents Erratic Reset
- Reset Output Capable of Sinking in Excess of 6.0 mA
- Internal Clamp Diode for Discharging Delay Capacitor
- Guaranteed Reset Operation With 1.0 V Input
- Extremely Low Standby Current: As Low as 9.0 µA
- Economical TO–226AA, SO–8 and Micro–8 Surface Mount Packages

Representative Block Diagram



Pin numbers adjacent to terminals are for the 3–pin TO–226AA package.
Pin numbers in parenthesis are for the 8–lead packages.

This device contains 28 active transistors.

357	4.7	470	6.8
421	4.7	470	5.6
530	4.7	470	4.3

Comparator hysteresis can be increased with the addition of resistor R_H. The hysteresis equation has been simplified and does not account for the change of input current I_{in} as V_{in} crosses the comparator threshold (Figure 8). An increase of the lower threshold $\Delta V_{th(lower)}$ will be observed due to I_{in} which is typically 10 µA at 4.3 V. The equations are accurate to ±10% with R_H less than 1.0 kΩ and R_L between 4.3 kΩ and 43 kΩ.

Power Switching Regulators

POWER SWITCHING REGULATORS

SEMICONDUCTOR TECHNICAL DATA

The MC34165 series are monolithic power switching regulators that contain the primary functions required for DC–to–DC converters. This series is specifically designed to be incorporated in step–up, step–down, and voltage–inverting applications with a minimum number of external components.

These devices consist of two high gain voltage feedback comparators, temperature compensated reference, controlled duty cycle oscillator, driver with bootstrap capability for increased efficiency, and a high current output switch. Protective features consist of cycle–by–cycle current limiting, and internal thermal shutdown. Also included is a low voltage indicator output designed to interface with microprocessor based systems.

These devices are contained in a 16 pin dual–in–line heat tab plastic package for improved thermal conduction.

- Output Switch Current in Excess of 1.5 A
- Operation from 3.0 V to 65 V Input
- Low Standby Current
- Precision 2% Reference
- Controlled Duty Cycle Oscillator
- Driver with Bootstrap Capability for Increased Efficiency
- Cycle–by–Cycle Current Limiting
- Internal Thermal Shutdown Protection
- Low Voltage Indicator Output for Direct Microprocessor Interface
- Heat Tab Power Package

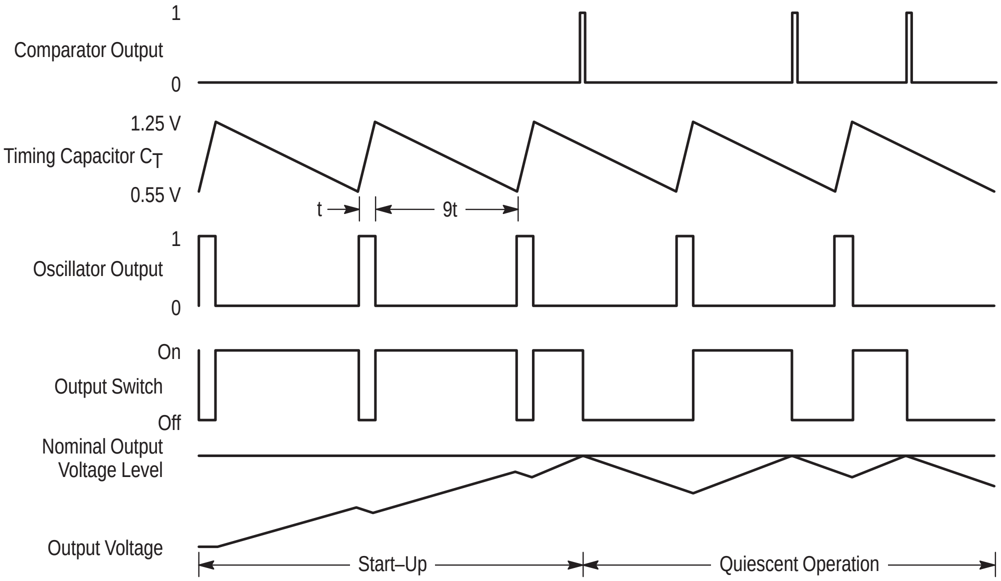

Figure 19. Typical Operating Waveforms

INTRODUCTION

The MC34165 series are monolithic power switching regulators optimized for DC–to–DC converter applications. The combination of features in this series enables the system designer to directly implement step–up, step–down, and voltage–inverting converters with a minimum number of external components. This series is constructed on a special high voltage process making it ideal for telecommunication applications. Other potential applications include cost sensitive consumer products as well as equipment for the automotive, computer, and industrial markets. The Representative Block Diagram is shown in Figure 18.

