The WDSVR register can be written to only once after reset and the key data (bits 5 through 1 of the WDSVR Register) must match to be a valid write. This write to the WDSVR register involves two irrevocable choices: (i) the selection of the WATCHDOG service window (ii) enabling or disabling of the Clock Monitor. Hence, the first write to WDSVR Register involves selecting or deselecting the Clock Monitor, select the WATCHDOG service window and match the WATCHDOG key data. Subsequent writes to the WDSVR register will compare the value being written by the user to the WATCHDOG service window value and the key data (bits 7 through 1) in the WDSVR Register. Table VI shows the sequence of events that can occur.

The user must service the WATCHDOG at least once before the upper limit of the service window expires. The WATCHDOG may not be serviced more than once in every lower limit of the service window. The user may service the WATCHDOG as many times as wished in the time period between the lower and upper limits of the service window. The first write to the WDSVR Register is also counted as a WATCHDOG service.

The WATCHDOG has an output pin associated with it. This is the WDOUT pin, on pin 1 of the port G. WDOUT is active low. The WDOUT pin is in the high impedance state in the inactive state. Upon triggering the WATCHDOG, the logic will pull the WDOUT (G1) pin low for an additional 16 t_C–32 t_C cycles after the signal level on WDOUT pin goes below the lower Schmitt trigger threshold. After this delay, the device will stop forcing the WDOUT output low.

The WATCHDOG service window will restart when the WDOUT pin goes high. It is recommended that the user tie the WDOUT pin back to V_{CC} through a resistor in order to pull WDOUT high.

A WATCHDOG service while the WDOUT signal is active will be ignored. The state of the WDOUT pin is not guaranteed on reset, but if it powers up low then the WATCHDOG will time out and WDOUT will enter high impedance state.

WATCHDOG Operation (Continued)

The Clock Monitor forces the G1 pin low upon detecting a clock frequency error. The Clock Monitor error will continue until the clock frequency has reached the minimum specified value, after which the G1 output will enter the high impedance TRI-STATE mode following 16 t_C–32 t_C clock cycles. The Clock Monitor generates a continual Clock Monitor error if the oscillator fails to start, or fails to reach the minimum specified frequency. The specification for the Clock Monitor is as follows:

$1/t_C > 10$ kHz—No clock rejection.

$1/t_C < 10$ Hz—Guaranteed clock rejection.

WATCHDOG AND CLOCK MONITOR SUMMARY

The following salient points regarding the WATCHDOG and CLOCK MONITOR should be noted:

- Both the WATCHDOG and CLOCK MONITOR detector circuits are inhibited during RESET.
- Following RESET, the WATCHDOG and CLOCK MONITOR are both enabled, with the WATCHDOG having he maximum service window selected.
- The WATCHDOG service window and CLOCK MONITOR enable/disable option can only be changed once, during the initial WATCHDOG service following RESET.
- The initial WATCHDOG service must match the key data value in the WATCHDOG Service register WDSVR in order to avoid a WATCHDOG error.
- Subsequent WATCHDOG services must match all three data fields in WDSVR in order to avoid WATCHDOG errors.
- The correct key data value cannot be read from the WATCHDOG Service register WDSVR. Any attempt to read this key data value of 01100 from WDSVR will read as key data value of all 0's.
- The WATCHDOG detector circuit is inhibited during both the HALT and IDLE modes.
- The CLOCK MONITOR detector circuit is active during both the HALT and IDLE modes. Consequently, the device inadvertently entering the HALT mode will be detected as a CLOCK MONITOR error (provided that the CLOCK MONITOR enable option has been selected by the program).
- With the single-pin R/C oscillator mask option selected and the CLKDLY bit reset, the WATCHDOG service window will resume following HALT mode from where it left off before entering the HALT mode.
- With the crystal oscillator mask option selected, or with the single-pin R/C oscillator mask option selected and the CLKDLY bit set, the WATCHDOG service window will be set to its selected value from WDSVR following HALT. Consequently, the WATCHDOG should not be serviced for at least 2048 instruction cycles following HALT, but must be serviced within the selected window to avoid a WATCHDOG error.
- The IDLE timer T0 is not initialized with RESET.
- The user can sync in to the IDLE counter cycle with an IDLE counter (T0) interrupt or by monitoring the T0PND flag. The T0PND flag is set whenever the thirteenth bit of the IDLE counter toggles (every 4096 instruction cycles). The user is responsible for resetting the T0PND flag.
- A hardware WATCHDOG service occurs just as the device exits the IDLE mode. Consequently, the WATCHDOG should not be serviced for at least 2048 instruction cycles following IDLE, but must be serviced within the selected window to avoid a WATCHDOG error.
- Following RESET, the initial WATCHDOG service (where the service window and the CLOCK MONITOR enable/disable must be selected) may be programmed anywhere within the maximum service window (65,536 instruction cycles) initialized by RESET. Note that this initial WATCHDOG service may be programmed within the initial 2048 instruction cycles without causing a WATCHDOG error.

Detection of Illegal Conditions

The device can detect various illegal conditions resulting from coding errors, transient noise, power supply voltage drops, runaway programs, etc.

Reading of undefined ROM gets zeros. The opcode for software interrupt is zero. If the program fetches instructions from undefined ROM, this will force a software interrupt, thus signaling that an illegal condition has occurred.

The subroutine stack grows down for each call (jump to subroutine), interrupt, or PUSH, and grows up for each return or POP. The stack pointer is initialized to RAM location 06F Hex during reset. Consequently, if there are more returns than calls, the stack pointer will point to addresses 070 and 071 Hex (which are undefined RAM). Undefined RAM from addresses 070 to 07F (Segment 0), 140 to 17F (Segment 1), and all other segments (i.e., Segments 2 . . . etc.) is read as all 1's, which in turn will cause the program to return to address 7FFF Hex. This is an undefined ROM location and the instruction fetched (all 0's) from this location will generate a software interrupt signaling an illegal condition.

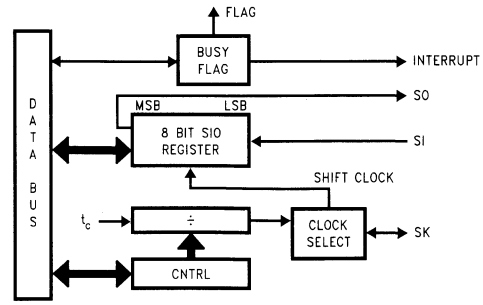
Thus, the chip can detect the following illegal conditions:

a. Executing from undefined ROM
b. Over "POP"ing the stack by having more returns than calls.

When the software interrupt occurs, the user can re-initialize the stack pointer and do a recovery procedure before restarting (this recovery program is probably similar to that following reset, but might not contain the same program initialization procedures). The recovery program should reset the software interrupt pending bit using the RPND instruction.

MICROWIRE/PLUS

MICROWIRE/PLUS is a serial synchronous communications interface. The MICROWIRE/PLUS capability enables the device to interface with any of National Semiconductor's MICROWIRE peripherals (i.e. A/D converters, display drivers, E^2PROMs etc.) and with other microcontrollers which support the MICROWIRE interface. It consists of an 8-bit serial shift register (SIO) with serial data input (SI), serial data output (SO) and serial shift clock (SK). *Figure 17* shows a block diagram of the MICROWIRE/PLUS logic.



TL/DD/12602–22

FIGURE 17. MICROWIRE/PLUS Block Diagram

The shift clock can be selected from either an internal source or an external source. Operating the MICROWIRE/PLUS arrangement with the internal clock source is called the Master mode of operation. Similarly, operating the MICROWIRE/PLUS arrangement with an external shift clock is called the Slave mode of operation.

The CNTRL register is used to configure and control the MICROWIRE/PLUS mode. To use the MICROWIRE/PLUS, the MSEL bit in the CNTRL register is set to one. In the master mode, the SK clock rate is selected by the two bits, SL0 and SL1, in the CNTRL register. Table VII details the different clock rates that may be selected.

TABLE VI. WATCHDOG Service Actions

Key Data	Window Data	Clock Monitor	Action
Match	Match	Match	Valid Service: Restart Service Window
Don't Care	Mismatch	Don't Care	Error: Generate WATCHDOG Output
Mismatch	Don't Care	Don't Care	Error: Generate WATCHDOG Output
Don't Care	Don't Care	Mismatch	Error: Generate WATCHDOG Output

TABLE VII. MICROWIRE/PLUS Master Mode Clock Select

SL1	SL0	SK
0	0	$2 \times t_c$
0	1	$4 \times t_c$
1	x	$8 \times t_c$

Where t_c is the instruction cycle clock

MICROWIRE/PLUS (Continued)

MICROWIRE/PLUS OPERATION

Setting the BUSY bit in the PSW register causes the MICROWIRE/PLUS to start shifting the data. It gets reset when eight data bits have been shifted. The user may reset the BUSY bit by software to allow less than 8 bits to shift. If enabled, an interrupt is generated when eight data bits have been shifted. The device may enter the MICROWIRE/PLUS mode either as a Master or as a Slave. *Figure 18* shows how two devices, microcontrollers and several peripherals may be interconnected using the MICROWIRE/PLUS arrangements.

Warning:

The SIO register should only be loaded when the SK clock is low. Loading the SIO register while the SK clock is high will result in undefined data in the SIO register. SK clock is normally low when not shifting.

Setting the BUSY flag when the input SK clock is high in the MICROWIRE/PLUS slave mode may cause the current SK clock for the SIO shift register to be narrow. For safety, the BUSY flag should only be set when the input SK clock is low.

MICROWIRE/PLUS Master Mode Operation

In the MICROWIRE/PLUS Master mode of operation the shift clock (SK) is generated internally by the device. The MICROWIRE Master always initiates all data exchanges. The MSEL bit in the CNTRL register must be set to enable the SO and SK functions onto the G Port. The SO and SK pins must also be selected as outputs by setting appropriate bits in the Port G configuration register. Table VII summarizes the bit settings required for Master mode of operation.

MICROWIRE/PLUS Slave Mode Operation

In the MICROWIRE/PLUS Slave mode of operation the SK clock is generated by an external source. Setting the MSEL bit in the CNTRL register enables the SO and SK functions onto the G Port. The SK pin must be selected as an input and the SO pin is selected as an output pin by setting and resetting the appropriate bits in the Port G configuration register. Table VII summarizes the settings required to enter the Slave mode of operation.

The user must set the BUSY flag immediately upon entering the Slave mode. This will ensure that all data bits sent by the Master will be shifted properly. After eight clock pulses the BUSY flag will be cleared and the sequence may be repeated.

Alternate SK Phase Operation

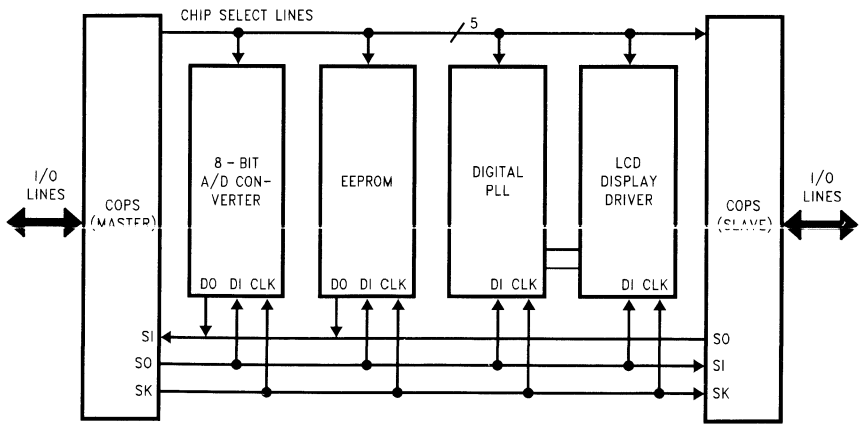
The device allows either the normal SK clock or an alternate phase SK clock to shift data in and out of the SIO register. In both the modes the SK is normally low. In the normal mode data is shifted in on the rising edge of the SK clock and the data is shifted out on the falling edge of the SK clock. The SIO register is shifted on each falling edge of the SK clock. In the alternate SK phase operation, data is shifted in on the falling edge of the SK clock and shifted out on the rising edge of the SK clock.

A control flag, SKSEL, allows either the normal SK clock or the alternate SK clock to be selected. Resetting SKSEL causes the MICROWIRE/PLUS logic to be clocked from the normal SK signal. Setting the SKSEL flag selects the alternate SK clock. The SKSEL is mapped into the G6 configuration bit. The SKSEL flag will power up in the reset condition, selecting the normal SK signal.

TABLE VIII

This table assumes that the control flag MSEL is set.

G4 (SO) Config. Bit	G5 (SK) Config. Bit	G4 Fun.	G5 Fun.	Operation
1	1	SO	Int. SK	MICROWIRE/PLUS Master
0	1	TRI-STATE	Int. SK	MICROWIRE/PLUS Master
1	0	SO	Ext. SK	MICROWIRE/PLUS Slave
0	0	TRI-STATE	Ext. SK	MICROWIRE/PLUS Slave



TL/DD/12602–23

Memory Map

All RAM, ports and registers (except A and PC) are mapped into data memory address space.

Address S/ADD REG	Contents
0000 to 006F	On-Chip RAM bytes (112 bytes)
0070 to 007F	Unused RAM Address Space (Reads As All Ones)
xx80 to xxAF	Unused RAM Address Space (Reads Undefined Data)
0098	Dividend or Result Byte (MDR1)
0099	Dividend/Multiplier or Result Byte (MDR2)
009A	Dividend/Result Byte or Undefined (MDR3)
009B	Dividend/Multiplicand or Result Byte (MDR4)
009C	Divisor or Multiplicand Byte (MDR5) Multiply/Divide Control Register (MDCR)
xxB0	Timer T3 Lower Byte
XXB1	Timer T3 Upper Byte
xxB2	Timer T3 Autoload Register T3RA Lower Byte
xxB3	Timer T3 Autoload Register T3RA Upper Byte
xxB4	Timer T3 Autoload Register T3RB Lower Byte
xxB5	Timer T3 Autoload Register T3RB Upper Byte
xxB6	Timer T3 Control Register
xxB7	Comparator Select Register (CMPSL)
xxB8	UART Transmit Buffer (TBUF)
xxB9	UART Receive Buffer (RBUF)
xxBA	UART Control and Status Register (ENU)
xxBB	UART Receive Control and Status Register (ENUR)
xxBC	UART Interrupt and Clock Source Register (ENUI)
xxBD	UART Baud Register (BAUD)
xxBE	UART Prescale Select Register (PSR)
xxBF	Reserved for UART
xxC0	Timer T2 Lower Byte
xxC1	Timer T2 Upper Byte
xxC2	Timer T2 Autoload Register T2RA Lower Byte
xxC3	Timer T2 Autoload Register T2RA Upper Byte
xxC4	Timer T2 Autoload Register T2RB Lower Byte
xxC5	Timer T2 Autoload Register T2RB Upper Byte
xxC6	Timer T2 Control Register
xxC7	WATCHDOG Service Register (Reg:WDSVR)
xxC8	MIWU Edge Select Register (Reg:WKEDG)
xxC9	MIWU Enable Register (Reg:WKEN)
xxCA	MIWU Pending Register (Reg:WKPND)
xxCB	Reserved
xxCC	Reserved
xxCD to xxCF	Reserved

Address S/ADD REG	Contents
xxD0	Port L Data Register
xxD1	Port L Configuration Register
xxD2	Port L Input Pins (Read Only)
xxD3	Reserved for Port L
xxD4	Port G Data Register
xxD5	Port G Configuration Register
xxD6	Port G Input Pins (Read Only)
xxD7	Port I Input Pins (Read Only)
xxD8	Port C Data Register
xxD9	Port C Configuration Register
xxDA	Port C Input Pins (Read Only)
xxDB	Reserved for Port C
xxDC	Port D
xxDD to DF	Reserved for Port D
xxE0 to xxE5	Reserved for EE Control Registers
xxE6	Timer T1 Autoload Register T1RB Lower Byte
xxE7	Timer T1 Autoload Register T1RB Upper Byte
xxE8	ICNTRL Register
xxE9	MICROWIRE/PLUS Shift Register
xxEA	Timer T1 Lower Byte
xxEB	Timer T1 Upper Byte
xxEC	Timer T1 Autoload Register T1RA Lower Byte
xxED	Timer T1 Autoload Register T1RA Upper Byte
xxEE	CNTRL Control Register
xxEF	PSW Register
xxF0 to FB	On-Chip RAM Mapped as Registers
xxFC	X Register
xxFD	SP Register
xxFE	B Register
xxFF	S Register
0100 to 017F	On-Chip 128 RAM Bytes
0200 to 027F	On-Chip 128 RAM Bytes
0300 to 037F	On-Chip 128 RAM Bytes

Reading memory locations 0070H–007FH (Segment 0) will return all ones. Reading unused memory locations 0080H–00AFH (Segment 0) will return undefined data. Reading memory locations from other unused Segments (i.e., Segment 4, Segment 5, ... etc.) will return all ones.

Addressing Modes

There are ten addressing modes, six for operand addressing and four for transfer of control.

OPERAND ADDRESSING MODES

Register Indirect

This is the "normal" addressing mode. The operand is the data memory addressed by the B pointer or X pointer.

Register Indirect (with auto post increment or decrement of pointer)

This addressing mode is used with the LD and X instructions. The operand is the data memory addressed by the B pointer or X pointer. This is a register indirect mode that automatically post increments or decrements the B or X register after executing the instruction.

Direct

The instruction contains an 8-bit address field that directly points to the data memory for the operand.

Immediate

The instruction contains an 8-bit immediate field as the operand.

Short Immediate

This addressing mode is used with the Load B Immediate instruction. The instruction contains a 4-bit immediate field as the operand.

Indirect

This addressing mode is used with the LAID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a data operand from the program memory.

TRANSFER OF CONTROL ADDRESSING MODES

Relative

This mode is used for the JP instruction, with the instruction field being added to the program counter to get the new program location. JP has a range from −31 to +32 to allow a 1-byte relative jump (JP + 1 is implemented by a NOP instruction). There are no "pages" when using JP, since all 15 bits of PC are used.

Absolute

This mode is used with the JMP and JSR instructions, with the instruction field of 12 bits replacing the lower 12 bits of the program counter (PC). This allows jumping to any location in the current 4k program memory segment.

Absolute Long

This mode is used with the JMPL and JSRL instructions, with the instruction field of 15 bits replacing the entire 15 bits of the program counter (PC). This allows jumping to any location up to 32k program memory space.

Indirect

This mode is used with the JID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a location in the program memory. The contents of this program memory location serve as a partial address (lower 8 bits of PC) for the jump to the next instruction.

Note: The VIS is a special case of the Indirect Transfer of Control addressing mode, where the double byte vector associated with the interrupt is transferred from adjacent addresses in the program memory into the program counter (PC) in order to jump to the associated interrupt service routine.

Instruction Set

Register and Symbol Definition

Registers	
A	8-Bit Accumulator Register
B	8-Bit Address Register
X	8-Bit Address Register
SP	8-Bit Stack Pointer Register
PC	15-Bit Program Counter Register
PU	Upper 7 Bits of PC
PL	Lower 8 Bits of PC
C	1 Bit of PSW Register for Carry
HC	1 Bit of PSW Register for Half Carry
GIE	1 Bit of PSW Register for Global Interrupt Enable
VU	Interrupt Vector Upper Byte
VL	Interrupt Vector Lower Byte

Symbols	
[B]	Memory Indirectly Addressed by B Register
[X]	Memory Indirectly Addressed by X Register
MD	Direct Addressed Memory
Mem	Direct Addressed Memory or [B]
Meml	Direct Addressed Memory or [B] or Immediate Data
Imm	8-Bit Immediate Data
Reg	Register Memory: Addresses F0 to FF (Includes B, X and SP)
Bit	Bit Number (0 to 7)
←	Loaded with
⟷	Exchanged with

Instruction Set (Continued)

INSTRUCTION SET

ADD	A,Meml	ADD	A ← A + Meml
ADC	A,Meml	ADD with Carry	A ← A + Meml + C, C ← Carry HC ← Half Carry
SUBC	A,Meml	Subtract with Carry	A ← A − $\overline{\text{Meml}}$ + C, C ← Carry HC ← Half Carry
AND	A,Meml	Logical AND	A ← A and Meml
ANDSZ	A,Imm	Logical AND Immed., Skip if Zero	Skip next if (A and Imm) = 0
OR	A,Meml	Logical OR	A ← A or Meml
XOR	A,Meml	Logical EXclusive OR	A ← A xor Meml
IFEQ	MD,Imm	IF EQual	Compare MD and Imm, Do next if MD = Imm
IFEQ	A,Meml	IF EQual	Compare A and Meml, Do next if A = Meml
IFNE	A,Meml	IF Not Equal	Compare A and Meml, Do next if A ≠ Meml
IFGT	A,Meml	IF Greater Than	Compare A and Meml, Do next if A > Meml
IFBNE	#	If B Not Equal	Do next if lower 4 bits of B ≠ Imm
DRSZ	Reg	Decrement Reg., Skip if Zero	Reg ← Reg − 1, Skip if Reg = 0
SBIT	#,Mem	Set BIT	1 to bit, Mem (bit = 0 to 7 immediate)
RBIT	#,Mem	Reset BIT	0 to bit, Mem
IFBIT	#,Mem	IF BIT	If bit in A or Mem is true do next instruction
RPND		Reset PeNDing Flag	Reset Software Interrupt Pending Flag
X	A,Mem	EXchange A with Memory	A ⟷ Mem
X	A,[X]	EXchange A with Memory [X]	A ⟷ [X]
LD	A,Meml	LoaD A with Memory	A ← Meml

INTR		Generate an Interrupt	[SP] ← PL, [SP−1] ← PU, SP−2, PC ← 0FF
NOP		No OPeration	PC ← PC + 1

Instruction Execution Time

Most instructions are single byte (with immediate addressing mode instructions taking two bytes).

Most single byte instructions take one cycle time to execute.

Skipped instructions require x number of cycles to be skipped, where x equals the number of bytes in the skipped instruction opcode.

See the BYTES and CYCLES per INSTRUCTION table for details.

Bytes and Cycles per Instruction

The following table shows the number of bytes and cycles for each instruction in the format of byte/cycle.

Where,

i is the immediate data

Md is a directly addressed memory location

* is an unused opcode

Note: The opcode 60 Hex is also the opcode for IFBIT #i,A

Mask Options

The mask programmable options are shown below. The options are programmed at the same time as the ROM pattern submission.

```
OPTION 1: CLOCK CONFIGURATION
  = 1     Crystal Oscillator (CKI/IO)
              G7 (CKO) is clock generator
              output to crystal/resonator
              CKI is the clock input
  = 2     Extend (CKI/IO) CKO available as
          G7 input
Crystal Oscillator (CKI/IO)
  = 3     Single-pin RC controlled
              oscillator (CKI/IO)
              G7 is available as a HALT
              restart and/or general purpose
              input
OPTION 2: HALT
  = 1     Enable HALT mode
  = 2     Disable HALT mode
OPTION 3: BONDING OPTIONS
  = 1     44-Pin PLCC
  = 2     40-Pin DIP
  = 3     N/A
  = 4     28-Pin DIP
  = 5     28-Pin SO
```

The chip can be driven by a clock input on the CKI input pin which can be between DC and 10 MHz. The CKO output clock is on pin G7 (if clock option = 1 has been selected). The CKI input frequency is divided down by 10 to produce the instruction cycle clock ($1/t_C$).

Development Support

Summary

- iceMASTER™: IM-COP8/400—Full feature in-circuit emulation for all COP8 products. A full set of COP8 Basic and Feature Family device and package specific probes are available.
- COP8 Debug Module: Moderate cost in-circuit emulation and development programming unit.
- COP8 Evaluation and Programming Unit: EPU-COP888GG—low cost In-circuit simulation and development programming unit.
- Assembler: COP-8-DEV-IBMA. A DOS installable cross development Assembler, Linker, Librarian and Utility Software Development Tool Kit.
- C Compiler: COP8C. A DOS installable cross development Software Tool Kit.
- OTP/EPROM Programmer Support: Covering needs from engineering prototype, pilot production to full production environments.

IceMASTER (IM) IN-CIRCUIT EMULATION

The iceMASTER IM-COP8/400 is a full feature, PC based, in-circuit emulation tool developed and marketed by Meta-Link Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 19* for configuration.

The iceMASTER IM-COP8/400 with its device specific COP8 Probe provides a rich feature set for developing, testing and maintaining product:

- Real-time in-circuit emulation; full 2.4V–5.5V operation range, full DC-10 MHz clock. Chip options are programmable or jumper selectable.
- Direct connection to application board by package compatible socket or surface mount assembly.
- Full 32k byte of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated on the probe as necessary.
- Full 4k frame synchronous trace memory. Address, instruction, and 8 unspecified, circuit connectable trace lines. Display can be HLL source (e.g., C source), assembly or mixed.
- A full 64k hardware configurable break, trace on, trace off control, and pass count increment events.
- Tool set integrated interactive symbolic debugger—supports both assembler (COFF) and C Compiler (.COD) linked object formats.
- Real time performance profiling analysis; selectable bucket definition.
- Watch windows, content updated automatically at each execution break.
- Instruction by instruction memory/register changes displayed on source window when in single step operation.
- Single base unit and debugger software reconfigurable to support the entire COP8 family; only the probe personality needs to change. Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- On-line HELP customized to specific processor using master model file.
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

IceMASTER DEBUG MODULE (DM)

The iceMASTER Debug Module is a PC based, combination in-circuit emulation tool and COP8 based OTP/EPROM programming tool developed and marketed by MetaLink Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 20* for configuration.

The iceMASTER Debug Module is a moderate cost development tool. It has the capability of in-circuit emulation for a specific COP8 microcontroller and in addition serves as a programming tool for COP8 OTP and EPROM product families. Summary of features is as follows:

- Real-time in-circuit emulation; full operating voltage range operation, full DC-10 MHz clock.
- All processor I/O pins can be cabled to an application development board with package compatible cable to socket and surface mount assembly.
- Full 32k byte of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated as necessary.
- 100 frames of synchronous trace memory. The display can be HLL source (C source), assembly or mixed. The most recent history prior to a break is available in the trace memory.
- Configured break points; uses INTR instruction which is modestly intrusive.
- Software—only supported features are selectable.
- Tool set integrated interactive symbolic debugger—supports both assembler (COFF) and C Compiler (.COD) SDK linked object formats.
- Instruction by instruction memory/register changes displayed when in single step operation.
- Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- Programming menu supports full product line of programmable OTP and EPROM COP8 products. Program data is taken directly from the overlay RAM.
- Programming of 44PLCC 68PLCC parts requires external programming adapters.
- Power supply. (Includes wallmount)
- On-board V_{PP} generator from 5V input or connection to external supply supported. Requires V_{PP} level adjustment per the family programming specification (correct level is provided on an on-screen pop-down display). On-line HELP customized to specific processor using master model file.
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

Development Support (Continued)

COP8 ASSEMBLER/LINKER SOFTWARE DEVELOPMENT TOOL KIT

National Semiconductor offers a relocateable COP8 macro cross assembler, linker, librarian and utility software development tool kit. Features are summarized as follows:

- Basic and Feature Family instruction set by "device" type.
- Nested macro capability.
- Extensive set of assembler directives.
- Supported on PC/DOS platform.
- Generates National standard COFF output files.
- Integrated Linker and Librarian.
- Integrated utilities to generate ROM code file outputs.
- DUMPCOFF utility.

This product is integrated as a part of MetaLink tools as a development kit, fully supported by the MetaLink debugger. It may be ordered separately or it is bundled with the MetaLink products at no additional cost.

Order Information

Assembler SDK	
COP8-DEV-IBMA	Assembler SDK on installable 3.5" PC/DOS Floppy Disk Drive format. Periodic upgrades and most recent version is available on National's BBS and Internet.

COP8 C COMPILER

A C Compiler is developed and marketed by Byte Craft Limited. The COP8C compiler is a fully integrated development tool specifically designed to support the compact embedded configuration of the COP8 family of products.

Features are summarized as follows:

- ANSI C with some restrictions and extensions that optimize development for the COP8 embedded application.
- BITS data type extension. Register declaration #pragma with direct bit level definitions.
- C language support for interrupt routines.
- Expert system, rule based code geration and optimization.
- Performs consistency checks against the architectural definitions of the target COP8 device.
- Generates program memory code.
- Supports linking of compiled object or COP8 assembled object formats.
- Global optimization of linked code.
- Symbolic debug load format fully source level supported by the MetaLink debugger.

SINGLE CHIP OTP/EMULATOR SUPPORT

The COP8 family is supported by single chip OTP emulators. For detailed information refer to the emulator specific datasheet and the emulator selection table below:

OTP Emulator Ordering Information

Device Number	Clock Option	Package	Emulates
COP87L84FHN-XE	Crystal	28N	COP884FH
COP87L84FHN-XE	External	28N	COP884FH
COP87L84FHM-XE	Crystal	28 SO	COP884FH
COP87L84FHM-XE	External	28 SO	COP884FH

Development Support (Continued)

INDUSTRY WIDE OTP/EPROM PROGRAMMING SUPPORT

Programming support, in addition to the MetaLink development tools, is provided by a full range of independent approved vendors to meet the needs from the engineering laboratory to full production.

AVAILABLE LITERATURE

For more information, please see the COP8 Basic Family User's Manual, Literature Number 620895, COP8 Feature Family User's Manual Literature Number 620897 and National's Family of 8-bit Microcontrollers COP8 Selection Guide, Literature Number 630009.

DIAL-A-HELPER SERVICE

Dial-A-Helper is a service provided by the Microcontroller Applications group. The Dial-A-Helper is an Electronic Information System that may be accessed as a Bulletin Board System (BBS) via data modem, as an FTP site on the Internet via standard FTP client application or as an FTP site on the Internet using a standard Internet browser such as Netscape or Mosaic.

The Dial-A-Helper system provides access to an automated information storage and retrieval system. The system capabilities include a MESSAGE SECTION (electronic mail, when accessed as a BBS) for communication to and from the Microcontroller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities could be found.

National Semiconductor

COP688GG/COP888GG
8-Bit Microcontroller with UART and Three Multi-Function Timers

General Description

The COP8™ feature family of microcontrollers uses an 8-bit single chip core architecture fabricated with National Semiconductor's M²CMOS™ process technology. The COP888GG is a member of this expandable 8-bit core processor family of microcontrollers. (Continued)

Key Features

- Full duplex UART
- Three 16-bit timers, each with two 16-bit registers supporting:
  - — Processor Independent PWM mode
  - — External Event counter mode
  - — Input Capture mode
- Quiet design (low radiated emissions)
- 16 kbytes on-board ROM
- 512 bytes on-board RAM

Additional Peripheral Features

- Idle Timer
- Multi-Input Wake-Up (MIWU) with optional interrupts (8)
- Two analog comparators
- WATCHDOG™ and Clock Monitor logic
- MICROWIRE/PLUS™ serial I/O

I/O Features

- Memory mapped I/O
- Software selectable I/O options (TRI-STATE® Output, Push-Pull Output, Weak Pull-Up Input, High Impedance Input)
- Schmitt trigger inputs on ports G and L
- Packages:
  - — 40 DIP with 36 I/O pins
  - — 44 PQFP with 40 I/O pins
  - — 44 PLCC with 40 I/O pins

CPU/Instruction Set Features

- 1 μs instruction cycle time
- Fourteen multi-source vectored interrupts servicing
  - — External Interrupt with selectable edge
  - — Idle Timer T0
  - — Three Timers (Each with 2 Interrupts)
  - — MICROWIRE/PLUS™
  - — Multi-Input Wake-Up
  - — Software Trap
  - — UART (2)
  - — Default VIS (default interrupt)
- Versatile and easy-to-use instruction set
- 8-bit Stack Pointer (SP) — stack in RAM
- Two 8-bit Register Indirect Data Memory Pointers (B and X)

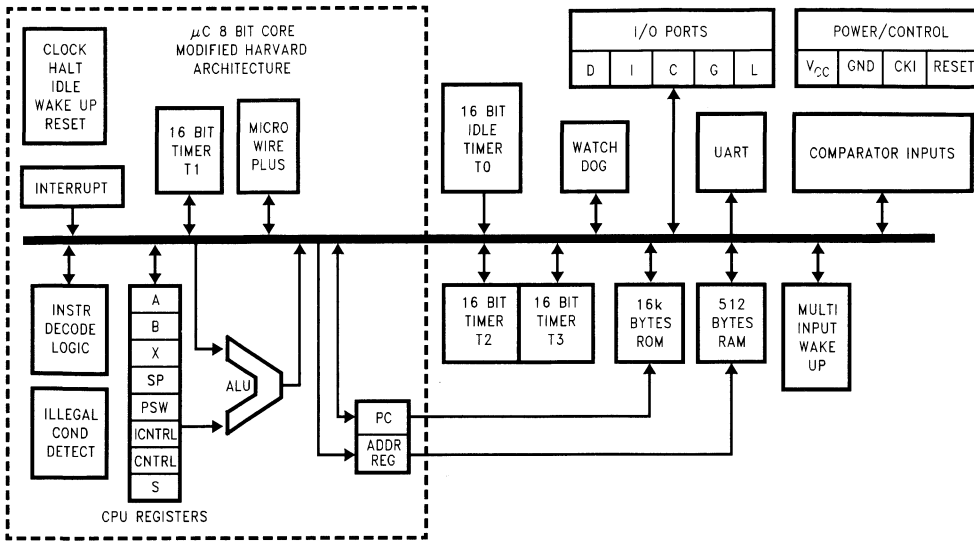
Fully Static CMOS

- Two power saving modes: HALT and IDLE
- Low current drain (typically <1 μA)
- Single supply operation: 2.5V to 5.5V
- Temperature ranges:
  $-40°C$ to $+85°C$, $-55°C$ to $+125°C$

Development Support

- Emulation and OTP devices
- Real time emulation and full program debug offered by MetaLink Development System

Block Diagram



TL/DD/12823–1

FIGURE 1. Block Diagram

General Description (Continued)

It is a fully static part, fabricated using double-metal silicon gate microCMOS technology. Features include an 8-bit memory mapped architecture, MICROWIRE/PLUS serial I/O, three 16-bit timer/counters supporting three modes (Processor Independent PWM generation, External Event counter, and Input Capture mode capabilities), full duplex UART, two comparators, and two power saving modes (HALT and IDLE), both with a multi-sourced wakeup/interrupt capability. This multi-sourced interrupt capability may also be used independent of the HALT or IDLE modes. Each I/O pin has software selectable configurations. The devices operate over a voltage range of 2.5V to 5.5V. High throughput is achieved with an efficient, regular instruction set operating at a maximum rate of 1 μs per instruction.

Low radiated emissions are achieved by gradual turn-on output drivers and internal I_{CC} smoothing filters on the chip logic and crystal oscillator.

	$2.5V \leq V_{CC} \leq 4.0V$	150			ns
Output Propagation Delay	$R_L = 2.2k, C_L = 100$ pF				
t_{PD1}, t_{PD0}					
SO, SK	$4.0V \leq V_{CC} \leq 5.5V$			0.7	μs
	$2.5V \leq V_{CC} \leq 4.0V$			1.75	μs
All Others	$4.0V \leq V_{CC} \leq 5.5V$			1.0	μs
	$2.5V \leq V_{CC} \leq 4.0V$			2.5	μs
MICROWIRE Setup Time (t_{UWS}) (Note 7)	$V_{CC} \geq 4.0V$	20			ns
MICROWIRE Hold Time (t_{UWH}) (Note 7)	$V_{CC} \geq 4.0V$	56			ns
MICROWIRE Output Propagation Delay (t_{UPD})	$V_{CC} \geq 4.0V$			220	ns
Input Pulse Width					
Interrupt Input High Time		1.0			t_c
Interrupt Input Low Time		1.0			t_c
Timer 1, 2, 3 Input High Time		1.0			t_c
Timer 1, 2, 3 Input Low Time		1.0			t_c
Reset Pulse Width		1.0			μs

t_c = Instruction Cycle Time

Note 1: Maximum rate of voltage change must be less than 0.5 V/ms.

Note 2: Supply and IDLE currents are measured with CKI driven with a square wave Oscillator, CKO driven 180° out of phase with CKI, inputs connected to V_{CC} and outputs driven low but not connected to a load.

Note 3: The HALT mode will stop CKI from oscillating in the RC and the Crystal configurations by bringing CKI high. Test Conditions: All inputs tied to V_{CC}, L and G ports in the TRI-STATE mode and tied to ground, all outputs low and tied to ground. The clock monitor is disabled.

Note 4: The user must guarantee that D2 pin does not source more than 10 mA during RESET. If D2 sources more than 10 mA during reset, the device will go into programming mode.

Note 5: Pins G6 and $\overline{\text{RESET}}$ are designed with a high voltage input network. These pins allow input voltages $> V_{CC}$ and the pins will have sink current to V_{CC} when biased at voltages $> V_{CC}$ (the pins do not have source current when biased at a voltage below V_{CC}). The effective resistance to V_{CC} is 750Ω (typical). These two pins will not latch up. The voltage at the pins must be limited to $< 14V$. **WARNING: Voltages in excess of 14V will cause damage to the pins. This warning excludes ESD transients.**

Note 6: The output propagation delay is referenced to the end of the instruction cycle where the output change occurs.

Note 7: Parameter characterized but not tested.

Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Supply Voltage (V_{CC})	7V
Voltage at Any Pin	−0.3V to V_{CC} + 0.3V
Total Current into V_{CC} Pin (Source)	100 mA
Total Current out of GND Pin (Sink)	110 mA
Storage Temperature Range	−65°C to +140°C

Note: *Absolute maximum ratings indicate limits beyond which damage to the device may occur. DC and AC electrical specifications are not ensured when operating the device at absolute maximum ratings.*

DC Electrical Characteristics

Reset Pulse Width		1			μs

Note 1: Maximum rate of voltage change must be less than 0.5 V/ms.

Note 2: Supply current is measured after running 2000 cycles with a square wave, CKI input, CKO open, inputs at rails and outputs open.

Note 3: The HALT mode will stop CKI from oscillating in the RC and the Crystal configurations. Measurement of IDD HALT is done with device neither sourcing or sinking current; with L, C, and G0–G5 programmed as low outputs and not driving a load; all outputs programmed low and not driving a load; all inputs tied to V_{CC}; clock monitor and comparators disabled. Parameter refers to HALT mode entered via setting bit 7 of the G Port data register. Part will pull up CKI during HALT in crystal clock mode.

Note 4: Pins G6 and $\overline{\text{RESET}}$ are designed with a high voltage input network. These pins allow input voltages $> V_{CC}$ and the pins will have sink current to V_{CC} when biased at voltages $> V_{CC}$ (the pins do not have source current when biased at a voltage below V_{CC}). The effective resistance to V_{CC} is 750Ω (typical). These two pins will not latch up. The voltage at the pins must be limited to $< 14V$. **WARNING: Voltages in excess of 14V will cause damage to the pins. This warning excludes ESD transients.**

Note 5: Parameter characterized but not tested.

Note 6: t_c = Instruction Cycle Time.

Comparators AC and DC Characteristics $V_{CC} = 5V, -40°C \leq T_A \leq \pm 85°C$.

FIGURE 3. MICROWIRE/PLUS Timing

Pin Descriptions

V_{CC} and GND are the power supply pins. All V_{CC} and GND pins must be connected.

CKI is the clock input. This can come from an R/C generated oscillator, or a crystal oscillator (in conjunction with CKO). See Oscillator Description section.

$\overline{\text{RESET}}$ is the master reset input. See Reset Description section.

The device contains three bidirectional 8-bit I/O ports (C, G and L), where each individual bit may be independently configured as an input (Schmitt Trigger inputs on ports L and G), output or TRI-STATE under program control. Three data memory address locations are allocated for each of these I/O ports. Each I/O port has two associated 8-bit memory mapped registers, the CONFIGURATION register and the output DATA register. A memory mapped address is also reserved for the input pins of each I/O port. (See the memory map for the various addresses associated with the I/O ports.) *Figure 4* shows the I/O port configurations. The DATA and CONFIGURATION registers allow for each port bit to be individually configured under software control as shown below:

CONFIGURATION Register	DATA Register	Port Set-Up
0	0	Hi-Z Input (TRI-STATE Output)
0	1	Input with Weak Pull-Up
1	0	Push-Pull Zero Output
1	1	Push-Pull One Output

PORT L is an 8-bit I/O port. All L-pins have Schmitt triggers on the inputs.

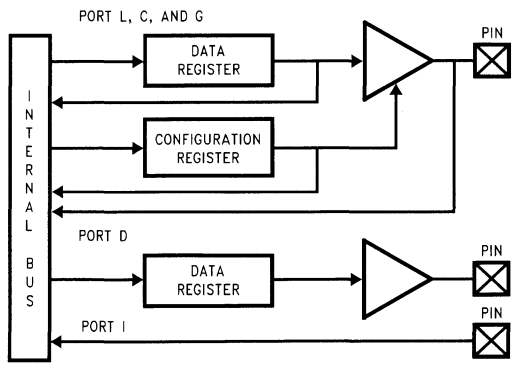
The Port L supports Multi-Input Wake Up on all eight pins. L1 is used for the UART external clock. L2 and L3 are used for the UART transmit and receive. L4 and L5 are used for the timer input functions T2A and T2B. L6 and L7 are used for the timer input functions T3A and T3B.

The Port L has the following alternate features:

- L0 MIWU
- L1 MIWU or CKX
- L2 MIWU or TDX
- L3 MIWU or RDX
- L4 MIWU or T2A
- L5 MIWU or T2B
- L6 MIWU or T3A
- L7 MIWU or T3B

Port G is an 8-bit port with 5 I/O pins (G0, G2–G5), an input pin (G6), and a dedicated output pin (G7). Pins G0 and G2–G6 all have Schmitt Triggers on their inputs. Pin G1 serves as the dedicated WDOUT WATCHDOG output, while pin G7 is either input or output depending on the oscillator mask option selected. With the crystal oscillator option selected, G7 serves as the dedicated output pin for the CKO clock output. With the single-pin R/C oscillator mask option selected, G7 serves as a general purpose input pin but is also used to bring the device out of HALT mode with a low to high transition on G7. There are two registers associated with the G Port, a data register and a configuration register. Therefore, each of the 5 I/O bits (G0, G2–G5) can be individually configured under software control.

Since G6 is an input only pin and G7 is the dedicated CKO clock output pin (crystal clock option) or general purpose input (R/C clock option), the associated bits in the data and configuration registers for G6 and G7 are used for special purpose functions as outlined on the next page. Reading the G6 and G7 data bits will return zeros.



TL/DD/12823–5

FIGURE 4. I/O Port Configurations

Pin Descriptions (Continued)

Note that the chip will be placed in the HALT mode by writing a "1" to bit 7 of the Port G Data Register. Similarly the chip will be placed in the IDLE mode by writing a "1" to bit 6 of the Port G Data Register.

Writing a "1" to bit 6 of the Port G Configuration Register enables the MICROWIRE/PLUS to operate with the alternate phase of the SK clock. The G7 configuration bit, if set high, enables the clock start up delay after HALT when the R/C clock configuration is used.

	Config Reg.	Data Reg.
G7	CLKDLY	HALT
G6	Alternate SK	IDLE

Port G has the following alternate features:

- G0 INTR (External Interrupt Input)
- G2 T1B (Timer T1 Capture Input)
- G3 T1A (Timer T1 I/O)
- G4 SO (MICROWIRE Serial Data Output)
- G5 SK (MICROWIRE Serial Clock)
- G6 SI (MICROWIRE Serial Data Input)

Port G has the following dedicated functions:

- G1 WDOUT WATCHDOG and/or Clock Monitor dedicated output
- G7 CKO Oscillator dedicated output or general purpose input

Port C is an 8-bit I/O port. The 40-pin device does not have a full complement of Port C pins. The unavailable pins are not terminated. A read operation for these unterminated pins will return unpredicatable values.

Port I is an eight-bit Hi-Z input port.

Port I1–I3 are used for Comparator 1. Port I4–I6 are used for Comparator 2.

The Port I has the following alternate features:

- I1 COMP1 − IN (Comparator 1 Negative Input)
- I2 COMP1 + IN (Comparator 1 Positive Input)
- I3 COMP1OUT (Comparator 1 Output)
- I4 COMP2 − IN (Comparator 2 Negative Input)
- I5 COMP2 + IN (Comparator 2 Positive Input)
- I6 COMP2OUT (Comparator 2 Output)

Port D is an 8-bit output port that is preset high when $\overline{\text{RESET}}$ goes low. The user can tie two or more D port outputs (except D2) together in order to get a higher drive.

Functional Description

The architecture of the device is modified Harvard architecture. With the Harvard architecture, the control store program memory (ROM) is separated from the data store memory (RAM). Both ROM and RAM have their own separate addressing space with separate address buses. The architecture, though based on Harvard architecture, permits transfer of data from ROM to RAM.

CPU REGISTERS

The CPU can do an 8-bit addition, subtraction, logical or shift operation in one instruction (t_C) cycle time.

There are six CPU registers:

A is the 8-bit Accumulator Register

PC is the 15-bit Program Counter Register

PU is the upper 7 bits of the program counter (PC)
PL is the lower 8 bits of the program counter (PC)

B is an 8-bit RAM address pointer, which can be optionally post auto incremented or decremented.

X is an 8-bit alternate RAM address pointer, which can be optionally post auto incremented or decremented.

SP is the 8-bit stack pointer, which points to the subroutine/interrupt stack (in RAM). The SP is initialized to RAM address 06F with reset.

S is the 8-bit Data Segment Address Register used to extend the lower half of the address range (00 to 7F) into 256 data segments of 128 bytes each.

All the CPU registers are memory mapped with the exception of the Accumulator (A) and the Program Counter (PC).

PROGRAM MEMORY

The program memory consists of 16 kbytes of ROM. These bytes may hold program instructions or constant data (data tables for the LAID instruction, jump vectors for the JID instruction, and interrupt vectors for the VIS instruction). The program memory is addressed by the 15-bit program counter (PC). All interrupts in the devices vector to program memory location 0FF Hex.

DATA MEMORY

The data memory address space includes the on-chip RAM and data registers, the I/O registers (Configuration, Data and Pin), the control registers, the MICROWIRE/PLUS SIO shift register, and the various registers, and counters associated with the timers (with the exception of the IDLE timer). Data memory is addressed directly by the instruction or indirectly by the B, X, SP pointers and S register.

The data memory consists of 512 bytes of RAM. Sixteen bytes of RAM are mapped as "registers" at addresses 0F0 to 0FF Hex. These registers can be loaded immediately, and also decremented and tested with the DRSZ (decrement register and skip if zero) instruction. The memory pointer registers X, SP, B and S are memory mapped into this space at address locations 0FC to 0FF Hex respectively, with the other registers being available for general usage.

The instruction set permits any bit in memory to be set, reset or tested. All I/O and registers (except A and PC) are memory mapped; therefore, I/O bits and register bits can be directly and individually set, reset and tested. The accumulator (A) bits can also be directly and individually tested.

Note: RAM contents are undefined upon power-up.

Data Memory Segment RAM Extension

Data memory address 0FF is used as a memory mapped location for the Data Segment Address Register (S).

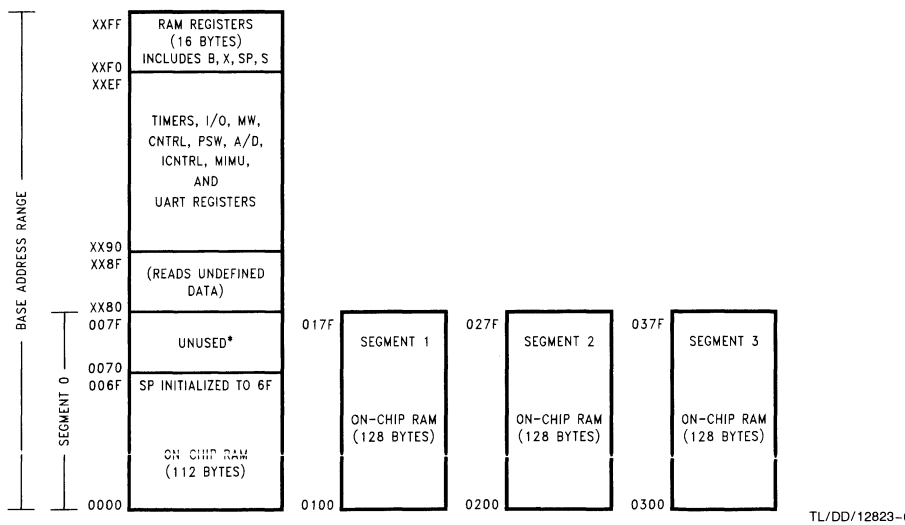
The data store memory is either addressed directly by a single byte address within the instruction, or indirectly relative to the reference of the B, X, or SP pointers (each contains a single-byte address). This single-byte address allows an addressing range of 256 locations from 00 to FF hex. The upper bit of this single-byte address divides the data store memory into two separate sections as outlined previously. With the exception of the RAM register memory from address locations 00F0 to 00FF, all RAM memory is memory mapped with the upper bit of the single-byte address being equal to zero. This allows the upper bit of the single-byte address to determine whether or not the base address range (from 0000 to 00FF) is extended. If this upper bit equals one (representing address range 0080 to 00FF), then address extension does not take place. Alternatively, if this upper bit equals zero, then the data segment extension register S is used to extend the base address range (from 0000 to 007F) from XX00 to XX7F, where XX represents the 8 bits from the S register. Thus the 128-byte data segment extensions are located from addresses 0100 to 017F for data segment 1, 0200 to 027F for data segment 2, etc., up to FF00 to FF7F for data segment 255. The base address range from 0000 to 007F represents data segment 0.

Figure 5 illustrates how the S register data memory extension is used in extending the lower half of the base address range (00 to 7F hex) into 256 data segments of 128 bytes each, with a total addressing range of 32 kbytes from XX00 to XX7F. This organization allows a total of 256 data segments of 128 bytes each with an additional upper base segment of 128 bytes. Furthermore, all addressing modes are available for all data segments. The S register must be changed under program control to move from one data segment (128 bytes) to another. However, the upper base segment (containing the 16 memory registers, I/O registers, control registers, etc.) is always available regardless of the contents of the S register, since the upper base segment (address range 0080 to 00FF) is independent of data segment extension.

The instructions that utilize the stack pointer (SP) always reference the stack as part of the base segment (Segment 0), regardless of the contents of the S register. The S register is not changed by these instructions. Consequently, the stack (used with subroutine linkage and interrupts) is always located in the base segment. The stack pointer will be initialized to point at data memory location 006F as a result of reset.

The 128 bytes of RAM contained in the base segment are split between the lower and upper base segments. The first 112 bytes of RAM are resident from address 0000 to 006F in the lower base segment, while the remaining 16 bytes of RAM represent the 16 data memory registers located at addresses 00F0 to 00FF of the upper base segment. No RAM is located at the upper sixteen addresses (0070 to 007F) of the lower base segment.

Additional RAM beyond these initial 128 bytes, however, will always be memory mapped in groups of 128 bytes (or less) at the data segment address extensions (XX00 to XX7F) of the lower base segment. The additional 128 bytes of RAM are memory mapped at address locations 0100 to 017F hex.



*Reads as all ones.

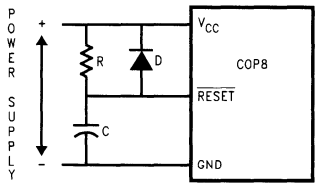
FIGURE 5. RAM Organization

Reset

The $\overline{\text{RESET}}$ input when pulled low initializes the microcontroller. Initialization will occur whenever the $\overline{\text{RESET}}$ input is pulled low. Upon initialization, the data and configuration registers for ports L, G and C are cleared, resulting in these Ports being initialized to the TRI-STATE mode. Pin G1 of the G Port is an exception (as noted below) since pin G1 is dedicated as the WATCHDOG and/or Clock Monitor error output pin. Port D is set high. The PC, PSW, ICNTRL, CNTRL, T2CNTRL and T3CNTRL control registers are cleared. The Comparator Select Register is cleared. The S register is initialized to zero. The Multi-Input Wakeup registers WKEN and WKEDG are cleared. Wakeup register WKPND is unknown. The stack pointer, SP, is initialized to 6F hex.

The device comes out of reset with both the WATCHDOG logic and the Clock Monitor detector armed, with the WATCHDOG service window bits set and the Clock Monitor bit set. The WATCHDOG and Clock Monitor circuits are inhibited during reset. The WATCHDOG service window bits being initialized high default to the maximum WATCHDOG service window of 64k t_C clock cycles. The Clock Monitor bit being initialized high will cause a Clock Monitor error following reset if the clock has not reached the minimum specified frequency at the termination of reset. A Clock Monitor error will cause an active low error output on pin G1. This error output will continue until 16 t_C–32 t_C clock cycles following the clock frequency reaching the minimum specified value, at which time the G1 output will enter the TRI-STATE mode.

The external RC network shown in *Figure 6* should be used to ensure that the $\overline{\text{RESET}}$ pin is held low until the power supply to the chip stabilizes.



TL/DD/12823-7

RC > 5 × Power Supply Rise Time

FIGURE 6. Recommended Reset Circuit

Oscillator Circuits

The chip can be driven by a clock input on the CKI input pin which can be between DC and 10 MHz. The CKO output clock is on pin G7 (crystal configuration). The CKI input frequency is divided down by 10 to produce the instruction cycle clock ($1/t_C$).

Figure 7 shows the Crystal and R/C oscillator diagrams.

CRYSTAL OSCILLATOR

CKI and CKO can be connected to make a closed loop crystal (or resonator) controlled oscillator.

Table I shows the component values required for various standard crystal values.

R/C OSCILLATOR

By selecting CKI as a single pin oscillator input, a single pin R/C oscillator circuit can be connected to it. CKO is available as a general purpose input, and/or HALT restart input.

Table II shows the variation in the oscillator frequencies as functions of the component (R and C) values.

Control Registers

CNTRL Register (Address X'00EE)

The Timer1 (T1) and MICROWIRE/PLUS control register contains the following bits:

- SL1 & SL0 Select the MICROWIRE/PLUS clock divide by (00 = 2, 01 = 4, 1x = 8)
- IEDG External interrupt edge polarity select (0 = Rising edge, 1 = Falling edge)
- MSEL Selects G5 and G4 as MICROWIRE/PLUS signals SK and SO respectively
- T1C0 Timer T1 Start/Stop control in timer modes 1 and 2
  Timer T1 Underflow Interrupt Pending Flag in timer mode 3
- T1C1 Timer T1 mode control bit
- T1C2 Timer T1 mode control bit
- T1C3 Timer T1 mode control bit

T1C3	T1C2	T1C1	T1C0	MSEL	IEDG	SL1	SL0

Bit 7 Bit 0

PSW Register (Address X'00EF)

The PSW register contains the following select bits:

- GIE Global interrupt enable (enables interrupts)
- EXEN Enable external interrupt
- BUSY MICROWIRE/PLUS busy shifting flag
- EXPND External interrupt pending
- T1ENA Timer T1 Interrupt Enable for Timer Underflow or T1A Input capture edge
- T1PNDA Timer T1 Interrupt Pending Flag (Autoreload RA in mode 1, T1 Underflow in Mode 2, T1A capture edge in mode 3)
- C Carry Flag
- HC Half Carry Flag

HC	C	T1PNDA	T1ENA	EXPND	BUSY	EXEN	GIE

Bit 7 Bit 0

The Half-Carry bit is also affected by all the instructions that affect the Carry flag. The SC (Set Carry) and RC (Reset Carry) instructions will respectively set or clear both the carry flags. In addition to the SC and RC instructions, ADC, SUBC, RRC and RLC instructions affect the carry and Half Carry flags.

ICNTRL Register (Address X'00E8)

The ICNTRL register contains the following bits:

- T1ENB Timer T1 Interrupt Enable for T1B Input capture edge
- T1PNDB Timer T1 Interrupt Pending Flag for T1B capture edge
- μWEN Enable MICROWIRE/PLUS interrupt
- μWPND MICROWIRE/PLUS interrupt pending
- T0EN Timer T0 Interrupt Enable (Bit 12 toggle)
- T0PND Timer T0 Interrupt pending
- LPEN L Port Interrupt Enable (Multi-Input Wakeup/Interrupt)
  Bit 7 could be used as a flag

Unused	LPEN	T0PND	T0EN	μWPND	μWEN	T1PNDB	T1ENB

Bit 7 Bit 0

T2CNTRL Register (Address X'00C6)

The T2CNTRL register contains the following bits:

- T2ENB Timer T2 Interrupt Enable for T2B Input capture edge
- T2PNDB Timer T2 Interrupt Pending Flag for T2B capture edge
- T2ENA Timer T2 Interrupt Enable for Timer Underflow or T2A Input capture edge
- T2PNDA Timer T2 Interrupt Pending Flag (Autoreload RA in mode 1, T2 Underflow in mode 2, T2A capture edge in mode 3)
- T2C0 Timer T2 Start/Stop control in timer modes 1 and 2 Timer T2 Underflow Interrupt Pending Flag in timer mode 3
- T2C1 Timer T2 mode control bit
- T2C2 Timer T2 mode control bit
- T2C3 Timer T2 mode control bit

T2C3	T2C2	T2C1	T2C0	T2PNDA	T2ENA	T2PNDB	T2ENB

Bit 7 Bit 0

T3CNTRL Register (Address X'00B6)

The T3CNTRL register contains the following bits:

- T3ENB Timer T3 Interrupt Enable for T3B Input capture edge
- T3PNDB Timer T3 Interrupt Pending Flag for T3B capture edge
- T3ENA Timer T3 Interrupt Enable for Timer Underflow or T3A Input capture edge

Timers

The device contains a very versatile set of timers (T0, T1, T2, T3). All timers and associated autoreload/capture registers power up containing random data.

TIMER T0 (IDLE TIMER)

The device supports applications that require maintaining real time and low power with the IDLE mode. This IDLE mode support is furnished by the IDLE timer T0, which is a 16-bit timer. The Timer T0 runs continuously at the fixed rate of the instruction cycle clock, t_C. The user cannot read or write to the IDLE Timer T0, which is a count down timer.

The Timer T0 supports the following functions:

- Exit out of the Idle Mode (See Idle Mode description)
- WATCHDOG logic (See WATCHDOG description)
- Start up delay out of the HALT mode

The IDLE Timer T0 can generate an interrupt when the thirteenth bit toggles. This toggle is latched into the T0PND pending flag, and will occur every 4 ms at the maximum clock frequency (t_C = 1 μs). A control flag T0EN allows the interrupt from the thirteenth bit of Timer T0 to be enabled or disabled. Setting T0EN will enable the interrupt, while resetting it will disable the interrupt.

TIMER T1, TIMER T2 AND TIMER T3

The device has a set of three powerful timer/counter blocks, T1, T2 and T3. The associated features and functioning of a timer block are described by referring to the timer block Tx. Since the three timer blocks, T1, T2 and T3 are identical, all comments are equally applicable to any of the three timer blocks.

Each timer block consists of a 16-bit timer, Tx, and two supporting 16-bit autoreload/capture registers, RxA and RxB. Each timer block has two pins associated with it, TxA and TxB. The pin TxA supports I/O required by the timer block, while the pin TxB is an input to the timer block. The powerful and flexible timer block allows the device to easily perform all timer functions with minimal software overhead. The timer block has three operating modes: Processor Independent PWM mode, External Event Counter mode, and Input Capture mode.

The control bits TxC3, TxC2, and TxC1 allow selection of the different modes of operation.

Mode 1. Processor Independent PWM Mode

As the name suggests, this mode allows the device to generate a PWM signal with very minimal user intervention. The user only has to define the parameters of the PWM signal (ON time and OFF time). Once begun, the timer block will continuously generate the PWM signal completely independent of the microcontroller. The user software services the timer block only when the PWM parameters require updating.

In this mode the timer Tx counts down at a fixed rate of t_C. Upon every underflow the timer is alternately reloaded with the contents of supporting registers, RxA and RxB. The very first underflow of the timer causes the timer to reload from the register RxA. Subsequent underflows cause the timer to be reloaded from the registers alternately beginning with the register RxB.

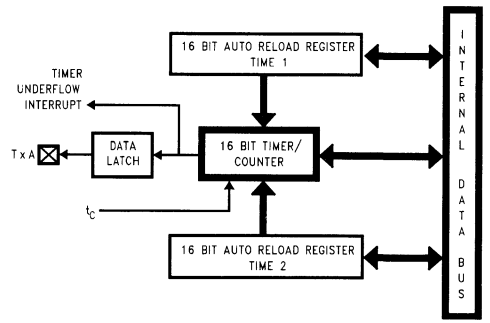
The Tx Timer control bits, TxC3, TxC2 and TxC1 set up the timer for PWM mode operation.

Figure 8 shows a block diagram of the timer in PWM mode.

The underflows can be programmed to toggle the TxA output pin. The underflows can also be programmed to generate interrupts.

Underflows from the timer are alternately latched into two pending flags, TxPNDA and TxPNDB. The user must reset these pending flags under software control. Two control enable flags, TxENA and TxENB, allow the interrupts from the timer underflow to be enabled or disabled. Setting the timer enable flag TxENA will cause an interrupt when a timer underflow causes the RxA register to be reloaded into the timer. Setting the timer enable flag TxENB will cause an interrupt when a timer underflow causes the RxB register to be reloaded into the timer. Resetting the timer enable flags will disable the associated interrupts.

Either or both of the timer underflow interrupts may be enabled. This gives the user the flexibility of interrupting once per PWM period on either the rising or falling edge of the PWM output. Alternatively, the user may choose to interrupt on both edges of the PWM output.



TL/DD/12823–10

FIGURE 8. Timer in PWM Mode

Mode 2. External Event Counter Mode

This mode is quite similar to the processor independent PWM mode described above. The main difference is that the timer, Tx, is clocked by the input signal from the TxA pin. The Tx timer control bits, TxC3, TxC2 and TxC1 allow the timer to be clocked either on a positive or negative edge from the TxA pin. Underflows from the timer are latched into the TxPNDA pending flag. Setting the TxENA control flag will cause an interrupt when the timer underflows.

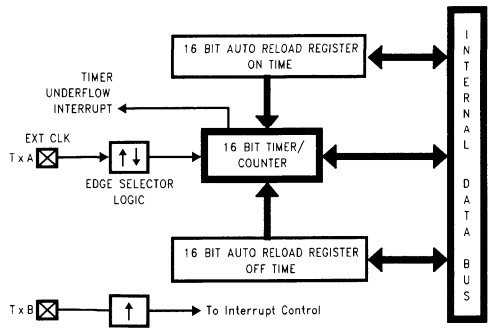
In this mode the input pin TxB can be used as an independent positive edge sensitive interrupt input if the TxENB control flag is set. The occurrence of a positive edge on the TxB input pin is latched into the TxPNDB flag.

5

Timers (Continued)

Figure 9 shows a block diagram of the timer in External Event Counter mode.

Note: The PWM output is not available in this mode since the TxA pin is being used as the counter input clock.



TL/DD/12823–11

FIGURE 9. Timer in External Event Counter Mode

Mode 3. Input Capture Mode

The device can precisely measure external frequencies or time external events by placing the timer block, Tx, in the input capture mode.

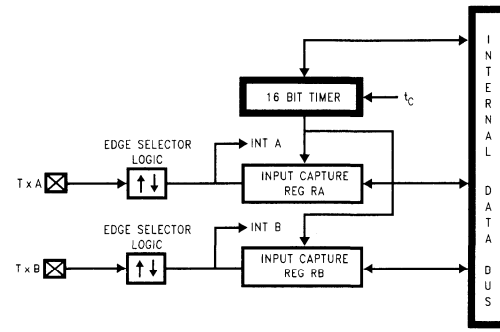
In this mode, the timer Tx is constantly running at the fixed t_C rate. The two registers, RxA and RxB, act as capture registers. Each register acts in conjunction with a pin. The register RxA acts in conjunction with the TxA pin and the register RxB acts in conjunction with the TxB pin.

The timer value gets copied over into the register when a trigger event occurs on its corresponding pin. Control bits, TxC3, TxC2 and TxC1, allow the trigger events to be specified either as a positive or a negative edge. The trigger condition for each input pin can be specified independently.

The trigger conditions can also be programmed to generate interrupts. The occurrence of the specified trigger condition on the TxA and TxB pins will be respectively latched into the pending flags, TxPNDA and TxPNDB. The control flag TxENA allows the interrupt on TxA to be either enabled or disabled. Setting the TxENA flag enables interrupts to be generated when the selected trigger condition occurs on the TxA pin. Similarly, the flag TxENB controls the interrupts from the TxB pin.

Underflows from the timer can also be programmed to generate interrupts. Underflows are latched into the timer TxC0 pending flag (the TxC0 control bit serves as the timer underflow interrupt pending flag in the Input Capture mode). Consequently, the TxC0 control bit should be reset when entering the Input Capture mode. The timer underflow interrupt is enabled with the TxENA control flag. When a TxA interrupt occurs in the Input Capture mode, the user must check both the TxPNDA and TxC0 pending flags in order to determine whether a TxA input capture or a timer underflow (or both) caused the interrupt.

Figure 10 shows a block diagram of the timer in Input Capture mode.



TL/DD/12823–12

FIGURE 10. Timer in Input Capture Mode

TIMER CONTROL FLAGS

The timers T1, T2 and T3 have indentical control structures. The control bits and their functions are summarized below.

TxC0	Timer Start/Stop control in Modes 1 and 2 (Processor Independent PWM and External Event Counter), where 1 = Start, 0 = Stop Timer Underflow Interrupt Pending Flag in Mode 3 (Input Capture)
TxPNDA	Timer Interrupt Pending Flag
TxPNDB	Timer Interrupt Pending Flag
TxENA	Timer Interrupt Enable Flag
TxENB	Timer Interrupt Enable Flag 1 = Timer Interrupt Enabled 0 = Timer Interrupt Disabled
TxC3	Timer mode control
TxC2	Timer mode control
TxC1	Timer mode control

Timers (Continued)

The timer mode control bits (TxC3, TxC2 and TxC1) are detailed below:

TxC3	TxC2	TxC1	Timer Mode	Interrupt A Source	Interrupt B Source	Timer Counts On
0	0	0	MODE 2 (External Event Counter)	Timer Underflow	Pos. TxB Edge	TxA Pos. Edge
0	0	1	MODE 2 (External Event Counter)	Timer Underflow	Pos. TxB Edge	TxA Neg. Edge
1	0	1	MODE 1 (PWM) TxA Toggle	Autoreload RA	Autoreload RB	t_C
1	0	0	MODE 1 (PWM) No TxA Toggle	Autoreload RA	Autoreload RB	t_C
0	1	0	MODE 3 (Capture) Captures: TxA Pos. Edge TxB Pos. Edge	Pos. TxA Edge or Timer Underflow	Pos. TxB Edge	t_C
1	1	0	MODE 3 (Capture) Captures: TxA Pos. Edge TxB Neg. Edge	Pos. TxA Edge or Timer Underflow	Neg. TxB Edge	t_C
0	1	1	MODE 3 (Capture) Captures: TxA Neg. Edge TxB Pos. Edge	Neg. TxA Edge or Timer Underflow	Pos. TxB Edge	t_C
1	1	1	MODE 3 (Capture) Captures: TxA Neg. Edge TxB Neg. Edge	Neg. TxA Edge or Timer Underflow	Neg. TxB Edge	t_C

Power Save Modes

The device offers the user two power save modes of operation: HALT and IDLE. In the HALT mode, all microcontroller activities are stopped. In the IDLE mode, the on-board oscillator circuitry the WATCHDOG logic, the Clock Monitor and timer T0 are active but all other microcontroller activities are stopped. In either mode, all on-board RAM, registers, I/O states, and timers (with the exception of T0) are unaltered.

HALT MODE

The device can be placed in the HALT mode by writing a "1" to the HALT flag (G7 data bit). All microcontroller activities, including the clock and timers, are stopped. The WATCHDOG logic is disabled during the HALT mode. However, the clock monitor circuitry if enabled remains active and will cause the WATCHDOG output pin (WDOUT) to go low. If the HALT mode is used and the user does not want to activate the WDOUT pin, the Clock Monitor should be disabled after the device comes out of reset (resetting the Clock Monitor control bit with the first write to the WDSVR register). In the HALT mode, the power requirements of the device are minimal and the applied voltage (V_{CC}) may be decreased to V_r (V_r = 2.0V) without altering the state of the machine.

The device supports three different ways of exiting the HALT mode. The first method of exiting the HALT mode is with the Multi-Input Wakeup feature on the L port. The second method is with a low to high transition on the CKO (G7) pin. This method precludes the use of the crystal clock configuration (since CKO becomes a dedicated output), and so may be used with an RC clock configuration. The third method of exiting the HALT mode is by pulling the $\overline{\text{RESET}}$ pin low.

Since a crystal or ceramic resonator may be selected as the oscillator, the Wakeup signal is not allowed to start the chip running immediately since crystal oscillators and ceramic resonators have a delayed start up time to reach full amplitude and frequency stability. The IDLE timer is used to generate a fixed delay to ensure that the oscillator has indeed stabilized before allowing instruction execution. In this case, upon detecting a valid Wakeup signal, only the oscillator circuitry is enabled. The IDLE timer is loaded with a value of 256 and is clocked with the t_C instruction cycle clock. The t_C clock is derived by dividing the oscillator clock down by a factor of 10. The Schmitt trigger following the CKI inverter on the chip ensures that the IDLE timer is clocked only when the oscillator has a sufficiently large amplitude to meet the Schmitt trigger specifications. This Schmitt trigger is not part of the oscillator closed loop. The startup timeout from the IDLE timer enables the clock signals to be routed to the rest of the chip.

If an RC clock option is being used, the fixed delay is introduced optionally. A control bit, CLKDLY, mapped as configuration bit G7, controls whether the delay is to be introduced or not. The delay is included if CLKDLY is set, and excluded if CLKDLY is reset. The CLKDLY bit is cleared on reset.

Power Save Modes (Continued)

The device has two mask options associated with the HALT mode. The first mask option enables the HALT mode feature, while the second mask option disables the HALT mode. With the HALT mode enable mask option, the device will enter and exit the HALT mode as described above. With the HALT disable mask option, the device cannot be placed in the HALT mode (writing a "1" to the HALT flag will have no effect, the HALT flag will remain "0").

IDLE MODE

The device is placed in the IDLE mode by writing a "1" to the IDLE flag (G6 data bit). In this mode, all activities, except the associated on-board oscillator circuitry and the IDLE Timer T0, are stopped. The power supply requirements of the micro-controller in this mode of operation are typically around 30% of normal power requirement of the microcontroller.

As with the HALT mode, the device can be returned to normal operation with a reset, or with a Multi-Input Wakeup from the L Port. Alternately, the microcontroller resumes normal operation from the IDLE mode when the thirteenth bit (representing 4.096 ms at internal clock frequency of 1 MHz, t_c = 1 μs) of the IDLE Timer toggles.

This toggle condition of the thirteenth bit of the IDLE Timer T0 is latched into the T0PND pending flag.

The user has the option of being interrupted with a transition on the thirteenth bit of the IDLE Timer T0. The interrupt can be enabled or disabled via the T0EN control bit. Setting the T0EN flag enables the interrupt and vice versa.

The user can enter the IDLE mode with the Timer T0 interrupt enabled. In this case, when the T0PND bit gets set, the device will first execute the Timer T0 interrupt service routine and then return to the instruction following the "Enter Idle Mode" instruction.

Alternatively, the user can enter the IDLE mode with the IDLE Timer T0 interrupt disabled. In this case, the device will resume normal operation with the instruction immediately following the "Enter IDLE Mode" instruction.

Note: It is necessary to program two NOP instructions following both the set HALT mode and set IDLE mode instructions. These NOP instructions are necessary to allow clock resynchronization following the HALT or IDLE modes.

Multi-Input Wakeup

The Multi-Input Wakeup feature is ued to return (wakeup) the device from either the HALT or IDLE modes. Alternately Multi-Input Wakeup/Interrupt feature may also be used to generate up to 8 edge selectable external interrupts.

Figure 11 shows the Multi-Input Wakeup logic.

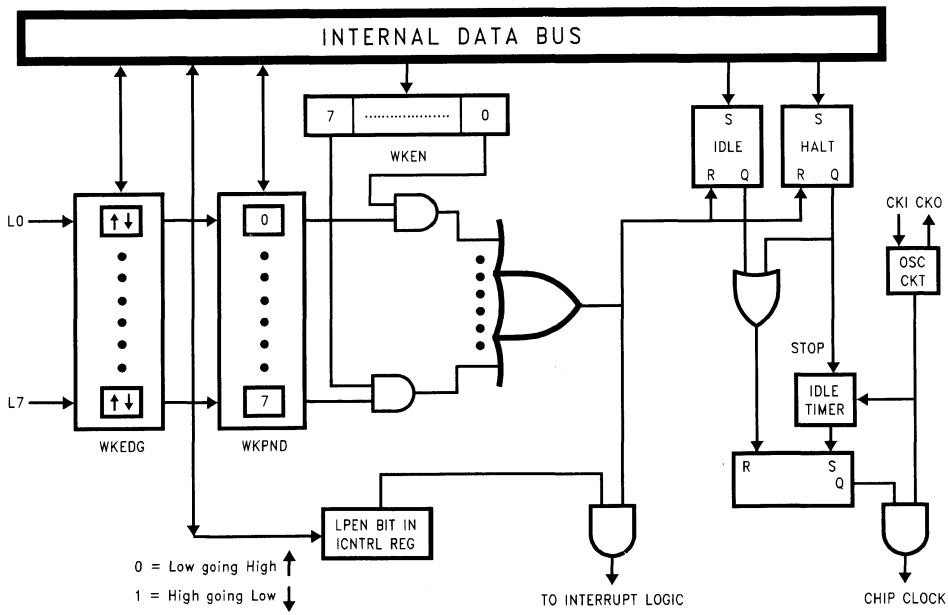


FIGURE 11. Multi-Input Wake Up Logic

Multi-Input Wakeup (Continued)

The Multi-Input Wakeup feature utilizes the L Port. The user selects which particular L port bit (or combination of L Port bits) will cause the device to exit the HALT or IDLE modes. The selection is done through the Reg: WKEN. The Reg: WKEN is an 8-bit read/write register, which contains a control bit for every L port bit. Setting a particular WKEN bit enables a Wakeup from the associated L port pin.

The user can select whether the trigger condition on the selected L Port pin is going to be either a positive edge (low to high transition) or a negative edge (high to low transition). This selection is made via the Reg: WKEDG, which is an 8-bit control register with a bit assigned to each L Port pin. Setting the control bit will select the trigger condition to be a negative edge on that particular L Port pin. Resetting the bit selects the trigger condition to be a positive edge. Changing an edge select entails several steps in order to avoid a pseudo Wakeup condition as a result of the edge change. First, the associated WKEN bit should be reset, followed by the edge select change in WKEDG. Next, the associated WKPND bit should be cleared, followed by the associated WKEN bit being re-enabled.

An example may serve to clarify this procedure. Suppose we wish to change the edge select from positive (low going high) to negative (high going low) for L Port bit 5, where bit 5 has previously been enabled for an input interrupt. The program would be as follows:

```
RBIT  5, WKEN      ; Disable Port bit 5 for
                   ; Wakeup
SBIT  5, WKEDG     ; Select neg going edge
                   ; sensitivity
RBIT  5, WKPND     ; Clear pending bit
SBIT  5, WKEN      ; Re-enable the bit for
                   ; Wakeup
```

If the L port bits have been used as outputs and then changed to inputs with Multi-Input Wakeup/Interrupt, a safety procedure should also be followed to avoid inherited pseudo wakeup conditions. After the selected L port bits have been changed from output to input but before the associated WKEN bits are enabled, the associated edge select bits in WKEDG should be set or reset for the desired edge selects, followed by the associated WKPND bits being cleared.

This same procedure should be used following reset, since the L port inputs are left floating as a result of reset.

The occurrence of the selected trigger condition for Multi-Input Wakeup is latched into a pending register called WKPND. The respective bits of the WKPND register will be set on the occurrence of the selected trigger edge on the corresponding Port L pin. The user has the responsibility of clearing these pending flags. Since WKPND is a pending register for the occurrence of selected wakeup conditions, the device will not enter the HALT mode if any Wakeup bit is both enabled and pending. Consequently, the user has the responsibility of clearing the pending flags before attempting to enter the HALT mode.

WKEN, WKPND and WKEDG are all read/write registers, and are cleared at reset.

PORT L INTERRUPTS

Port L provides the user with an additional eight fully selectable, edge sensitive interrupts which are all vectored into the same service subroutine.

The interrupt from Port L shares logic with the wake up circuitry. The register WKEN allows interrupts from Port L to be individually enabled or disabled. The register WKEDG specifies the trigger condition to be either a positive or a negative edge. Finally, the register WKPND latches in the pending trigger conditions.

The GIE (Global Interrupt Enable) bit enables the interrupt function.

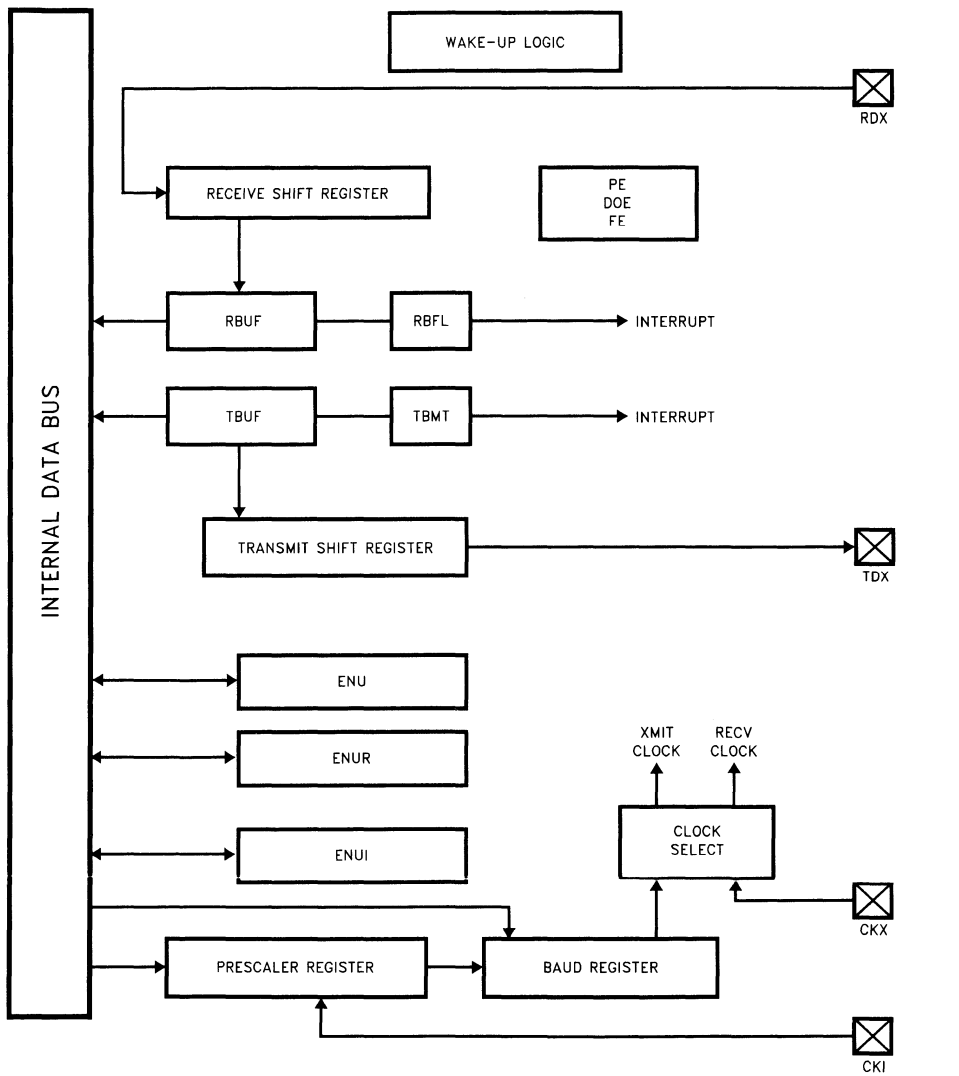
A control flag, LPEN, functions as a global interrupt enable for Port L interrupts. Setting the LPEN flag will enable interrupts and vice versa. A separate global pending flag is not needed since the register WKPND is adequate.

Since Port L is also used for waking the device out of the HALT or IDLE modes, the user can elect to exit the HALT or IDLE modes either with or without the interrupt enabled. If he elects to disable the interrupt, then the device will restart execution from the instruction immediately following the instruction that placed the microcontroller in the HALT or IDLE modes. In the other case, the device will first execute the interrupt service routine and then revert to normal operation. (See HALT MODE for clock option wakeup information.)

UART

The device contains a full-duplex software programmable UART. The UART *(Figure 12)* consists of a transmit shift register, a receive shift register and seven addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR), a UART interrupt and clock source register (ENUI), a prescaler select register (PSR) and baud (BAUD) register. The ENU register contains flags for transmit and receive functions; this register also determines the length of the data frame (7, 8 or 9 bits), the value of the ninth bit in transmission, and parity selection bits. The ENUR register flags framing, data overrun and parity errors while the UART is receiving.

Other functions of the ENUR register include saving the ninth bit received in the data frame, enabling or disabling the UART's attention mode of operation and providing additional receiver/transmitter status information via RCVG and XMTG bits. The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits and enabling or disabling transmit and receive interrupts. A control flag in this register can also select the UART mode of operation: asynchronous or synchronous.



TL/DD/12823–14

FIGURE 12. UART Block Diagram

UART (Continued)

UART CONTROL AND STATUS REGISTERS

The operation of the UART is programmed through three registers: ENU, ENUR and ENUI. The function of the individual bits in these registers is as follows:

ENU-UART Control and Status Register (Address at 0BA)

PEN	PSEL1	XBIT9/ PSEL0	CHL1	CHL0	ERR	RBFL	TBMT
0RW	0RW	0RW	0RW	0RW	0R	0R	1R

Bit 7 Bit 0

ENUR-UART Receive Control and Status Register (Address at 0BB)

DOE	FE	PE	SPARE	RBIT9	ATTN	XMTG	RCVG
0RD	0RD	0RD	0RW*	0R	0RW	0R	0R

Bit 7 Bit 0

ENUI-UART Interrupt and Clock Source Register (Address at 0BC)

STP2	STP78	ETDX	SSEL	XRCLK	XTCLK	ERI	ETI
0RW	0RW	0RW	0RW	0RW	0RW	0RW	0RW

Bit 7 Bit 0

*Bit is not used.

0 Bit is cleared on reset.

1 Bit is set to one on reset.

R Bit is read-only; it cannot be written by software.

RW Bit is read/write.

D Bit is cleared on read; when read by software as a one, it is cleared automatically. Writing to the bit does not affect its state.

DESCRIPTION OF UART REGISTER BITS

ENU—UART CONTROL AND STATUS REGISTER

TBMT: This bit is set when the UART transfers a byte of data from the TBUF register into the TSFT register for transmission. It is automatically reset when software writes into the TBUF register.

RBFL: This bit is set when the UART has received a complete character and has copied it into the RBUF register. It is automatically reset when software reads the character from RBUF.

ERR: This bit is a global UART error flag which gets set if any or a combination of the errors (DOE, FE, PE) occur.

CHL1, CHL0: These bits select the character frame format. Parity is not included and is generated/verified by hardware.

CHL1 = 0, CHL0 = 0 The frame contains eight data bits.
CHL1 = 0, CHL0 = 1 The frame contains seven data bits.
CHL1 = 1, CHL0 = 0 The frame contains nine data bits.
CHL1 = 1, CHL0 = 1 Loopback Mode selected. Transmitter output internally looped back to receiver input. Nine bit framing format is used.

XBIT9/PSEL0: Programs the ninth bit for transmission when the UART is operating with nine data bits per frame. For seven or eight data bits per frame, this bit in conjunction with PSEL1 selects parity.

PSEL1, PSEL0: Parity select bits.

PSEL1 = 0, PSEL0 = 0 Odd Parity (if Parity enabled)
PSEL1 = 0, PSEL0 = 1 Odd Parity (if Parity enabled)
PSEL1 = 1, PSEL0 = 0 Mark(1) (if Parity enabled)
PSEL1 = 1, PSEL0 = 1 Space(0) (if Parity enabled)

PEN: This bit enables/disables Parity (7- and 8-bit modes only).

PEN = 0 Parity disabled.
PEN = 1 Parity enabled.

ENUR—UART RECEIVE CONTROL AND STATUS REGISTER

RCVG: This bit is set high whenever a framing error occurs and goes low when RDX goes high.

XMTG: This bit is set to indicate that the UART is transmitting. It gets reset at the end of the last frame (end of last Stop bit).

ATTN: ATTENTION Mode is enabled while this bit is set. This bit is cleared automatically on receiving a character with data bit nine set.

RBIT9: Contains the ninth data bit received when the UART is operating with nine data bits per frame.

SPARE: Reserved for future use.

PE: Flags a Parity Error.

PE = 0 Indicates no Parity Error has been detected since the last time the ENUR register was read.
PE = 1 Indicates the occurrence of a Parity Error.

FE: Flags a Framing Error.

FE = 0 Indicates no Framing Error has been detected since the last time the ENUR register was read.
FE = 1 Indicates the occurrence of a Framing Error.

DOE: Flags a Data Overrun Error.

DOE = 0 Indicates no Data Overrun Error has been detected since the last time the ENUR register was read.
DOE = 1 Indicates the occurrence of a Data Overrun Error.

ENUI—UART INTERRUPT AND CLOCK SOURCE REGISTER

ETI: This bit enables/disables interrupt from the transmitter section.

ETI = 0 Interrupt from the transmitter is disabled.
ETI = 1 Interrupt from the transmitter is enabled.

ERI: This bit enables/disables interrupt from the receiver section.

ERI = 0 Interrupt from the receiver is disabled.
ERI = 1 Interrupt from the receiver is enabled.

XTCLK: This bit selects the clock source for the transmitter section.

XTCLK = 0 The clock source is selected through the PSR and BAUD registers.
XTCLK = 1 Signal on CKX (L1) pin is used as the clock.

XRCLK: This bit selects the clock source for the receiver section.

XRCLK = 0 The clock source is selected through the PSR and BAUD registers.
XRCLK = 1 Signal on CKX (L1) pin is used as the clock.

SSEL: UART mode select.

SSEL = 0 Asynchronous Mode.
SSEL = 1 Synchronous Mode.

UART (Continued)

ETDX: TDX (UART Transmit Pin) is the alternate function assigned to Port L pin L2; it is selected by setting ETDX bit. To simulate line break generation, software should reset ETDX bit and output logic zero to TDX pin through Port L data and configuration registers.

STP78: This bit is set to program the last Stop bit to be 7/8th of a bit in length.

STP2: This bit programs the number of Stop bits to be transmitted.

STP2 = 0 One Stop bit transmitted.
STP2 = 1 Two Stop bits transmitted.

Associated I/O Pins

Data is transmitted on the TDX pin and received on the RDX pin. TDX is the alternate function assigned to Port L pin L2; it is selected by setting ETDX (in the ENUI register) to one. RDX is an inherent function of Port L pin L3, requiring no setup.

The baud rate clock for the UART can be generated on-chip, or can be taken from an external source. Port L pin L1 (CKX) is the external clock I/O pin. The CKX pin can be either an input or an output, as determined by Port L Configuration and Data registers (Bit 1). As an input, it accepts a clock signal which may be selected to drive the transmitter and/or receiver. As an output, it presents the internal Baud Rate Generator output.

UART Operation

The UART has two modes of operation: asynchronous mode and synchronous mode.

ASYNCHRONOUS MODE

This mode is selected by resetting the SSEL (in the ENUI register) bit to zero. The input frequency to the UART is 16 times the baud rate.

The TSFT and TBUF registers double-buffer data for transmission. While TSFT is shifting out the current character on the TDX pin, the TBUF register may be loaded by software with the next byte to be transmitted. When TSFT finishes transmitting the current character the contents of TBUF are transferred to the TSFT register and the Transmit Buffer Empty Flag (TBMT in the ENU register) is set. The TBMT flag is automatically reset by the UART when software loads a new character into the TBUF register. There is also the XMTG bit which is set to indicate that the UART is transmitting. This bit gets reset at the end of the last frame (end of last Stop bit). TBUF is a read/write register.

The RSFT and RBUF registers double-buffer data being received. The UART receiver continually monitors the signal on the RDX pin for a low level to detect the beginning of a Start bit. Upon sensing this low level, it waits for half a bit time and samples again. If the RDX pin is still low, the receiver considers this to be a valid Start bit, and the remaining bits in the character frame are each sampled a single time, at the mid-bit position. Serial data input on the RDX pin is shifted into the RSFT register. Upon receiving the complete character, the contents of the RSFT register are copied into the RBUF register and the Received Buffer Full Flag (RBFL) is set. RBFL is automatically reset when software reads the character from the RBUF register. RBUF is a read only register. There is also the RCVG bit which is set high when a framing error occurs and goes low once RDX goes high. TBMT, XMTG, RBFL and RCVG are read only bits.

SYNCHRONOUS MODE

In this mode data is transferred synchronously with the clock. Data is transmitted on the rising edge and received on the falling edge of the synchronous clock.

This mode is selected by setting SSEL bit in the ENUI register. The input frequency to the UART is the same as the baud rate.

When an external clock input is selected at the CKX pin, data transmit and receive are performed synchronously with this clock through TDX/RDX pins.

If data transmit and receive are selected with the CKX pin as clock output, the device generates the synchronous clock output at the CKX pin. The internal baud rate generator is used to produce the synchronous clock. Data transmit and receive are performed synchronously with this clock.

FRAMING FORMATS

The UART supports several serial framing formats *(Figure 13)*. The format is selected using control bits in the ENU, ENUR and ENUI registers.

The first format (1, 1a, 1b, 1c) for data transmission (CHL0 = 1, CHL1 = 0) consists of Start bit, seven Data bits (excluding parity) and 7/8, one or two Stop bits. In applications using parity, the parity bit is generated and verified by hardware.

The second format (CHL0 = 0, CHL1 = 0) consists of one Start bit, eight Data bits (excluding parity) and 7/8, one or two Stop bits. Parity bit is generated and verified by hardware.

The third format for transmission (CHL0 = 0, CHL1 = 1) consists of one Start bit, nine Data bits and 7/8, one or two Stop bits. This format also supports the UART "ATTENTION" feature. When operating in this format, all eight bits of TBUF and RBUF are used for data. The ninth data bit is transmitted and received using two bits in the ENU and ENUR registers, called XBIT9 and RBIT9. RBIT9 is a read only bit. Parity is not generated or verified in this mode.

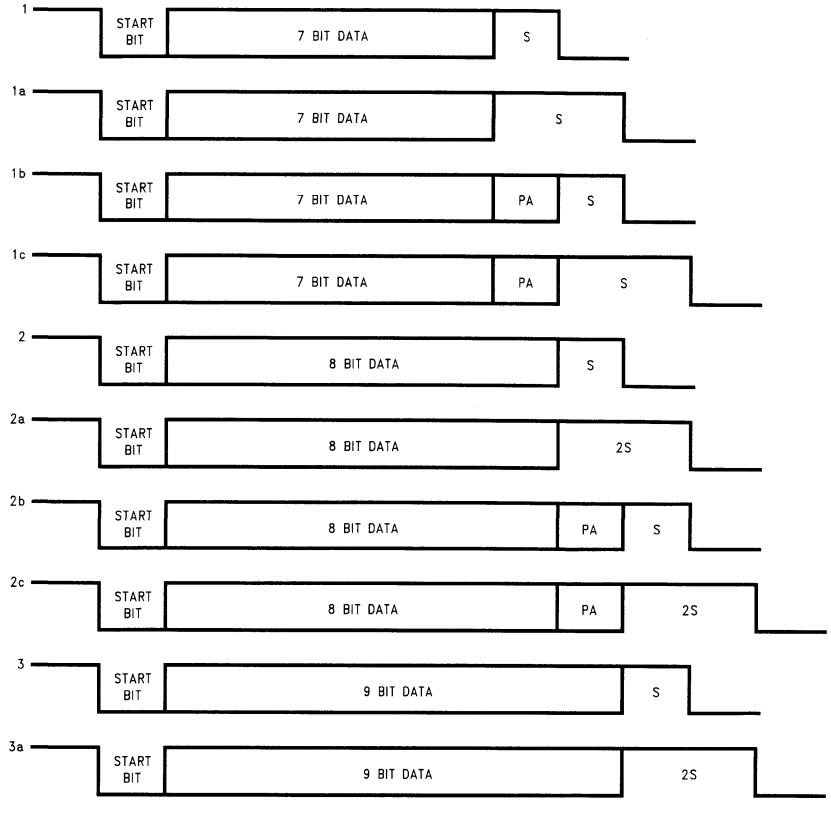
For any of the above framing formats, the last Stop bit can be programmed to be 7/8th of a bit in length. If two Stop bits are selected and the 7/8th bit is set (selected), the second Stop bit will be 7/8th of a bit in length.

The parity is enabled/disabled by PEN bit located in the ENU register. Parity is selected for 7- and 8-bit modes only. If parity is enabled (PEN = 1), the parity selection is then performed by PSEL0 and PSEL1 bits located in the ENU register.

Note that the XBIT9/PSEL0 bit located in the ENU register serves two mutually exclusive functions. This bit programs the ninth bit for transmission when the UART is operating with nine data bits per frame. There is no parity selection in this framing format. For other framing formats XBIT9 is not needed and the bit is PSEL0 used in conjunction with PSEL1 to select parity.

The frame formats for the receiver differ from the transmitter in the number of Stop bits required. The receiver only requires one Stop bit in a frame, regardless of the setting of the Stop bit selection bits in the control register. Note that an implicit assumption is made for full duplex UART operation that the framing formats are the same for the transmitter and receiver.

UART Operation (Continued)



TL/DD/12823–15

FIGURE 13. Framing Formats

UART INTERRUPTS

The UART is capable of generating interrupts. Interrupts are generated on Receive Buffer Full and Transmit Buffer Empty. Both interrupts have individual interrupt vectors. Two bytes of program memory space are reserved for each interrupt vector. The two vectors are located at addresses 0xEC to 0xEF Hex in the program memory space. The interrupts can be individually enabled or disabled using Enable Transmit Interrupt (ETI) and Enable Receive Interrupt (ERI) bits in the ENUI register.

The interrupt from the Transmitter is set pending, and remains pending, as long as both the TBMT and ETI bits are set. To remove this interrupt, software must either clear the ETI bit or write to the TBUF register (thus clearing the TBMT bit).

The interrupt from the receiver is set pending, and remains pending, as long as both the RBFL and ERI bits are set. To remove this interrupt, software must either clear the ERI bit or read from the RBUF register (thus clearing the RBFL bit).

Baud Clock Generation

The clock inputs to the transmitter and receiver sections of the UART can be individually selected to come either from an external source at the CKX pin (port L, pin L1) or from a source selected in the PSR and BAUD registers. Internally, the basic baud clock is created from the oscillator frequency through a two-stage divider chain consisting of a 1–16 (increments of 0.5) prescaler and an 11-bit binary counter. *(Figure 14).* The divide factors are specified through two read/write registers shown in *Figure 15.* Note that the 11-bit Baud Rate Divisor spills over into the Prescaler Select Register (PSR). PSR is cleared upon reset.

As shown in Table IV, a Prescaler Factor of 0 corresponds to NO CLOCK. This condition is the UART power down mode where the UART clock is turned off for power saving purpose. The user must also turn the UART clock off when a different baud rate is chosen.

The correspondences between the 5-bit Prescaler Select and Prescaler factors are shown in Table IV. There are many ways to calculate the two divisor factors, but one particularly effective method would be to achieve a 1.8432 MHz frequency coming out of the first stage. The 1.8432 MHz prescaler output is then used to drive the software programmable baud rate counter to create a 16x clock for the following baud rates: 110, 134.5, 150, 300, 600, 1200, 1800, 2400, 3600, 4800, 7200, 9600, 19200 and 38400 (Table III). Other baud rates may be created by using appropriate divisors. The 16x clock is then divided by 16 to provide the rate for the serial shift registers of the transmitter and receiver.

FIGURE 15. UART BAUD Clock Divisor Registers

Baud Clock Generation (Continued)

TABLE III. Baud Rate Divisors (1.8432 MHz Prescaler Output)

Baud Rate	Baud Rate Divisor − 1 (N-1)
110 (110.03)	1046
134.5 (134.58)	855
150	767
300	383
600	191
1200	95
1800	63
2400	47
3600	31
4800	23
7200	15
9600	11
19200	5
38400	2

Note: The entries in Table IV assume a prescaler output of 1.8432 MHz. In the asynchronous mode the baud rate could be as high as 625k.

TABLE IV. Prescaler Factors

Prescaler Select	Prescaler Factor
00000	NO CLOCK
00001	1
00010	1.5
00011	2
00100	2.5
00101	3
00110	3.5
00111	4
01000	4.5
01001	5
01010	5.5
01011	6
01100	6.5
01101	7
01110	7.5
01111	8
10000	8.5
10001	9
10010	9.5
10011	10
10100	10.5
10101	11
10110	11.5
10111	12
11000	12.5
11001	13
11010	13.5
11011	14
11100	14.5
11101	15
11110	15.5
11111	16

As an example, considering Asynchronous Mode and a CKI clock of 4.608 MHz, the prescaler factor selected is:

$$4.608/1.8432 = 2.5$$

The 2.5 entry is available in Table IV. The 1.8432 MHz prescaler output is then used with proper Baud Rate Divisor (Table IV) to obtain different baud rates. For a baud rate of 19200 e.g., the entry in Table IV is 5.

$N - 1 = 5$ ($N - 1$ is the value from Table III)

$N = 6$ (N is the Baud Rate Divisor)

$$\text{Baud Rate} = 1.8432\ \text{MHz}/(16 \times 6) = 19200$$

The divide by 16 is performed because in the asynchronous mode, the input frequency to the UART is 16 times the baud rate. The equation to calculate baud rates is given below.

The actual Baud Rate may be found from:

$$BR = Fc/(16 \times N \times P)$$

5

Baud Clock Generation (Continued)

Where:

BR is the Baud Rate

Fc is the CKI frequency

N is the Baud Rate Divisor (Table III).

P is the Prescaler Divide Factor selected by the value in the Prescaler Select Register (Table IV)

Note: In the Synchronous Mode, the divisor 16 is replaced by two.

Example:

Asynchronous Mode:

Crystal Frequency = 5 MHz

Desired baud rate = 9600

Using the above equation N × P can be calculated first.

$$N \times P = (5 \times 106)/(16 \times 9600) = 32.552$$

Now 32.552 is divided by each Prescaler Factor (Table IV) to obtain a value closest to an integer. This factor happens to be 6.5 (P = 6.5).

$$N = 32.552/6.5 = 5.008 \ (N = 5)$$

The programmed value (from Table III) should be 4 (N − 1).

Using the above values calculated for N and P:

$$BR = (5 \times 106)/(16 \times 5 \times 6.5) = 9615.384$$

$$\% \text{ error} = (9615.385 - 9600)/9600 = 0.16$$

Effect of HALT/IDLE

The UART logic is reinitialized when either the HALT or IDLE modes are entered. This reinitialization sets the TBMT flag and resets all read only bits in the UART control and status registers. Read/Write bits remain unchanged. The Transmit Buffer (TBUF) is not affected, but the Transmit Shift register (TSFT) bits are set to one. The receiver registers RBUF and RSFT are not affected.

The device will exit from the HALT/IDLE modes when the Start bit of a character is detected at the RDX (L3) pin. This feature is obtained by using the Multi-Input Wakeup scheme provided on the device.

Before entering the HALT or IDLE modes the user program must select the Wakeup source to be on the RDX pin. This selection is done by setting bit 3 of WKEN (Wakeup Enable) register. The Wakeup trigger condition is then selected to be high to low transition. This is done via the WKEDG register (Bit 3 is one.)

If the device is halted and crystal oscillator is used, the Wakeup signal will not start the chip running immediately because of the finite start up time requirement of the crystal oscillator. The idle timer (T0) generates a fixed (256 t_c) delay to ensure that the oscillator has indeed stabilized before allowing the device to execute code. The user has to consider this delay when data transfer is expected immediately after exiting the HALT mode.

Diagnostic

Bits CHARL0 and CHARL1 in the ENU register provide a loopback feature for diagnostic testing of the UART. When these bits are set to one, the following occur: The receiver input pin (RDX) is internally connected to the transmitter output pin (TDX); the output of the Transmitter Shift Register is "looped back" into the Receive Shift Register input. In this mode, data that is transmitted is immediately received. This feature allows the processor to verify the transmit and receive data paths of the UART.

Note that the framing format for this mode is the nine bit format; one Start bit, nine data bits, and 7/8, one or two Stop bits. Parity is not generated or verified in this mode.

Attention Mode

The UART Receiver section supports an alternate mode of operation, referred to as ATTENTION Mode. This mode of operation is selected by the ATTN bit in the ENUR register. The data format for transmission must also be selected as having nine Data bits and either 7/8, one or two Stop bits.

The ATTENTION mode of operation is intended for use in networking the device with other processors. Typically in such environments the messages consists of device addresses, indicating which of several destinations should receive them, and the actual data. This Mode supports a scheme in which addresses are flagged by having the ninth bit of the data field set to a 1. If the ninth bit is reset to a zero the byte is a Data byte.

While in ATTENTION mode, the UART monitors the communication flow, but ignores all characters until an address character is received. Upon receiving an address character, the UART signals that the character is ready by setting the RBFL flag, which in turn interrupts the processor if UART Receiver interrupts are enabled. The ATTN bit is also cleared automatically at this point, so that data characters as well as address characters are recognized. Software examines the contents of the RBUF and responds by deciding either to accept the subsequent data stream (by leaving the ATTN bit reset) or to wait until the next address character is seen (by setting the ATTN bit again).

Operation of the UART Transmitter is not affected by selection of this Mode. The value of the ninth bit to be transmitted is programmed by setting XBIT9 appropriately. The value of the ninth bit received is obtained by reading RBIT9. Since this bit is located in ENUR register where the error flags reside, a bit operation on it will reset the error flags.

Comparators

The device contains two differential comparators, each with a pair of inputs (positive and negative) and an output. Ports I1–I3 and I4–I6 are used for the comparators. The following is the Port I assignment:

- I1 Comparator1 negative input
- I2 Comparator1 positive input
- I3 Comparator1 output
- I4 Comparator2 negative input
- I5 Comparator2 positive input
- I6 Comparator2 output

A Comparator Select Register (CMPSL) is used to enable the comparators, read the outputs of the comparators internally, and enable the outputs of the comparators to the pins. Two control bits (enable and output enable) and one result bit are associated with each comparator. The comparator result bits (CMP1RD and CMP2RD) are read only bits which will read as zero if the associated comparator is not enabled. The Comparator Select Register is cleared with reset, resulting in the comparators being disabled. The comparators should also be disabled before entering either the HALT or IDLE modes in order to save power. The configuration of the CMPSL register is as follows:

Comparators (Continued)

CMPSL REGISTER (ADDRESS X'00B7)

The CMPSL register contains the following bits:

CMP1EN Enable comparator 1

CMP1RD Comparator 1 result (this is a read only bit, which will read as 0 if the comparator is not enabled)

CMP10E Selects pin I3 as comparator 1 output provided that CMPIEN is set to enable the comparator

CMP2EN Enable comparator 2

CMP2RD Comparator 2 result (this is a read only bit, which will read as 0 if the comparator is not enabled)

CMP20E Selects pin I6 as comparator 2 output provided that CMP2EN is set to enable the comparator

Unused	CMP20E	CMP2RD	CMP2EN	CMP10E	CMP1RD	CMP1EN	Unused
Bit 7							Bit 0

Note that the two unused bits of CMPSL may be used as software flags.

Comparator outputs have the same spec as Ports L and G except that the rise and fall times are symmetrical.

Interrupts

The device supports a vectored interrupt scheme. It supports a total of fourteen interrupt sources. The following table lists all the possible interrupt sources, their arbitration ranking and the memory locations reserved for the interrupt vector for each source.

Two bytes of program memory space are reserved for each interrupt source. All interrupt sources except the software interrupt are maskable. Each of the maskable interrupts have an Enable bit and one or more Pending bits. A maskable interrupt is active if its associated enable and pending bits are set. If GIE = 1 and an interrupt is active, then the processor will be interrupted as soon as it is ready to start executing an instruction except if the above conditions happen during the Software Trap service routine. This exception is described in the Software Trap sub-section.

The interruption process is accomplished with the INTR instruction (opcode 00), which is jammed inside the Instruction Register and replaces the opcode about to be executed. The following steps are performed for every interrupt:

1. The GIE (Global Interrupt Enable) bit is reset.
2. The address of the instruction about to be executed is pushed into the stack.
3. The PC (Program Counter) branches to address 00FF.

This procedure takes 7 t_C cycles to execute.

Arbitration Ranking	Source	Description	Vector* Address Hi-Low Byte
(1) Highest	Software	INTR Instruction	0yFE–0yFF
(2)	Reserved		0yFC–0yFD
(3)	External	G0	0yFA–0yFB
(4)	Timer T0	Underflow	0yF8–0yF9
(5)	Timer T1	T1A/Underflow	0yF6–0yF7
(6)	Timer T1	T1B	0yF4–0yF5
(7)	MICROWIRE/PLUS	BUSY Low	0yF2–0yF3
(8)	Reserved		0yF0–0yF1
(9)	UART	Receive	0yEE–0yEF
(10)	UART	Transmit	0yEC–0yED
(11)	Timer T2	T2A/Underflow	0yEA–0yEB
(12)	Timer T2	T2B	0yE8–0yE9
(13)	Timer T3	T3A/Underflow	0yE6–0yE7
(14)	Timer T3	T3B	0yE4–0yE5
(15)	Port L/Wakeup	Port L Edge	0yE2–0yE3
(16) Lowest	Default VIS	Reserved	0yE0–0yE1

*y is a variable which represents the VIS block. VIS and the vector table must be located in the same 256-byte block except if VIS is located at the last address of a block. In this case, the table must be in the next block.

Interrupts (Continued)

At this time, since GIE = 0, other maskable interrupts are disabled. The user is now free to do whatever context switching is required by saving the context of the machine in the stack with PUSH instructions. The user would then program a VIS (Vector Interrupt Select) instruction in order to branch to the interrupt service routine of the highest priority interrupt enabled and pending at the time of the VIS. Note that this is not necessarily the interrupt that caused the branch to address location 00FF Hex prior to the context switching.

Thus, if an interrupt with a higher rank than the one which caused the interruption becomes active before the decision of which interrupt to service is made by the VIS, then the interrupt with the higher rank will override any lower ones and will be acknowledged. The lower priority interrupt(s) are still pending, however, and will cause another interrupt immediately following the completion of the interrupt service routine associated with the higher priority interrupt just serviced. This lower priority interrupt will occur immediately following the RETI (Return from Interrupt) instruction at the end of the interrupt service routine just completed.

Inside the interrupt service routine, the associated pending bit has to be cleared by software. The RETI (Return from Interrupt) instruction at the end of the interrupt service routine will set the GIE (Global Interrupt Enable) bit, allowing the processor to be interrupted again if another interrupt is active and pending.

The VIS instruction looks at all the active interrupts at the time it is executed and performs an indirect jump to the beginning of the service routine of the one with the highest rank.

The addresses of the different interrupt service routines, called vectors, are chosen by the user and stored in ROM in a table starting at 01E0 (assuming that VIS is located between 00FF and 01DF). The vectors are 15-bit wide and therefore occupy 2 ROM locations.

VIS and the vector table must be located in the same 256-byte block (0y00 to 0yFF) except if VIS is located at the last address of a block. In this case, the table must be in the next block. The vector table cannot be inserted in the first 256-byte block (y ≠ 0).

The vector of the maskable interrupt with the lowest rank is located at 0yE0 (Hi-Order byte) and 0yE1 (Lo-Order byte) and so forth in increasing rank number. The vector of the maskable interrupt with the highest rank is located at 0yFA (Hi-Order byte) and 0yFB (Lo-Order byte).

The Software Trap has the highest rank and its vector is located at 0yFE and 0yFF.

If, by accident, a VIS gets executed and no interrupt is active, then the PC (Program Counter) will branch to a vector located at 0yE0–0yE1.

WARNING

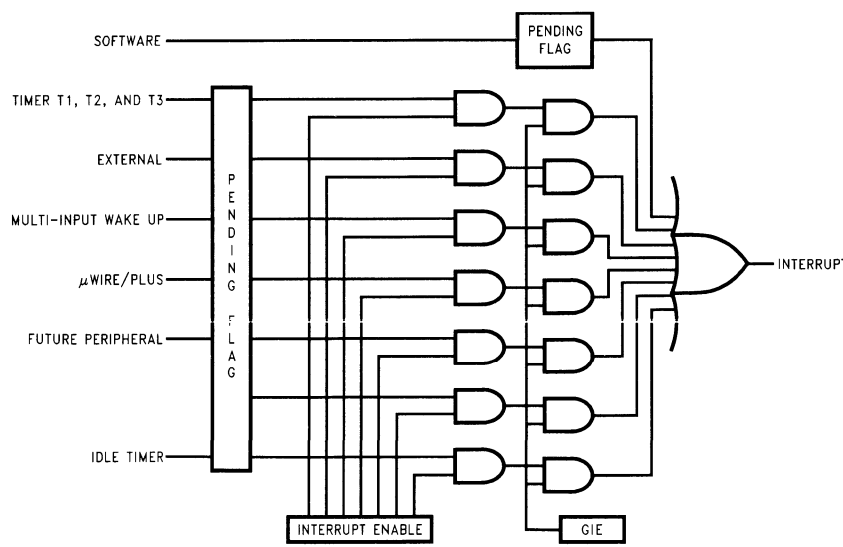
A Default VIS interrupt handler routine must be present. As a minimum, this handler should confirm that the GIE bit is cleared (this indicates that the interrupt sequence has been taken), take care of any required housekeeping, restore context and return. Some sort of Warm Restart procedure should be implemented. These events can occur without any error on the part of the system designer or programmer.

Note: There is always the possibility of an interrupt occurring during an instruction which is attempting to reset the GIE bit or any other interrupt enable bit. If this occurs when a single cycle instruction is being used to reset the interrupt enable bit, the interrupt enable bit will be reset but an interrupt may still occur. This is because interrupt processing is started at the same time as the interrupt bit is being reset. To avoid this scenario, the user should always use a two, three, or four cycle instruction to reset interrupt enable bits.

Figure 16 shows the Interrupt block diagram.

SOFTWARE TRAP

The Software Trap (ST) is a special kind of non-maskable interrupt which occurs when the INTR instruction (used to acknowledge interrupts) is fetched from ROM and placed inside the instruction register. This may happen when the PC is pointing beyond the available ROM address space or when the stack is over-popped.



TL/DD/12823–18

FIGURE 16. Interrupt Block Diagram

Interrupts (Continued)

When an ST occurs, the user can re-initialize the stack pointer and do a recovery procedure (similar to reset, but not necessarily containing all of the same initialization procedures) before restarting.

The occurrence of an ST is latched into the ST pending bit. The GIE bit is not affected and the ST pending bit **(not accessible by the user)** is used to inhibit other interrupts and to direct the program to the ST service routine with the VIS instruction. The RPND instruction is used to clear the software interrupt pending bit. This pending bit is also cleared on reset.

The ST has the highest rank among all interrupts.

Nothing (except another ST) can interrupt an ST being serviced.

WATCHDOG

The device contains a WATCHDOG and clock monitor. The WATCHDOG is designed to detect the user program getting stuck in infinite loops resulting in loss of program control or "runaway" programs. The Clock Monitor is used to detect the absence of a clock or a very slow clock below a specified rate on the CKI pin.

The WATCHDOG consists of two independent logic blocks: WD UPPER and WD LOWER. WD UPPER establishes the upper limit on the service window and WD LOWER defines the lower limit of the service window.

Servicing the WATCHDOG consists of writing a specific value to a WATCHDOG Service Register named WDSVR which is memory mapped in the RAM. This value is composed of three fields, consisting of a 2-bit Window Select, a 5-bit Key Data field, and the 1-bit Clock Monitor Select field. Table V shows the WDSVR register.

TABLE V. WATCHDOG Service Register (WDSVR)

Window Select		Key Data					Clock Monitor
X	X	0	1	1	0	0	Y
7	6	5	4	3	2	1	0

The lower limit of the service window is fixed at 2048 instruction cycles. Bits 7 and 6 of the WDSVR register allow the user to pick an upper limit of the service window.

Table VI shows the four possible combinations of lower and upper limits for the WATCHDOG service window. This flexibility in choosing the WATCHDOG service window prevents any undue burden on the user software.

Bits 5, 4, 3, 2 and 1 of the WDSVR register represent the 5-bit Key Data field. The key data is fixed at 01100. Bit 0 of the WDSVR Register is the Clock Monitor Select bit

TABLE VI. WATCHDOG Service Window Select

WDSVR Bit 7	WDSVR Bit 6	Service Window (Lower-Upper Limits)
0	0	2k–8k t_C Cycles
0	1	2k–16k t_C Cycles
1	0	2k–32k t_C Cycles
1	1	2k–64k t_C Cycles

Clock Monitor

The Clock Monitor aboard the device can be selected or deselected under program control. The Clock Monitor is guaranteed not to reject the clock if the instruction cycle clock ($1/t_C$) is greater or equal to 10 kHz. This equates to a clock input rate on CKI of greater or equal to 100 kHz.

WATCHDOG Operation

The WATCHDOG and Clock Monitor are disabled during reset. The device comes out of reset with the WATCHDOG armed, the WATCHDOG Window Select bits (bits 6, 7 of the WDSVR Register) set, and the Clock Monitor bit (bit 0 of the WDSVR Register) enabled. Thus, a Clock Monitor error will occur after coming out of reset, if the instruction cycle clock frequency has not reached a minimum specified value, including the case where the oscillator fails to start.

The WDSVR register can be written to only once after reset and the key data (bits 5 through 1 of the WDSVR Register) must match to be a valid write. This write to the WDSVR register involves two irrevocable choices: (i) the selection of the WATCHDOG service window (ii) enabling or disabling of the Clock Monitor. Hence, the first write to WDSVR Register involves selecting or deselecting the Clock Monitor, select the WATCHDOG service window and match the WATCHDOG key data. Subsequent writes to the WDSVR register will compare the value being written by the user to the WATCHDOG service window value and the key data (bits 7 through 1) in the WDSVR Register. Table VII shows the sequence of events that can occur.

The user must service the WATCHDOG at least once before the upper limit of the service window expires. The WATCHDOG may not be serviced more than once in every lower limit of the service window. The user may service the WATCHDOG as many times as wished in the time period between the lower and upper limits of the service window. The first write to the WDSVR Register is also counted as a WATCHDOG service.

The WATCHDOG has an output pin associated with it. This is the WDOUT pin, on pin 1 of the port G. WDOUT is active low. The WDOUT pin is in the high impedance state in the inactive state. Upon triggering the WATCHDOG, the logic will pull the WDOUT (G1) pin low for an additional 16 t_C–32 t_C cycles after the signal level on WDOUT pin goes below the lower Schmitt trigger threshold. After this delay, the device will stop forcing the WDOUT output low.

The WATCHDOG service window will restart when the WDOUT pin goes high. It is recommended that the user tie the WDOUT pin back to V_{CC} through a resistor in order to pull WDOUT high.

A WATCHDOG service while the WDOUT signal is active will be ignored. The state of the WDOUT pin is not guaranteed on reset, but if it powers up low then the WATCHDOG will time out and WDOUT will enter high impedance state.

The Clock Monitor forces the G1 pin low upon detecting a clock frequency error. The Clock Monitor error will continue until the clock frequency has reached the minimum specified value, after which the G1 output will enter the high impedance TRI-STATE mode following 16 t_C–32 t_C clock cycles. The Clock Monitor generates a continual Clock Monitor error if the oscillator fails to start, or fails to reach the minimum specified frequency. The specification for the Clock Monitor is as follows:

$1/t_C > 10$ kHz—No clock rejection.

$1/t_C < 10$ Hz—Guaranteed clock rejection.

WATCHDOG Operation (Continued)

WATCHDOG AND CLOCK MONITOR SUMMARY

The following salient points regarding the WATCHDOG and CLOCK MONITOR should be noted:

- Both the WATCHDOG and CLOCK MONITOR detector circuits are inhibited during RESET.
- Following RESET, the WATCHDOG and CLOCK MONITOR are both enabled, with the WATCHDOG having he maximum service window selected.
- The WATCHDOG service window and CLOCK MONITOR enable/disable option can only be changed once, during the initial WATCHDOG service following RESET.
- The initial WATCHDOG service must match the key data value in the WATCHDOG Service register WDSVR in order to avoid a WATCHDOG error.
- Subsequent WATCHDOG services must match all three data fields in WDSVR in order to avoid WATCHDOG errors.
- The correct key data value cannot be read from the WATCHDOG Service register WDSVR. Any attempt to read this key data value of 01100 from WDSVR will read as key data value of all 0's.
- The WATCHDOG detector circuit is inhibited during both the HALT and IDLE modes.
- The CLOCK MONITOR detector circuit is active during both the HALT and IDLE modes. Consequently, the device inadvertently entering the HALT mode will be detected as a CLOCK MONITOR error (provided that the CLOCK MONITOR enable option has been selected by the program).
- With the single-pin R/C oscillator mask option selected and the CLKDLY bit reset, the WATCHDOG service window will resume following HALT mode from where it left off before entering the HALT mode.
- With the crystal oscillator mask option selected, or with the single-pin R/C oscillator mask option selected and the CLKDLY bit set, the WATCHDOG service window will be set to its selected value from WDSVR following HALT. Consequently, the WATCHDOG should not be serviced for at least 2048 instruction cycles following HALT, but must be serviced within the selected window to avoid a WATCHDOG error.
- The IDLE timer T0 is not initialized with RESET.
- The user can sync in to the IDLE counter cycle with an IDLE counter (T0) interrupt or by monitoring the T0PND flag. The T0PND flag is set whenever the thirteenth bit of the IDLE counter toggles (every 4096 instruction cycles). The user is responsible for resetting the T0PND flag.
- A hardware WATCHDOG service occurs just as the device exits the IDLE mode. Consequently, the WATCHDOG should not be serviced for at least 2048 instruction cycles following IDLE, but must be serviced within the selected window to avoid a WATCHDOG error.
- Following RESET, the initial WATCHDOG service (where the service window and the CLOCK MONITOR enable/disable must be selected) may be programmed anywhere within the maximum service window (65,536 instruction cycles) initialized by RESET. Note that this initial WATCHDOG service may be programmed within the initial 2048 instruction cycles without causing a WATCHDOG error.

Detection of Illegal Conditions

The device can detect various illegal conditions resulting from coding errors, transient noise, power supply voltage drops, runaway programs, etc.

Reading of undefined ROM gets zeros. The opcode for software interrupt is zero. If the program fetches instructions from undefined ROM, this will force a software interrupt, thus signaling that an illegal condition has occurred.

The subroutine stack grows down for each call (jump to subroutine), interrupt, or PUSH, and grows up for each return or POP. The stack pointer is initialized to RAM location 06F Hex during reset. Consequently, if there are more returns than calls, the stack pointer will point to addresses 070 and 071 Hex (which are undefined RAM). Undefined RAM from addresses 070 to 07F (Segment 0), and all other segments (i.e., Segments 4 . . . etc.) is read as all 1's, which in turn will cause the program to return to address 7FFF Hex. This is an undefined ROM location and the instruction fetched (all 0's) from this location will generate a software interrupt signaling an illegal condition.

Thus, the chip can detect the following illegal conditions:

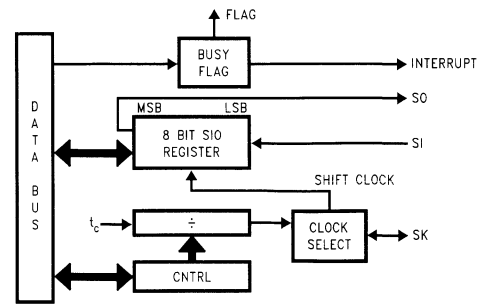
a. Executing from undefined ROM

b. Over "POP"ing the stack by having more returns than calls.

When the software interrupt occurs, the user can re-initialize the stack pointer and do a recovery procedure before restarting (this recovery program is probably similar to that following reset, but might not contain the same program initialization procedures). The recovery program should reset the software interrupt pending bit using the RPND instruction.

MICROWIRE/PLUS

MICROWIRE/PLUS is a serial synchronous communications interface. The MICROWIRE/PLUS capability enables the device to interface with any of National Semiconductor's MICROWIRE peripherals (i.e. A/D converters, display drivers, E^{2}PROMs etc.) and with other microcontrollers which support the MICROWIRE interface. It consists of an 8-bit serial shift register (SIO) with serial data input (SI), serial data output (SO) and serial shift clock (SK). *Figure 17* shows a block diagram of the MICROWIRE/PLUS logic.



TL/DD/12823–19

FIGURE 17. MICROWIRE/PLUS Block Diagram

The shift clock can be selected from either an internal source or an external source. Operating the MICROWIRE/PLUS arrangement with the internal clock source is called the Master mode of operation. Similarly, operating the MICROWIRE/PLUS arrangement with an external shift clock is called the Slave mode of operation.

The CNTRL register is used to configure and control the MICROWIRE/PLUS mode. To use the MICROWIRE/PLUS, the MSEL bit in the CNTRL register is set to one. In the master mode, the SK clock rate is selected by the two bits, SL0 and SL1, in the CNTRL register. Table VIII details the different clock rates that may be selected.

TABLE VII. WATCHDOG Service Actions

MICROWIRE/PLUS (Continued)

MICROWIRE/PLUS OPERATION

Setting the BUSY bit in the PSW register causes the MICROWIRE/PLUS to start shifting the data. It gets reset when eight data bits have been shifted. The user may reset the BUSY bit by software to allow less than 8 bits to shift. If enabled, an interrupt is generated when eight data bits have been shifted. The device may enter the MICROWIRE/PLUS mode either as a Master or as a Slave. *Figure 18* shows how two microcontroller devices and several peripherals may be interconnected using the MICROWIRE/PLUS arrangements.

Warning:

The SIO register should only be loaded when the SK clock is low. Loading the SIO register while the SK clock is high will result in undefined data in the SIO register. SK clock is normally low when not shifting.

Setting the BUSY flag when the input SK clock is high in the MICROWIRE/PLUS slave mode may cause the current SK clock for the SIO shift register to be narrow. For safety, the BUSY flag should only be set when the input SK clock is low.

MICROWIRE/PLUS Master Mode Operation

In the MICROWIRE/PLUS Master mode of operation the shift clock (SK) is generated internally by the device. The MICROWIRE Master always initiates all data exchanges. The MSEL bit in the CNTRL register must be set to enable the SO and SK functions onto the G Port. The SO and SK pins must also be selected as outputs by setting appropriate bits in the Port G configuration register. Table IX summarizes the bit settings required for Master mode of operation.

MICROWIRE/PLUS Slave Mode Operation

In the MICROWIRE/PLUS Slave mode of operation the SK clock is generated by an external source. Setting the MSEL bit in the CNTRL register enables the SO and SK functions onto the G Port. The SK pin must be selected as an input and the SO pin is selected as an output pin by setting and resetting the appropriate bits in the Port G configuration register. Table IX summarizes the settings required to enter the Slave mode of operation.

The user must set the BUSY flag immediately upon entering the Slave mode. This will ensure that all data bits sent by the Master will be shifted properly. After eight clock pulses the BUSY flag will be cleared and the sequence may be repeated.

Alternate SK Phase Operation

The device allows either the normal SK clock or an alternate phase SK clock to shift data in and out of the SIO register. In both the modes the SK is normally low. In the normal mode data is shifted in on the rising edge of the SK clock and the data is shifted out on the falling edge of the SK clock. The SIO register is shifted on each falling edge of the SK clock. In the alternate SK phase operation, data is shifted in on the falling edge of the SK clock and shifted out on the rising edge of the SK clock.

A control flag, SKSEL, allows either the normal SK clock or the alternate SK clock to be selected. Resetting SKSEL causes the MICROWIRE/PLUS logic to be clocked from the normal SK signal. Setting the SKSEL flag selects the alternate SK clock. The SKSEL is mapped into the G6 configuration bit. The SKSEL flag will power up in the reset condition, selecting the normal SK signal.

TABLE IX

This table assumes that the control flag MSEL is set.

G4 (SO) Config. Bit	G5 (SK) Config. Bit	G4 Fun.	G5 Fun.	Operation
1	1	SO	Int. SK	MICROWIRE/PLUS Master
0	1	TRI-STATE	Int. SK	MICROWIRE/PLUS Master
1	0	SO	Ext. SK	MICROWIRE/PLUS Slave
0	0	TRI-STATE	Ext. SK	MICROWIRE/PLUS Slave

Memory Map

All RAM, ports and registers (except A and PC) are mapped into data memory address space.

Address S/ADD REG	Contents
0000 to 006F	On-Chip RAM bytes (112 bytes)
0070 to 007F	Unused RAM Address Space (Reads As All Ones)
xx80 to xxAF	Unused RAM Address Space (Reads Undefined Data)
xxB0	Timer T3 Lower Byte
XXB1	Timer T3 Upper Byte
xxB2	Timer T3 Autoload Register T3RA Lower Byte
xxB3	Timer T3 Autoload Register T3RA Upper Byte
xxB4	Timer T3 Autoload Register T3RB Lower Byte
xxB5	Timer T3 Autoload Register T3RB Upper Byte
xxB6	Timer T3 Control Register
xxB7	Comparator Select Register (CMPSL)
xxB8	UART Transmit Buffer (TBUF)
xxB9	UART Receive Buffer (RBUF)
xxBA	UART Control and Status Register (ENU)
xxBB	UART Receive Control and Status Register (ENUR)
xxBC	UART Interrupt and Clock Source Register (ENUI)
xxBD	UART Baud Register (BAUD)
xxBE	UART Prescale Select Register (PSR)
xxBF	Reserved for UART
xxC0	Timer T2 Lower Byte
xxC1	Timer T2 Upper Byte
xxC2	Timer T2 Autoload Register T2RA Lower Byte
xxC3	Timer T2 Autoload Register T2RA Upper Byte
xxC4	Timer T2 Autoload Register T2RB Lower Byte
xxC5	Timer T2 Autoload Register T2RB Upper Byte
xxC6	Timer T2 Control Register
xxC7	WATCHDOG Service Register (Reg:WDSVR)
xxC8	MIWU Edge Select Register (Reg:WKEDG)
xxC9	MIWU Enable Register (Reg:WKEN)
xxCA	MIWU Pending Register (Reg:WKPND)
xxCB	Reserved
xxCC	Reserved
xxCD to xxCF	Reserved

Address S/ADD REG	Contents
xxD0	Port L Data Register
xxD1	Port L Configuration Register
xxD2	Port L Input Pins (Read Only)
xxD3	Reserved for Port L
xxD4	Port G Data Register
xxD5	Port G Configuration Register
xxD6	Port G Input Pins (Read Only)
xxD7	Port I Input Pins (Read Only)
xxD8	Port C Data Register
xxD9	Port C Configuration Register
xxDA	Port C Input Pins (Read Only)
xxDB	Reserved for Port C
xxDC	Port D
xxDD to xxDF	Reserved for Port D
xxE0 to xxE5	Reserved for EE Control Registers
xxE6	Timer T1 Autoload Register T1RB Lower Byte
xxE7	Timer T1 Autoload Register T1RB Upper Byte
xxE8	ICNTRL Register
xxE9	MICROWIRE/PLUS Shift Register
xxEA	Timer T1 Lower Byte
xxEB	Timer T1 Upper Byte
xxEC	Timer T1 Autoload Register T1RA Lower Byte
xxED	Timer T1 Autoload Register T1RA Upper Byte
xxEE	CNTRL Control Register
xxEF	PSW Register
xxF0 to FB	On-Chip RAM Mapped as Registers
xxFC	X Register
xxFD	SP Register
xxFE	B Register
xxFF	S Register
0100 to 017F	On-Chip 128 RAM Bytes
0200 to 027F	On-Chip 128 RAM Bytes
0300 to 037F	On-Chip 128 RAM Bytes

Reading memory locations 0070H–007FH (Segment 0) will return all ones. Reading unused memory locations 0080H–00AFH (Segment 0) will return undefined data. Reading memory locations from other Segments (i.e., Segment 4, Segment 5, ... etc.) will return all ones.

Addressing Modes

There are ten addressing modes, six for operand addressing and four for transfer of control.

OPERAND ADDRESSING MODES

Register Indirect

This is the "normal" addressing mode. The operand is the data memory addressed by the B pointer or X pointer.

Register Indirect (with auto post increment or decrement of pointer)

This addressing mode is used with the LD and X instructions. The operand is the data memory addressed by the B pointer or X pointer. This is a register indirect mode that automatically post increments or decrements the B or X register after executing the instruction.

Direct

The instruction contains an 8-bit address field that directly points to the data memory for the operand.

Immediate

The instruction contains an 8-bit immediate field as the operand.

Short Immediate

This addressing mode is used with the Load B Immediate instruction. The instruction contains a 4-bit immediate field as the operand.

Indirect

This addressing mode is used with the LAID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a data operand from the program memory.

TRANSFER OF CONTROL ADDRESSING MODES

Relative

This mode is used for the JP instruction, with the instruction field being added to the program counter to get the new program location. JP has a range from −31 to +32 to allow a 1-byte relative jump (JP + 1 is implemented by a NOP instruction). There are no "pages" when using JP, since all 15 bits of PC are used.

Absolute

This mode is used with the JMP and JSR instructions, with the instruction field of 12 bits replacing the lower 12 bits of the program counter (PC). This allows jumping to any location in the current 4k program memory segment.

Absolute Long

This mode is used with the JMPL and JSRL instructions, with the instruction field of 15 bits replacing the entire 15 bits of the program counter (PC). This allows jumping to any location up to 32k in the program memory space.

Indirect

This mode is used with the JID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a location in the program memory. The contents of this program memory location serve as a partial address (lower 8 bits of PC) for the jump to the next instruction.

Note: The VIS is a special case of the Indirect Transfer of Control addressing mode, where the double byte vector associated with the interrupt is transferred from adjacent addresses in the program memory into the program counter (PC) in order to jump to the associated interrupt service routine.

Instruction Set

Register and Symbol Definition

Registers	
A	8-Bit Accumulator Register
B	8-Bit Address Register
X	8-Bit Address Register
S	8-Bit Segment Register
SP	8-Bit Stack Pointer Register
PC	15-Bit Program Counter Register
PU	Upper 7 Bits of PC
PL	Lower 8 Bits of PC
C	1 Bit of PSW Register for Carry
HC	1 Bit of PSW Register for Half Carry
GIE	1 Bit of PSW Register for Global Interrupt Enable
VU	Interrupt Vector Upper Byte
VL	Interrupt Vector Lower Byte

Symbols	
[B]	Memory Indirectly Addressed by B Register
[X]	Memory Indirectly Addressed by X Register
MD	Direct Addressed Memory
Mem	Direct Addressed Memory or [B]
Meml	Direct Addressed Memory or [B] or Immediate Data
Imm	8-Bit Immediate Data
Reg	Register Memory: Addresses F0 to FF (Includes B, X and SP)
Bit	Bit Number (0 to 7)
←	Loaded with
⟷	Exchanged with

Instruction Set (Continued)

INSTRUCTION SET

ADD	A,Meml	ADD	A ← A + Meml
ADC	A,Meml	ADD with Carry	A ← A + Meml + C, C ← Carry HC ← Half Carry
SUBC	A,Meml	Subtract with Carry	A ← A − $\overline{\text{Meml}}$ + C, C ← Carry HC ← Half Carry
AND	A,Meml	Logical AND	A ← A and Meml
ANDSZ	A,Imm	Logical AND Immed., Skip if Zero	Skip next if (A and Imm) = 0
OR	A,Meml	Logical OR	A ← A or Meml
XOR	A,Meml	Logical EXclusive OR	A ← A xor Meml
IFEQ	MD,Imm	IF EQual	Compare MD and Imm, Do next if MD = Imm
IFEQ	A,Meml	IF EQual	Compare A and Meml, Do next if A = Meml
IFNE	A,Meml	IF Not Equal	Compare A and Meml, Do next if A ≠ Meml
IFGT	A,Meml	IF Greater Than	Compare A and Meml, Do next if A > Meml
IFBNE	#	If B Not Equal	Do next if lower 4 bits of B ≠ Imm
DRSZ	Reg	Decrement Reg., Skip if Zero	Reg ← Reg − 1, Skip if Reg = 0
SBIT	#,Mem	Set BIT	1 to bit, Mem (bit = 0 to 7 immediate)
RBIT	#,Mem	Reset BIT	0 to bit, Mem
IFBIT	#,Mem	IF BIT	If bit in A or Mem is true do next instruction
RPND		Reset PeNDing Flag	Reset Software Interrupt Pending Flag
X	A,Mem	EXchange A with Memory	A ⟷ Mem
X	A,[X]	EXchange A with Memory [X]	A ⟷ [X]
LD	A,Meml	LoaD A with Memory	A ← Meml
LD	A,[X]	LoaD A with Memory [X]	A ← [X]
LD	B,Imm	LoaD B with Immed.	B ← Imm
LD	Mem,Imm	LoaD Memory Immed	Mem ← Imm
LD	Reg,Imm	LoaD Register Memory Immed.	Reg ← Imm
X	A, [B ±]	EXchange A with Memory [B]	A ⟷ [B], (B ← B ±1)
X	A, [X ±]	EXchange A with Memory [X]	A ⟷ [X], (X ← X ±1)
LD	A, [B±]	LoaD A with Memory [B]	A ← [B], (B ← B ±1)
LD	A, [X±]	LoaD A with Memory [X]	A ← [X], (X ← X±1)
LD	[B±],Imm	LoaD Memory [B] Immed.	[B] ← Imm, (B ← B±1)
CLR	A	CLeaR A	A ← 0
INC	A	INCrement A	A ← A + 1
DEC	A	DECrement A	A ← A − 1
LAID		Load A InDirect from ROM	A ← ROM (PU,A)
DCOR	A	Decimal CORrect A	A ← BCD correction of A (follows ADC, SUBC)
RRC	A	Rotate A Right thru C	C → A7 → . . . → A0 → C
RLC	A	Rotate A Left thru C	C ← A7 ← . . . ← A0 ← C
SWAP	A	SWAP nibbles of A	A7 . . . A4 ⟷ A3 . . . A0
SC		Set C	C ← 1, HC ← 1
RC		Reset C	C ← 0, HC ← 0
IFC		IF C	IF C is true, do next instruction
IFNC		IF Not C	If C is not true, do next instruction
POP	A	POP the stack into A	SP ← SP + 1, A ← [SP]
PUSH	A	PUSH A onto the stack	[SP] ← A, SP ← SP − 1
VIS		Vector to Interrupt Service Routine	PU ← [VU], PL ← [VL]
JMPL	Addr.	Jump absolute Long	PC ← ii (ii = 15 bits, 0 to 32k)
JMP	Addr.	Jump absolute	PC9 . . . 0 ← i (i = 12 bits)
JP	Disp.	Jump relative short	PC ← PC + r (r is −31 to +32, except 1)
JSRL	Addr.	Jump SubRoutine Long	[SP] ← PL, [SP−1] ← PU,SP−2, PC ← ii
JSR	Addr	Jump SubRoutine	[SP] ← PL, [SP−1] ← PU,SP−2, PC9 . . . 0 ← i
JID		Jump InDirect	PL ← ROM (PU,A)
RET		RETurn from subroutine	SP + 2, PL ← [SP], PU ← [SP−1]
RETSK		RETurn and SKip	SP + 2, PL ← [SP],PU ← [SP−1], skip next instruction
RETI		RETurn from Interrupt	SP + 2, PL ← [SP],PU ← [SP−1],GIE ← 1
INTR		Generate an Interrupt	[SP] ← PL, [SP−1] ← PU, SP−2, PC ← 0FF
NOP		No OPeration	PC ← PC + 1

Instruction Execution Time

Most instructions are single byte (with immediate addressing mode instructions taking two bytes).

Most single byte instructions take one cycle time to execute.

Skipped instructions require x number of cycles to be skipped, where x equals the number of bytes in the skipped instruction opcode.

See the BYTES and CYCLES per INSTRUCTION table for details.

Bytes and Cycles per Instruction

The following table shows the number of bytes and cycles for each instruction in the format of byte/cycle.

Arithmetic and Logic Instructions

Where,

i is the immediate data

Md is a directly addressed memory location

* is an unused opcode

Note: The opcode 60 Hex is also the opcode for IFBIT #i,A

Mask Options

The mask programmable options are shown below. The options are programmed at the same time as the ROM pattern submission.

OPTION 1: CLOCK CONFIGURATION

= 1 Crystal Oscillator (CKI/10)
G7 (CKO) is clock generator output to crystal/ resonator with CKI being the clock input

= 2 Single-pin RC controlled oscillator (CKI/10)
G7 is available as a HALT restart and/or general purpose input

OPTION 2: HALT

= 1 Enable HALT mode

= 2 Disable HALT mode

OPTION 3: BONDING

= 1 44-Pin PLCC

= 2 40-Pin DIP

The chip can be driven by a clock input on the CKI input pin which can be between DC and 10 MHz. The CKO output clock is on pin G7 (if clock option = 1 has been selected). The CKI input frequency is divided down by 10 to produce the instruction cycle clock (1/tc).

Development Support

Summary

- iceMASTER: IM-COP8/400—Full feature in-circuit emulation for all COP8 products. A full set of COP8 Basic and Feature Family device and package specific probes are available.
- COP8 Debug Module: Moderate cost in-circuit emulation and development programming unit.
- COP8 Evaluation and Programming Unit: EPU-COP888GG—low cost In-circuit simulation and development programming unit.
- Assembler: COP8-DEV-IBMA. A DOS installable cross development Assembler, Linker, Librarian and Utility Software Development Tool Kit.
- C Compiler: COP8C. A DOS installable cross development Software Tool Kit.
- OTP/EPROM Programmer Support: Covering needs from engineering prototype, pilot production to full production environments.
- In-factory Programming Support: Covering high volume production OTP programming with 2 week turn-on capability.

Development Support (Continued)

IceMASTER (IM) IN-CIRCUIT EMULATION

The iceMASTER IM-COP8/400 is a full feature, PC based, in-circuit emulation tool developed and marketed by MetaLink Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 19* for configuration.

The iceMASTER IM-COP8/400 with its device specific COP8 Probe provides a rich feature set for developing, testing and maintaining product:

- Real-time in-circuit emulation; full 2.4V–5.5V operation range, full DC-10 MHz clock. Chip options are programmable or jumper selectable.
- Direct connection to application board by package compatible socket or surface mount assembly.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated on the probe as necessary.
- Full 4K frame synchronous trace memory. Address, instruction, and 8 unspecified, circuit connectable trace lines. Display can be HLL source (e.g., C source), assembly or mixed.
- A full 64K hardware configurable break, trace on, trace off control, and pass count increment events.
- Tool set integrated interactive symbolic debugger—supports both assembler (COFF) and C Compiler (.COD) linked object formats.
- Real time peformance profiling analysis; selectable bucket definition.
- Watch windows, content updated automatically at each execution break.
- Instruction by instruction memory/register changes displayed on source window when in single step operation.
- Single base unit and debugger software reconfigurable to support the entire COP8 family; only the probe personality needs to change. Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- On-line HELP customized to specific processor using master model file.
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

Development Support (Continued)

IceMASTER DEBUG MODULE (DM)

The iceMASTER Debug Module is a PC based, combination in-circuit emulation tool and COP8 based OTP/EPROM programming tool developed and marketed by MetaLink Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 20* for configuration.

The iceMASTER Debug Module is a moderate cost development tool. It has the capability of in-circuit emulation for a specific COP8 microcontroller and in addition serves as a programming tool for COP8 OTP and EPROM product families. Summary of features is as follows:

- Real-time in-circuit emulation; full operating voltage range operation, full DC-10 MHz clock.
- All processor I/O pins can be cabled to an application development board with package compatible cable to socket and surface mount assembly.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated as necessary.
- 100 frames of synchronous trace memory. The display can be HLL source (C source), assembly or mixed. The most recent history prior to a break is available in the trace memory.
- Configured break points; uses INTR instruction which is modestly intrusive.
- Software—only supported features are selectable.
- Tool set integrated interactive symbolic debugger—supports both
- Assembler (COFF) and C Compiler (.COD) SDK linked object formats.
- Instruction by instruction memory/register changes displayed when in single step operation.
- Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- Programming menu supports full product line of programmable OTP and EPROM COP8 products. Program data is taken directly from the overlay RAM.
- Programming of 44 PLCC and 68 PLCC parts requires external programming adapters.
- Includes wall-mount power supply
- On-board V_{PP} generator from 5V input or connection to external supply supported. Requires V_{PP} level adjustment per the family programming specification (correct level is provided on an on-screen pop-down display). On-line HELP customized to specific processor using master model file.
- On-line HELP customized to specific processor using master model file
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

IceMASTER EVALUATION PROGRAMMING UNIT (EPU)

The iceMASTER EPU-COP888GG is a PC based, in-circuit. simulation tool to support the feature family COP8 products. See *Figure 21* for configuration.

The simulation capability is a very low cost means of evaluating the general COP8 architecture. In addition, the EPU has programming capability, with added adapters, for programming the whole COP8 product family of OTP and EPROM products. The product includes the following features:

- Non-real-time in-circuit simulation. Program overlay memory is PC resident; instructions are downloaded over RS-232 as executed. Approximate performance is 20 kHz.
- Includes a 40-pin DIP cable adapter. Other target packages are not supported. All processor I/O pins are cabled to the application development environment.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated as necessary.
- On-chip timer and watch-dog execution are not well synchronized to the instruction simulation.
- 100 frames of synchronous trace memory. The display can be HLL source (e.g., C source), assembly or mixed. The most recent history prior to a break is available in the trace memory.
- Up to 8 software configured break points; uses INTR instruction which is modestly intrusive.
- Common look-feel debugger software across all MetaLink products—only supported features are selectable.
- Tool set integrated interactive symbolic debugger—supports both assembler (COFF) and C Compiler (.COD) SDK linked object formats.
- Instruction by instruction memory/register changes displayed when in single step operation.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification. Restart requires special handling.
- Programming menu supports full product line of programmable OTP and EPROM COP8 products. Only a 40 ZIF socket is available on the EPU unit. Adapters are available for other part package configurations.
- Integral wall mount power supply provides 5V and develops the required V_{PP} to program parts.
- Includes a copy of COP8-DEV-IBMA assembler, linker SDK.

Development Support (Continued)

COP8 ASSEMBLER/LINKER SOFTWARE DEVELOPMENT TOOL KIT

National Semiconductor offers a relocateable COP8 macro cross assembler, linker, librarian and utility software development tool kit. Features are summarized as follows:

- Basic and Feature Family instruction set by "device" type.
- Nested macro capability.
- Extensive set of assembler directives.
- Supported on PC/DOS platform.
- Generates National standard COFF output files.
- Integrated Linker and Librarian.
- Integrated utilities to generate ROM code file outputs.
- DUMPCOFF utility.

This product is integrated as a part of MetaLink tools as a development kit, fully supported by the MetaLink debugger. It may be ordered separately or it is bundled with the MetaLink products at no additional cost.

Order Information

Assembler SDK	
COP8-DEV-IBMA	Assembler SDK on installable 3.5" PC/DOS Floppy Disk Drive format. Periodic upgrades and most recent version is available on National's BBS and Internet.

COP8 C COMPILER

A C Compiler is developed and marketed by Byte Craft Limited. The COP8C compiler is a fully integrated development tool specifically designed to support the compact embedded configuration of the COP8 family of products.

Features are summarized as follows:

- ANSI C with some restrictions and extensions that optimize development for the COP8 embedded application.
- BITS data type extension. Register declaration #pragma with direct bit level definitions.
- C language support for interrupt routines.
- Expert system, rule based code geration and optimization.
- Performs consistency checks against the architectural definitions of the target COP8 device.
- Generates program memory code.
- Supports linking of compiled object or COP8 assembled object formats.
- Global optimization of linked code.
- Symbolic debug load format fully source level supported by the MetaLink debugger.

