The delay time is controlled by the Reset Delay Low Voltage, Delay Switching Threshold, and the Delay Charge Current. The delay follows the equation:

$$
\text { tDELAY }=\frac{\left[\text { CDELAY }\left(\mathrm{V}_{\mathrm{dt}}-\text { Reset Delay Low Voltage }\right)\right]}{\text { Delay Charge Current }}
$$

Example:
Using C $_{\text {DELAY }}=33 \mathrm{nF}$.
Assume reset Delay Low Voltage $=0$.
Use the typical value for $\mathrm{V}_{\mathrm{dt}}=1.8 \mathrm{~V}$.
Use the typical value for Delay Charge Current $=3.0 \mu \mathrm{~A}$.

$$
\text { tDELAY }=\frac{[33 \mathrm{nF}(1.8-0)]}{3.0 \mu \mathrm{~A}}=19.8 \mathrm{~ms}
$$

## STABILITY CONSIDERATIONS

The output or compensation capacitor helps determine three main characteristics of a linear regulator: start-up delay, load transient response and loop stability.

The capacitor value and type should be based on cost, availability, size and temperature constraints. A tantalum or aluminum electrolytic capacitor is best, since a film or ceramic capacitor with almost zero ESR can cause instability. The aluminum electrolytic capacitor is the least expensive solution, but, if the circuit operates at low temperatures $\left(-25^{\circ} \mathrm{C}\right.$ to $\left.-40^{\circ} \mathrm{C}\right)$, both the value and ESR of the capacitor will vary considerably. The capacitor manufacturers data sheet usually provides this information.

The value for the output capacitor Cout shown in Figure 8 should work for most applications, however it is not necessarily the optimized solution.

${ }^{*} \mathrm{C}_{\text {IN }}$ required if regulator is located far from the power supply filter
${ }^{* *}$ Cout required for stability. Capacitor must operate at minimum temperature expected

Figure 8. Test and Application Circuit Showing Output Compensation

## CALCULATING POWER DISSIPATION IN A SINGLE OUTPUT LINEAR REGULATOR

The maximum power dissipation for a single output regulator (Figure 9) is:

$$
\begin{align*}
\mathrm{PD}(\max )^{=} & {\left[\mathrm{VIN}_{\operatorname{IN}(\max )}-\mathrm{VOUT}_{\mathrm{min})}\right) \operatorname{lOUT}(\max ) }  \tag{1}\\
& +\mathrm{V}_{\mathrm{IN}(\max )} \mathrm{I} \mathrm{Q}
\end{align*}
$$

where:
$\mathrm{V}_{\mathrm{IN}(\max )}$ is the maximum input voltage,
$\mathrm{V}_{\text {OUT }(\mathrm{min})}$ is the minimum output voltage,
IOUT(max) is the maximum output current for the application, and
$\mathrm{I}_{\mathrm{Q}}$ is the quiescent current the regulator consumes at
$I_{O U T(m a x)}$.
Once the value of $\mathrm{P}_{\mathrm{D}(\max )}$ is known, the maximum permissible value of $\mathrm{R}_{\Theta J A}$ can be calculated:

$$
\begin{equation*}
\mathrm{R}_{\Theta J A}=\frac{150^{\circ} \mathrm{C}-\mathrm{T}_{\mathrm{A}}}{\mathrm{P}_{\mathrm{D}}} \tag{2}
\end{equation*}
$$

The value of $\mathrm{R}_{\Theta \mathrm{JA}}$ can then be compared with those in the package section of the data sheet. Those packages with $\mathrm{R}_{\Theta J A}$ 's less than the calculated value in equation 2 will keep the die temperature below $150^{\circ} \mathrm{C}$.
In some cases, none of the packages will be sufficient to dissipate the heat generated by the IC, and an external heatsink will be required.

Figure 9. Single Output Regulator with Key Performance Parameters Labeled

## HEAT SINKS

A heat sink effectively increases the surface area of the package to improve the flow of heat away from the IC and into the surrounding air.

Each material in the heat flow path between the IC and the outside environment will have a thermal resistance. Like series electrical resistances, these resistances are summed to determine the value of $\mathrm{R}_{\Theta J A}$ :

$$
\begin{equation*}
R_{\Theta J A}=R_{\Theta J C}+R_{\Theta C S}+R_{\Theta S A} \tag{3}
\end{equation*}
$$

where:
$\mathrm{R}_{\Theta \mathrm{JJC}}=$ the junction-to-case thermal resistance,
$\mathrm{R}_{\Theta C S}=$ the case-to-heatsink thermal resistance, and
$\mathrm{R}_{\Theta S A}=$ the heatsink-to-ambient thermal resistance.
$\mathrm{R}_{\Theta \mathrm{JC}}$ appears in the package section of the data sheet. Like $R_{\Theta J A}$, it too is a function of package type. $R_{\Theta C S}$ and $R_{\Theta S A}$ are functions of the package type, heatsink and the interface between them. These values appear in heat sink data sheets of heat sink manufacturers.

## NCV8508 Series

## Advance Information <br> Low Dropout Linear Regulators with Watchdog, RESET, and Wake Up

The NCV8508 is a precision micropower voltage regulator family. The part contains many of the required operational requirements for powering microprocessors. Its robustness makes it suitable for severe automotive environments. The devices low dropout voltage ensures operation of loads (i.e. microprocessors) when the battery voltage is low such as during the cranking cycle of an automobile. In addition to being a good fit for the automotive environment, the NCV8508 is ideal for use in battery operated, microprocessor controlled equipment because of its extremely low quiescent current.

## Features

- Output Voltage Options: 3.3 V or 5.0 V
- $\pm 3.0 \%$ Output Voltage
- IOUT Up to 250 mA
- Quiescent Current Independent of Load
- Micropower Compatible Control Functions:
- Wake Up
- Watchdog
- $\overline{\text { RESET }}$
- Low Dropout Voltage
- Low Quiescent Current (100 $\mu \mathrm{A}$ typ)
- Protection Features:
- Thermal Shutdown
- Short Circuit
- 45 V Operation
- Internally Fused Leads in SO-16L Package

## DEFINITION OF TERMS

Dropout Voltage: The input-output voltage differential at which the circuit ceases to regulate against further reduction in input voltage. Measured when the output voltage has dropped 100 mV from the nominal value obtained at 14 V input, dropout voltage is dependent upon load current and junction temperature.

Input Voltage: The DC voltage applied to the input terminals with respect to ground.

Line Regulation: The change in output voltage for a change in the input voltage. The measurement is made under conditions of low dissipation or by using pulse techniques
such that the average chip temperature is not significantly affected.

Load Regulation: The change in output voltage for a change in load current at constant chip temperature.

Quiescent Current: The part of the positive input current that does not contribute to the positive load current. The regulator ground lead current.

Ripple Rejection: The ratio of the peak-to-peak input ripple voltage to the peak-to-peak output ripple voltage.

Current Limit: Peak current that can be delivered to the output.

## DETAILED OPERATING DESCRIPTION

The NCV8508 is a precision micro-power voltage regulator with very low quiescent current $(100 \mu \mathrm{~A}$ typical at 250 mA load). A typical dropout voltage is 425 mV at 150 mA . Microprocessor control logic includes Watchdog,

Wake Up and RESET. This unique combination of extremely low quiescent current and full microprocessor control makes the NCV8508 ideal for use in battery
operated, microprocessor controlled equipment in addition to being a good fit in the automotive environment.

The NCV8508 Wake Up function brings the microprocessor out of Sleep mode. The microprocessor in turn, signals its Wake Up status back to the NCV8508 by issuing a Watchdog signal.

The Watchdog logic function monitors an input signal (WDI) from the microprocessor. The NCV8508 responds to the falling edge of the Watchdog signal which it expects at least once during each wake-up period. When the correct Watchdog signal is received, a falling edge is issued on the wake-up signal line.
$\overline{\text { RESET }}$ is independent of $\mathrm{V}_{\text {IN }}$ and operates correctly to an output voltage as low as 1.0 V . A signal is issued in any of three situations. During power up the $\overline{\operatorname{RESET}}$ is held low until the output voltage is in regulation. During operation if
the output voltage shifts below the regulation limits, the $\overline{\text { RESET }}$ toggles low and remains low until proper output voltage regulation is restored. And finally, a $\overline{\text { RESET }}$ signal is issued if the regulator does not receive a Watchdog signal within the Wake Up period.

The RESET pulse width, Wake Up signal frequency, and Wake Up delay time are all set by one external resistor, $\mathrm{R}_{\text {Delay }}$.
The Delay pin is a buffered bandgap voltage (1.25 V). It can be used as a reference for an external tracking regulator like the CS8182.

The regulator is protected against short circuit and thermal runaway conditions. The device runs through 45 volt transients, making it suitable for use in automotive environments.

## CIRCUIT DESCRIPTION

## Functional Description

To reduce the drain on the battery a system can go into a low current consumption mode when ever its not performing a main routine. The Wake Up signal is generated continuously and is used to interrupt a microcontroller that is in sleep mode. The nominal output is a 5.0 volt square wave with a duty cycle of $50 \%$ at a frequency that is determined by a timing resistor, $\mathrm{R}_{\text {Delay }}$.

When the microprocessor receives a rising edge from the Wake Up output, it must issue a watchdog pulse and check its inputs to decide if it should resume normal operations or remain in the sleep mode.

The first falling edge of the watchdog signal causes the Wake Up to go low within $2.0 \mu \mathrm{~s}$ (typ) and remain low until the next Wake Up cycle (see Figure 15). Other watchdog pulses received within the same cycle are ignored (Figure 3).

During power up, $\overline{\mathrm{RESET}}$ is held low until the output voltage is in regulation. During operation, if the output voltage shifts below the regulation limits, the $\overline{\text { RESET }}$ toggles low and remains low until proper output voltage regulation is restored. After the $\overline{\text { RESET }}$ delay, $\overline{\text { RESET }}$ returns high.

The Watchdog circuitry continuously monitors the input watchdog signal (WDI) from the microprocessor. The absence of a falling edge on the Watchdog input during one Wake Up cycle will cause a RESET pulse to occur at the end of the Wake Up cycle. (see Figure 4).

The Wake Up output is pulled low during a $\overline{\text { RESET }}$ regardless of the cause of the $\overline{\text { RESET. After the } \overline{\text { RESET }}}$ returns high, the Wake Up cycle begins again (see Figure 4).

The RESET Delay Time, Wake Up signal frequency and $\overline{\text { RESET }}$ high to Wake Up delay time are all set by one external resistor $\mathrm{R}_{\text {Delay. }}$

Wake Up period $=\left(4.17 \times 10^{-7}\right) \mathrm{R}_{\text {Delay }}$
$\overline{\text { RESET }}$ Delay Time $=\left(5.21 \times 10^{-8}\right)$ R Delay
$\overline{\text { RESET }}$ HIGH to Wake Up Delay Time $=\left(2.08 \times 10^{-7}\right) \mathrm{R}_{\text {Delay }}$

Capacitor temperature coefficient and tolerance as well as the tolerance of the NCV8508 must be taken into account in order to get the correct system tolerance for each parameter.

Figure 16. Wake Up Response to RESET (Low Voltage)

## NCV8508 Series

## APPLICATION NOTES

## Calculating Power Dissipation in a Single Output Linear Regulator

The maximum power dissipation for a single output regulator (Figure 17) is:

$$
\begin{align*}
\left.\mathrm{PD}_{\mathrm{D}} \max \right)= & {\left[\mathrm{V}_{\mathrm{IN}(\max )}-\mathrm{V}_{\mathrm{OUT}}(\min )\right] \mathrm{IOUT}(\max ) }  \tag{1}\\
& +\mathrm{V}_{\mathrm{IN}(\max )} \mathrm{Q} \mathrm{Q}
\end{align*}
$$

where:
$\mathrm{V}_{\mathrm{IN}(\text { max })}$ is the maximum input voltage,
$\mathrm{V}_{\text {OUT }(\mathrm{min})}$ is the minimum output voltage,
IOUT(max) is the maximum output current for the application, and
$\mathrm{I}_{\mathrm{Q}}$ is the quiescent current the regulator consumes at
IOUT(max).

Figure 17. Single Output Regulator with Key Performance Parameters Labeled
Once the value of $\mathrm{P}_{\mathrm{D}(\max )}$ is known, the maximum permissible value of $\mathrm{R}_{\Theta \mathrm{JA}}$ can be calculated:

$$
\begin{equation*}
\mathrm{R}_{\Theta J A}=\frac{150^{\circ} \mathrm{C}-\mathrm{T}_{\mathrm{A}}}{\mathrm{P}_{\mathrm{D}}} \tag{2}
\end{equation*}
$$

The value of $\mathrm{R}_{\Theta \mathrm{JA}}$ can then be compared with those in the package section of the data sheet. Those packages with $\mathrm{R}_{\Theta \mathrm{JA}}$ 's less than the calculated value in equation 2 will keep the die temperature below $150^{\circ} \mathrm{C}$.

In some cases, none of the packages will be sufficient to dissipate the heat generated by the IC, and an external heatsink will be required.

## Heat Sinks

A heat sink effectively increases the surface area of the package to improve the flow of heat away from the IC and into the surrounding air.

Each material in the heat flow path between the IC and the outside environment will have a thermal resistance. Like series electrical resistances, these resistances are summed to determine the value of $\mathrm{R}_{\Theta J A}$ :

$$
\begin{equation*}
R_{\Theta J A}=R_{\Theta J C}+R_{\Theta C S}+R_{\Theta S A} \tag{3}
\end{equation*}
$$

where:
$\mathrm{R}_{\Theta \mathrm{JC}}=$ the junction-to-case thermal resistance,
$\mathrm{R}_{\Theta C S}=$ the case-to-heatsink thermal resistance, and
$\mathrm{R}_{\Theta S A}=$ the heatsink-to-ambient thermal resistance.
$\mathrm{R}_{\Theta \mathrm{JC}}$ appears in the package section of the data sheet. Like $R_{\Theta J A}$, it too is a function of package type. $R_{\Theta C S}$ and $R_{\Theta S A}$ are functions of the package type, heatsink and the interface between them. These values appear in heat sink data sheets of heat sink manufacturers.

## CS5101

## Secondary Side Post Regulator for AC/DC and DC/DC Multiple Output Converters

The CS5101 is a bipolar monolithic secondary side post regulator (SSPR) which provides tight regulation of multiple output voltages in AC-DC or DC-DC converters. Leading edge pulse width modulation is used with the CS5101.

The CS5101 is designed to operate over an 8.0 V to 45 V supply voltage ( $\mathrm{V}_{\mathrm{CC}}$ ) range and up to a 75 V drive voltage $\left(\mathrm{V}_{\mathrm{C}}\right)$.

The CS5101 features include a totem pole output with 1.5 A peak output current capability, externally programmable overcurrent protection, an on chip $2.0 \%$ precision 5.0 V reference, internally compensated error amplifier, externally synchronized switching frequency, and a power switch drain voltage monitor. It is available in a 14 lead plastic DIP or a 16 lead wide body SO package.

## Features

- 1.5 A Peak Output (Grounded Totem Pole)
- 8.0 V to 75 V Gate Drive Voltage
- 8.0 V to 45 V Supply Voltage
- 300 ns Propagation Delay
- $1.0 \%$ Error Amplifier Reference Voltage
- Lossless Turn On and Turn Off
- Sleep Mode: < $100 \mu \mathrm{~A}$
- Overcurrent Protection with Dedicated Differential Amp
- Synchronization to External Clock
- External Power Switch Drain Voltage Monitor

## CIRCUIT DESCRIPTION

Figure 2. Block Diagram

## Theory of Operation

The CS5101 is designed to regulate voltages in multiple output power supplies. Functionally, it is similar to a magnetic amplifier, operating as a switch with a delayed turn-on. It can be used with both single ended and dual ended topologies.

The $\mathrm{V}_{\mathrm{FB}}$ voltage is monitored by the error amplifier EA. It is compared to an internal reference voltage and the amplified differential signal is fed through an inverting amplifier into the buffer, BUF. The buffered signal is compared at the PWM comparator with the ramp voltage generated by capacitor $C_{R}$. When the ramp voltage $V_{R}$, exceeds the control voltage $\mathrm{V}_{\mathrm{C}}$, the output of the PWM comparator goes high, latching its state through the LATCH, the output stage transistor $\mathrm{Q}_{1}$ turns on, and the external power switch, usually an $\mathrm{N}-\mathrm{FET}$, turns on.

## SYNC Function

The SYNC circuit is activated at time $t_{1}$ (Figure 3) when the voltage at the SYNC pin exceeds the threshold level (2.5V) of the SYNC comparator. The external ramp capacitor $C_{R}$ is allowed to charge through the internal current source $I(200 \mu \mathrm{~A})$. At time $t_{2}$, the ramp voltage intersects with the control voltage $\mathrm{V}_{\mathrm{C}}$ and the output of the PWM comparator goes high, turning on the output stage and the external power switch. At the same time, the PWM comparator is latched by the RS latch, LATCH.

Figure 3. Waveforms for CS5101. The Number to the Left of Each Curve Refers to a Node On the Application Diagram on Page 956.

The logic state of the LATCH can be changed only when both the voltage level of the trailing edge of the power pulse at the SYNC pin is less than the threshold voltage of the SYNC comparator ( 2.5 V ) and the RAMP voltage is less than the threshold voltage of the RAMP comparator (1.65 V). On the negative going transition of the secondary side pulse $\mathrm{V}_{\mathrm{SY}}$, gate $\mathrm{G}_{2}$ output goes high, resetting the latch at time $\mathrm{t}_{3}$. Capacitor $C_{R}$ is discharged through transistor $Q_{4} . C_{R}$ 's output goes low disabling the output stage, and the external power switch (an N-FET) is turned off.

## RAMP Function

The value of the ramp capacitor $C_{R}$ is based on the switching frequency of the regulator and the maximum duty cycle of the secondary pulse $\mathrm{V}_{\mathrm{SY}}$.
If the RAMP pin is pulled externally to 0.3 V or below, the SSPR is disabled. Current drawn by the IC is reduced to less than $100 \mu \mathrm{~A}$, and the IC is in SLEEP mode.

## FAULT Function

The voltage at the $\mathrm{V}_{\mathrm{CC}}$ pin is monitored by the undervoltage lockout comparator with hysteresis. When $\mathrm{V}_{\mathrm{CC}}$ falls below the UVL threshold, the 5.0 V reference and all the circuitry running off of it is disabled. Under this condition the supply current is reduced to less than $500 \mu \mathrm{~A}$.
The $\mathrm{V}_{\mathrm{CC}}$ supply voltage is further monitored by the $\mathrm{V}_{\mathrm{CC}}$ OK comparator. When $\mathrm{V}_{\mathrm{CC}}$ is reduced below $\mathrm{V}_{\mathrm{REF}}$ -0.7 V , a fault signal is sent to gate $\mathrm{G}_{1}$. This fault signal, which determines if $\mathrm{V}_{\mathrm{CC}}$ is absent, works in conjunction with the ramp signal to disable the output, but only after the current cycle has finished and the RS latch is reset. Therefore this fault will not cause the output to turn off during the middle of an on pulse, but rather will utilize lossless turn-off. This feature protects the FET from overvoltage stress. This is accomplished through gate $G_{1}$ by driving transistor $\mathrm{Q}_{4}$ on.

An additional fault signal is derived from the REF_OK comparator. $\mathrm{V}_{\text {REF }}$ is monitored so to disable the output through gate $G_{1}$ when the $V_{\text {REF }}$ voltage falls below the OK threshold. As in the $\mathrm{V}_{\mathrm{CC}}$ _OK fault, the REF_OK fault disables the output after the current cycle has been completed. The fault logic will operate normally only when $\mathrm{V}_{\mathrm{REF}}$ voltage is within the specification limits of REF_OK.

## DRAIN Function

The drain pin, $\mathrm{V}_{\mathrm{D}}$ monitors the voltage on the drain of the power switch and derives energy from it to keep the output stage in an off state when $\mathrm{V}_{\mathrm{C}}$ or $\mathrm{V}_{\mathrm{CC}}$ is below the minimum specified voltage.

## NCP4300A

## Dual Operational Amplifier and Voltage Reference

The NCP4300A is a monolithic integrated circuit specifically designed to control the output current and voltage levels of switch mode battery chargers and power supplies. This device contains a precision 2.6 V shunt reference and two operational amplifiers. Op-Amp 1 is designed to perform voltage control and has its non-inverting input internally connected to the reference. Op-Amp 2 is designed for current control and has both inputs uncommitted. The NCP4300A offers the power converter designer a control solution that features increased precision with a corresponding reduction in system complexity and cost. This device is available in an 8-lead surface mount package.

## Features

## Operational Amplifier

- Low Input Offset Voltage: 0.5 mV
- Input Common Mode Voltage Range Includes Ground
- Low Supply Current: $210 \mu \mathrm{~A} / \mathrm{Op}-\mathrm{Amp}\left(@ \mathrm{~V}_{\mathrm{CC}}=5.0 \mathrm{~V}\right.$ )
- Medium Unity Gain Bandwidth: 0.7 MHz
- Large Output Voltage Swing: 0 V to $\mathrm{V}_{\mathrm{CC}}-1.5 \mathrm{~V}$
- Wide Power Supply Voltage Range: 3.0 V to 35 V

## Voltage Reference

- Fixed Output Voltage Reference: 2.60 V
- High Precision Over Temperature: $1.0 \%$
- Wide Sink Current Range: $80 \mu \mathrm{~A}$ to 80 mA

## Typical Applications

- Battery Charger
- Switch Mode Power Supply

## DETAILED OPERATING DESCRIPTION

## INTRODUCTION

Power supplies and battery chargers require precise control of output voltage and current in order to prevent catastrophic damage to the system connected. Many present day power sources contain a wide assortment of building blocks and glue devices to perform the required sensing for proper regulation. Typical feedback loop circuits may consist of a voltage and current amplifier, summing circuitry and a reference. The NCP4300A contains all of these basic functions in a manner that is easily adaptable to many of the various power source-load configurations.

## OPERATING DESCRIPTION

The NCP4300A is an analog regulation control circuit that is designed to simultaneously close the voltage and current feedback loops in power supply and battery charger applications. This device can control the feedback loop in either constant-voltage (CV) or constant-current (CC) mode with smooth crossover. A concise description of the integrated circuit blocks is given in below. The functional block diagram of the IC is shown in Figure 1.

## Internal Reference

An internal precision band gap reference is used to set the 2.6 V voltage threshold and current threshold setting. The
reference is initially trimmed to a $\pm 0.5 \%$ tolerance at $\mathrm{T}_{\mathrm{A}}=25^{\circ} \mathrm{C}$ and is guaranteed to be within $\pm 1.0 \%$ over an ambient temperature range of $0^{\circ} \mathrm{C}$ to $105^{\circ} \mathrm{C}$.

## Voltage Sensing Operational Amplifier (Op-Amp 1)

The internal Op-Amp 1 is designed to perform the voltage control function. The non-inverting input of the op-amp is connected to the precision voltage reference internally. The inverting input of the op-amp monitors the voltage information derived from the system output. As the control threshold is internally connected to the voltage reference, the voltage regulation threshold is fixed at 2.6 V . For any output voltage from 2.6 V up to the maximum limit can be configurated with an external resistor divider. The output terminal of Op-Amp 1 (pin 1) provides the error signal for output voltage control. The output pin also provides a means for external compensation.

## Independent Operational Amplifier (Op-Amp 2)

The internal Op-Amp 2 is configurated as a general purpose op-amp with all terminals available for the user. With the low offset voltage provided, 0.5 mV , this op-amp can be used for current sensing in a constant current regulator.

The above circuit demonstrates the use of the NCP4300A in a constant-current constant-voltage switch mode battery charger application. The charging current level is set by resistors R3, R4, and R5. The reference voltage is divided down by resistors R3 and R4 to create an offset voltage at pin 6. This results in a high state at the op amp output, pin 7. As the battery pack charge current increases, a proportional increasing voltage is developed across R5 that will eventually cancel out the pin 6 offset voltage. This will cause the op amp output to sink current from the opto isolator diode, and control the SMPS block in a constant-current mode. Resistors R1 and R2 divide the battery pack voltage down to the 2.6 V reference level. As the battery pack voltage exceeds the desired programmed level, the voltage at pin 2 will become slightly greater than pin 3 . This will cause the op amp output to sink current from the opto isolator diode, and control the SMPS block in a constant-voltage mode. The formulas for programming the output current and voltage are given below.

$$
\begin{array}{rl}
\mathrm{l}_{\text {out }}=\frac{V_{\text {ref }}}{\left(\frac{R 3}{R 4}+1\right) R 5} & V_{\text {out }}=\left(\frac{R 1}{R 2}+1\right) V_{\text {ref }} \\
& \\
\text { With }: \begin{array}{l}
R 3=30 \mathrm{k} \\
R 4=1.2 \mathrm{k}
\end{array} & \text { With }: R 1=4.7 \mathrm{k} \\
R 5=0.1 & R 2=3.6 \mathrm{k} \\
l_{\text {out }}=1.0 \mathrm{~A} & V_{\text {out }}=6.0 \mathrm{~V}
\end{array}
$$

## MC44608

## Few External Components Reliable and Flexible SMPS Controller

The MC44608 is a high performance voltage mode controller designed for off-line converters. This high voltage circuit that integrates the start-up current source and the oscillator capacitor, requires few external components while offering a high flexibility and reliability.

The device also features a very high efficiency stand-by management consisting of an effective Pulsed Mode operation. This technique enables the reduction of the stand-by power consumption to approximately 1.0 W while delivering 300 mW in a 150 W SMPS.

- Integrated Start-Up Current Source
- Lossless Off-Line Start-Up
- Direct Off-Line Operation
- Fast Start-Up

## General Features

- Flexibility
- Duty Cycle Control
- Undervoltage Lockout with Hysteresis
- On Chip Oscillator Switching Frequency 40, 75, or 100 kHz
- Secondary Control with Few External Components

## Protections

- Maximum Duty Cycle Limitation
- Cycle by Cycle Current Limitation
- Demagnetization (Zero Current Detection) Protection
- "Over V ${ }_{\text {CC }}$ Protection" Against Open Loop
- Programmable Low Inertia Over Voltage Protection Against Open Loop
- Internal Thermal Protection

## SMPS Controller

- Pulsed Mode Techniques for a Very High Efficiency Low Power Mode
- Lossless Startup
- Low dV/dT for Low EMI Radiations

2. Adjust $\mathrm{V}_{\mathrm{CC}}$ above the start-up threshold before setting to 12 V . Low duty cycle pulse techniques are used during test to maintain junction temperature as close to ambient as possible.
3. This function can be inhibited by connecting pin 1 to GND.
4. Guaranteed by design (non tested).

PIN FUNCTION DESCRIPTION

| Pin | Name | Description |
| :---: | :---: | :---: |
| 1 | Demag | The Demag pin offers 3 different functions: Zero voltage crossing detection ( 50 mV ), $24 \mu \mathrm{~A}$ current detection and $120 \mu \mathrm{~A}$ current detection. The $24 \mu \mathrm{~A}$ level is used to detect the secondary reconfiguration status and the $120 \mu \mathrm{~A}$ level to detect an Over Voltage status called Quick OVP. |
| 2 | $\mathrm{I}_{\text {sense }}$ | The Current Sense pin senses the voltage developed on the series resistor inserted in the source of the power MOSFET. When $I_{\text {sense }}$ reaches 1.0 V , the Driver output (pin 5 ) is disabled. This is known as the Over Current Protection function. A $200 \mu \mathrm{~A}$ current source is flowing out of the pin 3 during the start-up phase and during the switching phase in case of the Pulsed Mode of operation. A resistor can be inserted between the sense resistor and the pin 2 , thus a programmable peak current detection can be performed during the SMPS stand-by mode. |
| 3 | Control Input | A feedback current from the secondary side of the SMPS via the opto-coupler is injected into this pin. A resistor can be connected between this pin and GND to allow the programming of the Burst duty cycle during the Stand-by mode. |
| 4 | Ground | This pin is the ground of the primary side of the SMPS. |
| 5 | Driver | The current and slew rate capability of this pin are suited to drive Power MOSFETs. |
| 6 | $\mathrm{V}_{\mathrm{CC}}$ | This pin is the positive supply of the IC. The driver output gets disabled when the voltage becomes higher than 15 V and the operating range is between 6.6 V and 13 V . An intermediate voltage level of 10 V creates a disabling condition called Latched Off phase. |
| 7 |  | This pin is to provide isolation between the $\mathrm{V}_{\mathrm{i}}$ pin 8 and the $\mathrm{V}_{\mathrm{CC}}$ pin 6. |
| 8 | $\mathrm{V}_{\mathrm{i}}$ | This pin can be directly connected to a 500 V voltage source for start-up function of the IC. During the Start-up phase a 9.0 mA current source is internally delivered to the $\mathrm{V}_{\mathrm{CC}}$ pin 6 allowing a rapid charge of the $\mathrm{V}_{\mathrm{CC}}$ capacitor. As soon as the IC starts-up, this current source is disabled. |

## OPERATING DESCRIPTION

## Regulation

Figure 2. Regulator

The pin 3 senses the feedback current provided by the opto coupler. During the switching phase the switch S2 is closed and the shunt regulator is accessible by the pin 3 . The shunt regulator voltage is typically 5.0 V . The dynamic resistance of the shunt regulator represented by the zener diode is $20 \Omega$. The gain of the Control input is given on Figure 11 which shows the duty cycle as a function of the current injected into the pin 3 .

A 4.0 kHz filter network is inserted between the shunt regulator and the PWM comparator to cancel the high frequency residual noise.

The switch S3 is closed in Stand-by mode during the Latched Off Phase while the switch S2 remains open. (See section PULSED MODE DUTY CYCLE CONTROL).
The resistor Rdpulsed (Rduty cycle burst) has no effect on the regulation process. This resistor is used to determine the burst duty cycle described in the chapter "Pulsed Duty Cycle Control" on page 8.

## PWM Latch

The MC44608 works in voltage mode. The on-time is controlled by the PWM comparator that compares the oscillator sawtooth with the regulation block output (refer to the block diagram on page 2).
The PWM latch is initialized by the oscillator and is reset by the PWM comparator or by the current sense comparator in case of an over current. This configuration ensures that only a single pulse appears at the circuit output during an oscillator cycle.

## Current Sense

The inductor current is converted to a positive voltage by inserting a ground reference sense resistor $\mathrm{R}_{\text {Sense }}$ in series with the power switch.
The maximum current sense threshold is fixed at 1.0 V . The peak current is given by the following equation:

$$
\mathrm{Ipk}_{\text {max }}=\frac{1}{\mathrm{R}_{\text {sense }^{(\Omega)}}}(\mathrm{A})
$$

In stand-by mode, this current can be lowered as due to the activation of a $200 \mu \mathrm{~A}$ current source:

$$
\mathrm{Ipk}_{\max -\mathrm{stby}}=\frac{1-\left(\mathrm{R}_{\mathrm{cs}}(\mathrm{k} \Omega) \times 0,2\right)}{\mathrm{R}_{\mathrm{sense}^{(\Omega)}}(\mathrm{A})}
$$

Figure 3. Current Sense

The current sense input consists of a filter ( $6.0 \mathrm{k} \Omega, 4.0 \mathrm{pF}$ ) and of a leading edge blanking. Thanks to that, this pin is not sensitive to the power switch turn on noise and spikes and practically in most applications, no filtering network is required to sense the current.

Finally, this pin is used:

- as a protection against over currents (Isense $>\mathrm{I}$ )
- as a reduction of the peak current during a Pulsed Mode switching phase.

The overcurrent propagation delay is reduced by producing a sharp output turn off (high slew rate). This results in an abrupt output turn off in the event of an over current and in the majority of the pulsed mode switching sequence.

## Demagnetization Section

The MC44608 demagnetization detection consists of a comparator designed to compare the $\mathrm{V}_{\mathrm{CC}}$ winding voltage to a reference that is typically equal to 50 mV .

This reference is chosen low to increase effectiveness of the demagnetization detection even during start-up.

A latch is incorporated to turn the demagnetization block output into a low level as soon as a voltage less than 50 mV is detected, and to keep it in this state until a new pulse is generated on the output. This avoids any ringing on the input signal which may alter the demagnetization detection.

For a higher safety, the demagnetization block output is also directly connected to the output, which is disabled during the demagnetization phase.

The demagnetization pin is also used for the quick, programmable OVP. In fact, the demagnetization input current is sensed so that the circuit output is latched off when this current is detected as higher than $120 \mu \mathrm{~A}$.

Figure 4. Demagnetization Block
This function can be inhibited by grounding it but in this case, the quick and programmable OVP is also disabled.

## Oscillator

The MC44608 contains a fixed frequency oscillator. It is built around a fixed value capacitor CT successively charged and discharged by two distinct current sources ICH and IDCH. The window comparator senses the CT voltage value and activates the sources when the voltage is reaching the 2.4 V/4.0 V levels.

Figure 5. Oscillator Block
The complete demagnetization status DMG is used to inhibit the recharge of the CT capacitor. Thus in case of incomplete transformer demagnetization the next switching cycle is postpone until the DMG signal appears. The oscillator remains at 2.4 V corresponding to the sawtooth valley voltage. In this way the SMPS is working in the so called SOPS mode (Self Oscillating Power Supply). In that case the effective switching frequency is variable and no longer depends on the oscillator timing but on the external working conditions (Refer to DMG signal in the Figure 6).

Figure 6.

The OSC and Clock signals are provided according to the Figure 6. The Clock signals correspond to the CT capacitor discharge. The bottom curve represents the current flowing in the sense resistor Rcs. It starts from zero and stops when the sawtooth value is equal to the control voltage Vcont. In this way the SMPS is regulated with a voltage mode control.

## Overvoltage Protection

The MC44608 offers two OVP functions:

- a fixed function that detects when $\mathrm{V}_{\mathrm{CC}}$ is higher than 15.4 V
- a programmable function that uses the demag pin. The current flowing into the demag pin is mirrored and compared to the reference current $\operatorname{Iovp}(120 \mu \mathrm{~A})$. Thus this OVP is quicker as it is not impacted by the $\mathrm{V}_{\mathrm{CC}}$ inertia and is called QOVP.

In both cases, once an OVP condition is detected, the output is latched off until a new circuit START-UP.

## Start-up Management

The $V_{i}$ pin 8 is directly connected to the HV DC rail Vin. This high voltage current source is internally connected to the $V_{C C}$ pin and thus is used to charge the $V_{C C}$ capacitor. The $\mathrm{V}_{\mathrm{CC}}$ capacitor charge period corresponds to the Start-up phase. When the $\mathrm{V}_{\mathrm{CC}}$ voltage reaches 13 V , the high voltage 9.0 mA current source is disabled and the device starts working. The device enters into the switching phase.

It is to be noticed that the maximum rating of the $\mathrm{V}_{\mathrm{i}}$ pin 8 is 500 V . ESD protection circuitry is not currently added to this pin due to size limitations and technology constraints. Protection is limited by the drain-substrate junction in avalanche breakdown. To help increase the application safety against high voltage spike on that pin it is possible to insert a small wattage $1.0 \mathrm{k} \Omega$ series resistor between the $\mathrm{V}_{\mathrm{in}}$ rail and pin 8.

The Figure 7 shows the $\mathrm{V}_{\mathrm{CC}}$ voltage evolution in case of no external current source providing current into the $\mathrm{V}_{\mathrm{CC}}$ pin during the switching phase. This case can be encountered in SMPS when the self supply through an auxiliary winding is not present (strong overload on the SMPS output for example). The Figure 17 also depicts this working configuration.

Figure 7. Hiccup Mode
In case of the hiccup mode, the duty cycle of the switching phase is in the range of $10 \%$.

## Mode Transition

The LW latch Figure 8 is the memory of the working status at the end of every switching sequence.

Two different cases must be considered for the logic at the termination of the SWITCHING PHASE:

1. No Over Current was observed
2. An Over Current was observed

These 2 cases are corresponding to the signal labelled NOC in case of "No Over Current" and "OC" in case of Over Current. So the effective working status at the end of the ON time memorized in LW corresponds to $\mathrm{Q}=1$ for no over current and $\mathrm{Q}=0$ for over current.

This sequence is repeated during the Switching phase.
Several events can occur:

1. SMPS switch OFF
2. SMPS output overload
3. Transition from Normal to Pulsed Mode
4. Transition from Pulsed Mode to Normal Mode

Figure 8. Transition Logic

## - 1. SMPS SWITCH OFF

When the mains is switched OFF, so long as the bulk electrolithic bulk capacitor provides energy to the SMPS, the controller remains in the switching phase. Then the peak current reaches its maximum peak value, the switching frequency decreases and all the secondary voltages are reduced. The $\mathrm{V}_{\mathrm{CC}}$ voltage is also reduced. When $\mathrm{V}_{\mathrm{CC}}$ is equal to 10 V , the SMPS stops working.

## - 2. Overload

In the hiccup mode the 3 distinct phases are described as follows (refer to Figure 7):

The SWITCHING PHASE: The SMPS output is low and the regulation block reacts by increasing the ON time (dmax $=80 \%$ ). The OC is reached at the end of every switching cycle. The LW latch (Figure 8) is reset before the VPWM signal appears. The SMPS output voltage is low. The $\mathrm{V}_{\mathrm{CC}}$ voltage cannot be maintained at a normal level as the auxiliary winding provides a voltage which is also reduced in a ratio similar to the one on the output (i.e. Vout nominal / Vout short-circuit). Consequently the $\mathrm{V}_{\mathrm{CC}}$ voltage is reduced at an operating rate given by the combination $\mathrm{V}_{\mathrm{CC}}$ capacitor value together with the $\mathrm{I}_{\mathrm{CC}}$ working consumption ( 3.2 mA ) according to the equation 2 . When $\mathrm{V}_{\mathrm{CC}}$ crosses 10V the WORKING PHASE gets terminated. The LW latch remains in the reset status.

The LATCHED-OFF PHASE: The $\mathrm{V}_{\mathrm{CC}}$ capacitor voltage continues to drop. When it reaches 6.5 V this phase is terminated. Its duration is governed by equation 3 .

The START-UP PHASE is reinitiated. The high voltage start-up current source $\left(-\mathrm{I}_{\mathrm{CC} 1}=9.0 \mathrm{~mA}\right)$ is activated and the MODE latch is reset. The $\mathrm{V}_{\mathrm{CC}}$ voltage ramps up according to the equation 1 . When it reaches 13 V , the IC enters into the SWITCHING PHASE.

The NEXT SWITCHING PHASE: The high voltage current source is inhibited, the MODE latch $(\mathrm{Q}=0)$ activates the NORMAL mode of operation. Figure 3 shows that no current is injected out pin 2 . The over current sense level corresponds to 1.0 V .

As long as the overload is present, this sequence repeats. The SWITCHING PHASE duty cycle is in the range of $10 \%$.

## - 3. Transition from Normal to Pulsed Mode

In this sequence the secondary side is reconfigured (refer to the typical application schematic on page 13). The high voltage output value becomes lower than the NORMAL mode regulated value. The TL431 shunt regulator is fully OFF. In the SMPS stand-by mode all the SMPS outputs are lowered except for the low voltage output that supply the wake-up circuit located at the isolated side of the power supply. In that mode the secondary regulation is performed by the zener diode connected in parallel to the TL431.

The secondary reconfiguration status can be detected on the SMPS primary side by measuring the voltage level present on the auxiliary winding Laux. (Refer to the Demagnetization Section). In the reconfigured status, the Laux voltage is also reduced. The $\mathrm{V}_{\mathrm{CC}}$ self-powering is no longer possible thus the SMPS enters in a hiccup mode similar to the one described under the Overload condition.

In the SMPS stand-by mode the 3 distinct phases are:
The SWITCHING PHASE: Similar to the Overload mode. The current sense clamping level is reduced
according to the equation of the current sense section, page 5 . The C.S. clamping level depends on the power to be delivered to the load during the SMPS stand-by mode. Every switching sequence ON/OFF is terminated by an OC as long as the secondary Zener diode voltage has not been reached. When the Zener voltage is reached the ON cycle is terminated by a true PWM action. The proper SWITCHING PHASE termination must correspond to a NOC condition. The LW latch stores this NOC status.

The LATCHED OFF PHASE: The MODE latch is set.
The START-UP PHASE is similar to the Overload Mode. The MODE latch remains in its set status $(\mathrm{Q}=1)$.

The SWITCHING PHASE: The Stand-by signal is validated and the $200 \mu \mathrm{~A}$ is sourced out of the Current Sense pin 2.

## - 4. Transition from Stand-by to Normal

The secondary reconfiguration is removed. The regulation on the low voltage secondary rail can no longer be achieved, thus at the end of the SWITCHING PHASE, no PWM condition can be encountered. The LW latch is reset.
At the next WORKING PHASE a NORMAL mode status takes place.

In order to become independent of the recovery time constant on the secondary side of the SMPS an additional reset input R2 is provided on the MODE latch. The condition Idemag $<24 \mu \mathrm{~A}$ corresponds to the activation of the secondary reconfiguration status. The R2 reset insures a direct return into the Normal Mode.

## Pulsed Mode Duty Cycle Control

During the sleep mode of the SMPS the switch S3 is closed and the control input pin 3 is connected to a 4.6 V voltage source thru a $500 \Omega$ resistor. The discharge rate of the $\mathrm{V}_{\mathrm{CC}}$ capacitor is given by $\mathrm{I}_{\mathrm{CC} \text {-latch }}$ (device consumption during the LATCHED OFF phase) in addition to the current drawn out of the pin 3. Connecting a resistor between the Pin 3 and GND ( $\mathrm{R}_{\text {DPULSED }}$ ) a programmable current is drawn from the $\mathrm{V}_{\mathrm{CC}}$ through pin 3. The duration of the LATCHED OFF phase is impacted by the presence of the resistor R $_{\text {DPULSED. }}$. The equation 3 shows the relation to the pin 3 current.

## Pulsed Mode Phases

Equations 1 through 8 define and predict the effective behavior during the PULSED MODE operation. The equations 6,7 , and 8 contain $\mathrm{K}, \mathrm{Y}$, and D factors. These factors are combinations of measured parameters. They appear in the parameter section "Kfactors for pulsed mode operation" page 4 . In equations 3 through 8 the pin 3 current is the current defined in the above section "Pulsed Mode Duty Cycle Control".

## EQUATION 1

Start-up Phase Duration:

$$
\mathrm{t}_{\text {start-up }}=\frac{\mathrm{C}_{\mathrm{Vcc}} \times\left(\mathrm{V}_{\text {stup }}-\mathrm{UVLO} 2\right)}{\mathrm{I}_{\text {stup }}}
$$

where: $I_{\text {stup }}$ is the start-up current flowing through $V_{C C}$ pin
$\mathrm{C}_{\mathrm{Vcc}}$ is the $\mathrm{V}_{\mathrm{CC}}$ capacitor value

## EQUATION 2

Switching Phase Duration:

$$
\mathrm{t}_{\text {switch }}=\frac{\mathrm{C}_{\mathrm{V}_{c c}} \times\left(\mathrm{V}_{\text {stup }}-\text { UVLO1 }\right)}{\mathrm{I}_{\mathrm{ccS}}+\mathrm{I}_{\mathrm{G}}}
$$

where: $I_{C C S}$ is the no load circuit consumption in switching phase $I_{G}$ is the current consumed by the Power Switch

## EQUATION 3

Latched-off Phase Duration:

$$
\mathrm{t}_{\text {latched }- \text { off }}=\frac{\mathrm{C}_{\mathrm{Vcc}} \times(\mathrm{UVLO} 1-\text { UVLO2 })}{\mathrm{I}_{\mathrm{ccL}}+\mathrm{I}_{\mathrm{pin} 3}}
$$

where: $I_{\mathrm{CCL}}$ is the latched off phase consumption
$I_{\text {pin3 }}$ is the current drawn from pin3 adding a resistor

## EQUATION 4

Burst Mode Duty Cycle:

$$
d_{B M}=\frac{t_{\text {switch }}}{t_{\text {start }- \text { up }}+t_{\text {switch }}+t_{\text {latched-off }}}
$$

## EQUATION 5

$$
d_{B M}=\frac{\frac{C_{V c c} \times\left(V_{\text {stup }}-U V L O 1\right)}{I_{c c S}+I_{G}}}{\frac{C_{V c c} \times\left(V_{\text {stup }}-U V L O 2\right)}{I_{\text {stup }}}+\frac{C_{V_{c c}} \times\left(V_{\text {stup }}-U V L O 1\right)}{I_{c c S}+I_{G}}+\frac{C_{V_{c c}} \times(U V L O 1-U V L O 2)}{I_{c c L}+I_{\text {pin3 }}}}
$$

## EQUATION 6

$$
\mathrm{d}_{\mathrm{BM}}=\frac{1}{1+\left(\mathrm{k}_{\mathrm{S} / \text { Stup }} \times \frac{\mathrm{I}_{\mathrm{CCS}}+\mathrm{I}_{\mathrm{G}}}{\mathrm{I}_{\text {stup }}}\right)+\left(\mathrm{k}_{\mathrm{S} / \mathrm{L}} \times \frac{\mathrm{I}_{\mathrm{ccS}}+\mathrm{I}_{\mathrm{G}}}{\mathrm{I}_{\mathrm{ccL}}+\mathrm{I}_{\mathrm{pin} 3}}\right)}
$$

where: $\mathrm{k}_{\mathrm{S} / \text { Stup }}=\left(\mathrm{V}_{\text {stup }}-\mathrm{UVLO} 2\right) /\left(\mathrm{V}_{\text {stup }}-\mathrm{UVLO} 1\right)$
$\mathrm{k}_{\mathrm{S} / \mathrm{L}}=(\mathrm{UVLO} 1-\mathrm{UVLO} 2) /\left(\mathrm{V}_{\text {stup }}-\mathrm{UVLO} 1\right)$

## EQUATION 7

$$
\mathrm{d}_{\mathrm{BM}}=\frac{1}{1+\left(\frac{\mathrm{I}_{\mathrm{CCS}}+\mathrm{I}_{\mathrm{G}}}{\mathrm{I}_{\text {stup }}} \times\left(\mathrm{k}_{\mathrm{S} / \text { Stup }}+\left(\mathrm{k}_{\mathrm{S} / \mathrm{L}} \times \frac{\mathrm{I}_{\text {stup }}}{\mathrm{I}_{\mathrm{ccL}}+\mathrm{I}_{\text {pin3 }}}\right)\right)\right.}
$$

## EQUATION 8

$$
\mathrm{d}_{\mathrm{BM}}=\frac{1}{1+\left\{\left(\mathrm{k} 1+\frac{\mathrm{I}_{\mathrm{G}}}{\mathrm{I}_{\text {stup }}}\right) \times\left(\mathrm{k}_{\mathrm{S} / \text { Stup }}+\left(\mathrm{k}_{\mathrm{S} / \mathrm{L}} \times \frac{1}{\mathrm{k} 2+\left(\frac{\mathrm{I}_{\text {pin3 }}}{I_{\text {stup }}}\right)}\right)\right]\right\}}
$$

where: $\mathrm{k} 1=\mathrm{I}_{\text {ccs }} / \mathrm{I}_{\text {stup }}$
$\mathrm{k} 2=\mathrm{I}_{\mathrm{ccL}} / \mathrm{s}_{\text {stup }}$
$\mathrm{k}_{\mathrm{S} / \text { Stup }}=\left(\mathrm{V}_{\text {stup }}-\mathrm{UVLO} 2\right) /\left(\mathrm{V}_{\text {stup }}-\mathrm{UVLO} 1\right)$
$\mathrm{k}_{\mathrm{S} / \mathrm{L}}=(\mathrm{UVLO} 1-\mathrm{UVLO} 2) /\left(\mathrm{V}_{\text {stup }}-\mathrm{UVLO} 1\right)$

## PULSED MODE CURRENT SENSE CLAMPING LEVEL

Equations 9, 10, 11 and 12 allow the calculation of the Rcs value for the desired maximum current peak value during the SMPS stand-by mode.

## EQUATION 9

$$
\text { Ipk }_{\text {stby }}=\frac{\mathrm{V}_{\mathrm{cs}-\mathrm{th}}-\left(\mathrm{R}_{\mathrm{cs}} \times \mathrm{I}_{\mathrm{cs}}\right)}{\mathrm{R}_{\mathrm{S}}}
$$

where: $\mathrm{V}_{\mathrm{cs}-\mathrm{th}}$ is the CS comparator threshold
$\mathrm{I}_{\text {CS }}$ is the CS internal current source
$R_{S}$ is the sensing resistor
$R_{\text {cs }}$ is the resistor connected between pin 2 and $R_{S}$

## EQUATION 10

$$
\mathrm{Ipk}_{\mathrm{stby}}=\mathrm{V}_{\mathrm{cs}-\mathrm{th}} \times \frac{1-\left(\mathrm{R}_{\mathrm{cs}} \times \frac{\mathrm{I}_{\mathrm{cs}}}{\mathrm{~V}_{\mathrm{cs}-\mathrm{th}}}\right)}{\mathrm{R}_{\mathrm{S}}}
$$

## EQUATION 11

$$
\mathrm{lpk}_{\mathrm{stby}}=\mathrm{V}_{\mathrm{cs}-\mathrm{th}} \times \frac{1-\left(\mathrm{R}_{\mathrm{cs}} \times \mathrm{Y}_{\mathrm{cs}-\mathrm{stby}}\right)}{\mathrm{R}_{\mathrm{S}}}
$$

where: $\mathrm{Y}_{\text {cs-stby }}=\mathrm{I}_{\text {cs }} / \mathrm{V}_{\text {cs-th }}$
Taking into account the circuit propagation delay ( $\delta \mathrm{t}_{\mathrm{cs}}$ ) and the Power Switch reaction time ( $\delta \mathrm{t}_{\mathrm{ps}}$ ):
EQUATION 12

$$
\text { Ipk }_{\text {stby }}=\left[V_{\mathrm{cs}-\mathrm{th}} \times \frac{1-\left(\mathrm{R}_{\mathrm{cs}} \times \mathrm{Y}_{\mathrm{cs}-\mathrm{stby}}\right)}{R_{\mathrm{S}}}\right]+\frac{\mathrm{V}_{\mathrm{in}} \times\left(\delta \mathrm{t}_{\mathrm{cs}}+\delta \mathrm{t}_{\mathrm{ps}}\right)}{\mathrm{L}_{\mathrm{p}}}
$$

Figure 12. Vpin3 During the Working Period

Figure 14. Device Consumption when Switching

Figure 15. High Voltage Current Source

Figure 16. Overload Burst Mode

Figure 17. Hiccup Mode Waveforms

The data in Figure 16 corresponds to the waveform in Figure 17. The Figure 17 shows $\mathrm{V}_{\mathrm{CC}}, \mathrm{I}_{\mathrm{CC}}, \mathrm{I}_{\text {sense }}(\mathrm{pin} 2)$ and $\mathrm{V}_{\text {out }}$ (pin 5). $\mathrm{V}_{\text {out }}$ (pin 5) in fact shows the envelope of the
output switching pulses. This mode corresponds to an overload condition.

The Figure 19 represents a complete power supply using the secondary reconfiguration.

| The specification is as follows: | Input source: <br>  <br> 3 Outputs | 85 Vac to 265 Vac |
| :--- | :--- | :--- |
|  | $112 \mathrm{~V} / 0.45 \mathrm{~A}$ |  |
|  | $16 \mathrm{~V} / 1.5 \mathrm{~A}$ |  |
|  | Output power | $8.0 \mathrm{~V} / 1.0 \mathrm{~A}$ |
|  | 80 W |  |
|  | Stand-by mode | @ Pout $=300 \mathrm{~mW}, 1.3 \mathrm{~W}$ |

Figure 18. Typical Application

The secondary reconfiguration is activated by the $\mu \mathrm{P}$ through the switch. The dV/dt appearing on the high voltage winding (pins 14 of the transformer) at every TMOS switch off, produces a current spike through the series RC network R7, C17. According to the switch position this spike is either absorbed by the ground (switch closed) or flows into the thyristor gate (switch open) thus firing the MCR22-6. The closed position of the switch corresponds to the Pulsed Mode activation. In this secondary side SMPS status the high voltage winding (12-14) is connected through D12 and DZ 1 to the 8.0 V low voltage secondary rail. The voltages
applied to the secondary windings $12-14,10-11$ and $6-7$ (Vaux) are thus divided by ratio N12-14 / N9-8 (number of turns of the winding 12-14 over number of turns of the winding 9-8). In this reconfigured status all the secondary voltages are lowered except the 8.0 V one. The regulation during every pulsed or burst is performed by the zener diode DZ3 which value has to be chosen higher than the normal mode regulation level. This working mode creates a voltage ripple on the 8.0 V rail which generally must be post regulated for the microProcessor supply.

Figure 19. SMPS Pulsed Mode

The Figure 19 shows the SMPS behavior while working in the reconfigured mode. The top curve represents the $\mathrm{V}_{\mathrm{CC}}$ voltage (pin 6 of the MC44608). The middle curve represents the 8.0 V rail. The regulation is taking place at 11.68 V . On the bottom curve the pin 2 voltage is shown. This voltage represents the current sense signal. The pin 2
voltage is the result of the $200 \mu \mathrm{~A}$ current source activated during the start-up phase and also during the working phase which flows through the R4 resistor. The used high resolution mode of the oscilloscope does not allow to show the effective ton current flowing in the sensing resistor R11.

## PWM Current-Mode Controller for Low-Power Universal Off-Line Supplies

Housed in SO-8 or DIP-8 package, the NCP1200 represents a major leap toward ultra-compact Switch-Mode Power Supplies. Thanks to a novel concept, the circuit allows the implementation of a complete offline battery charger or a standby SMPS with few external components. Furthermore, an integrated output short-circuit protection lets the designer build an extremely low-cost AC/DC wall adapter associated with a simplified feedback scheme.

With an internal structure operating at a fixed $40 \mathrm{kHz}, 60 \mathrm{kHz}$ or 100 kHz , the controller drives low gate-charge switching devices like an IGBT or a MOSFET thus requiring a very small operating power. Thanks to current-mode control, the NCP1200 drastically simplifies the design of reliable and cheap offline converters with extremely low acoustic generation and inherent pulse-by-pulse control.

When the current setpoint falls below a given value, e.g. the output power demand diminishes, the IC automatically enters the skip cycle mode and provides excellent efficiency at light loads. Because this occurs at low peak current, no acoustic noise takes place.

Finally, the IC is self-supplied from the DC rail, eliminating the need of an auxiliary winding. This feature ensures operation in presence of low output voltage or shorts.

## Features

- No Auxiliary Winding Operation
- Internal Output Short-Circuit Protection
- Extremely Low No-Load Standby Power
- Current-Mode with Skip-Cycle Capability
- Internal Leading Edge Blanking
- 110 mA Peak Current Source/Sink Capability
- Internally Fixed Frequency at $40 \mathrm{kHz}, 60 \mathrm{kHz}$ and 100 kHz
- Direct Optocoupler Connection
- Built-in Frequency Jittering for Lower EMI
- SPICE Models Available for TRANsient and AC Analysis
- Internal Temperature Shutdown

## Typical Applications

- AC/DC Adapters
- Offline Battery Chargers
- Auxiliary/Ancillary Power Supplies (USB, Appliances, TVs, etc.)

## ORDERING INFORMATION

See detailed ordering and shipping information in the package dimensions section on page 995 of this data sheet.

Figure 1. Typical Application

## PIN FUNCTION DESCRIPTION

| Pin No. | Pin Name | Function | Description |
| :---: | :---: | :--- | :--- |
| 1 | Adj | Adjust the skipping peak current | This pin lets you adjust the level at which the cycle skipping process <br> takes place |
| 2 | FB | Sets the peak current setpoint | By connecting an optocoupler to this pin, the peak current setpoint is <br> adjusted accordingly to the output power demand |
| 3 | CS | Current sense input | This pin senses the primary current and routes it to the internal <br> comparator via an L.E.B |
| 4 | Gnd | The IC ground |  |
| 5 | Drv | Driving pulses | The driver's output to an external MOSFET |
| 6 | VCC | Supplies the IC | This pin is connected to an external bulk capacitor of typically $10 \mu \mathrm{~F}$ |
| 7 | NC | No Connection | This un-connected pin ensures adequate creepage distance |
| 8 | HV | Generates the $\mathrm{V}_{\mathrm{CC}}$ from the line | Connected to the high-voltage rail, this pin injects a constant current into <br> the $\mathrm{V}_{\mathrm{CC}}$ bulk capacitor |

## APPLICATIONS INFORMATION

## INTRODUCTION

The NCP1200 implements a standard current mode architecture where the switch-off time is dictated by the peak current setpoint. This component represents the ideal candidate where low part-count is the key parameter, particularly in low-cost AC/DC adapters, auxiliary supplies etc. Thanks to its high-performance High-Voltage technology, the NCP1200 incorporates all the necessary components normally needed in UC384X based supplies: timing components, feedback devices, low-pass filter and self-supply. This later point emphasizes the fact that ON Semiconductor's NCP1200 does NOT need an auxiliary winding to operate: the product is naturally supplied from the high-voltage rail and delivers a $\mathrm{V}_{\mathrm{CC}}$ to the IC. This system is called the Dynamic Self-Supply (DSS).

## Dynamic Self-Supply

The DSS principle is based on the charge/discharge of the $\mathrm{V}_{\mathrm{CC}}$ bulk capacitor from a low level up to a higher level. We can easily describe the current source operation with a bunch of simple logical equations:

POWER-ON: IF $\mathrm{V}_{\mathrm{CC}}<\mathrm{V}_{\mathrm{CCOFF}}$ THEN Current Source is ON , no output pulses

IF $\mathrm{V}_{\mathrm{CC}}$ decreasing $>\mathrm{V}_{\mathrm{CCON}}$ THEN Current Source is OFF, output is pulsing
IF $\mathrm{V}_{\mathrm{CC}}$ increasing $<\mathrm{V}_{\text {CCOFF }}$ THEN Current Source is ON, output is pulsing

Typical values are: $\mathrm{V}_{\mathrm{CCOFF}}=11.4 \mathrm{~V}, \mathrm{~V}_{\mathrm{CCON}}=9.8 \mathrm{~V}$
To better understand the operational principle, Figure 15's sketch offers the necessary light:

Figure 15. The Charge/Discharge Cycle Over a $10 \mu \mathrm{~F} \mathrm{~V}_{\mathrm{cc}}$ Capacitor

The DSS behavior actually depends on the internal IC consumption and the MOSFET's gate charge, Qg. If we select a MOSFET like the MTD1N60E, Qg equals 11 nC (max). With a maximum switching frequency of 48 kHz (for the P40 version), the average power necessary to drive the MOSFET (excluding the driver efficiency and neglecting various voltage drops) is:
Fsw $\cdot \mathrm{Qg} \cdot \mathrm{V}_{\mathrm{Cc}} \quad$ with
Fsw $=$ maximum switching frequency
$\mathrm{Qg}=$ MOSFET's gate charge
$\mathrm{V}_{\mathrm{CC}}=\mathrm{V}_{\mathrm{GS}}$ level applied to the gate
To obtain the final driver contribution to the IC consumption, simply divide this result by $\mathrm{V}_{\mathrm{CC}}$ : Idriver $=$ $\mathrm{Fsw} \cdot \mathrm{Qg}=530 \mu \mathrm{~A}$. The total standby power consumption at no-load will therefore heavily rely on the internal IC consumption plus the above driving current (altered by the driver's efficiency). Suppose that the IC is supplied from a 400 V DC line. To fully supply the integrated circuit, let's imagine the 4 mA source is ON during 8 ms and OFF during 50 ms . The IC power contribution is therefore: 400 V .4 mA
. $0.16=256 \mathrm{~mW}$. If for design reasons this contribution is still too high, several solutions exist to diminish it:

1. Use a MOSFET with lower gate charge Qg
2. Connect pin through a diode (1N4007 typically) to one of the mains input. The average value on pin 8 becomes $\frac{2 \text { * } V_{\text {mains PEAK }}}{\pi}$. Our power contribution example drops to: 160 mW .

Figure 16. A simple diode naturally reduces the average voltage on pin 8
3. Permanently force the $\mathrm{V}_{\mathrm{CC}}$ level above $\mathrm{V}_{\mathrm{CCH}}$ with an auxiliary winding. It will automatically disconnect the internal start-up source and the IC will be fully self-supplied from this winding. Again, the total power drawn from the mains will significantly decrease. Make sure the auxiliary voltage never exceeds the 16 V limit.

## Skipping Cycle Mode

The NCP1200 automatically skips switching cycles when the output power demand drops below a given level. This is accomplished by monitoring the FB pin. In normal operation, pin 2 imposes a peak current accordingly to the load value. If the load demand decreases, the internal loop asks for less peak current. When this setpoint reaches a determined level, the IC prevents the current from decreasing further down and starts to blank the output pulses: the IC enters the so-called skip cycle mode, also named controlled burst operation. The power transfer now depends upon the width of the pulse bunches (Figure 18 ). Suppose we have the following component values:
Lp, primary inductance $=1 \mathrm{mH}$
$\mathrm{F}_{\mathrm{SW}}$, switching frequency $=48 \mathrm{kHz}$
Ip skip $=300 \mathrm{~mA}$ (or $350 \mathrm{mV} /$ Rsense)
The theoretical power transfer is therefore:
$\frac{1}{2} \cdot \mathrm{Lp} \cdot \mathrm{Ip}^{2} \cdot \mathrm{Fsw}=2.2 \mathrm{~W}$
If this IC enters skip cycle mode with a bunch length of 10 ms over a recurrent period of 100 ms , then the total power transfer is: 2.2 . $0.1=220 \mathrm{~mW}$.

To better understand how this skip cycle mode takes place, a look at the operation mode versus the FB level immediately gives the necessary insight:

Figure 17. Feedback Voltage Variations

When FB is above the skip cycle threshold (1.4 V by default), the peak current cannot exceed $1 \mathrm{~V} /$ Rsense. When the IC enters the skip cycle mode, the peak current cannot go below Vpin1 / 4 (Figure 19). The user still has the flexibility to alter this 1.4 V by either shunting pin 1 to ground through a resistor or raising it through a resistor up to the desired level.

Figure 18. Output pulses at various power levels ( $\mathrm{X}=5 \mu \mathrm{~s} / \mathrm{div}$ ) $\mathrm{P} 1<\mathrm{P} 2<\mathrm{P} 3$

Figure 19. The skip cycle takes place at low peak currents which guarantees noise free operation

## Power Dissipation

The NCP1200 is directly supplied from the DC rail through the internal DSS circuitry. The current flowing through the DSS is therefore the direct image of the NCP1200 current consumption. The total power dissipation can be evaluated using: $\left(\mathrm{V}_{\text {HVDC }}-11 \mathrm{~V}\right) \cdot I C C 2$. If we operate the device on a 250 VAC rail, the maximum rectified voltage can go up to 350 VDC . As a result, the worse case dissipation occurs on the 100 kHz version which will dissipate $340.1 .8 \mathrm{~mA} @ \mathrm{Tj}=-25^{\circ} \mathrm{C}=612 \mathrm{~mW}$ (however this 1.8 mA number will drop at higher operating temperatures). A DIP8 package offers a junction-to-ambient thermal resistance of $\mathrm{R}_{\theta \mathrm{J}-\mathrm{A}} 100^{\circ} \mathrm{C} / \mathrm{W}$. The maximum power dissipation can thus be computed knowing the maximum operating ambient temperature (e.g. $70^{\circ} \mathrm{C}$ ) together with the maximum allowable junction temperature ( $125^{\circ} \mathrm{C}$ ): Pmax $=\frac{\mathrm{T}_{\mathrm{Jmax}}-\mathrm{T}_{\text {Amax }}}{\mathrm{R}_{\text {R日J-A }}}=550 \mathrm{~mW}$. As we can see, we do not reach the worse consumption budget imposed by the 100 kHz version. Two solutions exist to cure this trouble. The first one consists in adding some copper area around the NCP1200 DIP8 footprint. By adding a min-pad area of $80 \mathrm{~mm}^{2}$ of $35 \mu$ copper ( 1 oz .) $\mathrm{R}_{\theta \mathrm{J}-\mathrm{A}}$ drops to about $75^{\circ} \mathrm{C} / \mathrm{W}$ which allows the use of the 100 kHz version. The other solutions are:

1. Add a series diode with pin 8 (as suggested in the above lines) to drop the maximum input voltage down to $222 \mathrm{~V}((2 \times 350) / \mathrm{pi})$ and thus dissipate less than 400 mW
2. Implement a self-supply through an auxiliary winding to permanently disconnect the self-supply.
SO-8 package offers a worse $\mathrm{R}_{\theta \mathrm{J}-\mathrm{A}}$ compared to that of the DIP8 package: $178^{\circ} \mathrm{C} / \mathrm{W}$. Again, adding some copper area around the PCB footprint will help decrease this number: 12 mm x 12 mm to drop $\mathrm{R}_{\theta \mathrm{J}-\mathrm{A}}$ down to $100^{\circ} \mathrm{C} / \mathrm{W}$ with $35 \mu$ copper thickness ( 1 oz. ) or $6.5 \mathrm{~mm} \times 6.5 \mathrm{~mm}$ with $70 \mu$ copper thickness ( 2 oz .). As one can see, we do not recommend using the SO-8 package for the 100 kHz version with DSS active as the IC may not be able to sustain the power (except if you have the adequate place on your PCB). However, using the solution of the series diode or the self-supply through the auxiliary winding does not cause any problem with this frequency version. These options are thoroughly described in the AND8023/D.

## Overload Operation

In applications where the output current is purposely not controlled (e.g. wall adapters delivering raw DC level), it is interesting to implement a true short-circuit protection. A short-circuit actually forces the output voltage to be at a low level, preventing a bias current to circulate in the optocoupler LED. As a result, the FB pin level is pulled up to 4.1 V , as internally imposed by the IC. The peak current setpoint goes to the maximum and the supply delivers a rather high power with all the associated effects. Please note that this can also happen in case of feedback loss, e.g. a broken optocoupler. To account for this situation, the NCP1200 hosts a dedicated overload detection circuitry. Once activated, this circuitry imposes to deliver pulses in a burst manner with a low duty-cycle. The system recovers when the fault condition disappears.
During the start-up phase, the peak current is pushed to the maximum until the output voltage reaches its target and the feedback loop takes over. This period of time depends on normal output load conditions and the maximum peak current allowed by the system. The time-out used by this IC works with the $\mathrm{V}_{\mathrm{CC}}$ decoupling capacitor: as soon as the $\mathrm{V}_{\mathrm{CC}}$ decreases from the $\mathrm{V}_{\mathrm{CCOFF}}$ level (typically 11.4 V ) the device internally watches for an overload current situation. If this condition is still present when $\mathrm{V}_{\mathrm{CCON}}$ is reached, the controller stops the driving pulses, prevents the self-supply current source to restart and puts all the circuitry in standby, consuming as little as $350 \mu \mathrm{~A}$ typical ( $\mathrm{I}_{\mathrm{CC} 3}$ parameter). As a result, the $\mathrm{V}_{\mathrm{CC}}$ level slowly discharges toward 0 . When this level crosses 6.3 V typical, the controller enters a new startup phase by turning the current source on: $\mathrm{V}_{\mathrm{CC}}$ rises toward 11.4 V and again delivers output pulses at the $\mathrm{UVLO}_{\mathrm{H}}$ crossing point. If the fault condition has been removed before $\mathrm{UVLO}_{\mathrm{L}}$ approaches, then the IC continues its normal operation. Otherwise, a new fault cycle takes place. Figure 20 shows the evolution of the signals in presence of a fault.

Figure 20. If the fault is relaxed during the $\mathrm{V}_{\mathrm{CC}}$ natural fall down sequence, the IC automatically resumes. If the fault persists when $\mathrm{V}_{\mathrm{Cc}}$ reached $\mathrm{UVLO}_{\mathrm{L}}$, then the controller cuts everything off until recovery.

## Calculating the $\mathrm{V}_{\mathrm{cc}}$ Capacitor

As the above section describes, the fall down sequence depends upon the $\mathrm{V}_{\mathrm{CC}}$ level: how long does it take for the $\mathrm{V}_{\mathrm{CC}}$ line to go from 11.4 V to 9.8 V ? The required time depends on the start-up sequence of your system, i.e. when you first apply the power to the IC. The corresponding transient fault duration due to the output capacitor charging must be less than the time needed to discharge from 11.4 V to 9.8 V , otherwise the supply will not properly start. The test consists in either simulating or measuring in the lab how much time the system takes to reach the regulation at full load. Let's suppose that this time corresponds to 6 ms . Therefore a $\mathrm{V}_{\mathrm{CC}}$ fall time of 10 ms could be well appropriated in order to not trigger the overload detection circuitry. If the corresponding IC consumption, including the MOSFET drive, establishes at 1.5 mA , we can calculate the required capacitor using the following formula: $\Delta t=\frac{\Delta V \cdot C}{i}$, with $\Delta V=2 V$. Then for a wanted $\Delta t$ of 10 ms ,

C equals $8 \mu \mathrm{~F}$ or $10 \mu \mathrm{~F}$ for a standard value. When an overload condition occurs, the IC blocks its internal circuitry and its consumption drops to $350 \mu \mathrm{~A}$ typical. This appends at $\mathrm{V}_{\mathrm{CC}}=9.8 \mathrm{~V}$ and it remains stuck until $\mathrm{V}_{\mathrm{CC}}$ reaches 6.5 V : we are in latch-off phase. Again, using the calculated $10 \mu \mathrm{~F}$ and $350 \mu \mathrm{~A}$ current consumption, this latch-off phase lasts: 109 ms .

## A Typical Application

Figure 21 depicts a low-cost 3.5 W AC/DC 6.5 V wall adapter. This is a typical application where the wall-pack must deliver a raw DC level to a given internally regulated apparatus: toys, calculators, CD-players etc. Thanks to the inherent short-circuit protection of the NCP1200, you only need a bunch of components around the IC, keeping the final cost at an extremely low level. The transformer is available from different suppliers as detailed on the following page.

Figure 21. A typical AC/DC wall adapter showing the reduced part count thanks to the NCP1200

T1: Lp $=2.9 \mathrm{mH}, \mathrm{Np}: \mathrm{Ns}=1: 0.08$, leakage $=80 \mu \mathrm{H}, \mathrm{E} 16$ core, NCP1200P40
To help designers during the design stage, several manufacturers propose ready-to-use transformers for the above application, but can also develop devices based on your particular specification:

## Improving the Output Drive Capability

The NCP1200 features an asymmetrical output stage used to soften the EMI signature. Figure 22 depicts the way the driver is internally made:

Figure 22. The higher ON resistor slows down the MOSFET while the lower OFF resistor ensures fast turn-off.
In some cases, it is possible to expand the output drive capability by adding either one or two bipolar transistors. Figures 23, 24, and 25 give solutions whether you need to improve the turn-on time only, the turn-off time or both. Rd is there to damp any overshoot resulting from long copper traces. It can be omitted with short connections. Results showed a rise fall time improvement by 5 X with standard 2N2222/2N2907:

Figure 23. Improving Both Turn-On and Turn-Off Times

Figure 24. Improving Turn-Off Time Only

Figure 25. Improving Turn-On Time Only

If the leakage inductance is kept low, the MTD1N60E can withstand accidental avalanche energy, e.g. during a high-voltage spike superimposed over the mains, without the help of a clamping network. If this leakage path permanently forces a drain-source voltage above the MOSFET BVdss ( 600 V ), a clamping network is mandatory and must be built around Rclamp and Clamp. Dclamp shall react extremely fast and can be a MUR160 type. To calculate the component values, the following formulas will help you:

$$
\begin{aligned}
& \frac{\mathrm{R}_{\text {clamp }}=}{2 \cdot \mathrm{~V}_{\text {clamp }} \cdot\left(\mathrm{V}_{\text {clamp }}-\left(\mathrm{V}_{\text {out }}+\mathrm{Vf} \mathrm{sec}\right) \cdot \mathrm{N}\right)} \\
& \mathrm{L}_{\text {leak }} \cdot \mathrm{Ip}^{2} \cdot \mathrm{Fsw} \\
& \mathrm{C}_{\text {clamp }}=\frac{\mathrm{V}_{\text {clamp }}}{\mathrm{V}_{\text {ripple }} \cdot \mathrm{Fsw} \cdot \mathrm{R}_{\text {clamp }}}
\end{aligned}
$$

with:
$\mathbf{V}_{\text {clamp: }}$ the desired clamping level, must be selected to be between 40 to 80 volts above the reflected output voltage when the supply is heavily loaded.
$\mathbf{V}_{\text {out }}+\mathbf{V f}$ : the regulated output voltage level + the secondary diode voltage drop
$\mathbf{L}_{\text {leak }}$ : the primary leakage inductance
$\mathbf{N}$ : the Ns:Np conversion ratio
$\mathbf{F}_{\mathbf{S W}}$ : the switching frequency
$V_{\text {ripple: }}$ the clamping ripple, could be around 20 V
Another option lies in implementing a snubber network which will damp the leakage oscillations but also provide more capacitance at the MOSFET's turn-off. The peak voltage at which the leakage forces the drain is calculated by:

$$
\mathrm{V}_{\text {max }}=\mathrm{lp} \cdot \sqrt{\frac{\mathrm{~L}_{\text {leak }}}{\mathrm{C}_{\text {lump }}}}
$$

where $\mathrm{C}_{\text {lump }}$ represents the total parasitic capacitance seen at the MOSFET opening. Typical values for Rsnubber and Csnubber in this 4 W application could respectively be 1.5 $\mathrm{k} \Omega$ and 47 pF . Further tweaking is nevertheless necessary to tune the dissipated power versus standby power.

## NCP1203

## Advance Information <br> PWM Current-Mode Controller for Universal Off-Line Supplies Featuring Standby and Short Circuit Protection

Housed in SO-8 or DIP8 package, the NCP1203 represents a major leap toward ultra-compact Switch-Mode Power Supplies and represents an excellent candidate to replace the UC384X devices. Thanks to its proprietary SmartMOS Very High Voltage Technology, the circuit allows the implementation of complete off-line AC/DC adapters, battery charger and a high-power SMPS with few external components.

With an internal structure operating at a fixed $40 \mathrm{kHz}, 60 \mathrm{kHz}$ or 100 kHz switching frequency, the controller features a high-voltage start-up FET which ensures a clean and loss-less start up sequence. Its current-mode control naturally provides good audio-susceptibility and inherent pulse-by-pulse control.

When the current set point falls below a given value, e.g. the output power demand diminishes, the IC automatically enters the so-called skip cycle mode and provides improved efficiency at light loads while offering excellent performance in standby conditions. Because this occurs at a user adjustable low peak current, no acoustic noise takes place.

The NCP1203 also includes an efficient protective circuitry which, in presence of an output over load condition, disables the output pulses while the device enters a safe burst mode, trying to restart. Once the default has gone, the device auto-recovers. Finally, a temperature shutdown with hysteresis helps building safe and robust power supplies.

## Features

- High-Voltage Start Up Current Source
- Auto-Recovery Internal Output Short-Circuit Protection
- Extremely Low No-Load Standby Power
- Current-Mode with Adjustable Skip-Cycle Capability
- Internal Leading Edge Blanking
- 250 mA Peak Current Capability
- Internally Fixed Frequency at $40 \mathrm{kHz}, 61 \mathrm{kHz}$ and 100 kHz
- Direct Optocoupler Connection
- Undervoltage Lockout at 7.6 V Typical
- SPICE Models Available for TRANsient and AC Analysis
- Pin to Pin Compatible with NCP1200

## Applications

- AC/DC Adapters for Notebooks, etc.
- Offline Battery Chargers
- Auxiliary Power Supplies (USB, Appliances, TVs, etc.)

## APPLICATION INFORMATION

## Introduction

The NCP1203 implements a standard current mode architecture where the switch-off time is dictated by the peak current setpoint. This component represents the ideal candidate where low part-count is the key parameter, particularly in low-cost AC/DC adapters, auxiliary supplies etc. Thanks to its high-performance SmartMOS High-Voltage technology, the NCP1203 incorporates all the necessary components normally needed in UC384X based supplies: timing components, feedback devices, low-pass filter and start up device. This later point emphasizes the fact that ON Semiconductor's NCP1203 does not need an external start up resistance but supplies the start up current directly from the high-voltage rail. On the other hand, more and more applications are requiring low no-load standby power, e.g. for AC/DC adapters, VCRs etc. UC384X series have a lot of difficulty to reduce the switching losses at low power levels. NCP1203 elegantly solves this problem by
skipping unwanted switching cycles at a user-adjustable power level. By ensuring that skip cycles take place at low peak current, the device ensures quiet, noise free operation. Finally, an auto-recovery output short-circuit protection (OCP) prevents from any lethal thermal runaway in overload conditions.

## Start-Up Sequence

When the power supply is first powered from the mains outlet, the internal current source (typically 4.0 mA ) is biased and charges up the Vcc capacitor. When the voltage on this Vcc capacitor reaches the VccOFF level (typically 12.8 V ), the current source turns off and no longer wastes any power. At this time, the Vcc capacitor only supplies the controller and the auxiliary supply is supposed to take over before Vcc collapses below Vcc(min). Figure 13 shows the internal arrangement of this structure:

Figure 13. The Current Source Brings $\mathrm{V}_{\mathrm{Cc}}$ Above 12.8 V and then Turns Off

Once the power supply has started, the Vcc shall be constrained below 16 V , which is the maximum rating on pin 6 . Figure 14 portrays a typical start up sequence with a Vcc regulated at 12.5 V :

Figure 14. A Typical Start Up Sequence for the NCP1203

## Overload Operation

In applications where the output current is purposely not controlled (e.g. wall adapters delivering raw DC level), it is interesting to implement a true short-circuit protection. A short-circuit actually forces the output voltage to be at a low level, preventing a bias current to circulate in the optocoupler LED. As a result, the auxiliary voltage also decreases because it also operates in Flyback and thus duplicates the output voltage, providing the leakage inductance between windings is kept low. To account for this situation and properly protect the power supply, NCP1203 hosts a dedicated overload detection circuitry. Once activated, this circuitry imposes to deliver pulses in a burst manner with a low duty-cycle. The system auto-recovers when the fault condition disappears.

During the start-up phase, the peak current is pushed to the maximum until the output voltage reaches its target and the feedback loop takes over. The auxiliary voltage takes place after a few switching cycles and self-supplies the IC. In presence of a short circuit on the output, the auxiliary voltage will go down until it crosses the undervoltage
lockout level of typically 7.6 V . When this happens, NCP1203 immediately stops the switching pulses and unbias all unnecessary logical blocks. The overall consumption drops, while keeping the gate grounded, and the Vcc slowly falls down. As soon as Vcc reaches typically 4.6 V, the start up source turns-on again and a new start up
sequence occurs, bringing Vcc toward 12.8 V as an attempt to restart. If the default has gone, then the power supply normally restarts. If not, a new protective burst is initiated, shielding the SMPS from any runaway. Figure 15 portrays the typical operating signals in short circuit:

Figure 15. Typical Waveforms in Short Circuit Conditions

## Calculating the Vcc Capacitor

The Vcc capacitor can be calculated knowing the IC consumption as soon as Vcc reaches 12.8 V . Suppose that a NCP1203P60 is used and drives a MOSFET with a 30 nC total gate charge $(\mathrm{Qg})$. The total average current is thus made of Icc1 $(700 \mu \mathrm{~A})$ plus the driver current, Fsw x Qg or 1.8 mA . The total current is therefore 2.5 mA . The $\Delta \mathrm{V}$ available to fully start up the circuit (e.g. never reach the 7.6 V UVLO during power on) is $12.8-7.6=5.2 \mathrm{~V}$. We have a capacitor who then needs to supply the NCP1203 with 2.5 mA during a given time until the auxiliary supply takes over. Suppose that this time was measured at around 15 ms .