OPERATING DESCRIPTION

The MC34165 operates as a fixed on–time, variable off–time voltage mode ripple regulator. In general, this mode of operation is somewhat analogous to a capacitor charge pump and does not require dominant pole loop compensation for converter stability. The Typical Operating Waveforms are shown in Figure 19. The output voltage waveform shown is for a step–down converter, with the ripple and phasing exaggerated for clarity. During initial converter start–up, the feedback comparator senses that the output voltage level is below nominal. This causes the output switch to turn on and off at a frequency and duty cycle controlled by the oscillator, thus pumping up the output filter capacitor. When the output voltage level reaches nominal, the feedback comparator sets the latch, immediately terminating switch conduction. The feedback comparator will inhibit the switch until the load current causes the output voltage to fall below nominal. Under these conditions, output switch conduction can be inhibited for a partial oscillator cycle, a partial cycle plus a complete cycle, multiple cycles, or a partial cycle plus multiple cycles.

Oscillator

The oscillator frequency and on–time of the output switch are programmed by the value selected for timing capacitor C_T. Capacitor C_T is charged and discharged by a 9 to 1 ratio internal current source and sink, generating a negative going sawtooth waveform at Pin 6. As C_T charges, an internal pulse is generated at the oscillator output. This pulse is connected to the NOR gate center input, preventing output switch conduction, and to the AND gate upper input, allowing the latch to be reset if the comparator output is low. Thus, the output switch is always disabled during ramp–up and can be enabled by the comparator output only at the start of ramp–down. The oscillator peak and valley thresholds are 1.25 V and 0.55 V, respectively, with a charge current of 225 μA and a discharge current of 25 μA, yielding a maximum on–time duty cycle of 90%. Since the MC34165 is a ripple mode regulator, the switch frequency will vary with line and load. The value selected for C_T will set the maximum switching frequency of the converter. A reduction of the maximum duty cycle may be required for specific converter configurations. This can be accomplished with the addition of an external dead–time resistor (R_{DT}) placed across C_T. The resistor increases the discharge current which reduces the on–time of the output switch. A graph of the Output Switch On–Off Time versus Oscillator Timing Capacitance for various values of R_{DT} is shown in Figure 1. Note that the maximum output duty cycle, $t_{on}/t_{on} + t_{off}$, remains constant for values of C_T greater than 0.2 nF. The converter output can be inhibited by clamping C_T to ground with an external NPN small–signal transistor.

Feedback and Low Voltage Indicator Comparators

Output voltage control is established by the Feedback comparator. The inverting input is internally biased at 1.25 V and is not pinned out. The converter output voltage is typically divided down with two external resistors and monitored by the high impedance noninverting input at Pin 2. The maximum input bias current is ±0.4 μA, which can cause an output voltage error that is equal to the product of the input bias current and the upper divider resistance value. For applications that require 5.0 V, the converter output can be directly connected to the noninverting input at Pin 3. The high impedance input, Pin 2, must be grounded to prevent noise pickup. The internal resistor divider is set for a nominal voltage of 5.05 V. The additional 50 mV compensates for a 1.0% voltage drop in the cable and connector from the converter output to the load. The Feedback comparator's output state is controlled by the highest voltage applied to either of the two noninverting inputs.

The Low Voltage Indicator (LVI) comparator is designed for use as a reset controller in microprocessor–based systems. The inverting input is internally biased at 1.125 V, which sets the noninverting input thresholds to 90% of nominal. The LVI comparator has 15 mV of hysteresis to prevent erratic reset operation. The open collector output is capable of sinking in excess of 1.5 mA (see Figure 10). An external resistor (R_{LVI}) and capacitor (C_{DLY}) can be used to program a reset delay time (t_{DLY}) by the formula shown below, where $V_{th(MPU)}$ is the microprocessor reset input threshold.

$$t_{DLY} = R_{LVI}\, C_{DLY} \ln\left(\frac{1}{1 - \dfrac{V_{th(MPU)}}{V_{out}}}\right)$$