SINGLE-CHIP OTP/EMULATOR SUPPORT

The COP8 family is supported by single-chip OTP emulators. For detailed information, refer to the emulator specific datasheet and the emulator selection table below:

OTP Emulator Ordering Information

Device Number	Clock Option	Package	Emulates
COP87L88GGV-XE	Crystal/ HALT En	44 PLCC	COP888GG
COP87L88GGN-XE	Crystal/ HALT En	40 DIP	COP888GG

INDUSTRY WIDE OTP/EPROM PROGRAMMING SUPPORT

Programming support, in addition to the MetaLink development tools, is provided by a full range of independent approved vendors to meet the needs from the engineering laboratory to full production.

AVAILABLE LITERATURE

For more information, please see the COP8 Basic Family User's Manual, Literature Number 620895, COP8 Feature Family User's Manual Literature Number 620897 and National's Family of 8-bit Microcontrollers COP8 Selection Guide, Literature Number 630009.

DIAL-A-HELPER

Dial-A-Helper is a service provided by the Microcontroller Applications group. The Dial-A-Helper is an Electronic Information System that may be accessed as a Bulletin Board System (BBS) via data modem, as an FTP site on the Internet via standard FTP client application or as an FTP site on the Internet using a standard Internet browser such as Netscape or Mosaic.

The Dial-A-Helper system provides access to an automated information storage and retrieval system. The system capabilities include a MESSAGE SECTION (electronic mail, when accessed as a BBS) for communication to and from the Microcontroller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities could be found.

National Semiconductor

COP688HG/COP888HG
8-Bit Microcontroller with UART and Three Multi-Function Timers

General Description

The COP8™ feature family of microcontrollers uses an 8-bit single chip core architecture fabricated with National Semiconductor's M²CMOS™ process technology. The COP888HG is a member of this expandable 8-bit core processor family of microcontrollers. (Continued)

Key Features

- Full duplex UART
- Three 16-bit timers, each with two 16-bit registers supporting:
  - — Processor Independent PWM mode
  - — External Event counter mode
  - — Input Capture mode
- Quiet design (low radiated emissions)
- 20 kbytes on-board ROM
- 512 bytes on-board RAM

Additional Peripheral Features

- Idle Timer
- Multi-Input Wake-Up (MIWU) with optional interrupts (8)
- Two analog comparators
- WATCHDOG™ and Clock Monitor logic
- MICROWIRE/PLUS™ serial I/O

I/O Features

- Memory mapped I/O
- Software selectable I/O options (TRI-STATE® Output, Push-Pull Output, Weak Pull-Up Input, High Impedance Input)
- Schmitt trigger inputs on ports G and L
- Packages:
  - — 40 DIP with 35 I/O pins
  - — 44 PLCC with 39 I/O pins

CPU/Instruction Set Features

- 1 μs instruction cycle time
- Fourteen multi-source vectored interrupts servicing
  - — External Interrupt with selectable edge
  - — Idle Timer T0
  - — Three Timers (Each with 2 Interrupts)
  - — MICROWIRE/PLUS™
  - — Multi-Input Wake-Up
  - — Software Trap
  - — UART (2)
  - — Default VIS (default interrupt)
- Versatile and easy-to-use instruction set
- 8-bit Stack Pointer (SP) — stack in RAM
- Two 8-bit Register Indirect Data Memory Pointers (B and X)

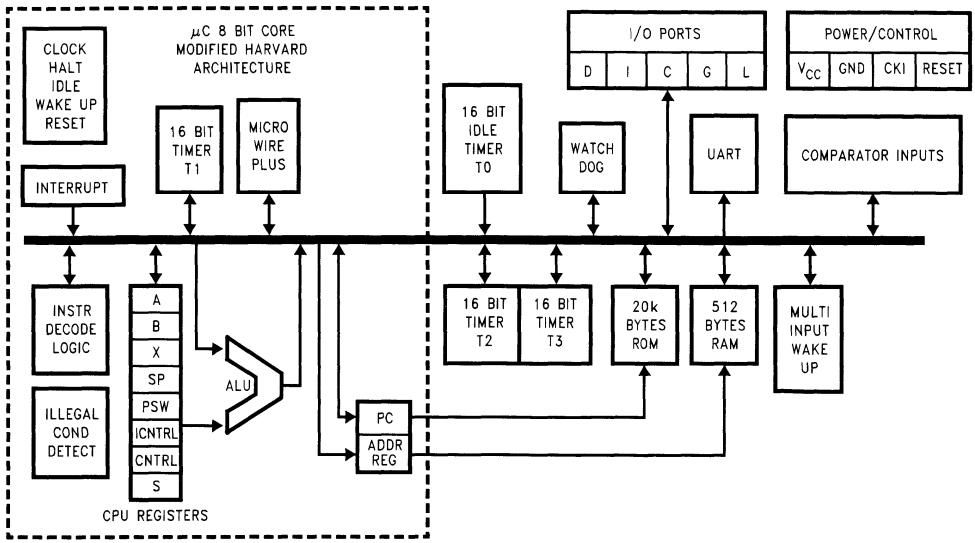
Fully Static CMOS

- Two power saving modes: HALT and IDLE
- Low current drain (typically <1 μA)
- Single supply operation: 2.5V to 5.5V
- Temperature ranges:
  $-40°C$ to $+85°C$, $-55°C$ to $+125°C$

Development Support

- Emulation and OTP devices
- Real time emulation and full program debug offered by MetaLink's Development System

Block Diagram



TL/DD/12858–1

FIGURE 1. COP888HG Block Diagram

General Description (Continued)

It is a fully static part, fabricated using double-metal silicon gate microCMOS technology. Features include an 8-bit memory mapped architecture, MICROWIRE/PLUS serial I/O, three 16-bit timer/counters supporting three modes (Processor Independent PWM generation, External Event counter, and Input Capture mode capabilities), full duplex UART, two comparators, and two power saving modes (HALT and IDLE), both with a multi-sourced wakeup/interrupt capability. This multi-sourced interrupt capability may also be used independent of the HALT or IDLE modes. Each I/O pin has software selectable configurations. The devices operate over a voltage range of 2.5V to 5.5V. High throughput is achieved with an efficient, regular instruction set operating at a maximum rate of 1 μs per instruction.

Low radiated emissions are achieved by gradual turn-on output drivers and internal I_{CC} smoothing filters on the chip logic and crystal oscillator.

	$2.5V \le V_{CC} \le 4.0V$	150			ns
Output Propagation Delay	$R_L = 2.2k, C_L = 100$ pF				
t_{PD1}, t_{PD0}					
SO, SK	$4.0V \le V_{CC} \le 5.5V$			0.7	μs
	$2.5V \le V_{CC} \le 4.0V$			1.75	μs
All Others	$4.0V \le V_{CC} \le 5.5V$			1.0	μs
	$2.5V \le V_{CC} \le 4.0V$			2.5	μs
MICROWIRE Setup Time (t_{UWS}) (Note 7)	$V_{CC} \ge 4.0V$	20			ns
MICROWIRE Hold Time (t_{UWH}) (Note 7)	$V_{CC} \ge 4.0V$	56			ns
MICROWIRE Output Propagation Delay (t_{UPD})	$V_{CC} \ge 4.0V$			220	ns
Input Pulse Width					
Interrupt Input High Time		1.0			t_c
Interrupt Input Low Time		1.0			t_c
Timer 1, 2, 3 Input High Time		1.0			t_c
Timer 1, 2, 3 Input Low Time		1.0			t_c
Reset Pulse Width		1.0			μs

t_c = Instruction Cycle Time

Note 1: Maximum rate of voltage change must be less than 0.5 V/ms.

Note 2: Supply and IDLE currents are measured with CKI driven with a square wave Oscillator, CKO driven 180° out of phase with CKI, inputs connected to V_{CC} and outputs driven low but not connected to a load.

Note 3: The HALT mode will stop CKI from oscillating in the RC and the Crystal configurations by bringing CKI high. Test Conditions: All inputs tied to V_{CC}, L and G ports in the TRI-STATE mode and tied to ground, all outputs low and tied to ground. The clock monitor is disabled.

Note 4: The user must guarantee that D2 pin does not source more than 10 mA during RESET. If D2 sources more than 10 mA during reset, the device will go into programming mode.

Note 5: Pins G6 and $\overline{\text{RESET}}$ are designed with a high voltage input network. These pins allow input voltages $> V_{CC}$ and the pins will have sink current to V_{CC} when biased at voltages $> V_{CC}$ (the pins do not have source current when biased at a voltage below V_{CC}). The effective resistance to V_{CC} is 750Ω (typical). These two pins will not latch up. The voltage at the pins must be limited to $< 14V$. **WARNING: Voltages in excess of 14V will cause damage to the pins. This warning excludes ESD transients.**

Note 6: The output propagation delay is referenced to the end of the instruction cycle where the output change occurs.

Note 7: Parameter characterized but not tested.

Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Supply Voltage (V_{CC})	7V
Voltage at Any Pin	$-0.3V$ to $V_{CC} + 0.3V$
Total Current into V_{CC} Pin (Source)	100 mA
Total Current out of GND Pin (Sink)	110 mA
Storage Temperature Range	$-65°C$ to $+140°C$

Note: *Absolute maximum ratings indicate limits beyond which damage to the device may occur. DC and AC electrical specifications are not ensured when operating the device at absolute maximum ratings.*

Note 1: Maximum rate of voltage change must be less than 0.5 V/ms.

Note 2: Supply current is measured after running 2000 cycles with a square wave, CKI input, CKO open, inputs at rails and outputs open.

Note 3: The HALT mode will stop CKI from oscillating in the RC and the Crystal configurations. Measurement of IDD HALT is done with device neither sourcing or sinking current; with L, C, and G0–G5 programmed as low outputs and not driving a load; all outputs programmed low and not driving a load; all inputs tied to V_{CC}; clock monitor and comparators disabled. Parameter refers to HALT mode entered via setting bit 7 of the G Port data register. Part will pull up CKI during HALT in crystal clock mode.

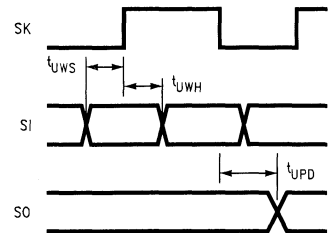
Note 4: Pins G6 and $\overline{\text{RESET}}$ are designed with a high voltage input network. These pins allow input voltages $> V_{CC}$ and the pins will have sink current to V_{CC} when biased at voltages $> V_{CC}$ (the pins do not have source current when biased at a voltage below V_{CC}). The effective resistance to V_{CC} is 750Ω (typical). These two pins will not latch up. The voltage at the pins must be limited to $< 14V$. **WARNING: Voltages in excess of 14V will cause damage to the pins. This warning excludes ESD transients.**

Note 5: Parameter characterized but not tested.

Note 6: t_c = Instruction Cycle Time.

Comparators AC and DC Characteristics $V_{CC} = 5V, -40°C \leq T_A \leq \pm 85°C$.

Parameter	Conditions	Min	Typ	Max	Units
Input Offset Voltage	$0.4V \leq V_{IN} \leq V_{CC} - 1.5V$		±10	±25	mV
Input Common Mode Voltage Range		0.4		$V_{CC} - 1.5$	V
Low Level Output Current	$V_{OL} = 0.4V$	1.6			mA
High Level Output Current	$V_{OH} = 4.6V$	1.6			mA
DC Supply Current per Comparator (When Enabled)				250	μA
Response Time	100 mV Overdrive, 100 pF Load			1	μs



TL/DD/12858–4

FIGURE 3. MICROWIRE/PLUS Timing

Pin Descriptions

V_{CC} and GND are the power supply pins. All V_{CC} and GND pins must be connected.

CKI is the clock input. This can come from an R/C generated oscillator, or a crystal oscillator (in conjunction with CKO). See Oscillator Description section.

$\overline{\text{RESET}}$ is the master reset input. See Reset Description section.

The device contains three bidirectional 8-bit I/O ports (C, G and L), where each individual bit may be independently configured as an input (Schmitt Trigger inputs on ports L and G), output or TRI-STATE under program control. Three data memory address locations are allocated for each of these I/O ports. Each I/O port has two associated 8-bit memory mapped registers, the CONFIGURATION register and the output DATA register. A memory mapped address is also reserved for the input pins of each I/O port. (See the memory map for the various addresses associated with the I/O ports.) *Figure 4* shows the I/O port configurations. The DATA and CONFIGURATION registers allow for each port bit to be individually configured under software control as shown below:

CONFIGURATION Register	DATA Register	Port Set-Up
0	0	Hi-Z Input (TRI-STATE Output)
0	1	Input with Weak Pull-Up
1	0	Push-Pull Zero Output
1	1	Push-Pull One Output

PORT L is an 8-bit I/O port. All L-pins have Schmitt triggers on the inputs.

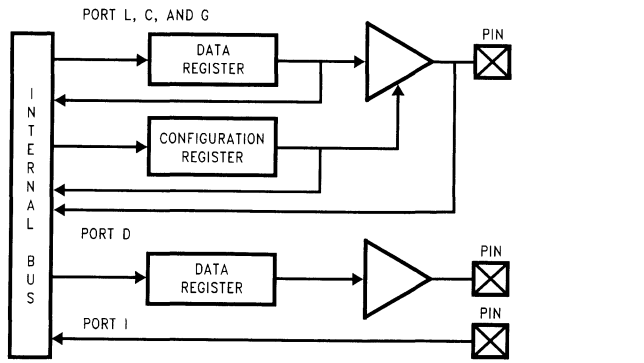
The Port L supports Multi-Input Wake Up on all eight pins. L1 is used for the UART external clock. L2 and L3 are used for the UART transmit and receive. L4 and L5 are used for the timer input functions T2A and T2B. L6 and L7 are used for the timer input functions T3A and T3B.

The Port L has the following alternate features:

- L0 MIWU
- L1 MIWU or CKX
- L2 MIWU or TDX
- L3 MIWU or RDX
- L4 MIWU or T2A
- L5 MIWU or T2B
- L6 MIWU or T3A
- L7 MIWU or T3B

Port G is an 8-bit port with 5 I/O pins (G0, G2–G5), an input pin (G6), and a dedicated output pin (G7). Pins G0 and G2–G6 all have Schmitt Triggers on their inputs. Pin G1 serves as the dedicated WDOUT WATCHDOG output, while pin G7 is either input or output depending on the oscillator mask option selected. With the crystal oscillator option selected, G7 serves as the dedicated output pin for the CKO clock output. With the single-pin R/C oscillator mask option selected, G7 serves as a general purpose input pin but is also used to bring the device out of HALT mode with a low to high transition on G7. There are two registers associated with the G Port, a data register and a configuration register. Therefore, each of the 5 I/O bits (G0, G2–G5) can be individually configured under software control.

Since G6 is an input only pin and G7 is the dedicated CKO clock output pin (crystal clock option) or general purpose input (R/C clock option), the associated bits in the data and configuration registers for G6 and G7 are used for special purpose functions as outlined on the next page. Reading the G6 and G7 data bits will return zeros.



TL/DD/12858–5

FIGURE 4. I/O Port Configurations

Pin Descriptions (Continued)

Note that the chip will be placed in the HALT mode by writing a "1" to bit 7 of the Port G Data Register. Similarly the chip will be placed in the IDLE mode by writing a "1" to bit 6 of the Port G Data Register.

Writing a "1" to bit 6 of the Port G Configuration Register enables the MICROWIRE/PLUS to operate with the alternate phase of the SK clock. The G7 configuration bit, if set high, enables the clock start up delay after HALT when the R/C clock configuration is used.

	Config Reg.	Data Reg.
G7	CLKDLY	HALT
G6	Alternate SK	IDLE

Port G has the following alternate features:

- G0 INTR (External Interrupt Input)
- G2 T1B (Timer T1 Capture Input)
- G3 T1A (Timer T1 I/O)
- G4 SO (MICROWIRE Serial Data Output)
- G5 SK (MICROWIRE Serial Clock)
- G6 SI (MICROWIRE Serial Data Input)

Port G has the following dedicated functions:

- G1 WDOUT WATCHDOG and/or Clock Monitor dedicated output
- G7 CKO Oscillator dedicated output or general purpose input

Port C is an 8-bit I/O port. The 40-pin device does not have a full complement of Port C pins. The unavailable pins are not terminated. A read operation for these unterminated pins will return unpredicatable values.

Port I is an eight-bit Hi-Z input port.

Port I1–I3 are used for Comparator 1. Port I4–I6 are used for Comparator 2.

The Port I has the following alternate features:

- I1 COMP1 − IN (Comparator 1 Negative Input)
- I2 COMP1 + IN (Comparator 1 Positive Input)
- I3 COMP1OUT (Comparator 1 Output)
- I4 COMP2 − IN (Comparator 2 Negative Input)
- I5 COMP2 + IN (Comparator 2 Positive Input)
- I6 COMP2OUT (Comparator 2 Output)

Port D is an 8-bit output port that is preset high when $\overline{\text{RESET}}$ goes low. The user can tie two or more D port outputs (except D2) together in order to get a higher drive.

Functional Description

The architecture of the device is modified Harvard architecture. With the Harvard architecture, the control store program memory (ROM) is separated from the data store memory (RAM). Both ROM and RAM have their own separate addressing space with separate address buses. The architecture, though based on Harvard architecture, permits transfer of data from ROM to RAM.

CPU REGISTERS

The CPU can do an 8-bit addition, subtraction, logical or shift operation in one instruction (t_c) cycle time.

There are six CPU registers:

A is the 8-bit Accumulator Register

PC is the 15-bit Program Counter Register

PU is the upper 7 bits of the program counter (PC)
PL is the lower 8 bits of the program counter (PC)

B is an 8-bit RAM address pointer, which can be optionally post auto incremented or decremented.

X is an 8-bit alternate RAM address pointer, which can be optionally post auto incremented or decremented.

SP is the 8-bit stack pointer, which points to the subroutine/interrupt stack (in RAM). The SP is initialized to RAM address 06F with reset.

S is the 8-bit Data Segment Address Register used to extend the lower half of the address range (00 to 7F) into 256 data segments of 128 bytes each.

All the CPU registers are memory mapped with the exception of the Accumulator (A) and the Program Counter (PC).

PROGRAM MEMORY

The program memory consists of 20 kbytes of ROM. These bytes may hold program instructions or constant data (data tables for the LAID instruction, jump vectors for the JID instruction, and interrupt vectors for the VIS instruction). The program memory is addressed by the 15-bit program counter (PC). All interrupts in the devices vector to program memory location 0FF Hex.

DATA MEMORY

The data memory address space includes the on-chip RAM and data registers, the I/O registers (Configuration, Data and Pin), the control registers, the MICROWIRE/PLUS SIO shift register, and the various registers, and counters associated with the timers (with the exception of the IDLE timer). Data memory is addressed directly by the instruction or indirectly by the B, X, SP pointers and S register.

The data memory consists of 512 bytes of RAM. Sixteen bytes of RAM are mapped as "registers" at addresses 0F0 to 0FF Hex. These registers can be loaded immediately, and also decremented and tested with the DRSZ (decrement register and skip if zero) instruction. The memory pointer registers X, SP, B and S are memory mapped into this space at address locations 0FC to 0FF Hex respectively, with the other registers being available for general usage.

The instruction set permits any bit in memory to be set, reset or tested. All I/O and registers (except A and PC) are memory mapped; therefore, I/O bits and register bits can be directly and individually set, reset and tested. The accumulator (A) bits can also be directly and individually tested.

Note: RAM contents are undefined upon power-up.

Data Memory Segment RAM Extension

Data memory address 0FF is used as a memory mapped location for the Data Segment Address Register (S).

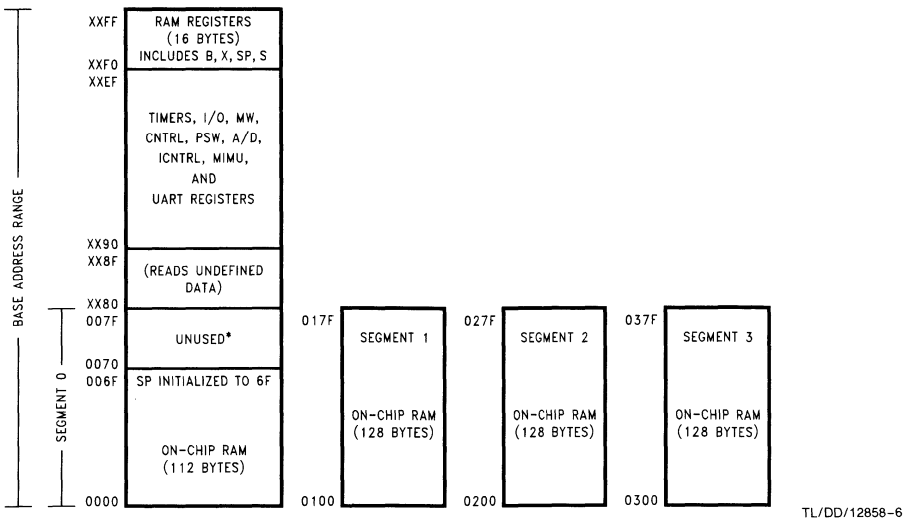
The data store memory is either addressed directly by a single byte address within the instruction, or indirectly relative to the reference of the B, X, or SP pointers (each contains a single-byte address). This single-byte address allows an addressing range of 256 locations from 00 to FF hex. The upper bit of this single-byte address divides the data store memory into two separate sections as outlined previously. With the exception of the RAM register memory from address locations 00F0 to 00FF, all RAM memory is memory mapped with the upper bit of the single-byte address being equal to zero. This allows the upper bit of the single-byte address to determine whether or not the base address range (from 0000 to 00FF) is extended. If this upper bit equals one (representing address range 0080 to 00FF), then address extension does not take place. Alternatively, if this upper bit equals zero, then the data segment extension register S is used to extend the base address range (from 0000 to 007F) from XX00 to XX7F, where XX represents the 8 bits from the S register. Thus the 128-byte data segment extensions are located from addresses 0100 to 017F for data segment 1, 0200 to 027F for data segment 2, etc., up to FF00 to FF7F for data segment 255. The base address range from 0000 to 007F represents data segment 0.

Figure 5 illustrates how the S register data memory extension is used in extending the lower half of the base address range (00 to 7F hex) into 256 data segments of 128 bytes each, with a total addressing range of 32 kbytes from XX00 to XX7F. This organization allows a total of 256 data segments of 128 bytes each with an additional upper base segment of 128 bytes. Furthermore, all addressing modes are available for all data segments. The S register must be changed under program control to move from one data segment (128 bytes) to another. However, the upper base segment (containing the 16 memory registers, I/O registers, control registers, etc.) is always available regardless of the contents of the S register, since the upper base segment (address range 0080 to 00FF) is independent of data segment extension.

The instructions that utilize the stack pointer (SP) always reference the stack as part of the base segment (Segment 0), regardless of the contents of the S register. The S register is not changed by these instructions. Consequently, the stack (used with subroutine linkage and interrupts) is always located in the base segment. The stack pointer will be initialized to point at data memory location 006F as a result of reset.

The 128 bytes of RAM contained in the base segment are split between the lower and upper base segments. The first 112 bytes of RAM are resident from address 0000 to 006F in the lower base segment, while the remaining 16 bytes of RAM represent the 16 data memory registers located at addresses 00F0 to 00FF of the upper base segment. No RAM is located at the upper sixteen addresses (0070 to 007F) of the lower base segment.

Additional RAM beyond these initial 128 bytes, however, will always be memory mapped in groups of 128 bytes (or less) at the data segment address extensions (XX00 to XX7F) of the lower base segment. The additional 128 bytes of RAM are memory mapped at address locations 0100 to 017F hex.



*Reads as all ones.

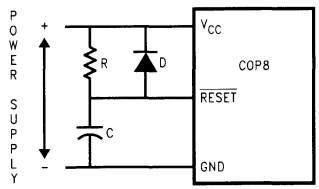
FIGURE 5. RAM Organization

Reset

The $\overline{\text{RESET}}$ input when pulled low initializes the microcontroller. Initialization will occur whenever the $\overline{\text{RESET}}$ input is pulled low. Upon initialization, the data and configuration registers for ports L, G and C are cleared, resulting in these Ports being initialized to the TRI-STATE mode. Pin G1 of the G Port is an exception (as noted below) since pin G1 is dedicated as the WATCHDOG and/or Clock Monitor error output pin. Port D is set high. The PC, PSW, ICNTRL, CNTRL, T2CNTRL and T3CNTRL control registers are cleared. The Comparator Select Register is cleared. The S register is initialized to zero. The Multi-Input Wakeup registers WKEN and WKEDG are cleared. Wakeup register WKPND is unknown. The stack pointer, SP, is initialized to 6F hex.

The device comes out of reset with both the WATCHDOG logic and the Clock Monitor detector armed, with the WATCHDOG service window bits set and the Clock Monitor bit set. The WATCHDOG and Clock Monitor circuits are inhibited during reset. The WATCHDOG service window bits being initialized high default to the maximum WATCHDOG service window of 64k t_C clock cycles. The Clock Monitor bit being initialized high will cause a Clock Monitor error following reset if the clock has not reached the minimum specified frequency at the termination of reset. A Clock Monitor error will cause an active low error output on pin G1. This error output will continue until 16 t_C–32 t_C clock cycles following the clock frequency reaching the minimum specified value, at which time the G1 output will enter the TRI-STATE mode.

The external RC network shown in *Figure 6* should be used to ensure that the $\overline{\text{RESET}}$ pin is held low until the power supply to the chip stabilizes.



TL/DD/12858–7

RC > 5 × Power Supply Rise Time

FIGURE 6. Recommended Reset Circuit

Oscillator Circuits

The chip can be driven by a clock input on the CKI input pin which can be between DC and 10 MHz. The CKO output clock is on pin G7 (crystal configuration). The CKI input frequency is divided down by 10 to produce the instruction cycle clock ($1/t_C$).

Figure 7 shows the Crystal and R/C oscillator diagrams.

CRYSTAL OSCILLATOR

CKI and CKO can be connected to make a closed loop crystal (or resonator) controlled oscillator.

Table I shows the component values required for various standard crystal values.

R/C OSCILLATOR

By selecting CKI as a single pin oscillator input, a single pin R/C oscillator circuit can be connected to it. CKO is available as a general purpose input, and/or HALT restart input.

Table II shows the variation in the oscillator frequencies as functions of the component (R and C) values.

Control Registers

CNTRL Register (Address X'00EE)

The Timer1 (T1) and MICROWIRE/PLUS control register contains the following bits:

- SL1 & SL0 Select the MICROWIRE/PLUS clock divide by (00 = 2, 01 = 4, 1x = 8)
- IEDG External interrupt edge polarity select (0 = Rising edge, 1 = Falling edge)
- MSEL Selects G5 and G4 as MICROWIRE/PLUS signals SK and SO respectively
- T1C0 Timer T1 Start/Stop control in timer modes 1 and 2
  Timer T1 Underflow Interrupt Pending Flag in timer mode 3
- T1C1 Timer T1 mode control bit
- T1C2 Timer T1 mode control bit
- T1C3 Timer T1 mode control bit

T1C3	T1C2	T1C1	T1C0	MSEL	IEDG	SL1	SL0

Bit 7 Bit 0

PSW Register (Address X'00EF)

The PSW register contains the following select bits:

- GIE Global interrupt enable (enables interrupts)
- EXEN Enable external interrupt
- BUSY MICROWIRE/PLUS busy shifting flag
- EXPND External interrupt pending
- T1ENA Timer T1 Interrupt Enable for Timer Underflow or T1A Input capture edge
- T1PNDA Timer T1 Interrupt Pending Flag (Autoreload RA in mode 1, T1 Underflow in Mode 2, T1A capture edge in mode 3)
- C Carry Flag
- HC Half Carry Flag

HC	C	T1PNDA	T1ENA	EXPND	BUSY	EXEN	GIE

Bit 7 Bit 0

The Half-Carry bit is also affected by all the instructions that affect the Carry flag. The SC (Set Carry) and RC (Reset Carry) instructions will respectively set or clear both the carry flags. In addition to the SC and RC instructions, ADC, SUBC, RRC and RLC instructions affect the carry and Half Carry flags.

ICNTRL Register (Address X'00E8)

The ICNTRL register contains the following bits:

- T1ENB Timer T1 Interrupt Enable for T1B Input capture edge
- T1PNDB Timer T1 Interrupt Pending Flag for T1B capture edge
- μWEN Enable MICROWIRE/PLUS interrupt
- μWPND MICROWIRE/PLUS interrupt pending
- T0EN Timer T0 Interrupt Enable (Bit 12 toggle)
- T0PND Timer T0 Interrupt pending
- LPEN L Port Interrupt Enable (Multi-Input Wakeup/Interrupt)
  Bit 7 could be used as a flag

Unused	LPEN	T0PND	T0EN	μWPND	μWEN	T1PNDB	T1ENB

Bit 7 Bit 0

T2CNTRL Register (Address X'00C6)

The T2CNTRL register contains the following bits:

- T2ENB Timer T2 Interrupt Enable for T2B Input capture edge
- T2PNDB Timer T2 Interrupt Pending Flag for T2B capture edge
- T2ENA Timer T2 Interrupt Enable for Timer Underflow or T2A Input capture edge
- T2PNDA Timer T2 Interrupt Pending Flag (Autoreload RA in mode 1, T2 Underflow in mode 2, T2A capture edge in mode 3)
- T2C0 Timer T2 Start/Stop control in timer modes 1 and 2 Timer T2 Underflow Interrupt Pending Flag in timer mode 3
- T2C1 Timer T2 mode control bit
- T2C2 Timer T2 mode control bit
- T2C3 Timer T2 mode control bit

T2C3	T2C2	T2C1	T2C0	T2PNDA	T2ENA	T2PNDB	T2ENB

Bit 7 Bit 0

T3CNTRL Register (Address X'00B6)

The T3CNTRL register contains the following bits:

- T3ENB Timer T3 Interrupt Enable for T3B Input capture edge
- T3PNDB Timer T3 Interrupt Pending Flag for T3B capture edge
- T3ENA Timer T3 Interrupt Enable for Timer Underflow or T3A Input capture edge
- T3PNDA Timer T3 Interrupt Pending Flag (Autoload RA in mode 1, T3 Underflow in mode 2, T3A capture edge in mode 3)
- T3C0 Timer T3 Start/Stop control in timer modes 1 and 2
  Timer T3 Underflow Interrupt Pending Flag in timer mode 3
- T3C1 Timer T3 mode control bit
- T3C2 Timer T3 mode control bit
- T3C3 Timer T3 mode control bit

T3C3	T3C2	T3C1	T3C0	T3PNDA	T3ENA	T3PNDB	T3ENB

Bit 7 Bit 0

Timers

The device contains a very versatile set of timers (T0, T1, T2, T3). All timers and associated autoreload/capture registers power up containing random data.

TIMER T0 (IDLE TIMER)

The device supports applications that require maintaining real time and low power with the IDLE mode. This IDLE mode support is furnished by the IDLE timer T0, which is a 16-bit timer. The Timer T0 runs continuously at the fixed rate of the instruction cycle clock, t_C. The user cannot read or write to the IDLE Timer T0, which is a count down timer.

The Timer T0 supports the following functions:

- Exit out of the Idle Mode (See Idle Mode description)
- WATCHDOG logic (See WATCHDOG description)
- Start up delay out of the HALT mode

The IDLE Timer T0 can generate an interrupt when the thirteenth bit toggles. This toggle is latched into the T0PND pending flag, and will occur every 4 ms at the maximum clock frequency (t_C = 1 μs). A control flag T0EN allows the interrupt from the thirteenth bit of Timer T0 to be enabled or disabled. Setting T0EN will enable the interrupt, while resetting it will disable the interrupt.

TIMER T1, TIMER T2 AND TIMER T3

The device has a set of three powerful timer/counter blocks, T1, T2 and T3. The associated features and functioning of a timer block are described by referring to the timer block Tx. Since the three timer blocks, T1, T2 and T3 are identical, all comments are equally applicable to any of the three timer blocks.

Each timer block consists of a 16-bit timer, Tx, and two supporting 16-bit autoreload/capture registers, RxA and RxB. Each timer block has two pins associated with it, TxA and TxB. The pin TxA supports I/O required by the timer block, while the pin TxB is an input to the timer block. The powerful and flexible timer block allows the device to easily perform all timer functions with minimal software overhead. The timer block has three operating modes: Processor Independent PWM mode, External Event Counter mode, and Input Capture mode.

The control bits TxC3, TxC2, and TxC1 allow selection of the different modes of operation.

Mode 1. Processor Independent PWM Mode

As the name suggests, this mode allows the device to generate a PWM signal with very minimal user intervention. The user only has to define the parameters of the PWM signal (ON time and OFF time). Once begun, the timer block will continuously generate the PWM signal completely independent of the microcontroller. The user software services the timer block only when the PWM parameters require updating.

In this mode the timer Tx counts down at a fixed rate of t_C. Upon every underflow the timer is alternately reloaded with the contents of supporting registers, RxA and RxB. The very first underflow of the timer causes the timer to reload from the register RxA. Subsequent underflows cause the timer to be reloaded from the registers alternately beginning with the register RxB.

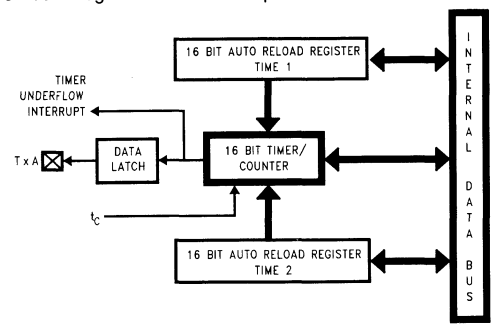
The Tx Timer control bits, TxC3, TxC2 and TxC1 set up the timer for PWM mode operation.

Figure 8 shows a block diagram of the timer in PWM mode.

The underflows can be programmed to toggle the TxA output pin. The underflows can also be programmed to generate interrupts.

Underflows from the timer are alternately latched into two pending flags, TxPNDA and TxPNDB. The user must reset these pending flags under software control. Two control enable flags, TxENA and TxENB, allow the interrupts from the timer underflow to be enabled or disabled. Setting the timer enable flag TxENA will cause an interrupt when a timer underflow causes the RxA register to be reloaded into the timer. Setting the timer enable flag TxENB will cause an interrupt when a timer underflow causes the RxB register to be reloaded into the timer. Resetting the timer enable flags will disable the associated interrupts.

Either or both of the timer underflow interrupts may be enabled. This gives the user the flexibility of interrupting once per PWM period on either the rising or falling edge of the PWM output. Alternatively, the user may choose to interrupt on both edges of the PWM output.



TL/DD/12858–10

FIGURE 8. Timer in PWM Mode

Mode 2. External Event Counter Mode

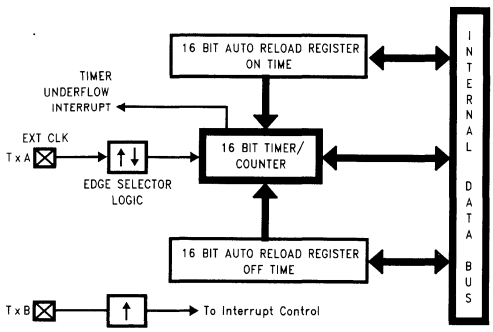
This mode is quite similar to the processor independent PWM mode described above. The main difference is that the timer, Tx, is clocked by the input signal from the TxA pin. The Tx timer control bits, TxC3, TxC2 and TxC1 allow the timer to be clocked either on a positive or negative edge from the TxA pin. Underflows from the timer are latched into the TxPNDA pending flag. Setting the TxENA control flag will cause an interrupt when the timer underflows.

In this mode the input pin TxB can be used as an independent positive edge sensitive interrupt input if the TxENB control flag is set. The occurrence of a positive edge on the TxB input pin is latched into the TxPNDB flag.

Timers (Continued)

Figure 9 shows a block diagram of the timer in External Event Counter mode.

Note: The PWM output is not available in this mode since the TxA pin is being used as the counter input clock.



TL/DD/12858–11

FIGURE 9. Timer in External Event Counter Mode

Mode 3. Input Capture Mode

The device can precisely measure external frequencies or time external events by placing the timer block, Tx, in the input capture mode.

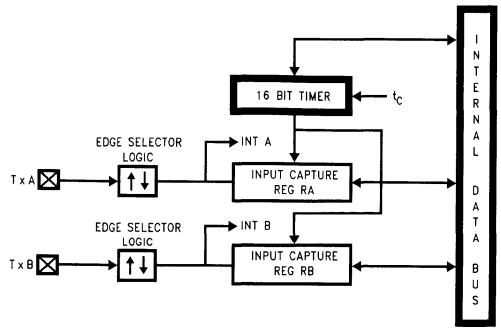
In this mode, the timer Tx is constantly running at the fixed t_C rate. The two registers, RxA and RxB, act as capture registers. Each register acts in conjunction with a pin. The register RxA acts in conjunction with the TxA pin and the register RxB acts in conjunction with the TxB pin.

The timer value gets copied over into the register when a trigger event occurs on its corresponding pin. Control bits, TxC3, TxC2 and TxC1, allow the trigger events to be specified either as a positive or a negative edge. The trigger condition for each input pin can be specified independently.

The trigger conditions can also be programmed to generate interrupts. The occurrence of the specified trigger condition on the TxA and TxB pins will be respectively latched into the pending flags, TxPNDA and TxPNDB. The control flag TxENA allows the interrupt on TxA to be either enabled or disabled. Setting the TxENA flag enables interrupts to be generated when the selected trigger condition occurs on the TxA pin. Similarly, the flag TxENB controls the interrupts from the TxB pin.

Underflows from the timer can also be programmed to generate interrupts. Underflows are latched into the timer TxC0 pending flag (the TxC0 control bit serves as the timer underflow interrupt pending flag in the Input Capture mode). Consequently, the TxC0 control bit should be reset when entering the Input Capture mode. The timer underflow interrupt is enabled with the TxENA control flag. When a TxA interrupt occurs in the Input Capture mode, the user must check both the TxPNDA and TxC0 pending flags in order to determine whether a TxA input capture or a timer underflow (or both) caused the interrupt.

Figure 10 shows a block diagram of the timer in Input Capture mode.



TL/DD/12858–12

FIGURE 10. Timer in Input Capture Mode

TIMER CONTROL FLAGS

The timers T1, T2 and T3 have indentical control structures. The control bits and their functions are summarized below.

TxC0	Timer Start/Stop control in Modes 1 and 2 (Processor Independent PWM and External Event Counter), where 1 = Start, 0 = Stop Timer Underflow Interrupt Pending Flag in Mode 3 (Input Capture)
TxPNDA	Timer Interrupt Pending Flag
TxPNDB	Timer Interrupt Pending Flag
TxENA	Timer Interrupt Enable Flag
TxENB	Timer Interrupt Enable Flag 1 = Timer Interrupt Enabled 0 = Timer Interrupt Disabled
TxC3	Timer mode control
TxC2	Timer mode control
TxC1	Timer mode control

Timers (Continued)

The timer mode control bits (TxC3, TxC2 and TxC1) are detailed below:

TxC3	TxC2	TxC1	Timer Mode	Interrupt A Source	Interrupt B Source	Timer Counts On
0	0	0	MODE 2 (External Event Counter)	Timer Underflow	Pos. TxB Edge	TxA Pos. Edge
0	0	1	MODE 2 (External Event Counter)	Timer Underflow	Pos. TxB Edge	TxA Neg. Edge
1	0	1	MODE 1 (PWM) TxA Toggle	Autoreload RA	Autoreload RB	t_C
1	0	0	MODE 1 (PWM) No TxA Toggle	Autoreload RA	Autoreload RB	t_C
0	1	0	MODE 3 (Capture) Captures: TxA Pos. Edge TxB Pos. Edge	Pos. TxA Edge or Timer Underflow	Pos. TxB Edge	t_C
1	1	0	MODE 3 (Capture) Captures: TxA Pos. Edge TxB Neg. Edge	Pos. TxA Edge or Timer Underflow	Neg. TxB Edge	t_C
0	1	1	MODE 3 (Capture) Captures: TxA Neg. Edge TxB Pos. Edge	Neg. TxA Edge or Timer Underflow	Pos. TxB Edge	t_C
1	1	1	MODE 3 (Capture) Captures: TxA Neg. Edge TxB Neg. Edge	Neg. TxA Edge or Timer Underflow	Neg. TxB Edge	t_C

Power Save Modes

The device offers the user two power save modes of operation: HALT and IDLE. In the HALT mode, all microcontroller activities are stopped. In the IDLE mode, the on-board oscillator circuitry the WATCHDOG logic, the Clock Monitor and timer T0 are active but all other microcontroller activities are stopped. In either mode, all on-board RAM, registers, I/O states, and timers (with the exception of T0) are unaltered.

HALT MODE

The device can be placed in the HALT mode by writing a "1" to the HALT flag (G7 data bit). All microcontroller activities, including the clock and timers, are stopped. The WATCHDOG logic is disabled during the HALT mode. However, the clock monitor circuitry if enabled remains active and will cause the WATCHDOG output pin (WDOUT) to go low. If the HALT mode is used and the user does not want to activate the WDOUT pin, the Clock Monitor should be disabled after the device comes out of reset (resetting the Clock Monitor control bit with the first write to the WDSVR register). In the HALT mode, the power requirements of the device are minimal and the applied voltage (V_{CC}) may be decreased to V_r (V_r = 2.0V) without altering the state of the machine.

The device supports three different ways of exiting the HALT mode. The first method of exiting the HALT mode is with the Multi-Input Wakeup feature on the L port. The second method is with a low to high transition on the CKO (G7) pin. This method precludes the use of the crystal clock configuration (since CKO becomes a dedicated output), and so may be used with an RC clock configuration. The third method of exiting the HALT mode is by pulling the $\overline{\text{RESET}}$ pin low.

Since a crystal or ceramic resonator may be selected as the oscillator, the Wakeup signal is not allowed to start the chip running immediately since crystal oscillators and ceramic resonators have a delayed start up time to reach full amplitude and frequency stability. The IDLE timer is used to generate a fixed delay to ensure that the oscillator has indeed stabilized before allowing instruction execution. In this case, upon detecting a valid Wakeup signal, only the oscillator circuitry is enabled. The IDLE timer is loaded with a value of 256 and is clocked with the t_C instruction cycle clock. The t_C clock is derived by dividing the oscillator clock down by a factor of 10. The Schmitt trigger following the CKI inverter on the chip ensures that the IDLE timer is clocked only when the oscillator has a sufficiently large amplitude to meet the Schmitt trigger specifications. This Schmitt trigger is not part of the oscillator closed loop. The startup timeout from the IDLE timer enables the clock signals to be routed to the rest of the chip.

If an RC clock option is being used, the fixed delay is introduced optionally. A control bit, CLKDLY, mapped as configuration bit G7, controls whether the delay is to be introduced or not. The delay is included if CLKDLY is set, and excluded if CLKDLY is reset. The CLKDLY bit is cleared on reset.

Power Save Modes (Continued)

The device has two mask options associated with the HALT mode. The first mask option enables the HALT mode feature, while the second mask option disables the HALT mode. With the HALT mode enable mask option, the device will enter and exit the HALT mode as described above. With the HALT disable mask option, the device cannot be placed in the HALT mode (writing a "1" to the HALT flag will have no effect, the HALT flag will remain "0").

IDLE MODE

The device is placed in the IDLE mode by writing a "1" to the IDLE flag (G6 data bit). In this mode, all activities, except the associated on-board oscillator circuitry and the IDLE Timer T0, are stopped. The power supply requirements of the micro-controller in this mode of operation are typically around 30% of normal power requirement of the microcontroller.

As with the HALT mode, the device can be returned to normal operation with a reset, or with a Multi-Input Wakeup from the L Port. Alternately, the microcontroller resumes normal operation from the IDLE mode when the thirteenth bit (representing 4.096 ms at internal clock frequency of 1 MHz, t_c = 1 μs) of the IDLE Timer toggles.

This toggle condition of the thirteenth bit of the IDLE Timer T0 is latched into the T0PND pending flag.

The user has the option of being interrupted with a transition on the thirteenth bit of the IDLE Timer T0. The interrupt can be enabled or disabled via the T0EN control bit. Setting the T0EN flag enables the interrupt and vice versa.

The user can enter the IDLE mode with the Timer T0 interrupt enabled. In this case, when the T0PND bit gets set, the device will first execute the Timer T0 interrupt service routine and then return to the instruction following the "Enter Idle Mode" instruction.

Alternatively, the user can enter the IDLE mode with the IDLE Timer T0 interrupt disabled. In this case, the device will resume normal operation with the instruction immediately following the "Enter IDLE Mode" instruction.

Note: It is necessary to program two NOP instructions following both the set HALT mode and set IDLE mode instructions. These NOP instructions are necessary to allow clock resynchronization following the HALT or IDLE modes.

Multi-Input Wakeup

The Multi-Input Wakeup feature is ued to return (wakeup) the device from either the HALT or IDLE modes. Alternately Multi-Input Wakeup/Interrupt feature may also be used to generate up to 8 edge selectable external interrupts.

Figure 11 shows the Multi-Input Wakeup logic.

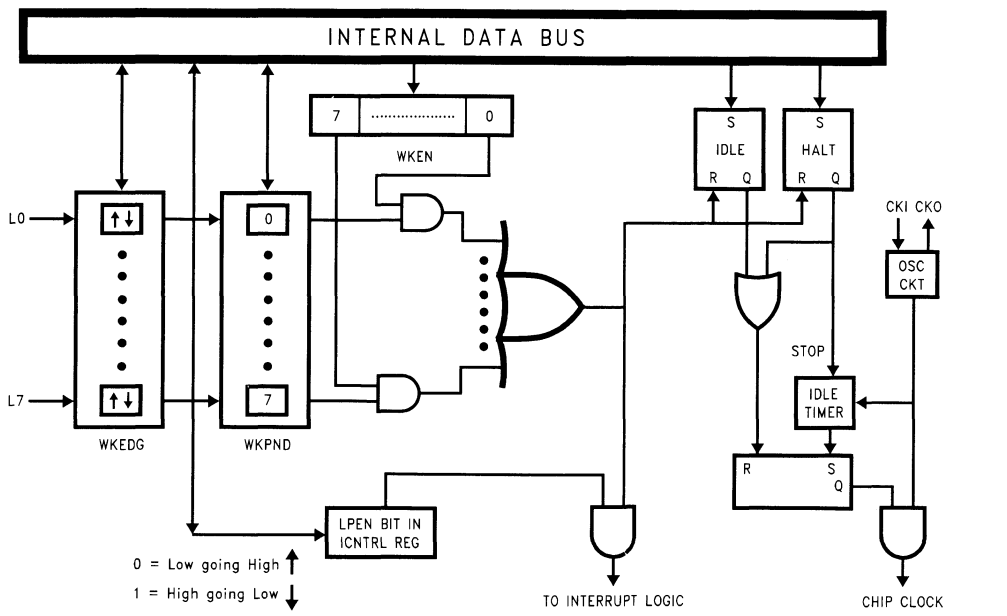


FIGURE 11. Multi-Input Wake Up Logic

Multi-Input Wakeup (Continued)

The Multi-Input Wakeup feature utilizes the L Port. The user selects which particular L port bit (or combination of L Port bits) will cause the device to exit the HALT or IDLE modes. The selection is done through the Reg: WKEN. The Reg: WKEN is an 8-bit read/write register, which contains a control bit for every L port bit. Setting a particular WKEN bit enables a Wakeup from the associated L port pin.

The user can select whether the trigger condition on the selected L Port pin is going to be either a positive edge (low to high transition) or a negative edge (high to low transition). This selection is made via the Reg: WKEDG, which is an 8-bit control register with a bit assigned to each L Port pin. Setting the control bit will select the trigger condition to be a negative edge on that particular L Port pin. Resetting the bit selects the trigger condition to be a positive edge. Changing an edge select entails several steps in order to avoid a pseudo Wakeup condition as a result of the edge change. First, the associated WKEN bit should be reset, followed by the edge select change in WKEDG. Next, the associated WKPND bit should be cleared, followed by the associated WKEN bit being re-enabled.

An example may serve to clarify this procedure. Suppose we wish to change the edge select from positive (low going high) to negative (high going low) for L Port bit 5, where bit 5 has previously been enabled for an input interrupt. The program would be as follows:

```
RBIT  5, WKEN      ; Disable Port bit 5 for
                   ; Wakeup
SBIT  5, WKEDG     ; Select neg going edge
                   ; sensitivity
RBIT  5, WKPND     ; Clear pending bit
SBIT  5, WKEN      ; Re-enable the bit for
                   ; Wakeup
```

If the L port bits have been used as outputs and then changed to inputs with Multi-Input Wakeup/Interrupt, a safety procedure should also be followed to avoid inherited pseudo wakeup conditions. After the selected L port bits have been changed from output to input but before the associated WKEN bits are enabled, the associated edge select bits in WKEDG should be set or reset for the desired edge selects, followed by the associated WKPND bits being cleared.

This same procedure should be used following reset, since the L port inputs are left floating as a result of reset.

The occurrence of the selected trigger condition for Multi-Input Wakeup is latched into a pending register called WKPND. The respective bits of the WKPND register will be set on the occurrence of the selected trigger edge on the corresponding Port L pin. The user has the responsibility of clearing these pending flags. Since WKPND is a pending register for the occurrence of selected wakeup conditions, the device will not enter the HALT mode if any Wakeup bit is both enabled and pending. Consequently, the user has the responsibility of clearing the pending flags before attempting to enter the HALT mode.

WKEN, WKPND and WKEDG are all read/write registers, and are cleared at reset.

PORT L INTERRUPTS

Port L provides the user with an additional eight fully selectable, edge sensitive interrupts which are all vectored into the same service subroutine.

The interrupt from Port L shares logic with the wake up circuitry. The register WKEN allows interrupts from Port L to be individually enabled or disabled. The register WKEDG specifies the trigger condition to be either a positive or a negative edge. Finally, the register WKPND latches in the pending trigger conditions.

The GIE (Global Interrupt Enable) bit enables the interrupt function.

A control flag, LPEN, functions as a global interrupt enable for Port L interrupts. Setting the LPEN flag will enable interrupts and vice versa. A separate global pending flag is not needed since the register WKPND is adequate.

Since Port L is also used for waking the device out of the HALT or IDLE modes, the user can elect to exit the HALT or IDLE modes either with or without the interrupt enabled. If he elects to disable the interrupt, then the device will restart execution from the instruction immediately following the instruction that placed the microcontroller in the HALT or IDLE modes. In the other case, the device will first execute the interrupt service routine and then revert to normal operation. (See HALT MODE for clock option wakeup information.)

UART

The device contains a full-duplex software programmable UART. The UART *(Figure 12)* consists of a transmit shift register, a receive shift register and seven addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR), a UART interrupt and clock source register (ENUI), a prescaler select register (PSR) and baud (BAUD) register. The ENU register contains flags for transmit and receive functions; this register also determines the length of the data frame (7, 8 or 9 bits), the value of the ninth bit in transmission, and parity selection bits. The ENUR register flags framing, data overrun and parity errors while the UART is receiving.

Other functions of the ENUR register include saving the ninth bit received in the data frame, enabling or disabling the UART's attention mode of operation and providing additional receiver/transmitter status information via RCVG and XMTG bits. The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits and enabling or disabling transmit and receive interrupts. A control flag in this register can also select the UART mode of operation: asynchronous or synchronous.

FIGURE 12. UART Block Diagram

UART (Continued)

UART CONTROL AND STATUS REGISTERS

The operation of the UART is programmed through three registers: ENU, ENUR and ENUI. The function of the individual bits in these registers is as follows:

ENU-UART Control and Status Register (Address at 0BA)

PEN	PSEL1	XBIT9/ PSEL0	CHL1	CHL0	ERR	RBFL	TBMT
0RW	0RW	0RW	0RW	0RW	0R	0R	1R

Bit 7 Bit 0

ENUR-UART Receive Control and Status Register (Address at 0BB)

DOE	FE	PE	SPARE	RBIT9	ATTN	XMTG	RCVG
0RD	0RD	0RD	0RW*	0R	0RW	0R	0R

Bit 7 Bit 0

ENUI-UART Interrupt and Clock Source Register (Address at 0BC)

STP2	STP78	ETDX	SSEL	XRCLK	XTCLK	ERI	ETI
0RW	0RW	0RW	0RW	0RW	0RW	0RW	0RW

Bit 7 Bit 0

*Bit is not used.

0 Bit is cleared on reset.

1 Bit is set to one on reset.

R Bit is read-only; it cannot be written by software.

RW Bit is read/write.

D Bit is cleared on read; when read by software as a one, it is cleared automatically. Writing to the bit does not affect its state.

DESCRIPTION OF UART REGISTER BITS

ENU—UART CONTROL AND STATUS REGISTER

TBMT: This bit is set when the UART transfers a byte of data from the TBUF register into the TSFT register for transmission. It is automatically reset when software writes into the TBUF register.

RBFL: This bit is set when the UART has received a complete character and has copied it into the RBUF register. It is automatically reset when software reads the character from RBUF.

ERR: This bit is a global UART error flag which gets set if any or a combination of the errors (DOE, FE, PE) occur.

CHL1, CHL0: These bits select the character frame format. Parity is not included and is generated/verified by hardware.

CHL1 = 0, CHL0 = 0 The frame contains eight data bits.
CHL1 = 0, CHL0 = 1 The frame contains seven data bits.
CHL1 = 1, CHL0 = 0 The frame contains nine data bits.
CHL1 = 1, CHL0 = 1 Loopback Mode selected. Transmitter output internally looped back to receiver input. Nine bit framing format is used.

XBIT9/PSEL0: Programs the ninth bit for transmission when the UART is operating with nine data bits per frame. For seven or eight data bits per frame, this bit in conjunction with PSEL1 selects parity.

PSEL1, PSEL0: Parity select bits.

PSEL1 = 0, PSEL0 = 0 Odd Parity (if Parity enabled)
PSEL1 = 0, PSEL0 = 1 Odd Parity (if Parity enabled)
PSEL1 = 1, PSEL0 = 0 Mark(1) (if Parity enabled)
PSEL1 = 1, PSEL0 = 1 Space(0) (if Parity enabled)

PEN: This bit enables/disables Parity (7- and 8-bit modes only).

PEN = 0 Parity disabled.
PEN = 1 Parity enabled.

ENUR—UART RECEIVE CONTROL AND STATUS REGISTER

RCVG: This bit is set high whenever a framing error occurs and goes low when RDX goes high.

XMTG: This bit is set to indicate that the UART is transmitting. It gets reset at the end of the last frame (end of last Stop bit).

ATTN: ATTENTION Mode is enabled while this bit is set. This bit is cleared automatically on receiving a character with data bit nine set.

RBIT9: Contains the ninth data bit received when the UART is operating with nine data bits per frame.

SPARE: Reserved for future use.

PE: Flags a Parity Error.

PE = 0 Indicates no Parity Error has been detected since the last time the ENUR register was read.
PE = 1 Indicates the occurrence of a Parity Error.

FE: Flags a Framing Error.

FE = 0 Indicates no Framing Error has been detected since the last time the ENUR register was read.
FE = 1 Indicates the occurrence of a Framing Error.

DOE: Flags a Data Overrun Error.

DOE = 0 Indicates no Data Overrun Error has been detected since the last time the ENUR register was read.
DOE = 1 Indicates the occurrence of a Data Overrun Error.

ENUI—UART INTERRUPT AND CLOCK SOURCE REGISTER

ETI: This bit enables/disables interrupt from the transmitter section.

ETI = 0 Interrupt from the transmitter is disabled.
ETI = 1 Interrupt from the transmitter is enabled.

ERI: This bit enables/disables interrupt from the receiver section.

ERI = 0 Interrupt from the receiver is disabled.
ERI = 1 Interrupt from the receiver is enabled.

XTCLK: This bit selects the clock source for the transmitter section.

XTCLK = 0 The clock source is selected through the PSR and BAUD registers.
XTCLK = 1 Signal on CKX (L1) pin is used as the clock.

XRCLK: This bit selects the clock source for the receiver section.

XRCLK = 0 The clock source is selected through the PSR and BAUD registers.
XRCLK = 1 Signal on CKX (L1) pin is used as the clock.

SSEL: UART mode select.

SSEL = 0 Asynchronous Mode.
SSEL = 1 Synchronous Mode.

UART (Continued)

ETDX: TDX (UART Transmit Pin) is the alternate function assigned to Port L pin L2; it is selected by setting ETDX bit. To simulate line break generation, software should reset ETDX bit and output logic zero to TDX pin through Port L data and configuration registers.

STP78: This bit is set to program the last Stop bit to be 7/8th of a bit in length.

STP2: This bit programs the number of Stop bits to be transmitted.

STP2 = 0 One Stop bit transmitted.
STP2 = 1 Two Stop bits transmitted.

Associated I/O Pins

Data is transmitted on the TDX pin and received on the RDX pin. TDX is the alternate function assigned to Port L pin L2; it is selected by setting ETDX (in the ENUI register) to one. RDX is an inherent function of Port L pin L3, requiring no setup.

The baud rate clock for the UART can be generated on-chip, or can be taken from an external source. Port L pin L1 (CKX) is the external clock I/O pin. The CKX pin can be either an input or an output, as determined by Port L Configuration and Data registers (Bit 1). As an input, it accepts a clock signal which may be selected to drive the transmitter and/or receiver. As an output, it presents the internal Baud Rate Generator output.

UART Operation

The UART has two modes of operation: asynchronous mode and synchronous mode.

ASYNCHRONOUS MODE

This mode is selected by resetting the SSEL (in the ENUI register) bit to zero. The input frequency to the UART is 16 times the baud rate.

The TSFT and TBUF registers double-buffer data for transmission. While TSFT is shifting out the current character on the TDX pin, the TBUF register may be loaded by software with the next byte to be transmitted. When TSFT finishes transmitting the current character the contents of TBUF are transferred to the TSFT register and the Transmit Buffer Empty Flag (TBMT in the ENU register) is set. The TBMT flag is automatically reset by the UART when software loads a new character into the TBUF register. There is also the XMTG bit which is set to indicate that the UART is transmitting. This bit gets reset at the end of the last frame (end of last Stop bit). TBUF is a read/write register.

The RSFT and RBUF registers double-buffer data being received. The UART receiver continually monitors the signal on the RDX pin for a low level to detect the beginning of a Start bit. Upon sensing this low level, it waits for half a bit time and samples again. If the RDX pin is still low, the receiver considers this to be a valid Start bit, and the remaining bits in the character frame are each sampled a single time, at the mid-bit position. Serial data input on the RDX pin is shifted into the RSFT register. Upon receiving the complete character, the contents of the RSFT register are copied into the RBUF register and the Received Buffer Full Flag (RBFL) is set. RBFL is automatically reset when software reads the character from the RBUF register. RBUF is a read only register. There is also the RCVG bit which is set high when a framing error occurs and goes low once RDX goes high. TBMT, XMTG, RBFL and RCVG are read only bits.

SYNCHRONOUS MODE

In this mode data is transferred synchronously with the clock. Data is transmitted on the rising edge and received on the falling edge of the synchronous clock.

This mode is selected by setting SSEL bit in the ENUI register. The input frequency to the UART is the same as the baud rate.

When an external clock input is selected at the CKX pin, data transmit and receive are performed synchronously with this clock through TDX/RDX pins.

If data transmit and receive are selected with the CKX pin as clock output, the device generates the synchronous clock output at the CKX pin. The internal baud rate generator is used to produce the synchronous clock. Data transmit and receive are performed synchronously with this clock.

FRAMING FORMATS

The UART supports several serial framing formats *(Figure 13).* The format is selected using control bits in the ENU, ENUR and ENUI registers.

The first format (1, 1a, 1b, 1c) for data transmission (CHL0 = 1, CHL1 = 0) consists of Start bit, seven Data bits (excluding parity) and 7/8, one or two Stop bits. In applications using parity, the parity bit is generated and verified by hardware.

The second format (CHL0 = 0, CHL1 = 0) consists of one Start bit, eight Data bits (excluding parity) and 7/8, one or two Stop bits. Parity bit is generated and verified by hardware.

The third format for transmission (CHL0 = 0, CHL1 = 1) consists of one Start bit, nine Data bits and 7/8, one or two Stop bits. This format also supports the UART "ATTENTION" feature. When operating in this format, all eight bits of TBUF and RBUF are used for data. The ninth data bit is transmitted and received using two bits in the ENU and ENUR registers, called XBIT9 and RBIT9. RBIT9 is a read only bit. Parity is not generated or verified in this mode.

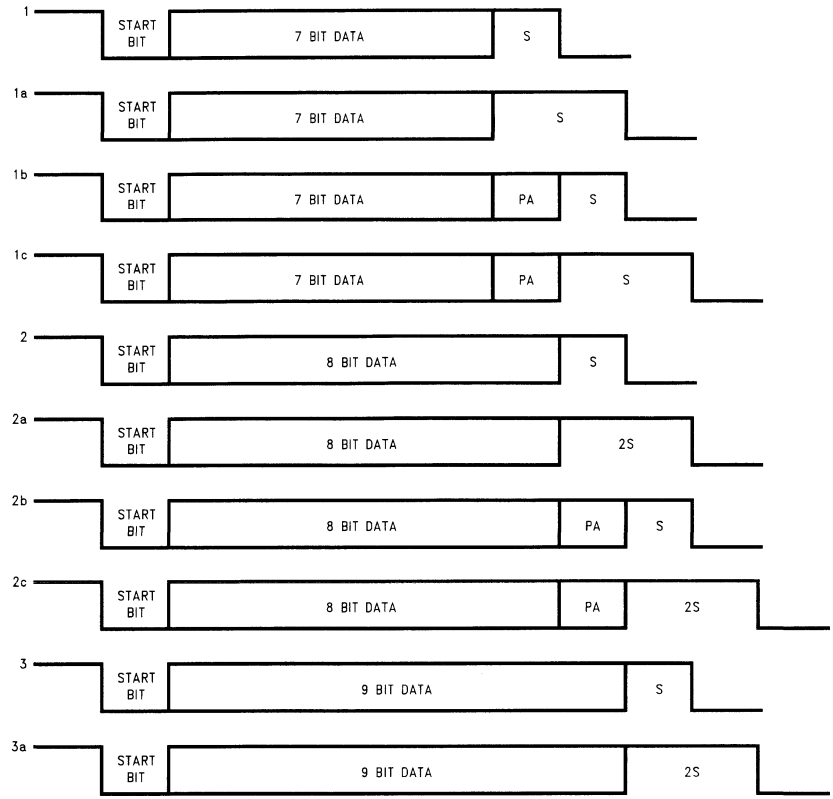
For any of the above framing formats, the last Stop bit can be programmed to be 7/8th of a bit in length. If two Stop bits are selected and the 7/8th bit is set (selected), the second Stop bit will be 7/8th of a bit in length.

The parity is enabled/disabled by PEN bit located in the ENU register. Parity is selected for 7- and 8-bit modes only. If parity is enabled (PEN = 1), the parity selection is then performed by PSEL0 and PSEL1 bits located in the ENU register.

Note that the XBIT9/PSEL0 bit located in the ENU register serves two mutually exclusive functions. This bit programs the ninth bit for transmission when the UART is operating with nine data bits per frame. There is no parity selection in this framing format. For other framing formats XBIT9 is not needed and the bit is PSEL0 used in conjunction with PSEL1 to select parity.

The frame formats for the receiver differ from the transmitter in the number of Stop bits required. The receiver only requires one Stop bit in a frame, regardless of the setting of the Stop bit selection bits in the control register. Note that an implicit assumption is made for full duplex UART operation that the framing formats are the same for the transmitter and receiver.

UART Operation (Continued)



TL/DD/12858–15

FIGURE 13. Framing Formats

UART INTERRUPTS

The UART is capable of generating interrupts. Interrupts are generated on Receive Buffer Full and Transmit Buffer Empty. Both interrupts have individual interrupt vectors. Two bytes of program memory space are reserved for each interrupt vector. The two vectors are located at addresses 0xEC to 0xEF Hex in the program memory space. The interrupts can be individually enabled or disabled using Enable Transmit Interrupt (ETI) and Enable Receive Interrupt (ERI) bits in the ENUI register.

The interrupt from the Transmitter is set pending, and remains pending, as long as both the TBMT and ETI bits are set. To remove this interrupt, software must either clear the ETI bit or write to the TBUF register (thus clearing the TBMT bit).

The interrupt from the receiver is set pending, and remains pending, as long as both the RBFL and ERI bits are set. To remove this interrupt, software must either clear the ERI bit or read from the RBUF register (thus clearing the RBFL bit).

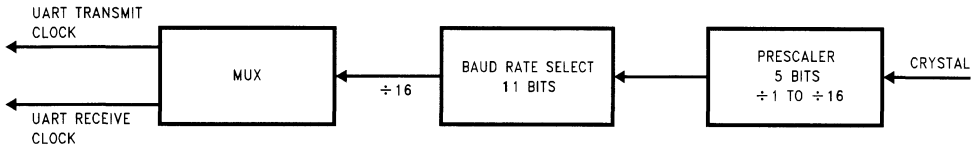
Baud Clock Generation

The clock inputs to the transmitter and receiver sections of the UART can be individually selected to come either from an external source at the CKX pin (port L, pin L1) or from a source selected in the PSR and BAUD registers. Internally, the basic baud clock is created from the oscillator frequency through a two-stage divider chain consisting of a 1–16 (increments of 0.5) prescaler and an 11-bit binary counter. *(Figure 14).* The divide factors are specified through two read/write registers shown in *Figure 15.* Note that the 11-bit Baud Rate Divisor spills over into the Prescaler Select Register (PSR). PSR is cleared upon reset.

As shown in Table IV, a Prescaler Factor of 0 corresponds to NO CLOCK. This condition is the UART power down mode where the UART clock is turned off for power saving purpose. The user must also turn the UART clock off when a different baud rate is chosen.

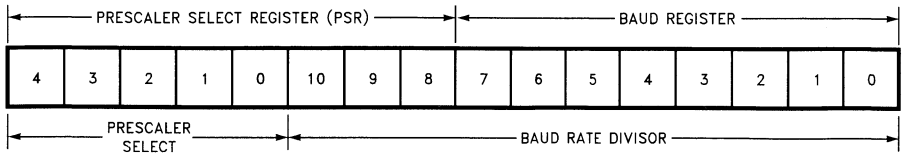
The correspondences between the 5-bit Prescaler Select and Prescaler factors are shown in Table IV. There are many ways to calculate the two divisor factors, but one particularly effective method would be to achieve a 1.8432 MHz frequency coming out of the first stage. The 1.8432 MHz prescaler output is then used to drive the software programmable baud rate counter to create a 16x clock for the following baud rates: 110, 134.5, 150, 300, 600, 1200, 1800, 2400, 3600, 4800, 7200, 9600, 19200 and 38400 (Table III). Other baud rates may be created by using appropriate divisors. The 16x clock is then divided by 16 to provide the rate for the serial shift registers of the transmitter and receiver.

Baud Clock Generation (Continued)



TL/DD/12858–16

FIGURE 14. UART BAUD Clock Generation



TL/DD/12858–17

FIGURE 15. UART BAUD Clock Divisor Registers

Baud Clock Generation (Continued)

TABLE III. Baud Rate Divisors (1.8432 MHz Prescaler Output)

Baud Rate	Baud Rate Divisor − 1 (N-1)
110 (110.03)	1046
134.5 (134.58)	855
150	767
300	383
600	191
1200	95
1800	63
2400	47
3600	31
4800	23
7200	15
9600	11
19200	5
38400	2

Note: The entries in Table IV assume a prescaler output of 1.8432 MHz. In the asynchronous mode the baud rate could be as high as 625k.

TABLE IV. Prescaler Factors

Prescaler Select	Prescaler Factor
00000	NO CLOCK
00001	1
00010	1.5
00011	2
00100	2.5
00101	3
00110	3.5
00111	4
01000	4.5
01001	5
01010	5.5
01011	6
01100	6.5
01101	7
01110	7.5
01111	8
10000	8.5
10001	9
10010	9.5
10011	10
10100	10.5
10101	11
10110	11.5
10111	12
11000	12.5
11001	13
11010	13.5
11011	14
11100	14.5
11101	15
11110	15.5
11111	16

As an example, considering Asynchronous Mode and a CKI clock of 4.608 MHz, the prescaler factor selected is:

$$4.608/1.8432 = 2.5$$

The 2.5 entry is available in Table IV. The 1.8432 MHz prescaler output is then used with proper Baud Rate Divisor (Table IV) to obtain different baud rates. For a baud rate of 19200 e.g., the entry in Table IV is 5.

$$N - 1 = 5 \text{ (N} - 1 \text{ is the value from Table III)}$$

$$N = 6 \text{ (N is the Baud Rate Divisor)}$$

$$\text{Baud Rate} = 1.8432 \text{ MHz}/(16 \times 6) = 19200$$

The divide by 16 is performed because in the asynchronous mode, the input frequency to the UART is 16 times the baud rate. The equation to calculate baud rates is given below.

The actual Baud Rate may be found from:

$$BR = Fc/(16 \times N \times P)$$

Baud Clock Generation (Continued)

Where:

BR is the Baud Rate

Fc is the CKI frequency

N is the Baud Rate Divisor (Table III).

P is the Prescaler Divide Factor selected by the value in the Prescaler Select Register (Table IV)

Note: In the Synchronous Mode, the divisor 16 is replaced by two.

Example:

Asynchronous Mode:

Crystal Frequency = 5 MHz

Desired baud rate = 9600

Using the above equation N × P can be calculated first.

$$N \times P = (5 \times 106)/(16 \times 9600) = 32.552$$

Now 32.552 is divided by each Prescaler Factor (Table IV) to obtain a value closest to an integer. This factor happens to be 6.5 (P = 6.5).

$$N = 32.552/6.5 = 5.008 \ (N = 5)$$

The programmed value (from Table III) should be 4 (N − 1).

Using the above values calculated for N and P:

$$BR = (5 \times 106)/(16 \times 5 \times 6.5) = 9615.384$$

$$\% \text{ error} = (9615.385 - 9600)/9600 = 0.16$$

Effect of HALT/IDLE

The UART logic is reinitialized when either the HALT or IDLE modes are entered. This reinitialization sets the TBMT flag and resets all read only bits in the UART control and status registers. Read/Write bits remain unchanged. The Transmit Buffer (TBUF) is not affected, but the Transmit Shift register (TSFT) bits are set to one. The receiver registers RBUF and RSFT are not affected.

The device will exit from the HALT/IDLE modes when the Start bit of a character is detected at the RDX (L3) pin. This feature is obtained by using the Multi-Input Wakeup scheme provided on the device.

Before entering the HALT or IDLE modes the user program must select the Wakeup source to be on the RDX pin. This selection is done by setting bit 3 of WKEN (Wakeup Enable) register. The Wakeup trigger condition is then selected to be high to low transition. This is done via the WKEDG register (Bit 3 is one.)

If the device is halted and crystal oscillator is used, the Wakeup signal will not start the chip running immediately because of the finite start up time requirement of the crystal oscillator. The idle timer (T0) generates a fixed (256 t_C) delay to ensure that the oscillator has indeed stabilized before allowing the device to execute code. The user has to consider this delay when data transfer is expected immediately after exiting the HALT mode.

Diagnostic

Bits CHARL0 and CHARL1 in the ENU register provide a loopback feature for diagnostic testing of the UART. When these bits are set to one, the following occur: The receiver input pin (RDX) is internally connected to the transmitter output pin (TDX); the output of the Transmitter Shift Register is "looped back" into the Receive Shift Register input. In this mode, data that is transmitted is immediately received. This feature allows the processor to verify the transmit and receive data paths of the UART.

Note that the framing format for this mode is the nine bit format; one Start bit, nine data bits, and 7/8, one or two Stop bits. Parity is not generated or verified in this mode.

Attention Mode

The UART Receiver section supports an alternate mode of operation, referred to as ATTENTION Mode. This mode of operation is selected by the ATTN bit in the ENUR register. The data format for transmission must also be selected as having nine Data bits and either 7/8, one or two Stop bits.

The ATTENTION mode of operation is intended for use in networking the device with other processors. Typically in such environments the messages consists of device addresses, indicating which of several destinations should receive them, and the actual data. This Mode supports a scheme in which addresses are flagged by having the ninth bit of the data field set to a 1. If the ninth bit is reset to a zero the byte is a Data byte.

While in ATTENTION mode, the UART monitors the communication flow, but ignores all characters until an address character is received. Upon receiving an address character, the UART signals that the character is ready by setting the RBFL flag, which in turn interrupts the processor if UART Receiver interrupts are enabled. The ATTN bit is also cleared automatically at this point, so that data characters as well as address characters are recognized. Software examines the contents of the RBUF and responds by deciding either to accept the subsequent data stream (by leaving the ATTN bit reset) or to wait until the next address character is seen (by setting the ATTN bit again).

Operation of the UART Transmitter is not affected by selection of this Mode. The value of the ninth bit to be transmitted is programmed by setting XBIT9 appropriately. The value of the ninth bit received is obtained by reading RBIT9. Since this bit is located in ENUR register where the error flags reside, a bit operation on it will reset the error flags.

Comparators

The device contains two differential comparators, each with a pair of inputs (positive and negative) and an output. Ports I1-I3 and I4-I6 are used for the comparators. The following is the Port I assignment:

- I1 Comparator1 negative input
- I2 Comparator1 positive input
- I3 Comparator1 output
- I4 Comparator2 negative input
- I5 Comparator2 positive input
- I6 Comparator2 output

A Comparator Select Register (CMPSL) is used to enable the comparators, read the outputs of the comparators internally, and enable the outputs of the comparators to the pins. Two control bits (enable and output enable) and one result bit are associated with each comparator. The comparator result bits (CMP1RD and CMP2RD) are read only bits which will read as zero if the associated comparator is not enabled. The Comparator Select Register is cleared with reset, resulting in the comparators being disabled. The comparators should also be disabled before entering either the HALT or IDLE modes in order to save power. The configuration of the CMPSL register is as follows:

Comparators (Continued)

CMPSL REGISTER (ADDRESS X'00B7)

The CMPSL register contains the following bits:

CMP1EN Enable comparator 1

CMP1RD Comparator 1 result (this is a read only bit, which will read as 0 if the comparator is not enabled)

CMP10E Selects pin I3 as comparator 1 output provided that CMPIEN is set to enable the comparator

CMP2EN Enable comparator 2

CMP2RD Comparator 2 result (this is a read only bit, which will read as 0 if the comparator is not enabled)

CMP20E Selects pin I6 as comparator 2 output provided that CMP2EN is set to enable the comparator

Unused	CMP20E	CMP2RD	CMP2EN	CMP10E	CMP1RD	CMP1EN	Unused
Bit 7							Bit 0

Note that the two unused bits of CMPSL may be used as software flags.

Comparator outputs have the same spec as Ports L and G except that the rise and fall times are symmetrical.

Interrupts

The device supports a vectored interrupt scheme. It supports a total of fourteen interrupt sources. The following table lists all the possible interrupt sources, their arbitration ranking and the memory locations reserved for the interrupt vector for each source.

Two bytes of program memory space are reserved for each interrupt source. All interrupt sources except the software interrupt are maskable. Each of the maskable interrupts have an Enable bit and one or more Pending bits. A maskable interrupt is active if its associated enable and pending bits are set. If GIE = 1 and an interrupt is active, then the processor will be interrupted as soon as it is ready to start executing an instruction except if the above conditions happen during the Software Trap service routine. This exception is described in the Software Trap sub-section.

The interruption process is accomplished with the INTR instruction (opcode 00), which is jammed inside the Instruction Register and replaces the opcode about to be executed. The following steps are performed for every interrupt:

1. The GIE (Global Interrupt Enable) bit is reset.
2. The address of the instruction about to be executed is pushed into the stack.
3. The PC (Program Counter) branches to address 00FF.

This procedure takes 7 t_C cycles to execute.

Arbitration Ranking	Source	Description	Vector* Address Hi-Low Byte
(1) Highest	Software	INTR Instruction	0yFE–0yFF
(2)	Reserved		0yFC–0yFD
(3)	External	G0	0yFA–0yFB
(4)	Timer T0	Underflow	0yF8–0yF9
(5)	Timer T1	T1A/Underflow	0yF6–0yF7
(6)	Timer T1	T1B	0yF4–0yF5
(7)	MICROWIRE/PLUS	BUSY Low	0yF2–0yF3
(8)	Reserved		0yF0–0yF1
(9)	UART	Receive	0yEE–0yEF
(10)	UART	Transmit	0yEC–0yED
(11)	Timer T2	T2A/Underflow	0yEA–0yEB
(12)	Timer T2	T2B	0yE8–0yE9
(13)	Timer T3	T3A/Underflow	0yE6–0yE7
(14)	Timer T3	T3B	0yE4–0yE5
(15)	Port L/Wakeup	Port L Edge	0yE2–0yE3
(16) Lowest	Default VIS	Reserved	0yE0–0yE1

*y is a variable which represents the VIS block. VIS and the vector table must be located in the same 256-byte block except if VIS is located at the last address of a block. In this case, the table must be in the next block.

Interrupts (Continued)

At this time, since GIE = 0, other maskable interrupts are disabled. The user is now free to do whatever context switching is required by saving the context of the machine in the stack with PUSH instructions. The user would then program a VIS (Vector Interrupt Select) instruction in order to branch to the interrupt service routine of the highest priority interrupt enabled and pending at the time of the VIS. Note that this is not necessarily the interrupt that caused the branch to address location 00FF Hex prior to the context switching.

Thus, if an interrupt with a higher rank than the one which caused the interruption becomes active before the decision of which interrupt to service is made by the VIS, then the interrupt with the higher rank will override any lower ones and will be acknowledged. The lower priority interrupt(s) are still pending, however, and will cause another interrupt immediately following the completion of the interrupt service routine associated with the higher priority interrupt just serviced. This lower priority interrupt will occur immediately following the RETI (Return from Interrupt) instruction at the end of the interrupt service routine just completed.

Inside the interrupt service routine, the associated pending bit has to be cleared by software. The RETI (Return from Interrupt) instruction at the end of the interrupt service routine will set the GIE (Global Interrupt Enable) bit, allowing the processor to be interrupted again if another interrupt is active and pending.

The VIS instruction looks at all the active interrupts at the time it is executed and performs an indirect jump to the beginning of the service routine of the one with the highest rank.

The addresses of the different interrupt service routines, called vectors, are chosen by the user and stored in ROM in a table starting at 01E0 (assuming that VIS is located between 00FF and 01DF). The vectors are 15-bit wide and therefore occupy 2 ROM locations.

VIS and the vector table must be located in the same 256-byte block (0y00 to 0yFF) except if VIS is located at the last address of a block. In this case, the table must be in the next block. The vector table cannot be inserted in the first 256-byte block (y ≠ 0).

The vector of the maskable interrupt with the lowest rank is located at 0yE0 (Hi-Order byte) and 0yE1 (Lo-Order byte) and so forth in increasing rank number. The vector of the maskable interrupt with the highest rank is located at 0yFA (Hi-Order byte) and 0yFB (Lo-Order byte).

The Software Trap has the highest rank and its vector is located at 0yFE and 0yFF.

If, by accident, a VIS gets executed and no interrupt is active, then the PC (Program Counter) will branch to a vector located at 0yE0–0yE1.

WARNING

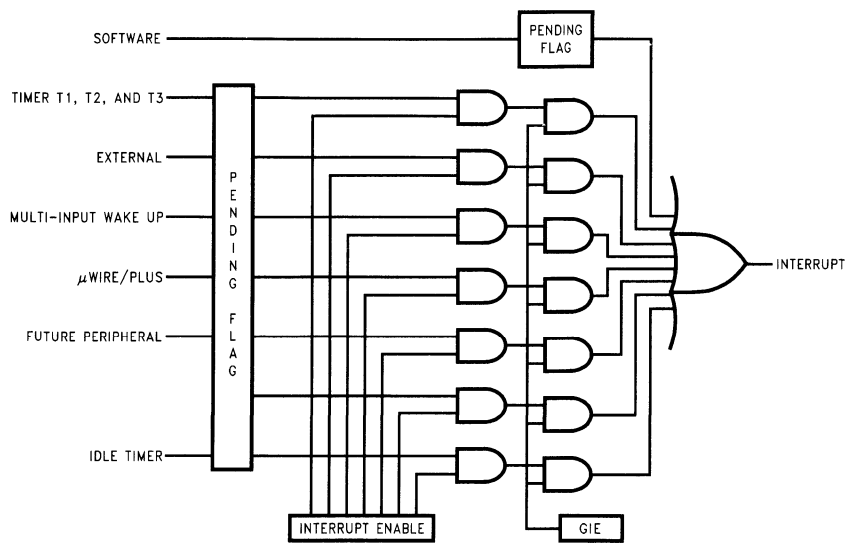
A Default VIS interrupt handler routine must be present. As a minimum, this handler should confirm that the GIE bit is cleared (this indicates that the interrupt sequence has been taken), take care of any required housekeeping, restore context and return. Some sort of Warm Restart procedure should be implemented. These events can occur without any error on the part of the system designer or programmer.

Note: There is always the possibility of an interrupt occurring during an instruction which is attempting to reset the GIE bit or any other interrupt enable bit. If this occurs when a single cycle instruction is being used to reset the interrupt enable bit, the interrupt enable bit will be reset but an interrupt may still occur. This is because interrupt processing is started at the same time as the interrupt bit is being reset. To avoid this scenario, the user should always use a two, three, or four cycle instruction to reset interrupt enable bits.

Figure 16 shows the Interrupt block diagram.

SOFTWARE TRAP

The Software Trap (ST) is a special kind of non-maskable interrupt which occurs when the INTR instruction (used to acknowledge interrupts) is fetched from ROM and placed inside the instruction register. This may happen when the PC is pointing beyond the available ROM address space or when the stack is over-popped.



TL/DD/12858–18

FIGURE 16. Interrupt Block Diagram

5

Interrupts (Continued)

When an ST occurs, the user can re-initialize the stack pointer and do a recovery procedure (similar to reset, but not necessarily containing all of the same initialization procedures) before restarting.

The occurrence of an ST is latched into the ST pending bit. The GIE bit is not affected and the ST pending bit **(not accessible by the user)** is used to inhibit other interrupts and to direct the program to the ST service routine with the VIS instruction. The RPND instruction is used to clear the software interrupt pending bit. This pending bit is also cleared on reset.

The ST has the highest rank among all interrupts.

Nothing (except another ST) can interrupt an ST being serviced.

WATCHDOG

The device contains a WATCHDOG and clock monitor. The WATCHDOG is designed to detect the user program getting stuck in infinite loops resulting in loss of program control or "runaway" programs. The Clock Monitor is used to detect the absence of a clock or a very slow clock below a specified rate on the CKI pin.

The WATCHDOG consists of two independent logic blocks: WD UPPER and WD LOWER. WD UPPER establishes the upper limit on the service window and WD LOWER defines the lower limit of the service window.

Servicing the WATCHDOG consists of writing a specific value to a WATCHDOG Service Register named WDSVR which is memory mapped in the RAM. This value is composed of three fields, consisting of a 2-bit Window Select, a 5-bit Key Data field, and the 1-bit Clock Monitor Select field. Table V shows the WDSVR register.

TABLE V. WATCHDOG Service Register (WDSVR)

Window Select		Key Data					Clock Monitor
X	X	0	1	1	0	0	Y
7	6	5	4	3	2	1	0

The lower limit of the service window is fixed at 2048 instruction cycles. Bits 7 and 6 of the WDSVR register allow the user to pick an upper limit of the service window.

Table VI shows the four possible combinations of lower and upper limits for the WATCHDOG service window. This flexibility in choosing the WATCHDOG service window prevents any undue burden on the user software.

Bits 5, 4, 3, 2 and 1 of the WDSVR register represent the 5-bit Key Data field. The key data is fixed at 01100. Bit 0 of the WDSVR Register is the Clock Monitor Select bit.

TABLE VI. WATCHDOG Service Window Select

WDSVR Bit 7	WDSVR Bit 6	Service Window (Lower-Upper Limits)
0	0	2k–8k t_C Cycles
0	1	2k–16k t_C Cycles
1	0	2k–32k t_C Cycles
1	1	2k–64k t_C Cycles

Clock Monitor

The Clock Monitor aboard the device can be selected or deselected under program control. The Clock Monitor is guaranteed not to reject the clock if the instruction cycle clock ($1/t_C$) is greater or equal to 10 kHz. This equates to a clock input rate on CKI of greater or equal to 100 kHz.

WATCHDOG Operation

The WATCHDOG and Clock Monitor are disabled during reset. The device comes out of reset with the WATCHDOG armed, the WATCHDOG Window Select bits (bits 6, 7 of the WDSVR Register) set, and the Clock Monitor bit (bit 0 of the WDSVR Register) enabled. Thus, a Clock Monitor error will occur after coming out of reset, if the instruction cycle clock frequency has not reached a minimum specified value, including the case where the oscillator fails to start.

The WDSVR register can be written to only once after reset and the key data (bits 5 through 1 of the WDSVR Register) must match to be a valid write. This write to the WDSVR register involves two irrevocable choices: (i) the selection of the WATCHDOG service window (ii) enabling or disabling of the Clock Monitor. Hence, the first write to WDSVR Register involves selecting or deselecting the Clock Monitor, select the WATCHDOG service window and match the WATCHDOG key data. Subsequent writes to the WDSVR register will compare the value being written by the user to the WATCHDOG service window value and the key data (bits 7 through 1) in the WDSVR Register. Table VII shows the sequence of events that can occur.

The user must service the WATCHDOG at least once before the upper limit of the service window expires. The WATCHDOG may not be serviced more than once in every lower limit of the service window. The user may service the WATCHDOG as many times as wished in the time period between the lower and upper limits of the service window. The first write to the WDSVR Register is also counted as a WATCHDOG service.

The WATCHDOG has an output pin associated with it. This is the WDOUT pin, on pin 1 of the port G. WDOUT is active low. The WDOUT pin is in the high impedance state in the inactive state. Upon triggering the WATCHDOG, the logic will pull the WDOUT (G1) pin low for an additional 16 t_C–32 t_C cycles after the signal level on WDOUT pin goes below the lower Schmitt trigger threshold. After this delay, the device will stop forcing the WDOUT output low.

The WATCHDOG service window will restart when the WDOUT pin goes high. It is recommended that the user tie the WDOUT pin back to V_{CC} through a resistor in order to pull WDOUT high.

A WATCHDOG service while the WDOUT signal is active will be ignored. The state of the WDOUT pin is not guaranteed on reset, but if it powers up low then the WATCHDOG will time out and WDOUT will enter high impedance state.

The Clock Monitor forces the G1 pin low upon detecting a clock frequency error. The Clock Monitor error will continue until the clock frequency has reached the minimum specified value, after which the G1 output will enter the high impedance TRI-STATE mode following 16 t_C–32 t_C clock cycles. The Clock Monitor generates a continual Clock Monitor error if the oscillator fails to start, or fails to reach the minimum specified frequency. The specification for the Clock Monitor is as follows:

$1/t_C > 10$ kHz—No clock rejection.

$1/t_C < 10$ Hz—Guaranteed clock rejection.

WATCHDOG Operation (Continued)

WATCHDOG AND CLOCK MONITOR SUMMARY

The following salient points regarding the WATCHDOG and CLOCK MONITOR should be noted:

- Both the WATCHDOG and CLOCK MONITOR detector circuits are inhibited during RESET.
- Following RESET, the WATCHDOG and CLOCK MONITOR are both enabled, with the WATCHDOG having he maximum service window selected.
- The WATCHDOG service window and CLOCK MONITOR enable/disable option can only be changed once, during the initial WATCHDOG service following RESET.
- The initial WATCHDOG service must match the key data value in the WATCHDOG Service register WDSVR in order to avoid a WATCHDOG error.
- Subsequent WATCHDOG services must match all three data fields in WDSVR in order to avoid WATCHDOG errors.
- The correct key data value cannot be read from the WATCHDOG Service register WDSVR. Any attempt to read this key data value of 01100 from WDSVR will read as key data value of all 0's.
- The WATCHDOG detector circuit is inhibited during both the HALT and IDLE modes.
- The CLOCK MONITOR detector circuit is active during both the HALT and IDLE modes. Consequently, the device inadvertently entering the HALT mode will be detected as a CLOCK MONITOR error (provided that the CLOCK MONITOR enable option has been selected by the program).
- With the single-pin R/C oscillator mask option selected and the CLKDLY bit reset, the WATCHDOG service window will resume following HALT mode from where it left off before entering the HALT mode.
- With the crystal oscillator mask option selected, or with the single-pin R/C oscillator mask option selected and the CLKDLY bit set, the WATCHDOG service window will be set to its selected value from WDSVR following HALT. Consequently, the WATCHDOG should not be serviced for at least 2048 instruction cycles following HALT, but must be serviced within the selected window to avoid a WATCHDOG error.
- The IDLE timer T0 is not initialized with RESET.
- The user can sync in to the IDLE counter cycle with an IDLE counter (T0) interrupt or by monitoring the T0PND flag. The T0PND flag is set whenever the thirteenth bit of the IDLE counter toggles (every 4096 instruction cycles). The user is responsible for resetting the T0PND flag.
- A hardware WATCHDOG service occurs just as the device exits the IDLE mode. Consequently, the WATCHDOG should not be serviced for at least 2048 instruction cycles following IDLE, but must be serviced within the selected window to avoid a WATCHDOG error.
- Following RESET, the initial WATCHDOG service (where the service window and the CLOCK MONITOR enable/disable must be selected) may be programmed anywhere within the maximum service window (65,536 instruction cycles) initialized by RESET. Note that this initial WATCHDOG service may be programmed within the initial 2048 instruction cycles without causing a WATCHDOG error.

Detection of Illegal Conditions

The device can detect various illegal conditions resulting from coding errors, transient noise, power supply voltage drops, runaway programs, etc.

Reading of undefined ROM gets zeros. The opcode for software interrupt is zero. If the program fetches instructions from undefined ROM, this will force a software interrupt, thus signaling that an illegal condition has occurred.

The subroutine stack grows down for each call (jump to subroutine), interrupt, or PUSH, and grows up for each return or POP. The stack pointer is initialized to RAM location 06F Hex during reset. Consequently, if there are more returns than calls, the stack pointer will point to addresses 070 and 071 Hex (which are undefined RAM). Undefined RAM from addresses 070 to 07F (Segment 0), and all other segments (i.e., Segments 4 . . . etc.) is read as all 1's, which in turn will cause the program to return to address 7FFF Hex. This is an undefined ROM location and the instruction fetched (all 0's) from this location will generate a software interrupt signaling an illegal condition.

Thus, the chip can detect the following illegal conditions:

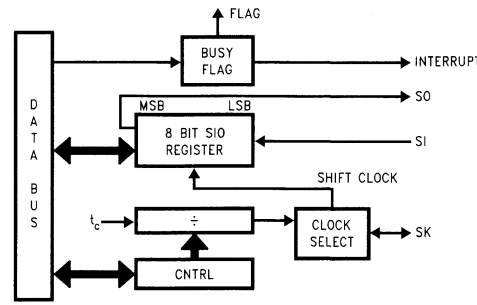
a. Executing from undefined ROM

b. Over "POP"ing the stack by having more returns than calls.

When the software interrupt occurs, the user can re-initialize the stack pointer and do a recovery procedure before restarting (this recovery program is probably similar to that following reset, but might not contain the same program initialization procedures). The recovery program should reset the software interrupt pending bit using the RPND instruction.

MICROWIRE/PLUS

MICROWIRE/PLUS is a serial synchronous communications interface. The MICROWIRE/PLUS capability enables the device to interface with any of National Semiconductor's MICROWIRE peripherals (i.e. A/D converters, display drivers, E^2PROMs etc.) and with other microcontrollers which support the MICROWIRE interface. It consists of an 8-bit serial shift register (SIO) with serial data input (SI), serial data output (SO) and serial shift clock (SK). *Figure 17* shows a block diagram of the MICROWIRE/PLUS logic.



TL/DD/12858–19

FIGURE 17. MICROWIRE/PLUS Block Diagram

The shift clock can be selected from either an internal source or an external source. Operating the MICROWIRE/PLUS arrangement with the internal clock source is called the Master mode of operation. Similarly, operating the MICROWIRE/PLUS arrangement with an external shift clock is called the Slave mode of operation.

The CNTRL register is used to configure and control the MICROWIRE/PLUS mode. To use the MICROWIRE/PLUS, the MSEL bit in the CNTRL register is set to one. In the master mode, the SK clock rate is selected by the two bits, SL0 and SL1, in the CNTRL register. Table VIII details the different clock rates that may be selected.

TABLE VII. WATCHDOG Service Actions

Key Data	Window Data	Clock Monitor	Action
Match	Match	Match	Valid Service: Restart Service Window
Don't Care	Mismatch	Don't Care	Error: Generate WATCHDOG Output
Mismatch	Don't Care	Don't Care	Error: Generate WATCHDOG Output
Don't Care	Don't Care	Mismatch	Error: Generate WATCHDOG Output

TABLE VIII. MICROWIRE/PLUS Master Mode Clock Select

0	1	$4 \times t_c$
1	x	$8 \times t_c$

Where t_c is the instruction cycle clock

MICROWIRE/PLUS (Continued)

MICROWIRE/PLUS OPERATION

Setting the BUSY bit in the PSW register causes the MICROWIRE/PLUS to start shifting the data. It gets reset when eight data bits have been shifted. The user may reset the BUSY bit by software to allow less than 8 bits to shift. If enabled, an interrupt is generated when eight data bits have been shifted. The device may enter the MICROWIRE/PLUS mode either as a Master or as a Slave. *Figure 18* shows how two microcontroller devices and several peripherals may be interconnected using the MICROWIRE/PLUS arrangements.

Warning:

The SIO register should only be loaded when the SK clock is low. Loading the SIO register while the SK clock is high will result in undefined data in the SIO register. SK clock is normally low when not shifting.

Setting the BUSY flag when the input SK clock is high in the MICROWIRE/PLUS slave mode may cause the current SK clock for the SIO shift register to be narrow. For safety, the BUSY flag should only be set when the input SK clock is low.

MICROWIRE/PLUS Master Mode Operation

In the MICROWIRE/PLUS Master mode of operation the shift clock (SK) is generated internally by the device. The MICROWIRE Master always initiates all data exchanges. The MSEL bit in the CNTRL register must be set to enable the SO and SK functions onto the G Port. The SO and SK pins must also be selected as outputs by setting appropriate bits in the Port G configuration register. Table IX summarizes the bit settings required for Master mode of operation.

MICROWIRE/PLUS Slave Mode Operation

In the MICROWIRE/PLUS Slave mode of operation the SK clock is generated by an external source. Setting the MSEL bit in the CNTRL register enables the SO and SK functions onto the G Port. The SK pin must be selected as an input and the SO pin is selected as an output pin by setting and resetting the appropriate bits in the Port G configuration register. Table IX summarizes the settings required to enter the Slave mode of operation.

The user must set the BUSY flag immediately upon entering the Slave mode. This will ensure that all data bits sent by the Master will be shifted properly. After eight clock pulses the BUSY flag will be cleared and the sequence may be repeated.

Alternate SK Phase Operation

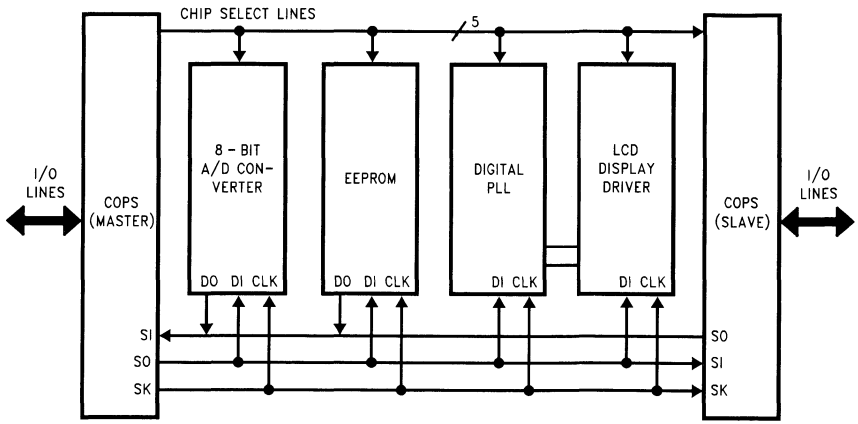
The device allows either the normal SK clock or an alternate phase SK clock to shift data in and out of the SIO register. In both the modes the SK is normally low. In the normal mode data is shifted in on the rising edge of the SK clock and the data is shifted out on the falling edge of the SK clock. The SIO register is shifted on each falling edge of the SK clock. In the alternate SK phase operation, data is shifted in on the falling edge of the SK clock and shifted out on the rising edge of the SK clock.

A control flag, SKSEL, allows either the normal SK clock or the alternate SK clock to be selected. Resetting SKSEL causes the MICROWIRE/PLUS logic to be clocked from the normal SK signal. Setting the SKSEL flag selects the alternate SK clock. The SKSEL is mapped into the G6 configuration bit. The SKSEL flag will power up in the reset condition, selecting the normal SK signal.

TABLE IX

This table assumes that the control flag MSEL is set.

G4 (SO) Config. Bit	G5 (SK) Config. Bit	G4 Fun.	G5 Fun.	Operation
1	1	SO	Int. SK	MICROWIRE/PLUS Master
0	1	TRI-STATE	Int. SK	MICROWIRE/PLUS Master
1	0	SO	Ext. SK	MICROWIRE/PLUS Slave
0	0	TRI-STATE	Ext. SK	MICROWIRE/PLUS Slave



TL/DD/12858–20

FIGURE 18. MICROWIRE/PLUS Application

Memory Map

All RAM, ports and registers (except A and PC) are mapped into data memory address space.

Address S/ADD REG	Contents
0000 to 006F	On-Chip RAM bytes (112 bytes)
0070 to 007F	Unused RAM Address Space (Reads As All Ones)
xx80 to xxAF	Unused RAM Address Space (Reads Undefined Data)
xxB0	Timer T3 Lower Byte
XXB1	Timer T3 Upper Byte
xxB2	Timer T3 Autoload Register T3RA Lower Byte
xxB3	Timer T3 Autoload Register T3RA Upper Byte
xxB4	Timer T3 Autoload Register T3RB Lower Byte
xxB5	Timer T3 Autoload Register T3RB Upper Byte
xxB6	Timer T3 Control Register
xxB7	Comparator Select Register (CMPSL)
xxB8	UART Transmit Buffer (TBUF)
xxB9	UART Receive Buffer (RBUF)
xxBA	UART Control and Status Register (ENU)
xxBB	UART Receive Control and Status Register (ENUR)
xxBC	UART Interrupt and Clock Source Register (ENUI)
xxBD	UART Baud Register (BAUD)
xxBE	UART Prescale Select Register (PSR)
xxBF	Reserved for UART
xxC0	Timer T2 Lower Byte
xxC1	Timer T2 Upper Byte
xxC2	Timer T2 Autoload Register T2RA Lower Byte
xxC3	Timer T2 Autoload Register T2RA Upper Byte
xxC4	Timer T2 Autoload Register T2RB Lower Byte
xxC5	Timer T2 Autoload Register T2RB Upper Byte
xxC6	Timer T2 Control Register
xxC7	WATCHDOG Service Register (Reg:WDSVR)
xxC8	MIWU Edge Select Register (Reg:WKEDG)
xxC9	MIWU Enable Register (Reg:WKEN)
xxCA	MIWU Pending Register (Reg:WKPND)
xxCB	Reserved
xxCC	Reserved
xxCD to xxCF	Reserved

Address S/ADD REG	Contents
xxD0	Port L Data Register
xxD1	Port L Configuration Register
xxD2	Port L Input Pins (Read Only)
xxD3	Reserved for Port L
xxD4	Port G Data Register
xxD5	Port G Configuration Register
xxD6	Port G Input Pins (Read Only)
xxD7	Port I Input Pins (Read Only)
xxD8	Port C Data Register
xxD9	Port C Configuration Register
xxDA	Port C Input Pins (Read Only)
xxDB	Reserved for Port C
xxDC	Port D
xxDD to xxDF	Reserved for Port D
xxE0 to xxE5	Reserved for EE Control Registers
xxE6	Timer T1 Autoload Register T1RB Lower Byte
xxE7	Timer T1 Autoload Register T1RB Upper Byte
xxE8	ICNTRL Register
xxE9	MICROWIRE/PLUS Shift Register
xxEA	Timer T1 Lower Byte
xxEB	Timer T1 Upper Byte
xxEC	Timer T1 Autoload Register T1RA Lower Byte
xxED	Timer T1 Autoload Register T1RA Upper Byte
xxEE	CNTRL Control Register
xxEF	PSW Register
xxF0 to FB	On-Chip RAM Mapped as Registers
xxFC	X Register
xxFD	SP Register
xxFE	B Register
xxFF	S Register
0100 to 017F	On-Chip 128 RAM Bytes
0200 to 027F	On-Chip 128 RAM Bytes
0300 to 037F	On-Chip 128 RAM Bytes

Reading memory locations 0070H–007FH (Segment 0) will return all ones. Reading unused memory locations 0080H–00AFH (Segment 0) will return undefined data. Reading memory locations from other Segments (i.e., Segment 4, Segment 5, ... etc.) will return all ones.

Addressing Modes

There are ten addressing modes, six for operand addressing and four for transfer of control.

OPERAND ADDRESSING MODES

Register Indirect

This is the "normal" addressing mode. The operand is the data memory addressed by the B pointer or X pointer.

Register Indirect (with auto post increment or decrement of pointer)

This addressing mode is used with the LD and X instructions. The operand is the data memory addressed by the B pointer or X pointer. This is a register indirect mode that automatically post increments or decrements the B or X register after executing the instruction.

Direct

The instruction contains an 8-bit address field that directly points to the data memory for the operand.

Immediate

The instruction contains an 8-bit immediate field as the operand.

Short Immediate

This addressing mode is used with the Load B Immediate instruction. The instruction contains a 4-bit immediate field as the operand.

Indirect

This addressing mode is used with the LAID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a data operand from the program memory.

TRANSFER OF CONTROL ADDRESSING MODES

Relative

This mode is used for the JP instruction, with the instruction field being added to the program counter to get the new program location. JP has a range from −31 to +32 to allow a 1-byte relative jump (JP + 1 is implemented by a NOP instruction). There are no "pages" when using JP, since all 15 bits of PC are used.

Absolute

This mode is used with the JMP and JSR instructions, with the instruction field of 12 bits replacing the lower 12 bits of the program counter (PC). This allows jumping to any location in the current 4k program memory segment.

Absolute Long

This mode is used with the JMPL and JSRL instructions, with the instruction field of 15 bits replacing the entire 15 bits of the program counter (PC). This allows jumping to any location up to 32k in the program memory space.

Indirect

This mode is used with the JID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a location in the program memory. The contents of this program memory location serve as a partial address (lower 8 bits of PC) for the jump to the next instruction.

Note: The VIS is a special case of the Indirect Transfer of Control addressing mode, where the double byte vector associated with the interrupt is transferred from adjacent addresses in the program memory into the program counter (PC) in order to jump to the associated interrupt service routine.

Instruction Set

Register and Symbol Definition

Registers	
A	8-Bit Accumulator Register
B	8-Bit Address Register
X	8-Bit Address Register
S	8-Bit Segment Register
SP	8-Bit Stack Pointer Register
PC	15-Bit Program Counter Register
PU	Upper 7 Bits of PC
PL	Lower 8 Bits of PC
C	1 Bit of PSW Register for Carry
HC	1 Bit of PSW Register for Half Carry
GIE	1 Bit of PSW Register for Global Interrupt Enable
VU	Interrupt Vector Upper Byte
VL	Interrupt Vector Lower Byte

Symbols	
[B]	Memory Indirectly Addressed by B Register

SUBC	A,Meml	Subtract with Carry	A ← A − $\overline{\text{Meml}}$ + C, C ← Carry HC ← Half Carry
AND	A,Meml	Logical AND	A ← A and Meml
ANDSZ	A,Imm	Logical AND Immed., Skip if Zero	Skip next if (A and Imm) = 0
OR	A,Meml	Logical OR	A ← A or Meml
XOR	A,Meml	Logical EXclusive OR	A ← A xor Meml
IFEQ	MD,Imm	IF EQual	Compare MD and Imm, Do next if MD = Imm
IFEQ	A,Meml	IF EQual	Compare A and Meml, Do next if A = Meml
IFNE	A,Meml	IF Not Equal	Compare A and Meml, Do next if A ≠ Meml
IFGT	A,Meml	IF Greater Than	Compare A and Meml, Do next if A > Meml
IFBNE	#	If B Not Equal	Do next if lower 4 bits of B ≠ Imm
DRSZ	Reg	Decrement Reg., Skip if Zero	Reg ← Reg − 1, Skip if Reg = 0
SBIT	#,Mem	Set BIT	1 to bit, Mem (bit = 0 to 7 immediate)
RBIT	#,Mem	Reset BIT	0 to bit, Mem
IFBIT	#,Mem	IF BIT	If bit in A or Mem is true do next instruction
RPND		Reset PeNDing Flag	Reset Software Interrupt Pending Flag
X	A,Mem	EXchange A with Memory	A ⟷ Mem
X	A,[X]	EXchange A with Memory [X]	A ⟷ [X]
LD	A,Meml	LoaD A with Memory	A ← Meml
LD	A,[X]	LoaD A with Memory [X]	A ← [X]
LD	B,Imm	LoaD B with Immed.	B ← Imm
LD	Mem,Imm	LoaD Memory Immed	Mem ← Imm
LD	Reg,Imm	LoaD Register Memory Immed.	Reg ← Imm
X	A, [B ±]	EXchange A with Memory [B]	A ⟷ [B], (B ← B ±1)
X	A, [X ±]	EXchange A with Memory [X]	A ⟷ [X], (X ← X ±1)
LD	A, [B±]	LoaD A with Memory [B]	A ← [B], (B ← B ±1)
LD	A, [X±]	LoaD A with Memory [X]	A ← [X], (X ← X±1)
LD	[B±],Imm	LoaD Memory [B] Immed.	[B] ← Imm, (B ← B±1)
CLR	A	CLeaR A	A ← 0
INC	A	INCrement A	A ← A + 1
DEC	A	DECrement A	A ← A − 1
LAID		Load A InDirect from ROM	A ← ROM (PU,A)
DCOR	A	Decimal CORrect A	A ← BCD correction of A (follows ADC, SUBC)
RRC	A	Rotate A Right thru C	C → A7 → . . . → A0 → C
RLC	A	Rotate A Left thru C	C ← A7 ← . . . ← A0 ← C
SWAP	A	SWAP nibbles of A	A7 . . . A4 ⟷ A3 . . . A0
SC		Set C	C ← 1, HC ← 1
RC		Reset C	C ← 0, HC ← 0
IFC		IF C	IF C is true, do next instruction
IFNC		IF Not C	If C is not true, do next instruction
POP	A	POP the stack into A	SP ← SP + 1, A ← [SP]
PUSH	A	PUSH A onto the stack	[SP] ← A, SP ← SP − 1
VIS		Vector to Interrupt Service Routine	PU ← [VU], PL ← [VL]
JMPL	Addr.	Jump absolute Long	PC ← ii (ii = 15 bits, 0 to 32k)
JMP	Addr.	Jump absolute	PC9 . . . 0 ← i (i = 12 bits)
JP	Disp.	Jump relative short	PC ← PC + r (r is −31 to +32, except 1)
JSRL	Addr.	Jump SubRoutine Long	[SP] ← PL, [SP−1] ← PU,SP−2, PC ← ii
JSR	Addr	Jump SubRoutine	[SP] ← PL, [SP−1] ← PU,SP−2, PC9 . . . 0 ← i
JID		Jump InDirect	PL ← ROM (PU,A)
RET		RETurn from subroutine	SP + 2, PL ← [SP], PU ← [SP−1]
RETSK		RETurn and SKip	SP + 2, PL ← [SP],PU ← [SP−1], skip next instruction
RETI		RETurn from Interrupt	SP + 2, PL ← [SP],PU ← [SP−1],GIE ← 1
INTR		Generate an Interrupt	[SP] ← PL, [SP−1] ← PU, SP−2, PC ← 0FF
NOP		No OPeration	PC ← PC + 1

Instruction Execution Time

Most instructions are single byte (with immediate addressing mode instructions taking two bytes).

Most single byte instructions take one cycle time to execute.

Skipped instructions require x number of cycles to be skipped, where x equals the number of bytes in the skipped instruction opcode.

See the BYTES and CYCLES per INSTRUCTION table for details.

Bytes and Cycles per Instruction

The following table shows the number of bytes and cycles for each instruction in the format of byte/cycle.

Arithmetic and Logic Instructions

	[B]	Direct	Immed.

Where,

i is the immediate data

Md is a directly addressed me nory location

* is an unused opcode

Note: The opcode 60 Hex is also the opcode for IFBIT #i,A

Mask Options

The mask programmable options are shown below. The options are programmed at the same time as the ROM pattern submission.

OPTION 1: CLOCK CONFIGURATION

= 1 Crystal Oscillator (CKI/10)
G7 (CKO) is clock generator output to crystal/ resonator with CKI being the clock input

= 2 Single-pin RC controlled oscillator (CKI/10)
G7 is available as a HALT restart and/or general purpose input

OPTION 2: HALT

= 1 Enable HALT mode

= 2 Disable HALT mode

OPTION 3: BONDING

= 1 44-Pin PLCC

= 2 40-Pin DIP

The chip can be driven by a clock input on the CKI input pin which can be between DC and 10 MHz. The CKO output clock is on pin G7 (if clock option = 1 has been selected). The CKI input frequency is divided down by 10 to produce the instruction cycle clock (1/tc).

Development Support

Summary

- iceMASTER: IM-COP8/400—Full feature in-circuit emulation for all COP8 products. A full set of COP8 Basic and Feature Family device and package specific probes are available.
- COP8 Debug Module: Moderate cost in-circuit emulation and development programming unit.
- COP8 Evaluation and Programming Unit: EPU-COP888HG—low cost In-circuit simulation and development programming unit.
- Assembler: COP8-DEV-IBMA. A DOS installable cross development Assembler, Linker, Librarian and Utility Software Development Tool Kit.
- C Compiler: COP8C. A DOS installable cross development Software Tool Kit.
- OTP/EPROM Programmer Support: Covering needs from engineering prototype, pilot production to full production environments.

Development Support (Continued)

IceMASTER (IM) IN-CIRCUIT EMULATION

The iceMASTER IM-COP8/400 is a full feature, PC based, in-circuit emulation tool developed and marketed by MetaLink Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 19* for configuration.

The iceMASTER IM-COP8/400 with its device specific COP8 Probe provides a rich feature set for developing, testing and maintaining product:

- Real-time in-circuit emulation; full 2.4V–5.5V operation range, full DC-10 MHz clock. Chip options are programmable or jumper selectable.
- Direct connection to application board by package compatible socket or surface mount assembly.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated on the probe as necessary.
- Full 4K frame synchronous trace memory. Address, instruction, and 8 unspecified, circuit connectable trace lines. Display can be HLL source (e.g., C source), assembly or mixed.
- A full 64K hardware configurable break, trace on, trace off control, and pass count increment events.
- Tool set integrated interactive symbolic debugger—supports both assembler (COFF) and C Compiler (.COD) linked object formats.
- Real time peformance profiling analysis; selectable bucket definition.
- Watch windows, content updated automatically at each execution break.
- Instruction by instruction memory/register changes displayed on source window when in single step operation.
- Single base unit and debugger software reconfigurable to support the entire COP8 family; only the probe personality needs to change. Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- On-line HELP customized to specific processor using master model file.
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

IceMASTER DEBUG MODULE (DM)

The iceMASTER Debug Module is a PC based, combination in-circuit emulation tool and COP8 based OTP/EPROM programming tool developed and marketed by MetaLink Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 20* for configuration.

The iceMASTER Debug Module is a moderate cost development tool. It has the capability of in-circuit emulation for a specific COP8 microcontroller and in addition serves as a programming tool for COP8 OTP and EPROM product families. Summary of features is as follows:

- Real-time in-circuit emulation; full operating voltage range operation, full DC-10 MHz clock.
- All processor I/O pins can be cabled to an application development board with package compatible cable to socket and surface mount assembly.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated as necessary.
- 100 frames of synchronous trace memory. The display can be HLL source (C source), assembly or mixed. The most recent history prior to a break is available in the trace memory.
- Configured break points; uses INTR instruction which is modestly intrusive.
- Software—only supported features are selectable.
- Tool set integrated interactive symbolic debugger—supports both
- Assembler (COFF) and C Compiler (.COD) SDK linked object formats.
- Instruction by instruction memory/register changes displayed when in single step operation.
- Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- Programming menu supports full product line of programmable OTP and EPROM COP8 products. Program data is taken directly from the overlay RAM.
- Programming of 44 PLCC and 68 PLCC parts requires external programming adapters.
- Includes wall-mount power supply
- On-board V_{PP} generator from 5V input or connection to external supply supported. Requires V_{PP} level adjustment per the family programming specification (correct level is provided on an on-screen pop-down display). On-line HELP customized to specific processor using master model file.
- On-line HELP customized to specific processor using master model file
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

IceMASTER EVALUATION PROGRAMMING UNIT (EPU)

The iceMASTER EPU-COP888HG is a PC based, in-circuit. simulation tool to support the feature family COP8 products. See *Figure 21* for configuration.

The simulation capability is a very low cost means of evaluating the general COP8 architecture. In addition, the EPU has programming capability, with added adapters, for programming the whole COP8 product family of OTP and EPROM products. The product includes the following features:

- Non-real-time in-circuit simulation. Program overlay memory is PC resident; instructions are downloaded over RS-232 as executed. Approximate performance is 20 kHz.
- Includes a 40-pin DIP cable adapter. Other target packages are not supported. All processor I/O pins are cabled to the application development environment.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated as necessary.
- On-chip timer and watch-dog execution are not well synchronized to the instruction simulation.
- 100 frames of synchronous trace memory. The display can be HLL source (e.g., C source), assembly or mixed. The most recent history prior to a break is available in the trace memory.
- Up to 8 software configured break points; uses INTR instruction which is modestly intrusive.
- Common look-feel debugger software across all MetaLink products—only supported features are selectable.
- Tool set integrated interactive symbolic debugger—supports both assembler (COFF) and C Compiler (.COD) SDK linked object formats.
- Instruction by instruction memory/register changes displayed when in single step operation.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification. Restart requires special handling.
- Programming menu supports full product line of programmable OTP and EPROM COP8 products. Only a 40 ZIF socket is available on the EPU unit. Adapters are available for other part package configurations.
- Integral wall mount power supply provides 5V and develops the required V_{PP} to program parts.
- Includes a copy of COP8-DEV-IBMA assembler, linker SDK.

EPU Order Information

Evaluation Programming Unit	
EPU-COP888GG	Evaluation Programming Unit with debugger and programmer control software and 40 ZIF programming socket
General Programming Adapters	
COP8-PGMA-DS	28 & 20 DIP and SOIC adapter
COP8-PGMA-DS44P	28 & 20 DIP and SOIC plus 44 PLCC adapter

FIGURE 21. CPU-COP8 Tool Environment

Development Support (Continued)

COP8 ASSEMBLER/LINKER SOFTWARE DEVELOPMENT TOOL KIT

National Semiconductor offers a relocateable COP8 macro cross assembler, linker, librarian and utility software development tool kit. Features are summarized as follows:

- Basic and Feature Family instruction set by "device" type.
- Nested macro capability.
- Extensive set of assembler directives.
- Supported on PC/DOS platform.
- Generates National standard COFF output files.
- Integrated Linker and Librarian.
- Integrated utilities to generate ROM code file outputs.
- DUMPCOFF utility.

This product is integrated as a part of MetaLink tools as a development kit, fully supported by the MetaLink debugger. It may be ordered separately or it is bundled with the MetaLink products at no additional cost.

Order Information

Assembler SDK	
COP8-DEV-IBMA	Assembler SDK on installable 3.5" PC/DOS Floppy Disk Drive format. Periodic upgrades and most recent version is available on National's BBS and Internet.

COP8 C COMPILER

A C Compiler is developed and marketed by Byte Craft Limited. The COP8C compiler is a fully integrated development tool specifically designed to support the compact embedded configuration of the COP8 family of products.

Features are summarized as follows:

- ANSI C with some restrictions and extensions that optimize development for the COP8 embedded application.
- BITS data type extension. Register declaration #pragma with direct bit level definitions.
- C language support for interrupt routines.
- Expert system, rule based code geration and optimization.
- Performs consistency checks against the architectural definitions of the target COP8 device.
- Generates program memory code.
- Supports linking of compiled object or COP8 assembled object formats.
- Global optimization of linked code.
- Symbolic debug load format fully source level supported by the MetaLink debugger.

SINGLE-CHIP OTP/EMULATOR SUPPORT

The COP8 family is supported by single-chip OTP emulators. For detailed information, refer to the emulator specific datasheet and the emulator selection table below:

OTP Emulator Ordering Information

Device Number	Clock Option	Package	Emulates
COP87L88GGV-XE	Crystal/ HALT En	44 PLCC	COP888HG
COP87L88GGN-XE	Crystal/ HALT En	40 DIP	COP888HG

INDUSTRY WIDE OTP/EPROM PROGRAMMING SUPPORT

Programming support, in addition to the MetaLink development tools, is provided by a full range of independent approved vendors to meet the needs from the engineering laboratory to full production.

AVAILABLE LITERATURE

For more information, please see the COP8 Basic Family User's Manual, Literature Number 620895, COP8 Feature Family User's Manual Literature Number 620897 and National's Family of 8-bit Microcontrollers COP8 Selection Guide, Literature Number 630009.

DIAL-A-HELPER

Dial-A-Helper is a service provided by the Microcontroller Applications group. The Dial-A-Helper is an Electronic Information System that may be accessed as a Bulletin Board System (BBS) via data modem, as an FTP site on the Internet via standard FTP client application or as an FTP site on the Internet using a standard Internet browser such as Netscape or Mosaic.

The Dial-A-Helper system provides access to an automated information storage and retrieval system. The system capabilities include a MESSAGE SECTION (electronic mail, when accessed as a BBS) for communication to and from the Microcontroller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities could be found.

National Semiconductor

PRELIMINARY

COP688KG/COP888KG 8-Bit Microcontroller with UART and Three Multi-Function Timers

General Description

The COP8™ feature family of microcontrollers uses an 8-bit single-chip core architecture fabricated with National Semiconductor's M²CMOS™ process technology. The COP888KG is a member of this expandable 8-bit core processor family of microcontrollers. (Continued)

Key Features

- Full duplex UART
- Three 16-bit timers, each with two 16-bit registers supporting:
  - — Processor Independent PWM mode
  - — External Event counter mode
  - — Input Capture mode
- Quiet design (low radiated emissions)
- 24 kbytes on-board ROM
- 1088 bytes on-board RAM

Additional Peripheral Features

- Idle Timer
- Multi-Input Wake-Up (MIWU) with optional interrupts (8)
- Two analog comparators
- WATCHDOG™ and Clock Monitor logic
- MICROWIRE/PLUS™ serial I/O

I/O Features

- Memory mapped I/O
- Software selectable I/O options (TRI-STATE® Output, Push-Pull Output, Weak Pull-Up Input, High Impedance Input)
- Schmitt trigger inputs on ports G and L
- Packages:
  - — 40 DIP with 35 I/O pins
  - — 44 PLCC with 39 I/O pins

CPU/Instruction Set Features

- 1 μs instruction cycle time
- Fourteen multi-source vectored interrupts servicing
  - — External Interrupt with selectable edge
  - — Idle Timer T0
  - — Three Timers (each with 2 interrupts)
  - — MICROWIRE/PLUS
  - — Multi-Input Wake-Up
  - — Software Trap
  - — UART (2)
  - — Default VIS (default interrupt)
- Versatile and easy to use instruction set
- 8-bit Stack Pointer SP—(stack in RAM)
- Two 8-bit Register Indirect Data Memory Pointers (B and X)

Fully Static CMOS

- Two power saving modes: HALT and IDLE
- Low current drain (typically <1 μA)
- Single supply operation: 2.5V–5.5V
- Temperature ranges:
  $-40°C$ to $+85°C$, $-55°C$ to $+125°C$

Development Support

- Emulation and OTP devices
- Real time emulation and full program debug offered by MetaLink's Development System

5

Block Diagram

FIGURE 1. COP888KG Block Diagram

General Description (Continued)

It is a fully static part, fabricated using double-metal silicon gate microCMOS technology. Features include an 8-bit memory mapped architecture, MICROWIRE/PLUS serial I/O, three 16-bit timer/counters supporting three modes (Processor Independent PWM generation, External Event counter, and Input Capture mode capabilities), full duplex UART, two comparators, and two power saving modes (HALT and IDLE), both with a multi-sourced wakeup/interrupt capability. This multi-sourced interrupt capability may also be used independent of the HALT or IDLE modes. Each I/O pin has software selectable configurations. The devices operate over a voltage range of 2.5V to 5.5V. High throughput is achieved with an efficient, regular instruction set operating at a maximum rate of 1 μs per instruction. Low radiated emissions are achieved by gradual turn-on output drivers and internal I_{CC} smoothing filters on the chip logic and crystal oscillator.

MICROWIRE Setup Time (t_{UWS}) (Note 5)	$V_{CC} \ge 4V$	20			ns
MICROWIRE Hold Time (t_{UWH}) (Note 5)	$V_{CC} \ge 4V$	56			ns
MICROWIRE Output Propagation Delay (t_{UPD})	$V_{CC} \ge 4V$			220	ns
Input Pulse Width (Note 6)					
Interrupt Input High Time		1			t_c
Interrupt Input Low Time		1			t_c
Timer 1, 2, 3 Input High Time		1			t_c
Timer 1, 2, 3 Input Low Time		1			t_c
Reset Pulse Width		1			μs

Note 1: Maximum rate of voltage change must be less than 0.5 V/ms.

Note 2: Supply current is measured after running 2000 cycles with a square wave CKI input, CKO open, inputs at rails and outputs open.

Note 3: The HALT mode will stop CKI from oscillating in the RC and the Crystal configurations. Measurement of IDD HALT is done with device neither sourcing or sinking current; with L, C, and G0–G5 programmed as low outputs and not driving a load; all outputs programmed low and not driving a load; all inputs tied to V_{CC}; clock monitor and comparators disabled. Parameter refers to HALT mode entered via setting bit 7 of the G Port data register. Part will pull up CKI during HALT in crystal clock mode.

Note 4: Pins G6 and $\overline{\text{RESET}}$ are designed with a high voltage input network. These pins allow input voltages greater than V_{CC} and the pins will have sink current to V_{CC} when biased at voltages greater than V_{CC} (the pins do not have source current when biased at a voltage below V_{CC}). The effective resistance to V_{CC} is 750Ω (typical). These two pins will not latch up. The voltage at the pins must be limited to less than 14V. **WARNING: Voltages in excess of 14V will cause damage to the pins. This warning excludes ESD transients.**

Note 5: Parameter characterized but not tested.

Note 6: t_c Instruction Cycle Time

Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Supply Voltage (V_{CC})	7V
Voltage at Any Pin	−0.3V to V_{CC} + 0.3V
Total Current into V_{CC} Pin (Source)	100 mA
Total Current out of GND Pin (Sink)	110 mA
Storage Temperature Range	−65°C to +140°C

Note: *Absolute maximum ratings indicate limits beyond which damage to the device may occur. DC and AC electrical specifications are not ensured when operating the device at absolute maximum ratings.*

FIGURE 3. MICROWIRE/PLUS Timing

Pin Descriptions

V_{CC} and GND are the power supply pins. All V_{CC} and GND pins must be connected.

CKI is the clock input. This can come from an R/C generated oscillator, or a crystal oscillator (in conjunction with CKO). See Oscillator Description section.

$\overline{\text{RESET}}$ is the master reset input. See Reset Description section.

The device contains three bidirectional 8-bit I/O ports (C, G and L), where each individual bit may be independently configured as an input (Schmitt Trigger inputs on ports L and G), output or TRI-STATE under program control. Three data memory address locations are allocated for each of these I/O ports. Each I/O port has two associated 8-bit memory mapped registers, the CONFIGURATION register and the output DATA register. A memory mapped address is also reserved for the input pins of each I/O port. (See the memory map for the various addresses associated with the I/O ports.) *Figure 4* shows the I/O port configurations. The DATA and CONFIGURATION registers allow for each port bit to be individually configured under software control as shown below:

CONFIGURATION Register	DATA Register	Port Set-Up
0	0	Hi-Z Input (TRI-STATE Output)
0	1	Input with Weak Pull-Up
1	0	Push-Pull Zero Output
1	1	Push-Pull One Output

PORT L is an 8-bit I/O port. All L-pins have Schmitt triggers on the inputs.

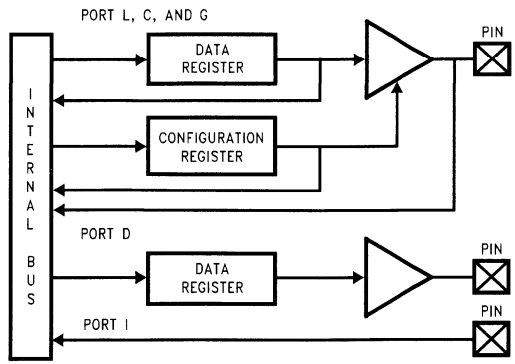
The Port L supports Multi-Input Wake Up on all eight pins. L1 is used for the UART external clock. L2 and L3 are used for the UART transmit and receive. L4 and L5 are used for the timer input functions T2A and T2B. L6 and L7 are used for the timer input functions T3A and T3B.

The Port L has the following alternate features:

- L0 MIWU
- L1 MIWU or CKX
- L2 MIWU or TDX
- L3 MIWU or RDX
- L4 MIWU or T2A
- L5 MIWU or T2B
- L6 MIWU or T3A
- L7 MIWU or T3B

Port G is an 8-bit port with 5 I/O pins (G0, G2–G5), an input pin (G6), and a dedicated output pin (G7). Pins G0 and G2–G6 all have Schmitt Triggers on their inputs. Pin G1 serves as the dedicated WDOUT WATCHDOG output, while pin G7 is either input or output depending on the oscillator mask option selected. With the crystal oscillator option selected, G7 serves as the dedicated output pin for the CKO clock output. With the single-pin R/C oscillator mask option selected, G7 serves as a general purpose input pin but is also used to bring the device out of HALT mode with a low to high transition on G7. There are two registers associated with the G Port, a data register and a configuration register. Therefore, each of the 5 I/O bits (G0, G2–G5) can be individually configured under software control.

Since G6 is an input only pin and G7 is the dedicated CKO clock output pin (crystal clock option) or general purpose input (R/C clock option), the associated bits in the data and configuration registers for G6 and G7 are used for special purpose functions as outlined on the next page. Reading the G6 and G7 data bits will return zeros.



TL/DD12829–5

FIGURE 4. I/O Port Configurations

Pin Descriptions (Continued)

Note that the chip will be placed in the HALT mode by writing a "1" to bit 7 of the Port G Data Register. Similarly the chip will be placed in the IDLE mode by writing a "1" to bit 6 of the Port G Data Register.

Writing a "1" to bit 6 of the Port G Configuration Register enables the MICROWIRE/PLUS to operate with the alternate phase of the SK clock. The G7 configuration bit, if set high, enables the clock start up delay after HALT when the R/C clock configuration is used.

	Config Reg.	Data Reg.
G7	CLKDLY	HALT
G6	Alternate SK	IDLE

Port G has the following alternate features:

- G0 INTR (External Interrupt Input)
- G2 T1B (Timer T1 Capture Input)
- G3 T1A (Timer T1 I/O)
- G4 SO (MICROWIRE Serial Data Output)
- G5 SK (MICROWIRE Serial Clock)
- G6 SI (MICROWIRE Serial Data Input)

Port G has the following dedicated functions:

- G1 WDOUT WATCHDOG and/or Clock Monitor dedicated output
- G7 CKO Oscillator dedicated output or general purpose input

Port C is an 8-bit I/O port. The 40-pin device does not have a full complement of Port C pins. The unavailable pins are not terminated. A read operation for these unterminated pins will return unpredicatable values.

Port I is an eight-bit Hi-Z input port.

Port I1–I3 are used for Comparator 1. Port I4–I6 are used for Comparator 2.

The Port I has the following alternate features:

- I1 COMP1 − IN (Comparator 1 Negative Input)
- I2 COMP1 + IN (Comparator 1 Positive Input)
- I3 COMP1OUT (Comparator 1 Output)
- I4 COMP2 − IN (Comparator 2 Negative Input)
- I5 COMP2 + IN (Comparator 2 Positive Input)
- I6 COMP2OUT (Comparator 2 Output)

Port D is an 8-bit output port that is preset high when $\overline{\text{RESET}}$ goes low. The user can tie two or more D port outputs (except D2) together in order to get a higher drive.

Functional Description

The architecture of the device is modified Harvard architecture. With the Harvard architecture, the control store program memory (ROM) is separated from the data store memory (RAM). Both ROM and RAM have their own separate addressing space with separate address buses. The architecture, though based on Harvard architecture, permits transfer of data from ROM to RAM.

CPU REGISTERS

The CPU can do an 8-bit addition, subtraction, logical or shift operation in one instruction (t_c) cycle time.

There are six CPU registers:

A is the 8-bit Accumulator Register

PC is the 15-bit Program Counter Register

PU is the upper 7 bits of the program counter (PC)
PL is the lower 8 bits of the program counter (PC)

B is an 8-bit RAM address pointer, which can be optionally post auto incremented or decremented.

X is an 8-bit alternate RAM address pointer, which can be optionally post auto incremented or decremented.

SP is the 8-bit stack pointer, which points to the subroutine/interrupt stack (in RAM). The SP is initialized to RAM address 06F with reset.

S is the 8-bit Data Segment Address Register used to extend the lower half of the address range (00 to 7F) into 256 data segments of 128 bytes each.

All the CPU registers are memory mapped with the exception of the Accumulator (A) and the Program Counter (PC).

PROGRAM MEMORY

The program memory consists of 24 kbytes of ROM. These bytes may hold program instructions or constant data (data tables for the LAID instruction, jump vectors for the JID instruction, and interrupt vectors for the VIS instruction). The program memory is addressed by the 15-bit program counter (PC). All interrupts in the devices vector to program memory location 0FF Hex.

DATA MEMORY

The data memory address space includes the on-chip RAM and data registers, the I/O registers (Configuration, Data and Pin), the control registers, the MICROWIRE/PLUS SIO shift register, and the various registers, and counters associated with the timers (with the exception of the IDLE timer). Data memory is addressed directly by the instruction or indirectly by the B, X, SP pointers and S register.

The data memory consists of 1088 bytes of RAM. Sixteen bytes of RAM are mapped as "registers" at addresses 0F0 to 0FF Hex. These registers can be loaded immediately, and also decremented and tested with the DRSZ (decrement register and skip if zero) instruction. The memory pointer registers X, SP, B and S are memory mapped into this space at address locations 0FC to 0FF Hex respectively, with the other registers being available for general usage.

The instruction set permits any bit in memory to be set, reset or tested. All I/O and registers (except A and PC) are memory mapped; therefore, I/O bits and register bits can be directly and individually set, reset and tested. The accumulator (A) bits can also be directly and individually tested.

Note: RAM contents are undefined upon power-up.

Data Memory Segment RAM Extension

Data memory address 0FF is used as a memory mapped location for the Data Segment Address Register (S).

The data store memory is either addressed directly by a single byte address within the instruction, or indirectly relative to the reference of the B, X, or SP pointers (each contains a single-byte address). This single-byte address allows an addressing range of 256 locations from 00 to FF hex. The upper bit of this single-byte address divides the data store memory into two separate sections as outlined previously. With the exception of the RAM register memory from address locations 00F0 to 00FF, all RAM memory is memory mapped with the upper bit of the single-byte address being equal to zero. This allows the upper bit of the single-byte address to determine whether or not the base address range (from 0000 to 00FF) is extended. If this upper bit equals one (representing address range 0080 to 00FF), then address extension does not take place. Alternatively, if this upper bit equals zero, then the data segment extension register S is used to extend the base address range (from 0000 to 007F) from XX00 to XX7F, where XX represents the 8 bits from the S register. Thus the 128-byte data segment extensions are located from addresses 0100 to 017F for data segment 1, 0200 to 027F for data segment 2, etc., up to FF00 to FF7F for data segment 255. The base address range from 0000 to 007F represents data segment 0.

Figure 5 illustrates how the S register data memory extension is used in extending the lower half of the base address range (00 to 7F hex) into 256 data segments of 128 bytes each, with a total addressing range of 32 kbytes from XX00 to XX7F. This organization allows a total of 256 data segments of 128 bytes each with an additional upper base segment of 128 bytes. Furthermore, all addressing modes are available for all data segments. The S register must be changed under program control to move from one data segment (128 bytes) to another. However, the upper base segment (containing the 16 memory registers, I/O registers, control registers, etc.) is always available regardless of the contents of the S register, since the upper base segment (address range 0080 to 00FF) is independent of data segment extension.

The instructions that utilize the stack pointer (SP) always reference the stack as part of the base segment (Segment 0), regardless of the contents of the S register. The S register is not changed by these instructions. Consequently, the stack (used with subroutine linkage and interrupts) is always located in the base segment. The stack pointer will be initialized to point at data memory location 006F as a result of reset.

The 128 bytes of RAM contained in the base segment are split between the lower and upper base segments. The first 112 bytes of RAM are resident from address 0000 to 006F in the lower base segment, while the remaining 16 bytes of RAM represent the 16 data memory registers located at addresses 00F0 to 00FF of the upper base segment. No RAM is located at the upper sixteen addresses (0070 to 007F) of the lower base segment.

Additional RAM beyond these initial 128 bytes, however, will always be memory mapped in groups of 128 bytes (or less) at the data segment address extensions (XX00 to XX7F) of the lower base segment. The additional 960 bytes of RAM are memory mapped at segment 1 through segment 8 (see *Figure 5*).

*Reads as all ones.

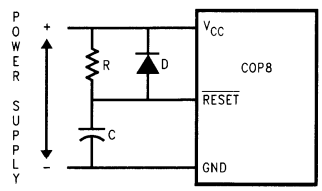
FIGURE 5. RAM Organization

Reset

The $\overline{\text{RESET}}$ input when pulled low initializes the microcontroller. Initialization will occur whenever the $\overline{\text{RESET}}$ input is pulled low. Upon initialization, the data and configuration registers for ports L, G and C are cleared, resulting in these Ports being initialized to the TRI-STATE mode. Pin G1 of the G Port is an exception (as noted below) since pin G1 is dedicated as the WATCHDOG and/or Clock Monitor error output pin. Port D is set high. The PC, PSW, ICNTRL, CNTRL, T2CNTRL and T3CNTRL control registers are cleared. The UART registers PSR, ENU (except that TBMT bit is set), ENUR and ENUI are cleared. The Comparator Select Register is cleared. The S register is initialized to zero. The Multi-Input Wakeup registers WKEN and WKEDG are cleared. Wakeup register WKPND is unknown. The stack pointer, SP, is initialized to 6F hex.

The device comes out of reset with both the WATCHDOG logic and the Clock Monitor detector armed, with the WATCHDOG service window bits set and the Clock Monitor bit set. The WATCHDOG and Clock Monitor circuits are inhibited during reset. The WATCHDOG service window bits being initialized high default to the maximum WATCHDOG service window of 64k t_C clock cycles. The Clock Monitor bit being initialized high will cause a Clock Monitor error following reset if the clock has not reached the minimum specified frequency at the termination of reset. A Clock Monitor error will cause an active low error output on pin G1. This error output will continue until 16 t_C–32 t_C clock cycles following the clock frequency reaching the minimum specified value, at which time the G1 output will enter the TRI-STATE mode.

The external RC network shown in *Figure 6* should be used to ensure that the $\overline{\text{RESET}}$ pin is held low until the power supply to the chip stabilizes.



TL/DD12829–7

FIGURE 6. Recommended Reset Circuit

Oscillator Circuits

The chip can be driven by a clock input on the CKI input pin which can be between DC and 10 MHz. The CKO output clock is on pin G7 (crystal configuration). The CKI input frequency is divided down by 10 to produce the instruction cycle clock ($1/t_C$).

Figure 7 shows the Crystal and R/C oscillator diagrams.

CRYSTAL OSCILLATOR

CKI and CKO can be connected to make a closed loop crystal (or resonator) controlled oscillator.

Table A shows the component values required for various standard crystal values.

R/C OSCILLATOR

By selecting CKI as a single pin oscillator input, a single pin R/C oscillator circuit can be connected to it. CKO is available as a general purpose input, and/or HALT restart input.

Table II shows the variation in the oscillator frequencies as functions of the component (R and C) values.

Control Registers

CNTRL Register (Address X'00EE)

The Timer1 (T1) and MICROWIRE/PLUS control register contains the following bits:

- SL1 & SL0 Select the MICROWIRE/PLUS clock divide by (00 = 2, 01 = 4, 1x = 8)
- IEDG External interrupt edge polarity select (0 = Rising edge, 1 = Falling edge)
- MSEL Selects G5 and G4 as MICROWIRE/PLUS signals SK and SO respectively
- T1C0 Timer T1 Start/Stop control in timer modes 1 and 2
  Timer T1 Underflow Interrupt Pending Flag in timer mode 3
- T1C1 Timer T1 mode control bit
- T1C2 Timer T1 mode control bit
- T1C3 Timer T1 mode control bit

T1C3	T1C2	T1C1	T1C0	MSEL	IEDG	SL1	SL0

Bit 7 Bit 0

PSW Register (Address X'00EF)

The PSW register contains the following select bits:

- GIE Global interrupt enable (enables interrupts)
- EXEN Enable external interrupt
- BUSY MICROWIRE/PLUS busy shifting flag
- EXPND External interrupt pending
- T1ENA Timer T1 Interrupt Enable for Timer Underflow or T1A Input capture edge
- T1PNDA Timer T1 Interrupt Pending Flag (Autoreload RA in mode 1, T1 Underflow in Mode 2, T1A capture edge in mode 3)
- C Carry Flag
- HC Half Carry Flag

HC	C	T1PNDA	T1ENA	EXPND	BUSY	EXEN	GIE

Bit 7 Bit 0

The Half-Carry bit is also affected by all the instructions that affect the Carry flag. The SC (Set Carry) and RC (Reset Carry) instructions will respectively set or clear both the carry flags. In addition to the SC and RC instructions, ADC, SUBC, RRC and RLC instructions affect the carry and Half Carry flags.

ICNTRL Register (Address X'00E8)

The ICNTRL register contains the following bits:

- T1ENB Timer T1 Interrupt Enable for T1B Input capture edge
- T1PNDB Timer T1 Interrupt Pending Flag for T1B capture edge
- μWEN Enable MICROWIRE/PLUS interrupt
- μWPND MICROWIRE/PLUS interrupt pending
- T0EN Timer T0 Interrupt Enable (Bit 12 toggle)
- T0PND Timer T0 Interrupt pending
- LPEN L Port Interrupt Enable (Multi-Input Wakeup/Interrupt)
  Bit 7 could be used as a flag

T2CNTRL Register (Address X'00C6)

The T2CNTRL register contains the following bits:

- T2ENB Timer T2 Interrupt Enable for T2B Input capture edge
- T2PNDB Timer T2 Interrupt Pending Flag for T2B capture edge
- T2ENA Timer T2 Interrupt Enable for Timer Underflow or T2A Input capture edge
- T2PNDA Timer T2 Interrupt Pending Flag (Autoreload RA in mode 1, T2 Underflow in mode 2, T2A capture edge in mode 3)
- T2C0 Timer T2 Start/Stop control in timer modes 1 and 2 Timer T2 Underflow Interrupt Pending Flag in timer mode 3
- T2C1 Timer T2 mode control bit
- T2C2 Timer T2 mode control bit
- T2C3 Timer T2 mode control bit

T2C3	T2C2	T2C1	T2C0	T2PNDA	T2ENA	T2PNDB	T2ENB

Bit 7 Bit 0

T3CNTRL Register (Address X'00B6)

The T3CNTRL register contains the following bits:

- T3ENB Timer T3 Interrupt Enable for T3B Input capture edge
- T3PNDB Timer T3 Interrupt Pending Flag for T3B capture edge
- T3ENA Timer T3 Interrupt Enable for Timer Underflow or T3A Input capture edge
- T3PNDA Timer T3 Interrupt Pending Flag (Autoreload RA in mode 1, T3 Underflow in mode 2, T3A capture edge in mode 3)
- T3C0 Timer T3 Start/Stop control in timer modes 1 and 2
  Timer T3 Underflow Interrupt Pending Flag in timer mode 3
- T3C1 Timer T3 mode control bit
- T3C2 Timer T3 mode control bit
- T3C3 Timer T3 mode control bit

Bit 7 Bit 0

Timers

The device contains a very versatile set of timers (T0, T1, T2, T3). All timers and associated autoreload/capture registers power up containing random data.

TIMER T0 (IDLE TIMER)

The device supports applications that require maintaining real time and low power with the IDLE mode. This IDLE mode support is furnished by the IDLE timer T0, which is a 16-bit timer. The Timer T0 runs continuously at the fixed rate of the instruction cycle clock, t_C. The user cannot read or write to the IDLE Timer T0, which is a count down timer.

The Timer T0 supports the following functions:

- Exit out of the Idle Mode (See Idle Mode description)
- WATCHDOG logic (See WATCHDOG description)
- Start up delay out of the HALT mode

The IDLE Timer T0 can generate an interrupt when the thirteenth bit toggles. This toggle is latched into the T0PND pending flag, and will occur every 4 ms at the maximum clock frequency (t_C = 1 μs). A control flag T0EN allows the interrupt from the thirteenth bit of Timer T0 to be enabled or disabled. Setting T0EN will enable the interrupt, while resetting it will disable the interrupt.

TIMER T1, TIMER T2 AND TIMER T3

The device has a set of three powerful timer/counter blocks, T1, T2 and T3. The associated features and functioning of a timer block are described by referring to the timer block Tx. Since the three timer blocks, T1, T2 and T3 are identical, all comments are equally applicable to any of the three timer blocks.

Each timer block consists of a 16-bit timer, Tx, and two supporting 16-bit autoreload/capture registers, RxA and RxB. Each timer block has two pins associated with it, TxA and TxB. The pin TxA supports I/O required by the timer block, while the pin TxB is an input to the timer block. The powerful and flexible timer block allows the device to easily perform all timer functions with minimal software overhead. The timer block has three operating modes: Processor Independent PWM mode, External Event Counter mode, and Input Capture mode.

The control bits TxC3, TxC2, and TxC1 allow selection of the different modes of operation.

Mode 1. Processor Independent PWM Mode

As the name suggests, this mode allows the device to generate a PWM signal with very minimal user intervention. The user only has to define the parameters of the PWM signal (ON time and OFF time). Once begun, the timer block will continuously generate the PWM signal completely independent of the microcontroller. The user software services the timer block only when the PWM parameters require updating.

In this mode the timer Tx counts down at a fixed rate of t_C. Upon every underflow the timer is alternately reloaded with the contents of supporting registers, RxA and RxB. The very first underflow of the timer causes the timer to reload from the register RxA. Subsequent underflows cause the timer to be reloaded from the registers alternately beginning with the register RxB.

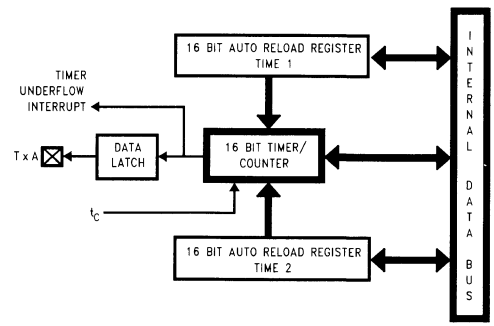
The Tx Timer control bits, TxC3, TxC2 and TxC1 set up the timer for PWM mode operation.

Figure 8 shows a block diagram of the timer in PWM mode.

The underflows can be programmed to toggle the TxA output pin. The underflows can also be programmed to generate interrupts.