CVcc is calculated using the equation

$$
C=\frac{\Delta t \cdot i}{\Delta V \text { or }}
$$ $C \geq 7.2 \mu \mathrm{~F}$. Select a $10 \mu \mathrm{~F} / 16 \mathrm{~V}$ and this will fit.

## Skipping Cycle Mode

The NCP1203 automatically skips switching cycles when the output power demand drops below a given level. This is accomplished by monitoring the FB pin. In normal operation, pin 2 imposes a peak current accordingly to the load value. If the load demand decreases, the internal loop asks for less peak current. When this setpoint reaches a determined level (Vpin 1), the IC prevents the current from decreasing further down and starts to blank the output pulses: the IC enters the so-called skip cycle mode, also named controlled burst operation. The power transfer now
depends upon the width of the pulse bunches (Figure 17). Suppose we have the following component values:
Lp, primary inductance $=350 \mu \mathrm{H}$
Fsw, switching frequency $=61 \mathrm{kHz}$
Ip skip $=600 \mathrm{~mA}$ (or $333 \mathrm{mV} /$ Rsense)
The theoretical power transfer is therefore:

$$
\frac{1}{2} \cdot \mathrm{Lp} \cdot \mathrm{lp} 2 \cdot \mathrm{Fsw}=3.8 \mathrm{~W}
$$

If this IC enters skip cycle mode with a bunch length of 10 ms over a recurrent period of 100 ms , then the total power transfer is: 3.8. $0.1=380 \mathrm{~mW}$.

To better understand how this skip cycle mode takes place, a look at the operation mode versus the FB level immediately gives the necessary insight:

Figure 16.

When FB is above the skip cycle threshold (1.0 V by default), the peak current cannot exceed $1.0 \mathrm{~V} /$ Rsense. When the IC enters the skip cycle mode, the peak current cannot go below Vpin1/3.3. The user still has the flexibility
to alter this 1.0 V by either shunting pin 1 to ground through a resistor or raising it through a resistor up to the desired level. Grounding pin 1 permanently invalidates the skip cycle operation.

Figure 17. Output Pulses at Various Power Levels (X=5.0 $\mu \mathrm{s} / \mathrm{div}$ ) P1 < P2 < P3

Figure 18. The Skip Cycle Takes Place at Low Peak Currents which Guaranties Noise-Free Operation

We recommend a pin1 operation between 400 mV and 1.3 V that will fix the skip peak current level between $120 \mathrm{mV} /$ Rsense and $390 \mathrm{mV} /$ Rsense.

## Non-Latching Shutdown

In some cases, it might be desirable to shut off the part temporarily and authorize its restart once the default has
disappeared. This option can easily be accomplished through a single NPN bipolar transistor wired between FB and ground. By pulling FB below the Adj pin 1 level, the output pulses are disabled as long as FB is pulled below pin 1. As soon as FB is relaxed, the IC resumes its operation. Figure 9 depicts the application example:

Figure 19. Another Way of Shutting Down the IC without a Definitive Latch-Off State

## Full Latching Shutdown

Other applications require a full latching shutdown, e.g. when an abnormal situation is detected (over temp or overvoltage). This feature can easily be implemented through two external transistors wired as a discrete SCR.

When the Vcc level exceeds the zener breakdown voltage, the NPN biases the PNP and fires the equivalent SCR, permanently bringing down the FB pin. The switching pulses are disabled until the user unplugs the power supply.

Figure 20. Two Bipolars Ensure a Total Latch-Off of the SMPS in Presence of an OVP

Rhold ensures that the SCR stays on when fired. The bias current flowing through Rhold should be small enough to let the Vcc ramp up ( 12.8 V ) and down $(4.6 \mathrm{~V})$ when the SCR is fired. The NPN base can also receive a signal from a
temperature sensor. Typical bipolars can be MMBT2222 and MMBT2907 for the discrete latch. The MMBT3946 features two bipolars NPN+PNP in the same package and could also be used.

## MC33364

## Critical Conduction GreenLine ${ }^{\text {TM }}$ SMPS Controller

The MC33364 series are variable frequency SMPS controllers that operate in the critical conduction mode. They are optimized for high density power supplies requiring minimum board area, reduced component count, and low power dissipation. Integration of the high voltage startup saves approximately 0.7 W of power compared to the value of the resistor bootstrapped circuits.

Each MC33364 features an on-board reference, UVLO function, a watchdog timer to initiate output switching, a zero current detector to ensure critical conduction operation, a current sensing comparator, leading edge blanking, a CMOS driver and cycle-by-cycle current limiting.

The MC33364D1 has an internal 126 kHz frequency clamp. The MC33364D2 is available without an internal frequency clamp. The MC33364D has an internal 126 kHz frequency clamp which is pinned out, so that the designer can adjust the clamp frequency by connecting appropriate values of resistance.

- Lossless Off-Line Startup
- Leading Edge Blanking for Noise Immunity
- Watchdog Timer to Initiate Switching
- Operating Temperature Range $-25^{\circ}$ to $+125^{\circ} \mathrm{C}$
- Shutdown Capability
- Over Temperature Protection
- Optional/Adjustable Frequency Clamp to Limit EMI

## MC33364

This device contains 335 active transistors.

Figure 1. Representative Block Diagram

PIN DESCRIPTION

| Pin | Function | Description |
| :---: | :---: | :---: |
| 1 (1) | Zero Current Detect | The ZCD Pin ensures critical conduction mode. ZCD monitors the voltage on the auxiliary winding, during the demagnetization phase of the transformer, comparing it to an internal reference. The ZCD sets the latch for the output driver. |
| 3 (2) | Current Sense | The Current Sense Pin monitors the current in the power switch by measuring the voltage across a resistor. Leading Edge Blanking is utilized to prevent false triggering. The voltage is compared to a resistor divider connected to the Voltage Feedback Pin. A 110 mV voltage off-set is applied to compensate the natural optocoupler saturation voltage. |
| 4 (3) | Voltage Feedback | The Voltage Feedback Pin is typically connected to the collector of the optocoupler for feedback from the isolated secondary output. The Feedback is connected to the $\mathrm{V}_{\text {ref }}$ Pin via a 5 k resistor providing bias for the external optocoupler. |
| 6 (4) | $\mathrm{V}_{\text {ref }}$ | The $\mathrm{V}_{\text {ref }}$ Pin is a buffered internal 5.0 V reference with Undervoltage Lockout. |
| 8 (NA) | Frequency Clamp | The Frequency Clamp Pin ensures a minimum off-time value, typically 6.9 us. It prevents the MOSFET from restarting within a fixed (33364D1) or adjustable (33364D) delay. The minimum off-time is disabled in the 33364D2. Therefore the maximum switching frequency cannot exceed $1 /\left(T_{O N}+T_{\text {OFFmin }}\right)$. |
| 9 (5) | A GND | This pin is the ground for the internal circuitry excluding the gate drive stage. |
| 10 (5) | P GND | This pin is the ground for the gate drive stage. |
| 11 (6) | Gate Drive | The gate drive is the output to drive the gate of the power MOSFET. |
| 12 (7) | $\mathrm{V}_{\mathrm{CC}}$ | Provides the voltage for all internal circuitry including the gate drive stage and $\mathrm{V}_{\text {ref }}$. This pin has Undervoltage Lockout with hysteresis. |
| 16 (8) | Line | The Line Pin provides the initial power to the $\mathrm{V}_{\mathrm{CC}}$ pins. Internally the line pin is a high voltage current source, eliminating the need for an external startup network. |

## FUNCTIONAL DESCRIPTION

## INTRODUCTION

With the goal of reducing the size and cost of off-line power supplies, there is an ever increasing demand for an economical method of obtaining a regulated galvanically isolated dc output voltage using a control which operates
directly from the ac line. This data sheet describes a monolithic control IC that was specifically designed for power supply control with a minimal number of external components. It offers the designer a simple cost effective solution to obtain the benefits of off-line power regulation.

Figure 8. Functional Block Diagram

## Operating Description

The MC33364 contains many of the building blocks and protection features that are employed in modern high performance current mode power supply controllers. Referring to the block diagram in Figure 8, note that this device does not contain an oscillator. A description of each of the functional blocks is given below.

## Zero Current Detector

The MC33364 operates as a critical conduction current mode controller, whereby the output switch conduction is initiated by the Zero Current Detector pin and terminated when the peak inductor current reaches the programmed threshold level. The ZCD pin indirectly monitors the inductor current by sensing the auxiliary winding voltage. When the voltage falls below the set threshold, 1.0 volt, the comparator resets the latch to turn on the MOSFET. There is 200 mV of hysteresis built into the comparator for noise immunity and to prevent false tripping

The ZCD pin is internally protected by a 10 volt and -0.7 volt clamp. An external resistor is necessary to limit the input current to 2 mA to protect the clamp.

Since the MC33364 implements the ZCD pin, the SMPS circuit has the following benefits:

1. A less expensive rectifier can be used on the output windings because of the zero current switching which naturally softens the diode turn-off.
2. The second benefit is the peak drain current which is limited to twice the average input current. By combining the ZCD series resistor with the pin capacitance, a drain-source valley switching can be implemented, further reducing the turn-on losses and the EMI disturbances.
3. By preventing the SMPS from entering the Continuous Conduction Mode (CCM), the MC33364 forces the system to stay a first-order device (in the lower frequency range) in any operating condition (output short, start-up, low mains). The feedback compensation network is thus considerably simplified.

## Current Sense and Feedback Inputs

The Current Sense pin and the Feedback pin are linked internally in the device via the current sense comparator. The output of the comparator is connected to the Set of the RS Latch, which turns the external MOSFET off.

The current sense operates by using a resistor, connected between the source of the MOSFET and ground, to convert the current through the inductor to a voltage. Leading Edge Blanking is implemented to prevent false triggering due to parasitics. The current sense voltage is level shifted up by 0.1 volt into the non-inverting input of the comparator. This offset accounts for the optocoupler VCEsat and allows the duty-cycle to be zero.

The maximum peak switch current is 1.15 V (the maximum voltage at the inverting input, 1.25 volts, minus 0.1 volt, the level shift) divided by the external current sense
resistance. The Current Sense Input to Drive Output propagation delay is 232 nsec typically.

The Feedback pin is internally pulled up with a 5 kOhm resistor from the 5.0 volt Vref pin. The Feedback pin uses a resistor divider to proportionally adjust the voltage into the inverting input of the comparator. The inverting input also has a 1.25 volt clamp. Typically the Feedback pin is connected to the collector of the optocoupler.

## Timer

A watchdog timer function was added to the IC to eliminate the need for an external oscillator when used in stand alone applications. The Timer provides a means to automatically start or restart the preconverter if the Drive Output has been off for more than 410 microseconds after the inductor current reaches zero. This time-out thus ensures the IC will restart when the demagnetization signal is lower than the internal ZCD 1V threshold or has simply been lost.

## Undervoltage Lockout

The MC33364 has a hysteretic UVLO associated with the $\mathrm{V}_{\mathrm{CC}}$ pin. During startup, $\mathrm{V}_{\mathrm{CC}}$ must rise to 15 volts to turn off the startup circuit associated with the Line pin and to enable the output drivers. The voltage at $\mathrm{V}_{\mathrm{CC}}$ must remain above 7.6 volts for the part to remain operational.

## Internal Reference

The MC33364 has an internal buffered 5.0 volt reference. The reference requires a $0.1 \mu \mathrm{~F}$ bypass capacitor for noise immunity. The reference is capable of sourcing 10 mA typically. The reference contains an independant UVLO which will disable the output drive circuitry.

## Startup Circuit and Restart Delay

A high voltage Startup Circuit is contained within the MC33364 eliminating the need for external components. The internal startup circuit operates as a constant current source to charge up the bypass capacitor on the $\mathrm{V}_{\mathrm{CC}}$ pin. The Startup Circuitry is controlled by the Restart Delay circuitry. The threshold levels of the turn on and turn off are below 4.5 volts and above 15 volts, respectively, as measured on the $\mathrm{V}_{\mathrm{CC}}$ pin.

A restart delay function is provided to allow hiccup mode fault protection in case of a short circuit condition and to prevent the SMPS from repeatedly trying to restart after the input line voltage has been removed. During a short circuit, the restart delay prevents excessive power dissipation in the primary side of the SMPS and allows time for the output to reset the fault condition. The restart delay time is approximately 100 msec .

## Output Switching Frequency Clamp

In normal operation, the MC33364 operates the flyback transformer in the critical conduction mode. The CCM is defined by the transformer ramping to a peak current value, ramping down to zero, then immediately ramping positive again. The peak current is programmed by the current sense resistor and is compared with a divided down voltage from
the feedback pin. When the output is reduced from full load to standby or no load, the switching frequency can increase dramatically to hundreds of kilohertz. Due to EMI regulations above 150 kHz , the Frequency Clamp on the MC33364D and MC33364D1 will limit the upper frequency by inserting a minimum off time.

The frequency of a switching regulator is determined by $\mathrm{f}=1 /\left(\mathrm{T}_{\text {on }}+\mathrm{T}_{\text {off }}\right)$. During light load and no load conditions, $\mathrm{T}_{\text {off }}$ is the reset time of the transformer plus dead time. At no load conditions, $\mathrm{T}_{\text {on }}$ is approximately the LEB and $\mathrm{T}_{\text {off }}$ is the programmed minimum off-time. With the addition of logic delay times, the maximum frequency when the FC pin floats is 126 kHz nominally.

The Frequency Clamp inserts a minimum off-time immediately after the driving signal goes low. If the ZCD signal comes within this minimum off-time, the information is ignored until the minimum off-time expires. By forcing the minimum off-time, the transformer will operate in the Discontinuous Mode. The next coming ZCD signal starts the latch. The MC33364 is available in three versions:

MC33364D1: the internal minimum off-time is fixed at $6.9 \mu \mathrm{sec}$ typically
MC33364D2: there is no internal minimum off-time
MC33364D: the internal minimum off-time can be either lengthened, shortened or eliminated by biasing the appropriate pin The FC pin contains a 4.0 kOhm series resistor into the non-inverting input of a comparator. The non-inverting input has a 10 volt clamp to limit overvoltage. Refer to Figure 9 for a detailed circuit of the Frequency Clamp.

NOTE: For proper operation, use either $\mathrm{R}_{\mathrm{Vcc}}$ or $\mathrm{R}_{\mathrm{gnd}}$ or let the pin float.
Figure 9. Simplified Frequency Clamp Circuit

The MC33364D has a Frequency Clamp pin which can vary the maximum frequency. If the FC pin floats, the minimum off-time is fixed at $6.9 \mu \mathrm{sec}$ typically. If the FC pin is grounded, the clamp is disabled. Sinking or sourcing a current up to $100 \mu \mathrm{~A}$ into the FC pin will vary the maximum frequency (see Figure 6). However, we do not recommend exceeding $80 \mu \mathrm{~A}$ because the high dDT/dIFC would not ensure a stable operation.

## Output

The IC contains a CMOS output driver specifically designed for direct drive of power MOSFETs. The Drive Output typical rise and fall time is 50 nS with a 1.0 nF load. Unbalanced Source and Sink capability eliminates the need for an external resistor between the IC Drive output and the Gate of the external MOSFET. Additional internal circuitry has been added to keep the Drive Output in a sinking mode whenever the UVLO is active. This characteristic eliminates the need for an external gate pull-down resistor.

## APPLICATION INFORMATION

## Design Example

Design an off-line Flyback converter according to the following requirements:

Output Power: $\quad 12 \mathrm{~W}$
Output: $\quad 6.0$ V @ 2 Amperes
Input voltage range: $90 \mathrm{Vac}-270 \mathrm{Vac}, 50 / 60 \mathrm{~Hz}$
The operation for the circuit shown in Figure 8 is as follows: the rectifier bridge D1-D4 and the capacitor C1 convert the ac line voltage to dc. This voltage supplies the primary winding of the transformer T1 and the startup circuit in U1 through the line pin. The primary current loop is closed by the transformer's primary winding, the TMOS switch Q1 and the current sense resistor R7. The resistors R5, R6, diode D6 and capacitor C4 create a snubber clamping network that protects Q1 from spikes on the primary winding. The network consisting of capacitor C3, diode D5 and resistor R1 provides a $\mathrm{V}_{\mathrm{CC}}$ supply voltage for U1 from the auxiliary winding of the transformer. The resistor R1 makes $\mathrm{V}_{\mathrm{CC}}$ more stable and resistant to noise. The resistor R2 reduces the current flow through the internal clamping and protection zener diode of the Zero Crossing Detector (ZCD) within U1. C3 is the decoupling capacitor of the supply voltage. The resistor R3 can provide additional bias current for the optoisolator's transistor. The diode D8 and the capacitor C5 rectify and filter the output voltage. The TL431, a programmable voltage reference, drives the primary side of the optoisolator to provide isolated feedback to the MC33364. The resistor divider consisting of R10 and R11 program the voltage of the TL431. The resistor R9 and the capacitors C7 and C8 provide frequency compensation of the feedback loop. Resistor R8 provides a current limit for the opto coupler and the TL431.

Since the critical conduction mode converter is a variable frequency system, the MC33364 has a built-in special block to reduce switching frequency in the no load condition. This block is named the "frequency clamp" block. MC33364 used in the design example has an internal frequency clamp set to 126 kHz . However, optional versions with a disabled or variable frequency clamp are available. The frequency clamp works as follows: the clamp controls the part of the switching cycle when the MOSFET switch is turned off. If this "off-time" (determined by the reset time of the transformer's core) is too short, then the frequency clamp does not allow the switch to turn-on again until the defined frequency clamp time is reached (i.e., the frequency clamp will insert a dead time).

There are several advantages of the MC33364's startup circuit. The startup circuit includes a special high voltage switch that controls the path between the rectified line voltage and the $\mathrm{V}_{\mathrm{CC}}$ supply capacitor to charge that capacitor by a limited current when the power is applied to the input. After a few switching cycles the IC is supplied from the transformer's auxiliary winding. After $\mathrm{V}_{\mathrm{CC}}$ reaches the undervoltage lockout threshold value, the startup switch is turned off by the undervoltage and the
overvoltage control circuit. Because the power supply can be shorted on the output, causing the auxiliary voltage to be zero, the MC33364 will periodically start its startup block. This mode is named "hiccup mode". During this mode the temperature of the chip rises but remains protected by the thermal shutdown block. During the power supply's normal operation, the high voltage internal MOSFET is turned off, preventing wasted power, and thereby, allowing greater circuit efficiency.
Since a bridge rectifier is used, the resulting minimum and maximum dc input voltages can be calculated:

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{in}(\min )} \mathrm{dc}=\sqrt{2} x \mathrm{~V}_{\text {in(min) }} \mathrm{ac}=(\sqrt{2})(90 \mathrm{Vac})=127 \mathrm{~V} \\
& \mathrm{~V}_{\mathrm{in}(\mu \mathrm{ax})} \mathrm{dc}=\sqrt{2} \mathrm{x} \mathrm{~V}_{\mathrm{in}(\mu \mathrm{ax})} \mathrm{ac}=(\sqrt{2})(270 \mathrm{Vac})=382 \mathrm{~V}
\end{aligned}
$$

The maximum average input current is:
$\mathrm{I}_{\text {in }}=\frac{\mathrm{P}_{\text {out }}}{\mathrm{nV} \mathrm{V}_{\text {in }(\min )}}=\frac{12 \mathrm{~W}}{0.8(127 \mathrm{~V})}=0.118 \mathrm{~A}$
where $\mathrm{n}=$ estimated circuit efficiency.
A TMOS switch with 600 V avalanche breakdown voltage is used. The voltage on the switch's drain consists of the input voltage and the flyback voltage of the transformer's primary winding. There is a ringing on the rising edge's top of the flyback voltage due to the leakage inductance of the transformer. This ringing is clamped by the RCD network. Design this clamped wave for an amplitude of 50 V below the avalanche breakdown of the TMOS device. Add another 50 V to allow a safety margin for the MOSFET. Then a suitable value of the flyback voltage may be calculated:

$$
\begin{gathered}
\mathrm{V}_{\mathrm{flbk}}=\mathrm{V}_{\text {TMOS }}-\mathrm{V}_{\text {in }(\max )}-100 \mathrm{~V}= \\
600 \mathrm{~V}-382 \mathrm{~V}-100 \mathrm{~V}=118 \mathrm{~V}
\end{gathered}
$$

Since this value is very close to the $\mathrm{V}_{\mathrm{in}(\mathrm{min})}$, set:
$\mathrm{V}_{\mathrm{flbk}}=\mathrm{V}_{\mathrm{in}(\min )}=127 \mathrm{~V}$
The $\mathrm{V}_{\text {flbk }}$ value of the duty cycle is given by:
$\partial \max =\frac{\mathrm{V}_{\mathrm{flbk}}}{\mathrm{V}_{\mathrm{flbk}}+\mathrm{V}_{\mathrm{in}(\min )}}=\frac{127 \mathrm{~V}}{[127 \mathrm{~V}+127 \mathrm{~V}]}=0.5$

The maximum input primary peak current:
$I_{p p k}=\frac{2 I_{\text {in }}}{\partial \max }=\frac{2.0(0.118 \mathrm{~A})}{0.5}=0.472 \mathrm{~A}$
Choose the desired minimum frequency $f_{\text {min }}$ of operation to be 70 kHz .
After reviewing the core sizing information provided by a core manufacturer, a EE core of size about 20 mm was chosen. Siemens' N67 magnetic material is used, which corresponds to a Philips 3C85 or TDK PC40 material.

The primary inductance value is given by:
$\mathrm{L}_{\mathrm{p}}=\frac{\partial \max \mathrm{V}_{\mathrm{in}(\mathrm{min})}}{\left(\mathrm{I}_{\mathrm{ppk}}\right)\left(\mathrm{f}_{\mathrm{min}}\right)}=\frac{0.5(127 \mathrm{~V})}{(0.472 \mathrm{~A})(70 \mathrm{kHz})}=1.92 \mathrm{mH}$
The manufacturer recommends for that magnetic core a maximum operating flux density of:
$\mathrm{B}_{\text {max }}=0.2 \mathrm{~T}$
The cross-sectional area $A_{c}$ of the EF20 core is:
$\mathrm{A}_{\mathrm{C}}=33.5 \mathrm{~mm}^{2}$
The operating flux density is given by:
$B_{\text {max }}=\frac{L_{p} I_{p p k}}{N_{p} A_{c}}$
From this equation the number of turns of the primary winding can be derived:
$n_{p}=\frac{L_{p} I_{p p k}}{B_{\max } A_{c}}$
The $A_{L}$ factor is determined by:

$$
\begin{aligned}
A_{L}=\frac{L_{p}}{n^{2} p}= & \frac{L_{p}\left(B_{\max } A_{c}\right)^{2}}{\left[L_{p}\left(I_{p p k}\right)^{2}\right]} \\
& =\frac{(0.2 \mathrm{~T})\left(33.5 \mathrm{E}-6 \mathrm{~m}^{2}\right)^{2}}{(.00192 \mathrm{H})(0.472 \mathrm{~A})^{2}}=105 \mathrm{nH}
\end{aligned}
$$

From the manufacturer's catalogue recommendation the core with an $\mathrm{A}_{\mathrm{L}}$ of 100 nH is selected. The desired number of turns of the primary winding is:
$n_{p}=\left(\frac{L_{p}}{A_{L}}\right)^{1 / 2}=\left[\frac{(0.00192 H)}{(100 n H)}\right]^{1 / 2}=139$ turns
The number of turns needed by the 6.0 V secondary is (assuming a Schottky rectifier is used):

$$
\begin{aligned}
&\left.\left.\mathrm{n}_{\mathrm{S}}=\frac{\left(\mathrm{V}_{\mathrm{S}}+\mathrm{V}_{\mathrm{fwd}}\right)(1-\partial \max ) \mathrm{n}_{\mathrm{p}}}{[\partial \max ( } \mathrm{V}_{\text {in }(\min )}\right)\right] \\
&=\frac{(6.0 \mathrm{~V}+0.3 \mathrm{~V})(1-0.5) 139}{[0.5(127 \mathrm{~V})]}=7 \text { turns }
\end{aligned}
$$

The auxiliary winding to power the control IC is 16 V and its number of turns is given by:

$$
\begin{aligned}
& \operatorname{naux}= \frac{\left(\mathrm{V}_{\mathrm{aux}}+\mathrm{V}_{\mathrm{fwd}}\right)(1-\partial \max ) \mathrm{n}_{\mathrm{p}}}{} \\
& {\left[\partial \max \left(\mathrm{~V}_{\mathrm{in}(\min )}\right)\right] } \\
&=\frac{(16 \mathrm{~V}+0.9 \mathrm{~V})(1-0.5) 139}{[0.5(127 \mathrm{~V})]}=19 \text { turns }
\end{aligned}
$$

The approximate value of rectifier capacitance needed is:
$\mathrm{C} 1=\frac{\mathrm{t}_{\text {off }}\left(\mathrm{I}_{\text {in }}\right)}{\mathrm{V}_{\text {ripple }}}=\frac{(5 \mathrm{~m} \mathrm{sec})(0.118 \mathrm{~A})}{50 \mathrm{~V}}=11.8 \mu \mathrm{~F}$
where the minimum ripple frequency is 2 times the 50 Hz line frequency and $\mathrm{t}_{\mathrm{off}}$, the discharge time of C 1 during the haversine cycle, is assumed to be half the cycle period.
Because we have a variable frequency system, all the calculations for the value of the output filter capacitors will be done at the lowest frequency, since the ripple voltage will be greatest at this frequency. When selecting the output capacitor select a capacitor with low ESR to minimize ripple from the current ripple. The approximate equation for the output capacitance value is given by:

$$
\mathrm{C} 5=\frac{\mathrm{I}_{\text {out }}}{\left({ }_{\text {min }}\right)\left(\mathrm{V}_{\text {rip }}\right)}=\frac{2 \mathrm{~A}}{(70 \mathrm{kHz})(0.1 \mathrm{~V})}=286 \mu \mathrm{~F}
$$

Determining the value of the current sense resistor (R7), one uses the peak current in the predesign consideration. Since within the IC there is a limitation of the voltage for the current sensing, which is set to 1.2 V , the design of the current sense resistor is simply given by:
$\mathrm{R} 7=\frac{\mathrm{V}_{\mathrm{CS}}}{\mathrm{I}_{\mathrm{ppk}}}=\frac{1.2 \mathrm{~V}}{0.472 \mathrm{~A}}=2.54 \Omega \approx 2.2 \Omega$
The error amplifier function is provided by a TL431 on the secondary, connected to the primary side via an optoisolator, the MOC8102.

The voltage of the optoisolator collector node sets the peak current flowing through the power switch during each cycle. This pin will be connected to the feedback pin of the MC33364, which will directly set the peak current.

Starting on the secondary side of the power supply, assign the sense current through the voltage-sensing resistor divider to be approximately 0.25 mA . One can immediately calculate the value of the lower and upper resistor:

$$
\begin{aligned}
& R_{\text {lower }}=R 11=\frac{V_{\text {ref }}(\mathrm{TL431)}}{\mathrm{I}_{\text {div }}}=\frac{2.5 \mathrm{~V}}{0.25 \mathrm{~mA}}=10 \mathrm{k} \\
& R_{\text {upper }}=\mathrm{R} 10=\frac{\mathrm{V}_{\text {out }}-\mathrm{V}_{\text {ref }}(\mathrm{TL431)}}{\mathrm{I}_{\mathrm{div}}} \\
& \quad=\frac{6.0 \mathrm{~V}-2.5 \mathrm{~V}}{0.25 \mathrm{~mA}}=14 \mathrm{k}
\end{aligned}
$$

The value of the resistor that would provide the bias current through the optoisolator and the TL431 is set by the minimum operating current requirements of the TL431. This current is minimum 1.0 mA . Assign the maximum current through the branch to be 5 mA . That makes the bias resistor value equal to:

$$
\begin{aligned}
R_{\text {bias }}=R_{S} & =\frac{\mathrm{V}_{\text {out }}-\left[\mathrm{V}_{\text {ref }}(\mathrm{TL431})+\mathrm{V}_{\mathrm{LED}}\right]}{\mathrm{I}_{\mathrm{LED}}} \\
& =\frac{6.0 \mathrm{~V}-[2.5 \mathrm{~V}+1.4 \mathrm{~V}]}{5.0 \mathrm{~mA}}=420 \Omega \approx 430 \Omega
\end{aligned}
$$

The MOC8102 has a typical current transfer ratio (CTR) of $100 \%$ with $25 \%$ tolerance. When the TL431 is full-on, 5 mA will be drawn from the transistor within the MOC8102. The transistor should be in saturated state at that time, so its collector resistor must be

$$
R_{\text {collector }}=\frac{V_{\text {ref }}-V_{\text {sat }}}{I_{\text {LED }}}=\frac{5.0 \mathrm{~V}-0.3 \mathrm{~V}}{5.0 \mathrm{~mA}}=940 \Omega
$$

Since a resistor of 5.0 k is internally connected from the reference voltage to the feedback pin of the MC33364, the external resistor can have a higher value

$$
\begin{aligned}
R_{\text {ext }}=R 3=\frac{\left(R_{\text {int }}\right)\left(R_{\text {collector }}\right)}{\left(R_{\text {int }}\right)-\left(R_{\text {collector }}\right)} & =\frac{(5.0 k)(940)}{5.0 k-940} \\
= & 1157 \Omega \approx 1200 \Omega
\end{aligned}
$$

This completes the design of the voltage feedback circuit.
In no load condition there is only a current flowing through the optoisolator diode and the voltage sense divider on the secondary side.

The load at that condition is given by:

$$
\begin{aligned}
R_{\text {noload }}= & \frac{V_{\text {out }}}{\left(I_{\text {LED }}+I_{\text {div }}\right)} \\
& =\frac{6.0 \mathrm{~V}}{(5.0 \mathrm{~mA}+0.25 \mathrm{~mA})}=1143 \Omega
\end{aligned}
$$

The output filter pole at no load is:

$$
\begin{aligned}
& \mathrm{f}_{\mathrm{pn}}=\frac{1}{\left(2 \pi \mathrm{R}_{\text {noload }} \mathrm{C}_{\text {out }}\right)} \\
& \quad=\frac{1}{(2 \pi)(1143)(300 \mu \mathrm{~F})}=0.46 \mathrm{~Hz}
\end{aligned}
$$

In heavy load condition the $\mathrm{I}_{\text {LED }}$ and $\mathrm{I}_{\text {div }}$ is negligible. The heavy load resistance is given by:

$$
R_{\text {heavy }}=\frac{V_{\text {out }}}{I_{\text {out }}}=\frac{6.0 \mathrm{~V}}{2.0 \mathrm{~A}}=3.0 \Omega
$$

The output filter pole at heavy load of this output is
$f_{p n}=\frac{1}{\left(2 \pi R_{\text {heavy }} C_{o u t}\right)}=\frac{1}{(2 \pi)(3)(300 \mu \mathrm{~F})}=177 \mathrm{~Hz}$
The gain exhibited by the open loop power supply at the high input voltage will be:

$$
A=\frac{\left(V_{\text {in max }}-V_{\text {out }}\right)^{2} N s}{\left(\left(V_{\text {in max }}\right)\left(V_{\text {error }}\right)(N p)\right)}=\frac{(382 \mathrm{~V}-6.0 \mathrm{~V})^{2}(7)}{(382 \mathrm{~V})(1.2 \mathrm{~V})(139)}
$$

$$
=15.53=23.82 \mathrm{~dB}
$$

The maximum recommended bandwidth is approximately:
$\mathrm{f}_{\mathrm{C}}=\frac{\mathrm{fs} \mathrm{min}}{5}=\frac{70 \mathrm{kHz}}{5}=14 \mathrm{kHz}$
The gain needed by the error amplifier to achieve this bandwidth is calculated at the rated load because that yields the bandwidth condition, which is:

$$
\mathrm{Gc}=20 \log \left(\frac{\mathrm{f}_{\mathrm{C}}}{f_{\mathrm{ph}}}\right)-\mathrm{A}=20 \log \left(\frac{14 \mathrm{kHz}}{177}\right)-23.82 \mathrm{~dB}
$$

$$
=14.14 \mathrm{~dB}
$$

The gain in absolute terms is:
$A_{C}=10^{(G c / 20)}=10^{(14.14 / 20)}=51$
Now the compensation circuit elements can be calculated. The output resistance of the voltage sense divider is given by the parallel combination of resistors in the divider:

$$
\begin{aligned}
& R_{\text {in }}=R_{\text {upper }}\left\|R_{\text {lower }}=10 k\right\| 14 k=5833 \Omega \\
& R 9=(A c)\left(R_{\text {in }}\right)=29.75 k \approx 30 k \\
& C 8=\frac{1}{\left[2 \pi\left(A_{c}\right)\left(R_{i n}\right)\left(f_{c}\right)\right]}=382 p F \approx 390 \mathrm{pF}
\end{aligned}
$$

The compensation zero must be placed at or below the light load filter pole:
$C 7=\frac{1}{\left[2 \pi(R 9)\left(f_{p n}\right)\right]}=11.63 \mu \mathrm{~F} \approx 10 \mu \mathrm{~F}$

## High Voltage Switching Regulator

The MC33363 is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 240 Vac line source. This integrated circuit features an on-chip 700 V/1.0 A SenseFET power switch, 450 V active off-line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle-by-cycle current limiting, input undervoltage lockout with hysteresis, output overvoltage protection, and thermal shutdown. This device is available in a 16-lead dual-in-line and wide body surface mount packages.

- On-Chip 700 V, 1.0 A SenseFET Power Switch
- Rectified 240 Vac Line Source Operation
- On-Chip 450 V Active Off-Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle-By-Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Output Overvoltage Protection Comparator
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown

Simplified Application

This device contains 221 active transistors.

PIN FUNCTION DESCRIPTION

| Pin | Function | Description |
| :---: | :---: | :---: |
| 1 | Startup Input | This pin connects directly to the rectified ac line voltage source. Internally Pin 1 is tied to the drain of a high voltage startup MOSFET. During startup, the MOSFET supplies internal bias, and charges an external capacitor that connects from the $\mathrm{V}_{\mathrm{CC}}$ pin to ground. |
| 2 | - | This pin has been omitted for increased spacing between the rectified ac line voltage on Pin 1 and the $\mathrm{V}_{\mathrm{CC}}$ potential on Pin 3. |
| 3 | $\mathrm{V}_{C C}$ | This is the positive supply voltage input. During startup, power is supplied to this input from Pin 1. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold, the startup MOSFET turns off and power is supplied from an auxiliary transformer winding. |
| 4, 5, 12, 13 | Ground | These pins are the control circuit grounds. They are part of the IC lead frame and provide a thermal path from the die to the printed circuit board. |
| 6 | $\mathrm{R}_{\text {T }}$ | Resistor $\mathrm{R}_{\mathrm{T}}$ connects from this pin to ground. The value selected will program the Current Limit Comparator threshold and affect the Oscillator frequency. |
| 7 | $\mathrm{C}_{\text {T }}$ | Capacitor $\mathrm{C}_{\top}$ connects from this pin to ground. The value selected, in conjunction with resistor $\mathrm{R}_{\mathrm{T}}$, programs the Oscillator frequency. |
| 8 | Regulator Output | This 6.5 V output is available for biasing external circuitry. It requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability. |
| 9 | Compensation | This pin is the Error Amplifier output and is made available for loop compensation. It can be used as an input to directly control the PWM Comparator. |
| 10 | Voltage Feedback Input | This is the inverting input of the Error Amplifier. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output. |
| 11 | Overvoltage Protection Input | This input provides runaway output voltage protection due to an external component or connection failure in the control loop feedback signal path. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output. |
| 14, 15 | - | These pins have been omitted for increased spacing between the high voltages present on the Power Switch Drain, and the ground potential on Pins 12 and 13. |
| 16 | Power Switch Drain | This pin is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A . |

Figure 17. Representative Block Diagram

Figure 18. Timing Diagram

## OPERATING DESCRIPTION

## Introduction

The MC33363 represents a new higher level of integration by providing all the active high voltage power, control, and protection circuitry required for implementation of a flyback or forward converter on a single monolithic chip. This device is designed for direct operation from a rectified 240 Vac line source and requires a minimum number of external components to implement a complete converter. A description of each of the functional blocks is given below, and the representative block and timing diagrams are shown in Figures 17 and 18.

## Oscillator and Current Mirror

The oscillator frequency is controlled by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Resistor $\mathrm{R}_{\mathrm{T}}$ programs the oscillator charge/discharge current via the Current Mirror 4 I output, Figure 3. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged and discharged by an equal magnitude internal current source and sink. This generates a symmetrical 50 percent duty cycle waveform at Pin 7, with a peak and valley threshold of 2.6 V and 0.6 V respectively. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gate Driver high. This causes the Power Switch gate drive to be held in a low state, thus producing a well controlled amount of output deadtime. The amount of deadtime is relatively constant with respect to the oscillator frequency when operating below 1.0 MHz . The maximum Power Switch duty cycle at Pin 16 can be modified from the internal 50\% limit by providing an additional charge or discharge current path to $\mathrm{C}_{\mathrm{T}}$, Figure 19. In order to increase the maximum duty cycle, a discharge current resistor $R_{D}$ is connected from Pin 7 to ground. To decrease the maximum duty cycle, a charge current resistor $\mathrm{R}_{\mathrm{C}}$ is connected from Pin 7 to the Regulator Output. Figure 4 shows an obtainable range of maximum output duty cycle versus the ratio of either $\mathrm{R}_{\mathrm{C}}$ or $\mathrm{R}_{\mathrm{D}}$ with respect to $\mathrm{R}_{\mathrm{T}}$.

Figure 19. Maximum Duty Cycle Modification

The formula for the charge/discharge current along with the oscillator frequency are given below. The frequency formula is a first order approximation and is accurate for $\mathrm{C}_{\mathrm{T}}$ values greater than 500 pF . For smaller values of $\mathrm{C}_{\mathrm{T}}$, refer to Figure 1. Note that resistor $\mathrm{R}_{\mathrm{T}}$ also programs the Current Limit Comparator threshold.

$$
\mathrm{I}_{\mathrm{chg} / \mathrm{dscg}}=\frac{5.4}{\mathrm{R}_{\mathrm{T}}} \quad \mathrm{f} \approx \frac{\mathrm{I}_{\mathrm{chg} / \mathrm{dscg}}}{4 \mathrm{C}_{\mathrm{T}}}
$$

## PWM Comparator and Latch

The pulse width modulator consists of a comparator with the oscillator ramp voltage applied to the non-inverting input, while the error amplifier output is applied into the inverting input. The Oscillator applies a set pulse to the PWM Latch while $\mathrm{C}_{\mathrm{T}}$ is discharging, and upon reaching the valley voltage, Power Switch conduction is initiated. When $\mathrm{C}_{\mathrm{T}}$ charges to a voltage that exceeds the error amplifier output, the PWM Latch is reset, thus terminating Power Switch conduction for the duration of the oscillator ramp-up period. This PWM Comparator/Latch combination prevents multiple output pulses during a given oscillator clock cycle. The timing diagram shown in Figure 18 illustrates the Power Switch duty cycle behavior versus the Compensation voltage.

## Current Limit Comparator and Power Switch

The MC33363 uses cycle-by-cycle current limiting as a means of protecting the output switch transistor from overstress. Each on-cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch current buildup during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the oscillator ramp-up period.

The Power Switch is constructed as a SenseFET allowing a virtually lossless method of monitoring the drain current. It consists of a total of 1780 cells, of which 46 are connected to a $9.0 \Omega$ ground-referenced sense resistor. The Current Sense Comparator detects if the voltage across the sense resistor exceeds the reference level that is present at the inverting input. If exceeded, the comparator quickly resets the PWM Latch, thus protecting the Power Switch. The current limit reference level is generated by the 2.25 I output of the Current Mirror. This current causes a reference voltage to appear across the $450 \Omega$ resistor. This voltage level, as well as the Oscillator charge/discharge current are both set by resistor $\mathrm{R}_{\mathrm{T}}$. Therefore when selecting the values for $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}, \mathrm{R}_{\mathrm{T}}$ must be chosen first to set the Power Switch peak drain current, while $\mathrm{C}_{\mathrm{T}}$ is chosen second to set the desired Oscillator frequency. A graph of the Power Switch peak drain current versus $\mathrm{R}_{\mathrm{T}}$ is shown in Figure 2 with the related formula below.

$$
\mathrm{I}_{\mathrm{pk}}=8.8\left(\frac{\mathrm{R}_{\mathrm{T}}}{1000}\right)-1.077
$$

The Power Switch is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A . Proper device voltage snubbing and heatsinking are required for reliable operation.

A Leading Edge Blanking circuit was placed in the current sensing signal path. This circuit prevents a premature reset of the PWM Latch. The premature reset is generated each time the Power Switch is driven into conduction. It appears as a narrow voltage spike across the current sense resistor, and is due to the MOSFET gate to source capacitance, transformer interwinding capacitance, and output rectifier recovery time. The Leading Edge Blanking circuit has a dynamic behavior in that it masks the current signal until the Power Switch turn-on transition is completed. The current limit propagation delay time is typically 233 ns . This time is measured from when an overcurrent appears at the Power Switch drain, to the beginning of turn-off.

## Error Amplifier

An fully compensated Error Amplifier with access to the inverting input and output is provided for primary side voltage sensing, Figure 17. It features a typical dc voltage gain of 82 dB , and a unity gain bandwidth of 1.0 MHz with 78 degrees of phase margin, Figure 5. The noninverting input is internally biased at $2.6 \mathrm{~V} \pm 3.1 \%$ and is not pinned out. The Error Amplifier output is pinned out for external loop compensation and as a means for directly driving the PWM Comparator. The output was designed with a limited sink current capability of $270 \mu \mathrm{~A}$, allowing it to be easily overridden with a pull-up resistor. This is desirable in applications that require secondary side voltage sensing, Figure 20. In this application, the Voltage Feedback Input is connected to the Regulator Output. This disables the Error Amplifier by placing its output into the sink state, allowing the optocoupler transistor to directly control the PWM Comparator.

## Overvoltage Protection

An Overvoltage Protection Comparator is included to eliminate the possibility of runaway output voltage. This condition can occur if the control loop feedback signal path is broken due to an external component or connection failure. The comparator is normally used to monitor the primary side $\mathrm{V}_{\mathrm{CC}}$ voltage. When the 2.6 V threshold is exceeded, it will immediately turn off the Power Switch, and protect the load from a severe overvoltage condition. This input can also be driven from external circuitry to inhibit converter operation.

## Undervoltage Lockout

An Undervoltage Lockout comparator has been incorporated to guarantee that the integrated circuit has sufficient voltage to be fully functional before the output stage is enabled. The UVLO comparator monitors the $\mathrm{V}_{\mathrm{CC}}$ voltage at Pin 3 and when it exceeds 14.5 V , the reset signal is removed from the PWM Latch allowing operation of the Power Switch. To prevent erratic switching as the threshold is crossed, 5.0 V of hysteresis is provided.

## Startup Control

An internal Startup Control circuit with a high voltage enhancement mode MOSFET is included within the MC33363. This circuitry allows for increased converter efficiency by eliminating the external startup resistor, and its associated power dissipation, commonly used in most off-line converters that utilize a UC3842 type of controller. Rectified ac line voltage is applied to the Startup Input, Pin 1. This causes the MOSFET to enhance and supply internal bias as well as charge current to the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor that connects from Pin 3 to ground. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold of 15.2 V , the IC commences operation and the startup MOSFET is turned off. Operating bias is now derived from the auxiliary transformer winding, and all of the device power is efficiently converted down from the rectified ac line.

The startup MOSFET will provide an initial peak current of 20 mA , Figure 10, which decreases rapidly as $\mathrm{V}_{\mathrm{CC}}$ and the die temperature rise. The steady state current will self limit in the range of 8.0 mA with $\mathrm{V}_{\mathrm{CC}}$ shorted to ground. The startup MOSFET is rated at a maximum of 400 V with $\mathrm{V}_{\mathrm{CC}}$ shorted to ground, and 500 V when charging a $\mathrm{V}_{\mathrm{CC}}$ capacitor of $1000 \mu \mathrm{~F}$ or less.

## Regulator

A low current 6.5 V regulated output is available for biasing the Error Amplifier and any additional control system circuitry. It is capable of up to 10 mA and has short-circuit protection. This output requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability.

## Thermal Shutdown and Package

Internal thermal circuitry is provided to protect the Power Switch in the event that the maximum junction temperature is exceeded. When activated, typically at $155^{\circ} \mathrm{C}$, the Latch is forced into a 'reset' state, disabling the Power Switch. The Latch is allowed to 'set' when the Power Switch temperature falls below $145^{\circ} \mathrm{C}$. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a substitute for proper heatsinking.

The MC33363 is contained in a heatsinkable plastic dual-in-line package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figures 15 and 17 show a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction to air thermal resistance. The examples are for a symmetrical layout on a single-sided board with two ounce per square foot of copper. Figure 22 shows a practical example of a printed circuit board layout that utilizes the copper foil as a heat dissipater. Note that a jumper was added to the layout from Pins 8 to 10 in order to enhance the copper area near the device for improved thermal conductivity. The application circuit requires two ounce copper foil in order to obtain 8.0 watts of continuous output power at room temperature.

|  | $\mathrm{V}_{\text {in }}=230 \mathrm{Vac}, \mathrm{I}_{\mathrm{O}}=1.6 \mathrm{~A}$ | Triangular $=2.0 \mathrm{mVpp}$, Spike $=12 \mathrm{mVpp}$ |
| Efficiency | $\mathrm{V}_{\text {in }}=115 \mathrm{Vac}, \mathrm{I}_{\mathrm{O}}=1.6 \mathrm{~A}$ | $78.6 \% *$ |
|  | $\mathrm{~V}_{\text {in }}=230 \mathrm{Vac}, \mathrm{I}_{\mathrm{O}}=1.6 \mathrm{~A}$ | $75.6 \%$ |

This data was taken with the components listed below mounted on the printed circuit board shown in Figure 22.

* With MBR2535CTL, $79.8 \%$ efficiency. PCB layout modification is required to use this rectifier.

For high efficiency and small circuit board size, the Sanyo Os-Con capacitors are recommended for C8, C9, C10 and C11.
C8, C9, C10 = Sanyo Os-Con \#6SA330M, 330 нF 6.3 V.
C11 = Sanyo Os-Con \#10SA220M, $220 \mu \mathrm{~F} 10 \mathrm{~V}$.
L1 = Coilcraft S5088-A, $5.0 \mu \mathrm{H}, 0.11 \Omega$.
T1 = Coilcraft S5502-A
Primary: 77 turns of \# 28 AWG, Pin $1=$ start, Pin $8=$ finish.
Two layers 0.002" Mylar tape.
Secondary: 5 turns of \# 22 AWG, 2 strands bifiliar wound, Pin $5=$ start, Pin $4=$ finish.
Two layers 0.002" Mylar tape.
Auxiliary: 13 turns of \# 28 AWG wound in center of bobbin, Pin $2=$ start, Pin $7=$ finish.
Two layers $0.002^{\prime \prime}$ Mylar tape.
Gap: 0.006 " total for a primary inductance ( $L_{p}$ ) of 1.0 mH .
Core and Bobbin: Coilcraft PT1950, E187, 3F3 material.

## MC33363A

## High Voltage Switching Regulator

The MC33363A is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 240 Vac line source. This integrated circuit features an on-chip $700 \mathrm{~V} / 1.5 \mathrm{~A}$ SenseFET power switch, 500 V active off-line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle-by-cycle current limiting, input undervoltage lockout with hysteresis, output overvoltage protection, and thermal shutdown. This device is available in a 16-lead dual-in-line and wide body surface mount packages.

- Enhanced Power Capability Over MC33363
- On-Chip 700 V, 1.5 A SenseFET Power Switch
- Rectified 240 Vac Line Source Operation
- On-Chip 500 V Active Off-Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle-By-Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Output Overvoltage Protection Comparator
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown

PIN FUNCTION DESCRIPTION

| Pin | Function | Description |
| :---: | :---: | :---: |
| 1 | Startup Input | This pin connects directly to the rectified ac line voltage source. Internally Pin 1 is tied to the drain of a high voltage startup MOSFET. During startup, the MOSFET supplies internal bias, and charges an external capacitor that connects from the $\mathrm{V}_{\mathrm{CC}}$ pin to ground. |
| 2 | - | This pin has been omitted for increased spacing between the rectified ac line voltage on Pin 1 and the $\mathrm{V}_{\mathrm{CC}}$ potential on Pin 3. |
| 3 | $\mathrm{V}_{C C}$ | This is the positive supply voltage input. During startup, power is supplied to this input from Pin 1. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold, the startup MOSFET turns off and power is supplied from an auxiliary transformer winding. |
| 4, 5, 12, 13 | Ground | These pins are the control circuit grounds. They are part of the IC lead frame and provide a thermal path from the die to the printed circuit board. |
| 6 | $\mathrm{R}_{\mathrm{T}}$ | Resistor $\mathrm{R}_{\mathrm{T}}$ connects from this pin to ground. The value selected will program the Current Limit Comparator threshold and affect the Oscillator frequency. |
| 7 | $\mathrm{C}_{\text {T }}$ | Capacitor $\mathrm{C}_{\mathrm{T}}$ connects from this pin to ground. The value selected, in conjunction with resistor $\mathrm{R}_{\mathrm{T}}$, programs the Oscillator frequency. |
| 8 | Regulator Output | This 6.5 V output is available for biasing external circuitry. It requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability. |
| 9 | Compensation | This pin is the Error Amplifier output and is made available for loop compensation. It can be used as an input to directly control the PWM Comparator. |
| 10 | Voltage Feedback Input | This is the inverting input of the Error Amplifier. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output. |
| 11 | Overvoltage Protection Input | This input provides runaway output voltage protection due to an external component or connection failure in the control loop feedback signal path. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output. |
| 14, 15 | - | These pins have been omitted for increased spacing between the high voltages present on the Power Switch Drain, and the ground potential on Pins 12 and 13. |
| 16 | Power Switch Drain | This pin is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A . |

Figure 18. Representative Block Diagram

Figure 19. Timing Diagram

## OPERATING DESCRIPTION

## Introduction

The MC33363A represents a new higher level of integration by providing all the active high voltage power, control, and protection circuitry required for implementation of a flyback or forward converter on a single monolithic chip. This device is designed for direct operation from a rectified 240 Vac line source and requires a minimum number of external components to implement a complete converter. A description of each of the functional blocks is given below, and the representative block and timing diagrams are shown in Figures 18 and 19.

## Oscillator and Current Mirror

The oscillator frequency is controlled by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Resistor $\mathrm{R}_{\mathrm{T}}$ programs the oscillator charge/discharge current via the Current Mirror 4 I output, Figure 4. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged and discharged by an equal magnitude internal current source and sink. This generates a symmetrical 50 percent duty cycle waveform at Pin 7, with a peak and valley threshold of 2.6 V and 0.6 V respectively. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gate Driver high. This causes the Power Switch gate drive to be held in a low state, thus producing a well controlled amount of output deadtime. The amount of deadtime is relatively constant with respect to the oscillator frequency when operating below 1.0 MHz . The maximum Power Switch duty cycle at Pin 16 can be modified from the internal 50\% limit by providing an additional charge or discharge current path to $\mathrm{C}_{\mathrm{T}}$, Figure 20. In order to increase the maximum duty cycle, a discharge current resistor $R_{D}$ is connected from Pin 7 to ground. To decrease the maximum duty cycle, a charge current resistor $\mathrm{R}_{\mathrm{C}}$ is connected from Pin 7 to the Regulator Output. Figure 5 shows an obtainable range of maximum output duty cycle versus the ratio of either $\mathrm{R}_{\mathrm{C}}$ or $\mathrm{R}_{\mathrm{D}}$ with respect to $\mathrm{R}_{\mathrm{T}}$.

The formula for the charge/discharge current along with the oscillator frequency are given below. The frequency formula is a first order approximation and is accurate for $\mathrm{C}_{\mathrm{T}}$ values greater than 500 pF . For smaller values of $\mathrm{C}_{\mathrm{T}}$, refer to Figure 2. Note that resistor $\mathrm{R}_{\mathrm{T}}$ also programs the Current Limit Comparator threshold.

$$
\mathrm{I}_{\mathrm{chg} / \mathrm{dscg}}=\frac{5.4}{\mathrm{R}_{\mathrm{T}}} \quad \mathrm{f} \approx \frac{\mathrm{I}_{\mathrm{chg} / \mathrm{dscg}}}{4 \mathrm{C}_{\mathrm{T}}}
$$

## PWM Comparator and Latch

The pulse width modulator consists of a comparator with the oscillator ramp voltage applied to the non-inverting input, while the error amplifier output is applied into the inverting input. The Oscillator applies a set pulse to the PWM Latch while $\mathrm{C}_{\mathrm{T}}$ is discharging, and upon reaching the valley voltage, Power Switch conduction is initiated. When $\mathrm{C}_{\mathrm{T}}$ charges to a voltage that exceeds the error amplifier output, the PWM Latch is reset, thus terminating Power Switch conduction for the duration of the oscillator ramp-up period. This PWM Comparator/Latch combination prevents multiple output pulses during a given oscillator clock cycle. The timing diagram shown in Figure 19 illustrates the Power Switch duty cycle behavior versus the Compensation voltage.

## Current Limit Comparator and Power Switch

The MC33363A uses cycle-by-cycle current limiting as a means of protecting the output switch transistor from overstress. Each on-cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch current buildup during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the oscillator ramp-up period.

The Power Switch is constructed as a SenseFET allowing a virtually lossless method of monitoring the drain current. It consists of a total of 2819 cells, of which 65 are connected to a $6.0 \Omega$ ground-referenced sense resistor. The Current Sense Comparator detects if the voltage across the sense resistor exceeds the reference level that is present at the inverting input. If exceeded, the comparator quickly resets the PWM Latch, thus protecting the Power Switch. The current limit reference level is generated by the 2.25 I output of the Current Mirror. This current causes a reference voltage to appear across the $450 \Omega$ resistor. This voltage level, as well as the Oscillator charge/discharge current are both set by resistor $\mathrm{R}_{\mathrm{T}}$. Therefore when selecting the values for $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}, \mathrm{R}_{\mathrm{T}}$ must be chosen first to set the Power Switch peak drain current, while $\mathrm{C}_{\mathrm{T}}$ is chosen second to set the desired Oscillator frequency. A graph of the Power Switch peak drain current versus $\mathrm{R}_{\mathrm{T}}$ is shown in Figure 3 with the related formula below.

$$
\mathrm{I}_{\mathrm{pk}}=15.95\left(\frac{\mathrm{R}_{\mathrm{T}}}{1000}\right)-1.14
$$

Figure 20. Maximum Duty Cycle Modification

The Power Switch is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A . Proper device voltage snubbing and heatsinking are required for reliable operation.

A Leading Edge Blanking circuit was placed in the current sensing signal path. This circuit prevents a premature reset of the PWM Latch. The premature reset is generated each time the Power Switch is driven into conduction. It appears as a narrow voltage spike across the current sense resistor, and is due to the MOSFET gate to source capacitance, transformer interwinding capacitance, and output rectifier recovery time. The Leading Edge Blanking circuit has a dynamic behavior in that it masks the current signal until the Power Switch turn-on transition is completed. The current limit propagation delay time is typically 300 ns . This time is measured from when an overcurrent appears at the Power Switch drain, to the beginning of turn-off.

## Error Amplifier

An fully compensated Error Amplifier with access to the inverting input and output is provided for primary side voltage sensing, Figure 18. It features a typical dc voltage gain of 82 dB , and a unity gain bandwidth of 1.0 MHz with 78 degrees of phase margin, Figure 6. The noninverting input is internally biased at $2.6 \mathrm{~V} \pm 3.1 \%$ and is not pinned out. The Error Amplifier output is pinned out for external loop compensation and as a means for directly driving the PWM Comparator. The output was designed with a limited sink current capability of $270 \mu \mathrm{~A}$, allowing it to be easily overridden with a pull-up resistor. This is desirable in applications that require secondary side voltage sensing, Figure 21. In this application, the Voltage Feedback Input is connected to the Regulator Output. This disables the Error Amplifier by placing its output into the sink state, allowing the optocoupler transistor to directly control the PWM Comparator.

## Overvoltage Protection

An Overvoltage Protection Comparator is included to eliminate the possibility of runaway output voltage. This condition can occur if the control loop feedback signal path is broken due to an external component or connection failure. The comparator is normally used to monitor the primary side $\mathrm{V}_{\mathrm{CC}}$ voltage. When the 2.6 V threshold is exceeded, it will immediately turn off the Power Switch, and protect the load from a severe overvoltage condition. This input can also be driven from external circuitry to inhibit converter operation.

## Undervoltage Lockout

An Undervoltage Lockout comparator has been incorporated to guarantee that the integrated circuit has sufficient voltage to be fully functional before the output stage is enabled. The UVLO comparator monitors the $\mathrm{V}_{\mathrm{CC}}$ voltage at Pin 3 and when it exceeds 14.5 V , the reset signal is removed from the PWM Latch allowing operation of the

Power Switch. To prevent erratic switching as the threshold is crossed, 5.0 V of hysteresis is provided.

## Startup Control

An internal Startup Control circuit with a high voltage enhancement mode MOSFET is included within the MC33363A. This circuitry allows for increased converter efficiency by eliminating the external startup resistor, and its associated power dissipation, commonly used in most off-line converters that utilize a UC3842 type of controller. Rectified ac line voltage is applied to the Startup Input, Pin 1. This causes the MOSFET to enhance and supply internal bias as well as charge current to the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor that connects from Pin 3 to ground. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold of 15.2 V , the IC commences operation and the startup MOSFET is turned off. Operating bias is now derived from the auxiliary transformer winding, and all of the device power is efficiently converted down from the rectified ac line.

The startup MOSFET will provide an initial peak current of 20 mA , Figure 11 , which decreases rapidly as $\mathrm{V}_{\mathrm{CC}}$ and the die temperature rise. The steady state current will self limit in the range of 8.0 mA with $\mathrm{V}_{\mathrm{CC}}$ shorted to ground. The startup MOSFET is rated at a maximum of 400 V with $\mathrm{V}_{\mathrm{CC}}$ shorted to ground, and 500 V when charging a $\mathrm{V}_{\mathrm{CC}}$ capacitor of $1000 \mu \mathrm{~F}$ or less.

## Regulator

A low current 6.5 V regulated output is available for biasing the Error Amplifier and any additional control system circuitry. It is capable of up to 10 mA and has short-circuit protection. This output requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability.

## Thermal Shutdown and Package

Internal thermal circuitry is provided to protect the Power Switch in the event that the maximum junction temperature is exceeded. When activated, typically at $155^{\circ} \mathrm{C}$, the Latch is forced into a 'reset' state, disabling the Power Switch. The Latch is allowed to 'set' when the Power Switch temperature falls below $145^{\circ} \mathrm{C}$. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a substitute for proper heatsinking.

The MC33363A is contained in a heatsinkable plastic dual-in-line package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figures 16 and 17 show a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction to air thermal resistance. The examples are for a symmetrical layout on a single-sided board with two ounce per square foot of copper. Figure 23 shows a practical example of a printed circuit board layout

## MC33363A

that utilizes the copper foil as a heat dissipater. Note that a jumper was added to the layout from Pins 8 to 10 in order to enhance the copper area near the device for improved thermal
conductivity. The application circuit requires two ounce copper foil in order to obtain 8.0 watts of continuous output power at room temperature.

Figure 21. 15 W Off-Line Converter

| Test | Conditions | Results |
| :--- | :--- | :--- |
| Line Regulation | $\mathrm{V}_{\text {in }}=92 \mathrm{Vac}$ to $276 \mathrm{Vac}, \mathrm{I}_{\mathrm{O}} 3.0 \mathrm{~A}$ | $\Delta=1.0 \mathrm{mV}$ |

|  | $\mathrm{V}_{\text {in }}=230 \mathrm{Vac}, \mathrm{I}_{\mathrm{O}}=3.0 \mathrm{~A}$ | Triangular $=2.0 \mathrm{mVpp}$, Spike $=34 \mathrm{mVpp}$ |
| Efficiency | $\mathrm{V}_{\text {in }}=115 \mathrm{Vac}, \mathrm{I}_{\mathrm{O}}=3.0 \mathrm{~A}$ | $76.8 \%^{*}$ |
|  | $\mathrm{~V}_{\text {in }}=230 \mathrm{Vac}, \mathrm{I}_{\mathrm{O}}=3.0 \mathrm{~A}$ | $76.8 \%$ |

This data was taken with the components listed below mounted on the printed circuit board shown in Figure 23.

* With MBR2535CTL, $78.8 \%$ efficiency. PCB layout modification is required to use this rectifier.

For high efficiency and small circuit board size, the Sanyo Os-Con capacitors are recommended for C8, C9, C10 and C11.
C8, C9, C10 = Sanyo Os-Con \#6SA330M, $330 \mu \mathrm{~F} 6.3 \mathrm{~V}$.
C11 = Sanyo Os-Con \#10SA220M, $220 \mu \mathrm{~F} 10 \mathrm{~V}$.
L1 = Coilcraft S5088-A, $5.0 \mu \mathrm{H}, 0.11 \Omega$.
T1 = Coilcraft U6875-A
Primary: 77 turns of \# 28 AWG, Pin $1=$ start, Pin $8=$ finish.
Two layers $0.002^{\prime \prime}$ Mylar tape.
Secondary: 5 turns of \# 22 AWG, 2 strands bifiliar wound, Pin $5=$ start, Pin $4=$ finish.
Two layers $0.002^{\prime \prime}$ Mylar tape.
Auxiliary: 13 turns of \# 28 AWG wound in center of bobbin, Pin $2=$ start, Pin $7=$ finish.
Two layers $0.002^{\prime \prime}$ Mylar tape.
Gap: $0.011^{\prime \prime}$ total for a primary inductance ( $L_{P}$ ) of $620 \mu \mathrm{H}$.
Core and Bobbin: Coilcraft PT1950, E187, 3F3 material.

## MC33363B

## High Voltage Switching Regulator

The MC33363B is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 240 Vac line source. This integrated circuit features an on-chip $700 \mathrm{~V} / 1.0 \mathrm{~A}$ SENSEFET power switch, 450 V active off-line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle-by-cycle current limiting, input undervoltage lockout with hysteresis, overvoltage protection, and thermal shutdown. This device is available in a 16-lead dual-in-line and wide body surface mount packages.

- On-Chip 700 V, 1.0 A SENSEFET Power Switch
- Rectified 240 Vac Line Source Operation
- On-Chip 450 V Active Off-Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle-By-Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Over-Voltage Protection
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown

PIN FUNCTION DESCRIPTION

| Pin | Function | Description |
| :---: | :---: | :---: |
| 1 | Startup Input | This pin connects directly to the rectified ac line voltage source. Internally Pin 1 is tied to the drain of a high voltage startup MOSFET. During startup, the MOSFET supplies internal bias, and charges an external capacitor that connects from the $\mathrm{V}_{\mathrm{CC}}$ pin to ground. |
| 2 | - | This pin has been omitted for increased spacing between the rectified ac line voltage on Pin 1 and the $\mathrm{V}_{\mathrm{CC}}$ potential on Pin 3. |
| 3 | $\mathrm{V}_{C C}$ | This is the positive supply voltage input. During startup, power is supplied to this input from Pin 1. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold, the startup MOSFET turns off and power is supplied from an auxiliary transformer winding. |
| 4, 5, 12, 13 | Ground | These pins are the control circuit grounds. They are part of the IC lead frame and provide a thermal path from the die to the printed circuit board. |
| 6 | $\mathrm{R}_{\mathrm{T}}$ | Resistor $\mathrm{R}_{\mathrm{T}}$ connects from this pin to ground. The value selected will program the Current Limit Comparator threshold and affect the Oscillator frequency. |
| 7 | $\mathrm{C}_{\text {T }}$ | Capacitor $\mathrm{C}_{\mathrm{T}}$ connects from this pin to ground. The value selected, in conjunction with resistor $\mathrm{R}_{\mathrm{T}}$, programs the Oscillator frequency. |
| 8 | Regulator Output | This 6.5 V output is available for biasing external circuitry. It requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability. |
| 9 | Compensation | This pin is the Error Amplifier output and is made available for loop compensation. It can be used as an input to directly control the PWM Comparator. |
| 10 | Voltage Feedback Input | This is the inverting input of the Error Amplifier. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output. |
| 11 | Overvoltage Protection Input | This input provides runaway output voltage protection due to an external component or connection failure in the control loop feedback signal path. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output. |
| 14, 15 | - | These pins have been omitted for increased spacing between the high voltages present on the Power Switch Drain, and the ground potential on Pins 12 and 13. |
| 16 | Power Switch Drain | This pin is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A . |

Figure 18. Representative Block Diagram

Figure 19. Timing Diagram

## OPERATING DESCRIPTION

## Introduction

The MC33363B represents a new higher level of integration by providing all the active high voltage power, control, and protection circuitry required for implementation of a flyback or forward converter on a single monolithic chip. This device is designed for direct operation from a rectified 240 Vac line source and requires a minimum number of external components to implement a complete converter. A description of each of the functional blocks is given below, and the representative block and timing diagrams are shown in Figures 18 and 19.

## Oscillator and Current Mirror

The oscillator frequency is controlled by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Resistor $\mathrm{R}_{\mathrm{T}}$ programs the oscillator charge/discharge current via the Current Mirror 4 I output, Figure 4. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged and discharged by an equal magnitude internal current source and sink. This generates a symmetrical 50 percent duty cycle waveform at Pin 7, with a peak and valley threshold of 2.6 V and 0.6 V respectively. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gate Driver high. This causes the Power Switch gate drive to be held in a low state, thus producing a well controlled amount of output deadtime. The amount of deadtime is relatively constant with respect to the oscillator frequency when operating below 1.0 MHz . The maximum Power Switch duty cycle at Pin 16 can be modified from the internal 50\% limit by providing an additional charge or discharge current path to $\mathrm{C}_{\mathrm{T}}$, Figure 20. In order to increase the maximum duty cycle, a discharge current resistor $\mathrm{R}_{\mathrm{D}}$ is connected from Pin 7 to ground. To decrease the maximum duty cycle, a charge current resistor $\mathrm{R}_{\mathrm{C}}$ is connected from Pin 7 to the Regulator Output. Figure 5 shows an obtainable range of maximum output duty cycle versus the ratio of either $R_{C}$ or $\mathrm{R}_{\mathrm{D}}$ with respect to $\mathrm{R}_{\mathrm{T}}$.

Figure 20. Maximum Duty Cycle Modification

The formula for the charge/discharge current along with the oscillator frequency are given below. The frequency formula is a first order approximation and is accurate for $\mathrm{C}_{\mathrm{T}}$ values greater than 500 pF . For smaller values of $\mathrm{C}_{\mathrm{T}}$, refer to Figure 2. Note that resistor $\mathrm{R}_{\mathrm{T}}$ also programs the Current Limit Comparator threshold.

$$
\mathrm{I}_{\mathrm{chg} / \mathrm{dscg}}=\frac{5.4}{\mathrm{R}_{\mathrm{T}}} \quad \mathrm{f} \approx \frac{\mathrm{I}_{\mathrm{chg} / \mathrm{dscg}}}{4 \mathrm{C}_{\mathrm{T}}}
$$

## PWM Comparator and Latch

The pulse width modulator consists of a comparator with the oscillator ramp voltage applied to the non-inverting input, while the error amplifier output is applied into the inverting input. The Oscillator applies a set pulse to the PWM Latch while $\mathrm{C}_{\mathrm{T}}$ is discharging, and upon reaching the valley voltage, Power Switch conduction is initiated. When $\mathrm{C}_{\mathrm{T}}$ charges to a voltage that exceeds the error amplifier output, the PWM Latch is reset, thus terminating Power Switch conduction for the duration of the oscillator ramp-up period. This PWM Comparator/Latch combination prevents multiple output pulses during a given oscillator clock cycle. The timing diagram shown in Figure 19 illustrates the Power Switch duty cycle behavior versus the Compensation voltage.

## Current Limit Comparator and Power Switch

The MC33363B uses cycle-by-cycle current limiting as a means of protecting the output switch transistor from overstress. Each on-cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch current buildup during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the oscillator ramp-up period.

The Power Switch is constructed as a SENSEFET allowing a virtually lossless method of monitoring the drain current. It consists of a total of 1462 cells, of which 36 are connected to a $8.1 \Omega$ ground-referenced sense resistor. The Current Sense Comparator detects if the voltage across the sense resistor exceeds the reference level that is present at the inverting input. If exceeded, the comparator quickly resets the PWM Latch, thus protecting the Power Switch. The current limit reference level is generated by the 2.25 I output of the Current Mirror. This current causes a reference voltage to appear across the $405 \Omega$ resistor. This voltage level, as well as the Oscillator charge/discharge current are both set by resistor $\mathrm{R}_{\mathrm{T}}$. Therefore when selecting the values for $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}, \mathrm{R}_{\mathrm{T}}$ must be chosen first to set the Power Switch peak drain current, while $\mathrm{C}_{\mathrm{T}}$ is chosen second to set the desired Oscillator frequency. A graph of the Power Switch peak drain current versus $\mathrm{R}_{\mathrm{T}}$ is shown in Figure 3 with the related formula below.

$$
\mathrm{I}_{\mathrm{pk}}=8.8\left(\frac{\mathrm{R}_{\mathrm{T}}}{1000}\right)-1.077
$$

The Power Switch is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A . Proper device voltage snubbing and heatsinking are required for reliable operation.

A Leading Edge Blanking circuit was placed in the current sensing signal path. This circuit prevents a premature reset of the PWM Latch. The premature reset is generated each time the Power Switch is driven into conduction. It appears as a narrow voltage spike across the current sense resistor, and is due to the MOSFET gate to source capacitance, transformer interwinding capacitance, and output rectifier recovery time. The Leading Edge Blanking circuit has a dynamic behavior in that it masks the current signal until the Power Switch turn-on transition is completed. The current limit propagation delay time is typically 262 ns . This time is measured from when an overcurrent appears at the Power Switch drain, to the beginning of turn-off.

## Error Amplifier

An fully compensated Error Amplifier with access to the inverting input and output is provided for primary side voltage sensing, Figure 18. It features a typical dc voltage gain of 82 dB , and a unity gain bandwidth of 1.0 MHz with 78 degrees of phase margin, Figure 6. The noninverting input is internally biased at $2.6 \mathrm{~V} \pm 3.1 \%$ and is not pinned out. The Error Amplifier output is pinned out for external loop compensation and as a means for directly driving the PWM Comparator. The output was designed with a limited sink current capability of $270 \mu \mathrm{~A}$, allowing it to be easily overridden with a pull-up resistor. This is desirable in applications that require secondary side voltage sensing.

## Overvoltage Protection

An Overvoltage Protection Comparator is included to eliminate the possibility of runaway output voltage. This condition can occur if the control loop feedback signal path is broken due to an external component or connection failure. The comparator is normally used to monitor the primary side $\mathrm{V}_{\mathrm{CC}}$ voltage. When the 2.6 V threshold is exceeded, it will immediately turn off the Power Switch, and protect the load from a severe overvoltage condition. This input can also be driven from external circuitry to inhibit converter operation.

## Undervoltage Lockout

An Undervoltage Lockout comparator has been incorporated to guarantee that the integrated circuit has sufficient voltage to be fully functional before the output stage is enabled. The UVLO comparator monitors the $\mathrm{V}_{\mathrm{CC}}$ voltage at Pin 3 and when it exceeds 14.5 V , the reset signal is removed from the PWM Latch allowing operation of the Power Switch. To prevent erratic switching as the threshold is crossed, 5.0 V of hysteresis is provided.

## Startup Control

An internal Startup Control circuit with a high voltage enhancement mode MOSFET is included within the MC33363B. This circuitry allows for increased converter efficiency by eliminating the external startup resistor, and its associated power dissipation, commonly used in most off-line converters that utilize a UC3842 type of controller. Rectified ac line voltage is applied to the Startup Input, Pin 1. This causes the MOSFET to enhance and supply internal bias as well as charge current to the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor that connects from Pin 3 to ground. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold of 15.2 V , the IC commences operation and the startup MOSFET is turned off. Operating bias is now derived from the auxiliary transformer winding, and all of the device power is efficiently converted down from the rectified ac line.

The startup MOSFET will provide a steady current of 1.7 mA , Figure 11, as $\mathrm{V}_{\mathrm{CC}}$ increases or shorted to ground. The startup MOSFET is rated at a maximum of 400 V with $\mathrm{V}_{\mathrm{CC}}$ shorted to ground, and 500 V when charging a $\mathrm{V}_{\mathrm{CC}}$ capacitor of $1000 \mu \mathrm{~F}$ or less.

## Regulator

A low current 6.5 V regulated output is available for biasing the Error Amplifier and any additional control system circuitry. It is capable of up to 10 mA and has short-circuit protection. This output requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability.

## Thermal Shutdown and Package

Internal thermal circuitry is provided to protect the Power Switch in the event that the maximum junction temperature is exceeded. When activated, typically at $150^{\circ} \mathrm{C}$, the Latch is forced into a 'reset' state, disabling the Power Switch. The Latch is allowed to 'set' when the Power Switch temperature falls below $140^{\circ} \mathrm{C}$. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a substitute for proper heatsinking.

The MC33363B is contained in a heatsinkable plastic dual-in-line package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figures 16 and 17 show a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction to air thermal resistance. The examples are for a symmetrical layout on a single-sided board with two ounce per square foot of copper.

## MC33365

## High Voltage Switching Regulator

The MC33365 is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 240 Vac line source. This integrated circuit features an on-chip $700 \mathrm{~V} / 1.0 \mathrm{~A} \mathrm{SENSEFET}^{\text {TM }}$ power switch, 450 V active off-line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle-by-cycle current limiting, input undervoltage lockout with hysteresis, bulk capacitor voltage sensing, and thermal shutdown. This device is available in a 16-lead dual-in-line package.

- On-Chip 700 V, 1.0 A SENSEFET Power Switch
- Rectified 240 Vac Line Source Operation
- On-Chip 450 V Active Off-Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle-By-Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Bulk Capacitor Voltage Comparator
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown

PIN FUNCTION DESCRIPTION

| Pin | Function | Description |
| :---: | :---: | :---: |
| 1 | Startup Input | This pin connects directly to the rectified ac line voltage source. Internally Pin 1 is tied to the drain of a high voltage startup MOSFET. During startup, the MOSFET supplies internal bias, and charges an external capacitor that connects from the $\mathrm{V}_{\mathrm{CC}}$ pin to ground. |
| 2 | - | This pin has been omitted for increased spacing between the rectified ac line voltage on Pin 1 and the $\mathrm{V}_{\mathrm{CC}}$ potential on Pin 3. |
| 3 | $\mathrm{V}_{\mathrm{CC}}$ | This is the positive supply voltage input. During startup, power is supplied to this input from Pin 1. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold, the startup MOSFET turns off and power is supplied from an auxiliary transformer winding. |
| 4, 5, 12, 13 | Gnd | These pins are the control circuit grounds. They are part of the IC lead frame and provide a thermal path from the die to the printed circuit board. |
| 6 | $\mathrm{R}_{\mathrm{T}}$ | Resistor $\mathrm{R}_{\mathrm{T}}$ connects from this pin to ground. The value selected will program the Current Limit Comparator threshold and affect the Oscillator frequency. |
| 7 | $\mathrm{C}_{\text {T }}$ | Capacitor $\mathrm{C}_{\mathrm{T}}$ connects from this pin to ground. The value selected, in conjunction with resistor $\mathrm{R}_{\mathrm{T}}$, programs the Oscillator frequency. |
| 8 | Regulator Output | This 6.5 V output is available for biasing external circuitry. It requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability. |
| 9 | Compensation | This pin is the Error Amplifier output and is made available for loop compensation. It can be used as an input to directly control the PWM Comparator. |
| 10 | Voltage Feedback Input | This is the inverting input of the Error Amplifier. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output. |
| 11 | BOK | This is the non-inverting input of the bulk capacitor voltage comparator. It has an input threshold voltage of 1.25 V . This pin is connected through a resistor divider to the bulk capacitor line voltage. |
| 14, 15 | - | These pins have been omitted for increased spacing between the high voltages present on the Power Switch Drain, and the ground potential on Pins 12 and 13. |
| 16 | Power Switch Drain | This pin is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A . |

Figure 17. Representative Block Diagram

Figure 18. Timing Diagram

## OPERATING DESCRIPTION

## Introduction

The MC33365 represents a new higher level of integration by providing all the active high voltage power, control, and protection circuitry required for implementation of a flyback or forward converter on a single monolithic chip. This device is designed for direct operation from a rectified 240 Vac line source and requires a minimum number of external components to implement a complete converter. A description of each of the functional blocks is given below, and the representative block and timing diagrams are shown in Figures 17 and 18.

## Oscillator and Current Mirror

The oscillator frequency is controlled by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Resistor $\mathrm{R}_{\mathrm{T}}$ programs the oscillator charge/discharge current via the Current Mirror 4 I output, Figure 4. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged and discharged by an equal magnitude internal current source and sink. This generates a symmetrical 50 percent duty cycle waveform at Pin 7, with a peak and valley threshold of 2.6 V and 0.6 V respectively. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gate Driver high. This causes the Power Switch gate drive to be held in a low state, thus producing a well controlled amount of output deadtime. The amount of deadtime is relatively constant with respect to the oscillator frequency when operating below 1.0 MHz . The maximum Power Switch duty cycle at Pin 16 can be modified from the internal 50\% limit by providing an additional charge or discharge current path to $\mathrm{C}_{\mathrm{T}}$, Figure 19. In order to increase the maximum duty cycle, a discharge current resistor $R_{D}$ is connected from Pin 7 to ground. To decrease the maximum duty cycle, a charge current resistor $\mathrm{R}_{\mathrm{C}}$ is connected from Pin 7 to the Regulator Output. Figure 5 shows an obtainable range of maximum output duty cycle versus the ratio of either $\mathrm{R}_{\mathrm{C}}$ or $\mathrm{R}_{\mathrm{D}}$ with respect to $\mathrm{R}_{\mathrm{T}}$.

Figure 19. Maximum Duty Cycle Modification

The formula for the charge/discharge current along with the oscillator frequency are given below. The frequency formula is a first order approximation and is accurate for $\mathrm{C}_{\mathrm{T}}$ values greater than 500 pF . For smaller values of $\mathrm{C}_{\mathrm{T}}$, refer to Figure 2. Note that resistor $\mathrm{R}_{\mathrm{T}}$ also programs the Current Limit Comparator threshold.

$$
\mathrm{I}_{\mathrm{chg}} / \mathrm{dscg}=\frac{5.4}{\mathrm{RT}^{2}} \quad \mathrm{f} \approx \frac{\mathrm{I}_{\mathrm{chg}} / \mathrm{dscg}}{4 \mathrm{C}_{\top}}
$$

## PWM Comparator and Latch

The pulse width modulator consists of a comparator with the oscillator ramp voltage applied to the non-inverting input, while the error amplifier output is applied into the inverting input. The Oscillator applies a set pulse to the PWM Latch while $\mathrm{C}_{\mathrm{T}}$ is discharging, and upon reaching the valley voltage, Power Switch conduction is initiated. When $\mathrm{C}_{\mathrm{T}}$ charges to a voltage that exceeds the error amplifier output, the PWM Latch is reset, thus terminating Power Switch conduction for the duration of the oscillator ramp-up period. This PWM Comparator/Latch combination prevents multiple output pulses during a given oscillator clock cycle. The timing diagram shown in Figure 18 illustrates the Power Switch duty cycle behavior versus the Compensation voltage.