Current Limit Comparator, Latch and Thermal Shutdown

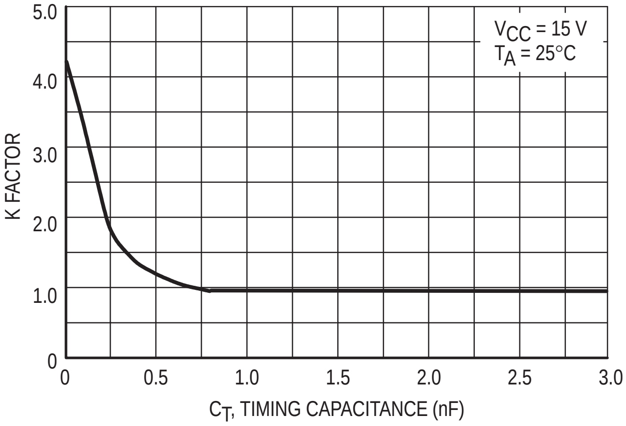
With a voltage mode ripple converter operating under normal conditions, output switch conduction is initiated by the oscillator and terminated by the Voltage Feedback comparator. Abnormal operating conditions occur when the converter output is overloaded or when feedback voltage sensing is lost. Under these conditions, the Current Limit comparator will protect the Output Switch.

The switch current is converted to a voltage by inserting a fractional ohm resistor, R_{SC}, in series with V_{CC} and output switch transistor Q_2. The voltage drop across R_{SC} is monitored by the Current Sense comparator. If the voltage drop exceeds 250 mV with respect to V_{CC}, the comparator will set the latch and terminate output switch conduction on a cycle–by–cycle basis. This Comparator/Latch configuration ensures that the Output Switch has only a single on–time during a given oscillator cycle. The calculation for a value of R_{SC} is:

$$R_{SC} = \frac{0.25\ \text{V} \cdot \text{K}}{I_{pk\,(Switch)}}$$

The K factor was added to the previous equation in order to account for a 200 ns propagation delay that occurs from the Current Limit comparator input to the output switch. This propagation delay can cause the actual peak switch current to rise above the calculated peak switch current for small values of C_T. The following figure shows the relationship of the ratio $I_{pk(actual)}/I_{pk\ (Switch)}$, expressed as K versus C_T. Note the ratio rises above 1.0 for C_T values less than 1.0 nF.

Figure 20. K Factor versus Timing Capacitance



When analyzing a design, the actual short circuit current must be measured to verify that it is less than the maximum rating of the device.

Figures 11 and 12 show that the Current Sense comparator threshold is tightly controlled over temperature and has a typical input bias current of 1.0 µA. The parasitic inductance associated with R_{SC} and the circuit layout should be minimized. This will prevent unwanted voltage spikes that may falsely trip the Current Limit comparator.

Internal thermal shutdown circuitry is provided to protect the IC in the event that the maximum junction temperature is exceeded. When activated, typically at 170°C, the Latch is forced into the “Set” state, disabling the Output Switch. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a replacement for proper heatsinking.

Driver and Output Switch

To aid in system design flexibility and conversion efficiency, the driver current source and collector, and output switch collector and emitter are pinned out separately. This allows the designer the option of driving the output switch into saturation with a selected force gain or driving it near saturation when connected as a Darlington. The output switch is designed to switch a maximum of 65 V collector to emitter, with up to 1.5 A peak collector current. The minimum value for R_{SC} is:

$$R_{SC(min)} = \frac{0.25\ V}{1.5\ A} = 0.166\ \Omega$$

When configured for step–down or voltage–inverting applications, as in Figures 20 and 24, the inductor will forward bias the output rectifier when the switch turns off. Rectifiers with a high forward voltage drop or long turn–on delay time should not be used. If the emitter is allowed to go sufficiently negative, collector current will flow, causing additional device heating and reduced conversion efficiency.

Figure 9 shows that by clamping the emitter to less than 0.5 V, the collector current will be in the range 10 µA over temperature. A MBR160 or equivalent Schottky barrier rectifier is recommended to fulfill these requirements.