Underflows from the timer are alternately latched into two pending flags, TxPNDA and TxPNDB. The user must reset these pending flags under software control. Two control enable flags, TxENA and TxENB, allow the interrupts from the timer underflow to be enabled or disabled. Setting the timer enable flag TxENA will cause an interrupt when a timer underflow causes the RxA register to be reloaded into the timer. Setting the timer enable flag TxENB will cause an interrupt when a timer underflow causes the RxB register to be reloaded into the timer. Resetting the timer enable flags will disable the associated interrupts.

Either or both of the timer underflow interrupts may be enabled. This gives the user the flexibility of interrupting once per PWM period on either the rising or falling edge of the PWM output. Alternatively, the user may choose to interrupt on both edges of the PWM output.



TL/DD/12829–10

FIGURE 8. Timer in PWM Mode

Mode 2. External Event Counter Mode

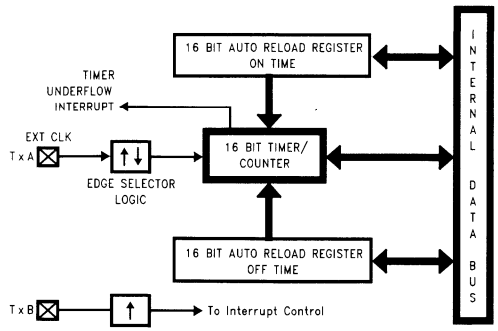
This mode is quite similar to the processor independent PWM mode described above. The main difference is that the timer, Tx, is clocked by the input signal from the TxA pin. The Tx timer control bits, TxC3, TxC2 and TxC1 allow the timer to be clocked either on a positive or negative edge from the TxA pin. Underflows from the timer are latched into the TxPNDA pending flag. Setting the TxENA control flag will cause an interrupt when the timer underflows.

In this mode the input pin TxB can be used as an independent positive edge sensitive interrupt input if the TxENB control flag is set. The occurrence of a positive edge on the TxB input pin is latched into the TxPNDB flag.

Timers (Continued)

Figure 9 shows a block diagram of the timer in External Event Counter mode.

Note: The PWM output is not available in this mode since the TxA pin is being used as the counter input clock.



TL/DD12829–11

FIGURE 9. Timer in External Event Counter Mode

Mode 3. Input Capture Mode

The device can precisely measure external frequencies or time external events by placing the timer block, Tx, in the input capture mode.

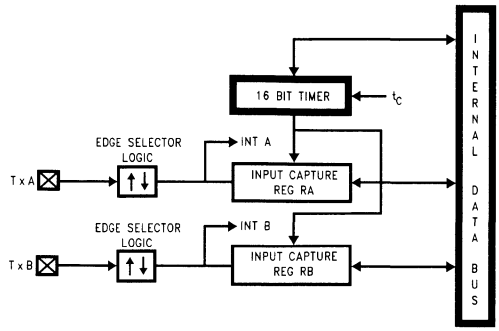
In this mode, the timer Tx is constantly running at the fixed t_C rate. The two registers, RxA and RxB, act as capture registers. Each register acts in conjunction with a pin. The register RxA acts in conjunction with the TxA pin and the register RxB acts in conjunction with the TxB pin.

The timer value gets copied over into the register when a trigger event occurs on its corresponding pin. Control bits, TxC3, TxC2 and TxC1, allow the trigger events to be specified either as a positive or a negative edge. The trigger condition for each input pin can be specified independently.

The trigger conditions can also be programmed to generate interrupts. The occurrence of the specified trigger condition on the TxA and TxB pins will be respectively latched into the pending flags, TxPNDA and TxPNDB. The control flag TxENA allows the interrupt on TxA to be either enabled or disabled. Setting the TxENA flag enables interrupts to be generated when the selected trigger condition occurs on the TxA pin. Similarly, the flag TxENB controls the interrupts from the TxB pin.

Underflows from the timer can also be programmed to generate interrupts. Underflows are latched into the timer TxC0 pending flag (the TxC0 control bit serves as the timer underflow interrupt pending flag in the Input Capture mode). Consequently, the TxC0 control bit should be reset when entering the Input Capture mode. The timer underflow interrupt is enabled with the TxENA control flag. When a TxA interrupt occurs in the Input Capture mode, the user must check both the TxPNDA and TxC0 pending flags in order to determine whether a TxA input capture or a timer underflow (or both) caused the interrupt.

Figure 10 shows a block diagram of the timer in Input Capture mode.



TL/DD12829–12

FIGURE 10. Timer in Input Capture Mode

TIMER CONTROL FLAGS

The timers T1, T2 and T3 have indentical control structures. The control bits and their functions are summarized below.

TxC0	Timer Start/Stop control in Modes 1 and 2 (Processor Independent PWM and External Event Counter), where 1 = Start, 0 = Stop Timer Underflow Interrupt Pending Flag in Mode 3 (Input Capture)
TxPNDA	Timer Interrupt Pending Flag
TxPNDB	Timer Interrupt Pending Flag
TxENA	Timer Interrupt Enable Flag
TxENB	Timer Interrupt Enable Flag 1 = Timer Interrupt Enabled 0 = Timer Interrupt Disabled
TxC3	Timer mode control
TxC2	Timer mode control
TxC1	Timer mode control

Timers (Continued)

The timer mode control bits (TxC3, TxC2 and TxC1) are detailed below:

TxC3	TxC2	TxC1	Timer Mode	Interrupt A Source	Interrupt B Source	Timer Counts On
0	0	0	MODE 2 (External Event Counter)	Timer Underflow	Pos. TxB Edge	TxA Pos. Edge
0	0	1	MODE 2 (External Event Counter)	Timer Underflow	Pos. TxB Edge	TxA Neg. Edge
1	0	1	MODE 1 (PWM) TxA Toggle	Autoreload RA	Autoreload RB	t_C
1	0	0	MODE 1 (PWM) No TxA Toggle	Autoreload RA	Autoreload RB	t_C
0	1	0	MODE 3 (Capture) Captures: TxA Pos. Edge TxB Pos. Edge	Pos. TxA Edge or Timer Underflow	Pos. TxB Edge	t_C
1	1	0	MODE 3 (Capture) Captures: TxA Pos. Edge TxB Neg. Edge	Pos. TxA Edge or Timer Underflow	Neg. TxB Edge	t_C
0	1	1	MODE 3 (Capture) Captures: TxA Neg. Edge TxB Pos. Edge	Neg. TxA Edge or Timer Underflow	Pos. TxB Edge	t_C
1	1	1	MODE 3 (Capture) Captures: TxA Neg. Edge TxB Neg. Edge	Neg. TxA Edge or Timer Underflow	Neg. TxB Edge	t_C

Power Save Modes

The device offers the user two power save modes of operation: HALT and IDLE. In the HALT mode, all microcontroller activities are stopped. In the IDLE mode, the on-board oscillator circuitry and timer T0 are active but all other microcontroller activities are stopped. In either mode, all on-board RAM, registers, I/O states, and timers (with the exception of T0) are unaltered.

HALT MODE

The device can be placed in the HALT mode by writing a "1" to the HALT flag (G7 data bit). All microcontroller activities, including the clock and timers, are stopped. The WATCHDOG logic on the device is disabled during the HALT mode. However, the clock monitor circuitry if enabled remains active and will cause the WATCHDOG output pin (WDOUT) to go low. If the HALT mode is used and the user does not want to activate the WDOUT pin, the Clock Monitor should be disabled after the device comes out of reset (resetting the Clock Monitor control bit with the first write to the WDSVR register). In the HALT mode, the power requirements of the device are minimal and the applied voltage (V_{CC}) may be decreased to V_r (V_r = 2.0V) without altering the state of the machine.

The device supports three different ways of exiting the HALT mode. The first method of exiting the HALT mode is with the Multi-Input Wakeup feature on the L port. The second method is with a low to high transition on the CKO (G7) pin. This method precludes the use of the crystal clock configuration (since CKO becomes a dedicated output), and so may only be used with an RC clock configuration. The third method of exiting the HALT mode is by pulling the $\overline{\text{RESET}}$ pin low.

Since a crystal or ceramic resonator may be selected as the oscillator, the Wakeup signal is not allowed to start the chip running immediately since crystal oscillators and ceramic resonators have a delayed start up time to reach full amplitude and frequency stability. The IDLE timer is used to generate a fixed delay to ensure that the oscillator has indeed stabilized before allowing instruction execution. In this case, upon detecting a valid Wakeup signal, only the oscillator circuitry is enabled. The IDLE timer is loaded with a value of 256 and is clocked with the t_C instruction cycle clock. The t_C clock is derived by dividing the oscillator clock down by a factor of 10. The Schmitt trigger following the CKI inverter on the chip ensures that the IDLE timer is clocked only when the oscillator has a sufficiently large amplitude to meet the Schmitt trigger specifications. This Schmitt trigger is not part of the oscillator closed loop. The startup timeout from the IDLE timer enables the clock signals to be routed to the rest of the chip.

If an RC clock option is being used, the fixed delay is introduced optionally. A control bit, CLKDLY, mapped as configuration bit G7, controls whether the delay is to be introduced or not. The delay is included if CLKDLY is set, and excluded if CLKDLY is reset. The CLKDLY bit is cleared on reset.

Power Save Modes (Continued)

The device has two mask options associated with the HALT mode. The first mask option enables the HALT mode feature, while the second mask option disables the HALT mode. With the HALT mode enable mask option, the device will enter and exit the HALT mode as described above. With the HALT disable mask option, the device cannot be placed in the HALT mode (writing a "1" to the HALT flag will have no effect, the HALT flag will remain "0").

IDLE MODE

The device is placed in the IDLE mode by writing a "1" to the IDLE flag (G6 data bit). In this mode, all activities, except the associated on-board oscillator circuitry and the IDLE Timer T0, are stopped. The power supply requirements of the micro-controller in this mode of operation are typically around 30% of normal power requirement of the microcontroller.

As with the HALT mode, the device can be returned to normal operation with a reset, or with a Multi-Input Wakeup from the L Port. Alternately, the microcontroller resumes normal operation from the IDLE mode when the thirteenth bit (representing 4.096 ms at internal clock frequency of 10 MHz, t_C = 1 μs) of the IDLE Timer toggles.

This toggle condition of the thirteenth bit of the IDLE Timer T0 is latched into the T0PND pending flag.

The user has the option of being interrupted with a transition on the thirteenth bit of the IDLE Timer T0. The interrupt can be enabled or disabled via the T0EN control bit. Setting the T0EN flag enables the interrupt and vice versa.

The user can enter the IDLE mode with the Timer T0 interrupt enabled. In this case, when the T0PND bit gets set, the device will first execute the Timer T0 interrupt service routine and then return to the instruction following the "Enter Idle Mode" instruction.

Alternatively, the user can enter the IDLE mode with the IDLE Timer T0 interrupt disabled. In this case, the device will resume normal operation with the instruction immediately following the "Enter IDLE Mode" instruction.

Note: It is necessary to program two NOP instructions following both the set HALT mode and set IDLE mode instructions. These NOP instructions are necessary to allow clock resynchronization following the HALT or IDLE modes.

Multi-Input Wakeup

The Multi-Input Wakeup feature is ued to return (wakeup) the device from either the HALT or IDLE modes. Alternately Multi-Input Wakeup/Interrupt feature may also be used to generate up to 8 edge selectable external interrupts.

Figure 11 shows the Multi-Input Wakeup logic.

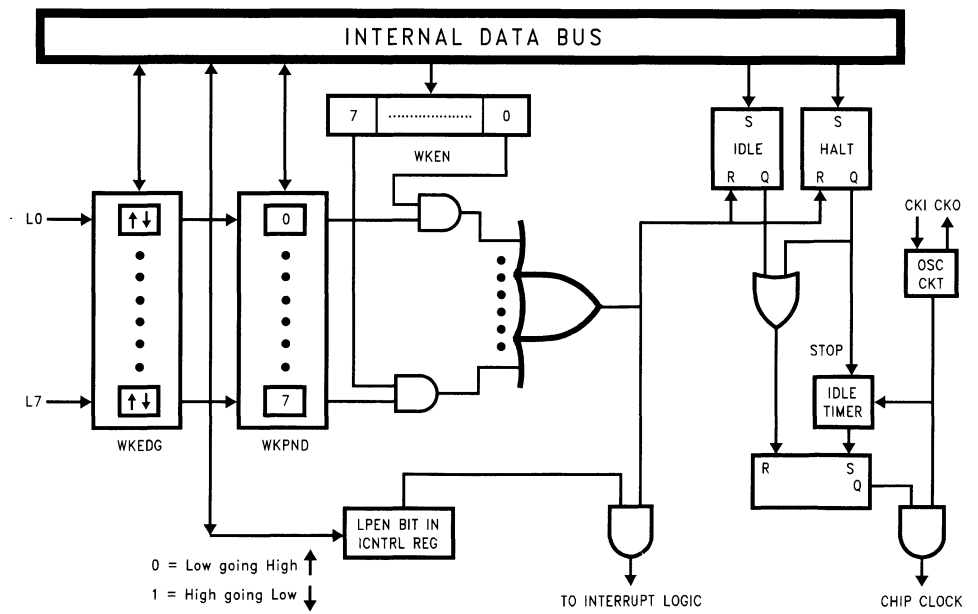


FIGURE 11. Multi-Input Wake Up Logic

Multi-Input Wakeup (Continued)

The Multi-Input Wakeup feature utilizes the L Port. The user selects which particular L port bit (or combination of L Port bits) will cause the device to exit the HALT or IDLE modes. The selection is done through the Register WKEN. The Register WKEN is an 8-bit read/write register, which contains a control bit for every L port bit. Setting a particular WKEN bit enables a Wakeup from the associated L port pin.

The user can select whether the trigger condition on the selected L Port pin is going to be either a positive edge (low to high transition) or a negative edge (high to low transition). This selection is made via the Register WKEDG, which is an 8-bit control register with a bit assigned to each L Port pin. Setting the control bit will select the trigger condition to be a negative edge on that particular L Port pin. Resetting the bit selects the trigger condition to be a positive edge. Changing an edge select entails several steps in order to avoid a Wakeup condition as a result of the edge change. First, the associated WKEN bit should be reset, followed by the edge select change in WKEDG. Next, the associated WKPND bit should be cleared, followed by the associated WKEN bit being re-enabled.

An example may serve to clarify this procedure. Suppose we wish to change the edge select from positive (low going high) to negative (high going low) for L Port bit 5, where bit 5 has previously been enabled for an input interrupt. The program would be as follows:

```
RBIT  5, WKEN      ; Disable Port bit 5 for
                   ; Wakeup
SBIT  5, WKEDG     ; Select neg going edge
                   ; sensitivity
RBIT  5, WKPND     ; Clear pending bit
SBIT  5, WKEN      ; Re-enable the bit for
                   ; Wakeup
```

If the L port bits have been used as outputs and then changed to inputs with Multi-Input Wakeup/Interrupt, a safety procedure should also be followed to avoid wakeup conditions. After the selected L port bits have been changed from output to input but before the associated WKEN bits are enabled, the associated edge select bits in WKEDG should be set or reset for the desired edge selects, followed by the associated WKPND bits being cleared.

This same procedure should be used following reset, since the L port inputs are left floating as a result of reset.

The occurrence of the selected trigger condition for Multi-Input Wakeup is latched into a pending register called WKPND. The respective bits of the WKPND register will be set on the occurrence of the selected trigger edge on the corresponding Port L pin. The user has the responsibility of clearing these pending flags. Since WKPND is a pending register for the occurrence of selected wakeup conditions, the device will not enter the HALT mode if any Wakeup bit is both enabled and pending. Consequently, the user must clear the pending flags before attempting to enter the HALT mode.

WKEN, WKPND and WKEDG are all read/write registers, and are cleared at reset.

PORT L INTERRUPTS

Port L provides the user with an additional eight fully selectable, edge sensitive interrupts which are all vectored into the same service subroutine.

The interrupt from Port L shares logic with the wake up circuitry. The register WKEN allows interrupts from Port L to be individually enabled or disabled. The register WKEDG specifies the trigger condition to be either a positive or a negative edge. Finally, the register WKPND latches in the pending trigger conditions.

The GIE (Global Interrupt Enable) bit enables the interrupt function.

A control flag, LPEN, functions as a global interrupt enable for Port L interrupts. Setting the LPEN flag will enable interrupts and vice versa. A separate global pending flag is not needed since the register WKPND is adequate.

Since Port L is also used for waking the device out of the HALT or IDLE modes, the user can elect to exit the HALT or IDLE modes either with or without the interrupt enabled. If he elects to disable the interrupt, then the device will restart execution from the instruction immediately following the instruction that placed the microcontroller in the HALT or IDLE modes. In the other case, the device will first execute the interrupt service routine and then revert to normal operation. (See HALT MODE for clock option wakeup information.)

UART

The device contains a full-duplex software programmable UART. The UART *(Figure 12)* consists of a transmit shift register, a receive shift register and seven addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR), a UART interrupt and clock source register (ENUI), a prescaler select register (PSR) and baud (BAUD) register. The ENU register contains flags for transmit and receive functions; this register also determines the length of the data frame (7, 8 or 9 bits), the value of the ninth bit in transmission, and parity selection bits. The ENUR register flags framing, data overrun and parity errors while the UART is receiving.

Other functions of the ENUR register include saving the ninth bit received in the data frame, enabling or disabling the UART's attention mode of operation and providing additional receiver/transmitter status information via RCVG and XMTG bits. The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits and enabling or disabling transmit and receive interrupts. A control flag in this register can also select the UART mode of operation: asynchronous or synchronous.

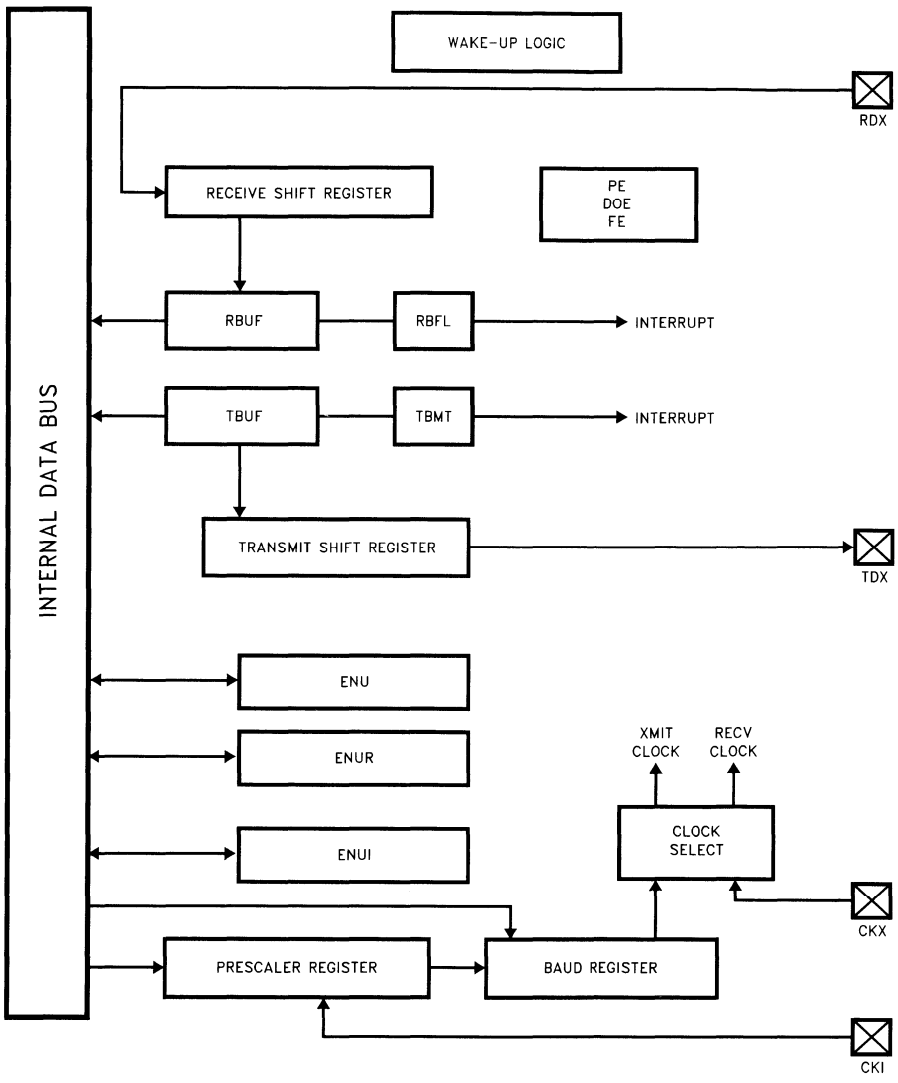

FIGURE 12. UART Block Diagram

UART (Continued)

UART CONTROL AND STATUS REGISTERS

The operation of the UART is programmed through three registers: ENU, ENUR and ENUI. The function of the individual bits in these registers is as follows:

ENUI-UART Interrupt and Clock Source Register (Address at 0BC)

STP2	STP78	ETDX	SSEL	XRCLK	XTCLK	ERI	ETI
0RW	0RW	0RW	0RW	0RW	0RW	0RW	0RW

Bit7 Bit0

*Bit is not used.

0 Bit is cleared on reset.

1 Bit is set to one on reset.

R Bit is read-only; it cannot be written by software.

RW Bit is read/write.

D Bit is cleared on read; when read by software as a one, it is cleared automatically. Writing to the bit does not affect its state.

DESCRIPTION OF UART REGISTER BITS

ENU—UART CONTROL AND STATUS REGISTER

TBMT: This bit is set when the UART transfers a byte of data from the TBUF register into the TSFT register for transmission. It is automatically reset when software writes into the TBUF register.

RBFL: This bit is set when the UART has received a complete character and has copied it into the RBUF register. It is automatically reset when software reads the character from RBUF.

ERR: This bit is a global UART error flag which gets set if any or a combination of the errors (DOE, FE, PE) occur.

CHL1, CHL0: These bits select the character frame format. Parity is not included and is generated/verified by hardware.

CHL1 = 0, CHL0 = 0 The frame contains eight data bits.
CHL1 = 0, CHL0 = 1 The frame contains seven data bits.
CHL1 = 1, CHL0 = 0 The frame contains nine data bits.
CHL1 = 1, CHL0 = 1 Loopback Mode selected. Transmitter output internally looped back to receiver input. Nine bit framing format is used.

XBIT9/PSEL0: Programs the ninth bit for transmission when the UART is operating with nine data bits per frame. For seven or eight data bits per frame, this bit in conjunction with PSEL1 selects parity.

PSEL1, PSEL0: Parity select bits.

PSEL1 = 0, PSEL0 = 0 Odd Parity (if Parity enabled)
PSEL1 = 0, PSEL0 = 1 Odd Parity (if Parity enabled)
PSEL1 = 1, PSEL0 = 0 Mark(1) (if Parity enabled)
PSEL1 = 1, PSEL0 = 1 Space(0) (if Parity enabled)

PEN: This bit enables/disables Parity (7- and 8-bit modes only).

PEN = 0 Parity disabled.
PEN = 1 Parity enabled.

ENUR—UART RECEIVE CONTROL AND STATUS REGISTER

RCVG: This bit is set high whenever a framing error occurs and goes low when RDX goes high.

XMTG: This bit is set to indicate that the UART is transmitting. It gets reset at the end of the last frame (end of last Stop bit).

ATTN: ATTENTION Mode is enabled while this bit is set. This bit is cleared automatically on receiving a character with data bit nine set.

RBIT9: Contains the ninth data bit received when the UART is operating with nine data bits per frame.

SPARE: Reserved for future use.

PE: Flags a Parity Error.

PE = 0 Indicates no Parity Error has been detected since the last time the ENUR register was read.
PE = 1 Indicates the occurrence of a Parity Error.

FE: Flags a Framing Error.

FE = 0 Indicates no Framing Error has been detected since the last time the ENUR register was read.
FE = 1 Indicates the occurrence of a Framing Error.

DOE: Flags a Data Overrun Error.

DOE = 0 Indicates no Data Overrun Error has been detected since the last time the ENUR register was read.
DOE = 1 Indicates the occurrence of a Data Overrun Error.

ENUI—UART INTERRUPT AND CLOCK SOURCE REGISTER

ETI: This bit enables/disables interrupt from the transmitter section.

ETI = 0 Interrupt from the transmitter is disabled.
ETI = 1 Interrupt from the transmitter is enabled.

ERI: This bit enables/disables interrupt from the receiver section.

ERI = 0 Interrupt from the receiver is disabled.
ERI = 1 Interrupt from the receiver is enabled.

XTCLK: This bit selects the clock source for the transmitter section.

XTCLK = 0 The clock source is selected through the PSR and BAUD registers.
XTCLK = 1 Signal on CKX (L1) pin is used as the clock.

XRCLK: This bit selects the clock source for the receiver section.

XRCLK = 0 The clock source is selected through the PSR and BAUD registers.
XRCLK = 1 Signal on CKX (L1) pin is used as the clock.

SSEL: UART mode select.

SSEL = 0 Asynchronous Mode.
SSEL = 1 Synchronous Mode.

UART (Continued)

ETDX: TDX (UART Transmit Pin) is the alternate function assigned to Port L pin L2; it is selected by setting ETDX bit. To simulate line break generation, software should reset ETDX bit and output logic zero to TDX pin through Port L data and configuration registers.

STP78: This bit is set to program the last Stop bit to be 7/8th of a bit in length.

STP2: This bit programs the number of Stop bits to be transmitted.

STP2 = 0 One Stop bit transmitted.
STP2 = 1 Two Stop bits transmitted.

Associated I/O Pins

Data is transmitted on the TDX pin and received on the RDX pin. TDX is the alternate function assigned to Port L pin L2; it is selected by setting ETDX (in the ENUI register) to one. RDX is an inherent function of Port L pin L3, requiring no setup.

The baud rate clock for the UART can be generated on-chip, or can be taken from an external source. Port L pin L1 (CKX) is the external clock I/O pin. The CKX pin can be either an input or an output, as determined by Port L Configuration and Data registers (Bit 1). As an input, it accepts a clock signal which may be selected to drive the transmitter and/or receiver. As an output, it presents the internal Baud Rate Generator output.

UART Operation

The UART has two modes of operation: asynchronous mode and synchronous mode.

ASYNCHRONOUS MODE

This mode is selected by resetting the SSEL (in the ENUI register) bit to zero. The input frequency to the UART is 16 times the baud rate.

The TSFT and TBUF registers double-buffer data for transmission. While TSFT is shifting out the current character on the TDX pin, the TBUF register may be loaded by software with the next byte to be transmitted. When TSFT finishes transmitting the current character the contents of TBUF are transferred to the TSFT register and the Transmit Buffer Empty Flag (TBMT in the ENU register) is set. The TBMT flag is automatically reset by the UART when software loads a new character into the TBUF register. There is also the XMTG bit which is set to indicate that the UART is transmitting. This bit gets reset at the end of the last frame (end of last Stop bit). TBUF is a read/write register.

The RSFT and RBUF registers double-buffer data being received. The UART receiver continually monitors the signal on the RDX pin for a low level to detect the beginning of a Start bit. Upon sensing this low level, it waits for half a bit time and samples again. If the RDX pin is still low, the receiver considers this to be a valid Start bit, and the remaining bits in the character frame are each sampled a single time, at the mid-bit position. Serial data input on the RDX pin is shifted into the RSFT register. Upon receiving the complete character, the contents of the RSFT register are copied into the RBUF register and the Received Buffer Full Flag (RBFL) is set. RBFL is automatically reset when software reads the character from the RBUF register. RBUF is a read only register. There is also the RCVG bit which is set high when a framing error occurs and goes low once RDX goes high. TBMT, XMTG, RBFL and RCVG are read only bits.

SYNCHRONOUS MODE

In this mode data is transferred synchronously with the clock. Data is transmitted on the rising edge and received on the falling edge of the synchronous clock.

This mode is selected by setting SSEL bit in the ENUI register. The input frequency to the UART is the same as the baud rate.

When an external clock input is selected at the CKX pin, data transmit and receive are performed synchronously with this clock through TDX/RDX pins.

If data transmit and receive are selected with the CKX pin as clock output, the device generates the synchronous clock output at the CKX pin. The internal baud rate generator is used to produce the synchronous clock. Data transmit and receive are performed synchronously with this clock.

FRAMING FORMATS

The UART supports several serial framing formats *(Figure 13).* The format is selected using control bits in the ENU, ENUR and ENUI registers.

The first format (1, 1a, 1b, 1c) for data transmission (CHL0 = 1, CHL1 = 0) consists of Start bit, seven Data bits (excluding parity) and 7/8, one or two Stop bits. In applications using parity, the parity bit is generated and verified by hardware.

The second format (CHL0 = 0, CHL1 = 0) consists of one Start bit, eight Data bits (excluding parity) and 7/8, one or two Stop bits. Parity bit is generated and verified by hardware.

The third format for transmission (CHL0 = 0, CHL1 = 1) consists of one Start bit, nine Data bits and 7/8, one or two Stop bits. This format also supports the UART "ATTENTION" feature. When operating in this format, all eight bits of TBUF and RBUF are used for data. The ninth data bit is transmitted and received using two bits in the ENU and ENUR registers, called XBIT9 and RBIT9. RBIT9 is a read only bit. Parity is not generated or verified in this mode.

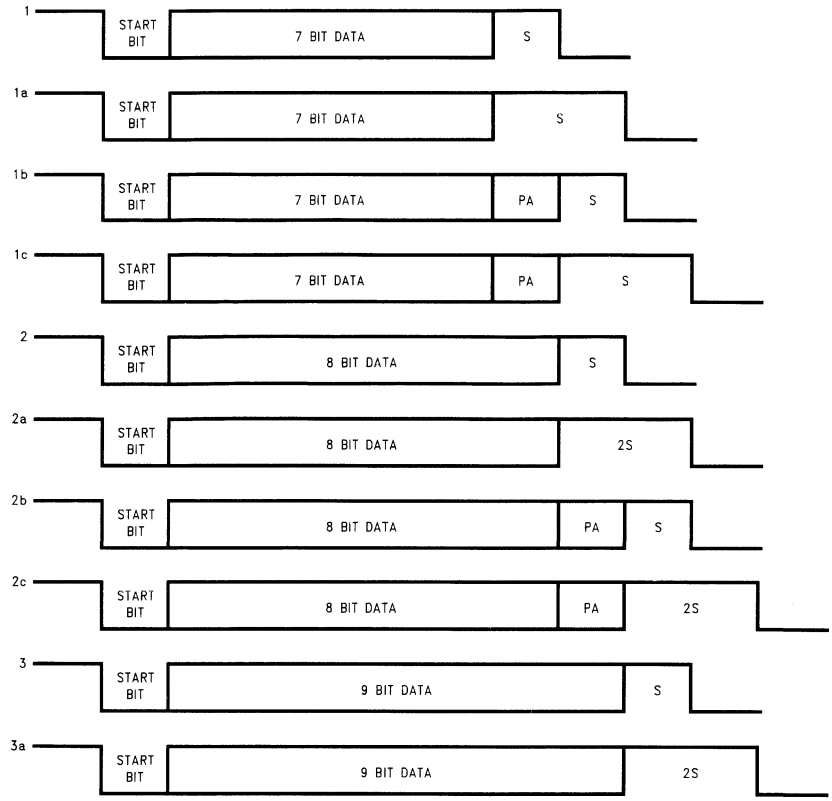
For any of the above framing formats, the last Stop bit can be programmed to be 7/8th of a bit in length. If two Stop bits are selected and the 7/8th bit is set (selected), the second Stop bit will be 7/8th of a bit in length.

The parity is enabled/disabled by PEN bit located in the ENU register. Parity is selected for 7- and 8-bit modes only. If parity is enabled (PEN = 1), the parity selection is then performed by PSEL0 and PSEL1 bits located in the ENU register.

Note that the XBIT9/PSEL0 bit located in the ENU register serves two mutually exclusive functions. This bit programs the ninth bit for transmission when the UART is operating with nine data bits per frame. There is no parity selection in this framing format. For other framing formats XBIT9 is not needed and the bit is PSEL0 used in conjunction with PSEL1 to select parity.

The frame formats for the receiver differ from the transmitter in the number of Stop bits required. The receiver only requires one Stop bit in a frame, regardless of the setting of the Stop bit selection bits in the control register. Note that an implicit assumption is made for full duplex UART operation that the framing formats are the same for the transmitter and receiver.

UART Operation (Continued)



TL/DD12829–15

FIGURE 13. Framing Formats

UART INTERRUPTS

The UART is capable of generating interrupts. Interrupts are generated on Receive Buffer Full and Transmit Buffer Empty. Both interrupts have individual interrupt vectors. Two bytes of program memory space are reserved for each interrupt vector. The two vectors are located at addresses 0xEC to 0xEF Hex in the program memory space. The interrupts can be individually enabled or disabled using Enable Transmit Interrupt (ETI) and Enable Receive Interrupt (ERI) bits in the ENUI register.

The interrupt from the Transmitter is set pending, and remains pending, as long as both the TBMT and ETI bits are set. To remove this interrupt, software must either clear the ETI bit or write to the TBUF register (thus clearing the TBMT bit).

The interrupt from the receiver is set pending, and remains pending, as long as both the RBFL and ERI bits are set. To remove this interrupt, software must either clear the ERI bit or read from the RBUF register (thus clearing the RBFL bit).

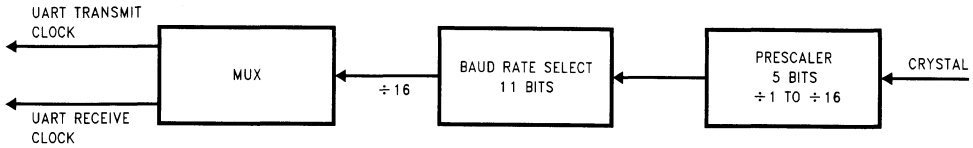
Baud Clock Generation

The clock inputs to the transmitter and receiver sections of the UART can be individually selected to come either from an external source at the CKX pin (port L, pin L1) or from a source selected in the PSR and BAUD registers. Internally, the basic baud clock is created from the oscillator frequency through a two-stage divider chain consisting of a 1–16 (increments of 0.5) prescaler and an 11-bit binary counter. *(Figure 14).* The divide factors are specified through two read/write registers shown in *Figure 15*. Note that the 11-bit Baud Rate Divisor spills over into the Prescaler Select Register (PSR). PSR is cleared upon reset.

As shown in Table V, a Prescaler Factor of 0 corresponds to NO CLOCK. This condition is the UART power down mode where the UART clock is turned off for power saving purpose. The user must also turn the UART clock off when a different baud rate is chosen.

The correspondences between the 5-bit Prescaler Select and Prescaler factors are shown in Table V. There are many ways to calculate the two divisor factors, but one particularly effective method would be to achieve a 1.8432 MHz frequency coming out of the first stage. The 1.8432 MHz prescaler output is then used to drive the software programmable baud rate counter to create a 16x clock for the following baud rates: 110, 134.5, 150, 300, 600, 1200, 1800, 2400, 3600, 4800, 7200, 9600, 19200 and 38400 (Table I). Other baud rates may be created by using appropriate divisors. The 16x clock is then divided by 16 to provide the rate for the serial shift registers of the transmitter and receiver.

Baud Clock Generation (Continued)



TL/DD12829–16

FIGURE 14. UART BAUD Clock Generation

FIGURE 15. UART BAUD Clock Divisor Registers

Baud Clock Generation (Continued)

TABLE III. Baud Rate Divisors (1.8432 MHz Prescaler Output)

Baud Rate	Baud Rate Divisor − 1 (N-1)
110 (110.03)	1046
134.5 (134.58)	855
150	767
300	383
600	191
1200	95
1800	63
2400	47
3600	31
4800	23
7200	15
9600	11
19200	5
38400	2

Note: The entries in Table IV assume a prescaler output of 1.8432 MHz. In the asynchronous mode the baud rate could be as high as 625k.

TABLE IV. Prescaler Factors

Prescaler Select	Prescaler Factor
00000	NO CLOCK
00001	1
00010	1.5
00011	2
00100	2.5
00101	3
00110	3.5
00111	4
01000	4.5
01001	5
01010	5.5
01011	6
01100	6.5
01101	7
01110	7.5
01111	8
10000	8.5
10001	9
10010	9.5
10011	10
10100	10.5
10101	11
10110	11.5
10111	12
11000	12.5
11001	13
11010	13.5
11011	14
11100	14.5
11101	15
11110	15.5
11111	16

As an example, considering Asynchronous Mode and a CKI clock of 4.608 MHz, the prescaler factor selected is:

$$4.608/1.8432 = 2.5$$

The 2.5 entry is available in Table IV. The 1.8432 MHz prescaler output is then used with proper Baud Rate Divisor (Table V) to obtain different baud rates. For a baud rate of 19200 e.g., the entry in Table IV is 5.

$N - 1 = 5$ ($N - 1$ is the value from Table III)

$N = 6$ (N is the Baud Rate Divisor)

$$\text{Baud Rate} = 1.8432\ \text{MHz}/(16 \times 6) = 19200$$

The divide by 16 is performed because in the asynchronous mode, the input frequency to the UART is 16 times the baud rate. The equation to calculate baud rates is given below.

The actual Baud Rate may be found from:

$$BR = Fc/(16 \times N \times P)$$

Baud Clock Generation (Continued)

Where:

BR is the Baud Rate

Fc is the CKI frequency

N is the Baud Rate Divisor (Table IV).

P is the Prescaler Divide Factor selected by the value in the Prescaler Select Register (Table III)

Note: In the Synchronous Mode, the divisor 16 is replaced by two.

Example:

Asynchronous Mode:

Crystal Frequency = 5 MHz

Desired baud rate = 9600

Using the above equation N × P can be calculated first.

$$N \times P = (5 \times 106)/(16 \times 9600) = 32.552$$

Now 32.552 is divided by each Prescaler Factor (Table III) to obtain a value closest to an integer. This factor happens to be 6.5 (P = 6.5).

$$N = 32.552/6.5 = 5.008\ (N = 5)$$

The programmed value (from Table III) should be 4 (N − 1).

Using the above values calculated for N and P:

$$BR = (5 \times 106)/(16 \times 5 \times 6.5) = 9615.384$$

$$\%\ \text{error} = (9615.385 - 9600)/9600 = 0.16$$

Effect of HALT/IDLE

The UART logic is reinitialized when either the HALT or IDLE modes are entered. This reinitialization sets the TBMT flag and resets all read only bits in the UART control and status registers. Read/Write bits remain unchanged. The Transmit Buffer (TBUF) is not affected, but the Transmit Shift register (TSFT) bits are set to one. The receiver registers RBUF and RSFT are not affected.

The device will exit from the HALT/IDLE modes when the Start bit of a character is detected at the RDX (L3) pin. This feature is obtained by using the Multi-Input Wakeup scheme provided on the device.

Before entering the HALT or IDLE modes the user program must select the Wakeup source to be on the RDX pin. This selection is done by setting bit 3 of WKEN (Wakeup Enable) register. The Wakeup trigger condition is then selected to be high to low transition. This is done via the WKEDG register (Bit 3 is one.)

If the device is halted and crystal oscillator is used, the Wakeup signal will not start the chip running immediately because of the finite start up time requirement of the crystal oscillator. The idle timer (T0) generates a fixed (256 t_c) delay to ensure that the oscillator has indeed stabilized before allowing the device to execute code. The user has to consider this delay when data transfer is expected immediately after exiting the HALT mode.

Diagnostic

Bits CHARL0 and CHARL1 in the ENU register provide a loopback feature for diagnostic testing of the UART. When these bits are set to one, the following occur: The receiver input pin (RDX) is internally connected to the transmitter output pin (TDX); the output of the Transmitter Shift Register is "looped back" into the Receive Shift Register input. In this mode, data that is transmitted is immediately received. This feature allows the processor to verify the transmit and receive data paths of the UART.

Note that the framing format for this mode is the nine bit format; one Start bit, nine data bits, and 7/8, one or two Stop bits. Parity is not generated or verified in this mode.

Attention Mode

The UART Receiver section supports an alternate mode of operation, referred to as ATTENTION Mode. This mode of operation is selected by the ATTN bit in the ENUR register. The data format for transmission must also be selected as having nine Data bits and either 7/8, one or two Stop bits.

The ATTENTION mode of operation is intended for use in networking the device with other processors. Typically in such environments the messages consists of device addresses, indicating which of several destinations should receive them, and the actual data. This Mode supports a scheme in which addresses are flagged by having the ninth bit of the data field set to a 1. If the ninth bit is reset to a zero the byte is a Data byte.

While in ATTENTION mode, the UART monitors the communication flow, but ignores all characters until an address character is received. Upon receiving an address character, the UART signals that the character is ready by setting the RBFL flag, which in turn interrupts the processor if UART Receiver interrupts are enabled. The ATTN bit is also cleared automatically at this point, so that data characters as well as address characters are recognized. Software examines the contents of the RBUF and responds by deciding either to accept the subsequent data stream (by leaving the ATTN bit reset) or to wait until the next address character is seen (by setting the ATTN bit again).

Operation of the UART Transmitter is not affected by selection of this Mode. The value of the ninth bit to be transmitted is programmed by setting XBIT9 appropriately. The value of the ninth bit received is obtained by reading RBIT9. Since this bit is located in ENUR register where the error flags reside, a bit operation on it will reset the error flags.

Comparators

The device contains two differential comparators, each with a pair of inputs (positive and negative) and an output. Ports I1–I3 and I4–I6 are used for the comparators. The following is the Port I assignment:

- I1 Comparator1 negative input
- I2 Comparator1 positive input
- I3 Comparator1 output
- I4 Comparator2 negative input
- I5 Comparator2 positive input
- I6 Comparator2 output

A Comparator Select Register (CMPSL) is used to enable the comparators, read the outputs of the comparators internally, and enable the outputs of the comparators to the pins. Two control bits (enable and output enable) and one result bit are associated with each comparator. The comparator result bits (CMP1RD and CMP2RD) are read only bits which will read as zero if the associated comparator is not enabled. The Comparator Select Register is cleared with reset, resulting in the comparators being disabled. The comparators should also be disabled before entering either the HALT or IDLE modes in order to save power. The configuration of the CMPSL register is as follows:

Comparators (Continued)

CMPSL REGISTER (ADDRESS X'00B7)

The CMPSL register contains the following bits:

CMP1EN Enable comparator 1

CMP1RD Comparator 1 result (this is a read only bit, which will read as 0 if the comparator is not enabled)

CMP10E Selects pin I3 as comparator 1 output provided that CMPIEN is set to enable the comparator

CMP2EN Enable comparator 2

CMP2RD Comparator 2 result (this is a read only bit, which will read as 0 if the comparator is not enabled)

CMP20E Selects pin I6 as comparator 2 output provided that CMP2EN is set to enable the comparator

Unused	CMP20E	CMP2RD	CMP2EN	CMP10E	CMP1RD	CMP1EN	Unused
Bit 7							Bit 0

Note that the two unused bits of CMPSL may be used as software flags.

Comparator outputs have the same spec as Ports L and G except that the rise and fall times are symmetrical.

Interrupts

The device supports a vectored interrupt scheme. It supports a total of fourteen interrupt sources. The following table lists all the possible interrupt sources, their arbitration ranking and the memory locations reserved for the interrupt vector for each source.

Two bytes of program memory space are reserved for each interrupt source. All interrupt sources except the software interrupt are maskable. Each of the maskable interrupts have an Enable bit and one or more Pending bit. A maskable interrupt is active if its associated enable and pending bits are set. If GIE = 1 and an interrupt is active, then the processor will be interrupted as soon as it is ready to start executing an instruction except if the above conditions happen during the Software Trap service routine. This exception is described in the Software Trap sub-section.

The interruption process is accomplished with the INTR instruction (opcode 00), which is jammed inside the Instruction Register and replaces the opcode about to be executed. The following steps are performed for every interrupt:

1. The GIE (Global Interrupt Enable) bit is reset.
2. The address of the instruction about to be executed is pushed into the stack.
3. The PC (Program Counter) branches to address 00FF.

This procedure takes 7 t_C cycles to execute.

Arbitration Ranking	Source	Description	Vector* Address Hi-Low Byte
(1) Highest	Software	INTR Instruction	0yFE–0yFF
(2)	Reserved		0yFC–0yFD
(3)	External	G0	0yFA–0yFB
(4)	Timer T0	Underflow	0yF8–0yF9
(5)	Timer T1	T1A/Underflow	0yF6–0yF7
(6)	Timer T1	T1B	0yF4–0yF5
(7)	MICROWIRE/PLUS	BUSY Low	0yF2–0yF3
(8)	Reserved		0yF0–0yF1
(9)	UART	Receive	0yEE–0yEF
(10)	UART	Transmit	0yEC–0yED
(11)	Timer T2	T2A/Underflow	0yEA–0yEB
(12)	Timer T2	T2B	0yE8–0yE9
(13)	Timer T3	T3A/Underflow	0yE6–0yE7
(14)	Timer T3	T3B	0yE4–0yE5
(15)	Port L/Wakeup	Port L Edge	0yE2–0yE3
(16) Lowest	Default VIS	Reserved	0yE0–0yE1

*y is a variable which represents the VIS block. VIS and the vector table must be located in the same 256-byte block except if VIS is located at the last address of a block. In this case, the table must be in the next block.

Interrupts (Continued)

At this time, since GIE = 0, other maskable interrupts are disabled. The user is now free to do whatever context switching is required by saving the context of the machine in the stack with PUSH instructions. The user would then program a VIS (Vector Interrupt Select) instruction in order to branch to the interrupt service routine of the highest priority interrupt enabled and pending at the time of the VIS. Note that this is not necessarily the interrupt that caused the branch to address location 00FF Hex prior to the context switching.

Thus, if an interrupt with a higher rank than the one which caused the interruption becomes active before the decision of which interrupt to service is made by the VIS, then the interrupt with the higher rank will override any lower ones and will be acknowledged. The lower priority interrupt(s) are still pending, however, and will cause another interrupt immediately following the completion of the interrupt service routine associated with the higher priority interrupt just serviced. This lower priority interrupt will occur immediately following the RETI (Return from Interrupt) instruction at the end of the interrupt service routine just completed.

Inside the interrupt service routine, the associated pending bit has to be cleared by software. The RETI (Return from Interrupt) instruction at the end of the interrupt service routine will set the GIE (Global Interrupt Enable) bit, allowing the processor to be interrupted again if another interrupt is active and pending.

The VIS instruction looks at all the active interrupts at the time it is executed and performs an indirect jump to the beginning of the service routine of the one with the highest rank.

The addresses of the different interrupt service routines, called vectors, are chosen by the user and stored in ROM in a table starting at 01E0 (assuming that VIS is located between 00FF and 01DF). The vectors are 15-bit wide and therefore occupy 2 ROM locations.

VIS and the vector table must be located in the same 256-byte block (0y00 to 0yFF) except if VIS is located at the last address of a block. In this case, the table must be in the next block. The vector table cannot be inserted in the first 256-byte block (y ≠ 0).

The vector of the maskable interrupt with the lowest rank is located at 0yE0 (Hi-Order byte) and 0yE1 (Lo-Order byte) and so forth in increasing rank number. The vector of the maskable interrupt with the highest rank is located at 0yFA (Hi-Order byte) and 0yFB (Lo-Order byte).

The Software Trap has the highest rank and its vector is located at 0yFE and 0yFF.

If, by accident, a VIS gets executed and no interrupt is active, then the PC (Program Counter) will branch to a vector located at 0yE0–0yE1.

WARNING

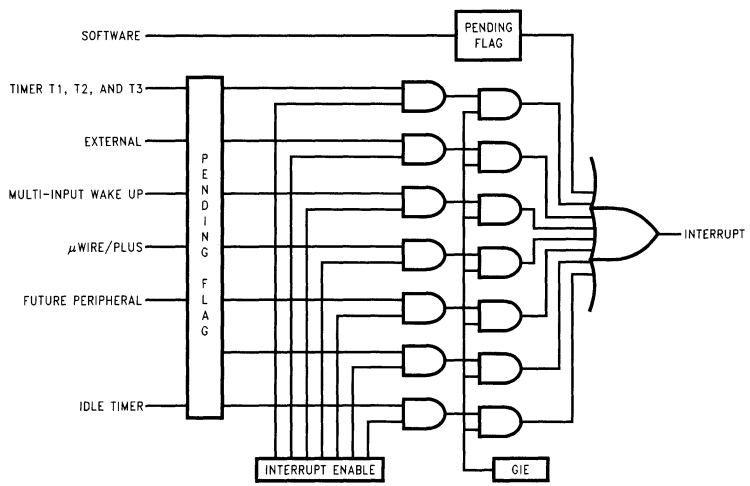
A Default VIS interrupt handler routine must be present. As a minimum, this handler should confirm that the GIE bit is cleared (this indicates that the interrupt sequence has been taken), take care of any required housekeeping, restore context and return. Some sort of Warm Restart procedure should be implemented. These events can occur without any error on the part of the system designer or programmer.

Note: There is always the possibility of an interrupt occurring during an instruction which is attempting to reset the GIE bit or any other interrupt enable bit. If this occurs when a single cycle instruction is being used to reset the interrupt enable bit, the interrupt enable bit will be reset but an interrupt may still occur. This is because interrupt processing is started at the same time as the interrupt bit is being reset. To avoid this scenario, the user should always use a two, three, or four cycle instruction to reset interrupt enable bits.

Figure 16 shows the Interrupt block diagram.

SOFTWARE TRAP

The Software Trap (ST) is a special kind of non-maskable interrupt which occurs when the INTR instruction (used to acknowledge interrupts) is fetched from ROM and placed inside the instruction register. This may happen when the PC is pointing beyond the available ROM address space or when the stack is over-popped.



TL/DD12829–18

FIGURE 16. Interrupt Block Diagram

Interrupts (Continued)

When an ST occurs, the user can re-initialize the stack pointer and do a recovery procedure (similar to reset, but not necessarily containing all of the same initialization procedures) before restarting.

The occurrence of an ST is latched into the ST pending bit. The GIE bit is not affected and the ST pending bit **(not accessible by the user)** is used to inhibit other interrupts and to direct the program to the ST service routine with the VIS instruction. The RPND instruction is used to clear the software interrupt pending bit. This pending bit is also cleared on reset.

The ST has the highest rank among all interrupts.

Nothing (except another ST) can interrupt an ST being serviced.

WATCHDOG

The device contains a WATCHDOG and clock monitor. The WATCHDOG is designed to detect the user program getting stuck in infinite loops resulting in loss of program control or "runaway" programs. The Clock Monitor is used to detect the absence of a clock or a very slow clock below a specified rate on the CKI pin.

The WATCHDOG consists of two independent logic blocks: WD UPPER and WD LOWER. WD UPPER establishes the upper limit on the service window and WD LOWER defines the lower limit of the service window.

Servicing the WATCHDOG consists of writing a specific value to a WATCHDOG Service Register named WDSVR which is memory mapped in the RAM. This value is composed of three fields, consisting of a 2-bit Window Select, a 5-bit Key Data field, and the 1-bit Clock Monitor Select field. Table II shows the WDSVR register.

TABLE V. WATCHDOG Service Register (WDSVR)

Window Select		Key Data					Clock Monitor
X	X	0	1	1	0	0	Y
7	6	5	4	3	2	1	0

The lower limit of the service window is fixed at 2048 instruction cycles. Bits 7 and 6 of the WDSVR register allow the user to pick an upper limit of the service window.

Table III shows the four possible combinations of lower and upper limits for the WATCHDOG service window. This flexibility in choosing the WATCHDOG service window prevents any undue burden on the user software.

Bits 5, 4, 3, 2 and 1 of the WDSVR register represent the 5-bit Key Data field. The key data is fixed at 01100. Bit 0 of the WDSVR Register is the Clock Monitor Select bit.

TABLE VI. WATCHDOG Service Window Select

WDSVR Bit 7	WDSVR Bit 6	Service Window (Lower-Upper Limits)
0	0	2k–8k t_C Cycles
0	1	2k–16k t_C Cycles
1	0	2k–32k t_C Cycles
1	1	2k–64k t_C Cycles

Clock Monitor

The Clock Monitor aboard the device can be selected or deselected under program control. The Clock Monitor is guaranteed not to reject the clock if the instruction cycle clock ($1/t_C$) is greater or equal to 10 kHz. This equates to a clock input rate on CKI of greater or equal to 100 kHz.

WATCHDOG Operation

The WATCHDOG and Clock Monitor are disabled during reset. The device comes out of reset with the WATCHDOG armed, the WATCHDOG Window Select bits (bits 6, 7 of the WDSVR Register) set, and the Clock Monitor bit (bit 0 of the WDSVR Register) enabled. Thus, a Clock Monitor error will occur after coming out of reset, if the instruction cycle clock frequency has not reached a minimum specified value, including the case where the oscillator fails to start.

The WDSVR register can be written to only once after reset and the key data (bits 5 through 1 of the WDSVR Register) must match to be a valid write. This write to the WDSVR register involves two irrevocable choices: (i) the selection of the WATCHDOG service window (ii) enabling or disabling of the Clock Monitor. Hence, the first write to WDSVR Register involves selecting or deselecting the Clock Monitor, select the WATCHDOG service window and match the WATCHDOG key data. Subsequent writes to the WDSVR register will compare the value being written by the user to the WATCHDOG service window value and the key data (bits 7 through 1) in the WDSVR Register. Table IV shows the sequence of events that can occur.

The user must service the WATCHDOG at least once before the upper limit of the service window expires. The WATCHDOG may not be serviced more than once in every lower limit of the service window. The user may service the WATCHDOG as many times as wished in the time period between the lower and upper limits of the service window. The first write to the WDSVR Register is also counted as a WATCHDOG service.

The WATCHDOG has an output pin associated with it. This is the WDOUT pin, on pin 1 of the port G. WDOUT is active low. The WDOUT pin is in the high impedance state in the inactive state. Upon triggering the WATCHDOG, the logic will pull the WDOUT (G1) pin low for an additional 16 t_C–32 t_C cycles after the signal level on WDOUT pin goes below the lower Schmitt trigger threshold. After this delay, the device will stop forcing the WDOUT output low.

The WATCHDOG service window will restart when the WDOUT pin goes high. It is recommended that the user tie the WDOUT pin back to V_{CC} through a resistor in order to pull WDOUT high.

A WATCHDOG service while the WDOUT signal is active will be ignored. The state of the WDOUT pin is not guaranteed on reset, but if it powers up low then the WATCHDOG will time out and WDOUT will enter high impedance state.

The Clock Monitor forces the G1 pin low upon detecting a clock frequency error. The Clock Monitor error will continue until the clock frequency has reached the minimum specified value, after which the G1 output will enter the high impedance TRI-STATE mode following 16 t_C–32 t_C clock cycles. The Clock Monitor generates a continual Clock Monitor error if the oscillator fails to start, or fails to reach the minimum specified frequency. The specification for the Clock Monitor is as follows:

$1/t_C > 10$ kHz—No clock rejection.

$1/t_C < 10$ Hz—Guaranteed clock rejection.

WATCHDOG Operation (Continued)

WATCHDOG AND CLOCK MONITOR SUMMARY

The following salient points regarding the WATCHDOG and CLOCK MONITOR should be noted:

- Both the WATCHDOG and CLOCK MONITOR detector circuits are inhibited during RESET.
- Following RESET, the WATCHDOG and CLOCK MONITOR are both enabled, with the WATCHDOG having he maximum service window selected.
- The WATCHDOG service window and CLOCK MONITOR enable/disable option can only be changed once, during the initial WATCHDOG service following RESET.
- The initial WATCHDOG service must match the key data value in the WATCHDOG Service register WDSVR in order to avoid a WATCHDOG error.
- Subsequent WATCHDOG services must match all three data fields in WDSVR in order to avoid WATCHDOG errors.
- The correct key data value cannot be read from the WATCHDOG Service register WDSVR. Any attempt to read this key data value of 01100 from WDSVR will read as key data value of all 0's.
- The WATCHDOG detector circuit is inhibited during both the HALT and IDLE modes.
- The CLOCK MONITOR detector circuit is active during both the HALT and IDLE modes. Consequently, the device inadvertently entering the HALT mode will be detected as a CLOCK MONITOR error (provided that the CLOCK MONITOR enable option has been selected by the program).
- With the single-pin R/C oscillator mask option selected and the CLKDLY bit reset, the WATCHDOG service window will resume following HALT mode from where it left off before entering the HALT mode.
- With the crystal oscillator mask option selected, or with the single-pin R/C oscillator mask option selected and the CLKDLY bit set, the WATCHDOG service window will be set to its selected value from WDSVR following HALT. Consequently, the WATCHDOG should not be serviced for at least 2048 instruction cycles following HALT, but must be serviced within the selected window to avoid a WATCHDOG error.
- The IDLE timer T0 is not initialized with RESET.
- The user can sync in to the IDLE counter cycle with an IDLE counter (T0) interrupt or by monitoring the T0PND flag. The T0PND flag is set whenever the thirteenth bit of the IDLE counter toggles (every 4096 instruction cycles). The user is responsible for resetting the T0PND flag.
- A hardware WATCHDOG service occurs just as the device exits the IDLE mode. Consequently, the WATCHDOG should not be serviced for at least 2048 instruction cycles following IDLE, but must be serviced within the selected window to avoid a WATCHDOG error.
- Following RESET, the initial WATCHDOG service (where the service window and the CLOCK MONITOR enable/disable must be selected) may be programmed anywhere within the maximum service window (65,536 instruction cycles) initialized by RESET. Note that this initial WATCHDOG service may be programmed within the initial 2048 instruction cycles without causing a WATCHDOG error.

Detection of Illegal Conditions

The device can detect various illegal conditions resulting from coding errors, transient noise, power supply voltage drops, runaway programs, etc.

Reading of undefined ROM gets zeros. The opcode for software interrupt is zero. If the program fetches instructions from undefined ROM, this will force a software interrupt, thus signaling that an illegal condition has occurred.

The subroutine stack grows down for each call (jump to subroutine), interrupt, or PUSH, and grows up for each return or POP. The stack pointer is initialized to RAM location 06F Hex during reset. Consequently, if there are more returns than calls, the stack pointer will point to addresses 070 and 071 Hex (which are undefined RAM). Undefined RAM from addresses 070 to 07F (Segment 0), and all other segments (i.e., Segments 4 . . . etc.) is read as all 1's, which in turn will cause the program to return to address 7FFF Hex. This is an undefined ROM location and the instruction fetched (all 0's) from this location will generate a software interrupt signaling an illegal condition.

Thus, the chip can detect the following illegal conditions:

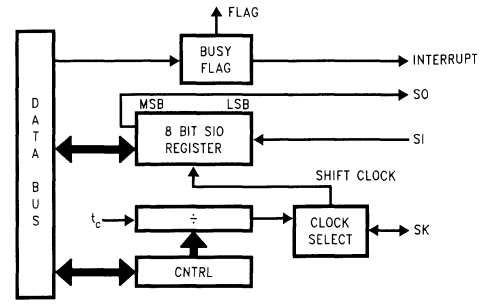
a. Executing from undefined ROM

b. Over "POP"ing the stack by having more returns than calls.

When the software interrupt occurs, the user can re-initialize the stack pointer and do a recovery procedure before restarting (this recovery program is probably similar to that following reset, but might not contain the same program initialization procedures). The recovery program should reset the software interrupt pending bit using the RPND instruction.

MICROWIRE/PLUS

MICROWIRE/PLUS is a serial synchronous communications interface. The MICROWIRE/PLUS capability enables the device to interface with any of National Semiconductor's MICROWIRE peripherals (i.e. A/D converters, display drivers, E^2PROMs etc.) and with other microcontrollers which support the MICROWIRE interface. It consists of an 8-bit serial shift register (SIO) with serial data input (SI), serial data output (SO) and serial shift clock (SK). *Figure 17* shows a block diagram of the MICROWIRE/PLUS logic.



TL/DD12829–19

FIGURE 17. MICROWIRE/PLUS Block Diagram

The shift clock can be selected from either an internal source or an external source. Operating the MICROWIRE/PLUS arrangement with the internal clock source is called the Master mode of operation. Similarly, operating the MICROWIRE/PLUS arrangement with an external shift clock is called the Slave mode of operation.

The CNTRL register is used to configure and control the MICROWIRE/PLUS mode. To use the MICROWIRE/PLUS, the MSEL bit in the CNTRL register is set to one. In the master mode, the SK clock rate is selected by the two bits, SL0 and SL1, in the CNTRL register. Table VIII details the different clock rates that may be selected.

TABLE VII. WATCHDOG Service Actions

Key Data	Window Data	Clock Monitor	Action
Match	Match	Match	Valid Service: Restart Service Window
Don't Care	Mismatch	Don't Care	Error: Generate WATCHDOG Output
Mismatch	Don't Care	Don't Care	Error: Generate WATCHDOG Output
Don't Care	Don't Care	Mismatch	Error: Generate WATCHDOG Output

TABLE VIII. MICROWIRE/PLUS Master Mode Clock Select

SL1	SL0	SK
0	0	$2 \times t_c$
0	1	$4 \times t_c$
1	x	$8 \times t_c$

Where t_c is the instruction cycle clock

MICROWIRE/PLUS (Continued)

MICROWIRE/PLUS OPERATION

Setting the BUSY bit in the PSW register causes the MICROWIRE/PLUS to start shifting the data. It gets reset when eight data bits have been shifted. The user may reset the BUSY bit by software to allow less than 8 bits to shift. If enabled, an interrupt is generated when eight data bits have been shifted. The device may enter the MICROWIRE/PLUS mode either as a Master or as a Slave. *Figure 18* shows how two microcontroller devices and several peripherals may be interconnected using the MICROWIRE/PLUS arrangements.

Warning:

The SIO register should only be loaded when the SK clock is low. Loading the SIO register while the SK clock is high will result in undefined data in the SIO register. SK clock is normally low when not shifting.

Setting the BUSY flag when the input SK clock is high in the MICROWIRE/PLUS slave mode may cause the current SK clock for the SIO shift register to be narrow. For safety, the BUSY flag should only be set when the input SK clock is low.

MICROWIRE/PLUS Master Mode Operation

In the MICROWIRE/PLUS Master mode of operation the shift clock (SK) is generated internally by the device. The MICROWIRE Master always initiates all data exchanges. The MSEL bit in the CNTRL register must be set to enable the SO and SK functions onto the G Port. The SO and SK pins must also be selected as outputs by setting appropriate bits in the Port G configuration register. Table IX summarizes the bit settings required for Master mode of operation.

MICROWIRE/PLUS Slave Mode Operation

In the MICROWIRE/PLUS Slave mode of operation the SK clock is generated by an external source. Setting the MSEL bit in the CNTRL register enables the SO and SK functions onto the G Port. The SK pin must be selected as an input and the SO pin is selected as an output pin by setting and resetting the appropriate bits in the Port G configuration register. Table VI summarizes the settings required to enter the Slave mode of operation.

The user must set the BUSY flag immediately upon entering the Slave mode. This will ensure that all data bits sent by the Master will be shifted properly. After eight clock pulses the BUSY flag will be cleared and the sequence may be repeated.

Alternate SK Phase Operation

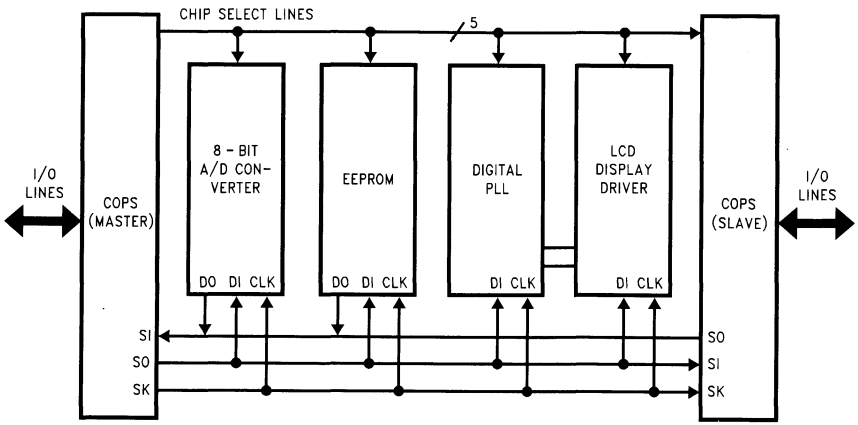
The device allows either the normal SK clock or an alternate phase SK clock to shift data in and out of the SIO register. In both the modes the SK is normally low. In the normal mode data is shifted in on the rising edge of the SK clock and the data is shifted out on the falling edge of the SK clock. The SIO register is shifted on each falling edge of the SK clock. In the alternate SK phase operation, data is shifted in on the falling edge of the SK clock and shifted out on the rising edge of the SK clock.

A control flag, SKSEL, allows either the normal SK clock or the alternate SK clock to be selected. Resetting SKSEL causes the MICROWIRE/PLUS logic to be clocked from the normal SK signal. Setting the SKSEL flag selects the alternate SK clock. The SKSEL is mapped into the G6 configuration bit. The SKSEL flag will power up in the reset condition, selecting the normal SK signal.

TABLE IX

This table assumes that the control flag MSEL is set.

G4 (SO) Config. Bit	G5 (SK) Config. Bit	G4 Fun.	G5 Fun.	Operation
1	1	SO	Int. SK	MICROWIRE/PLUS Master
0	1	TRI-STATE	Int. SK	MICROWIRE/PLUS Master
1	0	SO	Ext. SK	MICROWIRE/PLUS Slave
0	0	TRI-STATE	Ext. SK	MICROWIRE/PLUS Slave



TL/DD12829-20

FIGURE 18. MICROWIRE/PLUS Application

Memory Map

All RAM, ports and registers (except A and PC) are mapped into data memory address space.

Address S/ADD REG	Contents
0000 to 006F	On-Chip RAM bytes (112 bytes)
0070 to 007F	Unused RAM Address Space (Reads As All Ones)
xx80 to xxAF	Unused RAM Address Space (Reads Undefined Data)
xxB0	Timer T3 Lower Byte
XXB1	Timer T3 Upper Byte
xxB2	Timer T3 Autoload Register T3RA Lower Byte
xxB3	Timer T3 Autoload Register T3RA Upper Byte
xxB4	Timer T3 Autoload Register T3RB Lower Byte
xxB5	Timer T3 Autoload Register T3RB Upper Byte
xxB6	Timer T3 Control Register
xxB7	Comparator Select Register (CMPSL)
xxB8	UART Transmit Buffer (TBUF)
xxB9	UART Receive Buffer (RBUF)
xxBA	UART Control and Status Register (ENU)
xxBB	UART Receive Control and Status Register (ENUR)
xxBC	UART Interrupt and Clock Source Register (ENUI)
xxBD	UART Baud Register (BAUD)
xxBE	UART Prescale Select Register (PSR)
xxBF	Reserved for UART
xxC0	Timer T2 Lower Byte
xxC1	Timer T2 Upper Byte
xxC2	Timer T2 Autoload Register T2RA Lower Byte
xxC3	Timer T2 Autoload Register T2RA Upper Byte
xxC4	Timer T2 Autoload Register T2RB Lower Byte
xxC5	Timer T2 Autoload Register T2RB Upper Byte
xxC6	Timer T2 Control Register
xxC7	WATCHDOG Service Register (Reg:WDSVR)
xxC8	MIWU Edge Select Register (Reg:WKEDG)
xxC9	MIWU Enable Register (Reg:WKEN)
xxCA	MIWU Pending Register (Reg:WKPND)
xxCB	Reserved
xxCC	Reserved
xxCD to xxCF	Reserved

Address S/ADD REG	Contents
xxD0	Port L Data Register
xxD1	Port L Configuration Register
xxD2	Port L Input Pins (Read Only)
xxD3	Reserved for Port L
xxD4	Port G Data Register
xxD5	Port G Configuration Register
xxD6	Port G Input Pins (Read Only)
xxD7	Port I Input Pins (Read Only)
xxD8	Port C Data Register
xxD9	Port C Configuration Register
xxDA	Port C Input Pins (Read Only)
xxDB	Reserved for Port C
xxDC	Port D
xxDD to xxDF	Reserved for Port D
xxE0 to xxE5	Reserved for EE Control Registers
xxE6	Timer T1 Autoload Register T1RB Lower Byte
xxE7	Timer T1 Autoload Register T1RB Upper Byte
xxE8	ICNTRL Register
xxE9	MICROWIRE/PLUS Shift Register
xxEA	Timer T1 Lower Byte
xxEB	Timer T1 Upper Byte
xxEC	Timer T1 Autoload Register T1RA Lower Byte
xxED	Timer T1 Autoload Register T1RA Upper Byte
xxEE	CNTRL Control Register
xxEF	PSW Register
xxF0 to FB	On-Chip RAM Mapped as Registers
xxFC	X Register
xxFD	SP Register
xxFE	B Register
xxFF	S Register
0100–017F	On-Chip 128 RAM Bytes
0200–027F	On-Chip 128 RAM Bytes
0300–037F	On-Chip 128 RAM Bytes
0400–047F	On-Chip 128 RAM Bytes
0500–057F	On-Chip 128 RAM Bytes
0600–067F	On-Chip 128 RAM Bytes
0700–077F	On-Chip 128 RAM Bytes
0800–083F	On-Chip 64 RAM Bytes

Reading memory locations 0070H–007FH (Segment 0) will return all ones. Reading unused memory locations 0080H–00AFH (Segment 0) will return undefined data. Reading memory locations from other Segments (i.e., Segment 8 (084H–087FH), Segment 9, ... etc.) will return all ones.

Addressing Modes

There are ten addressing modes, six for operand addressing and four for transfer of control.

OPERAND ADDRESSING MODES

Register Indirect

This is the "normal" addressing mode. The operand is the data memory addressed by the B pointer or X pointer.

Register Indirect (with auto post increment or decrement of pointer)

This addressing mode is used with the LD and X instructions. The operand is the data memory addressed by the B pointer or X pointer. This is a register indirect mode that automatically post increments or decrements the B or X register after executing the instruction.

Direct

The instruction contains an 8-bit address field that directly points to the data memory for the operand.

Immediate

The instruction contains an 8-bit immediate field as the operand.

Short Immediate

This addressing mode is used with the Load B Immediate instruction. The instruction contains a 4-bit immediate field as the operand.

Indirect

This addressing mode is used with the LAID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a data operand from the program memory.

TRANSFER OF CONTROL ADDRESSING MODES

Relative

This mode is used for the JP instruction, with the instruction field being added to the program counter to get the new program location. JP has a range from −31 to +32 to allow a 1-byte relative jump (JP + 1 is implemented by a NOP instruction). There are no "pages" when using JP, since all 15 bits of PC are used.

Absolute

This mode is used with the JMP and JSR instructions, with the instruction field of 12 bits replacing the lower 12 bits of the program counter (PC). This allows jumping to any location in the current 4k program memory segment.

Absolute Long

This mode is used with the JMPL and JSRL instructions, with the instruction field of 15 bits replacing the entire 15 bits of the program counter (PC). This allows jumping to any location up to 32k in the program memory space.

Indirect

This mode is used with the JID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a location in the program memory. The contents of this program memory location serve as a partial address (lower 8 bits of PC) for the jump to the next instruction.

Note: The VIS is a special case of the Indirect Transfer of Control addressing mode, where the double byte vector associated with the interrupt is transferred from adjacent addresses in the program memory into the program counter (PC) in order to jump to the associated interrupt service routine.

Instruction Set

Register and Symbol Definition

Registers	
A	8-Bit Accumulator Register
B	8-Bit Address Register
X	8-Bit Address Register
S	8-Bit Segment Register
SP	8-Bit Stack Pointer Register
PC	15-Bit Program Counter Register
PU	Upper 7 Bits of PC
PL	Lower 8 Bits of PC
C	1 Bit of PSW Register for Carry
HC	1 Bit of PSW Register for Half Carry
GIE	1 Bit of PSW Register for Global Interrupt Enable
VU	Interrupt Vector Upper Byte
VL	Interrupt Vector Lower Byte

Symbols	
[B]	Memory Indirectly Addressed by B Register
[X]	Memory Indirectly Addressed by X Register
MD	Direct Addressed Memory
Mem	Direct Addressed Memory or [B]
Meml	Direct Addressed Memory or [B] or Immediate Data
Imm	8-Bit Immediate Data
Reg	Register Memory: Addresses F0 to FF (Includes B, X and SP)
Bit	Bit Number (0 to 7)
←	Loaded with
↔	Exchanged with

NOP		No OPeration	PC ← PC + 1

Instruction Execution Time

Most instructions are single byte (with immediate addressing mode instructions taking two bytes).

Most single byte instructions take one cycle time to execute.

Skipped instructions require x number of cycles to be skipped, where x equals the number of bytes in the skipped instruction opcode.

See the BYTES and CYCLES per INSTRUCTION table for details.

Bytes and Cycles per Instruction

The following table shows the number of bytes and cycles for each instruction in the format of byte/cycle.

Arithmetic and Logic Instructions

	[B]	Direct	Immed.

Where,

i is the immediate data

Md is a directly addressed memory location

* is an unused opcode

Note: The opcode 60 Hex is also the opcode for IFBIT #i,A

Mask Options

The mask programmable options are shown below. The options are programmed at the same time as the ROM pattern submission.

OPTION 1: CLOCK CONFIGURATION

= 1 Crystal Oscillator (CKI/10)
G7 (CKO) is clock generator output to crystal/ resonator with CKI being the clock input

= 2 Single-pin RC controlled oscillator (CKI/10)
G7 is available as a HALT restart and/or general purpose input

OPTION 2: HALT

= 1 Enable HALT mode

= 2 Disable HALT mode

The chip can be driven by a clock input on the CKI input pin which can be between DC and 10 MHz. The CKO output clock is on pin G7 (if clock option = 1 has been selected). The CKI input frequency is divided down by 10 to produce the instruction cycle clock (1/tc).

Development Support

Summary

- iceMASTER: IM-COP8/400—Full feature in-circuit emulation for all COP8 products. A full set of COP8 Basic and Feature Family device and package specific probes are available.
- COP8 Debug Module: Moderate cost in-circuit emulation and development programming unit.
- COP8 Evaluation and Programming Unit: EPU-COP888GG—low cost In-circuit simulation and development programming unit.
- Assembler: COP8-DEV-IBMA. A DOS installable cross development Assembler, Linker, Librarian and Utility Software Development Tool Kit.
- C Compiler: COP8C. A DOS installable cross development Software Tool Kit.
- OTP/EPROM Programmer Support: Covering needs from engineering prototype, pilot production to full production environments.

Development Support (Continued)

IceMASTER (IM) IN-CIRCUIT EMULATION

The iceMASTER IM-COP8/400 is a full feature, PC based, in-circuit emulation tool developed and marketed by MetaLink Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 19* for configuration.

The iceMASTER IM-COP8/400 with its device specific COP8 Probe provides a rich feature set for developing, testing and maintaining product:

- Real-time in-circuit emulation; full 2.4V–5.5V operation range, full DC-10 MHz clock. Chip options are programmable or jumper selectable.
- Direct connection to application board by package compatible socket or surface mount assembly.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated on the probe as necessary.
- Full 4K frame synchronous trace memory. Address, instruction, and 8 unspecified, circuit connectable trace lines. Display can be HLL source (e.g., C source), assembly or mixed.
- A full 64K hardware configurable break, trace on, trace off control, and pass count increment events.
- Tool set integrated interactive symbolic debugger—supports both assembler (COFF) and C Compiler (.COD) linked object formats.
- Real time peformance profiling analysis; selectable bucket definition.
- Watch windows, content updated automatically at each execution break.
- Instruction by instruction memory/register changes displayed on source window when in single step operation.
- Single base unit and debugger software reconfigurable to support the entire COP8 family; only the probe personality needs to change. Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- On-line HELP customized to specific processor using master model file.
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

IceMASTER DEBUG MODULE (DM)

The iceMASTER Debug Module is a PC based, combination in-circuit emulation tool and COP8 based OTP/EPROM programming tool developed and marketed by MetaLink Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 20* for configuration.

The iceMASTER Debug Module is a moderate cost development tool. It has the capability of in-circuit emulation for a specific COP8 microcontroller and in addition serves as a programming tool for COP8 OTP and EPROM product families. Summary of features is as follows:

- Real-time in-circuit emulation; full operating voltage range operation, full DC-10 MHz clock.
- All processor I/O pins can be cabled to an application development board with package compatible cable to socket and surface mount assembly.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated as necessary.
- 100 frames of synchronous trace memory. The display can be HLL source (C source), assembly or mixed. The most recent history prior to a break is available in the trace memory.
- Configured break points; uses INTR instruction which is modestly intrusive.
- Software—only supported features are selectable.
- Tool set integrated interactive symbolic debugger—supports both Assembler (COFF) and C Compiler (.COD) SDK linked object formats.
- Instruction by instruction memory/register changes displayed when in single step operation.
- Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- Programming menu supports full product line of programmable OTP and EPROM COP8 products. Program data is taken directly from the overlay RAM.
- Programming of 44 PLCC and 68 PLCC parts requires external programming adapters.
- Includes wall mount power supply
- On-board V_{PP} generator from 5V input or connection to external supply supported. Requires V_{PP} level adjustment per the family programming specification (correct level is provided on an on-screen pop-down display).
- On-line HELP customized to specific processor using master model file.
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

Development Support (Continued)

COP8 ASSEMBLER/LINKER SOFTWARE DEVELOPMENT TOOL KIT

National Semiconductor offers a relocateable COP8 macro cross assembler, linker, librarian and utility software development tool kit. Features are summarized as follows:

- Basic and Feature Family instruction set by "device" type.
- Nested macro capability.
- Extensive set of assembler directives.
- Supported on PC/DOS platform.
- Generates National standard COFF output files.
- Integrated Linker & Librarian.
- Integrated utilities to generate ROM code file outputs.
- DUMPCOFF utility.

This product is integrated as a part of MetaLink tools as a development kit, fully supported by the MetaLink debugger. It may be ordered separately or it is bundled with the MetaLink products at no additional cost.

Order-Information

Assembler SDK:	
COP8-DEV-IBMA	Assembler SDK on installable 3.5" PC/DOS Floppy Disk Drive format. Periodic upgrades and most recent version is available on National's BBS and Internet.

COP8 C COMPILER

A C Compiler is developed and marketed by Byte Craft Limited. The COP8C compiler is a fully integrated development tool specifically designed to support the compact embedded configuration of the COP8 family of products.

Features are summarized as follows:

- ANSI C wrth some restrictions and extensions that optimize development for the COP8 embedded application.
- BITS data type extension. Register declaration #pragma with direct bit level definitions.
- C language support for interrupt routines.
- Expert system, rule based code generation and optimization.
- Performs consistency checks against the architectural definitions of the target COP8 device.
- Generates program memory code.
- Supports linking of compiled object or COP8 assembled object formats.
- Global optimization of linked code.
- Symbolic debug load format fully source level supported by the MetaLink debugger.

SINGLE CHIP OTP/EMULATOR SUPPORT

The COP8 family is supported by single chip OTP emulators. For detailed information refer to the emulator specific datasheet and the emulator selection table below:

OTP Emulator Ordering Information

Device Number	Clock Option	Package	Emulates
COP87L88KGV-XE	Crystal/ HALT En	44 PLCC	COP888KG
COP87L88KGN-XE	Crystal/ HALT En	40 DIP	COP888KG

INDUSTRY WIDE OTP/EPROM PROGRAMMING SUPPORT

Programming support, in addition to the MetaLink development tools, is provided by a full range of independent approved vendors to meet the needs from the engineering laboratory to full production.

DIAL-A-HELPER

Dial-A-Helper is a service provided by the Microcontroller Applications group. The Dial-A-Helper is an Electronic Information System that may be accessed as a Bulletin Board System (BBS) via data modem, as an FTP site on the Internet via standard FTP client application or as an FTP site on the Internet using a standard Internet browser such as Netscape or Mosaic.

The Dial-A-Helper system provides access to an automated information storage and retrieval system. The system capabilities include a MESSAGE SECTION (electronic mail, when accessed as a BBS) for communication to and from the Microcontroller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities could be found.

National Semiconductor

PRELIMINARY

COP888GW
8-Bit Microcontroller with Pulse Train Generators and Capture Modules

General Description

The COP888 family of microcontrollers uses an 8-bit single chip core architecture fabricated with National Semiconductor's M²CMOS™ process technology. The COP888GW is a member of this expandable 8-bit core processor family of microcontrollers. It is a fully static part, fabricated using double-metal silicon gate microCMOS technology.

Features include an 8-bit memory mapped architecture, MICROWIRE/PLUS serial I/O, two 16-bit timer/counters supporting three modes (Processor Independent PWM generation, External Event counter and Input Capture mode capabilities), four independent 16-bit pulse train generators with 16-bit prescalers, two independent 16-bit input capture modules with 8-bit prescalers, multiply and divide functions, full duplex UART, and two power savings modes (HALT and IDLE), both with a multi-sourced wake up/interrupt capability. This multi-sourced interrupt capability may also be used independent of the HALT or IDLE modes.

Each I/O pin has software selectable configurations. The devices operate over a voltage range of 2.5V–6V. High throughput is achieved with an efficient, regular instruction set operating at a maximum of 1 μs per instruction rate. The device has low EMI emissions. Low radiated emissions are achieved by gradual turn-on output drivers and internal I_{CC} filters on the chip logic and crystal oscillator. The device is available in 68-pin PLCC package.

Key Features

- Two 16-bit input capture modules with 8-bit prescalers
- Four Pulse Train Generators with 16-bit prescalers
- Full duplex UART
- Two 16-bit timers, each with two 16-bit registers supporting:
  - — Processor independent PWM mode
  - — External event counter mode
  - — Input capture mode
- Quiet design (low radiated emissions)
- 16 kbytes on-board ROM
- 512 bytes on-board RAM

Additional Peripheral Features

- Idle Timer
- Multi-Input Wake-Up (MIWU) with optional interrupts (8)
- MICROWIRE/PLUS™ serial I/O

I/O Features

- Memory mapped I/O
- Software selectable I/O options (TRI-STATE® Output, Push-Pull Output, Weak Pull-Up Input, High Impedance Input)
- Schmitt trigger inputs on port G
- Package: 68-pin PLCC

CPU/Instruction Set Features

- 1 μs instruction cycle time
- Fourteen multi-source vectored interrupts servicing:
  - — External Interrupt with selectable edge
  - — Idle Timer T0
  - — Two Timers (each with 2 interrupts)
  - — MICROWIRE/PLUS
  - — Multi-Input Wake-Up
  - — Software Trap
  - — UART (2)
  - — Capture Timers
  - — Counters (one vector for all four counters)
  - — Default VIS (default interrupt)
- Versatile and easy-to-use instruction set
- 8-bit Stack Pointer SP—(stack in RAM)
- Two 8-bit register indirect data memory pointers (B and X)

Fully Static CMOS

- Two power saving modes: HALT and IDLE
- Low current drain (typically <1 μA)
- Single supply operation: 2.5V–5.5V
- Temperature range: $-40°C$ to $+85°C$

Development Support

- Emulation and OTP device
- Real time emulation and full program debug offered by MetaLink's Development System

	$2.5V \le V_{CC} < 4V$			2.5	μs
MICROWIRE™ Setup Time (t_{UWS}) (Note 6)	$V_{CC} \ge 4V$	20			ns
MICROWIRE Hold Time (t_{UWH}) (Note 6)	$V_{CC} \ge 4V$	56			ns
MICROWIRE Output Propagation Delay (t_{UPD})	$V_{CC} \ge 4V$			220	ns
Input Pulse Width (Note 7)					
Interrupt Input High Time		1			t_c
Interrupt Input Low Time		1			t_c
Timer 1, 2 Input High Time		1			t_c
Timer 1, 2 Input Low Time		1			t_c
Capture Timer High Time		1			CKI
Capture Timer Low Time		1			CKI
Reset Pause Width		1			t_c

Note 1: Maximum rate of voltage change to be defined.

Note 2: Supply current is measured after running 2000 cydes with a square wave CKI input, CKO open, inputs at rails and outputs open.

Note 3: The HALT mode will stop CKI from oscillatng. Test conditions: All inputs tied to V_{CC}, L, C, E, F, and G port I/O's configured as outputs and programmed low and not driving a load; D outputs programmed low and not driving a load. Parameter refers to HALT mode entered via setting bit 7 of the G Port data register. Part will pull up CKI during HALT in crystal clock mode.

Note 4: Pins G6 and $\overline{\text{RESET}}$ are designed with a high voltage input network. These pins allow input voltages greater than V_{CC} and the pins will have sink current to V_{CC} when biased at voltages greater than V_{CC} (the pins do not have source current when biased at a voltage below V_{CC}.) The effective resistance to V_{CC} is 750Ω (typical). These two pins will not latch up. The voltage at the pins must be limited to less than 14 volts. WARNING: Voltages in excess of 14 volts will cause damage to the pins. This warning excludes ESD transients.

Note 5: Condition and parameter valid only for part in HALT mode.

Note 6: Parameter characterized but not tested.

Note 7: t_c = Instruction Cycle Time

Note 8: The output propagation delay is referenced to the end of the instruction cycle where the output change occurs.

Pin Descriptions

V_{CC} and GND are the power supply pins. All V_{CC} and GND pins must be connected.

CKI is the clock input. This comes from an R/C generated oscillator, or a crystal oscillator (in conjunction with CKO). See Oscillator Description section.

$\overline{\text{RESET}}$ is the master reset input. See Reset description section.

The device contains five bidirectional 8-bit I/O ports (C, E, F, G and L), where each individual bit may be independently configured as an input (Schmitt trigger inputs on ports L and G), output or TRI-STATE under program control. Three data memory address locations are allocated for each of these I/O ports. Each I/O port has two associated 8-bit memory mapped registers, the CONFIGURATION register and the output DATA register. A memory mapped address is also reserved for the input pins of each I/O port. (See the memory map for the various addresses associated with the I/O ports.) *Figure 3* shows the I/O port configurations. The DATA and CONFIGURATION registers allow for each port bit to be individually configured under software control as shown below:

Configuration Register	Data Register	Port Set-Up
0	0	Hi-Z Input (TRI-STATE Output)
0	1	Input with Weak Pull-Up
1	0	Push-Pull Zero Output
1	1	Push-Pull One Output

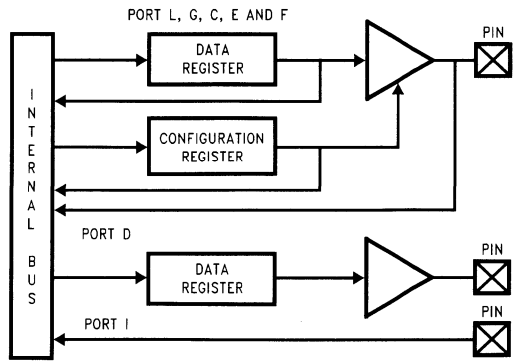
PORT L is an 8-bit I/O port. All L-pins have Schmitt triggers on the inputs.

The Port L supports Multi-Input Wake Up on all eight pins. L1 is used for the UART external clock. L2 and L3 are used for the UART transmit and receive. L4 and L5 are used for the timer input functions T2A and T2B. L6 and L7 are used for the capture timer input functions CAP1 and CAP2.

The Port L has the following alternate features:

- L0 MIWU
- L1 MIWU or CKX
- L2 MIWU or TDX
- L3 MIWU or RDX
- L4 MIWU or T2A
- L5 MIWU or T2B
- L6 MIWU or CAP1
- L7 MIWU or CAP2

Port G is an 8-bit port with 6 I/O pins (G0–G5), an input pin (G6), and a dedicated output pin (G7). Pins G0–G6 all have Schmitt Triggers on their inputs. Pin G7 serves as the dedicated output pin for the CKO clock output. There are two registers associated with the G Port, a data register and a configuration register. Therefore, each of the 6 I/O bits (G0–G5) can be individually configured under software control.



TL/DD/12065–4

FIGURE 3. I/O Port Configurations

5

Pin Descriptions (Continued)

Since G6 is an input only pin and G7 is dedicated CKO clock output pin, the associated bits in the data and configuration registers for G6 and G7 are used for special purpose functions as outlined below. Reading the G6 and G7 data bits will return zeros.

Note that the chip will be placed in the HALT mode by writing a "1" to bit 7 of the Port G Data Register. Similarly the chip will be placed in the IDLE mode by writing a "1" to bit 6 of the Port G Data Register.

Writing a "1" to bit 6 of the Port G Configuration Register enables the MICROWIRE/PLUS to operate with the alternate phase of the SK clock.

	Config Reg.	Data Reg.
G7	Not Used	HALT
G6	Alternate SK	IDLE

Port G has the following alternate features:

- G0 INTR (External Interrupt Input)
- G2 T1B (Timer T1 Capture Input)
- G3 T1A (Timer T1 I/O)
- G4 SO (MICROWIRE Serial Data Output)
- G5 SK (MICROWIRE Serial Clock)
- G6 SI (MICROWIRE Serial Data Input)

Port G has the following dedicated functions:

- G7 CKO Oscillator dedicated output

Ports C and F are 8-bit I/O ports.

Port E is an 8-bit I/O port. It has the following alternate features:

- E0 CT1 (Output for counter1, Pulse Train Generator)
- E1 CT2 (Output for counter2, Pulse Train Generator)
- E2 CT3 (Output for counter3, Pulse Train Generator)
- E3 CT4 (Output for counter4, Pulse Train Generator)

Port I is an eight-bit Hi-Z input port.

Port D is an 8-bit output port that is preset high when $\overline{\text{RESET}}$ goes low. The user can tie two or more D port outputs (except D2) together in order to get a higher drive.

Functional Description

The architecture of the device is modified Harvard architecture. With the Harvard architecture, the control store program memory (ROM) is separated from the data store memory (RAM). Both ROM and RAM have their own separate addressing space with separate address buses. The architecture, though based on Harvard architecture, permits transfer of data from ROM to RAM.

CPU REGISTERS

The CPU can do an 8-bit addition, subtraction, logical or shift operation in one instruction (t_c) cycle time.

There are six CPU registers:

A is the 8-bit Aocumulator Register

PC is the 15-bit Program Counter Register

- PU is the upper 7 bits of the program counter (PC)
- PL is the lower 8 bits of the program counter (PC)

B is an 8-bit RAM address pointer, which can be optionally post auto incremented or decremented.

X is an 8-bit alternate RAM address pointer, which can be optionally post auto incremented or decremented.

SP is the 8-bit stack pointer, which points to the subroutine/interrupt stack (in RAM). The SP is initialized to RAM address 06F with reset.

S is the 8-bit Data Segment Address Register used to extend the lower half of the address range (00 to 7F) into 256 data segments of 128 bytes each.

All the CPU registers are memory mapped with the exception of the Accumulator (A) and the Program Counter (PC).

PROGRAM MEMORY

The program memory consists of 16384 bytes of ROM. These bytes may hold program instructions or constant data (data tables for the LAID instruction, jump vectors for the JID instruction, and interrupt vectors for the VIS instruction). The program memory is addressed by the 15-bit program counter (PC). All interrupts in the devices Vector to program memory location OFF Hex.

DATA MEMORY

The data memory address space includes the on-chip RAM and data registers, the I/O registers (Configuration, Data and Pin), the control registers, the MICROWIRE/PLUS SIO shift register, and the various registers, and counters associated with the timers (with the exception of the IDLE timer). Data memory is addressed directly by the instruction or indirectly by the B, X, SP pointers and S register.

The data memory consists of 512 bytes of RAM. Sixteen bytes of RAM are mapped as "registers" at addresses 0F0 to 0FF Hex. These registers can be loaded immediately, and also decremented and tested with the DRSZ (decrement register and skip if zero) instruction. The memory pointer registers X, SP, B and S are memory mapped into this space at address locations 0FC to 0FF Hex respectively, with the other registers being available for general usage.

Note: RAM contents are undefined upon power-up.

Data Memory Segment RAM Extension

Data memory address 0FF is used as a memory mapped location for the Data Segment Address Register (S).

The data store memory is either addressed directly by a single-byte address within the instruction, or indirectly relative to the reference of the B, X, or SP pointers (each contains a single-byte address). This single-byte address allows an addressing range of 256 locations from 00 to FF hex. The upper bit of this single-byte address divides the data store memory into two separate sections as outlined previously. With the exception of the RAM register memory from address locations 00F0 to 00FF, all RAM memory is memory mapped with the upper bit of the single-byte address being equal to zero. This allows the upper bit of the single-byte address to determine whether or not the base address range (from 0000 to 00FF) is extended. If this upper bit equals one (representing address range 0080 to 00FF), then address extension does not take place. Alternatively, if this upper bit equals zero, then the data segment extension

Data Memory Segment RAM Extension (Continued)

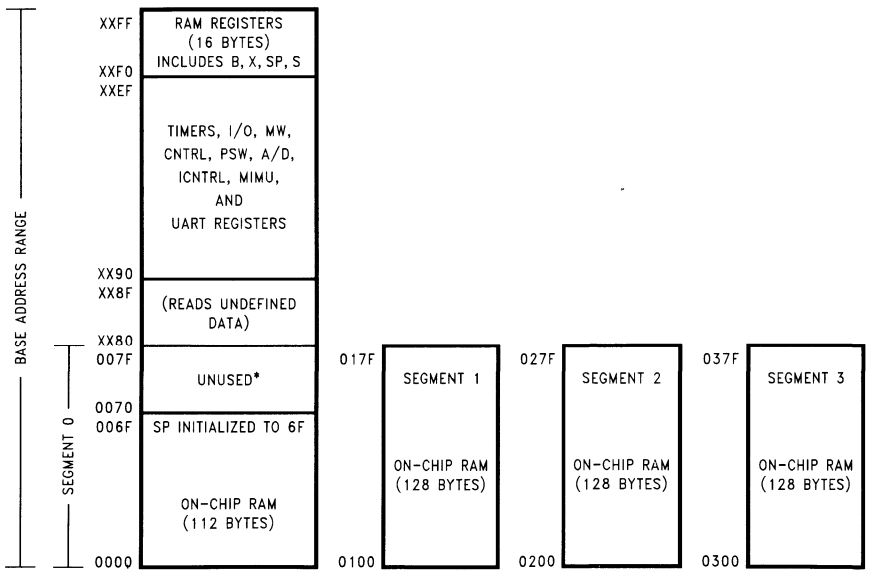
register S is used to extend the base address range (from 0000 to 007F) from XX00 to XX7F, where XX represents the 8 bits from the S register. Thus the 128-byte data segment extensions are located from addresses 0100 to 017F for data segment 1, 0200 to 027F for data segment 2, etc., up to FF00 to FF7F for data segment 255. The base address range from 0000 to 007F represents data segment 0.

Figure 4 illustrates how the S register data memory extension is used in extending the lower half of the base address range (00 to 7F hex) into 256 data segments of 128 bytes each, with a total addressing range of 32 kbytes from XX00 to XX7F. This organization allows a total of 256 data segments of 128-bytes each with an additional upper base segment of 128 bytes. Furthermore, all addressing modes are available for all data segments. The S register must be changed under program control to move from one data segment (128 bytes) to another. However, the upper base segment (containing the 16 memory registers, I/O registers, control registers, etc.) is always available regardless of the contents of the S register, since the upper base segment (address range 0080 to 00FF) is independent of data segment extension.

The instructions that utilize the stack pointer (SP) always reference the stack as part of the base segment (Segment 0), regardless of the contents of the S register. The S register is not changed by these instructions. Consequently, the stack (used with subroutine linkage and interrupts) is always located in the base segment. The stack pointer will be initialized to point at data memory location 006F as a result of reset.

The 128 bytes of RAM contained in the base segment are split between the lower and upper base segments. The first 112 bytes of RAM are resident from address 0000 to 006F in the lower base segment, while the remaining 16 bytes of RAM represent the 16 data memory registers located at addresses 00F0 to 00FF of the upper base segment. No RAM is located at the upper sixteen addresses (0070 to 007F) of the lower base segment.

Additional RAM beyond these initial 128 bytes, however, will always be memory mapped in groups of 128 bytes (or less) at the data segment address extensions (XX00 to XX7F) of the lower base segment. The additional 384 bytes of RAM in this device are memory mapped at address locations 0100 to 017F° 0200 to 027F, and 0300 to 037F hex.



TL/DD/12065–5

*Reads as all ones.

FIGURE 4. RAM Organization

Reset

This device enters a reset state immediately upon detecting a logic low on the $\overline{\text{RESET}}$ pin. The $\overline{\text{RESET}}$ pin must be held low for a minimum of one instruction cycle to guarantee a valid reset. During power-up initialization, the user must insure that the $\overline{\text{RESET}}$ pin is held low until this device is within the specified V_{CC} voltage. An R/C circuit on the $\overline{\text{RESET}}$ pin with a delay 5 times (5x) greater than the power supply rise time is recommended.

When the $\overline{\text{RESET}}$ input goes low, the I/O ports are initialized immediately, with any observed delay being only propagation delay. When the $\overline{\text{RESET}}$ pin goes high, this device comes out of the reset state synchronously. This device will be running within two instruction cycles of the $\overline{\text{RESET}}$ pin going high.

$\overline{\text{RESET}}$ may also be used to exit this device from the HALT mode.

Some registers are reset to a known state, whereas other registers and RAM are "unchanged" by reset. When the controller goes into reset state while it is performing a write operation to one of these registers or RAM that are "unchanged" by reset, the register or RAM value will become unknown (i.e. not unchanged). This is because the write operation is terminated prematurely by reset and the results become uncertain. These registers and RAM locations are unchanged by reset only if they are not written to when the controller resets.

The following initializations occur with $\overline{\text{RESET}}$:

Port L: TRI-STATE

Port C: TRI-STATE

Port G: TRI-STATE

Port E: TRI-STATE

Port F: TRI-STATE

Port D: HIGH

PC: CLEARED

PSW, CNTRL and ICNTRL registers: CLEARED

SIOR:

UNAFFECTED after RESET with power already applied

RANDOM after RESET at power-on

T1CNTRL: CLEARED

T2CNTRL: CLEARED

TxRA, TxRB: RANDOM

CCMR1, CCMR2: CLEARED

CM1PSC, CM1CRL, CM1CRH, CM2PSC, CM2CRL, and CM2CRH:

UNAFFECTED after RESET with power already applied

RANDOM after RESET at power-on

CCR1 and CCR2: CLEARED

CxPRH, CxPRL, CxCTH, and CxCTL:

UNAFFECTED after RESET with RC clock option (power already applied)

RANDOM after RESET at power-on

PSR, ENUR and ENUI: CLEARED

ENU: CLEARED except Bit 1 (TBMT) = 1

Accumulator, Timer 1 and Timer 2:

RANDOM after RESET with crystal clock option (power already applied)

RANDOM after RESET at power-on

MDCR: CLEARED

MDR1, MDR2, MDR3, MDR4, MDR5: RANDOM

WKEN, WKEDG: CLEARED

WKPND: RANDOM

S Register: CLEARED

SP (Stack Pointer): Loaded with 6F Hex

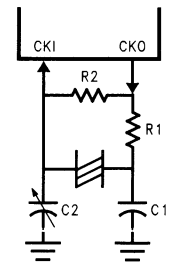
RC > 5 × POWER SUPPLY RISE TIME

FIGURE 5. Recommended Reset Circuit

Oscillator Circuits

The chip can be driven by a clock input on the CKI input pin which can be between DC and 10 MHz. The CKO output clock is on pin G7 (crystal configuration), The CKI input frequency is divided down by 10 to produce the instruction cycle clock (t_C).

Figure 6 shows the Crystal diagram



TL/DD/12065–7

FIGURE 6. Crystal Diagram

CRYSTAL OSCILLATOR

CKI and CKO can be connected to make a closed loop crystal (or resonator) controlled oscillator.

Oscillator Circuits (Continued)

Table I shows the component values required for various standard crystal values.

TABLE I. Crystal Oscillator Configuration, T_A = 25°C

R1 (kΩ)	R2 (MΩ)	C1 (pF)	C2 (pF)	CKI Freq (MHz)	Conditions
0	1	30	30–36	10	V_{CC} = 5V
0	1	30	30–36	4	V_{CC} = 5V
0	1	200	100–150	0.455	V_{CC} = 5V

Control Registers

CNTRL Register (Address X'00EE)

The Timer1 (T1) and MICROWIRE/PLUS control register contains the following bits:

SL1 & SL0 Select the MICROWIRE/PLUS clock divide by (00 = 2, 01 = 4, 1x = 8)

IEDG External interrupt edge polarity select (0 = Rising edge, 1 = Falling edge)

MSEL Selects G5 and G4 as MICROWIRE/PLUS signals SK and SO respectively

T1C0 Timer T1 Start/Stop control in timer modes 1 and 2

T1 Underflow Interrupt Pending Flag in timer mode 3

T1C1 Timer T1 mode control bit

T1C2 Timer T1 mode control bit

T1C3 Timer T1 mode control bit

T1C3	T1C2	T1C1	T1C0	MSEL	IEDG	SL1	SL0

Bit 7 Bit 0

PSW Register (Address X'00EF)

The PSW register contains the following select bits:

GIE Global interrupt enable (enables interrupts)

EXEN Enable external interrupt

BUSY MICROWIRE/PLUS busy shifting flag

EXPND External interrupt pending

T1ENA Timer T1 Interrupt Enable for Timer Underflow or T1A Input capture edge

T1PNDA Timer T1 Interrupt Pending Flag (Autoreload RA in mode 1, T1 Underflow in Mode 2, T1A capture edge in mode 3)

C Carry Flag

HC Half Carry Flag

HC	C	T1PNDA	T1ENA	EXPND	BUSY	EXEN	GIE

Bit 7 Bit 0

The Half-Carry flag is also affected by all the instructions that affect the Carry flag. The SC (Set Carry) and RC (Reset Carry) instructions will respectively set or clear both the carry flags. In addition to the SC and RC instructions, ADC, SUBC, RRC and RLC instructions affect the Carry and Half Carry flags.

ICNTRL Register (Address X'00E8)

The ICNTRL register contains the following bits:

T1ENB Timer T1 Interrupt Enable for T1B Input capture edge

T1PNDB Timer T1 Interrupt Pending Flag for T1B capture edge

μWEN Enable MICROWIRE/PLUS interrupt

μWPND MICROWIRE/PLUS interrupt pending

T0EN Timer T0 Interrupt Enable (Bit 12 toggle)

T0PND Timer T0 Interrupt pending

LPEN L Port Interrupt Enable (Multi-Input Wake up/Interrupt)

Bit 7 could be used as a flag

Unused	LPEN	T0PND	T0EN	WPND	WEN	T1PNDB	T1ENB

Bit 7 Bit 0

T2CNTRL Register (Address X'00C6)

The T2CNTRL register contains the following bits:

T2ENB Timer T2 Interrupt Enable for T2B Input capture edge

T2PNDB Timer T2 Interrupt Pending Flag for T2B capture edge

T2ENA Timer T2 Interrupt Enable for Timer Underflow or T2A Input capture edge

T2PNDA Timer T2 Interrupt Pending Flag (Auto reload RA in mode 1, T2 Underflow in mode 2, T2A capture edge in mode 3)

T2C0 Timer T2 Start/Stop control in timer modes 1 and 2 Timer T2 Underflow Interrupt Pending Flag in timer mode 3

T2C1 Timer T2 mode control bit

T2C2 Timer T2 mode control bit

T2C3 Timer T2 mode control bit

T2C3	T2C2	T2C1	T2C0	T2PNDA	T2ENA	T2PNDB	T2ENB

Bit 7 Bit 0

Timers

The device contains a very versatile set of timers (T0, T1, T2). All timers and associated autoreload/capture registers power up containing random data.

TIMER T0 (IDLE TIMER)

The device supports applications that require maintaining real time and low power with the IDLE mode. This IDLE mode support is furnished by the IDLE timer T0, which is a 16-bit timer. The Timer T0 runs continuously at the fixed rate of the instruction cycle clock, t_c. The user cannot read or write to the IDLE Timer T0, which is a count down timer.

The Timer T0 supports the following functions:

- Exit out of the Idle Mode (See Idle Mode description)
- Start up delay out of the HALT mode

The IDLE Timer T0 can generate an interrupt when the thirteenth bit toggles. This toggle is latched into the T0PND pending flag, and will occur every 4 ms at the maximum clock frequency (t_c = 1 μs). A control flag T0EN allows the interrupt from the thirteenth bit of Timer T0 to be enabled or disabled. Setting T0EN will enable the interrupt, while resetting it will disable the interrupt.

TIMER T1 AND TIMER T2

The device has a set of two powerful timer/counter blocks, T1 and T2. The associated features and functioning of a timer block are described by referring to the timer block Tx. Since the two timer blocks, T1 and T2 are identical, all comments are equally applicable to either of the two timer blocks.

Each timer block consists of a 16-bit timer, Tx, and two supporting 16-bit autoreload/capture registers, RxA and RxB. Each timer block has two pins associated with it, TxA and TxB. The pin TxA supports I/O required by the timer block, while the pin TxB is an input to the timer block. The powerful and flexible timer block allows the device to easily perform all timer functions with minimal software overhead. The timer block has three operating modes: Processor Independent PWM mode, External Event Counter mode, and Input Capture mode.

The control bits TxC3, TxC2, and TxC1 allow selection of the different modes of operation.

Mode 1. Processor Independent PWM Mode

As the name suggests, this mode allows the device to generate a PWM signal with very minimal user intervention. The user only has to define the parameters of the PWM signal (ON time and OFF time). Once begun, the timer block will continuously generate the PWM signal completely independent of the microcontroller. The user software services the timer block only when the PWM parameters require updating.

In this mode the timer Tx counts down at a fixed rate of tc. Upon every underflow the timer is alternately reloaded with the contents of supporting registers, RxA and RxB. The very first underflow of the timer causes the timer to reload from the register RxA. Subsequent underflows cause the timer to be reloaded from the registers alternately beginning with the register RxB.

The Tx Timer control bits, TxC3, TxC2 and TxC1 set up the timer for PWM mode operation.

Figure 7 shows a block diagram of the timer in PWM mode.

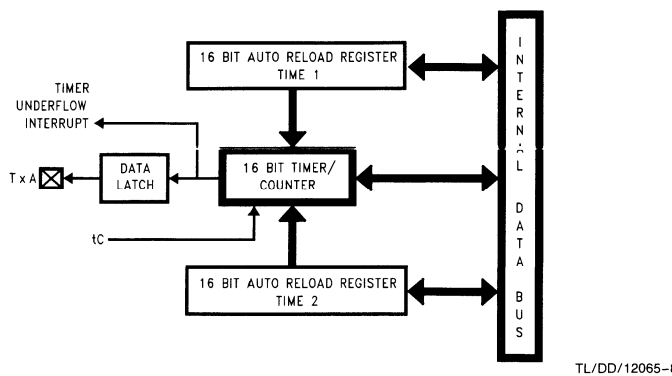
The underflows can be programmed to toggle the TxA output pin. The underflows can also be programmed to generate interrupts.

Underflows from the timer are alternately latched into two pending flags, TxPNDA and TxPNDB. The user must reset these pending flags under software control. Two control enable flags, TxENA and TxENB, allow the interrupts from the timer underflow to be enabled or disabled. Setting the timer enable flag TxENA will cause an interrupt when a timer underflow causes the RxA register to be reloaded into the timer. Setting the timer enable flag TxENB will cause an interrupt when a timer underflow causes the RxB register to be reloaded into the timer. Resetting the timer enable flags will disable the associated interrupts.

Either or both of the timer underflow interrupts may be enabled. This gives the user the flexibility of interrupting once per PWM period on either the rising or falling edge of the PWM output. Alternatively, the user may choose to interrupt on both edges of the PWM output.

Mode 2. External Event Counter Mode

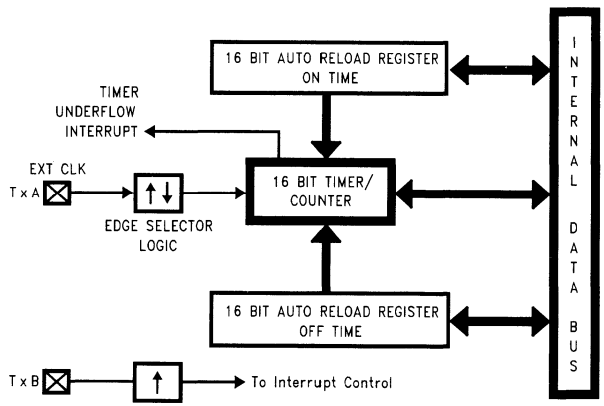
This mode is quite similar to the processor independent PWM mode described above. The main difference is that the timer, Tx, is clocked by the input signal from the TxA pin. The Tx timer control bits, TxC3, TxC2 and TxC1 allow the timer to be clocked either on a positive or negative edge from the TxA pin. Underflows from the timer are latched into the TxPNDA pending flag. Setting the TxENA control flag will cause an interrupt when the timer underflows.



TL/DD/12065–8

FIGURE 7. Timer in PWM Mode

Timers (Continued)



TL/DD/12065–9

FIGURE 8. Timer in External Event Counter Mode

In this mode the input pin TxB can be used as an independent positive edge sensitive interrupt input if the TxENB control flag is set. The occurrence of a positive edge on the TxB input pin is latched into the TxPNDB flag.

Figure 8 shows a block diagram of the timer in External Event Counter mode.

Note: The PWM output is not available in this mode since the TxA pin is being used as the counter input clock.

Mode 3. Input Capture Mode

The device can precisely measure external frequencies or time external events by placing the timer block, Tx, in the input capture mode.

In this mode, the timer Tx is constantly running at the fixed t_C rate. The two registers, RxA and RxB, act as capture registers. Each register acts in conjunction with a pin. The register RxA acts in conjunction with the TxA pin and the register RxB acts in conjunction with the TxB pin.

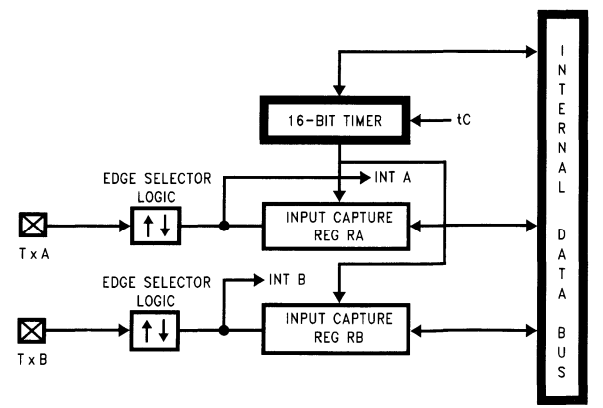
The timer value gets copied over into the register when a trigger event occurs on its corresponding pin. Control bits, TxC3, TxC2 and TxC1, allow the trigger events to be specified either as a positive or a negative edge. The trigger condition for each input pin can be specified independently.

The trigger conditions can also be programmed to generate interrupts. The occurrence of the specified trigger condition on the TxA and TxB pins will be respectively latched into the pending flags, TxPNDA and TxPNDB.

The control flag TxENA allows the interrupt on TxA to be either enabled or disabled. Setting the TxENA flag enables interrupts to be generated when the selected trigger condition occurs on the TxA pin. Similarly, the flag TxENB controls the interrupts from the TxB pin.

Underflows from the timer can also be programmed to generate interrupts. Underflows are latched into the timer TxC0 pending flag (the TxC0 control bit serves as the timer underflow interrupt pending flag in the Input Capture mode). Consequently, the TxC0 control bit should be reset when entering the Input Capture mode. The timer underflow interrupt is enabled with the TxENA control flag. When a TxA interrupt occurs in the Input Capture mode, the user must check both the TxPNDA and TxC0 pending flags in order to determine whether a TxA input capture or a timer underflow (or both) caused the interrupt.

Figure 9 shows a block diagram of the timer in Input Capture mode.



TL/DD/12065–10

FIGURE 9. Timer in Input Capture Mode

Timers (Continued)

TIMER CONTROL FLAGS

The timers T1 and T2 have identical control structures. The control bits and their functions are summarized below.

TxC0 Timer Start/Stop control in Modes 1 and 2 (Processor Independent PWM and External Event Counter), where 1 = Start, 0 = Stop Timer Underflow Interrupt Pending Flag in Mode 3 (Input Capture)

TxPNDA Timer Interrupt Pending Flag

TxPNDB Timer Interrupt Pending Flag

TxENA Timer Interrupt Enable Flag

0 = Timer Interrupt Disabled

TxC3 Timer mode control

TxC2 Timer mode control

TxC1 Timer mode control

The timer mode control bits (TxC3, TxC2 and TxC1) are detailed below:

Capture Timer

This device contains two independent capture timers, Capture Timer 1 and Capture Timer 2. Each capture timer contains an 8-bit programmable prescaler register, a 16-bit down counter, a 16-bit input capture register, and capture edge select logic. The 16-bit down counter is clocked at a specific frequency determined by the value loaded into the prnscaler register. A selected positive or negative edge transition on the capture input causes the contents of the down counter to be latched into the capture register. The values captured in the registers reflect the elapsed time between two positive or two negative transitions on the capture input. The time between a positive and negative edge (a pulse width) may be measured if the selected capture edge is switched after the first edge is captured. Each capture timer may be stopped/started under software control, and each capture timer may be configured to interrupt the microcontroller on an underflow or input capture.

Figure 10 shows the capture timer 1 block diagram.

TABLE II. Timer Mode Control

TxC3	TxC2	TxC1	Timer Mode	Interrupt A Source	Interrupt B Source	Timer Counts On
0	0	0	MODE 2 (External Event Counter)	Timer Underflow	Positive TxB Edge	TxA Positive Edge

FIGURE 10. Capture Timer 1 Block Diagram

The registers shown in the block diagram include those for Capture Timer 1 (CM1), as well as, the capture timer 1 control register. These registers are read/writable (with the exception of the capture registers, which are read-only) and may be accessed through the data memory address/data bus. The registers are designated as:

CM1PSC Capture Timer 1 Prescaler (8-bit)

CM1CRL Capture Timer 1 Capture Register (Low-byte), read-only

CM1CRH Capture Timer 1 Capture Register (High-byte), read-only

CM2PSC Capture Timer 2 Prescaler (8-bit)

CM2CRL Capture Timer 2 Capture Register (Low-byte), read-only

CM2CRH Capture Timer 2 Capture Register (High-byte), read-only

CCMR1 Control Register for Capture Timer 1

CCMR2 Control Register for Capture Timer 2

CONTROL REGISTER BITS

The control bits for Capture Timer 1 (CM1) and Capture Timer 2 (CM2) are contained in CCMR1 and CCMR2.

The CCMR1 Register Bits are:

CM1RUN CM1 start/stop control bit (1 = start; 0 = stop)

CM1IEN CM1 interrupt enable control bit (1 = enable IRQ)

CM1IP1 CM1 interrupt pending bit 1 (1 = CM1 underflowed)

CM1IP2 CM1 interrupt pending bit 2 (1 = CM1 captured)

CM1EC Select the active edge for capture on CM1 (0 = rising, 1 = falling)

CM1TM CM1 test mode control bit (1 = special test path in test mode. This bit is reserved during normal operation, and must never be set to one.)

CM1 TM	un- used	un- used	CM1 EC	CM1 IP2	CM1 IP1	CM1 IEN	CM1 RUN

Bit 7 Bit 0

All interrupt pending bits must be reset by software.

Timers (Continued)

The CCMR2 Register Bits are:

CM2RUN CM2 start/stop control bit (1 start; 0 = stop)

CM2IEN CM2 interrupt enable control bit (1 = enable IRQ)

CM2IP1 CM2 interrupt pending bit 1 (1 = CM2 underflowed)

CM2IP2 CM2 interrupt pending bit 2 (1 = CM2 captured)

CM2EC Select the active edge for capture on CM2 (0 = rising, 1 = falling)

CM2TM CM2 test mode control bit (1 = special test path in test mode. This bit is reserved during normal operation, and must never be set to one.)

CM2 TM	un- used	un- used	CM2 EC	CM2 IP2	CM2 IP1	CM2 IEN	CM RUN

Bit 7 Bit 0

All interrupt pending bits must be reset by software.

FUNCTIONAL DESCRIPTION

The capture timer is used to determine the time between events, where an event is simply a selected edge transition on the capture input. The resolution of the time measurement is dependent on the frequency at which the down counter is clocked. The value loaded into the prescaler controls this frequency.

The prescaler is clocked by CKI, while the down counter is clocked on every underflow of the prescaler. This means the prescaler simply divides the CKI clock before it is fed into the down counter. The prescaler register must be loaded with a value corresponding to the CKI divisor needed to produce the desired down counter clock. The appropriate prescaler value can be determined using the following equation:

Down Counter Clock Frequency = CKI/(CMxPSC + 1)

The capture input signal is set up by configuring the port pin associated with the capture timer as an input. The edge select bit for the capture input is then set or reset according to the desired transition. If the pin is configured as an input, the appropriate external transition will cause a capture. If the pin is configured as an output, toggling the data register bit will cause a capture. If interrupts are used, the capture timer interrupt pending bits are cleared and the capture timer interrupt enable bit is set. Both interrupt sources, down counter underflow and input capture edge, are enabled/disabled with the same CMxIEN bit. The GIE bit must also be set to enable interrupts. The interrupt signals from the two capture timers are gated to a single 16-bit interrupt vector located at addresses 0xE6 and 0xE7.

The capture timer is started by writing a "1" to the capture timer start/stop bit. Setting this bit also enables the port pin to be the capture input to the capture timer. The internal prescaler is loaded with the contents of the prescaler register, and begins counting down. Setting the start/stop bit also loads the down counter with 0FFFF Hex. The prescaler is clocked by CKI. An underflow of the prescaler decrements the 16-bit down counter, and reloads the value from the prescaler register into the prescaler. Each additional underflow of the prescaler decrements the down counter, and reloads the prescaler from the prescaler register.

If a selected edge transition on the input capture pin occurs, the contents of the down counter are immediately latched into the capture register, the down counter is re-initialized to 0FFFF Hex, and the capture input pending flag is set. The prescaler counter is not loaded. (In order for an input transition to be guaranteed recognized, the signal on the capture input pin must have a low pulse width and a high pulse width of at least one CKI period.) If interrupts are enabled, the capture timer generates an interrupt. The prescaler and down counter continue to operate until a reset condition occurs or the capture timer start/stop bit is reset. The user must process capture interrupts faster than the capture input frequency, otherwise input captures may be lost or erroneous values may be read.

If the down counter underflows (changes state from 0000 to FFFF) before a capture input is detected, the underflow interrupt pending flag is set. If interrupts are enabled, the capture timer generates an interrupt.

The capture timer may be stopped at any time under software control by resetting the capture timer start/stop bit. A capture may occur before the start/stop bit is physically cleared, due to the fully asynchronous nature of the input capture signal. The user must ensure that the software handles this situation correctly. If the user wishes to process this capture and interrupts are being used, the capture timer interrupts should not be disabled prior to stopping the timer. If interrupts are not being used, the user should poll the capture timer pending bits after stopping the timer. If the user wishes to ignore this capture and interrupts are being used, the capture timer interrupt service routine should check that the timer is still running prior to processing capture interrupts. If the user is polling the pending flags, these flags should be cleared after the timer is stopped. The contents of the prescaler and down counter remain unchanged while the capture timer is stopped. The capture edge detect logic is disabled, and no capture takes place even if an external capture signal occurs. The capture timer may be restarted under software control by writing a "1" to the start/stop bit. This causes the prescaler and down counter to be re-initialized. The prescaler is loaded from the prescaler register, and the down counter is loaded with 0FFFF Hex.

RESET STATE

A reset signal applied to the counter block during normal operation has the following effects:

- Clear CCMR1 register
- Clear CCMR2 register
- CM1PSC, CMICRL, CM1CRH, CM2PSC, CM2CRL and CM2CRH are unaffected. (At power-on, the contents of these registers are undefined.)

The bi-directional port pins are initialized during reset as HI-Z inputs. Setting the start/stop bits connects the pins to the capture timers.

Timers (Continued)

INITIALIZATION

The user should perform the following initialization prior to starting the capture timer:

1. Reset the CMxRUN bit
2. Configure the corresponding Port bits as inputs
3. Set the edge control bits CMxEC
4. Reset CMxIP1 (CMxIP1 = 0)
5. Reset CMxIP2 (CMxIP2 = 0)
6. Load the 8-bit prescaler register CMxPSC with the desired value (from 0 to 255)
7. Set CMxIEN (if interrupts are to be used)
8. Set the Global Interrupt Enable (GIE) bit (if interrupts are to be used)
9. Set CMxRUN bit to start the capture timer

WARNING

In order to avoid erroneous interrupts, the capture timer interrupts must be disabled prior to setting/resetting the capture edge control bits (CMxEC). In addition, after selecting the interrupt edge, the pending flags must be reset before the capture interrupts are enabled or re-enabled. If the initialization sequence outlined above is followed each time the user alters the edge control bits, the user is guaranteed to avoid erroneous interrupts.

Pulse Train Generators

This device contains four independent pulse train generators. Each individual generator is controlled by a corresponding 16-bit counter. Each counter has a 16-bit prescaler and a 16-bit count register. Each counter may be configured to output a selected number of 50% duty cycle pulses. The contents of the prescaler determine the width of the output pulses, and the value of the count register determines the number of pulses. Each counter may be stopped/started under software control, and each counter may be configured to interrupt the microcontroller on an underflow.

Figure 11 shows the pulse train generator 1 block diagram.

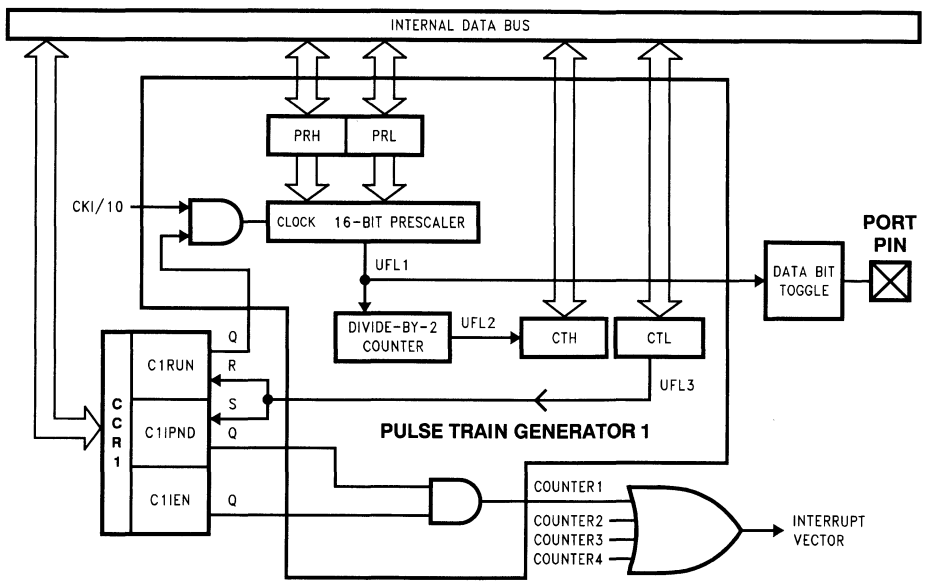

FIGURE 11. Pulse Train Generator 1 Block Diagram

Pulse Train Generators (Continued)

The four 8-bit registers shown in each individual counter in the block diagram constitute a 16-bit prescaler and a 16-bit count register. These registers are all read/writable and may be accessed through the data memory address/data bus. The registers are designated as:

CxPRL Low-byte of the Prescaler

CxPRH High-byte of the Prescaler

CxCTL Low-byte of the Count Register

CxCTH High-byte of the Count Register

CONTROL REGISTER BITS

The control bits for Counter 1 and Counter 2 are contained in the CCR1 register. The CCR1 Register bits are:

C1RUN COUNTER1 start/stop control bit (1 = start; 0 = stop)

C1IEN COUNTER1 interrupt enable control bit (1 = enable IRQ)

C1IPND COUNTER1 interrupt pending bit (1 counter 1 underflowed)

C1TM COUNTER1 test mode control bit (1 = special test path in test mode. This bit is reserved during normal operation, and must never be set to one.)

C2RUN COUNTER2 start/stop control bit (1 = start; 0 = stop)

C2IEN COUNTER2 interrupt enable control bit (1 = enable IRQ)

C2IPND COUNTER2 interrupt pending bit (1 = counter 2 underflowed)

C2TM COUNTER2 test mode control bit (1 = special test path. This bit is reserved during normal operation, and must never be set to one.)

All interrupt pending bits must be reset by software.

C2TM	C2 IPND	C2 IEN	C2 RUN	C1TM	C1 IPND	C1 IEN	C1 RUN

Bit 7 Bit 0

The control bits for Counter 3 and Counter 4 are contained in the CCR2 register. The CCR2 Register bits are:

C3RUN COUNTER3 start stop control bit (1 = start; 0 = stop)

C3IEN COUNTER3 interrupt enable control bit (1 = enable IRQ)

C3IPND COUNTER3 interrupt pending Bit (1 = counter 3 underflowed)

C3TM COUNTER3 test mode control bit (1 = special test path. This bit is reserved during normal operation, and must never be set to one.)

C4RUN COUNTER4 start/stop control bit (1 = start; 0 = stop)

C4IEN COUNTER4 interrupt enable control bit (1 = enable IRQ)

C4IPND COUNTER4 interrupt pending bit (1 = counter 4 underflowed

C4TM COUNTER4 test mode control bit (1 = special test path. This bit is reserved during normal operation, and must never be set to one.)

C4TM	C4 IPND	C4 IEN	C4 RUN	C3TM	C3 IPND	C3 IEN	C3 RUN

Bit 7 Bit 0

All interrupt pending bits must be reset by software.

FUNCTIONAL DESCRIPTION

The pulse train generator may be used to produce a series of output pulses of a given width. The high/low time of a pulse is determined by the contents of the prescaler. The number of pulses in a series is determined by the contents of the count register.

The prescaler is loaded with a value corresponding to the desired width of the output pulse (t_w). The high time and low time of the output signal are each equal to t_w, therefore the output signal produced has a 50% duty cycle and a period equal to 2 * t_w. The appropriate prescaler value can be determined using the following equation:

$$t_w = [(PRH * 256) + PRL + 1] * t_c$$

Since PRH and PRL are both 8-bit registers, this equation allows a maximum t_w of 65536 t_c and a minimum t_w of one t_c. The internal prescaler is automatically loaded from PRH and PRL when the counter start/stop bit is set.

The count register is loaded with a value corresponding to the desired number of output pulses. The appropriate count value is calculated with the following equation:

$$\text{Number of Pulses} = CTH * 256 + CTL + 1$$

The port pin associated with the counter OUT signal is configured in software as an output, and preset to the desired start logic level. If interrupts are to be used, the counter interrupt pending bit is cleared and the interrupt enable bit is set. The GIE bit must also be set to enable interrupts. The interrupt signals from the four counters are gated to a single interrupt vector located at addresses 0xF0–0xF1.

The counter is started by writing a "1" to the counter start/stop bit. This resets the divide-by-2 counter which produces the clock signal for the counter register from the prescaler underflow (See *Figure 11*). It also reloads the internal prescaler and starts the prescaler counting down on the next rising edge of t_c. The prescaler is clocked on the rising edge of t_c to ensure synchronization. Each subsequent rising edge of t_c causes the prescaler to be decremented. When the prescaler underflows, UFL1 is generated (see *Figure 12*). This signal causes the port pin to toggle. In addition, the internal prescaler is reloaded with the value from the PRH and PRL registers. Each additional underflow of the prescaler causes the port pin to toggle and reloads the internal prescaler.

Every second underflow of the prescaler generates the signal UFL2. (UFL2 occurs at half the frequency of UFL1, or once per output pulse.) This signal, UFL2, decrements the count register. Therefore, the count registers are decremented once per output pulse.

Pulse Train Generators (Continued)

The underflow of the counter register produces the signal UFL3. This signal stops the counter by resetting the counter start/stop bit, and sets the counter interrupt pending flag. If the counter interrupt is enabled, an interrupt occurs.

The counter may be stopped at any time under software control by resetting the counter start/stop bit. The contents of the count register and the output on the associated port pin are frozen. The counter may be restarted under software control by setting the start/stop bit. The internal prescaler is automatically reloaded from PRH and PRL when the counter start/stop bit is set, therefore a full width pulse will be generated before the output is toggled. The user may also choose to alter the logic level on the port pin before restarting. This is done by initializing the associated port pin data register bit. A counter underflow may occur before the start/stop bit is physically cleared by software. The user must ensure that the software handles this situation correctly. If the user wishes to process this underflow and interrupts are being used, the counter interrupts should not be disabled prior to stopping the timer. If interrupts are not being used, the user should poll the counter pending bits after stopping the timer. If the user wishes to ignore this underflow and interrupts are being used, the counter interrupt should be disabled prior to stopping the timer. If the user is polling the pending flags, these flags should be cleared after the timer is stopped.

If the default level of the output pin is high (associated port data register bit is set to "1") and the counter is stopped during a low level, the low level becomes the default level. The software must reinitialize the port pin to a high level before restarting if necessary. The programmer may also have to adjust the counter value (See *Figure 12*).

RESET STATE

A reset signal applied to the pulse train generator block during normal operation has the following effects:

- Counting stops immediately
- Interrupt enable bit is reset to zero
- Counter start/stop bit is reset to zero
- Interrupt pending bit is reset to zero
- Test mode control bit is reset to zero
- PRL, PRH, CTL and CTH are unaffected (At power-on reset, the contents of the prescaler and count register are undefined.)
- Divide-by-2 counter is reset
- The bi-directional port pins are initialized during reset as HI-Z inputs. The appropriate bits must be initialized as outputs, in order to route the Counter OUT signals to the port pins.

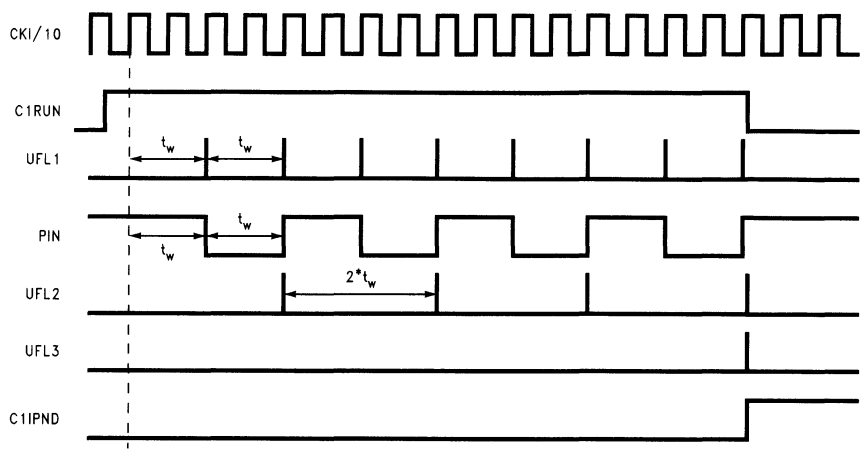
INITIALIZATION

The user should perform the following initialization prior to starting the counter:

1. Load PRL register
2. Load PRH register
3. Load CTL register
4. Load CTH register
5. Reset CxIPND bit
6. Set CxIEN (if interrupt is to be used)
7. Configure the associated port bit as an output (if OUT is to be used)
8. Set the Global Interrupt Enable (GIE) bit (if interrupt is to be used)
9. Set CxRUN bit to start counter

Multiply/Divide

This device contains a multiply/divide block. This block supports a 1 byte x 2 bytes (3 bytes result) multiply or a 3 bytes/2 bytes (2 bytes result) divide operation. The multiply or divide operation is executed by setting control bits located in the multiply/divide control register. The multiply or divide operands must be placed into the appropriate memory mapped locations before the operation is initiated.



TL/DD/12065–13

FIGURE 12. Timing Diagram for PRL = 1, PRH = 0, CTL = 3, CTH = 0

Multiply/Divide (Continued)

TABLE III. Multiply/Divide Registers

Register Name (Address)	Multiplication Assignment		Division Assignment	
	Before Operation	After Operation	Before Operation	After Operation
MDR1 (xx98)	Unused	Unchanged	Low byte of dividend	Low byte of result
MDR2 (xx99)	Multiplier	Low byte of result	Middle byte of dividend	High byte of result
MDR3 (xx9A)		Middle byte of result	High byte of dividend	Undefined
MDR4 (xx9B)	Low byte of multiplicand	High byte of result	Low byte of divisor	Low byte of divisor
MDR5 (xx9C)	High byte of multiplicand	Unchanged	High byte of divisor	High byte of divisor

CONTROL REGISTER BITS

The Multiply/Divide control register (MDCR) is located at address xx9D. It has the following bit assignments:

MULT Start Multiplication Operation (1 = start)

DIV Start Division Operation (1 = start)

DIVOVF Division Overflow (if the result of a division is greater than 16 bits or the user attempted to divide by zero; 1 = error)

Rsvd	Rsvd	Rsvd	Rsvd	Rsvd	DIV OVF	DIV	MULT

Bit 7 Bit 0

After the appropriate MDR registers are loaded, the MULT and DIV start bits are set by the user to start a multiply or divide operation. The division operation has priority, if both bits are set simultaneously. The MULT and DIV bits are BOTH automatically cleared by hardware at the end of a divide or multiply operation. Each division operation causes the DIVOVF flag to be set/reset as appropriate. The DIVOVF flag is cleared following a multiplication operation. DIVOVF is a read-only bit. The MULT and DIV bits are read/writable. Bits 3-7 in MDCR should not be used, as the MULT and DIV operations will change their values.

MULTIPLY/DIVIDE OPERATION

For the multiply operation, the multiplicand is placed at addresses xx9B and xx9C. The multiplier is placed at address xx99. For the divide operation, the dividend is placed at addresses xx98 to xx9A and the divisor is placed at addresses xx9B to xx9C. In both operations, all operands are interpreted as unsigned values. The divide or multiply operation is started by setting the appropriate MDCR bit. If both the MULT and DIV bits are set, the microcontroller performs a divide operation. (The user is not required to read or clear the DIVOVF error bit prior to beginning a new multiply/divide operation. This bit is ignored during subsequent operations. However, the next divide operation will overwrite the error flag as appropriate, and the next multiply operation will clear it.)

The multiply operation requires 1 instruction cycle to complete. The divide operation requires 2 instruction cycles to complete. A divide by zero or a division which produces an overflow requires only 1 instruction cycle to execute. The MDR1 through MDR5 registers and the MDCR register can not be read from or written to during a multiply or divide operation. Any attempt to write into these registers will be ignored. Any attempt to read these registers will return undefined data.

The result of a multiply is placed in addresses xx99-xx9B. The result of a divide is placed in addresses xx98-xx99. If a division by zero is attempted or if the resulting quotient of a divide operation is more than 16 bits long, then the DIVOVF bit is set in the multiply/divide control register. The dividend and the divisor are left unchanged. The divide operation always causes the DIVOVF flag to be set or reset as appropriate. The DIVOVF flag is cleared following a multiply operation.

RESET STATE

A reset signal applied to the device during normal operation has the following affects:

MDCR is cleared, and any operation in progress is stopped.

MDR1 through MDR5 are undefined.

Power Save Modes

The device offers the user two power save modes of operation: HALT and IDLE. In the HALT mode, all microcontroller activities are stopped. In the IDLE mode, the on-board oscillator circuitry and timer T0 are active but all other microcontroller activities are stopped. In either mode, all on-board RAM, registers, I/O states, and timers (with the exception of T0) are unaltered.

HALT MODE

The device can be placed in the HALT mode by writing a "1" to the HALT flag (G7 data bit). All microcontroller activities, including the clock and timers, are stopped. In the HALT mode, the power requirements of the device are minimal and the applied voltage (V_{CC}) may be decreased to V_r (V_r = 2.0V) without altering the state of the machine.

The device supports two different ways of exiting the HALT mode. The first method of exiting the HALT mode is with the Multi-Input Wakeup feature on the L port. The second method of exiting the HALT mode is by pulling the $\overline{\text{RESET}}$ pin low.

Since a crystal or ceramic resonator may be selected as the oscillator, the Wakeup signal is not allowed to start the chip running immediately since crystal oscillators and ceramic resonators have a delayed start up time to reach full amplitude and frequency stability. The IDLE timer is used to generate a fixed delay to ensure that the oscillator has indeed stabilized before allowing instruction execution. In this case, upon detecting a valid Wakeup signal, only the oscillator circuitry is enabled. The IDLE timer is loaded with a value of 256 and is clocked with the t_c instruction cycle clock. The t_c clock is derived by dividing the oscillator clock down by a

Power Save Modes (Continued)

factor of 10. The Schmitt trigger following the CKI inverter on the chip ensures that the IDLE timer is clocked only when the oscillator has a sufficiently large amplitude to meet the Schmitt trigger specifications. This Schmitt trigger is not part of the oscillator closed loop. The startup timeout from the IDLE timer enables the clock signals to be routed to the rest of the chip.

The devices have two mask options associated with the HALT mode. The first mask option enables the HALT mode feature, while the second mask option disables the HALT mode. With the HALT mode enable mask option, the device will enter and exit the HALT mode as described above. With the HALT disable mask option, the device cannot be placed in the HALT mode (writing a "1" to the HALT flag will have no effect, the HALT flag will remain "0").

IDLE MODE

The device is placed in the IDLE mode by writing a "1" to the IDLE flag (G6 data bit). In this mode, all activities, except the associated on-board oscillator circuitry and the IDLE Timer T0, are stopped.

As with the HALT mode, the device can be returned to normal operation with a reset, or with a Multi-Input Wake up from the L Port. Alternately, the microcontroller resumes normal operation from the IDLE mode when the thirteenth bit (representing 4.096 ms at internal clock frequency of 10 MHz, t_c = 1 μs) of the IDLE Timer toggles.

This toggle condition of the thirteenth bit of the IDLE Timer T0 is latched into the T0PND pending flag.

The user has the option of being interrupted with a transition on the thirteenth bit of the IDLE Timer T0. The interrupt can be enabled or disabled via the T0EN control bit. Setting the T0EN flag enables the interrupt and vice versa.

The user can enter the IDLE mode with the Timer T0 interrupt enabled. In this case, when the T0PND bit gets set, the device will first execute the Timer T0 interrupt service routine and then return to the instruction following the "Enter Idle Mode" instruction.

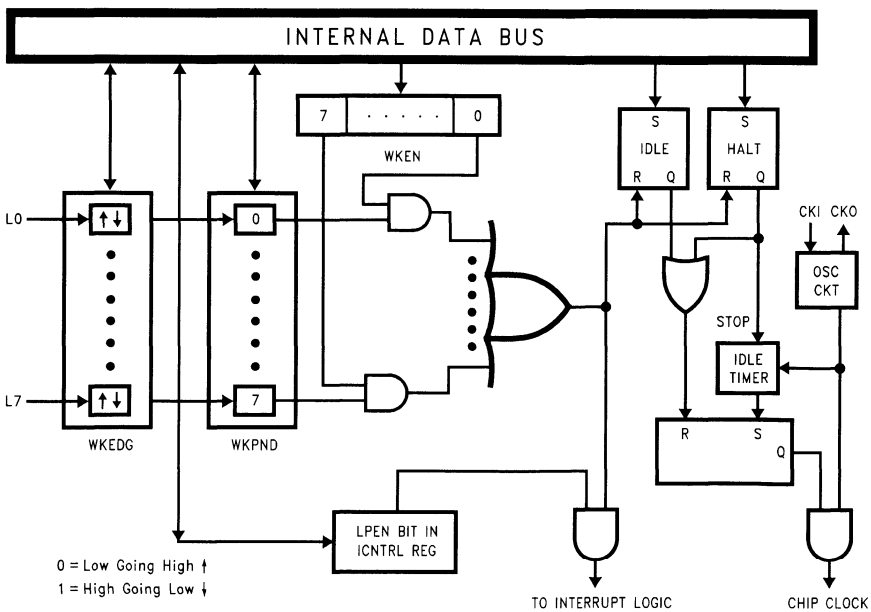
Alternatively, the user can enter the IDLE mode with the IDLE Timer T0 interrupt disabled. In this case, the device will resume normal operation with the instruction immediately following the "Enter IDLE Mode" instruction.

Note: It is necessary to program two NOP instructions following both the set HALT mode and set IDLE mode instructions. These NOP instructions are necessary to allow clock resynchronization following the HALT or IDLE modes.

Multi-Input Wakeup

The Multi-Input Wake Up feature is used to return (wake up) the device from either the HALT or IDLE modes. Alternately Multi-Input Wake Up/Interrupt feature may also be used to generate up to 8 edge selectable external interrupts.

Figure 13 shows the Multi-Input Wake Up logic.



TL/DD/12065–15

FIGURE 13. Multi-Input Wake Up Logic

Multi-Input Wakeup (Continued)

The Multi-Input Wake Up feature utilizes the L Port. The user selects which particular L port bit (or combination of L Port bits) will cause the device to exit the HALT or IDLE modes. The selection is done through the register WKEN. The register WKEN is an 8-bit read/write register, which contains a control bit for every L port bit. Setting a particular WKEN bit enables a Wake Up from the associated L port pin.

The user can select whether the trigger condition on the selected L Port pin is going to be either a positive edge (low to high transition) or a negative edge (high to low transition). This selection is made via the register WKEDG, which is an 8-bit control register with a bit assigned to each L Port pin. Setting the control bit will select the trigger condition to be a negative edge on that particular L Port pin. Resetting the bit selects the trigger condition to be a positive edge. Changing an edge select entails several steps in order to avoid a Wake Up condition as a result of the edge change. First, the associated WKEN bit should be reset, followed by the edge select change in WKEDG. Next, the associated WKPND bit should be cleared, followed by the associated WKEN bit being reenabled.

An example may serve to clarify this procedure. Suppose we wish to change the edge select from positive (low going high) to negative (high going low) for L Port bit 5, where bit 5 has previously been enabled for an input interrupt. The program would be as follows:

```
RBIT 5, WKEN
SBIT 5, WKEDG
RBIT 5, WKPND
SBIT 5, WKEN
```

If the L port bits have been used as outputs and then changed to inputs with Multi-Input Wake Up/Interrupt, a safety procedure should also be followed to avoid wakeup conditions. After the selected L port bits have been changed from output to input but before the associated WKEN bits are enabled, the associated edge select bits in WKEDG should be set or reset for the desired edge selects, followed by the associated WKPND bits being cleared,

This same procedure should be used following reset, since the L port inputs are left floating as a result of reset.

The occurrence of the selected trigger condition for Multi-Input Wake Up is latched into a pending register called WKPND. The respective bits of the WKPND register will be set on the occurrence of the selected trigger edge on the corresponding Port L pin. The user has the responsibility of clearing these pending flags. Since WKPND is a pending register for the occurrence of selected wake up conditions, the device will not enter the HALT mode if any Wake Up bit is both enabled and pending. Consequently, the user must clear the pending flags before attempting to enter the HALT mode.

WKEN, WKPND and WKEDG are all read/write registers, and are cleared at reset.

PORT L INTERRUPTS

Port L provides the user with an additional eight fully selectable, edge sensitive interrupts which are all vectored into the same service subroutine.

The interrupt from Port L shares logic with the wake up circuitry. The register WKEN allows interrupts from Port L to be individually enabled or disabled. The register WKEDG specifies the trigger condition to be either a positive or a negative edge. Finally, the register WKPND latches in the pending trigger conditions.

The GIE (Global Interrupt Enable) bit enables the interrupt function.

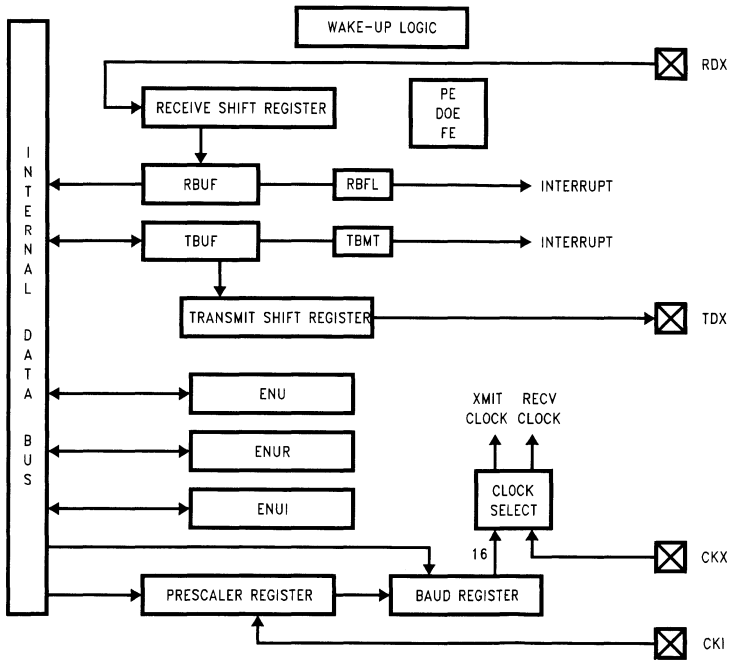
A control flag, LPEN, functions as a global interrupt enable for Port L interrupts. Setting the LPEN flag will enable interrupts and vice versa. A separate global pending flag is not needed since the register WKPND is adequate.