## Current Limit Comparator and Power Switch

The MC33365 uses cycle-by-cycle current limiting as a means of protecting the output power switch from overstress. Each on-cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch current buildup during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the oscillator ramp-up period.

The Power Switch is constructed as a SENSEFET allowing a virtually lossless method of monitoring the drain current. It consists of a total of 1462 cells, of which 36 are connected to a $8.1 \Omega$ ground-referenced sense resistor. The Current Sense Comparator detects if the voltage across the sense resistor exceeds the reference level that is present at the inverting input. If exceeded, the comparator quickly resets the PWM Latch, thus protecting the Power Switch. The current limit reference level is generated by the 2.25 I output of the Current Mirror. This current causes a reference voltage to appear across the $405 \Omega$ resistor. This voltage level, as well as the Oscillator charge/discharge current are both set by resistor $\mathrm{R}_{\mathrm{T}}$. Therefore when selecting the values for $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}, \mathrm{R}_{\mathrm{T}}$ must be chosen first to set the Power Switch peak drain current, while $\mathrm{C}_{\mathrm{T}}$ is chosen second to set the desired Oscillator frequency. A graph of the Power Switch peak drain current versus $\mathrm{R}_{\mathrm{T}}$ is shown in Figure 3 with the related formula below.

$$
\mathrm{I}_{\mathrm{pk}}=8.8\left(\frac{\mathrm{R}_{\mathrm{T}}}{1000}\right)-1.077
$$

The Power Switch is designed to directly drive the converter transformer and is capable of switching a maximum of 700 V and 1.0 A . Proper device voltage snubbing and heatsinking are required for reliable operation.

A Leading Edge Blanking circuit was placed in the current sensing signal path. This circuit prevents a premature reset of the PWM Latch. The premature reset is generated each time the Power Switch is driven into conduction. It appears as a narrow voltage spike across the current sense resistor, and is due to the MOSFET gate to source capacitance, transformer interwinding capacitance, and output rectifier recovery time. The Leading Edge Blanking circuit has a dynamic behavior in that it masks the current signal until the Power Switch turn-on transition is completed. The current limit propagation delay time is typically 262 ns . This time is measured from when an overcurrent appears at the Power Switch drain, to the beginning of turn-off.

## Error Amplifier

An fully compensated Error Amplifier with access to the inverting input and output is provided for primary side voltage sensing, Figure 17. It features a typical dc voltage gain of 82 dB , and a unity gain bandwidth of 1.0 MHz with 78 degrees of phase margin, Figure 6. The noninverting input is internally biased at $2.6 \mathrm{~V} \pm 3.1 \%$ and is not pinned out. The Error Amplifier output is pinned out for external loop compensation and as a means for directly driving the PWM Comparator. The output was designed with a limited sink current capability of $270 \mu \mathrm{~A}$, allowing it to be easily overridden with a pull-up resistor. This is desirable in applications that require secondary side voltage sensing.

## Bulk Capacitor Voltage Comparator

In order to avoid output voltage bouncing during electricity brownout condition, a Bulk Capacitor Voltage Comparator with programmable hysteresis is included in this device. The non-inverting input, pin 11, is connected to the voltage divider comprised of $\mathrm{R}_{\text {Upper }}$ and $\mathrm{R}_{\text {Lower }}$ as shown in Figure 20 monitoring the bulk capacitor voltage level. The inverting input is connected to a threshold voltage of 1.25 V internally. As bulk capacitor voltage drops below the pre-programmed level, (Pin 11 drops below 1.25 V ), a reset signal will be generated via internal protection logic to the PWM Latch so turning off the Power Switch immediately. An internal current source controlled by the state of the comparator provides a means to program the voltage hysteresis. The following equation shows the relationship between $V_{\text {BULK }}$ levels and the voltage divider network resistors.

$$
\begin{aligned}
& \text { RUpper }=20 \times\left[\text { VBulk_H }-V_{\text {Bulk_L }}\right] \quad \text { in K Ohm } \\
& \text { RLower }=\frac{25 \times\left[\text { VBulk_H }-V_{\text {Bulk_L }}\right]}{V_{\text {Bulk_H }}-1.25} \quad \text { in K Ohm }
\end{aligned}
$$

Figure 20. Bulk OK Functional Operation

## Undervoltage Lockout

An Undervoltage Lockout comparator has been incorporated to guarantee that the integrated circuit has sufficient voltage to be fully functional before the output stage is enabled. The UVLO comparator monitors the $\mathrm{V}_{\mathrm{CC}}$ voltage at Pin 3 and when it exceeds 14.5 V , the reset signal is removed from the PWM Latch allowing operation of the Power Switch. To prevent erratic switching as the threshold is crossed, 5.0 V of hysteresis is provided.

## Startup Control

An internal Startup Control circuit with a high voltage enhancement mode MOSFET is included within the MC33365. This circuitry allows for increased converter efficiency by eliminating the external startup resistor, and its associated power dissipation, commonly used in most off-line converters that utilize a UC3842 type of controller. Rectified ac line voltage is applied to the Startup Input, Pin 1. This causes the MOSFET to enhance and supply internal bias as well as charge current to the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor that connects from Pin 3 to ground. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold of 15.2 V , the IC commences operation and the startup MOSFET is turned off. Operating bias is now derived from the auxiliary transformer winding, and all of the device power is efficiently converted down from the rectified ac line.

The startup MOSFET will provide a steady current of 1.7 mA , Figure 11, as $\mathrm{V}_{\mathrm{CC}}$ increases or shorted to ground. The startup MOSFET is rated at a maximum of 400 V with $\mathrm{V}_{\mathrm{CC}}$ shorted to ground, and 500 V when charging a $\mathrm{V}_{\mathrm{CC}}$ capacitor of $1000 \mu \mathrm{~F}$ or less.

## Regulator

A low current 6.5 V regulated output is available for biasing the Error Amplifier and any additional control system circuitry. It is capable of up to 10 mA and has
short-circuit protection. This output requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability.

## Thermal Shutdown and Package

Internal thermal circuitry is provided to protect the Power Switch in the event that the maximum junction temperature is exceeded. When activated, typically at $150^{\circ} \mathrm{C}$, the Latch is forced into a 'reset' state, disabling the Power Switch. The Latch is allowed to 'set' when the Power Switch temperature falls below $140^{\circ} \mathrm{C}$. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a substitute for proper heatsinking.

The MC33365 is contained in a heatsinkable plastic dual-in-line package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figure 16 shows a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction to air thermal resistance. The examples are for a symmetrical layout on a single-sided board with two ounce per square foot of copper.

## MC33362

## High Voltage Switching Regulator

The MC33362 is a monolithic high voltage switching regulator that is specifically designed to operate from a rectified 120 VAC line source. This integrated circuit features an on-chip $500 \mathrm{~V} / 2.0 \mathrm{~A}$ SenseFET power switch, 250 V active off-line startup FET, duty cycle controlled oscillator, current limiting comparator with a programmable threshold and leading edge blanking, latching pulse width modulator for double pulse suppression, high gain error amplifier, and a trimmed internal bandgap reference. Protective features include cycle-by-cycle current limiting, input undervoltage lockout with hysteresis, output overvoltage protection, and thermal shutdown. This device is available in a 16-lead dual-in-line and wide body surface mount packages.

- On-Chip 500 V, 2.0 A SenseFET Power Switch
- Rectified 120 VAC Line Source Operation
- On-Chip 250 V Active Off-Line Startup FET
- Latching PWM for Double Pulse Suppression
- Cycle-By-Cycle Current Limiting
- Input Undervoltage Lockout with Hysteresis
- Output Overvoltage Protection Comparator
- Trimmed Internal Bandgap Reference
- Internal Thermal Shutdown

This device contains 221 active transistors.

PIN FUNCTION DESCRIPTION

| Pin | Function | Description |
| :---: | :---: | :---: |
| 1 | Startup Input | This pin connects directly to the rectified ac line voltage source. Internally Pin 1 is tied to the drain of a high voltage startup MOSFET. During startup, the MOSFET supplies internal bias, and charges an external capacitor that connects from the $\mathrm{V}_{\mathrm{CC}}$ pin to ground. |
| 2 | - | This pin has been omitted for increased spacing between the rectified AC line voltage on Pin 1 and the $\mathrm{V}_{\mathrm{CC}}$ potential on Pin 3. |
| 3 | $\mathrm{V}_{C C}$ | This is the positive supply voltage input. During startup, power is supplied to this input from Pin 1. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold, the startup MOSFET turns off and power is supplied from an auxiliary transformer winding. |
| 4, 5, 12, 13 | Ground | These pins are the control circuit grounds. They are part of the IC lead frame and provide a thermal path from the die to the printed circuit board. |
| 6 | $\mathrm{R}_{\mathrm{T}}$ | Resistor $\mathrm{R}_{\mathrm{T}}$ connects from this pin to ground. The value selected will program the Current Limit Comparator threshold and affect the Oscillator frequency. |
| 7 | $\mathrm{C}_{\text {T }}$ | Capacitor $\mathrm{C}_{\mathrm{T}}$ connects from this pin to ground. The value selected, in conjunction with resistor $\mathrm{R}_{\mathrm{T}}$, programs the Oscillator frequency. |
| 8 | Regulator Output | This 6.5 V output is available for biasing external circuitry. It requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability. |
| 9 | Compensation | This pin is the Error Amplifier output and is made available for loop compensation. It can be used as an input to directly control the PWM Comparator. |
| 10 | Voltage Feedback Input | This is the inverting input of the Error Amplifier. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output. |
| 11 | Overvoltage Protection Input | This input provides runaway output voltage protection due to an external component or connection failure in the control loop feedback signal path. It has a 2.6 V threshold and normally connects through a resistor divider to the converter output, or to a voltage that represents the converter output. |
| 14, 15 | - | These pins have been omitted for increased spacing between the high voltages present on the Power Switch Drain, and the ground potential on Pins 12 and 13. |
| 16 | Power Switch Drain | This pin is designed to directly drive the converter transformer and is capable of switching a maximum of 500 V and 2.0 A . |

Figure 18. Representative Block Diagram

Figure 19. Timing Diagram

## OPERATING DESCRIPTION

## Introduction

The MC33362 represents a new higher level of integration by providing all the active high voltage power, control, and protection circuitry required for implementation of a flyback or forward converter on a single monolithic chip. This device is designed for direct operation from a rectified 120 VAC line source and requires a minimum number of external components to implement a complete converter. A description of each of the functional blocks is given below, and the representative block and timing diagrams are shown in Figures 18 and 19.

## Oscillator and Current Mirror

The oscillator frequency is controlled by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Resistor $\mathrm{R}_{\mathrm{T}}$ programs the oscillator charge/discharge current via the Current Mirror 4 I output, Figure 4. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged and discharged by an equal magnitude internal current source and sink. This generates a symmetrical 50 percent duty cycle waveform at Pin 7, with a peak and valley threshold of 2.6 V and 0.6 V respectively. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gate Driver high. This causes the Power Switch gate drive to be held in a low state, thus producing a well controlled amount of output deadtime. The amount of deadtime is relatively constant with respect to the oscillator frequency when operating below 1.0 MHz . The maximum Power Switch duty cycle at Pin 16 can be modified from the internal 50\% limit by providing an additional charge or discharge current path to $\mathrm{C}_{\mathrm{T}}$, Figure 20. In order to increase the maximum duty cycle, a discharge current resistor $R_{D}$ is connected from Pin 7 to ground. To decrease the maximum duty cycle, a charge current resistor $\mathrm{R}_{\mathrm{C}}$ is connected from Pin 7 to the Regulator Output. Figure 5 shows an obtainable range of maximum output duty cycle versus the ratio of either $R_{C}$ or $R_{D}$ with respect to $R_{T}$.

Figure 20. Maximum Duty Cycle Modification

The formula for the charge/discharge current along with the oscillator frequency are given below. The frequency formula is a first order approximation and is accurate for $\mathrm{C}_{\mathrm{T}}$ values greater than 500 pF . For smaller values of $\mathrm{C}_{\mathrm{T}}$, refer to Figure 2. Note that resistor $\mathrm{R}_{\mathrm{T}}$ also programs the Current Limit Comparator threshold.

$$
\mathrm{I}_{\mathrm{chg} / \mathrm{dscg}}=\frac{5.4}{\mathrm{R}_{\mathrm{T}}} \quad \mathrm{f} \approx \frac{\mathrm{I}_{\mathrm{chg} / \mathrm{dscg}}}{4 \mathrm{C}_{\mathrm{T}}}
$$

## PWM Comparator and Latch

The pulse width modulator consists of a comparator with the oscillator ramp voltage applied to the non-inverting input, while the error amplifier output is applied into the inverting input. The Oscillator applies a set pulse to the PWM Latch while $\mathrm{C}_{\mathrm{T}}$ is discharging, and upon reaching the valley voltage, Power Switch conduction is initiated. When $\mathrm{C}_{\mathrm{T}}$ charges to a voltage that exceeds the error amplifier output, the PWM Latch is reset, thus terminating Power Switch conduction for the duration of the oscillator ramp-up period. This PWM Comparator/Latch combination prevents multiple output pulses during a given oscillator clock cycle. The timing diagram shown in Figure 19 illustrates the Power Switch duty cycle behavior versus the Compensation voltage.

## Current Limit Comparator and Power Switch

The MC33362 uses cycle-by-cycle current limiting as a means of protecting the output switch transistor from overstress. Each on-cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch current buildup during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the oscillator ramp-up period.

The Power Switch is constructed as a SenseFET allowing a virtually lossless method of monitoring the drain current. It consists of a total of 3770 cells, of which 50 are connected to a $9.0 \Omega$ ground-referenced sense resistor. The Current Sense Comparator detects if the voltage across the sense resistor exceeds the reference level that is present at the inverting input. If exceeded, the comparator quickly resets the PWM Latch, thus protecting the Power Switch. The current limit reference level is generated by the 2.25 I output of the Current Mirror. This current causes a reference voltage to appear across the $450 \Omega$ resistor. This voltage level, as well as the Oscillator charge/discharge current are both set by resistor $\mathrm{R}_{\mathrm{T}}$. Therefore when selecting the values for $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}, \mathrm{R}_{\mathrm{T}}$ must be chosen first to set the Power Switch peak drain current, while $C_{T}$ is chosen second to set the desired Oscillator frequency. A graph of the Power Switch peak drain current versus $\mathrm{R}_{\mathrm{T}}$ is shown in Figure 3 with the related formula below.

$$
\mathrm{I}_{\mathrm{pk}}=12.3\left(\frac{\mathrm{R}_{\mathrm{T}}}{1000}\right)^{-1.115}
$$

The Power Switch is designed to directly drive the converter transformer and is capable of switching a maximum of 500 V and 2.0 A . Proper device voltage snubbing and heatsinking are required for reliable operation.

A Leading Edge Blanking circuit was placed in the current sensing signal path. This circuit prevents a premature reset of the PWM Latch. The premature reset is generated each time the Power Switch is driven into conduction. It appears as a narrow voltage spike across the current sense resistor, and is due to the MOSFET gate to source capacitance, transformer interwinding capacitance, and output rectifier recovery time. The Leading Edge Blanking circuit has a dynamic behavior in that it masks the current signal until the Power Switch turn-on transition is completed. The current limit propagation delay time is typically 233 ns . This time is measured from when an overcurrent appears at the Power Switch drain, to the beginning of turn-off.

## Error Amplifier

An fully compensated Error Amplifier with access to the inverting input and output is provided for primary side voltage sensing, Figure 18. It features a typical dc voltage gain of 82 dB , and a unity gain bandwidth of 1.0 MHz with 78 degrees of phase margin, Figure 6. The noninverting input is internally biased at $2.6 \mathrm{~V} \pm 3.1 \%$ and is not pinned out. The Error Amplifier output is pinned out for external loop compensation and as a means for directly driving the PWM Comparator. The output was designed with a limited sink current capability of $270 \mu \mathrm{~A}$, allowing it to be easily overridden with a pull-up resistor. This is desirable in applications that require secondary side voltage sensing, Figure 21. In this application, the Voltage Feedback Input is connected to the Regulator Output. This disables the Error Amplifier by placing its output into the sink state, allowing the optocoupler transistor to directly control the PWM Comparator.

## Overvoltage Protection

An Overvoltage Protection Comparator is included to eliminate the possibility of runaway output voltage. This condition can occur if the control loop feedback signal path is broken due to an external component or connection failure. The comparator is normally used to monitor the primary side $\mathrm{V}_{\mathrm{CC}}$ voltage. When the 2.6 V threshold is exceeded, it will immediately turn off the Power Switch, and protect the load from a severe overvoltage condition. This input can also be driven from external circuitry to inhibit converter operation.

## Undervoltage Lockout

An Undervoltage Lockout comparator has been incorporated to guarantee that the integrated circuit has sufficient voltage to be fully functional before the output stage is enabled. The UVLO comparator monitors the $\mathrm{V}_{\mathrm{CC}}$ voltage at Pin 3 and when it exceeds 14.5 V , the reset signal is removed from the PWM Latch allowing operation of the

Power Switch. To prevent erratic switching as the threshold is crossed, 5.0 V of hysteresis is provided.

## Startup Control

An internal Startup Control circuit with a high voltage enhancement mode MOSFET is included within the MC33362. This circuitry allows for increased converter efficiency by eliminating the external startup resistor, and its associated power dissipation, commonly used in most off-line converters that utilize a UC3842 type of controller. Rectified ac line voltage is applied to the Startup Input, Pin 1. This causes the MOSFET to enhance and supply internal bias as well as charge current to the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor that connects from Pin 3 to ground. When $\mathrm{V}_{\mathrm{CC}}$ reaches the UVLO upper threshold of 14.5 V , the IC commences operation and the startup MOSFET is turned off. Operating bias is now derived from the auxiliary transformer winding, and all of the device power is efficiently converted down from the rectified ac line.

The startup MOSFET will provide an initial peak current of 55 mA , Figure 11, which decreases rapidly as $\mathrm{V}_{\mathrm{CC}}$ and the die temperature rise. The steady state current will self limit in the range of 12 mA with $\mathrm{V}_{\mathrm{CC}}$ shorted to ground. The startup MOSFET is rated at a maximum of 250 V with $\mathrm{V}_{\mathrm{CC}}$ shorted to ground, and 400 V when charging a $\mathrm{V}_{\mathrm{CC}}$ capacitor of $1000 \mu \mathrm{~F}$ or less.

## Regulator

A low current 6.5 V regulated output is available for biasing the Error Amplifier and any additional control system circuitry. It is capable of up to 10 mA and has short-circuit protection. This output requires an external bypass capacitor of at least $1.0 \mu \mathrm{~F}$ for stability.

## Thermal Shutdown and Package

Internal thermal circuitry is provided to protect the Power Switch in the event that the maximum junction temperature is exceeded. When activated, typically at $155^{\circ} \mathrm{C}$, the Latch is forced into a 'reset' state, disabling the Power Switch. The Latch is allowed to 'set' when the Power Switch temperature falls below $145^{\circ} \mathrm{C}$. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a substitute for proper heatsinking.

The MC33362 is contained in a heatsinkable plastic dual-in-line package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figures 16 and 17 show a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction to air thermal resistance. The examples are for a symmetrical layout on a single-sided board with two ounce per square foot of copper. Figure 23 shows a practical example of a printed circuit board layout
that utilizes the copper foil as a heat dissipater. Note that a jumper was added to the layout from Pins 8 to 10 in order to enhance the copper area near the device for improved thermal
conductivity. The application circuit requires two ounce copper foil in order to obtain 20 watts of continuous output power at room temperature.

## NCP1000, NCP1001, NCP1002

## Integrated Off-Line Switching Regulator

The NCP1000 through NCP1002 series of integrated switching regulators, combine a fixed frequency PWM controller with an integrated high voltage power switch circuit. This chip allows for simple design and minimal parts count for very low cost applications which utilize an ac input. This chip is designed to power a single ended topology, typically a discontinuous mode flyback, with secondary side sensing.

The internal high voltage switch circuit and start-up circuit can function in continuous operation over a wide range of inputs, from 85 Vac to 265 Vac , and thus can be used in any existing power system in the world. Though inexpensive, these devices include a number of features such as undervoltage lockout, over-temperature protection, bandgap reference and leading edge blanking that make them an excellent value.

## Features

- Highly Integrated Solution
- Operates Over Universal Input Voltage Range (85 Vac to 265 Vac )
- On-board 700 Volt Power Switch Circuit
- Minimal External Parts Required
- Input Undervoltage Lockout with Hysteresis
- Very Low Standby Current
- No Minimum Load Requirement
- Opto Fail-safe Shutdown Circuit

## Typical Applications

- Cell Phone Chargers
- Wall Adapters
- On-board AC-DC Converters

Figure 1. Simplified Block Diagram

## OPERATING DESCRIPTION

## Introduction

The NCP1000 thru NCP1002 represent a new higher level of integration by providing on a single monolithic chip all of the active power, control, logic, and protection circuitry required to implement a high voltage flyback or forward converter. This device series is designed for direct operation from a rectified 240 VAC line source and requires minimal external components for a complete cost sensitive converter solution. Potential markets include office automation, industrial, residential, personal computer, and consumer. A description of each of the functional blocks is given below, and the representative block diagram is shown in Figure 17.

## Oscillator

The Oscillator block consists of two comparators that alternately gate on and off a trimmed current source and current sink which are used to respectively charge and discharge an on-chip timing capacitor between two voltage levels. This configuration generates a precise linear sawtooth ramp signal that is used to pulse width modulate the MOSFET of the Power Switch circuit. During the charge of the timing capacitor, the Oscillator duty cycle output holds one input of the Driver low. This action keeps the MOSFET of the Power Switch Circuit off, thus limiting the maximum duty cycle. The Oscillator frequency is internally programmed for 100 kHz operation with a controlled charge to discharge current ratio that yields a maximum Power Switch Circuit duty cycle of $72 \%$. The Oscillator temperature characteristics are shown in Figure 7.

## PWM Comparator and Latch

The pulse width modulator (PWM) consists of a comparator with the Oscillator ramp output applied to the inverting input. The Oscillator clock output applies a set pulse to the PWM Latch when the timing capacitor reaches its peak voltage, initiating Power Switch Circuit conduction. As the timing capacitor discharges, the ramp voltage decreases to a level that is less than the Error Amplifier output, causing the PWM Comparator to reset the latch and terminate Power Switch Circuit conduction for the duration of the ramp-down period. This method of having the Oscillator set and the PWM Comparator reset the Latch prevents the possibility of multiple output pulses during a given Oscillator clock cycle. This circuit configuration is commonly referred to as double pulse suppression logic. A timing diagram is shown in Figure 18 that illustrates the behavior of the pulse width modulator.

No load operation. The pulse width modulator is designed to operate between $73 \%$ and $0 \%$ duty cycle. The ability to operate down to zero duty cycle allows for no load operation without the burden of preloads. This feature is consistent with the Blue Angle requirements, as it minimizes power
consumption while in the stand-by operation mode. For operation at no load, the output may skip cycles. This is a common occurrence for this type of control circuit. The converter will switch for several cycles, and due to delays in the output filter and feedback loop, the duty cycle will not be reduced until the output has exceeded it's regulation limit. The unit will then shut down for several cycles until the voltage is below the regulation limit, and then it will switch again. During the time that switching cycles are not present the output voltage will decay according to it's RC time constant, which is based on the output capacitance and internal loading from the regulation circuitry. During this interval, the voltage on the $\mathrm{V}_{\mathrm{CC}}$ supply will also decay. If it decays below the lower hysteretic turn off threshold, the unit will shut down and recycle. This mode of operation is not normally desirable. In order to avoid it, the time constant for the $V_{C C}$ cap and load should be equal to, or greater than the time constant of the output. If no load operation is not required, a relatively small value $(<10 \mu \mathrm{~F})$ for the $\mathrm{V}_{\mathrm{CC}}$ capacitor is acceptable.

## Feedback Input

The feedback input, pin 2, accepts the DC error signal that feeds the non-inverting input to the PWM. Pin 2 has a nominal 2.7 kOhm internal resistor to ground, which converts the optocoupler current into a voltage. Its' signal is filtered by a 7.0 kHz low pass filter which reduces high frequency noise to the input of the PWM comparator.
Typically, the photo transistor of the optocoupler is connected between $\mathrm{V}_{\mathrm{CC}}$ (pin 1) and the Feedback input (pin 2). The photo transistor is effectively a current source which is driven by the LED, which is connected to the output regulation circuit of the power supply. An external capacitor may be connected from pin 2 to ground for additional noise filtering if necessary.

When the feedback input is below the lower threshold of the ramp signal, the output of the power converter will be operating at full duty cycle. The input current vs. duty cycle transfer function is shown in Figure 2. As the voltage increases, the duty cycle will vary linearly with the change in voltage at the feedback input, between the upper and lower extremes of the ramp waveform 2.7 V to 4.1 volts. Above the upper extreme point of the ramp, the duty cycle will be zero and no power will be transmitted to the output.
The circuit should be designed such that when the output is low, the optocoupler will be off, leaving the voltage at pin 2 at ground (full duty cycle). As the output voltage increases, the optocoupler will begin to conduct, such that the voltage at pin 2 increases until the proper duty cycle is reached to maintain regulation.

Pin 2 is protected from ESD transients by a 10 volt zener diode to ground.

## Current Limit Comparator and Power Switch Circuit

The NCP1000 series uses cycle-by-cycle current limiting as a means of protecting the output switch transistor from overstress. Current limiting is implemented by monitoring the instantaneous output switch current during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the Oscillator ramp-down period.

The Power Switch Circuit is constructed using a SenseFET allowing a virtually lossless method of monitoring the drain current. A small number of the power MOSFET cells are used for current sensing by connecting their individual sources to a single ground referenced sense resistor, $\mathrm{R}_{\mathrm{pk}}$. The current limit comparator detects if the voltage across $R_{p k}$ exceeds the reference level that is present at the noninverting input. If exceeded, the comparator quickly resets the PWM Latch, thus protecting the Power Switch Circuit. Figure 9 shows that this detection method yields a relatively constant current limit threshold over temperature. The high voltage Power Switch Circuit is integrated with the control logic circuitry and is designed to directly drive the converter transformer. The Power Switch Circuit is capable of switching 700 V with an associated drain current that ranges from 0.5 A to 1.5 A . Proper drain voltage snubbing during converter start-up and overload is mandatory for reliable device operation.

A Leading Edge Blanking circuit was placed in the current sensing signal path to prevent a premature reset of the PWM Latch. A potential premature reset signal is generated each time the Power Switch Circuit is driven into conduction and appears as a narrow voltage spike across current sense resistor $\mathrm{R}_{\mathrm{pk}}$. The spike is due to the MOSFET gate to source capacitance, transformer interwinding capacitance, and output rectifier recovery time. The Leading Edge Blanking circuit has a dynamic behavior that masks the current signal until the Power Switch Circuit turn-on transition is completed.

The current limit propagation delay time is typically 220 ns . This time is measured from when an overcurrent appears at the Power Switch Circuit drain, to the beginning of turn-off. Care must be taken during transformer saturation so that the maximum device current limit rating is not exceeded. To determine the peak Power Switch Circuit current at turn off, the effect of the propagation delay must be taken into account. To do this, use the appropriate Current Limit Threshold value from the electrical tables, and then add the $\Delta \mathrm{Ipk}$ based on the $\mathrm{di} / \mathrm{dt}$ from Figure 16 . The di/dt of the circuit can be calculated by the following formula:

$$
\mathrm{di} / \mathrm{dt}(\mathrm{~A} / \mu \mathrm{s})=\mathrm{V} / \mathrm{L}
$$

where:
V is the rectified, filtered input voltage (volts)
L is the primary inductance of the flyback transformer (Henries)

## High Voltage Start-Up

The NCP1000-1002 contain an internal start-up circuit that eliminates the need for external start-up components. In addition, this circuit increases the efficiency of the supply as it uses no power when in the normal mode of operation, but instead uses the power supplied by the auxiliary winding.

Rectified, filtered ac line voltage is connected to pin 4. An internal JFET allows current to flow from the start-up pin, to the $\mathrm{V}_{\mathrm{CC}}$ pin at a current of approximately 3.0 mA . Figure 5 shows the startup current out of pin 1 which charges the capacitor(s) connected to this pin.

The start circuit will be enhanced (conducting) when the voltage at Pin $1\left(\mathrm{~V}_{\mathrm{CC}}\right)$ is less than 7.5 volts. It will remain enhanced until the $\mathrm{V}_{\mathrm{CC}}$ voltage reaches 8.5 volts. At this point the Power Switch Circuit will be disabled, and the unit will generate voltage via the auxiliary winding to maintain proper operation of the device. Figure 4 shows the charge time for turn-on vs. $\mathrm{V}_{\mathrm{CC}}$ capacitance when the unit is initially energized.

If the $\mathrm{V}_{\mathrm{CC}}$ voltage drops below 7.5 volts (e.g. current limit mode), the start circuit will again begin conducting, and will charge up the $\mathrm{V}_{\mathrm{CC}}$ cap until the 8.5 volt limit is reached.

## $\mathrm{V}_{\mathrm{CC}}$ Limiter and Undervoltage Lockout

The undervoltage lockout (UVLO) is designed to guarantee that the integrated circuit has sufficient voltage to be fully functional before the output stage is enabled. It inhibits operation of the major functions of the device by disabling the Internal Bias circuitry, and assures that the Power Switch Circuit remains in its "off" state as the bias voltage is initially brought up from zero volts. When the NCP100x is in the "off" state, the High Voltage Start-up circuit is operational. The UVLO is a hysteretic switch and will hold the device in its "off" state any time that the $\mathrm{V}_{\mathrm{CC}}$ voltage is less than 7.5 volts. As the $\mathrm{V}_{\mathrm{CC}}$ increases past 7.5 volts, the NCP100x will remain off until the upper threshold of 8.6 volts is reached. At this time the power converter is enabled and will commence operation. The UVLO will allow the unit to continue to operate as long as the $\mathrm{V}_{\mathrm{CC}}$ voltage exceeds 7.5 volts. The temperature characteristics of the UVLO circuit are shown in Figure 8.

If the converter output is overloaded or shorted, the device will enter the auto restart mode. This happens when the auxiliary winding of the power transformer does not have sufficient voltage to support the $\mathrm{V}_{\mathrm{CC}}$ requirements of the chip. Once the chip is operational, if the $\mathrm{V}_{\mathrm{CC}}$ voltage falls below 7.5 volts the unit will shut down, and the High Voltage Start-up circuit will be enabled. This will charge the $\mathrm{V}_{\mathrm{CC}}$ cap up to 8.5 volts, which will clock the divide by eight counter. The divide by eight counter holds the Power Switch Circuit off. This causes the $\mathrm{V}_{\mathrm{CC}}$ cap to discharge. It will continue to discharge and recharge for eight consecutive cycles. After the eighth cycle, the unit will turn on again. If the fault remains, the unit will again cycle through the auto restart mode; if the fault has cleared the unit will begin normal operation. The auto restart mode greatly reduces the power dissipation of the power devices in the circuit and

## NCP1000, NCP1001, NCP1002

improves reliability in overload conditions. Figure 20 shows the timing waveforms in auto restart mode.

The $\mathrm{V}_{\mathrm{CC}}$ pin receives its start-up power from the high voltage start-up circuit. Once the undervoltage lockout trip point is exceeded, the high voltage start-up circuit turns off, and the $\mathrm{V}_{\mathrm{CC}}$ pin receives its power from the auxiliary winding of the power transformer. Once the converter is enabled, the $\mathrm{V}_{\mathrm{CC}}$ voltage will be clamped by the 8.6 volt limiter. Since the voltage limiter will regulate the $\mathrm{V}_{\mathrm{CC}}$ voltage at 8.6 volts, it must shunt all excess current based on the input impedance to this pin. A resistor is required between the auxiliary winding filter capacitor and the $\mathrm{V}_{\mathrm{CC}}$ pin to limit the current.

## Optocoupler Fail-safe Circuit

The NCP100x has the ability to sense an open optocoupler and protect the load in the event of a failure. This circuit operates by sensing the current in the $\mathrm{V}_{\mathrm{CC}}$ limiter, and detecting a high current which is an indication of an open optocoupler.

The $\mathrm{V}_{\mathrm{CC}}$ pin receives the output of a current source which is created by the voltage drop between the auxiliary winding and the $\mathrm{V}_{\mathrm{CC}}$ limiter across the shunt resistor. The Vcc limiter will clamp the $\mathrm{V}_{\mathrm{CC}}$ voltage to approximately 8.6 volts. Any current that is available at this pin, that is not needed for either the chip bias current, or the opto current is shunted through this limiter.

The opto fail-safe circuit operates on the premise that under an open opto condition, the opto current will all be shunted through the $\mathrm{V}_{\mathrm{CC}}$ limiter, and the output voltage (and therefore the auxiliary winding voltage) will increase. The increase in auxiliary winding voltage will cause an amplified increase in the current into the $\mathrm{V}_{\mathrm{CC}}$ pin. To detect an open opto condition, the current in the limiter is measured and if it exceeds 10 milliamps, the chip will shut down and go into burst mode operation. After a shutdown signal, the optocoupler fail-safe circuit will enable the divide-by-eight counter and attempt to restart the unit after every eight $\mathrm{V}_{\mathrm{CC}}$ cycles.

For this circuit to operate properly, the shunt resistor must be chosen prudently. There is a range of values for $\mathrm{R}_{\mathrm{S}}$ that will determine the operation of this circuit. On one extreme, a large value of $\mathrm{R}_{\mathrm{S}}$ will minimize the bias current, which will have the effect of maximizing efficiency, while reducing the response to an open optocoupler. The other extreme is the minimum value of $\mathrm{R}_{\mathrm{S}}$, which will maximize the bias current into the chip and minimize the voltage overshoot in the event of an open optocoupler.
For minimum bias current:

$$
\mathrm{Rs}_{\max }=\frac{\left(\mathrm{V}_{\mathrm{AUX}} \min -8.8 \text { volts }\right)}{\mathrm{I}_{\mathrm{CC} 1 \max }}
$$

where:
$\mathrm{V}_{\mathrm{AUXmin}}$ is the minimum expected DC voltage from the auxiliary winding.
Typically, this voltage will vary between $\pm 5 \%$ to $\pm 10 \%$ from it's nominal value.
$\mathrm{I}_{\mathrm{CC} 1 \text { max }}$ is the maximum rated bias current for the device used. This value can found in the tables on the data sheet.
For the best optocoupler fail-safe response:

$$
\mathrm{Rs}_{\min }=\frac{\left(\mathrm{V}_{\mathrm{AUX} \text { max }}-7.2 \text { volts }\right)}{1.0 \mathrm{~mA}+\mathrm{I}_{\text {trip }}}
$$

where:
$\mathrm{V}_{\text {AUXmax }}$ is the maximum expected DC voltage from the auxiliary winding.
$\mathrm{I}_{\text {trip }}$ is the minimum trip current for the optocoupler fail-safe. This information can be found in the tables under
Current Limit and Thermal Protection, as well as in Figure 12.
The value of $R_{S}$ that is used in the circuit must be between the two extreme values calculated. Setting it closer to $\mathrm{R}_{\text {Smin }}$ will optimize the optocoupler fail-safe feature, while setting it closer to the $\mathrm{R}_{\mathrm{Smax}}$ value will minimize the bias current

## Thermal Shutdown and Package

The internal Thermal Shutdown block protects the device in the event that the maximum junction temperature is exceeded. When activated, typically at $140^{\circ} \mathrm{C}$, one input of the Driver is held low to disable the Power Switch Circuit. Thermal shutdown activation is non-latching and the Power Switch Circuit is allowed resume operation when the junction temperature falls below $110^{\circ} \mathrm{C}$. The thermal shutdown feature is provided to prevent catastrophic device failures from accidental overheating. It is not intended to be used as a substitute for proper heatsinking.

The die in the 8 -pin dual-in-line package is mounted on a special heat tab copper alloy lead frame. The tab consists of pins $3,6,7,8$ is specifically designed to improve the thermal conduction from the die to the printed circuit board. This permits the use of standard layout and mounting practices while having the ability to halve the junction to air thermal resistance.

The die in the 5-pin TO-220 style package is mounted directly on a copper alloy heat tab. This metal tab is exposed on the backside of the package for heatsink attachment and is electrically common to the device ground, Pin 3 . A wide variety of TO-220 style heatsinks are commercially available for enhancing the thermal performance and converter output power capability.

## NCP1000, NCP1001, NCP1002

## Applications

The TO-220 devices have a single Ground, pin 3, that serves the high current return path for the Power Switch Circuit. Do not attempt to construct a converter circuit on a wire-wrap or plug-in prototype board. In order to ensure proper device operation and stability, it is important to minimize the lead length and the associated inductance of the ground pin. This pin must connect as directly as possible
to the printed circuit ground plane and should not be bent or offset by the board layout. The Power Switch Circuit pin can be offset if additional layout creepage distance is required. Due to the potentially high rate of change in switch current, a capacitor (if used), at pin 2, should have traces as short as possible, from pin 2 and ground. This will significantly reduce the level of switching noise that can be imposed upon the feedback control signal.

## APPLICATIONS INFORMATION

## APPLICATION \#1: Offline Converter Provides 5.0 Volt, 1.0 Amp Output for Small Electronic Equipment

ON Semiconductor's NCP1000 series of offline converters offers a low cost, high efficiency power source for low power, electronic equipment. It serves the same function as small, line frequency transformers, but with the added benefits of line and load regulation, transient suppression, reduction in weight, and operation across the universal input voltage range.

This kit provides a 5.0 volt, 1.0 amp output, which is derived from an input source of 85 to 265 vac , and 50 Hz to 60 Hz . This range of input voltages will allow this circuit to function virtually anywhere in the world without modification. The output is regulated and current limited, and EMI filters are included on both the input and output.

Converter Test Data

| Parameter | Conditions | Data |
| :---: | :---: | :---: |
| Line Regulation | $85 \mathrm{v} \leq$ Vin $\leq 265 \mathrm{v}$ | $\Delta \mathrm{Vo}=6.0 \mathrm{mV}$ |
| Load Regulation | $0 \mathrm{~A} \leq \mathrm{lo} \leq 1.0 \mathrm{~A}$ | $\Delta \mathrm{Vo}=8.0 \mathrm{mV}$ |
| Combined Line/ Load Regulation | $\begin{aligned} & 85 \mathrm{v} \leq \mathrm{Vin} \leq 265 \mathrm{v} \\ & .09 \mathrm{~A} \leq \mathrm{lo} \leq 1.0 \mathrm{~A} \end{aligned}$ | $\Delta \mathrm{Vo}=10 \mathrm{mV}$ |
| Output Ripple | $\mathrm{lo}=1.0 \mathrm{~A}$ | 100 mV pp |
| Input Power | $\begin{aligned} & \mathrm{V}_{\text {in }}=115 \mathrm{v}, \mathrm{lo}=1.0 \mathrm{~A} \\ & \mathrm{~V}_{\mathrm{in}}=220 \mathrm{v}, \mathrm{lo}=1.0 \mathrm{~A} \end{aligned}$ | 7.75 watts <br> 7.88 watts |

## NCP1050, NCP1051, NCP1052, NCP1053, NCP1054, NCP1055

## Monolithic High Voltage Gated Oscillator Power Switching Regulator

The NCP1050 through NCP1055 are monolithic high voltage regulators that enable end product equipment to be compliant with low standby power requirements. This device series combines the required converter functions allowing a simple and economical power system solution for office automation, consumer, and industrial products. These devices are designed to operate directly from a rectified AC line source. In flyback converter applications they are capable of providing an output power that ranges from 6.0 W to 40 W with a fixed AC input of $100 \mathrm{~V}, 115 \mathrm{~V}$, or 230 V , and 3.0 W to 20 W with a variable AC input that ranges from 85 V to 265 V .

This device series features an active startup regulator circuit that eliminates the need for an auxiliary bias winding on the converter transformer, fault logic with a programmable timer for converter overload protection, unique gated oscillator configuration for extremely fast loop response with double pulse suppression, power switch current limiting, input undervoltage lockout with hysteresis, thermal shutdown, and auto restart fault detection. These devices are available in an economical 8-pin dual-in-line package.

## Features

- Startup Circuit Eliminates the Need for Transformer Auxiliary Bias Winding
- Optional Auxiliary Bias Winding Override for Lowest Standby Power Applications
- Converter Output Overload and Open Loop Protection
- Auto Restart Fault Protection
- IC Thermal Fault Protection
- Unique, Dual Edge, Gated Oscillator Configuration for Extremely Fast Loop Response
- Oscillator Frequency Dithering with Controlled Slew Rate Driver for Reduced EMI
- Low Power Consumption Allowing European Blue Angel Compliance
- On-Chip 700 V Power Switch Circuit and Active Startup Circuit
- Rectified AC Line Source Operation from 85 V to 265 V
- Input Undervoltage Lockout with Hysteresis
- Oscillator Frequency Options of $44 \mathrm{kHz}, 100 \mathrm{kHz}, 136 \mathrm{kHz}$

## Typical Applications

- AC-DC Converters
- Wall Adapters
- Portable Electronic Chargers
- Low Power Standby and Keep-Alive Supplies

Figure 1. Typical Application
Pin Function Description

| Pin \# | Function |  |
| :---: | :---: | :--- |
| 1 | $V_{\mathrm{CC}}$ | This is the positive supply voltage input. During startup, power is supplied to this input from <br> Pin 5. When $\mathrm{V}_{\mathrm{CC}}$ reaches $\mathrm{V}_{\mathrm{CC}}($ on), the Startup Circuit turns off and the output is allowed to <br> begin switching with 1.0 V hysteresis on the $\mathrm{V}_{\mathrm{CC}}$ pin. The capacitance connected to this pin <br> programs fault timing and frequency modulation rate. |
| 2 | Control Input | The Power Switch Circuit is turned off when a current greater than approximately $50 \mu \mathrm{~A}$ is <br> drawn out of or applied to this pin. A 10 V clamp is built onto the chip to protect the device <br> from ESD damage or overvoltage conditions. |
| $3,6,7,8$ | Ground | This pin is the control circuit and Power Switch Circuit ground. It is part of the integrated circuit <br> lead frame. |
| 4 | No Connection |  |
| 5 | Power Switch Circuit | This pin is designed to directly drive the converter transformer primary, and internally connects <br> to Power Switch Circuit and Startup Circuit. |

1. Maximum Ratings are those values beyond which damage to the device may occur. Exposure to these conditions or conditions beyond those indicated may adversely affect device reliability. Functional operation under absolute maximum-rated conditions is not implied. Functional operation should be restricted to the Recommended Operating Conditions.
A. This device series contains ESD protection and exceeds the following tests:

Pins 1-3: Human Body Model 2000 V per MIL-STD-883, Method 3015. Machine Model Method 400 V .
Pin 5: Human Body Model 1000 V per MIL-STD-883, Method 3015. Machine Model Method 400 V .
Pin 5 is connected to the power switch and start-up circuits, and is rated only to the max voltage of the part, or 700 V .
B. This device contains Latch-up protection and exceeds $\pm 100 \mathrm{~mA}$ per JEDEC Standard JESD78.

## Introduction

The NCP105X series represents a new higher level of integration by providing on a single monolithic chip all of the active power, control, logic, and protection circuitry required to implement a high voltage flyback converter and compliance with very low standby power requirements for modern consumer electronic power supplies. This device series is designed for direct operation from a rectified 240 VAC line source and requires minimal external components for a complete cost sensitive converter solution. Potential markets include cellular phone chargers, standby power supplies for personal computers, secondary bias supplies for microprocessor keep-alive supplies and IR detectors. A description of each of the functional blocks is given below, and the representative block diagram is shown in Figure 2.

This device series features an active startup regulator circuit that eliminates the need for an auxiliary bias winding on the converter transformer, fault logic with a programmable timer for converter overload protection, unique gated oscillator configuration for extremely fast loop response with double pulse suppression, oscillator frequency dithering with a controlled slew rate driver for reduced EMI, cycle-by-cycle current limiting, input undervoltage lockout with hysteresis, thermal shutdown, and auto restart or latched off fault detect device options. These devices are available in an economical 8-pin PDIP package.

## Oscillator

The Oscillator is a unique fixed-frequency, duty-cyclecontrolled oscillator. It charges and discharges an on chip timing capacitor to generate a precise square wave signal used to pulse width modulate the Power Switch Circuit. During the discharge of the timing capacitor, the Oscillator duty cycle output holds one input of the Driver low. This action keeps the Power Switch Circuit off, thus limiting the maximum duty cycle.

A frequency modulation feature is incorporated into the IC in order to aide in EMI reduction. Figure 3 illustrates this frequency modulation feature. The power supply voltage, $\mathrm{V}_{\mathrm{CC}}$, acts as the input to the built-in voltage controlled oscillator. As the $\mathrm{V}_{\mathrm{CC}}$ voltage is swept across its nominal operating range of 7.6 to 8.6 V , the oscillator frequency is swept across its corresponding range.

The center oscillator frequency is internally programmed for $44 \mathrm{kHz}, 100 \mathrm{kHz}$, or 136 kHz operation with a controlled charge to discharge current ratio that yields a maximum Power Switch duty cycle of $77 \%$. The Oscillator temperature characteristics are shown in Figures 5 through 9. Contact an ON Semiconductor sales representative for further information regarding frequency options.

## Control Input

The Control Input pin circuit has parallel source follower input stages with voltage clamps set at 1.3 and 4.6 V . Current sources clamp the input current through the followers at
approximately $47 \mu \mathrm{~A}$ with $10 \mu \mathrm{~A}$ hysteresis. When a source or sink current in excess of this value is applied to this input, a logic signal generated internally changes state to block power switch conduction. Since the output of the Control Input sense is sampled continuously during $\mathrm{t}_{\text {on }}$ ( $77 \%$ duty cycle), it is possible to turn the Power Switch Circuit on or off at any time within $t_{\text {on }}$. Because it does not have to wait for the next cycle (rising edge of the clock signal) to switch on, and because it does not have to wait for current limit to turn off, the circuit has a very fast transient response as shown in Figure 3.

In a typical converter application the control input current is drawn by an optocoupler. The collector of the optocoupler is connected to the Control Input pin and the emitter is connected to ground. The optocoupler LED is mounted in series with a shunt regulator (typically a TL431) at the DC output of the converter. When the power supply output is greater than the reference voltage (shunt regulator voltage plus optocoupler diode voltage drop), the optocoupler turns on, pulling down on the Control Input. The control input logic is configured for line input sensing as well.

## Turn On Latch

The Oscillator output is typically a $77 \%$ positive duty cycle square waveform. This waveform is inverted and applied to the reset input of the turn-on latch to prevent any power switch conduction during the guaranteed off time. This square wave is also gated by the output of the control section and applied to the set input of the same latch. Because of this gating action, the power switch can be activated when the control input is not asserted and the oscillator output is high.

The use of this unique gated Turn On Latch over an ordinary Gated Oscillator allows a faster load transient response. The power switch is allowed to turn on immediately, within the maximum duty cycle time period, when the control input signals a necessary change in state.

## Turn Off Latch

A Turn Off Latch feature has been incorporated into this device series to protect the power switch circuit from excessive current, and to reduce the possibility of output overshoot in reaction to a sudden load removal. If the Power Switch current reaches the specified maximum current limit, the Current Limit Comparator resets the Turn Off Latch and turns the Power Switch Circuit off. The turn off latch is also reset when the Oscillator output signal goes low or the Control Input is asserted, thus terminating output MOSFET conduction. Because of this response to control input signals, it provides a very fast transient response and very tight load regulation. The turn off latch has an edge triggered set input which ensures that the switch can only be activated once during any oscillator period. This is commonly referred to as double pulse suppression.

## NCP1050, NCP1051, NCP1052, NCP1053, NCP1054, NCP1055

## Current Limit Comparator and Power Switch Circuit

The Power Switch Circuit is constructed with a SENSEFET ${ }^{T M}$ in order to monitor the drain current. A portion of the current flowing through the circuit goes into a sense element, $\mathrm{R}_{\text {sense }}$. The current limit comparator detects if the voltage across $\mathrm{R}_{\text {sense }}$ exceeds the reference level that is present at its inverting input. If this level is exceeded, the comparator quickly resets the Turn Off Latch, thus protecting the Power Switch Circuit.

A Leading Edge Blanking circuit was placed in the current sensing signal path to prevent a premature reset of the Turn Off Latch. A potential premature reset signal is generated each time the Power Switch Circuit is driven into conduction and appears as a narrow voltage spike across current sense resistor $\mathrm{R}_{\text {sense }}$. The spike is due to the Power Switch Circuit gate to source capacitance, transformer interwinding capacitance, and output rectifier recovery time. The Leading Edge Blanking circuit has a dynamic behavior that masks the current signal until the Power Switch Circuit turn-on transition is completed. The current limit propagation delay time is typically 125 to 250 nanoseconds. This time is measured from when an overcurrent appears at the Power Switch Circuit drain, to the beginning of turn-off. Care must be taken during transformer saturation so that the maximum device current limit rating is not exceeded.

The high voltage Power Switch Circuit is monolithically integrated with the control logic circuitry and is designed to directly drive the converter transformer. Because the characteristics of the power switch circuit are well known, the gate drive has been tailored to control switching transitions to help limit electromagnetic interference (EMI). The Power Switch Circuit is capable of switching 700 V with an associated drain current that ranges nominally from 0.10 to 0.68 Amps.

## Startup Circuit

Rectified AC line voltage is applied to the Startup Circuit on Pin 5, through the primary winding. The circuit is self-biasing and acts as a constant current source, gated by control logic. Upon application of the AC line voltage, this circuit routes current into the supply capacitor typically connected to Pin 1. During normal operation, this capacitor is hysteretically regulated from 7.6 to 8.6 V by monitoring the supply voltage with a comparator and controlling the startup current source accordingly. This Dynamic Self-Supply (DSS) functionality offers a great deal of applications flexibility as well. The startup circuit is rated at a maximum 700 V (maximum power dissipation limits must be observed).

## Undervoltage Lockout

An Undervoltage Lockout (UVLO) comparator is included to guarantee that the integrated circuit has sufficient voltage to be fully functional. The UVLO comparator monitors the supply capacitor input voltage at Pin 1 and disables the Power Switch Circuit whenever the capacitor voltage drops below the undervoltage lockout threshold. When this level is crossed, the controller enters a new startup phase by turning the current source on. The supply voltage will then have to exceed the startup threshold in order to turn off the startup current source. Startup and normal operation of the converter are shown in Figure 3.

## Fault Logic and Timer Control

The NCP105X series has integrated Fault Logic and Timer Control circuitry for detecting application fault conditions such as open loop, overload or a short circuited output. A timer is generated by driving the supply capacitor with a known current and hysteretically regulating the supply voltage between set thresholds. The timer period starts when the supply voltage reaches the nominal upper threshold of 8.6 V and stops when the drain current of the integrated circuit draws the supply capacitor voltage down to the undervoltage lockout threshold of 7.6 V .

If, during this timer period, no feedback has been applied to the control input, the fault logic is set to indicate an abnormal condition. This may occur, for example, when the optocoupler fails or the output of the application is overloaded or completely shorted. In this case, the part will stop switching, go into a low power mode, and begin to draw down the supply capacitor to the reset threshold voltage of 4.6 V. At that time, the startup circuit will turn on again to drive the supply to the turn on threshold. Then the part will begin the cycle again, effectively sampling the control input to determine if the fault condition has been removed. This mode is commonly referred to as burst mode operation and is shown is Figure 4.
Proper selection of the supply capacitor allows successful startup with monotonically increasing output voltage, without falsely sensing a fault condition. Figure 4 shows successful startup and the evolution of the signals involved in the presence of a fault.

## Thermal Shutdown

The internal Thermal Shutdown block protects the device in the event that the maximum junction temperature is exceeded. When activated, typically at $160^{\circ} \mathrm{C}$, one input of the Driver is held low to disable the Power Switch Circuit. The Power Switch is allowed to resume operation when the junction temperature falls below $85^{\circ} \mathrm{C}$. The thermal shutdown feature is provided to prevent catastrophic device failures from accidental overheating. It is not intended to be used as a substitute for proper heatsinking.

## NCP1050, NCP1051, NCP1052, NCP1053, NCP1054, NCP1055

## APPLICATIONS

Two application examples have been provided in this document, and they are described in detail in this section. Figure 27 shows a Universal Input, 10 Watt Converter Application as well as a 5.5 Watt Charger Application using the NCP1053B. The Charger consists of the additional components Q1, C13, and R7 through R10, as shown. These were constructed and tested using the printed circuit board layout shown in Figure 39. The board consists of a fiberglass epoxy material (FR4) with a single side of two ounce per square foot ( $70 \mu \mathrm{~m}$ thick) copper foil. Test data from the two applications is given in Figures 28 through 38.

Both applications generate a well-regulated output voltage over a wide range of line input voltage and load current values. The charger application transitions to a constant current output if the load current is increased beyond a preset range. This can be very effective for battery charger application for portable products such as cellular telephones, personal digital assistants, and pagers. Using the NCP105X series in applications such as these offers a wide range of flexibility for the system designer.

The NCP105X application offers a low cost alternative to other applications. It uses a Dynamic Self-Supply (DSS) function to generate its own operating supply voltage such that an auxiliary transformer winding is not needed. (It also offers the flexibility to override this function with an auxiliary winding if ultra-low standby power is the designer's main concern.) This product also provides for automatic output overload, short circuit, and open loop protection by entering a programmable duty cycle burst mode of operation. This eliminates the need for expensive devices overrated for power dissipation or maximum current, or for redundant feedback loops.

The application shown in Figure 27 can be broken down into sections for the purpose of operating description. Components C1, L1 and C6 provide EMI filtering for the design, although this is very dependent upon board layout, component type, etc. D1 through D4 along with C2 provide the AC to bulk DC rectification. The NCP1053 drives the primary side of the transformer, and the capacitor, C 5 , is an integral part of the Dynamic Self-Supply. R1, C3, and D5 comprise an RCD snubber and R2 and C4 comprise a ringing damper both acting together to protect the IC from voltage transients greater than 700 volts and reduce radiated noise from the converter. Diode D6 along with C7-9, L2, C11, and C 12 rectify the transformer secondary and filter the output
to provide a tightly regulated DC output. IC3 is a shunt regulator that samples the output voltage by virtue of R5 and R6 to provide drive to the optocoupler, IC2, Light Emitting Diode (LED). C10 is used to compensate the shunt regulator. When the application is configured as a Charger, Q1 delivers additional drive to the optocoupler LED when in constant current operation by sampling the output current through R7 and R8.

## Component Selection Guidelines

Choose snubber components R1, C3, and D5 such that the voltage on pin 5 is limited to the range from 0 to 700 volts. These components protect the IC from substrate injection if the voltage was to go below zero volts, and from avalanche if the voltage was to go above 700 volts, at the cost of slightly reduced efficiency. For lower power design, a simple RC snubber as shown, or connected to ground, can be sufficient. Ensure that these component values are chosen based upon the worst-case transformer leakage inductance and worst-case applied voltage. Choose R2 and C4 for best performance radiated switching noise.

Capacitor C5 serves multiple purposes. It is used along with the internal startup circuitry to provide power to the IC in lieu of a separate auxiliary winding. It also serves to provide timing for the oscillator frequency sweep for limiting the conducted EMI emissions. The value of C 5 will also determine the response during an output fault (overload or short circuit) or open loop condition as shown in Figure 4, along with the total output capacitance.

Resistors R5 and R6 will determine the regulated output voltage along with the reference voltage chosen with IC3.
The base to emitter voltage drop of Q1 along with the value of R 7 will set the fixed current limit value of the Charger application. R9 is used to limit the base current of Q1. Component R8 can be selected to keep the current limit fixed with very low values of output voltage or to provide current limit foldback with results as shown in Figures 28 and 32. A relatively large value of R8 allows for enough output voltage to effectively drive the optocoupler LED for fixed current limit. A low value of R8, along with resistor R10, provides for a low average output power using the fault protection feature when the output voltage is very low. C13 provides for output voltage stability when the Charger application is in current limit.

## MC33368

## High Voltage GreenLine ${ }^{T M}$ Power Factor Controller

The MC33368 is an active power factor controller that functions as a boost preconverter in off-line power supply applications. MC33368 is optimized for low power, high density power supplies requiring a minimum board area, reduced component count and low power dissipation. The narrow body SOIC package provides a small footprint. Integration of the high voltage startup saves approximately 0.7 W of power compared to resistor bootstrapped circuits.

The MC33368 features a watchdog timer to initiate output switching, a one quadrant multiplier to force the line current to follow the instantaneous line voltage a zero current detector to ensure critical conduction operation, a transconductance error amplifier, a current sensing comparator, a 5.0 V reference, an undervoltage lockout (UVLO) circuit which monitors the $\mathrm{V}_{\mathrm{CC}}$ supply voltage and a CMOS driver for driving MOSFETs. The MC33368 also includes a programmable output switching frequency clamp. Protection features include an output overvoltage comparator to minimize overshoot, a restart delay timer and cycle-by-cycle current limiting.

- Lossless Off-Line Startup
- Output Overvoltage Comparator
- Leading Edge Blanking (LEB) for Noise Immunity
- Watchdog Timer to Initiate Switching

## FUNCTIONAL DESCRIPTION

## INTRODUCTION

With the goal of exceeding the requirements of legislation on line current harmonic content, there is an ever increasing demand for an economical method of obtaining a unity power factor. This data sheet describes a monolithic control IC that was specifically designed for power factor control with minimal external components. It offers the designer a simple cost effective solution to obtain the benefits of active power factor correction.

Most electronic ballasts and switching power supplies use a bridge rectifier and a bulk storage capacitor to derive raw dc voltage from the utility ac line, Figure 13.

Figure 13. Uncorrected Power Factor Circuit
This simple rectifying circuit draws power from the line when the instantaneous ac voltage exceeds the capacitor voltage. This occurs near the line voltage peak and results in a high charge current spike, Figure 14 . Since power is only taken near the line voltage peaks, the resulting spikes of current are extremely nonsinusoidal with a high content of harmonics. This results in a poor power factor condition where the apparent input power is much higher than the real power. Power factor ratios of 0.5 to 0.7 are common.

Figure 14. Uncorrected Power Factor Input Waveforms
Power factor correction can be achieved with the use of either a passive or active input circuit. Passive circuits usually contain a combination of large capacitors, inductors, and rectifiers that operate at the ac line frequency. Active circuits incorporate some form of a high frequency switching converter for the power processing with the boost converter being the most popular topology. Since active input circuits operate at a frequency much higher than that
of the ac line, they are smaller, lighter in weight, and more efficient than a passive circuit that yields similar results. With proper control of the preconverter, almost any complex load can be made to appear resistive to the ac line, thus significantly reducing the harmonic current content.

## Operating Description

The MC33368 contains many of the building blocks and protection features that are employed in modern high performance current mode power supply controllers. Referring to the block diagram in Figure 15, note that a multiplier has been added to the current sense loop and that this device does not contain an oscillator. A description of each of the functional blocks is given below.

## Error Amplifier

An Error Amplifier with access to the inverting input and output is provided. The amplifier is a transconductance type, meaning that it has high output impedance with controlled voltage-to-current gain ( $\mathrm{g}_{\mathrm{m}} \approx 50 \mu \mathrm{mhos}$ ). The noninverting input is internally biased at $5.0 \mathrm{~V} \pm 2.0 \%$. The output voltage of the power factor converter is typically divided down and monitored by the inverting input. The maximum input bias current is $-1.0 \mu \mathrm{~A}$ which can cause an output voltage error that is equal to the product of the input bias current and the value of the upper divider resistor R2. The Error Amplifier output is internally connected to the Multiplier and is pinned out (Pin 4) for external loop compensation. Typically, the bandwidth is set below 20 Hz so that the amplifier's output voltage is relatively constant over a given ac line cycle. In effect, the error amplifier monitors the average output voltage of the converter over several line cycles resulting in a fixed Drive Output on-time. The amplifier output stage can sink and source $11.5 \mu \mathrm{~A}$ of current and is capable of swinging from 1.7 to 5.0 V , assuring that the Multiplier can be driven over its entire dynamic range.

Note that by using a transconductance type amplifier, the input is allowed to move independently with respect to the output, since the compensation capacitor is connected to ground. This allows dual usage of the Voltage Feedback pin by the Error Amplifier and Overvoltage Comparator.

## Overvoltage Comparator

An Overvoltage Comparator is incorporated to eliminate the possibility of runaway output voltage. This condition can occur during initial startup, sudden load removal, or during output arcing and is the result of the low bandwidth that must be used in the Error Amplifier control loop. The Overvoltage Comparator monitors the peak output voltage of the converter, and when exceeded, immediately terminates MOSFET switching. The comparator threshold is internally set to $1.08 \mathrm{~V}_{\text {ref }}$. In order to prevent false tripping during normal operation, the value of the output filter capacitor C3 must be large enough to keep the peak-to-peak ripple less than $16 \%$ of the average dc output.

## Multiplier

A single quadrant, two input multiplier is the critical element that enables this device to control power factor. The ac haversines are monitored at Pin 5 with respect to ground while the Error Amplifier output at Pin 4 is monitored with respect to the Voltage Feedback Input threshold. A graph of the Multiplier transfer curve is shown in Figure 1. Note that both inputs are extremely linear over a wide dynamic range, 0 to 3.2 V for Pin 5 and 2.5 to 4.0 V for Pin 4. The Multiplier output controls the Current Sense Comparator threshold as the ac voltage traverses sinusoidally from zero to peak line. This has the effect of forcing the MOSFET on-time to track the input line voltage, thus making the preconverter load appear to be resistive.

$$
\text { Pin } 6 \text { Threshold } \approx 0.55\left(\mathrm{~V}_{\operatorname{Pin} 4}-\mathrm{V}_{\operatorname{Pin} 3}\right) \mathrm{V}_{\operatorname{Pin} 5}
$$

## Zero Current Detector

The MC33368 operates as a critical conduction current mode controller, whereby output switch conduction is initiated by the Zero Current Detector and terminated when the peak inductor current reaches the threshold level established by the Multiplier output. The Zero Current Detector initiates the next on-time by setting the $\mathrm{R}_{\mathrm{S}}$ Latch at the instant the inductor current reaches zero. This critical conduction mode of operation has two significant benefits. First, since the MOSFET cannot turn-on until the inductor current reaches zero, the output rectifier's reverse recovery time becomes less critical allowing the use of an inexpensive rectifier. Second, since there are no deadtime gaps between cycles, the ac line current is continuous thus limiting the peak switch to twice the average input current

The Zero Current Detector indirectly senses the inductor current by monitoring when the auxiliary winding voltage falls below 1.2 V . To prevent false tripping, 200 mV of hysteresis is provided. The Zero Current Detector input is internally protected by two clamps. The upper 10 V clamp prevents input overvoltage breakdown while the lower -0.7 V clamp prevents substrate injection. An external resistor must be used in series with the auxiliary winding to limit the current through the clamps to 5.0 mA or less.

## Current Sense Comparator and RS Latch

The Current Sense Comparator $\mathrm{R}_{\mathrm{S}}$ Latch configuration used ensures that only a single pulse appears at the Drive Output during a given cycle. The inductor current is converted to a voltage by inserting a ground-referenced sense resistor R7 in series with the source of output switch. This voltage is monitored by the Current Sense Input and compared to a level derived from the Multiplier output. The peak inductor current under normal operating conditions is controlled by the threshold voltage of Pin 6 where:

$$
I_{\mathrm{pk}}=\frac{\text { Pin } 6 \text { Threshold }}{\text { R7 }}
$$

Abnormal operating conditions occur when the preconverter is running at extremely low line or if output voltage sensing is lost. Under these conditions, the Current

Sense Comparator threshold will be internally clamped to 1.5 V . Therefore, the maximum peak switch current is:

$$
\mathrm{I}_{\mathrm{pk}(\max )}=\frac{1.5 \mathrm{~V}}{\mathrm{R7}}
$$

With the component values shown in Figure 15, the Current Sense Comparator threshold, at the peak of the haversine, varies from 110 mV at 90 Vac to 100 mV at 268 Vac. The Current Sense Input to Drive Output propagation delay is typically 200 ns .

## Timer

A watchdog timer function was added to the IC to eliminate the need for an external oscillator when used in stand alone applications. The Timer provides a means to automatically start or restart the preconverter if the Drive Output has been off for more than $385 \mu$ s after the inductor current reaches zero.

## Undervoltage Lockout and Quickstart

The MC33368 has a 5.0 V internal reference brought out to Pin 1 and capable of sourcing 10 mA typically. It also contains an Undervoltage Lockout (UVLO) circuit which suppresses the Gate output at Pin 11 if the $\mathrm{V}_{\mathrm{CC}}$ supply voltage drops below 8.5 V typical.

A Quickstart circuit has been incorporated to optimize converter startup. During initial startup, compensation capacitor C 1 will be discharged, holding the Error Amplifier output below the Multiplier's threshold. This will prevent Drive Output switching and delay bootstraping of capacitor C4 by diode D6. If Pin 4 does not reach the multiplier threshold before C 4 discharges below the lower SMPS UVLO threshold, the converter will hiccup and experience a significant startup delay. The Quickstart circuit is designed to precharge C 1 to 1.7 V . This level is slightly below the Pin 4 Multiplier threshold, allowing immediate Drive Output switching.

## Restart Delay

A restart delay pin is provided to allow hiccup mode fault protection in case of a short circuit condition and to prevent the SMPS from repeatedly trying to restart after the input line voltage has been removed. When power is first applied, there is no startup delay, but subsequent cycling of the $\mathrm{V}_{\mathrm{CC}}$ voltage will result in delay times that are programmed by an external resistor and capacitor. The Restart Delay, Pin 2, is a high impedance, so that an external capacitor can provide delay times as long as several seconds.

If the SMPS output is short circuited, the transformer winding, which provides the $\mathrm{V}_{\mathrm{CC}}$ voltage to the control IC and the MC33368, will be unable to sustain $\mathrm{V}_{\mathrm{CC}}$ to the control circuits. The restart delay capacitor at Pin 2 of the MC33368 prevents the high voltage startup transistor within the IC from maintaining the voltage on C 4 . After $\mathrm{V}_{\mathrm{CC}}$ drops below the UVLO threshold in the SMPS, the SMPS switching transistors are held off for the time programmed by the values of the restart capacitor (C9) and resistor (R8). In this manner, the SMPS switching transistors are operated
at very low duty cycles, preventing their destruction. If the short circuit fault is removed, the power supply system will turn on by itself in a normal startup mode after the restart delay has timed out.

## Output Switching Frequency Clamp

In normal operation, the MC33368 operates the boost inductor in the critical mode. That is, the inductor current ramps to a peak value, ramps down to zero, then immediately begins ramping positive again. The peak current is programmed by the multiplier output within the IC. As the input voltage haversine declines to near zero, the output switch on-time becomes constant, rather than going to zero because of the small integrated dc voltage at Pin 5 caused by C2, R3 and R5. Because of this, the average line current does not exactly follow the line voltage near the zero crossings. The Output Switching Frequency Clamp remedies this situation to improve power factor and minimize EMI generated in this operating region. The values of R10 and C7, as shown in Figure 15, program a minimum off-time in the frequency clamp which overrides the zero current detect signal, forcing a minimum off-time. This allows discontinuous conduction operation of the boost inductor in the zero crossing region, and the average line current more nearly follows the voltage. The Output Switching Frequency Clamp function can be disabled by connecting the FC input, Pin 13, to the $\mathrm{V}_{\mathrm{CC}}$ supply Pin 12.

For best results, the minimum off-time, determined by the values of R10 and C7, should be chosen so that $t_{s(\min )}=t_{(o n)}$ $+\mathrm{t}_{(\text {off }) \mathrm{fc}}$. Output drive is inhibited when the voltage at the frequency clamp input is less than 2.0 V . When the output drive is high, C 7 is discharged through an internal $100 \mu \mathrm{~A}$ current source. When the output drive switches low, C7 is charged through R10. The drive output is inhibited until the voltage across C7 reaches 2.0 V , establishing a minimum off-time where:

$$
\mathrm{t}_{\text {(off)fc }}=-\mathrm{R} 10 \mathrm{C} 7 \log _{\mathrm{e}}\left[1-\left(\frac{2}{\mathrm{~V}_{\mathrm{CC}}}\right)\right]
$$

## Output

The IC contains a CMOS output driver that was specifically designed for direct drive of power MOSFETs. The Gate Output is capable of up to $\pm 1500 \mathrm{~mA}$ peak current with a typical rise and fall time of 50 ns with a 1.0 nF load. Additional internal circuitry has been added to keep the Gate Output in a sinking mode whenever the Undervoltage Lockout is active. This characteristic eliminates the need for an external gate pull-down resistor. The totem-pole output has been optimized to minimize cross-conduction current during high speed operation.

Table 1. Design Equations

| Calculation | Formula | Notes |
| :---: | :---: | :---: |
| Converter Output Power | $\mathrm{P}_{\mathrm{O}}=\mathrm{V}_{\mathrm{O}} \mathrm{l}_{\mathrm{O}}$ | Calculate the maximum required output power. |
| Peak Indicator Current | $\mathrm{I}_{\mathrm{L}(\mathrm{pk})}=\frac{2 \sqrt{2} \mathrm{P}_{\mathrm{O}}}{\eta \mathrm{Vac}_{(\mathrm{LL})}}$ | Calculated at the minimum required ac line voltage for output regulation. Let the efficiency $\eta=0.92$ for low line operation. |
| Inductance | $\mathrm{L}_{\mathrm{P}}=\frac{\mathrm{t}\left(\frac{\mathrm{~V}_{\mathrm{O}}}{\sqrt{2}}-\mathrm{Vac}_{(\mathrm{LL})}\right) \eta \mathrm{Vac}_{(\mathrm{LL})}{ }^{2}}{\sqrt{2} \mathrm{~V}_{\mathrm{O}} \mathrm{P}_{\mathrm{O}}}$ | Let the switching cycle $\mathrm{t}=40 \mu \mathrm{~s}$ for universal input ( 85 to 265 Vac ) operation and $20 \mu \mathrm{~s}$ for fixed input ( 92 to 138 Vac , or 184 to 276 Vac ) operation. |
| Switch On-Time | $\mathrm{t}_{(\mathrm{on})}=\frac{2 \mathrm{P}_{\mathrm{O}} \mathrm{~L}_{\mathrm{P}}}{\eta \mathrm{Vac}^{2}}$ | In theory, the on-time $t_{(o n)}$ is constant. In practice, $t_{(o n)}$ tends to increase at the ac line zero crossings due to the charge on capacitor C 5 . Let $\mathrm{Vac}=\mathrm{Vac}_{(\mathrm{LL})}$ for initial $t_{\text {(on) }}$ and $t_{\text {(off) }}$ calculations. |
| Switch Off-Time | $t_{\text {(off) }}=\frac{t^{t} \text { on) }}{\frac{V_{O}}{\sqrt{2} \operatorname{Vac}\|\operatorname{Sin} \theta\|}-1}$ | The off-time $t_{\text {(off) }}$ is greatest at the peak of the ac line voltage and approaches zero at the ac line zero crossings. Theta $(\theta)$ represents the angle of the ac line voltage. |
| Minimum Switch Off-Time | ${ }^{\mathrm{t}}{ }_{(\mathrm{off})_{\text {min }}}=\frac{\mathrm{L}_{\mathrm{P}} \mathrm{I}_{\mathrm{L}(\mathrm{pk})}}{\mathrm{V}_{\mathrm{O}}}$ | The off-time is at a minimum at ac line crossings. This equation is used to calculate $t_{\text {(off) }}$ as Theta approaches zero. |
| Delay Time | $t_{d}=-R 10 C 7 \ln \left(\frac{v_{C C}-2}{V_{C C}}\right)$ | The delay time is used to override the minimum off-time at the ac line zero crossings by programming the Frequency Clamp with C7 and R10. |
| Switching Frequency | $f=\frac{1}{t_{(\text {on })}+t_{(\text {off })}}$ | The minimum switching frequency occurs at the peak of the ac line voltage. As the ac line voltage traverses from peak to zero, $\mathrm{t}_{(\text {off })}$ approaches zero producing an increase in switching frequency. |
| Peak Switch Current | $\mathrm{R7}=\frac{\mathrm{V}_{\text {CS }}}{\mathrm{I}_{\mathrm{L}(\mathrm{pk})}}$ | Set the current sense threshold $\mathrm{V}_{\mathrm{CS}}$ to 1.0 V for universal input ( 85 to 265 Vac ) operation and to 0.5 V for fixed input ( 92 to 138 Vac , or 184 to 276 Vac ) operation. Note that $\mathrm{V}_{\mathrm{CS}}$ must be less than 1.4 V . |
| Multiplier Input Voltage | $V_{M}=\frac{\operatorname{Vac} \sqrt{2}}{\left(\frac{R 5}{R 3}+1\right)}$ | Set the multiplier input voltage $\mathrm{V}_{\mathrm{M}}$ to 3.0 V at high line. Empirically adjust $\mathrm{V}_{\mathrm{M}}$ for the lowest distortion over the ac line voltage range while guaranteeing startup at minimum line. |
| Converter Output Voltage | $\mathrm{V}_{\mathrm{O}}=\mathrm{V}_{\text {ref }}\left(\frac{R 2}{R 1}+1\right)-I_{I B} R 1$ | The $I_{I B}$ R1 error term can be minimized with a divider current in excess of $100 \mu \mathrm{~A}$. |
| Converter Output Peak-to-Peak Ripple Voltage | $\Delta \mathrm{V}_{\mathrm{O}(\mathrm{pp})}=\mathrm{I}_{\mathrm{L}(\mathrm{pk})} \sqrt{\left(\frac{1}{2 \pi f_{\mathrm{ac}} \mathrm{C} 3}\right)^{2}+E S R^{2}}$ | The calculated peak-to-peak ripple must be less than $16 \%$ of the average dc output voltage to prevent false tripping of the Overvoltage Comparator. Refer to the Overvoltage Comparator Text. ESR is the equivalent series resistance of C3. |
| Error Amplifier Bandwidth | $\mathrm{BW}=\frac{\mathrm{g}_{\mathrm{m}}}{2 \pi \mathrm{C} 1}$ | The bandwidth is typically set to 20 Hz . When operating at high ac line, the value of C 1 may need to be increased. |

NOTE: The following converter characteristics must be chosen:
$\mathrm{V}_{\mathrm{O}}=$ Desired output voltage. $\quad \mathrm{Vac}_{(\mathrm{LL})}=\mathrm{AC}$ RMS minimum required operating line voltage for output regulation.
$\mathrm{I}_{\mathrm{O}}=$ Desired output current. $\quad \Delta \mathrm{V}_{\mathrm{O}}=$ Converter output peak-to-peak ripple voltage.
Vac = AC RMS operating line voltage.

Figure 16. 175 W Universal Input Power Factor Controller

An RFI filter is required for best performance when connecting the preconverter directly to the ac line. The filter attenuates the level of high frequency switching that appears on the ac line current waveform. Figures 15 and 16 work well with commercially available two stage filters such as the Delta Electronics 03DPCG6. Shown above is a single stage test filter that can easily be constructed with four ac line rated capacitors and a common-mode transformer. Coilcraft CMT3-28-2 was used to test Figures 15 and 16. It has a minimum inductance of 28 mH and a maximum current rating of 2.0 A . Coilcraft CMT4-17-9 was used to test Figure 19. It has a minimum inductance of 17 mH and a maximum current rating of 9.0 A . Circuit conversion efficiency $\eta(\%)$ was calculated without the power loss of the RFI filter.

## Power Factor Controllers

The MC34262/MC33262 are active power factor controllers specifically designed for use as a preconverter in electronic ballast and in off-line power converter applications. These integrated circuits feature an internal startup timer for stand-alone applications, a one quadrant multiplier for near unity power factor, zero current detector to ensure critical conduction operation, transconductance error amplifier, quickstart circuit for enhanced startup, trimmed internal bandgap reference, current sensing comparator, and a totem pole output ideally suited for driving a power MOSFET.

Also included are protective features consisting of an overvoltage comparator to eliminate runaway output voltage due to load removal, input undervoltage lockout with hysteresis, cycle-by-cycle current limiting, multiplier output clamp that limits maximum peak switch current, an RS latch for single pulse metering, and a drive output high state clamp for MOSFET gate protection. These devices are available in dual-in-line and surface mount plastic packages.

- Overvoltage Comparator Eliminates Runaway Output Voltage
- Internal Startup Timer
- One Quadrant Multiplier
- Zero Current Detector
- Trimmed 2\% Internal Bandgap Reference
- Totem Pole Output with High State Clamp
- Undervoltage Lockout with 6.0 V of Hysteresis
- Low Startup and Operating Current
- Supersedes Functionality of SG3561 and TDA4817

## FUNCTIONAL DESCRIPTION

## Introduction

With the goal of exceeding the requirements of legislation on line-current harmonic content, there is an ever increasing demand for an economical method of obtaining a unity power factor. This data sheet describes a monolithic control IC that was specifically designed for power factor control with minimal external components. It offers the designer a simple, cost-effective solution to obtain the benefits of active power factor correction.

Most electronic ballasts and switching power supplies use a bridge rectifier and a bulk storage capacitor to derive raw dc voltage from the utility ac line, Figure 15.

Figure 35. Uncorrected Power Factor Circuit

This simple rectifying circuit draws power from the line when the instantaneous ac voltage exceeds the capacitor voltage. This occurs near the line voltage peak and results in a high charge current spike, Figure 16. Since power is only taken near the line voltage peaks, the resulting spikes of current are extremely nonsinusoidal with a high content of harmonics. This results in a poor power factor condition where the apparent input power is much higher than the real power. Power factor ratios of 0.5 to 0.7 are common.

Power factor correction can be achieved with the use of either a passive or an active input circuit. Passive circuits usually contain a combination of large capacitors, inductors, and rectifiers that operate at the ac line frequency. Active circuits incorporate some form of a high frequency switching converter for the power processing, with the boost converter being the most popular topology, Figure 17. Since active input circuits operate at a frequency much higher than that of the ac line, they are smaller, lighter in weight, and more efficient than a passive circuit that yields similar results. With proper control of the preconverter, almost any complex load can be made to
appear resistive to the ac line, thus significantly reducing the harmonic current content.

Figure 36. Uncorrected Power Factor Input Waveforms

The MC34262, MC33262 are high performance, critical conduction, current-mode power factor controllers specifically designed for use in off-line active preconverters. These devices provide the necessary features required to significantly enhance poor power factor loads by keeping the ac line current sinusoidal and in phase with the line voltage.

## Operating Description

The MC34262, MC33262 contain many of the building blocks and protection features that are employed in modern high performance current mode power supply controllers. There are, however, two areas where there is a major difference when compared to popular devices such as the UC3842 series. Referring to the block diagram in Figure 19, note that a multiplier has been added to the current sense loop and that this device does not contain an oscillator. The reasons for these differences will become apparent in the following discussion. A description of each of the functional blocks is given below.