A bootstrap input is provided to reduce the output switch saturation voltage in step–down and voltage–inverting converter applications. This input is connected through a series resistor and capacitor to the switch emitter and is used to raise the internal 2.0 mA bias current source above V_{CC}. An internal zener limits the bootstrap input voltage to V_{CC} +7.0 V. The capacitor’s equivalent series resistance may be large enough to limit the zener current to less than the maximum 100 mA rating. However, in most high voltage applications, an additional series resistor will probably be required. It is recommended that this resistor limit the zener current to approximately 25 mA for optimal performance. The circuit can be optimized by adjusting the zener current (R_B) during operation, while observing the circuit’s efficiency. The value of the series resistor can be calculated as follows:

$$R_B \approx \frac{V_{in(max)}}{I_Z}$$

The equation below is used to calculate a minimum value bootstrap capacitor based on a minimum zener voltage and an upper limit current source.

$$C_{B(min)} = I\ \frac{\Delta t}{\Delta V} = 4.0\ \text{mA}\ \frac{t_{on}}{4.0\ V} = 0.001\ t_{on}$$

Parametric operation of the MC34165 is guaranteed over a supply voltage range of 3.0 V to 65 V. When operating below 3.0 V, the Bootstrap Input should be connected to V_{CC}. Figure 15 shows that non–parametric operation down to 1.7 V at room temperature is possible.

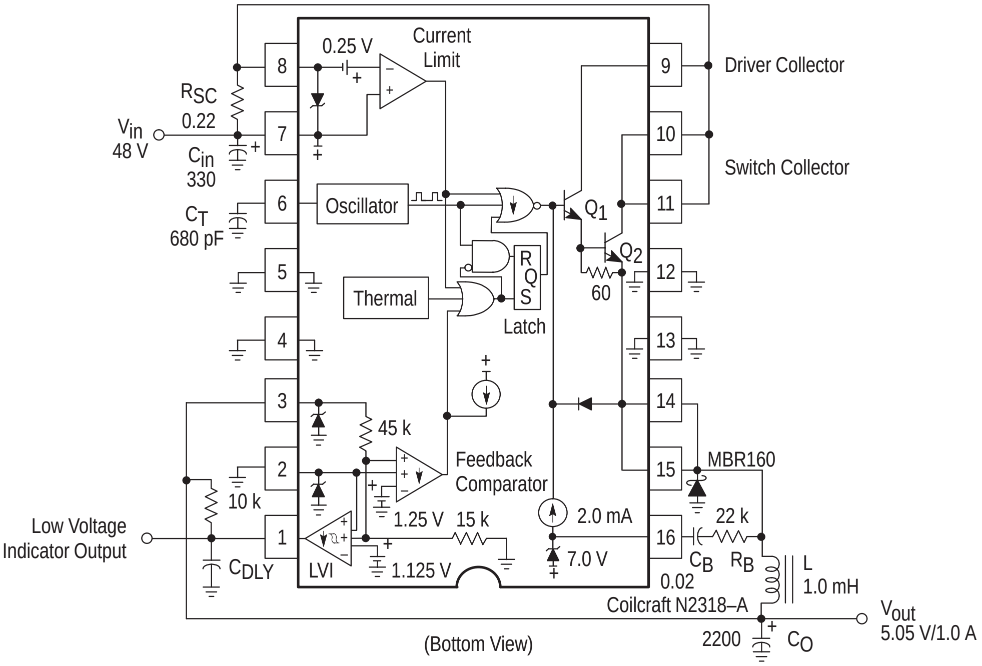
Package

The MC34165 is contained in a heatsinkable 16–lead plastic dual–in–line power package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figures 16 and 17 show a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction–to–air thermal resistance. These examples are for a symmetrical layout on a single–sided board with two ounce per square foot of copper.

APPLICATIONS

The following converter applications show the simplicity and flexibility of this circuit architecture. Three main converter topologies are demonstrated with actual test data shown below each of the circuit diagrams.

Figure 21. Step–Down Converter



Test	Condition	Results
Line Regulation	V_{in} = 12 V to 56 V, I_O = 1.0 A	9.0 mV = ± 0.049%
Load Regulation	V_{in} = 48 V, I_O = 0.1 A to 1.0 A	9.0 mV = ± 0.049%
Output Ripple	V_{in} = 48 V, I_O = 1.0 A	20 mVp–p
Short Circuit Current	V_{in} = 48 V, R_L = 0.1 Ω	1.23 A
Efficiency, Without Bootstrap	V_{in} = 48 V, I_O = 1.0 A	74.9%
Efficiency, With Bootstrap	V_{in} = 48 V, I_O = 1.0 A	75.5%

All printed circuit boards are 2.58” in width by 1.9” in height.