Since Port L is also used for waking the device out of the HALT or IDLE modes, the user can elect to exit the HALT or IDLE modes either with or without the interrupt enabled. If he elects to disable the interrupt, then the device will restart execution from the instruction immediately following the instruction that placed the microcontroller in the HALT or IDLE modes. In the other case, the device will first execute the interrupt service routine and then revert to normal operation. (See HALT MODE for clock option wake up information.)

UART

The device contains a full-duplex software programmable UART. The UART (*Figure 14*) consists of a transmit shift register, a receive shift register and seven addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR), a UART interrupt and clock source register (ENUI), a prescaler select register (PSR) and baud (BAUD) register. The ENU register contains flags for transmit and receive functions; this register also determines the length of the data frame (7, 8 or 9 bits), the value of the ninth bit in transmission, and parity selection bits. The ENUR register flags framing, data overrun and parity errors while the UART is receiving.

Other functions of the ENUR register include saving the ninth bit received in the data frame, enabling or disabling the UART's attention mode of operation and providing additional receiver/transmitter status information via RCVG and XMTG bits. The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits and enabling or disabling transmit and receive interrupts. A control flag in this register can also select the UART mode of operation: asynchronous or synchronous.



TL/DD/12065–16

FIGURE 14. UART Block Diagram

UART (Continued)

UART CONTROL AND STATUS REGISTERS

The operation of the UART is programmed through three registers: ENU, ENUR and ENUI. The function of the individual bits in these registers is as follows:

ENU-UART Control and Status Register (Address at 0BA)

PEN	PSEL1	XBIT9/ PSEL0	CHL1	CHL0	ERR	RBFL	TBMT
0RW	0RW	0RW	0RW	0RW	0R	0R	IR

Bit 7 Bit 0

ENUR-UART Receive Control and Status Register (Address at 0BB)

DOE	FE	PE	SPARE	RBIT9	ATTN	XMTG	RCVG
0RD	0RD	0RD	0RW*	0R	0RW	0R	0R

Bit 7 Bit 0

ENUI-UART Interrupt and Clock Source Register (Address at 0BC)

STP2	STP78	ETDX	SSEL	XRCLK	XTCLK	ERI	ETI
0RW	0RW	0RW	0RW	0RW	0RW	0RW	0RW

Bit 7 Bit 0

* Bit is not used.

0 Bit is cleared on reset.

1 Bit is set to one on reset.

R Bit is read-only; it cannot be written by software.

RW Bit is read/write.

D Bit is cleared on read; when read by software as a one, it is cleared automatically. Writing to the bit does not affect its state.

DESCRIPTION OF UART REGISTER BITS

ENU—UART CONTROL AND STATUS REGISTER

TBMT: This bit is set when the UART transfers a byte of data from the TBUF register into the TSFT register for transmission. It is automatically reset when software writes into the TBUF register.

RBFL: This bit is set when the UART has received a complete character and has copied it into the RBUF register. It is automatically reset when software reads the character from RBUF.

ERR: This bit is a global UART error flag which gets set if any or a combination of the errors (DOE, FE, PE) occur.

CHL1, CHL0: These bits select the character frame format. Parity is not included and is generated/verified by hardware.

CHL1 = 0, CHL0 = 0 The frame contains eight data bits.

CHL1 = 0, CHL0 = 1 The frame continues seven data bits.

CHL1 = 1, CHL0 = 0 The frame continues nine data bits.

CHL1 = 1. CHL0 = 1 Loopback Mode selected. Transmitter output internally looped back to receiver input. Nine bit framing format is used.

XBIT9/PSEL0: Programs the ninth bit for transmission when the UART is operating with nine data bits per frame. For seven or eight data bits per frame, this bit in conjunction with PSEL1 selects parity.

PSEL1, PSEL0: Parity select bits.

PSEL1 = 0, PSEL0 = 0 Odd Parity (if Parity enabled)

PSEL1 = 0, PSEL1 = 1 Odd Parity (if Parity enabled)

PSEL1 = 1, PSEL0 = 0 Mark(1) (if Parity enabled)

PSEL1 = 1, PSEL1 = 1 Space(0) (if Parity enabled)

PEN: This bit enables/disables Parity (7- and 8-bit modes only).

PEN = 0 Parity disabled.

PEN = 1 Parity enabled.

ENUR—UART RECEIVE CONTROL AND STATUS REGISTER

RCVG: This bit is set high whenever a framing error occurs and goes low when RDX goes high.

XMTG: This bit is set to indicate that the UART is transmitting. It gets reset at the end of the last frame (end of last Stop bit).

ATTN: ATTENTION Mode is enabled while this bit is set. This bit is cleared automatically on receiving a character with data bit nine set.

RBIT9: Contains the ninth data bit received when the UART is operating with nine data bits per frame.

SPARE: Reserved for future use.

PE: Flags a Parity Error.

PE = 0 Indicates no Parity Error has been detected since the last time the ENUR register was read.

PE = 1 Indicates the occurrence of a Parity Error.

FE: Flags a Framing Error.

FE = 0 Indicates no Framing Error has been detected since the last time the ENUR register was read.

FE = 1 Indicates the occurrence of a Framing Error.

DOE: Flags a Data Overrun Error.

DOE = 0 Indicates no Data Overrun Error has been detected since the last time the ENUR register was read.

DOE = 1 Indicates the occurrence of a Data Overrun Error.

ENUI—UART INTERRUPT AND CLOCK SOURCE REGISTER

ETI: This bit enables/disables interrupt from the transmitter section.

ETI = 0 Interrupt from the transmitter is disabled.

ETI = 1 Interrupt from the transmitter is enabled.

ERI: This bit enables/disables interrupt from the receiver section.

UART (Continued)

ERI = 0 Interrupt from the receiver is disabled.

ERI = 1 Interrupt from the receiver is enabled.

XTCLK: This bit selects the clock source for the transmitter section.

XTCLK = 0 The clock source is selected through the PSR and BAUD registers.

XTCLK = 1 Signal on CKX (L1) pin is used as the clock.

XRCLK: This bit selects the clock source for the receiver section.

XRCLK = 0 The clock source is selected through the PSR and BAUD registers.

XRCLK = 1 Signal on CKX (L1) pin is used as the clock.

SSEL: UART mode select.

SSEL = 0 Asynchronous Mode.

SSEL = 1 Synchronous Mode.

ETDX: TDX (UART Transmit Pin) is the alternate function assigned to Port L pin L2; it is selected by setting ETDX bit. To simulate line break generation, software should reset ETDX bit and output logic zero to TDX pin through Port L data and configuration registers.

STP78: This bit is set to program the last Stop bit to be 7/8th of a bit in length.

STP2: This bit programs the number of Stop bits to be transmitted.

STP2 = 0 One Stop bit transmitted.

STP2 = 1 Two Stop bits transmitted.

Associated I/O Pins

Data is transmitted on the TDX pin and received on the RDX pin. TDX is the alternate function assigned to Port L pin L2; it is selected by setting ETDX (in the ENUI register) to one. RDX is an inherent function of Port L pin L3, requiring no setup.

The baud rate clock for the UART can be generated on-chip, or can be taken from an external source. Port L pin L1 (CKX) is the external clock I/O pin. The CKX pin can be either an input or an output, as determined by Port L Configuration and Data registers (Bit 1). As an input, it accepts a clock signal which may be selected to drive the transmitter and/or receiver. As an output, it presents the internal Baud Rate Generator output.

UART Operation

The UART has two modes of operation: asynchronous mode and synchronous mode.

ASYNCHRONOUS MODE

This mode is selected by resetting the SSEL (in the ENUI register) bit to zero. The input frequency to the UART is 16 times the baud rate.

The TSFT and TBUF registers double-buffer data for transmission. While TSFT is shifting out the current character on the TDX pin, the TBUF register may be loaded by software with the next byte to be transmitted. When TSFT finishes transmitting the current character the contents of TBUF are transferred to the TSFT register and the Transmit Buffer Empty Flag (TBMT in the ENU register) is set. The TBMT flag is automatically reset by the UART when software loads a new character into the TBUF register. There is also the XMTG bit which is set to indicate that the UART is transmitting. This bit gets reset at the end of the last frame (end of last Stop bit). TBUF is a read/write register.

The RSFT and RBUF registers double-buffer data being received. The UART receiver continually monitors the signal on the RDX pin for a low level to detect the beginning of a Start bit. Upon sensing this low level, it waits for half a bit time and samples again. If the RDX pin is still low, the receiver considers this to be a valid Start bit, and the remaining bits in the character frame are each sampled a single time, at the mid-bit position. Serial data input on the RDX pin is shifted into the RSFT register. Upon receiving the complete character, the contents of the RSFT register are copied into the RBUF register and the Received Buffer Full Flag (RBFL) is set. RBFL is automatically reset when software reads the character from the RBUF register. RBUF is a read only register. There is also the RCVG bit which is set high when a framing error occurs and goes low once RDX goes high. TBMT, XMTG, RBFL and RCVG are read only bits.

SYNCHRONOUS MODE

In this mode data is transferred synchronously with the clock. Data is transmitted on the rising edge and received on the falling edge of the synchronous clock.

This mode is selected by setting SSEL bit in the ENUI register. The input frequency to the UART is the same as the baud rate.

When an external clock input is selected at the CKX pin, data transmit and receive are performed synchronously with this clock through TDX/RDX pins.

If data transmit and receive are selected with the CKX pin as clock output, the device generates the synchronous clock output at the CKX pin. The internal baud rate generator is used to produce the synchronous clock. Data transmit and receive are performed synchronously with this clock.

FRAMING FORMATS

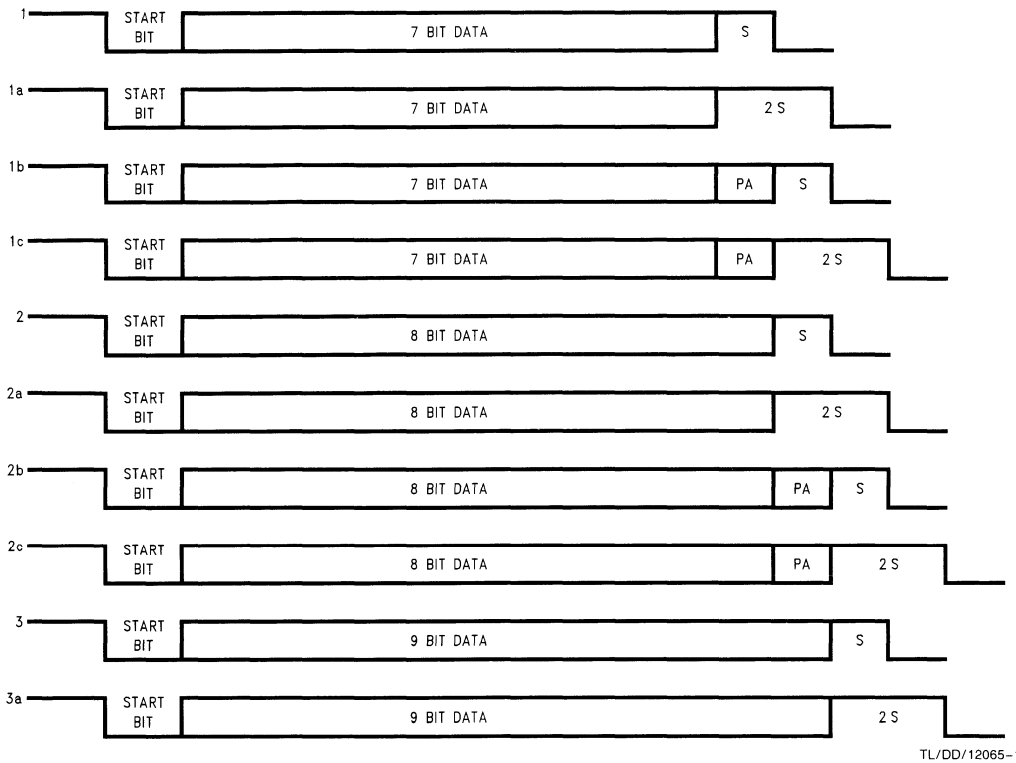
The UART supports several serial framing formats *(Figure 15)*. The format is selected using control bits in the ENU, ENUR and ENUI registers.

The first format (1,1a, 1b, 1c) for data transmission (CHL0 = 1, CHL1 = 0) consists of Start bit, seven Data bits (excluding parity) and 7/8, one or two Stop bits. In applications using parity, the parity bit is generated and verified by hardware.

The second format (CHL0 = 0, CHL1 = 0) consists of one Start bit, eight Data bits (excluding parity) and 7/8, one or two Stop bits. Parity bit is generated and verified by hardware.

The third format for transmission (CHL0 = 0, CHL1 = 1) consists of one Start bit, nine Data bits and 7/8, one or two Stop bits. This format also supports the UART "ATTENTION" feature. When operating in this format, all eight bits of TBUF and RBUF are used for data. The ninth data bit is transmitted and received using two bits in the ENU and ENUR registers, called XBIT9 and RBIT9. RBIT9 is a read only bit. Parity is not generated or verified in this mode.

UART Operation (Continued)



TL/DD/12065–17

FIGURE 15. Framing Formats

For any of the above framing formats, the last Stop bit can be programmed to be 7/8th of a bit in length. If two Stop bits are selected and the 7/8th bit is set (selected), the second Stop bit will be 7/8th of a bit in length.

The parity is enabled/disabled by PEN bit located in the ENU register. Parity is selected for 7- and 8-bit modes only. If parity is enabled (PEN = 1), the parity selection is then performed by PSEL0 and PSEL1 bits located in the ENU register.

Note that the XBIT9/PSEL0 bit located in the ENU register serves two mutually exclusive functions. This bit programs the ninth bit for transmission when the UART is operating with nine data bits per frame. There is no parity selection in this framing format. For other framing formats XBIT9 is not needed and the bit is PSEL0 used in conjunction with PSEL1 to select parity.

The frame formats for the receiver differ from the transmitter in the number of Stop bits required. The receiver only requires one Stop bit in a frame, regardless of the setting of the Stop bit selection bits in the control register. Note that an implicit assumption is made for full duplex UART operation that the framing formats are the same for the transmitter and receiver.

UART INTERRUPTS

The UART is capable of generating interrupts. Interrupts are generated on Receive Buffer Full and Transmit Buffer Empty. Both interrupts have individual interrupt vectors. Two bytes of program memory space are reserved for each interrupt vector. The two vectors are located at addresses 0xEC to 0xEF Hex in the program memory space. The interrupts can be individually enabled or disabled using Enable Transmit Interrupt (ETI) and Enable Receive Interrupt (ERI) bits in the ENUI register.

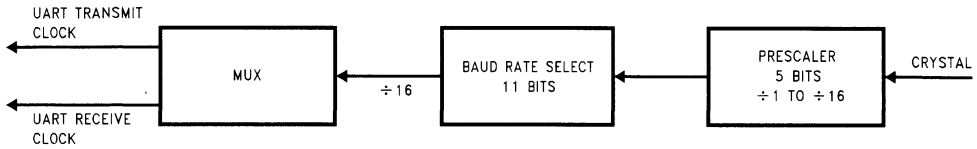
The interrupt from the Transmitter is set pending, and remains pending, as long as both the TBMT and ETI bits are set. To remove this interrupt, software must either clear the ETI bit or write to the TBUF register (thus clearing the TBMT bit).

The interrupt from the receiver is set pending, and remains pending, as long as both the RBFL and ERI bits are set. To remove this interrupt, software must either clear the ERI bit or read from the RBUF register (thus clearing the RBFL bit).

Baud Clock Generation

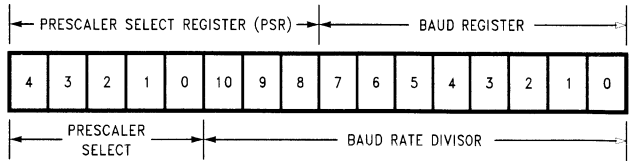
The clock inputs to the transmitter and receiver sections of the UART can be individually selected to come either from an external source at the CKX pin (port L, pin L1) or from a source selected in the PSR and BAUD registers. Internally, the basic baud clock is created from the oscillator frequency through a two-stage divider chain consisting of a 1–16 (increments of 0.5) prescaler and an 11-bit binary counter *(Figure 16)*. The divide factors are specified through two read/write registers shown in *Figure 17*. Note that the 11-bit Baud Rate Divisor spills over into the Prescaler Select Register (PSR). PSR is cleared upon reset.

Baud Clock Generation (Continued)



TL/DD/12065–18

FIGURE 16. UART BAUD Clock Generation



TL/DD/12065–19

FIGURE 17. UART BAUD Clock Divisor Registers

Baud Clock Generation (Continued)

As shown in Table V, a Prescaler Factor of 0 corresponds to NO CLOCK. This condition is the UART power down mode where the UART clock is turned off for power saving purpose. The user must also turn the UART clock off when a different baud rate is chosen.

The correspondences between the 5-bit Prescaler Select and Prescaler factors are shown in Table V. There are many ways to calculate the two divisor factors, but one particularly effective method would be to achieve a 1.8432 MHz frequency coming out of the first stage. The 1.8432 MHz prescaler output is then used to drive the software programmable baud rate counter to create a 16x clock for the following baud rates: 110, 134.5, 150, 300, 600, 1200, 1800, 2400, 3600, 4800, 7200, 9600, 19200 and 38400 (Table IV). Other baud rates may be created by using appropriate divisors. The 16x clock is then divided by 16 to provide the rate for the serial shift registers of the transmitter and receivers.

TABLE IV. Baud Rate Divisors (1.8432 MHz Prescaler Output)

Baud Rate	Baud Rate Divisor − 1 (N-1)
110 (110.03)	1046
134.5 (134.58)	855
150	767
300	383
600	191
1200	95
1800	63
2400	47
3600	31
4800	23
7200	15
9600	11
19200	5
38400	2

Note: The entries in Table IV assume a prescaler output of 1.8432 MHz. In asynchronous mode the baud rate could be as high as 625k.

TABLE V. Prescaler Factors

Prescaler Select	Prescaler Factor
00000	NO CLOCK
00001	1
00010	1.5
00011	2
00100	2.5
00101	3
00110	3.5
00111	4
01000	4.5
01001	5
01010	5.5
01011	6
01100	6.5
01101	7
01110	7.5
01111	8
10000	8.5
10001	9
10010	9.5
10011	10
10100	10.5
10101	11
10110	11.5
10111	12
11000	12.5
11001	13
11010	13.5
11011	14
11100	14.5
11101	15
11110	15.5
11111	16

Baud Clock Generation (Continued)

As an example, considering Asynchronous Mode and a CKI clock of 4.608 MHz, the prescaler factor selected is:

$$4.608/1.8432 = 2.5$$

The 2.5 entry is available in Table V. The 1.8432 MHz prescaler output is then used with proper Baud Rate Divisor (Table V) to obtain different baud rates. For a baud rate of 19200 e.g., the entry in Table IV is 5.

$$N - 1 = 5 \text{ (N} - 1 \text{ is the value from Table IV)}$$

$$N = 6 \text{ (N is the Baud Rate Divisor)}$$

$$\text{Baud Rate} = 1.8432 \text{ MHz}/(16 \times 6) = 19200$$

The divide by 16 is performed because in the asynchronous mode, the input frequency to the UART is 16 times the baud rate. The equation to calculate baud rates is given below.

The actual Baud Rate may be found from:

$$BR = Fc/(16 \times N \times P)$$

Where:

BR is the Baud Rate

Fc is the CKI frequency

N is the Baud Rate Divisor (Table IV).

P is the Prescaler Divide Factor selected by the value in the Prescaler Select Register (Table V)

Note: In the Synchronous Mode, the divisor 16 is replaced by two.

Example:

Asynchronous Mode:

Crystal Frequency = 5 MHz

Desired baud rate = 9600

Using the above equation N × P can be calculated first.

$$N \times P = (5 \times 106)/(16 \times 9600) = 32.552$$

Now 32.552 is divided by each Prescaler Factor (Table V) to obtain a value closest to an integer. This factor happens to be 6.5 (P = 6.5).

$$N = 32.552/6.5 = 5.008 \text{ (N} = 5)$$

The programmed value (from Table IV) should be 4 (N − 1).

Using the above values calculated for N and P:

$$BR = (5 \times 106)/(16 \times 5 \times 6.5) = 9615.384$$

$$\% \text{ error} = (9615.385 - 9600)/9600 = 0.16$$

Effect of HALT/IDLE

The UART logic is reinitialized when either the HALT or IDLE modes are entered. This reinitialization sets the TBMT flag and resets all read only bits in the UART control and status registers. Read/Write bits remain unchanged. The Transmit Buffer (TBUF) is not affected, but the Transmit Shift register (TSFT) bits are set to one. The receiver registers RBUF and RSFT are not affected.

The device will exit from the HALT/IDLE modes when the Start bit of a character is detected at the RDX (L3) pin. This feature is obtained by using the Multi-Input Wakeup scheme provided on the device.

Before entering the HALT or IDLE modes the user program must select the Wakeup source to be on the RDX pin. This selection is done by setting bit 3 of WKEN (Wakeup Enable) register. The Wakeup trigger condition is then selected to be high to low transition. This is done via the WKEDG register (Bit 3 is "one").

If the device is halted and crystal oscillator is used, the Wake Up signal will not start the chip running immediately because of the finite start up time requirement of the crystal oscillator. The idle timer (T0) generates a fixed (256 t_C) delay to ensure that the oscillator has indeed stabilized before allowing the device to execute code. The user has to consider this delay when data transfer is expected immediately after exiting the HALT mode.

Diagnostic

Bits CHARL0 and CHARL1 in the ENU register provide a loopback feature for diagnostic testing of the UART. When these bits are set to one, the following occur: The receiver input pin (RDX) is internally connected to the transmitter output pin (TDX); the output of the Transmitter Shift Register is "looped back" into the Receive Shift Register input. In this mode, data that is transmitted is immediately received. This feature allows the processor to verify the transmit and receive data paths of the UART.

Note that the framing format for this mode is the nine bit format; one Start bit, nine data bits, and 7/8, one or two Stop bits. Parity is not generated or verified in this mode.

Attention Mode

The UART Receiver section supports an alternate mode of operation, referred to as ATTENTION Mode. This mode of operation is selected by the ATTN bit in the ENUR register. The data format for transmission must also be selected as having nine Data bits and either 7/8, one or two Stop bits.

The ATTENTION mode of operation is intended for use in networking the device with other processors. Typically in such environments the messages consists of device addresses, indicating which of several destinations should receive them, and the actual data. This Mode supports a scheme in which addresses are flagged by having the ninth bit of the data field set to a 1. If the ninth bit is reset to a zero the byte is a Data byte.

While in ATTENTION mode, the UART monitors the communication flow, but ignores all characters until an address character is received. Upon receiving an address character, the UART signals that the character is ready by setting the RBFL flag, which in turn interrupts the processor if UART Receiver interrupts are enabled. The ATTN bit is also cleared automatically at this point, so that data characters as well as address characters are recognized. Software examines the contents of the RBUF and responds by deciding either to accept the subsequent data stream (by leaving the ATTN bit reset) or to wait until the next address character is seen (by setting the ATTN bit again).

Operation of the UART Transmitter is not affected by selection of this Mode. The value of the ninth bit to be transmitted is programmed by setting XBIT9 appropriately. The value of the ninth bit received is obtained by reading RBIT9. Since this bit is located in ENUR register where the error flags reside, a bit operation on it will reset the error flags.

Interrupts

The devices supports a vectored interrupt scheme. It supports a total of fourteen interrupt sources. Table VI lists all the possible device interrupt sources, their arbitration rankings and the memory locations reserved for the interrupt vector for each source.

Two bytes of program memory space are reserved for each interrupt source. All interrupt sources except the software interrupt are maskable. Each of the maskable interrupts have an Enable bit and one or more Pending bits. A maskable interrupt is active it its associated enable and pending bits are set. If GIE = 1 and an interrupt is active, then the processor will be interrupted as soon as it is ready to start executing an instruction except if the above conditions happen during the Software Trap service routine. This exception is described in the Software Trap sub-section.

The interruption process is accomplished with the INTR instruction (opcode 00), which is jammed inside the Instruction Register and replaces the opcode about to be executed. The following steps are performed for every interrupt:

1. The GIE (Global Interrupt Enable) bit is reset.
2. The address of the instruction about to be executed is pushed into the stack.
3. The PC (Program Counter) branches to address 00FF. This procedure takes 7 t_C cycles to execute.

At this time, since GIE = 0, other maskable interrupts are disabled. The user is now free to do whatever context switching is required by saving the context of the machine in the stack with PUSH instructions. The user would then program a VIS (Vector Interrupt Select) instruction in order to branch to the interrupt service routine of the highest priority interrupt enabled and pending at the time of the VIS. Note that this is not necessarily the interrupt that caused the branch to address location 00FF Hex prior to the context switching.

Thus, if an interrupt with a higher rank than the one which caused the interruption becomes active before the decision of which interrupt to service is made by the VIS, then the interrupt with the higher rank will override any lower ones and will be acknowledged. The lower priority interrupt(s) are still pending, however, and will cause another interrupt immediately following the completion of the interrupt service routine associated with the higher priority interrupt just serviced. This lower priority interrupt will occur immediately following the RETI (Return from Interrupt) instruction at the end of the interrupt service routine just completed.

Inside the interrupt service routine, the associated pending bit has to be cleared by software. The RETI (Return from Interrupt) instruction at the end of the interrupt service routine will set the GIE (Global Interrupt Enable) bit, allowing the processor to be interrupted again if another interrupt is active and pending.

The VIS instruction looks at all the active interrupts at the time it is executed and performs an indirect jump to the beginning of the service routine of the one with the highest rank.

The addresses of the different interrupt service routines, called vectors, are chosen by the user and stored in ROM in a table starting at 01E0 (assuming that VIS is located between 00FF and 01DF). The vectors are 15-bit wide and therefore occupy 2 ROM locations.

TABLE VI. Interrupt Vector Table

ARBITRATION RANKING	SOURCE DESCRIPTION		VECTOR* ADDRESS (Hi-Low Byte)
(1) Highest	Software		0yFE–0yFF
(2)	Reserved		0yFC–0yFD
(3)	External	G0	0yFA-0yFB
(4)	Timer T0	Underflow	0yF8–0yF9
(5)	Timer T1	T1A/Underflow	0yF6–0yF7
(6)	Timer T1	T1B	0yF4-0yF5
(7)	Microwire/Plus	Busy Low	0yF2–0yF3
(8)	Counters		0yF0–0yF1
(9)	UART	Receive	0yEE–0yEF
(10)	UART	Transmit	0yEC–0yED
(11)	Timer T2	T2A/Underflow	0yEA–0yEB
(12)	Timer T2	T2B	0yE8–0yE9
(13)	Capture Timer 1 and 2		0yE6–0yE7
(14)	Unused		0yE4–0yE5
(15)	Port L/Wakeup		0yE2–0yE3
(16) Lowest	Default VIS	Reserved	0yE0–0yE1

* y is a variable which represents the VIS block. VIS and the vector table must be located in the same 256-byte block except if VIS is located at the last address of a block, In this case, the table must be in the next block.

Interrupts (Continued)

VIS and the vector table must be located in the same 256-byte block (0y00 to 0yFF) except if VIS is located at the last address of a block. In this case, the table must be in the next block. The vector table cannot be inserted in the first 256-byte block (y ≠ 0).

The vector of the maskable interrupt with the lowest rank is located at 0yE0 (Hi-Order byte) and 0yE1 (Lo-Order byte) and so forth in increasing rank number. The vector of the maskable interrupt with the highest rank is located at 0yFA (Hi-Order byte) and 0yFB (Lo-Order byte).

The Software Trap has the highest rank and its vector is located at 0yFE and 0yFF.

If, by accident, a VIS gets executed and no interrupt is active, then the PC (Program Counter) will branch to a vector located at 0yE0–0yE1.

Warning:

A Default VIS interrupt handler routine must be present. As a minimum, this handler should confirm that the GIE bit is cleared (this indicates that the interrupt sequence has been taken), take care of any required housekeeping, restore context and return. Some sort of Warm Restart procedure should be implemented. These events can occur without any error on the part of the system designer or programmer.

Note: There is always the possibility of an interrupt occurring during an instruction which is attempting to reset the GIE bit or any other interrupt enable bit. If this occurs when a single cycle instruction is being used to reset the interrupt enable bit, the interrupt enable bit will be reset but an interrupt may still occur. This is because interrupt processing is started at the same time as the interrupt bit is being reset. To avoid this scenario, the user should always use a two-, three- or four-cycle instruction to reset interrupt enable bits.

Figure 18 shows the Interrupt block diagram.

SOFTWARE TRAP

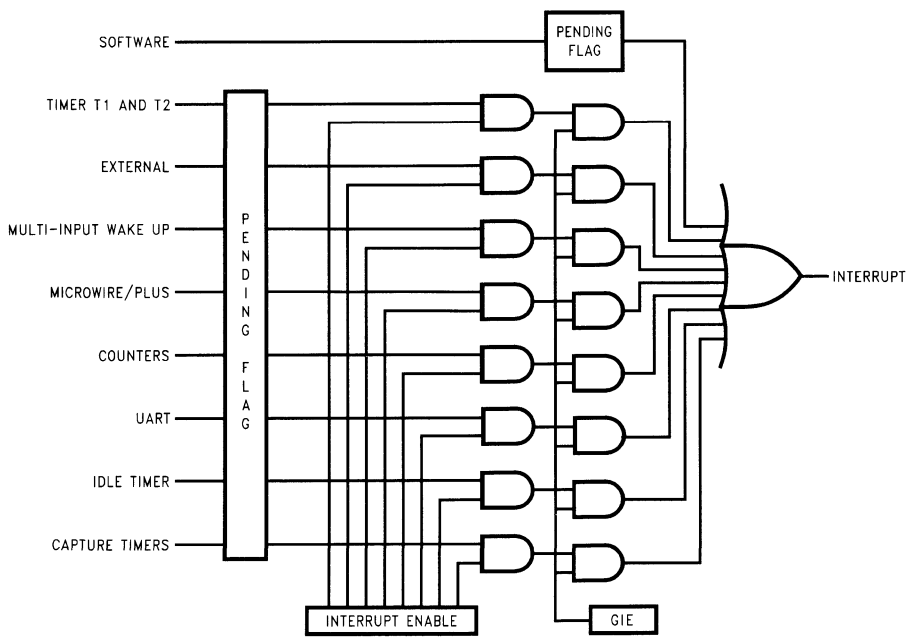
The Software Trap (ST) is a special kind of non-maskable interrupt which occurs when the INTR instruction (used to acknowledge interrupts) is fetched from ROM and placed inside the instruction register. This may happen when the PC is pointing beyond the available ROM address space or when the stack is over-popped.

When an ST occurs, the user can re-initialize the stack pointer and do a recovery procedure (similar to reset, but not necessarily containing all of the same initialization procedures) before restarting.

The occurrence of an ST is latched into the ST pending bit. The GIE bit is not affected and the ST pending bit (**not accessible by the user**) is used to inhibit other interrupts and to direct the program to the ST service routine with the VIS instruction. The RPND instruction is used to clear the software interrupt pending bit. This pending bit is also cleared on reset.

The ST has the highest rank among all interrupts.

Nothing (except another ST) can interrupt an ST being serviced.



TL/DD/12065–20

FIGURE 18. Interrupt Block Diagram

Detection of Illegal Conditions

The device can detect various illegal conditions resulting from coding errors, transient noise, power supply voltage drops, runaway programs, etc.

Reading of undefined ROM gets zeroes. The opcode for software interrupt is 00. If the program fetches instructions from undefined ROM, this will force a software interrupt, thus signaling that an illegal condition has occurred.

The subroutine stack grows down for each call (jump to subroutine), interrupt, or PUSH, and grows up for each return or POP. The stack pointer is initialized to RAM location 06F Hex during reset. Consequently, if there are more returns than calls, the stack pointer will point to addresses 070 and 071 Hex (which are undefined RAM). Undefined RAM from addresses 070 to 07F (Segment 0), 140 to 17F (Segment 1), and all other segments (i.e., Segments 3... etc.) is read as all 1's, which in turn will cause the program to return to address 7FFF Hex. This is an undefined ROM location and the instruction fetched (all 0's) from this location will generate a software interrupt signaling an illegal condition.

Thus, the chip can detect the following illegal conditions:

1. Executing from undefined ROM
2. Over "POP"ing the stack by having more returns than calls.

When the software interrupt occurs, the user can re-initialize the stack pointer and do a recovery procedure before restarting (this recovery program is probably similar to that following reset, but might not contain the same program initialization procedures). The recovery program should reset the software interrupt pending bit using the RPND instruction.

MICROWIRE/PLUS

MICROWIRE/PLUS is a serial synchronous communications interface. The MICROWIRE/PLUS capability enables the device to interface with any of National Semiconductor's MICROWIRE peripherals (i.e., A/D converters, display drivers, E2PROMs etc.) and with other microcontrollers which support the MICROWIRE interface. It consists of an 8-bit serial shift register (SIO) with serial data input (SI), serial data output (SO) and serial shift clock (SK). *Figure 19* shows a block diagram of the MICROWIRE/PLUS logic.

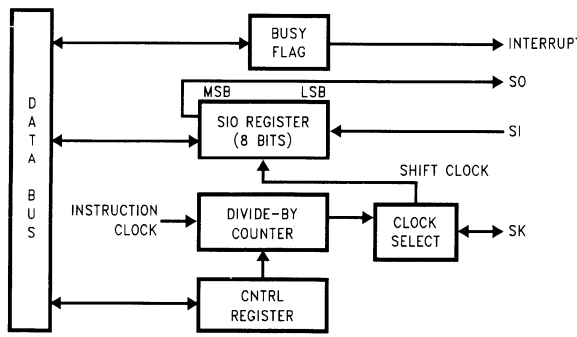
The shift clock can be selected from either an internal source or an external source. Operating the MICROWIRE/PLUS arrangement with the internal clock source is called the Master mode of operation. Similarly, operating the MICROWIRE/PLUS arrangement with an external shift clock is called the Slave mode of operation.

The CNTRL register is used to configure and control the MICROWIRE/PLUS mode. To use the MICROWIRE/PLUS, the MSEL bit in the CNTRL register is set to one. In the master mode, the SK clock rate is selected by the two bits, SL0 and SL1, in the CNTRL register. Table VII details the different clock rates that may be selected.

TABLE VII. MICROWIRE/PLUS Master Mode Clock Select

SL1	SL0	SK Period
0	0	$2 \times t_c$
0	1	$4 \times t_c$
1	x	$8 \times t_c$

Where t_c is the instruction cycle clock



TL/DD/12065-21

FIGURE 19. MICROWIRE/PLUS Block Diagram

MICROWIRE/PLUS (Continued)

MICROWIRE/PLUS OPERATION

Setting the BUSY bit in the PSW register causes the MICROWIRE/PLUS to start shifting the data. It gets reset when eight data bits have been shifted. The user may reset the BUSY bit by software to allow less than 8 bits to shift. If enabled, an interrupt is generated when eight data bits have been shifted. The device may enter the MICROWIRE/PLUS mode either as a Master or as a Slave. *Figure 20* shows how two devices, microcontrollers and several peripherals may be interconnected using the MICROWIRE/PLUS arrangements.

Warning:

The SIO register should only be loaded when the SK clock is low. Loading the SIO register while the SK clock is high will result in undefined data in the SIO register. SK clock is normally low when not shifting.

Setting the BUSY flag when the input SK clock is high in the MICROWIRE/PLUS slave mode may cause the current SK clock for the SIO shift register to be narrow. For safety, the BUSY flag should only be set when the input SK clock is low.

MICROWIRE/PLUS Master Mode Operation

In the MICROWIRE/PLUS Master mode of operation the shift clock (SK) is generated internally by the device. The MICROWIRE Master always initiates all data exchanges. The MSEL bit in the CNTRL register must be set to enable the SO and SK functions onto the G Port. The SO and SK pins must also be selected as outputs by setting appropriate bits in the Port G configuration register. Table VIII summarizes the bit settings required for Master mode of operation.

MICROWIRE/PLUS Slave Mode Operation

In the MICROWIRE/PLUS Slave mode of operation the SK clock is generated by an external source. Setting the MSEL bit in the CNTRL register enables the SO and SK functions onto the G Port. The SK pin must be selected as an input and the SO pin is selected as an output pin by setting and resetting the appropriate bits in the Port G configuration register. Table VIII summarizes the settings required to enter the Slave mode of operation.

TABLE VIII. MICROWIRE Mode Settings

G4 (SO) Config. Bit	G5 (SK) Config. Bit	G4 Fun.	G5 Fun.	Operation
1	1	SO	Int. SK	MICROWIRE/PLUS Master
0	1	TRI-STATE	Int. SK	MICROWIRE/PLUS Master
1	0	SO	Ext. SK	MICROWIRE/PLUS Slave
0	0	TRI-STATE	Ext. SK	MICROWIRE/PLUS Slave

This table assumes that the control flag MSEL is set.

The user must set the BUSY flag immediately upon entering the Slave mode. This will ensure that all data bits sent by the Master will be shifted properly. After eight clock pulses the BUSY flag will be cleared and the sequence may be repeated.

Alternate SK Phase Operation

The device allows either the normal SK clock or an alternate phase SK clock to shift data in and out of the SIO register. in both the modes the SK is normally low. In the normal mode data is shifted in on the rising edge of the SK clock and the data is shifted out on the falling edge of the SK clock. The SIO register is shifted on each falling edge of the SK clock. In the alternate SK phase operation, data is shifted in on the falling edge of the SK clock and shifted out on the rising edge of the SK clock.

A control flag, SKSEL, allows either the normal SK clock or the alternate SK clock to be selected. Resetting SKSEL causes the MICROWIRE/PLUS logic to be clocked from the normal SK signal. Setting the SKSEL flag selects the alternate SK clock. The SKSEL is mapped into the G6 configuration bit. The SKSEL flag will power up in the reset condition, selecting the normal SK signal.

Reading memory locations 0070H-007FH (Segment 0) will return all ones. Reading unused memory locations between 0080H-00F0 Hex (Segment 0) will return undefined data. Reading memory locations from other segments (i.e., segment 4, segment 5, etc.) will return all ones.

Memory Map (Continued)

ADDRESSING MODES

There are ten addressing modes, six for operand addressing and four for transfer of control.

OPERAND ADDRESSING MODES

Register Indirect

This is the "normal" addressing mode. The operand is the data memory addressed by the B pointer or X pointer.

Register Indirect (with auto post Increment or decrement of pointer)

This addressing mode is used with the LD and X instructions. The operand is the data memory addressed by the B pointer or X pointer. This is a register indirect mode that automatically post increments or decrements the B or X register after executing the instruction.

Direct

The instruction contains an 8-bit address field that directly points to the data memory for the operand.

Immediate

The instruction contains an 8-bit immediate field as the operand.

Short Immediate

This addressing mode is used with the Load B Immediate instruction. The instruction contains a 4-bit immediate field as the operand.

Indirect

This addressing mode is used with the LAID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a data operand from the program memory.

TRANSFER OF CONTROL ADDRESSING MODES

Relative

This mode is used for the JP instruction, with the instruction field being added to the program counter to get the new program location. JP has a range from −31 to +32 to allow a 1-byte relative jump (JP + 1 is implemented by a NOP instruction). There are no "pages" when using JP, since all 15 bits of PC are used.

Absolute

This mode is used with the JMP and JSR instructions, with the instruction field of 12 bits replacing the lower 12 bits of the program counter (PC). This allows jumping to any location in the current 4k program memory segment.

Absolute Long

This mode is used with the JMPL and JSRL instructions, with the instruction field of 15 bits replacing the entire 15 bits of the program counter (PC). This allows jumping to any location up to 32k in the program memory space.

Indirect

This mode is used with the JID instruction. The contents of the accumulator are used as a partial address (lower 8 bits of PC) for accessing a location in the program memory. The contents of this program memory location serve as a partial address (lower 8 bits of PC) for the jump to the next instruction.

Note: The VIS is a special case of the Indirect Transfer of Control addressing mode, where the double byte vector associated with the interrupt is transferred from adjacent addresses in the program memory into the program counter (PC) in order to jump to the associated interrupt service routine.

Instruction Set

Register and Symbol Definition

Registers	
A	8-Bit Accumulator Register
B	8-Bit Address Register
X	8-Bit Address Register
SP	8-Bit Stack Pointer Register
PC	15-Bit Program Counter Register
PU	Upper 7 Bits of PC
PL	Lower 8 Bits of PC
C	1 Bit of PSW Register for Carry
HC	1 Bit of PSW Register for Half Carry
GIE	1 Bit of PSW Register for Global Interrupt Enable
VU	Interrupt Vector Upper Byte
VL	Interrupt Vector Lower Byte

Symbols	
[B]	Memory Indirectly Addressed by B Register
[X]	Memory Indirectly Addressed by X Register
MD	Direct Addressed Memory
Mem	Direct Addressed Memory or [B]
Meml	Direct Addressed Memory or [B] or Immediate Data
Imm	8-Bit Immediate Data
Reg	Register Memory: Addresses F0 to FF (Includes B, X and SP)
Bit	Bit Number (0 to 7)
←	Loaded with
⟷	Exchanged with

INSTRUCTION SET

ADD	A,Meml	ADD	A ← A + Meml
ADC	A,Meml	ADD with Carry	A ← A + Meml + C, C ← Carry, HC ← Half Carry
SUBC	A,Meml	Subtract with Carry	A ← A − Meml + C, C ← Carry, HC ← Half Carry
AND	A,Meml	Logical AND	A ← A and $\overline{\text{Meml}}$
ANDSZ	A,Imm	Logical AND Immed., Skip if Zero	Skip next if (A and Imm) = 0
OR	A,Meml	Logical OR	A ← A or Meml
XOR	A,Meml	Logical EXclusive OR	A ← A xor Meml
IFEQ	MD,Imm	IF EQual	Compare MD and Imm, Do next if MD = Imm
IFEQ	A,Meml	IF EQual	Compare A and Meml, Do next if A = Meml
IFNE	A,Meml	IF Not Equal	Compare A and Meml, Do next if A ≠ Meml
IFGT	A,Meml	IF Greater Than	Compare A and Meml, Do next if A > Meml
IFBNE	#	IF B Not Equal	Do next if lower 4 bits of B ≠ Imm
DRSZ	Reg	Decrement Reg., Skip if Zero	Reg ← Reg − 1, Skip if Reg = 0
SBIT	#,Mem	Set BIT	1 to bit, Mem (bit = 0 to 7 immediate)
RBIT	#,Mem	Reset BIT	0 to bit, Mem
IFBIT	#,Mem	IF BIT	If bit #, A or Mem is true do next instruction
RPND		Reset PeNDing Flag	Reset Software Interrupt Pending Flag
X	A,Mem	EXchange A with Memory	A ⟷ Mem
X	A,[X]	EXchange A with Memory [X]	A ⟷ [X]
LD	A,Meml	LoaD A with Memory	A ← Meml
LD	A,[X]	LoaD A with Memory [X]	A ← [X]
LD	B, Imm	LoaD B with Immed.	B ← Imm
LD	Mem, Imm	LoaD Memory Immed.	Mem ← Imm
LD	Reg, Imm	LoaD Register Memory Immed.	Reg ← Imm
X	A, [B±]	EXchange A with Memory [B]	A ⟷ [B], (B ← B ± 1)
X	A, [X±]	EXchange A with Memory [X]	A ⟷ [X], (X ← X ± 1)
LD	A, [B±]	LoaD A with Memory [B]	A ← [B], (B ← B ± 1)
LD	A, [X±]	LoaD A with Memory [X]	A ← [X], (X ← X ± 1)
LD	[B±],Imm	LoaD Memory [B] Immed.	[B] ← Imm, (B ← B ± 1)
CLR	A	CLeaR A	A ← 0
INC	A	INCrement A	A ← A + 1
DEC	A	DECrement A	A ← A − 1
LAID		Load A InDirect from ROM	A ← ROM (PU, A)
DCOR	A	Decimal CORrect A	A ← BCD correction of A (follows ADC, SUBC)
RRC	A	Rotate A Right thru C	C → A7 → . . . → A0 → C
RLC	A	Rotate A Left thru C	C ← A7 ← . . . ← A0 ← C
SWAP	A	SWAP nibbles of A	A7 . . . A4 ⟷ A3 . . . A0
SC		Set C	C ← 1, HC ← 1
RC		Reset C	C ← 0, HC ← 0
IFC		IF C	If C is true, do next instruction
IFNC		IF Not C	If C is not true, do next instruction
POP	A	POP the stack into A	SP ← SP + 1, A ← [SP]
PUSH	A	PUSH A onto the stack	[SP] ← A, SP ← SP − 1
VIS		Vector to Interrupt Service Routine	PU ← [VU], PL ← [VL]
JMPL	Addr.	Jump absolute Long	PC ← ii (ii = 15 bits, 0 to 32k)
JMP	Addr.	Jump absolute	PC9 . . . 0 ← i (i = 12 bits)
JP	Disp.	Jump relative short	PC ← PC + r (r is −31 to +32, except 1)
JSRL	Addr.	Jump SubRoutine Long	[SP] ← PL, [SP − 1] ← PU, SP − 2, PC ← ii
JSR	Addr	Jump SubRoutine	[SP] ← PL, [SP − 1] ← PU, SP − 2, PC9 . . . 0 ← i
JID		Jump InDirect	PL ← ROM (PU, A)
RET		RETurn from subroutine	SP + 2, PL ← [SP], PU ← [SP − 1]
RETSK		RETurn and SKip	SP + 2, PL ← [SP], PU ← [SP − 1], skip next instruction
RETI		RETurn from Interrupt	SP + 2, PL ← [SP], PU ← [SP − 1], GIE ← 1
INTR		Generate an Interrupt	[SP] ← PL, [SP − 1] ← PU, SP − 2, PC ← 0FF
NOP		No OPeration	PC ← PC + 1

Instruction Execution Time

Most instructions are single byte (with immediate addressing mode instructions taking two bytes).

Most single byte instructions take one cycle time to execute.

Skipped instructions require x number of cycles to be skipped, where x equals the number of bytes in the skipped instruction opcode.

See the BYTES and CYCLES per INSTRUCTION table for details.

Bytes and Cycles per Instruction

The following table shows the number of bytes and cycles for each instruction in the format of byte/cycle.

Arithmetic and Logic Instructions

	[B]	Direct	Immed.
ADD	1/1	3/4	2/2
ADC	1/1	3/4	2/2
SUBC	1/1	3/4	2/2

Memory Transfer Instructions

	Register Indirect		Direct	Immed.	Register Indirect Auto Incr. and Decr.		
	[B]	[X]			[B+, B−]	[X+, X−]	
X A, *	1/1	1/3	2/3		1/2	1/3	
LD A, *	1/1	1/3	2/3	2/2	1/2	1/3	
LD B, Imm				1/1			(IF B < 16)
LD B, Imm				2/2			(IF B > 15)
LD Mem, Imm	2/2		3/3		2/2		
LD Reg, Imm			2/3				
IFEQ MD, Imm			3/3				

Note: * = > Memory location addressed by B or X or directly.

Mask Options

The mask programmable options are shown below. The options are programmed at the same time as the ROM pattern submission.

OPTION 1: CLOCK CONFIGURATION

= 1 Crystal Oscillator (CKI/10)

G7 (CKO) is clock generator output to crystal/resonator with CKI being the clock input

OPTION 2: HALT

= 1 Enable HALT mode

= 2 Disable HALT mode

OPTION 3: BONDING OPTIONS

= 1 68 Pins PLCC

The chip can be driven by a clock input on the CKI input pin which can be between DC and 10 MHz. The CKO output clock is on pin G7 (if clock option = 1 has been selected). The CKI input frequency is divided down by 10 to produce the instruction cycle clock ($1/t_c$).

Md is a directly addressed memory location

* is an unused opcode

Note: The opcode 60 Hex is also the opcode for IFBIT #i,A.

Development Support

SUMMARY

- iceMASTER: IM-COP8/400—Full feature in-circuit emulation for all COP8 products. A full set of COP8 Basic and Feature Family device and package specific probes are available.
- COP8 Debug Module: Moderate cost in-circuit emulation and development programming unit.
- COP8 Evaluation and Programming Unit: EPU-COP888GG—low cost In-circuit simulation and development programming unit.
- Assembler: COP8-DEV-IBMA. A DOS installable cross development Assembler, Linker, Librarian and Utility Software Development Tool Kit.
- C Compiler: COP8C. A DOS installable cross development Software Tool Kit.
- OTP/EPROM Programmer Support: Covering needs from engineering prototype, pilot production to full production environments.

iceMASTER (IM) IN-CIRCUIT EMULATION

The iceMASTER IM-COP8/400 is a full feature, PC based, in-circuit emulation tool developed and marketed by MetaLink Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 21* for configuration.

The iceMASTER IM-COP8/400 with its device specific COP8 Probe provides a rich feature set for developing, testing and maintaining product:

- Real-time in-circuit emulation; full 2.4V–5.5V operation range, full DC-10 MHz clock. Chip options are programmable or jumper selectable.
- Direct connection to application board by package compatible socket or surface mount assembly.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated on the probe as necessary.
- Full 4k frame synchronous trace memory. Address, instruction, and 8 unspecified, circuit connectable trace lines. Display can be HLL source (e.g., C source), assembly or mixed.
- A full 64k hardware configurable break, trace on, trace oft control, and pass count increment events.
- Tool set integrated interactive symbolic debugger—supports both assembler (COFF) and C Compiler (.COD) linked object formats.
- Real time peformance profiling analysis; selectable bucket definition.
- Watch windows, content updated automatically at each execution break.
- Instruction by instruction memory/register changes displayed on source window when in single step operation.
- Single base unit and debugger software reconfigurable to support the entire COP8 family; only the probe personality needs to change. Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- On-line HELP customized to specific processor using master model file.
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

iceMASTER DEBUG MODULE (DM)

The iceMASTER Debug Module is a PC based, combination in-circuit emulation tool and COP8 based OTP/EPROM programming tool developed and marketed by MetaLink Corporation to support the whole COP8 family of products. National is a resale vendor for these products.

See *Figure 22* for configuration.

The iceMASTER Debug Module is a moderate cost development tool. It has the capability of in-circuit emulation for a specific COP8 microcontroller and in addition serves as a programming tool for COP8 OTP and EPROM product families. Summary of features is as follows:

- Real-time in-circuit emulation; full operating voltage range operation, full DC-10 MHz clock.
- All processor I/O pins can be cabled to an application development board with package compatible cable to socket and surface mount assembly.
- Full 32 kbytes of loadable programming space that overlays (replaces) the on-chip ROM or EPROM. On-chip RAM and I/O blocks are used directly or recreated as necessary.
- 100 frames of synchronous trace memory. The display can be HLL source (C source), assembly or mixed. The most recent history prior to a break is available in the trace memory.
- Configured break points; uses INTR instruction which is modestly intrusive.
- Software—only supported features are selectable.
- Tool set integrated interactive symbolic debugger—supports both assembler (COFF) and C Compiler (.COD) SDK linked object formats.
- Instruction by instruction memory/register changes displayed when in single step operation.
- Debugger software is processor customized, and reconfigured from a master model file.
- Processor specific symbolic display of registers and bit level assignments, configured from master model file.
- Halt/Idle mode notification.
- Programming menu supports full product line of programmable OTP and EPROM COP8 products. Program data is taken directly from the overlay RAM.
- Programming of 44 PLCC and 68 PLCC parts requires external programming adapters.
- Includes wallmount power supply.
- On-board V_{PP} generator from 5V input or connection to external supply supported. Requires V_{PP} level adjustment per the family programming specification (correct level is provided on an on-screen pop-down display).
- On-line HELP customized to specific processor using master model file.
- Includes a copy of COP8-DEV-IBMA assembler and linker SDK.

Development Support (Continued)

COP8 ASSEMBLER/LINKER SOFTWARE DEVELOPMENT TOOL KIT

National Semiconductor offers a relocateable COP8 macro cross assembler, linker, librarian and utility software development tool kit. Features are summarized as follows:

- Basic and Feature Family instruction set by "device" type.
- Nested macro capability.
- Extensive set of assembler directives.
- Supported on PC/DOS platform.
- Generates National standard COFF output files.
- Integrated Linker and Librarian.
- Integrated utilities to generate ROM code file outputs.
- DUMPCOFF utility.

This product is integrated as a part of MetaLink tools as a development kit, fully supported by the MetaLink debugger. It may be ordered separately or it is bundled with the MetaLink products at no additional cost.

Order-Information

Assembler SDK	
COP8-DEV-IBMA	Assembler SDK on installable 3.5" PC/DOS Floppy Disk Drive format. Periodic upgrades and most recent version is available on National's BBS and Internet.

COP8 C COMPILER

A C Compiler is developed and marketed by Byte Craft Limited. The COP8C compiler is a fully integrated development tool specifically designed to support the compact embedded configuration of the COP8 family of products. Features are summarized as follows:

- ANSI C with some restrictions and extensions that optimize development for the COP8 embedded application.
- BITS data type extension. Register declaration #pragma with direct bit level definitions.
- C language support for interrupt routines.
- Expert system, rule based code generation and optimization.
- Performs consistency checks against the architectural definitions of the target COP8 device.
- Generates program memory code.
- Supports linking of compiled object or COP8 assembled object formats.
- Global optimization of linked code.
- Symbolic debug load format fully source level supported by the MetaLink debugger.

SINGLE CHIP OTP/EMULATOR SUPPORT

The COP8 family is supported by single chip OTP emulators. For detailed information refer to the emulator specific datasheet and the emulator selection table below:

OTP Emulator Ordering Information

Device Number	Clock Option	Package	Emulates
COP87L88GWV-XE	Crystal/ HALT En	68 PLCC	COP888GW

INDUSTRY WIDE OTP/EPROM PROGRAMMING SUPPORT

Programming support, in addition to the MetaLink development tools, is provided by a full range of independent approved vendors to meet the needs from the engineering laboratory to full production.

DIAL-A-HELPER SERVICE

Dial-A-Helper is a service provided by the Microcontroller Applications group. The Dial-A-Helper is an Electronic Information System that may be accessed as a Bulletin Board System (BBS) via data modem, as an FTP site on the Internet via standard FTP client application or as an FTP site on the Internet using a standard Internet browser such as Netscape or Mosaic.

The Dial-A-Helper system provides access to an automated information storage and retrieval system. The system capabilities include a MESSAGE SECTION (electronic mail, when accessed as a BBS) for communications to and from the Microcontroller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities could be found.

DIAL-A-HELPER BBS via a Standard Modem

Modem: CANADA/U.S.: (800) NSC-MICRO

National Semiconductor

MICROWIRE/PLUS™ Serial Interface

National's MICROWIRE/PLUS provides for high-speed, serial communications in a simple 3-wire implementation.

MICROWIRE/PLUS consists of an 8-bit serial shift register (SIO), serial data input (SI), serial data output (SO), and a serial shift clock (SK).

The shift clock in MICROWIRE/PLUS can be internal or external, the interface can be designated as either bus master or slave, giving it the flexibility necessary for distributed and multiprocessing applications.

With its simple 3-wire interface, MICROWIRE/PLUS can connect a variety of nodes in a serial-communication network.

This simple 3-wire design also helps increase system reliability while reducing system size and development time.

Because the COP8 family has memory-mapped architectures, the contents of the SIO register can be accessed through standard memory-addressing instructions.

The control register (CNTRL) is used to configure and control the mode and operation of the interface through user-selectable bits that program the internal shift rate. This greatly increases the flexibility of the interface.

MICROWIRE/PLUS can also provide additional I/O capability by connecting, for example, external 8-bit parallel-to-serial shift registers to 8-bit serial-to-parallel shift registers.

And it can interface a wide variety of peripherals:

- Memory (CMOS RAM and EEPROM)
- A/D converters
- Timers/counters
- Digital phase locked-loops
- Telecom peripherals
- Vacuum fluorescent display drivers
- LED display drivers
- LCD display drivers

Both MICROWIRE and MICROWIRE/PLUS give all the members of National's microcontroller families the flexibility and design-ease to implement a solution quickly, simply, and cost-effectively.

ADC0811 8-Bit Serial I/O A/D Converter With 11-Channel Multiplexer

General Description

The ADC0811 is an 8-Bit successive approximation A/D converter with simultaneous serial I/O. The serial input controls an analog multiplexer which selects from 11 input channels or an internal half scale test voltage.

An input sample-and-hold is implemented by a capacitive reference ladder and sampled data comparator. This allows the input signal to vary during the conversion cycle.

Separate serial I/O and conversion clock inputs are provided to facilitate the interface to various microprocessors.

Features

- Separate asynchronous converter clock and serial data I/O clock.
- 11-Channel multiplexer with 4-Bit serial address logic.
- Built-in sample and hold function.
- Ratiometric or absolute voltage referencing.
- No zero or full-scale adjust required.
- Internally addressable test voltage.
- 0V to 5V input range with single 5V power supply.
- TTL/MOS input/output compatible.
- 0.3" standard width 20-pin dip or 20-pin molded chip carrier

Key Specifications

■ Resolution	8-Bits
■ Total unadjusted error	± ½LSB and ± 1LSB
■ Single supply	$5V_{DC}$
■ Low Power	15 mW
■ Conversion Time	32 μS

ADC08031/ADC08032/ADC08034/ADC08038 8-Bit High-Speed Serial I/O A/D Converters with Multiplexer Options, Voltage Reference, and Track/Hold Function

General Description

The ADC08031/ADC08032/ADC08034/ADC08038 are 8-bit successive approximation A/D converters with serial I/O and configurable input multiplexers with up to 8 channels. The serial I/O is configured to comply with the NSC MICROWIRE™ serial data exchange standard for easy interface to the COPS™ family of controllers, and can easily interface with standard shift registers or microprocessors.

The ADC08034 and ADC08038 provide a 2.6V band-gap derived reference. For devices offering guaranteed voltage reference performance over temperature see ADC08131, ADC08134 and ADC08138.

A track/hold function allows the analog voltage at the positive input to vary during the actual A/D conversion.

The analog inputs can be configured to operate in various combinations of single-ended, differential, or pseudo-differential modes. In addition, input voltage spans as small as 1V can be accommodated.

Applications

- Digitizing automotive sensors
- Process control monitoring
- Remote sensing in noisy environments
- Instrumentation
- Test systems
- Embedded diagnostics

Features

- Serial digital data link requires few I/O pins
- Analog input track/hold function
- 2-, 4-, or 8-channel input multiplexer options with address logic
- 0V to 5V analog input range with single 5V power supply
- No zero or full scale adjustment required
- TTL/CMOS input/output compatible
- On chip 2.6V band-gap reference
- 0.3" standard width 8-, 14-, or 20-pin DIP package
- 14-, 20-pin small-outline packages

Key Specifications

- Resolution — 8 bits
- Conversion time (f_C = 1 MHz) — 8μs (max)
- Power dissipation — 20mW (max)
- Single supply — $5V_{DC}$ (±5%)
- Total unadjusted error — ±½ LSB and ±1LSB
- No missing codes over temperature

ADC0852/ADC0854
Multiplexed Comparator with 8-Bit Reference Divider

General Description

The ADC0852 and ADC0854 are CMOS devices that combine a versatile analog input multiplexer, voltage comparator, and an 8-bit DAC which provides the comparator's threshold voltage (V_{TH}). The comparator provides a "1-bit" output as a result of a comparison between the analog input and the DAC's output. This allows for easy implementation of set-point, on-off or "bang-bang" control systems with several advantages over previous devices.

The ADC0854 has a 4 input multiplexer that can be software configured for single ended, pseudo-differential, and full-differential modes of operation. In addition the DAC's reference input is brought out to allow for reduction of the span.

The ADC0852 has a two input multiplexer that can be configured as 2 single-ended or 1 differential input pair. The DAC reference input is internally tied to V_{CC}.

The multiplexer and 8-bit DAC are programmed via a serial data input word. Once programmed the output is updated once each clock cycle up to a maximum clock rate of 400 kHz.

Features

- 2 or 4 channel multiplexer
- Differential or Single-ended input, software controlled
- Serial digital data interface
- 256 programmable reference voltage levels
- Continuous comparison after programming
- Fixed, ratiometric, or reduced span reference capability (ADC 0854)

Key Specifications

- Accuracy, ± ½ LSB or ± 1 LSB of Reference (0.2%)
- Single 5V power supply
- Low Power, 15 mW

ADC1031/ADC1034/ADC1038 10-Bit Serial I/O A/D Converters with Analog Multiplexer and Track/Hold Function

General Description

The ADC1031, ADC1034 and ADC1038 are 10-bit successive approximation A/D converters with serial I/O. The serial input, for the ADC1034 and ADC1038, controls a single-ended analog multiplexer that selects one of 4 input channels (ADC1034) or one of 8 input channels (ADC1038). The ADC1034 and ADC1038 serial output data can be configured into a left- or right-justified format.

An input track/hold is implemented by a capacitive reference ladder and sampled-data comparator. This allows the analog input to vary during the A/D conversion cycle.

Separate serial I/O and conversion clock inputs are provided to facilitate the interface to various microprocessors.

Applications

- Engine control
- Process control
- Instrumentation
- Test equipment

Features

- Serial I/O (MICROWIRE™ compatible)
- Separate asynchronous converter clock and serial data I/O clock
- Analog input track/hold function
- Ratiometric or absolute voltage referencing
- No zero or full scale adjustment required
- 0V to 5V analog input range with single 5V power supply
- TTL/MOS input/output compatible
- No missing codes

Key Specifications

■ Resolution	10 bits
■ Total unadjusted error	±1 LSB (max)
■ Single supply	5V ±5%
■ Power dissipation	20 mW (max)
■ Max. conversion time (f_C = 3 MHz)	13.7 μs (max)
■ Serial data exchange time (f_S = 1 MHz)	10 μs (max)

ADC12H030/ADC12H032/ADC12H034/ADC12H038, ADC12030/ADC12032/ADC12034/ADC12038 Self-Calibrating 12-Bit Plus Sign Serial I/O A/D Converters with MUX and Sample/Hold

General Description

The ADC12030, and ADC12H030 families are 12-bit plus sign successive approximation A/D converters with serial I/O and configurable input multiplexers. The ADC12032/ADC12H032, ADC12034/ADC12H034 and ADC12038/ADC12H038 have 2, 4 and 8 channel multiplexers, respectively. The differential multiplexer outputs and A/D inputs are available on the MUXOUT1, MUXOUT2, A/DIN1 and A/DIN2 pins. The ADC12030/ADC12H030 has a two channel multiplexer with the multiplexer outputs and A/D inputs internally connected. The ADC12030 family is tested with a 5 MHz clock, while the ADC12H030 family is tested with an 8 MHz clock. On request, these A/Ds go through a self calibration process that adjusts linearity, zero and full-scale errors to less than ±1 LSB each.

The analog inputs can be configured to operate in various combinations of single-ended, differential, or pseudo-differential modes. A fully differential unipolar analog input range (0V to +5V) can be accommodated with a single +5V supply. In the differential modes, valid outputs are obtained even when the negative inputs are greater than the positive because of the 12-bit plus sign output data format.

The serial I/O is configured to comply with the NSC MICROWIRE™. For complementary voltage references see the LM4040, LM4041 or LM9140.

Applications

- Medical instruments
- Process control systems
- Test equipment

Features

- Serial I/O (MICROWIRE Compatible)
- 2, 4, or 8 channel differential or single-ended multiplexer
- Analog input sample/hold function
- Power down mode
- Variable resolution and conversion rate
- Programmable acquisition time
- Variable digital output word length and format
- No zero or full scale adjustment required
- Fully tested and guaranteed with a 4.096V reference
- 0V to 5V analog input range with single 5V power supply
- No Missing Codes over temperature

COP472-3 Liquid Crystal Display Controller

General Description

The COP472–3 Liquid Crystal Display (LCD) Controller is a peripheral member of the COPS™ family, fabricated using CMOS technology. The COP472-3 drives a multiplexed liquid crystal display directly. Data is loaded serially and is held in internal latches. The COP472-3 contains an on-chip oscillator and generates all the multi-level waveforms for backplanes and segment outputs on a triplex display. One COP472-3 can drive 36 segments multiplexed as 3 x 12 (4½ digit display). Two COP472-3 devices can be used together to drive 72 segments (3 x 24) which could be an 8½ digit display.

Features

- Direct interface to TRIPLEX LCD
- Low power dissipation (100 μW typ.)
- Low cost
- Compatible with all COPS processors
- Needs no refresh from processor
- On-chip oscillator and latches
- Expandable to longer displays
- Operates from display voltage
- MICROWIRE™ compatible serial I/O
- 20-pin Dual-In-Line package and 20-pin SO

FIGURE 5. Typical Display Internal Connections
Epson LD-370

Functional Description

The COP472-3 drives 36 bits of display information organized as twelve segments and three backplanes. The COP472-3 requires 40 information bits: 36 data and 4 control. The function of each control bit is described below. Display information format is a function of the LCD interconnections. A typical segment/backplane configuration is illustrated in *Figure 5*, with this configuration the COP472-3 will drive 4 digits of 9 segments.

To adapt the COP472-3 to any LCD display configuration, the segment/backplane multiplex scheme is illustrated in Table I.

Two or more COP472-3 chips can be cascaded to drive additional segments. There is no limit to the number of COP472-3's that can be used as long as the output loading capacitance does not exceed specification.

TABLE I. COP472-3 Segment/Backplane Multiplex Scheme

Bit Number	Segment, Backplane	Data to Numeric Display	
1	SA1, BPC	SH	
2	SB1, BPB	SG	
3	SC1, BPA	SF	
4	SC1, BPB	SE	Digit 1
5	SB1, BPC	SD	
6	SA1, BPB	SC	
7	SA1, BPA	SB	
8	SB1, BPA	SA	
9	SA2, BPC	SH	
10	SB2, BPB	SG	
11	SC2, BPA	SF	
12	SC2, BPB	SE	Digit 2

36	SC4, BPC	SP4	Digit 4
37	not used		
38	Q6		
39	Q7		
40	SYNC		

SEGMENT DATA BITS

Data is loaded in serially, in sets of eight bits. Each set of segment data is in the following format:

SA	SB	SC	SD	SE	SF	SG	SH

Data is shifted into an eight bit shift register. The first bit of the data is for segment H, digit 1. The eighth bit is segment A, digit 1. A set of eight bits is shifted in and then loaded into the digit one latches. The second set of 8 bits is loaded into digit two latches. The third set into digit three latches, and the fourth set is loaded into digit four latches.

CONTROL BITS

The fifth set of 8 data bits contains special segment data and control data in the following format:

SYNC	Q7	Q6	X	SP4	SP3	SP2	SP1

The first four bits shifted in contain the special character segment data. The fifth bit is not used. The sixth and seventh bits program the COP472-3 as a stand alone LCD driver or as a master or slave for cascading COP472-3's. BPC of the master is connected to BPA of each slave. The following table summarizes the function of bits six and seven:

Q7	Q6	Function	BPC Output	BPA Output
1	1	Slave	Backplane Output	Oscillator Input
0	1	Stand Alone	Backplane Output	Backplane Output
1	0	Not Used	Internal Osc. Output	Oscillator Input
0	0	Master	Internal Osc. Output	Backplane Output

The eighth bit is used to synchronize two COP472-3's to drive an 8½-digit display.

LOADING SEQUENCE TO DRIVE A 4½-DIGIT DISPLAY

Steps:

1. Turn $\overline{CE}$ low.
2. Clock in 8 bits of data for digit 1.
3. Clock in 8 bits of data for digit 2.
4. Clock in 8 bits of data for digit 3.
5. Clock in 8 bits of data for digit 4.
6. Clock in 8 bits of data for special segment and control function of BPC and BPA.

0	0	1	1	SP4	SP3	SP2	SP1

7. Turn $\overline{CS}$ high.

Note: $\overline{CS}$ may be turned high after any step. For example to load only 2 digits of data, do steps 1, 2, 3, and 7.

$\overline{CS}$ must make a high to low transition before loading data in order to reset internal counters.

LOADING SEQUENCE TO DRIVE AN 8½-DIGIT DISPLAY

Two or more COP472-3's may be connected together to drive additional segments. An eight digit multiplexed display is shown in *Figure 7*. The following is the loading sequence to drive an eight digit display using two COP472-3's. The right chip is the master and the left the slave.

Steps:

1. Turn $\overline{CS}$ low on both COP472-3's.
2. Shift in 32 bits of data for the slave's four digits.
3. Shift in 4 bits of special segment data: a zero and three ones.

1	1	1	0	SP4	SP3	SP2	SP1

   This synchronizes both the chips and BPA is oscillator input. Both chips are now stopped.
4. Turn CS high to both chips.
5. Turn CS low to master COP472-3.
6. Shift in 32 bits of data for the master's 4 digits.
7. Shift in four bits of special segment data, a one and three zeros.

0	0	0	1	SP4	SP3	SP2	SP1

   This sets the master COP472-3 to BPA as a normal backplane output and BPC as oscillator output. Now both the chips start and run off the same oscillator.
8. Turn $\overline{CS}$ high.

The chips are now synchronized and driving 8 digits of display. To load new data simply load each chip separately in the normal manner, keeping the correct status bits to each COP472-3 (0110 or 0001).

MM5450/MM5451 LED Display Drivers

General Description

The MM5450 and MM5451 are monolithic MOS integrated circuits utilizing N-channel metal-gate low threshold, enhancement mode, and ion-implanted depletion mode devices. They are available in 40-pin molded or cavity dual-in-line packages. The MM5450/MM5451 is designed to drive common anode-separate cathode LED displays. A single pin controls the LED display brightness by setting a reference current through a variable resistor connected to V_{DD}.

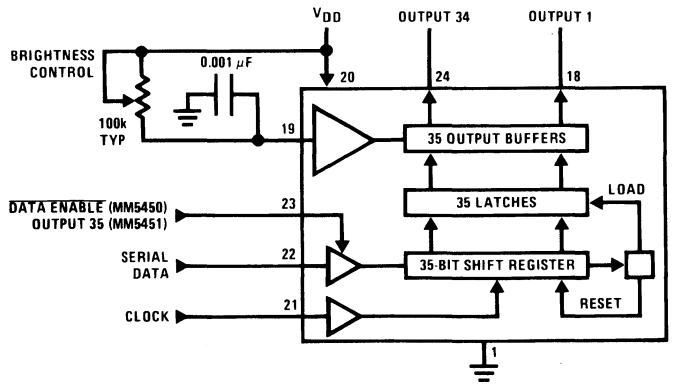
Applications

- COPS™ or microprocessor displays
- Industrial control indicator
- Relay driver
- Digital clock, thermometer, counter, voltmeter
- Instrumentation readouts

Features

- Continuous brightness control
- Serial data input
- No load signal required
- Enable (on MM5450)
- Wide power supply operation
- TTL compatibility
- 34 or 35 outputs, 15 mA sink capability
- Alphanumeric capability
- θ_{JA} DIP — Board = 49°C/W, Socket = 54°C/W

Block Diagram



TL/F/6136–1

National Semiconductor

MM5483 Liquid Crystal Display Driver

General Description

The MM5483 is a monolithic integrated circuit utilizing CMOS metal-gate low-threshold enhancement mode devices. It is available in a 40-pin molded package. The chip can drive up to 31 segments of LCD and can be cascaded to increase this number. This chip is capable of driving a 4½-digit 7-segment display with minimal interface between the display and the data source.

The MM5483 stores the display data in latches after it is latched in, and holds the data until another load pulse is received

Features

- Serial data input
- Serial data output
- Wide power supply operation
- TTL compatibility
- 31 segment outputs
- Alphanumeric and bar graph capability
- Cascade capability

Applications

- COPS™ or microprocessor displays
- Industrial control indicator
- Digital clock, thermometer, counter, voltmeter
- Instrumentation readouts
- Remote displays

MM5484 16-Segment LED Display Driver

General Description

The MM5484 is a low threshold N-channel metal gate circuit using low threshold enhancement and ion implanted depletion devices. The MM5484 is available in a 22-pin molded package and is capable of driving 16 LED segments. The MM5484 is designed to drive common anode separate cathode LED displays.

Features

- Serial data input
- Wide power supply operation
- 16 output, 15 mA sink capability
- MM5484 is cascadeable
- TTL compatibility
- No load signal required
- Non multiplex display
- 2½ digit capability—MM5484

Applications

- COPS™ or microprocessor displays
- Instrumentation readouts
- Industrial control indicator
- Relay driver

MM5486 LED Display Driver

General Description

The MM5486 is a monolithic MOS integrated circuit utilizing N-channel metal-gate low-threshold, enhancement mode and ion-implanted depletion mode devices. It is available in a 40-pin molded dual-in-line package. The MM5486 is designed to drive common anode-separate cathode LED displays. A single pin controls the LED display brightness by setting a reference current through a variable resistor connected to V_{DD}.

Features

- Continuous brightness control
- Serial data input/outut
- External load input
- Cascaded operation capability
- Wide power supply operation
- TTL compatibility
- 33 outputs, 15 mA sink capability
- Alphanumeric capability

Applications

- COPS™ or microprocessor displays
- Industrial control indicator
- Relay driver
- Digital clock, thermometer, counter, voltmeter
- Instrumentation readouts

MM58241 High Voltage Display Driver

General Description

The MM58241 is a monolithic MOS integrated circuit utilizing CMOS metal gate low threshold P- and N-channel devices. It is available both in 40-pin molded dual-in-line packages or as dice. The MM58241 is particularly suited for driving high voltage (60V max) vacuum fluorescent (VF) displays (e.g., a 32-digit alphanumeric or dot matrix display).

Applications

- COPS™ or microprocessor-driven displays
- Instrumentation readouts
- Industrial control indicator
- Digital clock, thermostat, counter, voltmeter
- Word processor text displays
- Automotive dashboards

Features

- Direct interface to high voltage display
- Serial data input
- No external resistors required
- Wide display power supply operation
- LSTTL compatible inputs
- Software compatible with NS display driver family
- Compatible with alphanumeric or dot matrix displays
- Display blanking control input
- Simple to cascade

Block Diagram

MM58341 High Voltage Display Driver

General Description

The MM58341 is a monolithic MOS integrated circuit utilizing CMOS metal gate low threshold P and N-channel devices. It is available both in 40-pin molded dual-in-line packages or as dice. The MM58341 is particularly suited for driving high voltage (35V max) vacuum fluorescent (VF) displays, (e.g., a 32-digit alphanumeric or dot matrix display).

Applications

- COPS™ or microprocessor-driven displays
- Instrumentation readouts
- Industrial control indicator
- Digital clock, thermostat, counter, voltmeter
- Word processor text displays
- Automotive dashboards

Features

- Direct interface to high voltage display
- Serial data input
- No external resistors required
- Wide display power supply operation

MM58342 High Voltage Display Driver

General Description

The MM58342 is a monolithic MOS integrated circuit utilizing CMOS metal gate low threshold P- and N-channel devices. It is available both in 28-pin molded dual-in-line packages or as dice. The MM58342 is particularly suited for driving high voltage (35V max) vacuum fluorescent (VF) displays (e.g., a 20-digit alphanumeric or dot matrix display).

Applications

- COPS™ or microprocessor-driven displays
- Instrumentation readouts
- Industrial control indicator
- Digital clock, thermostat, counter, voltmeter
- Word processor text displays
- Automotive dashboards

Features

- Direct interface to high voltage display
- Serial data input
- No external resistors required
- Wide display power supply operation
- LSTTL compatible inputs
- Software compatible with NS display driver family
- Compatible with alphanumeric or dot matrix displays
- Display blanking control input
- Simple to cascade

NM93C13/C14
256-/1024-Bit Serial EEPROM

General Description

The NM93C13/C14 is 256/1024, respectively, bits of CMOS electrically erasable memory divided into 16/64 16-bit registers. They are fabricated using National Semiconductor's floating-gate CMOS process for high speed, high reliability and low power. The NM93C13/C14 is available in an 8-pin SO package to save board space.

The serial interface of the NM93C13/C14 is MICROWIRE™ compatible for simple interface to standard microcontrollers and microprocessors. There are 7 instructions: Read, Erase/Write Enable, Erase, Erase All, Write, Write All, and Erase/Write Disable.

All programming cycles are completely self-timed for simplified operation. The ready/busy status is available on the DO pin to indicate the completion of a programming cycle.

Features

- Typical active current 400 μA; Typical standby current 25 μA
- Reliable CMOS floating gate technology
- 4.5V to 5.5V operation in all modes
- MICROWIRE compatible serial I/O
- Self-timed programming cycle
- Device status indication during programming mode
- 15 years data retention
- Endurance: 100,000 read/write cycles minimum
- Packages available: 8-pin DIP, 8-pin SO

Block Diagram

National Semiconductor

NM93C06/C46/C56/C66
256-/1024-/2048-/4096-Bit Serial EEPROM (MICROWIRE™ Bus Interface)

General Description

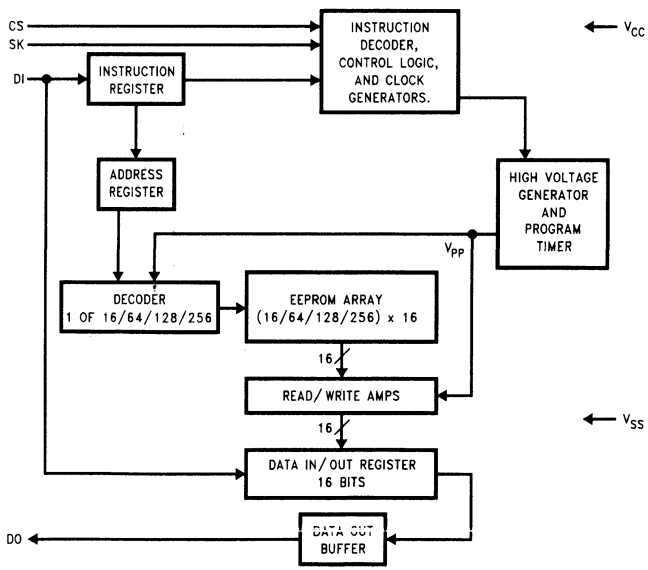
The NM93C06/C46/C56/C66 devices are 256/1024/2048/4096 bits, respectively, of CMOS non-volatile electrically erasable memory divided into 16/64/128/256 16-bit registers. They are fabricated using National Semiconductor's floating-gate CMOS process for high reliability and low power consumption. These memory devices are available in both SO and TSSOP packages for small space considerations.

The EEPROM Interfacing is MICROWIRE compatible for simple interface to standard microcontrollers and microprocessors. There are 7 instructions that control these devices: Read, Erase/Write Enable, Erase, Erase All, Write, Write All, and Erase/Write Disable. The ready/busy status is available on the DO pin during programming.

Features

- Device status during programming mode
- Typical active current of 200 μA; Typical standby current of 10 μA
- No erase required before write
- Reliable CMOS floating gate technology
- 4.5V to 5.5V operation in all modes
- MICROWIRE compatible serial I/O
- Self-timed programming cycle
- 40 years data retention
- Endurance: 10^6 data changes
- Packages available: 8-pin SO, 8-pin DIP, 8-pin TSSOP

Block Diagram



TL/D/10751–1

National Semiconductor

NM93C46A
1,024-Bit Serial Interface, Standard Voltage CMOS EEPROM (MICROWIRE™ Synchronous Bus)

General Description

The NM93C46A is 1,024 bits of CMOS nonvolatile, electrically erasable memory available as either 64 16-bit registers or 128 8-bit registers. The user organization is determined by the status of the ORG input. The memory device is fabricated using National Semiconductor's floating gate CMOS process for high reliability, high endurance, and low power consumption. The NM93C46A is available in both 8-pin SO and TSSOP packages for space considerations.

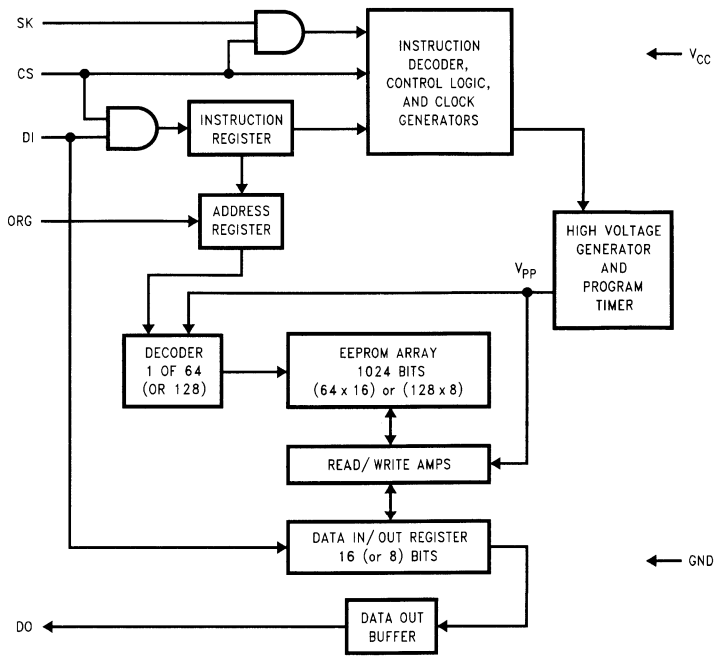
The EEPROM is MICROWIRE compatible for simple interfacing to a wide variety of microcontrollers and microprocessors. There are 7 instructions that operate the NM93C46A: Read, Erase/Write Enable, Erase, Write, Erase/Write Disable, Write All, and Erase All.

The NM93C46A defaults to the 64 x 16 configuration if the ORG pin (Pin 6) is left floating, as it is internally pulled up to V_{CC}.

Features

- 4.5V to 5.5V operation in all modes
- Typical active current of 200 μA; typical standby current of 10 μA
- Self-timed programming cycle
- Device status indication during programming mode
- No erase required before write
- Reliable CMOS floating gate technology
- MICROWIRE compatible serial I/O
- 40 years data retention
- Endurance: 10^6 data changes
- Packages available: 8-pin TSSOP, 8-pin SO, 8-pin DIP

Block Diagram



TL/D/11042–1

National Semiconductor

NM93C56A
2,048-Bit Serial Interface, Standard Voltage CMOS EEPROM (MICROWIRE™ Synchronous Bus)

General Description

The NM93C56A is 2,048 bits of CMOS non-volatile, electrically erasable memory user organized as either 128 16-bit registers or 256 8-bit registers. The user organization is determined by the status of the ORG input. The memory device is fabricated using National Semiconductor's floating gate CMOS process for high reliability, high endurance and low power consumption. The NM93C56A is available in both 8-pin SO and TSSOP packages for space considerations.

The EEPROM is MICROWIRE compatible for simple interfacing to a wide variety of microcontrollers and microprocessors. There are 7 instructions that operate the NM93C56A: Read, Erase/Write Enable, Erase, Write, Erase/Write Disable, Write All, and Erase All.

The NM93C56A defaults to the 128 x 16 configuration if the ORG pin (Pin 6) is left floating, as it is internally pulled up to V_{CC}.

Features

- 4.5V to 5.5V operation in all modes
- Typical active current of 200 μA; typical standby current of 10 μA
- Self-timed programming cycle
- Device status indication during programming mode
- No erase required before write
- Reliable CMOS floating gate technology
- MICROWIRE compatible serial I/O
- 40 years data retention
- Endurance: 10^6 data changes
- Packages available: 8-Pin TSSOP, 8-pin SO, 8-pin DIP

Block Diagram

National Semiconductor

NM93C66A
4,096-Bit Serial Interface, Standard Voltage CMOS EEPROM (MICROWIRE™ Synchronous Bus)

General Description

The NM93C66A is 4,096 bits of CMOS non-volatile, electrically erasable memory available user organized as either 256 16-bit registers or 512 8-bit registers. The user organization is determined by the status of the ORG input. The memory device is fabricated using National Semiconductor's floating gate CMOS process for high reliability, high endurance and low power consumption. The NM93C66A is available in both 8-pin SO and TSOP packages for space considerations.

The EEPROM is MICROWIRE compatible for simple interfacing to a wide variety of microcontrollers and microprocessors. There are 7 instructions that operate the NM93C66A: Read, Erase/Write Enable, Erase, Write, Erase/Write Disable, Write All, and Erase All.

The NM93C66A defaults to the 256 x 16 configuration if the ORG pin (Pin 6) is left floating, as it is internally pulled up to V_{CC}.

Features

- 4.5V to 5.5V operation in all modes
- Typical active current of 200 μA; typical standby current of 10 μA
- Self-timed programming cycle
- Device status indication during programming mode
- No erase required before write
- Reliable CMOS floating gate technology
- MICROWIRE compatible serial I/O
- 40 years data retention

National Semiconductor

NM93CS06/CS46/CS56/CS66 (MICROWIRE™ Bus Interface) 256-/1024-/2048-/4096-Bit Serial EEPROM with Data Protect and Sequential Read

General Description

The NM93CS06/CS46/CS56/CS66 devices are 256/1024/2048/4096 bits, respectively, of CMOS non-volatile electrically erasable memory divided into 16/64/128/256 16-bit registers. Selected registers can be protected against data modification by programming the Protect Register with the address of the first register to be protected against data modification (all registers greater than, or equal to, the selected address are then protected from further change). Additionally, this address can be "locked" into the device, making all future attempts to change data impossible. These devices are fabricated using National Semiconductor floating-gate CMOS process for high reliability, high endurance and low power consumption. The NM93CSXX Family is offered in both SO and TSSOP packages for small space considerations.

The EEPROM interfacing is MICROWIRE compatible providing simple interfacing to standard microcontrollers and microprocessors. There are a total of 10 instructions, 5 which operate on the EEPROM memory, and 5 which operate on the Protect Register. The memory instructions are READ, WRITE, WRITE ALL, WRITE ENABLE, and WRITE DISABLE. The Protect register instructions are PRREAD, PRWRITE, PRENABLE, PRCLEAR, and PRDISABLE.

Features

- Write protection in a user defined section of memory
- Sequential register read
- Typical active current of 200 μA and standby current of 10 μA
- No erase required before write
- Reliable CMOS floating gate technology
- MICROWIRE compatible serial I/O
- Self timed write cycle
- Device status during programming mode
- 40 year data retention
- Endurance: 10^6 data changes
- 4.5V to 5.5V operation in all modes of operation
- Packages available: 8-pin SO, 8-pin DIP, 8-pin TSSOP

LMC1982
Digitally-Controlled Stereo Tone and Volume Circuit with Two Selectable Stereo Inputs

General Description

The LMC1982 is a monolithic integrated circuit that provides volume, balance, tone (bass and treble), enhanced stereo, and loudness controls and selection between two pairs of stereo inputs. These functions are digitally controlled through a three-wire communication interface. There are two digital inputs for easy interface to other audio peripherals such as stereo decoders. The LMC1982 is designed for line level input signals (300 mV–2V) and has a maximum gain of −0.5 dB. Volume is set at minimum and tone controls are flat when supply voltage is first applied.

Low noise and distortion result from using analog switches and poly-silicon resistor networks in the signal path.

Additional tone control can be achieved using the LMC835 stereo 7-band graphic equalizer connected to the LMC1982's SELECT OUT/SELECT IN external processor loop.

Features

- Low noise and distortion
- Two pairs of stereo inputs
- Enhanced stereo function
- Loudness compensation
- 40 position 2 dB/step volume attenuator plus mute
- Independent left and right volume controls
- Low noise-suitable for use with DNR® and Dolby® noise reduction
- External processor loop
- Signal handling suitable for compact discs
- Pop-free switching
- Serially programmable: INTERMETAL bus (IM) interface
- 6V to 12V single supply operation
- 28 Pin DIP or PLCC package

Applications

- Stereo television
- Music reproduction systems
- Sound reinforcement systems
- Electronic music (MIDI)
- Personal computer audio control

LMC1983
Digitally-Controlled Stereo Tone and Volume Circuit with Three Selectable Stereo Inputs

General Description

The LMC1983 is a monolithic integrated circuit that provides volume, balance, tone (bass and treble), loudness controls and selection between three pairs of stereo inputs. These functions are digitally controlled through a three-wire communication interface. There are two digital inputs for easy interface to other audio peripherals such as stereo decoders. The LMC1983 is designed for line level input signals (300 mV–2V) and has a maximum gain of −0.5 dB. Volume is set at minimum and tone controls are flat when supply voltage is first applied.

Low noise and distortion result from using analog switches and poly-silicon resistor networks in the signal path.

Additional tone control can be achieved using the LMC835 stereo 7-band graphic equalizer connected to the LMC1983's SELECT OUT/SELECT IN external processor loop.

Features

- Low noise and distortion
- Three pairs of stereo inputs
- Loudness compensation
- 40 position 2 dB/step volume attenuator plus mute
- Independent left and right volume controls
- Low noise-suitable for use with DNR® and Dolby® noise reduction
- External processor loop
- Signal handling suitable for compact discs
- Pop-free switching
- Serially programmable: INTERMETAL bus (IM) interface
- 6V to 12V single supply operation
- 28 Pin DIP or PLCC Package

Applications

- Stereo television
- Music reproduction systems
- Sound reinforcement systems
- Electronic music (MIDI)
- Personal computer audio control

LMC1992 Digitally-Controlled Stereo Tone and Volume Circuit with Four-Channel Input-Selector

General Description

The LMC1992 is a monolithic integrated circuit that provides four stereo inputs, bass and treble tone controls, and volume, balance, and front-rear fader controls. These functions are digitally controlled through a three-wire communication interface. All of the LMC1992s functions are achieved with only three external capacitors per channel. It is designed for line level input signals (300 mV – 2V) and has a maximum gain of 0 dB.

The internal design is optimized for external capacitors having values of 0.1 μF or less. This allows the use of chip capacitors for coupling and tone control functions.

Low noise and distortion result from using analog switches and thin-film silicon-chromium resistor networks in the signal path.

Volume and fader are at minimum and tone controls are flat when supply voltage is first applied.

Additional tone control can be achieved using the LMC835 stereo 7-band graphic equalizer connected to the LMC1992's select-out/select-in external processor loop.

Features

- Low noise and distortion
- Four stereo inputs
- 40 volume levels including mute
- 20 fader levels
- All attenuators have a 2 dB of attenuation per step
- Front/back fade control
- External processor loop
- Only three external components per channel
- Serial programmable: standard MICROWIRE™ interface
- Single supply operation: 6V to 12V supply voltage
- Protection address (similar to DS8906)
- DC-coupled inputs
- Single supply operation

Applications

- Automotive audio systems
- Sound reinforcement systems
- Home entertainment—stereo television and music reproduction systems
- Electronic music (MIDI)

LMC835 Digital Controlled Graphic Equalizer

General Description

The LMC835 is a monolithic, digitally-controlled graphic equalizer CMOS LSI for Hi-Fi audio. The LMC835 consists of a Logic section and a Signal Path section made of analog switches and thin-film silicon-chromium resistor networks. The LMC835 is used with external resonator circuits to make a stereo equalizer with seven bands, ±12 dB or ±6 dB gain range and 25 steps each. Only three digital inputs are needed to control the equalization. The LMC835 makes it easy to build a μP-controlled equalizer.

The signal path is designed for very low noise and distortion, resulting in very high performance, compatible with PCM audio.

Features

- No volume controls required
- Three-wire interface
- 14 bands, 25 steps each
- ±12 dB or ±6 dB gain ranges
- Low noise and distortion
- TTL, CMOS logic compatible

Applications

- Hi-Fi equalizer
- Receiver
- Car stereo
- Musical instrument
- Tape equalization
- Mixer
- Volume controller

LM1971 *Overture*™ Audio Attenuator Series
Digitally Controlled 62 dB Audio Attenuator with/Mute

General Description

The LM1971 is a digitally controlled single channel audio attenuator fabricated on a CMOS process. Attenuation is variable in 1 dB steps from 0 dB to −62 dB. A mute function disconnects the input from the output, providing over 100 dB of attenuation.

The performance of the device is exhibited by its ability to change attenuation levels without audible clicks or pops. In addition, the LM1971 features a low Total Harmonic Distortion (THD) of 0.0008%, and a Dynamic Range of 115 dB, making it suitable for digital audio needs. The LM1971 is available in both 8-pin plastic DIP or SO packages.

The LM1971 is controlled by a TTL/CMOS compatible 3-wire serial digital interface. The active low LOAD line enables the data input registers while the CLOCK line provides system timing. Its DATA pin receives serial data on the rising edge of each CLOCK pulse, allowing the desired attenuation setting to be selected.

Key Specifications

- Total harmonic distortion 0.0008% (typ)
- Frequency response > 200 kHz (−3 dB) (typ)
- Attenuation range (excluding mute) 62 dB (typ)
- Dynamic range 115 dB (typ)
- Mute attenuation 102 dB (typ)

Features

- 3-wire serial interface
- Mute function
- Click and pop free attenuation changes
- 8-pin plastic DIP and SO packages available

Applications

- Communication systems
- Cellular Phones and Pagers
- Personal computer audio control
- Electronic music (MIDI)
- Sound reinforcement systems
- Audio mixing automation

Typical Application

LM1972
μPot™ 2-Channel 78dB Audio Attenuator with Mute

General Description

The LM1972 is a digitally controlled 2-channel 78dB audio attenuator fabricated on a CMOS process. Each channel has attenuation steps of 0.5dB from 0dB–47.5dB, 1.0dB steps from 48dB–78dB, with a mute function attenuating 104dB. Its logarithmic attenuation curve can be customized through software to fit the desired application.

The performance of a μPot is demonstrated through its excellent Signal-to-Noise Ratio, extremely low (THD+N), and high channel separation. Each μPot contains a mute function that disconnects the input signal from the output, providing a minimum attenuation of 96dB. Transitions between any attenuation settings are pop free.

The LM1972's 3-wire serial digital interface is TTL and CMOS compatible; receiving data that selects a channel and the desired attenuation level. The Data-Out pin of the LM1972 allows multiple μPots to be daisy-chained together, reducing the number of enable and data lines to be routed for a given application.

Key Specifications

- Total Harmonic Distortion + Noise 0.003% (max)
- Frequency response 100 kHz (−3dB) (min)
- Attenuation range (excluding mute) 78dB (typ)
- Differential attenuation ±0.25dB (max)
- Signal-to-noise ratio (ref. 4 Vrms) 110dB (min)
- Channel separation 100dB (min)

Features

- 3-wire serial interface
- Daisy-chain capability
- 104dB mute attenuation
- Pop and click free attenuation changes

Applications

- Automated studio mixing consoles
- Music reproduction systems
- Sound reinforcement systems
- Electronic music (MIDI)
- Personal computer audio control

Typical Application

LM1973
μPot™ 3-Channel 76dB Audio Attenuator with Mute

General Description

The LM1973 is a digitally controlled 3-channel 76dB audio attenuator fabricated on a CMOS process. Each channel has attenuation steps of 0.5dB from 0dB–15.5dB, 1.0dB steps from 16dB–47dB, and 2.0dB steps from 48dB–76dB, with a mute function attenuating 104dB. Its logarithmic attenuation curve can be customized through software to fit the desired application.

The performance of a μPot is demonstrated through its excellent Signal-to-Noise Ratio, extremely low (THD+N), and high channel separation. Each μPot contains a mute function that disconnects the input signal from the output, providing a minimum attenuation of 96dB. Transitions between any attenuation settings are pop free.

The LM1973's 3-wire serial digital interface is TTL and CMOS compatible; receiving data that selects a channel and the desired attenuation level. The Data-Out pin of the LM1973 allows multiple μPots to be daisy-chained together, reducing the number of enable and data lines to be routed for a given application.

Key Specifications

- Total Harmonic Distortion + Noise 0.003% (max)
- Frequency response 100 kHz (−3dB) (min)
- Attenuation range (excluding mute) 76dB (typ)
- Differential attenuation ±0.25dB (max)

Protecting Data in Serial EEPROMs

National Semiconductor
Application Brief 15
Paul Lubeck

National offers a broad line of serial interface EEPROMs which share a common set of features:

- Low cost
- Single supply in all modes (+5V ± 10%)
- TTL compatible interface
- MICROWIRE™ compatible interface
- Read-Only mode or read-write mode

This Application Brief will address protecting data in any of National's Serial Interface EEPROMs by using read-only mode.

Whereas EEPROM is non-volatile and does not require V_{CC} to retain data, the problem exists that stored data can be destroyed during power transitions. This is due to either uncontrolled interface signals during power transitions or noise on the power supply lines. There are various hardware design considerations which can help eliminate the problem although the simplest most effective method may be the following programming method.

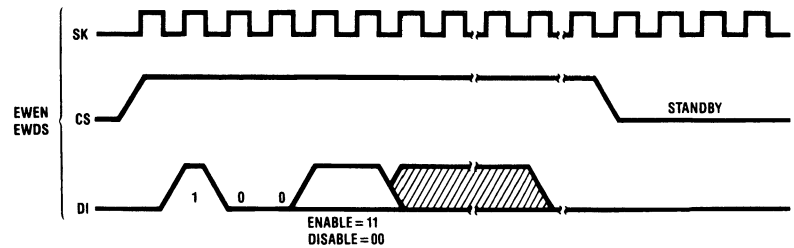
All National Serial EEPROMs, when initially powered up are in the Program Disable Mode*. In this mode, the EEPROM will abort any requested Erase or Write cycles. Prior to Erasing or Writing it is necessary to place the device in the Program Enable Mode†. Following placing the device in the Program Enable Mode, Erase and Write will remain enabled until either executing the Disable instruction or removing V_{CC}. Having V_{CC} unexpectedly removed often results in uncontrolled interface signals which could result in the EEPROM interpreting a programming instruction causing data to be destroyed.

Upon power up the EEPROM will automatically enter the Program Disable Mode. Subsequently the design should incorporate the following to achieve protection of stored data.

1) The device powers up in the read-only mode. However, as a backup, the EWDS instruction should be executed as soon as possible after V_{CC} to the EEPROM is powered up to ensure that it is in the read-only mode.
2) Immediately preceding a programming instruction (ERASE, WRITE, ERAL or WRAL), the EWEN instruction should be executed to enable the device for programming; the EWDS instruction should be executed immediately following the programming instruction to return

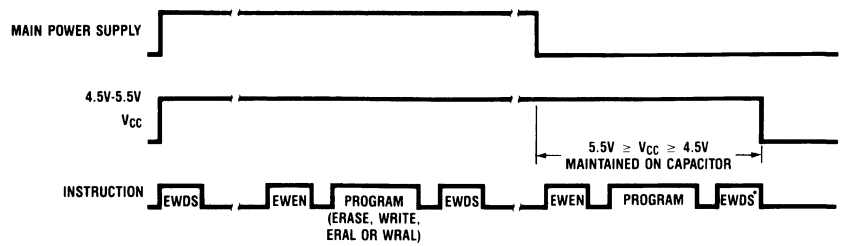
*EWDS or WDS, depending on exact device.

†EWEN or WEN, depending on exact device.



TL/D/7085–1

FIGURE 1. EWEN, EWDS Instruction Timing



TL/D/7085–2

*EWDS must be executed before V_{CC} drops below 4.5V to prevent accidental data loss during subsequent power down and/or power up transients.

FIGURE 2. Typical Instruction Flow for Maximum Data Protection

the device to the read-only mode and protect the stored data from accidental disturb during subsequent power transients or noise.

3) Special care must be taken in designs in which programming instructions are initiated to store data in the EEPROM after the main power supply has gone down. This is usually accomplished by maintaining V_{CC} for the EEPROM and its controller on a capacitor for a sufficient amount of time (approximately 50 ms, depending on the clock rate) to complete these operations. This capacitor must be large enough to maintain V_{CC} between 4.5 and 5.5 volts for the total duration of the store operation, INCLUDING the execution of the EWDS instruction immediately following the last programming instruction. FAILURE TO EXECUTE THE LAST EWDS INSTRUCTION BEFORE V_{CC} DROPS BELOW 4.5 VOLTS MAY CAUSE INADVERTENT DATA DISTURB DURING SUBSEQUENT POWER DOWN AND/OR POWER UP TRANSIENTS.

Automatic Low Cost Thermostat

National Semiconductor
Application Brief 22
Kent Brooten

Ths application brief describes the use of the NMC9346 (64 x 16) serial EEPROM. With the advent of the inexpensive COPS™ family from National Semiconductor, heretofore "expensive" applications can now be realized inexpensively. Such an application is a low cost thermostat. Typical features of such a device are:

1) Ability to interface to local and remote temperature sensors,
2) Ability to hold changeable settings,
3) Digital display of present temperature,
4) Inexpensive in high volume.

CIRCUIT DESCRIPTION

The basis of the thermostat is the COP410 microcontroller. This, with the addition of 2 ADC0854 A/D converters, an NMC9346 EEPROM and some logic for LED display, comprise an extremely versatile, yet low cost, system. The ADC0854 allows 4 channels of temperature sensors, 1 local and 3 remote. Temperature sensors used are LM34 (for readings in °F) or LM35 (for readings in °C).

While there are several possible choices for A/D converters that are MICROWIRE™ compatible, the ADC0854 was chosen because of its "settability". By presetting the "cold" temperature (i.e., when the cooling unit should come on—say 80°F) all the microcomputer has to do is to multiplex the inputs and read the data in line. Similarly, the "hot" A/D can be preset to the temperature where the furnace should come on (e.g., 60°F) and scanned in a like manner. Since the microcomputer is also keeping time of day, selecting an A/D with more "smarts" (as in the ADC0854) the software can be kept manageable and an external real time clock chip is not needed.

The EEPROM (NMC9346) holds the presettable temperature ranges (high and low settings) by day of the week. Since data is in EEPROM rather than in mask ROM, it can be changed.

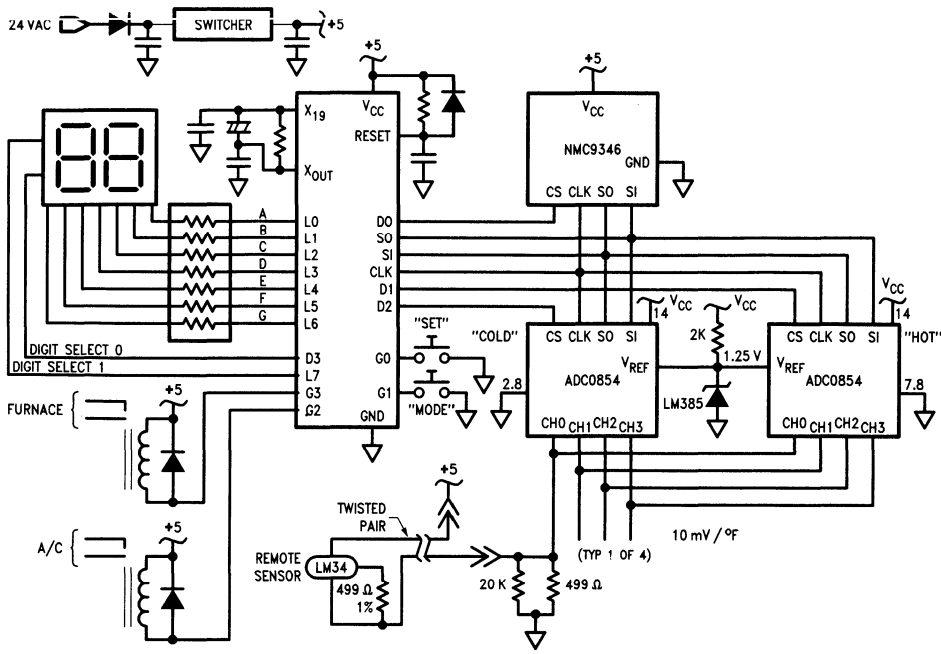
The LED display is multiplexed by the microcomputer. Depending on the type of display selected, external drivers may be necessary.

Input power is typically 24 VAC. Using a linear regulator would cause too much heat to be dissipated, which would upset the local temperature sensors. Thus, a switch mode regulator must be used. Fortunately, National Semiconductor has provided a solution to the problem with the LM3578, a switching regulator in an 8-pin mini-DIP, providing more than enough current for the application, using only a minimum of external components.

SOFTWARE DESCRIPTION

Since a real time clock is implemented in software, all routines must execute the same number of cycles independent of the input. Because of the flexibility of the COPS family instruction set, this is not as difficult a problem as it first appears. Since the EEPROM contains the settings that are periodically sent to the A/D converters, the COPS program merely fetches data from one source and dumps it to another while monitoring the output. Even the SET and MODE keys can be acted upon in a predictable manner IF the software designer carefully plans the program flow BEFORE writing code.

Note: Also see App Brief 15.



TL/D/8647–1

FIGURE 1

Dual Tone Multiple Frequency (DTMF)

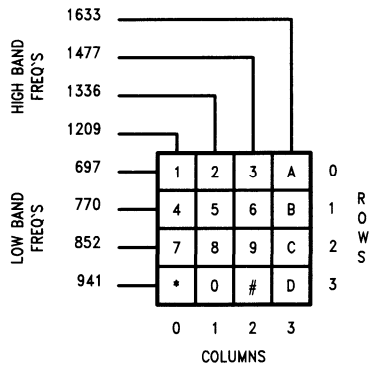
National Semiconductor
Application Note 521
Verne H. Wilson

The DTMF (Dual Tone Multiple Frequency) application is associated with digital telephony, and provides two selected output frequencies (one high band, one low band) for a duration of 100 ms. A benchmark subroutine has been written for the COP820C/840C microcontrollers, and is outlined in detail in this application note. This DTMF subroutine takes 110 bytes of COP820C/840C code, consisting of 78 bytes of program code and 32 bytes of ROM table. The timings in this DTMF subroutine are based on a 20 MHz COP820C/840C clock, giving an instruction cycle time of 1 μs.

The matrix for selecting the high and low band frequencies associated with each key is shown in *Figure 1*. Each key is uniquely referenced by selecting one of the four low band frequencies associated with the matrix rows, coupled with selecting one of the four high band frequencies associated with the matrix columns. The low band frequencies are 697, 770, 852, and 941 Hz, while the high band frequencies are 1209, 1336, 1477, and 1633 Hz. The DTMF subroutine assumes that the key decoding is supplied as a low order hex digit in the accumulator. The COP820C/840C DTMF subroutine will then generate the selected high band and low band frequencies on port G output pins G3 and G2 respectively for a duration of 100 ms.

The COP820C/840C each contain only one timer. The problem is that three different times must be generated to satisfy the DTMF application. These three times are the periods of the two selected frequencies and the 100 ms duration period. Obviously the single timer can be used to generate any one (or possibly two) of the required times, with the program having to generate the other two (or one) times.

The solution to the DTMF problem lies in dividing the 100 ms time duration by the half periods (rounded to the nearest micro second) for each of the eight frequencies, and then examining the respective high band and low band quotients and remainders. The results of these divisions are detailed in Table I. The low band frequency quotients range from 139 to 188, while the high band quotients range from 241 to 326. The observation that only the low band quotients will each fit in a single byte dictates that the high band frequency be produced by the 16 bit (2 byte) COP820C/840C timer running in PWM (Pulse Width Modulation) Mode.



TL/DD/9662–1

FIGURE 1. DTMF Keyboard Matrix

The solution then is to use the program to produce the selected low band frequency as well as keep track of the 100 ms duration. This is achieved by using three programmed register counters R0, R2, and R3, with a backup register R1 to reload the counter R0. These three counters represent the half period, the 100 ms quotient, and the 100 ms remainder associated with each of the four low band frequencies.

The theory of operation in producing the selected low band frequency starts with loading the three counters with values obtained from a ROM table. The half period for the selected frequency is counted out, after which the G2 output bit is toggled. During this half period countout, the quotient counter is decremented. This procedure is repeated until the quotient counter counts out, after which the program branches to the remainder loop. During the remainder loop, the remainder counter counts out to terminate the 100 ms. Following the remainder countout, the G2 and G3 bits are both reset, after which the DTMF subroutine is exited. Great care must be taken in time balancing the half period loop for the selected low band frequency. Furthermore, the toggling of the G2 output bit (achieved with either a set or reset bit instruction) must also be exactly time balanced to maintain the half period time integrity. Local stall loops (consisting of a DRSZ instruction followed by a JP jump back to the DRSZ for a two byte, six instruction cycle loop) are embedded in both the half period and remainder loops. Consequently, the ROM table parameters for the half period and remainder counters are approximately only one sixth of what otherwise might be expected. The program for the half period loop, along with the detailed time balancing of the loop for each of the low band frequencies, is shown in *Figure 2*.

The DTMF subroutine makes use of two 16 byte ROM tables. The first ROM table contains the translation table for the input hex digit into the core vector. The encoding of the hex digit along with the hex digit ROM translation table is shown in Table II. The row and column bits (RR, CC) representing the low band and high band frequencies respectively of the keyboard matrix shown in *Figure 1*, are encoded in

TABLE I. Frequency Half Periods, Quotients, and Remainders

	Freq. Hz	Half Period 0.5P	Half Period in μs	100 ms/0.5P	
				Quotient	Remainder
Low Band Freq.'s	697	717.36	717	139	337
	770	649.35	649	154	54
	852	586.85	587	170	210
	941	531.35	531	188	172
High Band Freq.'s	1209	413.56	414 (256 + 158)	241	226
	1336	374.25	374 (256 + 118)	267	142
	1477	338.52	339 (256 + 83)	294	334
	1633	306.18	306 (256 + 50)	326	244

the two upper and two lower bits of the hex digit respectively. Consequently, the format for the hex digit bits is RRCC, so that the input byte in the accumulator will consist of 0000RRCC. The program changes this value into 1101RRCC before using it in setting up the address for the hex digit ROM translation table.

The core vectors from the hex digit ROM translation table consist of a format of XX00TT00, where the two T (Timer) bits select one of four high band frequencies, while the two X bits select one of four low band frequencies. The core vector is transformed into four different inputs for the second ROM table. This transformation of the core vector is shown in Table III. The core vector transformation produces a timer vector 1100TT00 (T), and three programmed counter vectors for R1, R2, and R3. The formats for the three counter vectors are 1100XX11 (F), 1100XX10 (Q), and 1100XX01 (R) for R1, R2, and R3 respectively. These four vectors produced from the core vector are then used as inputs to the second ROM table. One of these four vectors (the T vector) is a function of the T bits from the core vector, while the other three vectors (F, Q, R) are a function of the X bits. This correlates to only one parameter being needed for the timer (representing the selected high band frequency), while three parameters are needed for the three counters (half period, 100 ms quotient, 100 ms remainder) associated with the low band frequency and 100 ms duration. The frequency parameter ROM translation table, accessed by the T, F, Q, and R vectors, is shown in Table IV.

0xCD	25	R
0xCE	189	Q
0xCF	83	F

In summary, the input hex digit selects one of 16 core vectors from the first ROM table. This core vector is then transformed into four other vectors (T, F, Q, R), which in turn are used to select four parameters from the second ROM table. These four parameters are used to load the timer, and the respective half period, quotient, and remainder counters. The first ROM table (representing the hex digit matrix table) is arbitrarily placed starting at ROM location 01D0, and has a reference setup with the ADD A,#0D0 instruction. The second ROM table (representing the frequency parameter table) must be placed starting at ROM location 01C0 (or 0xC0) in order to minimize program size, and has reference setups with the OR A,#0C3 instruction for the F vector and with the OR A,#0C0 instruction for the T vector.

The three parameters associated with the two X bits of the core vector require a multi-level table lookup capability with the LAID instruction. This is achieved with the following section of code in the DTMF subroutine:

```
        LD      B,#R1
        LD      X,#R4
        X       A,[X]
LUP:    LD      A,[X]
        LAID
        X       A,[B+]
        DRSZ    R4
        IFBNE   #4
        JP      LUP
```

This program code loads the F frequency vector into R4, and then decrements the vector each time around the loop. This successive loop decrementation of the R4 vector changes the F vector into the Q vector, and then changes the Q vector into the R vector. This R4 vector is used to access the ROM table with the LAID instruction. The X pointer references the R4 vector, while the B pointer is incremented each time around the loop after it has been used to store away the three selected ROM table parameters (one per loop). These three parameters are stored in sequential RAM locations R1, R2, and R3. The IFBNE test instruction is used to skip out of the loop once the three selected ROM table parameters have been accessed and stored away.

The timer is initialized to a count of 15 so that the first timer underflow and toggling of the G3 output bit (with timer PWM mode and G3 toggle output selected) will occur at the same time as the first toggling of the G2 output bit. The half period counts for the high band frequencies range from 306 to 414, so these values minus 256 are stored in the timer section of the second ROM table. The selected value from this frequency ROM table is then stored in the lower half of the timer autoreload register, while a 1 is stored in the upper half. The timer is selected for PWM output mode and started with the instruction LD [B],#0B0 where the B pointer is selecting the CNTRL register at memory location 0EE.

The DTMF subroutine for the COP820C/840C uses 110 bytes of code, consisting of 78 bytes of program code and 32 bytes of ROM table. A program routine to sequentially call the DTMF subroutine for each of the 16 hex digit inputs is supplied with the listing for the DTMF subroutine.

The code listed in this App Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communications package and a PC, the code detailed in this App Note can be down loaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

Modem (408) 739-1162
Voice (408) 721-5582

MICROWIRE/PLUS™ Serial Interface for COP800 Family

National Semiconductor
Application Note 579
Ramesh Sivakolundu
Sunder Velamuri

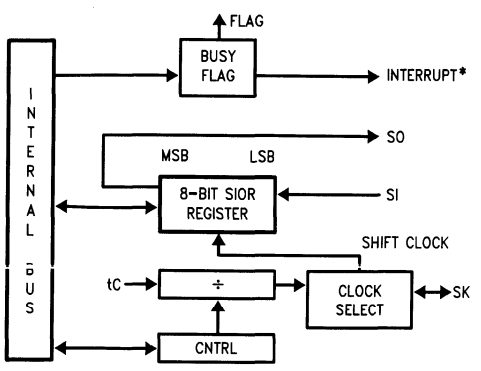
INTRODUCTION

National Semiconductor's COP800 family of full-feature, cost-effective microcontrollers use a new 8-bit single chip core architecture fabricated with M²CMOS process technology. These high performance microcontrollers provide efficient system solutions with a versatile instruction set and high functionality.

The COP800 family of microcontrollers feature the MICROWIRE/PLUS mode of serial communication. MICROWIRE/PLUS is an enhancement of the MICROWIRE™ synchronous serial communications scheme, originally implemented on the COP400 family of microcontrollers. The MICROWIRE/PLUS interface on the COP800 family of microcontrollers enables easy I/O expansion and interfacing to several COPS peripheral devices (A/D converters, EEPROMs, Display drivers etc.), and interfacing with other microcontrollers which support MICROWIRE/PLUS or SPI* modes of serial interface.

MICROWIRE/PLUS DEFINITION

MICROWIRE/PLUS is a versatile three wire, SI (serial input), SO (serial output), and SK (serial clock), bidirectional serial synchronous communication scheme where the COP800 is either the Master providing the Shift Clock (SK) or a slave accepting an external Shift Clock (SK). The COP800 MICROWIRE/PLUS system block diagram is shown in *Figure 1*. The MICROWIRE/PLUS serial interface utilizes an 8-bit memory mapped MICROWIRE/PLUS serial shift register, SIOR, clocked by the SK signal. As the name suggests, the SIOR register serves as the shift register for serial transfers. SI, the serial input line to the COP800 microcontroller, is the shift register input. SO, the shift register output, is the serial output to external devices. SK is the serial synchronous clock. Data is clocked into and out of the peripheral devices with the SK clock. The SO, SK and SI are mapped as alternate functions on pins 4, 5, and 6 respectively of the 8-bit bidirectional G Port.



*only in COP888XX series

FIGURE 1. MICROWIRE/PLUS Block Diagram

MICROWIRE/PLUS OPERATION

In MICROWIRE/PLUS serial interface, the input data on the SI pin is shifted high order first into the Least Significant Bit (LSB) of the 8-bit SIOR shift register. The output data is shifted out high order first from the Most Significant Bit (MSB) of the shift register onto the SO pin. The SIOR register is clocked on the falling edge of the SK clock signal. The input data on the SI pin is shifted into the LSB of the SIOR register on the rising edge of the SK clock. The MSB of the SIOR register is shifted out to the SO pin on the falling edge of the SK clock signal. The SK clock signal is generated internally by the COP800 for the master mode of MICROWIRE/PLUS operation. In the slave mode, the SK clock is generated by an external device (which acts as the master) and is input to the COP800.

The MSEL (MICROWIRE Select) flag in the CNTRL register is used to enable MICROWIRE/PLUS operation. Setting the MSEL flag enables the gating of the MICROWIRE/PLUS interface signals through the G port. Pins G4, G5, and G6 of the G port are used for the signals SO, SK and SI, respectively. It should be noted that the G port configuration register must be set up appropriately for MICROWIRE/PLUS operation. Table I illustrates the G-port configurations. In the master mode of MICROWIRE/PLUS operation, G4 and G5 need to be selected as outputs for SO and SK signals. Alternatively, in the slave mode of operation, G5 needs to be configured as an input for the external SK. The SI signal is a dedicated input on G6 and therefore no further setup is required.

TABLE I. G Port Configurations

G4 (SO) Config. Bit	G5 (SK) Config Bit.	G4 Fun.	G5 Fun.	Operation
1	1	SO	Int. SK	MICROWIRE Master
0	1	TRI-STATE	Int. SK	MICROWIRE Master
1	0	SO	Ext. SK	MICROWIRE Slave
0	0	TRI-STATE	Ext. SK	MICROWIRE Slave

The SL1 and SL0 (S1 and S0 in COP820C and COP840C) bits of the CNTRL register are used to select the clock division factor (2, 4, or 8) for SK clock generation in MICROWIRE/PLUS master mode operation. A clock select table for these bits of the CNTRL register along with the CNTRL register is shown in Table II. The counter associated with

the master mode clock division factor is cleared when the MICROWIRE/PLUS BUSY flag is low. The clock division factor is relative to the instruction cycle frequency. For example, if the COP800 is operating with an internal clock of 1 MHz, the SK clock rate would be 500 kHz, 250 kHz, or 125 kHz for SL1 and SL0 values of 00, 01 and 10 (or 11) respectively.

TABLE II

CNTRL Register (Address X'00EE)

The Timer1 (T1) and MICROWIRE control register contains the following bits:

SL1 & SL0 Select the MICROWIRE clock divide by (00 = 2, 01 = 4, 1X = 8)

IEDG External Interrupt Edge Polarity Select (0 = Rising Edge, 1 = Falling Edge)

MSEL Selects G5 and G4 as MICROWIRE Signals SK and SO Respectively

T1C0 Timer T1 Start/Stop Control in Timer Modes 1 and 2
Timer T1 Underflow Interrupt Pending Flag in Timer Mode 3

Bit 7 Bit 0

SL1	SL0	SK
0	0	$2 \times t_C$
0	1	$4 \times t_C$
1	x	$8 \times t_C$

Where t_C is the instruction cycle clock

MICROWIRE/PLUS MASTER MODE OPERATION

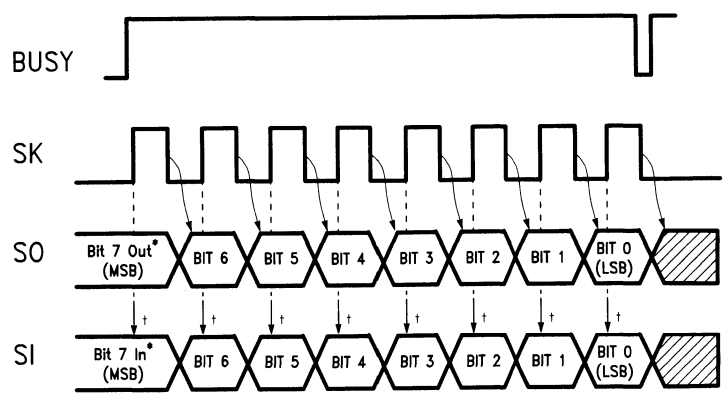
In the MICROWIRE/PLUS master mode, the BUSY flag of PSW (Processor Status Word) is used to control the shifting of the MICROWIRE/PLUS 8-bit shift register. Setting the BUSY flag causes the SIOR register to shift out 8 bits of data from SO at the high order end of the shift register. During the same time, 8 new bits of data from SI are shifted into the low order end of the SIOR register. The BUSY flag is automatically reset after the 8 bits of data have been shifted *(Figure 2)*. The COP888XX series of microcontrollers provide a vectored maskable interrupt when the BUSY goes low indicating the end of an 8-bit shift. Input data is clocked into the SIOR register from the SI pin with the rising edge of the SK clock, while the MSB of the SIOR is shifted onto the SO pin with the falling edge of the SK clock. The user may reset the BUSY bit by software to allow less than 8 bits to shift. However, the user should ensure that the software BUSY resets only occurs when the SK clock is low, in order to avoid a narrow SK terminal clock.

MICROWIRE/PLUS SLAVE MODE OPERATION

In the MICROWIRE/PLUS Slave mode of operation the SK clock is generated by an external source. Setting the MSEL bit in the CNTRL register enables the SO and SK functions onto the G Port. The SK pin must be configured as an input and the SO pin configured as an output by resetting and setting the appropriate bits in the Port G configuration register. The user must set the BUSY flag immediately upon entering the Slave mode. After eight clock pulses the Busy flag will be cleared and the sequence may be repeated. However, in the Slave mode the COP888 series does not shift data if the BUSY flag is reset, whereas the COP820C and COP840C continues to shift regardless of the BUSY flag, if the SK clock is active.

MICROWIRE/PLUS ALTERNATE SK MODE

The COP888XX series of microcontrollers also allow an additional Alternate SK Phase Operation. In the normal mode data is shifted in on the rising edge of the SK clock and data is shifted out on the falling edge of the SK clock *(Figure 2)*. The SIOR register is shifted on each falling edge of the SK clock. In the alternate SK phase operation, data is shifted in on the falling edge of the SK clock and data is shifted out on the rising edge of the SK clock *(Figure 3)*.

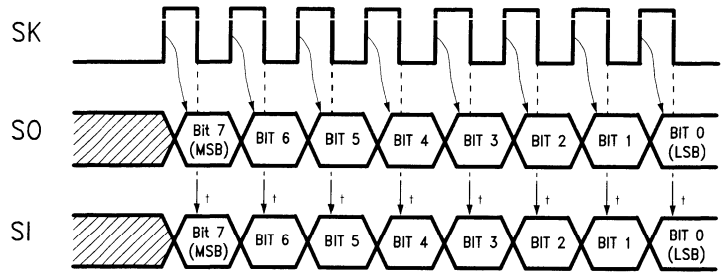


TL/DD/10252–2

*This bit becomes valid immediately after loading the SIOR register of the transmitting device.

†Arrows indicate points at which SI is sampled.

FIGURE 2. MICROWIRE/PLUS Timing



↑ Arrows indicates points at which SI is sampled.

FIGURE 3. Alternate Phase SK Clock Timing

A control flag, SKSEL, allows either the normal SK clock or alternate SK clock to be selected. Resetting SKSEL selects the normal SK clock and setting SKSEL selects the alternate SK clock for the MICROWIRE/PLUS logic. The SKSEL flag is mapped into the G6 configuration bit. The SKSEL flag is reset after power up, selecting the normal SK clock signal. The alternate mode facilitates the usage of the MICROWIRE/PLUS protocol for serial data transfer between peripheral devices which are not compatible with the normal SK clock operation, i.e., shifting data out on the falling edge of the SK clock and shifting in data on the rising edge of the SK clock.

MICROWIRE/PLUS SAMPLE PROTOCOL

This section gives a sample MICROWIRE/PLUS protocol using a COP888CL and COP840C. The slave mode operating procedure for this sample protocol is explained, and a timing illustration of the protocol is provided.

1. The MSEL bit in the CNTRL register is set to enable MICROWIRE; G0 ($\overline{CS}$) and G5 (SK) are configured as inputs and G4 (SO) as an output. G6 (SI) is always an input.
2. Chip Select line ($\overline{CS}$) from master device is connected to G0 of the slave device. An active-low level on $\overline{CS}$ line causes the slave to interrupt.
3. From the high-to-low transistion on the $\overline{CS}$ line, there is no data transfer on the MICROWIRE until time "T" (See *Figure 4*).
4. The master initiates data transfer on the MICROWIRE by turning on the SK clock.
5. A series of data transfers take place between the master and slave devices.
6. The master pulls the $\overline{CS}$ line high to end the MICROWIRE operation. The slave device returns to normal mode of operation.

SLAVE MODE OPERATING PROCEDURE

1. The MSEL bit in the CNTRL register is set to enable MICROWIRE; G0 ($\overline{CS}$) and G5 (SK) are configured as inputs and G4 (SO) as an output. G6 (SI) is always an input.
2. Normal mode of operation until interrupted by $\overline{CS}$ going low.
3. Set the BUSY flag and load SIOR register with the data to be sent out on SO. (The shift register shifts 8 bits of data from SO at the high order end of the shift register. During the same time, 8 new bits of data from SI are loaded into the low order end of the shift register.)
4. Wait for the BUSY flag to reset. (The BUSY flag is automatically reset after 8 bits of data have been shifted).
5. If data is being read in, the user should save contents of the SIOR register.
6. The prearranged set of data transfers are performed.
7. Repeat steps 3 through 6. The user must ensure steps 3 through 6 are performed in time "t" (See *Figure 4*) as agreed upon in the protocol.

DIFFERENCES BETWEEN COP888 AND COP820/COP840

The COP888 series MICROWIRE/PLUS feature differs from that of the COP820/COP840 in some respects. The COP888 series can be configured to interrupt the processor after the completion of a MICROWIRE/PLUS operation indicated by the BUSY flag going low. The COP888 series supports a vectored interrupt scheme. Two bytes of program memory space are reserved for each interrupt source. The user would do any required context switching and then program a VIS (Vector Interrupt Select) instruction in order to branch to the interrupt service routine of the highest priority interrupt enabled and pending at the time of the VIS instruction. The addresses of the different interrupt service routines are chosen by the user and stored in ROM in a table starting at 0yE0 where "y" depends on the 256 byte block (0y00 to 0yFF) in which the VIS instruction is located. The vector address for the MICROWIRE/PLUS interrupt is 0yF2-0yF3.

Secondly, the COP888 series supports the alternate SK phase mode of MICROWIRE/PLUS operation. This feature facilitates the usage of the MICROWIRE/PLUS protocol for serial data transfer between peripheral devices which are not compatible with the normal SK clock operation, i.e., shifting data out on the falling edge of SK clock and shifting in data on the rising edge of the SK clock.

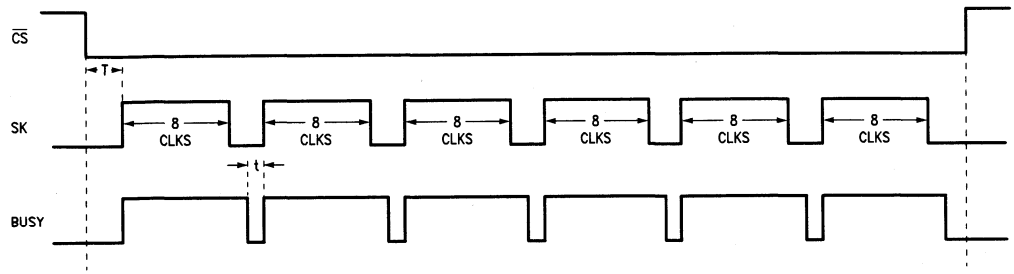


FIGURE 4. MICROWIRE/PLUS Sample Protocol Timing Diagram

INTERFACE CONSIDERATIONS

To preserve the integrity of data exchange using MICROWIRE/PLUS, two aspects have to be considered:

1. Serial data exchange timing.
2. Fan-out/fan-in requirements.

Theoretically, infinite devices can access the same interface and be uniquely enabled sequentially in time. In practice, however, the actual number of devices that can access the same serial interface depends on the following: System data transfer rate, system supply requirement, capacitive loading on SK and SO outputs, the fan-in requirements of the logic families or discrete devices to be interfaced.

HARDWARE INTERFACE

For proper data transfer to occur the output should be able to switch between a HIGH level and a LOW level in a predetermined amount of time. The transfer is strictly synchronous and the timing is related to the MICROWIRE/PLUS system clock (SK). For example, if a COPS controller outputs a value at the falling edge of the clock and is latched in by the peripheral device at the rising edge, then the following relationship has to be satisifed:

$$t_{DELAY} + t_{SETUP} \leq t_{CK}$$

where t_{CK} is the time from data output starts to switch to data being latched into the peripheral chip, t_{SETUP} is the setup time for the peripheral device where the data has to be at a valid level, and t_{DELAY} is the time for the output to read the valid level. t_{CK} is related to the system clock provided by the SK pin of the COPS controller and can be increased by increasing the COPS instruction cycle time.

Besides the timing requirements, system supply and fan-out/fan-in requirements also have to be considered when interfacing with MICROWIRE/PLUS. To drive multi-devices on the same MICROWIRE/PLUS, the output drivers of the controller need to source and sink the total maximum leakage current of all the inputs connected to it and keep the signal level within the valid logic "1" and "0" input voltage levels. Thus, if devices of different types are connected to the same serial interface, output driver of the controller must satisfy all the input requirements of each device. Similarly, devices with TRI-STATE® outputs, when connected to the SI input, must satisfy the minimum valid input level of the controller and the maximum TRI-STATE® leakage current of all outputs.

So, for devices that have incompatible input levels or source/sink requirements, external pull-up resistors or buffers are necessary to provide level-shifting or driving.

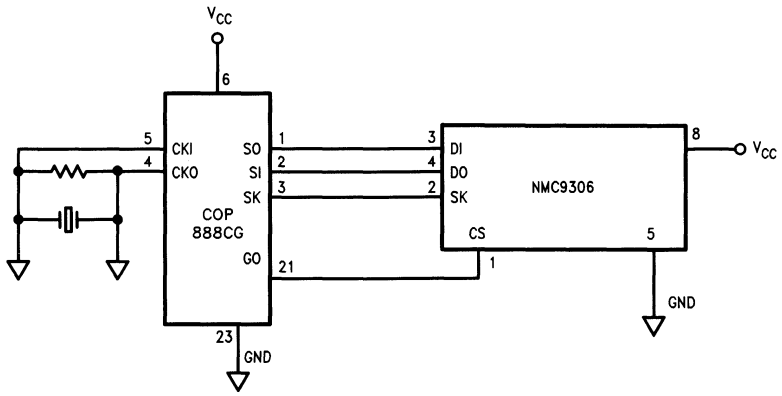
TYPICAL APPLICATIONS

A whole family of off-the shelf devices exist that are directly compatible with MICROWIRE/PLUS protocol. This allows direct interface with the COP800 family of microcontrollers. Table III provides a summary of the existing devices, their function and specification.

NMC9306-COP888CG INTERFACE

The pin connection involved in interfacing an NMC9306 (COP494), a 256 bit E²PROM, with the COP888CG microcontroller is shown in *Figure 5*. Some notes on the NMC9306 interface requirements are:

1. The SK clock frequency should be in the 0 kHz–250 kHz range.
2. $\overline{CS}$ low period following an Erase/Write instruction must not exceed 30 ms maximum. It should be set at typical or minimum specification of 10 ms.
3. The start bit on DI must be set by a "0" to "1" transition following a $\overline{CS}$ enable ("0" to "1") when executing any instruction. One $\overline{CS}$ enable transition can only execute one instruction.
4. In the read mode, following an instruction and data train, the DI can be a "don't care", while the data is being outputted, i.e., for the next 17 bits or clocks. The same is true for other instructions after the instrution and data has been fed in.
5. The data out train starts with a dummy bit 0 and is terminated by chip deselect. Any extra SK cycle after 16 bits is not essential.
   If $\overline{CS}$ is held on after all 16 of the data bits have been outputed, the DO will output the state of DI until another $\overline{CS}$ LO to HI transition starts a new instruction cycle.
6. After a read cycle, the $\overline{CS}$ must be brought low for one SK clock cycle before another instruction cycle starts.



TL/DD/10252–5

FIGURE 5. NMC9306-COP888CG Interface

Instruction Set

Commands	Start Bit	Opcode	Address	Comments
READ	1	0000	A3A2A1A0	Read Register 0–15
WRITE	1	1000	A3A2A1A0	Write Register 0–15
ERASE	1	0100	A3A2A1A0	Erase Register 0–15
EWEN	1	1100	00 01	Write/Erase Enable
ENDS	1	1100	00 10	Write/Erase Disable
***WRAL	1	1100	01 00	Write All Registers
ERAL	1	1100	01 01	Read All Registers

Where A3A2A1A0 corresponds to one of the sixteen 16-bit registers.

All commands, data in, and data out are shifted in/out on the rising edge of the SK clock.

Write/Erase is then done by pulsing $\overline{CS}$ low for 10 ms.

All instructions are initiated by a LO–HI transition on $\overline{CS}$ followed by a LO–HI transition on DI.

READ— After read command is shifted in DI becomes don't care and data can be read out on data out, starting with dummy bit zero.

WRITE— Write command shifted in followed by data in (16 bits) the$\overline{CS}$ pulsed low for 10 ms minimum.

ERASE/ERASE ALL— Command shifted in followed by $\overline{CS}$ low.

WRITE ALL— Pulsing $\overline{CS}$ low for 10 ms.

ENABLE/DISABLE— Command shifted in.

A detailed explanation of the E²PROM timing diagrams, instruction set and the various considerations could be found in the NMC9306 data sheet. A source listing of the software to interface the NMC9306 with the COP888CG is provided.

COP472-COP820 Interface

The pin connection required for interfacing COP472-3 Liquid Crystal Display (LCD) Controller with COP820C microcontroller is shown in *Figure 6*. The COP472-3 drives a multiplexed liquid crystal display directly. Data is loaded serially and is held in internal latches. One COP472-3 can drive 36 segments and two or more COP472-3's can be cascaded to drive additional segments as long as the output loading capacitance does not exceed specifications.

The COP472-3 requires 40 information bits: 36 data and 4 control. The function of each control bit is described briefly. Data is loaded in serially, in sets of eight bits. Each set of segment data is in the following format:

SA	SB	SC	SD	SE	SF	SG	SH

Data is shifted into an eight bit shift register. The first bit of data is for segment H, digit 1, and the eight bit is for segment A, digit 1. A set of eight bits are shifted in and then loaded into the digit one latches. The second, third, and fourth set is then loaded sequentially. The fifth set of data bits contain special segment data and control data in the following format:

SYNC	Q7	Q6	X	SP4	SP3	SP2	SP1

The first four bits shifted in contain the special character segment data. The fifth bit is not used. The sixth and seventh bits program the COP472-3 as a stand alone LCD driver or as a master or slave for cascading COP472-3's. The Table IV summarizes the function of bits six and seven.

The eight bit is used to synchronize two COP472-3's to drive an $8\frac{1}{2}$ digit display. A detailed explanation of the various timing diagrams, loading sequence and segment/backplane multiplex scheme can be found in the data sheets of COP472-3. The source listing of the software used in the interface is provided.

The code listed in this App Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communications package and a PC, the code detailed in this App Note can be downloaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

Modem (408) 739-1162
Voice (408) 721-5582

National Semiconductor
Application Note 596
Verne H. Wilson

OVERVIEW

This application note discusses the various arithmetic operations for National Semiconductor's COP800 family of 8-bit microcontrollers. These arithmetic operations include both binary and BCD (Binary Coded Decimal) operation. The four basic arithmetic operations (add, subtract, multiply, divide) are outlined in detail, with several examples shown for both binary and BCD addition and subtraction. Multiplication, division, and BCD conversion algorithms are also provided. Both BCD to binary and binary to BCD conversion subroutines are included, as well as the various multiplication and division subroutines.

Four sets of optimal subroutines are provided for

1. Multiplication
2. Division
3. Decimal (Packed BCD) to binary conversion
4. Binary to decimal (Packed BCD) conversion

One class of subroutines is optimized for minimal COP800 program code, while the second class is optimized for minimal execution time in order to optimize throughput time.

This application note is organized in four different sections. The first section outlines various addition and subtraction routines, including both binary and BCD (Binary Coded Decimal). The second section outlines the multiplication algorithm and provides several optimal multiply subroutines for 1, 2, 3, and 4 byte operation. The third section outlines the division algorithm and provides several optimal division subroutines for 1, 2, 3, and 4 byte operation. The fourth section outlines both the decimal (Packed BCD) to binary and binary to decimal (Packed BCD) conversion algorithms. This section provides several optimal subroutines for these BCD conversions.

The COP800 arithmetic instructions include the Add (ADD), Add with Carry (ADC), Subtract with Carry (SUBC), Increment (INCR), Decrement (DECR), Decimal Correct (DCOR), Clear Accumulator (ACC), Set Carry (SC), and Reset Carry (RC). The shift and rotate instructions, which include the Rotate Right through Carry (RRC) and the Swap Accumulator Nibbles (SWAP), may also be considered as arithmetic instruction variations. The RRC instruction is instrumental in writing a fast multiply routine.

1.0 BINARY AND BCD ADDITION AND SUBTRACTION

In subtraction, a borrow is represented by the absence of a carry and vice versa. Consequently, the carry flag needs to be set (no borrow) before a subtraction, just as the carry flag is reset before an addition. The ADD instruction does not use the carry flag as an input, nor does it change the carry flag. It should also be noted that both the carry and half carry flags (bits 6 and 7, respectively, of the PSW control register) are cleared with reset, and remain unchanged with the ADD, INC, DEC, DCOR, CLR and SWAP instructions. The DCOR instruction uses both the carry and half carry flags. The SC instruction sets both the carry and half carry flags, while the RC instruction resets both these flags.

The following program examples illustrate additions and subtractions of 4-byte data fields in both binary and BCD (Binary Coded Decimal). The four bytes from data memory locations 24 through 27 are added to or subtracted from the four bytes in data memory locations 16 through 19. The results replace the data in memory locations 24 through 27.

These operations are performed both in Binary and BCD. It should be noted that the BCD pre-conditioning of Adding (ADD) the hex 66 is only necessary with the BCD addition, not with the BCD subtraction. The (Binary Coded Decimal) DCOR (Decimal Correct) instruction uses both the carry and half carry flags as inputs, but does not change the carry and half carry flags. Also note that the #12 with the IFBNE instruction represents 28 − 16, since the IFBNE operand is modulo 16 (remainder when divided by 16).

BINARY ADDITION:

```
        LD          X,#16           ;  NO LEADING ZERO

        IFC                         ;  IF TERMINAL CARRY
        JP          OVFLOW          ;     JUMP TO OVERFLOW
```

BCD SUBTRACTION:

```
        LD          X,#16           ;  NO LEADING ZERO
        LD          B,#24           ;     INDICATES DECIMAL
        C
LOOP:   LD          A,[X+]          ;  [X] TO ACC
        SUBC        A,[B]           ;  SUBTRACT [B] FROM ACC
        DCOR        A               ;  DECIMAL CORRECT RESULT
        X           A,[B+]          ;  RESULT TO [B]
        IFBNE       #12             ;  IF STILL IN DATA FIELD
        JP          LOOP            ;     JUMP BACK TO REPEAT LOOP
        IFNC                        ;  IF TERMINAL BORROW
        JP          NEGRSLT         ;     JUMP TO NEGATIVE RESULT
```

The astute observer will notice that these previous additions and subtractions are not "adding machine" type arithmetic operations in that the result replaces the second operand rather than the first. The following program examples illustrate "adding machine" type operation where the result replaces the first operand. With subtraction, this entails the result replacing the minuend rather than the subtrahend. Note that the B and X pointers are now reversed.

BINARY ADDITION:

```

        JP          NEGRSLT         ;     JUMP TO NEGATIVE RESULT
```

Let us now consider a hybrid arithmetic example, where we wish to add five successive bytes of a data table in ROM program memory to a two byte sum, and then subtract the SUM result from a two byte total TOT. Let us further assume that the ROM table is located starting at program memory address 0401, while SUM and TOT are at RAM data memory locations [1, 0] and [3, 2] respectively, and that we wish to encode the program as a subroutine.

ROM Table:

. = 0401
. Byte 102
. Byte 41
. Byte 31
. Byte 26
. Byte 5

ROM Table Accessed Top Down

SUMLO = 0
SUMHI = 1
TOTLO = 2
TOTHI = 3

```
ARITH1: LD      X,#5            ; SET UP ROM TABLE POINTER
        LD      B,#0            ; SET UP SUM POINTER
LOOP:   RC                      ; RESET CARRY TO START ADDITION
        LD      A,X             ; ROM POINTER TO ACC
        LAID                    ; TABLE VALUE FROM ROM TO ACC
        ADC     A,[B]           ; ADD SUMLO TO ACC
        X       A,[B+]          ; RESULT TO SUMLO
        CLR     A               ; CLEAR ACC
        ADC     A,[B]           ; ADD SUMHI TO ACC
        X       A,[B-]          ; RESULT TO SUMHI

        RET                     ; RETURN FROM SUBROUTINE
```

2.0 MULTIPLICATION

The COP800 multiplications are all based on starting the multiplier in the low order end of the double length product space. The high end of the double length product space is initially cleared, and then the double length product is shifted right one bit. The bit shifted out from the low order end represents the low order bit of the multiplier. If this bit is a "1", the multiplicand is added to the high end of the double length product space. The entire shifting process and the conditional addition of the multiplicand to the upper end of the double length product is then repeated. The number of shift cycles is equal to the number of bit positions in the multiplier plus one extra shift cycle. This extra terminal shift cycle is necessary to correctly align the resultant product.

Note that an M byte multiplicand multiplied by an N byte multiplier will result in an M + N byte double length product. However, these multiplication subroutines will only use 2M + N + 1 bytes of RAM memory space, since the multiplier initially occupies the low order end of the double length product. The one extra byte is necessary for the shift counter CNTR.

The minimal code (28 byte) general multiplication subroutine is shown with two different examples, MY2448 and MY4824. Both examples multiply 24 bits by 48 bits. The MY2448 subroutine uses the 48-bit operand as the multiplier, and consequently uses minimal RAM as well as minimal program code. The MY4824 subroutine uses the 24-bit operand as the multiplier, and consequently executes considerably faster than the minimal RAM MY2448 subroutine.

MPY88
- 8 by 8 Multiplication Subroutine
- 19 Bytes
- 180 Instruction Cycles
- Minimum Code

MLT88
- Fast 8 by 8 Multiplication Subroutine
- 42 Bytes
- 145 Instruction Cycles

VFM88
- Very Fast 8 by 8 Multiply Subroutine
- 96 Bytes
- 116 Instruction Cycles

MPY168
- Fast 16 by 8 Multiplication Subroutine
- 36 Bytes
- 230 Instruction Cycles Average
- 254 Instruction Cycles Maximum

MPY816 (or MPY824, MPY832)
- 8 by 16 (or 24, 32) Multiply Subroutine
- 22 Bytes
- 589 (or 1065, 1669) Instruction Cycles Average
- 597 (or 1077, 1685) Instruction Cycles Maximum
- Minimum Code, Minimum RAM
- Extendable Routine for MPY8XX by Changing Parameters, with Number of Bytes (22) Remaining a Constant

MPY248
- Fast 24 by 8 Multiplication Subroutine
- 47 Bytes
- 289 Instruction Cycles Average
- 333 Instruction Cycles Maximum

MX1616
- Fast 16 by 16 Multiplication Subroutine
- 39 Bytes
- 498 Instruction Cycles Average
- 546 Instruction Cycles Maximum

MP1616
- 16 by 16 Multiplicand Subroutine
- 29 Bytes
- 759 Instruction Cycles Average
- 807 Instruction Cycles Maximum
- Almost Minimum Code

MY1616 (or MY1624, MY1632)
- 28 Bytes
- 16 by 16 (or 24, 32) Multiply Subroutine
- 861 (or 1473, 2213) Inst. Cycles Average
- 1029 (or 1725, 2549) Inst. Cycles Maximum
- Minimum Code, Minimum RAM
- Extendable Routne for MY16XX by Changing Parameters, with Number of Bytes (28) Remaining a Constant

Minimal general multiplication subroutine for any number of bytes in multiplicand and multiplier
- 28 Bytes
- Minimum Code
- MY2448 Used as First Example, with Minimum RAM and 4713 Instruction Cycles Average 5457 Instruction Cycles Maximum
- MY4824 Used as Second Example, with Non Minimal RAM and 2751 Instruction Cycles Average 3483 Instruction Cycles Maximum

3.0 DIVISION

The COP 800 divisions are all based on shifting the dividend left up into a test field equal in length to the number of bytes in the divisor. The divisor is resident immediately above this test field. After each shift cycle of the dividend into the test field, a trial subtraction is made of the test field minus the divisor. If the divisor is found equal to or less than the contents of the test field, then the divisor is subtracted from the test field and a 1's quotient digit is recorded by setting the low order bit of the dividend field. The dividend and test field left shift cycle is then repeated. The number of left shift cycles is equal to the number of bit positions in the dividend. The quotient from the division is formed in the dividend field, while the remainder from the division is resident in the test field.