Figure 37. Active Power Factor Correction Preconverter

## Error Amplifier

An Error Amplifier with access to the inverting input and output is provided. The amplifier is a transconductance type, meaning that it has high output impedance with controlled voltage-to-current gain. The amplifier features a typical gm of $100 \mu \mathrm{mhos}$ (Figure 5). The noninverting input is internally biased at $2.5 \mathrm{~V} \pm 2.0 \%$ and is not pinned out. The output voltage of the power factor converter is typically divided down and monitored by the inverting input. The maximum input bias current is $-0.5 \mu \mathrm{~A}$, which can cause an output voltage error that is equal to the product of the input bias current and the value of the upper divider resistor $\mathrm{R}_{2}$. The Error Amp output is internally connected to the Multiplier and is pinned out (Pin 2) for external loop compensation. Typically, the bandwidth is set below 20 Hz , so that the amplifier's output voltage is relatively constant over a given ac line cycle. In effect, the error amp monitors the average output voltage of the converter over several line cycles. The Error Amp output stage was designed to have a relatively constant transconductance over temperature. This allows the designer to define the compensated bandwidth over the intended operating temperature range. The output stage can sink and source $10 \mu \mathrm{~A}$ of current and is capable of swinging from 1.7 V to 6.4 V , assuring that the Multiplier can be driven over its entire dynamic range.

A key feature to using a transconductance type amplifier, is that the input is allowed to move independently with respect to the output, since the compensation capacitor is connected to ground. This allows dual usage of of the Voltage Feedback Input pin by the Error Amplifier and by the Overvoltage Comparator.

## Overvoltage Comparator

An Overvoltage Comparator is incorporated to eliminate the possibility of runaway output voltage. This condition can occur during initial startup, sudden load removal, or during output arcing and is the result of the low bandwidth that must be used in the Error Amplifier control loop. The Overvoltage Comparator monitors the peak output voltage of the converter, and when exceeded, immediately terminates MOSFET switching. The comparator threshold is internally set to $1.08 \mathrm{~V}_{\text {ref }}$. In order to prevent false tripping during normal operation, the value of the output filter capacitor $C_{3}$ must be large enough to keep the peak-to-peak ripple less than $16 \%$ of the average dc output. The Overvoltage Comparator input to Drive Output turn-off propagation delay is typically 400 ns. A comparison of startup overshoot without and with the Overvoltage Comparator circuit is shown in Figure 23.

## Multiplier

A single quadrant, two input multiplier is the critical element that enables this device to control power factor. The ac full wave rectified haversines are monitored at Pin 3
with respect to ground while the Error Amp output at Pin 2 is monitored with respect to the Voltage Feedback Input threshold. The Multiplier is designed to have an extremely linear transfer curve over a wide dynamic range, 0 V to 3.2 V for Pin 3, and 2.0 V to 3.75 V for Pin 2, Figure 1. The Multiplier output controls the Current Sense Comparator threshold as the ac voltage traverses sinusoidally from zero to peak line, Figure 18. This has the effect of forcing the MOSFET on-time to track the input line voltage, resulting in a fixed Drive Output on-time, thus making the preconverter load appear to be resistive to the ac line. An approximation of the Current Sense Comparator threshold can be calculated from the following equation. This equation is accurate only under the given test condition stated in the electrical table.

$$
\mathrm{V}_{\mathrm{CS}} \text {, Pin } 4 \text { Threshold } \approx 0.65\left(\mathrm{~V}_{\text {Pin } 2}-\mathrm{V}_{\mathrm{th}(\mathrm{M})}\right) \mathrm{V}_{\text {Pin } 3}
$$

A significant reduction in line current distortion can be attained by forcing the preconverter to switch as the ac line voltage crosses through zero. The forced switching is achieved by adding a controlled amount of offset to the Multiplier and Current Sense Comparator circuits. The equation shown below accounts for the built-in offsets and is accurate to within ten percent. Let $\mathrm{V}_{\mathrm{th}(\mathrm{M})}=1.991 \mathrm{~V}$

$$
\begin{gathered}
V_{\text {CS }} \text {, Pin } 4 \text { Threshold }=0.544\left(V_{\text {Pin 2 }}-V_{\text {th }}(\mathrm{M})\right) \mathrm{V}_{\text {Pin } 3} \\
+0.0417\left(\mathrm{~V}_{\text {Pin 2 }}-\mathrm{V}_{\text {th }(\mathrm{M})}\right)
\end{gathered}
$$

## Zero Current Detector

The MC34262 operates as a critical conduction current mode controller, whereby output switch conduction is initiated by the Zero Current Detector and terminated when the peak inductor current reaches the threshold level established by the Multiplier output. The Zero Current Detector initiates the next on-time by setting the RS Latch at the instant the inductor current reaches zero. This critical conduction mode of operation has two significant benefits. First, since the MOSFET cannot turn-on until the inductor current reaches zero, the output rectifier reverse recovery time becomes less critical, allowing the use of an inexpensive rectifier. Second, since there are no deadtime gaps between cycles, the ac line current is continuous, thus limiting the peak switch to twice the average input current.
The Zero Current Detector indirectly senses the inductor current by monitoring when the auxiliary winding voltage falls below 1.4 V . To prevent false tripping, 200 mV of hysteresis is provided. Figure 9 shows that the thresholds are well-defined over temperature. The Zero Current Detector input is internally protected by two clamps. The upper 6.7 V clamp prevents input overvoltage breakdown while the lower 0.7 V clamp prevents substrate injection. Current limit protection of the lower clamp transistor is provided in the event that the input pin is accidentally shorted to ground. The Zero Current Detector input to Drive Output turn-on propagation delay is typically 320 ns .

Figure 38. Inductor Current and MOSFET Gate Voltage Waveforms

## Current Sense Comparator and RS Latch

The Current Sense Comparator RS Latch configuration used ensures that only a single pulse appears at the Drive Output during a given cycle. The inductor current is converted to a voltage by inserting a ground-referenced sense resistor $\mathrm{R}_{7}$ in series with the source of output switch Q1. This voltage is monitored by the Current Sense Input and compared to a level derived from the Multiplier output. The peak inductor current under normal operating conditions is controlled by the threshold voltage of Pin 4 where:

$$
\left.\mathrm{I}_{\mathrm{L}(\mathrm{pk}}\right)=\frac{\text { Pin } 4 \text { Threshold }}{\mathrm{R}_{7}}
$$

Abnormal operating conditions occur during preconverter startup at extremely high line or if output voltage sensing is lost. Under these conditions, the Multiplier output and Current Sense threshold will be internally clamped to 1.5 V . Therefore, the maximum peak switch current is limited to:

$$
\mathrm{I}_{\mathrm{pk}(\max )}=\frac{1.5 \mathrm{~V}}{\mathrm{R}_{7}}
$$

An internal RC filter has been included to attenuate any high frequency noise that may be present on the current waveform. This filter helps reduce the ac line current distortion especially near the zero crossings. With the component values shown in Figure 20, the Current Sense Comparator threshold, at the peak of the haversine varies from 1.1 V at 90 Vac to 100 mV at 268 Vac . The Current Sense Input to Drive Output turn-off propagation delay is typically less than 200 ns .

## Timer

A watchdog timer function was added to the IC to eliminate the need for an external oscillator when used in stand-alone applications. The Timer provides a means to
automatically start or restart the preconverter if the Drive Output has been off for more than $620 \mu$ s after the inductor current reaches zero. The restart time delay versus temperature is shown in Figure 8.

## Undervoltage Lockout and Quickstart

An Undervoltage Lockout comparator has been incorporated to guarantee that the IC is fully functional before enabling the output stage. The positive power supply terminal $\left(\mathrm{V}_{\mathrm{CC}}\right)$ is monitored by the UVLO comparator with the upper threshold set at 13 V and the lower threshold at 8.0 V . In the stand-by mode, with $\mathrm{V}_{\mathrm{CC}}$ at 7.0 V , the required supply current is less than 0.4 mA . This large hysteresis and low startup current allow the implementation of efficient bootstrap startup techniques, making these devices ideally suited for wide input range off-line preconverter applications. An internal 36 V clamp has been added from $\mathrm{V}_{\mathrm{CC}}$ to ground to protect the IC and capacitor $\mathrm{C}_{4}$ from an overvoltage condition. This feature is desirable if external circuitry is used to delay the startup of the preconverter. The supply current, startup, and operating voltage characteristics are shown in Figures 13 and 14.

A Quickstart circuit has been incorporated to optimize converter startup. During initial startup, compensation capacitor $\mathrm{C}_{1}$ will be discharged, holding the error amp output below the Multiplier threshold. This will prevent Drive Output switching and delay bootstrapping of capacitor $\mathrm{C}_{4}$ by diode $\mathrm{D}_{6}$. If Pin 2 does not reach the multiplier threshold before $\mathrm{C}_{4}$ discharges below the lower UVLO threshold, the converter will "hiccup" and experience a significant startup delay. The Quickstart circuit is designed to precharge $\mathrm{C}_{1}$ to 1.7 V , Figure 7 . This level is slightly below the Pin 2 Multiplier threshold, allowing immediate Drive Output switching and bootstrap operation when $\mathrm{C}_{4}$ crosses the upper UVLO threshold.

## Drive Output

The MC34262/MC33262 contain a single totem-pole output stage specifically designed for direct drive of power MOSFETs. The Drive Output is capable of up to $\pm 500 \mathrm{~mA}$ peak current with a typical rise and fall time of 50 ns with a 1.0 nF load. Additional internal circuitry has been added to keep the Drive Output in a sinking mode whenever the Undervoltage Lockout is active. This characteristic eliminates the need for an external gate pull-down resistor. The totem-pole output has been optimized to minimize cross-conduction current during high speed operation. The addition of two $10 \Omega$ resistors, one in series with the source output transistor and one in series with the sink output transistor, helps to reduce the cross-conduction current and radiated noise by limiting the output rise and fall time. A 16 V clamp has been incorporated into the output stage to limit the high state $\mathrm{V}_{\mathrm{OH}}$. This prevents rupture of the MOSFET gate when $\mathrm{V}_{\mathrm{CC}}$ exceeds 20 V .

## APPLICATIONS INFORMATION

The application circuits shown in Figures 19, 20 and 21 reveal that few external components are required for a complete power factor preconverter. Each circuit is a peak detecting current-mode boost converter that operates in critical conduction mode with a fixed on-time and variable off-time. A major benefit of critical conduction operation is that the current loop is inherently stable, thus eliminating the need for ramp compensation. The application in Figure 19 operates over an input voltage range of 90 Vac to 138 Vac and provides an output power of $80 \mathrm{~W}(230 \mathrm{~V}$ at 350 mA ) with an associated power factor of approximately
0.998 at nominal line. Figures 20 and 21 are universal input preconverter examples that operate over a continuous input voltage range of 90 Vac to 268 Vac. Figure 20 provides an output power of $175 \mathrm{~W}(400 \mathrm{~V}$ at 440 mA$)$ while Figure 21 provides $450 \mathrm{~W}(400 \mathrm{~V}$ at 1.125 A$)$. Both circuits have an observed worst-case power factor of approximately 0.989 . The input current and voltage waveforms of Figure 20 are shown in Figure 22 with operation at 115 Vac and 230 Vac. The data for each of the applications was generated with the test set-up shown in Figure 24.

Table 1. Design Equations

| Notes | Calculation | Formula |
| :---: | :---: | :---: |
| Calculate the maximum required output power. | Required Converter Output Power | $\mathrm{P}_{\mathrm{O}}=\mathrm{V}_{\mathrm{O}} \mathrm{l}_{0}$ |
| Calculated at the minimum required ac line voltage for output regulation. Let the efficiency $\eta=0.92$ for low line operation. | Peak Inductor Current | $\mathrm{L}_{\mathrm{L}(\mathrm{pk})}=\frac{2 \sqrt{2} \mathrm{P}_{\mathrm{O}}}{\eta \operatorname{Vac}_{(\mathrm{LL})}}$ |
| Let the switching cycle $t=40 \mu$ s for universal input ( 85 to 265 Vac ) operation and $20 \mu \mathrm{~s}$ for fixed input ( 92 to 138 Vac , or 184 to 276 Vac ) operation. | Inductance | $\mathrm{L}_{\mathrm{P}}=\frac{\mathrm{t}\left(\frac{\mathrm{~V}_{\mathrm{O}}}{\sqrt{2}}-\mathrm{Vac}_{(\mathrm{LL})}\right) \eta \operatorname{Vac}_{(\mathrm{LL})}{ }^{2}}{\sqrt{2} \mathrm{~V}_{\mathrm{O}} \mathrm{P}_{\mathrm{O}}}$ |
| In theory the on-time $\mathrm{t}_{\mathrm{on}}$ is constant. In practice $\mathrm{t}_{\mathrm{on}}$ tends to increase at the ac line zero crossings due to the charge on capacitor $\mathrm{C}_{5}$. Let $\mathrm{Vac}=\mathrm{Vac}_{(\mathrm{LL})}$ for initial $\mathrm{t}_{\mathrm{on}}$ and $\mathrm{t}_{\text {off }}$ calculations. | Switch On-Time | $\mathrm{t}_{\mathrm{on}}=\frac{2 \mathrm{P}_{\mathrm{O}} \mathrm{LP}}{\eta \mathrm{Vac}^{2}}$ |
| The off-time $t_{\text {off }}$ is greatest at the peak of the ac line voltage and approaches zero at the ac line zero crossings. Theta ( $\theta$ ) represents the angle of the ac line voltage. | Switch Off-Time | $\mathrm{t}_{\mathrm{off}}=\frac{\mathrm{t}_{\mathrm{on}}}{\frac{\mathrm{~V}_{\mathrm{O}}}{\sqrt{2} \mathrm{Vac}\|\operatorname{Sin} \theta\|}-1}$ |
| The minimum switching frequency occurs at the peak of the ac line voltage. As the ac line voltage traverses from peak to zero, $t_{\text {off }}$ approaches zero producing an increase in switching frequency. | Switching Frequency | $f=\frac{1}{t_{\text {on }}+t_{\text {off }}}$ |
| Set the current sense threshold $\mathrm{V}_{\mathrm{CS}}$ to 1.0 V for universal input ( 85 Vac to 265 Vac ) operation and to 0.5 V for fixed input ( 92 Vac to 138 Vac , or 184 Vac to 276 Vac ) operation. Note that $\mathrm{V}_{\mathrm{CS}}$ must be <1.4 V. | Peak Switch Current | $\mathrm{R}_{7}=\frac{\mathrm{V}_{\mathrm{CS}}}{\mathrm{I}_{\mathrm{L}(\mathrm{pk})}}$ |
| Set the multiplier input voltage $\mathrm{V}_{\mathrm{M}}$ to 3.0 V at high line. Empirically adjust $\mathrm{V}_{\mathrm{M}}$ for the lowest distortion over the ac line voltage range while guaranteeing startup at minimum line. | Multiplier Input Voltage | $V_{M}=\frac{\operatorname{Vac} \sqrt{2}}{\left(\frac{R_{5}}{R_{3}}+1\right)}$ |
| The $I_{\mathrm{IB}} \mathrm{R}_{1}$ error term can be minimized with a divider current in excess of $50 \mu \mathrm{~A}$. | Converter Output Voltage | $\mathrm{V}_{\mathrm{O}}=\mathrm{V}_{\text {ref }}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)-\mathrm{I}_{\mathrm{IB}} \mathrm{R}_{2}$ |
| The calculated peak-to-peak ripple must be less than $16 \%$ of the average dc output voltage to prevent false tripping of the Overvoltage Comparator. Refer to the Overvoltage Comparator text. ESR is the equivalent series resistance of $\mathrm{C}_{3}$ | Converter Output Peak to Peak Ripple Voltage | $\Delta \mathrm{V}_{\mathrm{O}(\mathrm{pp})}=\mathrm{I}_{\mathrm{O}} \sqrt{\left(\frac{1}{2 \pi \mathrm{f}_{\mathrm{ac}} \mathrm{C}_{3}}\right)^{2}+\mathrm{ESR}^{2}}$ |
| The bandwidth is typically set to 20 Hz . When operating at high ac line, the value of $\mathrm{C}_{1}$ may need to be increased. (See Figure 25) | Error Amplifier Bandwidth | $\mathrm{BW}=\frac{\mathrm{gm}}{2 \pi \mathrm{C}_{1}}$ |

The following converter characteristics must be chosen:

$$
\begin{array}{cc}
\mathrm{V}_{\mathrm{O}}-\text { Desired output voltage } & \mathrm{Vac}-\mathrm{AC} \text { RMS line voltage } \\
\mathrm{I}_{\mathrm{O}}-\text { Desired output current } & \mathrm{Vac}_{(\mathrm{LL})}-\mathrm{AC} R \mathrm{RMS} \text { low line voltage } \\
\Delta \mathrm{V}_{\mathrm{O}}-\text { Converter output peak-to-peak ripple voltage }
\end{array}
$$

(Figure 20 Circuit)

Figure 43. Output Voltage Startup Overshoot
(Figure 20 Circuit)

Figure 44. Power Factor Test Set-Up

An RFI filter is required for best performance when connecting the preconverter directly to the ac line. The filter attenuates the level of high frequency switching that appears on the ac line current waveform. Figures 19 and 20 work well with commercially available two stage filters such as the Delta Electronics 03DPCG5. Shown above is a single stage test filter that can easily be constructed with four ac line rated capacitors and a common-mode transformer. Coilcraft CMT3-28-2 was used to test Figures 19 and 20. It has a minimum inductance of 28 mH and a maximum current rating of 2.0 A . Coilcraft CMT4-17-9 was used to test Figure 21. It has a minimum inductance of 17 mH and a maximum current rating of 9.0 A. Circuit conversion efficiency $\eta(\%)$ was calculated without the power loss of the RFI filter.

Figure 45. Error Amp Compensation

The Error Amp output is a high impedance node and is susceptible to noise pickup. To minimize pickup, compensation capacitor $\mathrm{C}_{1}$ must be connected as close to Pin 2 as possible with a short, heavy ground returning directly to $\operatorname{Pin} 6$. When operating at high ac line, the voltage at Pin 2 may approach the lower threshold of the Multiplier, $\approx 2.0 \mathrm{~V}$. If there is excessive ripple on Pin 2, the Multiplier will be driven into cut-off causing circuit instability, high distortion and poor power factor. This problem can be eliminated by increasing the value of $C_{1}$.

Figure 46. Current Waveform Spike Suppression

A narrow turn-on spike is usually present on the leading edge of the current waveform and can cause circuit instability. The MC34262 provides an internal RC filter with a time constant of 220 ns . An additional external RC filter may be required in universal input applications that are above 200 W . It is suggested that the external filter be placed directly at the Current Sense Input and have a time constant that approximates the spike duration.

Figure 47. Negative Current Waveform Spike Suppression

A negative turn-off spike can be observed on the trailing edge of the current waveform. This spike is due to the parasitic inductance of resistor $\mathrm{R}_{7}$, and if it is excessive, it can cause circuit instability. The addition of Schottky diode $D_{1}$ can effectively clamp the negative spike. The addition of the external RC filter shown in Figure 26 may provide sufficient spike attenuation.

## MC33260

## GreenLine ${ }^{\text {TM }}$ Compact Power Factor Controller: Innovative Circuit for Cost Effective Solutions

The MC33260 is a controller for Power Factor Correction preconverters meeting international standard requirements in electronic ballast and off-line power conversion applications. Designed to drive a free frequency discontinuous mode, it can also be synchronized and in any case, it features very effective protections that ensure a safe and reliable operation.

This circuit is also optimized to offer extremely compact and cost effective PFC solutions. While it requires a minimum number of external components, the MC33260 can control the follower boost operation that is an innovative mode allowing a drastic size reduction of both the inductor and the power switch. Ultimately, the solution system cost is significantly lowered.

Also able to function in a traditional way (constant output voltage regulation level), any intermediary solutions can be easily implemented. This flexibility makes it ideal to optimally cope with a wide range of applications.

## General Features

- Standard Constant Output Voltage or "Follower Boost" Mode
- Switch Mode Operation: Voltage Mode
- Latching PWM for Cycle-by-Cycle On-Time Control
- Constant On-Time Operation That Saves the Use of an Extra Multiplier
- Totem Pole Output Gate Drive
- Undervoltage Lockout with Hysteresis
- Low Start-Up and Operating Current
- Improved Regulation Block Dynamic Behavior
- Synchronization Capability
- Internally Trimmed Reference Current Source

## Safety Features

- Overvoltage Protection: Output Overvoltage Detection
- Undervoltage Protection: Protection Against Open Loop
- Effective Zero Current Detection
- Accurate and Adjustable Maximum On-Time Limitation
- Overcurrent Protection
- ESD Protection on Each Pin

## TYPICAL APPLICATION

PIN FUNCTION DESCRIPTION

| Pin No. DIP-8 | Pin No. SO-8 | Function | Description |
| :---: | :---: | :---: | :---: |
| 1 | 7 | Feedback Input | This pin is designed to receive a current that is proportional to the preconverter output voltage. This information is used for both the regulation and the overvoltage and undervoltage protections. The current drawn by this pin is internally squared to be used as oscillator capacitor charge current. |
| 2 | 8 | $\mathrm{V}_{\text {control }}$ | This pin makes available the regulation block output. The capacitor connected between this pin and ground, adjusts the control bandwidth. It is typically set below 20 Hz to obtain a nondistorted input current. |
| 3 | 1 | Oscillator Capacitor $\left(\mathrm{C}_{\mathrm{T}}\right)$ | The circuit uses an on-time control mode. This on-time is controlled by comparing the $\mathrm{C}_{\boldsymbol{T}}$ voltage to the $\mathrm{V}_{\text {control }}$ voltage. $\mathrm{C}_{\boldsymbol{T}}$ is charged by the squared feedback current. |
| 4 | 2 | Zero Current Detection Input | This pin is designed to receive a negative voltage signal proportional to the current flowing through the inductor. This information is generally built using a sense resistor. The Zero Current Detection prevents any restart as long as the pin 4 voltage is below $(-60 \mathrm{mV})$. This pin is also used to perform the peak current limitation. The overcurrent threshold is programmed by the resistor connected between the pin and the external current sense resistor. |
| 5 | 3 | Synchronization Input | This pin is designed to receive a synchronization signal. For instance, it enables to synchronize the PFC preconverter to the associated SMPS. If not used, this pin must be grounded. |
| 6 | 4 | Ground | This pin must be connected to the preregulator ground. |
| 7 | 5 | Gate Drive | The gate drive current capability is suited to drive an IGBT or a power MOSFET. |
| 8 | 6 | $\mathrm{V}_{\mathrm{CC}}$ | This pin is the positive supply of the IC. The circuit turns on when $\mathrm{V}_{\mathrm{CC}}$ becomes higher than 11 V , the operating range after start-up being 8.5 V up to 16 V . |

APPLICATION SCHEMATIC

## FUNCTIONAL DESCRIPTION Pin Numbers are Relevant to the DIP-8 Version <br> OPERATION DESCRIPTION

## INTRODUCTION

The need of meeting the requirements of legislation on line current harmonic content, results in an increasing demand for cost effective solutions to comply with the Power Factor regulations. This data sheet describes a monolithic controller specially designed for this purpose.

Most off-line appliances use a bridge rectifier associated to a huge bulk capacitor to derive raw dc voltage from the utility ac line.

Figure 19. Typical Circuit Without PFC
This technique results in a high harmonic content and in poor power factor ratios. In effect, the simple rectification technique draws power from the mains when the instantaneous ac voltage exceeds the capacitor voltage. This occurs near the line voltage peak and results in a high charge current spike. Consequently, a poor power factor (in the range of $0.5-0.7$ ) is generated, resulting in an apparent input power that is much higher than the real power.

Figure 20. Line Waveforms Without PFC
Active solutions are the most popular way to meet the legislation requirements. They consist of inserting a PFC pre-regulator between the rectifier bridge and the bulk capacitor. This interface is, in fact, a step-up SMPS that outputs a constant voltage while drawing a sinusoidal current from the line.

Figure 21. PFC Preconverter
The MC33260 was developed to control an active solution with the goal of increasing its robustness while lowering its global cost.

The MC33260 is optimized to just as well drive a free running as a synchronized discontinuous voltage mode.

It also features valuable protections (overvoltage and undervoltage protection, overcurrent limitation, ...) that make the PFC preregulator very safe and reliable while requiring very few external components. In particular, it is able to safely face any uncontrolled direct charges of the output capacitor from the mains which occur when the output voltage is lower than the input voltage (start-up, overload, ...).
In addition to the low count of elements, the circuit can control an innovative mode named "Follower Boost" that permits to significantly reduce the size of the preconverter inductor and power MOSFET. With this technique, the output regulation level is not forced to a constant value, but can vary according to the a.c. line amplitude and to the power. The gap between the output voltage and the ac line is then lowered, what allows the preconverter inductor and power MOSFET size reduction. Finally, this method brings a significant cost reduction.

A description of the functional blocks is given below.

## REGULATION SECTION

Connecting a resistor between the output voltage to be regulated and the pin 1, a feedback current is obtained. Typically, this current is built by connecting a resistor between the output voltage and the pin 1 . Its value is then given by the following equation:

$$
I_{\text {pin1 }}=\frac{V_{0}-V_{\text {pin1 }}}{R_{0}}
$$

where:
$\mathrm{R}_{\mathrm{O}}$ is the feedback resistor,
$\mathrm{V}_{\mathrm{o}}$ is the output voltage,
$\mathrm{V}_{\mathrm{pin} 1}$ is the pin 1 clamp value.
The feedback current is compared to the reference current so that the regulation block outputs a signal following the characteristic depicted in Figure 22. According to the power and the input voltage, the output voltage regulation level varies between two values $\left(\mathrm{V}_{\mathrm{o}}\right)_{\text {regL }}$ and $\left(\mathrm{V}_{\mathrm{o}}\right)_{\text {regH }}$ corresponding to the $I_{\text {regL }}$ and $I_{\text {regH }}$ levels.

Figure 22. Regulation Characteristic
The feedback resistor must be chosen so that the feedback current should equal the internal current source $I_{\text {regH }}$ when the output voltage exceeds the chosen upper regulation voltage $\left[\left(\mathrm{V}_{\mathrm{o}}\right)_{\text {regH }}\right]$. Consequently:

## Pin Numbers are Relevant to the DIP-8 Version

$$
\mathrm{R}_{\mathrm{O}}=\frac{\left(\mathrm{V}_{\mathrm{o}}\right)_{\mathrm{regH}}-\mathrm{V}_{\mathrm{pin} 1}}{\mathrm{I}_{\mathrm{reg}}}
$$

In practice, $\mathrm{V}_{\text {pin1 }}$ is small compared to $\left(\mathrm{V}_{\mathrm{o}}\right)_{\text {regH }}$ and this equation can be simplified as follows ( $\mathrm{I}_{\mathrm{regH}}$ being also replaced by its typical value $200 \mu \mathrm{~A}$ ):

$$
\mathrm{R}_{\mathrm{o}} \approx 5 \times\left(\mathrm{V}_{\mathrm{o}}\right)_{\mathrm{regH}}<\mathrm{k}^{>}
$$

The regulation block output is connected to the pin 2 through a $300 \mathrm{k} \Omega$ resistor. The pin 2 voltage $\left(\mathrm{V}_{\text {control }}\right)$ is compared to the oscillator sawtooth for PWM control.

An external capacitor must be connected between pin 2 and ground, for external loop compensation. The bandwidth is typically set below 20 Hz so that the regulation block output should be relatively constant over a given ac line cycle. This integration that results in a constant on-time over the ac line period, prevents the mains frequency output ripple from distorting the ac line current.

## OSCILLATOR SECTION

The oscillator consists of three phases:

- Charge Phase: The oscillator capacitor voltage grows up linearly from its bottom value (ground) until it exceeds $\mathrm{V}_{\text {control }}$ (regulation block output voltage). At that moment, the PWM latch output gets low and the oscillator discharge sequence is set.
- Discharge Phase: The oscillator capacitor is abruptly discharged down to its valley value $(0 \mathrm{~V})$.
- Waiting Phase: At the end of the discharge sequence, the oscillator voltage is maintained in a low state until the PWM latch is set again.

The oscillator charge current is dependent on the feedback current ( $\mathrm{I}_{\mathrm{o}}$ ). In effect

$$
I_{\text {charge }}=2 \times \frac{I_{0}^{2}}{I_{\text {ref }}}
$$

where:
$\mathrm{I}_{\text {charge }}$ is the oscillator charge current,
$\mathrm{I}_{0}$ is the feedback current (drawn by pin 1),
$\mathrm{I}_{\mathrm{ref}}$ is the internal reference current $(200 \mu \mathrm{~A})$.
So, the oscillator charge current is linked to the output voltage level as follows:

$$
I_{\text {charge }}=\frac{2 \times\left\langle v_{0}-v_{\text {pin1 }}\right\rangle^{2}}{R_{0}^{2} \times I_{\text {ref }}}
$$

where:
$\mathrm{V}_{\mathrm{o}}$ is the output voltage,
$\mathrm{R}_{\mathrm{O}}$ is the feedback resistor,
$\mathrm{V}_{\text {pin1 }}$ is the pin 1 clamp voltage.
In practice, $\mathrm{V}_{\text {pin1 }}$ that is in the range of 2.5 V , is very small compared to $\mathrm{V}_{\mathrm{o}}$. The equation can then be simplified by neglecting $\mathrm{V}_{\mathrm{pin} 1}$ :

$$
I_{\text {charge }} \approx \frac{2 \times \mathrm{V}_{0}^{2}}{\mathrm{R}_{\mathrm{o}}^{2} \times \mathrm{I}_{\mathrm{ref}}}
$$

It must be noticed that the oscillator terminal (pin 3) has an internal capacitance ( $\mathrm{C}_{\mathrm{int}}$ ) that varies versus the pin 3 voltage. Over the oscillator swing, its average value typically equals $15 \mathrm{pF}(\min 10 \mathrm{pF}$, max 20 pF ).

The total oscillator capacitor is then the sum of the internal and external capacitors.

$$
C_{\mathrm{pin3}}=\mathrm{C}_{\mathrm{T}}+\mathrm{C}_{\mathrm{int}}
$$

## PWM LATCH SECTION

The MC33260 operates in voltage mode: the regulation block output ( $\mathrm{V}_{\text {control }}$ - pin 2 voltage) is compared to the oscillator sawtooth so that the gate drive signal (pin 7) is high until the oscillator ramp exceeds $\mathrm{V}_{\text {control }}$.

The on-time is then given by the following equation:

$$
t_{\text {on }}=\frac{C_{\text {pin3 }} \times V_{\text {control }}}{I_{c h}}
$$

where:
$t_{\text {on }}$ is the on-time,
$\mathrm{C}_{\mathrm{pin} 3}$ is the total oscillator capacitor (sum of the internal and external capacitor),
$\mathrm{I}_{\text {charge }}$ is the oscillator charge current (pin 3 current),
$\mathrm{V}_{\text {control }}$ is the pin 2 voltage (regulation block output).
Consequently, replacing $\mathrm{I}_{\text {charge }}$ by the expression given in the Oscillator Section:

$$
\mathrm{t}_{\mathrm{on}}=\frac{\mathrm{R}_{\mathrm{o}}^{2} \times \mathrm{I}_{\mathrm{ref}} \times \mathrm{C}_{\mathrm{pin} 3} \times \mathrm{V}_{\text {control }}}{2 \times \mathrm{V}_{\mathrm{o}}^{2}}
$$

One can notice that the on-time depends on $V_{o}$ (preconverter output voltage) and that the on-time is maximum when Vcontrol is maximum (1.5 V typically).
At a given $\mathrm{V}_{\mathrm{o}}$, the maximum on-time is then expressed by the following equation:

$$
\left\langle\mathrm{t}_{\mathrm{on}}\right\rangle \max =\frac{\mathrm{C}_{\text {pin3 }} \times \mathrm{R}_{\mathrm{o}}^{2} \times \mathrm{I}_{\text {ref }} \times\left\langle\mathrm{V}_{\text {control }}\right\rangle_{\max }}{2 \times \mathrm{V}_{\mathrm{o}}^{2}}
$$

This equation can be simplified replacing

$$
\left\{2 /\left[\left(\mathrm{V}_{\text {contro }}\right)_{\max }{ }^{*} \mathrm{I}_{\text {ref }}\right]\right\} \text { by } \mathrm{K}_{\text {osc }}
$$

## Refer to Electrical Characteristics, Oscillator Section.

 Then:$$
\left\langle\mathrm{t}_{\mathrm{on}}\right\rangle \max =\frac{\mathrm{C}_{\mathrm{pin} 3} \times \mathrm{R}_{\mathrm{o}}^{2}}{\mathrm{~K}_{\mathrm{osc}} \times \mathrm{V}_{\mathrm{O}}^{2}}
$$

This equation shows that the maximum on-time is inversely proportional to the squared output voltage. This

## Pin Numbers are Relevant to the DIP-8 Version

property is used for follower boost operation (refer to Follower Boost section).

## CURRENT SENSE BLOCK

The inductor current is converted into a voltage by inserting a ground referenced resistor $\left(\mathrm{R}_{\mathrm{cs}}\right)$ in series with the input diodes bridge (and the input filtering capacitor). Therefore a negative voltage proportional to the inductor current is built:

$$
\mathrm{V}_{\mathrm{cs}}=-\left\langle\mathrm{R}_{\mathrm{cs}} \times \mathrm{I}_{\mathrm{L}}\right\rangle
$$

where:
$\mathrm{I}_{\mathrm{L}}$ is the inductor current,
$\mathrm{R}_{\mathrm{cs}}$ is the current sense resistor,
$\mathrm{V}_{\mathrm{cs}}$ is the measured $\mathrm{R}_{\mathrm{cs}}$ voltage.

Figure 24. Current Sensing
The negative signal $\mathrm{V}_{\text {cs }}$ is applied to the current sense through a resistor $\mathrm{R}_{\mathrm{OCP}}$. The pin is internally protected by a negative clamp $(-0.7 \mathrm{~V})$ that prevents substrate injection.

As long as the pin 4 voltage is lower than $(-60 \mathrm{mV})$, the Current Sense comparator resets the PWM latch to force the gate drive signal low state. In that condition, the power MOSFET cannot be on.

During the on-time, the pin 4 information is used for the overcurrent limitation while it serves the zero current detection during the off time.

## Zero Current Detection

The Zero Current Detection function guarantees that the MOSFET cannot turn on as long as the inductor current hasn't reached zero (discontinuous mode).

The pin 4 voltage is simply compared to the $(-60 \mathrm{mV})$ threshold so that as long as $\mathrm{V}_{\mathrm{cs}}$ is lower than this threshold, the circuit gate drive signal is kept in low state. Consequently, no power MOSFET turn on is possible until the inductor current is measured as smaller than $\left(60 \mathrm{mV} / \mathrm{R}_{\mathrm{cs}}\right)$ that is, the inductor current nearly equals zero.

Figure 25. Current Sense Block

## Overcurrent Protection

During the power switch conduction (i.e. when the Gate Drive pin voltage is high), a current source is applied to the pin 4. A voltage drop $\mathrm{V}_{\mathrm{OCP}}$ is then generated across the resistor $\mathrm{R}_{\mathrm{OCP}}$ that is connected between the sense resistor and the Current Sense pin (refer to Figure 25). So, instead of $\mathrm{V}_{\mathrm{cs}}$, the sum $\left(\mathrm{V}_{\mathrm{cs}}+\mathrm{V}_{\mathrm{OCP}}\right)$ is compared to $(-60 \mathrm{mV})$ and the maximum permissible current is the solution of the following equation:

$$
-\left\langle\mathrm{R}_{\mathrm{CS}} \times \mathrm{lpk}_{\max }\right\rangle+\mathrm{V}_{\mathrm{OCP}}=-60 \mathrm{mV}
$$

where:
$\mathrm{Ipk}_{\text {max }}$ is maximum allowed current,
$\mathrm{R}_{\mathrm{cs}}$ is the sensing resistor.
The overcurrent threshold is then:

$$
\mathrm{Ipk}_{\max }=\frac{\left\langle\mathrm{R}_{\mathrm{OCP}} \times \mathrm{I} \mathrm{OCP}\right\rangle+60 \times 10^{-3}}{\mathrm{R}_{\mathrm{CS}}}
$$

where:
$\mathrm{R}_{\mathrm{OCP}}$ is the resistor connected between the pin and the sensing resistor $\left(\mathrm{R}_{\mathrm{cs}}\right)$,
$\mathrm{I}_{\mathrm{OCP}}$ is the current supplied by the Current Sense pin when the gate drive signal is high (power switch conduction phase). I
Practically, the $\mathrm{V}_{\mathrm{OCP}}$ offset is high compared to 60 mV and the precedent equation can be simplified. The maximum current is then given by the following equation:

$$
\mathrm{lpk}_{\max } \approx \frac{\mathrm{R}_{\mathrm{OCP}}{ }^{<\mathrm{k}^{>}}}{\mathrm{R}_{\mathrm{CS}} \Omega^{\prime}} \times 0.205^{<\mathrm{A}^{>}}
$$

Consequently, the $\mathrm{R}_{\mathrm{OCP}}$ resistor can program the OCP level whatever the $\mathrm{R}_{\mathrm{cs}}$ value is. This gives a high freedom in the choice of $\mathrm{R}_{\mathrm{cs}}$. In particular, the inrush resistor can be utilized.

Pin Numbers are Relevant to the DIP-8 Version

Figure 26. PWM Latch

A LEB (Leading Edge Blanking) has been implemented. This circuitry disconnects the Current Sense comparator from pin 4 and disables it during the 400 first ns of the power switch conduction. This prevents the block from reacting on the current spikes that generally occur at power switch turn on. Consequently, proper operation does not require any filtering capacitor on pin 4.

## PROTECTIONS

## OCP (Overcurrent Protection)

Refer to Current Sense Block.

## OVP (Overvoltage Protection)

The feedback current ( $\mathrm{I}_{0}$ ) is compared to a threshold current $\left(\mathrm{I}_{\mathrm{ovpH}}\right)$. If it exceeds this value, the gate drive signal is maintained low until this current gets lower than a second level ( $\mathrm{I}_{\mathrm{ovpL}}$ ).

Figure 27. Internal Current Thresholds
So, the OVP upper threshold is:

$$
\mathrm{V}_{\mathrm{ovpH}}=\mathrm{V}_{\mathrm{pin} 1}+\left(\mathrm{R}_{\mathrm{o}} \times \mathrm{I}_{\mathrm{ovpH}}\right)
$$

where:
$\mathrm{R}_{\mathrm{o}}$ is the feedback resistor that is connected between pin 1 and the output voltage,
$\mathrm{I}_{\text {ovp-H }}$ is the internal upper OVP current threshold,
$\mathrm{V}_{\mathrm{pin} 1}$ is the pin 1 clamp voltage.

Practically, $\mathrm{V}_{\mathrm{pin} 1}$ that is in the range of 2.5 V , can be neglected. The equation can then be simplified:

$$
\mathrm{V}_{\mathrm{ovpH}}=\mathrm{R}_{\mathrm{o}}<_{\mathrm{M} \Omega^{>} \times \mathrm{I}_{\mathrm{ovpH}}}^{<\mu \mathrm{A}^{>}<_{\mathrm{V}}>}
$$

On the other hand, the OVP low threshold is:

$$
\mathrm{v}_{\mathrm{ovpL}}=\mathrm{V}_{\mathrm{pin} 1}+\left(\mathrm{R}_{\mathrm{o}} \times \mathrm{I}_{\mathrm{ovpL}}\right)
$$

where $\mathrm{I}_{\text {ovp-L }}$ is the internal low OVP current threshold. Consequently, $\mathrm{V}_{\text {pin1 }}$ being neglected:

$$
\mathrm{V}_{\mathrm{ovpL}}=\mathrm{R}_{\mathrm{o}}{ }^{<} \mathrm{M} \Omega^{>} \times \mathrm{I}_{\mathrm{ovpL}}{ }^{<} \mu \mathrm{A}^{>}<_{\mathrm{V}}{ }^{>}
$$

The OVP hysteresis prevents erratic behavior.
$\mathrm{I}_{\mathrm{ovpL}}$ is guaranteed to be higher than IregH (refer to parameters specification). This ensures that the OVP function doesn't interfere with the regulation one.

## UVP (Undervoltage Protection)

This function detects when the feedback current is lower than $14 \%$ of $\mathrm{I}_{\text {ref }}$. In this case, the PWM latch is reset and the power switch is kept off.

This protection is useful to:

- Protect the preregulator from working in too low mains conditions.
- To detect the feedback current absence (in case of a nonproper connection for instance).
The UVP threshold is:

$$
\mathrm{V}_{\mathrm{uvp}} \approx \mathrm{~V}_{\mathrm{pin} 1}+\left(\mathrm{R}_{\mathrm{o}}^{<} \mathrm{M}^{>} \times \mathrm{I}_{\mathrm{uvp}}{ }^{<} \mu \mathrm{A}^{>}\right)(\mathrm{V})
$$

Practically ( $\mathrm{V}_{\mathrm{pin} 1}$ being neglected),

$$
\mathrm{V}_{\mathrm{uvp}}=\mathrm{R}_{\mathrm{o}}^{<} \mathrm{M}^{>} \times \mathrm{I}_{\mathrm{uvp}}{ }^{<} \mu \mathrm{A}^{><}{ }_{\mathrm{V}}{ }^{>}
$$

## Maximum On-Time Limitation

As explained in PWM Latch, the maximum on-time is accurately controlled.

## Pin Protection

All the pins are ESD protected.

Pin Numbers are Relevant to the DIP-8 Version

In particular, a 11 V zener diode is internally connected between the terminal and ground on the following pins:

Feedback, $V_{\text {control }}$, Oscillator, Current Sense, and Synchronization.

Figure 28. Synchronization Arrangement

## SYNCHRONIZATION BLOCK

The MC33260 features two modes of operation:

- Free Running Discontinuous Mode: The power switch is turned on as soon as there is no current left in the inductor (Zero Current Detection). This mode is simply obtained by grounding the synchronization terminal (pin 5).
- Synchronization Mode: This mode is set as soon as a signal crossing the 1 V threshold, is applied to the pin 5. In this case, operation in free running can only be recovered after a new circuit start-up. In this mode, the power switch cannot turn on before the two following conditions are fulfilled.
- Still, the zero current must have been detected.
- The precedent turn on must have been followed by (at least) one synchronization raising edge crossing the 1 V threshold.
In other words, the synchronization acts to prolong the power switch off time.

Consequently, a proper synchronized operation requires that the current cycle (on-time + inductor demagnetization) is shorter than the synchronization period. Practically, the inductor must be chosen accordingly. Otherwise, the system will keep working in free running discontinuous mode. Figure 33 illustrates this behavior.

It must be noticed that whatever the mode is, a $2 \mu \mathrm{~s}$ minimum off-time is forced. This delay limits the switching frequency in light load conditions.

## OUTPUT SECTION

The output stage contains a totem pole optimized to minimize the cross conduction current during high speed
operation. The gate drive is kept in a sinking mode whenever the Undervoltage Lockout is active. The rise and fall times have been controlled to typically equal 50 ns while loaded by 1 nF .

## REFERENCE SECTION

An internal reference current source ( $\mathrm{I}_{\text {ref }}$ ) is trimmed to be $\pm 4 \%$ accurate over the temperature range (the typical value is $200 \mu \mathrm{~A}$ ). $\mathrm{I}_{\text {ref }}$ is the reference used for the regulation ( $\mathrm{I}_{\mathrm{regH}}$ $=\mathrm{I}_{\mathrm{ref}}$ ).

## UNDERVOLTAGE LOCKOUT SECTION

An Undervoltage Lockout comparator has been implemented to guarantee that the integrated circuit is operating only if its supply voltage $\left(\mathrm{V}_{\mathrm{CC}}\right)$ is high enough to enable a proper working. The UVLO comparator monitors the pin 8 voltage and when it exceeds 11 V , the device gets active. To prevent erratic operation as the threshold is crossed, 2.5 V of hysteresis is provided.

The circuit off state consumption is very low: in the range of $100 \mu \mathrm{~A} @ \mathrm{~V}_{\mathrm{CC}}=5 \mathrm{~V}$. This consumption varies versus $\mathrm{V}_{\mathrm{CC}}$ as the circuit presents a resistive load in this mode.

## THERMAL SHUTDOWN

An internal thermal circuitry is provided to disable the circuit gate drive and then to prevent it from oscillating, if the junction temperature exceeds $150^{\circ} \mathrm{C}$ typically.

The output stage is again enabled when the temperature drops below $120^{\circ} \mathrm{C}$ typically ( $30^{\circ} \mathrm{C}$ hysteresis).

## Pin Numbers are Relevant to the DIP-8 Version

FOLLOWER BOOST
Traditional PFC preconverters provide the load with a fixed and regulated voltage that generally equals 230 V or 400 V according to the mains type (U.S., European, or universal).

In the "Follower Boost" operation, the preconverter output regulation level is not fixed but varies linearly versus the ac line amplitude at a given input power.

Figure 29. Follower Boost Characteristics
This technique aims at reducing the gap between the output and the input voltages to minimize the boost efficiency degradation.

## Follower Boost Benefits

The boost presents two phases:

- The on-time during which the power switch is on. The inductor current grows up linearly according to a slope $\left(\mathrm{V}_{\text {in }} / \mathrm{L}_{\mathrm{p}}\right)$, where $\mathrm{V}_{\text {in }}$ is the instantaneous input voltage and $\mathrm{L}_{\mathrm{p}}$ the inductor value.
- The off-time during which the power switch is off. The inductor current decreases linearly according the slope $\left(V_{o}-V_{i n}\right) / L_{p}$, where $V_{o}$ is the output voltage. This sequence that terminates when the current equals zero, has a duration that is inversely proportional to the gap between the output and input voltages. Consequently, the off-time duration becomes longer in follower boost.
Consequently, for a given peak inductor current, the longer the off time, the smaller power switch duty cycle and then its conduction dissipation. This is the first benefit of this technique: the MOSFET on-time losses are reduced.

The increase of the off time duration also results in a switching frequency diminution (for a given inductor value). Given that in practise, the boost inductor is selected big enough to limit the switching frequency down to an acceptable level, one can immediately see the second benefit
of the follower boost: it allows the use of smaller, lighter and cheaper inductors compared to traditional systems.
Finally, this technique utilization brings a drastic system cost reduction by lowering the size and then the cost of both the inductor and the power switch.

Figure 30. Off-Time Duration Increase

## Follower Boost Implementation

In the MC33260, the on-time is differently controlled according to the feedback current level. Two areas can be defined:

- When the feedback current is higher than $\mathrm{I}_{\text {regL }}$ (refer to regulation section), the regulation block output ( $\mathrm{V}_{\text {control }}$ ) is modulated to force the output voltage to a desired value.
- On the other hand, when the feedback current is lower than $\mathrm{I}_{\text {regL }}$, the regulation block output and therefore, the on-time are maximum. As explained in PWM Latch Section, the on-time is then inversely proportional to the output voltage square. The Follower Boost is active in these conditions in which the on-time is simply limited by the output voltage level. Note: In this equation, the feedback pin voltage ( $\mathrm{V}_{\mathrm{pin} 1}$ ) is neglected compared to the output voltage (refer to the PWM Latch Section).

$$
\mathrm{t}_{\text {on }}=\left\langle\mathrm{t}_{\mathrm{on}}\right\rangle \max =\frac{\mathrm{C}_{\mathrm{pin} 3} \times \mathrm{R}_{\mathrm{o}}^{2}}{\mathrm{~K}_{\mathrm{osc}} \times \mathrm{V}_{\mathrm{o}}^{2}}
$$

where:
$\mathrm{C}_{\mathrm{pin} 3}$ is the total oscillator capacitor (sum of the internal and external capacitors $-\mathrm{C}_{\mathrm{int}}+\mathrm{C}_{\mathrm{T}}$ ),
$\mathrm{K}_{\mathrm{osc}}$ is the ratio (oscillator swing over oscillator gain),
$\mathrm{V}_{\mathrm{o}}$ is the output voltage,
$\mathrm{R}_{\mathrm{O}}$ is the feedback resistor.

## Pin Numbers are Relevant to the DIP-8 Version

On the other hand, the boost topology has its own rule that dictates the on-time necessary to deliver the required power:

$$
\mathrm{t}_{\mathrm{on}}=\frac{4 \times \mathrm{L}_{\mathrm{p}} \times \mathrm{P}_{\mathrm{in}}}{\mathrm{~V}_{\mathrm{pk}}^{2}}
$$

where:
$\mathrm{V}_{\mathrm{pk}}$ is the peak ac line voltage,
$\mathrm{L}_{\mathrm{p}}$ is the inductor value,
$P_{\text {in }}$ is the input power.
Combining the two equations, one can obtain the Follower Boost equation:

$$
\mathrm{V}_{\mathrm{o}}=\frac{\mathrm{R}_{0}}{2} \times \sqrt{\frac{\mathrm{C}_{\mathrm{pin} 3}}{\mathrm{~K}_{\mathrm{osc}} \times \mathrm{L}_{\mathrm{p}} \times P_{\mathrm{in}}}} \times \mathrm{V}_{\mathrm{pk}}
$$

Consequently, a linear dependency links the output voltage to the ac line amplitude at a given input power.

Figure 31. Follower Boost Characteristics
The behavior of the output voltage is depicted in Figures 31 and 32. In particular, Figure 31 illustrates how the output voltage converges to a stable equilibrium level. First, at a given ac line voltage, the on-time is dictated by the power demand. Then, the follower boost characteristic makes correspond one output voltage level to this on-time. Combining these two laws, it appears that the power level forces the output voltage.

One can notice that the system is fully stable:

- If an output voltage increase makes it move away from its equilibrium value, the on-time will immediately diminish according to the follower boost law. This will result in a delivered power decrease. Consequently, the supplied power being too low, the output voltage will decrease back,
- In the same way, if the output voltage decreases, more power will be transferred and then the output voltage will increase back.

Figure 32. Follower Boost Output Voltage

## Mode Selection

The operation mode is simply selected by adjusting the oscillator capacitor value. As shown in Figure 32, the output voltage first has an increasing linear characteristic versus the ac line magnitude and then is clamped down to the regulation value. In the traditional mode, the linear area must be rejected. This is achieved by dimensioning the oscillator capacitor so that the boost can deliver the maximum power while the output voltage equals its regulation level and this, whatever the given input voltage. Practically, that means that whatever the power and input voltage conditions are, the follower boost would generate output voltages values higher than the regulation level, if there was no regulation block.
In other words, if $\left(\mathrm{V}_{\mathrm{o}}\right)_{\text {regL }}$ is the low output regulation level:

$$
\left\langle V_{o}\right\rangle_{\text {regL }} \leq \frac{R_{0}}{2} \times \sqrt{\frac{C_{T}+C_{i n t}}{K_{o s c} \times L_{p} \times\left\langle P_{i n}\right\rangle \max }} \times V_{p k}
$$

Consequently,
$\mathrm{C}_{\mathrm{T}} \geq-\mathrm{C}_{\mathrm{int}}+\frac{4 \times \mathrm{K}_{\mathrm{osc}} \times \mathrm{L}_{\mathrm{p}} \times\left\langle\mathrm{P}_{\mathrm{in}}\right\rangle \max \times\left\langle\mathrm{V}_{\mathrm{o}}\right\rangle_{\mathrm{regL}}^{2}}{\mathrm{R}_{\mathrm{o}}^{2} \times \mathrm{V}_{\mathrm{pk}}^{2}}$
Using $\mathrm{I}_{\text {regL }}$ (regulation block current reference), this equation can be simplified as follows:

$$
\mathrm{C}_{\mathrm{T}} \geq-\mathrm{C}_{\mathrm{int}}+\frac{4 \times \mathrm{K}_{\mathrm{osc}} \times \mathrm{L}_{\mathrm{p}} \times\left\langle\mathrm{P}_{\mathrm{in}}\right\rangle \max \times \mathrm{I}_{\mathrm{regL}}^{2}}{\mathrm{~V}_{\mathrm{pk}}^{2}}
$$

In the Follower Boost case, the oscillator capacitor must be chosen so that the wished characteristics are obtained.

Consequently, the simple choice of the oscillator capacitor enables the mode selection.

Figure 33. Typical Waveforms

MAIN DESIGN EQUATIONS (Note 1)

| rms Input Current (lac) $\mathrm{I}_{\mathrm{ac}}=\frac{\mathrm{P}_{\mathrm{o}}}{\eta \times \mathrm{V}_{\mathrm{ac}}}$ | $\eta$ (preconverter efficiency) is generally in the range of $90-95 \%$. |
| :---: | :---: |
| Maximum Inductor Peak Current ((1 $\left.\mathrm{l}_{\mathrm{pk}}\right)$ max $)$ : $\left(\mathrm{I}_{\mathrm{pk}}\right) \max =\frac{2 \times \sqrt{2} \times\left(\mathrm{P}_{\mathrm{o}}\right) \max }{\eta \times V_{\mathrm{acLL}}}$ | $\left(\mathrm{I}_{\mathrm{pk}}\right) \mathrm{max}$ is the maximum inductor current. |
| Output Voltage Peak to Peak $100 \mathrm{~Hz}(120 \mathrm{~Hz})$ Ripple (( $\Delta \mathrm{Vo}) \mathrm{pk}-\mathrm{pk})$ : $\left(\Delta V_{o}\right)_{p k-p k}=\frac{P_{0}}{2 \pi \times f_{a c} \times C_{o} \times V_{o}}$ | $\mathrm{fac}_{\text {ac }}$ is the ac line frequency ( 50 or 60 Hz ) |
| $\begin{aligned} & \text { Inductor Value ( } \left.\mathrm{L}_{\mathrm{p}}\right): \\ & \mathrm{L}_{\mathrm{p}}=\frac{2 \times \mathrm{t} \times\left(\frac{\mathrm{V}_{\mathrm{o}}}{\sqrt{2}}-\mathrm{V}_{\mathrm{acLL}}\right) \times \mathrm{V}_{\mathrm{acLL}}{ }^{2}}{\mathrm{~V}_{\mathrm{o}} \times \mathrm{V}_{\mathrm{acLL}} \times\left(\mathrm{I}_{\mathrm{pk}}\right) \max } \end{aligned}$ | $t$ is the maximum switching period. ( $\mathrm{t}=40 \mu \mathrm{~s}$ ) for universal mains operation and ( $\mathrm{t}=20 \mu \mathrm{~s}$ ) for narrow range are generally used. |
| Maximum Power MOSFET Conduction Losses (( $\mathrm{p}_{\mathrm{on}}$ )max): $\left(\mathrm{P}_{\mathrm{on}}\right) \max \approx \frac{1}{3} \times(\text { Rds }) \mathrm{on} \times\left(\mathrm{I}_{\mathrm{pk}}\right) \max ^{2} \times\left[1-\frac{1.2 \times \mathrm{V}_{\mathrm{acLL}}}{\mathrm{~V}_{\mathrm{o}}}\right]$ | (Rds)on is the MOSFET drain source on-time resistor. <br> In Follower Boost, the ratio $\left(\mathrm{V}_{\text {acLL }} / \mathrm{V}_{0}\right)$ is higher. The on-time MOSFET losses are then reduced |
| Maximum Average Diode Current ( $\left(\mathrm{I}_{\mathrm{d}}\right)$ : $\left(I_{\mathrm{d}}\right) \max =\frac{\left(\mathrm{P}_{\mathrm{o}}\right) \max }{\left(\mathrm{V}_{\mathrm{o}}\right) \min }$ | The Average Diode Current depends on the power and on the output voltage. |
| Current Sense Resistor Losses ( $\mathrm{pR}_{\mathrm{cs}}$ ): $\mathrm{pR}_{\mathrm{cs}}=\frac{1}{6} \times(\mathrm{Rds}) \mathrm{on} \times\left(\mathrm{I}_{\mathrm{pk}}\right)^{2} \max$ | This formula indicates the required dissipation capability for $\mathrm{R}_{\text {cs }}$ (current sense resistor). |
| Over Current Protection Resistor ( $\mathrm{R}_{\mathrm{OCP}}$ ): $\mathrm{R}_{\mathrm{OCP}} \approx \frac{\mathrm{R}_{\mathrm{cs}} \times\left(\mathrm{I}_{\mathrm{pk}}\right) \max }{0.205}$ | The overcurrent threshold is adjusted by ROCP at a given $\mathrm{R}_{\mathrm{cs}}$. <br> $\mathrm{R}_{\mathrm{cs}}$ can be a preconverter inrush resistor |
| Oscillator External Capacitor Value ( $\mathrm{C}_{\mathrm{T}}$ ): <br> -Traditional Operation $\mathrm{C}_{\mathrm{T}} \geq-\mathrm{C}_{\mathrm{int}}+\frac{2 \times \mathrm{K}_{\mathrm{osc}} \times \mathrm{L}_{\mathrm{p}} \times\left(\mathrm{P}_{\mathrm{in}}\right) \max \times \mathrm{I}_{\mathrm{regL}}^{2}}{\mathrm{~V}_{\mathrm{ac}}^{2}}$ <br> - Follower Boost: $v_{o}=\frac{R_{0}}{2} \times \sqrt{\frac{C_{T}+C_{i n t}}{K_{o s c} \times L_{p} \times P_{i n}}} \times v_{p k}$ | The Follower Boost characteristic is adjusted by the $\mathrm{C}_{\mathrm{T}}$ choice. <br> The Traditional Mode is also selected by $\mathrm{C}_{\mathrm{T}}$. $\mathrm{C}_{\text {int }}$ is the oscillator pin internal capacitor. |
| Feedback Resistor ( $\mathrm{R}_{\mathrm{o}}$ ): $R_{O}=\frac{\left(V_{0}\right)_{\mathrm{reg}}-V_{F B}}{I_{\text {regH }}} \approx \frac{V_{0}}{200}$ | The output voltage regulation level is adjusted by $\mathrm{R}_{0}$. |

Note 1. The preconverter design requires the following characteristics specification:

- $\left(\mathrm{V}_{0}\right)_{\text {reg }}$ : desired output voltage regulation level
$-\left(\Delta \mathrm{V}_{0}\right)_{\text {pk-pk }}$ : admissible output peak to peak ripple voltage
- $P_{0}$ : desired output power
$-\mathrm{V}_{\mathrm{ac}}$ : ac rms operating line voltage
- $\mathrm{V}_{\mathrm{acLL}}$ : minimum ac rms operating line voltage
- $V_{F B}$ : feedback pin voltage

Figure 35. Circuit Supply Voltage

## MC33260 V Cc SUPPLY VOLTAGE

In some applications, the arrangement shown in Figure 35 must be implemented to supply the circuit. A start-up resistor is connected between the rectified voltage (or one-half wave) to charge the MC33260 $\mathrm{V}_{\mathrm{CC}}$ up to its start-up threshold (11 V typically). The MC33260 turns on and the $\mathrm{V}_{\mathrm{CC}}$ capacitor $\left(\mathrm{C}_{\mathrm{pin} 8}\right)$ starts to be charged by the PFC transformer auxiliary winding. A resistor, $r$ (in the range of $22 \Omega$ ) and a 15 V zener should be added to protect the circuit from excessive voltages.

When the PFC preconverter is loaded by an SMPS, the MC33260 should preferably be supplied by the SMPS itself. In this configuration, the SMPS starts first and the PFC gets active when the MC33260 $\mathrm{V}_{\mathrm{CC}}$ supplied by the power supply, exceeds the device start-up level. With this configuration, the PFC preconverter doesn't require any auxiliary winding and finally a simple coil can be used.

## PCB LAYOUT

The connections of the oscillator and $\mathrm{V}_{\text {control }}$ capacitors should be as short as possible.

Figure 36. Preconverter loaded by a Flyback SMPS: MC33260 VCC Supply

## MC33349

## Lithium Battery Protection Circuit for One Cell Battery Packs

The MC33349 is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of a one cell rechargeable battery pack. Cell protection features consist of internally trimmed charge and discharge voltage limits, discharge current limit detection, and a low current standby mode when the cell is discharged. This protection circuit requires a minimum number of external components and is targeted for inclusion within the battery pack.

- Internally Trimmed Charge and Discharge Voltage Limits
- Discharge Current Limit Detection
- Low Current Standby Mode when Cells are Discharged
- Dedicated for One Cell Applications
- Minimum Components for Inclusion within the Battery Pack
- Available in a Low Profile Surface Mount Package

## OPERATING DESCRIPTION

## VD1 / Over-Charge Detector

VD1 monitors the voltage at the $\mathrm{V}_{\text {CELL }}$ pin $\left(\mathrm{V}_{\mathrm{DD}}\right)$. When it exceeds the over-charge detector threshold, $\mathrm{V}_{\mathrm{DET} 1}$. VD1 senses an over-charging condition, the CO pin goes to a "Low" level, and the external charge control, Nch-MOSFET turns off.

Resetting VD1 allows resumption of the charging process. VD1 resets under two conditions, thus, making the CO pin level "High." The first case occurs when the cell voltage drops below " $\mathrm{V}_{\mathrm{DET1}}-\mathrm{V}_{\mathrm{HYS} 1}$." ( $\mathrm{V}_{\mathrm{HYS}}$ is typically 200 mV ). In the second case, disconnecting the charger from the battery pack can reset VD1 after $\mathrm{V}_{\mathrm{DD}}$ drops between "V $V_{\text {DET1 }}$ " and " $V_{\text {DET1 }}-V_{\text {HYS1 }}$ ".

After detecting over-charge, connecting a load to the battery pack allows load current to flow through the parasitic diode of the external charge control FET. The CO level goes "High" when the cell voltage drops below $\mathrm{V}_{\text {DET1 }}$ due to load current draw through the parasitic diode.

An external capacitor connected between the Gnd pin and Ct pin sets the output delay time for over-charge detection. The external capacitor sets up a delay time from the moment of over-charge detection to the time CO outputs a signal, which enables the charge control FET to turn off. If the voltage fault occurs within the time delay window. CO will not turn off the charge control FET. The output delay time can be calculated as follows:

$$
{ }^{\mathrm{t} V D E T 1} 1[\mathrm{sec}]=\left(\mathrm{Ct}[\mathrm{~F}] \times(\mathrm{VDD}[\mathrm{~V}]-0.7) /\left(0.48 \times 10^{-6}\right)\right.
$$

A level shifter incorporated in a buffer driver for the CO pin drives the "Low" level of CO pin to the $\mathrm{P}-$ pin voltage. A CMOS buffer sets the "High" level of CO pin to $V_{D D}$.

## VD2 / Over-Discharge Detector

VD2 monitors the voltage at the $\mathrm{V}_{\text {CELL }}$ pin ( $\mathrm{V}_{\mathrm{DD}}$ ). When it drops below the over-discharge detector threshold, $\mathrm{V}_{\text {DET2 }}$, VD2 senses an over-discharge condition, the DO
pin goes to a "Low" level, and the external discharge control Nch MOSFET turns off. The IC enters a low current standby mode after detection of an over-discharged voltage by VD2. Supply current then reduces to approximately $0.3 \mu \mathrm{~A}$. During standby mode, only the charger detector operates.

VD2 can only reset after connecting the pack to a charger. While $\mathrm{V}_{\mathrm{DD}}$ remains under the over-discharge detector threshold, $\mathrm{V}_{\text {DET2 }}$, discharge current can flow through the parasitic diode of the external discharge control FET. The DO level goes "High" when the cell voltage rises above $\mathrm{V}_{\text {DET2 }}$ due to the charging current through the parasitic diode. Connecting a charger to the battery pack will instantly set DO "High" if this causes $V_{\text {DD }}$ to rise above $V_{\text {DET2 }}$.
When cell voltage equals zero, one can charge the battery pack if the voltage is greater than the minimum charge voltage, $\mathrm{V}_{\mathrm{ST}}$.

Output delay time for the over-discharge detection ( $\mathrm{t}_{\text {VDET2 }}$ ) is fixed internally. If the voltage fault occurs within the time delay window, DO will not turn off the discharge control FET.
A CMOS buffer sets the output of the DO pin to a "High" level of $\mathrm{V}_{\mathrm{DD}}$ and a "Low" level of Gnd.

## VD3 / Excess Current Detector, Short Circuit Detector

Both the excess current detector and the short circuit detector can work when the two control FET's are on. When the voltage at the P - pin rises to a value between the short circuit protection voltage, $\mathrm{V}_{\text {SHORT }}$, and the excess current threshold, $\mathrm{V}_{\mathrm{DET}}$, the excess current detector operates. Increasing $\mathrm{V}_{(\mathrm{P}-)}$ higher than $\mathrm{V}_{\text {SHORT }}$ enables the short circuit detector. The DO pin then goes to a "Low" level, and the external discharge control Nch MOSFET turns off.

Output delay time for excess current detection ( $\mathrm{t}_{\mathrm{VDET}}$ ) is fixed internally. If the excess current fault occurs within the time delay window, DO will not turn off the discharge control FET. However, when the short circuit protector is
enabled, DO can turn off the discharge control FET. Its delay time would be approximately $5 \mu \mathrm{~s}$.

The P-pin has a built-in pull down resistor, typically $100 \mathrm{k} \Omega$, which connects to the Gnd pin. Once an excess current or short circuit fault is removed, the internal resistor pulls $\mathrm{V}_{(\mathrm{P}-)}$ to the Gnd pin potential. Therefore, the voltage from P - to Gnd drops below the current detection thresholds and DO turns the external MOSFET back on.

## -NOTE-

If $\mathrm{V}_{\mathrm{DD}}$ voltage is higher than the over-discharge voltage threshold, $\mathrm{V}_{\mathrm{DET}}$, when excess current is detected the IC will not enter a standby mode. However, if $\mathrm{V}_{\mathrm{DD}}$ is below $\mathrm{V}_{\text {DET2 }}$ when excess current is detected, the IC will enter a standby mode. This will not occur when the short circuit detector activates.

Figure 23. Timing Diagram / Operational Description

Figure 24. Typical Application Circuit

## Technical Notes

R1 and C1 will stabilize a supply voltage to the MC33349. A recommended R1 value is less than $1 \mathrm{k} \Omega$. A larger value of R1 leads to higher detection voltage because of shoot through current into the IC.
R2 and C2 stabilize P - pin voltage. Larger R2 values could possibly disable reset from over-discharge by connecting a charger. Recommended values are less than $1 \mathrm{k} \Omega$. After an over-charge detection even connecting a battery pack to a system could probably not allow a system to draw load current if one uses a larger R2C2 time constant. The recommended C 2 value is less than $1 \mu \mathrm{~F}$.
R1 and R2 can operate as a current limiter against setting cell reverse direction or for applying excess charging voltage to the IC and battery pack. Smaller R1 and R2 values may cause excessive power consumption over the specified power dissipation rating. Therefore $\mathrm{R} 1+\mathrm{R} 2$ should be more than $1 \mathrm{k} \Omega$.
The time constants R1C1 and R2C2 must have a relation as follows:
$\mathrm{R} 1 \mathrm{C} 1 \leq \mathrm{R} 2 \mathrm{C} 2$
If the R1C1 time constant for the Vcell pin is larger than the R2C2 time constant for the $\mathrm{P}-$ pin, the IC might enter a standby mode after detecting excess current. This was noted in the operating description of the current detectors.

## NCP800

## Lithium Battery Protection Circuit for One Cell Battery Packs

The NCP800 resides in a lithium battery pack where the battery cell continuously powers it. In order to maintain cell operation within specified limits, this protection circuit senses cell voltage and discharge current, and correspondingly controls the state of two, N-channel, MOSFET switches. These switches reside in series with the negative terminal of the cell and the negative terminal of the battery pack. During a fault condition, the NCP800 open circuits the pack by turning off one of these MOSFET switches, which disconnects the current path.

- Internally Trimmed Precision Charge and Discharge Voltage Limits
- Discharge Current Limit Detection
- Automatic Reset from Discharge Current Faults
- Low Current Standby State when Cells are Discharged
- Available in a Low Profile Surface Mount Package

## OPERATING DESCRIPTION

## VD1 / Over-Charge Detector

VD1 monitors the voltage at the $\mathrm{V}_{\text {CELL }}$ pin $\left(\mathrm{V}_{\mathrm{DD}}\right)$. When it exceeds the over-charge detector threshold, $\mathrm{V}_{\mathrm{DET1}}$. VD1 senses an over-charging condition, the CO pin goes to a "Low" level, and the external charge control, Nch-MOSFET turns off.

Resetting VD1 allows resumption of the charging process. VD1 resets under two conditions, thus, making the CO pin level "High." The first case occurs when the cell voltage drops below "V $\mathrm{V}_{\mathrm{DET} 1}-\mathrm{V}_{\mathrm{HYS1}}$." ( $\mathrm{V}_{\mathrm{HYS}}$ is typically 200 mV ). In the second case, disconnecting the charger from the battery pack can reset VD1 after $\mathrm{V}_{\mathrm{DD}}$ drops between " $V_{\text {DETI }}$ " and " $\mathrm{V}_{\text {DET1 }}-\mathrm{V}_{\text {HYSI }}$ ".

After detecting over-charge, connecting a load to the battery pack allows load current to flow through the parasitic diode of the external charge control FET. The CO level goes "High" when the cell voltage drops below $\mathrm{V}_{\text {DET1 }}$ due to load current draw through the parasitic diode.

An external capacitor connected between the Gnd pin and Ct pin sets the output delay time for over-charge detection. The external capacitor sets up a delay time from the moment of over-charge detection to the time CO outputs a signal, which enables the charge control FET to turn off. If the voltage fault occurs within the time delay window. CO will not turn off the charge control FET. The output delay time can be calculated as follows:

$$
{ }^{\mathrm{t}} \mathrm{DET} 1[\mathrm{sec}]=\left(\mathrm{Ct}[\mathrm{~F}] \times(\mathrm{VDD}[\mathrm{~V}]-0.7) /\left(0.48 \times 10^{-6}\right)\right.
$$

A level shifter incorporated in a buffer driver for the CO pin drives the "Low" level of CO pin to the $\mathrm{P}-$ pin voltage. A CMOS buffer sets the "High" level of CO pin to $\mathrm{V}_{\mathrm{DD}}$.

## VD2 / Over-Discharge Detector

VD2 monitors the voltage at the $\mathrm{V}_{\text {CELL }}$ pin $\left(\mathrm{V}_{\mathrm{DD}}\right)$. When it drops below the over-discharge detector threshold, $\mathrm{V}_{\text {DET2 }}, \mathrm{VD} 2$ senses an over-discharge condition, the DO pin goes to a "Low" level, and the external discharge control

Nch MOSFET turns off. The IC enters a low current standby mode after detection of an over-discharged voltage by VD2. Supply current then reduces to approximately $0.3 \mu \mathrm{~A}$. During standby mode, only the charger detector operates.
VD2 can only reset after connecting the pack to a charger. While $\mathrm{V}_{\mathrm{DD}}$ remains under the over-discharge detector threshold, $\mathrm{V}_{\mathrm{DET} 2}$, discharge current can flow through the parasitic diode of the external discharge control FET. The DO level goes "High" when the cell voltage rises above $\mathrm{V}_{\text {DET2 }}$ due to the charging current through the parasitic diode. Connecting a charger to the battery pack will instantly set DO "High" if this causes $\mathrm{V}_{\mathrm{DD}}$ to rise above $\mathrm{V}_{\text {DET2 }}$.
Output delay time for the over-discharge detection ( $\mathrm{t}_{\text {DET2 }}$ ) is fixed internally. If the voltage fault occurs within the time delay window, DO will not turn off the discharge control FET.
A CMOS buffer sets the output of the DO pin to a "High" level of $\mathrm{V}_{\mathrm{DD}}$ and a "Low" level of Gnd.

## VD3 / Excess Current Detector, Short Circuit Detector

Both the excess current detector and the short circuit detector can work when the two control FET's are on. When the voltage at the $\mathrm{P}-$ pin rises to a value between the short circuit protection voltage, $\mathrm{V}_{\text {SHORT }}$, and the excess current threshold, $\mathrm{V}_{\mathrm{DET3}}$, the excess current detector operates. Increasing $\mathrm{V}_{(\mathrm{P}-)}$ higher than $\mathrm{V}_{\text {SHORT }}$ enables the short circuit detector. The DO pin then goes to a "Low" level, and the external discharge control Nch MOSFET turns off.
Output delay time for excess current detection ( $\mathrm{t}_{\text {DET3 }}$ ) is fixed internally. If the excess current fault occurs within the time delay window, DO will not turn off the discharge control FET. However, when the short circuit protector is enabled, DO can turn off the discharge control FET. Its delay time is approximately $10 \mu \mathrm{~s}$.
The P-pin has a built-in pull down resistor, typically $100 \mathrm{k} \Omega$, which connects to the Gnd pin. Once an excess current or short circuit fault is removed, the internal resistor
pulls $\mathrm{V}_{(\mathrm{P}-)}$ to the Gnd pin potential. Therefore, the voltage from P - to Gnd drops below the current detection thresholds and DO turns the external MOSFET back on.
NOTE: If $\mathrm{V}_{\mathrm{DD}}$ voltage is higher than the over-discharge voltage threshold, $\mathrm{V}_{\mathrm{DET}}$, when excess current is detected
the IC will not enter a standby mode. However, if $\mathrm{V}_{\mathrm{DD}}$ is below $\mathrm{V}_{\text {DET2 }}$ when excess current is detected, the IC will enter a standby mode. This will not occur when the short circuit detector activates.

Figure 22. Timing Diagram / Operational Description

Figure 23. Typical Application Circuit

## Technical Notes

R 1 and C 1 will stabilize a supply voltage to the NCP800. A recommended R1 value is less than $1 \mathrm{k} \Omega$. A larger value of R1 leads to higher detection voltage because of shoot through current into the IC.
R2 and C2 stabilize P - pin voltage. Larger R2 values could possibly disable reset from over-discharge by connecting a charger. Recommended values are less than $1 \mathrm{k} \Omega$. After an over-charge detection even connecting a battery pack to a system could probably not allow a system to draw load current if one uses a larger R2C2 time constant. The recommended C2 value is less than $1 \mu \mathrm{~F}$.
R1 and R2 can operate as a current limiter against setting cell reverse direction or for applying excess charging voltage to the IC and battery pack. Smaller R1 and R2 values may cause excessive power consumption over the specified power dissipation rating. Therefore $\mathrm{R} 1+\mathrm{R} 2$ should be more than $1 \mathrm{k} \Omega$.
The time constants R1C1 and R2C2 must have a relation as follows:
$\mathrm{R} 1 \mathrm{C} 1 \leq \mathrm{R} 2 \mathrm{C} 2$
If the R1C1 time constant for the Vcell pin is larger than the R2C2 time constant for the $\mathrm{P}-$ pin, the IC might enter a standby mode after detecting excess current. This was noted in the operating description of the current detectors.

## Advanced Information <br> Lithium Battery Protection Circuit for Three Battery Packs

The MC33351A is a monolithic lithium battery protection circuit that is designed to enhance the useful operating life of three cell rechargeable battery packs. The MC33351A is specifically designed to be placed in a lithium battery pack where the battery cells continuously power it. In order to maintain cell operation within specified limits, the protection circuit senses cell voltages, and discharge current, and correspondingly controls the state of two P-channel MOSFET switches. These switches are connected in series with the positive terminal of the third cell and the positive terminal of the battery pack. During a fault condition, the MC33351A open circuits the pack by turning off one of these MOSFET switches.