Table 1. Design Equations

Calculation	Step–Down	Step–Up	Voltage–Inverting
$\frac{t_{on}}{t_{off}}$ (Notes 1, 2, 3)	$\frac{V_{out} + V_F}{V_{in} - V_{sat} - V_{out}}$	$\frac{V_{out} + V_F - V_{in}}{V_{in} - V_{sat}}$	$\frac{\lvert V_{out}\rvert + V_F}{V_{in} - V_{sat}}$
t_{on}	$\frac{\frac{t_{on}}{t_{off}}}{f\left(\frac{t_{on}}{t_{off}} + 1\right)}$	$\frac{\frac{t_{on}}{t_{off}}}{f\left(\frac{t_{on}}{t_{off}} + 1\right)}$	$\frac{\frac{t_{on}}{t_{off}}}{f\left(\frac{t_{on}}{t_{off}} + 1\right)}$
C_T	$\frac{32.143 \cdot 10^{-6}}{f}$	$\frac{32.143 \cdot 10^{-6}}{f}$	$\frac{32.143 \cdot 10^{-6}}{f}$
$I_{L(avg)}$	I_{out}	$I_{out}\left(\frac{t_{on}}{t_{off}} + 1\right)$	$I_{out}\left(\frac{t_{on}}{t_{off}} + 1\right)$
$I_{pk\ (Switch)}$	$I_{L(avg)} + \frac{\Delta I_L}{2}$	$I_{L(avg)} + \frac{\Delta I_L}{2}$	$I_{L(avg)} + \frac{\Delta I_L}{2}$
R_{SC}	$\frac{0.25 \cdot K}{I_{pk\ (Switch)}}$	$\frac{0.25 \cdot K}{I_{pk\ (Switch)}}$	$\frac{0.25 \cdot K}{I_{pk\ (Switch)}}$
L	$\left(\frac{V_{in} - V_{sat} - V_{out}}{\Delta I_L}\right) t_{on}$	$\left(\frac{V_{in} - V_{sat}}{\Delta I_L}\right) t_{on}$	$\left(\frac{V_{in} - V_{sat}}{\Delta I_L}\right) t_{on}$
$V_{ripple(p-p)}$	$\Delta I_L \sqrt{\left(\frac{1}{8 f C_O}\right)^2 + (ESR)^2}$	$\approx \frac{t_{on}\ I_{out}}{C_O}$	$\approx \frac{t_{on}\ I_{out}}{C_O}$
V_{out}	$V_{ref}\left(\frac{R_2}{R_1} + 1\right)$	$V_{ref}\left(\frac{R_2}{R_1} + 1\right)$	$V_{ref}\left(\frac{R_2}{R_1} + 1\right)$

The following Converter Characteristics must be chosen:

V_{in} – Nominal operating input voltage.
V_{out} – Desired output voltage.
I_{out} – Desired output current.
ΔI_L – Desired peak–to–peak inductor ripple current. For maximum output current, it is suggested that ΔI_L be chosen to be less than 10% of the average inductor current $I_{L(avg)}$. This will help prevent $I_{pk\ (Switch)}$ from reaching the current threshold set by R_{SC}. If the design goal is to use a minimum inductance value, let $\Delta I_L = 2(I_{L(avg)})$. This will proportionally reduce converter output current capability.
f – Maximum output switch frequency.
$V_{ripple(p-p)}$ – Desired peak–to–peak output ripple voltage. For best performance, the ripple voltage should be kept to a low value since it will directly affect line and load regulation. Capacitor C_O should be a low equivalent series resistance (ESR) electrolytic designed for switching regulator applications.
K – Multiplier number as determined by Figure 20, for determining the appropriate value for R_{SC}.

NOTES: 1. V_{sat} – Saturation voltage of the output switch, refer to Figures 7 and 8.
2. V_F – Output rectifier forward voltage drop. Typical value for MBR160 Schottky barrier rectifier is 0.6 V.
3. The calculated t_{on}/t_{off} must not exceed the minimum guaranteed oscillator charge to discharge ratio of 8, at the minimum operating input voltage.