Note that an M byte dividend divided by an N byte divisor will result in an M byte quotient and an N byte remainder.

These division algorithms will use M + 2N + 1 bytes of RAM memory space, since the test field is equal to the length of the divisor. The one extra byte is necessary for the shift counter CNTR.

In special cases where the dividend has an upper bound and the divisor has a lower bound, the upper bytes of the dividend may be used as the test field. One example is shown (DV2815), where a 28 bit dividend is divided by a 15-bit divisor. The dividend is less than 2**28 (upper nibble of high order byte is zero), while the divisor is greater than 2**12 (4096) and less than 2**15 (32768). In this case, the upper limit for the quotient is 2**28/2**12, which indicates a 16-bit quotient (2**16) and a 15-bit remainder. Consequently, the upper two bytes of the dividend may be used as the test field for the remainder, since the divisor is greater than the test field (upper two bytes of the 28-bit dividend) initially.

The minimal code (40 byte) general division subroutine is shown with the example DV3224, which divides a 32 bit dividend by a 24 bit divisor.

DIV88 — 8 by 8 Division Subroutine

DECBIN—Decimal (Packed BCD) to Binary

This 24 byte subroutine represents very minimal code for translating a packed BCD decimal number of any length to binary.

ALGORITHM:

The binary result is resident just below the packed BCD decimal number. During each cycle of the algorithm, the decimal operand and the binary result are shifted right one bit position, with the low order bit of the decimal operand shifting down into the high order bit position of the binary field. The residual decimal operand is then tested for a high order bit in each of its nibbles. A three is subtracted from each nibble in the BCD operand space that is found to contain a high order bit equal to one. (This process effectively right shifts the BCD operand one bit position, and then corrects the result to BCD format.) The entire cycle is then repeated, with the total number of cycles being equal to the number of bit positions in the decimal field.

16 Bit: Binary IN [1,0]
Packed BCD in [3, 2]

24 Bit: Binary in [2, 1, 0]
Packed BCD in [5, 4, 3]

32 Bit: Binary in [3, 2, 1, 0]
Packed BCD in [7, 6, 5, 4]

BINDEC—Binary to Decimal (Packed BCD)

This 25 byte subroutine represents very minimal code for translating a binary number of any length to packed BCD decimal.

ALGORITHM:

The packed BCD decimal result is resident just above the binary number. A sufficient number of bytes must be allowed for the BCD result. During each cycle of the algorithm the binary number is shifted left one bit position. The packed BCD decimal result is also shifted left one bit position, with the high order bit of the binary field being shifted up into the low order bit position of the BCD field. The shifted result in the BCD field is decimal corrected by using the DCOR instruction. Note that for addition an "ADD A, #066" instruction must be used in conjunction with the DCOR (Decimal Correct) instruction. The entire cycle is then repeated, with the total number of cycles being equal to the number of bit positions in the binary field.

16 Bit:	Binary in [1, 0]
	Packed BCD in [4, 3, 2]
24 Bit:	Binary in [2, 1, 0]
	Packed BCD in [6, 5, 4, 3]
32 Bit:	Binary in [3, 2, 1, 0]
	Packed BCD in [8, 7, 6, 5, 4]

VFBTOD—VERY FAST BINARY TO DECIMAL (PACKED BCD)

Algorithm: Decimal (Packed BCD) result is equal to summation in BCD of powers of two corresponding to 1's bits present in binary number.

Note that binary field (2 bytes) is initially one's complemented by program, in order to facilitate bypass branching when a tested bit in the binary field is found equal to zero.

Binary in [1, 0]
BCD in [4, 3, 2]

189 Bytes
144 Instruction Cycles Average
208 Instruction Cycles Maximum

Pulse Width Modulation A/D Conversion Techniques with COP800 Family Microcontrollers

National Semiconductor
Application Note 607
Kevin Daugherty

1.0 BASIC TECHNIQUE

This application note describes a technique for creating an analog to digital converter using a microcontroller with other low cost components. Many applications do not require the speed associated with a dedicated hardware A/D converter and it is worth evaluating a more cost effective approach.

With a high speed CMOS microcontroller an eight bit A/D can be implemented that converts in approximately 10 ms. This method is based on the fact that if a repetitive waveform is applied to an RC network, the capacitor will charge to the average voltage, provided that the RC time constant is much larger than the pulse widths. The basic equation for computing the analog to digital result is:

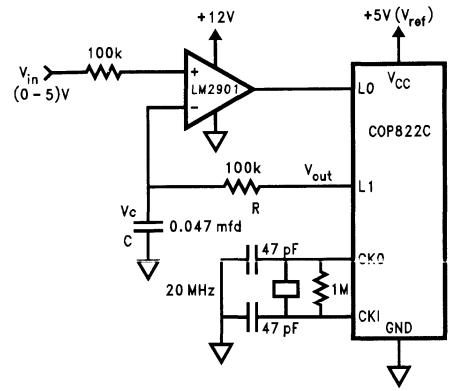
$$V_{in} = V_{ref}[T_{on}/(T_{on} + T_{off})] \quad (1)$$

With this equation it is necessary to precisely measure several time periods within both the T_{on} and T_{off} in order to achieve the desired resolution. Additionally, the waveform would have to be gradually adjusted to allow for the large RC time constant to settle out. This results in a relatively long conversion cycle. Modifying the equation and technique slightly, significantly speeds up the process. This technique works by averaging several pulses over a fixed period of time and is based on the following equation:

$$V_{in} = V_{ref}[\text{Sum of } T_{on}/(\text{Sum of } (T_{on} + T_{off}))] \quad (2)$$

2.0 IMPLEMENTATION

Figure 1 describes the basic circuit schematic that uses a National Semiconductor COP822C microcontroller, a low cost LM2901 comparator, two 100k resistors, and a 0.047 mfd film capacitor. The CMOS COP822C microcontroller provides a squarewave signal with logic levels very close to GND and V_{CC}. This generates a small ramp voltage on the capacitor for the LM2901 quad comparator input.



TL/DD/10407-1

FIGURE 1. Basic Circuit

To minimize error, a tradeoff must be made when selecting the resistor. The microcontroller output (L1) should have a large resistor to minimize the output switching offset (V_{os}), and the comparator should have a small resistor due to error caused by I_{bos} (input bias offset current).

Once the resistor is determined, the capacitor should be chosen so that the RC time constant is large enough to provide a small incremental voltage ramp. This design has a sample time of 20 μs and has a 4.7 ms time constant with a 0.047 mfd film type capacitor which has low leakage current to prevent errors. Since a 100k resistor is used in the RC network for one comparator input, another 100k resistor is required for the V_{in} input to balance the offset voltage caused by the comparator I_b (input bias current).

Figure 2 illustrates the relationship between the microcontroller squarewave output and the capacitor charge and discharge. Every 20 μs the comparator is sampled. If the capacitor voltage (V_c) is below V_{in} the RC network will receive a positive pulse. The inverse is true if V_c is above V_{in} at sample time. Note that with this approach, the PWM waveform is broken up into several small pulses over a fixed period instead of having a single pulse represent the duty cycle; thus a relatively small RC time constant can be used.

Mathematical Analysis:

let n = total number of T_{on} pulses and
m = total number of T_{off} pulses

then $V_c(t) = V_c + n[(V_{out} - V_c)(1 - e - t/RC)] - m[(V_c - V_o)(1 - e - t/RC)]$

let $V_c = V_{in}$ at start of conversion and
$K = (1 - e - t/RC)$

then $V_{in} = V_{in} + K_nV_{out} - K_nV_{in} - K_mV_{in} + K_mV_O$
$0 = K_nV_{out} + K_mV_o - KV_{in}(n + m)$

let $V_{out} = V_{ref} - V_{os}$

solving for V_{in}:

$$V_{in} = nV_{ref}/(n + m) - (nV_{os} - mV_o)(1/(n + m)) \quad (3)$$

Note that the RC value drops out of the equation and therefore is not an error factor.

3.0 SOFTWARE DESCRIPTION

Single Channel

Referring to the flow chart in *Figure 3*, and the code listed in *Figure 4*, the software counters T_{on} and TOTAL are first preloaded with the FF. The accumulator and register 0F1 are then loaded with 2 to provide for an initialization and final conversion cycle. Next, the L port is configured to complete the initialization of the microcontroller.

The comparator output is checked with the IFBIT 0,0D2 instruction. This will determine whether the RC network will receive a positive (V_{ref}) or ground pulse. You can think of the microcontroller as part of the feedback path of the comparator. The microcontroller uses the comparator output to decide what level output on L1 is required to keep the capacitor equal to the unknown input voltage. Each time the negative or GND pulse is applied, the T_{on} counter is decremented by DRSZ. Similarly, each time a sample loop is completed the TOTAL counter is decremented by DRSZ. Note that NOP instructions are used in the high and low loops. These are necessary to provide exactly the same cycles for a high or low L1 output pulse.

Once the TOTAL register is decremented to zero, the initialization loop is completed. Immediately afterwards, the L1 output is put in TRI-STATE® mode to minimize capacitor voltage variations while other instructions are completed. After the first conversion, the IFEQ A,0F1 instruction will be true and the T_{on} and TOTAL registers will be reloaded with FF. Following this, the L1 pin is restored as a high output and the 0F1 multiplier is decremented.

At this point the capacitor is equal to V_{in} and the actual conversion is started. When the TOTAL register is decremented to zero (255 samples later), the conversion is complete. T_{on} will not be reloaded since 0F1 was decremented and IFEQ A,0F1 will no longer be true. The accumulator is then loaded with T_{on} and stored in RAM location 00 with X A,00.

The final two instructions (RBIT 1,LCONF & RBIT 1[B]) are optional depending on the application and the amount of additional code required. This will prevent the capacitor from decaying appreciably between conversions and allow for a much quicker capacitor initialization time. Otherwise more time may be required, or a diode speed-up circuit as shown in *Figure 7d* is required to fully charge the capacitor prior to starting the actual conversion.

Eight Channel

This is bascially the same as that for the single channel. Referring to the flow chart in *Figure 5* and the code in *Figure 6*, the differences are in the front and back ends. Before the conversions are started, the X register is initialized to 00 for RAM location 00. The accumulator is then loaded with the current RAM pointer (LD A,X), OR'ed with the LDATA (OR A,LDATA), and finally the LDATA register is modified to provide for the proper output select (X A,LDTA).

Following the actual conversion cycle, the result is stored at the current RAM pointer (X A,[X+]) which also auto-increments the X register. The next conversion will use this to select the next channel and determine where to store the result. Once the eighth channel is converted, the IFEQ A,X instruction will be true and the RAM pointer will be reset (LD X,#00) before the next conversion is started.

FIGURE 6. 8-Channel PWM A/D Listing

4.0 ACCURACY AND CIRCUIT CONSIDERATIONS

The basic circuit will provide 8 bits ±1 LSB accuracy depending on the choice of comparator, and passive components. With this type of design several tradeoffs and error sources should be considered. First of all, conversion equation 2 assumes that the microcontroller output switches exactly to GND and V_{CC} (or V_{ref}). The COP822C will typically switch between 10 mV and 20 mV from GND and V_{CC} with a light load. This will cause an error equal to the offset voltage times the duty cycle (equ. 3). Fortunately, the offsets tend to cancel each other at mid range voltages. At near GND and V_{CC} input voltages the offsets are minimal due to the very small voltage drop across the resistor. If the error is undesirable, the offset voltage can be reduced by paralleling outputs with the same levels together, or by using a CMOS buffer such as a 74HC04 to drive the RC network (see *Figure 7* for suggested circuits).

Another possible source of error is with the LM2901 worst case input bias offset current of 200 nA over temperature. This will cause an error equal to R_{in} X I_{bos}, which equals 20 mV with a 100k resistor. Either the resistor or the I_{bos} can be reduced to improve the error. If the resistor is reduced then the L port offset voltages will increase so the preferred approach is to select a comparator with lower I_{bos} such as the LP339 which has an I_{bos} of only ±15 nA. The comparator V_{os} may also introduce error. The LM2901 V_{os} is ±9 mV, the LP339 V_{os} is only ±5 mV. An added benefit of using the LP339 is that since the I_{bos} is so small, the resistor for the RC network can be larger. In addition, one RC network could be used for several comparator input channels (refer to *Figure 7A*).

By using the LM604 *(Figure 7B)* the basic software can be easily extended for converting several channels. This will only require a control line to be selected before a conversion is started. Since the LM604 needs to be powered from a higher voltage than the input voltage range, the output voltage will also be higher than the microcontroller supply. This requires a current limiting resistor to be used in series between the LM604 output and the COP8XX. Note that two or more LM604's can be paralleled for providing several more A/D channels by utilizing the EN control input that can TRI-STATE the LM604 output when high.

When more than 4 channels of analog signals are required to be measured, the circuit in *Figure 7(d)* is recommended. This circuit utilizes an inexpensive CD4051 8:1 multiplexer with a single comparator (which could be on-board the micro). When measuring several input voltages that can vary, TRI-STATING the output driving the RC between conversions is not possible. It is necessary to provide 6x RC time constants to charge the capacitor to within 0.25%. Note that there are two 1N4148's across the comparator inputs. The diodes provide a quick capacitor charge path providing that the total input resistance is much smaller than the resistor used in the RC network (a 2k resistor will meet the requirements within 255 sample times). Once the capacitor is charged to within about 0.6V, the diodes will start turning off. At this point the microcontroller will start dominating the charge/discharge of the capacitor. After the initialization cycle is complete, the capacitor is very close to the unknown V_{in} and the diodes are effectively out of the circuit.

Depending on the speed and accuracy requirements, the total number of counts used in the conversion can be changed. Increasing the counts will give more accuracy with the practical limit of about 9–10 bits. With increased resolution, the capacitor ramp voltage per sample time should be decreased so that the capacitor can be initialized to within 1 LSB prior to conversion. This can be done by either increasing the RC time constant, or by using an initialization routine with a shorter sample time. The conversion time will depend on the total counts and the microcontroller oscillator frequency as described below:

$$T_{con} = \text{Total counts} \times (20 \text{ cycles}) \times (\text{instruction cycle time})$$

Another factor to consider is when a non-ratiometric conversion is required, the reference voltage must have the tolerance to match the desired accuracy.

5.0 CONCLUSION

The PWM A/D technique described in this application note provides a relatively fast discrete implementation with substantial cost savings compared to a dedicated hardware A/D. Minimal microcontroller I/O and software is required to interface with a comparator and RC network. Depending on the application requirements, the designer can tailor the basic 8-bit A/D a number of ways. By varying the total software counts, the desired speed and resolution can be adjusted. The number of A/D channels will determine the number of comparators used. In chosing the comparator, it is recommended that the designer refer to the data sheets and match the I_{bos} and V_{os} to the desired accuracy.

When other than a 1 μs instruction cycle is used, the RC time constant of 4.7 ms should be scaled to provide for a maximum peak-peak ramp voltage of <1 LSB of the desired accuracy. For example, if 8-bit accuracy is desired and the instruction cycle time is now 4 μs instead of 1 μs, multiply 4.7 ms by 4 to calculate the new RC.

Keep in mind that the comparator input voltage is limited so that you do not get erroneous/nonlinear results. Another possible problem is during development. When doing in-circuit emulation with the development equipment, note that there will be ground loops in the cable thus causing errors in your measurements. You can reduce this by connecting an extra GND and V_{CC} wire between your prototype and development system power and GND. It is still possible to see offsets in the sockets holding the COP8XX in the development board, however this should be relatively small. The best test is to take accurate measurements with an emulator in the actual prototype circuit.

COP800 Based Automated Security/Monitoring System

National Semiconductor
Application Note 662
Ramesh Sivakolundu

INTRODUCTION

National Semiconductor's COP800 family of full-feature, cost effective, fully static, single chip micro CMOS microcontrollers provide efficient system solutions with a versatile instruction set and high functionality. The heart of the ASM System prototype is a COP800 family member with at least the following features: 4k bytes of on-board program memory, 192 bytes of on-board data memory, memory mapped I/O, fourteen multi-sourced vectored interrupts and a versatile instruction set. The family member used is the COP888CG microcontroller.

This application note describes the implementation of a Security/Monitoring System using the COP888CG microcontroller. The COP888CG contains features such as:

- Low power HALT and IDLE modes
- MICROWIRE/PLUS™ serial communication
- Multiple multi-mode general purpose timers
- Multi-input wakeup/interrupt
- WATCHDOG™ and Clock monitor
- Maskable vectored interrupt scheme
- UART

In addition to these features common to the COP888 subfamily of microcontrollers, COP888CG has a full duplex, double buffered UART and two Differential Comparators.

The COP888CG based Automated Security/Monitoring (ASM) System consists of several features:

- Automatic Telephone Dialing
- Real Time Clock
- Non-Volatile storage of real time information of events
- Continuous display of events on the terminal
- Battery operated remote sensors and transmitters
- Exit and Entry delays
- Expandable to add new features

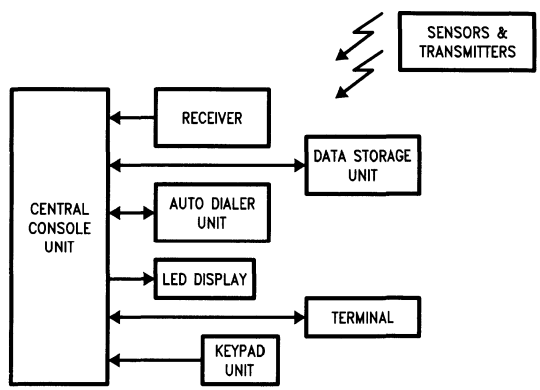
SYSTEM OVERVIEW

Figure 1 gives the block diagram of the ASM System prototype hardware. The application consists of following major blocks:

- Central Controlling Unit
- Receiver
- Sensors and Transmitters
- Keypad Unit
- Auto-Dialer Unit
- Data Storage Unit
- Display Terminal Unit
- LED Display Unit

The implementation allows easy expansion of the ASM System features by adding new blocks to the Central Controlling Unit.

COP888CG is the workhorse of the ASM System and provides the processing power to scan the keypad, service the Receiver interrupts, update the real time clock, serially communicate with the LED display unit and Data Storage Unit, activate the Auto-Dialer Unit and use the full-duplex double buffered UART to interface with the Display Terminal Unit. System capabilities may be enhanced or scaled down by simply changing the processor's algorithm. The subsequent sections describe each of the units and their interface with the COP888CG.



TL/DD/10607–1

FIGURE 1. Block Diagram of Security/Monitoring System

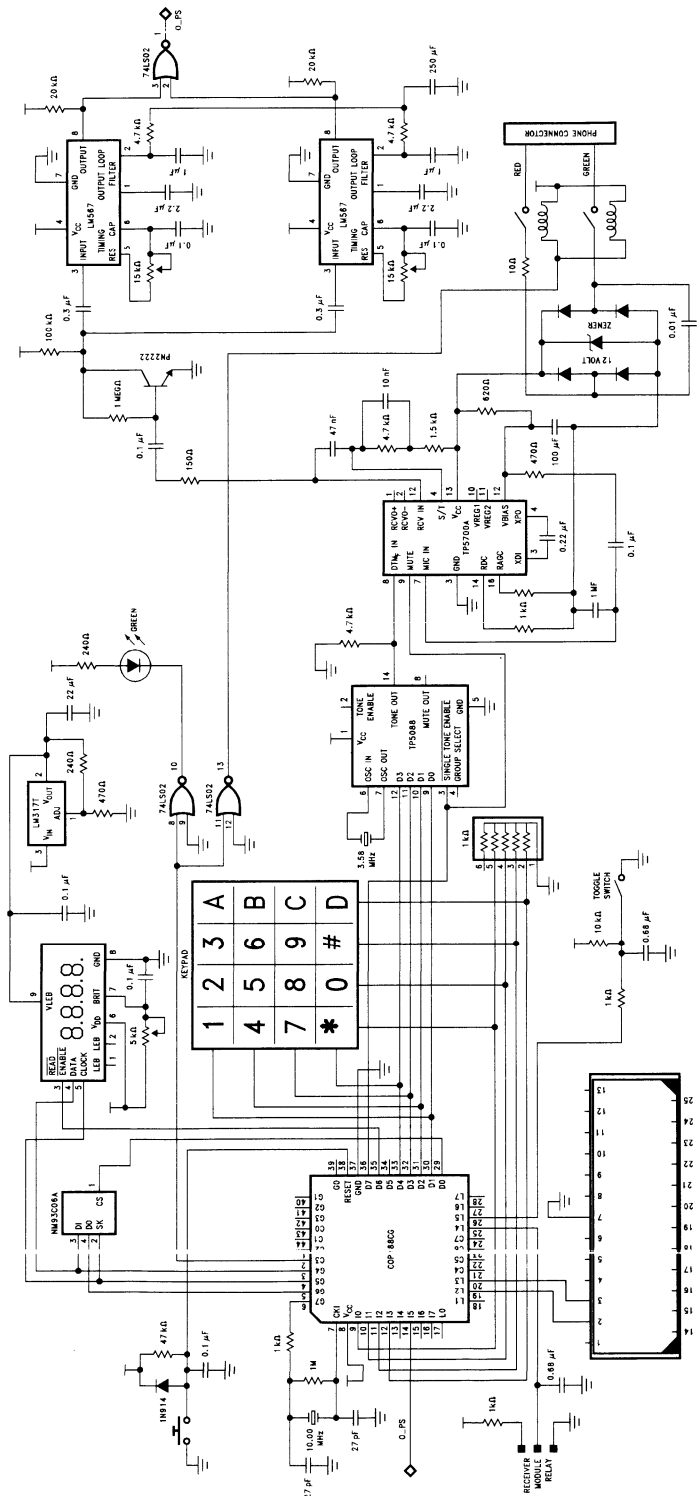


FIGURE 2. Schematic of the ASM System Prototype

HARDWARE DESCRIPTION

This section describes the various blocks in the ASM System briefly and highlights the hardware considerations in the design of the System.

Receiver Unit

The Receiver Unit operates with the Sensors and Transmitter Unit. An eight-key dip switch makes it possible to select 256 different digital codes. A detector LED indicates the level of the radio frequency (RF) energy detected by the receiver and enables the user to determine the best locations for the transmitter(s) and receiver, assuring reliable operation.

Figure 2 shows the interface between the COP888CG and the Receiver Unit on the bi-directional I/O Port L capable of functioning as Multi-Input WakeUp (MIWU). In this implementation the WR-200 series of receivers manufactured by Visonic Ltd was used. These receivers are designed to operate with Visonic standard transmitters. The receiver operates on 12 VDC. When RF signal from the transmitter(s) is detected, the receiver activates a relay which in turn interrupts the microcontroller. The output of the relay is connected to the Port L of the COP888CG whose alternate function includes, the Multi-Input WakeUp feature. The COP888CG, after a time delay of 10 seconds, activates the Auto-Dialer Unit. The microcontroller turns on a LED to indicate an alarm signal was detected and is being processed.

Sensors and Transmitters

This unit has a built-in reed switch which can be used with a magnet to activate the transmitter. An eight-key dip switch forms the code selector and each key can be set to either ON or OFF position to create a unique code. This code should match with the code selected on the receiver unit.

Model WR-100 Universal Wireless Transmitter, manufactured by Visonic Ltd. was used in the implementation of the Security/Monitoring System.

Keypad Unit

The Keypad Unit consists of 4 x 4 matrix keyboard. The *Figure 2* shows the keyboard matrix interface to COP888CG. The keyboard is scanned periodically by addressing a column in the keyboard matrix. The program senses the key closure in that column by testing the Port I lines (I0 to I3) which are connected to the rows of the keyboard matrix. Thus, each key is associated with the conjunction of one Port D output line and one Port I input line only.

The keypad unit is used to program the real time clock in order to set the time and date. The telephone number to be dialed in case of a security breach can also be programmed through the keypad as well as the terminal keyboard in the Terminal Unit.

Auto-Dialer Unit

The Auto-Dialer Unit dials the number programmed by the user upon detection of RF signal by the Receiver from the Sensors and Transmitter Unit. The unit consists of two ICs and some peripheral circuitry. National Semiconductor's TP5700A is the Telephone Speech Circuit and TP5088 is the DTMF generator. These two chips are interfaced to the COP888CG as in *Figure 2*. The COP888CG outputs the digit to be dialed to TP5088 and the output of the DTMF generator is inputted to the Speech Circuit. The Speech Circuit interfaces with the telephone lines.

TP5088 is a low cost CMOS device that provides the tone-dialing capability in microprocessor-controlled telephone applications. TP5700A is a linear bipolar device which includes the functions required to build the speech circuit of a telephone. It replaces the hybrid transformer, compensation circuit and sidetone network used traditional designs.

Data Storage Unit

The Data Storage Unit stores the real time data of events that the Receiver Unit detects and informs the Central Controlling Unit. The storage is non-volatile and can be archived for later references. The Terminal Unit can request the Central Controlling Unit to display the events and the data stored in the Storage Unit. The telephone number to be dialed by the Auto-Dialer Unit is also stored in this unit. This unit interfaces with the COP888CG using the MICROWIRE/PLUS™ serial communication protocol.

In this implementation the COP888CG microcontroller interfaces with NM93C06A Serial EEPROM Memory. The NM93C06A contains 256 bits of read/write EEPROM organized as 16 registers of 16 bits each. Written information has a retention period of at least 10 years. *Figure 2* shows the interface between COP888CG and NMC9306.

Any sequentially accessible memory device that is compatible with the MICROWIRE/PLUS™ serial communication protocol can be used as a Data Storage Unit. The Central Controlling Unit checks for the availability of memory and informs the user of the same if memory is full. Upon receipt of memory full prompt, the user can decide to overwrite or replace the memory device.

Display Terminal Unit

The Display Terminal Unit interfaces with the COP888CG through the full-duplex, double buffered UART. The COP888CG is interrupted by the terminal and the microcontroller decodes the ASCII character sent and services the corresponding request. The terminal keyboard can be used to program the telephone number to be dialed by the Auto-Dialer Unit. The real time clock is displayed on the terminal screen. The user can request the Central Controlling Unit to display the history of events monitored by the AMS System. The Central Controlling Unit retrieves the information from the Date Storage Unit and displays it on the screen.

The ASM System utilized a Visual 550 terminal. The terminal employs two independent display memories: alphanumerics and graphics. The alphanumeric functions of the V550 is ANSI X3.64 compatible and the graphics functions are fully compatible with Tectronix Plot 10® software.

With slight modification of the Central Controlling Unit's algorithm it is possible to make the ASM System interface with any other terminal unit.

LED Display Unit

The LED Display Unit is used to display the time and date information. *Figure 2* shows the interface between COP888CG and the Display Terminal Unit. The COP888CG communicates with this unit serially using the MICROWIRE/PLUS protocol.

The NSM4000A LED Display with Driver is used in the ASM System. The NSM4000A is a 4-digit 0.3" height LED display with serial data-in parallel data-out LED driver designed to operate with minimal interface to the data source. The Cen-

tral Controlling Unit does not update the display when it is servicing the Receiver Unit. The APS System has a toggle switch that enables toggling the display between Hours-Minutes to Seconds-1/80th of Seconds. The Keypad Unit is used to toggle the display between time and date.

Central Controlling Unit

This is the main unit in the application and is responsible for the efficient operation of the various units in the ASM System. The unit consists of COP888CG and the application software. The next section describes the application software in detail. The COP888CG interfaces with the various units described in the previous sections *(Figure 2)*.

The application is a real time system and is totally interrupt driven with some of the tasks being executed in the background. The various units that interface with the COP888CG can be considered as tasks and the Central Controlling Unit executes these tasks based on their priority and the sequence of occurrence. The real time clock counter is given the highest priority. The Receiver Unit uses the Multi-Input Wakeup/Interrupt feature of the COP888CG to wakeup the microcontroller and service the Alarm routine. The Display Unit has a display toggle switch which also uses the Multi-Input Wakeup/Interrupt to toggle the display between Hours-Minutes and Seconds-1/80th of Seconds.

The COP888CG communicates with the Terminal Unit through the on-board, full duplex, double buffered UART. The terminal keyboard can be used to interrupt the COP888CG to program the phone number to dial in case of an emergency. The COP888CG uses the MICROWIRE/PLUS™ serial communication protocol to display the time and date information on the LED display and also to store real time information of events in the non-volatile data storage unit. Thus the MICROWIRE/PLUS protocol is time shared between the Display Unit and Data Storage Unit.

The Keypad Unit is a 4 x 4 array of keys and the COP888CG periodically polls the keypad. The input/output ports of the COP888CG is used to read the key pressed and is decoded by the software. The Auto-Dialer Unit is driven by the input/output lines and the interface between COP888CG. This unit is activated by the COP888CG 10 seconds after the Receiver Unit interrupts the microcontroller. This delay is used to disarm the Alarm routine.

SOFTWARE DESCRIPTION

The instruction set of the COP800 family of microcontrollers provide easy optimization of program size and throughput efficiency. Most of the instructions of the COP800 family are single-byte, single-cycle instructions (approximately 60%). The COP800 family of microcontrollers has three memory mapped registers (B, X and SP). The B and X registers can be used as data store memory pointers for register indirect addressing with optional auto post incrementing or decrementing of the associated pointer. This allows greater efficiency in cycle time and program code. The COP800 family allows true bit-manipulation i.e., the ability to set, reset or test any individual bit in data memory including the memory mapped I/O ports.

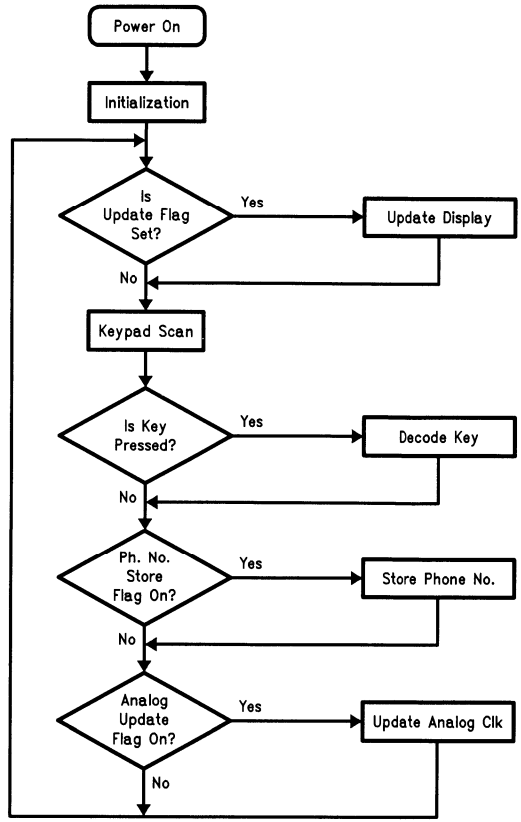
The architecture of COP800 family is based on a modified Harvard type architecture, where the Control Store Program (in ROM) is separated from the Data Store Memory (in RAM). Both types of memory have their own separate addressing space and separate address busses. This architecture allows the overlap of ROM and RAM memory accesses which is not possible with single-address bus Von Neumann-style architecture. The modified Harvard architecture allows access to ROM data tables which is not possible with the classical Harvard architecture.

The COP888 sub-family of microcontrollers support a total of sixteen vectored interrupts, of which fourteen are maskable interrupts and two high-priority, non-maskable interrupts. A 2-byte interrupt vector is reserved for each of these sixteen interrupts and they are stored in a user-defined 32-byte program memory (ROM) table. Please refer to the COP888 users manual or the Microcontrollers Databook for more detailed information on interrupts.

The MIWU feature, which utilizes the Port L, of the COP888 sub-family can be used to wakeup the microcontroller from the two power saving modes, i.e., HALT or IDLE modes. Alternately, the MIWU/Interrupt allows the user to generate eight additional edge selectable external interrupts. Three 8-bit memory mapped registers (WKEDG, WKEN and WKPND) are used to implement the MIWU/Interrupt. The three control registers each contain an associated pin for each L port pin. The WKEN register is used to select which particular Port L inputs will be used. The user can select whether the trigger condition on a selected L port pin is to be a positive edge (low to high transition) or a negative edge (high to low transition). This selection is made through the WKEDG register. The occurrence of the selected trigger condition for MIWU/Interrupt is latched into the associated bit of the Wakeup Pending Register (WKPND).

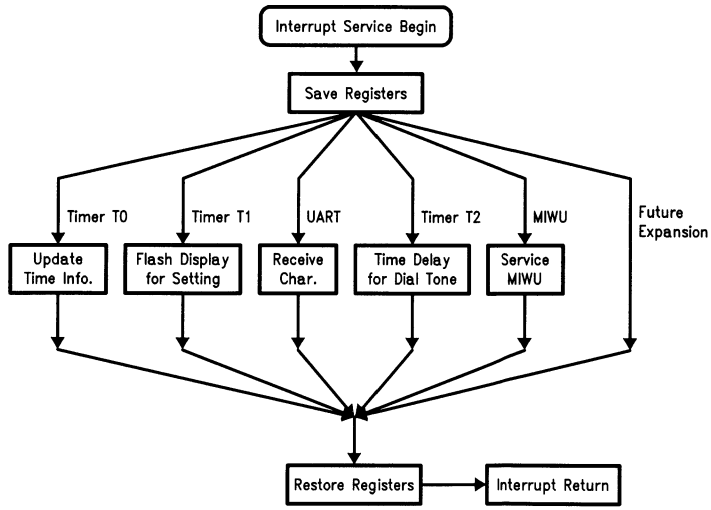
The COP800 family has the ability to detect various illegal conditions resulting from coding errors, transient noise, power supply voltage drops, runaway programs, etc. Reading an undefined ROM location gets zeroes, which results in a non-maskable software interrupt thus signalling an illegal condition has occurred. In addition to this, the COP888 sub-family supports both WATCHDOG™ and Clock Monitor. The WATCHDOG™ is used to monitor the number of instruction cycles between WATCHDOG™ services in order to avoid runaway programs or infinite loops. The Clock Monitor is used to detect the absence of a clock or a very slow clock below a specified rate. These features of the COP800 family provide easy implementation of real time applications where the proper execution of the software plays a crucial role.

The major features of the software written for the ASM System implementation are described on the flow chart *Figure 3*. The main program flow is to detect the flags set, service the flags and scan the Keypad. The rest of the software is interrupt driven. The program is real time and the interrupts are serviced as and when they occur. Some of the routines are running in the background all the time, such as, Time Keeping Routine and Keypad Scan Routine. *Figures 4* and *5* gives the flow of the various interrupt service routines. The following sub-sections briefly describe each module of software connected to the units described earlier.



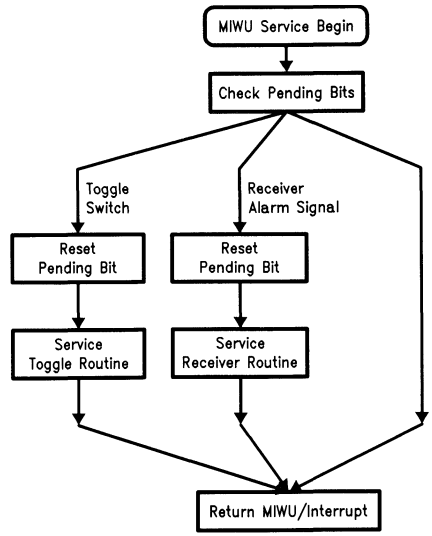
TL/DD/10607–3

FIGURE 3. ASM System Program Flow



TL/DD/10607–4

FIGURE 4. Interrupt Service Routines Flow



TL/DD/10607–5

FIGURE 5. Multi-Input Wakeup/Interrupt Service Routines

Initialization Routine

The Initialization Routine loads the Data Memory locations being used in the program with default values and initializes the various control and configuration registers. It also brings up the display on the Terminal Unit and the LED Display Unit.

Time Keeping Routine

The Time Keeping Routine is the most important routine and is executed irrespective of the other modules being executed. The program uses the IDLE Timer T0 for this purpose. The IDLE Timer is a 16-bit timer and runs continuously at a fixed rate of the instruction cycle clock. The IDLE Timer counter is not memory mapped and consequently, the user cannot read or write to it. The toggling of the twelfth bit of the IDLE counter can be programmed to generate an interrupt. This interrupt is generated every 4 ms at the maximum instruction cycle clock rate of 1 MHz. The software uses this interrupt to update counters in Data Memory for time keeping. The Time Keeping routine then sets a flag to update the display which is then used by the main program.

LED Display Routine

The COP888CG uses the MICROWIRE/PLUS to interface with NSM4000 LED Display with Driver. The time and date information is displayed on the 4-digit LED display. The user is provided with a toggle switch connected to MIWU/Interrupt feature of the COP888CG to toggle the display between Hours Minutes and Seconds 1/80th of Seconds. The toggle switch is connected to L port pin 5. Upon receipt of the MIWU/Interrupt of L port pin 5 this routine toggles the display. This routine upon receipt of the date display request through the Keypad Unit responds by switching the LED Display to show the date. The toggle switch could be used to change the display back to time. However, the display changes to time after a minute by default.

Keypad Scan Routine

This module scans the 4 x 4 matrix keyboard connected to Port D (D1–D4) as rows and to Port I (I0–I3) as columns. Thus each key in the matrix is associated with one Port D line and one Port I line. Each row in the matrix is addressed in sequence and the key closure is sensed by testing the Port I lines. The moment one key closure is detected the program jumps to load the debounce counter. The keypad scan is stopped at that particular row and the program returns to its main flow. The keypad is again scanned and when the debounce counter is decremented. When the debounce counter is zero the key pressed is accepted and decoded. The versatility of the COP888 family of instructions set allows decoding the key pressed with one instruction. The Port D (lines D1–D4) and Port I (lines I0–I3) in conjunction form an eight bit number that is unique to each key. The JID (Jump Indirect) instruction uses the contents of the accumulator to point to the indirect vector table of program address. The accumulator contents are transferred to the program counter (lower 8 bits). The data accessed from the program memory location addressed by program counter is transferred to the program counter (lower 8 bits). The JID instruction is a single-byte, three cycle instruction and provides an efficient way to decode and branch to service the appropriate routine based upon the key pressed.

The Keypad is used to set the time and data information after power up and can also be used to program the phone number to be dialed by the Auto-Dialing Unit.

Non-Volatile Data Storage Routine

The COP888CG interfaces with NM93C06A in the ASM System to store the real time data of the events monitored and also the telephone number to be dialed by the Auto-Dialer Unit. This routine is executed whenever the Receiver Unit detects a signal and the ASM System is not disarmed within 10 seconds of detection of the signal or when the

Display Terminal Unit programs the telephone number to be dialed. The Keypad can also be used to program the phone number to be dialed by the Auto-Dialer Unit. The Terminal Unit can request for the history of events, during which the COP888CG reads the NM93C06A. Please refer to the application note on MICROWIRE/PLUS for details regarding the interface between COP888CG and NMC9306.

Display Terminal Interface Routine

The Display Terminal as previously mentioned interfaces with the COP888CG through the full-duplex, double buffered UART. The terminal is used to display the history of events, real time, and sequence of operations upon detection of signal by the Receiver Unit.

The request for display of events and programming the phone number interrupts the COP888CG. However, the Time Keeping Routine updates the LED display and terminal with real time periodically, except when the COP888CG is servicing the Receiver Unit.

The operation mode of the UART may be selected in conjunction with both a prescaler and baud rate register. Character data lengths of seven, eight or nine bits are program selectable, in conjunction with a start bit, an optional parity bit, and stop bits of 7/8, 1, 1 and 7/8, or 2. The UART also contains a full set of error detection circuitry and a diagnostic test capability, as well as an ATTENTION mode to facilitate networking with other processors.

Please refer to the Users Manual or Microcontroller Databook for details.

In the ASM System the COP888CG interfaces with the V550 terminal at 2400 baud, 8 data bits, 1 Stop bit, no parity. The receiver buffer full and transmit buffer empty generates an interrupt. The Port L (pins L1, L2, L3) are used for the UART interface as CKX (clock), TDX (transmit) and RDX (receive), respectively.

The display terminal is used to display time both in analog and digital form. The V550 allows interfacing both in alphanumeric and graphic modes with separate memory for each of the modes. The COP888CG is programmed to send out the ASCII ESC sequence required to generate the graphics on the screen.

Auto-Dialing Routine

This routine is responsible for dialing the number in the event of an emergency. The COP888CG interfaces with TP5088, which in turn interfaces with TP5700A. The COP888CG activates the relay that keeps the telephone line on-hook to the off-hook position. After this it times out to get the dial tone. After a fixed amount of time, the digit to be dialed is sent out on the D port, lines D1–D4, to TP5088 along with the Chip Select. The TP5088 generates the DTMF signal for the digit. The COP888CG takes care of the timing required between two digits and also the on-time of the DTMF signal for each digit. The output of the DTMF signal goes to the TP5700A which interfaces with the Tip and Ring of the telephone lines. The TP5700A receives the signal from the telephone lines and LM567 along with the associated circuitry is used to detect whether the required frequency signal was sent by the unit responding to the telephone. The output of the LM567 is connected to Port I pin 5.

The Receiver Routine polls the Port I pin 5 periodically to check for response from the unit dialed by the Auto-Dialer Unit.

Receiver Routine

This is the main interrupt service routine of the ASM System. The Receiver Unit interfaces with the COP888CG through the L port pin 4. Upon receipt of the signal from the Sensors and Transmitter Unit the Receiver Unit activates a relay which causes a MIWU/Interrupt. The interrupt service routine then waits for 10 seconds before reacting to the signal. This time is allowed to disarm the Security/Monitoring System. The Time Keeping Routine is used to caculate the delay and if the user disarms the System by toggling a switch the signal is ignored. Otherwide the Non-Volatile Storage Routine is executed to read the telephone number and this information is passed on to the Auto-Dialer Unit. The Auto-Dialer Unit dials the number and looks for a response over the telephone line. If however, there is no response, the Receiver Routine times out after a minute and tries the same number again. The number of trials can be modified in software and the time out period can also be changed. In the ASM System the number of trials is two. With slight modification the Auto-Dialer Unit can be made to dial a different number during the second attempt. The real time and date of occurrence of the event is stored in the NMC9306 along with the outcome of the telephone call. This routine keeps track of the non-volatile memory capacity and if it overflows, it prompts the user on the terminal of the same. The user is given the choice to overwrite the non-volatile memory or replace the device.

USING THE ASM SYSTEM

The ASM System upon installation and initial power-up has some preliminary steps to be performed. The time and date should be set, the phone number to be dialed by the Auto-Dialer Unit should be programmed. The toggle switch could be used to toggle the display between Hours-Minutes and Seconds-1/80th of Seconds.

Setting Time and Date

The steps involved in setting the time and date are:

1. Press key A on the keypad. The LED display flashes.
2. Set the desired time (Hours and Minutes) using the keypad.
3. The LED display and the Terminal Screen displays the time set.
4. Press key C on the keypad. The display toggles and displays the date.
5. Press key A on the keypad. The LED display begins to flash.
6. Set the date (month and day) using the keypad.
7. The LED display now shows the date set.
8. The LED display could be toggled to show the time using the toggle switch. However, the system after one minute will default to display time.

Programming the Phone Number

The phone number to be dialed could be programmed in two ways, i.e., using the terminal or the keypad. Using the terminal, the steps to be performed are:

1. Press CNTRL B on the terminal keyboard. The COP888CG sends a carriage return to terminal.
2. Press CNTRL D on the terminal keyboard. Then type the number to be dialed. At the end press CNTRL C to end programming.

Using the keypad, perform the following steps:

1. Press "*" key on the keypad.
2. Press the digits to be dialed.

3. Press "#" key on the keypad to end programming the number.

The ASM System is now ready to start monitoring. Upon receipt of the alarm signal from the Receiving Unit the ASM System will dial the number programmed. In order to display the history of events on the terminal screen press CNTRL S from the terminal keyboard.

CONCLUSIONS

The architecture, features and flexibility of the COP800 family of microcontrollers makes it cost-effective as the workhorse of any system by eliminating external components from the circuit. This approach not only reduces the system cost and development time, but also increases the flexibility and market life of the product.

The Automated Security/Monitoring System implemented using the COP888CG illustrates a single chip system solution. The application also illustrates interfacing the COP888CG to a number of specialized peripherals using an absolute minimum number of I/O lines. The ASM System approximately uses 3k bytes of program memory (ROM) space and demonstrates an efficient method of handling multi-sourced interrupts.

Sound Effects for the COP800 Family

National Semiconductor
Application Note 663
Jerry Leventer

This application note describes the creation of sound effects using National Semiconductor's COP800 family of microcontrollers. The following applications are described in detail:

1. Whistle
2. White Noise
3. Explosion
4. Bomb
5. Laser Gun

These applications were developed on a COP820C using a 20 MHz crystal and a 1 μs instruction cycle time. By making the appropriate changes to control registers within the routines, slower clock speeds may be used. Program flow diagrams and complete source codes are included in this document.

I. WHISTLE

The whistle routine utilizes the timer underflow interrupt and employs the TIO function on pin G3. Each timer underflow causes the TIO pin to toggle. This creates a tone whose frequency remains constant as long as the timer autoreload register value remains unchanged. In order to create a desending or ascending whistle tone, the autoreload register value is increased or decreased after every thirty-two timer interrupts (FCNTR register is used to count the interrupts). When the maximum or minimum frequency has been reached, the autoreload value must be reinitialized so that the whistle frequency does not exceed the desired range.

II. WHITE NOISE

White noise is generated by using a random number generating algorithm called a RING COUNTER. One random number is extracted periodically and placed into the MICROWIRE/PLUS™ serial shift register. These bits are shifted onto the serial output (SO) pin which is wired to a transistor amplifier that drives a speaker. The serial input (SI) and serial output (SO) pins must be tied together.

The RING COUNTER is a pseudo-random number generator which operates on the principle of a linear feedback shift register (see *Figure 1*). This shift register is not to be confused with the MICROWIRE/PLUS serial shift register. Rather it is created using two bytes of data memory (RAM), and the carry flag. Each bit is called a "stage" with the carry flag being "stage 1" and bit 0 of the two byte data register being "stage 17". Using a seventeen stage shift register results in a clean tone with little distortion.

Implementation of the ring counter shift register is accomplished by a rotate right with carry instruction (RRC A). The linear feedback function is accomplished using an "exclusive or" on stages fourteen and seventeen. This particular choice of feedback stages results in a complete cycle of bit combinations, ($2^{17} - 1$), as long as the loop does not begin with zero in the RNGVAL register.

The "exclusive or" function is not explicit in that the XOR instruction is not used. Rather, stages seventeen and fourteen are tested in software using the principle that if only one of them is set then the result is a logic one, otherwise the result is logic zero. It turns out that since the rotate occurs prior to the test, the actual bits tested are the carry flag (stage 1) and bit 2 (stage 15).

A short example using four bits can be used to demonstrate how the ring counter works (see *Figure 2*). If you perform the "exclusive or" on stages three and four, then a complete cycle results. If instead, you use stages two and four, two cycles of six and one cycle of three results depending on the bit combination you begin with.

III. EXPLOSION

The explosion sound effect is generated by manipulating the white noise algorithm to begin with a high pitch and progress to a lower pitch. This is done by altering the rate (contained in the register LUPREG) at which the random numbers are extracted from the ring counter before being placed into the MICROWIRE/PLUS serial shift register (SIOR). If for example LUPREG initially contains the value 4, the white noise will be at a high pitch. By incrementing this number after every ten timer interrupts (using the register TCNTR) the white noise pitch will be reduced. Several other registers are used to provide control of strategic portions of sound within the routine. First and last tones are controlled with FIRSTR and LASTR. The value in EXITR is used to control the overall length of the explosion and the length of each tone is controlled by the register TCNTR. To vary the white noise pitch, the register LUPCNT is used. The value in LUPCNT is incremented each time the pitch of the white noise is decreased within the timer interrupt routine. Prior to entering the ring count loop, LUPCNT is loaded into LUPREG. The serial input (SI) pin must be tied to the serial output (SO) pin.

IV. BOMB

The bomb sound effect combines the descending whistle with an explosion at the end. The TIMER I/O (TIO) and serial input (SI) pins must be tied to the serial output (SO) pin. The explosion portion of this routine was altered slightly in that the first tone control register (FIRSTR) was removed. The first initialization of TCNTR, the tone control register, provides a means to control the first tone length. Subsequent tones are controlled (at label NF2 in the timer interrupt routine) where TCNTR is reinitialized. Both versions were retained for comparison and in the event that greater control of the first tone is needed.

V. LASER GUN

The laser gun sound effect combines the output from the white noise routine and the COP800 timer I/O (TIO) pin (tie TIO to SO). The SI pin is not tied to SO in this application and the ring counter uses only nine stages instead of seventeen.

The registers used for program control are EXITR, TCNTR, and the TIMER. By adjusting the value in EXITR the duration of the laser "shot" can be shortened or lengthened. (A value larger than 03F hex may create problems.) By adjusting the TIMER values (TVALO, TVALHI) and the tone counter (TCNTR) value, interesting variations in the laser sound can be attained.

NOTE: This note applies to all routines that use both the timer interrupt and the ring counter. In order to return to the main program from which the subroutine was called, the stack pointer must be manually restored during the timer interrupt before executing the return (RET) instruction. The reason for this is that the timer interrupt is two levels below the main program. A simple return statement will only serve to return to the ring counter routine from the point at which the timer interrupt occurred. By adding two to the stack pointer (SP + 2), the return statement will force the address of the instruction following the JSR in MAIN into the program counter (PC) from which point execution will continue.

DTMF Generation with a 3.58 MHz Crystal

National Semiconductor
Application Note 666
Verne H. Wilson

DTMF (Dual Tone Multiple Frequency) is associated with digital telephony, and provides two selected output frequencies (one high band, one low band) for a duration of 100 ms. DTMF generation consists of selecting and combining two audio tone frequencies associated with the rows (low band frequency) and columns (high band frequency) of a push-button touch tone telephone keypad.

This application note outlines two different methods of DTMF generation using a COP820C/840C microcontroller clocked with a 3.58 MHz crystal in the divide by 10 mode. This yields an instruction cycle time of 2.79 μs. The application note also provides a low true row/column decoder for the DTMF keyboard.

The first method of DTMF generation provides two PWM (Pulse Width Modulation) outputs on pins G3 and G2 of the G port for 100 ms. These two PWM outputs represent the selected high band and low band frequencies respectively, and must be combined externally with an LM324 op amp or equivalent feed back circuit to produce the DTMF signal.

The second method of DTMF generation uses ROM lookup tables to simulate the two selected DTMF frequencies. These table lookup values for the selected high band and low band frequencies are then combined arithmetically. The high band frequencies contain a higher bias value to compensate for the DTMF requirement that the high band frequency component be 2 dB above the low band frequency component to compensate for losses in transmission. The resultant value from the arithmetic combination of sine wave values is output on L port pins L0 to L5, and must be combined externally with a six input resistor ladder network to produce the DTMF signal. This resultant value is updated every 118 μs. The COP820C/840C timer is used to time out the 100 ms duration of the DTMF. A timer interrupt at the end of the 100 ms is used to terminate the DTMF output. The external ladder network need not contain any active components, unlike the first method of DTMF generation with the two PWM outputs into the LM324 op amp.

The associated COP820C/840C program for the DTMF generation is organized as three subroutines. The first subroutine (KBRDEC) converts the low true column/row input from the DTMF keyboard into the associated DTMF hexadecimal digit. In turn, this hex digit provides the input for the other two subroutines (DTMFGP and DTMFLP), which represent the two different methods of DTMF generation. These three subroutines contain 35, 94, and 301 bytes of COP820C/840C code respectively, including all associated ROM tables. The Program Code/ROM table breakdowns are 19/16, 78/16, and 88/213 bytes respectively.

DTMF KEYBOARD MATRIX

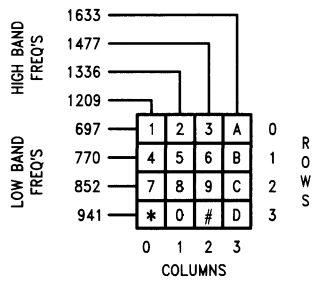
The matrix for selecting the high and low band frequencies associated with each key is shown in *Figure 1*. Each key is uniquely referenced by selecting one of the four low band frequencies associated with the matrix rows, coupled with selecting one of the four high band frequencies associated with the matrix columns. The low band frequencies are 697 Hz, 770 Hz, 852 Hz, and 941 Hz, while the high band frequencies are 1209 Hz, 1336 Hz, 1477 Hz, and 1633 Hz. The DTMF keyboard input decode subroutine assumes that the keyboard is encoded in a low true row/column format, where the keyboard is strobed sequentially with four low true column selects with each returning a low true row select. The low true column and row selects are encoded in the upper and lower nibbles respectively of the accumulator, which serves as the input to the DTMF keyboard input decode subroutine. The subroutine will then generate the DTMF hexadecimal digit associated with the DTMF keyboard input digit.

The DTMF keyboard decode subroutine (KBRDEC) utilizes a common ROM table lookup for each of the two nibbles representing the low true column and row encodings for the keyboard. The only legal low true nibbles for a single key input are E, D, B, and 7. All other low true nibble values represent multiple keys, no key, or no column strobe. Results from two legal nibble table lookups (from the same 16 byte ROM table) are combined to form a hex digit with the binary format of 0000RRCC, where RR represents the four row values and CC represents the four column values. The illegal nibbles are trapped, and the subroutine is exited with a RET (return) command to indicate multiple keys or no key. A pair of legal nibble table lookups result in the subroutine being exited with a RETSK (return and skip) command to indicate a single key input. This KBRDEC subroutine uses 35 bytes of code, consisting of 19 bytes of program code and 16 bytes of ROM table.

DTMF GENERATION USING PWM AND AN OP AMP

The first DTMF generation method (using the DTMFGP subroutine) generates the selected high band and low band frequencies as PWM (Pulse Width Modulation) outputs on pins G3 and G2 respectively of the G port. The COP820C/840C microcontrollers each contain only one timer, and three times must be generated to satisfy the DTMF application. These three times are the half periods of the two selected frequencies and the 100 ms duration period. Obviously the single timer can only generate one of the required times, while the program must generate the two remaining times. The solution lies in dividing the 100 ms duration time by the half periods for each of the eight DTMF frequencies, and then examining the respective high band and low band quotients and remainders. Naturally these divisions must be normalized to the instruction cycle time (t_C). 100 ms represents 35796 t_C's. The results of these divisions are detailed in Table I.

The four high band frequencies are produced by running the COP820C/840C timer in PWM (Pulse Width Modulation) mode, while the program produces the four low band frequencies and the 100 ms duration timeout. The programmed times are achieved by using three programmed register counters R0, R2 and R3, with a backup register R1 to reload the counter R0. These three counters represent the half period, the 100 ms quotient, and the 100 ms remainder associated with each of the four low band frequencies.



TL/DD/10740–22

FIGURE 1. DTMF Keyboard Matrix

TABLE I. Frequency Half Periods, Quotients and Remainders

	Freq. Hz	Half Period in μs	Half Period in t_C's	100 ms/0.5P in t_C's	
				Quotient	Remainder
Low Band Frequencies	697	717.36	257	139	73
	770	649.35	232	154	68
	852	586.85	210	170	96
	941	531.35	190	188	76
High Band Frequencies	1209	413.56	148	241	128
	1336	374.25	134	267	18
	1477	338.53	121	295	101
	1633	306.18	110	325	46

Note: 100 ms represents 35796 t_C's.

The DTMFGP subroutine starts by transforming the DTMF hex digit in the accumulator (with binary format 0000RRCC) into low and high frequency vectors with binary formats 0011RR11 and 0011CC00 respectively. The transformation of the hex digit 0000RRCC (where RR is the row select and CC is the column select) into the frequency vectors is shown in Table II. The conversion produces a timer vector 0011CC00 (T), and three programmed counter vectors for R1, R2, and R3. The formats for the three counter vectors are 0011RR11 (F), 0011RR10 (Q), and 0011RR01 (R). These four vectors created from the core vector are used as inputs for a 16 byte ROM table using the LAID (Load Accumulator InDirect) instruction. One of these four vectors (the T vector) is a function of the column bits (CC), while the other three vectors (F, Q, R) are a function of the row bits (RR). This correlates to only one parameter being needed for the timer (representing the selected high band frequency), while three parameters are needed for the three counters (half period, 100 ms quotient, 100 ms remainder) associated with the low band frequency and 100 ms duration. The frequency parameter ROM translation table, accessed by the T, F, Q, and R vectors, is shown in Table III.

TABLE II. DTMF Hex Digit Translation

DTMF Hex Digit— 0000RRCC

Timer Vector	Timer	T	0011CC00
Half Period Vector	R1	F	0011RR11
100 ms Quotient Vector	R2	Q	0011RR10
100 ms Remainder Vector	R3	R	0011RR01

TABLE III. Frequency Parameter ROM Translation Table

T— Timer **F— Frequency** **Q— Quotient** **R— Remainder**

0x39	14	R
0x3A	171	Q
0x3B	31	F
0x3C	109	T
0x3D	10	R
0x3E	189	Q
0x3F	26	F

The theory of operation in producing the selected low band frequency starts with loading the three counters with values obtained from a ROM table. The half period for the selected frequency is counted out, after which the G2 output bit is toggled. During this half period countout, the quotient counter is decremented. This procedure is repeated until the quotient counter counts out, after which the program branches to the remainder loop. During the remainder loop, the remainder counter counts out to terminate the 100 ms. Following the remainder countout, the G2 and G3 bits are both reset, after which the DTMF subroutine is exited. Great care must be taken in time balancing the half period loop for the selected low band frequency. Furthermore, the toggling of the G2 output bit (achieved with either a set or reset bit instruction) must also be exactly time balanced to maintain the half period time integrity. Local stall loops (consisting of a DRSZ instruction followed by a JP jump back to the DRSZ for a two byte, six instruction cycle loop) are embedded in both the half period and remainder loops. Consequently, the ROM table parameters for the half period and remainder counters are approximately only one-sixth of what otherwise might be expected. The program for the half period loop, along with the detailed time balancing of the loop for each of the low band frequencies, is shown in *Figure 2*.

Table III Frequency	Stall Loop	Total Cycles	Half Period
[(38 − 1)	× 6]	+ 35	= 257
[(33 − 1)	× 6]	+ 40	= 232
[(31 − 1)	× 6]	+ 30	= 210
[(26 − 1)	× 6]	+ 40	= 190

FIGURE 2. Time Balancing for Half Period Loop

TABLE IV. Time Balancing for Remainder Loop

Table III Remainder	Stall Loop	R Loop Overhead	Total Cycles	Table I Remainder
[(10 − 1)	× 6]	+ 20	= 74	73
[(9 − 1)	× 6]	+ 20	= 68	68
[(14 − 1)	× 6]	+ 20	= 98	96
[(10 − 1)	× 6]	+ 20	= 74	76

Note that the Q value in Table III is one greater than the quotient in Table I to compensate for the fact that the quotient count down to zero test is performed early in the half period loop. The overhead in the remainder loop is 20 instruction cycles. The detailed time balancing for the remainder loop is shown in Table IV.

The selected high band frequency is achieved by loading the half period count in t_C's minus one (from Table III) into the timer autoreload register and running the timer in PWM output mode. The minus one is necessary since the timer toggles the G3 output bit when it underflows (counts down through zero), at which time the contents of the autoreload register are transferred into the timer.

In summary, the input digit from the keyboard (encoded in low true column/row format) is translated into a digit matrix vector XXXXRRCC which is checked for 1001RRCC to indicate a single key entry. No key or multiple key entries will set a flag and terminate the DTMF subroutine. The digit matrix vector for a single key is transformed into the core vector 0000RRCC. The core vector is then translated into four other vectors (T, F, Q, R) which in turn are used to select four parameters from a 16 byte ROM table. These four parameters are used to load the timer, and the respective half period, quotient, and remainder counters. The 16 byte ROM table must be located starting at ROM location 0030 (or 0X30) in order to minimize program size, and has reference setups with the "OR A,#033" instruction for the F vector and the "OR A,#030" instruction for the T vector.

The three parameters associated with the two R bits of the core vector require a multi-level table lookup capability with the LAID instruction. This is achieved with the following section of code in the DTMF subroutine:

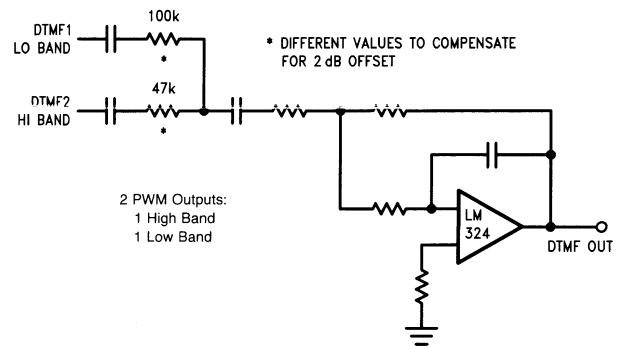
```
        LD      B,#R1
LUP:    X       A,[B]
        LD      A,[B,]
        LAID
        X       A,[B+]
        DEC     A
        IFBNE   #4
        JP      LUP
```

This program loads the F frequency vector into R1, and then decrements the vector each time around the loop. The vector is successively moved with the exchange commands from R1 to R2 to R3 as one of the same exchange commands loads the data from the ROM table into R1, R2, and R3. This successive decrementation of the F vector changes the F vector into the Q vector, and then changes the Q vector into the R vector. These vectors are used to access the ROM table with the LAID instruction. The B pointer is incremented each time around the loop after it has been used to store away the three selected ROM table parameters (one per loop). These three parameters are stored in sequential RAM locations R1, R2, and R3. The IFBNE test instruction is used to skip out of the loop once the three selected ROM table parameters have been accessed and stored away.

The timer is initialized to a count of 15 so that the first timer underflow and toggling of the G3 output bit (with timer PWM mode and G3 toggle output selected) will occur at the same time as the first toggling of the G2 output bit. The half period counts for the high band frequencies minus one are stored in the timer section of the ROM table. The selected value from this frequency ROM table is stored in the timer autoreload register. The timer is selected for PWM output mode and started with the instruction LD [B],#0B0 where the B pointer is selecting the CNTRL register at memory location 0EE.

This first DTMF generation subroutine for the COP820C/840C uses 94 bytes of code, consisting of 78 bytes of program code and 16 bytes of ROM table. A program test routine to sequentially call the DTMFGP subroutine for each of the 16 keyboard input digits is supplied with the listing for the DTMF35 program. This test routine uses a 16 byte ROM table to supply the low true encoded column/row keyboard input to the accumulator. An input from the I0 input pin of the I port is used to select which DTMF generation subroutine is to be used. The DTMFGP subroutine is selected with I0 = 0.

A TYPICAL OP AMP CONFIGURATION FOR MIXING THE TWO DTMF PWM OUTPUTS IS SHOWN IN *FIGURE 3*.



TL/DD/10740–23

FIGURE 3. Typical Op Amp Configuration for Mixing DTMF PWM Outputs

DTMF GENERATION USING A RESISTOR LADDER NETWORK

The second DTMF generation method (using the DTMFLP subroutine) generates and combines values from two table lookups simulating the two selected sine waves. The high band frequency table values have a higher base line value (16 versus 13) than the low band frequency table values. This higher bias for the high frequency values is necessary to satisfy the DTMF requirement that the high band DTMF frequencies need a value 2 dB greater than the low band DTMF frequencies to compensate for losses in transmission.

The resultant value from arithmetically combining the table lookup low band and high band frequency values is output on pins L0 to L5 of the L port in order to feed into a six input external resistor ladder network. The resultant value is updated every 117⅓ μs (one cycle of the LUP42 program loop). The LUP42 program loop contains 42 instruction cycles (t_C's) of 2.7936511 μs each for a total loop time of 117⅓ μs. The COP820C/840C timer is used to count out the 100 ms DTMF duration time.

An interrupt from the timer terminates the 100 ms DTMF output. Note that the Stack Pointer (SP) must be adjusted following the timer interrupt before returning from the DTMFLP subroutine.

The DTMFLP subroutine starts by quadrupling the value of the DTMF hex digit value in the accumulator, and then adding an offset value to reach the first value in the telephone key table. The telephone key ROM table contains four values associated with each of the 16 DTMF hex keys. These four values represent the low and high frequency table sizes and table starting addresses associated with the pair of frequencies (one low band, one high band) associated with each DTMF key. The FRLUP section of the program loads the four associated telephone key table values from the ROM table into the registers LFTBSZ (Low Freq Table Size), LFTADR (Low Freq Table Address), HFTBSZ (High Freq Table Size), and HFTADR (High Freq Table Address). The program then initializes the timer and autoreload register, starts the timer, and then jumps to LUP42. Note that the timer value in t_C's is 100 ms plus one LUP42 time, since the initial DTMF output is not until the end of the LUP42 program.

Multiples of the magic number 118 μs (approximately) are close approximations to all eight of the DTMF frequencies. The LUP42 program uses 42 instruction cycles (of 2.7936511 μs each) to yield a LUP42 time of 117⅓ μs. The purpose of the LUP42 program is to update the six L port outputs by accessing and then combining the next set of values from the selected low band and high band sine wave frequency tables in the ROM. The ROM table offset frequency pointers (LFPTR and HFPTR) must increment each time and then wrap around from top to bottom of the two selected ROM tables. The ROM table size parameters (LFTBSZ and HFTBSZ) for the selected frequencies are tested during each LUP42 to determine if the wrap around from ROM table top to bottom is necessary. The wrap around is implemented by clearing the frequency pointer in question. Note that the ROM tables are mapped from a reference of 0 to table size minus one, so that the table size is used in a direct comparison with the frequency offset pointer to test for the need for a wrap around. Also note that the offset pointer incremented value is used during the following LUP42 cycle, while the pre-incremented value of the pointer is used during the current cycle. However, it is the incremented value that is tested versus the table size for the need to wrap around.

After the low band and high band ROM table sine wave frequency values are accessed in each cycle of the LUP42 program, they are added together and then output to pins L0–L5 of the L port. As stated previously, the low band frequency values have a lower bias than the high band frequency values to compensate for the required 2 dB offset. Specifically, the base line and maximum values for the low frequency values are 13 and 26 respectively, while the base line and maximum values for the high frequency values are 16 and 32 respectively. Thus the combined base line value is 29, while the combined maximum value is 58. This gives a range of values on the L port output (L0–L5) from 0 to 58.

The minimum time necessary for the LUP42 update program loop is 36 instruction cycles including the jump back to the start of the loop. Consequently, two LAID instructions are inserted just prior to the jump back instruction at the end of LUP42 to supply the six extra NOP instruction cycles needed to increase the LUP42 instruction cycles from 36 to 42. A three cycle LAID instruction can always be used to simulate three single cycle NOP instructions if the accumulator data is not needed.

Table V shows the multiple LUP42 approximation to the eight DTMF frequencies, including the number of sine wave cycles and data points in the approximation. As an example, three cycles of a sine wave with a total of 19 data points across the three cycles is used to approximate the 1336 Hz DTMF frequency. The 19 cycles of LUP42 times the LUP42 time of 117⅓ μs is divided into the three cycles to yield a value of 1345.69 Hz. This gives an error of +0.73% when compared with the DTMF value of 1336 Hz. This is well within the 1.5% North American DTMF error range.

TABLE V. DTMF Frequency Approximation Table

DTMF Freq.	# of Sine Wave Cycles	# of Data Points	Calculation	Approx. Freq.	% Error
697	4	49	4/(49 x 117⅓)	= 695.73	−0.18
770	1	11	1/(11 x 117⅓)	= 774.79	+0.62
852	1	10	1/(10 x 117⅓)	= 852.27	+0.03
941	1	9	1/(9 x 117⅓)	= 946.97	+0.63
1209	1	7	1/(7 x 117⅓)	= 1217.53	+0.71
1336	3	19	3/(19 x 117⅓)	= 1345.69	+0.73
1477	4	23	4/(23 x 117⅓)	= 1482.21	+0.35
1633	4	21	4/(21 x 117⅓)	= 1623.38	−0.59

The frequency approximation is equal to the number of cycles of sine wave divided by the time in the total number of LUP42 cycles before the ROM table repeats.

The values in the DTMF sine wave ROM tables are calculated by computing the sine value at the appropriate points, scaling the sine value up to the base line value, and then adding the result to the base line value. The following example will help to clarify this calculation.

Consider the three cycles of sine wave across 19 data points for the 1336 Hz high band frequency. The first value in the table is the base line value of 16. With 2π radians per sine wave cycle, the succeeding values in the table represent the sine values of $1 \times (6\pi/19)$, $2 \times (6\pi/19)$, $3 \times (6\pi/19)$, . . . , up to $18 \times (6\pi/19)$. Consider the seventh and eighth values in the table, representing the sine values of $6 \times (6\pi/19)$ and $7 \times (6\pi/19)$ respectively. The respective calculatons of $16 \times \sin[6 \times (6\pi/19)]$ and $16 \times \sin[7 \times (6\pi/19)]$ yield values of -5.20 and 9.83. Rounding to the nearest integer gives values of -5 and 10. When added to the base line value of 16, these values yield the results 11 and 26 for the seventh and eighth values in the 1336 Hz DTMF ROM table. Symmetry in the loop of 19 values in the DTMF table dictates that the fourteenth and thirteenth values in the table are 21 and 6, representing values of 5 and -10 from the calculations.

The area under a half cycle of sine wave relative to the area of the surrounding rectangle is $2/\pi$, where π radians represent the sine wave half cycle. This surrounding rectangle has a length of π and a height of 1, with the height representing the maximum sine value. Consequently, the area of the surrounding rectangle is π. The integral of the area under the half sine wave from 0 to π is equal to 2. The ratio of $2/\pi$ is equal to 63.66%, so that the total of the values for each half sine wave should approximate 63.66% of the sum of the max values. The maximum values (relative to the base line) are 13 and 16 respectively for the low and high band DTMF frequencies.

For the previous 1336 Hz example, the total of the absolute values for the 19 sine values from the 1336 Hz ROM table is equal to 196. The surrounding rectangle for the three cycles of sine wave is 19 by 16 for a total area of 304. The ratio of 196/304 is 64.47% compared with the $2/\pi$ ratio of 63.66%. Thus the sine wave approximation gives an area abundance of 0.81% (equal to 64.47 − 63.66).

An application of the sine wave area criteria is shown in the generation of the DTMF 852 Hz frequency. The ten sine values calculated are 0, 7.64, 12.36, 12.36, 7.64, 0, −7.64, −12.36, −12.36, and −7.64. Rounding off to the nearest integer yields values of 0, 8, 12, 12, 8, 0, −8, −12, −12 and −8. The total of these values (absolute numbers) is 80, while the area of the surrounding rectangle is 130 (10 x 13). The ratio of 80/130 is 61.54% compared with the $2/\pi$ ratio of 63.66%. Thus the sine wave approximation gives an area deficiency of 2.12% (equal to 63.66 − 61.54), which is overly deficient. Consequently, two of the ten sine values are augmented to yield sine values of 0, 8, 12, 13*, 8, 0, −8, −12, −13*, and −8. This gives an absolute total of 82 and a ratio of 82/130, which equals 63.08% and serves as a much better approximation to the $2/\pi$ ratio of 63.66%.

The sine wave area criteria is also used to modify two values in the DTMF 941 Hz frequency. The nine sine values calculated are 0, 8.36, 12.80, 11.26, 4.45, −4.45, −11.26, −12.80, and −8.36. Rounding off to the nearest integer yields values of 0, 8, 13, 11, 4, −4, −11, −13, and −8. The total of these values (absolute numbers) is 72, while the area of the surrounding rectangle is 117 (9 x 13). The ratio of 72/117 is 61.54% compared to the $2/\pi$ ratio of 63.66%. Thus the sine wave approximation gives an area deficiency of 2.12% (equal to 63.66 − 61.54),which is overly deficient. Rounding up the two values of 4.45 and −4.45 to 5 and −5, rather than down to 4 and −4, yields values of 0, 8, 13, 11, 5, −5, −11, −13 and −8. This gives an absolute total of 74 and a ratio of 74/117, which equals 63.25% and serves as a much better approximation to the $2/\pi$ ratio of 63.66%.

With these modified values for the 852 and 941 DTMF frequencies, the area criteria ratio of $2/\pi$ = 63.66% for the sine wave compared to the surrounding rectangle has the following values:

DTMF Freq.	Sum of Values	Rectangle Area	Percentage	Diff.
697 Hz	406	49 x 13 = 637	63.74%	+0.08%
770 Hz	92	11 x 13 = 143	64.34%	+0.68%
852 Hz	82	10 x 13 = 130	63.08%	−0.58%
941 Hz	74	9 x 13 = 117	63.25%	−0.41%
1209 Hz	72	7 x 16 = 112	64.29%	+0.63%
1336 Hz	196	19 x 16 = 304	64.47%	+0.81%
1477 Hz	232	23 x 16 = 368	63.04%	−0.62%
1633 Hz	216	21 x 16 = 336	64.29%	+0.63%

The LUP42 program loop is interrupted by the COP820C/840C timer after 100 ms of DTMF output. As stated previously, the Stack Pointer (SP) must be adjusted (incremented by 2) following the timer interrupt before returning from the DTMFLP subroutine.

This second DTMF generation subroutine for the COP820C/840C uses 301 bytes of code, consisting of 88 bytes of program code and 213 bytes of ROM table. The following is a summary of the DTMFLP subroutine code allocation.

DTMFLP Code Allocation	# of Bytes
1. Subroutine Header Code	42
2. Interrupt Code	16
3. LUP42 Code	30
4. Telephone Key Table	64
5. Sine Value Tables	149
Total	301

A program test routine to sequentially call the DTMFLP subroutine for each of the 16 DTMF keyboard input digits is supplied with the listing for the DTMF35 program. This test routine uses a 16 byte ROM table to supply the low true encoded column/row keyboard input to the accumulator. An input from the I0 pin of the I port is used to select which DTMF generation subroutine is to be used. The DTMFLP subroutine is selected with I0 = 1.

A TYPICAL RESISTOR LADDER NETWORK IS SHOWN IN *FIGURE 4*.

SUMMARY

In summary, the DTMF35 program assumes a COP820C/840C clocked with a 3.58 MHz crystal in divide by 10 mode. The DTMF35 program contains three subroutines, KBRDEC, DTMFGP, and DTMFLP. The KBRDEC subroutine is a low true DTMF keyboard decoder, while the DTMFGP and DTMFLP subroutines represent the alternative methods of DTMF generation.

The KBRDEC subroutine provides a low true decoding of the DTMF keyboard input and assumes that the keyboard input has been encoded in a low true column/row format, with the columns of the keyboard being sequentially strobed.

The DTMFGP subroutine produces two PWM (Pulse Width Modulation) outputs (representing the selected high and low band DTMF frequencies) for combination with an external op amp network (LM324 or equivalent).

The DTMFLP subroutine produces six bits of combined high band and low band DTMF frequency output for combination in an external resistor ladder network. This output represents a combined sine wave simulation of the two selected DTMF frequencies by combining values from two selected ROM tables, and updating these values every 118 μs.

The three DTMF35 subroutines contain the following number of bytes of program and ROM table memory:

Subroutine	# of Bytes of Program	# of Bytes of ROM Table	Total # of Bytes
KBRDEC	19	16	35
DTMFGP	78	16	94
DTMFLP	88	213	301

                ;
                ; THE FREQUENCY APPROXIMATION IS EQUAL TO THE NUMBER OF
                ; CYCLES OF SINE WAVE DIVIDED BY THE TIME IN THE TOTAL
                ; NUMBER OF LUP42 CYCLES BEFORE THE REPETITION OF THE
                ; ROM TABLE. AS AN EXAMPLE, CONSIDER THE THREE CYCLES
                ; OF SINE WAVE AND 19 VALUES IN THE ASSOCIATED 1336 HZ
                ; ROM TABLE. THE 19 CYCLES OF LUP42 TIMES THE LUP42
                ; TIME OF 117 1/3 uSEC IS DIVIDED INTO THE THREE CYCLES
                ; OF SINE WAVE TO YIELD A VALUE OF 1345.69 HZ AS THE
                ; 1336 HZ APPROXIMATION.
                ;
                ; THE VALUES IN THE ROM TABLES FOR THE DTMF SINE WAVES
                ; SHOULD WRAP AROUND END TO END IN EITHER DIRECTION TO
                ; FORM A SYMETRICAL LOOP. THE FIRST VALUE IN THE ROM
                ; TABLE REPRESENTS THE BASE LINE FOR THAT FREQUENCY.
                ;
                ; THE HIGH BAND DTMF FREQUENCIES HAVE A BASE LINE VALUE
                ; OF 16 AND A MAXIMUM VALUE OF 32. THE LOW BAND DTMF
                ; FREQUENCIES HAVE A BASE LINE VALUE OF 13 AND A
                ; MAXIMUM VALUE OF 26. THIS DIFFERENCE IN BASE LINE
                ; VALUES IS NECESSARY TO SATISFY THE REQUIREMENT OF THE
                ; HIGH BAND FREQUENCIES NEEDING A LEVEL 2 dB ABOVE THE
                ; LEVEL OF THE LOW BAND FREQUENCIES TO COMPENSATE FOR
                ; LOSSES IN TRANSMISSION. THE SUM OF THE TWO BASE LINE
                ; VALUES YIELDS A BASE LINE VALUE OF 29, WHILE THE SUM
                ; OF THE TWO MAXIMUM VALUES YIELDS A MAXIMUM VALUE OF
                ; 58. THUS THE SIX BIT DTMF OUTPUT FROM THE L PORT TO
                ; THE LADDER NETWORK RANGES FROM 0 TO 58, WITH A BASE
                ; LINE VALUE OF 29.
                ;
                ; THE VALUES IN THE DTMF SINE WAVE TABLES ARE
                ; CALCULATED BY COMPUTING THE SINE VALUE AT THE
                ; APPROPIATE POINTS, SCALING THE SINE VALUE UP TO THE
                ; BASE LINE VALUE, AND THEN ADDING THE RESULT TO THE
                ; BASE LINE VALUE. THE FOLLOWING EXAMPLE WILL HELP TO
                ; CLARIFY THIS CALCULATION.
                ;
                ; CONSIDER THE THREE CYCLES OF SINE WAVE ACROSS 19
                ; DATA POINTS FOR THE 1336 HZ DTMF HIGH BAND FREQUENCY.
                ; THE FIRST VALUE IN THE TABLE IS THE BASE LINE VALUE
                ; OF 16. WITH 2 PI RADIANS PER SINE WAVE CYCLE,
                ; THE SUCCEEDING VALUES IN THE TABLE REPRESENT THE
                ; SINE VALUES OF 1 X (6 PI / 19), 2 X (6 PI / 19),
                ; 3 X (6 PI / 19), . . . . , UP TO 18 X (6 PI / 19).
                ; LET US NOW CONSIDER THE SEVENTH AND EIGHTH VALUES
                ; IN THE TABLE, REPRESENTING THE SINE VALUES OF
                ; 6 X (6 PI / 19) AND 7 X (6 PI / 19) RESPECTIVELY.
                ; THE CALCULATIONS OF 16 X SIN [6 X (6 PI / 19)] AND
                ; 16 X SIN [7 X (6 PI / 19)] YIELD VALUES OF - 5.20 AND
                ; 9.83 RESPECTIVELY. ROUNDED TO THE NEAREST INTEGER
```

2-Way Multiplexed LCD Drive and Low Cost A/D Converter Using V/F Techniques with COP8 Microcontrollers

National Semiconductor
Application Note 673
Volker Soffel

ABSTRACT

This application note is intended to show a general solution for implementing a low cost A/D and a 2-way multiplexed LCD drive using National Semiconductor's COP840C 8-bit microcontroller. The implementation is demonstrated by means of a digital personal scale. Details and function of the weight sensor itself are not covered in this note. Also the algorithms used to calculate the weight from the measured frequency are not included, as they are too specific and depend on the kind of sensor used.

Typical Applications

- Weighing scales
- Sensors with voltage output
- Capacitive or resistive sensors
- All kinds of measuring equipment
- Automotive test and control systems

Features

- 2-way multiplexed LCD drive capability up to 30 segments (4 digit and 2 dot points)
- Precision frequency measurement
- Low current consumption
- Current saving HALT mode
- Additional computing power for application specific tasks

INTRODUCTION

Today's most popular digital scales all have the following characteristics:

They are battery powered and use a LCD to display the weight. Instead of using a discrete A/D-converter, in many cases a V/F converter is used, which converts an output voltage change of the weight sensor to a frequency change. This frequency is measured by a microcontroller and is used to calculate the weight. The advantages of a V/F over an A/D converter are multifold. Only one line from the V/F to the microcontroller is needed, whereas a parallel A/D needs at least 8 lines or even more (National also offers A/Ds with serial output). A V/F can be constructed very simply using National Semiconductor's low cost, precision voltage to frequency converters LM331 or LM331A. Other possibilities are using Op-amps or a 555-timer in astable mode.

V/F-CONVERSION

Hardware

The basic configuration of the scale described in this application note is shown in *Figure 1*.

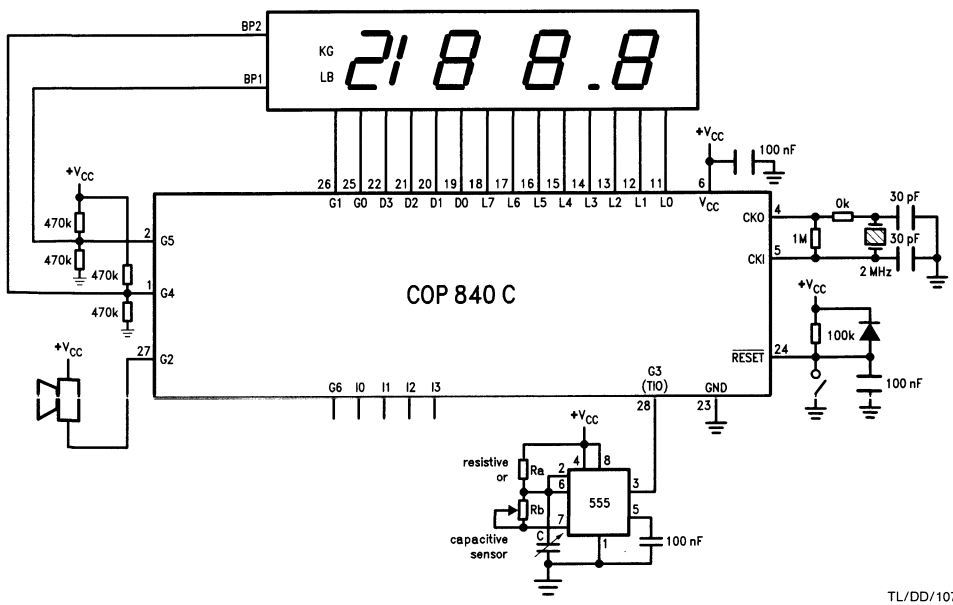

FIGURE 1. System Diagram

A capacitive or resistive sensor's weight related capacitance or resistance change is transformed by a 555 timer (in astable mode) to a change of frequency. The output frequency f is determined by the formula:

$$f = 1.44/((Ra + 2Rb) *C)$$

The output high time is given by:

$$t1 = 0.693* (Ra + Rb) *C$$

The output low time is given by:

$$t2 = 0.693* Rb* C$$

This frequency is measured using the COP800 16-bit timer in the "input capture" mode. After calculation, the weight is displayed on a 2-way multiplexed LCD. Using this configuration a complete scale can be built using only two ICs and a few external passive components.

For more information on V/F converters generally used with voltage output sensors, refer to the literature listed in the reference section.

Frequency Measurement

The COP 16-bit timer is ideally suited for precise frequency measurements with minimum software overhead. This timer has three programmable operating modes, of which the "input capture" mode is used for the frequency measurement. Allocated with the timer is a 16-bit "autoload/capture register". The G3-I/O-pin serves as the timer capture input (TIO). In the "input capture" mode the timer is decremented with the instruction cycle frequency (tc). Each positive going edge at TIO (also neg. edge programmable) causes the timer value to be copied automatically to the autoload/capture register without stopping the timer or destroying its contents. The "timer pending" flag (TPND) in the PSW-register is set to indicate a capture has occurred, and if the timer-interrupt is enabled, an interrupt is generated. The frequency measurement routine listed below executes the following operations (refer to the RAM/register definition file listed at the beginning for symbolic names used in the routines):

The timer is preset with FFFF Hex and is started by setting the TRUN bit, after which the software checks the TPND-flag in a loop (timer interrupt is disabled). When the TPND flag is set the first time, the contents of the capture register is saved in RAM locations STALO and STAHI (start value). The TPND pending flag now must be reset by the software. Then, another 255 positive going edges are counted (equal to 255 pulses) before the capture register is saved in RAM locations ENDLO, ENDHI (end value). The shortest time period that can be measured depends on the number of instruction cycles needed to save the capture register, because with the next positive going edge on TIO the contents of the capture register is overwritten (worst case is 18 instruction cycles, which equals a max. frequency of 55.5 kHz at tc = 1 μs).

The end-value is subtracted from the start-value and the result is restored in RAM locations STALO, STAHI. This value can then be used to calculate the time period of the frequency applied to TIO (G3) by multiplying it with the tc-time and dividing the result by the number of pulses measured (N = 255).

$$T = (\text{startvalue} - \text{endvalue}) *tc/N$$

2-WAY MULTIPLEXED LCD DRIVE

Today a wide variety of LCDs, ranging from static to multiplex rates of 1:64 are available on the market. The multiplex rate of a LCD can be determined by the number of its backplanes (segment-common plate). The higher the multiplex rate the more individual segments can be controlled using only one line. e.g. a static LCD only has one backplane; only one segment can be controlled with one line. A two-way multiplexed LCD has two backplanes and two segments can be controlled with one line, etc.

Common to all LCDs is the fact that the drive voltage applied to the backplane(s) and segments has to be alternating. DC-components higher than 100 mV can cause electrochemical reactions (refer to manufacturer's spec), which reduce reliability and lifetime of the display.

If the multiplex ratio of the LCD is N and the amount of available outputs is M, the number of segments that can be driven is:

$$S = (M - N) * N$$

So the maximum number of a 2-way mux LCD's segments that can be driven with a COP800 in 28-pin package (if all outputs can be used to drive the LCD) is:

$$S = (18 - 2) * 2 = 32$$

During one LCD refresh cycle tx (typical values for $1/tx = fx$ are in the range 30 Hz . . . 60 Hz), three different voltages levels: Vop, 0.5*Vop and 0V have to be generated. The "off" voltage across a segment is not 0V as with static LCDs and also the "on" voltage is not Vop, but only a fraction of it. The ratio of "on" to "off" r.m.s.-voltage (discrimination) is determined by the multiplex ratio and the number of voltage levels involved. The most desirable discrimination ratio is one that maximizes the ratio of V_{ON} to V_{OFF}, allowing the maximum voltage difference between activated and non-activated states. In general the maximum achievable ratio for any particular value of N is given by:

$$(V_{ON}/V_{OFF})\ max = SQR((SQR(N) + 1)/(SQR(N) - 1))$$

$$SQR = \text{square root}$$

Using this formula the maximum achievable discrimination ratio for a 2-way multiplex LCD is 2.41, however, it is also possible to order a customized display with a smaller ratio. For ease of operation, most LCD drivers use equal voltage steps (0V, 0.5 *Vop, Vop). Thus a discrimination ratio of 2.24 is achieved. When using the COP800 to drive a 2-way multiplexed LCD the only external hardware required to achieve the three voltage steps are 4 equal resistors that form two voltage dividers—one for each backplane *(Figure 1)*. The procedure is to set G4 and G5 to "0" for 0V, to HI-Z (TRI-STATE®) for 0.5*Vop and to "1" in order to establish Vop at the backplane electrodes.

With the COP800 each I/O pin can be set individually to TRI-STATE, "1" or "0", so this procedure can be implemented very easily.

The current consumption of typical LCDs is in the range of 3 μA to 4 μA (at Vop = 4.5V, refresh rate 60 Hz) per square centimeter of activated area. Thus the backplane and segment terminals can be treated as Hi-Z loads. At high refresh rates the LCD's current consumption increases dramatically, which is the reason why many LCD manufacturers recommend not using a refresh frequency higher than 60 Hz.

Timing Considerations

As shown in *Figures 2* and *3*, one LCD refresh cycle tx is subdivided into four equally distant time sections ta, tb, tc and td during which the backplane and segment terminals have to be updated in order to switch a specific segment on or off. Considering a refresh frequency of 50 Hz (tx = 20 ms) ta, tb, tc and td are equal to 5 ms; a COP800 running from an external clock of 2 MHz has an internal instruction cycle time of 5 μs and a typical current consumption of less than 350 μA (at V_{CC} = 3V and room temperature), thus meeting both the requirements of low current consumption and additional computing power between LCD refreshes.

The timing is done using the COP800's 16-bit timer in the PWM autoload mode. The timer and the assigned 16-bit autoload register are preset with proper values. By setting the TRUN-flag in the CNTRL-register the timer is decremented each instruction cycle. A flag (TPND) is set at underflow and the timer is automatically reloaded with the value stored in the autoload-register. Timer underflow can also be programmed to generate an interrupt.

Segment Control

Figure 2 shows the voltage-waveforms applied to the two backplane-electrodes (a) and the waveform at a segement-electrode (b), which is needed to switch segment A on and segment B off. The resulting voltage over the segments (c and d) is achieved by subtracting waveform (b) from BP1 (segment A) and waveform (b) from BP2 (segment B).

Figure 3 shows the four different waveforms which must be generated to meet all possible combinations of two segments connected to the same driving terminal (off-off, on-off, off-on, on-on).

Figure 4 shows the internal segment and backplane connections for a typical 2-way mux LCD.

LCD Drive Subroutine

The LCD drive subroutine DISPL converts a 16-bit binary value to a 24-bit BCD-value for easier display data fetch. The drive subroutine itself is built up of a main routine doing the backplane refresh and 7 subroutines (SEG0, SEG1, SEG2, SEG3, SEGOUT, TTPND, DISPD). The subroutines SEG0 to SEG4 are used to get the LCD segment data from a look-up table in ROM for time phases ta, tb, tc and td respectively. Subroutine SEGOUT writes the segment data for each time phase to the corresponding output ports. One time phase takes 5 ms, giving a total refresh cycle time of 20 ms (50 Hz). The exact timing is done by using the COP800 16-bit timer in the PWM autoload mode. In that mode the timer is reloaded with the value stored in the autoload register on every timer underflow. At the same time the timer pending flag is set. The subroutine TTPND checks this flag in a loop. If the timer pending flag is set, this subroutine resets it and returns to the calling program. Thus a 5 ms time delay is created before the segment and backplane data for the next time phase is written to the output ports. Finally the subroutine DISPD switches off the LCD by setting the backplane and segment connections to "0". In this digital scale application a frequency measurement is made while the LCD is off. Then the weight is calculated from this frequency and is displayed for 10s. After this 10s the LCD is switched off again and the COP800 is programmed to enter the current saving HALT mode ($I_{DD} < 10\ \mu A$). A new weight cycle on the digital scale is initiated by pressing a push button, which causes a reset of the microcontroller.

CONCLUSIONS

National Semiconductor's COP800 Microcontroller family is ideally suited for use with V/F converters and 2-way multiplexed LCDs, as they offer features, which are essential for these types of applications. The high resolution, 3-mode programmable 16-bit timer allows precise frequency measurement in the input capture mode with minimum software overhead. The timer's PWM autoreload mode offers an easy way to implement a precise timebase for the LCD refresh. The COP800's programmable I/O ports provide flexibility in driving 2-way multiplexed LCDs directly. The COP800 family, fabricated using M2CMOS technology, offers both low voltage (min V_{CC} of 2.5V) and low current drain.

PC® MOUSE Implementation Using COP800

National Semiconductor
Application Note 681
Alvin Chan

ABSTRACT

The mouse is a very convenient and popular device used in data entry in desktop computers and workstations. For desktop publishing, CAD, paint or drawing programs, using the mouse is inevitable. This application note will describe how to use the COP822C microcontroller to implement a mouse controller.

INTRODUCTION

Mouse Systems was the first company to introduce a mouse for PCs. Together with Microsoft and Logitech, they are the most popular vendors in the PC mouse market. Most mainstream PC programs that use pointing devices are able to support the communication protocols laid down by Mouse Systems and Microsoft.

A typical mouse consists of a microcontroller and its associated circuitry, which are a few capacitors, resistors and transistors. Accompanying the electronics are the mechanical parts, consisting of buttons, roller ball and two disks with slots. Together they perform several major functions: motion detection, host communication, power supply, and button status detection.

MOTION DETECTION

Motion detection with a mouse consists of four commonly known mechanisms. They are the mechanical mouse, the opto-mechanical mouse, the optical mouse and the wheel mouse.

The optical mouse differs from the rest as it requires no mechanical parts. It uses a special pad with a reflective surface and grid lines. Light emitted from the LEDs at the bottom of the mouse is reflected by the surface and movement is detected with photo-transistors.

The mechanical and the opto-mechanical mouse use a roller ball. The ball presses against two rollers which are connected to two disks for the encoding of horizontal and vertical motion. The mechanical mouse has contact points on the disks. As the disks move they touch the contact bars, which in turn generates signals to the microcontroller. The opto-mechanical mouse uses disks that contain evenly spaced slots. Each disk has a pair of LEDs on one side and a pair of photo-transistors on the other side.

The wheel mouse has the same operation as the mechanical mouse except that the ball is eliminated and the rollers are rotated against the outside surface on which the mouse is placed.

HOST COMMUNICATION

Besides having different operating mechanisms, the mouse also has different modes of communication with the host. It can be done through the system bus, the serial port or a special connector. The bus mouse takes up an expansion slot in the PC. The serial mouse uses one of the COM ports.

Although the rest of this report will be based on the opto-mechanical mouse using the serial port connection, the same principle applies to the mechanical and the wheel mouse.

MOTION DETECTION FOR THE OPTO-MECHANICAL MOUSE

The mechanical parts of the opto-mechanical mouse actually consist of one roller ball, two rollers connected to the disks and two pieces of plastic with two slots on each one for LED light to pass through. The two slots are cut so that they form a 90 degree phase difference. The LEDs and the photo-transistors are separated by the disks and the plastic. As the disks move, light pulses are received by the photo-transistors. The microcontroller can then use these quadrature signals to decode the movement of the mouse.

Figure 1a shows the arrangement of the LEDs, disks, plastic and photo-transistors. The shaft connecting the disk and the ball is shown separately on *Figure 1b*. *Figure 2* shows the signals obtained from the photo-transistors when the mouse moves. The signals will not be exactly square waves because of unstable hand movements.

FIGURE 2

RESOLUTION, TRACKING SPEED AND BAUD RATE

The resolution of the mouse is defined as the number of movement counts the mouse can provide for each fixed distance travelled. It is dependent on the physical dimension of the ball and the rollers. It can be calculated by measuring the sizes of the mechanical parts.

An example for the calculation can be shown by making the following assumptions:

- The disks have 40 slots and 40 spokes
- Each spoke has two data counts
  (This will be explained in the section "An Algorithm for Detecting Movements")
- Each slot also has two data counts
- The roller has a diameter of 5mm

For each revolution of the roller, there will be $40 \times 2 \times 2 = 160$ counts of data movement. At the same time, the mouse would have travelled a distance of $\pi \times 5 = 15.7$mm. Therefore the resolution of the mouse is $15.7/160 = 0.098$mm per count. This is equivalent to 259 counts or dots per inch (dpi).

The tracking speed is defined as the fastest speed that the mouse can move without the microcontroller losing track of the movement. This depends on how fast the microcontroller can sample the pulses from the photo-transistors. The effect of a slow tracking speed will contribute to jerking movements of the cursor on the screen.

The baud rate is fixed by the software and the protocol of the mouse type that is being emulated. For mouse systems and microsoft mouse, they are both 1200. Baud rate will affect both the resolution and the tracking speed. The internal movement counter may overflow while the mouse is still sending the last report with a slow baud rate. With a fast baud rate, more reports can be sent for a certain distance moved and the cursor should appear to be smoother.

POWER SUPPLY FOR THE SERIAL MOUSE

Since the serial port of the PC has no power supply lines, the RTS, CTS, DTR and DSR RS232 interface lines are utilized. Therefore the microcontroller and the mouse hardware should have very little power consumption. National Semiconductor's COP822C fits into this category perfectly. The voltage level in the RS232 lines can be either positive or negative. When they are positive, the power supply can be obtained by clamping down with diodes. When they are negative, a 555 timer is used as an oscillator to transform the voltage level to positive. The 1988 National Semiconductor Linear 3 Databook has an example of how to generate a variable duty cycle oscillator using the LMC555 in page 5-282.

While the RTS and DTR lines are used to provide the voltage for the mouse hardware, the TXD line of the host is utilized as the source for the communication signals. When idle, the TXD line is in the mark state, which is the most negative voltage. A pnp transistor can be used to drive the voltage of the RXD pin to a voltage level that is compatible with the RS232 interface standard.

AN ALGORITHM FOR DETECTING MOVEMENTS

The input signal of the photo-transistors is similar to that shown in *Figure 2*. Track 1 leads track 0 by 90 degrees. Movement is recorded as either of the tracks changes state. State tables can be generated for clockwise and counter-clockwise motions.

With the two tracks being 90 degrees out of phase, there could be a total of four possible track states. It can be observed that the binary values formed by combining the present and previous states are unique for clockwise and counter-clockwise motion. A sixteen entry jump table can be formed to increment or decrement the position of the cursor. If the value obtained does not correspond to either the clockwise or counter-clockwise movement, it could be treated as noise. In that case either there is noise on the microcontroller input pins or the microcontroller is tracking motions faster than the movement of the mouse. A possible algorithm can be generated as follows. The number of instruction cycles for some instructions are shown on the left.

$(TRK1, TRK0)_t$		$(TRK1, TRK0)_{t-1}$		Binary Value
		CCW		
0	1	0	0	4
1	1	0	1	D

```

Going through the longest route in the sensor routine takes 75 instruction cycles. So at 5 MHz the microcontroller can track movement changes within 150 μs by using this algorithm.

MOUSE PROTOCOLS

Since most programs in the PC support the mouse systems and microsoft mouse, these two protocols will be discussed here. The protocols are byte-oriented and each byte is framed by one start-bit and two stop-bits. The most commonly used reporting mode is that a report will be sent if there is any change in the status of the position or of the buttons.

MICROSOFT COMPATIBLE DATA FORMAT

6	5	4	3	2	1	0	Bit Number
1	L	R	Y7	Y6	X7	X6	Byte 1
0	X5	X4	X3	X2	X1	X0	Byte 2
0	Y5	Y4	Y3	Y2	Y1	Y0	Byte 3

L, R = Key data (Left, Right key) 1 = key depressed

X0–X7 = X distance 8-bit two's complement value −128 to +127

Y0–Y7 = Y distance 8-bit two's complement value −128 to +127

Positive = South

In the Microsoft Compatible Format, data is transferred in the form of seven-bit bytes. Y movement is positive to the south and negative to the north.

FIVE BYTE PACKED BINARY FORMAT (MOUSE SYSTEMS CORP)

7	6	5	4	3	2	1	0	Bit Number
1	0	0	0	0	L*	M*	R*	Byte 1
X7	X6	X5	X4	X3	X2	X1	X0	Byte 2
Y7	Y6	Y5	Y4	Y3	Y2	Y1	Y0	Byte 3
X7	X6	X5	X4	X3	X2	X1	X0	Byte 4
Y7	Y6	Y5	Y4	Y3	Y2	Y1	Y0	Byte 5

L*, M*, R* = Key data (Left, Middle, Right key), 0 = key depressed

X0–X7 = X distance 8-bit two's complement value −127 to +127

Y0–Y7 = Y distance 8-bit two's complement value −127 to +127

In the Five Byte Packed Binary Format data is transferred in the form of eight-bit bytes (eight data bits without parity). Bytes 4 and 5 are the movement of the mouse during the transmission of the first report.

THE COP822C MICROCONTROLLER

The COP822C is an 8-bit microcontroller with 20 pins, of which 16 are I/O pins. The I/O pins are separated into two ports, port L and port G. Port G has built-in Schmitt-triggered inputs. There is 1k of ROM and 64 bytes of RAM. In the mouse application, the COP822C's features used can be summarized below. Port G is used for the photo-transistor's input. Pin G0 is used as the external interrupt input to monitor the RTS signal for the microsoft compatible protocol. The internal timer can be used for baud rate timing and interrupt generation. The COP822C draws only 4 mA at a crystal frequency of 5 MHz. The instruction cycle time when operating at this frequency is 2 μs.

A MOUSE EXAMPLE

The I/O pins for the COP822C are assigned as follows:

Pin	Function
G0	Interrupt Input (Monitoring RTS Toggle)
G1	Reserved for Input Data (TXD of Host)
G2	Output Data (RXD of Host)
G3–G6	LED Sensor Input
L0–L2	Button Input
L3	Jumper Input (for Default Mouse Mode)

The timer is assigned for baud rate generation. It is configured in the PWM auto-reload mode (with no G3 toggle output) with a value of 1A0 hex in both the timer and the auto-reload register. When operating at 5 MHz, it is equivalent to 833 μs or 1200 baud. When the timer counts down, an interrupt is generated and the service routine will indicate in a timer status byte that it is time for the next bit. The subroutine that handles the transmission will look at this status byte to send the data.

The other interrupt comes from the G0 pin. This is implemented to satisfy the microsoft mouse requirement. As the RTS line toggles, it causes the microcontroller to be interrupted. The response to the toggling is the transmission of the character "M" to indicate the presence of the mouse.

The main program starts by doing some initializations. Then it loops through four subroutines that send the report, sense the movement, sense the buttons, and set up the report format.

Subroutine "SDATA" uses a state table to determine what is to be transmitted. There are 11 or 12 states because microsoft has only 7 data bits and mouse systems has 8. The state table is shown below:

SENDST	State
0	IDLE
1	START BIT
2–8	DATA (FOR MICROSOFT)
2–9	DATA (FOR MOUSE SYSTEMS)
9–10	STOP BIT (FOR MICROSOFT)
10–11	STOP BIT (FOR MOUSE SYSTEMS)
11	NEXT WORD (FOR MICROSOFT)
12	NEXT WORD (FOR MOUSE SYSTEMS)

The G2 pin is set to the level according to the state and the data bit that is transmitted.

Subroutine "SENSOR" checks the input pins connected to the LEDs. The horizontal direction is checked first followed by the vertical direction. Two jump tables are needed to decode the binary value formed by combining the present and previous status of the wheels. The movements are recorded in two counters.

Subroutines "BUTUS" and "BUTMS" are used for polling the button input. They compare the button input with the value polled last time and set up a flag if the value changes. Two subroutines are used for the ease of setting up reports for different mice. The same applies for subroutines "SRPTMS" and "SRPTUS" which set up the report format for transmission. The status change flag is checked and the report is formatted according to the mouse protocol. The

movement counters are then cleared. Since the sign of the vertical movement of mouse systems and microsoft is reversed, the counter value in subroutine "SRPTMS" is complemented to form the right value.

There is an extra subroutine "SY2RPT" which sets up the last two bytes in the mouse systems' report. It is called after the first three bytes of the report are sent.