## Features

- Selectable Charge Interrupt Voltage Sensing Mode for Precise Cell Voltage Measurements
- Programmable Overvoltage Delay
- Choice of Discharge Current Limit Sensing Elements consisting of either Low-Side Resistor or High-Side MOSFET Switches
- Programmable Discharge Current Limit Threshold and Shutdown Delay
- Selectable Cell Voltage Balancing
- Virtually Zero Current Sleepmode State when Cells are Discharged
- Minimum External Components for Inclusion within the Battery Pack
- Available in Low Profile Surface Mount Package

PIN FUNCTION DESCRIPTION

| Pin <br> No. | Function | Description |
| :---: | :---: | :---: |
| 1 | Charge Inhibit Input | A logic low level at this input will disable battery pack charging. A 10 k internal pull-up resistor connects from this pin to $\mathrm{V}_{\mathrm{C}}$. |
| 2 | Discharge Inhibit Input | A logic low level at this input will disable battery pack discharging. A 10 k internal pull-up resistor connects from this pin to $\mathrm{V}_{\mathrm{C}}$. Also, connecting this pin to 3.0 V above $\mathrm{V}_{\mathrm{C}}$ the internal logic is held in reset state and both MOSFET switches are turned on. |
| 3 | Overvoltage Shutdown Delay | This input controls the required number of cell overvoltage events that must be detected before charge switch Q1 is turned off. With a logic level low at this input, charge switch Q1 turns off after a single overvoltage event is detected. With a logic level high, charge switch Q1 turns off after two successive overvoltage events are detected. |
| 4 | Discharge Current Limit Shutdown Delay | A capacitor connects from this pin to ground and is used to program a time delay from when the discharge current limit is exceeded to when discharge switch Q2 is turned off. |
| 5 | Low-Side Discharge Current Limit Input | This pin is used to monitor the load induced voltage drop that appears across current sensing resistor $\mathrm{R}_{\lim (\mathrm{LS})}$. This voltage drop is sensed by pins 13 and 5 . |
| 6 | Charge Interrupt Mode Select | The logic level that is applied to this input determines if the charge current will be interrupted during the cell voltage sampling period. The charge current is interrupted when this input is connected to $\mathrm{V}_{\mathrm{C}}$, and not interrupted when connected to ground, pin 13. |
| 7 | Discharge Gate Drive Output | This output connects to the gate of discharge switch Q2 allowing it to enable or disable battery pack discharging. |
| 8 | Charge and Discharge Gate Drive Common | This pin provides a gate turn-off path for charge switch Q1. The charge switch source and the battery pack positive terminal connect to this point. |
| 9 | Charge Gate Drive Output | This output connects to the gate of charge switch Q1 allowing it to enable or disable battery pack charging. |
| 10 | Undervoltage Fault Output | This is an open drain output that is active low when an undervoltage fault limit has been exceeded. Discharge switch Q2 will turn off 16 seconds after the Fault goes low. |
| 11 | High-Side Discharge Current Limit Threshold | A resistor connects from this pin to ground and is used to program the high-side discharge current limit threshold. The programmed threshold voltage is sensed by pins 16 and 8. |
| 12 | Cell 2 | This pin connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 2 and the negative terminal of Cell 3. |
| 13 | Ground | This is the protection IC ground and all voltage ratings are with respect to this pin. |
| 14 | Balance 2 | This pin is used if cell balancing is desired. It connects to the drain of an internal N-channel MOSFET and is active low during the balancing of Cell 2. |
| 15 | Cell $1 / \mathrm{V}_{\mathrm{C}}$ | This is a multi-function pin that connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 1 and the negative terminal of Cell 2 . This pin also provides bias for the internal logic. |
| 16 | $\mathrm{V}_{\mathrm{CC}} /$ High-Side Discharge Current Limit | This is a multi-function pin that connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 3 and to provide positive supply voltage for the protection IC. This pin can also be used for high-side discharge current limit protection by monitoring the load induced voltage drop that appears across the on-resistance of switches Q2 and diode of Q1. This voltage drop is sensed by pins 16 and 8 . |
| 17 | NC | No Connection |
| 18 | Cell 3 | This pin connects to a high impedance node of the Cell Selector where it is used to monitor the positive terminal of Cell 3 and $\mathrm{V}_{\mathrm{CC}}$. |
| 19 | Balance 3 | This pin is used if cell balancing is desired. It connects to the drain of an internal P-channel MOSFET and is active high during the balancing of Cell 3. |
| 20 | Balance 1 | This pin is used if cell balancing is desired. It connects to the drain of an internal $N$-channel MOSFET and is active low during the balancing of Cell 1. |

PROTECTION CIRCUIT OPERATING MODE TABLE

CELL CHARGING/DISCHARGING

| Storage or Nominal Operation: <br> No current or voltage faults | Both Charge MOSFET Q1 and Discharge MOSFET <br> Q2 are on. The battery pack is available for charging <br> or discharging. | On | On |
| :--- | :--- | :--- | :--- |

CELL CHARGING FAULT/RESET

| Charge Voltage Limit Fault: <br> $\mathrm{V}_{\text {Cell }} \geq \mathrm{V}_{\text {th(ov) }}$ for $\mathrm{t}_{\text {dly (OV) }}$ $\mathrm{t}_{\mathrm{dly}(\mathrm{OV})}=$ <br> 0 to 1.2 s , Pin 3 to 13 <br> 1.0 to 2.1 s , Pin 3 to 15 | Charge MOSFET Q1 is latched off and the cells are disconnected from the charging source. An internal hysteresis voltage is generated when the overvoltage cell is sensed. The shutdown delay is programmable for either one or two successive overvoltage events by the state of Pin 3 . The battery pack is available for discharging. | On to Off | On | Active |
| :---: | :---: | :---: | :---: | :---: |
| Charge Voltage Limit Reset: <br> $\mathrm{V}_{\text {Cell }}<\left(\mathrm{V}_{\text {th }(\mathrm{OV})}-\mathrm{V}_{\mathrm{H}}\right)$ for 1.2 s | Charge MOSFET Q1 will turn on when the voltage across the overvoltage cell falls sufficiently to overcome the internal hysteresis voltage. This can be accomplished by applying a load to the battery pack. | Off to On | On | Active |

CELL DISCHARGING FAULT/RESET

| Discharge Current Limit Fault: <br> $\mathrm{V}_{\text {Pin } 16} \geq\left(\mathrm{V}_{\text {Pin } 8}+\mathrm{Vth}_{\text {(HS dschg) }}\right.$ <br> for $t_{\text {dly }}$ (HS dschg) or <br> $\mathrm{V}_{\text {Pin } 5} \geq\left(\mathrm{V}_{\text {Pin } 13}+\mathrm{V}_{\text {th }(\text { LS dschg })}\right.$ <br> for $\mathrm{t}_{\text {dly }}$ (LS dschg) | Discharge MOSFET Q2 is latched off and the cells are disconnected from the load. Q2 will remain in the off state as long as $\mathrm{V}_{\text {Pin 16 }}$ exceeds $\mathrm{V}_{\text {Pin } 8}$ by $\approx \mathrm{V}_{\mathrm{TH} \text { (HSdschrg) }}$. A discharge current limit fault can be activated by either high-side or a low-side current sensing methods. The battery pack is available for charging. | On | On to Off | Active |
| :---: | :---: | :---: | :---: | :---: |
| Discharge Current Limit Reset: $\begin{aligned} & V_{\text {Pin } 16}-V_{\text {Pin } 8}<V_{T H(H S d s c h r g)} \\ & V_{\text {Pin } 5}-V_{\text {Pin } 13}<V_{T H(L S d s c h r g)} \end{aligned}$ | The Sense Enable circuit will reset and turn on discharge MOSFET Q2 when $V_{\text {Pin } 16}$ no longer exceeds $\mathrm{V}_{\text {Pin } 8}$ by 2.0 V . This can be accomplished by either disconnecting the load from the battery pack, or by connecting the battery pack to the charger. | On | Off to On | Active |
| Discharge Voltage Limit Fault: $\mathrm{V}_{\text {Cell }} \leq \mathrm{V}_{\mathrm{th}(\mathrm{UV})} \text { for } 2.1 \mathrm{~s}$ | Undervoltage Fault Output (Pin 10) is driven low after two successive undervoltage events are detected. After a 16 second delay, discharge MOSFET Q2 is latched off, the cells are disconnected from the load, and the protection circuit enters a low current sleepmode state. The battery pack is available for charging. | On | On to Off after 16 s | Disabled |
| Discharge Voltage Limit Reset: $V_{\text {Pin } 8}>\left(V_{\text {Pin 16 }}+0.6 \mathrm{~V}\right)$ | The Sense Enable circuit will reset and turn on discharge MOSFET Q2 when $\mathrm{V}_{\text {Pin } 8}$ exceeds $\mathrm{V}_{\text {Pin } 16}$ by 0.6 V . This can be accomplished by connecting the battery pack to the charger. | On | Off to On | Active |
| FAULTY CELL |  |  |  |  |
| Simultaneous Charge and Discharge Voltage Limit Faults | This condition can happen if there is a defective cell in the battery pack. The protection circuit will remain in the sleepmode state until the battery pack is connected to a charger. If Cell 2 , or 3 is faulty and a charger is connected, the protection circuit will cycle in and out of sleepmode. If Cell 1 is faulty ( $<1.5 \mathrm{~V}$ ) the protection circuit logic will not function and the battery pack cannot be charged. | Cycles <br> Cell 1 Good <br> Disabled Cell 1 Faulty | Cycles Cell 1 Good <br> Disabled Cell 1 Faulty | Cycles <br> Cell 1 Good <br> Disabled Cell 1 Faulty |

NOTE: 3 Charge switch Q1 and discharge switch Q2 can be selectively turned off via the appropriate inhibit input except during the sleepmode state.

## INTRODUCTION

The demand for smaller lightweight portable electronic equipment has dramatically increased the requirements of battery performance. Today's most attractive chemistries include lithium-polymer, lithium-ion, and lithium-metal. Each of these chemistries require electronic protection in order to constrain cell operation to within the manufacturers limits.

Rechargeable lithium-based cells require precise charge and discharge termination limits for both voltage and current in order to maximize cell capacity, cycle life, and to protect the end user from a catastrophic event.

The MC33351A features internally-fixed cell voltage limits, programmable cell voltage balancing, low operating current, a virtually zero current sleepmode state, and requires few external components.

## OPERATING DESCRIPTION

The MC33351A is specifically designed to be placed in the battery pack where it can be continuously powered from three lithium cells. In order to maintain cell operation within specified limits, the protection circuit senses both cell voltage and discharge current, and correspondingly controls the state of two P-channel MOSFET switches. These switches, Q1 and Q2, are placed within the series path of the positive terminal of cell 3 and the positive terminal of the battery pack. For lowside current limit sense, a resistor is placed within the series path of the negative terminal of Cell 1 and the negative terminal of the battery pack. This configuration allows the protection circuit to interrupt the appropriate charge or discharge path FET in the event that a programmed voltage or current limit for any cell has been exceeded.

A functional description of the protection circuit blocks follows. Refer to the detailed block diagram shown in Figure 1.

## Voltage Sensing

Individual cell voltage sensing is accomplished by the use of the Cell Selector in conjunction with the Floating Over/Under Voltage Detector and Reference block. The Cell Selector applies the voltage of each cell across an internal resistor divider string. The voltage at each of the tap points is sequentially polled and compared to an internal reference. If a limit has been exceeded, the result is stored in the Over/Under Data Latch and Control Logic block. The Cell Selector is gated on for a 4.0 ms period at a fixed one second repetition rate. This low duty cycle sampling technique reduces the average load current that the divider presents across each cell, thus extending the useful battery pack capacity.

Figure 12. Simplified Smart Battery Pack
Cell Sensing Sequence

| Polling <br> Sequence | Time <br> $(\mathbf{m s})$ | Cell <br> Sensed | Tested <br> Limit |
| :---: | :---: | :---: | :---: |
| 1 | 0.25 | Cell 1 | Overvoltage |
| 2 | 0.25 | Cell 2 | Overvoltage |
| 3 | 0.25 | Cell 3 | Overvoltage |
| 4 | 0.25 | Cell 1 | Undervoltage |
| 5 | 0.25 | Cell 2 | Undervoltage |
| 6 | 0.25 | Cell 3 | Undervoltage |

By incorporating this polling technique with a single floating comparator and voltage divider, a significant reduction of circuitry and trim elements is achieved. This results in a smaller die size, lower cost, and reduced operating current.

Figure 13. Cell Voltage Limit Sampling

## vs. Programming

The cell charge and discharge voltage limits are controlled by the values selected for the internal resistor divider string. As the battery pack reaches full charge, the Cell Voltage Detector will sense an overvoltage fault condition on the first cell that exceeds the pre-set overvoltage limit. The fault information is stored in a data latch and charge MOSFET Q1 is turned off, disconnecting the battery pack from the charging source. An internal current source pull-up is then applied to the lower tap of the divider when the overvoltage cell is again sensed. This creates an input hysteresis voltage with divider resistors R1 and R2. As a result of an overvoltage fault, the battery pack is available for discharging only.

The overvoltage fault is reset by applying a load to the battery pack. As the voltage across the highest voltage cell falls below the hysteresis level, charge MOSFET Q1 will turn on and the current source pull-up will turn off. The battery pack will now be available for charging or discharging.

As the load eventually depletes the battery pack charge, the Cell Voltage Detector will sense an undervoltage fault condition on the first cell that falls below the designed undervoltage limit. After an undervoltage cell is detected, undervoltage fault output goes low and discharge MOSFET Q2 is turned off, disconnecting the battery pack from the load after 16 seconds. The protection circuit will now enter a low current sleepmode state drawing less than 15.0 nA typically, thus preventing any further cell discharging. As a result of the undervoltage fault, the battery pack is available for charging only. An alternate method of turning discharge MOSFET Q2 can be employed using $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$ as shown in Figures 1 and 2. Recommended value of $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$ of $5.1 \mathrm{k} \Omega$ and $22 \mu \mathrm{fd}$ respectively generates a time delay of 110 $\pm 10 \%$ milliseconds.

The undervoltage fault is reset by applying charge current to the battery pack. When the voltage on Pin 8 exceeds Pin 16 by 0.6 V , discharge MOSFET Q2 will be turned on. The battery pack will now be available for charging or discharging.

## Cell Voltage Balancing

With series connected cells, successive charge and discharge cycles can result in a significant difference in cell voltage with a corresponding degradation of battery pack
capacity. Figure 13 illustrates the operation of an unbalanced three cell pack. As the cells become unbalanced, the full battery pack capacity is not realized. This is due to the requirement that charging must terminate when the highest voltage cell reaches the overvoltage limit, and discharging must terminate when the lowest voltage cell reaches the undervoltage limit. By employing a method of keeping the cell voltages equal, each of the cells can be charged and discharged to their specified limits, thus attaining the maximum possible capacity.

Figure 14. Unbalanced Battery Pack Operation
The MC33351A contains a Cell Voltage Balancing Logic circuit that controls three internal MOSFETs. These MOSFETs are connected to an external transistor and resistor combination across the individual cells. The circuit samples the voltage of each cell during the polling period. If all of the cells are below the programmed overvoltage fault limit, no cell balancing takes place. If one or more cells reach the overvoltage fault limit, a specific latch is set for each cell. At the end of the polling period, charge MOSFET Q1 is turned off and the latches are interrogated. If all of the latches were set, no cell balancing takes place. If one, two, or three latches were set, the required cell balancing MOSFETs are then activated. The overvoltage cells are discharged to the pre-set level. As each cell attains this level, the balancing MOSFETs successively turn off. Upon completion of cell balancing, charge MOSFET Q1 is turned on. Cell voltage balancing can be active during charging and discharging, but is disabled during the low current sleepmode state.

## Test Mode

A test option is provided to speed up device and battery pack testing. By connecting Pin 2 to 3.0 V above $V_{C}$ the internal logic is held in a reset state and both MOSFET switches are turned on. Upon release, the Control Logic becomes active and the cell are polled within 4.0 ms .

## Discharge Current Sensing

Discharge current limit protection can be selectively added to the battery pack with the addition of a sense resistor $\mathrm{R}_{\mathrm{lim}(\mathrm{dschg})}$ on the Low-Side or by monitoring the voltage drop across the series FETs on the High-Side.
Sense resistor - low-side
The sense resistor $\mathrm{R}_{\mathrm{lim}(\mathrm{dschg})}$ is placed in series with the negative terminal of Cell 1 and the negative terminal of the battery pack, Refer to Figure 1.

As the battery pack discharges, Pins 5 and 13 sense the voltage drop across $\mathrm{R}_{\text {Lim(dschg) }}$.

A discharge current limit fault is detected if the voltage at Pin 5 is greater than Pin 13 by $\mathbf{5 0} \mathbf{m V}$ for more than 3.0 ms . The fault information is stored in a data latch and discharge MOSFET Q2 is turned off, disconnecting the battery pack from the load. As a result of the discharge current fault, the battery pack is available for charging only. The discharge current limit is given by:

$$
\mathrm{I}_{\mathrm{Lim}(\mathrm{dschg})}=\frac{\mathrm{V}_{\text {th(dschg) }}}{\mathrm{R}_{\mathrm{Lim}(\mathrm{dschg})}}=\frac{50 \mathrm{mV}}{\mathrm{R}_{\mathrm{Lim}(\mathrm{dschg})}}
$$

## Voltage across FETs - high-side

A $1 \mathrm{M} \Omega$ or $2 \mathrm{M} \Omega$ resistor connected from pin\# 11 to ground is used to program the high-side discharge current limit threshold.

The discharge current fault is reset by either disconnecting the load from the battery pack, or by connecting the battery pack to the charger. When the voltage on Pin 16 no longer exceeds Pin 8 by approximately 2.0 V, the Sense Enable
circuit will turn on discharge MOSFET Q2. Discharge current sensing can be disabled by connecting Pin 16 to Pin 8.

The discharge current protection circuit contains a built in response delay of 3.0 ms . This helps to prevent fault activation when the battery pack is subjected to pulsed currents during charging or discharging.

## Battery Pack Application

Each of the application figures show a capacitor labeled $\mathrm{C}_{\mathrm{I}}$ that connects directly across the battery pack terminals, and two resistors labeled $\mathrm{R}_{\mathrm{g}}$ that are placed in series with the charge and discharge gate drive outputs. These components prevent excessive currents from flowing into the MC33351A when the battery pack terminals are shorted or arced and are mandatory. Capacitor $C_{I}$ is $\boldsymbol{a} 1.0 \mu \boldsymbol{F} \pm \mathbf{2 0 \%}$ ceramic leaded or surface mount type. It must be placed directly across the battery pack plus and minus terminals with extremely short lead lengths $(\leq 1 / 16$ ") and as close to the IC as possible. The gate drive output resistors for both Q1 and Q2 are $10 k \Omega \pm 5.0 \%$ carbon film type.
In applications where inordinately low leakage MOSFETs are used, the protection circuit may take several seconds to reset from an overcurrent fault after the load is removed. If desired, this situation can be remedied by providing a small leakage path for charging $\mathrm{C}_{\mathrm{I}}$, thus allowing Pin 8 to rapidly rise, so that it no longer exceeds Pin 16 by approximately 2.0 V . A $4.7 \mathrm{M} \Omega$ resistor placed across the MOSFET switches accomplishes this task with a minimum increase in cell discharge current when the battery pack is connected to the load.

Upon assembly of the battery pack, it is imperative that Cell 1 be connected first so that $V_{c}$ is properly biased. The remaining cells can then be connected in any order. This assembly method prevents forward biasing the protection IC substrate which can result in overheating and non-functionality.

MC33351A

MC33351A - Cell Voltage versus Undervoltage Fault

## MC33340, MC33342

## Battery Fast Charge Controllers

The MC33340 and MC33342 are monolithic control IC's that are specifically designed as fast charge controllers for Nickel Cadmium ( NiCd ) and Nickel Metal Hydride (NiMH) batteries. These devices feature negative slope voltage detection as the primary means for fast charge termination. Accurate detection is ensured by an output that momentarily interrupts the charge current for precise voltage sampling. An additional secondary backup termination method can be selected that consists of either a programmable time or temperature limit. Protective features include battery over and undervoltage detection, latched over temperature detection, and power supply input undervoltage lockout with hysteresis. Fast charge holdoff time is the only difference between the MC33340 and the MC33342. The MC33340 has a typical holdoff time of 177 seconds and the MC33342 has a typical holdoff time of 708 seconds.

- Negative Slope Voltage Detection with 4.0 mV Sensitivity
- Accurate Zero Current Battery Voltage Sensing
- High Noise Immunity with Synchronous VFC/Logic
- Programmable 1 to 4 Hour Fast Charge Time Limit
- Programmable Over/Under Temperature Detection
- Battery Over and Undervoltage Fast Charge Protection
- Power Supply Input Undervoltage Lockout with Hysteresis
- Operating Voltage Range of 3.25 V to 18 V
- 177 seconds Fast Change Hold-off Time (MC33340)
- 708 seconds Fast Change Hold-off Time (MC33342)

This device contains 2,512 active transistors.

## INTRODUCTION

Nickel Cadmium and Nickel Metal Hydride batteries require precise charge termination control to maximize cell capacity and operating time while preventing overcharging. Overcharging can result in a reduction of battery life as well as physical harm to the end user. Since most portable applications require the batteries to be charged rapidly, a primary and usually a secondary or redundant charge sensing technique is employed into the charging system. It is also desirable to disable rapid charging if the battery voltage or temperature is either too high or too low. In order to address these issues, an economical and flexible fast charge controller was developed.

The MC33340/342 contains many of the building blocks and protection features that are employed in modern high performance battery charger controllers that are specifically designed for Nickel Cadmium and Nickel Metal Hydride batteries. The device is designed to interface with either primary or secondary side regulators for easy implementation of a complete charging system. A representative block diagram in a typical charging application is shown in Figure 8.

The battery voltage is monitored by the $\mathrm{V}_{\text {sen }}$ input that internally connects to a voltage to frequency converter and
counter for detection of a negative slope in battery voltage. A timer with three programming inputs is available to provide backup charge termination. Alternatively, these inputs can be used to monitor the battery pack temperature and to set the over and under temperature limits also for backup charge termination.
Two active low open collector outputs are provided to interface this controller with the external charging circuit. The first output furnishes a gating pulse that momentarily interrupts the charge current. This allows an accurate method of sampling the battery voltage by eliminating voltage drops that are associated with high charge currents and wiring resistances. Also, any noise voltages generated by the charging circuitry are eliminated. The second output is designed to switch the charging source between fast and trickle modes based upon the results of voltage, time, or temperature. These outputs normally connect directly to a linear or switching regulator control circuit in non-isolated primary or secondary side applications. Both outputs can be used to drive optoisolators in primary side applications that require galvanic isolation. Figure 9 shows the typical charge characteristics for NiCd and NiMh batteries.

Figure 8. Typical Battery Charging Application

Figure 9. Typical Charge Characteristics for NiCd and NiMh Batteries

## OPERATING DESCRIPTION

The MC33340/342 starts up in the fast charge mode when power is applied to $\mathrm{V}_{\mathrm{CC}}$. A change to the trickle mode can occur as a result of three possible conditions. The first is if the $\mathrm{V}_{\text {sen }}$ input voltage is above 2.0 V or below 1.0 V . Above 2.0 V indicates that the battery pack is open or disconnected, while below 1.0 V indicates the possibility of a shorted or defective cell. The second condition is when the MC33340/342 detects a fully charged battery by measuring a negative slope in battery voltage. The MC33340/342 recognize a negative voltage slope after the preset holdoff time ( $\mathrm{t}_{\text {hold }}$ ) has elapsed during a fast charge cycle. This indicates that the battery pack is fully charged. The third condition is either due to the battery pack being out of a programmed temperature range, or that the preset timer period has been exceeded.

There are three conditions that will cause the controller to return from trickle to fast charge mode. The first is if the $\mathrm{V}_{\text {sen }}$ input voltage moved to within the 1.0 to 2.0 V range from initially being either too high or too low. The second is if the battery pack temperature moved to within the programmed temperature range, but only from initially being too cold. Third is by cycling $\mathrm{V}_{\mathrm{CC}}$ off and then back on causing the internal logic to reset. A concise description of the major circuit blocks is given below.

## Negative Slope Voltage Detection

A representative block diagram of the negative slope voltage detector is shown in Figure 10. It includes a Synchronous Voltage to Frequency Converter, a Sample Timer, and a Ratchet Counter. The $\mathrm{V}_{\text {sen }}$ pin is the input for the Voltage to Frequency Converter (VFC), and it connects to the rechargeable battery pack terminals through a
resistive voltage divider. The input has an impedance of approximately $6.0 \mathrm{M} \Omega$ and a maximum voltage range of -1.0 V to $\mathrm{V}_{\mathrm{CC}}+0.6 \mathrm{~V}$ or 0 V to 10 V , whichever is lower. The 10 V upper limit is set by an internal zener clamp that provides protection in the event of an electrostatic discharge. The VFC is a charge-balanced synchronous type which generates output pulses at a rate of $\mathrm{F}_{\mathrm{V}}=\mathrm{V}_{\text {sen }}(24 \mathrm{kHz})$.

The Sample Timer circuit provides a 95 kHz system clock signal (SCK) to the VFC. This signal synchronizes the $\mathrm{F}_{\mathrm{V}}$ output to the other Sample Timer outputs used within the detector. At 1.38 second intervals the $\mathrm{V}_{\text {sen }}$ Gate output goes low for a 33 ms period. This output is used to momentarily interrupt the external charging power source so that a precise voltage measurement can be taken. As the $\mathrm{V}_{\text {sen }}$ Gate goes low, the internal Preset control line is driven high for 11 ms . During this time, the battery voltage at the $\mathrm{V}_{\text {sen }}$ input is allowed to stabilize and the previous $\mathrm{F}_{\mathrm{V}}$ count is preloaded. At the Preset high-to-low transition, the Convert line goes high for 22 ms . This gates the $\mathrm{F}_{\mathrm{V}}$ pulses into the ratchet counter for a comparison to the preloaded count. Since the Convert time is derived from the same clock that controls the VFC, the number of $F_{V}$ pulses is independent of the clock frequency. If the new sample has more counts than were preloaded, it becomes the new peak count and the cycle is repeated 1.38 seconds later. If the new sample has two fewer counts, a less than peak voltage event has occurred, and a register is initialized. If two successive less than peak voltage events occur, the $-\Delta \mathrm{V}$ 'AND' gate output goes high and the Fast/Trickle output is latched in a low state, signifying that the battery pack has reached full charge status.

## MC33340, MC33342

Negative slope voltage detection starts after 60 ms have elapsed in the fast charge mode. This does not affect the Fast/Trickle output until the holdoff time ( $\mathrm{t}_{\text {hold }}$ ) has elapsed during the fast charge mode. Two scenarios then exist. Trickle mode holdoff is implemented to ignore any initial drop in voltage that may occur when charging batteries that have been stored for an extended time period. If the negative slope voltage detector senses that initial drop during the holdoff time, and the input voltage rises as the battery charges, the Fast/Trickle output will remain open. However, if the negative slope voltage detector senses a negative drop
in voltage during the holdoff time and the input voltage never rises above that last detected level, the Fast/Trickle output will latch into a low state. The negative slope voltage detector has a maximum resolution of 2.0 V divided by 1023 , or 1.955 mV per count with an uncertainty of $\pm 1.0$ count. This yields a detection range of 1.955 mV to 5.865 mV . In order to obtain maximum sensing accuracy, the $\mathrm{R} 2 / \mathrm{R} 1$ voltage divider must be adjusted so that the $\mathrm{V}_{\text {sen }}$ input voltage is slightly less than 2.0 V when the battery pack is fully charged. Voltage variations due to temperature and cell manufacturing must be considered.

Figure 10. Negative Slope Voltage Detector

## Fast Charge Timer

A programmable backup charge timer is available for fast charge termination. The timer is activated by the Time/Temp Select comparator, and is programmed from the $\mathrm{t} 1 / \mathrm{T}_{\text {ref }}$ High, $\mathrm{t} 2 / \mathrm{T}_{\text {sen }}$, and $\mathrm{t} 3 / \mathrm{T}_{\text {ref }}$ Low inputs. If one or more of these inputs is allowed to go above $\mathrm{V}_{\mathrm{CC}}-0.7 \mathrm{~V}$ or is left open, the comparator output will switch high, indicating that the timer feature is desired. The three inputs allow one of seven possible fast charge time limits to be selected. The programmable time limits, rounded to the nearest whole minute, are shown in Figure 11.

## Over/Under Temperature Detection

A backup over/under temperature detector is available and can be used in place of the timer for fast charge termination. The timer is disabled by the Time/Temp Select comparator when each of the three programming inputs are held below $\mathrm{V}_{\mathrm{CC}}-0.7 \mathrm{~V}$.

Temperature sensing is accomplished by placing a negative temperature coefficient (NTC) thermistor in thermal contact with the battery pack. The thermistor connects to the $t 2 / \mathrm{T}_{\text {sen }}$ input which has a $30 \mu \mathrm{~A}$ current source pull-up for developing a temperature dependent voltage. The temperature limits are set by a resistor that connects from the $\mathrm{t} 1 / \mathrm{T}_{\text {ref }}$ High and the $\mathrm{t} 3 / \mathrm{T}_{\text {ref }}$ Low inputs to ground. Since all three inputs contain matched $30 \mu \mathrm{~A}$ current source pull-ups, the required programming resistor values are identical to that of the thermistor at the desired over and under trip temperature. The temperature window detector is composed of two comparators with a common input that connects to the $\mathrm{t} 2 / \mathrm{T}_{\text {sen }}$ input.

The lower comparator senses the presence of an under temperature condition. When the lower temperature limit is exceeded, the charger is switched to the trickle mode. The comparator has 44 mV of hysteresis to prevent erratic
switching between the fast and trickle modes as the lower temperature limit is crossed. The amount of temperature rise to overcome the hysteresis is determined by the thermistor's rate of resistance change or sensitivity at the under temperature trip point. The required resistance change is:

$$
\Delta \mathrm{R}\left(\mathrm{~T}_{\text {Low }} \rightarrow \mathrm{T}_{\text {High }}\right)=\frac{\mathrm{V}_{\mathrm{H}(\mathrm{~T})}}{\mathrm{I}_{\text {in }}}=\frac{44 \mathrm{mV}}{30 \mu \mathrm{~A}}=1.46 \mathrm{k}
$$

The resistance change approximates a thermal hysteresis of $2^{\circ} \mathrm{C}$ with a $10 \mathrm{k} \Omega$ thermistor operating at $0^{\circ} \mathrm{C}$. The under temperature fast charge inhibit feature can be disabled by biasing the $\mathrm{t} 3 / \mathrm{T}_{\text {ref }}$ Low input to a voltage that is greater than that present at $\mathrm{t} 2 / \mathrm{T}_{\text {sen }}$, and less than $\mathrm{V}_{\mathrm{CC}}-0.7 \mathrm{~V}$. Under extremely cold conditions, it is possible that the thermistor resistance can become too high, allowing the $\mathrm{t} 2 / \mathrm{T}_{\text {sen }}$ input to go above $\mathrm{V}_{\mathrm{CC}}-0.7 \mathrm{~V}$, and activate the timer. This condition can be prevented by placing a resistor in parallel with the thermistor. Note that the time/temperature threshold of $\mathrm{V}_{\mathrm{CC}}-0.7 \mathrm{~V}$ is a typical value at room temperature. Refer to the Electrical Characteristics table and to Figure 4 for additional information.

The upper comparator senses the presence of an over temperature condition. When the upper temperature limit is exceeded, the comparator output sets the Over Temperature Latch and the charger is switched to trickle mode. Once the latch is set, the charger cannot be returned to fast charge, even after the temperature falls below the limit. This feature prevents the battery pack from being continuously temperature cycled and overcharged. The latch can be reset
by removing and reconnecting the battery pack or by cycling the power supply voltage.

If the charger does not require either the time or temperature backup features, they can both be easily disabled. This is accomplished by biasing the $\mathrm{t} 3 / \mathrm{T}_{\text {ref }}$ Low input to a voltage greater than $\mathrm{t} 2 / \mathrm{T}_{\text {sen }}$, and by grounding the $\mathrm{t} 1 / \mathrm{T}_{\text {ref }}$ High input. Under these conditions, the Time/Temp Select comparator output is low, indicating that the temperature mode is selected, and that the $t 2 / T_{\text {sen }}$ input is biased within the limits of an artificial temperature window.

Charging of battery packs that are used in portable power tool applications typically use temperature as the only means for fast charge termination. The MC33340/342 can be configured in this manner by constantly resetting the $-\Delta \mathrm{V}$ detection logic. This is accomplished by biasing the $\mathrm{V}_{\text {sen }}$ input to $\approx 1.5 \mathrm{~V}$ from a two resistor divider that is connected between the positive battery pack terminal and ground. The $\mathrm{V}_{\text {sen }}$ Gate output is also connected to the $\mathrm{V}_{\text {sen }}$ input. Now, each time that the Sample Timer causes the $\mathrm{V}_{\text {sen }}$ output to go low, the $\mathrm{V}_{\text {sen }}$ input will be pulled below the undervoltage threshold of 1.0 V . This causes a reset of the $-\Delta \mathrm{V}$ logic every 1.38 seconds, thus disabling detection.

## Operating Logic

The order of events in the charging process is controlled by the logic circuitry. Each event is dependent upon the input conditions and the chosen method of charge termination. A table summary containing all of the possible operating modes is shown in Figure 12.

| $\qquad$ | Programming Inputs |  |  | Time Limit Fast Charge (Minutes) |
| :---: | :---: | :---: | :---: | :---: |
|  | $\begin{gathered} \mathrm{t} 3 / \mathrm{T}_{\text {ref }} \text { Low } \\ \text { (Pin 5) } \end{gathered}$ | t2/T sen <br> (Pin 6) | $t 1 / T_{\text {ref }}$ High (Pin 7) |  |
| Time | Open | Open | Open | 283 |
| Time | Open | Open | Gnd | 247 |
| Time | Open | Gnd | Open | 212 |

Figure 11. Fast Charge Backup Termination Time/Temperature Limit

| Input Condition | Controller Operation |
| :---: | :---: |
| $\mathrm{V}_{\text {sen }}$ Input Voltage: <br> $>1.0 \mathrm{~V}$ and $<2.0 \mathrm{~V}$ | The divided down battery pack voltage is within the fast charge voltage range. The charger switches from trickle to fast charge mode as $\mathrm{V}_{\text {sen }}$ enters this voltage range, and a reset pulse is then applied to the timer and the over temperature latch. |
| $>1.0 \mathrm{~V}$ and $<2.0 \mathrm{~V}$ with two consecutive $-\Delta \mathrm{V}$ events detected after 160 s $<1.0 \mathrm{~V}$ or $>2.0 \mathrm{~V}$ | The battery pack has reached full charge and the charger switches from fast to a latched trickle mode. A reset pulse must be applied for the charger to switch back to the fast mode. The reset pulse occurs when entering the 1.0 V to 2.0 V window for $\mathrm{V}_{\text {sen }}$ or when $\mathrm{V}_{\mathrm{CC}}$ rises above 3.0 V . |
|  | The divided down battery pack voltage is outside of the fast charge voltage range. The charger switches from fast to trickle mode. |
| Timer Backup: Within time limit Beyond time limit | The timer has not exceeded the programmed limit. The charger will be in fast charge mode if $\mathrm{V}_{\text {sen }}$ and $\mathrm{V}_{\mathrm{CC}}$ are within their respective operating limits. |
|  | The timer has exceeded the programmed limit. The charger switches from fast to a latched trickle mode. |
| Temperature Backup: Within limits | The battery pack temperature is within the programmed limits. The charger will be in fast charge mode if $V_{\text {sen }}$ and $V_{C C}$ are within their respective operating limits. |
| Below lower limit | The battery pack temperature is below the programmed lower limit. The charger will stay in trickle mode until the lower temperature limit is exceeded. When exceeded, the charger will switch from trickle to fast charge mode. |
| Above upper limit | The battery pack temperature has exceeded the programmed upper limit. The charger switches from fast to a latched trickle mode. A reset signal must be applied and then released for the charger to switch back to the fast charge mode. The reset pulse occurs when entering the 1.0 V to 2.0 V window for $\mathrm{V}_{\text {sen }}$ or when $\mathrm{V}_{\mathrm{Cc}}$ rises above 3.0 V . |
| Power Supply Voltage: <br> $\mathrm{V}_{\mathrm{CC}}>3.0 \mathrm{~V}$ and $<18 \mathrm{~V}$ $\mathrm{V}_{\mathrm{CC}}>0.6 \mathrm{~V} \text { and }<2.8 \mathrm{~V}$ | This is the nominal power supply operating voltage range. The charger will be in fast charge mode if $\mathrm{V}_{\text {sen }}$, and temperature backup or timer backup are within their respective operating limits. |
|  | The undervoltage lockout comparator will be activated and the charger will be in trickle mode. A reset signal is applied to the timer and over temperature latch. |

Figure 12. Controller Operating Mode Table

## Testing

Under normal operating conditions, it would take 283 minutes to verify the operation of the 34 stage ripple counter used in the timer. In order to significantly reduce the test time, three digital switches were added to the circuitry and are used to bypass selected divider stages. Entering each of the test modes without requiring additional package pins or affecting normal device operation proved to be challenging. Refer to the timer functional block diagram in Figure 13.

Switch 1 bypasses 19 divider stages to provide a 524,288 times speedup of the clock. This switch is enabled when the $\mathrm{V}_{\text {sen }}$ input falls below 1.0 V . Verification of the programmed fast charge time limit is accomplished by measuring the propagation delay from when the $\mathrm{V}_{\text {sen }}$ input falls below 1.0 V , to when the $\mathrm{F} / \mathrm{T}$ output changes from a high-to-low state. The 71, 106, 141, 177, 212, 247 and 283 will now correspond to $8.1,12.1,16.2,20.2,24.3,28.3$ and 32.3 ms delays. It is possible to enter this test mode during operation if the equivalent battery pack voltage was to fall below 1.0 V . This will not present a problem since the device would normally switch from fast to trickle mode under these
conditions, and the relatively short variable time delay would be transparent to the user.
Switch 2 bypasses 11 divider stages to provide a 2048 times speedup of the clock. This switch is necessary for testing the 19 stages that were bypassed when switch 1 was enabled. Switch 2 is enabled when the $\mathrm{V}_{\text {sen }}$ input falls below 1.0 V and the $\mathrm{t} / \mathrm{T}_{\text {ref }}$ High input is biased at -100 mV . Verification of the 19 stages is accomplished by measuring a nominal propagation delay of 338.8 ms from when the $\mathrm{V}_{\text {sen }}$ input falls below 1.0 V , to when the $\mathrm{F} / \mathrm{T}$ output changes from a high-to-low state.
Switch 3 is a dual switch consisting of sections "A" and "B". Section "A" bypasses 5 divider stages to provide a 32 times speedup of the $\mathrm{V}_{\text {sen }}$ gate signal that is used in sampling the battery voltage. This speedup allows faster test verification of two successive $-\Delta V$ events. Section "B" bypasses 11 divider stages to provide a 2048 speedup of the trickle mode holdoff timer. Switches 3A and 3B are both activated when the $t 1 / T_{\text {ref }}$ High input is biased at -100 mV with respect to Pin 4.

Figure 13. Timer Functional Block Diagram

This application combines the MC33340/342 with an adjustable three terminal regulator to form an isolated secondary side battery charger. Regulator IC2 operates as a constant current source with R7 setting the fast charge level. The trickle charge level is set by R5. The R2/R1 divider should be adjusted so that the $\mathrm{V}_{\text {sen }}$ input is less than 2.0 V when the batteries are fully charged. The printed circuit board shown below will accept the several TO-220 style heatsinks for IC2 and are all manufactured by AAVID Engineering Inc.

Figure 15. Printed Circuit Board and Component Layout
(Circuit of Figure 14)

The MC33340/342 can be combined with any of the devices in the UC3842 family of current mode controllers to form a switch mode battery charger. In this example, optocouplers OC1 and OC2 are used to provide isolated control signals to the UC3842. During battery voltage sensing, OC2 momentarily grounds the Output/Compensation pin, effectively turning off the charger. When fast charge termination is reached, OC1 turns on, and grounds the lower side of R3. This reduces the peak switch current threshold of the Current Sense Comparator to a programmed trickle current level. For additional converter design information, refer to the UC3842 and UC3844 device family data sheets.

Figure 16. Line Isolated Switch Mode Charger

## MC33340, MC33342

The MC33340/342 can be used to control the MC34166 or MC34167 power switching regulators to produce an economical and efficient fast charger. These devices are capable of operating continuously in current limit with an input voltage range of 7.5 to 40 V . The typical charging current for the MC34166 and MC34167 is 4.3 A and 6.5 A respectively. Resistors R2 and R1 are used to set the battery pack fast charge float voltage. If precise float voltage control is not required, components R1, R2, R3 and C1 can be deleted, and Pin 1 must be grounded. The trickle current level is set by resistor R4. It is recommended that a redundant charge termination method be employed for end user protection. This is especially true for fast charger systems. For additional converter design information, refer to the MC34166 and MC34167 data sheets.

Figure 17. Switch Mode Fast Charger

## Power Supply Battery Charger Regulation Control Circuit

The MC33341 is a monolithic regulation control circuit that is specifically designed to close the voltage and current feedback loops in power supply and battery charger applications. This device features the unique ability to perform source high-side, load high-side, source low-side and load low-side current sensing, each with either an internally fixed or externally adjustable threshold. The various current sensing modes are accomplished by a means of selectively using the internal differential amplifier, inverting amplifier, or a direct input path. Positive voltage sensing is performed by an internal voltage amplifier. The voltage amplifier threshold is internally fixed and can be externally adjusted in all low-side current sensing applications. An active high drive output is provided to directly interface with economical optoisolators for isolated output power systems. This device is available in 8-lead dual-in-line and surface mount packages.

- Differential Amplifier for High-Side Source and Load Current Sensing
- Inverting Amplifier for Source Return Low-Side Current Sensing
- Non-Inverting Input Path for Load Low-Side Current Sensing
- Fixed or Adjustable Current Threshold in All Current Sensing Modes
- Positive Voltage Sensing in All Current Sensing Modes
- Fixed Voltage Threshold in All Current Sensing Modes
- Adjustable Voltage Threshold in All Low-Side Current Sensing Modes
- Output Driver Directly Interfaces with Economical Optoisolators
- Operating Voltage Range of 2.3 V to 16 V

## PIN FUNCTION DESCRIPTION

| Pin | Name | Description |
| :---: | :--- | :--- |
| 1 | Current Sense Input A | This multi-mode current sensing input can be used for either source high-side, load high-side, <br> source-return low-side, or load low-side sensing. It is common to a Differential Amplifier, Inverting <br> Amplifier, and a Noninverting input path. Each of these sensing paths indirectly connect to the <br> current sense input of the Transconductance Amplifier. This input is connected to the high potential <br> side of a current sense resistor when used in source high-side, load high-side, or load low-side <br> current sensing modes. In source return low-side current sensing mode, this pin connects to the low <br> potential side of a current sense resistor. |
| 2 | Current Threshold Adjust | The current sense threshold can be externally adjusted over a range of 0 V to 200 mV with respect <br> to Pin 4, or internally fixed at 200 mV by connecting Pin 2 to VCc. |
| 3 | Compensation | This pin is connected to a high impedance node within the transconductance amplifier and is made <br> available for loop compensation. It can also be used as an input to directly control the Drive Output. <br> An active low at this pin will force the Drive Output into a high state. |
| 4 | Ground | This pin is the regulation control IC ground. The control threshold voltages are with respect to this <br> pin. |
| 5 | Voltage Sense Input | This is the voltage sensing input of the Transconductance Amplifier. It is normally connected to the <br> power supply/battery charger output through a resistor divider. The input threshold is controlled by <br> Pin 6. |
| 6 | Current Sense Input B/ <br> Voltage Threshold Adjust | This is a dual function input that is used for either high-side current sensing, or as a voltage <br> threshold adjustment for Pin 5. This input is connected to the low potential side of a current sense <br> resistor when used in source high-side or load high-side current sensing modes. In all low-side <br> current sensing modes, Pin 6 is available as a voltage threshold adjustment for Pin 5. The threshold <br> can be externally adjusted over a range of 0 V to 1.2 V with respect to Pin 4, or internally fixed at <br> 1.2 V by connecting Pin 6 to VCc. |
| 7 | VCC | This is the positive supply voltage for the regulation control IC. The typical operating voltage range is <br> 2.3 V to 15 V with respect to Pin 4. |
| 8 | Drive Output | This is a source-only output that normally connects to a linear or switching regulator control circuit. <br> This output is capable of 15 mA, allowing it to directly drive an optoisolator in primary side control <br> applications where galvanic isolation is required. |

## INTRODUCTION

Power supplies and battery chargers require precise control of output voltage and current in order to prevent catastrophic damage to the system load. Many present day power sources contain a wide assortment of building blocks and glue devices to perform the required sensing for proper regulation. Typical feedback loop circuits may consist of a voltage and current amplifier, level shifting circuitry, summing circuitry and a reference. The MC33341 contains all of these basic functions in a manner that is easily adaptable to many of the various power source-load configurations.

## OPERATING DESCRIPTION

The MC33341 is an analog regulation control circuit that is specifically designed to simultaneously close the voltage and current feedback loops in power supply and battery charger applications. This device can control the feedback loop in either constant-voltage or constant-current mode with automatic crossover. A concise description of the integrated circuit blocks is given below. Refer to the block diagram in Figure 13.

## Transconductance Amplifier

A quad input transconductance amplifier is used to control the feedback loop. This amplifier has separate voltage and current channels, each with a sense and a threshold input. Within a given channel, if the sense input level exceeds that of the threshold input, the amplifier output is driven high. The channel with the largest difference between the sense and threshold inputs will set the output source current of the amplifier and thus dominate control of the feedback loop. The amplifier output appears at Pin 8 and is a source-only type that is capable of 15 mA .

A high impedance node within the transconductance amplifier is made available at Pin 3 for loop compensation. This pin can sink and source up to $10 \mu \mathrm{~A}$ of current. System stability is achieved by connecting a capacitor from Pin 3 to ground. The Compensation Pin signal is out of phase with respect to the Drive Output. By actively clamping Pin 3 low, the Drive Output is forced into a high state. This, in effect, will shutdown the power supply or battery charger, by forcing the output voltage and current regulation threshold down towards zero.

## Voltage Sensing

The voltage that appears across the load is monitored by the noninverting $\mathrm{V}_{\text {sen }}$ input of the transconductance amplifier. This voltage is resistively scaled down and connected to Pin 5. The threshold at which voltage regulation occurs is set by the level present at the inverting $\mathrm{V}_{\text {th }}$ input of the transconductance amplifier. This level is controlled by Pin 6. In source high-side and load high-side current sensing modes, Pin 6 must be connected to the low potential side of current sense resistor $\mathrm{R}_{\mathrm{S}}$. Under these conditions, the voltage regulation threshold is internally fixed at 1.2 V. In source return low-side and load low-side
current sensing modes, Pin 6 is available, and can be used to lower the regulation threshold of Pin 5. This threshold can be externally adjusted over a range of 0 V to 1.2 V with respect to the IC ground at Pin 4.

## Current Sensing

Current sensing is accomplished by monitoring the voltage that appears across sense resistor $\mathrm{R}_{\mathrm{S}}$, level shifting it with respect to Pin 4 if required, and applying it to the noninverting $\mathrm{I}_{\text {sen }}$ input of the transconductance amplifier. In order to allow for maximum circuit flexibility, there are three methods of current sensing, each with different internal paths.
In source high-side (Figures 13 and 14) and load high-side (Figures 17 and 18) current sensing, the Differential Amplifier is active with a gain of 1.0. Pin 1 connects to the high potential side of current sense resistor $\mathrm{R}_{\mathrm{S}}$ while Pin 6 connects to the low side. Logic circuitry is provided to disable the Differential Amplifier output whenever low-side current sensing is required. This circuit clamps the Differential Amplifier output high which disconnects it from the $I_{\text {sen }}$ input of the Transconductance Amplifier. This happens if Pin 1 is less than 1.2 V or if Pin 1 is less than Pin 6.
With source return low-side current sensing (Figures 15 and 16), the Inverting Amplifier is active with a gain of -1.0 . Pin 1 connects to the low potential side of current sense resistor $\mathrm{R}_{\mathrm{S}}$ while Pin 4 connects to the high side. Note that a negative voltage appears across $\mathrm{R}_{\mathrm{S}}$ with respect to Pin 4.
In load low-side current sensing (Figures 19 and 20) a Noninverting input path is active with a gain of 1.0. Pin 1 connects to the high potential side of current sense resistor $\mathrm{R}_{\mathrm{S}}$ while Pin 4 connects to the low side. The Noninverting input path lies from Pin 1, through the Inverting Amplifier input and feedback resistors R, to the cathode of the output diode. With load low-side current sensing, Pin 1 will be more positive than Pin 4, forcing the Inverting Amplifier output low. This causes the diode to be reverse biased, thus preventing the output stage of the amplifier from loading the input signal that is flowing through the feedback resistors.
The regulation threshold in all of the current sensing modes is internally fixed at 200 mV with Pin 2 connected to $\mathrm{V}_{\mathrm{CC}}$. Pin 2 can be used to externally adjust the threshold over a range of 0 to 200 mV with respect to the IC ground at Pin 4.

## Reference

An internal band gap reference is used to set the 1.2 V voltage threshold and 200 mV current threshold. The reference is initially trimmed to a $\pm 1.0 \%$ tolerance at $\mathrm{T}_{\mathrm{A}}=25^{\circ} \mathrm{C}$ and is guaranteed to be within $\pm 2.0 \%$ over an ambient operating temperature range of $-25^{\circ}$ to $85^{\circ} \mathrm{C}$.

## Applications

Each of the application circuits illustrate the flexibility of this device. The circuits shown in Figures 13 through 20 contain an optoisolator connected from the Drive Output at

Pin 8 to ground. This configuration is shown for ease of understanding and would normally be used to provide an isolated control signal to a primary side switching regulator controller. In non-isolated, primary or secondary side applications, a load resistor can be placed from Pin 8 to ground. This resistor will convert the Drive Output current to a voltage for direct control of a regulator.

In applications where excessively high peak currents are possible from the source or load, the load induced voltage
drop across $\mathrm{R}_{\mathrm{S}}$ could exceed 1.6 V. Depending upon the current sensing configuration used, this will result in forward biasing of either the internal $\mathrm{V}_{\mathrm{CC}}$ clamp diode, Pin 6, or the device substrate, Pin 1. Under these conditions, input series resistor R3 is required. The peak input current should be limited to 20 mA . Excessively large values for R3 will degrade the current sensing accuracy. Figure 21 shows a method of bounding the voltage drop across $\mathrm{R}_{\mathrm{S}}$ without sacrificing current sensing accuracy.

The above figure shows the MC33341 configured for source high-side current sensing allowing a common ground path between Load - and Source Return -. The Differential Amplifier inputs, Pins 1 and 6, are used to sense the load induced voltage drop that appears across resistor $\mathrm{R}_{\mathrm{S}}$. The internal voltage and current regulation thresholds are selected by the respective external connections of Pins 2 and 6 . Resistor R3 is required in applications where a high peak level of reverse current is possible if the source inputs are shorted. The resistor value should be chosen to limit the input current of the internal $\mathrm{V}_{\mathrm{Cc}}$ clamp diode to less than 20 mA . Excessively large values for R 3 will degrade the current sensing accuracy.

$$

$$

$$
\mathrm{R} 3=\frac{\left(\mathrm{I}_{\mathrm{pk}} \mathrm{R}_{\mathrm{S}}\right)-0.6}{0.02}
$$

Figure 20. Load Low-Side Current Sensing with Externally Adjustable Current and Voltage Thresholds

## MC33341

NOTE: An excessive load induced voltage across $R_{S}$ can occur if either the source input or load output is shorted. This voltage can easily be bounded with the addition of the diodes shown without degrading the current sensing accuracy. This bounding technique can be used in any of the MC33341 applications where high peak currents are anticipated.

Figure 21. Current Sense Resistor Bounding

NOTE: Multiple outputs can be controlled by summing the error signal into a common optoisolator. The converter output with the largest voltage or current error will dominate control of the feedback loop.

Figure 22. Multiple Output Current and Voltage Regulation

Figure 23. 10 V/1.0 A Constant-Voltage Constant-Current Regulator

Figure 23 shows the MC33341 configured as a source high-side constant-voltage constant-current regulator. The regulator is designed for an output voltage of 10 V at 1.0 A . Figure 24 shows the regulator's output characteristics as the load is varied. Source return low-side, load high-side, and load low-side configurations will each exhibit a nearly identical load regulation characteristic. A heatsink is required for the MTP2955 series pass element.

Figure 24. Output Load Regulation

Figure 25 shows that the MC33341 can be configured as a high-side constant-current constant-voltage switch mode charger. This circuit operates as a step down converter. With a nominal input voltage and output load current as stated above, the switching frequency is approximately 28 kHz with and an associated conversion efficiency of 86 percent. The switching frequency will vary with changes in input voltage and load current.

Figure 25. Constant-Current Constant-Voltage Switch Mode Charger

## NCP1500

## Advance Information Dual Mode PWM/Linear BUCK Converter

The NCP1500 is a dual mode converter that operates as either a pulse width modulated (PWM) buck converter or as a linear regulator. The converter automatically transitions between the two modes. The converter operates as a PWM when a synchronization signal is present at the sync input. The converter operates as a linear regulator in the absence of a synchronization signal. The PWM mode offers excellent performance at normal to heavy loads at the sacrifice of output ripple voltage. The linear mode offers excellent noise rejection at the sacrifice of system efficiency. The user is able to select which mode will give the best performance for a given operating condition. Internal protection features include thermal shutdown with hysteresis and cycle-by-cycle current limit in the PWM mode. Additionally, the converter transitions into PFM mode at very light loads if a synchronization signal is present and an output over voltage condition is detected.

## PWM Features

- Current Mode Control with Cycle-by-Cycle Current Limit
- Nominal Synchronization Frequency of 270 to 630 kHz
- Built-in Slope Compensation

## Linear Regulator Features

- Low Output Noise

## Overall Features

- Thermal Shutdown with Hysteresis
- Digitally Programmable Output Voltage Between 4 Voltages: $1.0,1.3,1.5$, and 1.8
- Fast Transient Response
- Input Voltage Range From 2.7 V to 5.4 V
- Space Saving Micro8 Package
- Low Shutdown Current of $0.18 \mu \mathrm{~A}$ Typical

Typical Applications

- Baseband Supplies for Portable Handsets
- PDAs
- Supplies for DSP Circuitry

## DETAILED OPERATING DESCRIPTION

## Introduction

The NCP1500 is a dual mode regulator intended for use in baseband supplies for portable equipment. Its unique features provide power to the baseband circuitry while, at the same time save valuable battery energy. When the handset is idle, the user can activate the linear regulator function. In this mode, the regulator provides a regulated low current, low noise output voltage keeping the baseband circuit biased. When the handset is in its normal operating mode, the regulator synchronizes to the baseband clock and turns into a switching regulator. This allows the regulator to provide efficient power to the baseband circuit.

## Operating Description

## Synchronization Protocol and Mode Selection

The NCP1500 has a SYNC input. The device operates at a fixed switch frequency determined by the frequency of the synchronization signal applied. The part automatically operates in PWM mode after synchronization pulses are present for several cycles, regardless of the pulse width. The NCP1500 will output 2 pulses when a sync signal is present. The first is a PWM pulse. This pulse 'sets' a latch that initiates output switch conduction. The width of this pulse controls the minimum on time in PWM mode. The second signal is a slope compensation ramp. A ramp signal is generated. This signal is summed with the current information before being fed into the PWM comparator. The purpose of this circuit is to provide stable operation at output switch duty cycles in excess of $50 \%$. The device automatically switches to linear mode when the SYNC signal is removed for approximately $6.0 \mu \mathrm{sec}$. It is recommended that the sync signal be externally pulled low to enable the linear mode. Pulling the pin high or open may cause portions of the circuit to remain active, increasing the total current consumption of the IC. The threshold level of the SYNC signal is typically 1.3 V . The duty cycle of the sync signal must be within 20 to $80 \%$.

Figure 3. Timing Diagram of the SYNC Signal

Figure 3 shows the waveform when the SYNC signal is applied. After several cycles, the MODE select changes and PWM operation is activated with the internal clock signal.

## Reference/Shutdown

The NCP1500 uses an internal reference, typically at 0.8 V . An external shutdown pin is provided. When this pin is pulled low, the reference and other circuitry are disabled, placing the part into a low quiescent current standby mode. In this mode, the pass device is off and the output voltage will be zero. The typical standby current is $0.18 \mu \mathrm{~A}$.

## Error Amplifier/Output Voltage Program

A fully compensated error amplifier is provided inside the NCP1500. No external circuitry is required to stabilize the operation of the NCP1500. The error amplifier provides an error signal to both the PWM circuit and the linear regulator circuit. The output of the error amplifier is directly connected to the linear regulator control circuit. However, the output of the error amplifier is connected first to a subtraction circuit before going to the input of the PWM comparator. The subtraction circuit is activated only during an over current condition. During this condition, a signal proportional to the amount of over current is subtracted from the error amplifier signal. This subtraction results in a lower signal applied to the PWM comparator, thus lowering the output duty cycle.
The output voltage is digitally programmable up to four voltages. Two program pins are provided to accomplish this task. The program pins control a mux, which switch a bank of resistors. The appropriate resistor bank is switched to the error amplifier input, depending on the program input. The following truth table can be used to program the output voltage:

| CB0 | CB1 | Output Voltage |
| :---: | :---: | :---: |
| 0 | 0 | 1.5 |
| 0 | 1 | 1.8 |
| 1 | 0 | 1.3 |
| 1 | 1 | 1.0 |

Both program pins are internally pulled low. Thus, if the input pins are left open, the output voltage will be 1.5 V .

## PWM Section

The PWM section consists of a PWM comparator, set dominant latch, slope compensation circuit, current sense circuit, and current limit circuit.

The NCP1500 operates as a current mode regulator in PWM mode. In this mode, a PWM pulse from the synchronization section initiates the output switch conduction. Output switch conduction is terminated when the peak inductor current reaches a threshold level established by the error amplifier. The output switch conduction duty cycle is allowed to go to $100 \%$ to increase transient load response when going from light load to heavy load.

A reset dominant latch is provided in the NCP1500. A 3 input OR gate controls the reset pin. Any one of the 3 inputs will terminate output switch conduction. Once terminated, output switch conduction cannot begin again until the next PWM pulse. Additionally, the output switch will not conduct until all 3 inputs reset to the same level. This means that the output can start to skip cycles or change to a 'PFM' mode of operation. One of the OR gate inputs can cause this

PFM mode, the over voltage detect input. Output switch conduction can begin at the next PWM cycle after the OVP input is reset.
Current mode controllers can exhibit an instability at duty cycles over $50 \%$. A slope compensation circuit is provided inside the NCP1500 to overcome the potential instability. Slope compensation consists of a ramp signal generated by the synchronization block and adding this to the current signal. The summed signal is then applied to the PWM comparator.
A current limit feature is provided in the PWM mode only. The current limit is set to allow peak switch current in excess of 800 mA . It is implemented as a cycle-by-cycle current limit. Each on-cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch transistor current buildup during conduction. An error signal is generated upon sensing an over-current condition. This signal is subtracted from the error amplifier output. This in turn reduces the PWM comparison threshold voltage, thus limiting the output duty cycle.

Figure 4. PWM Waveforms During Normal Operation

## Linear Mode Operation

The NCP1500 operates as a linear regulator if the synchronization signal is absent. The part is designed to provide up to 50 mA nominally in this mode. Transients of up to 100 mA can be accommodated if the thermal impact is low. The main output is in series with an external inductor. This can cause a lag in the transient response of the device
when going from light load to heavy load. A bypass transistor is incorporated to release the energy stored in the inductor in order to avoid oscillation within the operation range. ${ }^{\mathrm{PP}}$
The following figure shows the transient step load response of the NCP1500 in this mode of operation. NOTE: PP - Patent Pending

Figure 5. Load Transient Response in Linear Mode

## Over Voltage Protection

NCP1500 has an overvoltage protection circuit that protects the output during the PWM mode. Normally, in PWM mode, the output switch will conduct at the onset of every synchronization pulse. The minimum output duty cycle is $3 \%$. The output voltage will rise at minimum duty cycle and a light load or no load condition is present at the output. If the output rises more than $5 \%$ of the programmed
voltage, an overvoltage comparator will trip. This signal will reset the PWM latch and hold it in a reset condition until the output voltage decays below its threshold. The output will then be allowed to switch at the next synchronization pulse. This type of operation is usually referred to as PFM or skip mode operation.
The following figure is a simulation of the regulator during this condition:

Figure 6. Waveforms of PFM Mode Operation During Over Voltage

## Thermal Shutdown

Internal Thermal Shutdown circuitry is provided to protect the integrated circuit in the event at the maximum junction temperature is exceeded. When activated, typically at $150^{\circ} \mathrm{C}$, the PWM latch is reset and the linear regulator control circuitry is disabled. The thermal shutdown circuit is designed with $25^{\circ} \mathrm{C}$ of hysteresis. This means that the

PWM latch and the regulator control circuitry cannot be re-enabled until the die temperature drops by this amount. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended as a substitute for proper heatsinking. The NCP1500 is contained in the Micro8 package.

## CS5361

## Battery Charger Buck Controller

The CS5361 is a high voltage step down controller that provides a simple way to build a battery charger suited for various types of batteries. With an operating range of up to 30 V , it can be used to charge a multiple number of cells from a DC voltage, as is supplied by high AC-DC adapter voltages. Proprietary $\mathrm{I}^{2}$ architecture ensures full control over both Average and Peak charging currents. Independent voltage loop allows for precision regulation of the battery voltage. Average current outer control loop provides tight regulation and easy loop compensation while pulse by pulse inner control provides for fast response.

The CS5361 is designed to provide a high performance, full-featured battery charger that is simple to use. A 4.2 V reference with $0.8 \%$ tolerance can be used to implement $1.0 \%$ accurate output voltages. It also features an additional pulse-by-pulse current limit input to allow for fast output current control.

The CS5361 operates over a 7.0 V to 30 V range and is available in a 16 lead surface mount narrow body.

## Features

- Switching Regulator Controller
- Synchronous Buck Regulator Topology for High Efficiency
- Top Side P-Channel Allows High Input Voltage and Requires No Charge Pump
- Pulse-by-Pulse Inner Control Loop for Fast Response
- Programmable Peak Current Limit
- True Current Soft Start
- Clamped Gate-to-Source Voltage
- Oscillator
- Constant Frequency Design
- 100 kHz to 500 kHz Adjustable Frequency
- System Power Management
- Programmable UVLO
- $2.0 \mu \mathrm{~A}$ Sleep Mode Current (Typical)
- Bias Mode Uses Top Switch to Connect Battery to Load
$-4.2 \mathrm{~V} \pm 0.8 \%$ Reference Output
- Thermal Shutdown

PACKAGE PIN DESCRIPTION

| Package Pin \# |  |  |
| :---: | :---: | :---: |
| SO-16 | Pin Symbol | Function |
| 1 | ENABLE/UVLO | Shutdown input. Connect to $\mathrm{V}_{\mathbb{I N}}$ through a resistor divider to program minimum operating voltage. Pull below 2.5 V to shut down the IC. |
| 2 | OSC | Oscillator pin. Place resistor to GND to set the switching frequency. Enters bias mode when pulled above 2.75 V and the ENABLE/UVLO Input is low (PFET turned ON). |
| 3 | $\mathrm{V}_{\text {REF(IN) }}$ | Reference input of the voltage error amplifier. Connect to the built-in or external reference. |
| 4 | LGND | Logic Ground. IC Substrate Connection. |
| 5 | $\mathrm{I}_{\text {COMP }}$ | Current feedback compensation network. |
| 6 | $\mathrm{V}_{\text {REF }}$ | 4.2 V Reference output voltage. Capable of sourcing 3.0 mA . |
| 7 | $\mathrm{I}_{\text {AVG }}$ | Average current control loop input. Voltage at this pin sets average output current. |
| 8 | $\mathrm{V}_{\text {COMP }}$ | Voltage feedback compensation network. |
| 9 | $\mathrm{V}_{\mathrm{FB}}$ | Voltage feedback pin. Connect a resistor divider between output and this pin to set output voltage. |
| 10 | $I_{\text {PEAK }}$ | Peak current control loop input. This input is used to set peak value of the inductor ripple current. This pin can override average current loop setting. It can be used for fast current control. |
| 11 | IS- | Negative input of the current sense amplifier. |
| 12 | IS+ | Positive input of the current sense amplifier. |
| 13 | PGND | Power Ground. |
| 14 | GATE(L) | Low-Side FET Driver. This pin is capable of delivering peak currents of 1.0 A. |
| 15 | $\mathrm{V}_{\mathrm{CC}}$ | Input power supply pin or $\mathrm{V}_{\text {CC }}$ bias. |
| 16 | GATE(H) | High-Side FET Driver. This pin is capable of delivering peak currents of 1.0 A. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## Overview

The CS5361 battery charger controller has been designed with the flexibility to charge several types of batteries, such as Lithium Ion, Nickel Cadmium, Nickel Metal Hydride and Lead Acid. The differences in chemistry between different battery types result in differing charge requirements

Lithium Ion batteries are charged with a constant voltage, current limit supply. When the battery voltage is low, the charger operates in constant current mode. When the battery voltage reaches 4.2 V , the current begins to taper off and the charger enters into constant voltage mode until the current essentially reaches zero. Nickel Cadmium and Nickel Metal Hydride batteries can be charged with a constant current profile. Lead Acid batteries are charged with a constant voltage, current limiting supply or with a constant-current supply.

For a battery charger with the capability to charge all those battery types, at least two operation modes are required: constant current mode and constant voltage mode. Synchronous operation enables designs with greater than $94 \%$ efficiency to be realized.

## Control Method

## 1. Current Control

$I^{2}$ control scheme is employed to regulate the charging current. The sense resistor senses the inductor current. A low offset, high speed Current Sense amplifier with rail-to-rail inputs amplifies the voltage across the sense resistor. The output of the amplifier ( $\mathrm{I}_{\text {SENSE }}$ ), which is proportional to the inductor current, is used as feedback for two control loops. The DC level is used by the outer loop and is fed to the Average Current Error Amplifier. The Error Amplifier compares $\mathrm{I}_{\text {SENSE }}$ to an externally set reference voltage $\mathrm{I}_{\mathrm{AVG}}$ and generates a PWM control voltage $\mathrm{I}_{\text {COMP. }}$ Charger designers can use the $\mathrm{I}_{\text {COMP }}$ pin to design the compensation for the Average Current Amplifier. The current ripple is used as the ramp signal of the PWM comparator. $\mathrm{I}^{2}$ control has inherent compensation for duty cycle in response to line voltage or load changes. Changes in line and load conditions affect the inductor current. Because the ramp signal of the PWM comparator is generated from the inductor current, the duty cycle can be adjusted on a pulse by pulse basis. Since the fast PWM control loop handles transient response, a high gain, low bandwidth error amplifier can be used to improve DC accuracy, stability and noise immunity.

Figure 3. ${ }^{\mathbf{2}}$ Control Scheme

## 2. Voltage Control

Current mode voltage control method is used to regulate the voltage. The $\mathrm{V}_{\mathrm{FB}}$ pin monitors the battery voltage. A resistor divider is used to scale the voltage down to the reference level set at the $\mathrm{V}_{\text {REF(IN) }}$ pin. CS5361 provides a $4.2 \mathrm{~V} \pm 0.8 \%$ reference voltage which can obviate the need for a resistor network if charging a single 4.2 V cell. $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{REF}(\mathrm{IN})}$ are the two inputs of the Voltage Error Amplifier. The output $\mathrm{V}_{\text {COMP }}$ is compared with the ramp signal, which is generated from the inductor current, to adjust the duty cycle. Similar to $\mathrm{I}_{\text {COMP, }} \mathrm{V}_{\text {COMP }}$ provides user with compensation capability.

## Start-Up

CS5361 provides a controlled startup of regulator output current and voltage through the Error Amplifiers and external compensation networks. The capacitor at the $\mathrm{I}_{\text {COMP }}$ output provides true current soft start. As the capacitor charges up, the Average Current Error Amplifier signal increases. The output current of the regulator ramps up in a controlled manner. The compensation network at $\mathrm{V}_{\text {COMP }}$ has the similar function, which will prevent instantaneous switching of the output voltage.

## Oscillator

The battery charger controller is designed for constant frequency operation. The user can adjust the switching frequency from 100 kHz to 500 kHz by connecting a resistor from the OSC pin to GND. This function simplifies the
selection of external components and allows the user freedom to choose switching frequency.

## Gate Drivers GATE(H) and GATE(L)

In synchronous buck operation, $\operatorname{GATE}(\mathrm{H})$ and GATE(L) drive the high-side P -channel MOSFET and the low-side N -channel MOSFET respectively. The advantage of this circuit is that no charge pump is required. The low-side FET (the synchronous rectifier) behaves like a diode but has a smaller voltage drop and improves the efficiency. A 60 ns nonoverlap dead time is added between the time when the high-side FET is turned off and when the synchronous rectifier is turned on, and vice versa. This function effectively prevents crowbar currents during switching transitions.

## Gate Voltage Clamps

Internal clamps prevent driving the external power MOSFET gate voltages to levels higher than required for complete enhancement. This improves converter efficiency by reducing gate rise time, fall time, and the losses associated with the charge and discharge of gate capacitance.

## Bias Mode

When the battery is fully charged, the charger can be shut down externally by pulling the ENABLE/UVLO pin low. When the part is off and the OSC pin is pulled above 2.75 V , the charger will enter into Bias Mode. In Bias mode, the high-side PFET turns on and connect the battery to the load so that the battery starts discharging to the load.

## 100\% Duty Cycle

The maximum duty cycle of the CS5361 is $100 \%$. This feature is useful when the input voltage is marginally higher than the output voltage. If the battery voltage is very close to the input line voltage, the controller will simply go to $100 \%$ duty cycle.

## Slope Compensation

In both current and voltage controls, the sensed inductor current signal is used as the ramp of the PWM comparator to afford fast response to line and load variations. An artificial ramp signal with negative slope generated by the oscillator is added to the two negative inputs ( $\mathrm{V}_{\text {COMP }}$ and $\mathrm{I}_{\text {COMP }}$ ) of the PWM comparator to be compared with the ramp generated by the inductor current. The output of the PWM comparator is used to control the duty cycle. This method helps stabilize the system over the whole operation duty cycle range as well as minimize response time to output current changes.

## Error Amplifier Compensation

The outputs of the Average Current Error Amplifier and the Voltage Error Amplifier are available to users. Users have the freedom to design the compensation network to improve the dynamic characteristics such as transient response time, over/undershoot, and loop stability.

## Enable/Under-Voltage Lockout

The input voltage of the charger must remain above a certain level in order to work. Control is required to ensure that the charger will not start to operate without sufficient voltage. Under-Voltage Lockout provides this protection with a comparator, which compares the input to 2.5 V . The output of the comparator enables the charger's reference voltage, which in turn controls startup of the charger. The comparator's output also controls the high-side MOSFET so that the batteries will power the load when the charger is shut off. This pin also provides the function of manual shutdown by bringing the pin below 2.5 V . Chip current in the shutdown mode is only $2.0 \mu \mathrm{~A}$.

## Peak Current Control

The Peak Current Buffer Amplifier compares the current control signal (the output of the Average Current Error Amplifier) with a preset reference voltage, which can be set externally at pin IPEAK. When output of the Error Amplifier exceeds the limit, the output of the Peak Current Buffer Amplifier goes low and clamps current control signal. Therefore, the peak current control can override the average current control. In laptop computer systems, fast reducing the charge current is required to prevent overloading the input supply when the computer switches into active mode from sleep mode. On the other hand, a trickle charging mode is required in many battery chargers either to prevent over-discharged or fully charged cells from being damaged by constant-current charging. The current for trickle charging is usually much lower than that of constant-current charging. The Peak Current Control can be utilized to implement trickle charging mode without changing the setting of the average charging current.

## Input Current Limiting

An input current limiting function can be implemented externally using a dual op-amp, a sense resistor and several resistors and capacitors. The first op-amp is configured into a differential amplifier. The second op-amp compares the amplified input current signal with a reference voltage. The output is used to clamp the $\mathrm{I}_{\text {COMP }}$ pin voltage when input current exceeds the limit. See Figure 9 for detailed implementation.

Figure 4. Key Operation Waveforms

## DESIGN GUIDELINES

## 1. Selection of the Output Inductor

The value of the output inductor can be calculated based on the inductor ripple current requirement:

$$
\begin{equation*}
\mathrm{L}=(1.0-\mathrm{D}) \times \frac{\mathrm{TS}_{\mathrm{S}} \mathrm{VUT}}{\Delta \mathrm{I}_{\mathrm{L}}} \tag{52}
\end{equation*}
$$

where $\mathrm{V}_{\text {OUT }}$ is the output voltage; $\mathrm{T}_{\mathrm{S}}$ is the period of one switching cycle; $\Delta \mathrm{I}_{\mathrm{L}}$ is the peak-to-peak inductor ripple current given by design specification; and D is the duty cycle. Because both duty cycle and the output voltage change during charging operation, the designer should determine the maximum product of $(1.0-\mathrm{D})$ and $\mathrm{V}_{\text {OUT }}$ to calculate the inductance. The peak inductor current is given by:

$$
\begin{equation*}
\mathrm{I}, \mathrm{PEAK}=\mathrm{I}_{\mathrm{O}}+\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2.0} \tag{53}
\end{equation*}
$$

The peak current should not saturate the core of the inductor.

## 2. Selection of Output Capacitor

Both the output voltage ripple and the inductor current ripple determine the value of the output capacitance. The required minimum is given by:

$$
\begin{equation*}
\mathrm{C}=0.125 \times \frac{\Delta \mathrm{l}_{\mathrm{L} T \mathrm{~S}}}{\Delta \mathrm{~V}_{\mathrm{OUT}}} \tag{54}
\end{equation*}
$$

The capacitor ESR (Equivalent Series Resistance) of the capacitor also needs to be small enough to meet the ripple requirement.

$$
\begin{equation*}
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\Delta \mathrm{l}_{\mathrm{L}}} \tag{55}
\end{equation*}
$$

If the ESR obtained from the above equation is smaller than the ESR specified in the capacitor manufacturer's data
sheet; several capacitors should be paralleled. The number of capacitors is determined by:

$$
\begin{equation*}
\text { Number of Capacitors }=\frac{\text { ESRPER CAP }}{\text { ESRMAX }} \tag{56}
\end{equation*}
$$

## 3. Design of Resistor Divider for Voltage Sensing

Because the internal reference voltage is 4.2 V , which is equal to the voltage of one Lithium Ion battery cell, we have:

$$
\frac{\mathrm{R} 2}{\mathrm{R} 1+\mathrm{R} 2}=\frac{1.0}{\text { Cell Count }}
$$

The maximum input bias current of the Voltage Error Amplifier is $1.0 \mu \mathrm{~A}$, the resistor divider current should be much higher than that to ensure that there is sufficient bias current. For 4-cell charger, the output voltage is 16.8 V . If we choose $\mathrm{R} 1+\mathrm{R} 2=100 \mathrm{k} \Omega$, then

$$
\frac{16.8 \mathrm{~V}}{100 \mathrm{k} \Omega}=168 \mu \mathrm{~A} \gg 1.0 \mu \mathrm{~A}
$$

Therefore,

$$
\begin{equation*}
\mathrm{R} 2=\frac{100 \mathrm{k} \Omega}{\text { Cell Count }}, \mathrm{R} 1=100 \mathrm{k} \Omega-\mathrm{R} 2 \tag{57}
\end{equation*}
$$

R1 and R2 must be $\pm 0.1 \%$ precise resistors to meet the $\pm 1.0 \%$ overall charge voltage accuracy.

## 4. Design of Resistor Divider for Enable/Under-Voltage Lockout

The resistor divider should be so designed that the controller can be enabled at the required minimum input voltage.

$$
\frac{\mathrm{R} 4}{\mathrm{R} 3+\mathrm{R} 4}=\frac{2.5 \mathrm{~V}}{\mathrm{~V}_{\mathrm{IN}, \mathrm{MIN}}}
$$

The maximum bias current for this pin is also $1.0 \mu \mathrm{~A}$. The sum of R3 and R4 can also be chosen as $100 \mathrm{k} \Omega$, so

$$
\begin{equation*}
\mathrm{R} 4=\frac{100 \mathrm{k} \Omega \times 2.5 \mathrm{~V}}{\mathrm{VIN}, \mathrm{MIN}}, \mathrm{R} 3=100 \mathrm{k} \Omega-\mathrm{R} 4 \tag{58}
\end{equation*}
$$

## 5. Selection of Current Sense Resistor and Resistor Divider for Current Setting

The tolerance of the current sense resistor affects the accuracy of current regulation, so a sense resistor with $\pm 1.0 \%$ tolerance should be used. Since the Current Sense Amplifier is a high-speed, low voltage rail-to-rail amplifier, the value of the current sensing resistor should satisfy the following condition:

$$
\text { IPEAK } \times \text { RSENSE } \leq 125 \mathrm{mV}
$$

where 125 mV is the differential mode input range of the Current Sense Amplifier.

Therefore,

$$
\begin{equation*}
\text { RSENSE } \leq \frac{125 \mathrm{mV}}{\text { IPEAK }} \tag{59}
\end{equation*}
$$

After the value of current sense resistor is determined, the resistor divider for current setting can be designed.

$$
\frac{\mathrm{R} 6}{\mathrm{R} 5+\mathrm{R} 6}=\mathrm{IOUT} \times \text { RSENSE } \times \frac{25}{4.2 \mathrm{~V}}
$$

where IOUT is the target value of the output current.
The maximum bias current of the Current Error Amplifier is 1.0 mA . The voltage across the resistor divider is 4.2 V . If we choose $R 5+R 6=10 \mathrm{k} \Omega$, we have

$$
\frac{42}{10 \mathrm{k} \Omega}=420 \mu \mathrm{~A} \gg 1.0 \mu \mathrm{~A}
$$

Therefore,

$$
\begin{gather*}
\mathrm{R} 6=10 \mathrm{k} \Omega \times 25 \times \mathrm{IOUT} \times \frac{\mathrm{RSENSE}}{4.2 \mathrm{~V}},  \tag{60}\\
\mathrm{R} 5=10 \mathrm{k} \Omega-\mathrm{R} 6
\end{gather*}
$$

## 6. Design of Average Current Compensation Network

As mentioned before, there are two feedback loops in the $I^{2}$ control scheme. The slow outer loop provides tight regulation and easy loop compensation. The fast inner loop handles the transient response on a pulse-by-pulse basis. The design of the compensation network is based on the control-to-output transfer function with closed inner current feedback loop. In this case, "control" is the output of the Average Current Error Amplifier ( $\mathrm{I}_{\mathrm{COMP}}$ ) and "output" is the inductor current.

The approximate control-to-output transfer function for the Buck converter is given by:

$$
\begin{equation*}
\frac{\mathrm{I}_{\mathrm{L}}}{\mathrm{ICOMP}} \approx \frac{1.0+\mathrm{sC} \times(\mathrm{ESR}+\mathrm{R})}{\mathrm{R}_{\mathrm{l}}(1.0+\mathrm{sCR})\left[1.0+\mathrm{s} /\left(\omega_{\mathrm{n}} \mathrm{Q}\right)+\mathrm{s}^{2} / \omega_{\mathrm{n}}{ }^{2}\right]} \tag{61}
\end{equation*}
$$

where $R_{I}$ is the current sense gain, $\omega$ n is half of the switching frequency and

$$
\begin{equation*}
\mathrm{Q}=\frac{1.0}{\pi[(1.0+\mathrm{Se} / \mathrm{Sn}) \times(1.0-\mathrm{D})-0.5]} \tag{62}
\end{equation*}
$$

where Se is the slope of the external ramp signal and Sn is the inductor current up slope.

The transfer function is a third-order system with a double pole at half of the switching frequency and a low frequency pole. Because ESR of the output capacitor is usually very small compared to load resistor R , the zero and the low frequency pole can cancel out each other. The system degrades to second-order.

The compensation design for such a system becomes very easy. A single integrator pole gives the system high DC gain and makes it crossover with -1.0 slope. The Bode plot of the
closed loop control-to-output transfer function without and with compensation is shown in Figure 5.

Figure 5. Bode Plot of Control-to-Output Transfer Function

If a transconductance amplifier is used as the error amplifier, the integrator pole can be implemented by connecting a capacitor from the amplifier output to the ground. The compensation gain is given by:

$$
\begin{equation*}
\mathrm{F}_{\mathrm{C}}(\mathrm{~s})=\frac{\mathrm{G}}{(\mathrm{sCCOMP})} \tag{63}
\end{equation*}
$$

where G is the transconductance of the amplifier.
The total loop gain is

$$
\mathrm{T}(\mathrm{~s})=\frac{\mathrm{G}}{\mathrm{R}_{\boldsymbol{l}} \times \mathrm{sCCOMP}\left[1.0+\mathrm{s} /\left(\omega_{\mathrm{n}} \mathrm{Q}\right)+\mathrm{s}^{2} / \omega_{\mathrm{n}}^{2}\right]} \text { (64) }
$$

The value of the compensation capacitor $\mathrm{C}_{\text {COMP }}$ can be calculated if the crossover frequency is known. Generally, the crossover frequency should be chosen well below the switching frequency.

We can choose

$$
\mathrm{f} C O=1 / 6 \times \mathrm{fs}
$$

So

$$
\begin{equation*}
\mathrm{CCOMP}=\frac{\mathrm{G}}{\mathrm{R}_{\boldsymbol{l}} \times 2.0 \pi \mathrm{fCO}} \tag{65}
\end{equation*}
$$

## 7. Design of Voltage Compensation Network

For voltage, "control" is referred to the output of the Voltage Error Amplifier ( $\mathrm{V}_{\mathrm{COMP}}$ ) and "output" is the output voltage. The control-to-output transfer function with closed current loop is given by:
$\frac{V_{\text {OUT }}}{\mathrm{V}_{\mathrm{COMP}}} \approx \frac{\mathrm{R}(1.0+\mathrm{sC} \times \mathrm{ESR})}{\mathrm{R}_{\mathrm{l}}(1.0+\mathrm{sCR})\left[1.0+\mathrm{s} /\left(\omega_{\mathrm{n}} \mathrm{Q}\right)+\mathrm{s}^{2} / \omega_{\mathrm{n}}{ }^{2}\right]}$
Compare the above expression with equation (60), the transfer function of current mode voltage control has same poles as I ${ }^{2}$ control. The difference is the zero. For $\mathrm{I}^{2}$ control, the zero is determined by both ESR of the output capacitor and the load resistor and can be cancel out the low frequency pole. But for current mode voltage control, the zero is a high frequency ESR zero. The low frequency pole cannot be cancelled. So the system is third-order. The Bode plot of the control-to-output transfer function with closed current loop is illustrated in Figure 6

Figure 6. Bode Plot
For a transconductance error amplifier, a possible compensation network is shown in Figure 7. The compensation network has two poles and one zero.

Figure 7. Compensation Network
The compensation gain is given by:
$F(s)=\frac{G \times(1.0+\mathrm{sR} 1 \mathrm{C} 1)}{(\mathrm{C} 1+\mathrm{C} 2) \times \mathrm{s}[1.0+\mathrm{sR1C1C2} /(\mathrm{C} 1+\mathrm{C} 2)]}$
The integrator pole will give the system high DC gain. Use the zero to compensate the excessive phase delay caused by the low frequency pole of the control-to-output transfer function. The other pole of the compensation network should be placed around the ESR zero to make sure the amplitude decrease fast after the 0 dB crossover.

Figure 9. Additional Application Diagram, 16.8 V/2.0 A Four Cell Lithium-Ion Battery Charger with High Side Current Sensing and Input Current Limiting

## Single-Cell Lithium Ion Battery Charge Controller

The NCP1800 is a constant current, constant voltage (CCCV) lithium ion battery charge controller. The external sense resistor sets the full charging current, and the termination current is $10 \%$ of the full charge current $(0.1 \mathrm{C})$. The voltage is regulated at $\pm 1 \%$ during the final charge stage. There is virtually zero drain on the battery when the input power is removed.