The efficiency of the mouse depends solely on the effectiveness of the software to loop through sensing and transmission subroutines. For the COP822C, one of the most effective addressing modes is the B register indirect mode. It uses only one byte and one instruction cycle. With autoincrement or autodecrement, it uses one byte and two instruction cycles. In order to utilize this addressing mode more often, the organization of the RAM data has to be carefully thought out. In the mouse example, it can be seen that by placing related variables next to each other, the saving of code and execution time is significant. Also, if the RAM data can fit in the first 16 bytes, the load B immediate instruction is also more efficient. The subroutine "SRPTMS" is shown below and it can be seen that more than half the instructions are B register indirect which are efficient and compact.

```

CONCLUSION

The COP822C has been used as a mouse controller. The code presented is a minimum requirement for implementing a mouse systems and microsoft compatible mouse. About 550 bytes of ROM code has been used. The remaining ROM area can be used for internal diagnostics and for communicating with the host's mouse driver program. The unused I/O pins can be used to turn the LED's on only when necessary to save extra power. This report demonstrated the use of the efficient instruction set of the COP800 family. It can be seen that the architecture of the COP822C is most suitable for implementing a mouse controller. The table below summarizes the advantages of the COP822C.

Feature	Advantage
Port G	Schmitt Triggered Input for Photo-Transistors
G0	External Interrupt for RTS Toggling
Timer	For Baud Rate Generation
Low Power	4 mA at 5 MHz
Small Size	20-Pin DIP

REFERENCE

The mouse still reigns over data entry—Electronic Engineering Times, October 1988.

APPENDIX A—MEMORY UTILIZATION

RAM Variables

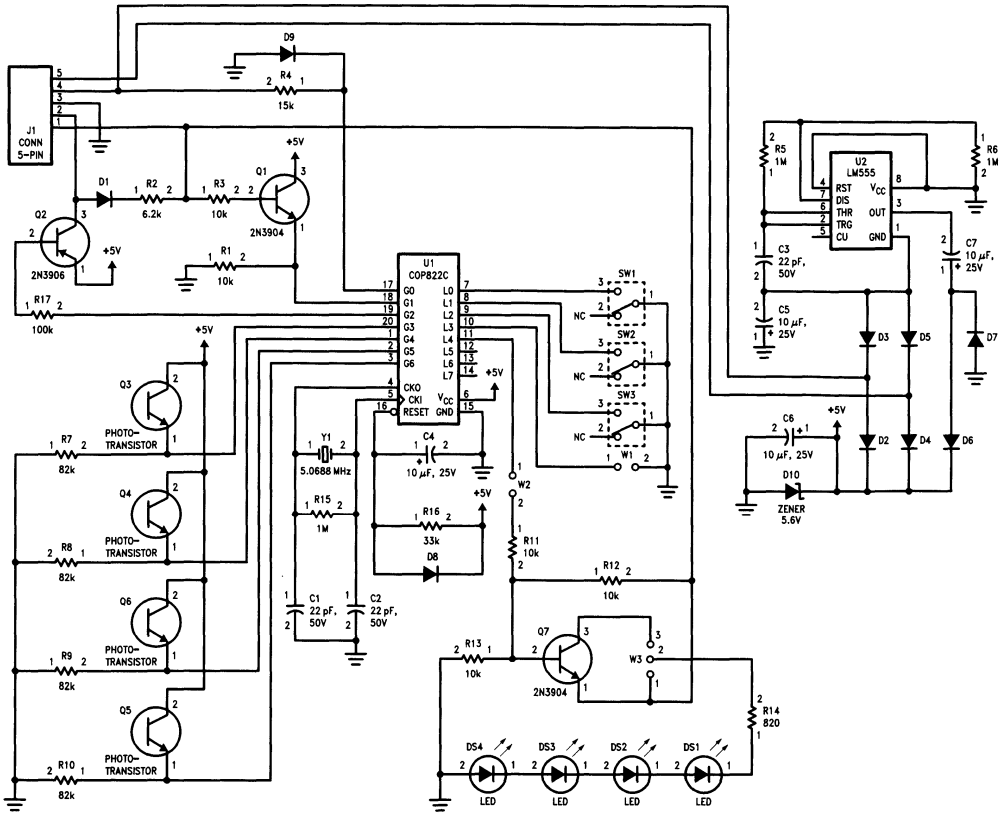
TEMP	=	0F1	Work Space
ASAVE	=	0F4	Save A Register
PSSAVE	=	0F6	Save PSW Register
WORDPT	=	000	Word Pointer
WORD1	=	001	Buffer to Store Report
WORD2	=	002	Buffer
WORD3	=	003	Buffer
CHANGE	=	004	Movement or Button Change
XINC	=	005	X Direction Counter
YINC	=	006	Y Direction Counter
NUMWORD	=	007	Number of Bytes to Send
SENDST	=	008	Serial Protocol State
TSTATUS	=	00A	Counter Status
MTYPE	=	00B	Mouse Type
GTEMP	=	00C	Track Input from G Port
TRACKS	=	00D	Previous Track Status
BTEMP	=	00E	Button Input from L Port
BUTSTAT	=	00F	Previous Button Status

APPENDIX B—SUBROUTINE SUMMARY

Subroutine	Location	Function
MLOOP	03D	Main Program Loop
SENSOR	077	Sample Photo-Transistor Input
INTRP	0FF	Interrupt Service Routines
SRPTUS	136	Set Up Report for Microsoft
SRPTMS	16C	Set Up 1st 3 Bytes Report for Mouse Systems
SDATA	191	Drive Data Transmission Pin According to Bit Value of Report
SY2RPT	1D1	Set Up Last 2 Bytes Report for Mouse Systems
BUTUS	200	Sample Button Input for Microsoft
BUTMS	210	Sample Button Input for Mouse Systems

APPENDIX C—SYSTEM SCHEMATIC, SYSTEM

Flowchart, complete program listing.



TL/DD/10799–5

Note 1: All diodes are 1N4148.

Note 2: All resistor values are in ohms, 5%, 1/8W.

Note: Unless otherwised specified

INTRODUCTION

COP800 devices can be used to control DC stepper motors with limited effort. This application note describes the use of a COP820 to control the speed, direction and rotation angle of a stepper motor. In addition to the COP820, this application requires a quad high current peripheral driver (DS3658) to meet the high current needs of the stepper motor.

DC STEPPER MOTOR

A DC stepper motor translates current pulses into rotor movement. A typical motor contains four winding coils labeled red, yellow/white, red/white, and yellow. Applying current to these windings forces the motor to step. For normal operation, two windings are activated (pulsed) concurrently. The motor moves clockwise one step per change in windings activated with the following activation sequence: red and yellow, yellow and red/white, red/white and yellow/white, yellow/white and red, repeat. Half-steps may be generated by altering the sequence to: red and yellow, yellow, yellow and red/white, red/white, red/white and yellow/white, yellow/white, yellow/white and red, red, repeat. The motor runs in a counterclockwise direction if either sequence is applied in reverse order. The speed of rotation (number of steps/second) is controlled by the frequency of the pulses.

COP820 CONTROL OF STEPPER MOTOR

The COP820 controls the stepper motor by sending pulse sequences to the motor windings in response to control commands. Commands executed by the code in this application include: single step the motor in a clockwise or counterclockwise direction (i.e. rotate the rotor through a certain number of degrees), run the motor continuously at one of four speeds in a clockwise or counterclockwise direction, and stop the motor.

Note: Half-stepping is not implemented in this example.

During continuous mode operation, the 16-bit timer of the COP820 is used to control the speed of the stepper motor. The timer is set up with a value that causes an underflow once every x seconds or at a frequency of 1/x. Each underflow of the timer interrupts the microcontroller. In response to the timer interrupt, the microcontroller generates a new pulse and causes a single step of the motor. Thus the motor steps at the frequency of the timer underflows. This application sets up the timer to generate interrupts at four different frequencies. These frequencies produce the following motor speeds: 25 steps/second, 100 steps/second, 200 steps/second, and 400 steps/second.

The determination of which windings to activate and deactivate to step the motor is performed by a single subroutine in this example. A block of memory is allocated to store a step pointer and the four possible stepper drive values are shown in Table I (9,C,6,3). Consecutive memory locations are used to store the stepper drive values so that applying the value from location X and then location X+1 (or X−1) causes the motor to step once. The motor drive subroutine increments or decrements the pointer to the current drive value based on the selection of a clockwise or counterclockwise direction. Writing the value from the newly selected location to the motor causes a single step of the motor in the appropriate direction.

During single step operation, the microcontroller steps the motor the exact number of times requested in the control command. Each step corresponds to 1.8 degrees of rotor movement. Therefore, a request to perform 200 steps will rotate the rotor through one complete revolution (360 degrees) at a fixed speed.

A block diagram of the application is shown in *Figure 1*. A flowchart of the code used to control the motor is given in *Figure 2*. The complete code is given at the end.

TABLE I. Stepper Motor Drive Sequence

Step	Yellow	Red/White	Yellow/White	Red	Hex Value
0	ON	OFF	OFF	ON	9
1	ON	ON	OFF	OFF	C
2	OFF	ON	ON	OFF	6
3	OFF	OFF	ON	ON	3
4	ON	OFF	OFF	ON	9

MF2 Compatible Keyboard with COP8 Microcontrollers

National Semiconductor
Application Note 734
Volker Soffel

ABSTRACT

This application note describes the implementation of an IBM MF2 compatible keyboard with National Semiconductor's COP888CL or COP943C/COP880CL microcontrollers. Two different solutions have been developed. One solution, suitable for laptop/notebook keyboards is based on the COP888CL with special power saving techniques. The other for most price competitive standard desktop keyboards is based on the COP943C/COP880C microcontrollers. The same principles can be applied to all types of keyboards or data input devices.

FEATURES

- Single chip solution
- Low cost R/C or ceramic oscillator optional
- LED direct drive capability
- I/Os with software programmable on chip pull-ups
- Current saving M2CMOS technology
- Multi-input wakeup and HALT mode for further power consumption reduction (COP888CL only)
- Software key rollover
- Schmitt triggers on keyboard data and clock lines

INTRODUCTION

The expression MF2 keyboard stands for multi-functional keyboard version 2. This type of keyboard was first developed and defined by IBM for use with all types of PC (XT, AT, PS/2). In the meantime it has become an industry standard and today nearly all PCs have an MF2 compatible keyboard. As the name suggests, this keyboard features all operation modes which are necessary to stay compatible with the older XT and AT type keyboards. In the following chapters the features and functions of an MF2 keyboard as well as their implementation with a COP8 microcontroller are described.

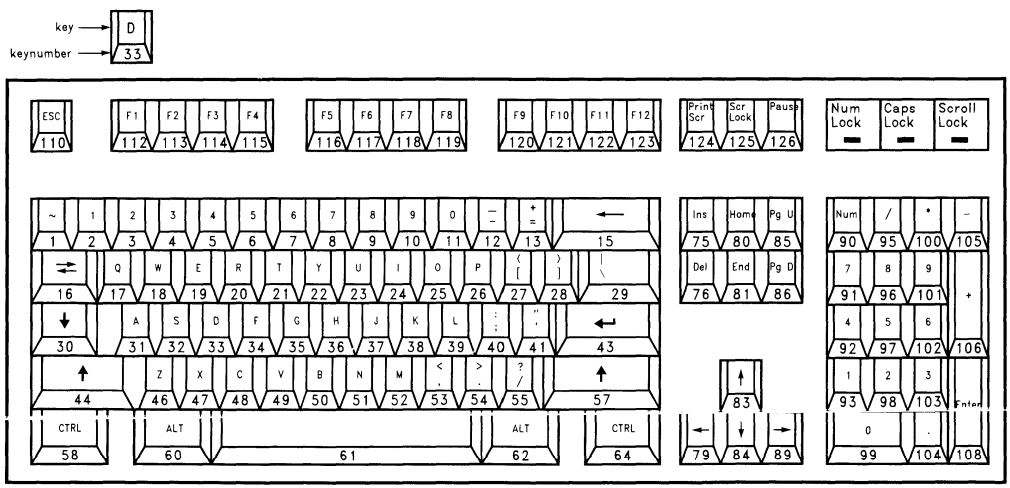
MF2 KEYBOARD KEY-LAYOUT

Figure 1 shows the key layout of the U.S. version of an MF2 keyboard. Its outer appearance is characterized by 101 keys (102 for some countries), a separate cursor and numeric key pad, and 12 function keys in the upper row. The keyboard sends a "make" code if a key is depressed and a "break" code if the key is released. These make and break codes are independent of any country-specific keyboard layouts, which means they are independent of the symbols printed on the keys. These codes are solely determined by the physical position of a key on the keyboard. The physical position of a key on an MF2 keyboard is defined by its assigned key number, which is shown in *Figure 1.*

HARDWARE

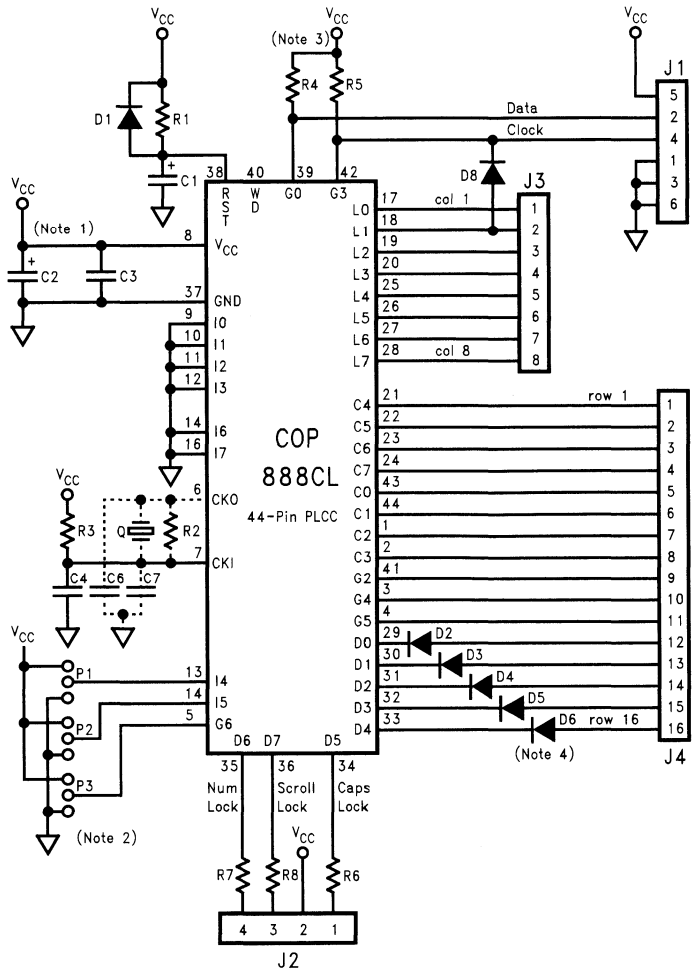
Laptop/Notebook Keyboard With COP888CL

Figure 2 shows the schematics of an MF2 keyboard with a COP888CL microcontroller. The G, C and L ports of the COP888CL are software programmable I/Os and can be programmed either as TRI-STATE® inputs, inputs with weak pull-up, push-pull output low, or push-pull output high.



TL/DD/11091–10

FIGURE 1. MF2 Keyboard U.S. Layout



TL/DD/11091–11

Note 1: C2 (47 μF level off capacitor) can be removed when the power supply ripple < ±10%, 0.5 V/ms.

Note 2: Jumper P1: Mode select: 0 = XT-mode, 1 = AT-mode. Jumper P2, P3: not used.

Note 3: Care must be taken if there are pullups in the computer system that clock/data line current < 3 mA.

Note 4: Diodes D2–D6 should be removed if keyboard has hardware keyrollover (diodes in matrix).

FIGURE 2. MF-2 Keyboard Schematics with a 44-Pin COP888CL

The keyboard is organized as an 8 input by 16 output matrix. The COP888CL's L port is configured as a weak pull-up input port, thus allowing the use of the multi-input wakeup feature. Most of the time the chip is in the current saving HALT mode (Idd $\leq$ 10 μA). Any keystroke or a data transmission from the computer will create a high to low transition on one of the L lines, which wakes up the μC from HALT mode. After returning from the HALT mode, the keyboard is scanned in order to detect which key is pressed and the appropriate key code is sent to the computer. This event-driven keyboard scanning results in lowest possible current consumption as HALT mode is even entered between successive single keystrokes. The diodes in the D-lines of the key matrix prevent a high current from being drawn. When two keys in the same column are pressed, two outputs could be potentially connected together: one of the D output lines, which is high and the polled line, which is pulled low. In this case, excessive current would be drawn without the protection diodes. These diodes can be omitted if the keyboard already has decoupling diodes in its matrix (hardware key rollover). All other matrix lines source current in the μA range and there is no need for current limiting diodes.

The G0 and G3 pins are used for the keyboard data and clock lines. The pull-ups on these lines ensure a defined logic "1" level. The keyboard interface on the computer side uses open collector drivers and the G0, G3 pins of the COP888CL are configured as TRI-STATE (Hi–Z) inputs when a "1" is written to the data or clock line. To output a logic "0" the μC pulls the data or clock line low (push-pull low output). A maximum current of 3 mA can be sunk into the data and clock pins. Schmitt triggers on the data and clock line inputs reduce the risk of errors in the data received by the keyboard.

The microcontroller provides the option of using a low cost R/C oscillator with frequency variation tight enough to fulfill the requirements for a keyboard, in addition to the option of using a crystal or a ceramic clock.

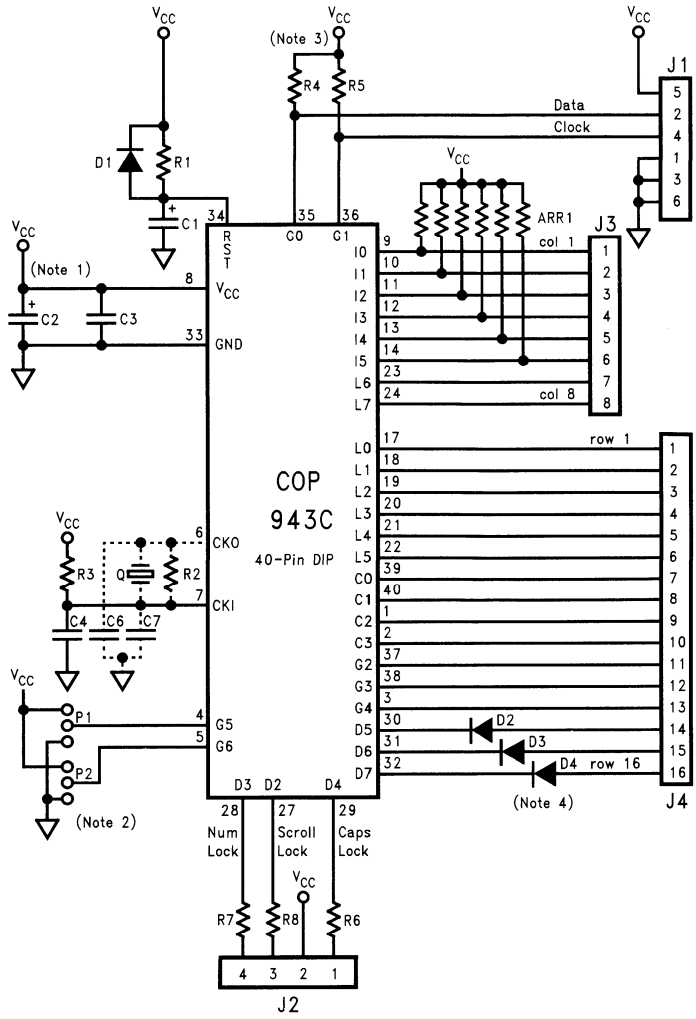
The XT or AT/PS-2 operation mode can be selected via a hardware switch. Additional inputs for customer specific settings are available.

The three LEDs of an MF2 keyboard are driven directly by three of the COP888CL's high sink D-lines (max. 15 mA for each pin), thus eliminating the need for additional LED drivers or transistors.

The keyboard logic generates a Power-On Reset (POR) signal when the power is first applied to the keyboard. After POR the keyboard performs the Basic Assurance Test (BAT). The BAT consists of a keyboard controller self-test. During the BAT, any activity on the data and clock lines is ignored. The 3 keyboard LEDs are turned on at the beginning and turned off at the end of the BAT. Upon satisfactory completion of the BAT, the keyboard sends the BAT completion code (hex AA) to the computer and keyboard scanning begins. Any code other than hex AA is interpreted by the computer as a BAT error.

Desktop Keyboard with COP943C or COP880C

Figure 3 shows the schematic for an MF2 keyboard with the COP943C/COP880C. The only difference compared to COP888CL solution is that the COP943C/COP880C microcontrollers do not have the multi-input wakeup feature, which allows an event driven keyboard scanning. The key matrix is therefore continuously scanned in a loop. With the COP943C/COP880C solution a part of the I port is used as the key matrix input. The I port is a TRI-STATE (Hi–Z) input port (requires external pull-ups).



TL/DD/11091–12

Note 1: C2 (47 μF level off capacitor) can be removed when the power supply ripple < ±10%, 0.5 V/ms.

Note 2: Jumper P1: Mode select: 0 = XT-mode, 1 = AT-mode. Jumper P2: P3: not used.

Note 3: Care must be taken if there are pullups in the computer system that clock/data line current < 3 mA.

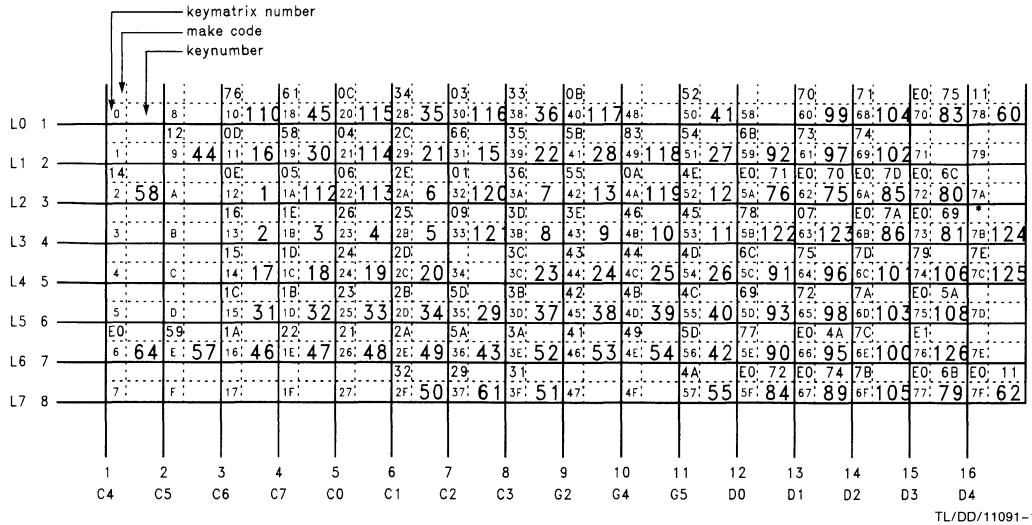
Note 4: Diodes D2–D4 should be removed if keyboard has hardware keyrollover (diodes in matrix).

FIGURE 3. MF-2 Keyboard Schematic with a 40-Pin COP943C/COP880C

Key Matrix Organization

Figure 4 shows an example of what an MF2 keyswitch matrix could look like. Each key position in the matrix is marked with its key number.

For example: Key number "58" is located at the key matrix position number "2" and has the AT-set make code "14 Hex". Looking at *Figure 1,* one can see that key number "58" belongs to the left "CNTRL" key. Note that the "SHIFT", "CNTRL" and "ALT" keys are located in their own matrix lines, separate from all other keys. The reasons for that will be explained in the chapter "Software Key Rollover".



TL/DD/11091–13

FIGURE 4. Keyboard Matrix COP888CL AT Code Set

Code Sets

The MF2 keyboard supports 3 different sets of make and break codes. Code set 1 is used for XT/PC and PS/2–30 compatible computers. Code set 2 is used for AT and all other PS/2 models compatible computers and code set 3 is used for workstations and terminal emulations on the PC. The country specific keyboard driver on the PC side converts the "key position" codes from the keyboard into the ASCII codes that correspond to the characters printed on the keycaps (as long as the right driver is installed on the PC). Appendix 1 gives a complete overview of the key numbers and their make and break codes for all 3 code sets. The symbols of the U.S. keyboard layout are only listed for reference and are different for other country layouts. The break code for code set 1 is equal to the make code with the most significant bit set. The make codes preceded with a "F0 Hex" code give the break codes of code sets 2 and 3.

KEYBOARD SOFTWARE

The software of the keyboard microcontroller can be subdivided into the following five main tasks:

- key detection
- software key rollover
- key decoding and encoding
- keycode transmission
- keyboard command set

Key Detection

Key detection is done by scanning the keyboard matrix in the following way. Sequentially each of the 16 matrix output lines are pulled low, while all the others are high. The 8 matrix input lines are read and the 8-bit input value is compared with the result of the previous scanning of the same matrix output line (a history of the previous scan is kept in the μC's RAM). Thus the keyboard microcontroller's key detection routine detects any key change in that matrix output line (key pressed or released) since the previous scan. It is important to recognize released keys, as the MF2 keyboard not only sends a key's "make" code when the key is pressed, but also a key's "break" code when the key is released. Key debouncing is performed by software by making sure that the time between two scans is bigger than the key bounce time (typically 8 ms).

Software Key Rollover

Software key rollover means that no decoupoing diodes are used in the key switch matrix. However, the keyboard action is still N key rollover in nature. That is, if N keys are depressd in some sequence and held down, the make code of these keys is transmitted in that sequence. However, if three keys from three corners of a rectangle in the key switching matrix are depressed, a "ghost" key (a key which is not really pressed) would be created (see *Figure 5*). To prevent this, a special algorithm, which checks for such special key combinations, has been implemented into the keyboard software. If a "ghost" key has been detected the keyboard outputs the "key detection error code" and the N key rollover reverts to a 2 key rollover. To ensure that all 3-key combinations used on a PC (e.g., CNTRL + ALT + DEL) are still possible, keyboard manufacturers using this method organize the key switch matrix accordingly (an example is given in *Figure 4*).

TL/DD/11091–3

Key Decoding and Encoding

After detection of a key change (pressing or releasing a key), the software first has to determine the physical location of the key in the key matrix. This decoding process is done by calculating an internal key number out of the key matrix column and row position of the changed key. At the same time, it is determined if the key has been pressed or released. A pressed or released key is then signaled by setting or resetting a "key down" flag in RAM. The internal key number and the "key down" status flag are the input parameters to the key encoding procedure. The internal key number is used to get the "make" code for the key out of a ROM look-up table, which has been matched to the physical matrix organization of the keyboard. If the "key down" flag is reset (key is released) the software calculates the key "break" code out of the previously fetched key "make" code. In this way, each pressed or released key is encoded with its appropriate "make" or "break" code, which is then written to the keyboard controllers 16 byte output buffer (FIFO) until the computer interface is ready to receive it. Before writing to the FIFO the software checks whether there is still enough capacity to store the key code.

Key Repetition

All keys are typematic (repetitive) by default. That means when a key is pressed and held down, the μC continues to send the "make" code for that key until it is released. When two or more keys are held down, only the code for the last key pressed is repeated. Typematic operation will stop when this key is released, even if other keys are still held down.

The default values for typematic operation are:

delay time = 500 ms
repetition rate = 10 characters/second,

where the delay time is the time which is inserted before a character is repeated for the first time.

Operating Protocol

There are two different transmission protocols for an MF2 keyboard: the AT transmission protocol and the XT transmission protocol. Data transmission to and from the keyboard is synchronous serial, the data format for the XT mode is:

9 bits in length
1 start bit (high)
8 data bits (LSB first)

The data format for AT and PS/2 modes is:

11 bits in length
1 start bit (low)
8 data bits (LSB first)
1 parity bit (odd)
1 stop bit (high)

If no data is transmitted, both data and clock lines are in the high state. The clock signal is always provided by the keyboard. *Figure 6* shows the XT and the AT protocol timings.

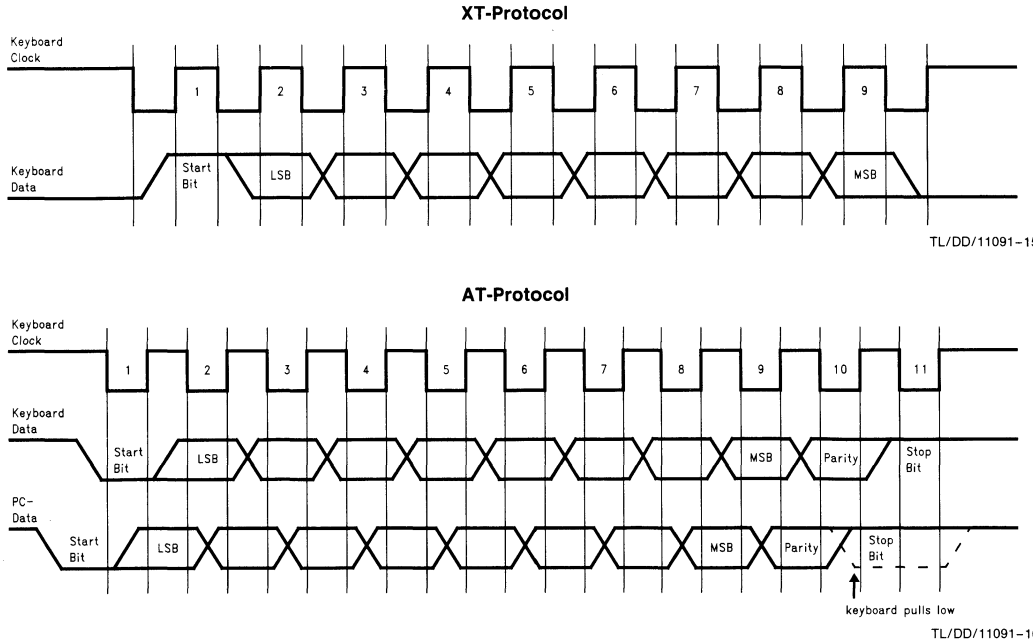

FIGURE 6. XT and AT Protocol Timings

Keyboard Data Transmission in XT Format

At the falling edge of the clock, the start bit (high) is shifted out, followed by the 8 data bits (least significant bit first). Data is valid on the rising edge of the clock and changes after the falling edge of the clock.

Keyboard Data Transmission in AT Format

Before sending data, the keyboard monitors the clock and data lines. If the clock line is low, then the keyboard is disabled by the computer and no data is transmitted. The microcontroller continues to scan the keyboard and stores key data in its output buffer. If the data line is low, while the clock line is high, the computer requests to send and the keyboard goes into receive mode. The keyboard is only allowed to transmit data when both data and clock lines are high.

The keyboard pulls the data line low (start bit) and starts the clock. The 8 data bits (least significant bit first) are shifted out, followed by the parity (odd) and stop bit (high). Data is valid after the falling edge of the clock and changes after the rising edge of the clock. If no data is transmitted both data and clock lines are high. If the computer pulls the clock line low for at least 60 μs before the 10th bit is transmitted, the keyboard stops transmission and stores the aborted data in its output buffer.

Keyboard Receives Data

The keyboard can only receive data from the computer in AT-PS/2 mode. The computer pulls the data line low (start bit) after which the keyboard starts to shift out 11 clock pulses within 15 ms. Transmission has to be completed within 2 ms. Data from the computer changes after the falling edge of the clock and is valid before the rising edge of the clock. After the start bit, 8 data bits (least significant bit first), followed by the parity bit (odd) and the stop bit (high) are shifted out by the computer with the clock signal provided by the keyboard. The keyboard pulls the stop bit low in order to acknowledge the receipt of the data. If a transmission error occurred (parity error or similar) the keyboard issues the "RESEND" command to the PC.

Commands from the Computer

The following table shows the commands and their hexadecimal values the computer may send to the keyboard. Only AT-PS/2 compatible computers can send commands to the keyboard and the keyboard can only receive the commands when operated in the AT-mode.

The commands can be sent to the keyboard at any time. The keyboard responds within 20 ms to any valid transmission with ACK (FA Hex), except for the ECHO command where the keyboard responds with EE Hex, the RESEND command and the reserved commands.

Command	Hex Value
Set/Reset Mode Indicators	ED
Echo	EE
Reserved	EF
Select Alternate Code Set	F0
Reserved	F1
Read Keyboard ID	F2
Set Typematic Rate/Delay	F3
Enable	F4
Default Disable	F5
Set Default	F6
Set All Keys	
Typematic/No Break	F7
Make/Break/No Typematic	F8
Make/No Typematic	F9
Typem./Make/Br.	FA
Set Key Type	
Typematic/No Break	FB
Make/Break/No Typematic	FC
Make/No Typematic	FD
Resend	FE
Reset	FF

In the XT mode the keyboard only accepts the RESET command, which is assumed when the computer pulls the clock line low for at least 10 ms.

Commands to the Computer

The following table shows the commands and their hexadecimal values the keyboard may send to the system.

Command	Hex Value
Key Detection Error/ Buffer Overrun	00 (Code Sets 2 and 3)
Keyboard ID	83AB
BAT Completion Code	AA
BAT Failure Code	FC
Echo	EE
Acknowledge	FA
Resend	FE
Key Detection Error/ Buffer Overrun	FF (Code Set 1)

SUMMARY

When using National Semiconductor's microcontroller to implement the functions of an MF2 keyboard, very few external components are necessary. *Figure 2* shows the complete schematic of an MF2 keyboard based on the COP888CL. The implementation of software key rollover eliminates the need for decoupling diodes in the 16 by 8 key matrix. LED direct drive capability of the COP8 and a RC oscillator with tolerances tight enough to meet the requirements for a keyboard further reduce component count and price. Schmitt triggers on the ports used for the keyboards data and clock lines add additional security against transmission errors. Where low power consumption is the most important design factor (e.g., laptop or notebook computers) the COP8's M2CMOS technology and the multi-input wakeup feature offer a remarkable improvement over the NMOS controllers used in most of today's existing solutions.

National Semiconductor offers three chips tailored for the needs of a keyboard designer. Starting with the most price competitive 2.5k ROM device COP943C, an upgrade path is provided with the COP880C to 4k ROM. Both devices are intended for the use in standard MF2 desktop keyboards. The COP888CL is ideally suited for notebook or laptop keyboards, as it has special power saving features. The complete software for an MF2 keyboard as well as complete demo keyboards and keyboard evaluation boards for the COP888CL and COP943C/COP880C microcontrollers are available. Contact National Semiconductor's μC marketing or applications for further information.

RS-232C Interface with COP800

National Semiconductor
Application Note 739
Michelle Giles

INTRODUCTION

This application note describes an implementation of the RS-232C interface with a COP888CG. The COP888CG 8-bit microcontroller features three 16-bit timer/counters, MICROWIRE/PLUS™ Serial I/O, multi-source vectored interrupt capability, two comparators, a full duplex UART, and two power saving modes (HALT and IDLE). The COP888CG feature set allows for efficient handling of RS-232C hardware handshaking and serial data transmission/reception.

SYSTEM OVERVIEW

In this application, a COP888CG is connected to a terminal using the standard RS-232C interface. The serial port of the terminal is attached to the COP888CG interface hardware using a standard ribbon cable with DB-25 connectors on either end. The terminal keyboard transmits ASCII characters via the cable to the COP888CG interface. All characters received by the COP888CG are echoed back to the terminal screen. If the COP888CG detects a parity or framing error, it transmits an error message back to the terminal screen.

HARDWARE DESCRIPTION

The COP888CG features used in this application include the user programmable UART, the 8-bit configurable L PORT, and vectored interrupts. In addition to the COP888CG, the RS-232C interface requires a DS14C88 driver and a DS14C89A receiver. The DS14C88 converts TTL/CMOS level signals to RS-232C defined levels and the DS14C89A does the opposite. *Figure 1* contains a diagram of the COP888CG interface hardware.

The COP888CG is configured as data communications equipment (DCE) and the terminal is assumed to be data terminal equipment (DTE). The following RS-232C signals are used to communicate between the COP888CG (DCE) and the terminal (DTE):

RS-232C Signal Name	Signal Origin
TxD (Transmit Data)	DTE
RxD (Receive Data)	DCE
CTS (Clear To Send)	DCE
RTS (Request To Send)	DTE
DSR (Data Set Ready)	DCE
DTR (Data Terminal Ready)	DTE
DCD (Data Carrier Detect)	DCE

Five general purpose I/O pins on the COP888CG L PORT are used for the control signals CTS, DSR, DCD, RTS and DTR. Two additional L PORT pins are used for TxD and RxD. These two general purpose pins are configured for their alternate functions, UART transmit (TDX) and UART receive (RDX). According to the RS-232C interface standard, DCE transmits data to DTE on RxD and receives data from DTE on TxD. Therefore, the UART transmit data pin (TDX) is used for the RS-232C receive data signal (RxD) and the UART receive data pin (RDX) is used for the RS-232C transmit data signal (TxD). In this example, all handshaking between DCE and DTE is performed in hardware.

The terminal is setup to interface with the COP888CG by selecting the 9600 baud, 7 bits/character, odd parity and one stop bit options. The local echo back of characters is disabled to allow the COP888CG to perform the echo back function. The terminal is also configured to use the hardware control signals (CTS, DSR, RTS, DTR) for handshaking.

SOFTWARE DESCRIPTION

The software for this application consists of an initialization routine, several interrupt routines, and a disable routine. These routines handle RS-232C handshaking, transmitting and receiving of characters, error checking, and echoing back of received characters. *Figures 2* thru *5* contain flowcharts of the routines. The complete code is given at the end of this application note.

The initialization routine configures the UART, initializes the transmit/receive data buffer, and enables the 8-bit L PORT handling of RS-232C control signals. In this particular example, the UART is configured to operate at 9600 BAUD in full duplex, asynchronous mode. The framing format is chosen to be: 7 bits/character, odd parity, and one stop bit. Different baud rates, modes of operation, and framing formats may be selected by setting the ENUCMD, ENUICMD, BAUDVAL and PSRVAL constants located at the beginning of the code to alternative values. (Refer to the COP888CG data sheet or COP888 Family User's Manual for details on configuring the UART.) Each RS-232C control signal is assigned to an L PORT pin. Pins L0, L2, L5 and L6 are configured as outputs for the DCD, TxD, CTS and DSR signals, respectively. Pins L3, L4 and L7 are configured as inputs for TxD, RTS and DTR, respectively. The transmit/receive data buffer is a circular buffer whose location and size is selected by setting the START and END constants located at the beginning of the program. The initialization routine sets up the buffer based on these constants.

The interrupt routines respond to transmit buffer empty, receive buffer full, and L PORT interrupts. A generic context switching routine is used for entering and exiting all interrupts. This routine saves the contents of the accumulator, the PSW register and the B pointer before vectoring to the appropriate interrupt routine. It also restores the contents of saved registers before a return from interrupt is executed.

The UART transmitter interrupt is called when the transmit buffer empty flag (TBMT) is set. This routine checks for active RTS and DTR control signals. If both signals are active and there is data to be transmitted, a byte of data is loaded into the UART transmit buffer. Otherwise, the UART transmitter is disabled.

The L PORT interrupts are used to indicate an active-low transition of RTS and/or DTR. When both signals are active (the remote receiver is ready to accept data), this routine enables the UART transmitter.

The UART receiver interrupt routine is called when the receive buffer full flag (RBFL) is set. This routine reads the

UART receive buffer and checks for errors. If no errors are detected, the incoming data is placed in the data buffer for echoing. If errors are detected, an error message is queued for transmission.

The receiver interrupt disables the remote transmitter by deactivating CTS whenever the transmit/receive data buffer is almost full. This action prevents the data buffer from overflowing. Note that CTS is turned off before the buffer is completely full to insure buffer space will exist for storing characters which are in the process of being sent when CTS is deactivated.

The disable routine clears the UART control registers, disables the L PORT interrupts, and de-activates the RS-232C control signals.

CONCLUSION

The user configurable UART, multiple external interrupt capabilities, and vectored interrupt scheme of the COP888CG microcontroller allow for an efficient implementation of the RS-232C interface standard. This application note shows how the COP888CG may be configured for connection to a terminal using these features. However, the code for this application can be easily adapted to other applications requiring different baud rates or framing formats, connection to a modem (DCE), separate transmit and receive buffers, incoming command decoding and/or handling of character strings. The versatility of the RS-232C standard and the COP888CG provides a means to develop practical solutions for many applications.

NM95C12 Flexibility in Industrial Control Applications

National Semiconductor
Application Note 755
Sean Long

INTRODUCTION

This application note describes a general purpose industrial controller and details how a NM95C12 can be used to integrate a number of different functions typically found in such a design.

General purpose application examples of the use of the NM95C12 are presented rather than a specific design. Each design idea and software can be incorporated into the designer's required application.

The basic building blocks of an industrial controller (for example, heating, process control, etc.) are a microcontroller, an Analogue to Digital Converter (ADC), an EEPROM, a display (LCD, LED, etc.), I/O interfaces, and power driver/control circuits. The NM95C12 forms the basis of this design performing the non-volatile parameter storage, a low cost ADC, an I/O expander, and providing a simple control interface.

Figure 1 shows the basic block diagram with the shaded parts representing the functions performed by the NM95C12.

This application note will describe the theory of operation behind the design and give detailed software examples to show how to interface a popular microcontroller to the NM95C12.

COP820/NM95C12 Industrial Controller

THE NM95C12 1024-BIT CMOS EEPROM WITH DIP SWITCHES

The NM95C12 features 1K-bit EEPROM memory with 8 switch logic terminals. These switch logic terminals are individually programmable outputs which may be used as DIP switch positions or as SPST switch positions.

The NM5C12 uses the MICROWIRE™ serial I/O interface which is fully compatible with COPS™ microcontrollers via 4 simple control lines:

SK — Serial Clock
CS — Chip Select
DI — Data In
DO — Data Out

The EPROM array (addresses 0 to 60) is addressed via five instructions:

READ — Read Data from register
WEN — Write enable
WRITE — Writes data to register
WRALL — Writes to all registers
WDS — Disables all programming instructions

This area of memory is used for the normal EEPROM applications such as the storage of user changeable, non-volatile parameters such as time on/off, temperature on/off limits, etc.

CONTROLLING THE SWITCH LOGIC

Address locations 61 to 63 control the switch operation.

Address	Name	Description
61	ISS	Provides the initial switch configuration automatically on power-up. Controlled via a WRITE operation.
62	SCR	The SCR is not an E2 location and hence is volatile. The SCR is loaded automatically from address 61 on power-up. The SCR controls the switch terminals A1–A4 and B1–B4.
63	SRR	The SRR allows the current logic levels of the switch terminals to be read back via the MICROWIRE bus.

THEORY OF OPERATION

The relationship for charge of a capacitor is as follows:

Charge (Q) = Voltage (V) × Capacitance (C)
= Current (I) × Time (T)

Therefore the voltage across the capacitor, V_{CAP}

$V_{CAP} = (I \times T)/C$

Assuming that the current I is a constant source, and the capacitance value C does not vary gives:

V_{CAP} is proportional to T.

Mode of Operation

— initially switch S1 is closed to short out V_{CAP} to measure input voltage V_{IN}

To Measure V_{IN}:

— microcontroller opens S1 and starts internal timer at T1
— V_{CAP} is proportional to time T
— when $V_{CAP} > V_{IN}$ then comparator output V_{COMP} goes high
— microcontroller stops internal timer at T2
— V_{IN} is proportional to time T = T2 − T1
— microcontroller closes S1 ready for next measurement

CURRENT SOURCE/VOLTAGE COMPARATOR FOR ADC

This is based on a LM932 which has an Operational Amplifier and a Voltage Comparator in the same 8-pin package. This device operates from a single +5V supply.

Refer to the National Semiconductor General Purpose Linear Databook for further details of the LM392.

INPUT SENSOR

For this example assume temperature needs to be controlled.

LM335: This is a precision, low-cost, easily calibrated two terminal temperature sensor that behaves like a zener diode with a voltage of +10 mV/degree Kelvin. The initial accuracy is ±1° and can be externally trimmed with a potentiometer connected to the ADJ pin.

Refer to the National Semiconductor Linear Databook 2 for further details of the LM335 Temperature Sensors.

NM95C12 SWITCH LOGIC APPLICATIONS/ CONFIGURATIONS

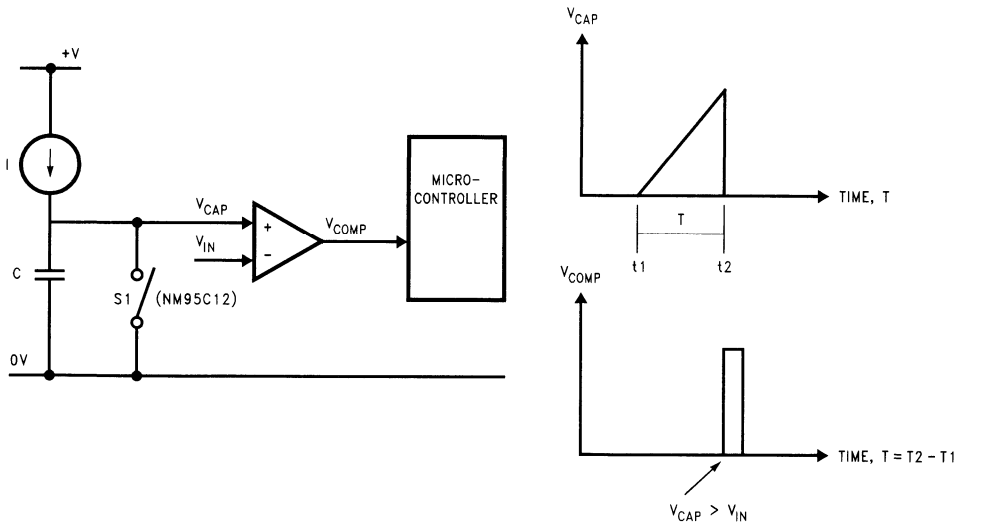
A_1, B_1—Control the Charge/Discharge of Capacitor for ADC

Switch Configuration:

Analog Switch Open: Mode 12, ZYXW = 110?
(? = don't care)

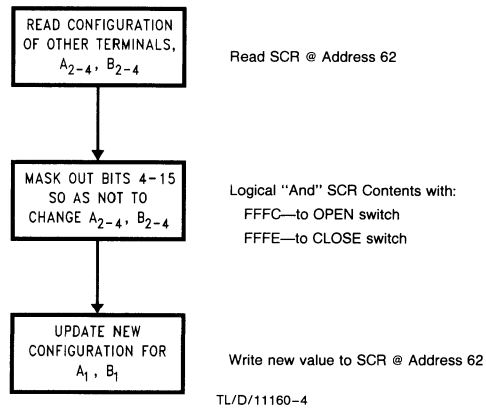
Analog Switch Closed: Mode 13, ZYXW = 111?

To change the state of the switch terminals A_1, B_1, follow the flowchart in *Figure 3*.



TL/D/11160–3

FIGURE 2. Single Slope Analogue to Digital Converter



TL/D/11160–4

FIGURE 3. Controlling Switch Terminals A1, B1

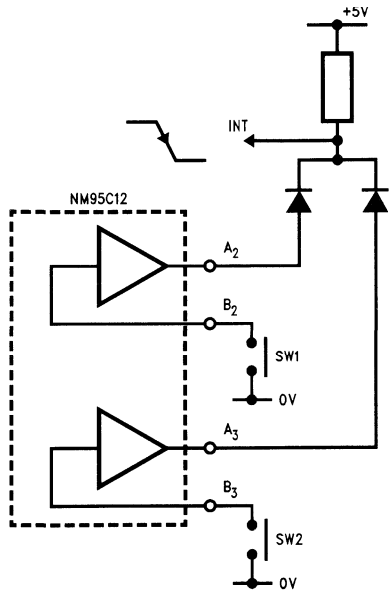
A_2, B_2 and A_3, B_3 — Switch Debouncing

The switch logic configuration is shown in *Figure 4*. When either of the mechanical switches SW1 or SW2 are pressed, this causes the interrupt line (INT) to be pulled low signalling to the microcontroller that a switch has been pressed. As part of the interrupt service routine the microcontroller can generate a delay to allow time for mechanical switch debouncing, before reading the NM95C12 SRR to determine which mechanical switch was pressed.

The advantage of this design is that it saves input pins on the microcontroller and means that the software does not have to perform periodic polling of the inputs to determine the mechanical switch status since the circuit is interrupt driven.

Switch Configuration: both A_2,B_2 and A_3,B_3 will be configured in mode 5; ZYXW = 0101.

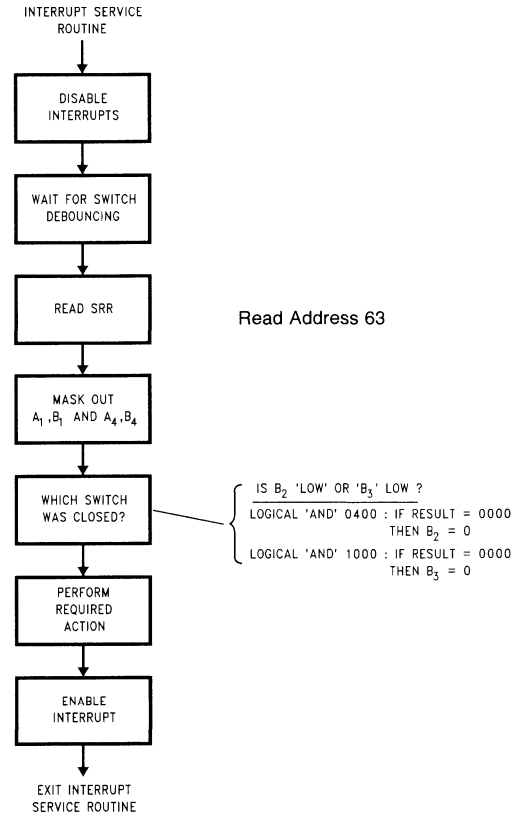
To change the state of the switch terminals A_2,B_2 and A_3,B_3 follow the flowchart in *Figure 5*.



TL/D/11160–5

A_2,B_2, A_3,B_3 Configured in mode 5, ZYXW = 0101

FIGURE 4. Switching Conditioning



TL/D/11160–6

FIGURE 5. Controlling Switch Terminals A_2,B_2, A_3,B_3

A_4,B_4 Programmable I/O

These two terminals use mode 1 to 4 according to the logic level required on the output. In this example A_4 is used for the Display Chip Select signal and B_4 is used for the Display On/Off control signal.

In order to update and display the contents of the Display then both terminals A_4 and B_4 need to be set to a logic "1" therefore A_4,B_4 are configured in mode 3 with ZYXW = 0011.

To change the state of the switch terminals A_2,B_2 and A_3,B_3 follow the flowchart in *Figure 6*.

SOFTWARE TO INTERFACING THE NM95C12 TO THE COP820 MICROCONTROLLER

This section includes a number of subroutines to interface to a NM95C12 as described in the design example above. There are subroutines to implement each of the basic instructions together with routines for configuring and controlling the switch logic. These subroutines can be used as the basis for a design and be tailored to meet the individual application requirements.

CONCLUSION

The NM95C12 is an extremely versatile and inexpensive device which allows simple interfacing to all popular microcontrollers and microprocessors via a 4-wire serial bus. The complete operation of the NM95C12 can be controlled by a few simple instructions.

The design outlined offers an inexpensive solution for industrial control applications with the key benefits of:

— simple interfacing between microcontroller, EEPROM, "ADC"

— low part count

— fully software controlled and changeable

This has highlighted the flexibility of the NM95C12 and how the switch terminals can be configured for a wide range of applications including: mechanical switch replacement, programmable Address Decoder, programmable I/O expander and a programmable interrupt controller. The NM95C12 offers greater reliability than mechanical switches with the benefits of software control and lower cost.

Plus you still get the 1K-bit EEPROM memory as well!; together with the 8 switch terminals it forms a truly remarkable device.

Using National's MICROWIRE™ EEPROM

National Semiconductor
Application Note 758
Paul Bryant

National Semiconductor manufactures a wide range of low density serial EEPROMs that use the MICROWIRE interface as a means of communication. Although all of these devices use the MICROWIRE interface, there are slight variations in interfacing due to differences in memory sizes, features, and technology used to implement the device. Additionally, the MICROWIRE interface does not specifically define any protocol, it only defines a basic set of signal lines to interconnect two or more devices. Due to these reasons, additional information is necessary to fully understand how to best interface to National's family of MICROWIRE EEPROM.

The goal of this application guide is to cover a diversity of information in regard to basic timing, interfacing options, and functionality of different EEPROMs. I will use an outline approach, so the appropriate heading can be located easily. Each section attempts to be stand alone so the information can be easily extracted. The outline appears below:

4.0 CONCLUSION

1.0 Description of EEPROM Families

1.1 CMOS EEPROM

National builds a range of MICROWIRE CMOS EEPROMs in memory sizes ranging from 256-bit to 16,384-bit. The NM93C family is the base family and the NM93CS is a similar family with additional features, there are also other devices with slight variations on the interface. All these devices are available with certain "standard" options such as operating temperature ranges and operating voltage ranges, packaging options and test options. These options being fairly standard variations for semiconductor devices, will not be addressed beyond this. The purpose of this article is to address basic functionality and interfacing, including various tricks to simplify or modify the interface.

1.1 NM93C Family

The NM93C family of EEPROM is available in 256-, 1024-, 2048-, 4096-bit, and 16,384-bit sizes. All of these are internally organized in 16-bit words, therefore all data transactions deal with 16 bits. This family of EEPROMs has 7 instructions that deal with read, write, and a basic level of data protection. The instructions are listed in Table I. It is important to note that there is a basic difference in length of the instruction between the NM93C06 or NM93C46 and the NM93C56 or NM93C66. This is due to the larger devices needing additional address bits.

The NM93C family of EEPROM, like all of National's serial EEPROMs have a basic level of write protection that can be turned on or off by the use of the ERASE/WRITE DISABLE (EWDS) and ERASE/WRITE ENABLE (EWEN) instructions. Although there are two erase instructions included in the NM93C family, these are included only for compatibility with older EEPROMs that require erase before write. These EEPROMs don't require erase before write and it is recommended that in application the erase not be used as this adversely affects endurance.

1.3 NM93CS Family

The NM93CS EEPROMs are available in 256-, 1024-, 2048-, and 4096-bit sizes. Making them different, they have two additional functions, sequential read and user configurable write protection, and don't have either of the erase functions, ERASE and ERASE-ALL as they are not needed. Like all of the CMOS EEPROMs, these have self timed programming cycles and operate from a single external supply of either 4.5V to 5.5V or 2.7V to 5.5V. In these devices it is necessary to eliminate the erase cycles from the code as they may adversely affect the performance of the device.

As these have additional functions, the instruction set includes a total of 10 instructions, 3 that operate on the memory array, 2 that deal with the basic write protection and 5 that deal with the user configurable write protection. Refer

to the NM93CS instruction set table (Table II) for definitions of these instructions. As with the NM93C family, there is a basic difference in instruction length depending on memory size.

To further increase data security in these EEPROMs there are also two additional input signals defined, Program Enable (PE) and Protect Register Enable (PRE). These signals are on pins that are unused on the NM93C family providing upward compatibility to the NM93CS devices.

TABLE I. NM93C Family Instruction Set Table

Instruction	SB	Op Code	Address	Data	Comments
READ	1	10	A7/A5–A0		Reads data stored in memory.
EWEN	1	00	11XXXX		Write enable must precede all programming modes.
ERASE	1	11	A5–A0		Erase register A5A4A3A2A1A0.
WRITE	1	01	A5–A0	D15–D0	Writes register.
ERAL	1	00	10XXXX		Erase all registers.
WRAL	1	00	01XXXX	D15–D0	Writes all registers.
EWDS	1	00	00XXXX		Disables all programming instructions.

TABLE II. NM93CS Family Instruction Set Table

Instruction	SB	Op Code	Address	Data	PRE	PE	Comments
READ	1	10	A5–A0		0	X	Reads data stored in memory, starting at specified address.
WEN	1	00	11XXXX		0	1	Write enable must precede all programming modes.
WRITE	1	01	A5–A0	D15–D0	0	1	Writes register if address is unprotected.
WRALL	1	00	01XXXX	D15–D0	0	1	Writes all registers. Valid only when Protect Register is cleared.
WDS	1	00	00XXXX		0	X	Disables all programming instructions.
PRREAD	1	10	XXXXXX		1	X	Reads address stored in Protect Register.
PREN	1	00	11XXXX		1	1	Must immediately precede PRCLEAR, PRWRITE, and PRDS instructions.
PRCLEAR	1	11	111111		1	1	Clears the Protect Register so that no registers are protected from WRITE.
PRWRITE	1	01	A5–A0		1	1	Program address into Protect Register. Thereafter, memory addresses $\geq$ the address in Protect Register are protected from WRITE.
PRDS	1	00	000000		1	1	One time only instruction after which the address in the Protect Register cannot be altered.

1.4 NM93CxxA Family

There are two variations on the standard implementation of the Microwire bus. Both variations can be viewed as enhancements. The first enhancement is a Organization (ORG) input that allows the user to select the internal configuration of the memory as either 8 bits wide or 16 bits wide. When the input is high or unconnected, the device is configured as 16 bits wide, when the ORG input is at a low level, the memory is configured as 8 bits wide, but twice as deep. The feature is present on the NM93C46A, NM93C56A, NM93C66A, and NM93C86A.

The second variation is the STATUS output. This is the Busy/Ready polling to indicate programming status. All other devices have this feature on the Data-Out (DO) output, the NM59C11 alone has status available as a separate output and not on the Data-Out output. This can simplify interfacing to a bidirectional data bus.

2.0 Hardware Connection

2.1 INTERFACE PIN DESCRIPTIONS

In this section, each possible input or output will be described followed by the most popular variations of bus connections. Not all devices have all of the described I/Os. The I/Os are available according to Table III, I/O Functionality.

2.1.1 CHIP SELECT (CS)

Chip Select is used to differentiate between various devices on the same Microwire bus. In the case of EEPROM it cannot be tied high even if it is the only device on the bus as it performs several additional functions. As it applies to any of the Microwire EEPROMs, the rising edge resets the internal circuitry of the device, a function necessary prior to initiating any new cycle. As shown in the functional block diagram *(Figure 1)* chip select also gates the data input and clock input, thus disabling these functions.

During the course of clocking in the start bit, op-code address and data-in or data-out, chip select must be held high continuously, otherwise the internal circuits will be reset and the cycle will have to be started again with a new start bit.

During programming cycles chip select initiates the internal programming cycle. The falling edge of chip select will start the internal programming cycle when a programming opcode has been entered (Erase, Write, Erase All, Write All) and then, in conjunction with Data-Out (DO), will indicate if programming is complete (except the NMOS NMC9306). If programming is complete, Data-Out will drive high, if incomplete it will drive low. In the case of the NMC9306, the user must provide the programming time and in this case chip select must be held low for a minimum of 10 ms, then brought high and clocked to end the programming cycle.

Several additional notes in regard to chip select:

If a programming cycle is partially clocked in and then chip select dropped, the EEPROM may enter into a programming mode. This is determined by how many bits have been clocked in when chip select is dropped. If the start bit, opcode, and all of the address has been clocked in, a programming cycle will be initiated with no or partial data. If less than a complete address has been clocked in, the programming cycle will not be initiated. Refer to *Figure 2*, reference line 1.

In the case of the NM59C11, a programming cycle will not be entered unless a full data field has been clocked in. A full data field may be either 8 or 16 bits depending on the logic level present at the ORG input. A programming cycle will be entered at reference line 2 in *Figure 2* for the NM59C11.

Chip select hold time at the end of a cycle is referenced to the last rising edge of clock (SK). The hold time from the rising edge is the same as the minimum SK high time for the particular device. This is stated in the datasheets as 0 ns hold time from the falling edge of SK which assumes that SK high time is always minimum. In this case SK can be left in the high state or taken low at a later time. Internally chip select gates SK, therefore SK is not critical.

TABLE III. I/O Functionality by Device

	CS	SK	DI	DO	PE	PRE	ORG	STAT
NMC9306	X	X	X	X				
NMC9346	X	X	X	X				
NM93C Family	X	X	X	X				
NM93CS Family	X	X	X	X	X	X		
NM93C46A	X	X	X	X			X	
NM59C11	X	X	X	X			X	X

TL/D/11169–2

FIGURE 2. Programming Cycle Point of No Return

2.1.2 SERIAL CLOCK (SK)

The clock input is used to clock all data, address, op-code, and start bits into or out of the EEPROMs. SK clocks both input and output on the rising edge only, the falling edge has no effect on the devices. The only function it is not necessary for is the Busy/Ready Polling which is an asynchronous function.

Since SK is gated by ship select, it is a "Don't Care" any time chip select is low. It is also don't care prior to a start bit being clocked in and during Busy/Ready Polling. During these conditions Data-In (DI) must be held at a low level, otherwise a start bit will be interpreted.

If it is desirable to insert additional clock cycles during a instruction sequence for the purpose of byte aligning the data, there are several places in the data stream they may be inserted as described below:

— On any instruction, zeros can be clocked into the DI input before the start bit. Any number of clock cycles may be added if Data-In (DI) is held at zero. The first 1 clocked in will be interpreted as the start bit. This requires special precautions if a bidirectional data bus is used (Data-In tied to Data-Out) as the Busy/Ready Polling will interfere with the Data-In if it is not cleared out at the end of each programming cycle. See Section 2.3, THREE WIRE BUS, for more information.

— During a Read instruction, it is allowable to continue to clock the device after the 16 bits of data has been clocked out. In the case of the NM93CS family this will cause the memory to increment to the next register and present its contents on the Data-Out pin. In the case of all other devices, whatever was present on the Data-In pin will become present on the Data-Out pin (Fall thru). Refer to *Figure 1,* Block Diagram.

— During a Write or Write-All, additional clock cycles may be added after address A0 and before the valid data. The EEPROM will write into the memory the most recent 16 bits, or in the case of the NM93C46A, the most recent 8 bits or 16 bits depending on the status of the ORG input. Adding additional clocks after the valid data will cause the data to be misaligned. In the case of the NM59C11, the device counts the data bits clocked in and automatically enters the programming mode when it receives a full data field, therefore bits cannot be inserted between A0 and valid data.

— During the EWEN, Erase, Erase All, EWDS, WEN, WDS cycles, it is not necessary to clock in a data field, although it is mandatory to clock in a complete address field, even if the addresses are "Don't Care". Additional clocks can be added after the address field.

2.1.3 DATA-IN (DI)

The Data-In input receives the Start-Bit, Address, and input data in a serial stream, each bit clocked in on the rising edge of SK. DI is gated by the chip select to provide a high degree of noise immunity. As shown in the block diagram, Data-In is routed to both the instruction shift register and the data shift register. When the start bit is clocked into the last bit of the instruction register, the clock is switched to the data register to receive input data and clock data out simultaneous. The Data-Out remains in high impedance unless a read cycle or Busy/Ready status is being done. The safest state is to keep the Data-In pin in a low level as a start bit is a high level.

2.1.4 DATA-OUT (DO)

The Data-Out (DO) output sends read data onto the microwire bus and is clocked out on the rising edge of SK. It also carries the programming status after a programming cycle which is an asynchronous function that does not require the clock. At all other times the Data-Out is in the high impedance state. During a Read cycle, the Data-Out output begins to drive actively after the last address bit (A0) is clocked in. During the Busy/Ready polling it begins to drive active after chip select is raised to a high level.

During the Busy/Ready Polling, the Data-Out output drives low while the device is still in the internal programming cycle. After the EEPROM has completed the internal programming cycle, the Data-Out pin will drive high when chip select is high. Subsequently, if chip select is brought high again, Data-Out will again drive high indicating it has completed the programming cycle. To clear the Busy/Ready Polling it is necessary to raise chip select and clock in a start bit. Once the start bit is clocked in, Data-Out will return to the high impedance state. It is not necessary to continue with a cycle after this start bit has been clocked in, although it is permissible to start a new cycle with this start bit. This clearing of the Busy/Ready status may be necessary if a bidirectional data bus is used (Data-In tied to Data-Out) as the Data-Out output will interfere with the new data being presented on the Data-In input.

2.1.5 PROGRAM ENABLE (PE)

The program enable (PE) input will enable all programming cycles when it is held at a high level during the duration of a programming cycle. Conversely, it will disable all programming, including programming of the protect register, while it is held low. This input has no affect on any other cycle, so it may be permanently tied high or low, or may be used in an active mode. This input is available on the NM93CS family only.

2.1.6 PROTECT REGISTER ENABLE (PRE)

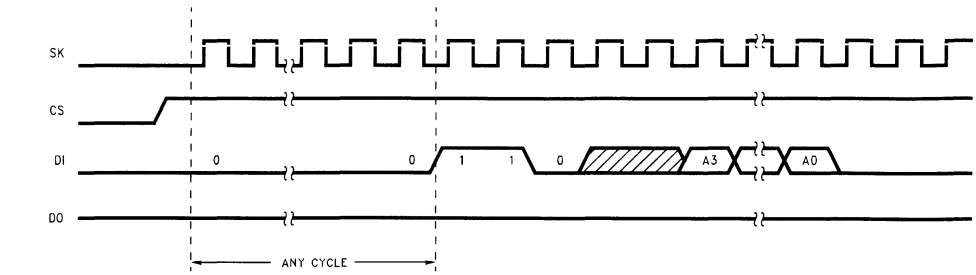
The protect register enable (PRE) input is used to switch between memory operations and protect register operations since the same op-codes are used for both. With the PRE input high, the op-codes define operations in the protect register, with the PRE input low, the op-codes define operations in the memory. This pin may be tied high or low, or used in the active mode. This input is available on the NM93CS family only.

2.1.7 ORGANIZATION (ORG)

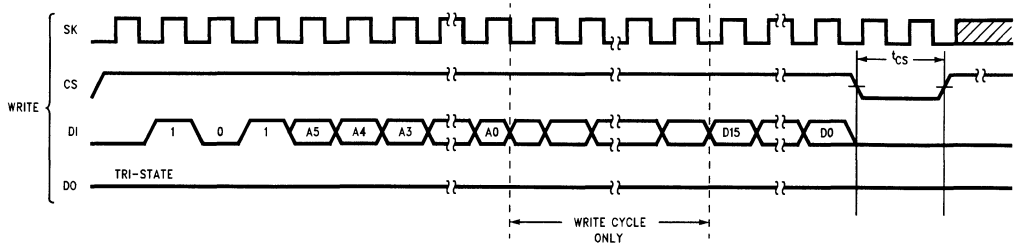
The Organization input (ORG) is used to control the internal organization of the memory. The two selectable organizations are 16-bit words and 8-bit words. Simply by holding the ORG pin at a high level, 16-bit words are selected, by holding the input at a low level 8-bit words are selected. When in the 8-bit mode, one additional address bit is required in the instruction sequence since the depth of the memory is doubled. This input is available only on certain device types, refer to the individual datasheets.

2.1.8 STATUS (RDY/BUSY)

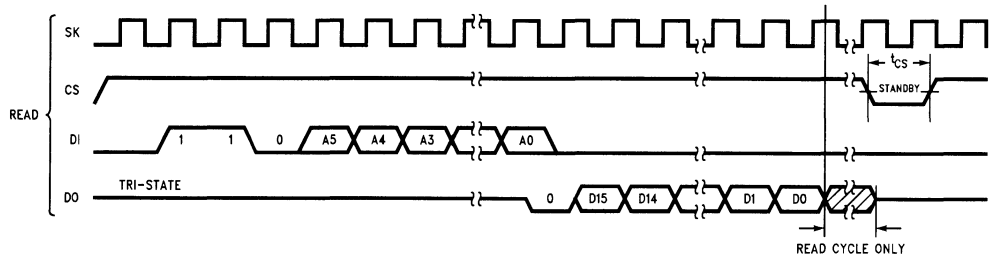
The status output indicates the programming cycle status after a programming cycle. When the device is in the programming mode and therefore cannot accept any other cycles, this pin will be low. After completion of the cycle the STATUS pin will be driven high. When this function is present, the Busy/Ready Polling is not available on the Data-Out



TL/D/11169–3



TL/D/11169–4



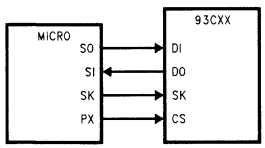
TL/D/11169–5

FIGURE 3. Possible Locations for Additional SK Cycles

output. In some systems, particularly those using a bi-directional data bus, this can simplify interfacing by eliminating the possible contention between the Ready indication and the incoming data from the host device. This output is available only on certain device types, refer to the individual datasheets.

2.2 FOUR WIRE BUS

The 4 wire bus is the simplest interconnection between the EEPROM and the host device. In most cases the only signals necessary to provide are clock, chip select, Data-In and Data-Out as shown in *Figure 5.* The PRE, PE, ORG, and STATUS pins are not shown as they are variations on this and the 3 wire bus connection. Multiple devices can be connected to the microwire bus, the only limitations being loading and available chip select means. In some systems it is necessary to have a bi-directional data line as described below in 3 wire bus.



TL/D/11169–7

FIGURE 5. Four Wire Connection

2.3 THREE WIRE BUS

The 3 wire bus operates in the same mode as the 4 wire bus with the exception that the Data-In and Data-Out pins on the EEPROM are tied together. When using this connection, there are two precautions that need to be observed.

— When Data-In is tied to Data-Out, there is a possible conflict between address A0 in the instruction sequence and the dummy bit. This only occurs during a READ cycle. This is not harmful to the device and the internal circuitry of the EEPROM guarantees that the device will function properly under this condition. To decrease the noise created by the condition, a resistor may be placed in the locations indicated in *Figure 6.* The timing diagram in *Figure 7* shows the bus conflict.

— The second possible area of conflict occurs when the Busy/Ready status is on the Data-Out output. Since the device will continue to indicate a Ready status indefinitely after a programming cycle (until a start-bit is clocked in), this can conflict with the beginning of the next cycle if leading zeros are clocked in (See *Figure 7*). The solution is to either use a separate cycle to clear the Ready bit or to eliminate any leading zeros from the instruction sequence. If the Busy/Ready Polling is not used in the application, the easiest solution is to use the NM59C11 that does not have the polling on Data-Out but has it on a separate output.

7

3.0 Timing Considerations

The following information describing the Microwire bus timing must be used in conjunction with the datasheet as it is an expansion and clarification of the datasheet. First, the basic timings with respect to the clock (SK) will be described, followed by instruction sequence timing, and finally, specific information in each instruction sequence.

3.1. BUS TIMING

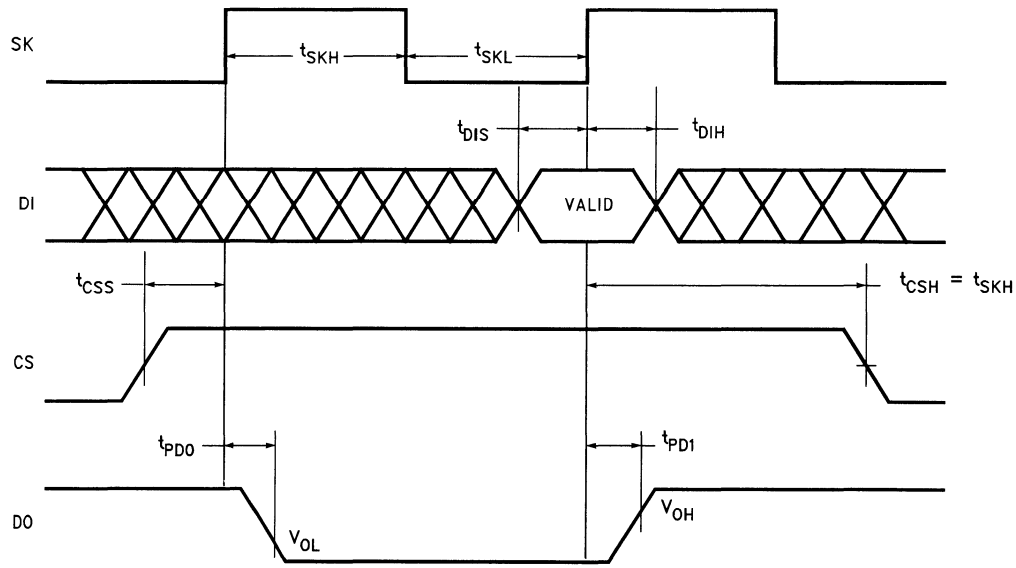
The synchronous data timing shown in *Figure 8* is similar to that shown in the various datasheets. There is one significant modification to the timing specification though, the chip select (CS) hold time is referenced to the rising edge of the clock rather than the falling edge. With this modification, the hold time specification must be changed to be the same as the minimum clock (SK) high time. Other significant points are:

— The only active edge of the clock is the rising edge.

— The only time the clock is necessary is when clocking data into or out of the EEPROM. It is not necessary during Busy/Ready Polling.

— The clock may be left in either the high state or low state between cycles. It is safer to leave the clock in the low state.

— When chip select (CS) is high, clock (SK) is a critical signal. With the exceptions noted in Section 2.1.2 tilted SERIAL CLOCK (SK), no additional clock cycles or noise that crosses the V_{IH} or V_{IL} thresholds can be tolerated.



TL/D/11169–11

FIGURE 8. Synchronous Timing

3.2 INSTRUCTION SEQUENCE DESCRIPTIONS

3.2.1 READ CYCLE

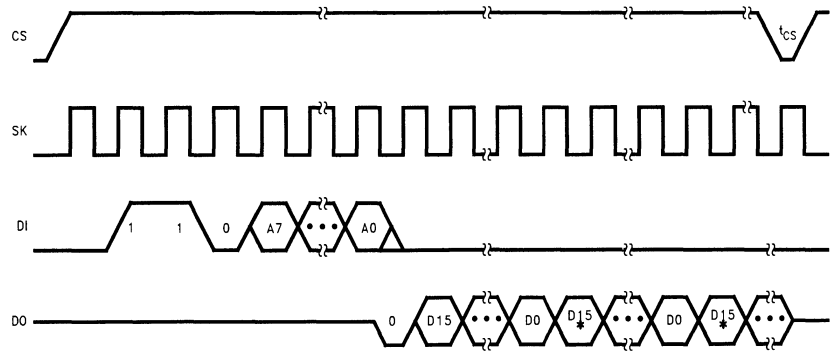
The READ cycle requires the host to raise chip select (CS) and then clock in thru the Data-In (DI) pin a start-bit, op-code, and address. Following clocking in the last address bit, the Data-Out (DO) output comes out of the high impedance state and drives a low level on the output. This is referred to as the dummy bit and is a good indication that a READ mode has been successfully entered if difficulty is encountered during initial debug of a system. The dummy bit is clocked out of the EEPROM on the same rising edge of SK that clocks in the last address bit, A0. This is shown in *Figure 9*.

3.2.2 SEQUENTIAL READ

Sequential read is a read mode available only on the NM93CS family. It is entered by entering a READ cycle and clocking out the first 16-bit word. After reading the first 16-bit word if chip select (CS) is kept high, address A + 1 may be clocked out followed by address A + 2 and so on. When the maximum address is reached, the memory continues in the sequential read mode at address 0. In this manner, the host may operate the memory in a continuous loop read. When initiating a SEQUENTIAL READ, the first data word is proceeded by a dummy bit as in a standard READ, although the dummy bit is supressed in all subsequent data words as shown in *Figure 9*.

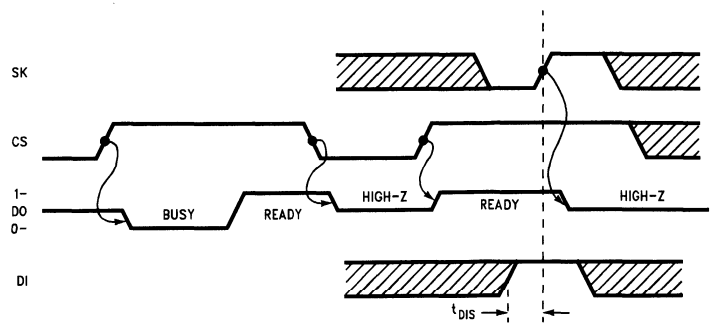
3.2.3 ERASE AND ERASE ALL

The ERASE cycles return the contents of the EEPROM to a clear state which is read as 1's. It is not necessary for any of the CMOS EEPROM described in this article, and is included in the NM93C family, NM93C46A, and NM59C11 only for compatibility with older devices that require erasing. It is recommended that the erase cycles be eliminated from the instructions to simplify the code, speed up writing and to improve the endurance obtained in the application. These modes are entered by clocking in a start-bit, op-code, and address. It is not necessary to clock in the data field as it is assumed to be all 1's. It is necessary to clock in the address, even in the case of ERASE-ALL where it is "don't care" in all except the first two bits of the address field which is used as additional op-code bits. After the full address field has been clocked in, chip select must be returned to a low level in initiate the erase cycle. In all devices, except the NMC9306, programming completion can be determined by Polling as shown in *Figure 4,* or a simple 10 ms timeout will guarantee programming is complete if polling is not used.



TL/D/11169–12

FIGURE 9. Sequential Read Sequence



TL/D/11169–6

FIGURE 4. Busy/Ready Polling Sequence

3.2.4 WRITE AND WRITE ALL

The Write and Write All cycles will write a specified data word into the specified address, or in the case of Write All, the same data pattern will be written into all locations. In all devices a new data pattern may be directly written over an existing data pattern without erasing the first data pattern. The write mode is entered by clocking in a start-bit, op-code, address, and data. The full address field must be clocked in for the Write All even though it is don't care in all but the first 2 bits. It is also necessary to clock in a full data field to assure correct alignment of data. The write cycle will be initiated after 8- or 16-bit have been clocked into the device in some of the devices and in other devices after chip select is brought low regardless of how many data bits have been clocked in. Refer to the specific datasheets to determine which method is used.

3.2.5 PROGRAM ENABLE AND PROGRAM DISABLE

Program enable and program disable are the instructions that enable or disable writing and, where included, erasing. The instruction name varies depending on the specific device but includes EWEN, EWDS, WEN, and WDS. These instructions enable or disable the entire memory array with a single instruction. All devices power up in the disable mode and once placed in the enabled mode remain enabled until a disable instruction is performed or V_{CC} is cycled. These instructions provide the most basic level of data protection. Although since most lost data is the result of the host device becoming uncontrolled and performing the "Program Subroutine" it may be helpful to structure the software such that the enable command is not included in the "Program Subroutine" but is in a separate subroutine. If a greater degree of data security is needed, a NM93CS family device is recommended, or other more elaborate schemes involving redundant data storage and polling.

3.2.6 PROTECT REGISTER READ

The protect register read (PRREAD) command is the same as a word read command except the input PRE must be held at a high level and the address is don't care. In spite of the address being don't care, the entire address field must be clocked in. On the Data-Out pin the contents of the protect register will be clocked out MSB first descending to LSB.

3.2.7 PROTECT REGISTER ENABLE

Similar to the programming enable instructions described above, the PREN instruction is necessary to perform any programming instruction the affects the Protect Register. Unlike the enable instructions described above, a PREN must immediately proceed each programming instruction that involves the protect register. The Protect Register programming instructions are PRCLEAR, PRWRITE, and PRDS.

3.2.8 PROTECT REGISTER DISABLE

The protect register disable instruction permanently disables any further programming instructions to the protect register. Therefore it can only be performed once in the lifetime of a NM93CS device. The purpose of it is to permanently configure a portion of the EEPROM as true ROM and a portion as Read/Write EEPROM. Great caution should be exercised prior to executing this instruction as there is no second chance. It is performed by sending a start-bit, op-code and an address field of all 0's while both the PRE and PE inputs are at a high level. This instruction must be immediately proceeded by a PREN instruction.

3.2.9 PROTECT REGISTER CLEAR

The protect register clear instruction will clear the contents of the Protect Register making the entire contents of the EEPROM alterable only if the PRDS instruction has not previously been executed. This is done by clocking in a start-bit, op-code, and address field of all ones. This instruction must be immediately proceeded by PREN instruction and requires that both PRE and PE inputs be held at a high level.

3.2.10 PROTECT REGISTER WRITE

The Protect Register write command (PRWRITE) allows the host to write the protect register with the address where the memory is to be segmented into ROM and EEPROM. The defined address is the first ROM address and the ROM field then continues to the top of memory. To execute this command a start-bit, op-code, and address must be clocked in, the address field containing the memory address that defines the ROM/EEPROM boundary. The PRE and PE inputs must be held at a high level.

3.3 INTERFACING SOLUTIONS

When interfacing serial microwire EEPROMs to microcontrollers there is an apparent conflict that occurs when selecting clock polarity and phase. This can be easily overcome in most situations, although when using some microcontrollers that do not allow selection of either clock polarity or clock phase, the only solution may be to resort to bit set and bit reset instructions to interface to the EEPROM rather than use of the serial interface provided on the microcontroller.

In the instance where there is a dedicated serial interface provided, the conflict typically occurs as follows. *Figure 10* demonstrates an EEPROM READ as this involves data being transferred from the micro to the EEPROM (Start bit, op-code, and address) and data transferred from the EEPROM to the micro (address contents). The conflict occurs in this example when the micros clock sets data up on the falling edge of SK and expects the EEPROM to accept it on the rising edge, but then expects the EEPROM to do the same when it sends data back to the micro.

1. The micro sets up a data bit. A propagation delay after the falling edge the data bit is valid at the EEPROM DI pin.
2. The EEPROM uses the rising edge of SK to clock the data bit into its internal register.
3. When the data direction changes the EEPROM sets the data up starting at the rising edge of SK.
4. The micro attempts to clock the data bit in that was set up on clock edge 3.

This example will work if the micro requires 20 ns or less data hold time after edge 4. If greater than 20 ns is required, an alternate strategy is needed.

1a. The micro sets up the data bit on the rising edge and a propagation delay later it is valid at the EEPROM.

2a. The EEPROM clocks the data into its internal register. The EEPROM requires only 10 ns data hold time, which can normally be guaranteed.

3a. The EEPROM sets the Data-Out up on the rising edge.

4a. The micro clocks the data into it's internal registers on the falling edge of the clock and a minimum data setup and hold time is guaranteed for the micro based on the minimum high and low time of the SK clock used in the application.

It should be noted that in the second example, CS (chip select) is asserted when SK is low. If this cannot be done, the DI input should be low when CS is asserted. If both DI and SK are high when CS is asserted the EEPROM will recognize this as a rising edge of SK. To accommodate this in a design, it is allowable to clock in any number of logic zeros prior to the start bit.

4.0 Conclusion

The serial EEPROM offered by National all share a common structure. Separating them are various features that give benefit to various applications such as the need for a bi-directional data bus or need for one byte word width. There are a number of "tricks" that may simplify interfacing to these which can easily be understood with the help of a functional block diagram. Given this information the overall job of using a serial interface EEPROM will be simpler.

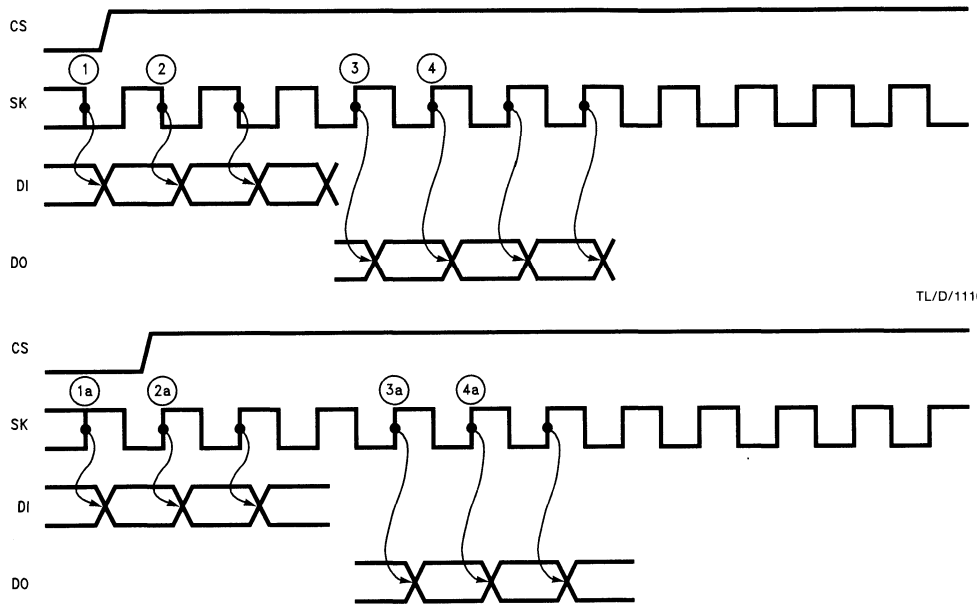


FIGURE 10

Using an EEPROM— I²C™ Interface NM24C02/03/04/05/08/09/16/17

National Semiconductor
Application Note 794
Paul Bryant

INTRODUCTION

National Semiconductor's NM24C EEPROMs are designed to interface with Inter-Integrated Circuit (I²C) buses and hardware. NSC's electrically erasable programmable read only memories (EEPROMs) offer valuable security features (write protection), two write modes, three read modes and a wide variety of memory sizes. Applications for the I²C bus and NM24C memories are included in SANs (small-area networks), stereos, televisions, automobiles and other scaled-down systems that don't require tremendous speeds but instead cost efficiency and design simplicity.

I²C BACKGROUND

The I²C bus configuration is an amalgam of microcontrollers and peripheral controllers. By definition: a device that transmits signals onto the I²C bus is the "transmitter" and a device that receives signals is the "receiver"; a device that controls signal transfers on the line in addition to controlling the clock frequency is the "master" and a device that is controlled by the master is the "slave". The master can transmit or receive signals to or from a slave, respectively, or control signal transfers between two slaves, where one is the transmitter and the other is the receiver. It is possible to combine several masters, in addition to several slaves, onto an I²C bus to form a multimaster system. If more than one master simultaneously tries to control the line, an arbitration procedure decides which master gets priority. The maximum number of devices connected to the bus is dictated by the maximum allowable capacitance on the lines, 400 pF, and the protocol's addressing limit of 16k; typical device capacitance is 10 pF. Up to eight E²PROMs can be connected to an I²C bus, depending on the size of the memory device implemented.

Simplicity of the I²C system is primarily due to the bidirectional 2-wire design, a serial data line (SDA) and serial clock line (SKL), and to the protocol format. Because of the efficient 2-wire configuration used by the I²C interface compared to that of the MICROWIRE™ and SPI interface, reduced board space and pin count allows the designer to have more creative flexibility while reducing interconnecting cost.

OPERATING NATIONAL SEMICONDUCTOR'S NM24Cs

The NM24C E²PROMs require only six simple operating codes for transmitting or receiving bits of information over the 2-wire I²C bus. These fields are explained in greater detail below and briefly described hereafter: a start bit, a 7-bit slave address, a read/write bit which defines whether the slave is a transmitter or receiver, an acknowledge bit, message bits divided into 8-bit segments and a stop bit.

For efficient and faster serial communication between devices, the NM24C Family features page write and sequential read.

The NM24C03/C05/C09/C16/C17 Family offers a security feature in addition to standard features found in the NM24C02/C04/C08/C16 Family. The security feature is beneficial in that it allows Read Only Memory (ROM) to be implemented in the upper half of the memory to prevent any future programming in that particular chip section; the remaining memory that has not been write protected can still be programmed. The security feature in the NM24C03/C05/C09/C17 Family does not require immediate implementation when the device is interfaced to the I²C bus, which gives the designer the option to choose this feature at a later date. Table I displays the following parameters: memory content, write protect and the maximum number of individual I²C E²PROMs allowed on an I²C bus at one time if the total line capacitance is kept below 400 pF.

Code used to interface the NM24Cs with National Semiconductor's COP8™ Microcontroller Family is listed in a latter section of this application note for further information to the reader.

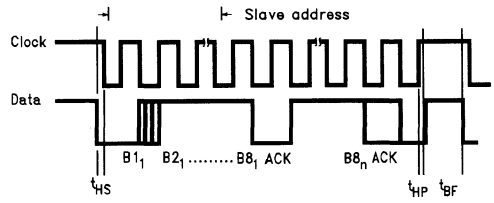
FIGURE 1. I²C-Bus Configurations



TL/D/11268–2

FIGURE 2. I²C Bus Timing

Start Condition

— Clock and Data line high (Bus free)

— Change Data line from high to low

— After $t_{HS(Min)}$ = 4 μs the master supplies the clock

Acknowledge

— Transmitting device releases the Data line

— The receiving device pulls the Data line low during the ACK-clock if there is no error

— If there is no ACK, the master will generate a Stop Condition to abort the transfer

Stop Condition

— Clock line goes high

— After $t_{HP(Min)}$ = 4.7 μs the Data lines go high

— The master maintains the Data and Clock line high

— Next Start Condition after $t_{FB(Min)}$ = 4.7 μs is possible

7

START/STOP CONDITIONS

If both the data and clock lines are HIGH, the bus is not busy. To attain control of the bus, a start condition is needed from a master; and to release the lines, a stop condition is required.

Start Condition: HIGH-to-LOW transition of the data line while the clock line is in a HIGH state.

Stop Condition: LOW-to-HIGH transition of the data line while the clock line is in a HIGH state.

The master always generates the start and stop conditions. After the start condition the bus is in the busy state. The bus becomes free after the stop condition.

DATA BIT TRANSFER

After a start condition "S" one databit is transferred during each clock pulse. The data must be stable during the HIGH-period of the clock. The data line can only change when the clock line is at a LOW level.

Normally each data transfer is done with 8 data bits and 1 acknowledge bit (byte format with acknowledge).

ACKNOWLEDGE

Each data transfer needs to be acknowledged. The master generates the acknowledge clock pulse. The transmitter releases the data line (SDA = HIGH) during the acknowledge clock pulse. If there was no error detected, the receiver will pull down the SDA-line during the HIGH period of the acknowledge clock pulse.

If a slave receiver is not able to acknowledge, the slave will keep the SDA line HIGH and the master can then generate a STOP condition to abort the transfer.

If a master receiver keeps the SDA line HIGH, during the acknowledge clock pulse the master signals the end of data transmission and the slave transmitter release the data line to allow the master to generate a STOP-condition.

ARBITRATION

Only in multimaster systems.

If more than one device are potential masters and more than one desires access to the bus, an arbitration procedure takes place: if a master transmits a HIGH level and another master transmits a LOW level, the master with the LOW level will get the bus and the other master will release the bus; and the clock line switches immediately to the slave receiver mode. This arbitration could carry on through many bits (address bits and data bits are used for arbitration).

FORMATS

There are three data transfer formats supported:

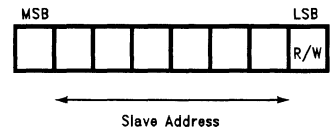
— Master transmitter writes to slave receiver; no direction change

— Master reads immediately after sending the address byte

— Combined format with multiple read or write tranfers.

ADDRESSING

The 7-bit address of an I²C device and the direction of the following data is coded in the first byte after the start condition:

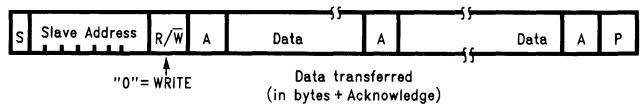


TL/D/11268–3

A "0" on the least significant bit indicates that the master will write information to the selected Slave address device; a "1" indicates that the master will read data from the slave.

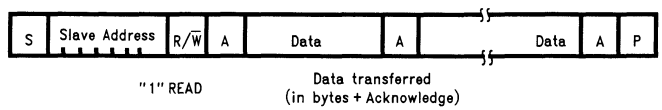
Some slave addresses are reserved for future use. These are all addresses with the bit combinations 1111XXX and 0000XXX. The address 00000000 is used for a general call address, for example, to initialize all I²C devices (refer to I²C bus specification for detailed information).

Master Transmits to Slave, No Directon Change



TL/D/11268–4

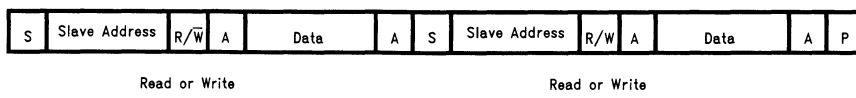
Master Reads Slave Immediately after First Byte



TL/D/11268–5

The master becomes a master receiver after first ACK

Combined Formats



TL/D/11268–6

n bytes Data + ACK n bytes Data + ACK

S = Start Condition A = Acknowledge P = Stop Condition

FIGURE 3. I²C-Bus Transfer Formats

TIMING

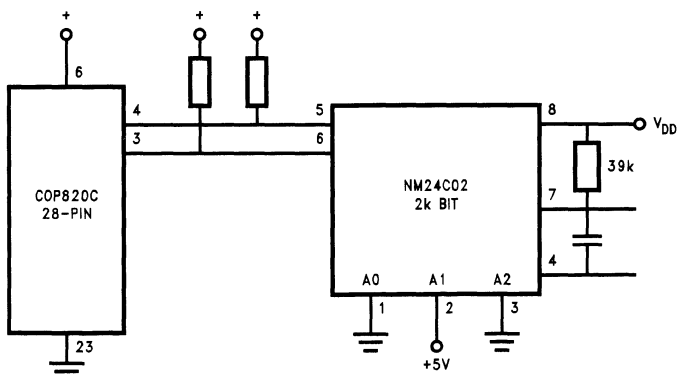
The master can generate a maximum clock frequency of 100 KHz. The minimum LOW period is defined as 4.7 μs; the minimum HIGH period width is 4 μs; the maximum rise time on SDA and SCL is 1 μs; and the maximum fall time on SDA and SCL is 300 ns.

Figure 4 shows the detailed timing requirements.

Symbol	Parameter	Min	Max	Units
f_{SCL}	SCL Clock Frequency	0	100	kHz
t_{BUF}	Time the Bus Must Be Free before a New Transmission Can Start	4.7		μs
t_{HD}; STA	Hold Time Start Condition. After this Period the First Clock Pulse is Generated	4.0		μs
t_{LOW}	The LOW Period of the Clock	4.7		μs
t_{SU}; STA	Setup Time for Start Condition (Only Relevant for a Repeated Start Condition)	4.7		μs
t_{HD}; DAT	Data in Hold Time	5 0*		μs μs
t_{SU}; DAT	Setup Time Data	250		ns
t_r	Rise Time of Both SDA and SCL Lines		1	μs
t_f	Fall time of Both SDA and SCL Lines		300	ns
t_{SU}; STO	Setup Time for Stop Condition	4.7		μs

*Note that a transmitter must internally provide at least a hold time to bridge the undefined region (max. 300 ns) of the falling edge of SCL.

FIGURE 4. I²C-Bus Timing Requirements



TL/D/11268–7

FIGURE 5. I²C Bus EEPROM/μController Configuration Used for Sample Code

SOFTWARE TASKS

I. Write fixed values to E2PROM cells

II. Read values back from E2PROM and save in RAM locations from COP

Note: I²C Bus Modes Used:

Master Transmitter $\overset{SDA}{SCL} \rightarrow$ Slave Receiver

Master Receiver $\overset{SDA}{SCL} \rightarrow$ Slave Receiver

REMARKS

— The I²C bus, 2-wire serial interface generally requires a pull-up resistor on the SDA line and the SCL line, depending on whether TTL or CMOS hardware interfacing exists.

— I²C bus compatible μC's or peripherals have OPEN DRAIN outputs at SDA and SCL.

— COP800 does not have OPEN DRAIN outputs, but the "bus requirements" can be met by switching SDA and SCL connections into TRI-STATE® for the following cases:

The bus is not accessed

A slave has to send an acknowledge bit.

— MICROWIRE can not be used for I²C bus operations.

— Current sink capability on SDA and SCL must be 3 mA to maintain "Low Level" (an I²C bus spec.).

Timekeeping Using a COP800 Microcontroller

National Semiconductor
Application Note 823
Mike Werstlein

ABSTRACT

Many applications require the time of day be available to the system so that a time stamp can be associated with an event. This application note discusses how National Semiconductor's COP820C microcontroller can be used to implement a timekeeping function. In addition, this paper demonstrates how two COP472 LCD display drivers are cascaded together to drive an 8 digit LCD display, which is used to display the time of day.

INTRODUCTION

Most often applications which use microcontrollers require some way of obtaining the time of day. Examples of these such applications are security systems, automatic sprinkler systems, telephone answering machines, automatic coffee makers, automatic thermostats, etc. One way of keeping track of the time and date is to use a dedicated real time clock IC. Although this is an easy and accurate option to implement, it is not very cost effective. The most cost effective method of timekeeping is to have the microcontroller itself perform the timekeeping function.

Timekeeping using the COP820C microcontroller is a relatively simple task. The system described here consists of a COP820C microcontroller, two COP472 LCD display drivers, and a Hamlin 8 digit LCD display (model #4216). The COP820C uses a 32.768 kHz crystal.

The timekeeping system described in this application note has many capabilities. The display can be toggled between two modes. One mode displays the time in the following format: HH-MM-SS (hours-minutes-seconds). The other mode displays the date in the following format: YR-MTH-DAY (year-month-day). Each part of the time or date can be individually set. In other words, one doesn't have to increment the seconds past 59 in order to increment the minutes by 1. Also, the real time clock automatically determines leap years and adjusts itself accordingly.

The following sections will detail the hardware and software portions of the real time clock.

HARDWARE

As previously stated, the hardware consists of a COP820C microcontroller, two COP472 LCD display drivers, a Hamlin 8 digit LCD display, and four normally open pushbuttons. These buttons are used to set the time/date and to select the display mode, either time or date. The schematic for the system is shown in *Figure 1*.

The four pushbuttons are interfaced to the COP820C via the lower four pins of the I port. 1 kΩ pullup resistors are used to keep the I lines high until a button is pressed, in which case the corresponding pin is pulled low.

G0 and G1 are used as chip select lines for the two COP472's. G0 is used for the slave while G1 is used for the master COP472. The technique used to cascade two COP472's together is detailed in the COP472 data sheet.

SOFTWARE

The software portion of the real time clock consists of several subroutines used to perform special functions. The program uses approximately 600 bytes of ROM. Included in the program are the routines to display the time/date to the LCD. There are also some overhead routines used for the LCD. This means that the clock portion of the program is actually less than 600 bytes.

The program relies on the 32.768 kHz crystal oscillator as its time base. The 16-bit timer is loaded with a value that will correspond to one underlow per second. This underflow will cause an interrupt to occur that will increment the seconds value by one.

The beginning of the program is used to initialize certain RAM locations and also to configure the proper I/O ports and timers.

The first subroutine to be called is labeled SYNC. This routine is used to synchronize two COP472 LCD displays. One COP472 can drive 4½ digits. Therefore, in order to display more data, additional COP472's can be cascaded together to drive more digits.

The next section of the program is used to set the time/date information. The first step is to read the value of port I. Since only I0–I3 are used, the value of port I is AND'ed with 0F hex to mask out the upper four bits. If a button is pressed, a status bit in the CLKSTAT register is checked to see if the clock is displaying the time or the date. The correct part of the time/date is then set accordingly. The program keeps scanning the buttons until one of them is pressed or a timer interrupt is encountered, at which time the appropriate routines are executed.

When the time underflow interrupt occurs (once per second) the program jumps to location 0FF hex. Here the program jumps to the timer interrupt service routine if the timer interrupt pending bit is set. The timer inerrupt service routine simply increments the seconds value by one. It also takes care of incrementing the minutes, hours, days, months, and years as needed. Leap years are also accounted for during this routine.

The next subroutine to be called is labeled ADJUST and is used to account for the clock inaccuracies. This is necessary because the instruction cycle time is 1/3276.8 seconds instead of the ideal time of 1/3277 seconds. An integer value for the instruction cycle time is considered ideal. The reason it is ideal is because if this value is loaded into the timer, then the underflow will occur exactly once per second. This inaccuracy can be fixed easily. By using a generic counter, one second can be added to the time whenever the clock becomes one second behind.

The next subroutine to be called is BCDDIG. This routine is used to convert the time/date information into a format that is usable by the COP472's. Memory locations 01–0A contain the COP472's digit data.

The subroutine CONVRT is then called. This routine is used to convert the data contained in memory locations 01–0A into the proper format for the Hamlin LCD. This conversion routine might vary depdending on the particular display being used.

The final subroutine to be called is DISP. This routine is used to send the contents of memory locations 01–0A to the COP472's so that the new time/date information can be updated on the display. The program then returns to the main loop at the beginning.

CONCLUSION

As can be seen, the COP820C can easily incorporate time-keeping functions into virtually any existing program. This approach can save the user the cost and time of adding additional circuit components to the overall system. Although this program takes about 600 bytes of memory, a significant portion of the program is overhead for the COP472's and the LCD display. Various parts of the program might not be necessary in a specific application.

8-Channel 8-Bit PWM Controller

National Semiconductor
Application Note 824
Patrick Furlan

INTRODUCTION

This application note discusses a cost effective implementation of an 8-channel DAC to replace potentiometers.

TECHNICAL OVERVIEW

The COP822C was considered for the application. At the outset since the DACs were replacing pots, speed of conversion was not an issue. The issue became in that how fast a frequency with 8-bits of resolution on eight channels could be implemented in software. This would then determine the response time and therefore the filtering components to convert the varying duty cycle squarewave to a DC voltage. A simple RC can be used or for better response a pie filter can be used. Depending on the load, buffering may be required. In preliminary testing ripple was less than 1-bit.

IMPLEMENTATION

Software was then written to determine the time required to execute one loop of the program that determined the resolution that could be achieved for 8 separate channels. The routine is basically a small loop that decrements 8 registers or counters and reloads these counters after 8-bits of resolution. It was determined that the loop could be done in 40 μs. This is the limiting factor. From this 40 μs (100 Hz instruction cycle frequency) per bit for 8 bits of resolution, the period turns out to be 10 ms. Therefore, in 10 ms all 8 channels are updated with their on/off times.

Since the outputs are constantly running, interrupts are not used so that the PWM outputs stay more stable. Also, this provides a faster throughput. Interface to the chip can be done in either a serial (MICROWIRE/PLUS™) or parallel fashion, depending on best fit for the application. For a serial implementation the Microwire busy bit can be polled each loop. If parallel interface is required, there are enough pins on the device to implement a simple handshake exchange; i.e., have 3 address lines, 4 data lines and a chip select. In either case, it requires a two byte protocol: address and data. Data is the PWM "on time" to determine duty cycle.

CONCLUSION

This low cost implementation of an 8-channel 8-bit PWM controller has multiple features. Besides a low speed DAC, PWM control in conjunction with NSC DMOS power products could also be a cost effective peripheral for power drive applications. It should be noted that using this approach, there is no CPU time for doing other tasks. One last item to note is the COP800 output structure. Depending on application the outputs (G and L) can be configured in TRI-STATE® mode, thereby putting the external filter in a holding pattern or low leakage state. In this way other small routines i.e., interface, could be accomplished.

Due to the software implementation methodology, there is flexibility, i.e., in the number of channels, resolution and the interface. Also, since it is based around a COP800 solution, packing (pins) and operating frequency including crystal options are also flexible.

The following pages show the code used in evaluating the concept as well as the filter components. Basically, eight register with varying "on times" were loaded so that the PWM outputs could be analyzed along with software performance. The remaining code for MICROWIRE/PLUS and the exact filter components are not finalized.

Software for Interfacing the COP8™ Family Microcontrollers to National's MICROWIRE™ EEPROMs

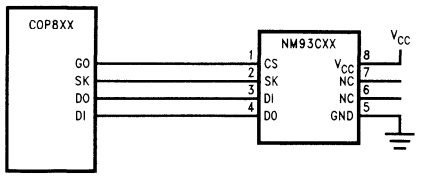
National Semiconductor
Application Note 841
Paul Bryant

ABSTRACT

National's NM93Cxx and NM93CSxx family of serial EEPROMs have MICROWIRE "slave" interfaces that directly connect to the MICROWIRE "master" interfaces on the COP8™ family of 8-bit microcontrollers. Peak data transfer rates are as high as 1 MB on the 4 wire MICROWIRE bus. This application note includes the essential assembly language software to address MICROWIRE EEPROMs.

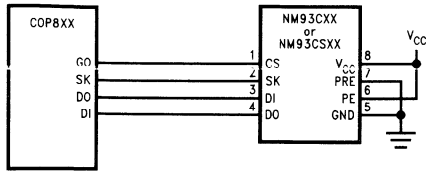
HARDWARE INTERFACE

A schematic for connecting a COP8 family microcontroller to one of Nationals NM93Cxx family MICROWIRE EEPROMs via the microcontrollers dedicated MICROWIRE port is shown in *Figure 1*. National makes two basic families of MICROWIRE EEPROMs, the classic NM93**C**xx series and the newer full featured NM93**CS**xx series. The NM93CSxx series EEPROMs have a sequential read capability and the "S" in "CS" stands for sequential (the "C" implies CMOS). As can be seen the "CS" series devices have two additional pins which control write protect features (consult a data sheet for information on their function). By connection these pins to V_{CC} and GND as shown in *Figure 2*, it becomes possible to use either "C" or "CS" family parts in the same physical socket. This would be desirable if a change from a "C" series part to a "CS" series part is possible for reasons of product upgrades or simply manufacturing inventory control. Pins 6 and 7 on the "C" series parts are true no connects and thus can be tied to V_{CC} or ground harmlessly.



TL/D/11491–1

FIGURE 1. Basic National MICROWIRE Interconnection to a COP8 Family Part



TL/D/11491–2

FIGURE 2. This schematic allows either a NM93Cxx or NM93CSxx part to be used in the same socket. Software can then be adjusted to take advantage of the "CS" series advantages without making changes to the board.

If it's desirable to use both types in the same socket without being forced to make software changes, one must be careful not to use the sequential read capability of the "CS" series. Both types of parts should be tested in the socket before the software is frozen.

NM93C06 to COP8 Family Software Details

Always consult the latest data sheets for information about timing variables mentioned in the text that follows. These numbers were correct at the time that this application note was written but are subject to change.

1. The SK clock frequency must not exceed 1 MHz. Consult the processor data sheet for details.
2. The CS low time following a write must exceed 250 ns. This starts the internally timed write operation. The DO line will leave the high impedance state if CS goes high again and will drive low until the internal write cycle is complete. After DO returns high, indicating "ready" the first rising edge of SK with CS high and DI high will return the DO pin to the high impedance condition. This condition is normally the start bit of the next instruction.

   The DO pin will be low for up to 10 ms and then go high to indicate that the write is complete. If a new instruction is attempted before the DO pin returns high it will be ignored and the DO pin will not go tristate. The DO pin will always go to the tristate condition when CS is low.
3. Opcodes are either 2-bits or 4-bits long depending on the instruction type and are always preceded by a "start-bit" of a logic one. Any number of leading zeros can be clocked in before the start-bit (the sample assembly code inserts seven). Addresses are either 6 or 8-bits long depending on the density of the device. The combined opcode and address field is 8-bits for the smaller devices (93C06 and 93C46) and 10-bits for the larger devices (93C56 and 93C66). On the opcode types that do not use addresses, all of the "dummy" address bits must be clocked anyway (the combined opcode/address field is constant number of clock cycles).
4. On read operations the data out stream starts with a dummy zero. On NM93Cxx family EEPROMs, it is acceptable but not required to have extra clocks after the 16th actual data bit. On NM93CSxx family EEPROMs, extra clocks after the 16th actual data bit will begin to read the next data word.

Notes on the Assembly Code:

The subroutines that follow are adequate to quickly pilot the programmers task of addressing a serial EEPROM of the NM93Cxx family. Additional subroutines can very easily be adapted from these to handle the additional opcode types of the NM93CSxx series parts. Enough code has been included to allow the code to operate in a stand-alone fashion. However, when integrating the routines in to another program, initialization statements affecting global variables such as initializing the stack point or the X or B registers will need to be moved, deleted or replaced by statements in the main program.

The assembly code uses a software timer loop to time out the write time of the EEPROM. The programmer should be aware that it is possible to use the EEPROMs own internal timer to accomplish this task. This is done by monitoring the EEPROMs DO line after taking the EEPROMs CS line low to start a write and then setting CS high again to re-enable the DO output. The write is complete when the DO (of the EEPROM) drives high. Using the EEPROMs internal timer will allows the microcontroller time to accomplish some other task in the 10 ms that the write or erase operation requires. If the DO line is to be used to indicate that the write is complete, other MICROWIRE components on the bus must wait for the EEPROM writes to time out before being accessed (the DO line is in use).

The code was tested on a COP820 device via a Metalink In Circuit Emulator. The code should translate to other COP8 devices with little or no modification.

Selling National's Write Protected "CS" Series EEPROMs to High Volume OEMs

National Semiconductor
Application Note 871
Robert Stodieck

ABSTRACT

National's 93CSxx family of serial EEPROMs offer sophisticated protection against accidental overwrite. Unfortunately, understanding why and when this protection is needed often requires an equally sophisticated design engineer. This application note sheds light on the causes of accidental overwrite and the solutions that the "CS" series provide for controlling the problem.

GETTING SOPHISTICATED

EEPROMs are an important refinement to digital electronic products of many types. As consumers become more sophisticated about features, the advantages of non-volatile and cost effective serial EEPROMs frequently become important. Digital systems from cordless phones to VCRs, and from keyless entry systems to thermostats, benefit from the ability to store small stashes of data that do not go away when the power goes down or the batteries die.

The designers first reflex is to grab the cheapest generic solution on the market and run with it. After all, serial EEPROMs are all really the same aren't they?

NO!

In the beginning National Semiconductor married its MICROWIRE™ serial bus to a small EEPROM and created a classic 8-pin device that has since been copied by dozens of makers and has become the industry standard. Its descendants are available now from National in densities from 256 bits to 16 kbits.

So buy the industry standard device (every one else does) and run with it right?

NO!

National Semiconductor's classic 8-pin device is clearly the correct choice for some, but not all systems, and not knowing the difference can be expensive. Designs that shine through prototyping and test may fail in the field.

Serial EEPROMs are connected to microprocessors, microcontrollers and ASICs. Under a variety of error conditions the controlling system can accidentally overwrite data in the EEPROM. Application environments vary widely as does the importance of the data the EEPROMs are used to retain. The bit of information retained in the non-volatile memory may control the shape of the graphic sprite used in a child's game or something of importance to a nuclear power plant. It is be to expected that there is a need for more than one type of EEPROM.

The economy of serial EEPROMs and their utility explains why they are often used in high volume consumer items. Quality here is paramount because a flaw in the design can lead to very expensive returns and even recalls.

WHAT'S THE PROBLEM?

Volatile DRAM and SRAM memory forget past mistakes on reset or power down. A malfunctioning computer or video game can usually be fixed by turning the unit off and back on again. In contrast, non-volatile memories retain data even after the power goes off. They also retain memory of past single event mistakes such as unintended write operations.

Accidental overwrites to EEPROM can be caused by power supply noise, electrical interface noise, errant software, or "crashing" microcontrollers and processors. Such an event may be rare indeed but needs to occur ONLY ONCE in a product's lifetime to cause a problem and . . . such events are not always so rare.

Overwrite problems are well understood in the parallel EEPROM world. Overwrite protection schemes have long been central to the parallel EEPROM's architecture. Parallel EEPROMs usually have V_{CC} voltage sensing circuitry that helps to prevent unintended write events on power-up or power-down and V_{CC} transients. In addition, fairly complex write protection algorithms are used to reduce the probability of accidental overwrite.

Serial EEPROMs are far less susceptible to accidental overwrites than are parallel devices. The long sequence of serial data required to trigger a write in a serial device makes many of the precautions used on parallel devices unnecessary. Random noise on power-up is not likely to imitate the 19 plus serial bit sequence required to initiate a write operation.

However, the difficult problem of overwrite protection during a processor "crash" remains. There are some applications where there is no definitive solution to this problem. However, in many other situations the write protect features of the NM93CSxx can limit or cleanly eliminate the problem.

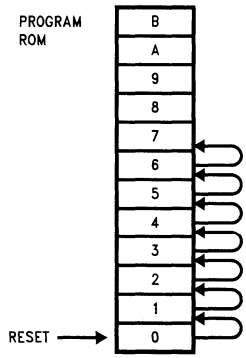
SO WHAT IS THE PROBLEM?

The fact that a long serial bit sequence is required to initiate a write operation into a serial non-volatile memory solves most accidental overwrite problems. But there is one persistent type of failure pathology that remains and can defeat this type of protection. It is particularly likely to occur in applications using small microcontrollers.

The problem is that no matter what input sequence is required to trigger a write operation, it has to be known to and be embedded in the software. The code segment that "knows" the write input sequence can be executed by unplanned jumps in the program sequencing induced by electrical noise, in practice usually V_{CC} noise or low V_{CC}. It can also be caused by imperfect software.

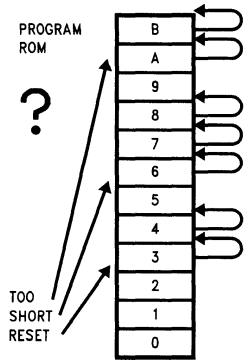
DOES THAT REALLY HAPPEN?

Yes. Understanding the problem requires a little reflection on how a processor works. A program counter is the device that generates addresses for program memory accesses. Remember that the program counter in a processor is basically a re-loadable binary counter. As long as V_{CC} is steady, and the clock and control signals to the control are noise free and within specified timing, the count (and program execution) normally advances one step at a time (see *Figure 1a*).



TL/D/11782–1

FIGURE 1a. Normal Program Flow after Power-On Reset



TL/D/11782–2

FIGURE 1b. Disturbed Reset Operation Following a Too Short Reset Pulse. This is a Common Scenario after a Short Interruption of V_{CC}.

If V_{CC} is not steady or is too low, and the clock or control signals are not noise free or are not within specified timings, the count may skip randomly. If V_{CC} or the offending control signals then return to normal, the count (and program execution) again begins to advance one increment at a time. But now the program is at a completely random location. If the program counter has skipped to the program segment that writes to the EEPROM, it will tend to write garbage to random locations. This is a particularly serious problem for microcontrollers which have relatively small program memory spaces. Thus, any skipping that occurs is more likely to overrun the serial write code.

THE SHORT RESET EXAMPLE

Normal processor reset is illustrated in *Figure 1a.* Faulty reset, possibly caused by short V_{CC} interruptions, is illustrated in *Figure 1b.* If the processor starts operation near the "WRITE_EEPROM" code segment it may trigger an accidental overwrite. It is difficult to prevent this type of misequencing in all cases because of the large spectrum of V_{CC} transients that may be experienced in the products lifetime. Some combination of low V_{CC} and V_{CC} interruption timing can usually be found that prevents the power up reset circuit from resetting correctly.

The slowly decaying V_{CC} level resulting from a discharging battery will also cause the program counter to begin skipping at some point. This is a common problem with the myriad of small electronic devices powered by unregulated batteries. Learning remote control units are a practical example of a system that uses EEPROM and suffers from this problem.

In large microprocessors with large memory spaces and various traps to stop errant operation, the possibility of accidental overwrite is not particularly high. But, in microcontrollers that may have only 1 kbyte to 2 kbytes of program code and few trapping techniques, this is a serious problem. Furthermore, in some applications conditions that can trigger this type of problem are repetitive and frequent.

FOR EXAMPLE

Room thermostats and refrigerators have historically used bi-metallic switches to maintain temperature control. If the line power dipped or dropped out there was no problem. Operating temperatures would soon return to normal when the power came back on. These kinds of controls are, of course, frequently being replaced with digital units, but these have a few problems. The temperature setting must be stored in battery backed-up RAM, or it must be stored in EEPROM. If not it will be volatile and lost after a power outage.

Serial EEPROM is by far the most desirable and cost effective way of providing non-volatility for this type of application, but care must be taken to guarantee data integrity in the EEPROM to prevent a change in temperature settings caused by an accidental overwrite.

Fortunately, the write security features of the NM93CSxx family of EEPROMs can not only guarantee security for the temperature data under the worst conditions, but at the same time has space for temperature calibration data, a serial number, and a date of manufacture, if required. Furthermore, the temperature calibration and serial number data can be rendered absolutely permanent. *Figure 3* shows how the write Protect Register of a NM93CSxx part can be used to protect a zone of memory from writes. This protection can be made permanent, if desired, by executing a one time only instruction that disables all writes to the protect register itself.

The write protect features are controlled by two new pin functions that replace two no connect pins on the standard MICROWIRE pinout *(Figure 3):* the Program Enable pin, PE, and the Protect Register Enable pin, PRE. The PE pin must be high to enable any write to the EEPROM. The PRE pin must be high to write to allow writes to the internal Write Protect Register.

Note: The words write and program are used interchangably.

TL/D/11782–4

FIGURE 3. With the Write Protect Register Programmed to 33, EEPROM Locations 33 to the End of Memory are Not Writable.

Figure 4 is a block diagram of a refrigerator controller example. *Figure 5* shows how a factory-only accessible jumper can be used to control the logic level of the Protect Register Enable pin, and a user accessible push button switch can be used to control the logic level of the Program Enable pin.

This arrangement allows the factory to enter and protect temperature calibration data in the EEPROM. The calibration data is located in the area protected by the protect register defined area. This data can only be altered by a trained technician who knows about the jumper.

At the same time, this arrangement allows the user to change the temperature settings which are located in the "writeable" area. Keep in mind though that this area is writeable only when the Program Enable (PE) pin is held high by the "SET" push button. The temperature setting is located in the "unprotected" area, where overwrites are controlled by using the PE pin. This example illustrates the use of two levels of write protection available with the "CS" series EEPROMs.

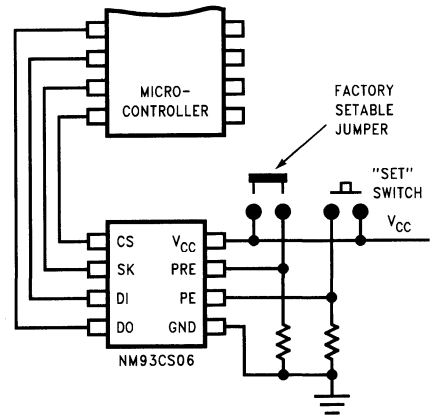
FIGURE 4. Refrigerator Temperature Controller. The Main Power Relay, Connected Directly to the Same power Line as the Controller, Cycles Off and On Frequently to Maintain Refrigerator Temperature, Creating an Ample Capacity for Generating Short Destructive V_{CC} Transients.



TL/D/11782–6

FIGURE 5. A Combination of a User-Accessible Switch, and a Factory Only Accessible Jumper, Allows Two Different Zones of Over-Write Protection in the Same EEPROM.

Most importantly though, the arrangement of the user accessible switch prevents accidental writes to the EEPROM from any source, and the write protection control is not software dependent. The EEPROM may not be altered in any way except when the user is actually pressing a front panel button labeled SET (*Figures 4* and *5*). This makes the probability of unintended overwrite vanishingly slight.

MORE EXAMPLES

Many contemporary applications have requirements similar to the refrigerator example. In all cases where an EEPROM is called for, data loss is expensive or even dangerous and the power supply cannot be guaranteed to be transient free. In these cases either the write protection required can be made permanent or a non-software dependent method is available to temporarily disable write protection when a data change is required, i.e., a switch or jumper allows the write protect pins to be toggled under controlled conditions. Alternatively, the part can be removed from the PC board for reprogramming.

AUTOMOTIVE APPLICATIONS

Automotive applications subject auto accessories to dead batteries, battery replacements, brown outs caused by cranking the engine on low batteries, etc. Thus, automotive applications are a prime environment for write protected serial EEPROMs. In the following applications and many others, hardware over-write protection is desirable and practical.

— **Auto Stereo Anti-Theft Codes**

The transients that the cassette deck's motors and relays generate in operation contribute to the normal automotive V_{CC} transients that the microcontroller must weather. Unless overwrite protection is provided for the EEPROM, one "crash" event could provoke an unintended overwrite and the deck may fail to work for its correct owner. Code changes are rare and overwrite protection can be controlled by a push button switch.

— **Automotive Engine Controls**

Engine control adjustments are retained in the EEPROM and must not be disturbed or the car may not operate correctly. Settings change only when the car is serviced and overwrite protection in this application can be controlled by the service equipment.

— **Automotive Keyless Entry Systems**

A keyless entry system must not forget its security codes and lock out its owner. Code changes are rare and overwrite protection can be controlled by a push button switch.

HOUSEHOLD APPLICATIONS

Household V_{CC} transients tend to come from brownouts, blackouts, and most commonly, simply plugging in or unplugging an appliance. Some contemporary applications include:

— Keyless Entry Systems

— Digital Room Thermostats

— Refrigerator Temperature Controls

TELECOM SWITCH APPLICATIONS

It is now a requirement that all boards found in common telecom switching systems have an electronically readable serial number. The serial number of any board in a switch must be readable from an operators console. This is an aid to repair. Reliability is a paramount consideration. With the NM93CSxx series serial EEPROMs the serial number can be recorded either permanently or alterably, changeable only by replacing the part in a socket or by a technician fitting a jumper during a rare, factory only, reprogramming event.

IN SUMMARY

The multiple write protect features of the NM93CSxx parts allow the parts to retain data such as serial numbers, date-of-manufacture codes, and calibration data, permanently and unalterably. The same part can provide application alterable EEPROM. In these applications one NM93CSxx series part takes the place of two devices. In other applications, just the fact that the data in the device can be rendered permanent may justify their use.

How to Use the NM93C86A Serial EEPROM as a PC/ Laptop Detachable Printer File Memory Card (DPFMC)

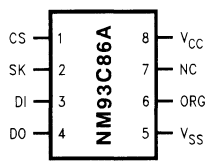
National Semiconductor
Application Note 936
Charles Watts

INTRODUCTION

This applications note describes how to build a DPFMC. The card will be designed around a COP888CG microcontroller and four NM93C86A serial EEPROMs. The card will be designed to plug into any standard IBM-PC/Laptop parallel port. Once the card has been installed, the user can download any document (text, graphic, or combination) and print out that document at a later time. The DPFMC will be designed to make the computer think a printer is actually connected by simulating the printer's input port. Once all documents have been sent, the user needs to press the SEND-DOC button once to save the pointer address. Next the user can remove the card and turn its power off. The documents contained in the card's EEPROMs can be stored for hours, days, months, or even years if needed. However, hours will probably be a more realistic time frame. When the user is ready to print-out the documents saved, the card can be plugged into a stand along printer by either using the printer's DB-25 cable or (with an appropriate adapter) the printer itself. After switching on the cards power, all the user has to do is press the SEND DOC button and the printer will begin to print out the saved documents.

NM93C86A DESCRIPTION

The NM93C86A is a 16,384-bit CMOS non-volatile serial EEPROM that can be configured to have a 1024 x 16 or a 2048 x 8 architecture. The configuration is determined by the state of the ORG pin. If the ORG pin is tied low the NM93C86A is configured as a 2048-byte-wide memory. If the ORG pin is left floating or tied to V_{CC}, the 1024 word wide configuration is enabled. An internal pull-up resistor to V_{CC} assures that a floating ORG pin is pulled high. *Figure 1* shows the NM93C86A pin arrangement.



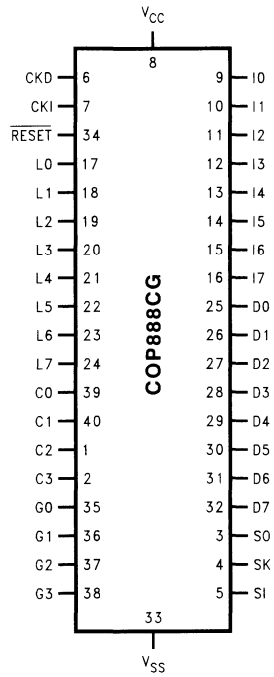
TL/D/12033–1

FIGURE 1. NM93C86A Pin Out

The NM93C86A has 7 instructions that can be performed. The instructions are: Read a byte/word (READ), Enable programming (EWEN), Disable programming (EWDS), Erase a byte/word (ERASE), Write a byte/word (WRITE), Erase all bytes/words (ERAL), and write a data pattern to all bytes/words (WALL). The NM93C86A uses the industry standard MICROWIRE™ interface.

COP888CG DESCRIPTION

The COP888CG is an 8-bit microcontroller. Its a fully static CMOS device containing RAM, ROM, and Microwire interface. The microcontroller contains 4,096 bytes of ROM used to store program code and 192 bytes of RAM used to store register data. It contains an 8-bit input, an 8-bit output, and two 8-bit bi-directional ports. The microcontroller also has a Microwire interface which will be used to connect the NM93C86A to it. These attributes make the COP888CG a good choice for this particular application.



TL/D/12033–2

FIGURE 2. COP888CG Microcontroller

CIRCUIT DESCRIPTION

Figure 3 shows the complete schematic diagram of the DPFMC. The L-port of the microcontroller is connected to the D0–D7 data lines of the computer's bidirectional data port. The LS-nibble of C-port is connected to the STROBE, ACKNLG, BUSY, and the PE pins of the computer's parallel port. Pin 13 is tied HIGH and all of the other pins are tied LOW. All of the bi-directional I/O lines are pulled HIGH through two 10 kΩ SIP resistors.

The MICROWIRE Interface of the COP888CG uses pins 3(SO), 4(SK), and 5(SI). These pins are connect to the equivalent pins of the EEPROM. The MS-nibble of the D-port is used as chip select outputs to the four EEPROMs. Since the data the DPFMC will be processing is 1-byte length data, the NM93C86A will be configured to deal with 8-bit chunks instead of 16-bit chunks of data.

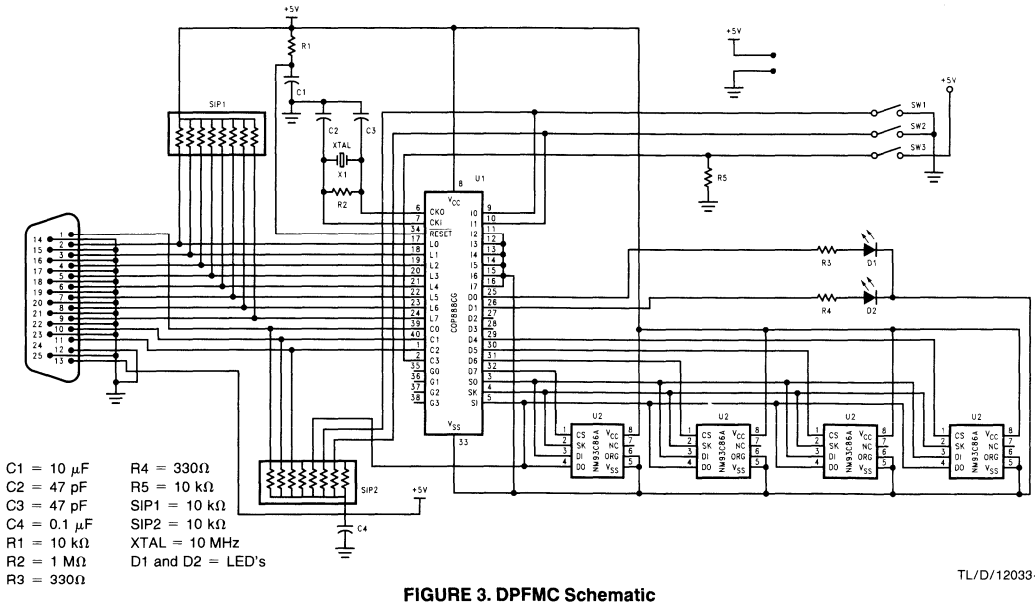


FIGURE 3. DPFMC Schematic

The DPFMC will have three inputs. Two are tied HIGH through 10 kΩ resistors. The third is tied LOW. The first input when LOW (pin 9) will indicate RECEIVE MODE. A LOW on the second input (pin 10) will indicate WRITE MODE. A HIGH on the third input (pin 11) will tell the microcontroller to save the current pointer address and begin sending the document data to the printer.

Their are also two LED outputs. LED1 will inform the user that the DPFMC cannot accept any more data. LED1 also informs the user that the pointer address has been saved. If LED1 flashes continuously the DPFMC is out of memory. If LED1 flashes irregular the DPFMC has saved the pointer address and is ready for power to be removed. LED2 informs the user of the current mode. Two flashes indicates the READ MODE and one flash indicates the WRITE MODE.

SOFTWARE DESCRIPTION

For simplicity and structure the software part of this application will be divided into three parts. The first or main block will monitor the three inputs and decide which mode the DPFMC will enter. The second block will control the interface logic between the computer's parallel port and the DPFMC.

In the case of a read operation, this block of code will start by configuring the STROBE and BUSY pins as inputs and the ACKNLG pin as an output. The routine then waits for the BUSY pin to fall LOW. When the BUSY pin falls low, the routine will begin monitoring the STROBE pin for a 0.5 μs LOW. When this happens, the routine reads the data port and stores that data into accumulator A. After the data is safely stored into accumulator A, the ACKNLG pin will be pulsed LOW for 5 μs to inform the computer that the data was received. Control is now passed to the final routine. This routine takes the data from ACC A stores the data into the EEPROMs. This routine basically will control the memory matrix part of the card. After the data is stored into the EEPROMs, control is passed back to the interface routine and the loop continues.

The write sequence will be just the opposite. The BUSY and STROBE pins are first configured to be outputs and the ACKNLG pin configured to be a input. The routine will then wait for the SEND DOC input to go low. When this happens the BUSY will go LOW to indicate the card is about to send a byte to the printer. The memory matrix routine the then stores the first byte of data into accumulator A. After that the interface routine sends that data to the port. The STROBE pin is pulsed LOW for 5 μs. From this point on the routine monitors the ACKNLG pin for a 5 μs LOW. When a LOW has occurred the routine loops back to the top, fetches the next byte, and starts a write loop.

Low Cost A/D Conversion Using COP800

National Semiconductor
Application Note 952
Robert Weiss

INTRODUCTION

Many microcontroller applications require a low cost analog to digital conversion. In most cases the controller applications do not need high accuracy and short conversion time.

This appnote describes a simple method for performing analog to digital conversion by reducing external elements and costs.

PRINCIPLE OF A/D CONVERSION

The principle of the single slope conversion technique is to measure the time it takes for the RC network to charge up to the threshold level on the port pin, by using Timer T1 in the input capture mode. The cycle count obtained in Timer T1 can be converted into voltage, either by direct calculation or by using a suitable approximation.

Figure 1 shows the block diagram for the simple A/D conversion which measures the temperature.

BASIC CIRCUIT IMPLEMENTATION

Usually most applications use a comparator to measure the time it takes for a RC network to charge up to the voltage level on the comparator input. To reduce cost, it is possible to switch both inputs as shown in *Figure 2*.

Port G3 is the Timer T1 input. Ports G2/G1 are general purpose I/O pins that can be configurated using the I/O configurations (push-pull output/tristate). All Port G pins are Schmitt Trigger inputs. R_{LIM} is required to reduce the discharge current.

GENERAL IMPLEMENTATION

The temperature is measured with a NTC which is linearized with a parallel resistor. Using a parallel resistor, a linearization in the range of 100 Kelvin can be reached. The value of the resistor can be calculated as follow:

$$R_P = R_{tm} * (B - 2T_m)/(B + 2T_m)$$

R_{tm} Value of the NTC at a medium temperature
T_m Medium Temperature
B NTC–material constant

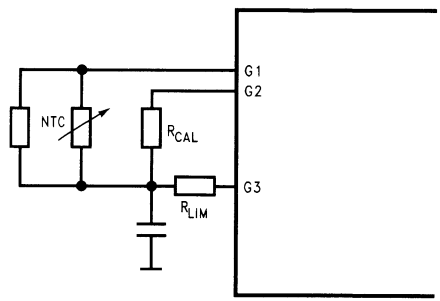
The linearization reduces the code, improves the accuracy and the tolerance of the NTC-R network (e.g. NTC = 100 kΩ ±10%, R = 12 kΩ ±1%, NTC//R ±2%). Using that method the useful range does not cover the whole operating temperature range of the NTC.

GENERAL ACCURACY CONSIDERATIONS

Using a single slope A/D conversion the accuracy is dependent on the following parameters:

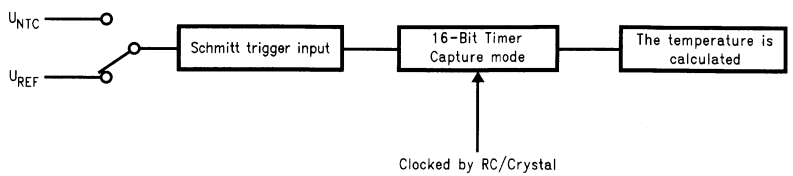
— Stability of the Clock frequency
— Time constant of the RC network
— Accuracy of the Schmitt Trigger level
— Non-linearity of the RC-network

Figure 3. The maximum failure that appears when a sawtooth is generated without using a current source. In the current application the maximum failure would be more than 15% without using methods for reducing the non-linearities of RC-network/NTC-network.



TL/DD/12075–2

FIGURE 2. Basic Circuit Implementation



TL/DD/12075–1

FIGURE 1. Simple A/D Conversion

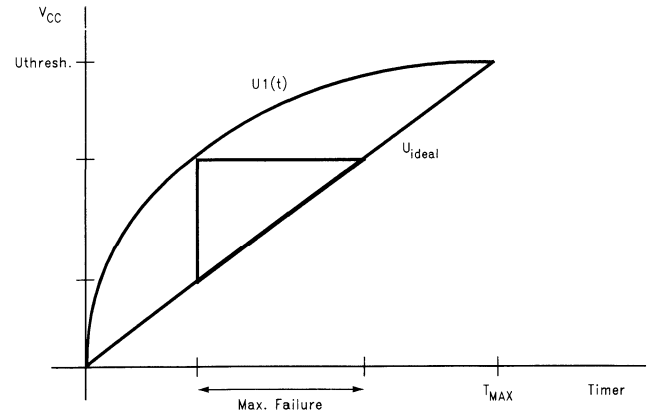


FIGURE 3. Single Slope A/D Conversion

The maximum error occurs when the gradient of the exponential function (RC) equals the gradient of the straight line (counter).

To reduce the error that is caused by the non-linearity of the RC-network a offset should be added to the calculated value. The offset reduce the failure to the middle.

Further, the accuracy can be improved by using a relative measurement method. The following diagram shows the method.

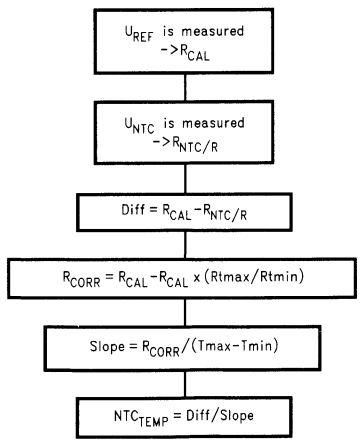

FIGURE 4. Accuracy Improvement

Measurement:

- — Timer Capture mode: R_{CAL} * C is measured
- — Timer Capture mode: $R_{NTC//R}$ * C is measured

Calculation:

- — Build the vertical-component (R_{TMIN} − R_{TMAX}) of the triangle
- — Calculate the slope
- — Calculate the actual temperature

Using this method the accuracy is primarily dependent on the accuracy of R_{TMIN} and R_{TMAX} and independent of the stability of the system clock, the capacitor and the threshold of the Schmitt Trigger level. The variation of the capacitor only leads to variation of the resolution.

The following diagram shows the ideal resistance/temperature characteristic of a NTC which is linearized with a parallel resistor.

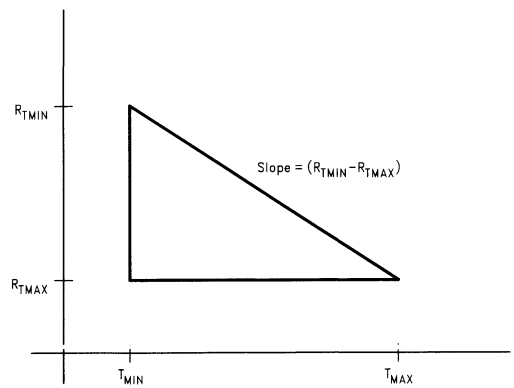

FIGURE 5. Resistance vs Temperature Characteristics

APPLICATION EXAMPLE

The following application example for temperature measurement demonstrates the procedure. The temperature is measured from 20° to 100° and is displayed on a Triplex LCD display.

NTC_{20} = 100 kΩ ±10%
R_P = 12 kΩ ±1%
T_m = 333 Kelvin → 60 Degrees
B = 4800 Kelvin
$NTC_{20}//R_P$ = 10.7 kΩ ±2%
R_{CAL} = 10.7 kΩ ±1%
T_{MIN} = 20 Degree
R_{TMIN} = 10.7 kΩ
T_{MAX} = 100 Degree
R_{TMAX} = 2.8 kΩ
C = 1 µF
RC-Clock = 2 MHz → 200 kHz instruction cycle, 5 µs
Timeconst. = R_{CAL} * C → 0.0107s
Resolution = 2140 → 11 byte, depends which Cap. value is used
Accuracy = ±2 Degree

This temperature measurment example shows a low cost technique ideally suited for cost sensitive applications which do not need high accuracy.

Figure 6 shows the complete circuit of the demoboard using the Triplex LCD method and the low cost A/D conversion technique.

The Triplex LCD drive technique is documented in a separate application note.

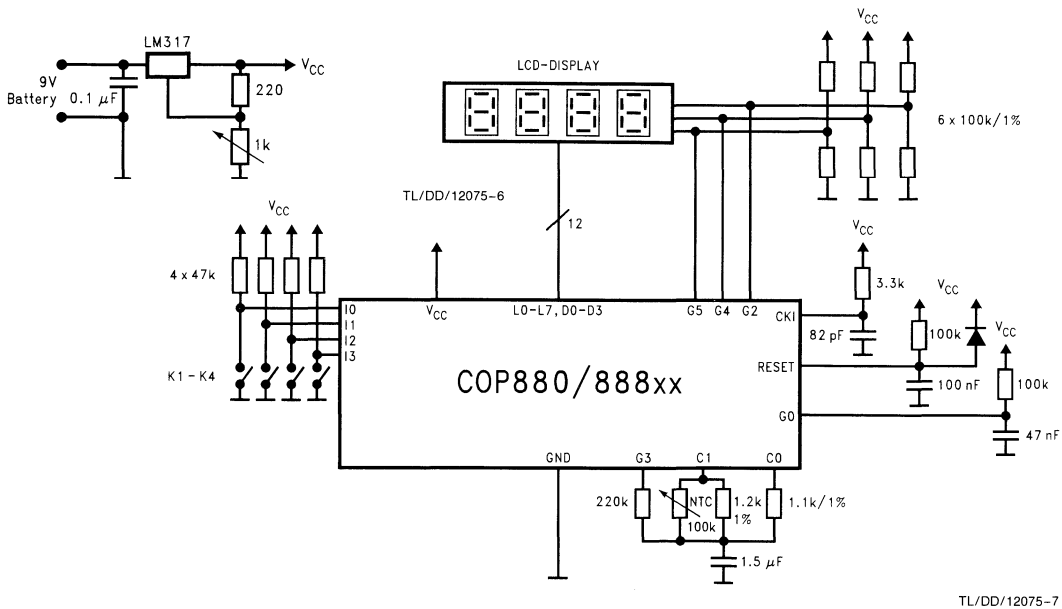

FIGURE 6. Circuit Diagram

Pressing key 1, key 2 the temperature is displayed in Degree/Fahrenheit.
Pressing key 3, key 4 Up/Down counter is displayed.

SOURCE CODE

Figure 7 shows the flow chart of the program.

LCD Triplex Drive with COP820CJ

National Semiconductor
Application Note 953
Klaus Jaensch and
Siegfried Rueth

INTRODUCTION

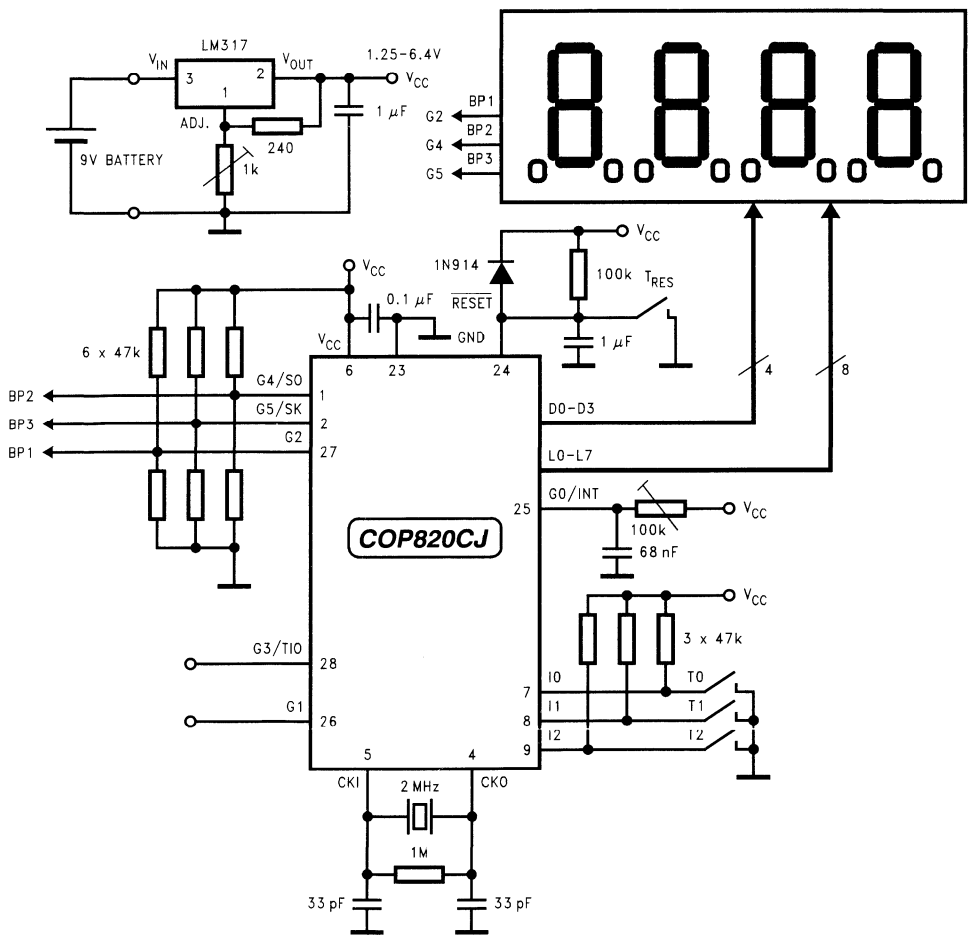
There are many applications which use a microcontroller in combination with a Liquid Crystal Display. The normal method to control a LCD panel is to connect it to a special LCD driver device, which receives the display data from a microcontroller. A cheaper solution is to drive the LCD directly from the microcontroller. With the flexibility of a COP8 microcontroller the multiplexed LCD direct drive is possible. This application note shows a way how to drive a three way multiplexed LCD with up to 36 segments using a 28-pin COP800 device.

ABOUT MULTIPLEXED LCD'S

There is a wide variety of LCD's, ranging from static devices to multiplexed versions with multiplex rates of up to 1:256.

The multiplex rate of a LCD is determined by the number of its backplanes (segment-common planes). The number of segments controlled by one line (with one segment pin) is equal to the number of backplanes on the LCD. So, a three way multiplexed LCD has three backplanes and three segments are controlled with one segment pin. For example in a three way multiplexed LCD with three segment inputs (SA, SB, SC) one can drive a 7-segment digit plus two special segments.

These are 3 × 3 = 7 + 2 = 9 segments. The special segments can have an application specific image. ("+", "−", ".", "mA", . . . etc).



TL/DD/12076-1

FIGURE 1. Schematic for LCD Triplex Driver

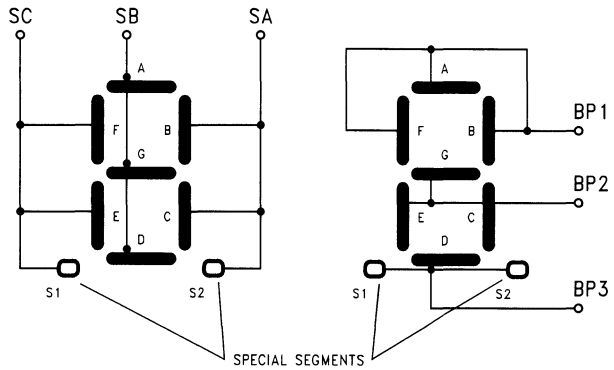


FIGURE 2. Example: Backplane-Segment Arrangement

A typical configuration of a triplex LCD is a four digit display with 8 special segments (thus having a total of 36 segments). Fifteen outputs of the COP8 are needed; **4 × 3 segment** pins and **3 backplane** pins.

Common to all LCD's is that the voltage across backplane(s) and segment(s) has to be an AC-voltage. This is to avoid electrochemical degradation of the liquid crystal layer. A segment being "off" or "on" depends on the **r.m.s.** voltage across a segment.

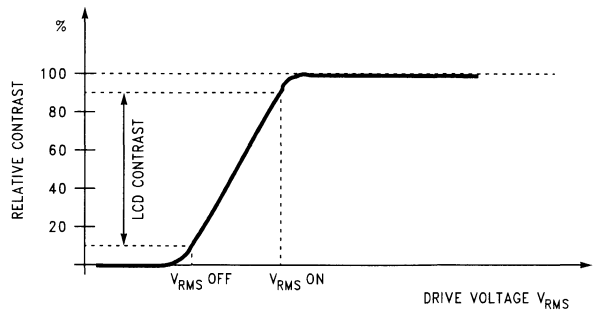
The maximum attainable ratio of "on" to "off" r.m.s. voltage (discrimination) is determined by the multiplex ratio. It is given by:

$(V_{ON}/V_{OFF})max = SQR((SQR(N) + 1)/(SQR(N) - 1))$

N is the multiplex ratio.

The maximum discrimination of a 3 way multiplexed LCD is 1.93, however, it is also possible to order a customized display with a smaller ratio. With the approach used in this application note, it may not be possible to acheive the optimum contrast acheived with a standard 3 way muxed driver. As a result of decreased discrimination (1.93 to 1.73) the user may have to live with a tighter viewing angle and a tighter temperature range.

In this application you get a **VrmsOFF** voltage of 0.408*Vop and a **VrmsON** voltage of 0.707*Vop. Vop is the operating voltage of the LCD. Typical Vop values range from 3V–5V. With the optoelectrical curve of the LCD you can evaluate the maximum contrast of the LCD by calculating the difference between the relative "OFF" contrast and the relative "ON" contrast.



In this example:

VrmsON = 0.707*Vop

VrmsOFF = 0.408*Vop

FIGURE 3. Example Curve: Contrast vs r.m.s. Drive Voltage

The backplane signals are generated with the voltage steps **0V, Vop/2** and **Vop** at the backplanes, also see *Figure 4*.

Two resistors are necessary for each backplane to establish all these levels.

The backplane connection scheme is shown in *Figure 1*.

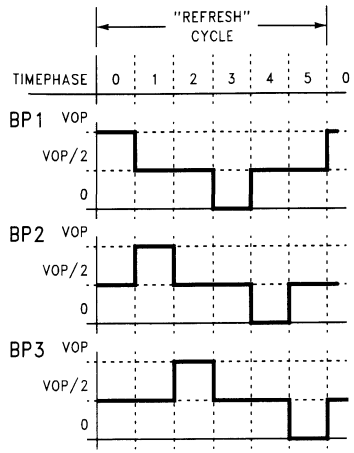
The Vop/2 level is generated by switching the appropriate COP's port pin to Hi-Z.

The following timing considerations show a simple way how to establish a discrimination ratio of 1,732.

TIMING CONSIDERATIONS

A Refresh cycle is subdivided in 6 timephases. *Figure 4* shows the timing for the backplanes during the equal distant timephases 0 . . . 5.

Backplane Control



TL/DD/12076–4

Note: After timephase 5 is over the backplane control timing starts with timephase 0 again.

FIGURE 4. Backplane Timing

While the backplane control timing continuously repeats after 6 timephases, the segment control depends on the combination of segments just being activated.

TABLE I. Possible Segment ON/OFF Variations

Tiphtab Address	Segment A	Segment B	Segment C
0	off	off	off
1	on	off	off
2	off	on	off
3	on	on	off
4	off	off	on
5	on	off	on
6	off	on	on
7	on	on	on

Figure 5 through *Figure 12* below show all possible combinations of controlling a **"Segment Triple"** with help of the 3 backplane connections and one segment pin. The segment switching has to be done according to the ON/OFF combination required (see also Table I).

Each figure shows in the first 3 graphs the constant backplane timing.

The 4th graph from the top shows the segment control timing necessary to switch the 3 segments (SA/SB/SC), activated from one pin, in the eight possible ways.

The 3 lower graphs show the resulting r.m.s. voltages across the 3 segments (SA, SB, SC).

FIGURE 12

REFRESH FREQUENCY

One period with six timephases is called a **refresh cycle** (also see *Figure 4*).

The refresh cycle should be in a frequency range of 30 . . . 60 Hz. A frequency below 30 Hz will cause a flickering display. On the other hand, current consumption increases with the LCD's frequency. So it is also recommended to choose a frequency below 60 Hz.

In order to periodically update the μC's port pins (involved in backplane or segment control) at the beginning of a new timephase, the COP8 needs a timebase of typ. 4 ms which is realized with an external RC-circuit at the G0/INT pin.

The G0 pin is programmable as input (Schmitt Trigger). The conditions for the external interrupt could be set for a low to high transition on the G0 pin setting the IPND-flag (external interrupt pending flag) upon an occurrence of such a transition. The external capacitor can be discharged, with the G0 pin configured as Push/Pull output and programmed to "0". When, switching G0 as input the Cap. will be charged through the resistor, until the threshold voltage of the Schmitt-Trigger input is reached. This triggers the external interrupt. The first thing the interrupt service routine has to do is to discharge the capacitor and switch G0 as input to restart the procedure.

This timing method has the advantage, that the timer of the device is free for other tasks (for example to do an A/D conversion).

The time interval between two interrupts depends on the RC circuit and the threshold of the G0 Schmitt Trigger V_{TH}.

The refresh frequency is independent of the clock frequency provided to the COPs device.

The variations of "threshold" levels relative to V_{CC} (over process) are as follows:

$$(V_{TH}/V_{CC})\ \text{min} = 0.376$$

$$(V_{TH}/V_{CC})\ \text{max} = 0.572$$

at V_{CC} = 5V

Charge Time:

$$T = -(\ln(1-V_{TH}/V_{CC})*RC)$$

To prevent a flickering display one should aim at a minimum refresh frequency of f_{refr} = 30 Hz. This means an interrupt frequency of f_{int} = 6 × 30 Hz = 180 Hz. So, the maximum charge up time T_{max} must not exceed 5.5 ms (T_{min} = 2.78 ms).

With the formula:

$$RC_{max} = T_{max}/(-\ln(1-(V_{TH}/V_{CC})\text{max})) = 5.5\ \text{ms} \times 0.849$$

$$RC_{max} = 6.48\ \text{ms}$$

$$(RC_{min} = 5.98\ \text{ms})$$

The maximum RC time-constant is calculated. The minimum RC time constant can be calculated similarly.

A capacitor in the nF-range should be used (e.g. 68 nF), because a bigger one needs too much time to discharge. To discharge a 68 nF Cap., the G0 pin of the device has to be low for about 40 μs.

On the other hand the capacitor should be large enough to reduce noise susceptibility.

When the RC combination is chosen, one can calculate the maximum refresh frequency by using the minimum values of the RC constant and the minimum threshold voltage:

$$T_{min} = RC_{min}*(-\ln(1-(V_{TH}/V_{CC})\text{min} = RC_{min}*0.472$$

and

$$f_{refr,max} = f_{int,max}/6 = 1/(T_{min}*6)$$

In the above example one timephase would be minimum 2.82 ms long. This means that about 250 instructions could be executed during this time.

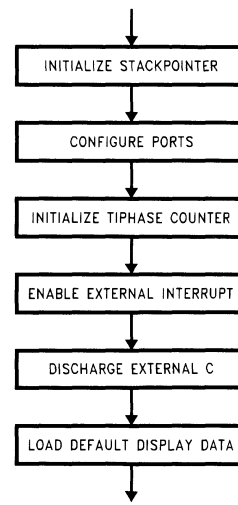
SOFTWARE

The software for the triplex LCD drive-demo is composed of three parts:

1. The initialization routine is executed only once after resetting the device, as part of the general initialization routine of the main program. The function of this routine is to **configure the ports, set the timephase counter (tiphase) to zero, discharge the external capacitor and enable the external interrupt.**

The initialization routine needs 37 bytes ROM.

Figure 13 shows the flowchart of this routine.



TL/DD/12076–13

FIGURE 13. Flowchart for Initialization Routine

2. The update routine calculates the port-data for each timephase according to the BCD codes in the RAM locations **'digit1' . . . 'digit4'** and the **special segments**. This routine is only called if the display image changes.

The routine converts the BCD code to a list **1st**, which is used by the refresh routine. *Figure 14* gives an overview and illustrates the data flow in this routine.

In *Figure 15* the data flow chart is filled with example data according to the display image in *Figure 16*.

First the routine creates the **seg1st** (4 bytes long), which contains the "on/off" configuration of each segment of the display. The display has 36 segments but the 4 bytes have only 32 bits, so the four special segments **S1** are stored in the **specbuf** location. The **bcdsegtab** table (in ROM) contains the LOOK-UP data for all possible Hex numbers from **0 to F**.

The routine takes three bits at the beginning of each time-phase from the **seg1st**.

These 3 bits address the 8 bytes of the **tiphtab** table in ROM. Each byte of this table contains the **time curve** for a segment pin (only 6 bits out of 8 are used).Using this information, the program creates the lists **for port D and port L (pod1st, pol1st)**. Every byte of this list contains the **timing representatives** for the pins D0–D3 and L0–L7, to allow an easy handling of the refresh routine.

The external interrupt has to be disabled while the **copy** routine is working, because the mixed data of two different display images would result in improper data on the display. *Figure 17* shows the flowchart of the **update** routine. The Flowchart of the **convert** subroutine is shown in *Figure 18*.

MEMORY REQUIREMENTS

ROM: 152 bytes incl. look up tables

RAM: 43 bytes (*Figure 15* illustrates the RAM locations)

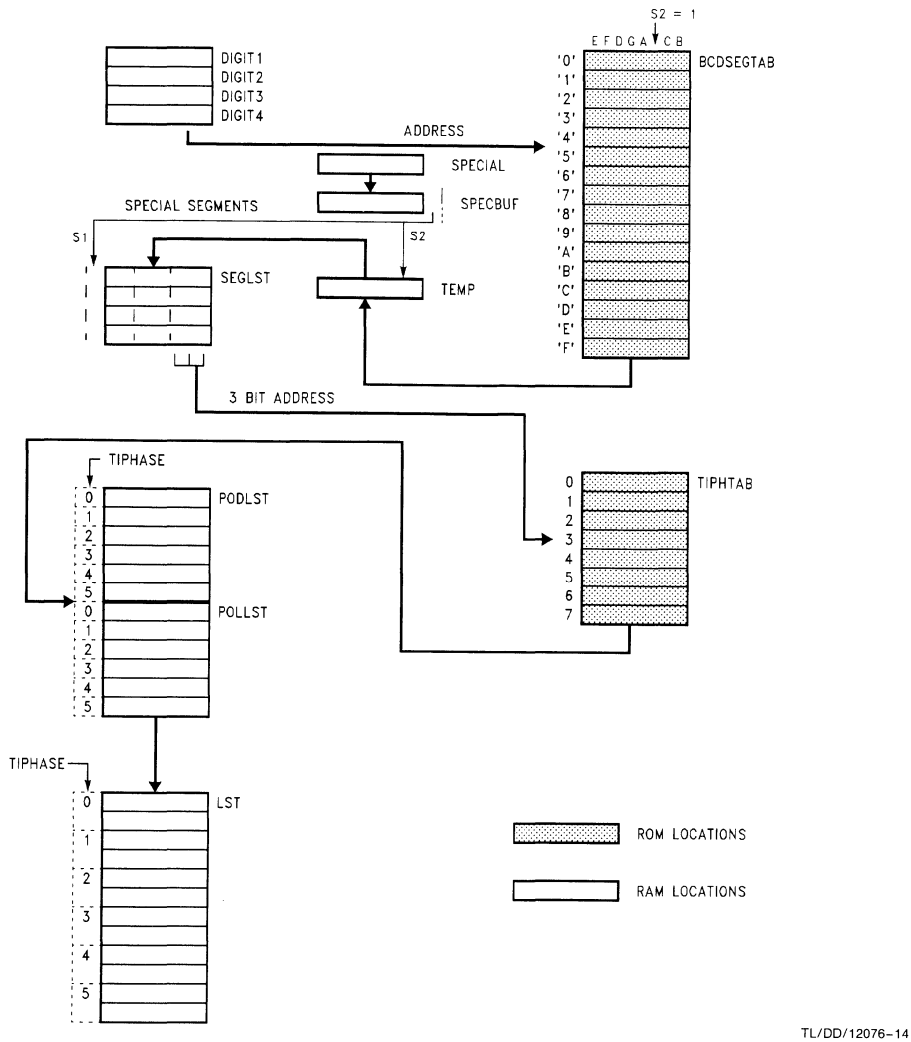


FIGURE 14. Data Flow Chart for Update Routine

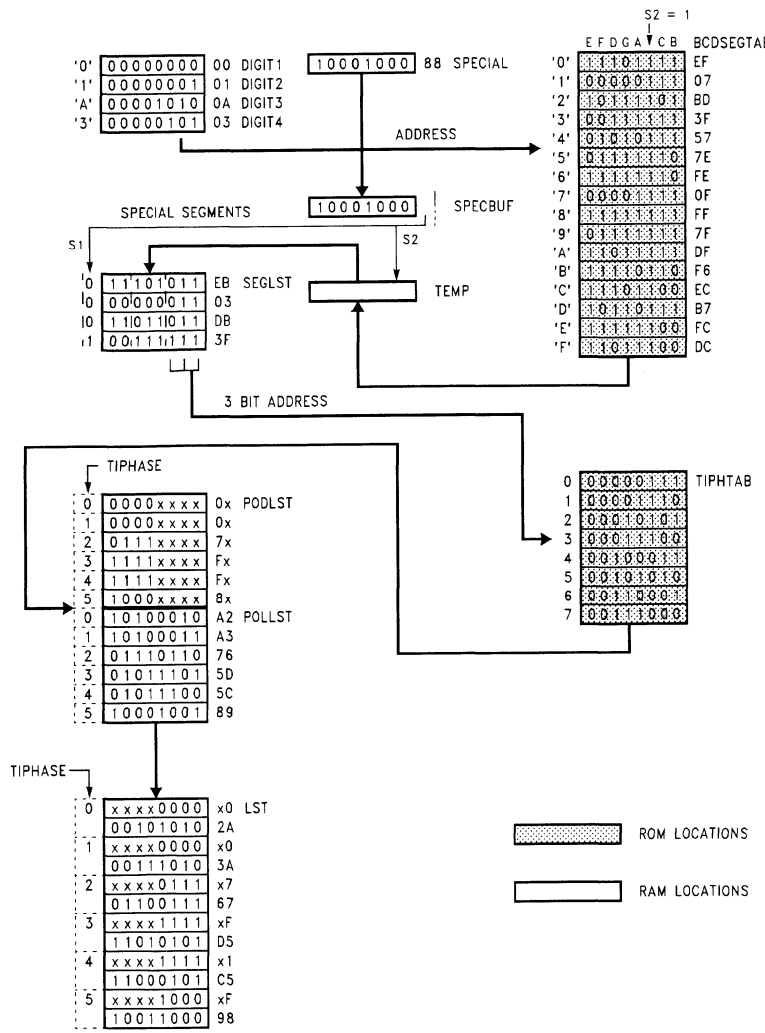

FIGURE 15. Data Flow Chart for Update Routine

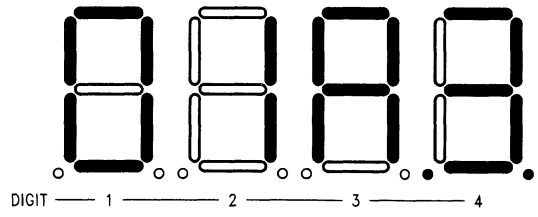

TL/DD/12076-16

FIGURE 16. Display Example

3. The refresh routine is the interrupt service routine of the external interrupt and is invoked at the beginning of a new timephase. First the routine discharges the external capacitor and switches the G0/INT pin back to the input mode, to initialize the next timephase. The backplane ports G2, G4 and G5 and the segment pin ports D and L are updated by this routine according to the actual timephase. For the backplanes the data are loaded from the **bptab** table in ROM.

Table II shows how the **bptab** values are gathered. *Figure 20* shows the flowchart for the refresh routine.

TIME REQUIREMENTS

The routine runs max. 150 cycles.

For a non flickering display, the refresh frequency must be 30 Hz minimum. One refresh cycle has six timephases and is max. 33 ms long. So each timephase is 5.5 ms long. With an oscillator (CKI) frequency of 2 MHz, one instruction cycle takes 1/(2 MHz/10) = 5 μs to execute. During one timephase the controller can execute:

5.5 ms/5 μs = 1100 cycles. So the refresh routine needs 134/1100 = 0.122 = 12.2% of the whole processing time (in this case).

With a refresh frequency of 50 Hz the routine needs about 20.1% of the whole processing time.

The refresh routine needs about **103** ROM bytes.

TABLE II. Phase Values

Tiphase	G5	G4	G2	Portg Data	Hex	Portg Config.	Hex
0	0/0	0/0	1/1	XX00X1XX	04	XX00X1XX	04
1	0/0	1/1	0/0	XX01X0XX	10	XX01X0XX	10
2	1/1	0/0	0/0	XX10X0XX	20	XX10X0XX	20
3	0/0	0/0	0/1	XX00X0XX	00	XX00X1XX	04
4	0/0	0/1	0/0	XX00X0XX	00	XX01X0XX	10
5	0/1	0/0	0/0	XX00X0XX	00	XX10X0XX	20

data/configuration register of portg

0/0 : Hi-Z input
0/1 : output low
1/1 : output high

SUMMARY OF IMPORTANT DATA

LCD type:	3 way multiplexed
Amount of segments:	36
$V_{OP} = (V_{CC})$ (range):	2.5V to 6V
Oscillator frequency:	2 MHz (typ.)
Instruction cycle time:	5 μs
ROM requirements:	
init routine:	37 bytes
update routine:	152 bytes
refresh routine:	103 bytes
total:	292 bytes
RAM requirements:	
permanent use:	25 bytes
temporary use:	18 bytes
stack:	6 bytes
total:	49 bytes
	(also see *Figure 19*)
Timer:	not used
External interrupt:	with RC circuit used as time-base generator
Ports D, L:	used for LCD control
Port G:	3 G-pins are still free for other purposes +
Port I:	can be used as key-inp.

COP888GW Features and Applications

National Semiconductor
Application Note 982
Martin Embacher

INTRODUCTION

The COP888GW is a member of National Semiconductor's COP888 family of microcontrollers fabricated in M²CMOS™ technology. The device was established using CCM (Configurable Controller Methodology) design techniques which provide a fast and reliable way to create new derivatives for a fast growing and demanding controller market. In addition to the COP888 feature core this controller includes a math unit to allow fast multiply/divide operations. The controller has special timers for motor control allowing it to be used in applications where enhanced processing power and motor control capabilities are required (as in plotters, robot-arms or information systems.)

This note describes the COP888GW microcontroller emphasizing the powerful new features. The reader will be given easy to use macros to take full advantage of the new CCM blocks.

COP888GW KEY FEATURES

- Multiply/Divide Unit
- Two 16-bit capture modules with 8-bit prescalers
- Four pulse train generators with 16-bit prescalers
- Full duplex UART
- MICROWIRE/PLUS™ serial port with interrupt
- 16 kbytes of on-board ROM
- 512 bytes of on-board RAM
- Multi-Input Wakeup pins (8) optionally usuable hardware interrupts either on falling or rising edge
- Two 16-bit timers, each with two 16-bit autoreload/capture registers supporting:
  — Processor independent PWM mode
  — External Event counter mode
  — Input Capture mode
- Low EMI
- Two power saving modes: HALT and IDLE
- Fourteen multi-source vectored interrupts
- Software selectable I/O options
- Package:
  — 68 PLCC with 56 I/O pins

CAPTURE TIMERS

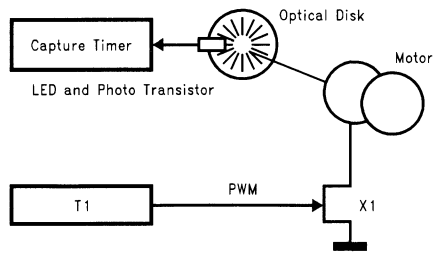
With its two high speed, high resolution capture timers, the COP888GW is ideally suited high resolution frequency measurement. To give a feeling for the capabilities, Table I shows the capture timers resolution versus the measured signal freuency with a processor clock (CKI) of 10 MHz. The sampling rate is CKI divided by a 8-bit prescaler. In the table, the prescaler is set to 1 to allow maximum performance. This results in a maximum resolution of 100 ns.

TABLE I. Capture Timer Resolution vs Signal Frequency

Resolution/ Bits	16	14	12	10	8
Max. Frequency	152 Hz	610 Hz	2.4 kHz	9.6 kHz	39 kHz

The capture timer can be used for a closed loop control in a DC motor. One of the standard COP888 timers (T1 or T2) generates a PWM signal to control the motor. One of the capture timer modules measures the actual RPM of the motor. A simple algorithm is used to adjust the motor's speed to the desired value.

Figure 1 shows a block diagram of a closed loop DC motor control with one capture and one PWM timer. The MOSFET X1 acts as a low-side driver for the motor and controls the current flow. The current through the motor is proportional to the duty cycle of the PWM signal, generated by T1, at the gate of X1. An optical disk, in conjunction with an LED/photo transistor senses the motor's RPM. The pulses generated by the photo transistor are directly fed to the capture timer's input. The capture timer inputs are alternate functions of Port-L. This I/O-port features integrated schmitt trigger inputs eliminating the need for external signal conditioning of the input signals.



TL/DD/12376–1

FIGURE 1. Closed Loop DC Motor Control Block Diagram

SOFTWARE MODULES

The following section provides a guide to general purpose macros and subroutines to set-up the capture timer and the standard timers T1 to T2. The fuctions are written as of macros so the user can easily include them in the application software.

CAPTURE TIMERS

Capture Timers Setup Routine

This routine sets the capture timer module CCM1 or CCM2 to allow input capture of a signal on the respective port pin. Additionally the I/O pins Port L6 for CCM1 and Port L7 for CCM2 are configured as inputs. This macro should be placed in a separate macro file and included in the source code after the processor specific include file. *Figure 2* shows the source code to include the macros in the applications program.

```
.incld cop888gw.inc
.incld gw_macros.inc
.sect main_prog, rom
..
..
.end
```

FIGURE 2. Including a Macro Into Source Code

The macro is called in the source code as:

__CT__SETUP, __MODULE, __PRESCALER, __EDGE, __INTR

__MODULE is the capture module number

1 = capture module 1
2 = capture module 2

__PRESCALER is the prescaler value the range is 0 to 255.

EDGE selects the input capture edge

0 = rising edge
1 = falling edge

__INTR select if capture interrupt is used

0 = disable capture interrrupt
1 = enable capture interrrupt

The macro will check that all values are in the acceptable range and warn the user if this is not the case.

An example of the generated code is shown below. The macro is called to setup capture timer 1 with a prescaler of 100 (dec) to capture signals on a falling edge without the generation of an interrupt.

```
_CT_SETUP 1 100 1 0

ld      b, #CCMR1 ; point to capture con
ld      [b], #0   ; stop capture, clear
rbit    6, portlc ; cm 1 input on port L
ld      cm1psc, #100 ; load prescaler of c
ld      [b], #ZZ0000 ; start capture
```

TL/DD/12376–2

FIGURE 3. __CT__SETUP Resulting Code

Special attention is needed if the interrupts are enabled in the macro by setting the __INTR directive to one. An appropriate interrupt handler must be placed elsewhere in the code. The macro will allow the capture timer to generate interrupts, however it will not provide the respective interrupt service routine.

Capture Timer Read Macro

__CT__READ __MODULE __VARIABLE

__MODULE is the capture module number

1 = capture module 1
2 = capture module 2

__VARIABLE is a variable to hold the contents of the capture register

Standard Timer Setup for PWM Output

__TIM__SETUP __NUMBER __CYCLE __TON __INIT

__NUMBER is the timer number

1 = timer 1
2 = timer 2
3 = timer 3

__CYCLE is the cycle time of the PWM signal the range is 0 to 65535

__TON is on time of the PWM signal

__INIT is the initialization value

0 = start with low
1 = start with high

Standard Timer Glitch Free PWM Output

This macro is used to provide a glitch free switched PWM output with the standard COP8 PWM timer. In the macro interrupts are disabled to wait until a PWM cycle is completed and then reload the registers are re-written. This produces—in difference to an interrupt driven routine—a glitch free output of the PWM signal.

__TIM__PWM __NUMBER __CYCLE __TON

__NUMBER is the timer number

1 = timer 1
2 = timer 2
3 = timer 3

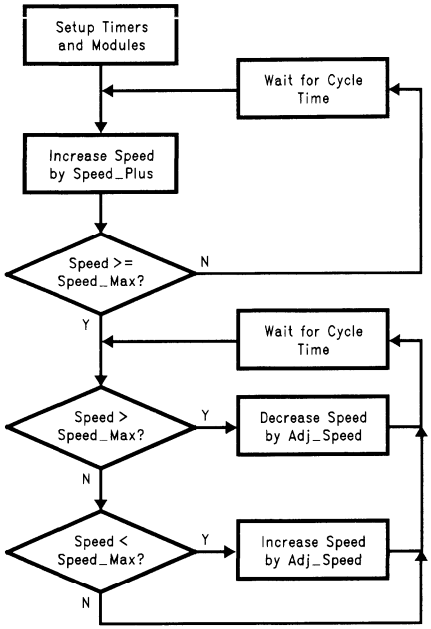
__CYCLE is the cycle time of the PWM signal the range is 0 to 65535

__TON is on the time of the PWM signal

Note: The source of the macros is found in Section Capture Module Macros on page 5.

DC Motor Control Example

An example for the application of the macros is basic DC motor closed loop control. The motor drive consists of the phases start and run. During start, the motor's speed increases up to the maximum speed set by speed__max. During run, the speed is kept around speed __max. The slope of speed increase is set by speed__plus and the maximum allowable speed increase or decrease during run is set by adj__speed. The speed update cycle time may be controlled by the IDLE timer, generating an interrupt every 4096 t_C. *Figure 4* shows the flowchart of a simple closed loop DC-motor control. The macros can be used to setup the times and to read the current speed value.



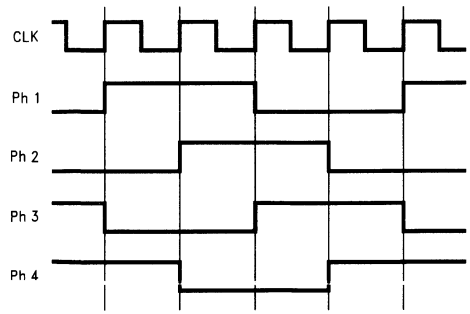
TL/DD/12376–3

FIGURE 4. Basic DC Motor Control Loop Flowchart

Pulse Train Generators

The COP888GW contains four independent pulse train generators designed for stepper motor control. The pulse train generator provides a programmable number of 50% duty cycle pulses on the output pin. Depending on the external sequencer logic these timers can be used for regular step control or for microstep driving.

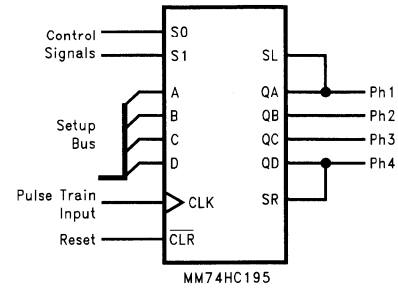
If the user does not require pulse train outputs on all pins the pulse train generators can be used as four independent timers with interrupt capability.



TL/DD/12376–4

FIGURE 5. Standard Stepper Motor Control Waveform (Two Phases On)

Microstepping is used in applications where the step sizes have to be very small to allow smooth transitions from one state to another. Special microstep drivers and motors have been developed. These devices turn the applied pulses into current steps to run the motor. The standard input of these drivers is a pulse train as generated by the COP888GW microcontrollers. To show the basic stepper motor control circuit a standard stepper motor drive circuit is discussed based on a four-phase motor. *Figure 5* shows the waveform required to control a standard motor. CLK is the pulse train generated by the pulse train generator, PH1–PH4 are the outputs to the motor drivers. These signals can be generated by using a simple shift/rotate register.



TL/DD/12376–5

FIGURE 6. Simple Stepper Motor Sequencer

Figure 6 shows an application circuit for a bidirectional stepper motor. The shift register is loaded under software control and then the pulse train is started. More than one motor can be connected in the same manner. Each motor gets its own sequencer the setup bus signals are common for every sequencer. Two control signals, unique for every motor, select the direction and the mode of the sequencer. Mode can be load new pattern, shift left and shift right. The circuit shown above is capable of controlling low current stepper motors used in some applications, if a higher output drive is required appropriate driver stages should be used.

As stepper motors usually have some inertia the pulse train starts up slowly and increases its frequency, under software control, up to full step speed. The same scheme as shown in *Figure 4* can be applied if increase speed is replaced by increase pulse train frequency and decrease speed accordingly to decrease pulse train frequency.

Pulse Train Generator Routines

The first routine sets up the pulse train generators PT1–PT4. Additionally the respective output pins Port E0 for PT1, Port E1 for PT2, Port E2 for PT3 and Port E3 for PT4 can be configured if the user needs to output the data.

Pulse Train Generator Setup

__PT__SETUP __MODULE, __PRESCALER, __PULSES, __OUT, __INTR, __RUN

__MODULE is the pulse train module number

1 = pulse train module 1
2 = pulse train module 2
3 = pulse train module 3
4 = pulse train module 4

__PRESCALER is the prescaler value the range is 0 to 65535.

__PULSES selects the number of pulses: 0 to 65535.

__OUT enables or disables pulse output

0 = output disabled
1 = output enabled

__INTR select if an interrupt is generated on completion of the pulse generation

0 = disable interrupt
1 = enable interrupt

__RUN selects if the pulses are output directly after initialization or at a later time.

0 = don't start pulse train generator

1 = start pulse train generator

The macro will check that all values are in the acceptable range and warn the user if this is not the case.

Pulse train output:

The second routine loads a new number of pulses into the pulse train registers and starts the generation. Setting regarding interrupts and output are not affected. The macro is called in the source code as:

__PT__CHANGE__MODULE,__PULSES

__MODULE is the pulse train module number

1 = pulse train module 1
2 = pulse train module 2
3 = pulse train module 3
4 = pulse train module 4

__PULSES selects the number of pulses: 0 to 65535.

MULTIPLE/DIVIDE

The device constains a multiply/divide block to speed up the multiply/divide operations. To give an idea about the speed increase, Table II shows a comparison of the standard multiply/divide operations done in software with the same operation performed using the MUL/DIV unit.

TABLE II. Multiply/Divide Operation Speed

Type of Operation	MUL/DIV Operation in Software	MUL/DIV Block
Multiply 8 x 8	129 t_C	11 t_C
Multiply 8 x 16	243 t_C	11 t_C
Divide 8 x 8	208 t_C	14 t_C
Divide 24 x 8	827 t_C	14 t_C

Note: Comparisons include loading the registers for the MUL/DIV block and accordingly the RAM cells used for software multiply/divide on standard COP8 microcontrollers. The actual 16 x 8 multiply operation takes one t_C and a 24 x 16 divide takes 2 t_C. However for accurate comparison the register setup times have to taken into account.

The following section provides software modules used to set up the multiply/divide unit and to load the respective registers. Although the MUL/DIV block does not allow signed arithmetic it can be used with some additional software to perform signed operations. The signed operations check for a sign in every number to be divided or multiplied—performs a sign conversion if negative—does the operation and adjusts the output accordingly.

Note: These software modules use constants to show the basic operation example of loading the MUL/DIV registers. These need to be customized in the application software.

Macro for unsigned 8 x 16 multiply

__MUL816U __MUL1 __MUL2
__MUL1 is the 8-bit unsigned multiplier
__MUL2 is the 16-bit unsigned multiplicand

Macro for unsigned 16 x 16 divide

__DIV1616U __DIV1 __DIV2
__DIV1 is the 16-bit unsigned dividend
__DIV2 is the 16-bit unsigned divisor

Macro for signed 6 x 16 multiply

__MUL816S __MUL1 __MUL2
__MUL1 is the 8-bit signed multiplier
__MU21 is the 16-bit signed multiplicand

Macro for signed 16 x 16 divide

__DIV1616S __DIV1 __DIV2
__DIV1 is the 16-bit unsigned dividend
__DIV2 is the 16-bit unsigned divisor

FURTHER APPLICATION HINTS

It was shown that the COP888GW with its new and enhanced functions can operate as a system contoller in various applications. Due to the large number of I/O lines additional features can be included in the system with minimal external hardware effort. For example it was shown in application note AN-673 how a simple two way multiplexed LCD control can be done with a COP8 microcontroller. The feature can be easily adopted to the COP888GW allowing system e.g. a simple plotter device to be controlled. Another application example is a climate control system, where COP888GW can be used to control the heating process. Control algorithms can be generated with National's NeuFuz™ software package. User interfaces can be done as described above with LCD drive. Diagnostics is possible with the on-chip UART.

Simple, Cost Effective A/D Conversion Using COP888EK

National Semiconductor
Application Note 983
Siegfried Rueth

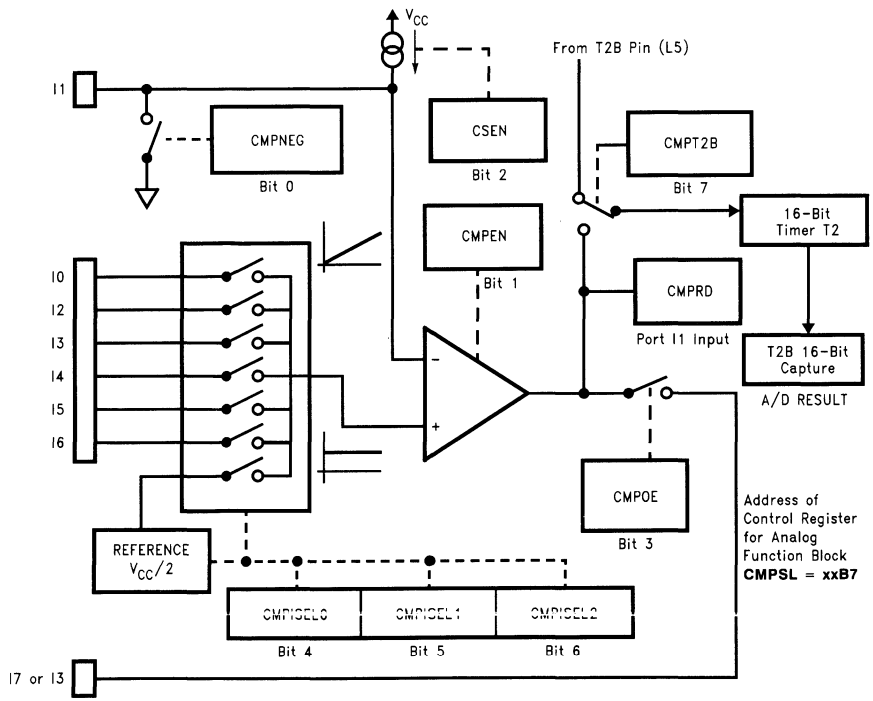
INTRODUCTION

The COP888EK is a member of National Semiconductor's COP888 feature family of microcontrollers fabricated in M²CMOS™ technology. The device was designed using CCM (Configurable Controller Methodology) design techniques, a fast and reliable way to create new derivatives for a fast growing and demanding controller market.

This Application Note describes the device emphasizing the new and powerful features.

KEY FEATURES

- Analog Function Block composed of a multiplexer with a total of 6 external analog inputs, a constant current source, an analog comparator, a software selectable $V_{CC}/2$ reference and a dedicated 16-bit timer/16-bit capture register pair (see below).
- MICROWIRE/PLUS™ serial port with interrupt.
- 8 kbytes of on-board ROM
- 256 bytes of on-board RAM
- Multi-Input Wakeup (8 pins) optionally usable as hardware interrupts with programmable transition
- Three 16-bit timers with two I/O pins assigned and two 16-bit autoreload/capture registers supporting:
  - — Processor independent PWM mode
  - — External Event counter mode
  - — Input Capture mode
- Quiet design (low radiated emissions)
- WATCHDOG™/Clock monitor and Idle Timer
- Two power saving modes, HALT and IDLE
- Twelve multi-source vectored interrupts
- Software selectable I/O options
- Packages:
  - — 28 SO or DIP with 23 I/O's each
  - — 40 DIP with 35 I/O's
  - — 44 PLCC with 39 I/O's



TL/DD/12377–1

FIGURE 1. COP888EK Analog Function Block

THE ANALOG FUNCTION BLOCK

The analog function block allows single slope (integration) type of A/D conversion on 6 analog multiplexed input pins. With this alternate function on the 8-bit I-port (which is an "input only" port in other devices) this derivative received a powerful enhancement.

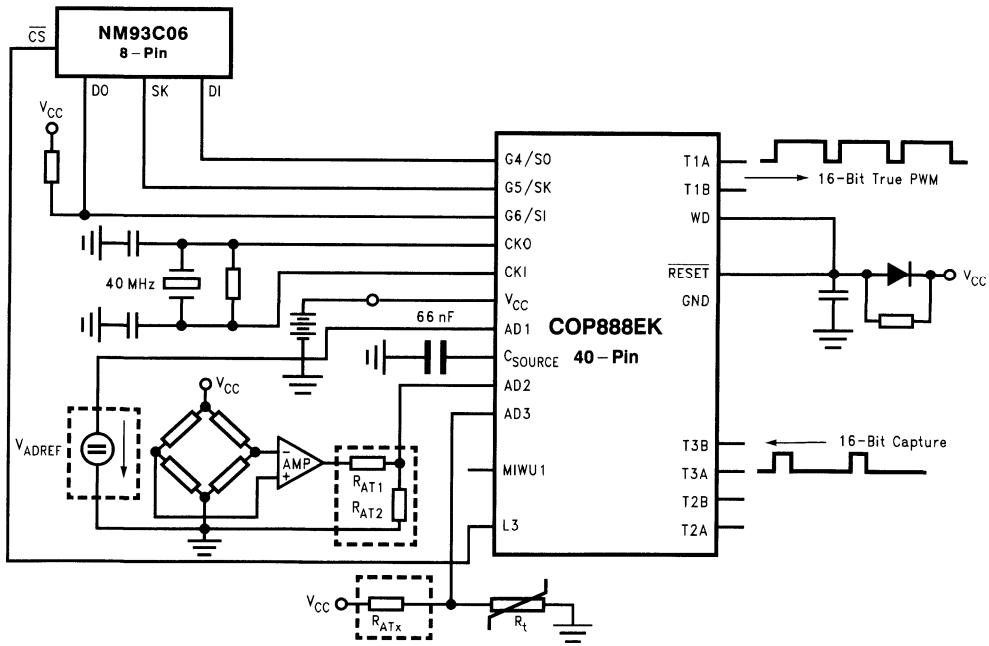
Figure 1 illustrates the principles of the whole block. One of the six I-pins (I0, I2, . . ., I6) or an internally available $V_{CC}/2$ reference can be multiplexed onto the positive terminal of an internal analog comparator. A ramp can be fed to the negative comparator terminal by simply applying a capacitor on pin I1 and initializing the on-chip constant current source. The 16-bit "T2B" capture register completes the analog function block and will be directly triggered from the output of the on-chip comparator. T2B is one of the two 16-bit autoreload/capture registers assigned to Timer 2.

A/D CONSIDERATIONS

Single slope (integration) A/D converters have sources of inaccuracy affecting the quality of the digital result of the conversion. In addition, this serial approach is slower than successive approximation type A/D's and can not be applied in cases where fast conversion is required. The following considerations may help the user to judge if this technique is adequate for the particular A/D conversion task(s) the microcontroller has to perform.

A resolution of 11 bits can be established with a CKI frequency of 2 MHz and a 66 nF capacitor. The linearity of the ramp is dependent on the constant current source, the common mode range of the comparator and the type of capacitor. The optimum linearity can be obtained if the voltage level on the selected input channel does not exceed a maximum of V_{CC} − 1.5V. Therefore it may be necessary to attenuate the input levels as shown in *Figure 2*. In order to maximize the accuracy of the A/D conversion there are some guidelines the user should follow:

- — An accurate reference is required. This can be a fixed reference (for example a reference diode) directly applied to one of the analog inputs. In many applications there is an EEPROM present which could hold a digital reference "burned in" during the manufacturing process. This can eliminate the need for an accurate and expensive crystal oscillator and a much cheaper RC clock can be used instead.
- — The user should limit the levels at the analog inputs to values less than or equal to V_{CC} − 1.5V.
- — Relating all measurements to the on-chip $V_{CC}/2$ reference will help to compensate for temperature variations.
- — Capacitors with values higher than 100 nF may not be useful because of decreasing linearity. For values higher than 33 nF, it is recommended to use styroflex capacitors or similar quality.



TL/DD/12377–2

FIGURE 2. COP888EK with Strain Gauge Transducer

The constant current delivered from the on-chip current source can vary in the range of 10 μA–30 μA. To calculate the minimum resolution, the following equation can be used:

$$X_{RES} = \frac{C \bullet dV}{I_{MAX} \bullet t_c}$$

with:

C = Value of capacitance in [nF]
dV = Range of channel input voltage in [V]
I_{MAX} = Max. current delivered from current source [μA]
t_c = Instruction cycle rate of microcontroller [10/CKI]
X_{RES} = Resolution of Digital value (found in T2B).

APPLICATIONS EXAMPLES

Frequently used sensors in industrial and consumer applications are "NTC's" and strain gauge transducers. *Figure 2* shows a configuration with both types connected. Using the above equation, the minimum resolution at 2 MHz CKI clock input and a 66 nF capacitor, is 10-bits with an input signal varying between 0V and 3V and a V_{CC} voltage of 5V. The typical resolution with these parameters is more than 11-bit and the achievable accuracy is already better than the accuracy of an 8-bit successive approximation type of A/D converter. Doubling the CKI frequency will increase the resolution by 1-bit. A typical software initialization sequence for an A/D conversion (measuring the on-chip $V_{CC}/2$ ref) looks as follows:

```
RESET:
                .
                .
                .
CONVERT:
   LD   CMPSL,#b'11110011   discharge Capacitor connected
                            to 'Csource' (I1); enable Comp.,
                            select timer 'T2B' input to be
                            driven from comparator output;
                            connect internal Vcc/2 ref. as a
                            positive input to the comparator;
                            disable constant current source.
DELAY:
   NOP                      give time to discharge the
   NOP                      capacitor.
                .
                .
   LD   TMR2LO,#0FF         Preset Timer T2
   LD   TMR2HI,#0FF         with #0FFFF, initialize capture
   LD   T2CNTRL,#0E0        mode and start timer.
   LD   CMPSL,#b'11110110   enable constant current source
                            and start charging the capacitor
                            on I1.
ADFIN:
   IFBIT 1,T2CNTRL          Testloop to check if T2B pending
   JP    DONE               flag is set. If this flag is set then
   JP    ADFIN              the A/D conversion is done. The
                            result can be picked up from the
                            T2B capture register.
                .
                .
                .
                                              TL/DD/12377-3
```

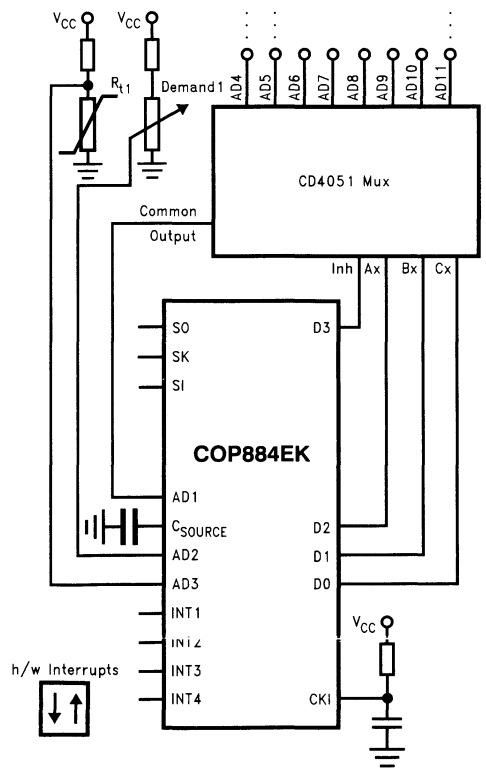
Similarly, the other (external) sources can be measured by appropriately setting bits 4, 5 and 6 in the **CMPSL** register, discharging the capacitor, setting the timer, and charging the capacitor.

A/D CONVERSION TIME

The minimum specified constant current fed into the capacitor connected to pin C_{SOURCE} (i1) is 10 μA and causes the longest possible conversion time. With the values given, the X_{RESmax} = 3960 counts. A 2 MHz crystal will yield a t_c-cycle of 5 μs in a COP800 microcontroller. This means the conversion time to measure one channel is maximum:

$$T = 3960 \times 5\ \mu s = 18.8\ ms$$

To ensure secure and stable measurements however it is recommended to do a minimum of 2 or 3 conversions on a particular input channel and compare subsequent results with each other. Taking the worst case with 3 A/D-cycles plus additional 3 cycles measuring the internal $V_{CC}/2$ reference will result in a total conversion time of 6 × 18.8 ms which gives 113 ms. The processing time to find the final digital value representing the analog level at the A/D channel will not contribute a significant period of time so that a total conversion time of 120 ms is a reasonable assumption for a worst case scenario. Likewise the total conversion time will be half with a CKI frequency of 4 MHz and a capacitance at pin C_{SOURCE} equal to half the original value.



TL/DD/12377-4

FIGURE 3. Expansion of A/D Channels

EXPANDING THE NUMBER OF A/D CHANNELS

Figure 3 shows an inexpensive way to establish additional A/D channels by using a CD4051 analog multiplexer. The COP884EK is a 28-pin version of the COP888EK and provides 3 analog inputs. One input must be used to connect the common output of the external mux which carries the channel selected via the pins (Ax, Bx, Cx). An additional control pin is required to enable the desired channel. The whole setup is capable of handling a total of 10 A/D channels. In many automotive and industrial applications, a controller has to scan temperature sensors, monitor fluid-levels and measure pots which hold "demand-values" for open- or closed-loop control systems. In these applications, timing is typically not a critical requirement. Also, the internal $V_{CC}/2$ reference is most likely adequate to gain sufficient accuracy.

TABLE I. Resolution and Accuracy vs dV and CKI

	Ex1	Ex2	Ex3	Ex4	Ex5
V_{CC}[V]	5	5	5	5	3
dV[V]	3	3	3	3	1.8
CKI[MHz]	1	2	4	5	2
t_c[μs]	10	5	2.5	2	5
X_{RESmin}	8-bit	9-bit	11-bit	12-bit	9-bit
X_{REStyp}	>9-bit	>10-bit	>12-bit	14-bit	>10
Acc	6-bit	7-bit	8-bit	>9-bit	7-bit
C[nF]	33	33	66	100	66

Table I shows some examples of achievable minimum resolution (row: X_{RESmin}) and accuracy (row: Acc) dependent on the V_{CC} voltage, the CKI frequency and the capacitor value (connected to pin I1).

OTHER FEATURES

I. Timers

The COP888EK has three 16-bit timers with two I/O pins assigned and two autoreload/capture registers associated with each.

Figure 4 shows one of the timers configured for PWM mode. The contents of the 2 autoreload registers are copied alternately into the 16-bit timer (upon underflow) one holding the high time and the other holding the low time of the pulses presented to the Timer I/O pin TxA (with x = 1, 2 or 3), thus being able to establish duty-cycles from 1/65535 to 65535/1.

In capture mode both I/O's assigned to a timer can be incorporated into time or frequency measurements. Inputs on TxA trigger measurements in capture register TxRA and inputs to pin TxB trigger measurements in capture register TxRB.

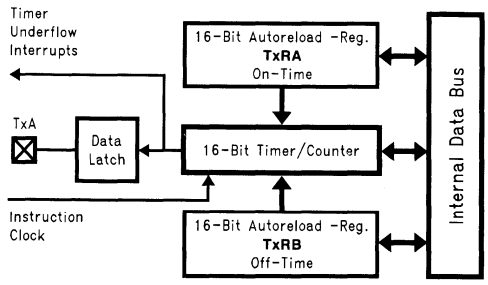


FIGURE 4. Timer in PWM-Mode

Thereby all possible combinations of transitions can be programmed.

There are many interrupt sources associated with all timer modes such as timer underflow, autoreloads on TxRA and TxRB and positive or negative transitions on the timer pins TxA and TxB thus allowing a very flexible use.

In addition, there is the free running 16-bit timer T0 that can be used for time base and to establish the low current idle-mode.

II. Low EMI and Low Current Oscillator

Low radiated emissions are achieved by gradual turn-on output drivers and internal I_{CC} filters on the chip logic and crystal oscillator. All precautions taken lowered the radiated noise by about 20 dB compared to older COP888 family devices.

III. Multi-Input Wakeup/Hardware Interrupts

The 8 pins of the 8-bit L-port can alternately be configured as wakeup inputs. The trigger condition can be either programmed on the "high to low" or "low to high" transition. The Multi-Input Wake-up can be used with the power saving Halt- (with Halt currents less than 10 μA) or Idle mode, to wakeup the device via one of the eight wakeup pins. Alternately these pins can serve as additional hardware interrupts with programmable transition polarity.

CONCLUSIONS

— With the performance and the combination of functions provided (low EMI, multi-channel high resolution A/D, powerful timer structure . . .) the COP888EK is ideally suited for many applications in automotive and industrial/consumer markets.

— The analog function block can be configured to perform integration type A/D conversions with resolutions of up to 14 bits and achievable accuracies significantly better than the 8-bit approximation type deliver.

— The strengths of the COP888EK can be supplemented from National's NeuFuz4™ development environment which supports the generation of intelligent control algorithms for open- and closed loop control systems delivering the final COP8 assembler code as a result.

COP8™ Instruction Set Performance Evaluation

National Semiconductor
Application Note 1042

1.0 OVERVIEW

National offers two families of 8-bit COP8 microcontrollers: Basic family and Feature family. The Feature family offers more on-chip peripheral and nine additional instructions compared to the Basic family. In this report, the COP8 Basic family instruction set performance is evaluated versus that of three competitive microcontrollers, the Motorola M68HC05, the Intel 80C51, and the Microchip PIC16C5X. The architecture, addressing modes, instruction sets and salient features of these microcontrollers are compared. Eight benchmark programs are developed, with each microcontroller programmed with full documentation for each of the benchmarks. Summary tables compare the results relative to both code efficiency and execution time.

The report examines only the instruction set efficiency and speed of execution of the selected microcontrollers. Factors related to on-chip hardware features (RAM/ROM sizes, interrupts, etc.) are not considered. Manufactures offer a variety of options of hardware features, but the instruction set efficiency and execution speed typically remain identical across a manufacturer's microcontroller product line.

When comparing a microcontroller to the competition, it is customary for manufacturers to select benchmark programs which particularly highlight the instruction set of their device. To avoid this phenomenon, general purpose commonly used benchmark routines were selected.

One word of caution—this benchmark report, like all others of its kind, relies on a set of small program fragments. The operations performed by each of these fragments may or may not correspond to the operations required for a particular application. When evaluating a microcontroller for a demanding application, it is important to examine how an individual microcontroller will perform in that particular case.

ARCHITECTURE

Three of the four microcontrollers have a modified Harvard architecture, while a fourth (the Motorola M68HC05) has a Von Neumann architecture (named after John Von Neumann, an early pioneer in the computer field at Princeton). With a Von Neumann architecture, a CPU (Central Processing Unit) and a memory are interconnected by a common address bus and a data bus. Positive aspects of this approach include convenient access to tables stored in ROM and a more orthogonal instruction set. The address bus is used to identify which memory location is being accessed, while the data bus is used to transfer information either from the CPU to the selected memory location or vice versa. Von Neumann was the first to realize that this architectural model could have the memory serve as either program memory or data memory. In earlier computers (both electronic and electromechanical), the program store (often a programmed patchboard) had been completely separate from the data store (often a bank of vacuum tubes or relays).

The single address bus of the Von Neumann architecture is used sequentially to access instructions from program memory and then execute the instructions by retrieving data from and/or storing data in data memory. This means that instruction fetch cannot overlap data access from memory.

A Harvard architecture (names after the Harvard Mark 1 and the early electromechanical computers developed at Harvard by Howard Aiken—another computer pioneer) has separate program memory and data memory with a separate address bus and data bus for each memory. One of the benefits of the Harvard architecture is that the operation of the microcontroller can be controlled more easily in the event of corrupted program counter. A modified Harvard architecture allows accessing data tables from program memory. This is very important with modern day computers, since the program memory is usually ROM (Read Only Memory) while the data memory is usually RAM (Random Access Memory). Consequently, data tables usually need to be in ROM so that they are not lost when the computer is powered down.

The obvious advantage of a Von Neumann architecture is the single address and single data bus linking memory with the CPU. A drawback is that code can be executed from data memory opening up the possibility for undesired operation due to corruption of the program counter or other registers. Alternatively, the advantage of a modified Harvard architecture is that instruction fetch and memory data transfers can be overlapped with a two stage pipeline, which means that the next instruction can be fetched from program memory while the current instruction is being executed using data memory. A drawback is that special instructions are required to access RAM and ROM data values making programming more difficult.

The instructions which cause the "Modified" Harvard architectures of the three microcontrollers are the instructions that provide a data path from program memory to the CPU. These instructions are listed below:

COP8	LAID	Load Accumulator indirect from program memory
80C51	MOVC A, @A + DPTR	Move Constant - Load Accumulator with a "fixed constant" from program memory
PIC16C5X	RETLW	Return Literal to W from program memory

COP8 offers the single-byte LAID instruction which uses the contents of the accumulator to point to a data table stored in the program memory. The data accessed from the program memory is transferred to the accumulator. This instruction can be used for table lookup operations and to read the entire program memory contents for checksum calculations.

The 80C51 family offers a similar instruction. The MC68HC05 family has a Von Neumann architecture where CPU and program memory are interconnected by a common address and data bus.

Microchips's PIC16C5x family offers the RETLW instruction. To do table lookup, the table must contain a string of RETLW instructions. The first instruction just in front of the table of the RETLW instructions, calculates the offset into the table. The table can only be used as a result of a CALL. This instruction certainly does not offer the flexibility of the COP8 LAID instruction and cannot be used to perform a checksum calculation on the entire program memory contents.

The use these instructions is demonstrated in the fourth benchmark program, which entails a three byte table search from a data table in program memory.

2.0 SELECTED MICROCONTROLLERS

COP8

The COP8 has a modified Harvard architecture with memory mapped input/output. The CPU registers include an 8-bit accumulator (A), a 16-bit program counter (PC), two 8-bit data pointers (B and X), an 8-bit stack pointer (SP), an 8-bit processor status word (PSW), and an 8-bit control register (CNTRL). The data memory includes a bank of 16 registers (including the three pointers) which have special attributes. All RAM, I/O ports, and registers (except A and PC) are mapped into the data memory address space. The timer section includes a 16-bit timer, and an associated 16-bit autoreload register. The generic COP8 I/O section includes two 8-bit I/O ports, each with an associated 8-bit configuration register and an associated 8-bit data register. The I/O section also contains one dedicated 8-bit output port with an associated 8-bit data register, one dedicated 8-bit input register, and one special purpose 8-bit I/O port with associated 8-bit configuration register and 8-bit data register.

M68HC05

The M68HC05 has a Von Neumann architecture with memory mapped input/output. The CPU registers include an 8-bit accumulator (A), a 16-bit program counter (PC), an 8-bit index register (X), a stack pointer (SP), and an 8-bit condition code register (CCR). The timer section includes a 16-bit free running counter, two 16-bit counter registers to read the counter, a 16-bit timer input capture register, a 16-bit counter output compare register, an 8-bit timer control register, and an 8-bit timer status register. The I/O section includes three bidirectional 8-bit I/O ports, each with an associated 8-bit data register and an 8-bit direction register. The I/O section also includes a 7-bit input port with an associated input register.

80C51

The 80C51 has a modified Harvard architecture with memory mapped input/output. The CPU registers include an 8-bit accumulator (A), an 8-bit auxilliary register (B) for multiply and divide, a 16-bit program counter (PC), and 8-bit program status word (PSW), an 8-bit stack pointer (SP), and a 16-bit data pointer (DPTR). The register bank consists of eight special working registers R0–R7. Registers R0 and R1 can be used as indirect address pointers to data memory. The timer section includes two 16-bit timers, an 8-bit timer mode register (TMOD), and an 8-bit timer control register (TCON). The I/O section includes four 8-bit I/O ports, each with an associated 8-bit register.

PIC16C5X

The PIC15C5X has a modified Harvard architecture with memory mapped input/output. The PIC16C5X also has a RISC (Reduced Instruction Set Computer) type architecture in that there are only 33 single word basic instructions. Actually these 33 instructions should be expanded to a total of 47 for comparison purposes with the other microcontrollers. This is necessary since 14 of the 33 instructions have a programmable destination bit, which selects one of two destinations for the result of the instruction. Consequently, each of these 14 instructions should be counted as dual instructions. The CPU registers include an 8-bit working register (W) which serves as a pseudo accumulator in that it holds the second operand, receives the literal in the immediate type instructions, and also can be program selected as the destination register. However, a bank of 31 file registers serve as the primary accumulators in that they represent the first operand and also may be program selected as the destination register. The first eight file registers include the real time clock/counter register (RTCC) mapped as F1, the 9-bit program counter (PC) mapped as F2, the 8-bit status word register (SWR) mapped as F3, and the 8-bit I/O port registers mapped as F5–F7. The 8-bit File Select Register (FSR) is mapped as F4, whose low order 5 bits select one of the 31 file registers in the indirect addressing mode. Calling for file F0 in any of the file oriented instructions selects indirect addressing and will use the File Select Register (FSR). It should be noted that file register F0 is not a physically implemented register. The CPU also contains a two level 12-bit hardware push/pop stack for subroutine linkage. The PIC16C5X also has a WATCHDOG™ timer as well as the real time clock/counter register (RTCC), but it does not have any hardware interrupts. Consequently, the counter register RTCC must be program sampled for any overflow.

The number of instructions in a program must also be calibrated differently with the PIC16C5X since the instruction word is 12 bits in length. Consequently, twenty 12-bit word instructions will contain the byte equivalent of thirty COP8 8-bit byte instructions. The larger size instruction word is instrumental in implementing the RISC architecture. It should also be noted that the upper members of the PIC family expand to having a 16-bit instruction word.

COP8 Instruction Set Features

1. Majority of single byte opcode instructions to minimize program size.
2. One instruction cycle for the majority of single byte instructions to minimize program execution time.
3. Many single byte multiple function instructions such as DRSZ.
4. Three memory mapped pointers: Two data pointers (B and X) for register indirect addressing, and one program memory stack pointer (SP) for the software stack.
5. Sixteen memory mapped registers which allow an optimized implementation of certain instructions.
6. Ability to set, reset, and test any individual bit in data memory address space, including the memory mapped I/O ports and associated registers.
7. Register indirect LOAD and EXCHANGE instructions with optional automatic post-incrementing or post-decrementing of the register pointers (Both B and X pointers). This allows for greater efficiency (both in throughput time and program code) in both loading and processing fields in data memory.
8. Unique instructions to optimize program size and throughput efficiency. Some of these instructions are:

DRSZ	IFBNE	DCOR
RETSK	RRC	LAID

9. Forty nine basic instructions.
10. Ten addressing modes provide great flexibility.

M68HC05 Instruction Set Features

1. Very flexible branch structure with 21 different branch instructions.
2. Twelve different read/modify/write instructions.
3. Five bit manipulation instructions (Clear, Set, Branch if Bit Clear, Branch if Bit Set, Bit Test Memory with Accumulator) provide great flexibility.
4. Indexed addressing with options of no offset, 8-bit offset, or 16-bit offset.
5. Data Tables located in page 0 address space (0000–00FF) take advantage of the direct addressing mode for optimal code.
6. Multiply instruction (unsigned, 8 × 8).
7. Sixty two basic instructions.
8. Eight addressing modes provide great flexibility.

80C51 Instruction Set Features

1. Optimized for 8-bit control applications.
2. Provides a variety of fast compact addressing modes for accessing data memory to facilitate operations on small data structures.
3. Offers extensive support for one bit variables, allowing direct bit manipulation in control and logic systems that require Boolean processing.
4. Eight working registers (R0–R7) selected by three bits allow a function code and register address to be combined in one single byte instruction.
5. Register R0 and R1 serve as indirect addressing data memory pointers.
6. Four banks of working registers, with only one bank active at a time, permit fast and effective "context switching".
7. Several register specific instructions referring to the accumulator (A), the accumulator and auxiliary register (B), register pair (AB), the carry flag (C), the data pointer (DPTR), and the program counter (PC) provide great efficiency.
8. Indexed addressing using a base register (either the program counter (PC) or the data pointer (DPTR) and an offset in the accumulator (A) provide great flexibility.
9. Multiply and Divide instruction (using A and B registers).
10. Fifty one basic instructions.
11. Eight addressing modes provide great flexibility.

PIC16C5X Instruction Set Features

1. All single word (12-bit) instructions for compact code efficiency.
2. All instructions are single cycle except the jump type instructions (GOTO, CALL) and failed test instructions (DECFSZ, INCFSZ, BTFSC, BTFSS) which are two cycle.
3. 32 File registers can be addressed directly or indirectly, and serve as accumulators to provide first operand, Working register (W) serves as pseudo accumulator, providing second operand.
4. Working register (W) also serves as destination for literal from program memory in MOVLW (Move Literal to W) and RETLW (Return Literal to W) instructions.
5. Many instructions include a destination bit which selects either the register file or the accumulator as the destination for the result.
6. Four bit manipulation instructions (Set, Clear, Test and Skip if Set, Test and Skip if Clear) provide great flexibility.
7. Status word register (SWR) memory mapped as register file F3 allows testing of status bits (carry, digit carry, zero, power down, and time-out).
8. Program counter (PC) memory mapped as register file F2 allows W to be used as offset register for indirect addressing of program memory.
9. Indirect addressing mode data pointer FSR (file select register) memory mapped as register file F4. Addressing F0 causes FSR to be used to select file register.
10. Literal in RETLW (Return Literal to W) instruction combined with file register mapped program counter allow data tables to be accessed from program memory.
11. Two level 12-bit push/pop hardware stack for subroutine linkage using the CALL and RETLW instructions.
12. WATCHDOG timer.
13. Thirty three basic instructions.
14. Six addressing modes provide great flexibility.

COMPARISON OF SALIENT INSTRUCTION SET FEATURES

Addressing

The three types of indexed addressing (no offset, single byte offset, and dual byte offset) in the M68HC05 provide great flexibility in walking across two or three data fields (two operands, result) simultaneously. The three other microcontrollers achieve the same result with indirect addressing and pointers. The COP8 and 80C51 both have dual pointers for indirect data addressing (B and X pointers in the COP8, R0 and R1 in the 80C51). The PIC16C5X only has one indirect data pointer F4, which is called by using F0. Consequently, processing two multiple byte operands with the PIC16C5X requires alternate loading of the operand addresses into the F4 pointer as the multiple byte data fields are processed.

All four microcontrollers have some form of indirect addressing for program memory, which is very useful in producing jump tables. The COP8 uses the JID (jump indirect) instruction, while the PIC16C51X can address the program counter as file register F2 and add an offset to it. The M68HC05 and 80C51 both use their indexed addressing modes to achieve indirect addressing of program memory. Both jump tables and lookup tables are easily created with indexed addressing. The COP8 uses the LAID (load accumulator indirect) instruction to implement lookup tables, while the PIC16C5X uses the RETLW (return literal to W) instruction as the table entries preceded by a table header which produces the table offset address.

Bit Manipulation

All four microcontrollers have instructions to set, reset, and test individual bits in data memory. However, the 80C51 allows bit manipulation in only 210-bit addressable locations of data memory (16 general purpose byte locations 20–2F, and the rest in the special function registers including the I/O ports). The other three microcontrollers are capable of bit addressing anywhere in data memory. Three of the four microcontrollers have direct bit tests for a bit being either set or reset, while the COP8 test is for bit set only. The 80C51 has two instructions (MOV C, bit and MOV bit, C) to either transfer a bit of data memory to or from the carry. This is very handy for saving a carry and restoring it for later use. The two bit test instructions (BRCLT and BRSET) in the M68HC05 also set the carry to the state of the bit tested. The 80C51 also has four logical (two logical AND, two logical OR) bit manipulation instructions, with the carry and a selected memory bit serving as the two operands. These four instructions are described more fully with the logical instructions.

Input/Output

The four microcontrollers all have mulitple I/O ports, with some of them (COP8, M68HC05) also having dedicated input and/or dedicated output ports. The COP8 and M68HC05 both have configuration registers for each I/O port, with each configuration bit determining whether the associated port bit is selected as input or output. The PIC16C5X contains a TRISTATE® instruction (TRIS) whose operand determines whether or not each associated port bit is put in the TRISTATE condition to serve as an input pin. The 80C51 configures a port by writing ones to TRISTATE the port bit positions selected as inputs. Otherwise the associated 80C51 port bit is selected as an output bit. The COP8 has three addresses associated with each I/O port. The first two addresses select the associated data and configuration register for the port, while the third address selects the actual port pins. If a COP8 port bit is configured as an input, then the associated bit in the data register selects whether the associated input is Hi-Z or weak pull-up. Input/Output manipulation with the I/O ports is demonstrated in the fifth benchmark program.

Increment/Decrement

All four micrcontrollers have accumulator increment and decrement instructions. The register file of the PIC16C5X serves as multiple accumulators. The COP8 has a DRSZ (decrement register and skip if zero) instruction for its sixteen registers located at data memory addresses 0F0–0FF. This register bank includes the B and X data memory pointers and also the SP stack pointer. The PIC16C5X also has both INCFSZ (increment file and skip if zero) and DECFSZ (decrement file and skip if zero) instructions. The M68HC05 increment and decrement instructions can be selected for the accumulator, the index register, or any memory location. The 80C51 increment and decrement instructions can be selected for the accumulator, the eight R registers including the R0 and R1 data pointers, or any memory location (selected either directly or indirectly). The 80C51 also has a DJNZ (decrement and jump if not zero) instruction which can be selected for any of the eight R registers including the R0 and R1 data pointers, or for any memory location selected with a relative address.

Load Memory Immediate

Only the COP8 and the 80C51 have instructions that can load memory with an immediate value. The memory location to be loaded can be selected with either direct or indirect addressing for both microcontrollers.

Post Incrementation or Decrementation of Data Pointers

Only the COP8 has instructions that can post increment, post decrement, or leave the data pointer unchanged. This feature applies to both the COP8 load and exchange instructions, and can be used with either of the two pointers B and X. The feature is very useful when processing multiple byte fields, especially with two operands (additions, subtractions) or an operand and a result (block move). Examples of the usage of this feature can be found in the first three COP8 benchmark programs.

Loop Counting and Data Pointing Testing

Three of the four microcontrollers (excluding M68HC05) have specific instructions to facilitate loop counting. The COP8 DRSZ (decrement register and skip if zero) instruction tests one of sixteen registers (including the two data pointers B and X) and skips the next instruction (a branch back to loop) if the result is zero. The PIC16C5X DECFSZ (decrement file register and skip if zero) is analogous to the COP8 DRSZ instruction. The 80C51 DJNZ (decrement and jump if not zero) instruction combines both the test and jump in a single instruction. These three instructions (COP8 DRSZ, PIC16C5X DECFSZ, 80C51 DJNZ) all operate on a loop counter, but uses the standard BNE (branch if not equal) branch instruction following the decrement to test if the counter is zero. The BNE instruction tests the M68HC05 zero status flag which is active with the decrement instruction. Only the COP8 contains a test data pointer uction (IFBNE—If B pointer not equal). This instruction is used to sense the end of a program loop where multiple byte fields are being processed.

The 80C51 CJNE (compare and jump if not equal) instruction used in the immediate addressing mode provides an alternative method of loop counting. This instruction is analogous to the COP8 IFBNE instruction but combines the test with the jump in a single instruction.

It should be noted that neither the COP8 IFBNE instruction nor the 80C51 CJNE instruction require the use of a counter, but rather depend on an end of field comparison for loop termination. Consequently these instructions are used in loops where a data pointer is being used to walk across a mulitple byte field. Examples of the usage of these two instructions can be found in the first three benchmarks.

Branch and Subroutine Call Instructions

All four micrcontrollers have absolute address branching, and three of the four (excluding the PIC16C5X) also have relative address branching. Only the COP8 and the M68HC05 have single byte branching. The COP8 single byte branching is with relative addressing, where six bits provide relative addressing of −31 to +32. The M68HC05 single byte branching is with no offset indexed addressing, where the index register X provides the absolute address. All of the myriad conditional branch instructions of the M68HC05 use two bytes, with the second bytes providing relative addressing of −127 to +128.

Three of the four microcontrollers have a software stack (excluding the PIC16C5X) where the return address is stored when a subroutine is called. Consequently, multiple levels of subroutine and interrupt nesting are possible with the software stack. The PIC16C5X has a two level hardware stack where the return address is stored with a subroutine call. Thus only two levels of subroutine nesting are possible with the PIC16C5X. The other three microcontrollers have absolute address subroutine calls, with the 80C51 also having a relative address call. Only the M68HC05 provides a single byte subroutine call, using no offset indexed addressing (with the index register providing the absolute address.

Return Instructions

All four microcontrollers have return from subroutine instructions and three of the four (excluding the PIC16C5X) have return from interrupt instructions. The PIC16C5X does not have an interrupt.

The COP8 has two return from subroutine instructions, RET and RETSK. The RET is the normal return from subroutine instruction, while the RETSK instruction returns from the subroutine and then skips the next instruction. These two instructions are very useful in passing back flag information from the subroutine in lieu of actually using a flag such as the carry. This is demonstrated in the fourth benchmark (table search) where a flag needs to be passed back from the subroutine to indicate whether or not the search was successful. The COP8 simply uses the RETSK instruction to indicate a successful search, whereas each of the other three microcontrollers need to set up the carry as the flag.

The PIC16C5X return from subroutine instruction is RETLW (return and place literal in W). The literal serves as an immediate data value from memory. The use of this instruction is demonstrated in the fourth benchmark (table search), where the program memory data table consists of a block of RETLW instructions preceded by the table header.

Comparison and Conditional Branch Instructions

Three of the four microcontrollers (excluding the PIC16C5X) have comparison instructions. The COP8 has two comparison instructions, IFEQ (if equal) and IFGT (if greater than). These comparison instructions compare the accumulator versus an immediate value or a number from memory (selected with either direct or indirect addressing). The M68HC05 has two comparison instructions, CMP (compare) and BIT (bit test memory with accumulator). The CMP instruction compares the accumulator versus an immediate value or a number from memory (selected with either direct or indexed addressing). The BIT instruction performs a logical AND comparison between the accumulator and an immediate value or a number from memory (selected with either direct or indexed addressing). The 80C51 has one comparison instruction CJNE (compare and jump if not equal) which is combined with a branch in the same instruction. All four microcontrollers have bit test instructions (including test carry.)

The M68HC05 has a myriad of test conditions and branch instructions, including BCC (branch if carry clear), BCS (branch if carry set), BRCLR (branch if memory bit clear), BRSET (branch if memory bit set), BEQ (branch if equal), BHI (branch if higher), BHS (branch if higher or same), BLO (branch if lower), BLS (branch if lower or same), BMI (branch if minus), BNE (branch if not equal), and BPL (branch if plus).

The 80C51 includes seven conditional branch instructions, consisting if JC (jump if carry), JNC (jump if no carry), JNZ (jump if not zero), JZ (jump if zero), JB (jump if memory bit set), JNB (jump if memory bit not set), and JBC (jump if memory bit set and clear bit).

The COP8 includes seven conditional test instructions, IFBIT (test if memory bit is set), IFC (if carry), IFNC (if no carry), IFEQ (if equal), IFGT (if greater than), IFBNE (if B pointer not equal), and DRSZ (decrement register and skip if zero). These seven instructions will all cause the next instruction to be skipped if the test is successful. The skipped instruction can either be a branch or some function (such as setting a bit flag or returning from a subroutine) that can be contained in one instruction.

The PIC16C5X includes four test instructions, consisting of DECFSZ (decrement file register and skip if zero), INCFSZ (increment file register and skip if zero), BTFSC (bit test file register and skip if bit clear), and BTFSS (bit test file register and skip if bit set). These four instructions will all cause the next instruction to be skipped if the test is successful.

Logical Instructions (AND, OR, Exclusive OR)

All four microcontrollers have a full complement of the logical instructions, with the accumulator and a selected memory location (using either direct or indirect addressing) serving as the two operands. Three of the four microcontrollers (excluding the PIC16C5X) can also perform the logical instructions with the accumulator and an immediate value serving as the operands. The 80C51 contains four logical bit instructions which perform either the logical AND or logical OR between the carry bit and a selected memory bit, with either polarity of the memory bit being selectable. The M68HC05 contains a logical compare instruction, which performs a logical AND comparison between the accumulator and an immediate value or a number from memory (selected with either direct or indexed addressing).

Shift and Rotate Instructions

Only the M68HC05 has shift instructions, both logical left shift and logical right shift. All four microcontrollers have a right rotate instruction through carry (none bit loop), and three of the four (excluding the COP8) also have a left rotate through carry. The 80C51 also has both a right and left rotate direct (eight bit loop).

Complement Instructions

Three of the four microcontrollers (excluding the COP8) have a complement instruction for the accumulator. The 80C51 also has two complement bit instructions, with the first being used to toggle the carry and the second to complement selected accumulator bits.

BDC Decimal Correct

Only the COP8 and the 80C51 provide instructions to expedite BCD processing. The DCOR (decimal correct) instruction of the COP8 is used following an add or subtract instruction to achieve the correct BCD result. Note that a hex 66 must be added to the first operand to start the addition process. The DA (decimal adjust) instruction of the 80C51 is used following an add instruction to achieve the correct BCD result. The decimal adjust instruction does not work following subtraction. Consequently, BCD subtraction in the 80C51 must be implemented by adding the complement of the subtrahend (second operand) and then using the decimal adjust instruction. BCD subtraction is demonstrated in the third benchmark program.

Exchange and Swap

Only the COP8 and the 80C51 have exchange instructions between the accumulator and memory. Both microcontrollers can select either direct or indirect addressing for the associated exchange memory selection. The 80C51 also has a XCHD A, @Ri (exchange digit) instruction which exchanges the low order nibble (digit) of the accumulator with the low order nibble of the indirectly addressed memory location selected.

All of the microcontrollers except the M68HC05 have a SWAP instruction which interchanges the low and high order nibbles of the accumulator. With the PIC16C5X, the SWAPF instruction can be selected for any of the register bank accumulators.

Push and Pop Instructions

Only the 80C51 has PUSH and POP instructions to augment operations with the software stack. Consequently, only the 80C51 has the ability to store temporary data in the software stack as well as subroutine and interrupt return addresses.

4.0 BENCHMARK PROGRAMS

1. FIVE BYTE BLOCK MOVE

This benchmark program moves a block of five data byte from one location to another.

2. FOUR BYTE BINARY ADDITION

This benchmark subroutine adds two four byte binary numbers and replaces the first operand with the result, like an adding machine (A + B replaces A). The carry flag is used to indicate an overflow.

3. FOUR BYTE PACKED BCD SUBTRACTION

This benchmark subroutine subtracts two eight digit packed BCD numbers and replaces the first operand with the result, like an adding machine. (A − B replaces A). The carry flag is used to indicate a negative result.

4. THREE BYTE TABLE SEARCH

This benchmark subroutine searches a program memory data table for a three byte match. A flag indicates whether or not the search was successful, with the address of the first byte of a matched string being returned.

5. INPUT/OUTPUT MANIPULATION

This benchmark compares two 8-bit I/O ports P1 and P2. If they are equal, a nine is output as the least significant digit of a third port P3. If P1 is greater than P2, then P2 data is output on P1. If P1 is < P2, then the higher order digit of P1 is copied to the lower order digit position of P3.

6. SERIAL INPUT/OUTPUT WITH OFFSET TABLE

This benchmark subroutine inputs a sequence of byte couplets, each of which consists of an address followed by a data byte. The address is used to access a data table to produce an offset value which is added to the data byte. The updated data byte is output while the next couplet's address byte is input.

7. TIMEKEEPING

This timekeeping benchmark program emulates a real time clock, keeping track of hours, minutes, and seconds in packed BCD format. The program is interrupt driven, using a timer interrupt.

8. SWITCH ACTIVATED FIVE SECOND LED

This benchmark samples a switch input to activate a five second output for turning on an LED. The switch is debounced with a 50 ms program delay both on opening and closure.

5.0 BENCHMARK DATA

This section provides the benchmark programs for each microcontroller. For each instruction, the byte count and instruction cycle count is given. The total cycle count is multiplied by the fastest cycle time of the selected microcontroller to yield the total benchmark execution time.

Microcontrollers	Instruction Cycle Time	XTAL
COP8	1.0 μs	10 MHz
M68HC05	0.5 μs	4 MHz
80C51	1.0 μs	12 MHz
PIC16C5X	0.5 μs	8 MHz

COP8 BENCHMARK # 1—FIVE BYTE BLOCK MOVE

This benchmark moves only a block of five data bytes from a specific source location to a specific destination location.

```
MOVE:   LD      B, #14      ; 1/1  Source address to B pointer
        LD      X, #50      ; 2/3  Destination address to X pointer
LOOP:   LD      A, [B+]     ; 1/2  Load A with source byte
        X       A, [X+]     ; 1/3  Source byte to destination
        IFBNE   #3          ; 1/1  Test (modulo 16) if block move finished (19-16=3)
        JP      LOOP        ; 1/3  Loop back if not finished

                             7 BYTES
                            47 CYCLES
```

68HC05 BENCHMARK # 1—FIVE BYTE BLOCK MOVE

This benchmark moves only a block of five data bytes from a specific source location to a specific destination location.

```
MOVE:   LDX     #5          ; 2/2  Load X with block length
LOOP:   LDA     24, X       ; 2/4  Load A with source byte (start at block top)
        STA     54, X       ; 2/5  Store A at destination (start at block top)
        DECX                ; 1/3  Decrement X
        BNE     LOOP        ; 2/3  Loop back if block transfer not finished

                             9 BYTES
                            76 CYCLES
```

80C51 BENCHMARK # 1—FIVE BYTE BLOCK MOVE

This benchmark moves only a block of five data bytes from a specific source location to a specific destination location.

```
MOVE:  MOV     R0, #20        ;  2/1  Load R0 pointer with source address
       MOV     R1, #50        ;  2/1  Load R1 pointer with destination address
LOOP:  MOV     A, @R0         ;  1/1  Load A with source byte
       MOV     @R1, A         ;  1/1  Store source byte at destination
       INC     R1             ;  1/1  Increment destination pointer
       INC     R0             ;  1/1  Increment source pointer
       CJNE    R0, #25, LOOP; 3/2  Compare & loop back if block transfer not finished

                              11 BYTES
                              32 CYCLES
```

PIC16C5X BENCHMARK # 1—FIVE BYTE BLOCK MOVE

This benchmark moves only a block of five data bytes from a specific source location to a specific destination location.

```
       TEMP    EQU F29        ;
       BASE    EQU F30        ;       Source @ F20-F24 Destination @ F25-F29
       CNTR    EQU F31        ;
MOVE:  MOVLW   5              ;  1/1  Load W with length of block
       MOVWF                  ;  1/1  Store block length in CNTR
       MOVLW   20             ;  1/1  Load W with address of source
LOOP:  MOVF    BASE, W            1/1  Source address to W
       MOVWF   F4             ;  1/1  Source address to F4 (indirect pointer)
       MOVF    F0, W          ;  1/1  Source byte to W
       MOVWF   TEMP           ;  1/1  Source byte to TEMP
       MOVLW   5              ;  1/1  Destination/source address difference to W
       ADDWF   F4             ;  1/1  Add to pointer to get destination address
       MOVF    TEMP, W        ;  1/1  Source byte to W
       MOVWF   F0             ;  1/1  Source byte to destination
       INCF    BASE           ;  1/1  Increment BASE
       DECFSZ  CNTR           ;  1/1  Test if block move finished
       GOTO    LOOP           ;  1/2  Loop back if not finished

                              14 WORDS (Equivalent to 21 BYTES)
                              62 CYCLES
```

COP8 BENCHMARK #2—FOUR BYTE BINARY ADDITION

This benchmark adds two four byte binary numbers and replaces the first operand with the result. This emulates an adding machine addition, where A + B replaces A. The benchmark is programmed as a subroutine, with the carry flag indicating an overflow.

```
ADDITION:  LD        B, #10        ; 1/1  Set up address of 1st operand in B pointer
           LD        X, #20        ; 2/3  Set up address of 2nd operand in X pointer
           RC                      ; 1/1  Reset carry
LOOP:      LD        A, [X+]       ; 1/3  Load 2nd operand to A
           ADC       A, [B]        ; 1/1  Add 1st operand to 2nd operand
           X         A, [B+]       ; 1/2  Result replaces 1st operand
           IFBNE     #14           ; 1/1  Test if addition finished
           JP        LOOP          ; 1/3  Loop back if not finished
           RET                     ; 1/5  Return from subroutine

                                   10 BYTES
                                   48 CYCLES
```

M68HC05 BENCHMARK #2—FOUR BYTE BINARY ADDITION

This benchmark adds two four byte binary numbers and replaces the first operand with the result. This emulates an adding machine addition, where A + B replaces A. The benchmark is programmed as a subroutine, with the carry flag indicating an overflow.

```
ADDITION:  LD        X, #16        ; 2/2  Load index register with 1st operand address
           CLC                     ; 1/2  Clear carry
LOOP:      LDA       X             ; 1/3  Load A with 1st operand
           ADC       4, X          ; 2/4  Add 2nd operand to A
           STA       X             ; 1/4  Replace 1st operand with result
           INCX                    ; 1/3  Increment index register
           CPX       #20           ; 2/2  Compare X with end of field
           BNE       LOOP          ; 2/3  Loop back if addition not finished
           RTS                     ; 1/6  Return from subroutine

                                   13 BYTES
                                   85 CYCLES
```

80C51 BENCHMARK #2—FOUR BYTE BINARY ADDITION

This benchmark adds two four byte binary numbers and replaces the first operand with the result. This emulates an adding machine addition, where A + B replaces A. The benchmark is programmed as a subroutine, with the carry flag indicating an overflow.

```
ADDITION:  MOV     R1, #20          ;  2/1  Load R1 pointer with address of 2nd operand
           MOV     R0, #16          ;  2/1  Load R0 pointer with address of 1st operand
           CLR     C                ;  1/1  Clear carry
LOOP:      MOV     A, @R0           ;  1/1  Load 1st operand to A
           ADD     A, @R1           ;  1/1  Add 2nd operand to A
           MOV     @R0, A           ;  1/1  Replace 1st operand with result
           INC     R1               ;  1/1  Increment 2nd operand pointer
           INC     R0               ;  1/1  Increment 1st operand pointer
           CJNE    R0, #20, LOOP    ;  3/2  Test if finished and loop back if not
           RET                      ;  1/2  Return from subroutine

                                    14 BYTES
                                    33 CYCLES
```

PIC16C5X BENCHMARK #2—FOUR BYTE BINARY ADDITION

This benchmark adds two four byte binary numbers and replaces the first operand with the result. This emulates an adding machine addition, where A + B replaces A. The benchmark is programmed as a subroutine, with the carry flag indicating an overflow.

```
           STATUS  EQU F3           ;       Status register
           BASE    EQU F26          ;       1st operand @ F16-F19 2nd operand @ F20-F23
           CNTR    EQU F25          ;
           TEMP    EQU F24          ;
ADDITION:  MOVLW   4                ;  1/1  Load W with byte count (length of field)
           MOVWF   CNTR             ;  1/1  Store byte count in CNTR
           MOVLW   20               ;  1/1  Load W with address of 2nd operand
           MOWWF   BASE             ;  1/1  Store address of 2nd operand in BASE
           BCF     STATUS, 0        ;  1/1  Clear carry (carry is bit 0 of F3 register)
LOOP:      MOVF    BASE, W          ;  1/1  2nd operand address to W
           MOVWF   F4               ;  1/1  2nd operand address to F4 (indirect pointer)
           MOVF    F0, W            ;  1/1  2nd operand to W
           MOVWF   TEMP             ;  1/1  2nd operand to TEMP
           MOVLW   4                ;  1/1  Byte count to W
           SUBWF   F4               ;  1/1  Subtract from pointer to get 1st operand address
           MOVF    TEMP, W          ;  1/1  2nd operand to W
           ADDWF   F0               ;  1/1  Add 2nd operand to 1st operand
           MOVLW   4                ;  1/1  Byte count to W
           ADDWF   F4               ;  1/1  Add to pointer to restore 2nd operand address
           INCF    BASE             ;  1/1  Increment BASE
           DECFSZ  CNTR             ;  1/1  Test if addition finished
           GOTO    LOOP             ;  1/2  Loop back if addition not finished
           RETLW   0                ;  1/2  Return from subroutine

                                    19 WORDS (Equivalent to 28 1/2 BYTES)
                                    62 CYCLES
```

COP8 BENCHMARK #3—FOUR BYTE PACKED BCD SUBTRACTION

This benchmark subtracts two eight digit packed BCD numbers (four bytes each) and replaces the minuend (first operand) with the result. This emulates an adding machine subtraction, where A - B replaces A. The benchmark is programmed as a subroutine, with the carry flag being used to indicate a positive or negative result (carry set for negative result). The BCD decimal correct (DCOR) command is used following the subtraction to achieve the correct BCD result.

```
BCDSUBT:  LD      B, #14        ;  1/1  Set up address of 1st operand in B pointer
          LD      X, #20        ;  2/3  Set up address of 2nd operand in X pointer
          SC                    ;  1/1  Set carry for no input borrow to subtraction
LOOP:     LD      A, [X+]       ;  1/3  Load 2nd operand to A
          X       A, [B]        ;  1/1  Exchange 1st and 2nd operands
          SUBC    A, [B]        ;  1/1  Subtract 2nd from 1st operand
          DCOR    A             ;  1/1  Decimal correct result of subtraction
          X       A, [B+]       ;  1/2  Result replaces 1st operand

M68HC05 BENCHMARK #3—FOUR BYTE PACKED BCD SUBTRACTION

This benchmark subtracts two eight digit packed BCD numbers (four bytes each) and replaces the minuend (first operand) with the result. This emulates an adding machine subtraction, where A - B replaces A. The benchmark is programmed as a subroutine, with the carry flag being used to indicate a positive or negative result (carry set for negative result). Note in the M68HC05 subtraction that the carry represents the borrow, unlike some microcontrollers where the carry represents the absence of borrow in subtraction. The M68HC05 does not have any decimal correct or decimal adjust instructions, so the BCD correction must be program implemented. The correction algorithm for BCD subtraction consists of subtracting six whenever a nibble borrow occurs from the BCD subtraction result for each digit.

80C51 BENCHMARK # 3—FOUR BYTE PACKED BCD SUBTRACTION

This benchmark subtracts two eight digit packed BCD numbers (four bytes each) and replaces the minuend (first operand) with the result. This emulates an adding machine subtraction, where A - B replaces A. The benchmark is programmed as a subroutine, with the carry flag being used to indicate a positive or negative result (carry set for negative result). It should be noted in the 80C51 subtraction that the carry represents the borrow, unlike some microcontrollers where the carry represents the absence of borrow in subtraction.

The BCD decimal adjust (DA) command only works following addition, not subtraction. Consequently, the BCD subtraction must be implemented as an addition by adding the complement of the subtrahend (2nd operand) to the 1st operand. This complement is achieved by subtracting the subtrahend from a packed BCD 99 (binary 10011001), and then adding one to the result. The following are examples of this complementation procedure:

1. 61−49 = 61 + (99−49) + 1 = 61 + 50 + 1 = 12 (mod 100) (Output borrow shows positive result)
2. 49−61 = 49 + (99−61) + 1 = 49 + 38 + 1 = 88 (No output borrow indicates negative result)
   Negative result correction: - (99−88 + 1) = −12

COP8 BENCHMARK #4—THREE BYTE TABLE SEARCH

This benchmark searches a 200 byte table (resident in program memory) for a three byte character string, which may be resident anywhere in the lookup table (not necessarily on three byte boundaries). The type of return from subroutine (RETSK versus RET) indicates the success or failure of the search, with the address of the first byte of a matched string being returned in BASE. The benchmark is programmed as a subroutine, which should be located following the table since the LAID instructions in the subroutine must be located in the same 256 byte page of program memory.

```
          CHAR1 = 00          ;       Three bytes of character string
          CHAR2 = 01          ;       resident in registers 00, 01, 02

PIC16C5X BENCHMARK #4—THREE BYTE TABLE SEARCH

This benchmark searches a 200 word table (resident in program memory) for a three byte character string, which may be resident anywhere in the lookup table (not necessarily on three word boundaries). The status of the carry bit indicates the success or failure of the search, with the address of the first byte of a matched string being returned in OFFSET. The benchmark is programmed as a subroutine, which in turn calls the table header (TABLE) as a subroutine. This table header should immediately precede the 200 word table.

```
TBLSRCH:  MOVLW   198                    ;  1/1  Set up table size (200) minus 2

```

80C51 BENCHMARK #5—INPUT/OUTPUT MANIPULATION

This benchmark compares two 8-bit I/O ports P1 and P2. If they are equal, a nine is output as the least significant digit (lower nibble) of a third port P3. If Port P1 is greater than Port P2, then Port P2 is output on Port P1. If Port P1 is less than Port P2, then the most significant digit of Port P1 is copied to the least significant digit of Port P3.

COP8 BENCHMARK #6—SERIAL INPUT/OUTPUT WITH OFFSET TABLE

This benchmark inputs a sequence of byte couplets, with each couplet consisting of an 8-bit offset address followed by a data byte. The address is used to access a program memory data table to produce an offset value which is added to the second byte of the input couplet. The updated data byte is output while the address byte of the next couplet is being input. The benchmark is written as a subroutine, with the size of the input stream being an input parameter.

The program is written using the MICROWIRE/PLUS fast burst technique, which utilizes a 500 kHz burst clock SK (instruction cycle clock divided by 2). Each byte of the I/O stream utilizes nine burst clock periods, yielding an effective byte rate of 55.6 kHz.

*** Setting the Microwire busy bit to initialize the Microwire must occur at the same time in each alternating 18 cycle loop for this program to work. Alternate cycle definitions are as follows:

```
                    Even cycle:    New address input for table lookup offset value
                                   Previous data result output

                    Odd cycle:     New data input added to offset value from table lookup
                                   New data input returned as output

```

80C51 BENCHMARK #6—SERIAL INPUT/OUTPUT WITH OFFSET TABLE

This benchmark inputs a sequence of byte couplets, with each couplet consisting of an 8-bit offset address followed by a data byte. The address is used to access a program memory data table to produce an offset value which is added to the second byte of the input couplet. The updated data byte is output while the address byte of the next couplet is being input. The benchmark is written as a subroutine, with the size of the input stream being an input parameter.

The program is written using the 8-bit Shift Register Mode 0, with the serial data being either transmitted or received (not both simultaneously) with the least significant bit first. The clock rate for this mode is 1/12 that of the on-chip oscillator frequency of 12 MHz, which equates to an I/O baud rate of 1 MHz. This is equivalent to the instruction cycle time of 1 μs. In Shift Register Mode 0, the RXD line is used for both data input and output, while the TXD line is used for the output clock. Consequently, the terms "RXD" and "TXD" are misleading in this mode of serial I/O.

The program takes 52 instruction cycles per couplet loop, which equates to 26 instruction cycles (26 μs) per byte. This yields an effective byte rate of 38.5 kHz.

M68HC05 BENCHMARK #7—TIMEKEEPING

This timekeeping benchmark is interrupt driven, using the timer output compare interrupt (in conjunction with the 131.072 ms timer cycle). The program emulates a real time clock, keeping track of hours, minutes, and seconds in packed BCD format.

The timer clock is equivalent to the instruction cycle clock (2 MHz) divided by 4, yielding a timer clock period of 2 μs. The 16-bit free running timer has a maximum of 65536 counts, which at 2 μs per count equates to a timer cycle of 131.072 ms. One second divided by the timer cycle (1,000,000 divided by 131,072) yields 7 cycles with a residual of 82.496 ms. This residual equates to 41248 timer counts, which represents the value (A120 in hex) added to the output compare register during each timer interrupt service.

```
TIMER SETUP ROUTINE:

PIC16C5X BENCHMARK #7—TIMEKEEPING

This timekeeping benchmark uses a pseudo software 5 ms delay loop as the basic core timing for emulating a real time clock. Note that the PIC16C5X does not have any hardware interrupts. Consequently, the program must keep track of when the counter RTCC overflows for real time applications. The RTTC F1 file register is only 8 bits, but with an 8-bit prescaler selected (1 : 256 RTTC rate), the RTTC emulates a 16-bit timer. The program keeps track of hours, minutes, and seconds in packed BCD format.

5 ms timing analysis: 0.5 μs (instruction cycle time) × 256 (prescaler) = 128 μs RTTC increment rate

5 ms emulation: 5000/128 = 39 cycles + residue of 8 μs

```
            RTCC        EQU 1           ;       Register File F1
            STATUS      EQU 3           ;       Reg File F3
            TEMP        EQU 20          ;       Reg File F20
            SEC         EQU 21          ;       Reg File F21
            MIN         EQU 22          ;       Reg File F22
            HOUR        EQU 23          ;       Reg File F23
            CNTR        EQU 24          ;       Reg File F24

COP8 BENCHMARK #8—SWITCH ACTIVATED FIVE SECOND LED

This benchmark samples a switch input to activate a five second output for turning on an LED. The switch is debounced with a 50 ms delay both on opening and closure. Once activated, the switch will turn on an LED output for five seconds and then turn it off, regardless of whether or not the switch is still activated. Once the switch is turned off, the procedure is repeated. Both the switch input and the LED output are low true.

PIC16C5X BENCHMARK #8—SWITCH ACTIVATED FIVE SECOND LED

This benchmark samples a switch input to activate a five second output for turning on an LED. The switch is debounced with a 50 ms delay both on opening and closure. Once activated, the switch will turn on an LED output for five seconds and then turn it off, regardless of whether or not the switch is still activated. Once the switch is turned off, the procedure is repeated. Both the switch input and the LED output are low true.

```

6.0 SUMMARY OF RESULTS (Both Positive (+) and Negative (−)

Benchmark #1 - BLOCK TRANSFER

COP8	Two indirect data pointers (+); IFBNE instruction (+)
M68HC05	Indexed addressing (+); Decrementing index to zero (+)
80C51	Two indirect data pointers (+)
PIC16C5X	Only one indirect data pointer (−)

Benchmark #2 - BINARY ADDITION

COP8	Two indirect data pointers (+); IFBNE instruction (+)
M68HC05	Indexed addressing with offset (+)
80C51	Two indirect data pointers (+)
PIC16C5X	Only one indirect data pointer (−)

Benchmark #3 - BCD SUBTRACTION

COP8	Two indirect data pointers (+); IFBNE instruction (+); DCOR (decimal correct) instruction (+)
M68HC05	Indexed addressing with offset (+); No BCD correction instruction (−)
80C51	Two indirect data pointers (+); DA instruction (BCD correction) only for add, not subtract (−)
PIC16C5X	Only one indirect data pointer (−); No BCD correction instruction (−)

Benchmark #4 - TABLE SEARCH

COP8	LAID instruction (+); Lack of IFNE comparison instruction (−); RETSK instruction (+)
M68HC05	Indexed addressing (+); Lack of loading immediate values directly to memory (−)
80C51	16-bit DPTR (data pointer (+); MOV A @A + DPTR instruction (+); CJNE instruction combine comparison and branch (+)
PIC16C5X	RETLW instruction (+)

Benchmark #5 - INPUT/OUTPUT MANIPULATION

COP8	I/O Port Configuration registers for individual bit control (+)
M68HC05	I/O Port Data Direction reg's for individual bit control (+); No SWAP to reverse nibbles (−)
80C51	Distinction between tristating for input versus output of 1 (?−); No configuration register (−)
PIC16C5X	TRIS (tristate instruction) (+); No configuration register (−)

Benchmark #6 - SERIAL INPUT/OUTPUT WITH OFFSET TABLE

COP8	Microwire/Plus for serial I/O (+); LAID instruction (+)
M68HC05	SPI (Serial Peripheral Interface) for serial I/O (+)
80C51	Serial I/O with 8-bit shift register mode cannot input and output simultaneously (−); MOV A, @A + DPTR instruction (+)
PIC16C5X	Lack of any dedicated serial I/O (−); RETLW instruction (+)

Benchmark #7 - TIMEKEEPING

COP8	Timer autoreload with interrupt very flexible (+)
M68HC05	Timer Output Compare interrupt structuring for real time cumbersome and confusing (−)
80C51	Lack of 16-bit timer autoreload (−)
PIC16C5X	OPTION instruction to select timer prescaler (+); Lack of timer interrupt (−); No timer autoreload (−)

Benchmark #8 - SWITCH ACTIVATED 5 SEC LED

COP8	Lack of bit testing for bit clear (−)
M68HC05	Bit testing for both set and clear (+); Versatility of index register (+)
80C51	DJNZ instruction combines testing and branch (+); JB and JNB instructions combine bit testing and branch (+)
PIC16C5X	Bit testing for both set and clear (+)

TABLE I. The Benchmark Results: Code Size Efficiency in Bytes

BENCHMARK BYTES	National COP8	Motorola 68HC05	Intel 80C51	Microchip PIC16C5X
Five Byte Block Move	7	9	11	21
Four Byte Binary Addition	10	13	14	28 ½

Input/Output Manipulation (Note 3)	24/24	53/26.5	17/17	21/10.5
Serial I/O with Offset Table (Note 1)	36/36	54/27	52/52	214/107
Timekeeping (Note 5)	80/80	218/109	49/49	69/34.5
Switch Activated 5s LED (Note 4)	76/76	88/44	27/27	37/18.5
TOTAL	485/485	1221/610.5	331/331	791/395.5
RATIO	1/1	2.53/1.26	0.68/0.68	1.63/0.82

Note 1: Couplet (address, data) loop time: address and data input, updated data output.

Note 2: First search iteration falls with 1st byte mismatch, second search iteration successful.

Note 3: Case where P1 < P2.

Note 4: Cycle times without wait loops.

Note 5: Case where 12:59:59 is advancing to 1:00:00.

7.0 CONCLUSIONS

This report provides a detailed study of the instruction sets of popular 8-bit single chip microcontrollers. Eight benchmark programs, demonstrating data movement, arithmetic operations, I/O manipulation, and timekeeping, were coded for four current microcontrollers.

In terms of byte efficiency, the COP8 from National, uses 8% less program space than its nearest competitor, the Intel 80C51. The COP8 uses, 26% less program space than Motorola 68HC05, 39% less program space than the Microchip PIC16C5X. Code efficiency is important because it enables designers to pack more on-chip functionality into less program memory space. Selecting a microcontroller with smaller program memory size translates into lower system costs, and the added security of knowing that more code can be packed into the microcontroller.

In terms of code execution, Intel's 80C51 is the fastest, while COP8 executes these benchmark routines faster than Motorola 68HC05 and Microchip PIC16C5X.

Comparison of COP878x to the Enhanced COP8SAx7 Family—Hardware/ Software Considerations

National Semiconductor
Application Note 1043
Abdul Aleaf

INTRODUCTION

The COP8780, COP8781 and COP8782 (COP878x family) are members of the COP8 Basic Family that contain EPROM, RAM, a 16-bit multi-function timer with a single 16-bit autoreload/capture register, 3 interrupt sources with polling scheme, and the MICROWIRE/PLUS™ serial interface. These devices are offered in 20-pin SO/DIP, 28-pin SO/DIP, 40-pin DIP, and 44-pin PLCC. The operating voltage range is from 4.5V to 6.0V.

The COP8SAA7, COP8SAB7 and COP8SAC7 (COP8SAx7 family) devices, on the other hand, are members of the COP8 Feature Family that contain EPROM, RAM, a 16-bit multi-function timer with two autoreload/capture registers, eight interrupt sources supporting vectored interrupt scheme, and the enhanced MICROWIRE/PLUS serial interface. In addition, these devices contain features such as Multi-Input Wakeup, WATCHDOG™/Clock Monitor, Idle timer supporting Idle mode, internal Power-On Reset, on-chip RC oscillator, 8 bytes of user storage space in EPROM, and on-chip EMI reduction circuitry. The devices are offered in 16-pin SO/DIP, 20-pin SO/DIP, 28-pin SO/DIP, 40-pin DIP, and 44-pin PLCC. The operating voltage range is from 2.7V to 5.5V. See the datasheet for more details.

The purpose of this Application Note is to provide a detailed comparison and feature analysis of these two family of devices. Where applicable, this report can be used to assist in converting the code written for the COP878x device to operate on an equivalent COP8SAx7 device.

As suggested, the COP8SAx7 family offers a broad range of additional useful and enhanced features as compared to the COP878x family. With the additional features, the COP8SAx7 family may appear much different, but this family is designed to maintain downward compatibility with the COP878x family as much as possible. The intention has been to offer the COP878x user the capability to maintain the same PCB when converting to COP8SAx7 without any PCB changes.

HIGHLIGHTS OF COP8SAx7 ENHANCEMENTS OVER COP878x

1. The operating voltage range is wider (2.7V to 5.5V).
2. The dynamic supply current is lower.
3. Four additional high sink current outputs (L0–L3) are added (min sink current of 15 mA at V_{OL} = 1.7, V_{CC} = 4.5V).
4. The R/C oscillator option is expanded to include the choice of selecting on-chip R/C components. The use of on-chip R/C eliminates the cost associated with external R/C oscillator components.
5. The crystal oscillator option is expanded to include the choice of selecting on-chip biasing resistor.
6. COP878x's Port I is replaced with a bi-directional Port F.
7. Schmitt trigger inputs are added to Port L.
8. Pins 21–24 (Ports C4–C7), on the 44-pin PLCC package, are general purpose I/O ports. They are No Connection (NC) on the COP878x.
9. Stack Pointer is automatically initialized by hardware.
10. The user selectable Power-On reset feature is added, in addition to the ability to reset the device externally. The on-chip power-on reset eliminates the need for using external components associated with reset circuitry.
11. The HALT feature is made user selectable.
12. The unique power saving Multi-Input Wakeup feature is added.
13. The interrupt handling is enhanced to support a versatile vectored interrupt scheme. It has a total of eight interrupt sources with independent vectors. The COP878x has a polled interrupt scheme.
14. The Software Trap scheme is enhanced to include its own pending flag.
15. The MICROWIRE/PLUS serial interface is enhanced to include shifting on the alternate clock edge and programmable idle polarity for the shift clock. This allows compatibility with SPI peripherals.
16. The 16-bit multi-function timer/counter is improved to include two autoreload/capture registers. The timer block contains two separate interrupt vectors and two I/O pins. The COP878x timer has a single autoreload/capture register, a single interrupt source, and a single I/O pin.
17. The ECON register is expanded to select additional user selectable features such as WATCHDOG, Power-On Reset, on-chip R/C oscillator, on-chip crystal oscillator biasing resistor, and HALT mode.
18. Added a free running IDLE timer.
19. Added the power saving IDLE mode.
20. Added the user selectable WATCHDOG/Clock Monitor logic.
21. Nine instructions are added to the basic instruction set. The instructions are ANDSZ, IFNE, RLCA, VIS, POP A, PUSH A. RPND. LD B and IFEQ Mem.Imm.
22. The device is offered in 16-pin DIP/SO.
23. Eight bytes of user storage space in EPROM are added in addition to regular program memory space.
24. EMI reduction circuitry is added to achieve low radiated emissions.

SUMMARY OF DIFFERENCES BETWEEN COP878x AND COP8SAx7

The following table provides a detailed summary of differences between the COP878x and COP8SAx7.

TABLE I

Features	COP878x Family	COP8SAx7
Operating Voltage	4.5V to 6.0V	2.7V to 5.5V
Dynamic Supply Current CKI = 10 MHz	21 mA	7 mA
Typical HALT Current	$< 1\ \mu A$	$< 4\ \mu A$
Port L0–L7	Port L does not have Schmitt Trigger inputs.	Port L has Schmitt Trigger inputs.
Port L0–L3 Min Sink Current V_{OL} = 1.7V at V_{CC} = 4.5V	2.0 mA	15 mA
R/C Oscillator	External RC Components	On-Chip RC or On-Chip RC with External C.
R/C Oscillator Frequency Tolerance	R/C Oscillator tolerance is different than COP8SAx7. For example: for CKI = 1 MHz, R = ±1%, C = ±5%, frequency tolerance is approximately ±25% (see Datasheet for more points).	R/C Oscillator tolerance is different than COP878x. For example: for CKI = 1 MHz, using on-chip R/C or on-chip RC with external C, frequency tolerance is approximately ±35% (see Datasheet for more data points).
Crystal Oscillator	External crystal circuitry with external bias Resistor.	External crystal circuitry with the option of choosing external or internal bias resistor.
Input Only Port	Port I is an 8-bit input only port.	Port I is replaced with an 8-bit I/O (Port F).
Pin G1	Pin G1 is an I/O pin.	Pin G1 is a dedicated WATCHDOG output pin if WATCHDOG logic enabled. It is a general purpose I/O if WATCHDOG is not enabled.
Pin G2	Pin G2 is a general purpose I/O.	Pin G2 is a general purpose I/O or the timer second input capture.
NC Pins on the 44-Pin Package	Pins 21–24 are No Connection (NC).	Pins 21–24 are C4–C7 (I/O Pins).
Stack Pointer	The Stack Pointer must be initialized with software.	The Stack Pointer is initialized by hardware internally on reset.
RAM Map	1. Location 0FF Hex is a general purpose RAM register. 2. Location 0D7 hex is for Port I input pins.	1. Location 0FF Hex is reserved for future RAM expansion. If compatibility with future devices (with more RAM) is not desired, this location can be used as a general purpose RAM location. 2. Location 0D7 Hex is reserved. Port I is replaced by Port F. Port F is read into RAM location 96 Hex instead of location D7 Hex.
Reset	External reset only.	External reset or using on-chip user selectable power-on reset. The external RC delay must be greater than 5x Power Supply Rise time or 15 μs, whichever is greater.
HALT Mode	HALT mode is always enabled.	HALT can be enabled or disabled through ECON control bit.
Exit from HALT Mode	Exit from HALT through Reset or G7 pin (if not used as the oscillator output).	Exit from HALT through reset or G7 pin (if not used as the oscillator output) or Multi-Input Wakeup.
Interrupt Handling	Polled Interrupts	Vectored Interrupts
Interrupt Sources	Software Trap External Interrupt Timer Interrupt	Software Trap External Interrupt Timer Interrupt (2) Multi-Input Wakeup IDLE MICROWIRE/PLUS Default VIS

SUMMARY OF DIFFERENCES BETWEEN COP878x AND COP8SAx7 (Continued)

The following table provides a detailed summary of differences between the COP878x and COP8SAx7. (Continued)

TABLE I (Continued)

Features	COP878x Family	COP8SAx7
Software Trap	Software Trap does not set a pending flag.	Software Trap sets a pending flag.
MICROWIRE/PLUS	1. Does not allow shifting at alternate clock edge. 2. Does not support programmable idle polarity for the shift clock. 3. In Slave mode, the shift clock does not stop after 8 clock pulses.	1. Allows shifting at alternate clock edge. 2. Supports programmable idle polarity for the shift clock for SPI compatibility. 3. In Slave mode, the shift clock stop after 8 clock pulses.
Multifunction 16-Bit Timer	The timer has: 1. One 16-bit counter with a single 16-bit register. 2. One I/O pin. 3. One interrupt source. 4. No underflow interrupt pending flag in the capture mode.	The timer has: 1. One 16-bit counter with two 16-bit registers. 2. One output and two input pins. 3. Two interrupt sources. 4. Underflow interrupt pending flag in the capture mode.
ECON Register	ECON register selects the security, clock, and RAM size options.	ECON register selects the security, clock, WATCHDOG, power-on reset, and HALT options. Bit functions for the clock option and bit polarity for the security option are different. RAM size is selected by device.
Idle Timer/Idle Mode	Does not contain an Idle Timer. Does not support Idle Mode.	Contains an Idle Time. Supports Idle Mode.
WATCHDOG/Clock Monitor	Does not contain WATCHDOG/Clock Monitor.	Contains WATCHDOG/Clock Monitor.
Instruction Set	COP8 Basic family instruction set.	COP888 Feature family instruction set (9 additional instructions as compared to Basic family). The instructions are ANDSZ, IFNE, RLCA, VIS, POP A, PUSH A, RPND, LD B, and IFEQ Mem,Imm.
Packages	20-pin SO/DIP, 28-pin SO/DIP, 40-pin DIP, 44-pin PLCC.	16-pin SO/DIP, 20-pin SO/DIP, 28-pin SO/DIP, 40-pin DIP, 44-pin PLCC.
Reading EPROM with Security Enabled	Reads E0 Hex	Reads FF Hex
Contents of ECON Register Shipped from the Factory	Windowed: FF Hex OTP: 7F Hex	Windowed: 00 Hex OTP: 80 Hex
Contents of Program Memory in the Erased State	FF Hex	00 Hex **Note:** Erasure time higher (see Datasheet).
EMI	Does not include EMI reduction circuitry.	Contains EMI reduction circuitry.

COMPATIBILITY—CONVERTING FROM COP878x TO COP8SAx7

The review of differences outlined in Table I, leads to the following steps to be followed in converting from the COP878x to COP8SAx7:

Hardware/ECON Register Considerations

1. R/C Oscillator

Bits 3 and 4 of ECON register must be programmed with 1 and 0 respectively. This will select the on-chip R/C components. External R/C components are not needed unless different operating frequency is required. For a different operating frequency, only a small external capacitor needs to be added from the CKI to the GND pin. See the datasheet for the appropriate capacitor value. There are differences in R/C oscillator tolerances between the COP878x and COP8SAx7. For comparison, see the datasheets for these devices.

2. Crystal Oscillator

Bits 3 and 4 of ECON register must be programmed with 0 and 1 respectively. This will select the crystal oscillator with external biasing resistor. No change to the external crystal oscillator circuitry is required.

3. External Oscillator

Bits 3 and 4 of ECON register must be both programmed with 0.

4. Security Feature

Bit 5 of ECON register must be programmed with 1 to enable the security feature, otherwise must contain a 0 for the security feature to be disabled. This polarity is opposite of COP878x.

5. Reset

Bit 6 of ECON register must be programmed with 0 to disable the on-chip Power-On Reset. The RC delay must be greater than 5x Power Supply rise time or 15 μs, whichever is greater.

6. HALT Mode

Bit 0 of ECON register must be programmed with 0 to enable the HALT mode.

7. WATCHDOG

Bit 2 of ECON register must be programmed with 1 to disable the WATCHDOG logic. This will allow the G1 pin to serve as a general purpose I/O.

8. RAM Select

RAM size is selected by device. For example, COP8SAA has 64 bytes of RAM and COP8SAB/COP8SAC has 128 bytes of RAM.

9. Bit 7 of ECON Register

It is a factory test bit. The polarity is "Don't Care".

Software Considerations

1. Pins 21–24 (Ports C4–C7) on the 44-Pin Package

These pins are No Connection (NC) on the COP878x, but are general purpose I/O on the COP8SAx7.

2. Stack Pointer

If the Stack Pointer (SP) is initialized to a value different than 2F Hex (64 bytes of RAM selected) or to 6F Hex (128 bytes of RAM selected), in the code written for COP878x, the SP initialization instruction can be kept in the user program as is although the hardware initializes SP to 2F or 6F (depending on RAM size). If the COP878x code is initializing the SP to 2F Hex or 6F (depending on the RAM size), the initializing instruction can be deleted. If no code changed is desired, the initialization instruction can stay as is (although redundant).

3. Port I/Port F Configuration

Since Port I is replaced by Port F on the COP8SAx7, Port F is configured as Hi-Z inputs upon reset. This means Port F data register (RAM location 94 Hex) and Port F configuration register (RAM location 95 Hex) both contain values of 0 upon reset and user code must ensure they stay at 0. In addition, Port F is read into RAM location 96 Hex instead of RAM location D7 Hex. The COP878x code must be modified to reflect this change.

4. RAM Location FF Hex

RAM location FF Hex is a general purpose RAM location on the COP878x, but it is reserved on the COP8SAx7 for future RAM expansion. If compatibility with future devices (with more RAM) is not desired, this location can be used as a general purpose RAM location to maintain compatibility with COP878x.

5. Multi-Input Wakeup

The COP8SAx7 offers the power saving Multi-Input Wakeup feature. This feature is an alternate function of Port L. The COP878x does not offer this feature. Still there is no code change required because during reset initialization, the Wakeup Enable (RAM address location C9 Hex) register is cleared thus disabling the Multi-Input Wakeup feature.

6. Interrupt Handling

COP878x supports the interrupt polling scheme and it has only three interrupt sources. With the polling scheme, all interrupts cause immediate jump to the single fixed program memory location 0FF Hex. The user program must poll all interrupt pending bits to determine the cause of the interrupt. Once the cause is determined, the user program may jump to an appropriate interrupt handling routine.

The COP8SAx7, with up to eight interrupt sources, supports both polled and vectored interrupt schemes. With the vectored interrupt scheme, a vector table is used. The vector table placed in the program memory, contains the start addresses for each of the user's interrupt routines. This table is used by the device to determine where to jump when a particular interrupt occurs. When an interrupt occurs, the device initially jumps to the single fixed program memory location 0FF Hex. Then user program may call a special instruction (VIS) to cause a jump to the vector table followed by a jump to user specified interrupt service routine. The user may elect not to use the VIS instruction, not place the vector table in the program memory, and simply poll each interrupt pending bit as described for the COP878x.

In order to keep the COP878x interrupt handling code compatible with the COP8SAx7, all additional interrupt sources that are available on the COP8SAx7 must be disabled. These additional sources include interrupts associated with the Idle timer, MICROWIRE/PLUS, and Multi-Input Wakeup. Since the COP8SAx7 multi-function timer block contains two interrupt sources, to maintain compatibility with the COP878x, the second interrupt source (Timer T1B Interrupt Enable) must be disabled. All the Enable bits associated with these additional interrupt sources reside in the ICNTRL register (RAM location E8 Hex) and are cleared upon reset. Therefore, there is no code modification required as long as the user keeps the new additional sources disabled, and not use the additional COP8SAx7 interrupt feature (VIS instruction and vector table).

Software Interrupt

The COP8SAx7 software interrupt has a pending flag. This flag is not memory mapped and is cleared by the special RPND instruction. To keep the COP878x code compatible with that of the COP8SAx7 and vectored interrupt scheme is not used, upon entering the interrupt routine (program memory location 0FF Hex), the user program must execute the RPND instruction. This will reset the software interrupt pending flag. The next step is to check the timer and external interrupt pending bits. If none are set, it gives the indication that a software interrupt has occurred.

7. Timer

The timer block contains a second 16-bit register that can be used as an autoreload or capture register depending on the timer operating mode. The following steps need to be considered to run the code written for the COP878x timer on the COP8SAx7.

PWM Mode

a. The second interrupt source must remain disabled (T1ENB bit in the ICNTRL register must be 0). T1ENB bit is cleared upon reset.

b. Pin G3 (T1A) must be used as the timer PWM output pin. Pin G2 is available as a general purpose I/O.

c. The timer's second reload register (T1RB) must be loaded with the same value as the contents of T1RA. This means an instruction must be inserted into the COP8SAx7 code to initialize T1RB.

External Event Mode

a. The second interrupt source must remain disabled (T1ENB bit in the ICNTRL register must be 0). T1ENB bit is cleared upon reset.

b. Pin G3 (T1A) must be used as the timer external event input pin. Pin G2 is available as a general purpose I/O.

c. The timer's second reload register (T1RB) must be loaded with the same value as the contents of T1RA. This means an instruction must be inserted into the COP8SAx7 code to initialize T1RB.

Capture Mode

a. The second interrupt source must remain disabled (T1ENB bit in the ICNTRL register must be 0). T1ENB bit is cleared upon reset.

b. Pin G3 (T1A) must be used as the timer input capture pin. The alternate function of pin G2 (G2 is available as a general purpose I/O) and the capture register T1RB must be ignored. The user can simply read the capture register T1RA.

8. MICROWIRE/PLUS

The MICROWIRE/PLUS feature on the COP8SAx7, supports shifting serial data with the alternate edge of the shift clock and has the ability to select idle polarity for the shift clock. To ensure compatibility with COP878x, bit 6 of Port G configuration register and bit 5 of Port G data register must both contain 0. Upon reset, these bits are cleared and the user code must ensure they stay at 0. In the slave mode, the shift clock on the COP8SAx7 does not stop after 8 clock pulses. The shift clock on the COP8SAx7, on the other hand, stops after 8 clock pulses. No change is required as a result of this difference.

Comparison of COP82xCJ to the Enhanced COP8SAx7 Family—Hardware/ Software Considerations

National Semiconductor
Application Note 1044
Abdul Aleaf

INTRODUCTION

The COP820CJ, COP822CJ and COP823CJ are members of the COP8 Basic Family that contain ROM, RAM, a 16-bit multi-function timer with a single 16-bit autoreload/capture register, 3 interrupt sources with polling scheme, WATCHDOG™ Timer, Modulator/Timer, Brown Out detection, Multi-Input Wakeup, and the MICROWIRE/PLUS™ serial interface. These devices are offered in 28-pin SO/DIP, 20-pin SO/DIP, 16-pin SO packages. The operating voltage range is from 2.5V to 6.0V.

The COP8SAA7, COP8SAB7 and COP8SAC7 (COP8SAx7 family) devices, on the other hand, are members of the COP8 Feature Family that contain EPROM, RAM, a 16-bit multi-function timer with two autoreload/capture registers, eight interrupt sources supporting vectored interrupt scheme, and the enhanced MICROWIRE/PLUS serial interface. In addition, these devices contain features such as Multi-Input Wakeup, WATCHDOG/Clock Monitor, Idle timer supporting Idle mode, internal Power-On Reset, on-chip RC oscillator, 8 bytes of user storage space in EPROM, and on-chip EMI reduction circuitry. The devices are offered in 44-pin PLCC, 40-pin DIP, 28-pin SO/DIP, 20-pin SO/DIP, and 16-pin SO/DIP packages. The operating voltage range is from 2.7V to 5.5V. See the datasheet for more details.

The purpose of this Application Note is to provide a detailed comparison and feature analysis of these two family of devices. Where applicable, this report can be used to assist in converting the code written for the COP82xCJ device to operate on an equivalent COP8SAx7 device.

As suggested, the COP8SAx7 family offers additional useful and enhanced features as compared to the COP82xCJ family. With the additional features, the COP8SAx7 family may appear much different, but this family is designed to maintain downward compatibility with the COP82xCJ family as much as possible.

The COP82xCJ family offers some features that are not supported by the COP8SAx7 family. Examples of such features are Brown Out detection, comparator, Modulator, and a second 8-bit timer with 8-bit prescaler (if WATCHDOG function is not used). If these features are already used on the COP82xCJ design, the conversion to the COP8SAx7 family will be more involved and may require additional external components and code changes.

HIGHLIGHTS OF COP8SAx7 ENHANCEMENTS OVER COP82xCJ

1. The operating voltage range is wider (2.7V–5.5V).
2. The R/C oscillator option is expanded to include the choice of selecting on-chip R/C components. The use of on-chip R/C eliminates the cost associated with external R/C oscillator components.
3. The crystal oscillator option is expanded to include the choice of selecting on-chip biasing resistor.
4. COP82xCJ's Port I is replaced with a bi-directional Port F.
5. Stack Pointer is automatically initialized by hardware.
6. The HALT feature is made user selectable.
7. The interrupt handling is enhanced to support a versatile vectored interrupt scheme. It has a total of eight interrupt sources with independent vectors. The COP82xCJ has a polled interrupt scheme.
8. The Software Trap scheme is enhanced to include its own pending flag.
9. The MICROWIRE/PLUS serial interface is enhanced to include shifting on the alternate clock edge and programmable idle polarity for the shift clock. This allows compatibility with SPI peripherals.
10. The 16-bit multi-function timer/counter is improved to include two autoreload/capture registers. The timer block contains two separate interrupt vectors and two I/O pins. The COP82xCJ timer has a single autoreload/capture register, a single interrupt source, and a single I/O pin.
11. Added a free running IDLE timer.
12. Added the power saving IDLE mode.
13. Nine instructions are added to the basic instruction set. The instructions are ANDSZ, IFNE, RLCA, VIS, POP A, PUSH A, RPND, LD B and IFEQ Mem,Imm.
14. The device is offered in 44-pin PLCC, 40-pin DIP, and 16-pin DIP, in addition to 28-pin SO/DIP, 20-pin SO/DIP, and 16-pin SO packages.
15. EMI reduction circuitry is added to achieve low radiated emissions.

SUMMARY OF DIFFERENCES BETWEEN COP82xCJ AND COP8SAx7

The following table provides a detailed summary of differences between the COP82xCJ and COP8SAx7.

TABLE I

Features	COP82xCJ Family	COP8SAx7
Operating Voltage	2.5V–6.0V	2.7V–5.5V
Dynamic Supply Current CKI = 10 MHz	6 mA	7 mA
Typical HALT Current	< 1 μA (Brown Out Disabled)	< 4 μA
R/C Oscillator	External RC Components.	On-Chip RC or On-Chip RC with External C.
R/C Oscillator Frequency Tolerance	R/C Oscillator tolerance is different than COP8SAx7. For example: for CKI = 1 MHz, R = ±1%, C = ±5%, frequency tolerance is approximately ±25% (see Datasheet for more data points).	R/C Oscillator tolerance is different than COP82xCJ. For example: for CKI = 1 MHz, using on-chip R/C or on-chip RC with external C, frequency tolerance is approximately ±35% (see Datasheet for more data points).
Crystal Oscillator	External crystal circuitry with external bias Resistor.	External crystal circuitry with the option of choosing external or internal bias resistor.
Input Only Port	Port I is an 8-bit input only port.	Port I is replaced with an 8-bit I/O (Port F).
Pin G1	Pin G1 is an I/O pin.	Pin G1 is a dedicated WATCHDOG output pin if WATCHDOG logic enabled. It is a general purpose I/O if WATCHDOG is not enabled.
Pin G2	Pin G2 is a general purpose I/O.	Pin G2 is a general purpose I/O or the timer second input capture.
Stack Pointer	The Stack Pointer must be initialized with software.	The Stack Pointer is initialized by hardware internally on reset.
RAM Map	1. Location 0FF Hex is a general purpose RAM register. 2. Location 0D7 hex is for Port I input pins.	1. Location 0FF Hex is reserved for future RAM expansion. If compatibility with future devices (with more RAM) is not desired, this location can be used as a general purpose RAM location. 2. Location 0D7 Hex is reserved. Port I is replaced by Port F. Port F is read into RAM location 96 Hex instead of location D7 Hex.
Reset	External reset or Brown Out reset. Brown Out reset can be used as a Power-On Reset.	External reset or using on-chip user selectable Power-On Reset. The external RC delay must be greater than 5x Power Supply Rise time or 15 μs, whichever is greater.
HALT Mode	HALT mode is always enabled.	HALT can be enabled or disabled through ECON control bit.
Interrupt Handling	Polled Interrupts	Vectored Interrupts
Interrupt Sources	Software Trap External Interrupt Timer Interrupt	Software Trap External Interrupt Timer Interrupt (2) Multi-Input Wakeup IDLE MICROWIRE/PLUS Default VIS
Software Trap	Software Trap does not set a pending flag.	Software Trap sets a pending flag.

SUMMARY OF DIFFERENCES BETWEEN COP82xCJ AND COP8SAx7 (Continued)

The following table provides a detailed summary of differences between the COP82xCJ and COP8SAx7. (Continued)

TABLE I (Continued)

Features	COP82xCJ Family	COP8SAx7
MICROWIRE/PLUS	1. Does not allow shifting at alternate clock edge. 2. Does not support programmable idle polarity for the shift clock. 3. In Slave mode, the shift clock does not stop after 8 clock pulses.	1. Allows shifting at alternate clock edge. 2. Supports programmable idle polarity for the shift clock for SPI compatibility. 3. In Slave mode, the shift clock stop after 8 clock pulses.
Multifunction 16-Bit Timer	The timer has: 1. One 16-bit counter with a single 16-bit register. 2. One I/O pin. 3. One interrupt source. 4. No underflow interrupt pending flag in the capture mode.	The timer has: 1. One 16-bit counter with two 16-bit registers. 2. One output and two input pins. 3. Two interrupt sources. 4. Underflow interrupt pending flag in the capture mode.
Program Memory Security	COP82xCJ are mask ROMed devices. Program memory contents cannot be read in an EPROM programmer environment.	Contains EPROM security feature.
ECON Register	No ECON register. Clock configuration is selected by a mask option. RAM size is fixed. WATCHDOG is enabled by software. Brown Out detection (can be used as Power-On-Reset) is a mask option. No ROM security feature.	ECON register selects the security, clock, WATCHDOG, Power-On Reset, and HALT options. Bit functions for the clock option and bit polarity for the security option are different. RAM size is selected by device.
Idle Timer/Idle Mode	Does not contain an Idle Timer. Does not support Idle Mode.	Contains an Idle Time. Supports Idle Mode.
WATCHDOG/Clock Monitor	WATCHDOG is enabled by software. WATCHDOG window is programmable through an 8-bit timer preceeded by an 8-bit prescaler. WATCHDOG trigger generates internal reset. No Clock Monitor logic.	WATCHDOG is active upon Power-up. WATCHDOG has a programmable upper window (4 choices) and a fixed lower window. WATCHDOG pin goes active low upon WATCHDOG trigger condition. Contains Clock Monitor logic.
Brown Out Detection	Contains on-chip Brown Out detection circuit.	Does not contain on-chip Brown Out detection circuit.
Comparator	Contains an on-chip comparator.	No on-chip comparator.
Modulator Timer	Contains a Modulator Timer	No Modulator Timer.
WATCHDOG Timer	If WATCHDOG function is not used, the WATCHDOG timer can be used as a general purpose timer for internal time keeping.	The Idle timer provides timing for the WATCHDOG logic. Cannot use Idle timer as a general purpose internal timer.
Instruction Set	COP8 Basic family instruction set.	COP888 Feature family instruction set (9 additional instructions as compared to Basic family). The instructions are ANDSZ, IFNE, RLCA, VIS, POP A, PUSH A, RPND, LD B, and IFEQ Mem,Imm.
Packages	28-pin SO/DIP, 20-pin SO/DIP, 16-pin SO.	44-pin PLCC, 40-pin DIP, 28-pin SO/DIP, 20-pin SO/DIP, 16-pin SO/DIP.
EMI	Does not include EMI reduction circuitry.	Contains EMI reduction circuitry.

COMPATIBILITY—CONVERTING FROM COP82xCJ TO COP8SAx7

The review of differences outlined in Table I, leads to the following steps to be followed in converting from the COP82xCJ to COP8SAx7:

Hardware/ECON Register Considerations

1. R/C Oscillator

Bits 3 and 4 of ECON register must be programmed with 1 and 0 respectively. This will select the on-chip R/C components. External R/C components are not needed unless different operating frequency is required. For a different operating frequency, only a small external capacitor needs to be added from the CKI to the GND pin. See the datasheet for the appropriate capacitor value. There are differences in R/C oscillator tolerances between the COP82xCJ and COP8SAx7. For comparison, see the datasheets for these devices.

2. Crystal Oscillator

Bits 3 and 4 of ECON register must be programmed with 0 and 1 respectively. This will select the crystal oscillator with external biasing resistor. No change to the external crystal oscillator circuitry is required.

3. External Oscillator

Bits 3 and 4 of ECON register must be both programmed with 0.

4. Security Feature

Bit 5 of ECON register (COP8SAx7) must be programmed with 1 to enable the EPROM security feature, otherwise must contain a 0 for the security feature to be disabled. COP82xCJ devices are mask ROMed. Program memory (ROM) cannot be read in an EPROM programmer environment.

5. Reset

Bit 6 of the COP8SAx7 ECON register can be programmed with "0" to disable the on-chip Power-On-Reset. By doing this, external reset can be used and the device will perform the same as the COP82xCJ except that RC delay must be greater than 5x Power Supply rise time or 15 μs, whichever is greater.

If Brown Out detection feature is selected on the COP82xCJ (by mask option) as a Power-On-Reset, bit 6 of the COP8SAx7 ECON register must be programmed with "1" to enable the on-chip Power-On-Reset.

If Power-On-Reset is selected, the user needs to consider the V_{CC} rise time specification of 10 ns to 50 ms. There is no spec limitation on COP82xCJ Brown Out detection feature.

6. HALT Mode

Bit 0 of ECON register must be programmed with 0 to enable the HALT mode.

7. WATCHDOG

The COP82xCJ has an on-chip 8-bit WATCHDOG timer. The timer contains an 8-bit READ/WRITE down counter clocked by an 8-bit prescaler. The WATCHDOG can be enabled or disabled (only once) after the device is reset as a result of brown out reset or external reset. On power-up the WATCHDOG is disabled. The WATCHDOG is enabled by writing a "1" to a bit in WATCHDOG register (WDREG). Once enabled, the user program should write periodically into the 8-bit counter before the counter underflows. An internal reset is generated if the user programs fail to do so.

The COP8SAx7 family, on the other hand, contains a user selectable WATCHDOG and Clock Monitor. The WATCHDOG is enabled by bit 2 of the ECON register. When this bit is 0, the WATCHDOG is enabled and pin G1 becomes the WATCHDOG output pin with a weak pullup. The WATCHDOG logic contains two separate service windows. While the user selectable upper window selects the WATCHDOG service time, (four choices of 8k t_C, 32k t_C, 64k t_C, where t_C = instruction cycle time), the lower window (fixed time of 256 instruction cycles) provides protection against an infinite program loop that contains the WATCHDOG service instruction. The Clock Monitor is used to detect the absence of a clock or a very slow clock below a specified rate on the CKI pin. The WATCHDOG and Clock Monitor are disabled during reset. The devices comes out of reset with the WATCHDOG armed, and the Clock Monitor enabled. Servicing the WATCHDOG consists of writing a specific value to a WATCHDOG Service Register (WDSVR) which is memory mapped in the RAM. The service value is composed of three fields, consisting of a 2-bit Window Select, a 5-bit Key Data field, and the 1-bit Clock Monitor Select field. The WDSVR register can be written to only once after reset to select the proper upper window and the Clock Monitor feature. Upon triggering the WATCHDOG, to the logic will pull the WATCHDOG output pin (G1) low for 16 t_C–32 t_C. The WATCHDOG pin may be connected to the Reset pin externally to reset the device upon WATCHDOG trigger condition.

If the WATCHDOG feature is used on the COP82xCJ, the following steps need to be considered to convert to COP8SAx7.

a. Clear bit 2 of the ECON register to select WATCHDOG feature.

b. Select the proper values for bit 6 and bit 7 of the WDSVR (WATCHDOG Service Register) to obtain the appropriate upper window service time. Select one of the four choices that is as close to the COP82xCJ service time as possible. If there is mismatch between the service times, adjust the code to service the WATCHDOG within the new selected upper window.

c. Locate the instruction that enables the WATCHDOG and is placed in the beginning of the COP82xCJ code. Replace this instruction with a new one to perform a write to the COP8SAx7 WATCHDOG Service Register (WDSVR). This instruction should select the proper upper window, enable or disable Clock Monitor, and write a 5-bit data to match the Key Data.

d. The COP8SAx7 must be serviced at least once before the upper window expires and not more than once within a 256 instruction cycle window (lower window).

e. The WATCHDOG output (pin G1) must be connected externally to the Reset pin.

8. Bit 7 of ECON Register

It is a factory test bit. The polarity is "Don't Care".

Software Considerations

1. Stack Pointer

If the Stack Pointer (SP) is initialized to a value different than 2F Hex (64 bytes of RAM selected) or to 6F Hex (128 bytes of RAM selected), in the code written for COP82xCJ, the SP initialization instruction can be kept in the user program as is although the hardware initializes SP to 2F or 6F (depending on RAM size). If the COP82xCJ code is initializing the SP to 2F Hex or 6F (depending on the RAM size), the initializing instruction can be deleted. If no code changed is desired, the initialization instruction can stay as is (although redundant).

2. Port I/Port F Configuration

Since Port I is replaced by Port F on the COP8SAx7, Port F is configured as Hi-Z inputs upon reset. This means Port F data register (RAM location 94 Hex) and Port F configuration register (RAM location 95 Hex) both contain values of 0 upon reset and user code must ensure they stay at 0. In addition, Port F is read into RAM location 96 Hex instead of RAM location D7 Hex. The COP82xCJ code must be modified to reflect this change.

3. RAM Location FF Hex

RAM location FF Hex is a general purpose RAM location on the COP82xCJ, but it is reserved on the COP8SAx7 for future RAM expansion. If compatibility with future devices (with more RAM) is not desired, this location can be used as a general purpose RAM location to maintain compatibility with COP82xCJ.

4. Interrupt Handling

COP82xCJ supports the interrupt polling scheme and it has only three interrupt sources. With the polling scheme, all interrupts cause immediate jump to the single fixed program memory location 0FF Hex. The user program must poll all interrupt pending bits to determine the cause of the interrupt. Once the cause is determined, the user program may jump to an appropriate interrupt handling routine.

The COP8SAx7, with up to eight interrupt sources, supports both polled and vectored interrupt schemes. With the vectored interrupt scheme, a vector table is used. The vector table placed in the program memory, contains the start addresses for each of the user's interrupt routines. This table is used by the device to determine where to jump when a particular interrupt occurs. When an interrupt occurs, the device initially jumps to the single fixed program memory location 0FF Hex. Then user program may call a special instruction (VIS) to cause a jump to the vector table followed by a jump to user specified interrupt service routine. The user may elect not to use the VIS instruction, not place the vector table in the program memory, and simply poll each interrupt pending bit as described for the COP82xCJ.

In order to keep the COP82xCJ interrupt handling code compatible with the COP8SAx7, all additional interrupt sources that are available on the COP8SAx7 must be disabled. These additional sources include interrupts associated with the Idle timer, MICROWIRE/PLUS, and Multi-Input Wakeup. Since the COP8SAx7 multi-function timer block contains two interrupt sources, to maintain compatibility with the COP82xCJ, the second interrupt source (Timer T1B Interrupt Enable) must be disabled. All the Enable bits associated with these additional interrupt sources reside in the ICNTRL register (RAM location E8 Hex) and are cleared upon reset. Therefore, there is no code modification required as long as the user keeps the new additional sources disabled, and not use the additional COP8SAx7 interrupt feature (VIS instruction and vector table).

Software Interrupt

The COP8SAx7 software interrupt has a pending flag. This flag is not memory mapped and is cleared by the special RPND instruction. To keep the COP82xCJ code compatible with that of the COP8SAx7 and vectored interrupt scheme is not used, upon entering the interrupt routine (program memory location 0FF Hex), the user program must execute the RPND instruction. This will reset the software interrupt pending flag. The next step is to check the timer and external interrupt pending bits. If none are set, it gives the indication that a software interrupt has occurred.

5. Timer

The timer block contains a second 16-bit register that can be used as an autoreload or capture register depending on the timer operating mode. The following steps need to be considered to run the code written for the COP82xCJ timer on the COP8SAx7.

PWM Mode

a. The second interrupt source must remain disabled (T1ENB bit in the ICNTRL register must be 0). T1ENB bit is cleared upon reset.

b. Pin G3 (T1A) must be used as the timer PWM output pin. Pin G2 is available as a general purpose I/O.

c. The timer's second reload register (T1RB) must be loaded with the same value as the contents of T1RA. This means an instruction must be inserted into the COP8SAx7 code to initialize T1RB.

External Event Mode

a. The second interrupt source must remain disabled (T1ENB bit in the ICNTRL register must be 0). T1ENB bit is cleared upon reset.

b. Pin G3 (T1A) must be used as the timer external event input pin. Pin G2 is available as a general purpose I/O.

c. The timer's second reload register (T1RB) must be loaded with the same value as the contents of T1RA. This means an instruction must be inserted into the COP8SAx7 code to initialize T1RB.

Capture Mode

a. The second interrupt source must remain disabled (T1ENB bit in the ICNTRL register must be 0). T1ENB bit is cleared upon reset.

b. Pin G3 (T1A) must be used as the timer input capture pin. The alternate function of pin G2 (G2 is available as a general purpose I/O) and the capture register T1RB must be ignored. The user can simply read the capture register T1RA.

6. MICROWIRE/PLUS

The MICROWIRE/PLUS feature on the COP8SAx7, supports shifting serial data with the alternate edge of the shift clock and has the ability to select idle polarity for the shift clock. To ensure compatibility with COP82xCJ, bit 6 of Port G configuration register and bit 5 of Port G data register must both contain 0. Upon reset, these bits are cleared and the user code must ensure they stay at 0. In the slave mode, the shift clock on the COP8SAx7 does not stop after 8 clock pulses. The shift clock on the COP8SAx7, on the other hand, stops after 8 clock pulses. No change is required as a result of this difference.

Replacing Dedicated Protocol Controllers with Code Efficient and Configurable Microcontrollers—Low Speed CAN Network Applications

National Semiconductor
Application Note 1048
Martin Embacher

BACKGROUND

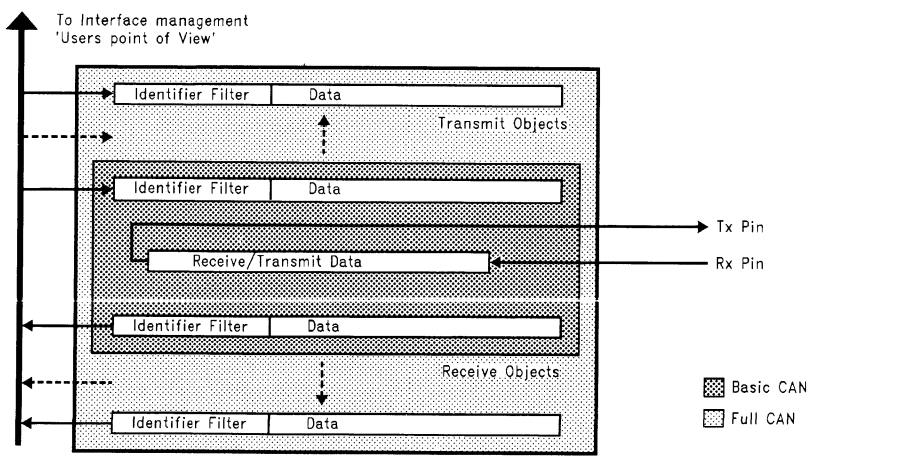
The CAN (Controller Area Network) is one of today's most widely accepted car networking systems. Various protocol implementations are available from different suppliers. Dedicated protocol controllers—Full-CAN controllers—are found as system bus interfaces connected to a main CPU or integrated into them. Yet in some applications, particularly in the low speed arena, these devices don't meet the price target or offer the flexibility required by the system designer. This Application Note outlines the application interfaces available for the CAN protocol, gives an overview to National Semiconductor's CAN devices and demonstrates in a practical example how these products can help to minimize the cost of Full-CAN controller applications while increasing the flexibility of such systems.

INTRODUCTION

CAN is designed to address the needs for a highly reliable protocol with maximum throughput for interconnecting multiple autonomous controller modules within harsh industrial or automotive applications. The need for such a system arose first when more and more electronic modules where introduced to the automobiles, resulting in huge amounts of wires being lain out within a car to perform interconnection between control modules and the sensors/actuators. The first objective of the CAN system was to reduce these kilometers of cabling and thereby reduce system cost by saving wiring effort. Additionally, the system had to have maximum reliability as basically all functions within a car could introduce a safety risk. Next to obviously important functions such as motor management and anti-blocking systems, comfort electronic functions can lead to unsafe operation of cars. Taking a faulty electronically controlled driver seat as an example this becomes more clear. Only assume due to a fault the seat is suddenly moving while the car runs at high speed.

BASIC AND Full-CAN IMPLEMENTATIONS

Many Semiconductor suppliers implemented various versions of a CAN user interface. Even the protocol remains the same. Basic-CAN implementations provide only the basic functionality of a CAN interface with the capability to buffer only one message with a limited acceptance filter. Though, an additional burden is placed on the CPU since it has to perform message filtering next to its regular task. Full-CAN controllers extend this basic features by not only implementing the protocol—moreover they implement a complete message "server" capable of automatically receiving and transmitting multiple messages on the CAN bus without interrupting the system's main CPU if it is not necessary. *Figure 1* shows the Basic-CAN interface with the extension for Full-CAN from the programmer's point of view.



TL/DD/12850–1

FIGURE 1. CAN Programming Model

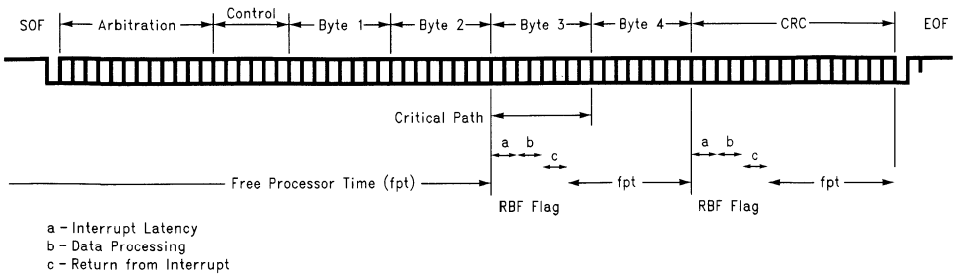
The hardware interface to the processor is provided with either serial links or a paralell interface with message data (identifier, control and data) being accesed on memory mapped address locations, so the user "sees" message data and control information.

Typical multiplex systems consist of one or more of each protocol implementation connected to each other over a common bus. The Full-CAN is used where the CPU has to perform a magnitute of other tasks and where communication needs to be highly independent from the rest of the software. A Basic-CAN controller is used in areas in which the CPU has some spare performance to assist the communication work. Full-CAN implementations with their higher level of functionality, require a larger silicon area than a Basic-CAN implementation, which translates directly into higher prices. Though, from a systems designer's point of view, it might be desirable to use as many Full-CAN controllers as possible to free up the CPU for applications tasks and provide free processing resources for future or different features. Common to both implementations is that they can process at least one receive and one transmit message object completely autonomously—which results in a specific number of registers being required on the CAN block to store the information. Lastly, fully autonomous CAN modules, commonly known as SLIO (Serial Linked I/O) devices are also available. These devices integrate a quasi Full-CAN controller with self-sufficient simple I/O capabilities, having no need for a main CPU within the module and therefore no dedicated programming requirements. With these devices a simple CAN module can be designed by only developing the input and output circurity required for the specific application. All I/O control is then provided via the CAN network. Examples are National's MM57C360 and MM57C362, which integrate a CAN cell, a message sequencer and I/O drivers. With this functionality the device is perfectly suited for simple modules like keypads or light clusters.

NATIONAL'S COPCAN INTERFACE

With the implementation of the COPCAN on the COP8™ microcontroller family, National has addressed especially the high implementation costs of previous CAN modules by reducing the amount of registers required to implement the CAN protocol. The driving factors were cost on the one side and the idea that not all applications require the high speed feature all CAN implementation known so far offered. To reduce cost the object buffer for both receive and transmit was reduced from 10 bytes (2 identifier + 8 data bytes) to 4 bytes (2 identifier + 2 data bytes). The "remainder" of the CAN interface, error management, BTL was not changed in order to achieve full compatibility. With the reduction of registers the interface is no longer capable to process messages with more than two bytes of data independently. Data needs to be provided by the main processor in time. This register reduction, however, has no influence on the interface performance in low speed (<125 kbit/s) applications, since the processor has enough time to store/provide the data when required. Interrupt flags indicate to the CPU when the processor needs to provide data to the COPCAN interface. This results in a ratio between the maximum possible bus speed and the time the processor needs to save and provide data which will now be explained in more detail. On the one side, the COP8 microcontroller core features an instruction cycle time of 1 μs = 1 t_C with an external clock of 10 MHz. Most instructions take one t_C to execute. On the other side, with a bus speed of 125 kbit/s, typical for low speed applications, one byte time on the CAN bus takes a minimum of: 8 (bit) * (1/125 kHz) (μs) = 64 μs, without the possible stuff bits. With a given interrupt latency time of 20 t_C maximum (including transfer of control instructions) this leaves 44 μs to store the receive data or write new data into the transmit register. *Figure 2* shows the timing of a message reception with four data bytes. It can be seen from the picture that adding data bytes to the frame would neither introduce a critical path nor decrease the processor's free time.

In this example, the CPU's usage to store the received data is given as approximately 20 t_C. The critical path is to read the first receive buffer byte after the receive buffer full flag (RBF) is set and before it gets overwritten by new incoming data. During the free processor time, other application tasks can be exceuted. Basically the same example is valid for a transmitter. The main difference is that transmitting data is mostly synchronus to the program's excecution where receiving is asynchronous. Thus, the transmission of data is not time-critical. Also, using a high speed link (>125 kbit/s) is possible for applications which don't need to receive more than two bytes of data.



TL/DD/12850-2

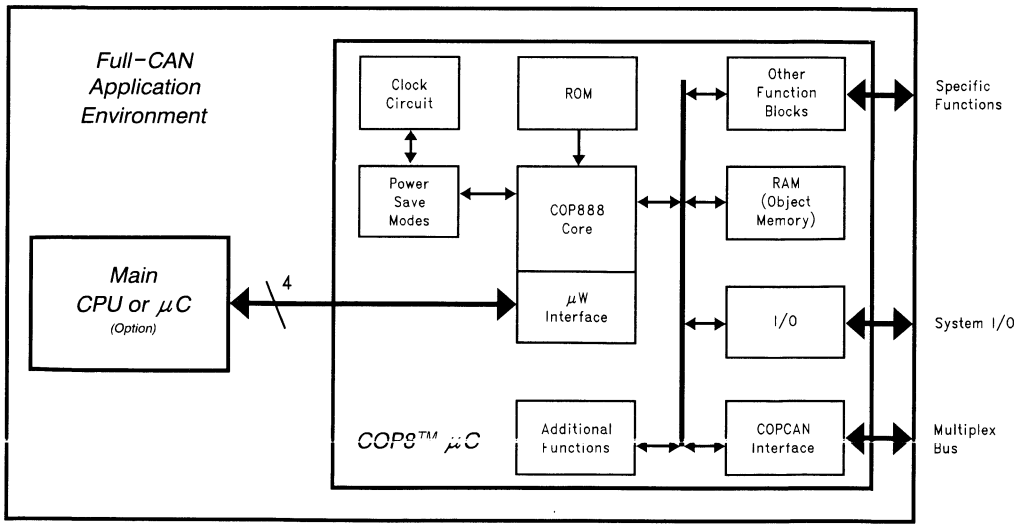
FIGURE 2. Message Processing with the COPCAN Interface

IMPLEMENTING A Full-CAN PROCESSOR WITH A COP8 MICROCONTROLLER

National's COP8 microcontroller core contains, beside the pure CPU, a serial synchronous MICROWIRE/PLUS™ interface and a processor independent Timer. Additional functional blocks like the COPCAN interface, Timers, USART, A/D convertors and various sizes of ROM and RAM can be added with the Configurable Controller Methodology (CCM). Today several standard parts are offered, of which two feature the COPCAN interface. The COP884BC and the COP888EB. All COP8 microcontroller family members are also available as one time programmable (OTP) devices. The following section shows how a protocol processor, providing a customizable Full-CAN interface, can be integrated with the COP8 family. A block diagram of the setup with the microcontroller and the main CPU is shown in *Figure 3*. Additional customized options, like time stamp for received messages or timed automatic transmission of data, can be integrated by simply altering the software. In addition, several data processing tasks, i.e., automatic keyboard scanning can be integrated—thus reducing the overhead on the main CPU and freeing up processing resources. Another advantage of having a second CPU in the system is automatic diagnostics, either with a specific protocol or with the WATCHDOG™ circuit integrated on the COP8. Finally, the power-save features of the COP8 microcontrollers help to minimize power consumption in the application by gradually switching off modules—including the main CPU. The multi-input wake-up feature allows multiple sources to return from the save mode to the active mode. The interface to the main CPU can be chosen to be provided with standard I/O ports of the microcontroller, the MICROWIRE/PLUS interface or, if very high speed communication is required, with a newly developed high-speed serial link.

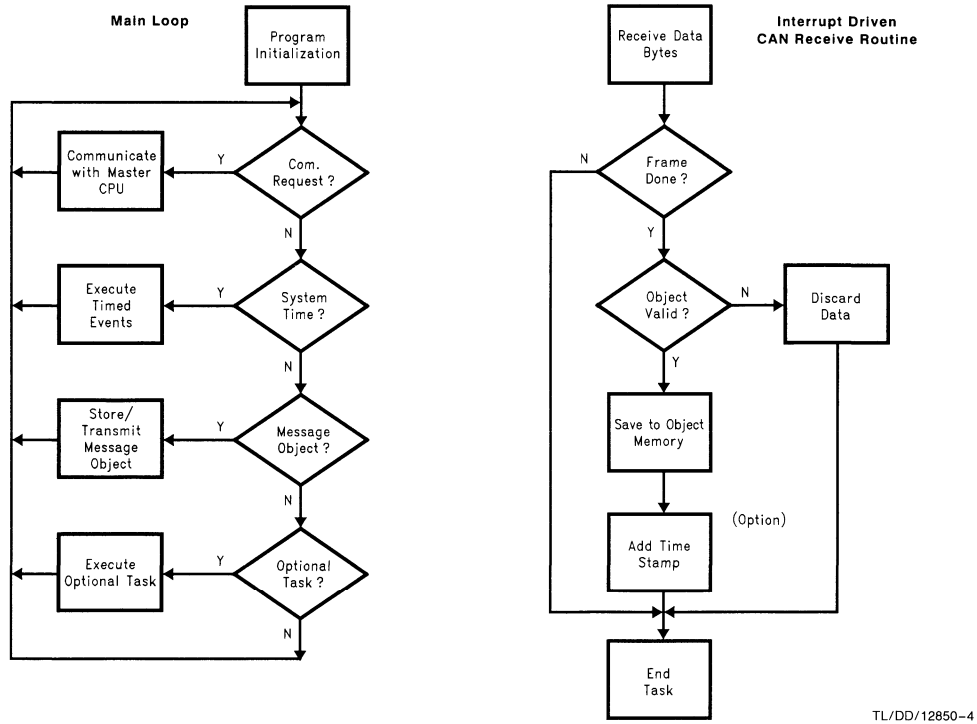
In this example, however, the MICROWIRE/PLUS interface is used. Communication is done with three wires and one handshake signal. The data from the main CPU to the microcontroller is transmitted in packets of eight bits with a customizable protocol. The MICROWIRE/PLUS interface can be programmed to generate an interrupt every eight clocks applied to the SK, thus indicating the master CPU wants to exchange some commands or data with the microcontroller. After the COP8 reads out the data from the MICROWIRE/PLUS register, it returns an acknowledge signal to the main processor, by toggling the handshake line. *Figure 3* shows a block diagram of the COP8 microcontroller linked with the main CPU. The instructions stored in the COP8 ROM first execute the protocol between the master and the COP8, then process CAN messages, and finally filter out unwanted data.

The software of the application is divided into several tasks which allow easy customization. A main loop continuously polls various flags. These are set by the microcontroller's hardware, like the system timer, the muti-sourced external interrupt/wake-up or by the interrupt handlers (e.g., of the MICROWIRE/PLUS interface or CAN interface). The MICROWIRE/PLUS interrupt indicates a main CPU communication request. The CAN interrupts are receive, transmit and error. All of them are leading to a separate interrupt vector within the COP8 memory. Upon detecting one flag to be set, the program branches to the certain subroutine. This program structure is chosen to ensure fast response times for the time-critical communication parts CAN and MICROWIRE/PLUS. A flowchart of the main routine is found in *Figure 4*, together with the CAN receive interrupt handler.



TL/DD/12850–3

FIGURE 3. COP8-Based Full-CAN Interface

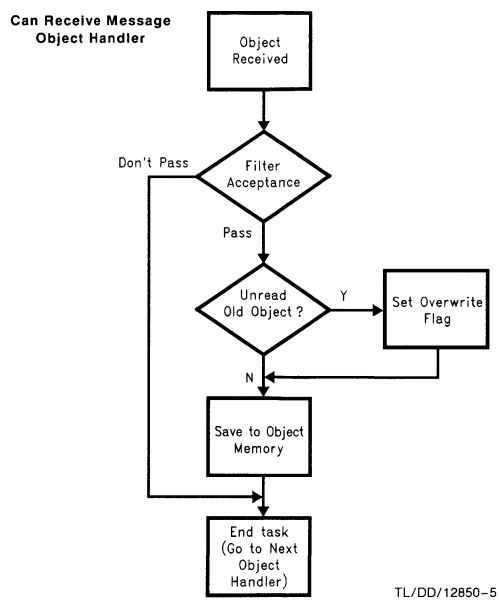


TL/DD/12850–4

FIGURE 4. Main Program and CAN Receive Interrupt Handler

The communication request flag is set as soon as the MICROWIRE/PLUS received the first byte, indicating the command for the COP8. This data was read from the μW shift register and the handshake signal set, to indicate the possibility to read or write the next data byte to the main CPU. Within the communication subroutine these data bytes are exchanged with the main processor. The system time can be generated by the idle timer's pending flag. This flag is set every 4096 t_C on the COP884BC and it can be programmed to be set every 4k, 8k, 16k or 32k t_C on the COP888EB. Secondly, the system time can be generated with a free programmable 16 bit auto-reload timer T1, for increased flexibility. Timed events, like automatic transmission of a CAN message or a software real time clock are then executed. CAN message objects are handled by a subroutine as described later. Finally, flags for optional tasks can be included and polled within the main loop in order to comprise additional features.

The CAN receive interrupt routine stores received data in receive buffers located within the RAM (*Figure 2*). For this data storage, special memory locations—base page RAM—are used as indirect addressing operations in this area and are executed faster than if used on the remaining RAM area. After a complete message object is received, and no errors occurred, a flag is set. Optionally, the system's time can be stored as well to allow verification of the creation time for a specific message in real time systems. Then the message object is filtered and stored into its final location within the message object handlers. One receive message object handler is shown in *Figure 5* and described below. CAN transmit interrupts work similarly to the receive routine on a different interrupt vector. Additions to the transmit



TL/DD/12850–5

FIGURE 5. CAN Receive Object Handler

schedule routine—which are not offered with standard Full-CAN chips—can be done as well. For example, a transmit object may be verified to be sent within a specific time or within a certain number of retries if they're likley to lose arbitration on a highly frequented bus. Another example is the automatic transmission of the system's (real) time in order to have a common time base over the network.

The CAN receive object handler is called after a CAN message was satisfactorily received. One object handler verifies the received message object with its specific acceptance filter and stores the data if the message's identifier matches. Otherwise, the next receive object handler is called until all possible receive objects are verified. Afterwards, a flag may be set to indicate the reception of a message by the main CPU. If new data for one object is received, a flag is set to indicate the data overwrite. The number of possible message objects to be stored is only limited by the processor's RAM.

SOFTWARE EXAMPLE

After theoretically outlining the implementation of the protocol processor's software, this section provides an example in COP8 assembly language to instanciate one receive object handler. The program is written in the form of a macro which allows multiple message handlers to be used within one program by simply calling the macro several times. The program uses 10 or 12 bytes of RAM for every message object and two global status bytes. One to indicate the reception of a message (rx__status) and one to indicate the overrun condition if new data is received before it was transmitted to the main controller (rx__overwrite).

The parameters to the macro are the number of the message object and a pointer to the message object memory. The program is executed as shown in *Figure 5*. After initializing some pointers (lines 004 and 005) the received message's identifier is compared with the identifier of the current object (lines 006 to 013). As the identifier now matches, it is checked if the object's data was read by the main processor. If the data was not read, the overrun flag is set (lines 014 and 015). Finally, the received data is copied into the object's memory (line 016 to 033).

This macro uses 41 bytes of ROM and takes a maximum of 19 t_C until the acceptance of one message is filtered.

CONCLUSION

This paper explained the different programming models of CAN chips. It showed how a Full-CAN controller to move and shape the information contained within the messages can be implemented at low cost. Finally, the flexibility of a microcontroller solution with customizable software compared to a fixed chip solution was outlined.

Using CAN Networking for Cost Effective DC Motor Control in Vehicle Body Electronics

National Semiconductor
Application Note 1049
Martin Embacher

BACKGROUND

DC motor control is the most distributed application in automotive body systems. As the number of DC motors in cars increases, a multiplexed architecture becomes the only viable solution, reducing cost and weight, improving reliability and control efficiency, and significantly increasing passenger convenience. This application note demonstrates in a practical example how products from National Semiconductor help minimize the cost of these applications, using CAN as the state of the art, fault tolerant networking solution.

INTRODUCTION

This application note decribes the issues associated with the implementation of DC motor control systems in automotive applications. It identifies the multiple locations of DC motors in automobiles. With reference to a basic DC motor control system structure it explains the approach National Semiconductor Corporation has taken to implement a system solution onto a single CAN microcontroller.

DC MOTORS IN AUTOMOTIVE APPLICATIONS

DC motors are used in automobiles to increase the convenience and safety of driving. These functions are distributed throughout the car in various applications. These include modules located in the door like window winders, mirror control or in the driver and passenger seat for seat positioning and functions such as trunk lock or sunroof control. All these systems have the characteristic that control is performed far away from the action. *Figure 1* shows various locations of DC-motors and their control systems in cars.

One example is a power seat where the driver wants to have the control buttons in the handrest and the motor is in the seat. Another example is the motors to control the mirror and window of the passenger door. Here again the driver needs to have the control buttons close to hand. Traditionally these systems require a large number of copper wires and a central control system to perform tasks like reading the switches and driving the motor to perform the desired action. The large number of wires used for control introduces a risk of malfunction. In a door module wires have to go through a small hole in the door and bend when the door opens and closes. If one wire breaks, the complete system may not operate any more. Also if the cabling to a motor in the power seat system breaks this could cause unwanted movement introducing a safety risk if this happens while the car is being driven.

The solution is to replace the wiring looms with a multiplexed wiring bus. This reduces the cost of wiring and improves system reliability, for example when a fault tolerant protocol, like CAN, is used for control. Moreover, multiplex wiring gives more "intelligence" to the motor helping to detect malfunctions directly. This can be done with the use of dedicated microcontrollers. This controller can directly take care of unwanted effects and can also perform a feasibility check of the command. Additionally a dedicated motor controller can react immediately when implementing safety critical functions. Take for example a window winder, which has to be switched off when something blocks the windows path, e.g. a child's head or the hand of an unconcentrating driver.

FIGURE 1. DC-Motors in Automobiles

Also in industrial applications sensors and actuators are increasingly controlled by fault tolerant multiplex bus systems producing the need for integrated applications optimized controllers.

DC Motor Control System

A basic DC motor control system is shown in *Figure 2*. The regulator reads in the DEMAND value, sets the CONTROL value and compares the actual speed FEEDBACK value.

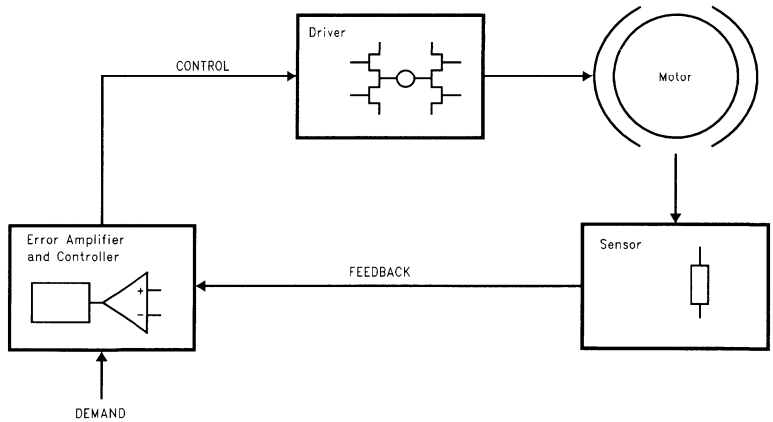
Currently there are two main implementations of a DC motor control system: an electromechanical solution where the motor is switched on and off by relays where only the speed of the motor is monitored, and secondly, a fully electrical solution with a discrete or integrated H-Bridge. In the latter the motor's speed can be adjusted much more precisely than in the former. The SENSOR block consists of either a slotted disk to scan the movement of the motor optoelectronically or of an converter measuring the current flowing through the motor.

INTEGRATING A DC MOTOR CONTROL SYSTEM USING NATIONAL'S COP884BC

National Semiconductor's COP884BC microcontroller addresses both implementations. The functional block found on this controller includes a high speed constant resolution PWM timer which can be used to control the H-Bridge with a minimum of external parts. However this PWM timer also has the option of monitoring the speed of the motor by high resolution frequency measurement if it runs in capture mode. Additionally two on-chip comparators allow sensing of the current through the motor. One of them has an input which can be switched to two pins. The integrated CAN interface addresses the need for highly reliable multiplexed data communication. *Figure 2* shows a block diagram of the implementation and the following paragraphs describe the functional blocks in more detail.

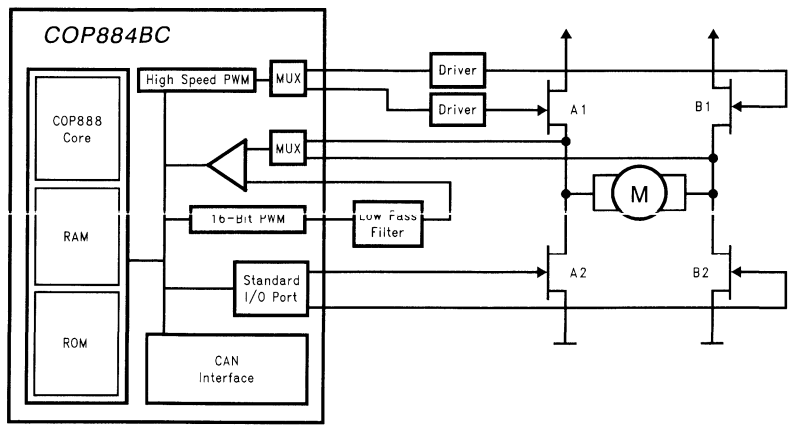
H-Bridge

The typical control means for DC motors is the H-bridge. It consists of four transistors A1, A2, B1 and B2 connected like an H with the motor in the middle. This scheme allows current to flow into the motor from either side. In *Figure 3* if



TL/DD/12852–2

FIGURE 2. Basic DC Motor Control System



TL/DD/12852–3

FIGURE 3. Motor Control with COP884BC Block Diagram

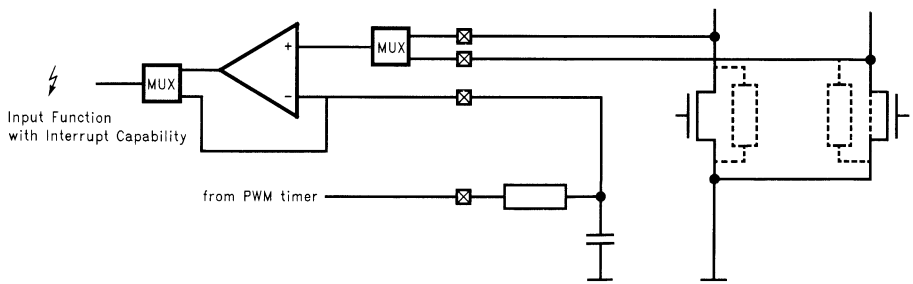
A1 and B2 conduct, current flows from left to right and vice versa if A2 and B1 are conducting. The other transistor pair is switched off. Care must be taken that both transistors of one side (A1 and B1 or A2 and B2) do not conduct at the same time, else a short circuit—called shoot-through—would result. The transistors are typically MOSFET type. To control the speed of the motor a PWM signal is applied to the gates A1 or B1. The voltage across the motor is dependent on the duty cycle of the PWM signal. If both transistors of one direction conduct, i.e. a duty cycle of 100% at the high side driver, the motor runs at full speed.

Two additional points have to be taken into consideration when operating a DC motor with a MOSFET H-bridge. Firstly, as the high side drivers typically are n-channel MOSFET devices, the voltage on the gate needs to be higher than the voltage on the drain. This can be done with a simple bootstrap circuit which charges up a capacitor during the PWM low cycle and generates a voltage of approximately Vbat*2 as soon as the MOSFET starts conducting. The higher the overall frequency of the PWM signal, the lower the required capacitor value. Secondly a motor consists of a coil and a magnetic core which resonates at the PWM frequency. The PWM signal permanently starts and stops the motor. If the PWM signal is below 20 kHz (audible range) someone next to the motor will hear the PWM induced resonance of the core. Therefore the PWM frequency should be chosen above the audible range.

National's COP884BC microcontroller offers a unique high speed constant resolution PWM timer which is capable of generating PWM frequencies up to 39 kHz completely processor independently and which covers the full PWM range from static high to static low with only one register. The PWM signal can be routed to two output pins of the microcontroller to directly connect to a bootstrap circuit for each of the two high side drivers saving external components. Both low side drivers can be directly connected to ports of the microcontroller.

Current Feedback

To measure the load of the motor and to be able to switch it off in the case that the rotor is jammed a comparator can be used with a current to voltage converter. Usually one wants to set a specific current limit which should not be exceeded to prevent motor failure. There are two solutions for voltage to current conversion: a resistor in the ground line of both low side drivers or to use the $r_{DS(ON)}$ resistance of each low side MOSFET. The latter has the advantage that no additional resistor is introduced to the system as an additional resistor would result in an additional voltage drop thus reducing the efficiency of the system. The COP884BC with its two comparators mapped to I/O ports supports both setups. Also the analog multiplexer on comparator 2 allows the measurement of two independent currents. A reference voltage, i.e. maximum voltage, is connected to the other terminal of the comparator. A simple way to generate this reference voltage is to use a PWM signal and a low pass RC-type filter. The PWM frequency is applied to the low pass filter. At the output of the filter a voltage directly proportional to the duty cycle will result. This circuit causes in the comparator output to toggle as soon as the voltage indicating the current through the motor exceeds the voltage set by the reference. *Figure 4* shows the block diagram of this comparator and the mapped I/O pins together with the PWM timer generating the reference value. The $r_{DS(ON)}$ resistances are also indicated in the figure.



TL/DD/12852–4

FIGURE 4. Comparator and PWM

Multiplex Interface

The highly reliable, state of the art CAN protocol was chosen. CAN operates in either single or dual wire configuration with minimal amount of external components (ISO low speed interface). The CAN interface implemented on the COP884BC addresses the need for a highly sophisticated—but low cost communication. The interface is fully compatible to the CAN specification 2.0 B (passive). To address the cost efficiency National reduced the number of registers down to four for each message resulting in fully automatic processing of two byte messages by the interface and the need for software interaction for longer messages. This scheme can be used as the part works as a motor controller and CAN is only used for set-up purposes. Also the acceptance filter is reduced to seven bits as fine filtering of the messages can be done by software as well. Typical bus speeds of a distributed controller are 125 kbit/s which gives 128 μs for two bit times which is sufficient for the controller to store away the data if the message is longer than two data bytes.

Glue Processor

The processor controlling the motor has to set the PWM frequency, read in the current and gets commands through the CAN interface. Additionally it may perform other tasks like doing diagnosis, reading in switches and setting status bits to the output world. For this functionality the 2 kbyte of ROM and 64 bytes of RAM are sufficient. The application optimized COP8 μC family provided by NSC offers a highly efficient code set and dedicated functional blocks for various applications. The feature family COP888 core supports a vectored interrupt scheme allowing the easy implementations of interrupt routines for the different on-chip peripherals. These include three interrupt sources for the CAN interface, one high prioritized external interrupt, one for the comparators and an additional multi-sourced external interrupt and a total of four for the various on-chip timers. To reduce the current consumption of the controller two power saving modes HALT and IDLE are implemented. The former completely freezes the processor and all on-chip peripheral blocks. However, the device will wake-up if a CAN message is received or by seven other input signals which are user programmable. IDLE mode freezes the core and all peripheral blocks except for the IDLE timer and the clock circuit alowing faster wake-up times or periodic wake-ups. All I/O ports of the chip have Schmitt trigger input and weak pull-up capability allowing the designer to reduce the external component count. Additionaly specific blocks to reduce electromagnetic emissions of the part have been implemented.

With the configurable controller methodology (CCM) and the newly installed European microcontroller design center, National Semiconductor addresses the need for system solutions and application optimized microcontrollers.

CONCLUSION

National's COP884BC, COPCAN-1, μC integrates most of the required blocks for highly sophisticated DC-motor control, allowing a designer to develop a cost effective network-controlled actuator with a few external components in a space saving 28-pin SO package. It integrates the PWM timer perfectly suited for H-bridge control and thereby removes an expensive integrated pure analog controller. Additionally COPCAN-1 shows that an application optimized CAN interface does not necesarily have to have the high cost associated with various CAN implementations.

Understanding and Eliminating EMI in Microcontroller Applications

National Semiconductor
Application Note 1050
Robin Getz
Bob Moeckel

1.0 ABSTRACT

In today's world, with increasing numbers of both fixed and mobile electronic devices, electromagnetic compatibility (EMC) is becoming a critical issue. Disastrous, if not annoying, results occur if a system, subsystem or component interferes with another through electromagnetic means. The EMC problem is first explained, and then the basic theory is presented with an explanation on how to use it to control an EMC problem during the initial design phase. The methods that some silicon manufacturers are using to control EMC and how these changes affect our systems will be examined. A total system (automobile radio) will be examined in detail to prove the effectiveness of a EMC reduced COP8™ (8-bit microcontroller). Overall design guidelines will also be given so that the designer can minimize EMI *before it becomes a problem.*

2.0 INTRODUCTION AND BACKGROUND

Electromagnetic Interference with Powered Wheelchairs

August 26, 1994

FDA is receiving inquiries about reports that electromagnetic interference (EMI) can cause some power-driven wheelchairs and scooters to move unexpectedly. The agency has investigated this matter and determined that EMI can cause unexpected movement in some power-driven wheelchairs when they are turned on. Not all brands and models of power wheelchairs and scooters have this problem. Some have greater immunity levels than others that may protect against EMI. Common sources of EMI include cellular phones, CB radios, TV and radio stations, amateur (HAM) radios and police, fire and ambulance radios.

After receiving reports of problems, FDA tested sample wheelchairs and scooters in its laboratories and obtained information from manufacturers and users about possible EMI-related incidents. As a result of its review, the agency last May asked wheelchair manufacturers to take steps to protect powered wheelchair users from the potential hazards of EMI. FDA required all firms to clearly label wheelchairs and scooters with the immunity level, or else state that the immunity level is not known. It also required them to label wheelchairs and scooters to warn users of the potential hazards of EMI. The agency also asked manufacturers to:

1. *Establish a minimum recommended immunity level of 20V per meter for all new motorized wheelchairs and scooters. This would provide a reasonable degree of protection against the more common sources of EMI.*
2. *Undertake an educational campaign to inform users and those who care for them about the risks of EMI and ways to avoid it; and*
3. *Solicit reports of possible EMI incidents and continue to monitor the full scope of the problem.*

FDA first learned of a possible problem with motorized wheelchairs from a complaint in June 1992. As a result, the agency began testing sample wheelchairs in its laboratories. Those tests, on several brands of power-driven wheelchairs and scooters, revealed that most—but not all—of those sampled were susceptible to interference at various radio frequencies. In some tests, the brakes released. In others, the wheels moved uncontrollably. Sometimes both occurred at once. The extent to which this happens in actual use is not known. In early 1993, FDA began inspecting facilities of all domestic and foreign motorized wheelchair and scooter manufacturers to gather information on the problem. The agency reviewed warranty and complaint files and looked at any manufacturing practices that could contribute to this type of problem. The inspections revealed numerous complaints about erratic, unintentional wheelchair movement, sometimes resulting in injuries. It is unclear, however, exactly what caused the chairs to move in those cases. In addition to EMI, unexpected movement can be caused by failure of an electronic component or by user error.

In May 1993, FDA sent letters to all U.S. manufacturers asking them to provide any information they had about possible problems with radio wave interference, including complaints, reports of injuries and studies on power-driven wheelchairs. In July 1993, the agency alerted consumer groups that represent wheelchair users about the possible problem and requested similar information. An estimated 10,000 motorized wheelchairs and 50,000 motorized scooters are sold annually in this country.

—FDA Report, August 1994

The control and minimization of EMC is a technology that is, out of necessity, growing rapidly. Manufacturers and regulatory agencies have made efforts to control this problem but the issue of meeting these ever tightening specifications is left to the system designer. EMC can no longer be a fix, designed in at the last moment, but must be a directed effort between the circuit designer, layout engineer, software engineer and purchaser. This paper will examine what can be done to reduce the chance of having a product fail EMC approval.

2.1 The EMC World Map

Before jumping into the midst of the EMC design methods used, it is best to gain an understanding of the problem situation and review or learn applicable electromagnetic (EM) theory. To begin, look at what I call the map of the EMC world, Table I. The EMC problem is between an emission culprit and susceptible victim which are coupled through a means, either radiation through space or conducted through wires *(Figure 1)*. We can map out the EMC problem cases with columns headed by radiation and conduction, and rows headed by emission and susceptibility, to get four cases abbreviated as RE, CE, RS, CS.

TABLE I. ElectroMagnetic Compatibility Map

	Radiation	Conduction
Emission	RE	CE
Susceptibility	RS	CS

2.2 What Designers Do Upon A Discovery of an EMC Problem

Typically, the first time system designers realize that they have a RE problem is after the prototype system has been built and evaluated. Instead of being close to market release they now find themselves applying costly and often ineffective patches and going back into redesign. The steps outlined in Table II are what a typical person does at this point. First reaction is to make the printed circuit board (PCB) trace length short or to upgrade to a higher cost PCB with a full ground plane. Although most system companies have experienced and good layout design rules for their PCBs, enforcing these rules is sometimes difficult to do as more and more components are being packed into smaller packages on a smaller board. Layout is often subcontracted and the designer may not have the necessary experience and motivation, cost reduction is the goal. Next, filters (RC, RL, or ferrite beads) are added in hopes that this may fix the problem. Also, the crystal frequency may be reduced by about 2x to run the system clock at a slower rate. Software may have to be rewritten to compensate for this new time base. Software can be redone to toggle the outputs less frequently. Shielding is added or the PCB is put into an electrically out of the way place (like hiding a monster in the basement). Having exhausted their design tricks, the designers now search other semiconductor suppliers to find a quieter part. Finally, when all the time and money runs out with EMC qualification failing, the decision is made not to market the product and everyone loses business.

It is from this examination that we can understand that EMC design issues have to be considered properly at the beginning of the design cycle, in order to reduce complex design changes which must be done at the completion of the project if EMC testing is failing.

TABLE II. List of Designer Efforts to Reduce EMI Emissions

Method	Complexity	Cost	Time
1. Revise PCB Layout	Medium	Low	High
2. Add Components (Filters)	Medium	Medium	Medium
3. Change Crystal Frequency	High	Low	High
4. Rewrite Software	High	Low	High
5. Add Shielding	Low	High	Low
6. Relocate PCB	Low	Low	Low
7. Change IC Supplier	High	Medium	Medium
8. Fail EMC Qualification—Don't Sell Product	High	High	High

3.0 DESCRIPTION OF NOISE

3.1 ElectroMagnetic Interference

EMI is a form of electrical-noise pollution. Consider the time when an electric drill or some other power tool jammed a nearby radio with buzzing or crackling noise. At times it got so bad that it prevented you from listening to the radio while the tool was in use. Or the ignition of an automobile idling outside your house caused interference to your TV picture making lines across the screen or even losing sync altogether making the picture flip. These examples are annoying but are not catastrophic.

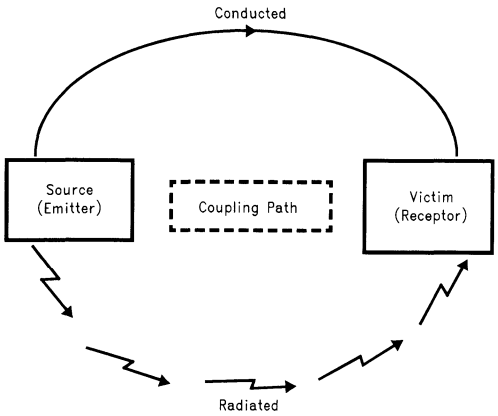
More serious, how about a sudden loss in telephone communication caused by electrical interference or noise while you are negotiating an important business deal? Now EMI can be economically damaging.

The results of EMI incidents can be even further reaching than these examples. Aircraft navigation errors resulting from EMI or interruption of air traffic controller service and may be even computer memory loss due to noise, could cause two aircraft to collide resulting in the loss of lives and property.

These were just a few instances to help identify the results of EMI in a familiar context. To help understand an EMI situation, the problem can be divided into three areas. They are the source, the victim, and the coupling path. Secondary categories involve the coupling path itself. If the source and victim are separated by space with no hard wire connection, then the coupling path may be a radiated path and we are dealing with radiated noise. If the source and victim are connected together through wires, cables, or connectors, then the coupling path may be a conducted path and we are dealing with conducted noise. It is possible for both types of noise to exist at the same time.

3.2 ElectroMagnetic Compatibility

EMI or electrical noise is of world wide concern. Governmental agencies and certain industry bodies have issued specifications with which all electrical, electromechanical, and electronic equipment must comply. These specifications and limitations are an attempt to ensure that proper EMC techniques are followed by manufacturers during the design and fabrication of their products. When these techniques are properly applied, the product can then operate and perform with other equipment in a common environment so that no degradation of performance exists due to internally or externally conducted or radiated electromagnetic emissions. This is defined as ElectroMagnetic Compatibility or EMC.



TL/DD/12857–1

FIGURE 1. EMI Situation

3.3 Inter-System EMI

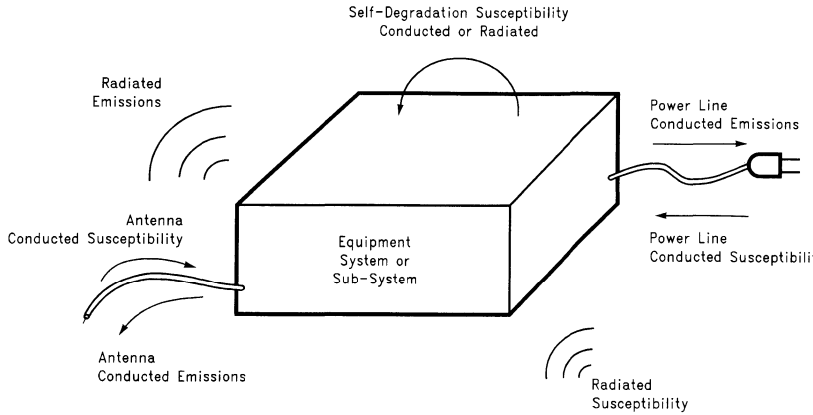
For the purpose of this paper, when the source of noise is a module, board, or system and the victim is a different and separate module, board, or system under the design or control of a different person, it will be considered an inter-system interference situation. Examples of inter-system interference situations could be a Personal Computer interfering with the operation of a TV or an anti-lock brake module in a car causing interference in the radio. This type of interference is more difficult to contain because, as mentioned earlier, the systems are generally not designed by a single person. However, design methods and control techniques used to contain the intra-system form of EMI, which are almost always under the control of a single user, will inherently help reduce the inter-system noise.

This paper will address problems and solutions in the area of intra-system noise. Intra-system interference situations occur when the sources, victims, and coupling paths are entirely within one system, module or PCB. Systems may provide emissions that are conducted out of power lines or be susceptible to emissions conducted through them. Systems may radiate emissions through space in addition to being susceptible to radiated noise. Noise conducted out antenna leads turns into radiated noise. By the same token, radiated noise picked up by the antenna is turned into conducted noise within the system. A perfect example is a PCB ground loop, which makes an excellent antenna. The system itself is capable of degrading its own performance due to its own internal generation of conducted and radiated noise and its susceptibility to it.

Some results of EMI within a system: Noise on power lines causing false triggering of logic circuits, rapidly changing signals causing "glitches" on adjacent steady state signal lines (crosstalk) causing erratic operation, multiple simultaneously switching logic outputs propagating ground bounce noise throughout system, etc.

3.4 Coupling Paths

The modes of coupling an emitter source to a receptor victim can become very complicated. Remember, each EMI situation can be classified into two categories of coupling, conducted and radiated. Coupling can also result from a combination of paths. Noise can be conducted from an emitter to a point of radiation at the source antenna, then picked up at the receptor antenna by induction, and re-conducted to the victim. A further complication that multiple coupling paths presents is that it makes it difficult to determine if eliminating a suspected path has actually done any good. If two or more paths contribute equally to the problem, eliminating only one path may provide little apparent improvement.



TL/DD/12857–2

FIGURE 2. Intra-System EMI Manifestations

3.5 Conducted Interference

In order to discuss the various ways in which EMI can couple from one system to another, it is necessary to define a few terms. There are two varieties of conducted interference which concern us. The first variety is differential-mode interference. That is an interference signal that appears between the input terminals of a circuit. The other variety of conducted interference is called common-mode interference. A common-mode interference signal appears between each input terminal and a third point, the common-mode reference. That reference may be the equipment chassis, an earth ground, or some other point.

Let's look at each type of interference individually. In *Figure 3* we show a simple circuit consisting of a signal source, V_S, and a load, R_L. In *Figure 4* we show what happens when differential-mode interference is introduced into the circuit by an outside source. As is shown, an interference voltage, V_D, appears between the two input terminals, and an interference current, I_D, flows in the circuit. The result is noise at the load. If, for instance, the load is a logic gate in a computer, and the amplitude of V_D is sufficiently high, it is possible for the gate to incorrectly change states.

Figure 5 shows what happens when a ground loop is added to our circuit. Ground loops, which are undesirable current paths through a grounded body (such as a chassis), are usually caused by poor design or by the failure of some component. In the presence of an interference source, common-mode currents, I_C, and a common-mode voltage, V_C, can develop, with the ground loop acting as the common-mode reference. The common-mode current flows on both input lines, and has the same instantaneous polarity and direction (the current and voltage are in phase), and returns through the common-mode reference. The common-mode voltage between each input and the common-mode reference is identical.

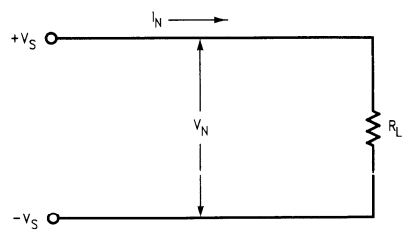
TL/DD/12857–5

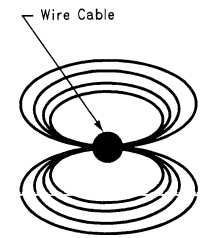
FIGURE 5. Common-Mode Interference

3.6 Radiated Interference

Radiated coupling itself can take place in one of several ways. Some of those include field-to-cable coupling, cable-to-cable coupling, and common-mode impedance coupling. Let's look at those types of coupling one at a time.

The principle behind field-to-cable coupling is the same as that behind the receiving antenna. That is, when a conductor is placed in a time-varying electromagnetic field, a current is induced in that conductor. That is shown in *Figure 6*. In this figure, we see a signal source, V_S, driving a load, R_L. Nearby there is a current carrying wire (or other conductor). Surrounding the wire is an electromagnetic field induced by the current flowing in the wire. The circuit acts like a loop antenna in the presence of this field. As such, an interference current, I_N, and an interference voltage, V_N, are induced in the circuit. The magnitude of the induced interference signal is roughly proportional to the magnitude of the incoming field, the frequency of the incoming field, the size of the loop, and the impedance of the loop.





TL/DD/12857–6

FIGURE 6. Field-to-Cable Coupling

Cable-to-cable coupling occurs when two wires or cables are run close to each other. *Figure 7* shows how cable-to-cable coupling works. *Figure 7a* shows two lengths of cable (or other conductors) that are running side-by-side. Because any two conducting bodies have capacitance between them, called stray capacitance, a time-varying signal in one wire can couple via that capacitance into the other wire. That is referred to as capacitive coupling. This stray capacitance, as shown in *Figure 7c* makes the two cables behave as if there were a coupling capacitor between them.