## Features

- Integrated Voltage and Programmable Current Regulation
- Integrated Cell Conditioning for Deeply Discharged Cell
- Integrated End of Charge Detection
- Better than 1\% Voltage Regulation
- Charger Status Output for LED or Host Processor Interface
- Charge Interrupt Input
- Safety Shutoff for Removal of Battery
- Blocking Diode Not Required with PNP Transistor
- Adjustable Charge Current Limit
- Input Over and Under Voltage Lockout
- Micro8 Package

## Applications

- Cellular Phones, PDAs
- Handheld Equipments
- Battery Operated Portable Devices

Figure 1. Typical Application
This device contains 1015 transistors.

## Operation Descriptions

The NCP1800 is a linear lithium ion (Li-ion) battery charge controller and provides the necessary control functions for charging $\mathrm{Li}-\mathrm{ion}$ batteries precisely and safely. It features the constant current and constant voltage method (CCCV) of charging.

## Conditioning and Pre-charge Phase

The NCP1800 initiates a charging cycle upon toggling the COMP/DIS to LOW or application of the valid external power source (i.e. $\mathrm{V}_{\mathrm{UVLO}}<\mathrm{V}_{\mathrm{CC}}<\mathrm{V}_{\mathrm{OVLO}}$ ) with the Li-ion battery present or when the Li-ion battery is inserted. Before a charge cycle can begin, the battery conditions are verified to be within safe limits. The battery will not be charged when its voltage is less than 0.9 V or higher than $\mathrm{V}_{\text {SOVLO }}$.

Li-ion batteries can be easily damaged when fast charged from a completely discharged state. Also, a fully discharged Li-ion battery may indicate an abnormal battery condition. With the built-in safety features of the NCP1800, the Li-ion battery pre-charges (Pre-Charge Phase) at $10 \%$ of the full rated charging current $\left(\mathrm{I}_{\mathrm{REG}}\right)$ when the battery voltage is lower than $\mathrm{V}_{\text {PCTH }}$ and the CFLG pin is HIGH. Typically, the battery voltage reaches $\mathrm{V}_{\text {PCTH }}$ in a few minutes and then the Full Charge phase begins.

## Full Charge (Current Regulation) Phase

When the battery voltage reaches $\mathrm{V}_{\mathrm{PCTH}}$, the NCP1800 begins fast charging the battery with full rate charging current $\mathrm{I}_{\text {REG }}$. The NCP1800 monitors the charging current at the $I_{\text {SNS }}$ input pin by the voltage drop across a current sense resistor, $\mathrm{R}_{\text {SNS }}$, and the charging current is maintained at $I_{\text {REG }}$ by the pass transistor throughout the full charge phase.
$\mathrm{I}_{\text {REG }}$ is determined by $\mathrm{R}_{\text {SNS }}$ and $\mathrm{R}_{\text {ISEL }}$ with the following formula:

$$
\begin{gathered}
\text { IREG }=\frac{(1.19 \times 12 \mathrm{k})}{(\mathrm{RISEL} \times \mathrm{RSNS})} \\
\text { And with } \mathrm{R}_{\mathrm{ISEL}}=60 \mathrm{k} \text { and } \mathrm{R}_{\mathrm{SNS}}=0.4 \Omega, \mathrm{I}_{\mathrm{REG}}=0.6 \mathrm{~A} .
\end{gathered}
$$

Since the external P channel MOSFET or PNP transistor is used to regulate the current to charge the battery and operates in linear mode as a linear regulator, power is dissipated in the pass transistor. Designing with a very well regulated external adaptor (e.g. $5.1 \mathrm{~V} \pm 1 \%$ ) can help to minimize the heat dissipation in the pass transistor. Care must be taken in heat sink designing in enclosed environments such as inside the battery operated portables or cellular phones.

The Full Charge phase continues until the battery voltage reaches $V_{\text {REG }}$. The NCP1800 comes in two options with $\mathrm{V}_{\text {REG }}$ thresholds of 4.1 and 4.2 V .

## Final Charge (Voltage Regulation) Phase

Once the battery voltage reaches $\mathrm{V}_{\mathrm{REG}}$, the pass transistor is controlled to regulate the voltage across the battery and the Final Charge phase (constant voltage mode) begins. Once the charger is in the Final Charge phase, the charger maintains a regulated voltage and the charging current will begin to decrease and is dependent on the state of the charge of the battery. As the battery approaches a fully charged condition, the charge current falls to a very low value.

## Trickle Charge Phase

During the Final Charge phase, the charging current continues to decrease and the NCP1800 monitors the charging current through the current sense resistor $\mathrm{R}_{\text {SNS }}$. When the charging current decreases to such a level that $\mathrm{I}_{\text {SNS }}$ $<0.1 \mathrm{X}_{\mathrm{REG}}$, the CFLG pin is set to LOW and the Trickle Charge phase begins. The charger stays in the Trickle Charge phase until any fault modes are detected or the COMP/DIS pin is pulled low to start over the charging cycle.

Figure 17. Typical Application Circuit with PNP Transistor

Figure 18. Typical Application Circuit with P Channel MOSFET

## Selecting External Components

## External Adaptor Power Supply Voltage Selection

Since the NCP1800 is using a linear, charging algorithm, the efficiency is lower. Adapter voltage selection must be done carefully in order to minimize the heat dissipation. In general, the power supply input voltage should be around 5.0 to 6.0 V . The minimum input voltage should be chosen to minimize the heat dissipation in the system. Excessively high input voltages can cause too much heat dissipation and will complicate the thermal design in applications like cellular phones. With the overvoltage protection feature of the NCP1800, input voltages higher than 7.0 V will activate the overvoltage protection circuit and disconnect the power supply input to the battery and other circuitry.

For applications with the MBT35200,

$$
\begin{aligned}
\mathrm{V}_{\mathrm{IN}(\min )>}> & \text { Li-ion regulated voltage, } \\
& \mathrm{V}_{\mathrm{REG}}+\max \mathrm{V}_{\mathrm{CE}}(\text { sat })+\text { voltage drop of RSNS } \\
> & 4.2 \mathrm{~V}+0.15 \mathrm{~V}+(0.6 \mathrm{~A})(0.4 \Omega) \\
= & 4.59 \mathrm{~V} \simeq 4.6 \mathrm{~V},
\end{aligned}
$$

(there is no blocking diode required with PNP)
For applications with the NTGS3441T1,

$$
\begin{aligned}
\mathrm{V}_{\mathrm{IN}(\min )}> & \text { Li-ion regulated voltage }, \\
& \mathrm{V}_{\mathrm{REG}}+(0.6 \mathrm{~A})\left(\mathrm{RDS}_{\mathrm{DS}(\mathrm{ON}))}\right. \\
& +\mathrm{V}_{\mathrm{F}} \text { of Schottky Diode }+ \text { voltage drop of RSNS } \\
> & 4.2 \mathrm{~V}+(0.6 \mathrm{~A})(100 \mathrm{~m} \Omega)+0.38 \mathrm{~V} \\
& +(0.6 \mathrm{~A})(0.4 \Omega)=4.88 \mathrm{~V} \simeq 4.9 \mathrm{~V}
\end{aligned}
$$

Therefore, with the PMOS application, if the output voltage accuracy is $5 \%$, then a typ. $5.2 \mathrm{~V} \pm 5 \%$ output voltage adaptor must be used.

And for a very good regulated adaptor of accuracy 1\%, 5.0 $\mathrm{V} \pm 1 \%$ output voltage adaptor can then be used. It is obvious that if tighter tolerance adaptors are used, heat dissipation can be minimized by using lower nominal voltage adaptors.

## Pass Element Selection

The pass element used with the NCP1800 can either be a PNP transistor or a P channel MOSFET. The type and size of the pass transistor is determined by input-output
differential voltage, charging current, current sense resistor and the type of blocking diode used.
The selected pass element must satisfy the following criteria:

Drop across pass element $=$

$$
\mathrm{VIN}_{\mathrm{IN}}(\min )-\text { Li-ion regulated voltage }-\mathrm{V}_{\mathrm{F}}-\mathrm{I}_{\mathrm{REG}} \times \text { RSNS }
$$

With:

$$
\begin{aligned}
\mathrm{V}_{\mathrm{IN}(\min )} & =5.0 \mathrm{~V} \\
\mathrm{~V}_{\mathrm{REG}} & =4.2 \mathrm{~V} \\
\mathrm{I} \mathrm{REG} & =0.6 \mathrm{~A} \\
\mathrm{R} \text { SNS } & =0.4 \Omega
\end{aligned}
$$

Dropout across pass element $=$

$$
5.0 \mathrm{~V}-4.2 \mathrm{~V}-0.38 \mathrm{~V}-(0.6 \mathrm{~A})(0.4 \Omega)=0.18 \mathrm{~V}
$$

When using p-channel MOSFET's, max. $\mathrm{R}_{\mathrm{DS}(\text { on })}$ should be less than $(0.18 \mathrm{~V}) /(0.6 \mathrm{~A})=0.3 \Omega$ at 0.6 A . And in PNP applications, as the blocking diode is not required, the blocking diode forward voltage drop must be neglected in the calculation.

## External Output Capacitor

Any good quality output filter can be used, independent of the capacitor's minimum ESR. However, a $10 \mu \mathrm{~F}$ tantalum capacitor or electrolytic capacitor is recommended at the output to suppress fast ramping spikes at the $\mathrm{V}_{\text {SNS }}$ input and to ensure stability for 1.0 A at full range. The capacitor should be mounted with the shortest possible lead or track length to the VSNS and GND pins.

## Current Sense Resistor

The charging current can be set by the value of the current sense resistor as in the previous formula. Proper de-rating is advised when selecting the power dissipation rating of the resistor. If necessary, $\mathrm{R}_{\text {ISEL }}$ can also be changed for proper selection of the $\mathrm{R}_{\mathrm{SNS}}$ values. Take note of the recommended full-charge current ranges specified in the electrical characteristics section. Also notice the effect of RISEL on the accuracy of pre-charge current and end-of-charge detection as noted in Figures 10 and 12, respectively.

NCP345

## Over Voltage Protection IC

The NCP345 over-voltage protection circuit (OVP) protects sensitive electronic circuitry from over-voltage transients and power supply faults when used in conjunction with an external P -channel FET. The device is designed to sense an over-voltage condition and quickly disconnect the input voltage supply from the load before any damage can occur. The OVP consists of a precise voltage reference, a comparator with hysteresis, control logic, and a MOSFET gate driver. The OVP is designed on a robust BiCMOS process and is intended to withstand voltage transients up to 30 V .

The device is optimized for applications that have an external AC/DC adapter or car accessory charger to power the product and/or recharge the internal batteries. The nominal over-voltage threshold is 6.85 V so it is suitable for single cell Li-Ion applications as well as $3 / 4$ cell NiCD/NiMH applications.

## Features

- Over-Voltage Turn-Off Time of less than $1.0 \mu \mathrm{sec}$
- Accurate Voltage Threshold of 6.85 V (nominal)
- Under-Voltage Lockout Protection
- CNTRL Input Compatible with 1.8 V Logic Levels

## Typical Applications

- Cellular Phones
- Digital Cameras
- Portable Computers and PDAs
- Portable CD and other Consumer Electronics

## APPLICATION INFORMATION

Figure 8.

## Introduction

In many electronic products, an external AC/DC wall adapter is used to convert the AC line voltage into a regulated DC voltage or a current limited source. Line surges or faults in the adapter may result in over-voltage events that can damage sensitive electronic components within the product. This is becoming more critical as the operating voltages of many integrated circuits have been lowered due to advances in sub-micron silicon lithography. In addition, portable products with removable battery packs pose special problems since the pack can be removed at any time. If the user removes a pack in the middle of charging, a large transient voltage spike can occur which can damage the product. Finally, damage can result if the user plugs in the wrong adapter into the charging jack. The challenge of the product designer is to improve the robustness of the design and avoid situations where the product can be damaged due to un-expected, but unfortunately, likely events that will occur as the product is used.

## Circuit Overview

To address these problems, the protection system above has been developed consisting of the NCP345 Over Voltage Protection IC and a P-channel MOSFET switch such as the MGSF3441. The NCP345 monitors the input voltage and will not turn on the MOSFET unless the input voltage is within a safe operating window that has an upper limit of 7.05 V. A zener diode can be placed in parallel to the load to provide for secondary protection during the brief time that it takes for the NCP345 to detect the over-voltage fault and disconnect the MOSFET. The decision to use this secondary diode is a function of the charging currents expected, load capacitance across the battery, and the desired protection
voltage by analyzing the $\mathrm{dV} / \mathrm{dT}$ rise that occurs during the brief time it takes to turn-off the MOSFET. For battery powered applications, a low-forward voltage Schottky diode such as the MBRM120LT3 can be placed in series with the MOSFET to block the body diode of the MOSFET and prevent shorting the battery out if the input is accidentally shorted to ground. This provides additional voltage margin at the load since there is a small forward drop across this diode that reduces the voltage at the load.

When the protection circuit turns off the MOSFET, there can be a sudden rise in the input voltage of the device. This transient can be quite large depending on the impedance of the supply and the current being drawn from the supply at the time of an over-voltage event. This inductive spike can be clamped with a zener diode from IN to ground. This diode breakdown voltage should be well above the worst case supply voltage provided from the AC/DC adapter or Cigarette Lighter Adapter (CLA), since the zener is only intended to clamp the transient. The NCP345 is designed so that the IN and $\mathrm{V}_{\mathrm{CC}}$ pin can safely protect up to 25 V and withstand transients to 30 V . Since these spikes can be very narrow in duration, it is important to use a high bandwidth probe and oscilloscope when prototyping the product to verify the operation of the circuit under all the transient conditions. A similar problem can result due to contact bounce as the DC source is plugged into the product.
For portable products it is normal to have a capacitor to ground in parallel with the battery. If the product has a battery pack that is easily removable during charging, this scenario should be analyzed. Under that situation, the charging current will go into the capacitor and the voltage may rise rapidly depending on the capacitor value, the charging current and the power supply response time.

## Normal Operation

Figure 1 illustrates a typical configuration. The external adapter provides power to the protection system so the circuitry is only active when the adapter is connected. The OVP monitors the voltage from the charger and if the voltage exceeds a nominal voltage of 6.85 V , the OUT signal drives the gate of the MOSFET to within 1.0 V of VCC, thus turning off the FET and disconnecting the source from the load. The nominal time it takes to drive the gate to this state is 400 nsec ( 1.0 usec maximum for gate capacitance of $<12 \mathrm{nF}$ ). Typical turn off performance using the CNTRL input can be seen in Figure 6. The CNTRL input can also be used to interrupt charging and allow the microcontroller to measure the cell voltage under a normal condition to get a more accurate measure of the battery voltage. Once the over voltage is removed, the NCP345 will turn on the MOSFET. The turn on circuitry is designed to turn on the MOSFET more gradually to limit the in-rush current. Typical turn-on
performance is illustrated using the MGSF3441 in Figure 7. This characteristic is a function of the threshold of the MOSFET and will vary depending on the device characteristics such as the gate capacitance.

The OVP has an under voltage lockout (UVLO) circuit which disables the gate driver circuit until the UVLO senses that the VCC voltage is above 2.6 V . Once the UVLO has released the gate driver circuit, the OUT signal will stay high until the voltage on the IN is sensed. If the input voltage to IN is less than 6.85 V nominal, then the OUT signal will be driven LOW and the FET will be turned on so the source can be connected to the load.

There are three events that will cause the OVP to drive the gate of the FET to a HIGH state.

- Voltage on VCC falls below the UVLO threshold
- Voltage on IN rises above 6.85 V (nominal)
- CNTRL input is driven to a logic High

# INFORMATION FOR USING THE THIN SOT23-5 SURFACE MOUNT PACKAGE MINIMUM RECOMMENDED FOOTPRINT FOR SURFACE MOUNTED APPLICATIONS 

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to insure proper solder connection
interface between the board and the package. With the correct pad geometry, the packages will self align when subjected to a solder reflow process.

THIN SOT23-5

## THIN SOT23-5 POWER DISSIPATION

The power dissipation of the Thin SOT23-5 is a function of the pad size. This can vary from the minimum pad size for soldering to a pad size given for maximum power dissipation. Power dissipation for a surface mount device is determined by $\mathrm{T}_{\mathrm{J}(\max )}$, the maximum rated junction temperature of the die, $\mathrm{R}_{\theta \mathrm{JA}}$, the thermal resistance from the device junction to ambient, and the operating temperature, $\mathrm{T}_{\mathrm{A}}$. Using the values provided on the data sheet for the Thin SOT23-5 package, $\mathrm{P}_{\mathrm{D}}$ can be calculated as follows:

$$
P_{D}=\frac{T_{J(\max )}-T_{A}}{R_{\theta J A}}
$$

The values for the equation are found in the maximum ratings table on the data sheet. Substituting these values into the equation for an ambient temperature $\mathrm{T}_{\mathrm{A}}$ of $25^{\circ} \mathrm{C}$, one can calculate the power dissipation of the device which in this case is 400 milliwatts.

$$
P_{D}=\frac{150^{\circ} \mathrm{C}-25^{\circ} \mathrm{C}}{300^{\circ} \mathrm{C} / \mathrm{W}}=417 \text { milliwatts }
$$

The $300^{\circ} \mathrm{C} / \mathrm{W}$ for the Thin SOT23-5 package assumes the use of the recommended footprint on a glass epoxy printed circuit board to achieve a power dissipation of 417 milliwatts.

## SOLDERING PRECAUTIONS

The melting temperature of solder is higher than the rated temperature of the device. When the entire device is heated to a high temperature, failure to complete soldering within a short time could result in device failure. Therefore, the following items should always be observed in order to minimize the thermal stress to which the devices are subjected.

- Always preheat the device.
- The delta temperature between the preheat and soldering should be $100^{\circ} \mathrm{C}$ or less.*
- When preheating and soldering, the temperature of the leads and the case must not exceed the maximum temperature ratings as shown on the data sheet. When using infrared heating with the reflow soldering method, the difference shall be a maximum of $10^{\circ} \mathrm{C}$.
- The soldering temperature and time shall not exceed $260^{\circ} \mathrm{C}$ for more than 10 seconds.
- When shifting from preheating to soldering, the maximum temperature gradient shall be $5^{\circ} \mathrm{C}$ or less.
- After soldering has been completed, the device should be allowed to cool naturally for at least three minutes. Gradual cooling should be used as the use of forced cooling will increase the temperature gradient and result in latent failure due to mechanical stress.
- Mechanical stress or shock should not be applied during cooling.
*Soldering a device without preheating can cause excessive thermal shock and stress which can result in damage to the device.

## CS51411, CS51412, CS51413, CS51414

### 1.5 A, 260 kHz and 520 kHz, Low Voltage Buck Regulators with External Bias or Synchronization Capability

The CS5141X products are 1.5 A buck regulator ICs. These devices are fixed-frequency operating at 260 kHz and 520 kHz . The regulators use the $V^{2 \mathrm{TM}}$ control architecture to provide unmatched transient response, the best overall regulation and the simplest loop compensation for today's high-speed logic. These products accommodate input voltages from 4.5 V to 40 V .

The CS51411 and CS51413 contain synchronization circuitry. The CS51412 and CS51414 have the option of powering the controller from an external 3.3 V to 6.0 V supply in order to improve efficiency, especially in high input voltage, light load conditions.

The on-chip NPN transistor is capable of providing a minimum of 1.5 A of output current, and is biased by an external "boost" capacitor to ensure saturation, thus minimizing on-chip power dissipation. Protection circuitry includes thermal shutdown, cycle-by-cycle current limiting and frequency foldback. The CS51411 and CS51413 are functionally pin-compatible with the LT1375. The CS51412 and CS51414 are functionally pin-compatible with the LT1376.

## Features

- $\mathrm{V}^{2}$ Architecture Provides Ultra-Fast Transient Response, Improved Regulation and Simplified Design
- $2.0 \%$ Error Amp Reference Voltage Tolerance
- Switch Frequency Decrease of 4:1 in Short Circuit Conditions Reduces Short Circuit Power Dissipation
- BOOST Lead Allows "Bootstrapped" Operation to Maximize Efficiency
- Sync Function for Parallel Supply Operation or Noise Minimization
- Shutdown Lead Provides Power-Down Option
- $85 \mu \mathrm{~A}$ Quiescent Current During Power-Down
- Thermal Shutdown
- Soft Start
- Pin-Compatible with LT1375 and LT1376

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## $\mathrm{V}^{2}$ Control

The CS5141X family of buck regulators provides leading edge technology, a high level of integration and high operating frequencies allowing the layout of a switch-mode power supply in a very small board area. These devices are based on the proprietary $\mathrm{V}^{2}$ control architecture. $\mathrm{V}^{2}$ control uses the output voltage and its ripple as the ramp signal, providing an ease of use not generally associated with voltage or current mode control. Improved line regulation, load regulation and very fast transient response are also major advantages.

Figure 3. Buck Converter with $\mathrm{V}^{2}$ Control.
As shown in Figure 3, there are two voltage feedback paths in $\mathrm{V}^{2}$ control, namely FFB (Fast Feedback) and SFB(Slow Feedback). In FFB path, the feedback voltage connects directly to the PWM comparator. This feedback path carries the ramp signal as well as the output DC voltage. Artificial ramp derived from oscillator is added to the feedback signal to improve stability. The other feedback path SFB connects the feedback voltage to the error amplifier whose output $\mathrm{V}_{\mathrm{C}}$ feeds to the other input of the PWM comparator. In a constant frequency mode, the oscillator signal sets the output latch and turns on the switch S1. This starts a new switch cycle. The ramp signal, composed of both artificial ramp and output ripple, eventually comes across the $\mathrm{V}_{\mathrm{C}}$ voltage, and consequently resets the latch to turn off the switch. The switch S 1 will turn on again at the beginning of the next switch cycle. In a buck converter, the output ripple is determined by the ripple
current of the inductor L1 and the ESR (equivalent series resistor) of the output capacitor C 1.
The slope compensation signal is a fixed voltage ramp provided by the oscillator. Adding this signal eliminates subharmonic oscillation associated with the operation at duty cycle greater than $50 \%$. The artificial ramp also ensures the proper PWM function when the output ripple voltage is inadequate. The slope compensation signal is properly sized to serve it purposes without sacrificing the transient response speed.
Under load and line transient, not only the ramp signal changes, but more significantly the DC component of the feedback voltage varies proportionally to the output voltage. FFB path connects both signals directly to the PWM comparator. This allows instant modulation of the duty cycle to counteract any output voltage deviations. The transient response time is independent of the error amplifier bandwidth. This eliminates the delay associated with error amplifier and greatly improves the transient response time. The error amplifier is used here to ensure excellent DC accuracy.

## Error Amplifier

The CS5141X has a transconductance error amplifier, whose non-inverting input is connected to an Internal Reference Voltage generated from the on-chip regulator. The inverting input connects to the $\mathrm{V}_{\mathrm{FB}}$ pin. The output of the error amplifier is made available at the $\mathrm{V}_{\mathrm{C}}$ pin. A typical frequency compensation requires only a $0.1 \mu \mathrm{~F}$ capacitor connected between the $\mathrm{V}_{\mathrm{C}}$ pin and ground, as shown in Figure 1. This capacitor and error amplifier's output resistance (approximately $8.0 \mathrm{M} \Omega$ ) create a low frequency pole to limit the bandwidth. Since $V^{2}$ control does not require a high bandwidth error amplifier, the frequency compensation is greatly simplified.
The $\mathrm{V}_{\mathrm{C}}$ pin is clamped below Output High Voltage. This allows the regulator to recover quickly from over current or short circuit conditions.

## Oscillator and Sync Feature (CS51411 and CS51413 only)

The on-chip oscillator is trimmed at the factory and requires no external components for frequency control. The high switching frequency allows smaller external components to be used, resulting in a board area and cost savings. The tight frequency tolerance simplifies magnetic components selection. The switching frequency is reduced to $25 \%$ of the nominal value when the $\mathrm{V}_{\mathrm{FB}}$ pin voltage is below Frequency Foldback Threshold. In short circuit or over-load conditions, this reduces the power dissipation of the IC and external components.
An external clock signal can sync CS51411/CS51414 to a higher frequency. The rising edge of the sync pulse turns on the power switch to start a new switching cycle, as shown in Figure 4. There is approximately $0.5 \mu$ s delay between the
rising edge of the sync pulse and rising edge of the $\mathrm{V}_{\mathrm{SW}}$ pin voltage. The sync threshold is TTL logic compatible, and duty cycle of the sync pulses can vary from $10 \%$ to $90 \%$. The frequency foldback feature is disabled during the sync mode.

Figure 4. A CS51411 Buck Regulator is Synced by an External 350 kHz Pulse Signal

## Power Switch and Current Limit

The collector of the built-in NPN power switch is connected to the $\mathrm{V}_{\text {IN }}$ pin, and the emitter to the $\mathrm{V}_{\text {SW }}$ pin. When the switch turns on, the $\mathrm{V}_{\mathrm{SW}}$ voltage is equal to the $\mathrm{V}_{\mathrm{IN}}$ minus switch Saturation Voltage. In the buck regulator, the $\mathrm{V}_{\mathrm{SW}}$ voltage swings to one diode drop below ground when the power switch turns off, and the inductor current is commutated to the catch diode. Due to the presence of high pulsed current, the traces connecting the $\mathrm{V}_{\text {SW }}$ pin, inductor and diode should be kept as short as possible to minimize the noise and radiation. For the same reason, the input capacitor should be placed close to the $\mathrm{V}_{\text {IN }}$ pin and the anode of the diode.

The saturation voltage of the power switch is dependent on the switching current, as shown in Figure 5.

Figure 5. The Saturation Voltage of the Power Switch Increases with the Conducting Current

Members of the CS5141X family contain pulse-by-pulse current limiting to protect the power switch and external components. When the peak of the switching current reaches the Current Limit, the power switch turns off after the Current Limit Delay. The switch will not turn on until the next switching cycle. The current limit threshold is independent of switching duty cycle. The maximum load current, given by the following formula under continuous conduction mode, is less than the Current Limit due to the ripple current.

$$
\mathrm{IO}(\mathrm{MAX})=\mathrm{I}_{\mathrm{LI}} \mathrm{M}-\frac{\mathrm{V}_{\mathrm{O}}\left(\mathrm{~V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{O}}\right)}{2(\mathrm{~L})\left(\mathrm{V}_{\mathrm{IN}}\right)\left(\mathrm{f}_{\mathrm{S}}\right)}
$$

where:
$\mathrm{f}_{\mathrm{S}}=$ switching frequency,
$\mathrm{I}_{\mathrm{LIM}}=$ current limit threshold,
$\mathrm{V}_{\mathrm{O}}=$ output voltage,
$\mathrm{V}_{\mathrm{IN}}=$ input voltage,
$\mathrm{L}=$ inductor value.
When the regulator runs under current limit, the subharmonic oscillation may cause low frequency oscillation, as shown in Figure 6. Similar to current mode control, this oscillation occurs at the duty cycle greater than $50 \%$ and can be alleviated by using a larger inductor value. The current limit threshold is reduced to Foldback Current when the FB pin falls below Foldback Threshold. This feature protects the IC and external components under the power up or over-load conditions.

Figure 6. The Regulator in Current Limit

## BOOST Pin

The BOOST pin provides base driving current for the power switch. A voltage higher than $\mathrm{V}_{\text {IN }}$ provides required headroom to turn on the power switch. This in turn reduces IC power dissipation and improves overall system efficiency. The BOOST pin can be connected to an external boost-strapping circuit which typically uses a $0.1 \mu \mathrm{~F}$ capacitor and a 1N914 or 1N4148 diode, as shown in Figure 1. When the power switch is turned on, the voltage on the BOOST pin is equal to

$$
\mathrm{V}_{\mathrm{BOOST}}=\mathrm{V}_{\mathrm{IN}}+\mathrm{V}_{\mathrm{O}}-\mathrm{V}_{\mathrm{F}}
$$

where:
$\mathrm{V}_{\mathrm{F}}=$ diode forward voltage.
The anode of the diode can be connected to any DC voltage other than the regulated output voltage. However, the maximum voltage on the BOOST pin shall not exceed 40 V .

As shown in Figure 7, the BOOST pin current includes a constant 7.0 mA pre-driver current and base current proportional to switch conducting current. A detailed discussion of this current is conducted in Thermal Consideration section. A $0.1 \mu \mathrm{~F}$ capacitor is usually adequate for maintaining the Boost pin voltage during the on time.

Figure 7. The Boost Pin Current Includes 7.0 mA Pre-Driver Current and Base Current when the Switch is Turned On. The Beta Decline of the Power Switch Further Increases the Base Current at High Switching Current

BIAS Pin (CS51412 and CS51414 Only)
The BIAS pin allows a secondary power supply to bias the control circuitry of the IC. The BIAS pin voltage should be between 3.3 V and 6.0 V . If the BIAS pin voltage falls below that range, use a diode to prevent current drain from the BIAS pin. Powering the IC with a voltage lower than the regulator's input voltage reduces the IC power dissipation and improves energy transfer efficiency.

## Shutdown

The internal power switch will not turn on until the $\mathrm{V}_{\mathrm{IN}}$ pin rises above the Start Up Voltage. This ensures no switching until adequate supply voltage is provided to the IC.

The IC enters a sleep mode when the SHDNB pin is pulled below Shutdown Threshold Voltage. In the sleep mode, the power switch keeps open and the supply current reduces to Shutdown Quiescent Current. This pin has internal pull-up current. So when this pin is not used, leave the SHDNB pin open.

## Start-Up

During power up, the regulator tends to quickly charge up the output capacitors to reach voltage regulation. This gives
rise to an excessive in-rush current which can be detrimental to the inductor, IC and catch diode. In $\mathrm{V}^{2}$ control, the compensation capacitor provides Soft Start with no need for extra pin or circuitry. During the power up, the Output Source Current of the error amplifier charges the compensation capacitor which forces $\mathrm{V}_{\mathrm{C}}$ pin and thus output voltage ramp up gradually. The Soft Start duration can be calculated by

$$
\mathrm{TSS}=\frac{\mathrm{V}_{\mathrm{C}} \times \mathrm{C}_{\mathrm{COMP}}}{\mathrm{I}_{\text {SOURCE }}}
$$

where:
$\mathrm{V}_{\mathrm{C}}=\mathrm{V}_{\mathrm{C}}$ pin steady-state voltage, which is approximately equal to error amplifier's reference voltage.
$\mathrm{C}_{\mathrm{COMP}}=$ Compensation capacitor connected to the $\mathrm{V}_{\mathrm{C}}$ pin $I_{\text {SOURCE }}=$ Output Source Current of the error amplifier.
Using a $0.1 \mu \mathrm{~F} \mathrm{C}_{\mathrm{COMP}}$, the calculation shows a $\mathrm{T}_{\mathrm{SS}}$ over 5.0 ms which is adequate to avoid any current stresses. Figure 8 shows the gradual rise of the $\mathrm{V}_{\mathrm{C}}, \mathrm{V}_{\mathrm{O}}$ and envelope of the $\mathrm{V}_{\mathrm{SW}}$ during power up. There is no voltage over-shoot after the output voltage reaches the regulation. If the supply voltage rises slower than the $\mathrm{V}_{\mathrm{C}}$ pin, output voltage may over-shoot.

Figure 8. The Power Up Transition of CS5141X Regulator

## Short Circuit

When the $\mathrm{V}_{\mathrm{FB}}$ pin voltage drops below Foldback Threshold, the regulator reduces the peak current limit by $40 \%$ and switching frequency to $1 / 4$ of the nominal frequency. These features are designed to protect the IC and external components during over load or short circuit conditions. In those conditions, peak switching current is clamped to the current limit threshold. The reduced switching frequency significantly increases the ripple current, and thus lowers the DC current. The short circuit can cause the minimum duty cycle to be limited by Minimum Output Pulse Width. The foldback frequency reduces the minimum duty cycle by extending the switching cycle. This protects the IC from overheating, and also limits the power that can be transferred to the output. The current limit
foldback effectively reduces the current stress on the inductor and diode. When the output is shorted, the DC current of the inductor and diode can approach the current limit threshold. Therefore, reducing the current limit by $40 \%$ can result in an equal percentage drop of the inductor and diode current. The short circuit waveforms are captured in Figure 9, and the benefit of the foldback frequency and current limit is self-evident.

Figure 9. In Short Circuit, the Foldback Current and Foldback Frequency Limit the Switching Current to Protect the IC, Inductor and Catch Diode

## Thermal Considerations

A calculation of the power dissipation of the IC is always necessary prior to the adoption of the regulator. The current drawn by the IC includes quiescent current, pre-driver current, and power switch base current. The quiescent current drives the low power circuits in the IC, which include comparators, error amplifier and other logic blocks. Therefore, this current is independent of the switching current and generates power equal to

$$
W_{Q}=V_{I N} \times I_{Q}
$$

where:
$\mathrm{I}_{\mathrm{Q}}=$ quiescent current.
The pre-driver current is used to turn on/off the power switch and is approximately equal to 12 mA in worst case. During steady state operation, the IC draws this current from the Boost pin when the power switch is on and then receives it from the $\mathrm{V}_{\text {IN }}$ pin when the switch is off. The pre-driver current always returns to the $\mathrm{V}_{\mathrm{SW}}$ pin. Since the pre-driver current goes out to the regulator's output even when the power switch is turned off, a minimum load is required to prevent overvoltage in light load conditions. If the Boost pin voltage is equal to $\mathrm{V}_{\mathrm{IN}}+\mathrm{V}_{\mathrm{O}}$ when the switch is on, the power dissipation due to pre-driver current can be calculated by

$$
\mathrm{W}_{\mathrm{DRV}}=12 \mathrm{~mA} \times\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{O}}+\frac{\mathrm{V}_{\mathrm{O}}^{2}}{\mathrm{~V}_{\mathrm{IN}}}\right)
$$

The base current of a bipolar transistor is equal to collector current divided by beta of the device. Beta of 60 is used here
to estimate the base current. The Boost pin provides the base current when the transistor needs to be on. The power dissipated by the IC due to this current is

$$
W_{\mathrm{BASE}}=\frac{\mathrm{V}_{\mathrm{O}^{2}}}{\mathrm{~V}_{\mathrm{IN}}} \times \frac{\mathrm{IS}}{60}
$$

where:
$\mathrm{I}_{\mathrm{S}}=\mathrm{DC}$ switching current.
When the power switch turns on, the saturation voltage and conduction current contribute to the power loss of a non-ideal switch. The power loss can be quantified as

$$
\mathrm{W}_{\mathrm{SAT}}=\frac{\mathrm{v}_{\mathrm{O}}}{\mathrm{v}_{\text {IN }}} \times \mathrm{IS}_{\mathrm{S}} \times \mathrm{v}_{\text {SAT }}
$$

where:
$\mathrm{V}_{\mathrm{SAT}}=$ saturation voltage of the power switch which is shown in Figure 5.
The switching loss occurs when the switch experiences both high current and voltage during each switch transition. This regulator has a 30 ns turn-off time and associated power loss is equal to

$$
W_{S}=\frac{\mathrm{IS} \times \mathrm{V}_{\mathrm{IN}}}{2} \times 20 \mathrm{~ns} \times \mathrm{fS}
$$

The turn-on time is much shorter and thus turn-on loss is not considered here.

The total power dissipated by the IC is sum of all the above

$$
W_{I C}=W_{Q}+W_{D R V}+W_{B A S E}+W_{S A T}+W_{S}
$$

The IC junction temperature can be calculated from the ambient temperature, IC power dissipation and thermal resistance of the package. The equation is shown as follows,

$$
T_{J}=W_{I C} \times R_{\theta J A}+T_{A}
$$

The maximum IC junction temperature shall not exceed $125^{\circ} \mathrm{C}$ to guarantee proper operation and avoid any damages to the IC.

## Minimum Load Requirement

As pointed out in the previous section, a minimum load is required for this regulator due to the pre-driver current feeding the output. Placing a resistor equal to $\mathrm{V}_{\mathrm{O}}$ divided by 12 mA should prevent any voltage overshoot at light load conditions. Alternatively, the feedback resistors can be valued properly to consume 12 mA current.

## COMPONENT SELECTION

## Input Capacitor

In a buck converter, the input capacitor witnesses pulsed current with an amplitude equal to the load current. This pulsed current and the ESR of the input capacitors determine the $\mathrm{V}_{\text {IN }}$ ripple voltage, which is shown in Figure 10. For $\mathrm{V}_{\mathrm{IN}}$ ripple, low ESR is a critical requirement for the input capacitor selection. The pulsed input current possesses a significant AC component, which is absorbed by the input
capacitors. The RMS current of the input capacitor can be calculated using:

$$
I_{R M S}=I_{O} \sqrt{D(1-D)}
$$

where:
$\mathrm{D}=$ switching duty cycle which is equal to $\mathrm{V}_{\mathrm{O}} / \mathrm{V}_{\mathrm{IN}}$.
$\mathrm{I}_{\mathrm{O}}=$ load current.

Figure 10. Input Voltage Ripple in a Buck Converter
To calculate the RMS current, multiply the load current with the constant given by Figure 11 at each duty cycle. It is a common practice to select the input capacitor with an RMS current rating more than half the maximum load current. If multiple capacitors are paralleled, the RMS current for each capacitor should be the total current divided by the number of capacitors.

Figure 11. Input Capacitor RMS Current can be Calculated by Multiplying Y Value with Maximum Load Current at any Duty Cycle
Selecting the capacitor type is determined by each design's constraint and emphasis. The aluminum electrolytic capacitors are widely available at lowest cost. Their ESR and ESL (equivalent series inductor) are relatively high. Multiple capacitors are usually paralleled to achieve lower ESR. In addition, electrolytic capacitors usually need to be paralleled with a ceramic capacitor for filtering high frequency noises. The OS-CON are solid aluminum electrolytic capacitors, and therefore has a much lower ESR. Recently, the price of the OS-CON capacitors has dropped significantly so that it is now feasible to use them for some low cost designs. Electrolytic capacitors are physically large, and not used in applications where the size, and especially height is the major concern.

Ceramic capacitors are now available in values over $10 \mu \mathrm{~F}$. Since the ceramic capacitor has low ESR and ESL, a single ceramic capacitor can be adequate for both low frequency and high frequency noises. The disadvantage of ceramic capacitors are their high cost. Solid tantalum capacitors can have low ESR and small size. However, the reliability of the tantalum capacitor is always a concern in the application where the capacitor may experience surge current.

## Output Capacitor

In a buck converter, the requirements on the output capacitor are not as critical as those on the input capacitor. The current to the output capacitor comes from the inductor and thus is triangular. In most applications, this makes the RMS ripple current not an issue in selecting output capacitors.

The output ripple voltage is the sum of a triangular wave caused by ripple current flowing through ESR, and a square wave due to ESL. Capacitive reactance is assumed to be
small compared to ESR and ESL. The peak to peak ripple current of the inductor is:

$$
\mathrm{IP}-\mathrm{P}=\frac{\mathrm{V}_{\mathrm{O}}\left(\mathrm{~V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{O}}\right)}{\left(\mathrm{V}_{\mathrm{IN}}\right)(\mathrm{L})\left(\mathrm{fS}_{\mathrm{S}}\right)}
$$

$\mathrm{V}_{\text {RIPPLE(ESR) }}$, the output ripple due to the ESR, is equal to the product of $\mathrm{I}_{\mathrm{P}-\mathrm{P}}$ and ESR. The voltage developed across the ESL is proportional to the di/dt of the output capacitor. It is realized that the $\mathrm{di} / \mathrm{dt}$ of the output capacitor is the same as the di/dt of the inductor current. Therefore, when the switch turns on, the di/dt is equal to $\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{O}}\right) / \mathrm{L}$, and it becomes $\mathrm{V}_{\mathrm{O}} / \mathrm{L}$ when the switch turns off. The total ripple voltage induced by ESL can then be derived from

$$
\mathrm{V}_{\mathrm{RIPPLE}(E S L)}=\operatorname{ESL}\left(\frac{\mathrm{V}_{\mathrm{IN}}}{\mathrm{~L}}\right)+\operatorname{ESL}\left(\frac{\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{O}}}{\mathrm{~L}}\right)=\operatorname{ESL}\left(\frac{\mathrm{V}_{\text {IN }}}{\mathrm{L}}\right)
$$

The total output ripple is the sum of the $V_{\text {RIPPLE(ESR) }}$ and $V_{\text {RIPPLE(ESR) }}$.

Figure 12. The Output Voltage Ripple Using Two $10 \mu \mathrm{~F}$ Ceramic Capacitors in Parallel

Figure 13. The Output Voltage Ripple Using One $100 \mu \mathrm{~F}$ POSCAP Capacitor

Figure 14. The Output Voltage Ripple Using One $100 \mu$ F OS-CON

Figure 15. The Output Voltage Ripple Using One $100 \mu \mathrm{~F}$ Tantalum Capacitor
Figure 12 to Figure 15 show the output ripple of a 5.0 V to $3.3 \mathrm{~V} / 500 \mathrm{~mA}$ regulator using $22 \mu \mathrm{H}$ inductor and various capacitor types. At the switching frequency, the low ESR and ESL make the ceramic capacitors behave capacitively as shown in Figure 12. Additional paralleled ceramic capacitors will further reduce the ripple voltage, but inevitably increase the cost. "POSCAP", manufactured by SANYO, is a solid electrolytic capacitor. The anode is sintered tantalum and the cathode is a highly conductive polymerized organic semiconductor. TPC series, featuring low ESR and low profile, is used in the measurement of Figure 13. It is shown that POSCAP presents a good balance of capacitance and ESR, compared with a ceramic capacitor. In this application, the low ESR generates less than 5.0 mV of ripple and the ESL is almost unnoticeable. The ESL of the through-hole OS-CON capacitor give rise to the inductive impedance. It is evident from Figure 14 which shows the
step rise of the output ripple on the switch turn-on and large spike on the switch turn-off. The ESL prevents the output capacitor from quickly charging up the parasitic capacitor of the inductor when the switch node is pulled below ground through the catch diode conduction. This results in the spike associated with the falling edge of the switch node. The D package tantalum capacitor used in Figure 15 has the same footprint as the POSCAP, but doubles the height. The ESR of the tantalum capacitor is apparently higher than the POSCAP. The electrolytic and tantalum capacitors provide a low-cost solution with compromised performance. The reliability of the tantalum capacitor is not a serious concern for output filtering because the output capacitor is usually free of surge current and voltage.

## Diode Selection

The diode in the buck converter provides the inductor current path when the power switch turns off. The peak reverse voltage is equal to the maximum input voltage. The peak conducting current is clamped by the current limit of the IC. The average current can be calculated from:

$$
\mathrm{ID}(\mathrm{AVG})=\frac{\mathrm{IO}\left(\mathrm{~V}_{\mathrm{IN}}+\mathrm{V}_{\mathrm{O}}\right)}{\mathrm{V}_{\mathrm{IN}}}
$$

The worse case of the diode average current occurs during maximum load current and maximum input voltage. For the diode to survive the short circuit condition, the current rating of the diode should be equal to the Foldback Current Limit. See Table 4 for schottky diodes from ON Semiconductor which are suggested for CS5141X regulator.
height, output ripple, EMI, saturation and cost. Lower inductor values are chosen to reduce the physical size of the inductor. Higher value cuts down the ripple current, core losses and allows more output current. For most applications, the inductor value falls in the range between $2.2 \mu \mathrm{H}$ and $22 \mu \mathrm{H}$. The saturation current ratings of the inductor shall not exceed the $\mathrm{I}_{\mathrm{L}(\mathrm{PK})}$, calculated according to

$$
\mathrm{I}_{\mathrm{L}(\mathrm{PK})}=\mathrm{I}_{\mathrm{O}}=+\frac{\mathrm{V}_{\mathrm{O}}\left(\mathrm{~V}_{\mathrm{IN}}+\mathrm{V}_{\mathrm{O}}\right)}{2(\mathrm{fS})(\mathrm{L})\left(\mathrm{V}_{\mathrm{IN}}\right)}
$$

The DC current through the inductor is equal to the load current. The worse case occurs during maximum load current. Check the vendor's spec to adjust the inductor value under current loading. Inductors can lose over $50 \%$ of inductance when it nears saturation.

The core materials have a significant effect on inductor performance. The ferrite core has benefits of small physical size, and very low power dissipation. But be careful not to operate these inductors too far beyond their maximum ratings for peak current, as this will saturate the core. Powered Iron cores are low cost and have a more gradual saturation curve. The cores with an open magnetic path, such as rod or barrel, tend to generate high magnetic field radiation. However, they are usually cheap and small. The cores providing a close magnetic loop, such as pot-core and toroid, generate low electro-magnetic interference (EMI).
There are many magnetic component vendors providing standard product lines suitable for CS5141X. Table 5 lists three vendors, their products and contact information.

## Inductor Selection

When choosing inductors, one might have to consider maximum load current, core and copper losses, component

## LM2574

### 0.5 A, Adjustable Output Voltage, Step-Down Switching Regulator

The LM2574 series of regulators are monolithic integrated circuits ideally suited for easy and convenient design of a step-down switching regulator (buck converter). All circuits of this series are capable of driving a 0.5 A load with excellent line and load regulation. These devices are available in fixed output voltages of $3.3 \mathrm{~V}, 5.0 \mathrm{~V}$, $12 \mathrm{~V}, 15 \mathrm{~V}$, and an adjustable output version.

These regulators were designed to minimize the number of external components to simplify the power supply design. Standard series of inductors optimized for use with the LM2574 are offered by several different inductor manufacturers.

Since the LM2574 converter is a switch-mode power supply, its efficiency is significantly higher in comparison with popular three-terminal linear regulators, especially with higher input voltages. In most cases, the power dissipated by the LM2574 regulator is so low, that the copper traces on the printed circuit board are normally the only heatsink needed and no additional heatsinking is required.

The LM2574 features include a guaranteed $\pm 4 \%$ tolerance on output voltage within specified input voltages and output load conditions, and $\pm 10 \%$ on the oscillator frequency ( $\pm 2 \%$ over $0^{\circ} \mathrm{C}$ to $+125^{\circ} \mathrm{C}$ ). External shutdown is included, featuring $60 \mu \mathrm{~A}$ (typical) standby current. The output switch includes cycle-by-cycle current limiting, as well as thermal shutdown for full protection under fault conditions.

## Features

- 3.3 V, 5.0 V, $12 \mathrm{~V}, 15 \mathrm{~V}$, and Adjustable Output Versions
- Adjustable Version Output Voltage Range, 1.23 to $37 \mathrm{~V} \pm 4 \%$ max over Line and Load Conditions
- Guaranteed 0.5 A Output Current
- Wide Input Voltage Range: 4.75 to 40 V
- Requires Only 4 External Components
- 52 kHz Fixed Frequency Internal Oscillator
- TTL Shutdown Capability, Low Power Standby Mode
- High Efficiency
- Uses Readily Available Standard Inductors
- Thermal Shutdown and Current Limit Protection

## Applications

- Simple and High-Efficiency Step-Down (Buck) Regulators
- Efficient Pre-regulator for Linear Regulators
- On-Card Switching Regulators
- Positive to Negative Converters (Buck-Boost)
- Negative Step-Up Converters
- Power Supply for Battery Chargers

Figure 16. Test Circuit and Layout Guidelines

## PCB LAYOUT GUIDELINES

As in any switching regulator, the layout of the printed circuit board is very important. Rapidly switching currents associated with wiring inductance, stray capacitance and parasitic inductance of the printed circuit board traces can generate voltage transients which can generate electromagnetic interferences (EMI) and affect the desired operation. As indicated in the Figure 16, to minimize inductance and ground loops, the length of the leads indicated by heavy lines should be kept as short as possible.

For best results, single-point grounding (as indicated) or ground plane construction should be used.

On the other hand, the PCB area connected to the Pin 7 (emitter of the internal switch) of the LM2574 should be kept to a minimum in order to minimize coupling to sensitive circuitry.

Another sensitive part of the circuit is the feedback. It is important to keep the sensitive feedback wiring short. To assure this, physically locate the programming resistors near to the regulator, when using the adjustable version of the LM2574 regulator.

PIN FUNCTION DESCRIPTION

| Pin |  |  |  |
| :---: | :---: | :---: | :--- |
| SO-16W | PDIP-8 | Symbol |  |
| 12 | 5 | $V_{\text {in }}$ | This pin is the positive input supply for the LM2574 step-down switching regulator. In order to <br> minimize voltage transients and to supply the switching currents needed by the regulator, a <br> suitable input bypass capacitor must be present ( $C_{\text {in }}$ in Figure 1). |
| 14 | 7 | Output | This is the emitter of the internal switch. The saturation voltage $\mathrm{V}_{\text {sat of this output switch is }}^{\text {typically 1.0 V. It should be kept in mind that the PCB area connected to this pin should be kept }}$ <br> to a minimum in order to minimize coupling to sensitive circuitry. |
| 4 | 2 | Sig Gnd | Circuit signal ground pin. See the information about the printed circuit board layout. |

## DESIGN PROCEDURE

## Buck Converter Basics

The LM2574 is a "Buck" or Step-Down Converter which is the most elementary forward-mode converter. Its basic schematic can be seen in Figure 17.

The operation of this regulator topology has two distinct time periods. The first one occurs when the series switch is on, the input voltage is connected to the input of the inductor.

The output of the inductor is the output voltage, and the rectifier (or catch diode) is reverse biased. During this period, since there is a constant voltage source connected across the inductor, the inductor current begins to linearly ramp upwards, as described by the following equation:

$$
\mathrm{I}_{\mathrm{L}(\mathrm{on})}=\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \mathrm{t}_{\text {on }}}{\mathrm{L}}
$$

During this "on" period, energy is stored within the core material in the form of magnetic flux. If the inductor is properly designed, there is sufficient energy stored to carry the requirements of the load during the "off" period.

Figure 17. Basic Buck Converter
The next period is the "off" period of the power switch. When the power switch turns off, the voltage across the inductor reverses its polarity and is clamped at one diode voltage drop below ground by the catch diode. Current now flows through the catch diode thus maintaining the load
current loop. This removes the stored energy from the inductor. The inductor current during this time is:

$$
I_{L(\text { off })}=\frac{\left(V_{\text {out }}-V_{D}\right) t_{\text {off }}}{L}
$$

This period ends when the power switch is once again turned on. Regulation of the converter is accomplished by varying the duty cycle of the power switch. It is possible to describe the duty cycle as follows:

$$
\mathrm{d}=\frac{\mathrm{t}_{\mathrm{on}}}{\mathrm{~T}} \text {, where } \mathrm{T} \text { is the period of switching. }
$$

For the buck converter with ideal components, the duty cycle can also be described as:

$$
\mathrm{d}=\frac{\mathrm{V}_{\text {out }}}{\mathrm{V}_{\text {in }}}
$$

Figure 18 shows the buck converter idealized waveforms of the catch diode voltage and the inductor current.

Figure 18. Buck Converter Idealized Waveforms

Procedure (Fixed Output Voltage Version) In order to simplify the switching regulator design, a step-by-step design procedure and example is provided.

| Procedure | Example |
| :---: | :---: |
| Given Parameters: <br> $\mathrm{V}_{\text {out }}=$ Regulated Output Voltage (3.3 V, 5.0 V, 12 V or 15 V ) <br> $\mathrm{V}_{\text {in(max })}=$ Maximum Input Voltage <br> $I_{\text {Load }(\max )}=$ Maximum Load Current | Given Parameters: $\begin{aligned} & V_{\text {out }}=5.0 \mathrm{~V} \\ & \mathrm{~V}_{\text {in }(\max )}=15 \mathrm{~V} \\ & \mathrm{I}_{\text {Load }(\max )}=0.4 \mathrm{~A} \end{aligned}$ |
| 1. Controller IC Selection <br> According to the required input voltage, output voltage and current, select the appropriate type of the controller IC output voltage version. | 1. Controller IC Selection <br> According to the required input voltage, output voltage, current polarity and current value, use the LM2574-5 controller IC. |
| 2. Input Capacitor Selection ( $\mathrm{C}_{\mathrm{in}}$ ) <br> To prevent large voltage transients from appearing at the input and for stable operation of the converter, an aluminium or tantalum electrolytic bypass capacitor is needed between the input pin $+\mathrm{V}_{\text {in }}$ and ground pin Gnd. This capacitor should be located close to the IC using short leads. This capacitor should have a low ESR (Equivalent Series Resistance) value. | 2. Input Capacitor Selection ( $\mathrm{C}_{\text {in }}$ ) <br> A $22 \mu \mathrm{~F}, 25 \mathrm{~V}$ aluminium electrolytic capacitor located near to the input and ground pins provides sufficient bypassing. |
| 3. Catch Diode Selection (D1) <br> A. Since the diode maximum peak current exceeds the regulator maximum load current, the catch diode current rating must be at least 1.2 times greater than the maximum load current. For a robust design the diode should have a current rating equal to the maximum current limit of the LM2574 to be able to withstand a continuous output short. <br> B. The reverse voltage rating of the diode should be at least 1.25 times the maximum input voltage. | 3. Catch Diode Selection (D1) <br> A. For this example the current rating of the diode is 1.0 A . <br> B. Use a 20 V 1 N 5817 Schottky diode, or any of the suggested fast recovery diodes shown in Table 1. |
| 4. Inductor Selection (L1) <br> A. According to the required working conditions, select the correct inductor value using the selection guide from Figures 19 to 23. <br> B. From the appropriate inductor selection guide, identify the inductance region intersected by the Maximum Input Voltage line and the Maximum Load Current line. Each region is identified by an inductance value and an inductor code. <br> C. Select an appropriate inductor from the several different manufacturers part numbers listed in Table 2. The designer must realize that the inductor current rating must be higher than the maximum peak current flowing through the inductor. This maximum peak current can be calculated as follows: $I_{p(\max )}=I_{\text {Load }(\max )}+\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \mathrm{t}_{\text {on }}}{2 \mathrm{~L}}$ <br> where $t_{o n}$ is the "on" time of the power switch and $t_{\text {on }}=\frac{V_{\text {out }}}{V_{\text {in }}} \times \frac{1.0}{f_{\text {osc }}}$ <br> For additional information about the inductor, see the inductor section in the "EXTERNAL COMPONENTS" section of this data sheet. | 4. Inductor Selection (L1) <br> A. Use the inductor selection guide shown in Figure 20. <br> B. From the selection guide, the inductance area intersected by the 15 V line and 0.4 A line is 330 . <br> C. Inductor value required is $330 \mu \mathrm{H}$. From Table 2, choose an inductor from any of the listed manufacturers. |

Procedure (Fixed Output Voltage Version) (continued) In order to simplify the switching regulator design, a step-by-step design procedure and example is provided.

| Procedure | Example |
| :---: | :---: |
| 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ ) <br> A. Since the LM2574 is a forward-mode switching regulator with voltage mode control, its open loop 2-pole-1-zero frequency characteristic has the dominant pole-pair determined by the output capacitor and inductor values. For stable operation and an acceptable ripple voltage, (approximately $1 \%$ of the output voltage) a value between $100 \mu \mathrm{~F}$ and $470 \mu \mathrm{~F}$ is recommended. <br> B. Due to the fact that the higher voltage electrolytic capacitors generally have lower ESR (Equivalent Series Resistance) numbers, the output capacitor's voltage rating should be at least 1.5 times greater than the output voltage. For a 5.0 V regulator, a rating at least 8.0 V is appropriate, and a 10 V or 16 V rating is recommended. | 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ ) <br> A. $\mathrm{C}_{\text {out }}=100 \mu \mathrm{~F}$ to $470 \mu \mathrm{~F}$ standard aluminium electrolytic. <br> B. Capacitor voltage rating $=20 \mathrm{~V}$. |

## Procedure (Adjustable Output Version: LM2574-ADJ)

| Procedure | Example |
| :---: | :---: |
| Given Parameters: <br> $\mathrm{V}_{\text {out }}=$ Regulated Output Voltage <br> $\mathrm{V}_{\text {in(max) }}=$ Maximum DC Input Voltage <br> $I_{\text {Load(max) }}=$ Maximum Load Current | Given Parameters: $\begin{aligned} & \mathrm{V}_{\text {out }}=24 \mathrm{~V} \\ & \mathrm{~V}_{\text {in }(\max )}=40 \mathrm{~V} \\ & \mathrm{~L}_{\text {Load }(\max )}=0.4 \mathrm{~A} \end{aligned}$ |
| 1. Programming Output Voltage <br> To select the right programming resistor R1 and R2 value (see Figure 2) use the following formula: $V_{\text {out }}=V_{\text {ref }}\left(1.0+\frac{R 2}{R 1}\right) \quad \text { where } V_{\text {ref }}=1.23 \mathrm{~V}$ <br> Resistor R1 can be between $1.0 \mathrm{k} \Omega$ and $5.0 \mathrm{k} \Omega$. (For best temperature coefficient and stability with time, use $1 \%$ metal film resistors). $\mathrm{R} 2=\mathrm{R} 1\left(\frac{\mathrm{~V}_{\text {out }}}{\mathrm{V}_{\text {ref }}}-1.0\right)$ | 1. Programming Output Voltage (selecting R1 and R2) Select R1 and R2 : $\begin{gathered} V_{\text {out }}=1.23\left(1.0+\frac{R 2}{R 1}\right) \text { Select } R 1=1.0 \mathrm{k} \Omega \\ R 2=R 1\left(\frac{V_{\text {out }}}{V_{\text {ref }}}-1.0\right)=1.0 \mathrm{k}\left(\frac{10 \mathrm{~V}}{1.23 \mathrm{~V}}-1.0\right) \\ R 2=18.51 \mathrm{k} \Omega \text {, choose a } 18.7 \mathrm{k} \Omega \text { metal film resistor. } \end{gathered}$ |
| 2. Input Capacitor Selection ( $\mathrm{C}_{\mathrm{in}}$ ) <br> To prevent large voltage transients from appearing at the input and for stable operation of the converter, an aluminium or tantalum electrolytic bypass capacitor is needed between the input pin $+\mathrm{V}_{\text {in }}$ and ground pin Gnd. This capacitor should be located close to the IC using short leads. This capacitor should have a low ESR (Equivalent Series Resistance) value. For additional information see input capacitor section in the "EXTERNAL COMPONENTS" section of this data sheet. | 2. Input Capacitor Selection ( $\mathrm{C}_{\mathrm{in}}$ ) <br> A $22 \mu \mathrm{~F}$ aluminium electrolytic capacitor located near the input and ground pin provides sufficient bypassing. |

3. Catch Diode Selection (D1)
A. Since the diode maximum peak current exceeds the regulator maximum load current the catch diode current rating must be at least 1.2 times greater than the maximum load current. For a robust design, the diode should have a current rating equal to the maximum current limit of the LM2574 to be able to withstand a continuous output short.
B. The reverse voltage rating of the diode should be at least 1.25 times the maximum input voltage.

## 3. Catch Diode Selection (D1)

A. For this example, a 1.0 A current rating is adequate.
B. Use a 50 V MBR150 Schottky diode or any suggested fast recovery diodes in Table 1.

Procedure (Adjustable Output Version: LM2574-ADJ)

| Procedure |
| :--- |
| 4. Inductor Selection (L1) |
| A. Use the following formula to calculate the inductor Volt x |
| microsecond $[\mathrm{V} \times \mu \mathrm{s}]$ constant: |
| $\mathrm{E} \times T=\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \frac{\mathrm{V}_{\text {out }}}{\mathrm{V}_{\text {in }}} \times \frac{10^{6}}{\mathrm{~F}[\mathrm{~Hz}]}[\mathrm{V} \times \mu \mathrm{s}]$ |

B. Match the calculated $\mathrm{E} \times \mathrm{T}$ value with the corresponding number on the vertical axis of the Inductor Value Selection Guide shown in Figure 23. This E x T constant is a measure of the energy handling capability of an inductor and is dependent upon the type of core, the core area, the number of turns, and the duty cycle.
C. Next step is to identify the inductance region intersected by the ExT value and the maximum load current value on the horizontal axis shown in Figure 27.
D. From the inductor code, identify the inductor value. Then select an appropriate inductor from Table 2. The inductor chosen must be rated for a switching frequency of 52 kHz and for a current rating of $1.15 \times \mathrm{I}_{\text {Load }}$. The inductor current rating can also be determined by calculating the inductor peak current:

$$
\mathrm{I}_{\mathrm{p}(\max )}=\mathrm{I}_{\mathrm{Load}(\max )}+\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \mathrm{t}_{\mathrm{on}}}{2 \mathrm{~L}}
$$

where $t_{\text {on }}$ is the "on" time of the power switch and

$$
t_{\text {on }}=\frac{V_{\text {out }}}{V_{\text {in }}} \times \frac{1.0}{f_{\text {osc }}}
$$

For additional information about the inductor, see the inductor section in the "External Components" section of this data sheet.

## 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ )

A. Since the LM2574 is a forward-mode switching regulator with voltage mode control, its open loop 2-pole-1-zero frequency characteristic has the dominant pole-pair determined by the output capacitor and inductor values.

For stable operation, the capacitor must satisfy the following requirement:

$$
C_{\text {out }} \geq 13,300 \frac{V_{\text {in }}^{\text {(max }}}{}[[\mu F]
$$

B. Capacitor values between $10 \mu \mathrm{~F}$ and $2000 \mu \mathrm{~F}$ will satisfy the loop requirements for stable operation. To achieve an acceptable output ripple voltage and transient response, the output capacitor may need to be several times larger than the above formula yields.
C. Due to the fact that the higher voltage electrolytic capacitors generally have lower ESR (Equivalent Series Resistance) numbers, the output capacitor's voltage rating should be at least 1.5 times greater than the output voltage. For a 5.0 V regulator, a rating of at least 8.0 V is appropriate, and a 10 V or 16 V rating is recommended.

## 4. Inductor Selection (L1)

A. Calculate $\mathrm{E} \times \mathrm{T}[\mathrm{V} \times \mu \mathrm{s}]$ constant :

$$
E \times T=(40-24) \times \frac{24}{40} \times \frac{1000}{52}=105[V \times \mu s]
$$

B. $\mathrm{E} \times \mathrm{T}=185[\mathrm{~V} \times \mu \mathrm{s}]$
C. $I_{\text {Load }(\max )}=0.4 \mathrm{~A}$

Inductance Region $=1000$
D. Proper inductor value $=1000 \mu \mathrm{H}$ Choose the inductor from Table 2.

## 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ )

A.

$$
C_{\text {out }} \geq 13,300 \times \frac{40}{24 \times 1000}=22.2 \mu \mathrm{~F}
$$

To achieve an acceptable ripple voltage, select $C_{\text {out }}=100 \mu \mathrm{~F}$ electrolytic capacitor.

## EXTERNAL COMPONENTS

## Input Capacitor ( $\mathrm{C}_{\text {in }}$ ) The Input Capacitor Should Have a Low ESR

For stable operation of the switch mode converter a low ESR (Equivalent Series Resistance) aluminium or solid tantalum bypass capacitor is needed between the input pin and the ground pin, to prevent large voltage transients from appearing at the input. It must be located near the regulator and use short leads. With most electrolytic capacitors, the capacitance value decreases and the ESR increases with lower temperatures. For reliable operation in temperatures below $-25^{\circ} \mathrm{C}$ larger values of the input capacitor may be needed. Also paralleling a ceramic or solid tantalum capacitor will increase the regulator stability at cold temperatures.

## RMS Current Rating of $C_{\text {in }}$

The important parameter of the input capacitor is the RMS current rating. Capacitors that are physically large and have large surface area will typically have higher RMS current ratings. For a given capacitor value, a higher voltage electrolytic capacitor will be physically larger than a lower voltage capacitor, and thus be able to dissipate more heat to the surrounding air, and therefore will have a higher RMS current rating. The consequences of operating an electrolytic capacitor beyond the RMS current rating is a shortened operating life. In order to assure maximum capacitor operating lifetime, the capacitor's RMS ripple current rating should be:

$$
\mathrm{I}_{\mathrm{rms}}>1.2 \times \mathrm{dx} \mathrm{I}_{\text {Load }}
$$

where $d$ is the duty cycle, for a continuous mode buck regulator

$$
\mathrm{d}=\frac{\mathrm{t}_{\mathrm{on}}}{\mathrm{~T}}=\frac{\mathrm{V}_{\text {out }}}{\mathrm{V}_{\text {in }}}
$$

and $d=\frac{t_{\text {on }}}{T}=\frac{\left|V_{\text {out }}\right|}{\left|V_{\text {out }}\right|+V_{\text {in }}}$ for a buck-boost regulator.

## Output Capacitor ( $\mathrm{C}_{\text {out }}$ )

For low output ripple voltage and good stability, low ESR output capacitors are recommended. An output capacitor has two main functions: it filters the output and provides regulator loop stability. The ESR of the output capacitor and the peak-to-peak value of the inductor ripple current are the main factors contributing to the output ripple voltage value. Standard aluminium electrolytics could be adequate for some applications but for quality design, low ESR types are recommended.

An aluminium electrolytic capacitor's ESR value is related to many factors, such as the capacitance value, the voltage rating, the physical size and the type of construction. In most cases, the higher voltage electrolytic capacitors have lower ESR value. Often capacitors with much higher
voltage ratings may be needed to provide low ESR values, that are required for low output ripple voltage.

## The Output Capacitor Requires an ESR Value that has an Upper and Lower Limit

As mentioned above, a low ESR value is needed for low output ripple voltage, typically $1 \%$ to $2 \%$ of the output voltage. But if the selected capacitor's ESR is extremely low (below $0.03 \Omega$ ), there is a possibility of an unstable feedback loop, resulting in oscillation at the output. This situation can occur when a tantalum capacitor, that can have a very low ESR, is used as the only output capacitor.

## At Low Temperatures, Put in Parallel Aluminium Electrolytic Capacitors with Tantalum Capacitors

Electrolytic capacitors are not recommended for temperatures below $-25^{\circ} \mathrm{C}$. The ESR rises dramatically at cold temperatures and typically rises 3 times at $-25^{\circ} \mathrm{C}$ and as much as 10 times at $-40^{\circ} \mathrm{C}$. Solid tantalum capacitors have much better ESR spec at cold temperatures and are recommended for temperatures below $-25^{\circ} \mathrm{C}$. They can be also used in parallel with aluminium electrolytics. The value of the tantalum capacitor should be about $10 \%$ or $20 \%$ of the total capacitance. The output capacitor should have at least $50 \%$ higher RMS ripple current rating at 52 kHz than the peak-to-peak inductor ripple current.

## Catch Diode <br> Locate the Catch Diode Close to the LM2574

The LM2574 is a step-down buck converter, it requires a fast diode to provide a return path for the inductor current when the switch turns off. This diode must be located close to the LM2574 using short leads and short printed circuit traces to avoid EMI problems.

## Use a Schottky or a Soft Switching Ultra-Fast Recovery Diode

Since the rectifier diodes are very significant source of losses within switching power supplies, choosing the rectifier that best fits into the converter design is an important process. Schottky diodes provide the best performance because of their fast switching speed and low forward voltage drop.

They provide the best efficiency especially in low output voltage applications ( 5.0 V and lower). Another choice could be Fast-Recovery, or Ultra-Fast Recovery diodes. It has to be noted, that some types of these diodes with an abrupt turnoff characteristic may cause instability or EMI troubles.

A fast-recovery diode with soft recovery characteristics can better fulfill some quality, low noise design requirements. Table 1 provides a list of suitable diodes for the LM2574 regulator. Standard $50 / 60 \mathrm{~Hz}$ rectifier diodes, such as the 1 N 4001 series or 1 N 5400 series are NOT suitable.

## Inductor

The magnetic components are the cornerstone of all switching power supply designs. The style of the core and the winding technique used in the magnetic component's design have a great influence on the reliability of the overall power supply.

Using an improper or poorly designed inductor can cause high voltage spikes generated by the rate of transitions in current within the switching power supply, and the possibility of core saturation can arise during an abnormal operational mode. Voltage spikes can cause the semiconductors to enter avalanche breakdown and the part can instantly fail if enough energy is applied. It can also cause significant RFI (Radio Frequency Interference) and EMI (Electro-Magnetic Interference) problems.

## Continuous and Discontinuous Mode of Operation

The LM2574 step-down converter can operate in both the continuous and the discontinuous modes of operation. The regulator works in the continuous mode when loads are relatively heavy, the current flows through the inductor continuously and never falls to zero. Under light load conditions, the circuit will be forced to the discontinuous mode when inductor current falls to zero for certain period of time (see Figure 24 and Figure 25). Each mode has distinctively different operating characteristics, which can affect the regulator performance and requirements. In many cases the preferred mode of operation is the continuous mode. It offers greater output power, lower peak currents in the switch, inductor and diode, and can have a lower output ripple voltage. On the other hand it does require larger inductor values to keep the inductor current flowing continuously, especially at low output load currents and/or high input voltages.

To simplify the inductor selection process, an inductor selection guide for the LM2574 regulator was added to this data sheet (Figures 19 through 23). This guide assumes that the regulator is operating in the continuous mode, and selects an inductor that will allow a peak-to-peak inductor ripple current to be a certain percentage of the maximum design load current. This percentage is allowed to change as different design load currents are selected. For light loads (less than approximately 0.2 A ) it may be desirable to operate the regulator in the discontinuous mode, because the inductor value and size can be kept relatively low. Consequently, the percentage of inductor peak-to-peak
current increases. This discontinuous mode of operation is perfectly acceptable for this type of switching converter. Any buck regulator will be forced to enter discontinuous mode if the load current is light enough.

## Selecting the Right Inductor Style

Some important considerations when selecting a core type are core material, cost, the output power of the power supply, the physical volume the inductor must fit within, and the amount of EMI (Electro-Magnetic Interference) shielding that the core must provide. There are many different styles of inductors available, such as pot core, E-core, toroid and bobbin core, as well as different core materials such as ferrites and powdered iron from different manufacturers.

For high quality design regulators the toroid core seems to be the best choice. Since the magnetic flux is contained within the core, it generates less EMI, reducing noise problems in sensitive circuits. The least expensive is the bobbin core type, which consists of wire wound on a ferrite rod core. This type of inductor generates more EMI due to the fact that its core is open, and the magnetic flux is not contained within the core.

When multiple switching regulators are located on the same printed circuit board, open core magnetics can cause interference between two or more of the regulator circuits, especially at high currents due to mutual coupling. A toroid, pot core or E-core (closed magnetic structure) should be used in such applications.

## Do Not Operate an Inductor Beyond its Maximum Rated Current

Exceeding an inductor's maximum current rating may cause the inductor to overheat because of the copper wire losses, or the core may saturate. Core saturation occurs when the flux density is too high and consequently the cross sectional area of the core can no longer support additional lines of magnetic flux.

This causes the permeability of the core to drop, the inductance value decreases rapidly and the inductor begins to look mainly resistive. It has only the dc resistance of the winding. This can cause the switch current to rise very rapidly and force the LM2574 internal switch into cycle-by-cycle current limit, thus reducing the dc output load current. This can also result in overheating of the inductor and/or the LM2574. Different inductor types have different saturation characteristics, and this should be kept in mind when selecting an inductor.

HORIZONTAL TIME BASE: $5.0 \mu \mathrm{~s} / \mathrm{DIV}$
Figure 24. Continuous Mode Switching Current Waveforms

HORIZONTAL TIME BASE: $5.0 \mu \mathrm{~s} /$ DIV
Figure 25. Continuous Mode Switching Current Waveforms

## GENERAL RECOMMENDATIONS

## Output Voltage Ripple and Transients Source of the Output Ripple

Since the LM2574 is a switch mode power supply regulator, its output voltage, if left unfiltered, will contain a sawtooth ripple voltage at the switching frequency. The output ripple voltage value ranges from $0.5 \%$ to $3 \%$ of the output voltage. It is caused mainly by the inductor sawtooth ripple current multiplied by the ESR of the output capacitor.

## Short Voltage Spikes and How to Reduce Them

The regulator output voltage may also contain short voltage spikes at the peaks of the sawtooth waveform (see Figure 26). These voltage spikes are present because of the fast switching action of the output switch, and the parasitic inductance of the output filter capacitor. There are some other important factors such as wiring inductance, stray capacitance, as well as the scope probe used to evaluate these transients, all these contribute to the amplitude of these spikes. To minimize these voltage spikes, low inductance capacitors should be used, and their lead lengths must be kept short. The importance of quality printed circuit board layout design should also be highlighted.

HORIZONTAL TIME BASE: $5.0 \mu \mathrm{~s} / \mathrm{DIV}$

Figure 26. Output Ripple Voltage Waveforms

## Minimizing the Output Ripple

In order to minimize the output ripple voltage it is possible to enlarge the inductance value of the inductor L1 and/or to use a larger value output capacitor. There is also another way to smooth the output by means of an additional LC filter $(20 \mu \mathrm{H}, 100 \mu \mathrm{~F})$, that can be added to the output (see Figure 35) to further reduce the amount of output ripple and transients. With such a filter it is possible to reduce the output ripple voltage transients 10 times or more. Figure 26 shows the difference between filtered and unfiltered output waveforms of the regulator shown in Figure 34.

The upper waveform is from the normal unfiltered output of the converter, while the lower waveform shows the output ripple voltage filtered by an additional LC filter.

## Heatsinking and Thermal Considerations

The LM2574 is available in both 8-pin DIP and SO-16L packages. When used in the typical application the copper lead frame conducts the majority of the heat from the die, through the leads, to the printed circuit copper. The copper and the board are the heatsink for this package and the other heat producing components, such as the catch diode and inductor.

For the best thermal performance, wide copper traces should be used and all ground and unused pins should be soldered to generous amounts of printed circuit board copper, such as a ground plane. Large areas of copper provide the best transfer of heat to the surrounding air. One exception to this is the output (switch) pin, which should not have large areas of copper in order to minimize coupling to sensitive circuitry.

Additional improvement in heat dissipation can be achieved even by using of double sided or multilayer boards which can provide even better heat path to the ambient. Using a socket for the 8-pin DIP package is not recommended because socket represents an additional thermal resistance, and as a result the junction temperature will be higher.

Since the current rating of the LM2574 is only 0.5 A , the total package power dissipation for this switcher is quite low, ranging from approximately 0.1 W up to 0.75 W under varying conditions. In a carefully engineered printed circuit board, the through-hole DIP package can easily dissipate up to 0.75 W , even at ambient temperatures of $60^{\circ} \mathrm{C}$, and still keep the maximum junction temperature below $125^{\circ} \mathrm{C}$.

## Thermal Analysis and Design

The following procedure must be performed to determine the operating junction temperature. First determine:

1. $\mathrm{P}_{\mathrm{D}(\max )}$ - maximum regulator power dissipation in the application.
2. $\mathrm{T}_{\mathrm{A}(\max )}$ - maximum ambient temperature in the application.
3. $\mathrm{T}_{\mathrm{J}(\max )}$ - maximum allowed junction temperature $\left(125^{\circ} \mathrm{C}\right.$ for the LM2574). For a conservative design, the maximum junction temperature should not exceed $110^{\circ} \mathrm{C}$ to assure safe operation. For every additional $+10^{\circ} \mathrm{C}$ temperature rise that the junction must withstand, the estimated operating lifetime of the component is halved.
4. $R_{\theta \mathrm{JC}}$ - package thermal resistance junction-case.
5. $\mathrm{R}_{\theta \mathrm{JA}}$ - package thermal resistance junction-ambient.
(Refer to Absolute Maximum Ratings on page 1279 of this data sheet or $R_{\theta J C}$ and $R_{\theta J \mathrm{~A}}$ values).

The following formula is to calculate the approximate total power dissipated by the LM2574:

$$
P_{D}=\left(V_{\text {in }} \times I_{Q}\right)+d \times I_{\text {Load }} \times V_{\text {sat }}
$$

where $d$ is the duty cycle and for buck converter

$$
\mathrm{d}=\frac{\mathrm{t}_{\mathrm{on}}}{\mathrm{~T}}=\frac{\mathrm{V}_{\mathrm{O}}}{\mathrm{~V}_{\mathrm{in}}},
$$

$\mathrm{I}_{\mathrm{Q}}$ (quiescent current) and $\mathrm{V}_{\text {sat }}$ can be found in the LM2574 data sheet,
$\mathrm{V}_{\text {in }}$ is minimum input voltage applied,
$\mathrm{V}_{\mathrm{O}}$ is the regulator output voltage,
$\mathrm{I}_{\text {Load }}$ is the load current.

Figure 27. Inverting Buck-Boost Develops -12 V

The dynamic switching losses during turn-on and turn-off can be neglected if a proper type catch diode is used. The junction temperature can be determined by the following expression:

$$
T_{J}=\left(R_{\theta J A}\right)\left(P_{D}\right)+T_{A}
$$

where $\left(R_{\theta J A}\right)\left(P_{D}\right)$ represents the junction temperature rise caused by the dissipated power and $\mathrm{T}_{\mathrm{A}}$ is the maximum ambient temperature.

## Some Aspects That can Influence Thermal Design

It should be noted that the package thermal resistance and the junction temperature rise numbers are all approximate, and there are many factors that will affect these numbers, such as PC board size, shape, thickness, physical position, location, board temperature, as well as whether the surrounding air is moving or still. At higher power levels the thermal resistance decreases due to the increased air current activity.
Other factors are trace width, total printed circuit copper area, copper thickness, single- or double-sided, multilayer board, the amount of solder on the board or even color of the traces.

The size, quantity and spacing of other components on the board can also influence its effectiveness to dissipate the heat. Some of them, like the catch diode or the inductor will generate some additional heat.

## ADDITIONAL APPLICATIONS

## Inverting Regulator

An inverting buck-boost regulator using the LM2574-12 is shown in Figure 27. This circuit converts a positive input voltage to a negative output voltage with a common ground by bootstrapping the regulators ground to the negative output voltage. By grounding the feedback pin, the regulator senses the inverted output voltage and regulates it.
In this example the LM2574-12 is used to generate a -12 V output. The maximum input voltage in this case cannot exceed 28 V because the maximum voltage appearing across the regulator is the absolute sum of the input and output voltages and this must be limited to a maximum of 40 V .

This circuit configuration is able to deliver approximately 0.1 A to the output when the input voltage is 8.0 V or higher. At lighter loads the minimum input voltage required drops to approximately 4.7 V , because the buck-boost regulator topology can produce an output voltage that, in its absolute value, is either greater or less than the input voltage.

Since the switch currents in this buck-boost configuration are higher than in the standard buck converter topology, the available output current is lower.

This type of buck-boost inverting regulator can also require a larger amount of startup input current, even for light loads. This may overload an input power source with a current limit less than 0.6 A .

Because of the relatively high startup currents required by this inverting regulator topology, the use of a delayed startup or an undervoltage lockout circuit is recommended.

While using a delayed startup arrangement, the input capacitor can charge up to a higher voltage before the switch-mode regulator begins to operate.

The high input current needed for startup is now partially supplied by the input capacitor $\mathrm{C}_{\mathrm{in}}$.

## Design Recommendations:

The inverting regulator operates in a different manner than the buck converter and so a different design procedure has to be used to select the inductor L1 or the output capacitor $\mathrm{C}_{\text {out }}$.

The output capacitor values must be larger than what is normally required for buck converter designs. Low input voltages or high output currents require a large value output capacitor (in the range of thousands of $\mu \mathrm{F}$ ).

The recommended range of inductor values for the inverting converter design is between $68 \mu \mathrm{H}$ and $220 \mu \mathrm{H}$. To select an inductor with an appropriate current rating, the inductor peak current has to be calculated.