Another mechanism of cable-to-cable coupling is mutual inductance. Any wire carrying a time-varying current will develop a magnetic field around it. If a second conductor is placed near enough to that wire, that magnetic field will induce a similar current in the second conductor. That type of coupling is called inductive coupling. Mutual inductance, as shown in *Figure 7b,* makes the cables behave as if a poorly wound transformer were connected between them.

In cable-to-cable coupling, either or both of those mechanisms may be responsible for the existence of an interference condition. Though there is no physical connection between the two cables, the properties we have just described make it possible for the signal on one cable to be coupled to the other. These effects, when combined are known as the transmission line effect and have been studied and described thoroughly in other texts.

The basic transmission line equations are derived for distributed parameters R (series resistance), G (shunt conductance), L (series inductance), and C (shunt capacitance), all defined per unit length of line.

Either or both of the above-mentioned properties cause the cables to be electromagnetically coupled such that a time-varying signal present on one will cause a portion of that signal to appear on the other. The "efficiency" of the coupling increases with frequency and inversely with the distance between the two cables. One example of cable-to-cable coupling is telephone "crosstalk", in which several phone conversations can be overheard at once. The term crosstalk is now commonly used to describe all types of cable-to-cable coupling.

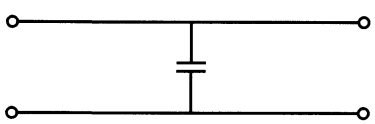
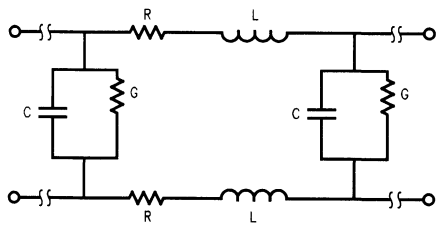
FIGURE 7b. Inductive Coupling



TL/DD/12857–8

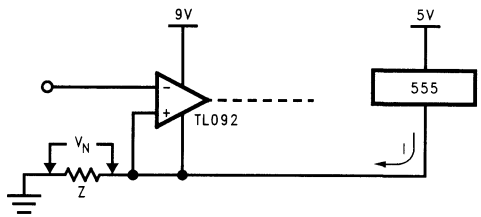
FIGURE 7c. Capacitive Coupling



TL/DD/12857–10

FIGURE 7d. Transmission Line Model

Common-mode impedance coupling occurs when two circuits share a common bus or wire. In *Figure 8* we show a circuit that is susceptible to that type of coupling. In that figure a TL092 op-amp and a 555 timer share a common return or ground. Since any conductor (including a PCB trace) is not ideal, that ground will have a non-zero impedance, Z. Because of that, the current, I, from pin 1 of the 555 will cause a noise voltage, V_N, to develop; that voltage is equal to I x Z. That noise voltage will appear in series with the input to the op-amp. If that voltage is of sufficient amplitude, a noise condition will result.



TL/DD/12857–11

FIGURE 8. Common-Mode Impedance Coupling

While not all inclusive, these coupling paths account for, perhaps, 98% of all intra-system EMI situations.

4.0 SOURCE OF NOISE

We will look at sources of EMI which involve components that may conduct or radiate electromagnetic energy. These sources, (component emitters), are different from the equipment and subsystems we have been talking about. Component emitters are sources of EMI which emanate from a single element rather than a combination of components such as was previously described. Actually, these component emitters require energy and connecting wires from other sources to function. Therefore, they are not true sources of EMI, but are EMI transducers. They convert electrical energy to electromagnetic noise.

4.1 Cables and Connectors

The three main concerns regarding the EMI role of cables are conceptualized in *Figure 9.* They act as (1) radiated emission antennae, (2) radiated susceptibility antennae, and (3) cable-to-cable or crosstalk couplers. Usually, whatever is done to harden a cable against radiated emission will also work in reverse for controlling EMI radiated susceptibility. The reason for this is usually, when differential-mode radiated emission or susceptibility is the failure mode, twisting leads and shielding cables reduces EMI. If the failure mechanism is due to common-mode currents circulating in the cable, twisting leads has essentially no effect on the rela-

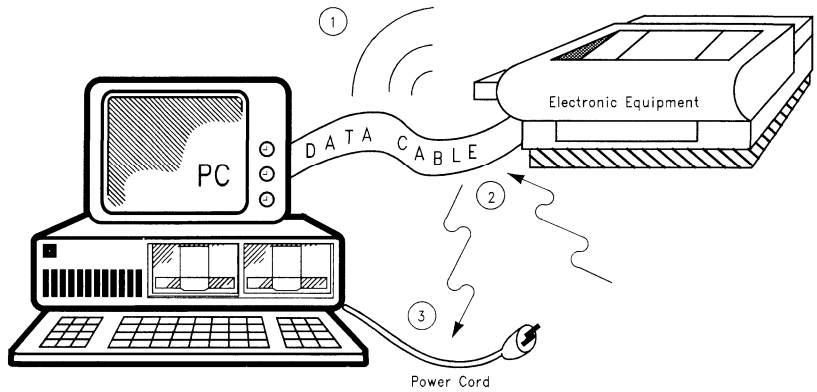
tionship between each conductor and the common-mode reference. Cable shields may help or aggravate EMI depending upon the value of the transfer impedance of the cable shield. Transfer impedance is a figure of merit of the quality of cable shield performance defined as the ratio of coupled voltage to surface current in Ω/meter. A good cable shield will have a low transfer impedance. The effectiveness of the shield also depends on whether or not the shield is terminated and, if so, how it is terminated.

Connectors usually are needed to terminate cables. When no cable shields or connector filters or absorbers are used, connectors play essentially no role in controlling EMI. The influence of connector types, however, can play a major role in the control of EMI above a few MHz. This applies especially when connectors must terminate a cable shield and/or contain lossy ferrites or filter-pins.

Connectors and cables should be viewed as a system to cost-effectively control EMI rather than to consider the role of each separately, even though each offers specific interference control opportunities.

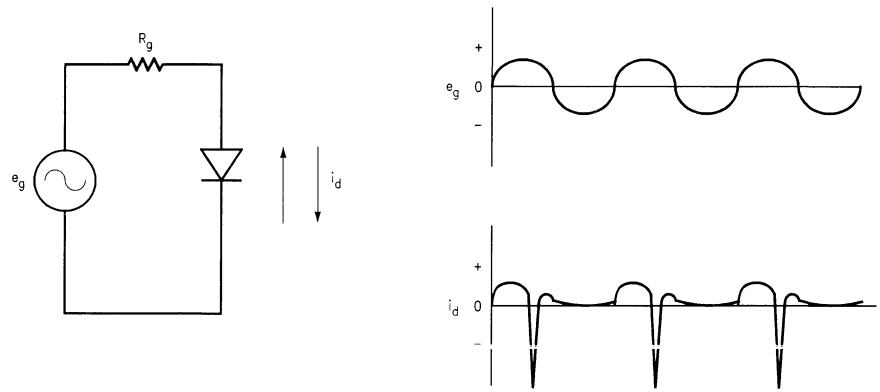
4.2 Components

Under conditions of forward bias, a semiconductor stores a certain amount of charge in the depletion region. If the diode is then reverse-biased, it conducts heavily in the reverse direction until all of the stored charge has been removed as shown in *Figure 10*. The duration, amplitude, and configuration of the recovery-time pulse (also called switching time or period) is a function of the diode characteristics and circuit parameters. These current spikes generate a broad spectrum of conducted transient emissions. Diodes with mechanical imperfections may generate noise when physically agitated. Such diodes may not cause trouble if used in a vibration-free environment.



TL/DD/12857-12

FIGURE 9. Cables and Connectors



TL/DD/12857-13

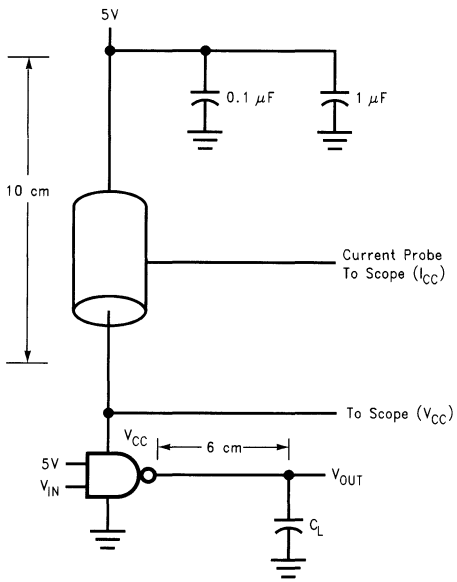
FIGURE 10. Diode Recovery Periods and Spikes

4.3 Power Supply Noise

Power-supply spiking is perhaps the most important contributor to system noise. When any element switches logic states, it generates a current spike that produces a voltage transient. If these transients become too large, they can cause logic errors because the supply voltage drop upsets internal logic, or because a supply spike on one circuit's output feeds an extraneous noise voltage into the next device's input.

With CMOS logic in its quiescent state, essentially no current flows between V_{CC} and ground. But when an internal gate or an output buffer switches state, a momentary current flows from V_{CC} to ground. The switching transient caused by an unloaded output changing state typically equals 20 mA peak. Using the circuit shown in *Figure 11,* you can measure and display these switching transients under different load conditions.

Figure 12a shows the current and voltage spikes resulting from switching a single unloaded ($C_L = 0$ in *Figure 11*) NAND gate. These current spikes, seen at the switching edges of the signal on V_{IN}, increase when the output is loaded. *Figures 12b, 12c,* and *12d* show the switching transients when the load capacitance, C_L, is 15 pF, 50 pF, and 100 pF, respectively. The large amount of ringing results from the test circuit's transmission line effects. This ringing occurs partly because the CMOS gate switches from a very high impedance to a very low one and back again. Even for medium-size loads, load capacitance current becomes a major current contributor.



TL/DD/12857–14

FIGURE 11. Test Circuit

TL/DD/12857–18

FIGURE 12d. V_{IN}, V_{CC}, I_{CC} for C_L = 100 pF

Although on standard CMOS logic internal gates generate current spikes when switching, the bulk of a spike's current comes from output circuit transitions. *Figure 13* shows the I_{CC} current for a NAND gate, as shown in the test circuit, with one input switching and the other at ground resulting in no output transitions. Note the very small power-supply glitches provoked by the input-circuit transitions.

FIGURE 13b. V_{IN}, V_{CC}, I_{CC}

4.4 High Speed CMOS Logic Switching

The magnitude of noise which can be tolerated in a system relates directly to the worst case noise immunity specified for the logic family. Noise immunity can be described as a device's ability to prevent noise on its input from being transferred to its output. It is the difference between the worst case output levels (V_{OH} and V_{OL}) of the driving circuit and the worst case input voltage requirements (V_{IH} and V_{IL}, respectively) of the receiving circuit.

Using Table III as a guide, it can be seen that for TTL (LS or ALS) devices the worst case noise immunity is typically 700 mV for the high logic level and 300 mV for the low logic level. For HCMOS devices the worst case noise immunity is typically 1.75V for high logic levels and 800 mV for low logic levels. AC high speed CMOS logic families have noise immunity of 1.75V for high logic levels and 1.25V for low logic levels. ACT CMOS logic families have noise immunity of 2.9V for high logic levels and 700 mV for low logic levels.

TABLE III. Logic Family Comparisons

Characteristic	Symbol	LS/ALS/TTL	HCMOS	AC	ACT
Input Voltage (Limits)	V_{IH} (Min)	2.0V	3.15V	3.15V	2.0V
	V_{IL} (Max)	0.8V	0.9V	1.35V	0.8V
Output Voltage (Limits)	V_{OH} (Min)	2.7V	$V_{CC}-0.1V$	$V_{CC}-0.1V$	$V_{CC}-0.1V$
	V_{OL} (Max)	0.5V	0.1V	0.1V	0.1V

To illustrate noise margin and immunity, *Figures 14b* and *14c* show the output that results when you apply several types of simulated noise to a 74HC00's input, *Figure 14a*. Typically, even 2V or more input noise produces little change in the output. The top trace shows noise present on the input logic level signal and the bottom trace shows resultant noise induced on the output logic level signal.

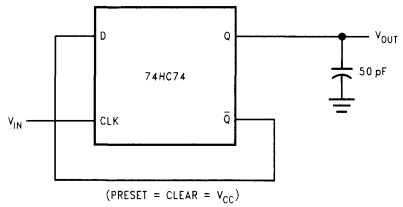
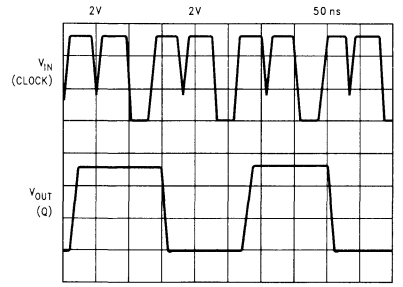
Figure 15b shows how noise affects 74HC74's clock input. Again, no logic errors occur with 2V or more of noise on the clock input.



TL/DD/12857-21

FIGURE 15a. Test Circuit



TL/DD/12857-22

FIGURE 15b. V_{IN}, V_{OUT}

When using high speed CMOS, even with its greater noise immunity, crosstalk, induced supply noise and noise transients become factors. Higher speeds allow the device to respond more quickly to externally induced noise transients and accentuate the parasitic interconnection inductances and capacitances that increase self-induced noise and crosstalk.

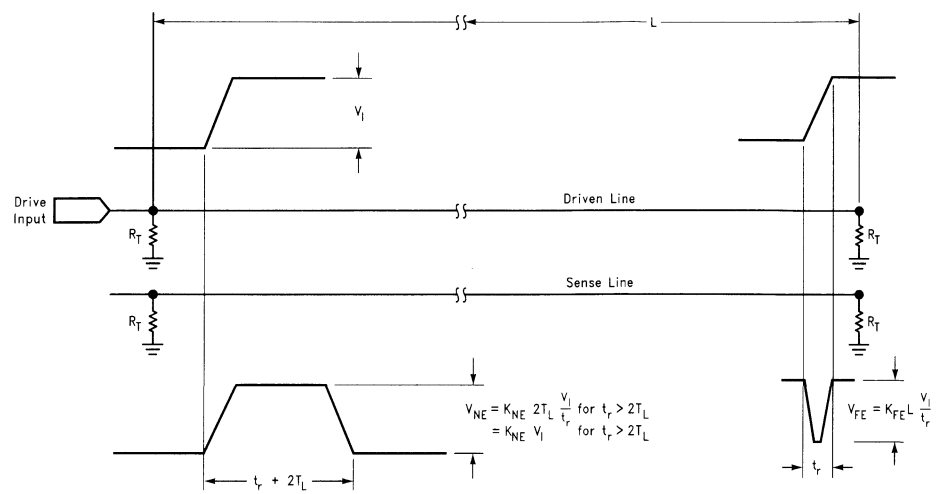
4.5 Signal Crosstalk

The problem of crosstalk, and how to deal with it, is becoming more important as system performance and board densities increase. Our discussion on cable-to-cable coupling described crosstalk as appearing due to the distributed capacitive coupling and the distributed inductive coupling between two signal lines. When crosstalk is measured on an undriven sense line next to a driven line (both terminated at their characteristic impedances), the near end crosstalk and the far end crosstalk have quite distinct features, as shown in *Figure 16*. It should be noted that the near end component reduces to zero at the far end and vice versa. At any point in between, the crosstalk is a fractional sum of the near and far end crosstalk waveforms as shown in the figure. It also can be noted that the far end crosstalk can have either polarity whereas the near end crosstalk always has the same polarity as the signal causing it.

The amplitude of the noise generated on the undriven sense line is directly related to the edge rates of the signal on the driven line. The amplitude is also directly related to the proximity of the two lines. This is factored into the coupling constants K_{NE} and K_{FE} by terms that include the distributed capacitance per unit length, the distributed inductance per unit length, and the length of the line. The lead-to-lead capacitance and mutual inductance thus created causes "noise" voltages to appear when adjacent signal paths switch.

Several useful observations that apply to a general case can then be made:

- The crosstalk always scales with the signal amplitude V_I.
- Absolute crosstalk amplitude is proportional to slew rate V_I/t_r not just $1/t_r$.
- Far end crosstalk width is always t_r.
- For $t_r << 2\ T_L$, where t_r is the transition time of the signal on the driven line and T_L is the propagation or bus delay down the line, the near end crosstalk amplitude, V_{NE}, expressed as a fraction of signal amplitude, V_I, is K_{NE} which is a function of physical layout only.
- The high the value of "t_r" (slower transition times) the lower the percentage of crosstalk (relative to signal amplitude).



TL/DD/12857-26

FIGURE 16. Crosstalk

Although all circuit conductors have transmission line properties, these characteristics become significant when the edge rates of the drivers are equal to or less than about three times the propagation delay of the line. Significant transmission line properties may be exhibited, for example, where devices having edge rates of 3 ns (or less) are used to drive traces of 8 inches or greater, assuming propagation delays of 1.7 ns/ft for an unloaded printed circuit trace.

4.6 Signal Interconnects

Of the many properties of transmission lines, two are of major interest to the system designer: Z_{OE}, the effective equivalent impedance of the line, and t_{pde}, the effective propagation delay down the line. It should be noted that the intrinsic values of line impedance and propagation delay, Z_O and t_{pd}, are geometry-dependent. Once the intrinsic values are known, the effects of gate loading can be calculated. The loaded values for Z_{OE} and t_{pde} can be calculated with:

$$Z_{OE} = \frac{Z_o}{\sqrt{1 + C_t/C_l}}$$

$$t_{pde} = t_{pd}\sqrt{1 + C_t/C_l}$$

where C_i = intrinsic line capacitance

C_t = additional capacitance due to gate loading.

These formulas indicate that the loading of lines decreases the effective impedance of the line and increases the propagation delay. As was mentioned earlier, lines that have a propagation delay greater than one third the rise time of the signal driver should be evaluated for transmission line effects. When performing transmission line analysis on a bus, only the longest, most heavily loaded and the shortest, least loaded lines need to be analyzed. All lines in a bus should be terminated equally; if one line requires termination, all lines in the bus should be terminated. This will ensure similar signal quality on all of the lines.

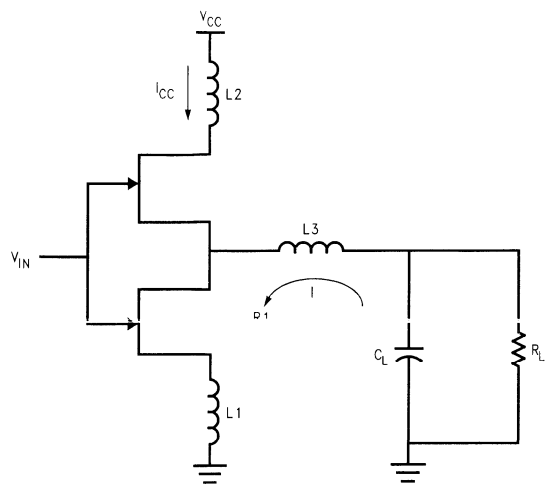
4.7 Ground Bounce

Ground bounce occurs as a result of the intrinsic characteristics of the leadframes and bond wires of the packages used to house CMOS devices. As edge rates and drive capability increase in advanced logic families, the effects of these intrinsic electrical characteristics become more pronounced. One of these parasitic electrical characteristics is the inductance found in all leadframe materials.

Figure 17 shows a simple circuit model for a CMOS device in a leadframe driving a standard test load. The inductor L1 represents the parasitic inductance in the ground lead of the package; inductor L2 represents the parasitic inductance in the power lead of the package; inductor L3 represents the parasitic inductance in the output lead of the package; the resistor R1 represents the output impedance of the device output, and the capacitor and resistor C_L and R_L represent the standard test load on the output of the device.

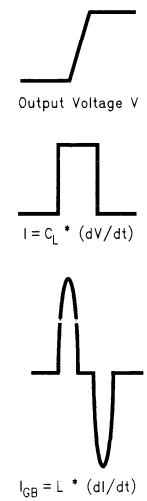
The three waveforms shown represent how ground bounce is generated. The top waveform shows the voltage (V) across the load as it is switched from a logic HIGH to a logic LOW. The output slew rate is dependent upon the characteristics of the output transistor, and the inductors L1 and L3, and C_L, the load capacitance. In order to change the output from a HIGH to a LOW, current must flow to discharge the load capacitance. The second waveform shows the current that is generated as the capacitor discharges [$I = -C_L{*}(dV/dt)$]. This current, as it changes, causes a voltage to be generated across the inductances in the circuit. The formula for the voltage across an inductor is $V = L(dI/dt)$. The third waveform shows the voltage that is induced across the inductance in the ground lead due to the changing currents [$V_{GB} = L1{*}(dI/dt)$]. This induced voltage creates what is known as ground bounce.

Because the inductor is between the external system ground and the internal device ground, the induced voltage causes the internal ground to be at a different potential than the external ground. This shift in potential causes the device inputs and outputs to behave differently than expected because they are referenced to the internal device ground, while the devices which are either driving into the inputs or being driven by the outputs are referenced to the their own device ground. External to the device, ground bounce causes input thresholds to shift and output levels to change.



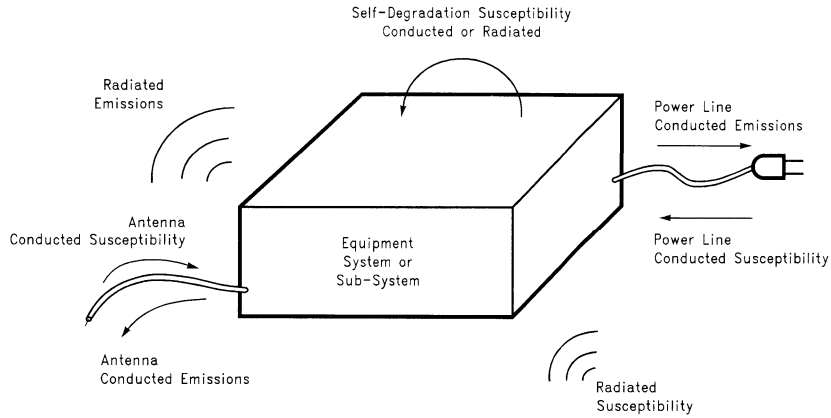
TL/DD/12857-27

FIGURE 17a. Test Circuit for Ground Bounce



TL/DD/12857-28

FIGURE 17b. V_{IN}, V_{CC}, I_{CC}



TL/DD/12857–29

FIGURE 18. Intra-System EMI Manifestations

Although this discussion is limited to ground bounce generated during HIGH-to-LOW transitions, it should be noted that the ground bounce is also generated during LOW-to-HIGH transitions. This ground bounce though, has a much smaller amplitude and therefore does not present the same concern.

There are many factors which affect the amplitude of the ground bounce. Included are:

- Number of outputs switching simultaneously: more outputs results in more ground bounce.
- Type of output load: capacitive loads generate two to three times more ground bounce than typical system traces. Increasing the capacitive load to approximately 60 pF–70 pF, increases ground bounce. Beyond 70 pF, ground bounce drops off due to the filtering effect of the load itself. Moving the load away from the output also reduces the ground bounce.
- Location of the output pin: outputs closer to the ground pin exhibit less ground bounce than those further away due to effectively lower L1 and L3.
- Voltage: lowering V_{CC} reduces ground bounce.

Ground bounce produces several symptoms:

- Altered device states.
- Propagation delay degradation.
- Undershoot on active outputs. The worst-case undershoot will be approximately equal to the worst-case quiet output noise.

5.0 NOISE SUPPRESSION TECHNIQUES

EMI control techniques involve both hardware implementations/methods and procedures. They may also be divided into intra-system and inter-system EMI control. Our major concern in this paper is intra-system EMI control, however, an overview of each may be appropriate at this time.

Figure 18 illustrates the basic elements of concern in an intra-system EMI problem. The test specimen may be a single box, an equipment, subsystem or system (an ensemble of boxes with interconnecting cables). From a strictly near-sighted or selfish point-of-view, the only EMI concern would appear to be degradation of performance due to self jamming such as suggested at the top of the figure. While this might be the primary emphasis, the potential problems associated with either (1) susceptibility to outside conducted and/or radiated emissions or (2) tendency to pollute the outside world from its own undesired emissions, come under the primary classification of intra-system EMI. Corresponding EMI-control techniques, however, address themselves to both self-jamming and emission/susceptibility in accordance with applicable EMI specifications. The techniques that will be discussed include filtering, shielding, wiring and grounding.

Inter-system EMI distinguishes itself by interference between two or more discrete and separate systems or platforms which are frequently under independent user control. Culprit emissions and/or susceptibility situations are divided into two classes: (1) antenna entry/exit and (2) back-door entry/exit. More than 95% of inter-system EMI problems involve the antenna entry/exit route of EMI. We can group inter-system EMI-control techniques by four fundamental categories: frequency management, time management, location management and direction management.

The first step in determining a solution is to identify the problem as either inter-system or intra-system EMI. Generally, if the specimen has an antenna and the problem develops from what exits or enters the antenna from another specimen or ambient, then the problem is identified as inter-system EMI. Otherwise, it is intra-system EMI which we will discuss now.

5.1 Intra-System EMI Control Techniques

5.1.1 Shielding

Shielding is used to reduce the amount of electromagnetic radiation reaching a sensitive victim circuit. Shields are made of metal and work on the principle that electromagnetic fields are reflected and/or attenuated by a metal surface. Different types of shielding are needed for different types of fields. Thus, the type of metal used in the shield and the shield's construction must be considered carefully if the shield is to function properly. The ideal shield has no holes or voids and, in order to accommodate cooling vents, buttons, lamps and access panels, special meshes and "EMI-hardened" components are needed.

TABLE IV. Effective Shielding for Different Materials

Shielding Material	Surface Resistance (Ω/square)	Shielding Effectiveness dB		
		At 10 MHz	At 100 MHz	At 1 GHz
Arc-Sprayed Zinc	0.002	106	92	98
Silver Acrylic Paint	0.004	67	93	97
Silver Deposition	0.05	57	82	89
Silver Epoxy Paint	0.1	59	81	87
Nickel Composite	3.0	35	47	57
Carbon Composite	10.0	27	35	41
Wire Screen (0.64 mm Grid)	N.A.	86	66	48

Effectiveness of shielding materials with 25 μm thickness and for frequencies for which the largest dimension of the shielding plate is less than a quarter of a wavelength.

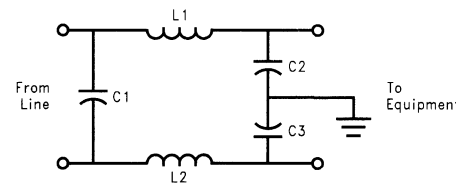
Once a printed-circuit board design has been optimized for minimal EMI, residual interference can be further reduced if the board is placed in a shielded enclosure. A box's shielding effectiveness depends on three main factors: its skin, the control of radiation leakage through the box's apertures or open areas (like cooling holes) and the use of filters or shields at interconnection points depending on shield grounding.

A box skin is typically fabricated from sheet metal or metallized plastic. Normally sheet metal skin that is 1 mm thick is more than adequate; it may have a shielding effectiveness of more than 100 dB throughout the high-frequency spectrum from 1 MHz to 20 GHz. Conductive coatings on plastic boxes are another matter. Table IV shows that at 10 MHz the shielding effectiveness can be as low as 27 dB if a carbon composite (cheap) is used, or it can run as high as 106 dB for zinc sprayed on plastic by an electric arc process (expensive). Plastic filled materials or composites having either conductive powder, flakes, or filament are also used in box shielding; they have an effectiveness similar to that of metallized plastics.

In many cases shielding effectiveness of at least 40 dB is required of plastic housings for microcontroller-based equipment to reduce printed-circuit board radiation to a level that meets FCC regulations in the United States or those of the VDE in Europe. Such skin shielding is easy to achieve. The problem is aperture leakage. The larger the aperture, the greater its radiation leakage because the shield's natural attenuation has been reduced. On the other hand, multiple small holes matching the same area as the single large aperture can attain the same amount of cooling with little or no loss of attenuation.

5.1.2 Filtering

Filters are used to eliminate conducted interference on cables and wires, and can be installed at either the source or the victim. *Figure 19* shows an AC power-line filter. The values of the components are not critical; as a guide, the capacitors can be between 0.01 and 0.001 μF, and the inductors are nominally 6.3 μH. Capacitor C1 is designed to shunt any high-frequency differential-mode currents before they can enter the equipment to be protected. Capacitors C2 and C3 are included to shunt any common-mode currents to ground. The inductors, L1 and L2, are called common-mode chokes, and are placed in the circuit to impede any common-mode currents.



TL/DD/12857–30

FIGURE 19. Filtering

5.1.3 Wiring

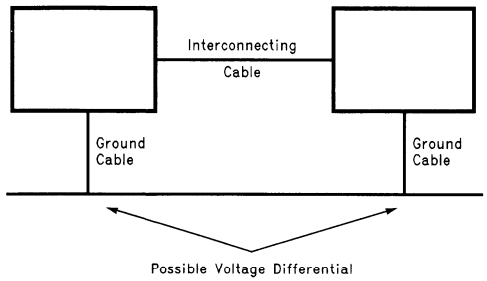
Now that the equipment in each box can be successfully designed to combat EMI emission and susceptibility separately, the boxes may be connected together to form a system. Here the input and output cables and, to a lesser extent, the power cable form an "antenna farm" that greatly threatens the overall electromagnetic compatibility of the system. Most field remedies for EMI problems focus on the coupling paths created by the wiring that interconnects systems. By this time most changes to the individual equipment circuits are out of the question.

Let us address five coupling paths that are encountered in typical systems comprised of two or more pieces of equipment connected by cables. These should adequately cover most EMI susceptibility problems. They are:

- common ground impedance coupling—a conducting path in which a common impedance is shared between an undesired emission source and the receptor.
- common-mode, radiated field-to-cable coupling—electromagnetic fields penetrate a loop formed by two pieces of equipment, a cable connecting them, and a ground plane.
- differential-mode, radiated field-to-cable coupling—the electromagnetic fields penetrate a loop formed by two pieces of equipment and an interconnecting transmission line or cable.
- crosstalk coupling—signals in one transmission line or cable are capacitively or inductively coupled into another transmission line.
- conductive path—through power lines feeding the equipment.

The first coupling path is formed when two pieces of equipment are connected to the same ground conductor at different points, an arrangement that normally produces a volt-

age difference between the two points. If possible, connecting both pieces of equipment to a single-point ground eliminates this voltage. Another remedy is to increase the high frequency impedance along a loop that includes the path between the ground connections of the two boxes. Examples include the isolation of printed-circuit boards from their cabinet or case, the use of a shielded isolation transformer in the signal path, or the insertion of an inductor between one or both boxes and the ground conductor. The use of balanced circuits, differential line drivers and receivers, and absorbing ferrite beads and rods on the interconnecting cable can further reduce currents produced by this undesirable coupling path.



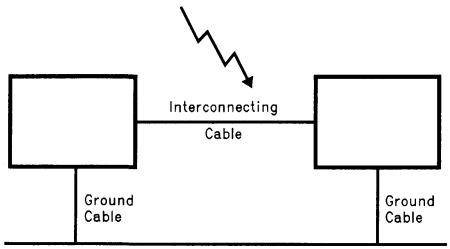
TL/DD/12857–31

FIGURE 20. Common Ground Impedance Coupling

A balanced circuit is configured so its two output signal leads are electrically symmetrical with respect to ground, as the signal increases on one output, the signal on the other decreases. Differential line drivers produce a signal that is electrically symmetrical with respect to ground from a single-ended circuit in which only one lead is changing with respect to ground. Ferrite beads, threaded over electrical conductors, substantially attenuate electromagnetic interference by turning radio-frequency energy into heat, which is dissipated in them.

In the second coupling path, a radiated electromagnetic field is converted into a common-mode voltage in the ground plane loop containing the interconnect cable and both boxes. This voltage may be reduced if the loop area is trimmed.

Ferrite beads and ferrite filtered connectors applied to the interconnecting cable can help reduce common mode currents.



TL/DD/12857–32

FIGURE 21. Common-Mode, Radiated Field-to-Cable Coupling

The third coupling path produces a differential-mode voltage that appears across the input terminals of the EMI receptor. One way of controlling this is to cancel or block the pickup of differential-mode radiation. In a balanced transmission line, this is done by use of twisted-wire pairs and a shielded cable.

For crosstalk, the fourth coupling path, the reduction of capacitive coupling, can be achieved by the implementation of at least one of these steps:

- Reducing the spacing between wire pairs in either or both of the transmission lines.
- Increasing the separation between the two transmission lines.
- Reducing the frequency of operation of the source, if possible.
- Adding a cable shield over either or both transmission lines.
- Twisting the source's or receptor's wire pairs.
- Twisting both wire pairs in opposite directions.

The fifth coupling path conductively produces both common-mode and differential-mode noise pollution on the power mains. Among several remedies that can suppress the EMI there are filters and isolation transformers.

There are only about 50 common practical remedies that can be used in most EMI situations. Of these, about 10 suffice in 80 percent of the situations. Most engineers are aware of at least some of these remedies—for example, twisting wires to reduce radiation pickup.

In order to attack the EMI problem, one can make use of the information contained in Tables V and VI. First, decide what coupling path has the worst EMI interference problem. From the 11 most common coupling paths listed at the top of the table, find the problem coupling path. Using the numbers found in that table entry, locate the recommended remedy or remedies from the 12 common EMI fixes identified at the bottom of the table. This procedure should be repeated until all significant coupling paths have been properly controlled and the design goal has been met.

TABLE V. Electromagnetic Interference Coupling Paths

Problem	Solution (See Table VI)
Radiated Field to Interconnecting Cable (Common-Mode)	2, 7, 8, 9, 11
Radiated Field to Interconnecting Cable (Differential-Mode)	2, 5, 6
Interconnecting Cable to Radiated Field (Common-Mode)	1, 3, 9, 11

5.2 Inter-System EMI-Control Techniques

There are many EMI controls that may be carried out to enhance the chances of inter-system EMC. They can be grouped into four categories which we will discuss briefly. The following discussion is not intended to be complete but merely provide an overview of some EMI control techniques available to the inter-system designer and user.

5.2.1 Frequency Management

Frequency management suggests both transmitter emission control and improvement of receptors against spurious responses. The object is to design and operationally maintain transmitters so that they occupy the least frequency spectrum possible in order to help control electromagnetic pollution. For example, this implies that long pulse rise and fall times should be used. Quite often one of the most convenient, economic and rapid solutions to an EMI problem in the field, is to change frequency of either the victim receiver or the culprit source.

5.2.2 Time Management

In those applications where information is passed between systems, a possible time management technique could be utilized where the amount of information transferred is kept to a minimum. This should reduce the amount of time that the receptor is susceptible to any EMI. In communication protocols, for example, essential data could be transmitted in short bursts or control information could be encoded into fewer bits.

5.2.3 Location Management

Location management refers to EMI control by the selection of location of the potential victim receptor with respect to all other emitters in the environment. In this regard, separation distance between transmitters and receivers is one of the most significant forms of control since interfering source emissions are reduced greatly with the distance between them. The relative position of potentially interfering transmitters to the victim receiver are also significant. If the emitting source and victim receiver are shielded by obstacles, the degree of interference would be substantially reduced.

5.2.4 Direction Management

Direction management refers to the technique of EMI control by gainfully using the direction and attitude of arrival of electromagnetic signals with respect to the potential victim's receiving antennae.

6.0 SILICON CHANGES

If we examine the modes of EMI emissions and the methods of suppression that were described, on standard CMOS silicon the techniques are exactly the same for what occurs on a PCB. What silicon design engineers at National Semiconductor's Embedded Technologies Division noticed, was that a majority of the EMI emitted from a controller or processor is caused by the transient I_{CC} current flowing in the loop formed from the bypass capacitor to the V_{CC} pin and out of the GND pin. When this current was measured by inserting a 1Ω resistor in this path, a 40 mA (10 ns) current spike was revealed at every clock edge (repetition rate = 2x clock frequency). This occurred even when outputs were toggling or tristated, and instructions that were being executed had very little impact on the magnitude or duration of the spike.

6.1 Chip Problems

Let's note the four items that produce higher amplitude and frequency fundamental and harmonics: large amplitude change, fast rise time or fall time, high repetition rate and finally large pulse width (a 50% duty cycle). Table VII lists these.

TABLE VII. IC Chip Problems

1. Large Amplitude Change
2. Fast Rise or Fall Time
3. High Repetition Rate
4. Large Pulse Width (i.e. 50% Duty Cycle).

As a rule, the waveforms di/dt (rate of change of current) and dv/dt (rate of change of voltage) must be kept to a minimum. If a silicon design engineer could shape both current and voltage waveforms around the device, these problems would be solved. If we look at the current and voltage problems separately, we can solve them both and decrease radiated emissions by more than 20 dB.

But, what about the antennae responsible for radiation? This is where packaging technology comes into the picture. The loop size of a typical system is approximately greater

than 90% PCB trace dimensions plus IC package dimensions and less than 10% IC chip dimensions, which both factor into the antenna gain. Therefore the IC package design should obey several rules, see Table VIII. First a ground pin (current return) adjacent to each power pin will minimize the loop sizes and simplify layout of decoupling circuits. Also an output pin which sources or sinks a large and frequent di/dt (for example crystal or clock pins) should also be adjacent to the power/ground pin pair to keep its current loops small. It helps to have small package dimensions. A last point is that sharing of a common power/ground should be limited to prevent their voltage from bouncing due to the total Ldi/dt + iR. This bouncing is conducted to inputs sharing the common power/ground which in several cases are susceptible since their V_{IH} and V_{IL} trip points are referenced to it. The bouncing is conducted through non-tristated outputs sharing this common power/ground and is passed on outside the IC as additional conducted and radiated emissions from bouncing V_{OH} or V_{OL} levels.

TABLE VIII. Package and PCB Traces form Loop or Whip Antennae which Radiate

1. Ground pin (current return) not adjacent to power pin). Pair should be together.
2. Power/Ground pair not adjacent to output pin (especially crystal of clock pins).
3. Too much sharing of common power/ground having voltage bounce due to its total Ldi/dt + iR. a. Conducted emissions to susceptible I/O b. Radiated emissions from susceptible I/O.
4. Large package dimensions.

6.2 Silicon Design Changes

National's design goal was to reshape the IC pin current waveforms from their original values as follows: I_{CC} pulses to 3X rise time, 0.2X amplitude and 5X width; I_{OL} and I_{OH} pulses to 10X rise time. A second goal is to provide separate power and ground bus systems on-chip for each of the following groups: Chip digital logic, Chip I/O buffers, and if present a chip A/D converter (or other analog intensive sections). This is an extension of proper IC packaging pinout covered earlier to prevent conducted emissions to susceptible circuitry.

Inspection of these goals leads us to divide the chip into separate areas which we named the nucleus, the perimeter and the A/D. Also the partitioning of the nucleus (containing the digital logic functions) and the perimeter (containing digital I/O, oscillator and comparator functions) allows use of an on-chip device to choke the nucleus' I_{CC} current, thereby wave shaping the I_{CC}. The I_{CC} choke, however, causes the nucleus V_{CC} voltage to dip by 0.5V to 1V at each clock edge. These V_{CC} voltage swings will be confined to within the chip's nucleus where the circuitry (digital logic) is tolerant and no significant radiation antennae exist.

On-chip level shifting circuitry is inserted as interface between the nucleus and the perimeter. It permits the nucleus to operate at a lower V_{CC} than the perimeter. This permits the nucleus V_{CC} to come through the on-chip I_{CC} choke emerging as a bouncing V_{CC}.

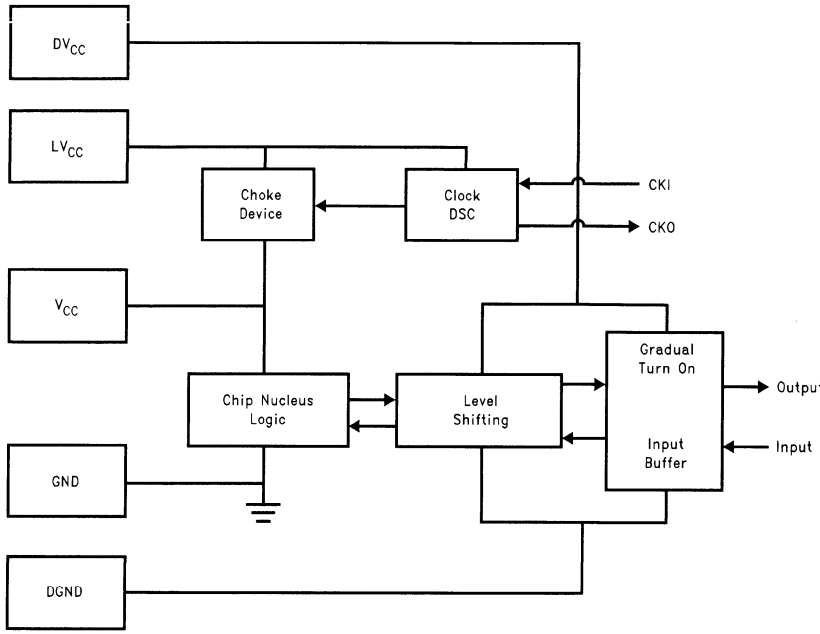
In general, outputs toggle much less frequently than the clock. This rate is limited by software execution rates. However, for the case of a clock or address/data bus outputs this may not be the case. Looking at time domain EMI instead of frequency domain EMI (which may have some time averaging) may motivate one to take action and reduce EMI from the chip's output drivers. CMOS output drivers turn on fast, in about 1 ns. This causes 2 problems. The first is called "shoot through" current which flows from DV_{CC} to DGND when both the pull up and the pull down drivers are on and the output load is small. The second is due to output current magnitude increasing to maximum in about 1 ns when the output changes state. Both problems are solved by using fast turn off, gradual turn on device drivers.

Figure 22 illustrates, in block diagram form, how the chip is partitioned for EMC. Note that the level shifter block is multichannel, and most channels need dedicated level shifting devices in one direction only as shown. The power/ground pads named DV_{CC} (Driver V_{CC}), LV_{CC} (Logic V_{CC}), V_{CC} (a global V_{CC} to most of the chip), GND (a global GND to most of the chip) and DGND (driver ground) are all available. To minimize package pin count, DV_{CC} and LV_{CC} can be bonded to the same pin, GND and DGND can be bonded to the same pin, and the V_{CC} pad is not bonded. A higher pin count package is used to bring out each pad to a separate pin to allow study of the several packaging options. The V_{CC} pad is not bonded when utilizing the on-chip I_{CC} choke to prevent RE (radiated emissions) from V_{CC} bounce.

Three operating modes can be evaluated with GND and DGND pads always connected together to 0V. The first mode applies 5V to DV_{CC}, LV_{CC} and V_{CC} to check the RE improvements due to gradual turn on outputs alone. The second mode applies 5V to DV_{CC} and LV_{CC} where V_{CC} floats as a test point. This checks the RE improvements due to gradual turn on and I_{CC} choking. The third mode applies 5V to DV_{CC} and 3V to V_{CC} and LV_{CC} to check the RE improvement in this mode which actually requires a V_{CC} additional package pin.

TABLE IX. Results of Various Pinout Configurations

Chip Pads	Configuration A	Configuration B	Configuration C
DV_{CC}	5V	5V	5V
LV_{CC}	5V	5V	3V
V_{CC}	5V	Test Point	3V
GND	0	0	0
DGND	0	0	0
EMI	Baseline	−20 dB	−6 dB
Clock Speed	10 MHz	>5 MHz	4 MHz

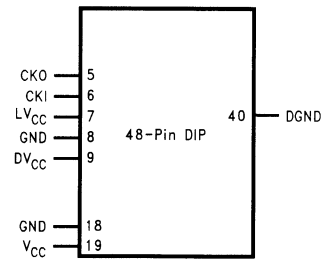


TL/DD/12857–33

FIGURE 22. Block Diagram of EMC Circuitry

6.3 Packaging Changes

Recalling our IC packaging rules for EMC, and upon reviewing the packaging pitfalls (Table VIII), one can now appreciate an IC package build sheet *(Figure 23)* that illustrates how to bond out and pin out the five power/ground pads on the die. As advised, power pins having current return ground pins adjacent are LV_{CC} and GND, V_{CC} and GND; but DV_{CC} and DGND are not adjacent. This is permitted since DV_{CC} current is returned via output high pins (not DGND), also DGND current is sourced via output low pins. Therefore placing DV_{CC} adjacent to DGND does not contribute to small area current loops. Note that CKI, CKO, LV_{CC}, and GND are all adjacent pins for the sake of clustering the oscillator external tank circuit into the smallest current loop area. Since the oscillator is supplied through LV_{CC} and GND, added benefit of running both oscillator and nucleus at 3V is possible if one were to choose defeating the on-chip choke by shorting LV_{CC} to V_{CC} in the choke block.



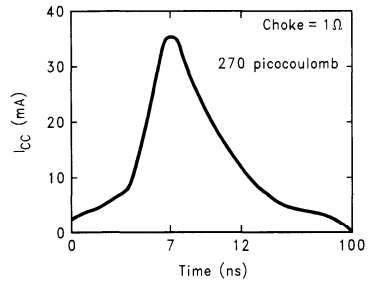
TL/DD/12857–34

FIGURE 23. EMC Pinout

6.4 Results of IC Circuit Changes

Simulations give an idea of the expected improvement from addition of the I_{CC} choke on the silicon. *Figure 24a* shows actual I_{CC} as measured by a series resistance during switching transients. Simulation of an equivalent circuit with the addition of the choke predicts a decrease of I_{CC} from about 37 mA to less than 4 mA.

This decrease of 10x would imply a 20 dB improvement in gross emissions.



TL/DD/12857-35

FIGURE 24a. Original I_{CC}

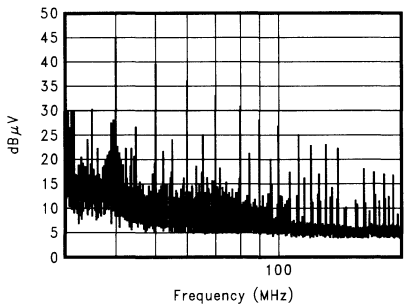
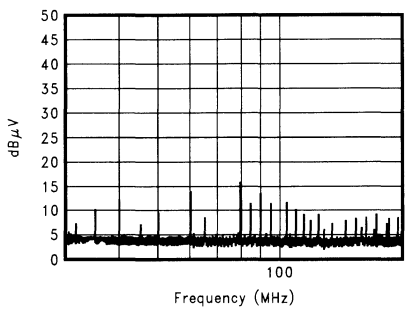
FIGURE 24b. I_{CC} with Improvements



TL/DD/12857-37

FIGURE 25a. Emissions without V_{CC} Choke



TL/DD/12857-38

FIGURE 25b. Emissions with Addition of V_{CC} Choke

Test results in *Figure 26* show emissions of 45 dBμV reduced to less than 20 dBμV on the same device. Unchoked tests were performed using the bonding options previously discussed.

Figure 25 gives the predicted performance degradation from implementing gradual turn-on outputs. High to low transition time propagation delays are doubled and low to high transitions are slowed by about 50%. Remember, though, that propagation delays for an embedded microcontroller are usually of minimal concern since control is based on levels or edges of individual signals or on timing which is under software control. Software control is slow enough that the change in hardware timing is probably negligible.

An indication of the type of emission reduction resulting from the implementation of gradual turn-on can be seen if you look at the baselines of the plots of *Figure 26*. Changes of the outputs occur at low frequency with large amplitude, fast rise time current spikes. The low frequency of the signal keeps the harmonic close together and makes the emissions appear broadband. The fast rise time maintains a higher level of emissions to a higher frequency.

7.0 SYSTEM PERFORMANCE USING EMI REDUCED PARTS

We have discussed in previous sections that we can reduce EMI by proper board design and by the selection of low EMI devices. We will now investigate whether EMI reduced parts are worth it. The goal of this testing is to determine the relative electromagnetic emissions from various production options of the COP8 microcontroller. Since most people use OTPs to qualify their end product for emissions approval, both OTPs and ROMmed devices will be tested. The options chosen were:

1. COP8788EGMH (OTP) part used for development and Prototype approval
2. COP888EK (masked ROM) part used for final production (EMI reduced)
3. COP8788GG (OTP) part used for development and Prototype approval
4. COP888GG (masked ROM) part used for final production (EMI reduced)

7.1 Test Procedure

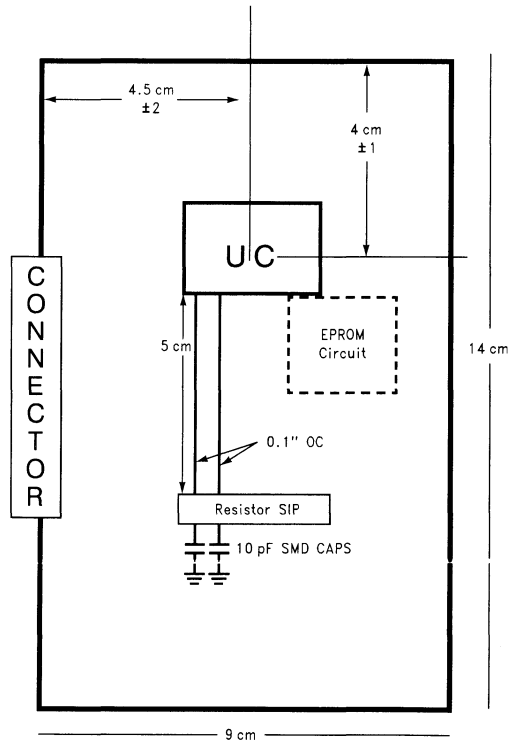
These tests were performed in two ways:

1. Two DIP parts, a COP888EK and a COP888EGMH OTP device, were programmed for use as the main processor in an automotive radio and the relative performance of the radio was measured for each device. The measure of performance chosen was Usable Sensitivity. This is defined as the minimum input required at the antenna in order to achieve a predetermined signal to noise ratio (SNR) at the speaker. In this case the input was chosen to be a 22 kHz deviation of a frequency modulated signal within the US commercial FM radio broadcast band. The signal to noise criterion used was 30 dB.
2. Two other devices, a COP888GG and a COP87M88GG OTP, were placed in a common two sided PCB in a TEM cell and were programmed to run a standard EMI test program included in National's first silicon engineering code. Load capacitors of 10 pF and 4.7 kΩ pull-up resistors used on the eight pins of Port L. The port was programmed to count in a binary manner with the least significant bit changing state every 100 μs. (*Figure 27* illustrates the board layout.) Four AA batteries were attached to the board and the supply voltage was regulated with a Zener diode.

   Emissions were measured with the TEM cell on a Tektronix Model 2754P Spectrum Analyzer over the range of DC to 750 MHz.

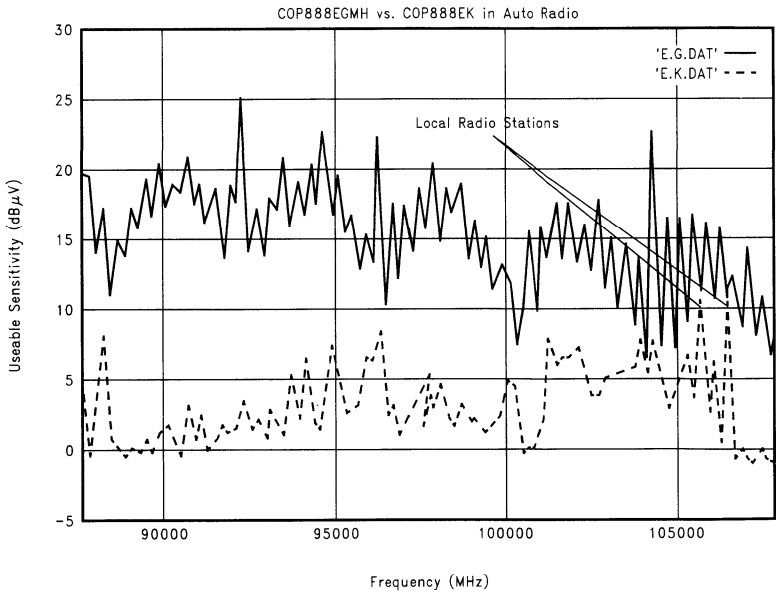
7.2 Radio Results

Worst case useable sensitivity is improved by about 17 dB (25 dBμV to 8 dBμV) by the change from the COP888EGMH OTP to the mask programmed COP888EK. Of course not all frequencies show this improvement, but there is some increased sensitivity throughout the spectrum. Note that two local radio stations (at 105.7 MHz and 106.5 MHz) were received even without an external antenna.



TL/DD/12857–42

FIGURE 27. PCB Layout for EMI Testing



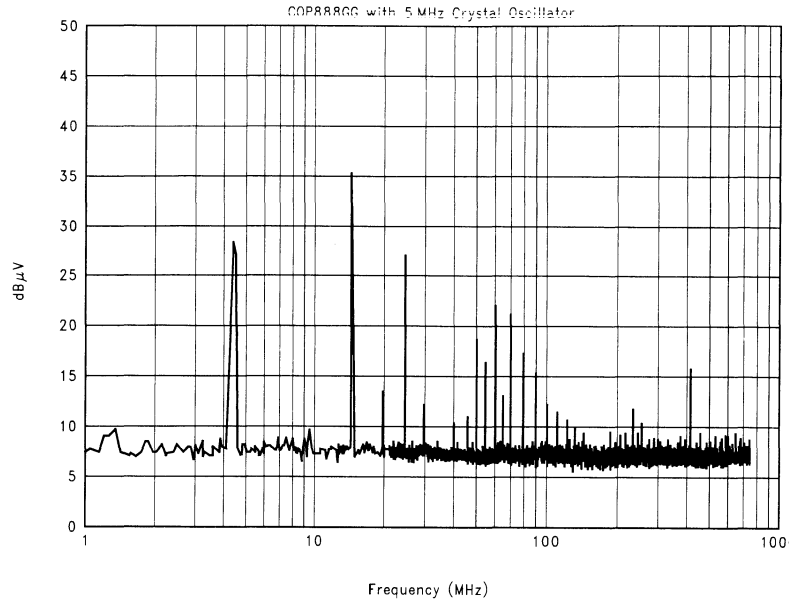
TL/DD/12857–41

FIGURE 28. Usable Sensitivity Comparison

7.3 EMI Board Results

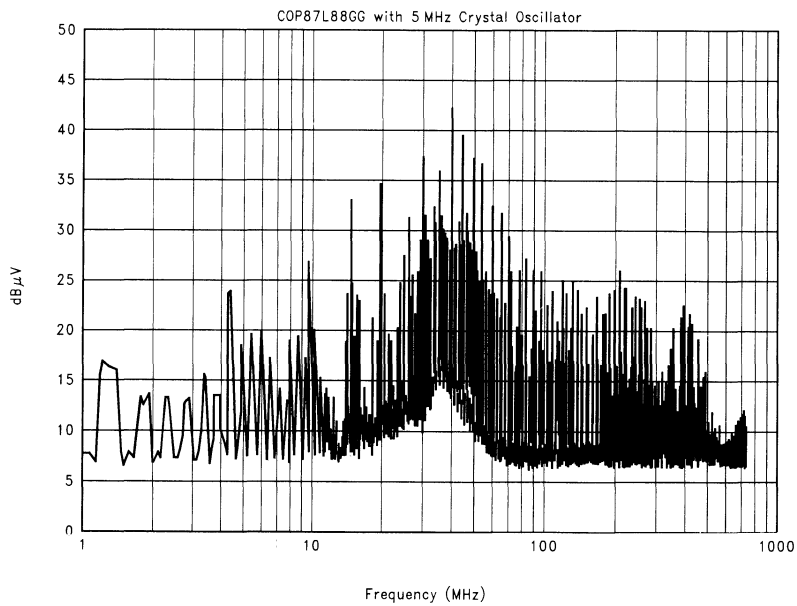
Except for the fundamental oscillator frequency of approximately 5 MHz, emissions are down at least 10 dB on the monolithic masked device over the multichip OTP device. Emissions beyond 100 MHz are practically eliminated.

Much more noticeable is the reduction of spectral density in the noise. Off harmonic noise is not noticeable.



TL/DD/12857–43

FIGURE 29. COP888GG with 5 MHz Crystal Oscillator



TL/DD/12857–44

FIGURE 30. COP87L88GG with 5 MHz Crystal Oscillator

7.4 Conclusions

Radiated Emissions do not come from a device, but from a board. Devices have some control over the emissions because they generate the noise which is radiated. The equation normally used to predict emission from a system is:

$$|E|_{Max} = \frac{1.32 \times 10^{-3} \times I \times A \times Freq^2}{D} \times \left[1 + \left(\frac{\lambda}{2\pi D}\right)^2\right]^{1/2}$$

where,

$|E|_{Max}$ is the maximum E-field in the plane of the loop in $\mu V/m$

I is the current amplitude, at the frequency of interest, in milliamps

A is the loop area is cm2

λ is the wavelength at the frequency of interest

D is the observation distance in meters

Freq is the frequency in MHz

and the perimeter of the loop $P << \lambda$

When applied to a chip, the area is very small and current is relatively low compared to current consumption in a typical system, thus the emissions are low.

8.0 DESIGN GUIDELINES

The growth of concern over electromagnetic compatibility (EMC) in electronic systems continues to rise in the years since the FCC proclaimed that there shall be no more pollution of the electromagnetic spectrum. Still, designers have not yet fully come to grips with a major source and victim of electromagnetic interference—the PCB. The most critical stage for addressing EMI is during the circuit board design. Numerous tales of woe can be recounted about the eleventh hour attempt at solving an EMI problem by retrofit because EMC was given no attention during design. This retrofit ultimately costs much more than design stage EMC, holds up production and generally makes managers unhappy. With these facts in mind, let's address electromagnetic compatibility considerations in PCB design.

8.1 Logic Selection

Logic selection can ultimately dictate how much attention must be given to EMC in the total circuit design. The first guideline should be: use the slowest speed logic that will do the job. Logic speed refers to transition times of output signals and gate responses to input signals. Many emissions and susceptibility problems can be minimized if a slow speed logic is used. For example, a square wave clock or signal pulse with a 3 ns rise time generates radio frequency (100 MHz and higher) energy that is gated about on the PCB. It also means that the logic can respond to comparable radio frequency energy if it gets onto the boards.

The type of logic to be used is normally an early design decision, so that control of edge speeds and, hence, emissions and susceptibiity is made early. Of course, other factors such as required system performance, speed, and timing considerations must enter into this decision. If possible, design the circuit with as slow speed logic as possible. The use of slow speed logic, however, does not guarantee that EMC will exist when the circuit is built; so proper EMC techniques should still be implemented consistently during the remainder of the circuit design.

8.2 Component Layout

Component layout is the second stage in PCB design. Schematics tell little or nothing about how systems will perform once the board is etched, stuffed, and powered. A circuit schematic is useful to the design engineer, but an experienced EMC engineer refers to the PCB when trouble-shooting. By controlling the board layout in the design stage, the designer realizes two benefits: (1) a decrease in EMI problems when the circuit or system is sent for EMI or quality assurance testing; and (2) the number of EMI coupling paths is reduced, saving troubleshooting time and effort later on.

Some layout guidelines for arranging components according to logic speed, frequency, and function are shown in *Figure 31*. These guidelines are very general. A particular circuit is likely to require a combination and/or trade-offs of these arrangements. Isolation of the I/O from digital circuitry is important where emissions or susceptibility may be a problem. For the case of emissions, a frequently encountered coupling path involves digital energy coupling through I/O circuitry and signal traces onto I/O cables and wires, where the latter subsequently radiate. When susceptibility is a problem, it is common for the EMI energy to couple from I/O circuits onto sensitive digital lines, even though the I/O lines may be "opto-coupled" or otherwise supposedly isolated. In both situations, the solution often lies in the proper electrical and physical isolation of analog and low speed digital lines from high speed circuits. When high speed signals are designed to leave the board, the reduction of EMI is usually performed via shielding of I/O cables and is not considered here.

Therefore, a major guideline in layout out boards is to isolate the I/O circuitry from the high speed logic. This method applies even if the logic is being clocked at "only" a few MHz. Often, the fundamental frequency is of marginal interest, with the harmonics generated from switching edges of the clock being the biggest emission culprits. Internal system input/output PCB circuitry should be mounted as close to the edge connector as possible and capacitive filtering of these lines may be necessary to reduce EMI on the lines.

High speed logic components should be grouped together. Digital interface circuitry and I/O circuitry should be physically isolated from each other and routed on separate connectors, if possible as shown in *Figure 27d*.

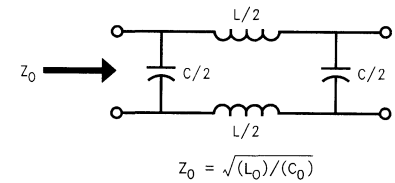
FIGURE 31d. Board Layout

8.3 Power Supply Bussing

Power supply bussing is the next major concern in the design phase. Isolated digital and analog power supplies must be used when mixing analog and digital circuitry on a board. The design preferably should provide for separate power supply distribution for both the analog and digital circuitry. Single point common grounding of analog and digital power supplies should be performed at one point and one point only—usually at the motherboard power supply input for multi-card designs, or at the power supply input edge connector on a single card system. The fundamental feature of good power supply bussing, however, is low impedance and good decoupling over a large range of frequencies. A low impedance distribution system requires two design features: (1) proper power supply and return trace layout and (2) proper use of decoupling capacitors.

An exception to the rule of analog and digital ground separation applies in the case of high speed interface between analog and digital portions. If possible, the ground plane should be continuous under these interface traces to improve the proximity of the return trace and thus minimize the size of the loop.

At high frequencies, PCB traces and the power supply busses ($+V_{CC}$ and 0V) are viewed as transmission lines with associated characteristic impedance, Z_O, as modeled in *Figure 28*. The goal of the designer is to maximize the capacitance between the lines and minimize the self-inductance, thus creating a low Z_O. Table X, shows the characteristic impedance of various two-trace configurations as a function of trace width, W, and trace separation, h.



TL/DD/12857–49

FIGURE 32. Transmission Line Modelling of PCB Traces

TABLE X. Characteristic Impedance of Different Conductor Pairs

			W/h or D/W	**Parallel Strips**	**Strips Over Ground Plane**	**Strips Side by Side**
0.5	377	377	N/A

1.2	140	140	34
1.5	112	112	53
1.7	99	99	62
2.0	84	84	73
2.5	67	67	87
3.0	56	56	98
3.5	48	48	107
4.0	42	42	114
5.0	34	34	127
6.0	28	28	137
7.0	24	24	146
8.0	21	21	153
9.0	19	19	160
10.0	17	17	166
12.0	14	14	176
15.0	11.2	11.2	188
20.0	8.4	8.4	204
25.0	6.7	6.7	217
30.0	5.6	5.6	227
40.0	4.2	4.2	243
50.0	3.4	3.4	255

Any one of the three configurations may be viewed as a possible method of routing power supply (or signal) traces. The most important feature of this table is the noticeable difference in impedance between the parallel strips and strip over ground plane compared with the side-by-side configurations.

As an example of the amount of voltage that can be generated across the impedance of a power bus, consider TTL logic which pulls a current of approximately 16 mA from a supply that has a 25Ω bus impedance (this assumes no decoupling present). The transient voltage is approximately $dV = 0.016 \times 25\Omega = 400$ mV, which is equal to the noise immunity level of the TTL logic. A 25Ω (or higher) impedance is not uncommon in many designs where the supply and return traces are routed on the same side of the board in a side-by-side fashion. In fact, it is not uncommon to find situations where the power supply and return traces are routed quite a distance from each other, thereby increasing the overall impedance of the distribution system and the size of the loop antenna. This is obviously a poor layout.

Power and ground planes offer the lowest overall impedance. The use of these planes leads the designer closer to a multi-layer board. At the very least, it is recommended that all open areas on the PCB be "landfilled" with an interconnected 0V reference plane so that ground impedance is minimized. This landfill technique may be ineffective, however if minimum width traces connect the filled areas.

Multi-layer boards offer a considerable reduction in power supply impedance, as well as other benefits. Extending the table we just saw, the impedance of a multi-layer power/ground plane bus grows very small (on the order of an Ω or less), assuming a W/h ratio greater than 100. Multi-layer board designs also pay dividends in terms of greatly reduced EMI, and they provide close control of line impedances where impedance matching is important. In addition,

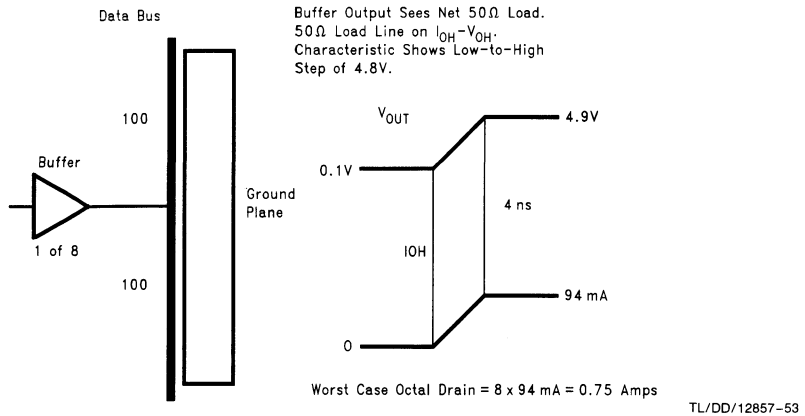

FIGURE 33. Decoupling Example

shielding benefits can be realized. For high-density, high-speed logic applications, the use of a multi-layer board is almost mandatory. The problem with multi-layer boards is the increased cost of design and fabrication and increased difficulty in board repair.

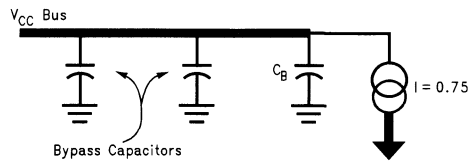
8.4 Decoupling

High-speed CMOS has special decoupling and PCB layout requirements. Adhering to these requirements will ensure that maximum advantage is gained with CMOS devices in system performance and EMC performance.

Local high frequency decoupling is required to supply power to the chip when it is transitioning from a LOW to a HIGH value. This power is necessary to charge the load capacitance or drive a line impedance.

For most power distribution networks, the typical impedance can be between 50Ω and 100Ω. This impedance appears in series with the load impedance and will cause a droop in the V_{CC} at the part. This droop limits the available voltage swing at the local node, unless some form of decoupling is used. This drooping of rails will cause the rise and fall times to become elongated. Consider the example presented in *Figure 29* used to help calculate the amount of decoupling necessary. This circuit utilizes an octal buffer driving a 100Ω bus from a point somewhere in the middle.

Being in the middle of the bus, the driver will see two 100Ω loads in parallel, or an effective impedance of 50Ω. To switch the line from rail to rail, a drive of 94 mA is needed (4.8V/50Ω) and more than 75 mA wil be required if all eight lines switch at once. This instantaneous current requirement will generate a voltage drop across the impedance of the power lines, causing the actual V_{CC} at the chip to droop. This droop limits the voltage swing available to the driver. The net effect of the voltage droop will be to lengthen device rise and fall times and slow system operation. A local decoupling capacitor is required to act as a low impedance supply for the driver chip during high current demands. It will maintain the voltage within acceptable limits and keep rise and fall times to a minimum. The necesssary values for decoupling capacitors can be calculated with the formula given in *Figure 30.*



Specify V_{CC} Droop = 0.1V max during switching time of 4 ns

Q = CV charge on capacitor

I = C dV/dt

C = I dt/dV = 750 mA × 4 ns/0.1V = 0.030 μF

Select C_B = 0.047 μF or greater

FIGURE 34. Decoupling Example

In this example, if the V_{CC} droop is to be kept below 0.1V and the edge rate equals 4 ns, we can calculate the value of the decoupling capacitor by use of the charge on a capacitor equation: Q = CV. The capacitor must supply the high demand current during the transition period and is represented by I = C(dV/dt). Rearranging this somewhat yields C = I(dt/dV).

Now, I = 750 mA assuming all 8 outputs switch simultaneously for worst case conditions, dt = switching period or 4 ns, and dV is the specified V_{CC} droop of 0.1V. This yields a calculated value of 0.030 μF for the decoupling capacitor. So, a selection of 0.047 μF or greater should be sufficient.

Higher gate count devices, e.g. microcontrollers, with high internal edge rates present additional decoupling problems. Capacitors often suffer from parasitic series inductive effects at high frequency. In fact, a poorly selected capacitor can become almost entirely inductive at high frequency. This can be counteracted by paralleling additional capacitors of lower value and corresponding higher self-resonant frequency. Of course the lower value capacitor should be placed closer to the chip to reduce the size of the resultant current loop.

Inductors or ferrite beads connected in series between the capacitors can help to minimize noise currents and voltages from reaching the rest of the circuit.

It is good practice to distribute decoupling capacitors evenly throughout the logic on the board, placing at least one capacitor for every package as close to the power and ground pins as possible. The parasitic inductance in the capacitor leads can be greatly reduced or eliminated by the use of surface mount chip capacitors soldered directly onto the board at the appropriate locations. Decoupling capacitors need to be of the high K ceramic type with low equivalent series resistance (ESR), consisting primarily of series inductance and series resistance. Capacitors using Z5U dielectric have suitable properties and make a good choice for decoupling capacitors; they offer minimum cost and effective performance.

8.5 Proper Signal Trace Layout

Although crosstalk cannot be totally eliminated, there are some design techniques that can reduce system problems resulting from crosstalk. In any design, the distance that lines run adjacent to each other should be kept as short as possible. The best situation is when the lines are perpendicular to each other. Crosstalk problems can also be reduced by moving lines further apart or by inserting ground lines or planes between them.

For those situations where lines must run parallel, as in address and data buses, the effects of crosstalk can be minimized by line termination. Terminating a line in its characteristic impedance reduces the amplitude of an initial crosstalk pulse by 50%. Terminating the line will also reduce the amount of ringing.

There are several termination schemes which may be used. They are series, parallel, AC parallel and Thevenin terminations. AC parallel and series terminations are the most useful for low power applications since they do not consume any DC power. Parallel and Thevenin terminations increase DC power consumption.

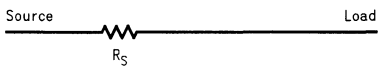
Series terminations are most useful in high-speed applications where most of the loads are at the far end of the line. Loads that are between the driver and the end of the line will receive a two-step waveform. The first wave will be the incident wave. The amplitude is dependent upon the output impedance of the driver, the value of the series resistor and the impedance of the line according to the formula:

$$V_W = \frac{V_{CC} \times Z_{OE}}{Z_{OE} + R_S + Z_S}$$

where R_S is the series Resistor

Z_S is the output impedance of the driver

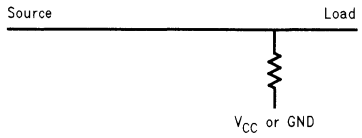
Z_{OE} is the equivalent line impedance



TL/DD/12857–55

FIGURE 35a. Series Termination

The amplitude will be one-half the voltage swing if R_S (the series resistor) plus the output impedance (Z_S) of the driver is equal to the line impedance (Z_{OE}). The second step of the waveform is the reflection from the end of the line and will have an amplitude equal to that of the first step. All devices on the line will receive a valid level only after the wave has propagated down the line and returned to the driver. Therefore, all inputs will see the full voltage swing within two times the delay of the line.



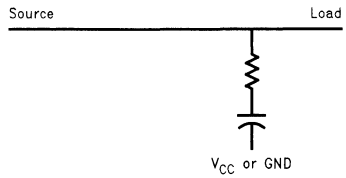
TL/DD/12857–56

FIGURE 35b. Parallel Termination

Parallel terminations are not generally recommended for CMOS circuits due to their power consumption, which can exceed the power consumption of the logic itself. The power consumption of parallel terminations is a function of the resistor value and the duty cycle of the signal. In addition, parallel termination tends to bias the output levels of the driver towards either V_{CC} or ground depending on which bus the resistor is connected to. While this feature is not desirable for driving CMOS inputs because the trip levels are typically $V_{CC}/2$, it can be useful for driving TTL inputs where level shifting is desirable in order to interface with CMOS devices.

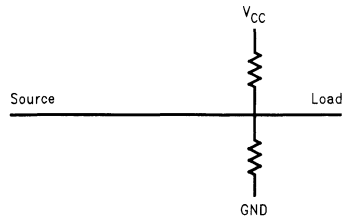
AC parallel terminations work well for applications where the increase in bus delays caused by series terminations are undesirable. The effects of AC parallel terminations are similar to the effects of standard parallel terminations. The major difference is that the capacitor blocks any DC current path and helps to reduce power consumption.

Thevenin terminations are not generally recommended due to their power consumption. Like parallel terminations, a DC path to ground is created by the terminating resistors. The power consumption of a Thevenin termination, though, will generally be independent of the signal duty cycle. Thevenin terminations are more applicable for driving CMOS inputs because they do not bias the output levels as paralleled terminations do. It should be noted that output lines with Thevenin terminations should not be left floating since this will cause the undriven input levels to float between V_{CC} and ground, increasing power consumption.



TL/DD/12857–57

FIGURE 36a. AC Parallel Termination



TL/DD/12857–58

FIGURE 36b. Thevenin Termination

8.6 Ground Bounce

Observing either one of the following rules is sufficient to avoid running into any of the problems associated with ground bounce:

- First, use caution when driving asynchronous TTL-level inputs from CMOS outputs. Ground bounce glitches may cause spurious inputs that will alter the state of non-clocked logic.
- Second, caution when running control lines (set, reset, load, clock, chip select) which are glitch-sensitive through the same devices that drive data or address lines.

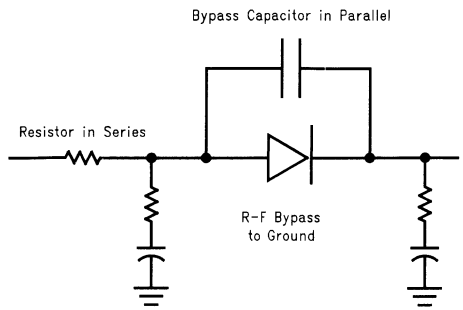
When it is not possible to avoid the above conditions, there are simple precautions available which can minimize ground bounce noise. These are:

- Choose package outputs that are as close to the ground pin as possible to drive asynchronous TTL-level inputs.
- Use the lowest V_{CC} possible or separate the power supplies.
- Use board design practices which reduce any additive noise sources, such as crosstalk, reflections, etc.

8.7 Components

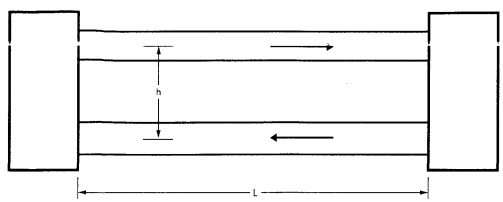
The interference effect by rectifier diodes, typically found in power supply sections of PCBs, can be minimized by one or more of the following measures:

- Placing a bypass capacitor in parallel with each rectifier diode
- Placing a resistor in series with each rectifier diode
- Placing an R-F bypass capacitor to ground from one or both sides of each rectifier diode
- Operating the rectifier diodes well below their rated current capability



TL/DD/12857–59

FIGURE 37a. RF Filtering of Diode



TL/DD/12857–60

FIGURE 37b. Connectors and Cables

8.8 Cables and Connectors

Several options are available to reduce EMI from a typical ribbon cable used to interconnect pieces of equipment. These include:

- Reduce spacing between conductors (h in *Figure 37*) by reducing the size of wires used and reducing the insulation thickness. (This could have a negative impact on crosstalk within the cable.)
- Join alternate signal returns together at the connectors at each end of the cable.
- Twist parallel wire pairs in ribbon cables.
- Shield ribbon cable with metal foil cover (superior to braid).
- Replace discrete ribbon cable with stripline flexprint cable.

In the case of joining alternate signal returns, wire N is carrying the signal current, I_N, whereas its mates, N − 1 and N + 1 wires are each carrying one half of the return currents, $I_N - 1$ and $I_N + 1$, respectively. Thus, radiation from pair N and N − 1 is out of phase with radiation from pair N and N + 1 and will tend to cancel. In practice, however, the net radiation is reduced by 20 dB–30 dB with 30 dB being a good default value.

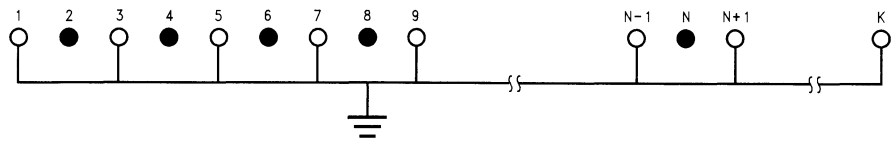
The opposite of this is to conserve signal returns by only using one, or two, wires to service N data lines in a ribbon cable. For data lines farther from the return line, the differential mode radiation becomes so great that this cable tends to maximize EMI radiation. Another disadvantage of this approach is poor impedance control in the resulting transmission line. This could result in distortion of pulses and causes reflections, especially for high-speed logic, and common return impedance noise in this single ground wire.

Ideally, connectors should have negligible resistance for obvious reasons other than EMI control. They should provide for foolproof alignment to minimize the possibility of contact damage over time and use which would increase the resistance and be prone to vibration and shock. The required force should be adequate to provide good mating between contacts which will insure low resistance, but should be minimized to limit likelihood of damage. Connectors should mate with little friction to minimize the effects of continual disconnections and connections increasing the contact resistance with use as the contacts wear out. A contamination free design should be used to avoid corrosion and oxidation increasing resistance and susceptibility to shock and vibration causing intermittent contact.

8.9 Special Considerations with Development Tools

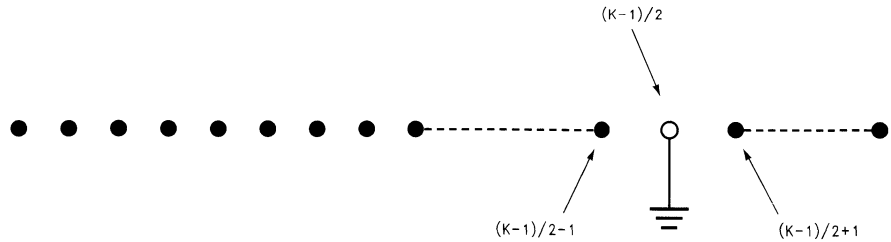
The following set of guidelines have been compiled from the experiences of the applications team at Embedded Technologies Division at National Semiconductor. They should be considered additional techniques and guidelines to be followed concurrently with the standard ones already presented. Some are general and some may be specific to development systems use.

Ground bounce prevention and minimization techniques presented in this paper should be strictly adhered to when using '373 type transparent latches on any controller's external address/data bus. Multiple simultaneously switching outputs could produce ground bounce significant enough to



TL/DD/12857-61

FIGURE 38a. Alternating Signal Return Minimizes Radiation



TL/DD/12857-62

FIGURE 38b. Single Signal Return Maximizes Radiation

cause false latching. Observe good EMI planning by locating the latches as close to the controller as possible. The use of multi-layer PCBs with good ground planes and following appropriate layout techniques is also essential, especially if emulation will be done at frequencies above 10 MHz. With the foregoing discussions about "antenna farms", radiated noise and ideal connector characteristics, it becomes obvious that wire-wrap boards and the use of IC sockets is absolutely out of the question. The concern here is not so much EMI affecting the outside world but EMI strangling the operation of the module itself.

The inputs to the buffers in a '244 type octal buffer package are placed adjacent or side-by-side outputs of other buffers in the package. This configuration would tend to maximize the crosstalk or noise coupling from the inputs to the outputs. On the other hand, the buffer inputs in a '544 type package are on one side of the package and the outputs are on the other. The use of these package types in high speed designs can facilitate board layout to help reduce the effects of crosstalk.

Use extra heavy ground wires between emulator and target board. Rely on the ground returns in the emulator cable for reduction of differential-mode noise radiated from the cable but heavy-duty help is required for reducing power line impedance in the integrated development system.

Unused controller inputs, most importantly any external interrupts and RDY, must be tied to V_{CC} (or GND) directly or through a pull-up (or pull-down) resistor. This not only tends to reduce power consumption, but will avoid noise problems triggering an unwanted action.

In order to reduce the effects of noise generated by high speed signal changes, a sort of Frequency Management technique might be applied. If possible, develop application hardware and software at a slower crystal operating frequency. If ringing, crosstalk, or other combination of radiated and conducted noise problems exists, the result may be to move the problem from one point in the affected signal waveform to a different point. Thus, apparent "noise glitches" that caused a latch to erroneously trigger when the input data was still changing, may now come at a time when they are non-destructive such as at a point when the input data is now stable.

Some applications require driving the controller clock input, CKI, with an external signal. Most emulator tools are all clocked using a crystal network with the controller so that the generation of the system timing is contained on the tool itself. Consequently, there is no connection between the emulator cable connector on the tool and the CKI pin at the controller. However, when the emulator cable is now inserted into the target board, the target board's clock signal traveling along the cable couples noise onto adjacent signal lines causing symptoms pointing to an apparent failure of the emulator tool. The recommendation is to disable the clock drive to the CKI pin at the controller pad on the target board whenever the emulator tool is connected. The emulator tools supply the system clock so there is no need for the clock on the target and signal crosstalk on the emulator cable can be greatly reduced with minimal implementation. If one insists that the emulator tool and the target be synchronous, then bring the clock signal from the target to the emulator tool external to the emulator cable via twisted wire pair or coax cable. Remove the clock drive connection to CKI at the target to prevent the signal from entering the cable. Finally, remove crystal components on the emulator tool to prevent problems with the signal.

Connecting boards and modules together to make a totally unique system in which EMC was practiced is necessary to ensure little problem with the environment. But, connecting an emulator tool makes it an entirely new and unique system, both in physical and electrical properties. Treat the emulator tool as part of the system during the design phase and development phase.

9.0 SUMMARY

The design and construction of an electromagnetically compatible PCB does not necessarily require a big change in current practices. On the contrary, the implementation of EMC principles during the design process can fit in with the ongoing design. When EMC is designed into the board, the requirements to shield circuitry, cables, and enclosures, as well as other costly eleventh hour surprises, will be drastically reduced or even eliminated. Without EMC in the design stage, production can be held up and the cost of the project increases.

Surface Mount

Cost pressures today are forcing many electronics manufacturers to automate their production lines. Surface mount technology plays a key role in this cost-savings trend because:

1. The mounting of devices on the PC board surface eliminates the expense of drilling holes;
2. The use of pick-and-place machines to assemble the PC boards greatly reduces labor costs;
3. The lighter and more compact assembled products resulting from the smaller dimensions of surface mount packages mean lower material costs.

Production processes now permit both surface mount and insertion mount components to be assembled on the same PC board.

SURFACE MOUNT PACKAGING AT NATIONAL

To help our customers take advantage of this new technology, National has developed a line of surface mount packages. Ranging in lead counts from 3 to 360, the package offerings are summarized in Table I.

Lead center spacing keeps shrinking with each new generation of surface mount package. Traditional packages (e.g., DIPs) have a 100 mil lead center spacing. Surface mount packages currently in production (e.g., SOT, SOIC, PCC, LCC, LDCC) have a 50 mil lead center spacing. Surface mount packages in production release (e.g., PQFP) have a 25 mil lead center spacing. Surface mount packages in development (e.g., TAPEPAK®) will have a lead center spacing of only 12–20 mils.

8

LINEAR PRODUCTS IN SURFACE MOUNT

Linear functions available in surface mount include:

- Op amps
- Comparators
- Regulators
- References
- Data conversion
- Industrial
- Consumer
- Automotive

A complete list of linear part numbers in surface mount is presented in Table III. Refer to the datasheet in the appropriate chapter of this databook for a complete description of the device. In addition, National is continually expanding the list of devices offered in surface mount. If the functions you need do not appear in Table III, contact the sales office or distributor branch nearest you for additional information.

Automated manufacturers can improve their cost savings by using Tape-and-Reel for surface mount devices. Simplified handling results because hundreds-to-thousands of semiconductors are carried on a single Tape-and-Reel pack (see ordering and shipping information—printed later in this section—for a comparison of devices/reel vs. devices/rail for those surface mount package types being used for linear products). With this higher device count per reel (when compared with less than a 100 devices per rail), pick-and-place machines have to be re-loaded less frequently and lower labor costs result.

With Tape-and-Reel, manufacturers save twice—once from using surface mount technology for automated PC board assembly and again from less device handling during shipment and machine set-up.

BOARD CONVERSION

Besides new designs, many manufacturers are converting existing printed circuit board designs to surface mount. The resulting PCB will be smaller, lighter and less expensive to manufacture; but there is one caveat—be careful about the thermal dissipation capability of the surface mount package.

Because the surface mount package is smaller than the traditional dual-in-line package, the surface mount package is not capable of conducting as much heat away as the DIP (i.e., the surface mount package has a higher thermal resistance—see Table II).

The silicon for most National devices can operate up to a 150°C junction temperature (check the datasheet for the rare exception). Like the DIP, the surface mount package can actually withstand an ambient temperature of up to 125°C (although a commercial temperature range device will only be specified for a max ambient temperature of 70°C and an industrial temperature range device will only be specified for a max ambient temperature of 85°C). See AN-336, "Understanding Integrated Circuit Package Power Capabilities", (reprinted in the appendix of each linear databook volume) for more information.

TABLE II: Surface Mount Package Thermal Resistance Range*

Package	Thermal Resistance** (θ_{jA}, °C/W)
SO-8	120–175
SO-14	100–140
SO-14 Wide	70–110
SO-16	90–130
SO-16 Wide	70–100
SO-20	60–90
SO-24	55–85
PCC-20	70–100
PCC-28	60–90
PCC-44	40–60

*Actual thermal resistance for a particular device depends on die size. Refer to the datasheet for the actual θ_{jA} value.

**Test conditions: PCB mount (FR4 material), still air (room temperature), copper traces (150 × 20 × 10 mils).

Given a max junction temperature of 150°C and a maximum allowed ambient temperature, the surface mount device will be able to dissipate less power than the DIP device. This factor must be taken into account for new designs.

For board conversion, the DIP and surface mount devices would have to dissipate the same power. This means the surface mount circuit would have a lower maximum allowable ambient temperature than the DIP circuit. For DIP circuits where the maximum ambient temperature required is substantially lower than the maximum ambient temperature allowed, there may be enough margin for safe operation of the surface mount circuit with its lower maximum allowable ambient temperature. But where the maximum ambient temperature required of the DIP current is close to the maximum allowable ambient temperature, the lower maximum ambient temperature allowed for the surface mount circuit may fall below the maximum ambient temperature required. The circuit designer must be aware of this potential pitfall so that an appropriate work-around can be found to keep the surface mount package from being thermally overstressed in the application.

SURFACE MOUNT LITERATURE

National has published extensive literature on the subject of surface mount packaging. Engineers from packaging, quality, reliability, and surface mount applications have pooled their experience to provide you with practical hands-on knowledge about the construction and use of surface mount packages.

The applications note AN-450 "Surface Mounting Methods and their Effect on Product Reliability" is referenced on each SMD datasheet. In addition, "Wave Soldering of Surface Mount Components" is reprinted in this section for your information.

A FINAL WORD

National is a world leader in the design and manufacture of surface mount components.

Because of design innovations such as perforated copper leadframes, our small outline package is as reliable as our DIP—the laws of physics would have meant that a straight "junior copy" of the DIP would have resulted in an "S.O." package of lower reliability. You benefit from this equivalence of reliability. In addition, our ongoing vigilance at each step of the production process assures that the reliability we designed in stays in so that only devices of the highest quality and reliability are shipped to your factory.

Our surface mount applications lab at our headquarters site in Santa Clara, California continues to research (and publish) methods to make it even easier for you to use surface mount technology. Your problems are our problems.

When you think "Surface Mount"—think "National"!

Ordering and Shipping Information

When you order a surface mount semiconductor, it will be in one of the several available surface mount package types. Specifying the Tape-and-Reel method of shipment means that you will receive your devices in the following quantities per Tape-and-Reel pack: SMD devices can also be supplied in conventional conductive rails.

Package	Package Designator	Max/Rail	Per Reel*
SO-8	M	100	2500
SO-14	M	50	2500
SO-14 Wide	WM	50	1000
SO-16	M	50	2500
SO-16 Wide	WM	50	1000
SO-20	M	40	1000
SO-24	M	30	1000
PCL-20	V	50	1000
PCL-28	V	40	1000
PCL-44	V	25	500
PQFP-196	VF	TBD	—
TP-40	TP	100	TBD
LCC-20	E	50	—
LCC-44	E	25	—

*Incremental ordering quantities. (National Semiconductor reserves the right to provide a smaller quantity of devices per Tape-and-Reel pack to preserve lot or date code integrity. See example below.)

Example: You order 5,000 LM324M ICs shipped in Tape-and-Reel.

- Case 1: All 5,000 devices have the same date code
  - You receive 2 SO-14 (Narrow) Tape-and-Reel packs, each having 2500 LM324M ICs
- Case 2: 3,000 devices have date code A and 2,000 devices have date code B
  - You receive 3 SO-14 (Narrow) Tape-and-Reel packs as follows:

    Pack #1 has 2,500 LM324M ICs with date code A

    Pack #2 has 500 LM324M ICs with date code A

    Pack #3 has 2,000 LM324M ICs with date code B

National Semiconductor will also offer additional labels containing information per your specific specification.

Wave Soldering of Surface Mount Components

ABSTRACT

In facing the upcoming surge of "surface mount technology", many manufacturers of printed circuit boards have taken steps to convert some portions of their boards to this new process. However, as the availability of surface mount components is still limited, may have taken to mixing the lead-inserted standard dual-in-line packages (DIPs) with the surface mounted devices (SMDs). Furthermore, to take advantage of using both sides of the board, surface-mounted components are generally adhered to the bottom side of the board while the top side is reserved for the conventional lead-inserted packages. If processed through a wave solder machine, the semiconductor components are now subjected to extra thermal stresses (now that the components are totally immersed into the molten solder).

A discussion of the effect of wave soldering on the reliability of plastic semiconductor packages follows. This is intended to highlight the limitations which should be understood in the use of wave soldering of surface mounted components.

ROLE OF WAVE-SOLDERING IN APPLICATION OF SMDs

The generally acceptable methods of soldering SMDs are vapor phase reflow soldering and IR reflow soldering, both requiring application of solder paste on PW boards prior to placement of the components. However, sentiment still exists for retaining the use of the old wave-soldering machine.

Wave Soldering of Surface Mount Components (Continued)

The reasons being:

1) Most PC Board Assembly houses already possess wave soldering equipment. Switching to another technology such as vapor phase soldering requires substantial investment in equipment and people.
2) Due to the limited number of devices that are surface mount components, it is necessary to mix both lead inserted components and surface mount components on the same board.
3) Some components such as relays and switches are made of materials which would not be able to survive the temperature exposure in a vapor phase or IR furnace.

PW BOARD ASSEMBLY PROCEDURES

There are two considerations in which through-hole ICs may be combined with surface mount components on the PW Board:

a) Whether to mount ICs on one or both sides of the board.
b) The sequence of soldering using Vapor Phase, IR or Wave Soldering singly or combination of two or more methods.

The various processes that may be employed are:

A) Wave Solder before Vapor/IR reflow solder.
   1. Components on the same side of PW Board.
      Lead insert standard DIPS onto PW Board Wave solder (conventional)
      Wash and lead trim
      Dispense solder paste on SMD pads
      Pick and place SMDs onto PW Board
      Bake
      Vapor phase/IR reflow
      Clean
   2. Components on opposite side of PW Board.
      Lead insert standard DIPs onto PW Board
      Wave Solder (conventional)
      Clean and lead trim
      Invert PW Board
      Dispense solder paste on SMD pads
      Dispense drop of adhesive on SMD sites (optional for smaller components)
      Pick and place SMDs onto board
      Bake/Cure
      Invert board to rest on raised fixture
      Vapor/IR reflow soldering
      Clean

B) Vapor/IR reflow solder then Wave Solder.
   1. Components on the same side of PW Board.
      Solder paste screened on SMD side of Printed Wire Board
      Pick and place SMDs
      Bake
      Vapor/IR reflow
      Lead insert on same side as SMDs
      Wave solder
      Clean and trim underside of PCB

C) Vapor/IR reflow only.
   1. Components on the same side of PW Board.
      Trim and form standard DIPs in "gull wing" configuration
      Solder paste screened on PW Board
      Pick and place SMDs and DIPs
      Bake
      Vapor/IR reflow
      Clean
   2. Components on opposite sides of PW Board.
      Solder paste screened on SMD-side of Printed Wire Board
      Adhesive dispensed at central location of each component
      Pick and place SMDs
      Bake
      Solder paste screened on all pads on DIP-side or alternatively apply solder rings (performs) on leads
      Lead insert DIPs
      Vapor/IR reflow
      Clean and lead trim

D) Wave Soldering Only
   1. Components on opposite sides of PW Board.
      Adhesive dispense on SMD side of PW Board
      Pick and place SMDs
      Cure adhesive
      Lead insert top side with DIPs
      Wave solder with SMDs down and into solder bath
      Clean and lead trim

All of the above assembly procedures can be divided into three categories for I.C. Reliability considerations:

1) Components are subjected to both a vapor phase/IR heat cycle then followed by a wave-solder heat cycle or vice versa.
2) Components are subjected to only a vapor phase/IR heat cycle.
3) Components are subjected to wave-soldering only and SMDs are subjected to heat by immersion into a solder pot.

Of these three categories, the last is the most severe regarding heat treatment to a semiconductor device. However, note that semiconductor molded packages generally possess a coating of solder on their leads as a final finish for solderability and protection of base leadframe material. Most semiconductor manufacturers solder-plate the component leads, while others perform hot solder dip. In the latter case the packages may be subjected to total immersion into a hot solder bath under controlled conditions (manual operation) or be partially immersed while in a 'pallet' where automatic wave or DIP soldering processes are used. It is, therefore, possible to subject SMDs to solder heat under certain conditions and not cause catastrophic failures.

Wave Soldering of Surface Mount Components (Continued)

THERMAL CHARACTERISTICS OF MOLDED INTEGRATED CIRCUITS

Since Plastic DIPs and SMDs are encapsulated with a thermoset epoxy, the thermal characteristics of the material generally correspond to a TMA (Thermo-Mechanical Analysis) graph. The critical parameters are (a) its Linear thermal expansion characteristics and (b) its glass transition temperature after the epoxy has been fully cured. A typical TMA graph is illustrated in *Figure 1*. Note that the epoxy changes to a higher thermal expansion once it is subjected to temperatures exceeding its glass transition temperature. Metals (as used on lead frames, for example) do not have this characteristic and generally will have a consistent Linear thermal expansion over the same temperature range.

In any good reliable plastic package, the choice of lead frame material should be such to match its thermal expansion properties to that of the encapsulating epoxy. In the event that there is a mismatch between the two, stresses can build up at the interface of the epoxy and metal. There now exists a tendency for the epoxy to separate from the metal lead frame in a manner similar to that observed on bi-metallic thermal range.

In most cases when the packages are kept at temperatures below their glass transition, there is a small possibility of separation at the expoxy-metal interface. Howerver, if the package is subjected to temprature above its glass-transition temperature, the epoxy will begin to expand much faster than the metal and the probability of separation is greatly increased.

CONVENTIONAL WAVE-SOLDERING

Most wave-soldering operations occur at temperatures between 240–260°C. Conventional epoxies for encapsulation have glass-transition temperature between 140–170°C. An I.C. directly exposed to these temperatures risks its long term functionality due to epoxy/metal separation.

Fortunately, there are factors that can reduce that element of risk:

1) The PW board has a certain amount of heat-sink effect and tends to shield the components from the temperature of the solder (if they were placed on the top side of the board). In actual measurements, DIPs achieve a temperature between 120–150°C in a 5-second pass over the solder. This accounts for the fact that DIPs mounted in the conventional manner are reliable.
2) In conventional soldering, only the tip of each lead in a DIP would experience the solder temperature because the epoxy and die are standing above the PW board and out of the solder bath.

EFFECT ON PACKAGE PERFORMANCE BY EPOXY-METAL SEPARATION

In wave soldering, it is necessary to use fluxes to assist the solderability of the components and PW boards. Some facilities may even process the boards and components through some form of acid cleaning prior to the soldering temperature. If separation occurs, the flux residues and acid residues (which may be present owing to inadequate cleaning) will be forced into the package mainly by capillary action as the residues move away from the solder heat source. Once the package is cooled, these contaminants are now trapped within the package and are available to diffuse with moisture from the epoxy over time. It should be noted that electrical tests performed immediately after soldering generally will give no indication of this potential problem. In any case, the end result will be corrosion of the chip metallization over time and premature failure of the device in the field.

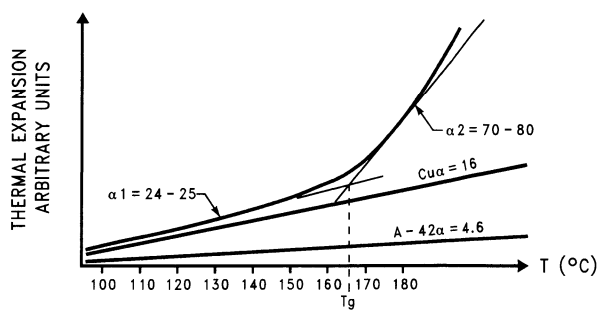
VAPOR PHASE/IR REFLOW SOLDERING

In both vapor phase and IR reflow soldering, the risk of separation between epoxy/metal can also be high. Operating temperatures are 215°C (vapor phase) or 240°C (IR) and duration may also be longer (30 sec–60 sec). On the same theoretical basis, there should also be separation. However, in both these methods, solder paste is applied to the pads of the boards; no fluxes are used. Also, the devices are not immersed into the hot solder. This reduces the possibility of solder forcing itself into the epoxy-lead frame interface. Furthermore, in the vapor phase system, the soldering environment is "oxygen-free" and considered "contaminant free". Being so, it could be visualized that as far as reliability with respect to corrosion, both of these methods are advantageous over wave soldering.

BIAS MOISTURE TEST

A bias moisture test was designed to determine the effect on package performance. In this test, the packages are pressured in a stream chamber to accelerate penetration of moisture into the package. An electrical bias is applied on the device. Should there be any contaminants trapped within the package, the moisture will quickly form an electrolyte and cause the electrodes (which are the lead fingers), the gold wire and the aluminum bond-pads of the silicon device to corrode. The aluminum bond-pads, being the weakest link of the system, will generally be the first to fail.

This proprietary accelerated bias/moisture pressure-test is significant in relation to the life test condition at 85°C and



TL/DD/11325–11

FIGURE 1. Thermal Expansion and Glass Transition Temperature

Wave Soldering of Surface Mount Components (Continued)

85% relative humidity. Once cycle of approximately 100 hours has been shown to be equivalent to 2000 hours in the 85/85 condition. Should the packages start to fail within the first cycle in the test, it is anticipated that the boards with these components in the harsh operating environment (85°C/85% RH) will experience corrosion and eventual electrical failures within its first 2000 hours of operation.

Whether this is significant to a circuit board manufacturer will obviously be dependent on the products being manufactured and the workmanship or reliability standards. Generally in systems with a long warranty and containing many components, it is advisable both on a reputation and cost basis to have the most reliable parts available.

TEST RESULTS

The comparison of vapor phase and wave-soldering upon the reliability of molded Small-Outline packages was performed using the bias moisture test (see Table IV). It is clearly seen that vapor phase reflow soldering gave more consistent results. Wave-soldering results were based on manual operation giving variations in soldering parameters such as temperature and duration.

TABLE IV. Vapor Phase vs. Wave Solder

1. Vapor phase (60 sec. exposure @ 215°C)
   = 9 failures/1723 samples
   = 0.5% (average over 32 sample lots)
2. Wave solder (2 sec total immersion @ 260°C)
   = 16 failures/1201 samples
   = 1.3% (average over 27 sample lots)

Package: SO-14 lead
Test: Bias moisture test 85% R.H., 85°C for 2000 hours
Device: LM324M

In Table V we examine the tolerance of the Small-Outlined (SOIC) package to varying immersion time in a hot solder pot. SO-14 lead molded packages were subjected to the bias moisture test after being treated to the various soldering conditions and repeated four (4) times. End point was an electrical test after an equivalent of 4000 hours 85/85 test. Results were compared for packages by itself against packages which were surface-mounted onto a FR-4 printed wire board.

TABLE V. Summary of Wave Solder Results (85% R.H./85°C Bias Moisture Test, 2000 hours) (# Failures/Total Tested)

	Unmounted	Mounted
Control/Vapor Phase 15 sec @ 215°C	0/114	0/84
Solder Dip 2 sec @ 260°C	2/144 (1.4%)	0/85
Solder Dip 4 sec @ 260°C	—	0/83
Solder Dip 6 sec @ 260°C	13/248 (5.2%)	1/76 (1.3%)
Solder Dip 10 sec @ 260°C	14/127 (11.0%)	3/79 (3.8%)
Package: SO-14 lead Device: LM324M		

Since the package is of very small mass and experiences a rather sharp thermal shock followed by stresses created by the mismatch in expansion, the results show the package being susceptible to failures after being immersed in excess of 6 seconds in a solder pot. In the second case where the packages were mounted, the effect of severe temperature excursion was reduced. In the second case where the packages were mounted, the effect of severe temperature excursion was reduced. In any case, because of the repeated treatment, the package had failures when subjected in excess of 6 seconds immersion in hot solder. The safety margin is therefore recommended as maximum 4 seconds immersion. If packages were immersed longer than 4 seconds, there is a probable chance of finding some long term reliability failures even though the immediate electrical test data could be acceptable.

Finally, Table VI examines the bias moisture test performed on surface mount (SOIC) components manufactured by various semiconductor houses. End point was an electrical test after an equivalent of 6000 hours in a 85/85 test. Failures were analyzed and corrosion was checked for in each case to detect flaws in package integrity.

TABLE VI. U.S. Manufacturers Integrated Circuits Reliability in Various Solder Environments (# Failure/Total Tested)

Test: Accelerated Bias Moisture Test; 85% R.H./85°C, 6000 equivalent hours.

SUMMARY

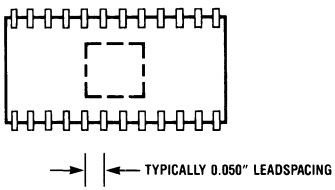
Based on the results presented, it is noted that surface-mounted components are as reliable as standard molded DIP packages. Whereas DIPs were never processed by being totally immersed in a hot solder wave during printed circuit board soldering, surface mounted components such as SOICs (Small Outline) are expected to survive a total immersion in the hot solder in order to capitalize on maximum population on boards. Being constructed from a thermoset plastic of relatively low Tg compared to the soldering temperature, the ability of the package to survive is dependent on the time of immersion and also the cleanliness of material. The results indicate that one should limit the immersion time of package in the solder wave to a maximum of 4 seconds in order to truly duplicate the reliability of a DIP. As the package size is reduced, as in a SO-8 lead, the requirement becomes even more critical. This is shown by the various manufacturers' performance. Results indicate there is room for improvement since not all survived the hot solder immersion without compromise to lower reliability.

Small Outline (SO) Package Surface Mounting Methods— Parameters and Their Effect on Product Reliability

The SO (small outline) package has been developed to meet customer demand for ever-increasing miniaturization and component density.

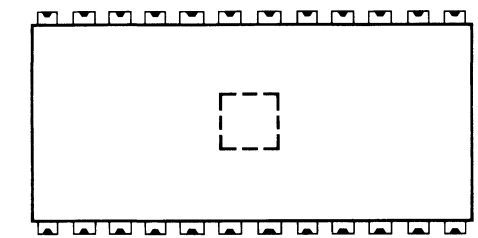
COMPONENT SIZE COMPARISON

S.O. Package



TL/DD/11325–12

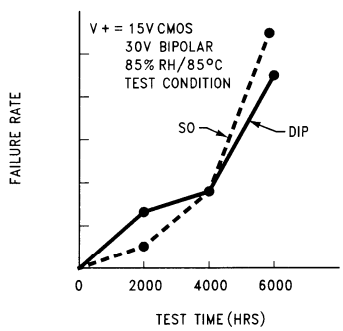
Standard DIP Package



TL/DD/11325–13

Because of its small size, reliability of the product assembled in SO packages needs to be carefully evaluated.

SO packages at National were internally qualified for production under the condition that they be of comparable reliability performance to a standard dual in line package under all accelerated environmental tests. *Figure A* is a summary of accelarated bias moisture test performance on 30V bipolar and 15V CMOS product assembled in SO and DIP (control) packages.



TL/DD/11325–14

FIGURE A

In order to achieve reliability performance comparable to DIPs—SO packages are designed and built with materials and processes that effectively compensate for their small size.

All SO packages tested on 85%RA, 85°C were assembled on PC conversion boards using vapor-phase reflow soldering. With this approach we are able to measure the effect of surface mounting methods on reliability of the process. As illustrated in *Figure A* no significant difference was detected between the long term reliability performance of surface mounted S.O. packages and the DIP control product for up to 6000 hours of accelerated 85%/85°C testing.

SURFACE-MOUNT PROCESS FLOW

The standard process flowcharts for basic surface-mount operation and mixed-lead insertion/surface-mount operations, are illustrated on the following pages.

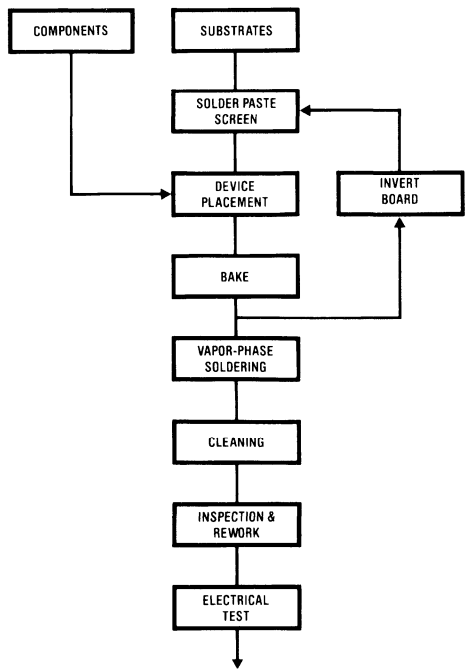
Usual variations encountered by users of SO packages are:

- Single-sided boards, surface-mounted components only.
- Single-sided boards, mixed-lead inserted and surface-mounted components.
- Double-sided boards, surface-mounted components only.
- Double-sided boards, mixed-lead inserted and surface-mounted components.

In consideration of these variations, it became necessary for users to utilize techniques involving wave soldering and adhesive applications, along with the commonly-used vapor-phase solder reflow soldering technique.

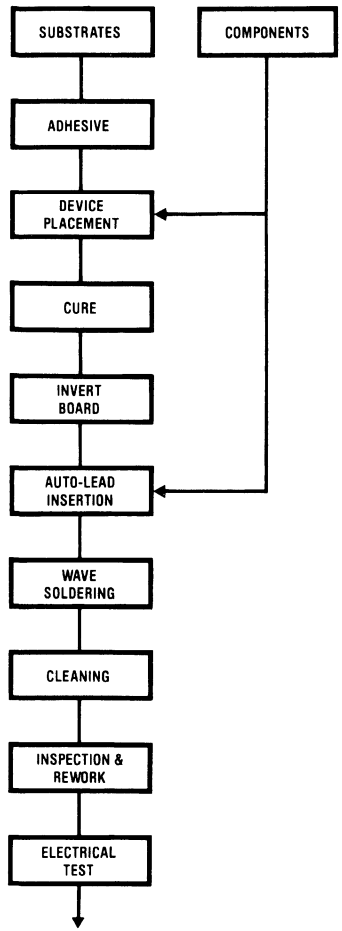
PRODUCTION FLOW

Basic Surface-Mount Production Flow



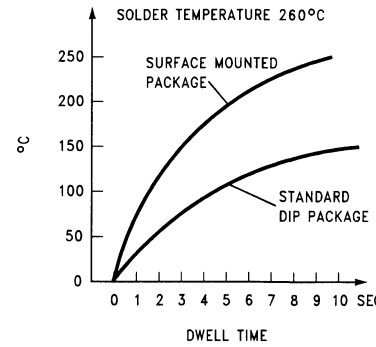
TL/DD/11325–15

Mixed Surface-Mount and Axial-Leaded Insertion Components Production Flow



TL/DD/11325–16

Thermal stress of the packages during surface-mounting processing is more severe than during standard DIP PC board mounting processes. *Figure B* illustrates package temperature versus wave soldering dwell time for surface mounted packages (components are immersed into the molten solder) and the standard DIP wave soldering process. (Only leads of the package are immersed into the molten solder).

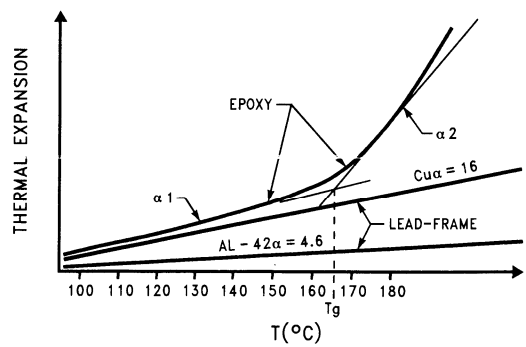


TL/DD/11325–17

FIGURE B

For an ideal package, the thermal expansion rate of the encapsulant should match that of the leadframe material in order for the package to maintain mechanical integrity during the soldering process. Unfortunately, a perfect matchup of thermal expansion rates with most presently used packaging materials is scarce. The problem lies primarily with the epoxy compound.

Normally, thermal expansion rates for epoxy encapsulant and metal lead frame materials are linear and remain fairly close at temperatures approaching 160°C, *Figure C*. At lower temperatures the difference in expansion rate of the two materials is not great enough to cause interface separation. However, when the package reaches the glass-transition temperature (T_g) of epoxy (typically 160–165°C), the thermal expansion rate of the encapsulant increases sharply, and the material undergoes a transition into a plastic state. The epoxy begins to expand at a rate three times or more greater than the metal leadframe, causing a separation at the interface.



TL/DD/11325–18

FIGURE C

When this happens during a conventional wave soldering process using flux and acid cleaners, process residues and even solder can enter the cavity created by the separation and become entrapped when the material cools. These contaminants can eventually diffuse into the interior of the package, especially in the presence of moisture. The result is die contamination, excessive leakage, and even catastrophic failure. Unfortunately, electrical tests performed immediately following soldering may not detect potential flaws.

Most soldering processes involve temperatures ranging up to 260°C, which far exceeds the glass-transition temperature of epoxy. Clearly, circuit boards containing SMD packages require tighter process controls than those used for boards populated solely by DIPs.

Figure D is a summary of accelerated bias moisture test performance on the 30V bipolar process.

Group 1 — Standard DIP package

Group 2 — SO packages vapor-phase reflow soldered on PC boards

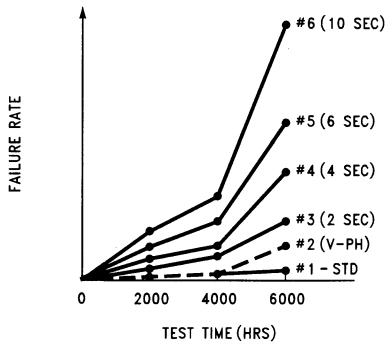
Group 3–6 SO packages wave soldered on PC boards

Group 3 — dwell time 2 seconds

4 — dwell time 4 seconds

5 — dwell time 6 seconds

6 — dwell time 10 seconds



TL/DD/11325–19

FIGURE D

It is clear based on the data presented that SO packages soldered onto PC boards with the vapor phase reflow process have the best long term bias moisture performance and this is comparable to the performance of standard DIP packages. The key advantage of reflow soldering methods is the clean environment that minimized the potential for contamination of surface mounted packages, and is preferred for the surface-mount process.

When wave soldering is used to surface mount components on the board, the dwell time of the component under molten solder should be no more than 4 seconds, preferrably under 2 seconds in order to prevent damage to the component. Non-Halide, or (organic acid) fluxes are highly recommended.

PICK AND PLACE

The choice of automatic (all generally programmable) pick-and-place machines to handle surface mounting has grown considerably, and their selection is based on individual needs and degree of sophistication.

The basic component-placement systems available are classified as:

(a) In-line placement

— Fixed placement stations

— Boards indexed under head and respective components placed

(b) Sequential placement

— Either a X-Y moving table system or a θ, X-Y moving pickup system used

—Individual components picked and placed onto boards

(c) Simultaneous placement

— Multiple pickup heads

— Whole array of components placed onto the PCB at the same time

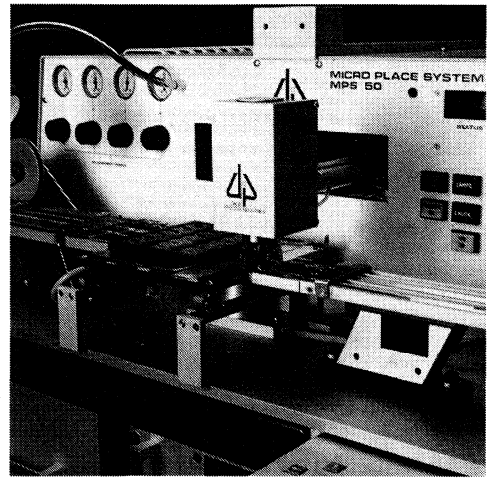
(d) Sequential/simultaneous placement

— X–Y moving table, multiple pickup heads system

— Components placed on PCB by successive or simultaneous actuation of pickup heads

The SO package is treated almost the same as surface-mount, passive components requiring correct orientation in placement on the board.

Pick and Place Action



TL/DD/11325–20

BAKE

This is recommended, despite claims made by some solder paste suppliers that this step be omitted.

The functions of this step are:

- Holds down the solder globules during subsequent reflow soldering process and prevents expulsion of small solder balls.
- Acts as an adhesive to hold the components in place during handling between placement to reflow soldering.
- Holds components in position when a double-sided surface-mounted board is held upside down going into a vapor-phase reflow soldering operation.
- Removes solvents which might otherwise contaminate other equipment.
- Initiates activator cleaning of surfaces to be soldered.
- Prevents moisture absorption.

The process is moreover very simple. The usual schedule is about 20 minutes in a 65°C–95°C (dependent on solvent system of solder paste) oven with adequate venting. Longer bake time is not recommended due to the following reasons:

- The flux will degrade and affect the characteristics of the paste.
- Solder globules will begin to oxidize and cause solderability problems.
- The paste will creep and after reflow, may leave behind residues between traces which are difficult to remove and vulnerable to electro-migration problems.

REFLOW SOLDERING

There are various methods for reflowing the solder paste, namely:

- Hot air reflow
- Infrared heating (furnaces)
- Convectional oven heating
- Vapor-phase reflow soldering
- Laser soldering

For SO applications, hot air reflow/infrared furnace may be used for low-volume production or prototype work, but vapor-phase soldering reflow is more efficient for consistency and speed. Oven heating is not recommended because of "hot spots" in the oven and uneven melting may result. Laser soldering is more for specialized applications and requires a great amount of investment.

HOT GAS REFLOW/INFRARED HEATING

A hand-held or table-mount air blower (with appropriate orifice mask) can be used.

The boards are preheated to about 100°C and then subjected to an air jet at about 260°C. This is a slow process and results may be inconsistent due to various heat-sink properties of passive components.

Use of an infrared furnace is the next step to automating the concept, except that the heating is promoted by use of IR lamps or panels. The main objection to this method is that certain materials may heat up at different rates under IR radiation and may result in damage to these components (usually sockets and connectors). This could be minimized by using far-infrared (non-focused) system.

VAPOR-PHASE REFLOW SOLDERING

Currently the most popular and consistent method, vapor-phase soldering utilizes a fluoroinert fluid with excellent heat-transfer properties to heat up components until the solder paste reflows. The maximum temperature is limited by the vapor temperature of the fluid.

The commonly used fluids (supplied by 3M Corp) are:

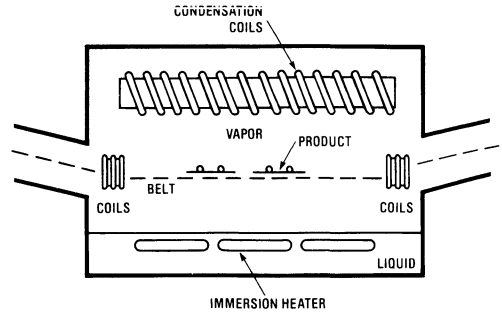
- FC-70, 215°C vapor (most applications) or FX-38
- FC-71, 253°C vapor (low-lead or tin-plate)

HTC, Concord, CA, manufactures equipment that utilizes this technique, with two options:

- Batch systems, where boards are lowered in a basket and subjected to the vapor from a tank of boiling fluid.
- In-line conveyorized systems, where boards are placed onto a continuous belt which transports them into a concealed tank where they are subjected to an environment of hot vapor.

Dwell time in the vapor is generally on the order of 15–30 seconds (depending on the mass of the boards and the loading density of boards on the belt).

In-Line Conveyorized Vapor-Phase Soldering



TL/DD/11325–21

The question of thermal shock is asked frequently because of the relatively sharp increase in component temperature from room temperature to 215°C. SO packages mounted on representative boards have been tested and have shown little effect on the integrity of the packages. Various packages, such as cerdips, metal cans and TO-5 cans with glass seals, have also been tested.

PRINTED CIRCUIT BOARD

The SO package is molded out of clean, thermoset plastic compound and has no particular compatibility problems with most printed circuit board substrates.

The package can be reliably mounted onto substrates such as:

- G10 or FR4 glass/resin
- FR5 glass/resin systems for high-temperature applications
- Polymide boards, also high-temperature applications
- Ceramic substrates

General requirements for printed circuit boards are:

- Mounting pads should be solder-plated whenever applicable.
- Solder masks are commonly used to prevent solder bridging of fine lines during soldering.

  The mask also protects circuits from processing chemical contamination and corrosion.

  If coated over pre-tinned traces, residues may accumulate at the mask/trace interface during subsequent reflow, leading to possible reliability failures.

  Recommended application of solder resist on bare, clean traces prior to coating exposed areas with solder.

  General requirements for solder mask:

  — Good pattern resolution.

  — Complete coverage of circuit lines and resistance to flaking during soldering.

  — Adhesion should be excellent on substrate material to keep off moisture and chemicals.

  — Compatible with soldering and cleaning requirements.

SOLDER PASTE SCREEN PRINTING

With the initial choice of printed circuit lithographic design and substrate material, the first step in surface mounting is the application of solder paste.

The typical lithographic "footprints" for SO packages are illustrated below. Note that the 0.050″ lead center-center spacing is not easily managed by commercially-available air pressure, hand-held dispensers.

Using a stainless-steel, wire-mesh screen stencilled with an emulsion image of the substrate pads is by far the most common and well-tried method. The paste is forced through the screen by a V-shaped plastic squeegee in a sweeping manner onto the board placed beneath the screen.

The setup for SO packages has no special requirement from that required by other surface-mounted, passive components. Recommended working specifications are:

- Use stainless-steel, wire-mesh screens, #80 or #120, wire diameter 2.6 mils. Rule of thumb: mesh opening should be approximately 2.5–5 times larger than the average particle size of paste material.
- Use squeegee of Durometer 70.
- Experimentation with squeegee travel speed is recommended, if available on machine used.
- Use solder paste of mesh 200–325.
- Emulsion thickness of 0.005″ usually used to achieve a solder paste thickness (wet) of about 0.008″ typical.
- Mesh pattern should be 90 degrees, square grid.
- Snap-off height of screen should not exceed $\frac{1}{8}$″, to avoid damage to screens and minimize distortion.

SOLDER PASTE

Selection of solder paste tends to be confusing, due to numerous formulations available from various manufacturers. In general, the following guidelines are sufficient to qualify a particular paste for production:

- Particle sizes (see photographs below). Mesh 325 (approximately 45 microns) should be used for general purposes, while larger (solder globules) particles are preferred for leadless components (LCC). The larger particles can easily be used for SO packages.

- Uniform particle distribution. Solder globules should be spherical in shape with uniform diameters and minimum amount of elongation (visual under 100/200 × magnification). Uneven distribution causes uneven melting and subsequent expulsion of smaller solder balls away from their proper sites.
- Composition, generally 60/40 or 63/37 Sn/Pb. Use 62/36 Sn/Pb with 2% Ag in the presence of Au on the soldering area. This formulation reduces problems of metal leaching from soldering pads.
- RMA flux system usually used.
- Use paste with aproximately 88–90% solids.

CLEANING

The most critical process in surface mounting SO packages is in the cleaning cycle. The package is mounted very close to the surface of the substrate and has a tendency to collect residue left behind after reflow soldering.

Important considerations in cleaning are:

- Time between soldering and cleaning to be as short as possible. Residue should not be allowed to solidify on the substrate for long periods of time, making it difficult to dislodge.
- A low surface tension solvent (high penetration) should be employed. Solvents commercially available are:

  Freon TMS (general purpose)
  Freon TE35/TP35 (cold-dip cleaning)
  Freon TES (general purpose)

  It should also be noted that these solvents generally will leave the substrate surface hydrophobic (moisture repellent), which is desirable.

  Prelete or 1,1,1-Trichloroethane
  Kester 5120/5121
- A defluxer system which allows the workpiece to be subjected to a solvent vapor, followed by a rinse in pure solvent and a high-pressure spray lance are the basic requirments for low-volume production.
- For volume production, a conveyorized, multiple hot solvent spray/jet system is recommended.
- Rosin, being a natural occurring material, is not readily soluble in solvents, and has long been a stumbling block to the cleaning process. In recent developments, synthetic flux (SA flux), which is readily soluble in Freon TMS solvent, has been developed. This should be explored where permissible.

The dangers of an inadequate cleaning cycle are:

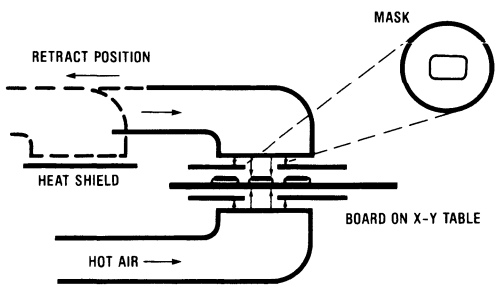
- Ion contamination, where ionic residue left on boards would cause corrosion to metallic components, affecting the performance of the board.
- Electro-migration, where ionic residue and moisture present on electrically-biased boards would cause dentritic growth between close spacing traces on the substrate, resulting in failures (shorts).

REWORK

Should there be a need to replace a component or re-align a previously disturbed component, a hot air system with appropriate orifice masking to protect surrounding components may be used.

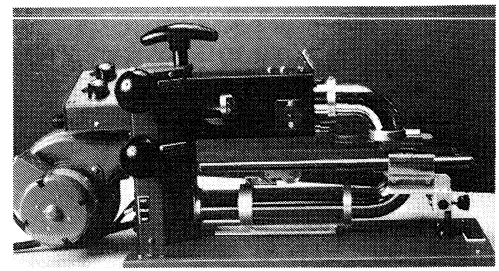
When rework is necessary in the field, specially-designed tweezers that thermally heat the component may be used to remove it from its site. The replacement can be fluxed at the lead tips or, if necessary, solder paste can be dispensed onto the pads using a varimeter. After being placed into position, the solder is reflowed by a hot-air jet or even a standard soldering iron.

Hot-Air Solder Rework Station



TL/DD/11325–34

Hot-Air Rework Machine



TL/DD/11325–35

WAVE SOLDERING

In a case where lead insertions are made on the same board as surface-mounted components, there is a need to include a wave-soldering operation in the process flow.

Two options are used:

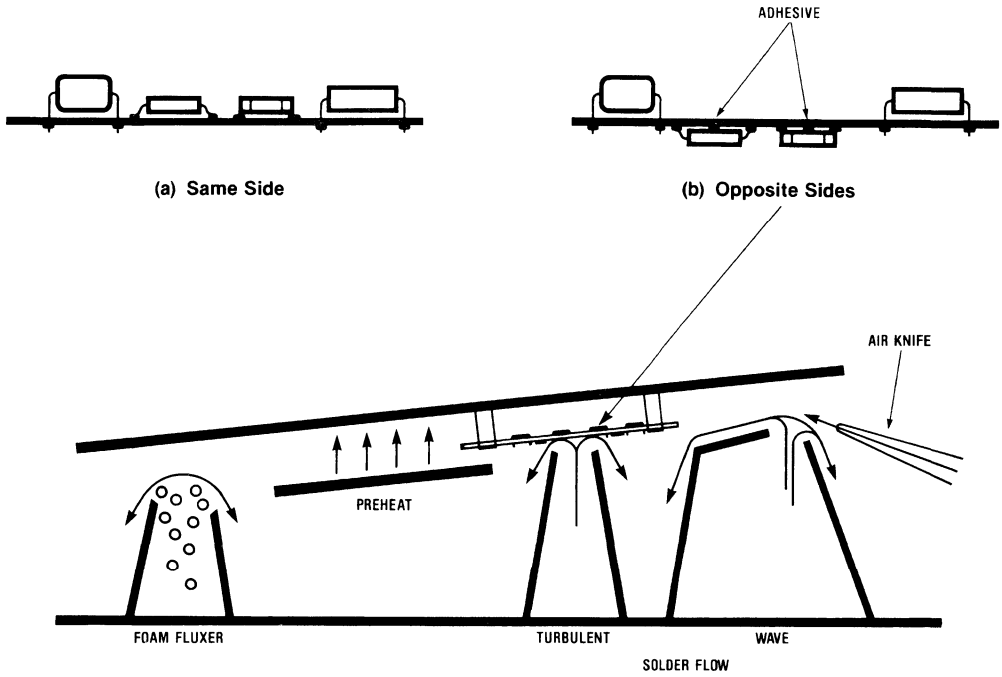
- Surface mounted components are placed and vapor phase reflowed before auto-insertion of remaining components. The board is carried over a standard wave-solder system and the underside of the board (only lead-inserted leads) soldered.
- Surface-mounted components are placed in position, but no solder paste is used. Instead, a drop of adhesive about 5 mils maximum in height with diameter not exceeding 25% width of the package is used to hold down the package. The adhesive is cured and then proceeded to auto-insertion on the reverse side of the board (surface-mounted side facing down). The assembly is then passed over a "dual wave" soldering system. Note that the surface-mounted components are immersed into the molten solder.

Lead trimming will pose a problem after soldering in the latter case, unless the leads of the insertion components are pre-trimmed or the board specially designed to localize certain areas for easy access to the trim blade.

The controls required for wave soldering are:

- Solder temperature to be 240–260°C. The dwell time of components under molten solder to be short (preferably kept under 2 seconds), to prevent damage to most components and semiconductor devices.
- RMA (Rosin Mildly Activated) flux or more aggressive OA (Organic Acid) flux are applied by either dipping or foam fluxing on boards prior to preheat and soldering. Cleaning procedures are also more difficult (aqueous, when OA flux is used), as the entire board has been treated by flux (unlike solder paste, which is more or less localized). Non-halide OA fluxes are highly recommended.
- Preheating of boards is essential to reduce thermal shock on components. Board should reach a temperature of about 100°C just before entering the solder wave.
- Due to the closer lead spacings (0.050" vs 0.100" for dual-in-line packages), bridging of traces by solder could occur. The reduced clearance between packages also causes "shadowing" of some areas, resulting in poor solder coverage. This is minimized by dual-wave solder systems.

Mixed Surface Mount and Lead Insertion



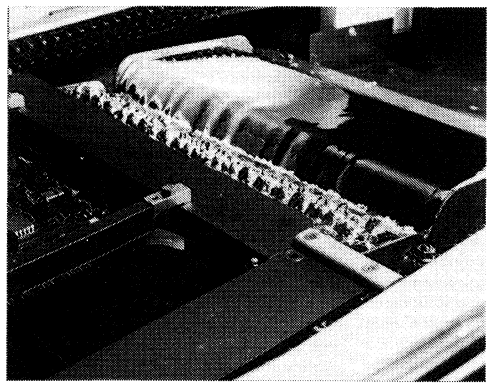
TL/DD/11325–36

A typical dual-wave system is illustrated below, showing the various stages employed. The first wave typically is in turbulence and given a transverse motion (across the motion of the board). This covers areas where "shadowing" occurs. A second wave (usually a broad wave) then proceeds to perform the standard soldering. The departing edge from the solder is such to reduce "icicles," and is still further reduced by an air knife placed close to the final soldering step. This air knife will blow off excess solder (still in the fluid stage) which would otherwise cause shorts (bridging) and solder bumps.

AQUEOUS CLEANING

- For volume production, a conveyorized system is often used with a heated recirculating spray wash (water temperature 130°C), a final spray rinse (water temperature 45–55°C), and a hot (120°C) air/air-knife drying section.
- For low-volume production, the above cleaning can be done manually, using several water rinses/tanks. Fast-drying solvents, like alcohols that are miscible with water, are sometimes used to help the drying process.
- Neutralizing agents which will react with the corrosive materials in the flux and produce material readily soluble in water may be used; the choice depends on the type of flux used.
- Final rinse water should be free from chemicals which are introduced to maintain the biological purity of the water. These materials, mostly chlorides, are detrimental to the assemblies cleaned because they introduce a fresh amount of ionizable material.

Dual Wave



TL/DD/11325–37

CONFORMAL COATING

Conformal coating is recommended for high-reliability PCBs to provide insulation resistance, as well as protection against contamination and degradation by moisture.

Requirements:

- Complete coating over components and solder joints.
- Thixotropic material which will not flow under the packages or fill voids, otherwise will introduce stress on solder joints on expansion.
- Compatibility and possess excellent adhesion with PCB material/components.
- Silicones are recommended where permissible in application.

SMD Lab Support

FUNCTIONS

Demonstration—Introduce first-time users to surface-mounting processes.

Service—Investigate problems experienced by users on surface mounting.

Reliability Builds—Assemble surface-mounted units for reliability data acquisition.

Techniques—Develop techniques for handling different materials and processes in surface mounting.

Equipment—In conjunction with equipment manufacturers, develop customized equipments to handle high density, new technology packages developed by National.

In-House Expertise—Availability of in-house expertise on semiconductor research/development to assist users on packaging queries.

National Semiconductor

Plastic Leaded Chip Carrier (PLCC) Packaging

General Description

The Plastic Leaded Chip Carrier (PLCC) is a miniaturized low cost semiconductor package designed to replace the Plastic Dual-In-Line Package (P-DIP) in high density applications. The PLCC utilizes a smaller lead-to-lead spacing—0.050" versus 0.100" - and leads on all four sides to achieve a significant footprint reduction over the P-DIP. The rolled under J-bend leadform separates this package style from other plastic quad packages with flat or gull wing lead forms. As with virtually all packages of 0.050" or less lead spacing, the PLCC requires surface mounting to printed circuit boards as opposed to the more conventional thru-hole mounting of the P-DIP.

History

The Plastic Leaded Chip Carrier with J-bend leadform was first introduced in 1976 as a premolded plastic package. The premolded version has yet to become popular but the quad format with J-Bend leads has been adapted to traditional post molded packaging technology (the same technology used to manufacture the P-DIP). In 1980 National Semiconductor developed a post molded version of the PLCC. The J-bend leadform allowed them to adopt the footprint connection pattern already registered with JEDEC for the leadless chip carrier (LCC). In 1981 a task force was organized within JEDEC to develop a PLCC registration for package I/O counts of 20, 28, 44, 52, 68, 84, 100, and 124. A registered outline was completed in 1984 (JEDEC Outline MO-047) after many changes and improvements over the original proposals. This first PLCC registration covers square packages with an equal number of leads on all sides. A second registration, MO-052, was completed in 1985 for rectangular packages with I/O counts of 18, 22, 28 and 32.

Since 1980 many additional semiconductor manufacturers and packaging subcontractors have developed PLCC capability. There are now well over 20 sources with the number growing steadily.

Surface Mounting

Surface mounting refers to component attachment whereby the component leads or pads rest on the surface of the PCB instead of the traditional approach of inserting the leads into through-holes which go through the board. With surface mounting there are solder pads on the PCB which align with the leads or pads on the component. The resulting solder joint forms both the mechanical and electrical connection.

ADVANTAGES

The primary reason for surface mounting is to allow leads to be placed closer together than the 0.100" standard for DIPs with through-hole mounting. Through-hole mounting on smaller than 0.100" spacing is difficult to achieve in production and generally avoided. The move to 0.050" lead spacing offered with the current generation of surface mounted components, along with a switch from a dual-in-line format to a quad format, has achieved a threefold increase in component mounting density. A need to achieve greater density is a major driving force in today's marketplace.

MANUFACTURING TECHNIQUES

Learning how to surface mount components to printed circuit boards requires the user to become educated in new assembly processes not typically associated with through-hole insertion/wave soldering assembly methods.

Surface mounting involves three basic process steps:

1) Application of solder or solder paste to the printed circuit board.
2) Positioning of the component onto the printed circuit board
3) Reflowing of the solder or solder paste.

As with any process, there are many details involved to achieve acceptable throughput and acceptable quality. National Semiconductor offers a surface mounting guide which deals with the specifics of successful surface mounting. We encourage the user to review this document and to contact us if further information on surface mounting is desired.

Benefits of the PLCC

There are four principle advantages offered the user by switching from P-DIP to PLCC. These four advantages are outlined below as follows:

1. Increased Density—
   - — Typically 3-to-1 size reduction of printed circuit boards. See *Figure 1* for a footprint comparison between PLCC and P-DIP. This can be as high as 6-to-1 in certain applications.
   - — Surface mounting allows components to be placed on both sides of the board.
   - — Surface mount and thru-hole mount components can be placed on the same board.
   - — The large diameter thru-holes can be reduced in number, entirely eliminated, or reduced in size (if needed for via connection).
2. Increased Performance—
   - — Shorter traces on printed circuit boards.
   - — Better high frequency operation.
   - — Shorter leads in package. *Figure 2* and Table I compare PLCC and P-DIP mechanical and electrical characteristics.
3. Increased Reliability—
   - — Leads are well protected.
   - — Fewer connectors.
   - — Simplified rework.
   - — Vibration and shock resistant.
4. Reduced Cost—
   - — Fewer or smaller printed circuit boards.
   - — Less hardware.
   - — Same low cost printed circuit board material.
   - — Plastic packaging material.
   - — Reduced number of costly plated-through-holes.
   - — Fewer circuit layers.

Package Design Criteria

Experience has taught us there are certain criteria to the PLCC design which must be followed to provide the user with the proper mechanical and thermal performance. These requirements should be carefully reviewed by the user when selecting suppliers for devices in PLCC. Some of these are covered by the JEDEC registration and some are not. These important requirements are listed in Table IV.

Reliability

National Semiconductor utilizes an assembly process for the PLCC which is similar to our P-DIP assembly process. We also utilize identical materials. This is a very important point when considering reliability. Many years of research and development have gone into steadily improving our P-DIP quality and maintaining a leadership position in plastic package reliability. All of this technology can be directly applied to the PLCC. Table V shows the results of applying this technology to the PLCC. As we make further advances in plastic package reliability, these will also be applied to the PLCC.

Sockets

There are several manufacturers currently offering sockets for the plastic chip carrier. Following is a listing of those manufacturers. The listing is divided into test/burn-in and production categories. There may be some individual sockets that will cover both requirements.

TABLE IV. Package Design Criteria

Criteria	Required to Comply with JEDEC Registration
Minimum Inside Bend Radius of Lead at Shoulder Equal or Greater than Lead Thickness—to Prevent Lead Cracking/Fatigue	Not Required
Minimum One Mil Clearance Between Lead and Plastic Body at all Points—to Provide Lead Compliancy and Prevent Shoulder Joint Cracking/Fatigue	Not Required
Copper Leads for Low Thermal Resistance	Not Required
Minimum 10 Mil Lead Thickness for Low Thermal Resistance and Good Handling Properties	Not Required
Minimum 26 Mil Lead Shoulder Width to Prevent Interlocking of Devices During Handling	Yes
Maximum 4 Mils coplanarity Across Seating Plane of all Leads	Yes

TABLE V. Reliability Test Data
(Expressed as Failures per Units Tested)

Device/Package	OPL	TMCL	TMSK	BHTL	ACLV

COP8™ DATABOOK—1996/1997

COP8 Family • COP8 OTP Products • COP8 32K OTP Products • COP8 Basic Family Products
COP8 Feature Family Products • MICROWIRE/PLUS Peripherals • COP8 Applications

CROSSVOLT™ LOW VOLTAGE LOGIC SERIES DATABOOK AND DESIGN GUIDE—1996

LCX Family • LVX Translator Family • LVX Bus Switch Family • LVX Family • LVQ Family • LVT Family
ALCX Family • GTL Family

DATA ACQUISITION DATABOOK—1995

Data Acquisition Systems • Analog-to-Digital Converters • Digital-to-Analog Converters • Voltage References
Temperature Sensors • Active Filters • Analog Switches/Multiplexers • Surface Mount

DATA ACQUISITION DATABOOK SUPPLEMENT—1992

New devices released since the printing of the 1989 Data Acquisition Linear Devices Databook.

DISCRETE SEMICONDUCTOR PRODUCTS DATABOOK—1989

Selection Guide and Cross Reference Guides • Diodes • Bipolar NPN Transistors
Bipolar PNP Transistors • JFET Transistors • Surface Mount Products • Pro-Electron Series
Consumer Series • Power Components • Transistor Datasheets • Process Characteristics

DRAM MANAGEMENT HANDBOOK—1993

Dynamic Memory Control • CPU Specific System Solutions • Error Detection and Correction
Microprocessor Applications

EEPROM MEMORY DATABOOK—1996

CMOS EEPROMs • Plug and Play Devices • Application Notes

EMBEDDED CONTROLLERS DATABOOK—1992

COP400 Family • COP800 Family • COPS Applications • HPC Family • HPC Applications
MICROWIRE and MICROWIRE/PLUS Peripherals • Microcontroller Development Tools

ETHERNET DATABOOK—1996

Integrated Network Interface Controller Products • 10 Mb/s Physical Layer Transceivers and ENDECs
10 Mb/s Repeater Interface Controller Products • 100 Mb/s Fast Ethernet Protocol Products
Glossary and Acronyms

FDDI DATABOOK—1994

Datasheets • Application Notes

F100K ECL LOGIC DATABOOK & DESIGN GUIDE—1992

Family Overview • 300 Series (Low-Power) Datasheets • 100 Series Datasheets • 11C Datasheets
Design Guide • Circuit Basics • Logic Design • Transmission Line Concepts • System Considerations
Power Distribution and Thermal Considerations • Testing Techniques • 300 Series Package Qualification
Quality Assurance and Reliability • Application Notes

FACT™ ADVANCED CMOS LOGIC DATABOOK—1993

Description and Family Characteristics • Ratings, Specifications and Waveforms
Design Considerations • 54AC/74ACXXX • 54ACT/74ACTXXX • Quiet Series: 54ACQ/74ACQXXX
Quiet Series: 54ACTQ/74ACTQXXX • 54FCT/74FCTXXX • FCTA: 54FCTXXXA/74FCTXXXA/B

FAST® APPLICATIONS HANDBOOK—1990

Reprint of 1987 Fairchild FAST Applications Handbook
Contains application information on the FAST family: Introduction • Multiplexers • Decoders • Encoders
Operators • FIFOs • Counters • TTL Small Scale Integration • Line Driving and System Design
FAST Characteristics and Testing • Packaging Characteristics

HIGH-PERFORMANCE BUS INTERFACE DATABOOK—1994

QuickRing • Futurebus+/BTL Devices • BTL Transceiver Application Notes • Futurebus+ Application Notes
High Performance TTL Bus Drivers • PI-Bus • Futurebus+/BTL Reference

IBM DATA COMMUNICATIONS HANDBOOK—1992

IBM Data Communications • Application Notes

INTERFACE DATABOOK—1996

LVDS Circuits, Bus Circuits, Data Transmission Circuits, System Design Guide

LINEAR APPLICATIONS HANDBOOK—1994

The purpose of this handbook is to provide a fully indexed and cross-referenced collection of linear integrated circuit applications using both monolithic and hybrid circuits from National Semiconductor.

Individual application notes are normally written to explain the operation and use of one particular device or to detail various methods of accomplishing a given function. The organization of this handbook takes advantage of this innate coherence by keeping each application note intact, arranging them in numerical order, and providing a detailed Subject Index.

LOW VOLTAGE DATABOOK—1992

This databook contains information on National's expanding portfolio of low and extended voltage products. Product datasheets included for: Low Voltage Logic (LVQ), Linear, EPROM, EEPROM, SRAM, Interface, ASIC, Embedded Controllers, Real Time Clocks, and Clock Generation and Support (CGS).

MASS STORAGE HANDBOOK—1989

Rigid Disk Pulse Detectors • Rigid Disk Data Separators/Synchronizers and ENDECs
Rigid Disk Data Controller • SCSI Bus Interface Circuits • Floppy Disk Controllers • Disk Drive Interface Circuits
Rigid Disk Preamplifiers and Servo Control Circuits • Rigid Disk Microcontroller Circuits • Disk Interface Design Guide

MEMORY APPLICATIONS HANDBOOK—1994

FLASH • EEPROMs • EPROMs • Application Notes

OPERATIONAL AMPLIFIERS DATABOOK—1995

Operational Amplifiers • Buffers • Voltage Comparators • Active Matrix/LCD Display Drivers
Special Functions • Surface Mount

PACKAGING DATABOOK—1993

Introduction to Packaging • Hermetic Packages • Plastic Packages • Advanced Packaging Technology
Package Reliability Considerations • Packing Considerations • Surface Mount Considerations

POWER IC's DATABOOK—1995

Linear Voltage Regulators • Low Dropout Voltage Regulators • Switching Voltage Regulators
Motion Control • Surface Mount

PRODUCTS FOR WIRELESS COMMUNICATIONS—1997

Radio Transceiver Components • Baseband Processing Components • Control and Signal Processing Components
Non-Volatile Memory • Audio Interface Components • Support Circuitry • Power Management
Complete Cordless Phone Solution

PROGRAMMABLE LOGIC DEVICE DATABOOK AND DESIGN GUIDE—1993

Product Line Overview • Datasheets • Design Guide: Designing with PLDs • PLD Design Methodology
PLD Design Development Tools • Fabrication of Programmable Logic • Application Examples

REAL TIME CLOCK HANDBOOK—1993

3-Volt Low Voltage Real Time Clocks • Real Time Clocks and Timer Clock Peripherals • Application Notes

RELIABILITY HANDBOOK—1987

Reliability and the Die • Internal Construction • Finished Package • MIL-STD-883 • MIL-M-38510
The Specification Development Process • Reliability and the Hybrid Device • VLSI/VHSIC Devices
Radiation Environment • Electrostatic Discharge • Discrete Device • Standardization
Quality Assurance and Reliability Engineering • Reliability and Documentation • Commercial Grade Device
European Reliability Programs • Reliability and the Cost of Semiconductor Ownership
Reliability Testing at National Semiconductor • The Total Military/Aerospace Standardization Program
883B/RETS™ Products • MILS/RETS™ Products • 883/RETS™ Hybrids • MIL-M-38510 Class B Products
Radiation Hardened Technology • Wafer Fabrication • Semiconductor Assembly and Packaging
Semiconductor Packages • Glossary of Terms • Key Government Agencies • AN/ Numbers and Acronyms
Bibliography • MIL-M-38510 and DESC Drawing Cross Listing

SCAN DATABOOK—1996

Design for Test Solutions • Description of Boundary SCAN • SCAN ABT Test Access Logic • SCAN CMOS Test Access Logic System Test Devices and Software • Application Notes

TELECOMMUNICATIONS—1994

COMBO and SLIC Devices • ISDN • Digital Loop Devices • Analog Telephone Components • Software • Application Notes

VHC ADVANCED CMOS LOGIC DATABOOK—1996

This databook introduces National's Very High Speed CMOS (VHC) and Very High Speed TTL Compatible CMOS (VHCT) designs. The databook includes Description and Family Characteristics • Ratings, Specifications and Waveforms Design Considerations • VHC Family Datasheets • VHC Specialty Function Datasheets and related Application Notes. The topics discussed are the advantages of VHC/VHCT AC Performance, Low Noise Characteristics and Improved Interface Capabilities.