Figure 28. Inverting Buck-Boost Regulator with Delayed Startup

The following formula is used to obtain the peak inductor current:

$$
\begin{aligned}
& \mathrm{I}_{\text {peak }} \approx \frac{\mathrm{I}_{\text {Load }}\left(\mathrm{V}_{\text {in }}+\left|\mathrm{V}_{\mathrm{O}}\right|\right)}{\mathrm{V}_{\mathrm{in}}}+\frac{\mathrm{V}_{\text {in }} \times \mathrm{t}_{\mathrm{on}}}{2 \mathrm{~L}_{1}} \\
& \text { where } \\
& \mathrm{t}_{\mathrm{on}}=\frac{\left|\mathrm{V}_{\mathrm{O}}\right|}{\mathrm{V}_{\mathrm{in}}+\left|\mathrm{V}_{\mathrm{O}}\right|} \times \frac{1.0}{f_{\mathrm{osc}}} \text {, and } \mathrm{f}_{\mathrm{osc}}=52 \mathrm{kHz} .
\end{aligned}
$$

Under normal continuous inductor current operating conditions, the worst case occurs when $\mathrm{V}_{\mathrm{in}}$ is minimal.

It has been already mentioned above, that in some situations, the delayed startup or the undervoltage lockout features could be very useful. A delayed startup circuit applied to a buck-boost converter is shown in Figure 28. Figure 34 in the "Undervoltage Lockout" section describes an undervoltage lockout feature for the same converter topology.

With the inverting configuration, the use of the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin requires some level shifting techniques. This is caused
by the fact, that the ground pin of the converter IC is no longer at ground. Now, the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin threshold voltage (1.3 V approximately) has to be related to the negative output voltage level. There are many different possible shutdown methods, two of them are shown in Figures 29 and 30.

NOTE: This picture does not show the complete circuit.
Figure 29. Inverting Buck-Boost Regulator Shutdown Circuit Using an Optocoupler

NOTE: This picture does not show the complete circuit.
Figure 30. Inverting Buck-Boost Regulator Shutdown Circuit Using a PNP Transistor

## Negative Boost Regulator

This example is a variation of the buck-boost topology and it is called negative boost regulator. This regulator experiences relatively high switch current, especially at low input voltages. The internal switch current limiting results in lower output load current capability.

The circuit in Figure 31 shows the negative boost configuration. The input voltage in this application ranges from -5.0 to -12 V and provides a regulated -12 V output. If the input voltage is greater than -12 V , the output will rise above -12 V accordingly, but will not damage the regulator.

Figure 31. Negative Boost Regulator

## Design Recommendations:

The same design rules as for the previous inverting buck-boost converter can be applied. The output capacitor $\mathrm{C}_{\text {out }}$ must be chosen larger than what would be required for a standard buck converter. Low input voltages or high output currents require a large value output capacitor (in the range of thousands of $\mu \mathrm{F}$ ). The recommended range of inductor values for the negative boost regulator is the same as for inverting converter design.

Another important point is that these negative boost converters cannot provide any current limiting load protection in the event of a short in the output so some other means, such as a fuse, may be necessary to provide the load protection.

## Delayed Startup

There are some applications, like the inverting regulator already mentioned above, which require a higher amount of startup current. In such cases, if the input power source is limited, this delayed startup feature becomes very useful.

To provide a time delay between the time when the input voltage is applied and the time when the output voltage comes up, the circuit in Figure 32 can be used. As the input voltage is applied, the capacitor C 1 charges up, and the voltage across the resistor R2 falls down. When the voltage on the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin falls below the threshold value 1.3 V , the regulator starts up. Resistor R1 is included to limit the maximum voltage applied to the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin. It reduces the power supply noise sensitivity, and also limits the capacitor C 1 discharge current, but its use is not mandatory.

When a high 50 Hz or $60 \mathrm{~Hz}(100 \mathrm{~Hz}$ or 120 Hz respectively) ripple voltage exists, a long delay time can cause some problems by coupling the ripple into the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin, the regulator could be switched periodically on and off with the line (or double) frequency.

NOTE: This picture does not show the complete circuit.
Figure 32. Delayed Startup Circuitry

## Undervoltage Lockout

Some applications require the regulator to remain off until the input voltage reaches a certain threshold level. Figure 33 shows an undervoltage lockout circuit applied to a buck regulator. A version of this circuit for buck-boost converter is shown in Figure 34. Resistor R3 pulls the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin high and keeps the regulator off until the input voltage reaches a predetermined threshold level, which is determined by the following expression:

NOTE: This picture does not show the complete circuit.
Figure 33. Undervoltage Lockout Circuit for Buck Converter

## LM2574

NOTE: This picture does not show the complete circuit (see Figure 27).
Figure 34. Undervoltage Lockout Circuit for Buck-Boost Converter

## Adjustable Output, Low-Ripple Power Supply

A 0.5 A output current capability power supply that features an adjustable output voltage is shown in Figure 35.
This regulator delivers 0.5 A into 1.2 to 35 V output. The input voltage ranges from roughly 3.0 to 40 V . In order to achieve a 10 or more times reduction of output ripple, an additional $\mathrm{L}-\mathrm{C}$ filter is included in this circuit.

## LM2575

### 1.0 A, Adjustable Output Voltage, Step-Down Switching Regulator

The LM2575 series of regulators are monolithic integrated circuits ideally suited for easy and convenient design of a step-down switching regulator (buck converter). All circuits of this series are capable of driving a 1.0 A load with excellent line and load regulation. These devices are available in fixed output voltages of $3.3 \mathrm{~V}, 5.0 \mathrm{~V}$, $12 \mathrm{~V}, 15 \mathrm{~V}$, and an adjustable output version.

These regulators were designed to minimize the number of external components to simplify the power supply design. Standard series of inductors optimized for use with the LM2575 are offered by several different inductor manufacturers.

Since the LM2575 converter is a switch-mode power supply, its efficiency is significantly higher in comparison with popular three-terminal linear regulators, especially with higher input voltages. In many cases, the power dissipated by the LM2575 regulator is so low, that no heatsink is required or its size could be reduced dramatically.

The LM2575 features include a guaranteed $\pm 4 \%$ tolerance on output voltage within specified input voltages and output load conditions, and $\pm 10 \%$ on the oscillator frequency ( $\pm 2 \%$ over $0^{\circ} \mathrm{C}$ to $125^{\circ} \mathrm{C}$ ). External shutdown is included, featuring $80 \mu \mathrm{~A}$ typical standby current. The output switch includes cycle-by-cycle current limiting, as well as thermal shutdown for full protection under fault conditions.

## Features

- 3.3 V, 5.0 V, $12 \mathrm{~V}, 15 \mathrm{~V}$, and Adjustable Output Versions
- Adjustable Version Output Voltage Range of 1.23 V to $37 \mathrm{~V} \pm 4 \%$ Maximum Over Line and Load Conditions
- Guaranteed 1.0 A Output Current
- Wide Input Voltage Range: 4.75 V to 40 V
- Requires Only 4 External Components
- 52 kHz Fixed Frequency Internal Oscillator
- TTL Shutdown Capability, Low Power Standby Mode
- High Efficiency
- Uses Readily Available Standard Inductors
- Thermal Shutdown and Current Limit Protection
- Moisture Sensitivity Level (MSL) Equals 1

## Applications

- Simple and High-Efficiency Step-Down (Buck) Regulators
- Efficient Pre-Regulator for Linear Regulators
- On-Card Switching Regulators
- Positive to Negative Converters (Buck-Boost)
- Negative Step-Up Converters
- Power Supply for Battery Chargers

3. The oscillator frequency reduces to approximately 18 kHz in the event of an output short or an overload which causes the regulated output voltage to drop approximately $40 \%$ from the nominal output voltage. This self protection feature lowers the average dissipation of the IC by lowering the minimum duty cycle from $5 \%$ down to approximately $2 \%$.
4. Output (Pin 2) sourcing current. No diode, inductor or capacitor connected to output pin.
5. Feedback (Pin 4) removed from output and connected to 0 V .
6. Feedback (Pin 4) removed from output and connected to +12 V for the Adjustable, 3.3 V , and 5.0 V versions, and +25 V for the 12 V and 15 V versions, to force the output transistor "off".
7. $\mathrm{V}_{\mathrm{in}}=40 \mathrm{~V}$.

## PCB LAYOUT GUIDELINES

As in any switching regulator, the layout of the printed circuit board is very important. Rapidly switching currents associated with wiring inductance, stray capacitance and parasitic inductance of the printed circuit board traces can generate voltage transients which can generate electromagnetic interferences (EMI) and affect the desired operation. As indicated in the Figure 14, to minimize inductance and ground loops, the length of the leads indicated by heavy lines should be kept as short as possible. For best results, single-point grounding (as indicated) or ground plane construction should be used.

On the other hand, the PCB area connected to the Pin 2 (emitter of the internal switch) of the LM2575 should be kept to a minimum in order to minimize coupling to sensitive circuitry.

Another sensitive part of the circuit is the feedback. It is important to keep the sensitive feedback wiring short. To assure this, physically locate the programming resistors near to the regulator, when using the adjustable version of the LM2575 regulator.

PIN FUNCTION DESCRIPTION

| Pin | Symbol | Description (Refer to Figure 1) |
| :---: | :---: | :--- |
| 1 | $V_{\text {in }}$ | This pin is the positive input supply for the LM2575 step-down switching regulator. In order to minimize <br> voltage transients and to supply the switching currents needed by the regulator, a suitable input bypass <br> capacitor must be present (C in in Figure 1). |
| 2 | Output | This is the emitter of the internal switch. The saturation voltage $V_{\text {sat }}$ of this output switch is typically 1.0 V . <br> It should be kept in mind that the PCB area connected to this pin should be kept to a minimum in order to <br> minimize coupling to sensitive circuitry. |
| 3 | Gnd | Circuit ground pin. See the information about the printed circuit board layout. |
| 4 | Feedback | This pin senses regulated output voltage to complete the feedback loop. The signal is divided by the <br> internal resistor divider network R2, R1 and applied to the non-inverting input of the internal error amplifier. <br> In the Adjustable version of the LM2575 switching regulator this pin is the direct input of the error amplifier <br> and the resistor network R2, R1 is connected externally to allow programming of the output voltage. |
| 5 | ON/OFF | It allows the switching regulator circuit to be shut down using logic level signals, thus dropping the total <br> input supply current to approximately 80 $\mu \mathrm{A}$. The input threshold voltage is typically 1.4 V . Applying a <br> voltage above this value (up to + $+\mathrm{V}_{\text {in }}$ ) shuts the regulator off. If the voltage applied to this pin is lower than <br> 1.4 V or if this pin is connected to ground, the regulator will be in the "on" condition. |

## DESIGN PROCEDURE

## Buck Converter Basics

The LM2575 is a "Buck" or Step-Down Converter which is the most elementary forward-mode converter. Its basic schematic can be seen in Figure 15.

The operation of this regulator topology has two distinct time periods. The first one occurs when the series switch is on, the input voltage is connected to the input of the inductor.

The output of the inductor is the output voltage, and the rectifier (or catch diode) is reverse biased. During this period, since there is a constant voltage source connected across the inductor, the inductor current begins to linearly ramp upwards, as described by the following equation:

$$
\mathrm{I}_{\mathrm{L}(\mathrm{on})}=\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \mathrm{t}_{\text {on }}}{\mathrm{L}}
$$

During this "on" period, energy is stored within the core material in the form of magnetic flux. If the inductor is properly designed, there is sufficient energy stored to carry the requirements of the load during the "off" period.

Figure 15. Basic Buck Converter

The next period is the "off" period of the power switch. When the power switch turns off, the voltage across the inductor reverses its polarity and is clamped at one diode voltage drop below ground by catch dioded. Current now flows through the catch diode thus maintaining the load current loop. This removes the stored energy from the inductor. The inductor current during this time is:

$$
I_{L(\text { off })}=\frac{\left(v_{\text {out }}-V_{D}\right) t_{\text {off }}}{L}
$$

This period ends when the power switch is once again turned on. Regulation of the converter is accomplished by varying the duty cycle of the power switch. It is possible to describe the duty cycle as follows:

$$
\mathrm{d}=\frac{\mathrm{t}_{\mathrm{on}}}{\mathrm{~T}} \text {, where } \mathrm{T} \text { is the period of switching. }
$$

For the buck converter with ideal components, the duty cycle can also be described as:

$$
\mathrm{d}=\frac{\mathrm{V}_{\text {out }}}{\mathrm{V}_{\text {in }}}
$$

Figure 16 shows the buck converter idealized waveforms of the catch diode voltage and the inductor current.

Figure 16. Buck Converter Idealized Waveforms

Procedure (Fixed Output Voltage Version) In order to simplify the switching regulator design, a step-by-step design procedure and example is provided.

| Procedure |
| :--- |
| Given Parameters: <br> $V_{\text {out }}=$ Regulated Output Voltage $(3.3 \mathrm{~V}, 5.0 \mathrm{~V}, 12 \mathrm{~V}$ or 15 V$)$ <br> $\mathrm{V}_{\text {in(max) }}=$ Maximum DC Input Voltage <br> $\mathrm{I}_{\text {Load(max) }}=$ Maximum Load Current |
| 1. Controller IC Selection |
| According to the required input voltage, output voltage and |
| current, select the appropriate type of the controller IC output |
| voltage version. |

## 3. Catch Diode Selection (D1)

A. Since the diode maximum peak current exceeds the regulator maximum load current the catch diode current rating must be at least 1.2 times greater than the maximum load current. For a robust design the diode should have a current rating equal to the maximum current limit of the LM2575 to be able to withstand a continuous output short
B. The reverse voltage rating of the diode should be at least 1.25 times the maximum input voltage.
4. Inductor Selection (L1)
A. According to the required working conditions, select the correct inductor value using the selection guide from Figures 17 to 21.
B. From the appropriate inductor selection guide, identify the inductance region intersected by the Maximum Input Voltage line and the Maximum Load Current line. Each region is identified by an inductance value and an inductor code.
C. Select an appropriate inductor from the several different manufacturers part numbers listed in Table 1 or Table 2. When using Table 2 for selecting the right inductor the designer must realize that the inductor current rating must be higher than the maximum peak current flowing through the inductor. This maximum peak current can be calculated as follows:

$$
\begin{aligned}
& \text { ws: } \\
& I_{p(\text { max })}=I_{\text {Load (max })}+\frac{\left(V_{\text {in }}-V_{\text {out }}\right) t_{\text {on }}}{2 L}
\end{aligned}
$$

where $\mathrm{t}_{\mathrm{on}}$ is the "on" time of the power switch and

$$
t_{\text {on }}=\frac{V_{\text {out }}}{V_{\text {in }}} \times \frac{1}{f_{\text {osc }}}
$$

For additional information about the inductor, see the inductor section in the "External Components" section of this data sheet.

1. Controller IC Selection

According to the required input voltage, output voltage, current polarity and current value, use the LM2575-5 controller IC
2. Input Capacitor Selection ( $\mathrm{C}_{\text {in }}$ )

A $47 \mu \mathrm{~F}, 25 \mathrm{~V}$ aluminium electrolytic capacitor located near to the input and ground pins provides sufficient bypassing.
3. Catch Diode Selection (D1)
A. For this example the current rating of the diode is 1.0 A .
B. Use a 30 V 1 N 5818 Schottky diode, or any of the suggested fast recovery diodes shown in the Table 4.
4. Inductor Selection (L1)
A. Use the inductor selection guide shown in Figures 17 to 21 .
B. From the selection guide, the inductance area intersected by the 20 V line and 0.8 A line is L330.
C. Inductor value required is $330 \mu \mathrm{H}$. From the Table 1 or Table 2, choose an inductor from any of the listed manufacturers.

## LM2575

Procedure (Fixed Output Voltage Version) (continued)In order to simplify the switching regulator design, a step-by-step design procedure and example is provided.

| Procedure | Example |
| :---: | :---: |
| 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ ) <br> A. Since the LM2575 is a forward-mode switching regulator with voltage mode control, its open loop 2-pole-2-zero frequency characteristic has the dominant pole-pair determined by the output capacitor and inductor values. For stable operation and an acceptable ripple voltage, (approximately $1 \%$ of the output voltage) a value between $100 \mu \mathrm{~F}$ and $470 \mu \mathrm{~F}$ is recommended. <br> B. Due to the fact that the higher voltage electrolytic capacitors generally have lower ESR (Equivalent Series Resistance) numbers, the output capacitor's voltage rating should be at least 1.5 times greater than the output voltage. For a 5.0 V regulator, a rating at least 8 V is appropriate, and a 10 V or 16 V rating is recommended. | 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ ) <br> A. $\mathrm{C}_{\text {out }}=100 \mu \mathrm{~F}$ to $470 \mu \mathrm{~F}$ standard aluminium electrolytic. <br> B. Capacitor voltage rating $=16 \mathrm{~V}$. |

## Procedure (Adjustable Output Version: LM2575-Adj)

| Procedure | Example |
| :---: | :---: |
| Given Parameters: <br> $\mathrm{V}_{\text {out }}=$ Regulated Output Voltage <br> $V_{\text {in(max) }}=$ Maximum DC Input Voltage <br> $I_{\text {Load(max) }}=$ Maximum Load Current | Given Parameters: $\begin{aligned} & V_{\text {out }}=8.0 \mathrm{~V} \\ & \mathrm{~V}_{\text {in }(\max )}=12 \mathrm{~V} \\ & I_{\text {Load }(\max )}=1.0 \mathrm{~A} \end{aligned}$ |
| 1. Programming Output Voltage <br> To select the right programming resistor R1 and R2 value (see Figure 14) use the following formula: $V_{\text {out }}=V_{\text {ref }}\left(1+\frac{R 2}{R 1}\right) \text { where } V_{\text {ref }}=1.23 \mathrm{~V}$ <br> Resistor R1 can be between 1.0 k and $5.0 \mathrm{k} \Omega$. (For best temperature coefficient and stability with time, use $1 \%$ metal film resistors). $\mathrm{R} 2=\mathrm{R} 1\left(\frac{\mathrm{~V}_{\text {out }}}{\mathrm{V}_{\text {ref }}}-1\right)$ | 1. Programming Output Voltage (selecting R1 and R2) Select R1 and R2: $\begin{aligned} & \mathrm{V}_{\text {out }}=1.23\left(1+\frac{\mathrm{R} 2}{\mathrm{R} 1}\right) \text { Select } \mathrm{R} 1=1.8 \mathrm{k} \Omega \\ & \mathrm{R} 2=\mathrm{R} 1\left(\frac{\mathrm{~V}_{\text {out }}}{\mathrm{V}_{\text {ref }}}-1\right)=1.8 \mathrm{k}\left(\frac{8.0 \mathrm{~V}}{1.23 \mathrm{~V}}-1\right) \end{aligned}$ <br> $R 2=9.91 \mathrm{k} \Omega$, choose a 9.88 k metal film resistor. |
| 2. Input Capacitor Selection ( $\mathrm{C}_{\text {in }}$ ) <br> To prevent large voltage transients from appearing at the input and for stable operation of the converter, an aluminium or tantalum electrolytic bypass capacitor is needed between the input pin $+\mathrm{V}_{\text {in }}$ and ground pin Gnd This capacitor should be located close to the IC using short leads. This capacitor should have a low ESR (Equivalent Series Resistance) value. <br> For additional information see input capacitor section in the "External Components" section of this data sheet. | 2. Input Capacitor Selection ( $\mathrm{C}_{\text {in }}$ ) A $100 \mu \mathrm{~F}$ aluminium electrolytic capacitor located near the input and ground pin provides sufficient bypassing. |
| 3. Catch Diode Selection (D1) <br> A. Since the diode maximum peak current exceeds the regulator maximum load current the catch diode current rating must be at least 1.2 times greater than the maximum load current. For a robust design, the diode should have a current rating equal to the maximum current limit of the LM2575 to be able to withstand a continuous output short. <br> B. The reverse voltage rating of the diode should be at least 1.25 times the maximum input voltage. | 3. Catch Diode Selection (D1) <br> A. For this example, a 3.0 A current rating is adequate. <br> B. Use a 20 V 1 N 5820 or MBR320 Schottky diode or any suggested fast recovery diode in the Table 4. |

Procedure (Adjustable Output Version: LM2575-Adj) (continued)

| Procedure |
| :--- |
| 4. Inductor Selection (L1) |
| A. Use the following formula to calculate the inducto |
| microsecond $[\mathrm{V} \times \mu \mathrm{s}]$ constant: |
| $E \mathrm{E} \times T=\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \frac{\mathrm{V}_{\text {out }}}{\mathrm{V}_{\text {on }}} \times \frac{10^{6}}{\mathrm{~F}[\mathrm{~Hz}]}[\mathrm{V} \times \mu \mathrm{s}]$ |

B. Match the calculated $\mathrm{E} \times \mathrm{T}$ value with the corresponding number on the vertical axis of the Inductor Value Selection Guide shown in Figure 21. This $\mathrm{E} \times \mathrm{T}$ constant is a measure of the energy handling capability of an inductor and is dependent upon the type of core, the core area, the number of turns, and the duty cycle.
C. Next step is to identify the inductance region intersected by the $E \times T$ value and the maximum load current value on the horizontal axis shown in Figure 21.
D. From the inductor code, identify the inductor value. Then select an appropriate inductor from the Table 1 or Table 2. The inductor chosen must be rated for a switching frequency of 52 kHz and for a current rating of $1.15 \times \mathrm{I}_{\text {Ioad }}$. The inductor current rating can also be determined by calculating the inductor peak current:

$$
I_{p(\max )}=I_{\text {Load }(\max )}+\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \mathrm{t}_{\text {on }}}{2 \mathrm{~L}}
$$

where $t_{o n}$ is the "on" time of the power switch and

$$
t_{\text {on }}=\frac{V_{\text {out }}}{V_{\text {in }}} \times \frac{1}{f_{\text {osc }}}
$$

For additional information about the inductor, see the inductor section in the "External Components" section of this data sheet.

## 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ )

A. Since the LM2575 is a forward-mode switching regulator with voltage mode control, its open loop 2-pole-2-zero frequency characteristic has the dominant pole-pair determined by the output capacitor and inductor values.

For stable operation, the capacitor must satisfy the following requirement:

$$
C_{\text {out }} \geq 7.785 \frac{V_{\text {in }(\max )}}{V_{\text {out }} \times L[\mu \mathrm{H}]}[\mu \mathrm{F}]
$$

B. Capacitor values between $10 \mu \mathrm{~F}$ and $2000 \mu \mathrm{~F}$ will satisfy the loop requirements for stable operation. To achieve an acceptable output ripple voltage and transient response, the output capacitor may need to be several times larger than the above formula yields.
C. Due to the fact that the higher voltage electrolytic capacitors generally have lower ESR (Equivalent Series Resistance) numbers, the output capacitor's voltage rating should be at least 1.5 times greater than the output voltage. For a 5.0 V regulator, a rating of at least 8 V is appropriate, and a 10 V or 16 V rating is recommended.

## 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ )

A.

$$
C_{\text {out }} \geq 7.785 \frac{12}{8.220}=53 \mu \mathrm{~F}
$$

To achieve an acceptable ripple voltage, select $\mathrm{C}_{\text {out }}=100 \mu \mathrm{~F}$ electrolytic capacitor.

## EXTERNAL COMPONENTS

## Input Capacitor ( $\mathrm{C}_{\text {in }}$ ) The Input Capacitor Should Have a Low ESR

For stable operation of the switch mode converter a low ESR (Equivalent Series Resistance) aluminium or solid tantalum bypass capacitor is needed between the input pin and the ground pin to prevent large voltage transients from appearing at the input. It must be located near the regulator and use short leads. With most electrolytic capacitors, the capacitance value decreases and the ESR increases with lower temperatures. For reliable operation in temperatures below $-25^{\circ} \mathrm{C}$ larger values of the input capacitor may be needed. Also paralleling a ceramic or solid tantalum capacitor will increase the regulator stability at cold temperatures.

## RMS Current Rating of $C_{\text {in }}$

The important parameter of the input capacitor is the RMS current rating. Capacitors that are physically large and have large surface area will typically have higher RMS current ratings. For a given capacitor value, a higher voltage electrolytic capacitor will be physically larger than a lower voltage capacitor, and thus be able to dissipate more heat to the surrounding air, and therefore will have a higher RMS current rating. The consequence of operating an electrolytic capacitor above the RMS current rating is a shortened operating life. In order to assure maximum capacitor operating lifetime, the capacitor's RMS ripple current rating should be:

$$
\mathrm{I}_{\mathrm{rms}}>1.2 \times \mathrm{dx} \mathrm{I}_{\text {Load }}
$$

where d is the duty cycle, for a buck regulator

$$
\mathrm{d}=\frac{\mathrm{t}_{\text {on }}}{\mathrm{T}}=\frac{\mathrm{V}_{\text {out }}}{\mathrm{V}_{\text {in }}}
$$

and $d=\frac{t_{\text {on }}}{T}=\frac{\left|V_{\text {out }}\right|}{\left|V_{\text {out }}\right|+V_{\text {in }}}$ for a buck-boost regulator.

## Output Capacitor ( $\mathrm{C}_{\text {out }}$ )

For low output ripple voltage and good stability, low ESR output capacitors are recommended. An output capacitor has two main functions: it filters the output and provides regulator loop stability. The ESR of the output capacitor and the peak-to-peak value of the inductor ripple current are the main factors contributing to the output ripple voltage value. Standard aluminium electrolytics could be adequate for some applications but for quality design low ESR types are recommended.

An aluminium electrolytic capacitor's ESR value is related to many factors such as the capacitance value, the voltage rating, the physical size and the type of construction. In most cases, the higher voltage electrolytic capacitors have lower ESR value. Often capacitors with much higher voltage ratings may be needed to provide low ESR values that are required for low output ripple voltage.

## The Output Capacitor Requires an ESR Value That Has an Upper and Lower Limit

As mentioned above, a low ESR value is needed for low output ripple voltage, typically $1 \%$ to $2 \%$ of the output voltage. But if the selected capacitor's ESR is extremely low (below $0.05 \Omega$ ), there is a possibility of an unstable feedback
loop, resulting in oscillation at the output. This situation can occur when a tantalum capacitor, that can have a very low ESR, is used as the only output capacitor.

## At Low Temperatures, Put in Parallel Aluminium Electrolytic Capacitors with Tantalum Capacitors

Electrolytic capacitors are not recommended for temperatures below $-25^{\circ} \mathrm{C}$. The ESR rises dramatically at cold temperatures and typically rises 3 times at $-25^{\circ} \mathrm{C}$ and as much as 10 times at $-40^{\circ} \mathrm{C}$. Solid tantalum capacitors have much better ESR spec at cold temperatures and are recommended for temperatures below $-25^{\circ} \mathrm{C}$. They can be also used in parallel with aluminium electrolytics. The value of the tantalum capacitor should be about $10 \%$ or $20 \%$ of the total capacitance. The output capacitor should have at least $50 \%$ higher RMS ripple current rating at 52 kHz than the peak-to-peak inductor ripple current.

## Catch Diode <br> Locate the Catch Diode Close to the LM2575

The LM2575 is a step-down buck converter; it requires a fast diode to provide a return path for the inductor current when the switch turns off. This diode must be located close to the LM2575 using short leads and short printed circuit traces to avoid EMI problems.

## Use a Schottky or a Soft Switching Ultra-Fast Recovery Diode

Since the rectifier diodes are very significant source of losses within switching power supplies, choosing the rectifier that best fits into the converter design is an important process. Schottky diodes provide the best performance because of their fast switching speed and low forward voltage drop.
They provide the best efficiency especially in low output voltage applications ( 5.0 V and lower). Another choice could be Fast-Recovery, or Ultra-Fast Recovery diodes. It has to be noted, that some types of these diodes with an abrupt turnoff characteristic may cause instability or EMI troubles.

A fast-recovery diode with soft recovery characteristics can better fulfill a quality, low noise design requirements. Table 4 provides a list of suitable diodes for the LM2575 regulator. Standard $50 / 60 \mathrm{~Hz}$ rectifier diodes such as the 1N4001 series or 1N5400 series are NOT suitable.

## Inductor

The magnetic components are the cornerstone of all switching power supply designs. The style of the core and the winding technique used in the magnetic component's design has a great influence on the reliability of the overall power supply.
Using an improper or poorly designed inductor can cause high voltage spikes generated by the rate of transitions in current within the switching power supply, and the possibility of core saturation can arise during an abnormal operational mode. Voltage spikes can cause the semiconductors to enter avalanche breakdown and the part can instantly fail if enough energy is applied. It can also cause significant RFI (Radio Frequency Interference) and EMI (Electro-Magnetic Interference) problems.

## Continuous and Discontinuous Mode of Operation

The LM2575 step-down converter can operate in both the continuous and the discontinuous modes of operation. The regulator works in the continuous mode when loads are relatively heavy, the current flows through the inductor continuously and never falls to zero. Under light load conditions, the circuit will be forced to the discontinuous mode when inductor current falls to zero for certain period of time (see Figure 22 and Figure 23). Each mode has distinctively different operating characteristics, which can affect the regulator performance and requirements. In many cases the preferred mode of operation is the continuous mode. It offers greater output power, lower peak currents in the switch, inductor and diode, and can have a lower output ripple voltage. On the other hand it does require larger inductor values to keep the inductor current flowing continuously, especially at low output load currents and/or high input voltages.

To simplify the inductor selection process, an inductor selection guide for the LM2575 regulator was added to this data sheet (Figures 17 through 21). This guide assumes that the regulator is operating in the continuous mode, and selects an inductor that will allow a peak-to-peak inductor ripple current to be a certain percentage of the maximum design load current. This percentage is allowed to change as different design load currents are selected. For light loads (less than approximately 200 mA ) it may be desirable to operate the regulator in the discontinuous mode, because the inductor value and size can be kept relatively low. Consequently, the percentage of inductor peak-to-peak current increases. This discontinuous mode of operation is perfectly acceptable for this type of switching converter. Any buck regulator will be forced to enter discontinuous mode if the load current is light enough.

HORIZONTAL TIME BASE: $5.0 \mu \mathrm{~s} / \mathrm{DIV}$
Figure 22. Continuous Mode Switching Current Waveforms

## Selecting the Right Inductor Style

Some important considerations when selecting a core type are core material, cost, the output power of the power supply, the physical volume the inductor must fit within, and the
amount of EMI (Electro-Magnetic Interference) shielding that the core must provide. The inductor selection guide covers different styles of inductors, such as pot core, E-core, toroid and bobbin core, as well as different core materials such as ferrites and powdered iron from different manufacturers.

For high quality design regulators the toroid core seems to be the best choice. Since the magnetic flux is completely contained within the core, it generates less EMI, reducing noise problems in sensitive circuits. The least expensive is the bobbin core type, which consists of wire wound on a ferrite rod core. This type of inductor generates more EMI due to the fact that its core is open, and the magnetic flux is not completely contained within the core.

When multiple switching regulators are located on the same printed circuit board, open core magnetics can cause interference between two or more of the regulator circuits, especially at high currents due to mutual coupling. A toroid, pot core or E-core (closed magnetic structure) should be used in such applications.

## Do Not Operate an Inductor Beyond its Maximum Rated Current

Exceeding an inductor's maximum current rating may cause the inductor to overheat because of the copper wire losses, or the core may saturate. Core saturation occurs when the flux density is too high and consequently the cross sectional area of the core can no longer support additional lines of magnetic flux.

This causes the permeability of the core to drop, the inductance value decreases rapidly and the inductor begins to look mainly resistive. It has only the dc resistance of the winding. This can cause the switch current to rise very rapidly and force the LM2575 internal switch into cycle-by-cycle current limit, thus reducing the dc output load current. This can also result in overheating of the inductor and/or the LM2575. Different inductor types have different saturation characteristics, and this should be kept in mind when selecting an inductor.

Figure 23. Discontinuous Mode Switching Current Waveforms

## GENERAL RECOMMENDATIONS

## Output Voltage Ripple and Transients Source of the Output Ripple

Since the LM2575 is a switch mode power supply regulator, its output voltage, if left unfiltered, will contain a sawtooth ripple voltage at the switching frequency. The output ripple voltage value ranges from $0.5 \%$ to $3 \%$ of the output voltage. It is caused mainly by the inductor sawtooth ripple current multiplied by the ESR of the output capacitor.

## Short Voltage Spikes and How to Reduce Them

The regulator output voltage may also contain short voltage spikes at the peaks of the sawtooth waveform (see Figure 24). These voltage spikes are present because of the fast switching action of the output switch, and the parasitic inductance of the output filter capacitor. There are some other important factors such as wiring inductance, stray capacitance, as well as the scope probe used to evaluate these transients, all these contribute to the amplitude of these spikes. To minimize these voltage spikes, low inductance capacitors should be used, and their lead lengths must be kept short. The importance of quality printed circuit board layout design should also be highlighted.

HORIZONTAL TIME BASE: $10 \mu \mathrm{~s} /$ DIV
Figure 24. Output Ripple Voltage Waveforms

## Minimizing the Output Ripple

In order to minimize the output ripple voltage it is possible to enlarge the inductance value of the inductor L1 and/or to use a larger value output capacitor. There is also another way to smooth the output by means of an additional LC filter $(20 \mu \mathrm{H}, 100 \mu \mathrm{~F})$, that can be added to the output (see Figure 33) to further reduce the amount of output ripple and transients. With such a filter it is possible to reduce the output ripple voltage transients 10 times or more. Figure 24 shows the difference between filtered and unfiltered output waveforms of the regulator shown in Figure 33.

The upper waveform is from the normal unfiltered output of the converter, while the lower waveform shows the output ripple voltage filtered by an additional LC filter.

## Heatsinking and Thermal Considerations The Through-Hole Package TO-220

The LM2575 is available in two packages, a $5-$ pin TO-220(T, TV) and a 5 -pin surface mount $\mathrm{D}^{2} \mathrm{PAK}(\mathrm{D} 2 \mathrm{~T})$. There are many applications that require no heatsink to keep the LM2575 junction temperature within the allowed operating range. The TO-220 package can be used without a heatsink for ambient temperatures up to approximately $50^{\circ} \mathrm{C}$ (depending on the output voltage and load current). Higher ambient temperatures require some heatsinking, either to the printed circuit (PC) board or an external heatsink.

## The Surface Mount Package D²PAK and its Heatsinking

The other type of package, the surface mount $\mathrm{D}^{2} \mathrm{PAK}$, is designed to be soldered to the copper on the PC board. The copper and the board are the heatsink for this package and the other heat producing components, such as the catch diode and inductor. The PC board copper area that the package is soldered to should be at least $0.4 \mathrm{in}^{2}$ (or $100 \mathrm{~mm}^{2}$ ) and ideally should have 2 or more square inches ( $1300 \mathrm{~mm}^{2}$ ) of 0.0028 inch copper. Additional increasing of copper area beyond approximately $3.0 \mathrm{in}^{2}\left(2000 \mathrm{~mm}^{2}\right)$ will not improve heat dissipation significantly. If further thermal improvements are needed, double sided or multilayer PC boards with large copper areas should be considered.

## Thermal Analysis and Design

The following procedure must be performed to determine whether or not a heatsink will be required. First determine:

1. $\mathrm{P}_{\mathrm{D}(\max )}$ maximum regulator power dissipation in the application.
2. $\mathrm{T}_{\mathrm{A}(\max )}$ maximum ambient temperature in the application.
3. $\mathrm{T}_{\mathrm{J}(\max )}$ maximum allowed junction temperature $\left(125^{\circ} \mathrm{C}\right.$ for the LM2575). For a conservative design, the maximum junction temperature should not exceed $110^{\circ} \mathrm{C}$ to assure safe operation. For every additional $10^{\circ} \mathrm{C}$ temperature rise that the junction must withstand, the estimated operating lifetime of the component is halved.
4. $\mathrm{R}_{\theta \mathrm{JC}}$ package thermal resistance junction-case. 5. $\mathrm{R}_{\theta \mathrm{JA}}$ package thermal resistance junction-ambient. (Refer to Absolute Maximum Ratings in this data sheet or $R_{\theta J C}$ and $R_{\theta J \mathrm{~A}}$ values).

The following formula is to calculate the total power dissipated by the LM2575:

$$
P_{D}=\left(V_{\text {in }} \times I_{Q}\right)+d \times I_{\text {Load }} \times V_{\text {sat }}
$$

where $d$ is the duty cycle and for buck converter

$$
\mathrm{d}=\frac{\mathrm{t}_{\mathrm{on}}}{\mathrm{~T}}=\frac{\mathrm{V}_{\mathrm{O}}}{\mathrm{~V}_{\mathrm{in}}}
$$

$\mathrm{I}_{\mathrm{Q}} \quad$ (quiescent current) and $\mathrm{V}_{\text {sat }}$ can be found in the LM2575 data sheet,
$\mathrm{V}_{\text {in }}$ is minimum input voltage applied,
$\mathrm{V}_{\mathrm{O}}$ is the regulator output voltage,
$\mathrm{I}_{\text {Load }}$ is the load current.
The dynamic switching losses during turn-on and turn-off can be neglected if proper type catch diode is used.

## Packages Not on a Heatsink (Free-Standing)

For a free-standing application when no heatsink is used, the junction temperature can be determined by the following expression:

$$
T_{J}=\left(R_{\theta J A}\right)\left(P_{D}\right)+T_{A}
$$

where $\left(R_{\theta J A}\right)\left(P_{D}\right)$ represents the junction temperature rise caused by the dissipated power and $\mathrm{T}_{\mathrm{A}}$ is the maximum ambient temperature.

## Packages on a Heatsink

If the actual operating junction temperature is greater than the selected safe operating junction temperature determined in step 3, than a heatsink is required. The junction temperature will be calculated as follows:

$$
T_{J}=P_{D}\left(R_{\theta J A}+R_{\theta C S}+R_{\theta S A}\right)+T_{A}
$$

where $\quad R_{\theta J C}$ is the thermal resistance junction-case, $\mathrm{R}_{\theta C S}$ is the thermal resistance case-heatsink, $\mathrm{R}_{\theta \mathrm{SA}}$ is the thermal resistance heatsink-ambient.
If the actual operating temperature is greater than the selected safe operating junction temperature, then a larger heatsink is required.

## Some Aspects That can Influence Thermal Design

It should be noted that the package thermal resistance and the junction temperature rise numbers are all approximate, and there are many factors that will affect these numbers, such as PC board size, shape, thickness, physical position, location, board temperature, as well as whether the surrounding air is moving or still.
Other factors are trace width, total printed circuit copper area, copper thickness, single- or double-sided, multilayer board, the amount of solder on the board or even color of the traces.

The size, quantity and spacing of other components on the board can also influence its effectiveness to dissipate the heat.

Figure 25. Inverting Buck-Boost Regulator Using the LM2575-12 Develops -12 V @ 0.35 A

## ADDITIONAL APPLICATIONS

## Inverting Regulator

An inverting buck-boost regulator using the LM2575-12 is shown in Figure 25. This circuit converts a positive input voltage to a negative output voltage with a common ground by bootstrapping the regulators ground to the negative output voltage. By grounding the feedback pin, the regulator senses the inverted output voltage and regulates it.

In this example the LM2575-12 is used to generate a -12 V output. The maximum input voltage in this case cannot exceed +28 V because the maximum voltage appearing across the regulator is the absolute sum of the input and output voltages and this must be limited to a maximum of 40 V .

This circuit configuration is able to deliver approximately 0.35 A to the output when the input voltage is 12 V or higher. At lighter loads the minimum input voltage required drops to approximately 4.7 V , because the buck-boost regulator topology can produce an output voltage that, in its absolute value, is either greater or less than the input voltage.
Since the switch currents in this buck-boost configuration are higher than in the standard buck converter topology, the available output current is lower.

This type of buck-boost inverting regulator can also require a larger amount of startup input current, even for light loads. This may overload an input power source with a current limit less than 1.5 A .

Such an amount of input startup current is needed for at least 2.0 ms or more. The actual time depends on the output voltage and size of the output capacitor.
Because of the relatively high startup currents required by this inverting regulator topology, the use of a delayed startup or an undervoltage lockout circuit is recommended.

Using a delayed startup arrangement, the input capacitor can charge up to a higher voltage before the switch-mode regulator begins to operate.

The high input current needed for startup is now partially supplied by the input capacitor $\mathrm{C}_{\mathrm{in}}$.

## Design Recommendations:

The inverting regulator operates in a different manner than the buck converter and so a different design procedure has to be used to select the inductor L1 or the output capacitor $\mathrm{C}_{\text {out }}$.

The output capacitor values must be larger than is normally required for buck converter designs. Low input voltages or high output currents require a large value output capacitor (in the range of thousands of $\mu \mathrm{F}$ ).

The recommended range of inductor values for the inverting converter design is between $68 \mu \mathrm{H}$ and $220 \mu \mathrm{H}$. To select an inductor with an appropriate current rating, the inductor peak current has to be calculated.

The following formula is used to obtain the peak inductor current:

$$
\begin{gathered}
\mathrm{I}_{\text {peak }} \approx \frac{\mathrm{I}_{\mathrm{Load}}\left(\mathrm{~V}_{\text {in }}+\left|\mathrm{V}_{\mathrm{O}}\right|\right)}{\mathrm{V}_{\text {in }}}+\frac{\mathrm{V}_{\text {in }} \times \mathrm{t}_{\mathrm{on}}}{2 \mathrm{~L}_{1}} \\
\text { where } \mathrm{t}_{\mathrm{on}}=\frac{\left|\mathrm{V}_{\mathrm{O}}\right|}{\mathrm{V}_{\mathrm{in}}+\left|\mathrm{V}_{\mathrm{O}}\right|} \times \frac{1}{f_{\mathrm{osc}}}, \text { and } \mathrm{f}_{\mathrm{osc}}=52 \mathrm{kHz} .
\end{gathered}
$$

Under normal continuous inductor current operating conditions, the worst case occurs when $\mathrm{V}_{\mathrm{in}}$ is minimal.

Note that the voltage appearing across the regulator is the absolute sum of the input and output voltage, and must not exceed 40 V .

Figure 26. Inverting Buck-Boost Regulator with Delayed Startup

It has been already mentioned above, that in some situations, the delayed startup or the undervoltage lockout features could be very useful. A delayed startup circuit applied to a buck-boost converter is shown in Figure 26. Figure 32 in the "Undervoltage Lockout" section describes an undervoltage lockout feature for the same converter topology.

NOTE: This picture does not show the complete circuit.
Figure 27. Inverting Buck-Boost Regulator Shut Down Circuit Using an Optocoupler

With the inverting configuration, the use of the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin requires some level shifting techniques. This is caused by the fact, that the ground pin of the converter IC is no longer at ground. Now, the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin threshold voltage (1.4 V approximately) has to be related to the negative output voltage level. There are many different possible shut down methods, two of them are shown in Figures 27 and 28.

NOTE: This picture does not show the complete circuit.
Figure 28. Inverting Buck-Boost Regulator Shut Down Circuit Using a PNP Transistor

## Negative Boost Regulator

This example is a variation of the buck-boost topology and is called a negative boost regulator. This regulator experiences relatively high switch current, especially at low input voltages. The internal switch current limiting results in lower output load current capability.
The circuit in Figure 29 shows the negative boost configuration. The input voltage in this application ranges from -5.0 V to -12 V and provides a regulated -12 V output.

If the input voltage is greater than -12 V , the output will rise above -12 V accordingly, but will not damage the regulator.

Figure 29. Negative Boost Regulator

## Design Recommendations:

The same design rules as for the previous inverting buck-boost converter can be applied. The output capacitor $\mathrm{C}_{\text {out }}$ must be chosen larger than would be required for a standard buck converter. Low input voltages or high output currents require a large value output capacitor (in the range of thousands of $\mu \mathrm{F}$ ). The recommended range of inductor values for the negative boost regulator is the same as for inverting converter design.

Another important point is that these negative boost converters cannot provide current limiting load protection in the event of a short in the output so some other means, such as a fuse, may be necessary to provide the load protection.

## Delayed Startup

There are some applications, like the inverting regulator already mentioned above, which require a higher amount of startup current. In such cases, if the input power source is limited, this delayed startup feature becomes very useful.

To provide a time delay between the time the input voltage is applied and the time when the output voltage comes up, the circuit in Figure 30 can be used. As the input voltage is applied, the capacitor C 1 charges up, and the voltage across the resistor R 2 falls down. When the voltage on the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin falls below the threshold value 1.4 V , the regulator starts up. Resistor R1 is included to limit the maximum voltage applied to the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin, reduces the power supply noise sensitivity, and also limits the capacitor C1 discharge current, but its use is not mandatory.

When a high 50 Hz or $60 \mathrm{~Hz}(100 \mathrm{~Hz}$ or 120 Hz respectively) ripple voltage exists, a long delay time can
cause some problems by coupling the ripple into the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin, the regulator could be switched periodically on and off with the line (or double) frequency.

NOTE: This picture does not show the complete circuit.
Figure 30. Delayed Startup Circuitry

## Undervoltage Lockout

Some applications require the regulator to remain off until the input voltage reaches a certain threshold level. Figure 31 shows an undervoltage lockout circuit applied to a buck regulator. A version of this circuit for buck-boost converter is shown in Figure 32. Resistor R3 pulls the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin high and keeps the regulator off until the input voltage reaches a predetermined threshold level, which is determined by the following expression:

$$
\mathrm{v}_{\mathrm{th}} \approx \mathrm{~V}_{\mathrm{Z} 1}+\left(1+\frac{\mathrm{R} 2}{\mathrm{R} 1}\right) \mathrm{v}_{\mathrm{BE}}(\mathrm{Q} 1)
$$

NOTE: This picture does not show the complete circuit.

## Adjustable Output, Low-Ripple Power Supply

A 1.0 A output current capability power supply that features an adjustable output voltage is shown in Figure 33.
This regulator delivers 1.0 A into 1.2 V to 35 V output. The input voltage ranges from roughly 8.0 V to 40 V . In order to achieve a 10 or more times reduction of output ripple, an additional $\mathrm{L}-\mathrm{C}$ filter is included in this circuit.

## LM2576

### 3.0 A, 15 V, Step-Down Switching Regulator

The LM2576 series of regulators are monolithic integrated circuits ideally suited for easy and convenient design of a step-down switching regulator (buck converter). All circuits of this series are capable of driving a 3.0 A load with excellent line and load regulation. These devices are available in fixed output voltages of $3.3 \mathrm{~V}, 5.0 \mathrm{~V}$, $12 \mathrm{~V}, 15 \mathrm{~V}$, and an adjustable output version.

These regulators were designed to minimize the number of external components to simplify the power supply design. Standard series of inductors optimized for use with the LM2576 are offered by several different inductor manufacturers.

Since the LM2576 converter is a switch-mode power supply, its efficiency is significantly higher in comparison with popular three-terminal linear regulators, especially with higher input voltages. In many cases, the power dissipated is so low that no heatsink is required or its size could be reduced dramatically.

A standard series of inductors optimized for use with the LM2576 are available from several different manufacturers. This feature greatly simplifies the design of switch-mode power supplies.

The LM2576 features include a guaranteed $\pm 4 \%$ tolerance on output voltage within specified input voltages and output load conditions, and $\pm 10 \%$ on the oscillator frequency ( $\pm 2 \%$ over $0^{\circ} \mathrm{C}$ to $125^{\circ} \mathrm{C}$ ). External shutdown is included, featuring $80 \mu \mathrm{~A}$ (typical) standby current. The output switch includes cycle-by-cycle current limiting, as well as thermal shutdown for full protection under fault conditions.

## Features

- 3.3 V, 5.0 V, $12 \mathrm{~V}, 15 \mathrm{~V}$, and Adjustable Output Versions
- Adjustable Version Output Voltage Range, 1.23 to $37 \mathrm{~V} \pm 4 \%$ Maximum Over Line and Load Conditions
- Guaranteed 3.0 A Output Current
- Wide Input Voltage Range
- Requires Only 4 External Components
- 52 kHz Fixed Frequency Internal Oscillator
- TTL Shutdown Capability, Low Power Standby Mode
- High Efficiency
- Uses Readily Available Standard Inductors
- Thermal Shutdown and Current Limit Protection
- Moisture Sensitivity Level (MSL) Equals 1

## Applications

- Simple High-Efficiency Step-Down (Buck) Regulator
- Efficient Pre-Regulator for Linear Regulators
- On-Card Switching Regulators
- Positive to Negative Converter (Buck-Boost)
- Negative Step-Up Converters
- Power Supply for Battery Chargers

3. The oscillator frequency reduces to approximately 18 kHz in the event of an output short or an overload which causes the regulated output voltage to drop approximately $40 \%$ from the nominal output voltage. This self protection feature lowers the average dissipation of the IC by lowering the minimum duty cycle from $5 \%$ down to approximately $2 \%$.
4. Output (Pin 2) sourcing current. No diode, inductor or capacitor connected to output pin.
5. Feedback (Pin 4) removed from output and connected to 0 V .
6. Feedback (Pin 4) removed from output and connected to +12 V for the Adjustable, 3.3 V , and 5.0 V versions, and +25 V for the 12 V and 15 V versions, to force the output transistor "off".
7. $\mathrm{V}_{\mathrm{in}}=40 \mathrm{~V}$.

## PCB LAYOUT GUIDELINES

As in any switching regulator, the layout of the printed circuit board is very important. Rapidly switching currents associated with wiring inductance, stray capacitance and parasitic inductance of the printed circuit board traces can generate voltage transients which can generate electromagnetic interferences (EMI) and affect the desired operation. As indicated in the Figure 15, to minimize inductance and ground loops, the length of the leads indicated by heavy lines should be kept as short as possible.

For best results, single-point grounding (as indicated) or ground plane construction should be used.

On the other hand, the PCB area connected to the Pin 2 (emitter of the internal switch) of the LM2576 should be kept to a minimum in order to minimize coupling to sensitive circuitry.

Another sensitive part of the circuit is the feedback. It is important to keep the sensitive feedback wiring short. To assure this, physically locate the programming resistors near to the regulator, when using the adjustable version of the LM2576 regulator.

PIN FUNCTION DESCRIPTION

| Pin | Symbol | Description (Refer to Figure 1) |
| :---: | :---: | :--- |
| 1 | $\mathrm{~V}_{\text {in }}$ | This pin is the positive input supply for the LM2576 step-down switching regulator. In order to minimize voltage <br> transients and to supply the switching currents needed by the regulator, a suitable input bypass capacitor must be <br> present ( $\mathrm{C}_{\text {in }}$ in Figure 1). |
| 2 | Output | This is the emitter of the internal switch. The saturation voltage $\mathrm{V}_{\text {sat }}$ of this output switch is typically 1.5 V. It should <br> be kept in mind that the PCB area connected to this pin should be kept to a minimum in order to minimize coupling <br> to sensitive circuitry. |
| 3 | Gnd | Circuit ground pin. See the information about the printed circuit board layout. |
| 4 | Feedback | This pin senses regulated output voltage to complete the feedback loop. The signal is divided by the internal resistor <br> divider network R2, R1 and applied to the non-inverting input of the internal error amplifier. In the Adjustable version <br> of the LM2576 switching regulator this pin is the direct input of the error amplifier and the resistor network R2, R1 is <br> connected externally to allow programming of the output voltage. |
| 5 | ON/OFF | It allows the switching regulator circuit to be shut down using logic level signals, thus dropping the total input supply <br> current to approximately 80 $\mu \mathrm{A}$. The threshold voltage is typically 1.4 V . Applying a voltage above this value (up to <br> +V $\mathrm{V}_{\text {in }}$ ) shuts the regulator off. If the voltage applied to this pin is lower than 1.4 V or if this pin is left open, the <br> regulator will be in the "on" condition. |

## DESIGN PROCEDURE

## Buck Converter Basics

The LM2576 is a "Buck" or Step-Down Converter which is the most elementary forward-mode converter. Its basic schematic can be seen in Figure 16.

The operation of this regulator topology has two distinct time periods. The first one occurs when the series switch is on, the input voltage is connected to the input of the inductor.

The output of the inductor is the output voltage, and the rectifier (or catch diode) is reverse biased. During this period, since there is a constant voltage source connected across the inductor, the inductor current begins to linearly ramp upwards, as described by the following equation:

$$
\mathrm{I}_{\mathrm{L}(\mathrm{on})}=\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \mathrm{t}_{\text {on }}}{\mathrm{L}}
$$

During this "on" period, energy is stored within the core material in the form of magnetic flux. If the inductor is properly designed, there is sufficient energy stored to carry the requirements of the load during the "off" period.

Figure 16. Basic Buck Converter
The next period is the "off" period of the power switch. When the power switch turns off, the voltage across the inductor reverses its polarity and is clamped at one diode voltage drop below ground by the catch diode. The current now flows through the catch diode thus maintaining the load current loop. This removes the stored energy from the inductor. The inductor current during this time is:

$$
\mathrm{I}_{\mathrm{L}(\text { off })}=\frac{\left(\mathrm{V}_{\text {out }}-\mathrm{V}_{\mathrm{D}}\right) \mathrm{t}_{\text {off }}}{\mathrm{L}}
$$

This period ends when the power switch is once again turned on. Regulation of the converter is accomplished by varying the duty cycle of the power switch. It is possible to describe the duty cycle as follows:

$$
\mathrm{d}=\frac{\mathrm{t}_{\mathrm{on}}}{\mathrm{~T}} \text {, where } \mathrm{T} \text { is the period of switching. }
$$

For the buck converter with ideal components, the duty cycle can also be described as:

$$
\mathrm{d}=\frac{\mathrm{V}_{\text {out }}}{\mathrm{V}_{\text {in }}}
$$

Figure 17 shows the buck converter, idealized waveforms of the catch diode voltage and the inductor current.

Figure 17. Buck Converter Idealized Waveforms

Procedure (Fixed Output Voltage Version) In order to simplify the switching regulator design, a step-by-step design procedure and some examples are provided.

| Procedure |
| :--- |
| Given Parameters: <br> $V_{\text {out }}=$ Regulated Output Voltage $(3.3 \mathrm{~V}, 5.0 \mathrm{~V}, 12 \mathrm{~V}$ or 15 V$)$ <br> $\mathrm{V}_{\text {in(max) }}=$ Maximum Input Voltage <br> $\mathrm{I}_{\text {Load(max) }}=$ Maximum Load Current |
| 1. Controller IC Selection |
| According to the required input voltage, output voltage and |
| current, select the appropriate type of the controller IC output |
| voltage version. |

3. Catch Diode Selection (D1)
A. Since the diode maximum peak current exceeds the regulator maximum load current the catch diode current rating must be at least 1.2 times greater than the maximum load current. For a robust design the diode should have a current rating equal to the maximum current limit of the LM2576 to be able to withstand a continuous output short
B. The reverse voltage rating of the diode should be at least 1.25 times the maximum input voltage.
4. Catch Diode Selection (D1)
A. For this example the current rating of the diode is 3.0 A .
B. Use a 20 V 1 N 5820 Schottky diode, or any of the suggested fast recovery diodes shown in Table 1.
5. Inductor Selection (L1)
A. Use the inductor selection guide shown in Figures 19.
B. From the selection guide, the inductance area intersected by the 15 V line and 3.0 A line is L 100 .
C. Inductor value required is $100 \mu \mathrm{H}$. From Table 2, choose an inductor from any of the listed manufacturers.

## LM2576

Procedure (Fixed Output Voltage Version) (continued)In order to simplify the switching regulator design, a step-by-step design procedure and some examples are provided.

| Procedure | Example |
| :---: | :---: |
| 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ ) <br> A. Since the LM2576 is a forward-mode switching regulator with voltage mode control, its open loop 2-pole-1-zero frequency characteristic has the dominant pole-pair determined by the output capacitor and inductor values. For stable operation and an acceptable ripple voltage, (approximately $1 \%$ of the output voltage) a value between $680 \mu \mathrm{~F}$ and $2000 \mu \mathrm{~F}$ is recommended. <br> B. Due to the fact that the higher voltage electrolytic capacitors generally have lower ESR (Equivalent Series Resistance) numbers, the output capacitor's voltage rating should be at least 1.5 times greater than the output voltage. For a 5.0 V regulator, a rating at least 8.0 V is appropriate, and a 10 V or 16 V rating is recommended. | 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ ) <br> A. $\mathrm{C}_{\text {out }}=680 \mu \mathrm{~F}$ to $2000 \mu \mathrm{~F}$ standard aluminium electrolytic. <br> B. Capacitor voltage rating $=20 \mathrm{~V}$. |

Procedure (Adjustable Output Version: LM2576-ADJ)

| Procedure |
| :--- |
| Given Parameters: <br> $\mathrm{V}_{\text {out }}=$ Regulated Output Voltage <br> $\mathrm{V}_{\text {in }(\max )}=$ Maximum DC Input Voltage |
| $\mathrm{I}_{\text {Load }(\max )}=$ Maximum Load Current |

Resistor R1 can be between 1.0 k and $5.0 \mathrm{k} \Omega$. (For best temperature coefficient and stability with time, use $1 \%$ metal film resistors).

$$
\mathrm{R} 2=\mathrm{R} 1\left(\frac{\mathrm{~V}_{\text {out }}}{\mathrm{V}_{\text {ref }}}-1.0\right)
$$

## 2. Input Capacitor Selection ( $\mathrm{C}_{\text {in }}$ )

To prevent large voltage transients from appearing at the input and for stable operation of the converter, an aluminium or tantalum electrolytic bypass capacitor is needed between the input pin $+\mathrm{V}_{\text {in }}$ and ground pin Gnd This capacitor should be located close to the IC using short leads. This capacitor should have a low ESR (Equivalent Series Resistance) value.

For additional information see input capacitor section in the "Application Hints" section of this data sheet.
3. Catch Diode Selection (D1)
A. Since the diode maximum peak current exceeds the regulator maximum load current the catch diode current rating must be at least 1.2 times greater than the maximum load current. For a robust design, the diode should have a current rating equal to the maximum current limit of the LM2576 to be able to withstand a continuous output short.
B. The reverse voltage rating of the diode should be at least 1.25 times the maximum input voltage.
B. Use a 30 V 1 N 5821 Schottky diode or any suggested fast recovery diode in the Table 1.

Procedure (Adjustable Output Version: LM2576-ADJ) (continued)

| Procedure |
| :--- |
| 4. Inductor Selection (L1) |
| A. Use the following formula to calculate the inducto |
| microsecond $[\mathrm{V} \times \mu \mathrm{s}]$ constant: |
| $E \mathrm{E} \times \mathrm{T}=\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \frac{\mathrm{V}_{\text {out }}}{\mathrm{V}_{\text {in }}} \times \frac{10^{6}}{\mathrm{~F}[\mathrm{~Hz}]}[\mathrm{V} \times \mu \mathrm{s}]$ |

B. Match the calculated $\mathrm{E} \times \mathrm{T}$ value with the corresponding number on the vertical axis of the Inductor Value Selection Guide shown in Figure 22. This E x T constant is a measure of the energy handling capability of an inductor and is dependent upon the type of core, the core area, the number of turns, and the duty cycle.
C. Next step is to identify the inductance region intersected by the $\mathrm{E} \times \mathrm{T}$ value and the maximum load current value on the horizontal axis shown in Figure 25.
D. From the inductor code, identify the inductor value. Then select an appropriate inductor from Table 2.
The inductor chosen must be rated for a switching frequency of 52 kHz and for a current rating of $1.15 \times \mathrm{I}_{\text {Load }}$. The inductor current rating can also be determined by calculating the inductor peak current:

$$
I_{p(\max )}=I_{\text {Load }(\max )}+\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {out }}\right) \mathrm{t}_{\text {on }}}{2 \mathrm{~L}}
$$

where $t_{o n}$ is the "on" time of the power switch and

$$
t_{\text {on }}=\frac{V_{\text {out }}}{V_{\text {in }}} \times \frac{1.0}{f_{\text {osc }}}
$$

For additional information about the inductor, see the inductor section in the "External Components" section of this data sheet.

## 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ )

A. Since the LM2576 is a forward-mode switching regulator with voltage mode control, its open loop 2-pole-1-zero frequency characteristic has the dominant pole-pair determined by the output capacitor and inductor values.

For stable operation, the capacitor must satisfy the following requirement:

$$
C_{\text {out }} \geq 13,300 \frac{V_{\text {in }(\text { max })}}{V_{\text {out }} \times L[\mu H]}[\mu \mathrm{F}]
$$

B. Capacitor values between $10 \mu \mathrm{~F}$ and $2000 \mu \mathrm{~F}$ will satisfy the loop requirements for stable operation. To achieve an acceptable output ripple voltage and transient response, the output capacitor may need to be several times larger than the above formula yields.
C. Due to the fact that the higher voltage electrolytic capacitors generally have lower ESR (Equivalent Series Resistance) numbers, the output capacitor's voltage rating should be at least 1.5 times greater than the output voltage. For a 5.0 V regulator, a rating of at least 8.0 V is appropriate, and a 10 V or 16 V rating is recommended.

## Example

4. Inductor Selection (L1)
A. Calculate $\mathrm{E} \times \mathrm{T}[\mathrm{V} \times \mu \mathrm{s}]$ constant:

$$
E \times T=(25-8.0) \times \frac{8.0}{25} \times \frac{1000}{52}=80[V \times \mu \mathrm{s}]
$$

B. $\mathrm{E} \times \mathrm{T}=80[\mathrm{~V} \times \mu \mathrm{s}]$
C. $I_{\text {Load }(\max )}=2.5 \mathrm{~A}$

Inductance Region $=\mathrm{H} 150$
D. Proper inductor value $=150 \mu \mathrm{H}$ Choose the inductor from Table 2.

## 5. Output Capacitor Selection ( $\mathrm{C}_{\text {out }}$ )

A.

$$
C_{\text {out }} \geq 13,300 \times \frac{25}{8 \times 150}=332.5 \mu \mathrm{~F}
$$

To achieve an acceptable ripple voltage, select $\mathrm{C}_{\text {out }}=680 \mu \mathrm{~F}$ electrolytic capacitor.

## EXTERNAL COMPONENTS

## Input Capacitor ( $\mathrm{C}_{\text {in }}$ ) <br> The Input Capacitor Should Have a Low ESR

For stable operation of the switch mode converter a low ESR (Equivalent Series Resistance) aluminium or solid tantalum bypass capacitor is needed between the input pin and the ground pin, to prevent large voltage transients from appearing at the input. It must be located near the regulator and use short leads. With most electrolytic capacitors, the capacitance value decreases and the ESR increases with lower temperatures. For reliable operation in temperatures below $-25^{\circ} \mathrm{C}$ larger values of the input capacitor may be needed. Also paralleling a ceramic or solid tantalum capacitor will increase the regulator stability at cold temperatures.

## RMS Current Rating of $C_{\text {in }}$

The important parameter of the input capacitor is the RMS current rating. Capacitors that are physically large and have large surface area will typically have higher RMS current ratings. For a given capacitor value, a higher voltage electrolytic capacitor will be physically larger than a lower voltage capacitor, and thus be able to dissipate more heat to the surrounding air, and therefore will have a higher RMS current rating. The consequence of operating an electrolytic capacitor beyond the RMS current rating is a shortened operating life. In order to assure maximum capacitor operating lifetime, the capacitor's RMS ripple current rating should be:

$$
I_{\mathrm{rms}}>1.2 \times \mathrm{dx} \mathrm{I}_{\text {Load }}
$$

where d is the duty cycle, for a buck regulator

$$
\mathrm{d}=\frac{\mathrm{t}_{\text {on }}}{\mathrm{T}}=\frac{\mathrm{V}_{\text {out }}}{\mathrm{V}_{\text {in }}}
$$

and $d=\frac{t_{\text {on }}}{T}=\frac{\left|V_{\text {out }}\right|}{\left|V_{\text {out }}\right|+V_{\text {in }}}$ for a buck-boost regulator.

## Output Capacitor (Cout)

For low output ripple voltage and good stability, low ESR output capacitors are recommended. An output capacitor has two main functions: it filters the output and provides regulator loop stability. The ESR of the output capacitor and the peak-to-peak value of the inductor ripple current are the main factors contributing to the output ripple voltage value. Standard aluminium electrolytics could be adequate for some applications but for quality design, low ESR types are recommended.
An aluminium electrolytic capacitor's ESR value is related to many factors such as the capacitance value, the voltage rating, the physical size and the type of construction. In most cases, the higher voltage electrolytic capacitors have lower ESR value. Often capacitors with much higher voltage ratings may be needed to provide low ESR values that, are required for low output ripple voltage.

## The Output Capacitor Requires an ESR Value That Has an Upper and Lower Limit

As mentioned above, a low ESR value is needed for low output ripple voltage, typically $1 \%$ to $2 \%$ of the output voltage. But if the selected capacitor's ESR is extremely low (below $0.05 \Omega$ ), there is a possibility of an unstable feedback loop, resulting in oscillation at the output. This situation can occur when a tantalum capacitor, that can have a very low ESR, is used as the only output capacitor.

## At Low Temperatures, Put in Parallel Aluminium Electrolytic Capacitors with Tantalum Capacitors

Electrolytic capacitors are not recommended for temperatures below $-25^{\circ} \mathrm{C}$. The ESR rises dramatically at cold temperatures and typically rises 3 times at $-25^{\circ} \mathrm{C}$ and as much as 10 times at $-40^{\circ} \mathrm{C}$. Solid tantalum capacitors have much better ESR spec at cold temperatures and are recommended for temperatures below $-25^{\circ} \mathrm{C}$. They can be also used in parallel with aluminium electrolytics. The value of the tantalum capacitor should be about $10 \%$ or $20 \%$ of the total capacitance. The output capacitor should have at least $50 \%$ higher RMS ripple current rating at 52 kHz than the peak-to-peak inductor ripple current.

## Catch Diode

## Locate the Catch Diode Close to the LM2576

The LM2576 is a step-down buck converter; it requires a fast diode to provide a return path for the inductor current when the switch turns off. This diode must be located close to the LM2576 using short leads and short printed circuit traces to avoid EMI problems.

## Use a Schottky or a Soft Switching Ultra-Fast Recovery Diode

Since the rectifier diodes are very significant sources of losses within switching power supplies, choosing the rectifier that best fits into the converter design is an important process. Schottky diodes provide the best performance because of their fast switching speed and low forward voltage drop.

They provide the best efficiency especially in low output voltage applications ( 5.0 V and lower). Another choice could be Fast-Recovery, or Ultra-Fast Recovery diodes. It has to be noted, that some types of these diodes with an abrupt turnoff characteristic may cause instability or EMI troubles.

A fast-recovery diode with soft recovery characteristics can better fulfill some quality, low noise design requirements. Table 1 provides a list of suitable diodes for the LM2576 regulator. Standard $50 / 60 \mathrm{~Hz}$ rectifier diodes, such as the 1N4001 series or 1N5400 series are NOT suitable.

## Inductor

The magnetic components are the cornerstone of all switching power supply designs. The style of the core and the winding technique used in the magnetic component's design has a great influence on the reliability of the overall power supply.

Using an improper or poorly designed inductor can cause high voltage spikes generated by the rate of transitions in current within the switching power supply, and the possibility of core saturation can arise during an abnormal operational mode. Voltage spikes can cause the semiconductors to enter avalanche breakdown and the part can instantly fail if enough energy is applied. It can also cause significant RFI (Radio Frequency Interference) and EMI (Electro-Magnetic Interference) problems.

## Continuous and Discontinuous Mode of Operation

The LM2576 step-down converter can operate in both the continuous and the discontinuous modes of operation. The regulator works in the continuous mode when loads are relatively heavy, the current flows through the inductor continuously and never falls to zero. Under light load conditions, the circuit will be forced to the discontinuous mode when inductor current falls to zero for certain period of time (see Figure 23 and Figure 24). Each mode has distinctively different operating characteristics, which can affect the regulator performance and requirements. In many cases the preferred mode of operation is the continuous mode. It offers greater output power, lower peak currents in the switch, inductor and diode, and can have a lower output
ripple voltage. On the other hand it does require larger inductor values to keep the inductor current flowing continuously, especially at low output load currents and/or high input voltages.

To simplify the inductor selection process, an inductor selection guide for the LM2576 regulator was added to this data sheet (Figures 18 through 22). This guide assumes that the regulator is operating in the continuous mode, and selects an inductor that will allow a peak-to-peak inductor ripple current to be a certain percentage of the maximum design load current. This percentage is allowed to change as different design load currents are selected. For light loads (less than approximately 300 mA ) it may be desirable to operate the regulator in the discontinuous mode, because the inductor value and size can be kept relatively low. Consequently, the percentage of inductor peak-to-peak current increases. This discontinuous mode of operation is perfectly acceptable for this type of switching converter. Any buck regulator will be forced to enter discontinuous mode if the load current is light enough.

Figure 23. Continuous Mode Switching Current Waveforms

## Selecting the Right Inductor Style

Some important considerations when selecting a core type are core material, cost, the output power of the power supply, the physical volume the inductor must fit within, and the amount of EMI (Electro-Magnetic Interference) shielding that the core must provide. The inductor selection guide covers different styles of inductors, such as pot core, E-core, toroid and bobbin core, as well as different core materials such as ferrites and powdered iron from different manufacturers.

For high quality design regulators the toroid core seems to be the best choice. Since the magnetic flux is contained within the core, it generates less EMI, reducing noise problems in sensitive circuits. The least expensive is the bobbin core type, which consists of wire wound on a ferrite rod core. This type of inductor generates more EMI due to the fact that its core is open, and the magnetic flux is not contained within the core.

When multiple switching regulators are located on the same printed circuit board, open core magnetics can cause interference between two or more of the regulator circuits, especially at high currents due to mutual coupling. A toroid, pot core or E-core (closed magnetic structure) should be used in such applications.

## Do Not Operate an Inductor Beyond its Maximum Rated Current

Exceeding an inductor's maximum current rating may cause the inductor to overheat because of the copper wire losses, or the core may saturate. Core saturation occurs when the flux density is too high and consequently the cross sectional area of the core can no longer support additional lines of magnetic flux.

This causes the permeability of the core to drop, the inductance value decreases rapidly and the inductor begins to look mainly resistive. It has only the DC resistance of the winding. This can cause the switch current to rise very rapidly and force the LM2576 internal switch into cycle-by-cycle current limit, thus reducing the DC output load current. This can also result in overheating of the
inductor and/or the LM2576. Different inductor types have different saturation characteristics, and this should be kept in mind when selecting an inductor.

HORIZONTAL TIME BASE: $5.0 \mu \mathrm{~s} / \mathrm{DIV}$
Figure 24. Discontinuous Mode Switching Current Waveforms

## GENERAL RECOMMENDATIONS

## Output Voltage Ripple and Transients Source of the Output Ripple

Since the LM2576 is a switch mode power supply regulator, its output voltage, if left unfiltered, will contain a sawtooth ripple voltage at the switching frequency. The output ripple voltage value ranges from $0.5 \%$ to $3 \%$ of the output voltage. It is caused mainly by the inductor sawtooth ripple current multiplied by the ESR of the output capacitor.

## Short Voltage Spikes and How to Reduce Them

The regulator output voltage may also contain short voltage spikes at the peaks of the sawtooth waveform (see Figure 25). These voltage spikes are present because of the fast switching action of the output switch, and the parasitic inductance of the output filter capacitor. There are some other important factors such as wiring inductance, stray capacitance, as well as the scope probe used to evaluate these transients, all these contribute to the amplitude of these spikes. To minimize these voltage spikes, low inductance capacitors should be used, and their lead lengths must be kept short. The importance of quality printed circuit board layout design should also be highlighted.

Figure 25. Output Ripple Voltage Waveforms

## Minimizing the Output Ripple

In order to minimize the output ripple voltage it is possible to enlarge the inductance value of the inductor L1 and/or to use a larger value output capacitor. There is also another way to smooth the output by means of an additional LC filter ( 20 $\mu \mathrm{H}, 100 \mu \mathrm{~F}$ ), that can be added to the output (see Figure 34) to further reduce the amount of output ripple and transients. With such a filter it is possible to reduce the output ripple voltage transients 10 times or more. Figure 25 shows the difference between filtered and unfiltered output waveforms of the regulator shown in Figure 34.

The lower waveform is from the normal unfiltered output of the converter, while the upper waveform shows the output ripple voltage filtered by an additional LC filter.

## Heatsinking and Thermal Considerations The Through-Hole Package TO-220

The LM2576 is available in two packages, a 5-pin TO-220(T, TV) and a 5-pin surface mount D ${ }^{2}$ PAK (D2T). Although the TO-220(T) package needs a heatsink under most conditions, there are some applications that require no heatsink to keep the LM2576 junction temperature within the allowed operating range. Higher ambient temperatures require some heat sinking, either to the printed circuit (PC) board or an external heatsink.

## The Surface Mount Package D²PAK and its Heatsinking

The other type of package, the surface mount $\mathrm{D}^{2} \mathrm{PAK}$, is designed to be soldered to the copper on the PC board. The copper and the board are the heatsink for this package and the other heat producing components, such as the catch diode and inductor. The PC board copper area that the package is soldered to should be at least $0.4 \mathrm{in}^{2}$ (or $260 \mathrm{~mm}^{2}$ ) and ideally should have 2 or more square inches ( $1300 \mathrm{~mm}^{2}$ ) of 0.0028 inch copper. Additional increases of copper area
beyond approximately $6.0 \mathrm{in}^{2}\left(4000 \mathrm{~mm}^{2}\right)$ will not improve heat dissipation significantly. If further thermal improvements are needed, double sided or multilayer PC boards with large copper areas should be considered. In order to achieve the best thermal performance, it is highly recommended to use wide copper traces as well as large areas of copper in the printed circuit board layout. The only exception to this is the OUTPUT (switch) pin, which should not have large areas of copper (see page 1333 'PCB Layout Guideline').

## Thermal Analysis and Design

The following procedure must be performed to determine whether or not a heatsink will be required. First determine:

1. $\mathrm{P}_{\mathrm{D}(\max )}$ maximum regulator power dissipation in the application.
2. $\mathrm{T}_{\mathrm{A}(\max )}$ maximum ambient temperature in the application.
3. $\mathrm{T}_{\mathrm{J}(\max )}$ maximum allowed junction temperature $\left(125^{\circ} \mathrm{C}\right.$ for the LM2576). For a conservative design, the maximum junction temperature should not exceed $110^{\circ} \mathrm{C}$ to assure safe operation. For every additional $+10^{\circ} \mathrm{C}$ temperature rise that the junction must withstand, the estimated operating lifetime of the component is halved.
4. $\mathrm{R}_{\theta \mathrm{JC}}$ package thermal resistance junction-case.
5. $\mathrm{R}_{\theta \mathrm{JA}}$ package thermal resistance junction-ambient.
(Refer to Absolute Maximum Ratings on page 1327 of this data sheet or $R_{\theta J C}$ and $R_{\theta J \mathrm{~A}}$ values).

The following formula is to calculate the approximate total power dissipated by the LM2576:

$$
P_{D}=\left(V_{\text {in }} \times I_{Q}\right)+d \times I_{\text {Load }} \times V_{\text {sat }}
$$

where $d$ is the duty cycle and for buck converter

$$
\mathrm{d}=\frac{\mathrm{t}_{\mathrm{on}}}{\mathrm{~T}}=\frac{\mathrm{V}_{\mathrm{O}}}{\mathrm{~V}_{\mathrm{in}}}
$$

$\mathrm{I}_{\mathrm{Q}} \quad$ (quiescent current) and $\mathrm{V}_{\text {sat }}$ can be found in the LM2576 data sheet,
$\mathrm{V}_{\mathrm{in}}$ is minimum input voltage applied,
$\mathrm{V}_{\mathrm{O}}$ is the regulator output voltage,
$\mathrm{I}_{\text {Load }}$ is the load current.
The dynamic switching losses during turn-on and turn-off can be neglected if proper type catch diode is used.

## Packages Not on a Heatsink (Free-Standing)

For a free-standing application when no heatsink is used, the junction temperature can be determined by the following expression:

$$
T_{J}=\left(R_{\theta J A}\right)\left(P_{D}\right)+T_{A}
$$

where $\left(R_{\theta J A}\right)\left(P_{D}\right)$ represents the junction temperature rise caused by the dissipated power and $\mathrm{T}_{\mathrm{A}}$ is the maximum ambient temperature.

## Packages on a Heatsink

If the actual operating junction temperature is greater than the selected safe operating junction temperature determined in step 3, than a heatsink is required. The junction temperature will be calculated as follows:

$$
T_{J}=P_{D}\left(R_{\theta J A}+R_{\theta C S}+R_{\theta S A}\right)+T_{A}
$$

where $\quad R_{\theta J C}$ is the thermal resistance junction-case, $\mathrm{R}_{\theta C S}$ is the thermal resistance case-heatsink, $\mathrm{R}_{\theta S A}$ is the thermal resistance heatsink-ambient.
If the actual operating temperature is greater than the selected safe operating junction temperature, then a larger heatsink is required.

## Some Aspects That can Influence Thermal Design

It should be noted that the package thermal resistance and the junction temperature rise numbers are all approximate, and there are many factors that will affect these numbers, such as PC board size, shape, thickness, physical position, location, board temperature, as well as whether the surrounding air is moving or still.

Other factors are trace width, total printed circuit copper area, copper thickness, single- or double-sided, multilayer board, the amount of solder on the board or even color of the traces.

The size, quantity and spacing of other components on the board can also influence its effectiveness to dissipate the heat.

Figure 26. Inverting Buck-Boost Develops -12 V

## ADDITIONAL APPLICATIONS

## Inverting Regulator

An inverting buck-boost regulator using the LM2576-12 is shown in Figure 26. This circuit converts a positive input voltage to a negative output voltage with a common ground by bootstrapping the regulators ground to the negative output voltage. By grounding the feedback pin, the regulator senses the inverted output voltage and regulates it.

In this example the LM2576-12 is used to generate a -12 V output. The maximum input voltage in this case cannot exceed +28 V because the maximum voltage appearing across the regulator is the absolute sum of the input and output voltages and this must be limited to a maximum of 40 V .

This circuit configuration is able to deliver approximately 0.7 A to the output when the input voltage is 12 V or higher. At lighter loads the minimum input voltage required drops to approximately 4.7 V , because the buck-boost regulator topology can produce an output voltage that, in its absolute value, is either greater or less than the input voltage.

Since the switch currents in this buck-boost configuration are higher than in the standard buck converter topology, the available output current is lower.

This type of buck-boost inverting regulator can also require a larger amount of start-up input current, even for light loads. This may overload an input power source with a current limit less than 5.0 A.

Such an amount of input start-up current is needed for at least 2.0 ms or more. The actual time depends on the output voltage and size of the output capacitor.

Because of the relatively high start-up currents required by this inverting regulator topology, the use of a delayed start-up or an undervoltage lockout circuit is recommended.

Using a delayed start-up arrangement, the input capacitor can charge up to a higher voltage before the switch-mode regulator begins to operate.

The high input current needed for start-up is now partially supplied by the input capacitor $\mathrm{C}_{\mathrm{in}}$.

It has been already mentioned above, that in some situations, the delayed start-up or the undervoltage lockout features could be very useful. A delayed start-up circuit applied to a buck-boost converter is shown in Figure 27, Figure 33 in the "Undervoltage Lockout" section describes an undervoltage lockout feature for the same converter topology.

## Design Recommendations:

The inverting regulator operates in a different manner than the buck converter and so a different design procedure has to be used to select the inductor L1 or the output capacitor $\mathrm{C}_{\text {out }}$.

The output capacitor values must be larger than what is normally required for buck converter designs. Low input voltages or high output currents require a large value output capacitor (in the range of thousands of $\mu \mathrm{F}$ ).

The recommended range of inductor values for the inverting converter design is between $68 \mu \mathrm{H}$ and $220 \mu \mathrm{H}$. To select an inductor with an appropriate current rating, the inductor peak current has to be calculated.

The following formula is used to obtain the peak inductor current:

$$
\begin{gathered}
\mathrm{I}_{\text {peak }} \approx \frac{\mathrm{I}_{\text {Load }}\left(\mathrm{V}_{\text {in }}+\left|\mathrm{V}_{\mathrm{O}}\right|\right)}{\mathrm{V}_{\text {in }}}+\frac{\mathrm{V}_{\text {in }} \times \mathrm{t}_{\text {on }}}{2 \mathrm{~L}_{1}} \\
\text { where } \mathrm{t}_{\mathrm{on}}=\frac{\left|\mathrm{V}_{\mathrm{O}}\right|}{\mathrm{V}_{\text {in }}+\left|\mathrm{V}_{\mathrm{O}}\right|} \times \frac{1.0}{f_{\mathrm{osc}}}, \text { and } \mathrm{f}_{\mathrm{osc}}=52 \mathrm{kHz} .
\end{gathered}
$$

Under normal continuous inductor current operating conditions, the worst case occurs when $\mathrm{V}_{\mathrm{in}}$ is minimal.

Figure 27. Inverting Buck-Boost Regulator with Delayed start-up

NOTE: This picture does not show the complete circuit.
Figure 28. Inverting Buck-Boost Regulator Shutdown Circuit Using an Optocoupler

With the inverting configuration, the use of the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin requires some level shifting techniques. This is caused by the fact, that the ground pin of the converter IC is no longer at ground. Now, the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin threshold voltage (1.3 V approximately) has to be related to the negative output voltage level. There are many different possible shut down methods, two of them are shown in Figures 28 and 29.

NOTE: This picture does not show the complete circuit.
Figure 29. Inverting Buck-Boost Regulator Shutdown Circuit Using a PNP Transistor

## Negative Boost Regulator

This example is a variation of the buck-boost topology and it is called negative boost regulator. This regulator experiences relatively high switch current, especially at low input voltages. The internal switch current limiting results in lower output load current capability.

The circuit in Figure 30 shows the negative boost configuration. The input voltage in this application ranges from -5.0 V to -12 V and provides a regulated -12 V output. If the input voltage is greater than -12 V , the output will rise above -12 V accordingly, but will not damage the regulator.

Figure 30. Negative Boost Regulator

## Design Recommendations:

The same design rules as for the previous inverting buck-boost converter can be applied. The output capacitor $\mathrm{C}_{\text {out }}$ must be chosen larger than would be required for a what standard buck converter. Low input voltages or high output currents require a large value output capacitor (in the range of thousands of $\mu \mathrm{F}$ ). The recommended range of inductor values for the negative boost regulator is the same as for inverting converter design.

Another important point is that these negative boost converters cannot provide current limiting load protection in the event of a short in the output so some other means, such as a fuse, may be necessary to provide the load protection.

## Delayed Start-up

There are some applications, like the inverting regulator already mentioned above, which require a higher amount of start-up current. In such cases, if the input power source is limited, this delayed start-up feature becomes very useful.

To provide a time delay between the time when the input voltage is applied and the time when the output voltage comes up, the circuit in Figure 31 can be used. As the input voltage is applied, the capacitor C 1 charges up, and the voltage across the resistor R2 falls down. When the voltage on the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin falls below the threshold value 1.3 V , the regulator starts up. Resistor R1 is included to limit the maximum voltage applied to the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin. It reduces the power supply noise sensitivity, and also limits the capacitor C1 discharge current, but its use is not mandatory.

When a high 50 Hz or $60 \mathrm{~Hz}(100 \mathrm{~Hz}$ or 120 Hz respectively) ripple voltage exists, a long delay time can cause some problems by coupling the ripple into the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin, the regulator could be switched periodically on and off with the line (or double) frequency.

NOTE: This picture does not show the complete circuit.
Figure 31. Delayed Start-up Circuitry

## Undervoltage Lockout

Some applications require the regulator to remain off until the input voltage reaches a certain threshold level. Figure 32 shows an undervoltage lockout circuit applied to a buck regulator. A version of this circuit for buck-boost converter is shown in Figure 33. Resistor R3 pulls the $\overline{\mathrm{ON}} / \mathrm{OFF}$ pin high and keeps the regulator off until the input voltage reaches a predetermined threshold level with respect to the ground Pin 3, which is determined by the following expression:

$$
\mathrm{V}_{\mathrm{th}} \approx \mathrm{~V}_{\mathrm{Z} 1}+\left(1.0+\frac{\mathrm{R} 2}{\mathrm{R} 1}\right) \mathrm{V}_{\mathrm{BE}}(\mathrm{Q} 1)
$$

NOTE: This picture does not show the complete circuit.
Figure 32. Undervoltage Lockout Circuit for Buck Converter

The following formula is used to obtain the peak inductor current:

$$
I_{\text {peak }} \approx \frac{I_{\text {Load }}\left(V_{\text {in }}+\left|V_{\mathrm{O}}\right|\right)}{V_{\text {in }}}+\frac{\mathrm{v}_{\text {in }} \times \mathrm{t}_{\text {on }}}{2 \mathrm{~L}_{1}}
$$

where $\mathrm{t}_{\mathrm{on}}=\frac{\left|\mathrm{V}_{\mathrm{O}}\right|}{\mathrm{V}_{\mathrm{in}}+\left|\mathrm{V}_{\mathrm{O}}\right|} \times \frac{1.0}{f_{\text {Osc }}}$, and $\mathrm{f}_{\text {osc }}=52 \mathrm{kHz}$.

Under normal continuous inductor current operating conditions, the worst case occurs when $\mathrm{V}_{\text {in }}$ is minimal.

NOTE: This picture does not show the complete circuit.
Figure 33. Undervoltage Lockout Circuit for Buck-Boost Converter

## Adjustable Output, Low-Ripple Power Supply

A 3.0 A output current capability power supply that features an adjustable output voltage is shown in Figure 34.
This regulator delivers 3.0 A into 1.2 V to 35 V output. The input voltage ranges from roughly 3.0 V to 40 V . In order to achieve a 10 or more times reduction of output ripple, an additional $\mathrm{L}-\mathrm{C}$ filter is included in this circuit.

## CS2001

### 1.2 A Switching Regulator, and 5.0 V , 100 mA Linear Regulator with RESET

The CS2001 is a smart power supply ASIC utilized in automotive airbag systems. It contains a current-mode switching regulator with a 1.2 A on-chip switch and a $5.0 \mathrm{~V}, 100 \mathrm{~mA}$ linear regulator. The linear output capacitor must be $3.3 \mu \mathrm{~F}$ or greater with an ESR in the range of $100 \mathrm{~m} \Omega$ to $1.0 \Omega$. If the ESR of the cap is less than $100 \mathrm{~m} \Omega$, a series resistor must be used. The switcher can be configured in either a boost or flyback topology. The boost topology produces energy reserve voltage VER which is externally adjustable ( 25 V maximum) through the resistor divider connected to the $\mathrm{V}_{\mathrm{FB}}$ pin. In the event of fault conditions that produce $\mathrm{V}_{\mathrm{FB}}$ either open or shorted, the switcher is shut down.

Under normal operating conditions $\left(\mathrm{V}_{\mathrm{BAT}}>8.0 \mathrm{~V}\right)$, the current loading on the linear regulator is directed through $\mathrm{V}_{\text {BAT }}$. A low battery or loss of battery condition switches the supply for the linear regulator from $\mathrm{V}_{\text {BAT }}$ to VER and shuts down the switcher using the ASIC's internal "smartswitch." This switchover feature minimizes the power dissipation in both the linear and switcher output devices and saves the cost of using a larger inductor.

The NERD (No Energy Reserve Detected) pin is a dual function output. If V OUT is not in regulation, it provides a Power On Reset function whose time interval is externally adjustable with the capacitor. This interval can be seen on the RESETB pin, which allows for clean power-up and power-down of the microprocessor. Once $\mathrm{V}_{\text {OUT }}$ is in regulation, the logic level of the NERD output (usually low) indicates to the microprocessor whether or not the VER pin is connected.

A switched-capacitor voltage tripler accepts input voltage VER and produces output voltage $\mathrm{V}_{\mathrm{CHG}}$ (typically VER +8.0 V ). This voltage is used in the system to drive high-side FETs.

This part is capable of withstanding a 50 V peak transient voltage. The linear regulator will not shut down during this event.

## Features

- Linear Regulator $5.0 \mathrm{~V} \pm 2 \%$ @ 100 mA
- Switching Regulator 1.2 A Peak Internal Switch
- Voltage Tripler
- Smart Functions
- Smartswitch
- RESET
- Energy Reserve Status
- Protection
- Overtemperature
- Current Limit
- 50 V Peak Transient Capability
- Internally Fused Leads in SO-20L Package

## CS5111

### 1.4 A Switching Regulator with 5.0 V, 100 mA Linear Regulator with Watchdog, RESET and ENABLE

The CS5111 is a dual output power supply integrated circuit. It contains a $5.0 \mathrm{~V} \pm 2 \%, 100 \mathrm{~mA}$ linear regulator, a watchdog timer, a linear output voltage monitor to provide a Power On Reset (POR) and a 1.4 A current mode PWM switching regulator.

The 5.0 V linear regulator is comprised of an error amplifier, reference, and supervisory functions. It has low internal supply current consumption and provides 1.2 V (typical) dropout voltage at maximum load current.

The watchdog timer circuitry monitors an input signal (WDI) from the microprocessor. It responds to the falling edge of this watchdog signal. If a correct watchdog signal is not received within the externally programmable time, a reset signal is issued.

The externally programmable active reset circuit operates correctly for an output voltage $\left(\mathrm{V}_{\mathrm{LIN}}\right)$ as low as 1.0 V . During power up, or if the output voltage shifts below the regulation limit, $\overline{\text { RESET }}$ toggles low and remains low for the duration of the delay after proper output voltage regulation is restored. Additionally a reset pulse is issued if the correct watchdog is not received within the programmed time. Reset pulses continue until the correct watchdog signal is received. The reset pulse width and frequency, as well as the Power On Reset delay, are set by one external RC network.

The current mode PWM switching regulator is comprised of an error amplifier with selectable feedback inputs, a current sense amplifier, an adjustable oscillator, and a 1.4 A output power switch with anti-saturation control. The switching regulator can be configured in a variety of topologies.

The CS5111 is load dump capable and has protection circuitry which includes overvoltage shutdown, current limit on the linear and switcher outputs, and an overtemperature limiter.

## Features

- Linear Regulator
$-5.0 \mathrm{~V} \pm 2 \%$ @ 100 mA
- Switching Regulator
- 1.4 A Peak Internal Switch
- 120 kHz Maximum Switching Frequency
- 5.0 V to 26 V Operating Supply Range
- Smart Functions
- Watchdog
- $\overline{\text { RESET }}$
- $\overline{\text { ENABLE }}$
- Protection
- Overvoltage
- Overtemperature
- Current Limit
- 54 V Peak Transient Capability
- Internally Fused Leads in SO-24L Package

## CIRCUIT DESCRIPTION

Figure 6. Block Diagram of 5.0 V Linear Regulator Portion of the CS5111

### 5.0 V LINEAR REGULATOR

The 5.0 V linear regulator consists of an error amplifier, bandgap voltage reference, and a composite pass transistor.

The 5.0 V linear regulator circuitry is shown in Figure 6. When an unregulated voltage greater than 6.6 V is applied to the $\mathrm{V}_{\text {REG }}$ input, a 5.0 V regulated DC voltage will be present at $\mathrm{V}_{\mathrm{LIN}}$. For proper operation of the 5.0 V linear regulator, the $\mathrm{I}_{\text {BIAS }}$ lead must have a $64.9 \mathrm{k} \Omega$ pull down resistor to ground. A $100 \mu \mathrm{~F}$ or larger capacitor with an ESR < $8.0 \Omega$ must be connected between $\mathrm{V}_{\text {LIN }}$ and ground. To operate the 5.0 V linear regulator as an independent regulator (i.e. separate from the switching supply), the input voltage must be tied to the $\mathrm{V}_{\text {REG }}$ lead.

As the voltage at the $\mathrm{V}_{\text {REG }}$ input is increased, $\mathrm{Q}_{1}$ is turned on. $\mathrm{Q}_{1}$ provides base drive for $\mathrm{Q}_{2}$ which in turn provides base current for $Q_{3}$. As $Q_{3}$ is turned on, the output voltage, $\mathrm{V}_{\mathrm{LIN}}$, begins to rise as $\mathrm{Q}_{3}$ 's output current charges the output capacitor, CoUT. Once $\mathrm{V}_{\text {LIN }}$ rises to a certain level, the error amplifier becomes biased and provides the appropriate amount of base current to $\mathrm{Q}_{1}$. The error amplifier monitors the scaled output voltage via an internal voltage divider, $\mathrm{R}_{2}$ through $\mathrm{R}_{5}$, and compares it to the bandgap voltage reference. The error amplifier output or error signal is an output current equal to the error amplifier's input differential voltage times the transconductance of the amplifier. Therefore, the error amplifier varies the base current to $Q_{1}$, which provides bias to $Q_{2}$ and $Q_{3}$, based on the difference between the reference voltage and the scaled $\mathrm{V}_{\mathrm{LIN}}$ output voltage.

## CONTROL FUNCTIONS

The watchdog timer circuitry monitors an input signal (WDI) from the microprocessor. It responds to the falling edge of this watchdog signal which it expects to see within an externally programmable time (see Figure 7).

The watchdog time is given by:

$$
\text { tWDI }=1.353 \times \text { CDelayRBIAS }^{2}
$$

Using $C_{\text {Delay }}=0.1 \mu \mathrm{~F}$ and $\mathrm{R}_{\text {BIAS }}=64.9 \mathrm{k} \Omega$ gives a time ranging from 6.25 ms to 11 ms assuming ideal components. Based on this, the software must be written so that the watchdog arrives at least every 6.25 ms . In practice, the tolerance of $\mathrm{C}_{\text {Delay }}$ and $\mathrm{R}_{\text {BIAS }}$ must be taken into account when calculating the minimum watchdog time ( $\mathrm{t}_{\mathrm{WDI}}$ ).

Figure 7. Timing Diagram for Normal Regulator Operation

If a correct watchdog signal is not received within the specified time a reset pulse train is issued until the correct watchdog signal is received. The nominal reset signal in this case is a 5 volt square wave with a $50 \%$ duty cycle as shown in Figure 8.

A: Watchdog waiting for low-going transition on WDI B: $\overline{R E S E T}$ stays low for twol time

Figure 8. Timing Diagram When WDI Fails to Appear Within the Preset Time Interval, twDI

The $\overline{\text { RESET }}$ signal frequency is given by:

$$
\mathrm{fRESET}=\frac{1}{2(\mathrm{tWDI})}
$$

The Power On Reset (POR) and low voltage $\overline{\text { RESET }}$ use the same circuitry and issue a reset when the linear output voltage is below the regulation limit. After $\mathrm{V}_{\text {LIN }}$ rises above the minimum specified value, $\overline{\text { RESET }}$ remains low for a fixed period tPOR as shown in Figures 9 and 10.

Figure 9. The Power On Reset Time Interval ( $\mathrm{t}_{\mathrm{POR}}$ ) Begins When VIIN Rises Above 4.45 V (Typical)

Figure 10. RESET Signal Is Issued Whenever $\mathrm{V}_{\text {LIN }}$ Falls Below 4.25 V (Typical)

The POR delay ( $\mathrm{t}_{\mathrm{POR}}$ ) is given by:

$$
\text { tPOR }=1.353 \times \text { CDelayRBIAS }
$$

## CURRENT MODE PWM SWITCHING CIRCUITRY

The current mode PWM switching voltage regulator contains an error amplifier with selectable feedback inputs, a current sense amplifier, an adjustable oscillator and a 1.4 A output power switch with antisaturation control. The switching regulator and external components, connected in a boost configuration, are shown in Figure 11.

The switching regulator begins operation when $V_{\text {REG }}$ and $\mathrm{V}_{\text {IN }}$ are raised above 5 volts. $\mathrm{V}_{\text {REG }}$ is required since the switching supply's control circuitry is powered through $\mathrm{V}_{\mathrm{LIN}}$. $\mathrm{V}_{\text {IN }}$ supplies the base drive to the switcher output transistor.

The output transistor turns on when the oscillator starts to charge the capacitor on Cosc. The output current will develop a voltage drop across the internal sense resistor $\left(\mathrm{R}_{\mathrm{S}}\right)$. This voltage drop produces a proportional voltage at the output of the current sense amplifier, which is compared to the output of the error amplifier. The error amplifier generates an output voltage which is proportional to the difference between the scaled down output boost voltage $\left(\mathrm{V}_{\mathrm{FB} 1}\right.$ or $\left.\mathrm{V}_{\mathrm{FB} 2}\right)$ and the internal bandgap voltage reference. Once the current sense amplifier output exceeds the error amplifier's output voltage, the output transistor is turned off.

The energy stored in the inductor during the output transistor on time is transferred to the load when the output transistor is turned off. The output transistor is turned back
on at the next rising edge of the oscillator. On a cycle by cycle basis, the current mode controller in a discontinuous mode of operation charges the inductor to the appropriate amount of energy, based on the energy demand of the load. Figure 12 shows the typical current and voltage waveforms for a boost supply operating in the discontinuous mode.
2. The switching regulator can be disabled by providing a logic high at the $\overline{\text { ENABLE input. }}$
3. The boost output voltage can be controlled dynamically by the feedback select input. If select is open, $\mathrm{V}_{\mathrm{FB} 2}$ is selected. If select is low, then $\mathrm{V}_{\mathrm{FB} 1}$ is selected.

## Notes:

1. Refer to Figure 5 to determine oscillator frequency.

Figure 11. Block Diagram of the 1.4 A Current Mode Control Switching Regulator Portion of the CS5111 in a Boost Configuration

Figure 12. Voltage and Current Waveforms for Boost Topology in CS5111

## PROTECTION CIRCUITRY

If the input voltage at $\mathrm{V}_{\text {REG }}$ is increased above the overvoltage threshold, the drive to the linear and switcher output transistors is shut off. Therefore, $\mathrm{V}_{\text {LIN }}$ is disabled and $\mathrm{V}_{\mathrm{SW}}$ can not be pulled low.

The current out of $\mathrm{V}_{\text {LIN }}$ is sensed in order to limit excessive power dissipation in the linear output transistor over the output range of 0 V to regulation. Also, the current into $\mathrm{V}_{\mathrm{SW}}$ is sensed in order to provide the current limit function in the switcher output transistor.

If the die temperature is increased above $160^{\circ} \mathrm{C}$, either due to excessive ambient temperature or excessive power dissipation, the drive to the linear output transistor is reduced proportionally with increasing die temperature. Therefore, $\mathrm{V}_{\text {LIN }}$ will decrease with increasing die temperature above $160^{\circ} \mathrm{C}$. Since the switcher control circuitry is powered through $\mathrm{V}_{\mathrm{LIN}}$, the switcher performance, including current limit, will be affected by the decrease in $\mathrm{V}_{\text {LIN }}$.

## APPLICATION NOTES

## DESIGN PROCEDURE FOR BOOST TOPOLOGY

This section outlines a procedure for designing a boost switching power supply operating in the discontinuous mode.

## Step 1

Determine the output power required by the load.
POUT = IOUTVOUT

## Step 2

Choose COSC based on the target oscillator frequency with an external resistor value, $\mathrm{R}_{\text {BIAS }}=64.9 \mathrm{k} \Omega$ (See Figure 5).

## Step 3

Next select the output voltage feedback sense resistor divider as follows (Figure 13).

For $\mathrm{V}_{\mathrm{FB} 1}$ active, choose a value for $\mathrm{R}_{1}$ and then solve for $R_{E Q}$ where:

$$
\begin{equation*}
R_{E Q}=\frac{R_{1}}{\frac{V_{O U T}}{V_{F B 1}}-1} \tag{2}
\end{equation*}
$$

For $\mathrm{V}_{\mathrm{FB} 2}$ active, find:

$$
\begin{equation*}
V_{\mathrm{FB} 1}=\operatorname{VOUT}\left(\frac{\mathrm{R}_{\mathrm{EQ}}}{\mathrm{R}_{1}+\mathrm{R}_{\mathrm{EQ}}}\right) \tag{3}
\end{equation*}
$$

and then calculate $\mathrm{R}_{2}$ where:

$$
\begin{equation*}
\mathrm{R}_{2}=\frac{\mathrm{V}_{\mathrm{R} 2}}{\mathrm{I}_{\mathrm{R} 2}}=\frac{\mathrm{V}_{\mathrm{FB} 1}-\mathrm{V}_{\mathrm{FB}} 2}{\mathrm{~V}_{\mathrm{FB} 1} / \mathrm{R}_{\mathrm{EQ}}} \tag{4}
\end{equation*}
$$

Then find $\mathrm{R}_{3}$, where:

$$
\begin{equation*}
R_{3}=R_{E Q}-R_{2} \tag{5}
\end{equation*}
$$

Figure 13. Feedback Sense Resistor Divider Connected Between V

## Step 4

Determine the maximum on time at the minimum oscillator frequency and $\mathrm{V}_{\text {IN }}$. For discontinuous operation, all of the stored energy in the inductor is transferred to the load prior to the next cycle. Since the current through the inductor cannot change instantaneously and the inductance is constant, a volt-second balance exists between the on time and off time. The voltage across the inductor during the on cycle is $\mathrm{V}_{\text {IN }}$ and the voltage across the inductor during the off cycle is $\mathrm{V}_{\text {OUT }}-\mathrm{V}_{\text {IN }}$. Therefore:

$$
\begin{equation*}
\text { VINtON }=(\text { VOUT }- \text { VIN }) \text { tOFF } \tag{6}
\end{equation*}
$$

where the maximum on time is:

## Step 5

Calculate the maximum inductance allowed for discontinuous operation:

$$
\begin{equation*}
\mathrm{L}(\mathrm{MAX})=\frac{\mathrm{f} \mathrm{SW}(\mathrm{MIN}) \mathrm{VIN}^{2}(\mathrm{MIN}) \mathrm{tON}^{2}(\mathrm{MAX})}{2 \mathrm{POUT} / \eta} \tag{8}
\end{equation*}
$$

where $\eta=$ efficiency.
Usually $\eta=0.75$ is a good starting point. The IC's power dissipation should be calculated after the peak current has been determined in Step 6. If the efficiency is less than originally assumed, decrease the efficiency and recalculate the maximum inductance and peak current.

## Step 6

Determine the peak inductor current at the minimum inductance, minimum $\mathrm{V}_{\text {IN }}$ and maximum on time to make sure the inductor current doesn't exceed 1.4 A.

$$
\begin{equation*}
\mathrm{IPK}=\frac{\mathrm{VIN}_{\mathrm{IN}}(\mathrm{MIN}) \mathrm{TON}(\mathrm{MAX})}{\mathrm{L}(\mathrm{MIN})} \tag{9}
\end{equation*}
$$

## Step 7

Determine the minimum output capacitance and maximum ESR based on the allowable output voltage ripple.

$$
\begin{align*}
\operatorname{COUT}(\mathrm{MIN}) & =\frac{\mathrm{IPK}}{8 \mathrm{f} \Delta \mathrm{~V}_{\text {RIPPLE }}}  \tag{10}\\
\mathrm{ESR}(\mathrm{MIN}) & =\frac{\Delta \mathrm{V}_{\text {RIPPLE }}}{\mathrm{IPK}} \tag{11}
\end{align*}
$$

In practice, it is normally necessary to use a larger capacitance value to obtain a low ESR. By placing capacitors in parallel, the equivalent ESR can be reduced.

## Step 8

Compensate the feedback loop to guarantee stability under all operating conditions. To do this, we calculate the modulator gain and the feedback resistor network attenuation and set the gain of the error amplifier so that the overall loop gain is 0 dB at the crossover frequency, $\mathrm{f}_{\mathrm{CO}}$. In addition, the gain slope should be $-20 \mathrm{~dB} /$ decade at the crossover frequency.

The low frequency gain of the modulator (i.e. error amplifier output to output voltage) is:

$$
\begin{equation*}
\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\Delta \mathrm{~V}_{\mathrm{EA}}}=\frac{\mathrm{IPK}(\mathrm{MAX})}{\mathrm{V}_{\mathrm{EA}(\mathrm{MAX})}} \sqrt{\frac{\mathrm{R}_{\mathrm{LOADLf}}}{2}} \tag{12}
\end{equation*}
$$

where:

$$
\operatorname{IPK}(\mathrm{MAX})=\frac{\mathrm{V}_{\mathrm{EA}(\mathrm{MAX}) / \mathrm{GCSA}}}{\mathrm{RS}}=\frac{2.4 \mathrm{~V} / 7}{150 \mathrm{~m} \Omega}=2.3 \mathrm{~A} \text { (13) }
$$

The $\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{EA}}$ transfer function has a pole at:

$$
\begin{equation*}
f_{p}=1 /\left(\pi R_{\text {LOADCOUT }}\right) \tag{14}
\end{equation*}
$$

and a zero due to the output capacitor's ESR at:

$$
\begin{equation*}
f_{Z}=1 /(2 \pi E S R(C O U T)) \tag{15}
\end{equation*}
$$

Since the error amplifier reference voltage is 1.25 V , the output voltage must be divided down or attenuated before being applied to the input of the error amplifier. The feedback resistor divider attenuation is:

$$
\frac{1.25 \mathrm{~V}}{\mathrm{VOUT}}
$$

The error amplifier in the CS5111 is an operational transconductance amplifier (OTA), with a gain given by:
GOTA = gmZOUT
where:

$$
\begin{equation*}
\mathrm{gm}=\frac{\Delta \mathrm{l}_{\mathrm{OUT}}}{\Delta \mathrm{~V}_{\mathrm{IN}}} \tag{17}
\end{equation*}
$$

For the CS5111, gm $=2700 \mu \mathrm{~A} / \mathrm{V}$ typical.
One possible error amplifier compensation scheme is shown in Figure 14. This gives the error amplifier a gain plot as shown in Figure 15.

For the error amplifier gain shown in Figure 15, a low frequency pole is generated by the error amplifier output impedance and $\mathrm{C}_{1}$. This is shown by the line AB with a $-20 \mathrm{~dB} /$ decade slope in Figure 15. The slope changes to zero at point B due to the zero at:

$$
\begin{equation*}
f_{Z}=1 /\left(2 \pi R_{4} C_{1}\right) \tag{18}
\end{equation*}
$$

Figure 14. RC Network Used to Compensate the Error Amplifier (OTA)

A pole at point C :

$$
\begin{equation*}
f_{p}=1 /\left(\pi R_{4} C_{2}\right) \tag{19}
\end{equation*}
$$

offsets the zero set by the ESR of the output capacitors.
An alternative scheme uses a single capacitor as shown in Figure 16 , to roll the gain off at a relatively low frequency.

## Step 9

Finally the watchdog timer period and Power on Reset time is determined by:

$$
\begin{equation*}
\text { tDelay }=1.353 \times \text { CDelay } R_{\text {BIAS }} \tag{20}
\end{equation*}
$$

Figure 15. Bode Plot of Error Amplifier (OTA) Gain and Modulator Gain Added to the Feedback Resistor Divider Attenuation

## CS5112

### 1.4 A Switching Regulator with 5.0 V, 100 mA Linear Regulator with Watchdog, RESET and ENABLE

The CS5112 is a dual output power supply integrated circuit. It contains a $5.0 \mathrm{~V} \pm 2 \%, 100 \mathrm{~mA}$ linear regulator, a watchdog timer, a linear output voltage monitor to provide a Power On Reset (POR) and a 1.4 A current mode PWM switching regulator.

The 5.0 V linear regulator is comprised of an error amplifier, reference, and supervisory functions. It has low internal supply current consumption and provides 1.2 V (typical) dropout voltage at maximum load current.

The watchdog timer circuitry monitors an input signal (WDI) from the microprocessor. It responds to the falling edge of this watchdog signal. If a correct watchdog signal is not received within the externally programmable time, a reset signal is issued.

The externally programmable active reset circuit operates correctly for an output voltage $\left(\mathrm{V}_{\mathrm{LIN}}\right)$ as low as 1.0 V . During power up, or if the output voltage shifts below the regulation limit, RESET toggles low and remains low for the duration of the delay after proper output voltage regulation is restored. Additionally a reset pulse is issued if the correct watchdog is not received within the programmed time. Reset pulses continue until the correct watchdog signal is received. The reset pulse width and frequency, as well as the Power On Reset delay, are set by one external RC network.

The current mode PWM switching regulator is comprised of an error amplifier with selectable feedback inputs, a current sense amplifier, an adjustable oscillator, and a 1.4 A output power switch with anti-saturation control. The switching regulator can be configured in a variety of topologies.

The CS5112 is load dump capable and has protection circuitry which includes current limit on the linear and switcher outputs, and an overtemperature limiter.

## Features

- Linear Regulator
- $5.0 \mathrm{~V} \pm 2 \%$ @ 100 mA
- Switching Regulator
- 1.4 A Peak Internal Switch
- 120 kHz Maximum Switching Frequency
- 5.0 V to 26 V Operating Supply Range
- Smart Functions
- Watchdog
- RESET
- $\overline{\text { ENABLE }}$
- Protection
- Overtemperature
- Current Limit
- Internally Fused Leads in SO-24L Package

## CIRCUIT DESCRIPTION

Figure 6. Block Diagram of 5.0 V Linear Regulator Portion of the CS5112

### 5.0 V LINEAR REGULATOR

The 5.0 V linear regulator consists of an error amplifier, bandgap voltage reference, and a composite pass transistor.

The 5.0 V linear regulator circuitry is shown in Figure 6. When an unregulated voltage greater than 6.6 V is applied to the $\mathrm{V}_{\text {REG }}$ input, a 5.0 V regulated DC voltage will be present at $\mathrm{V}_{\mathrm{LIN}}$. For proper operation of the 5.0 V linear regulator, the $\mathrm{I}_{\text {BIAS }}$ lead must have a $64.9 \mathrm{k} \Omega$ pull down resistor to ground. A $100 \mu \mathrm{~F}$ or larger capacitor with an ESR < $8.0 \Omega$ must be connected between $\mathrm{V}_{\text {LIN }}$ and ground. To operate the 5.0 V linear regulator as an independent regulator (i.e. separate from the switching supply), the input voltage must be tied to the $\mathrm{V}_{\text {REG }}$ lead.

As the voltage at the $\mathrm{V}_{\text {REG }}$ input is increased, $\mathrm{Q}_{1}$ is turned on. $\mathrm{Q}_{1}$ provides base drive for $\mathrm{Q}_{2}$ which in turn provides base current for $Q_{3}$. As $Q_{3}$ is turned on, the output voltage, $\mathrm{V}_{\mathrm{LIN}}$, begins to rise as $\mathrm{Q}_{3}$ 's output current charges the output capacitor, CoUT. Once $\mathrm{V}_{\text {LIN }}$ rises to a certain level, the error amplifier becomes biased and provides the appropriate amount of base current to $\mathrm{Q}_{1}$. The error amplifier monitors the scaled output voltage via an internal voltage divider, $\mathrm{R}_{2}$ through $\mathrm{R}_{5}$, and compares it to the bandgap voltage reference. The error amplifier output or error signal is an output current equal to the error amplifier's input differential voltage times the transconductance of the amplifier. Therefore, the error amplifier varies the base current to $Q_{1}$, which provides bias to $Q_{2}$ and $Q_{3}$, based on the difference between the reference voltage and the scaled $\mathrm{V}_{\mathrm{LIN}}$ output voltage.

## CONTROL FUNCTIONS

The watchdog timer circuitry monitors an input signal (WDI) from the microprocessor. It responds to the falling edge of this watchdog signal which it expects to see within an externally programmable time (see Figure 7).

The watchdog time is given by:

$$
\text { tWDI }=1.353 \times \text { CDelayRBIAS }^{2}
$$

Using $C_{\text {Delay }}=0.1 \mu \mathrm{~F}$ and $\mathrm{R}_{\text {BIAS }}=64.9 \mathrm{k} \Omega$ gives a time ranging from 6.25 ms to 11 ms assuming ideal components. Based on this, the software must be written so that the watchdog arrives at least every 6.25 ms . In practice, the tolerance of $\mathrm{C}_{\text {Delay }}$ and $\mathrm{R}_{\text {BIAS }}$ must be taken into account when calculating the minimum watchdog time ( $\mathrm{t}_{\mathrm{WDI}}$ ).

Figure 7. Timing Diagram for Normal Regulator Operation

If a correct watchdog signal is not received within the specified time a reset pulse train is issued until the correct watchdog signal is received. The nominal reset signal in this case is a 5 volt square wave with a $50 \%$ duty cycle as shown in Figure 8.

A: Watchdog waiting for low-going transition on WDI
B: $\overline{R E S E T}$ stays low for twol time
Figure 8. Timing Diagram When WDI Fails to Appear Within the Preset Time Interval, twDI

The $\overline{\text { RESET }}$ signal frequency is given by:

$$
\mathrm{fRESET}=\frac{1}{2(\mathrm{tWDI})}
$$

The Power On Reset (POR) and low voltage $\overline{\text { RESET }}$ use the same circuitry and issue a reset when the linear output voltage is below the regulation limit. After $\mathrm{V}_{\text {LIN }}$ rises above the minimum specified value, $\overline{\text { RESET }}$ remains low for a fixed period $t_{\text {POR }}$ as shown in Figures 9 and 10.

Figure 9. The Power On Reset Time Interval ( $\mathrm{t}_{\mathrm{POR}}$ ) Begins When V ${ }_{\text {LIN }}$ Rises Above 4.45 V (Typical)

Figure 10. RESET Signal Is Issued Whenever $\mathrm{V}_{\text {LIN }}$ Falls Below 4.25 V (Typical)

The POR delay ( $\mathrm{t}_{\mathrm{POR}}$ ) is given by:

$$
\text { tPOR }=1.353 \times \text { CDelay }_{\text {RIAS }}
$$

## CURRENT MODE PWM SWITCHING CIRCUITRY

The current mode PWM switching voltage regulator contains an error amplifier with selectable feedback inputs, a current sense amplifier, an adjustable oscillator and a 1.4 A output power switch with antisaturation control. The switching regulator and external components, connected in a boost configuration, are shown in Figure 11.

The switching regulator begins operation when $V_{\text {REG }}$ and $\mathrm{V}_{\text {IN }}$ are raised above 5 volts. $\mathrm{V}_{\text {REG }}$ is required since the switching supply's control circuitry is powered through $\mathrm{V}_{\text {LIN }} . \mathrm{V}_{\text {IN }}$ supplies the base drive to the switcher output transistor.

The output transistor turns on when the oscillator starts to charge the capacitor on $\mathrm{C}_{\text {OSC }}$. The output current will develop a voltage drop across the internal sense resistor $\left(\mathrm{R}_{\mathrm{S}}\right)$. This voltage drop produces a proportional voltage at the output of the current sense amplifier, which is compared to the output of the error amplifier. The error amplifier generates an output voltage which is proportional to the difference between the scaled down output boost voltage ( $\mathrm{V}_{\mathrm{FB} 1}$ or $\mathrm{V}_{\mathrm{FB} 2}$ ) and the internal bandgap voltage reference. Once the current sense amplifier output exceeds the error amplifier's output voltage, the output transistor is turned off.

The energy stored in the inductor during the output transistor on time is transferred to the load when the output transistor is turned off. The output transistor is turned back
on at the next rising edge of the oscillator. On a cycle by cycle basis, the current mode controller in a discontinuous mode of operation charges the inductor to the appropriate amount of energy, based on the energy demand of the load. Figure 12 shows the typical current and voltage waveforms for a boost supply operating in the discontinuous mode.
2. The switching regulator can be disabled by providing a logic high at the $\overline{\text { ENABLE input. }}$
3. The boost output voltage can be controlled dynamically by the feedback select input. If select is open, $\mathrm{V}_{\mathrm{FB} 2}$ is selected. If select is low, then $\mathrm{V}_{\mathrm{FB} 1}$ is selected.

## Notes:

1. Refer to Figure 5 to determine oscillator frequency.

Figure 11. Block Diagram of the 1.4 A Current Mode Control Switching Regulator Portion of the CS5112 in a Boost Configuration

Figure 12. Voltage and Current Waveforms for Boost Topology in CS5112

## PROTECTION CIRCUITRY

The current out of $\mathrm{V}_{\mathrm{LIN}}$ is sensed in order to limit excessive power dissipation in the linear output transistor over the output range of 0 V to regulation. Also, the current into $\mathrm{V}_{\mathrm{SW}}$ is sensed in order to provide the current limit function in the switcher output transistor.

If the die temperature is increased above $160^{\circ} \mathrm{C}$, either due to excessive ambient temperature or excessive power dissipation, the drive to the linear output transistor is reduced proportionally with increasing die temperature. Therefore, $\mathrm{V}_{\text {LIN }}$ will decrease with increasing die temperature above $160^{\circ} \mathrm{C}$. Since the switcher control circuitry is powered through $\mathrm{V}_{\mathrm{LIN}}$, the switcher performance, including current limit, will be affected by the decrease in $\mathrm{V}_{\text {LIN }}$.

## APPLICATION NOTES

## DESIGN PROCEDURE FOR BOOST TOPOLOGY

This section outlines a procedure for designing a boost switching power supply operating in the discontinuous mode.

## Step 1

Determine the output power required by the load.
POUT = IOUTVOUT

## Step 2

Choose COSC based on the target oscillator frequency with an external resistor value, $\mathrm{R}_{\text {BIAS }}=64.9 \mathrm{k} \Omega$ (See Figure 5).

## Step 3

Next select the output voltage feedback sense resistor divider as follows (Figure 13).

For $\mathrm{V}_{\mathrm{FB} 1}$ active, choose a value for $\mathrm{R}_{1}$ and then solve for $R_{E Q}$ where:

$$
\begin{equation*}
R_{E Q}=\frac{R_{1}}{\frac{V_{O U T}}{V_{F B 1}}-1} \tag{2}
\end{equation*}
$$

For $\mathrm{V}_{\mathrm{FB} 2}$ active, find:

$$
\begin{equation*}
V_{F B 1}=V_{O U T}\left(\frac{R_{E Q}}{R_{1}+R_{E Q}}\right) \tag{3}
\end{equation*}
$$

and then calculate $\mathrm{R}_{2}$ where:

$$
\begin{equation*}
\mathrm{R}_{2}=\frac{\mathrm{V}_{\mathrm{R} 2}}{\mathrm{I}_{\mathrm{R} 2}}=\frac{\mathrm{V}_{\mathrm{FB} 1}-\mathrm{V}_{\mathrm{FB} 2}}{\mathrm{~V}_{\mathrm{FB} 1} / \mathrm{R}_{\mathrm{EQ}}} \tag{4}
\end{equation*}
$$

Then find $\mathrm{R}_{3}$, where:

$$
\begin{equation*}
R_{3}=R_{E Q}-R_{2} \tag{5}
\end{equation*}
$$

Figure 13. Feedback Sense Resistor Divider Connected Between V

## Step 4

Determine the maximum on time at the minimum oscillator frequency and $\mathrm{V}_{\text {IN }}$. For discontinuous operation, all of the stored energy in the inductor is transferred to the load prior to the next cycle. Since the current through the inductor cannot change instantaneously and the inductance is constant, a volt-second balance exists between the on time and off time. The voltage across the inductor during the on cycle is $\mathrm{V}_{\text {IN }}$ and the voltage across the inductor during the off cycle is $\mathrm{V}_{\text {OUT }}-\mathrm{V}_{\text {IN }}$. Therefore:

$$
\begin{equation*}
\text { VINtON }=(\text { VOUT }- \text { VIN }) \text { tOFF } \tag{6}
\end{equation*}
$$

where the maximum on time is:

## Step 5

Calculate the maximum inductance allowed for discontinuous operation:

$$
\begin{equation*}
\mathrm{L}(\mathrm{MAX})=\frac{\mathrm{fSW}(\mathrm{MIN}) \mathrm{VIN}^{2}(\mathrm{MIN}) \mathrm{tON}^{2}(\mathrm{MAX})}{2 \mathrm{POUT} / \eta} \tag{8}
\end{equation*}
$$

where $\eta=$ efficiency.
Usually $\eta=0.75$ is a good starting point. The IC's power dissipation should be calculated after the peak current has been determined in Step 6. If the efficiency is less than originally assumed, decrease the efficiency and recalculate the maximum inductance and peak current.

## Step 6

Determine the peak inductor current at the minimum inductance, minimum $\mathrm{V}_{\text {IN }}$ and maximum on time to make sure the inductor current doesn't exceed 1.4 A.

$$
\begin{equation*}
\mathrm{IPK}=\frac{\mathrm{VIN}_{\mathrm{IN}}(\mathrm{MIN}) \mathrm{tON}(\mathrm{MAX})}{\mathrm{L}_{(\mathrm{MIN})}} \tag{9}
\end{equation*}
$$

## Step 7

Determine the minimum output capacitance and maximum ESR based on the allowable output voltage ripple.

$$
\begin{align*}
\operatorname{COUT}(\mathrm{MIN}) & =\frac{\mathrm{IPK}}{8 \mathrm{~V} \text { VIPPLE }}  \tag{10}\\
\mathrm{ESR}_{(\mathrm{MIN})} & =\frac{\Delta \mathrm{V}_{\text {RIPPLE }}}{\mathrm{IPK}} \tag{11}
\end{align*}
$$

In practice, it is normally necessary to use a larger capacitance value to obtain a low ESR. By placing capacitors in parallel, the equivalent ESR can be reduced.

## Step 8

Compensate the feedback loop to guarantee stability under all operating conditions. To do this, we calculate the modulator gain and the feedback resistor network attenuation and set the gain of the error amplifier so that the overall loop gain is 0 dB at the crossover frequency, $\mathrm{f}_{\mathrm{CO}}$. In addition, the gain slope should be $-20 \mathrm{~dB} /$ decade at the crossover frequency.
The low frequency gain of the modulator (i.e. error amplifier output to output voltage) is:

$$
\begin{equation*}
\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\Delta \mathrm{~V}_{\mathrm{EA}}}=\frac{\mathrm{IPK}(\mathrm{MAX})}{\mathrm{V}_{\mathrm{EA}(\mathrm{MAX})}} \sqrt{\frac{\mathrm{R}_{\mathrm{LOADLf}}}{2}} \tag{12}
\end{equation*}
$$

where:

$$
\operatorname{IPK}(\mathrm{MAX})=\frac{\mathrm{VEA}_{\mathrm{E}(\mathrm{MAX}) / \mathrm{GCSA}}}{\mathrm{RS}}=\frac{2.4 \mathrm{~V} / 7}{150 \mathrm{~m} \Omega}=2.3 \mathrm{~A}(13)
$$

The $\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{EA}}$ transfer function has a pole at:

$$
\begin{equation*}
f_{p}=1 /\left(\pi R_{\text {LOADCOUT }}\right) \tag{14}
\end{equation*}
$$

and a zero due to the output capacitor's ESR at:

$$
\begin{equation*}
f_{\mathrm{Z}}=1 /(2 \pi E S R(C O U T)) \tag{15}
\end{equation*}
$$

Since the error amplifier reference voltage is 1.25 V , the output voltage must be divided down or attenuated before being applied to the input of the error amplifier. The feedback resistor divider attenuation is:

$$
\frac{1.25 \mathrm{~V}}{\mathrm{~V}_{\mathrm{OUT}}}
$$

The error amplifier in the CS5112 is an operational transconductance amplifier (OTA), with a gain given by:
GOTA = gmZOUT
where:

$$
\begin{equation*}
\mathrm{gm}=\frac{\Delta \mathrm{l}_{\mathrm{OUT}}}{\Delta \mathrm{~V}_{\mathrm{IN}}} \tag{17}
\end{equation*}
$$

For the CS5112, gm $=2700 \mu \mathrm{~A} / \mathrm{V}$ typical.
One possible error amplifier compensation scheme is shown in Figure 14. This gives the error amplifier a gain plot as shown in Figure 15.

For the error amplifier gain shown in Figure 15, a low frequency pole is generated by the error amplifier output impedance and $\mathrm{C}_{1}$. This is shown by the line AB with a $-20 \mathrm{~dB} /$ decade slope in Figure 15. The slope changes to zero at point $B$ due to the zero at:

$$
\begin{equation*}
f_{z}=1 /\left(2 \pi R_{4} C_{1}\right) \tag{18}
\end{equation*}
$$

Figure 14. RC Network Used to Compensate the Error Amplifier (OTA)

A pole at point C :

$$
\begin{equation*}
f_{p}=1 /\left(\pi R_{4} C_{2}\right) \tag{19}
\end{equation*}
$$

offsets the zero set by the ESR of the output capacitors.
An alternative scheme uses a single capacitor as shown in Figure 16, to roll the gain off at a relatively low frequency.

## Step 9

Finally the watchdog timer period and Power on Reset time is determined by:

$$
\begin{equation*}
\text { tDelay }=1.353 \times \text { CDelay RBIAS } \tag{20}
\end{equation*}
$$

Figure 15. Bode Plot of Error Amplifier (OTA) Gain and Modulator Gain Added to the Feedback Resistor Divider Attenuation

## CS5171, CS5172, CS5173, CS5174

### 1.5 A 280 kHz/560 kHz Boost Regulators

The CS5171/2/3/4 products are $280 \mathrm{kHz} / 560 \mathrm{kHz}$ switching regulators with a high efficiency, 1.5 A integrated switch. These parts operate over a wide input voltage range, from 2.7 V to 30 V . The flexibility of the design allows the chips to operate in most power supply configurations, including boost, flyback, forward, inverting, and SEPIC. The ICs utilize current mode architecture, which allows excellent load and line regulation, as well as a practical means for limiting current. Combining high frequency operation with a highly integrated regulator circuit results in an extremely compact power supply solution. The circuit design includes provisions for features such as frequency synchronization, shutdown, and feedback controls for either positive or negative voltage regulation. These parts are pin-to-pin compatible with LT1372/1373.

| Part Number | Frequency | Feedback Voltage Polarity |
| :---: | :---: | :---: |
| CS5171 | 280 kHz | positive |
| CS5172 | 280 kHz | negative |
| CS5173 | 560 kHz | positive |
| CS5174 | 560 kHz | negative |

## Features

- Integrated Power Switch: 1.5 A Guaranteed
- Wide Input Range: 2.7 V to 30 V
- High Frequency Allows for Small Components
- Minimum External Components
- Easy External Synchronization
- Built in Overcurrent Protection
- Frequency Foldback Reduces Component Stress During an Overcurrent Condition
- Thermal Shutdown with Hysteresis
- Regulates Either Positive or Negative Output Voltages
- Shut Down Current: $50 \mu \mathrm{~A}$ Maximum
- Pin-to-Pin Compatible with LT1372/1373
- Wide Ambient Temperature Range
- Industrial Grade: $-40^{\circ} \mathrm{C}$ to $85^{\circ} \mathrm{C}$
- Commercial Grade: $0^{\circ} \mathrm{C}$ to $70^{\circ} \mathrm{C}$

## PACKAGE PIN DESCRIPTION

| Package Pin Number |  |  |
| :---: | :---: | :---: |
| 8 LEAD SO NARROW | Pin Symbol | Function |
| 1 | $\mathrm{V}_{\mathrm{C}}$ | Loop compensation pin. The $\mathrm{V}_{\mathrm{C}}$ pin is the output of the error amplifier and is used for loop compensation, current limit and soft start. Loop compensation can be implemented by a simple RC network as shown in the application diagram on page 1383 as R1 and C1. |
| 2 (CS5171/3 only) | FB | Positive regulator feedback pin. This pin senses a positive output voltage and is referenced to 1.276 V . When the voltage at this pin falls below 0.4 V , chip switching frequency reduces to $20 \%$ of the nominal frequency. |
| $\begin{aligned} & 2 \text { (CS5172/4 only) } \\ & 3 \text { (CS5171/3 only) } \end{aligned}$ | Test | These pins are connected to internal test logic and should either be left floating or tied to ground. Connection to a voltage between 2 V and 6 V shuts down the internal oscillator and leaves the power switch running. |
| 3 (CS5172/4 only) | NFB | Negative feedback pin. This pin senses a negative output voltage and is referenced to -2.5 V . When the voltage at this pin goes above -0.65 V , chip switching frequency reduces to $20 \%$ of the nominal frequency. |
| 4 | SS | Synchronization and shutdown pin. This pin may be used to synchronize the part to nearly twice the base frequency. A TTL low will shut the part down and put it into low current mode. If synchronization is not used, this pin should be either tied high or left floating for normal operation. |

PACKAGE PIN DESCRIPTION

| Package Pin Number | Pin Symbol | Function |
| :---: | :---: | :---: |
| 8 LEAD SO NARROW (continued) |  |  |
| 5 | $\mathrm{V}_{\mathrm{CC}}$ | Input power supply pin. This pin supplies power to the part and should have a bypass capacitor connected to AGND. |
| 6 | AGND | Analog ground. This pin provides a clean ground for the controller circuitry and should not be in the path of large currents. The output voltage sensing resistors should be connected to this ground pin. This pin is connected to the IC substrate. |
| 7 | PGND | Power ground. This pin is the ground connection for the emitter of the power switching transistor. Connection to a good ground plane is essential. |
| 8 | $\mathrm{V}_{\text {SW }}$ | High current switch pin. This pin connects internally to the collector of the power switch. The open voltage across the power switch can be as high as 40 V . To minimize radiation, use a trace as short as practical. |

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## Current Mode Control

Figure 28. Current Mode Control Scheme
The CS517x family incorporates a current mode control scheme, in which the PWM ramp signal is derived from the power switch current. This ramp signal is compared to the output of the error amplifier to control the on-time of the power switch. The oscillator is used as a fixed-frequency clock to ensure a constant operational frequency. The resulting control scheme features several advantages over conventional voltage mode control. First, derived directly from the inductor, the ramp signal responds immediately to line voltage changes. This eliminates the delay caused by the output filter and error amplifier, which is commonly found in voltage mode controllers. The second benefit comes from inherent pulse-by-pulse current limiting by merely clamping the peak switching current. Finally, since current mode commands an output current rather than voltage, the filter offers only a single pole to the feedback loop. This allows both a simpler compensation and a higher gain-bandwidth over a comparable voltage mode circuit.

Without discrediting its apparent merits, current mode control comes with its own peculiar problems, mainly, subharmonic oscillation at duty cycles over $50 \%$. The CS517x family solves this problem by adopting a slope compensation scheme in which a fixed ramp generated by the oscillator is added to the current ramp. A proper slope rate is provided to improve circuit stability without sacrificing the advantages of current mode control.

## Oscillator and Shutdown

Figure 29. Timing Diagram of Sync and Shutdown

The oscillator is trimmed to guarantee an $18 \%$ frequency accuracy. The output of the oscillator turns on the power switch at a frequency of $280 \mathrm{kHz}(\mathrm{CS} 5171 / 2)$ or 560 kHz (CS5173/4), as shown in Figure 28. The power switch is turned off by the output of the PWM Comparator.

A TTL-compatible sync input at the SS pin is capable of syncing up to 1.8 times the base oscillator frequency. As shown in Figure 29, in order to sync to a higher frequency, a positive transition turns on the power switch before the output of the oscillator goes high, thereby resetting the oscillator. The sync operation allows multiple power supplies to operate at the same frequency.
A sustained logic low at the SS pin will shut down the IC and reduce the supply current.

An additional feature includes frequency shift to $20 \%$ of the nominal frequency when either the NFB or FB pins trigger the threshold. During power up, overload, or short circuit conditions, the minimum switch on-time is limited by the PWM comparator minimum pulse width. Extra switch off-time reduces the minimum duty cycle to protect external components and the IC itself.
As previously mentioned, this block also produces a ramp for the slope compensation to improve regulator stability.

## Error Amplifier

Figure 30. Error Amplifier Equivalent Circuit
For CS5172/4, the NFB pin is internally referenced to -2.5 V with approximately a $250 \mathrm{k} \Omega$ input impedance. For CS5171/3, the FB pin is directly connected to the inverting input of the positive error amplifier, whose non-inverting input is fed by the 1.276 V reference. Both amplifiers are transconductance amplifiers with a high output impedance of approximately $1 \mathrm{M} \Omega$, as shown in Figure 30 . The $\mathrm{V}_{\mathrm{C}}$ pin is connected to the output of the error amplifiers and is internally clamped between 0.5 V and 1.7 V . A typical connection at the $\mathrm{V}_{\mathrm{C}}$ pin includes a capacitor in series with a resistor to ground, forming a pole/zero for loop compensation.
An external shunt can be connected between the $\mathrm{V}_{\mathrm{C}}$ pin and ground to reduce its clamp voltage. Consequently, the current limit of the internal power transistor current is reduced from its nominal value.

## Switch Driver and Power Switch

The switch driver receives a control signal from the logic section to drive the output power switch. The switch is grounded through emitter resistors ( $63 \mathrm{~m} \Omega$ total) to the PGND pin. PGND is not connected to the IC substrate so that switching noise can be isolated from the analog ground. The peak switching current is clamped by an internal circuit. The clamp current is guaranteed to be greater than 1.5 A and varies with duty cycle due to slope compensation. The power switch can withstand a maximum voltage of 40 V on the collector $\left(\mathrm{V}_{\mathrm{SW}} \mathrm{pin}\right)$. The saturation voltage of the switch is typically less than 1 V to minimize power dissipation.

## Short Circuit Condition

When a short circuit condition happens in a boost circuit, the inductor current will increase during the whole switching cycle, causing excessive current to be drawn from the input power supply. Since control ICs don't have the means to limit load current, an external current limit circuit (such as a fuse or relay) has to be implemented to protect the load, power supply and ICs.

In other topologies, the frequency shift built into the IC prevents damage to the chip and external components. This feature reduces the minimum duty cycle and allows the transformer secondary to absorb excess energy before the switch turns back on.

Figure 31. Startup Waveforms of Circuit Shown in the Application Diagram. Load $=400 \mathrm{~mA}$.

The CS517x can be activated by either connecting the $\mathrm{V}_{\mathrm{CC}}$ pin to a voltage source or by enabling the SS pin. Startup waveforms shown in Figure 31 are measured in the boost converter demonstrated in the Application Diagram on the page 1383 of this document. Recorded after the input voltage is turned on, this waveform shows the various phases during the power up transition.

When the $\mathrm{V}_{\mathrm{CC}}$ voltage is below the minimum supply voltage, the $\mathrm{V}_{\mathrm{SW}}$ pin is in high impedance. Therefore, current conducts directly from the input power source to the
output through the inductor and diode. Once $\mathrm{V}_{\mathrm{CC}}$ reaches approximately 1.5 V , the internal power switch briefly turns on. This is a part of the CS517x's normal operation. The turn-on of the power switch accounts for the initial current swing.
When the $\mathrm{V}_{\mathrm{C}}$ pin voltage rises above the threshold, the internal power switch starts to switch and a voltage pulse can be seen at the $\mathrm{V}_{\text {SW }}$ pin. Detecting a low output voltage at the FB pin, the built-in frequency shift feature reduces the switching frequency to a fraction of its nominal value, reducing the minimum duty cycle, which is otherwise limited by the minimum on-time of the switch. The peak current during this phase is clamped by the internal current limit.

When the FB pin voltage rises above 0.4 V , the frequency increases to its nominal value, and the peak current begins to decrease as the output approaches the regulation voltage. The overshoot of the output voltage is prevented by the active pull-on, by which the sink current of the error amplifier is increased once an overvoltage condition is detected. The overvoltage condition is defined as when the FB pin voltage is 50 mV greater than the reference voltage.

## COMPONENT SELECTION

## Frequency Compensation

The goal of frequency compensation is to achieve desirable transient response and DC regulation while ensuring the stability of the system. A typical compensation network, as shown in Figure 32, provides a frequency response of two poles and one zero. This frequency response is further illustrated in the Bode plot shown in Figure 33.

Figure 32. A Typical Compensation Network
The high DC gain in Figure 33 is desirable for achieving DC accuracy over line and load variations. The DC gain of a transconductance error amplifier can be calculated as follows:

GaindC $=G_{M} \times R_{O}$
where:
$\mathrm{G}_{\mathrm{M}}=$ error amplifier transconductance;
$\mathrm{R}_{\mathrm{O}}=$ error amplifier output resistance $\approx 1 \mathrm{M} \Omega$.

The low frequency pole, $\mathrm{f}_{\mathrm{P} 1}$, is determined by the error amplifier output resistance and C 1 as:
$\mathrm{fP}_{\mathrm{P}}=\frac{1}{2 \pi \mathrm{C} 1 \mathrm{RO}_{\mathrm{O}}}$
The first zero generated by C 1 and R 1 is:
$\mathrm{f} Z 1=\frac{1}{2 \pi \mathrm{C} 1 \mathrm{R} 1}$
The phase lead provided by this zero ensures that the loop has at least a $45^{\circ}$ phase margin at the crossover frequency. Therefore, this zero should be placed close to the pole generated in the power stage which can be identified at frequency:
$\mathrm{fP}=\frac{1}{2 \pi \mathrm{COR}_{\mathrm{LOAD}}}$
where:
$\mathrm{C}_{\mathrm{O}}=$ equivalent output capacitance of the error amplifier $\approx 120 \mathrm{pF}$;
$\mathrm{R}_{\mathrm{LOAD}}=$ load resistance.
The high frequency pole, $\mathrm{f}_{\mathrm{P} 2}$, can be placed at the output filter's ESR zero or at half the switching frequency. Placing the pole at this frequency will cut down on switching noise. The frequency of this pole is determined by the value of C2 and R1:
$\mathrm{fP} 2=\frac{1}{2 \pi \mathrm{C} 2 \mathrm{R} 1}$
One simple method to ensure adequate phase margin is to design the frequency response with a -20 dB per decade slope, until unity-gain crossover. The crossover frequency should be selected at the midpoint between $\mathrm{f}_{\mathrm{Z} 1}$ and $\mathrm{f}_{\mathrm{P} 2}$ where the phase margin is maximized.

Figure 33. Bode Plot of the Compensation Network Shown in Figure 32

## Negative Voltage Feedback

Since the negative error amplifier has finite input impedance as shown in Figure 34, its induced error has to be considered. If a voltage divider is used to scale down the negative output voltage for the NFB pin, the equation for calculating output voltage is:

$$
-\mathrm{V}_{\text {OUT }}=\left(\frac{-2.5(\mathrm{R} 1+\mathrm{R} 2)}{\mathrm{R} 2}\right)-10 \mu \mathrm{~A} \times \mathrm{R} 1
$$

Figure 34. Negative Error Amplifier and NFB Pin
It is shown that if R1 is less than 10 k , the deviation from the design target will be less than 0.1 V . If the tolerances of the negative voltage reference and NFB pin input current are considered, the possible offset of the output $V_{\text {OFFSET }}$ varies in the range of:

$$
\begin{aligned}
\left(\frac{-0.0 .5(\mathrm{R} 1+\mathrm{R} 2)}{\mathrm{R} 2}\right) & -(15 \mu \mathrm{~A} \times \mathrm{R} 1) \leq \mathrm{V}_{\text {OFFSET }} \\
& \leq\left(\frac{0.0 .5(\mathrm{R} 1+\mathrm{R} 2)}{\mathrm{R} 2}\right)-(5 \mu \mathrm{~A} \times \mathrm{R} 1)
\end{aligned}
$$

## $\mathrm{V}_{\text {SW }}$ Voltage Limit

In the boost topology, $\mathrm{V}_{\text {SW }}$ pin maximum voltage is set by the maximum output voltage plus the output diode forward voltage. The diode forward voltage is typically 0.5 V for Schottky diodes and 0.8 V for ultrafast recovery diodes

$$
V_{S W}(M A X)=V_{O U T}(M A X)+V_{F}
$$

where:
$\mathrm{V}_{\mathrm{F}}=$ output diode forward voltage.
In the flyback topology, peak $\mathrm{V}_{\mathrm{SW}}$ voltage is governed by:

$$
V_{S W}(M A X)=V_{C C}(M A X)+\left(V_{O U T}+V_{F}\right) \times N
$$

where:
$\mathrm{N}=$ transformer turns ratio, primary over secondary.
When the power switch turns off, there exists a voltage spike superimposed on top of the steady-state voltage. Usually this voltage spike is caused by transformer leakage inductance charging stray capacitance between the $\mathrm{V}_{\mathrm{SW}}$ and PGND pins. To prevent the voltage at the $\mathrm{V}_{\mathrm{SW}}$ pin from exceeding the maximum rating, a transient voltage suppressor in series with a diode is paralleled with the primary windings. Another method of clamping switch voltage is to connect a transient voltage suppressor between the $\mathrm{V}_{\mathrm{SW}}$ pin and ground.

## Magnetic Component Selection

When choosing a magnetic component, one must consider factors such as peak current, core and ferrite material, output voltage ripple, EMI, temperature range, physical size and cost. In boost circuits, the average inductor current is the product of output current and voltage gain $\left(\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{CC}}\right)$,
assuming $100 \%$ energy transfer efficiency. In continuous conduction mode, inductor ripple current is

$$
\text { IRIPPLE }=\frac{\mathrm{V}_{\mathrm{CC}}\left(\mathrm{~V}_{\text {OUT }}-\mathrm{V}_{\mathrm{CC}}\right)}{(\mathrm{f})(\mathrm{L})\left(\mathrm{V}_{\mathrm{OUT}}\right)}
$$

where:
$\mathrm{f}=280 \mathrm{kHz}$ for CS5171/2 and 560 kHz for CS5173/4.
The peak inductor current is equal to average current plus half of the ripple current, which should not cause inductor saturation. The above equation can also be referenced when selecting the value of the inductor based on the tolerance of the ripple current in the circuits. Small ripple current provides the benefits of small input capacitors and greater output current capability. A core geometry like a rod or barrel is prone to generating high magnetic field radiation, but is relatively cheap and small. Other core geometries, such as toroids, provide a closed magnetic loop to prevent EMI.

## Input Capacitor Selection

In boost circuits, the inductor becomes part of the input filter, as shown in Figure 36. In continuous mode, the input current waveform is triangular and does not contain a large pulsed current, as shown in Figure 35. This reduces the requirements imposed on the input capacitor selection. During continuous conduction mode, the peak to peak inductor ripple current is given in the previous section. As we can see from Figure 35, the product of the inductor current ripple and the input capacitor's effective series resistance (ESR) determine the $\mathrm{V}_{\mathrm{CC}}$ ripple. In most applications, input capacitors in the range of $10 \mu \mathrm{~F}$ to $100 \mu \mathrm{~F}$ with an ESR less than $0.3 \Omega$ work well up to a full 1.5 A switch current.

Figure 35. Boost Input Voltage and Current Ripple Waveforms

Figure 36. Boost Circuit Effective Input Filter
The situation is different in a flyback circuit. The input current is discontinuous and a significant pulsed current is seen by the input capacitors. Therefore, there are two requirements for capacitors in a flyback regulator: energy storage and filtering. To maintain a stable voltage supply to the chip, a storage capacitor larger than $20 \mu \mathrm{~F}$ with low ESR is required. To reduce the noise generated by the inductor, insert a $1.0 \mu \mathrm{~F}$ ceramic capacitor between $\mathrm{V}_{\mathrm{CC}}$ and ground as close as possible to the chip.

## Output Capacitor Selection

Figure 37. Typical Output Voltage Ripple
By examining the waveforms shown in Figure 37, we can see that the output voltage ripple comes from two major sources, namely capacitor ESR and the charging/discharging of the output capacitor. In boost circuits, when the power switch turns off, $\mathrm{I}_{\mathrm{L}}$ flows into the output capacitor causing an instant $\Delta \mathrm{V}=\mathrm{I}_{\mathrm{IN}} \times$ ESR. At the same time, current $\mathrm{I}_{\mathrm{L}}-\mathrm{I}_{\text {OUT }}$ charges the capacitor and
increases the output voltage gradually. When the power switch is turned on, $\mathrm{I}_{\mathrm{L}}$ is shunted to ground and $\mathrm{I}_{\text {OUT }}$ discharges the output capacitor. When the $\mathrm{I}_{\mathrm{L}}$ ripple is small enough, $\mathrm{I}_{\mathrm{L}}$ can be treated as a constant and is equal to input current $\mathrm{I}_{\text {IN }}$. Summing up, the output voltage peak-peak ripple can be calculated by:

$$
\begin{aligned}
\mathrm{V}_{\text {OUT }}(\text { RIPPLE })= & \frac{(\mathrm{IIN}-\operatorname{lOUT})(1-\mathrm{D})}{(\mathrm{COUT})(\mathrm{f})} \\
& +\frac{\mathrm{IOUTD}}{(\mathrm{COUT})(\mathrm{f})}+\mathrm{I}_{\mathrm{IN}} \times \mathrm{ESR}
\end{aligned}
$$

The equation can be expressed more conveniently in terms of $\mathrm{V}_{\mathrm{CC}}, \mathrm{V}_{\text {OUT }}$ and $\mathrm{I}_{\text {OUT }}$ for design purposes as follows:

$$
\begin{aligned}
\mathrm{V}_{\text {OUT }}(\mathrm{RIPPLE})= & \frac{\mathrm{IOUT}\left(\mathrm{~V}_{\text {OUT }}-\mathrm{V}_{\mathrm{CC}}\right)}{(\mathrm{COUT})(\mathrm{f})} \times \frac{1}{(\mathrm{COUT})(\mathrm{f})} \\
& +\frac{(\mathrm{lOUT})\left(\mathrm{V}_{\text {OUT }}\right)(\mathrm{ESR})}{\mathrm{V}_{\mathrm{CC}}}
\end{aligned}
$$

The capacitor RMS ripple current is:

$$
\begin{aligned}
\text { IRIPPLE } & =\sqrt{\left(\mathrm{I}_{\mathrm{IN}}-\mathrm{IOUT}\right)^{2}(1-\mathrm{D})+(\mathrm{IOUT})^{2}(\mathrm{D})} \\
& =\operatorname{IOUT} \sqrt{\frac{V_{O U T}-V_{C C}}{V_{C C}}}
\end{aligned}
$$

Although the above equations apply only for boost circuits, similar equations can be derived for flyback circuits.

## Reducing the Current Limit

In some applications, the designer may prefer a lower limit on the switch current than 1.5 A . An external shunt can be connected between the $\mathrm{V}_{\mathrm{C}}$ pin and ground to reduce its clamp voltage. Consequently, the current limit of the internal power transistor current is reduced from its nominal value.

The voltage on the $\mathrm{V}_{\mathrm{C}}$ pin can be evaluated with the equation
$V_{C}=I_{S W} R_{E A} A_{V}$
where:
$\mathrm{R}_{\mathrm{E}}=.063 \Omega$, the value of the internal emitter resistor;
$A_{V}=5 \mathrm{~V} / \mathrm{V}$, the gain of the current sense amplifier.
Since $R_{E}$ and $A_{V}$ cannot be changed by the end user, the only available method for limiting switch current below 1.5 A is to clamp the $\mathrm{V}_{\mathrm{C}}$ pin at a lower voltage. If the maximum switch or inductor current is substituted into the equation above, the desired clamp voltage will result.

A simple diode clamp, as shown in Figure 38, clamps the $\mathrm{V}_{\mathrm{C}}$ voltage to a diode drop above the voltage on resistor R 3 . Unfortunately, such a simple circuit is not generally acceptable if $\mathrm{V}_{\mathrm{IN}}$ is loosely regulated.

Figure 38. Current Limiting using a Diode Clamp
Another solution to the current limiting problem is to externally measure the current through the switch using a sense resistor. Such a circuit is illustrated in Figure 39.

Figure 39. Current Limiting using a Current Sense Resistor
The switch current is limited to
ISWITCH(PEAK) $=\frac{\mathrm{V}_{\mathrm{BE}(\mathrm{Q} 1)}}{\operatorname{RSENSE}}$
where:
$\mathrm{V}_{\mathrm{BE}(\mathrm{Q} 1)}=$ the base-emitter voltage drop of Q 1 , typically 0.65 V .

The improved circuit does not require a regulated voltage to operate properly. Unfortunately, a price must be paid for this convenience in the overall efficiency of the circuit. The designer should note that the input and output grounds are no longer common. Also, the addition of the current sense resistor, $\mathrm{R}_{\text {SENSE }}$, results in a considerable power loss which
increases with the duty cycle. Resistor R2 and capacitor C3 form a low-pass filter to remove noise.

## Subharmonic Oscillation

Subharmonic oscillation (SHM) is a problem found in current-mode control systems, where instability results when duty cycle exceeds $50 \%$. SHM only occurs in switching regulators with a continuous inductor current. This instability is not harmful to the converter and usually does not affect the output voltage regulation. SHM will increase the radiated EM noise from the converter and can cause, under certain circumstances, the inductor to emit high-frequency audible noise.

SHM is an easily remedied problem. The rising slope of the inductor current is supplemented with internal "slope compensation" to prevent any duty cycle instability from carrying through to the next switching cycle. In the CS517x family, slope compensation is added during the entire switch on-time, typically in the amount of $180 \mathrm{~mA} / \mu \mathrm{s}$.

In some cases, SHM can rear its ugly head despite the presence of the onboard slope compensation. The simple cure to this problem is more slope compensation to avoid the unwanted oscillation. In that case, an external circuit, shown in Figure 40, can be added to increase the amount of slope compensation used. This circuit requires only a few components and is "tacked on" to the compensation network.

Figure 40. Technique for Increasing Slope Compensation
The dashed box contains the normal compensation circuitry to limit the bandwidth of the error amplifier. Resistors R2 and R3 form a voltage divider off of the $\mathrm{V}_{\mathrm{SW}}$
pin. In normal operation, $\mathrm{V}_{\mathrm{SW}}$ looks similar to a square wave, and is dependent on the converter topology. Formulas for calculating $\mathrm{V}_{\mathrm{SW}}$ in the boost and flyback topologies are given in the section "V $V_{S W}$ Voltage Limit." The voltage on $\mathrm{V}_{\text {SW }}$ charges capacitor C 3 when the switch is off, causing the voltage at the $\mathrm{V}_{\mathrm{C}}$ pin to shift upwards. When the switch turns on, C3 discharges through R3, producing a negative slope at the $\mathrm{V}_{\mathrm{C}}$ pin. This negative slope provides the slope compensation.
The amount of slope compensation added by this circuit is

$$
\frac{\Delta I}{\Delta T}=V_{S W}\left(\frac{R_{3}}{R_{2}+R_{3}}\right)\left(1-e^{\frac{-(1-D)}{R_{3} C_{3} f W}}\right)\left(\frac{f S W}{(1-D) R_{E A V}}\right)
$$

where:
$\Delta \mathrm{I} / \Delta \mathrm{T}=$ the amount of slope compensation added (A/s);
$\mathrm{V}_{\mathrm{SW}}=$ the voltage at the switch node when the transistor is turned off (V);
$\mathrm{f}_{\mathrm{SW}}=$ the switching frequency, typically 280 kHz (CS5171/3) or 560 kHz (CS5172/4) (Hz);
$\mathrm{D}=$ the duty cycle;
$\mathrm{R}_{\mathrm{E}}=0.063 \Omega$, the value of the internal emitter resistor;
$\mathrm{A}_{\mathrm{V}}=5 \mathrm{~V} / \mathrm{V}$, the gain of the current sense amplifier.
In selecting appropriate values for the slope compensation network, the designer is advised to choose a convenient capacitor, then select values for R2 and R3 such that the amount of slope compensation added is $100 \mathrm{~mA} / \mu \mathrm{s}$. Then R2 may be increased or decreased as necessary. Of course, the series combination of R2 and R3 should be large enough to avoid drawing excessive current from $\mathrm{V}_{\mathrm{SW}}$. Additionally, to ensure that the control loop stability is improved, the time constant formed by the additional components should be chosen such that
$\mathrm{R}_{3} \mathrm{C}_{3}<\frac{1-\mathrm{D}}{\mathrm{fSW}}$
Finally, it is worth mentioning that the added slope compensation is a trade-off between duty cycle stability and transient response. The more slope compensation a designer adds, the slower the transient response will be, due to the external circuitry interfering with the proper operation of the error amplifier.

## Soft Start

Through the addition of an external circuit, a soft-start function can be added to the CS5171/2/3/4 family of components. Soft-start circuitry prevents the $\mathrm{V}_{\mathrm{C}}$ pin from slamming high during startup, thereby inhibiting the inductor current from rising at a high slope.

This circuit, shown in Figure 41, requires a minimum number of components and allows the soft-start circuitry to activate any time the SS pin is used to restart the converter.

Figure 41. Soft Start
Resistor R1 and capacitors C1 and C2 form the compensation network. At turn on, the voltage at the $\mathrm{V}_{\mathrm{C}}$ pin starts to come up, charging capacitor C3 through Schottky diode D 2, clamping the voltage at the $\mathrm{V}_{\mathrm{C}}$ pin such that switching begins when $\mathrm{V}_{\mathrm{C}}$ reaches the $\mathrm{V}_{\mathrm{C}}$ threshold, typically 1.05 V (refer to graphs for detail over temperature).
$V_{C}=V_{F}(D 2)+V_{C 3}$
Therefore, C 3 slows the startup of the circuit by limiting the voltage on the $\mathrm{V}_{\mathrm{C}}$ pin. The soft-start time increases with the size of C3.

Diode D1 discharges C3 when SS is low. If the shutdown function is not used with this part, the cathode of D1 should be connected to $\mathrm{V}_{\mathrm{IN}}$.

## Calculating Junction Temperature

To ensure safe operation of the CS5171/2/3/4, the designer must calculate the on-chip power dissipation and determine its expected junction temperature. Internal thermal protection circuitry will turn the part off once the junction temperature exceeds $180^{\circ} \mathrm{C} \pm 30^{\circ}$. However, repeated operation at such high temperatures will ensure a reduced operating life.

Calculation of the junction temperature is an imprecise but simple task. First, the power losses must be quantified. There are three major sources of power loss on the CS517x:

- biasing of internal control circuitry, PBIAS
- switch driver, P PRIVER
- switch saturation, $\mathrm{P}_{\text {SAT }}$

The internal control circuitry, including the oscillator and linear regulator, requires a small amount of power even when the switch is turned off. The specifications section of this datasheet reveals that the typical operating current, $\mathrm{I}_{\mathrm{Q}}$,
due to this circuitry is 5.5 mA . Additional guidance can be found in the graph of operating current vs. temperature. This graph shows that IQ is strongly dependent on input voltage, $\mathrm{V}_{\mathrm{IN}}$, and the ambient temperature, $\mathrm{T}_{\mathrm{A}}$. Then
PBIAS $=\mathrm{V}_{\text {IN }}{ }^{\prime} \mathrm{Q}$
Since the onboard switch is an NPN transistor, the base drive current must be factored in as well. This current is drawn from the $\mathrm{V}_{\text {IN }}$ pin, in addition to the control circuitry current. The base drive current is listed in the specifications as $\Delta \mathrm{I}_{\mathrm{CC}} / \Delta \mathrm{I}_{\mathrm{SW}}$, or switch transconductance. As before, the designer will find additional guidance in the graphs. With that information, the designer can calculate

$$
\text { PDRIVER }=\mathrm{V}_{\text {INIS }} \times \frac{\mathrm{I} \mathrm{CC}}{\Delta \mathrm{I} S W} \times \mathrm{D}
$$

where:
$\mathrm{I}_{\mathrm{SW}}=$ the current through the switch;
$\mathrm{D}=$ the duty cycle or percentage of switch on-time.
$\mathrm{I}_{\text {SW }}$ and D are dependent on the type of converter. In a boost converter,

$$
\begin{aligned}
\operatorname{ISW}(A V G) \cong \operatorname{LLOAD} & \times D \times \frac{1}{\text { Efficiency }} \\
D & \cong \frac{V_{O U T}-V_{I N}}{V_{O U T}}
\end{aligned}
$$

In a flyback converter,
$\operatorname{ISW}(A V G) \cong \frac{\text { VOUTILOAD }}{\text { VIN }} \times \frac{1}{\text { Efficiency }}$
$\mathrm{D} \cong \frac{\mathrm{V}_{\text {OUT }}}{\mathrm{V}_{\text {OUT }}+\frac{N_{S}}{N_{P}} \mathrm{~V}_{\text {IN }}}$
The switch saturation voltage, $\mathrm{V}_{(\mathrm{CE}) \mathrm{SAT}}$, is the last major source of on-chip power loss. $\mathrm{V}_{\text {(CE)SAT }}$ is the collector-emitter voltage of the internal NPN transistor when it is driven into saturation by its base drive current. The value for $\mathrm{V}_{(\mathrm{CE}) \text { SAT }}$ can be obtained from the specifications or from the graphs, as "Switch Saturation Voltage." Thus,

$$
\mathrm{PSAT}_{S A} \cong \mathrm{~V}_{(C E) S A T I S W} \times \mathrm{D}
$$

Finally, the total on-chip power losses are

```
PD = PBIAS + PDRIVER + PSAT
```

Power dissipation in a semiconductor device results in the generation of heat in the junctions at the surface of the chip. This heat is transferred to the surface of the IC package, but a thermal gradient exists due to the resistive properties of the package molding compound. The magnitude of the thermal gradient is expressed in manufacturers' data sheets as $\Theta_{\mathrm{JA}}$, or junction-to-ambient thermal resistance. The on-chip junction temperature can be calculated if $\Theta_{\mathrm{JA}}$, the air temperature near the surface of the IC, and the on-chip power dissipation are known.
$T J=T_{A}+(P D \Theta J A)$
where:
$\mathrm{T}_{\mathrm{J}}=\mathrm{IC}$ or FET junction temperature $\left({ }^{\circ} \mathrm{C}\right)$;

## CS5171, CS5172, CS5173, CS5174

$\mathrm{T}_{\mathrm{A}}=$ ambient temperature $\left({ }^{\circ} \mathrm{C}\right)$;
$\mathrm{P}_{\mathrm{D}}=$ power dissipated by part in question (W);
$\Theta_{\mathrm{JA}}=$ junction-to-ambient thermal resistance $\left({ }^{\circ} \mathrm{C} / \mathrm{W}\right)$.
For ON Semiconductor components, the value for $\Theta_{\mathrm{JA}}$ can be found on page 1402 of the datasheet, under "Package Thermal Data." Note that this value is different for every package style and every manufacturer. For the CS517x, $\Theta_{\mathrm{JA}}=165^{\circ} \mathrm{C} / \mathrm{W}$.

Once the designer has calculated $\mathrm{T}_{\mathrm{J}}$, the question of whether the CS517x can be used in an application is settled. If $\mathrm{T}_{\mathrm{J}}$ exceeds $150^{\circ} \mathrm{C}$, the absolute maximum allowable junction temperature, the CS517x is not suitable for that application.

If $\mathrm{T}_{\mathrm{J}}$ approaches $150^{\circ} \mathrm{C}$, the designer should consider possible means of reducing the junction temperature. Perhaps another converter topology could be selected to reduce the switch current. Increasing the airflow across the surface of the chip might be considered to reduce $T_{A}$. $A$ copper "landing pad" can be connected to the ground or $\mathrm{V}_{\text {IN }}$ pins - designers are referred to ON Semiconductor applications note SR-006 for more information on properly sizing a copper area.

## Circuit Layout Guidelines

In any switching power supply, circuit layout is very important for proper operation. Rapidly switching currents
combined with trace inductance generates voltage transitions that can cause problems. Therefore the following guidelines should be followed in the layout.

1. In boost circuits, high AC current circulates within the loop composed of the diode, output capacitor, and on-chip power transistor. The length of associated traces and leads should be kept as short as possible. In the flyback circuit, high AC current loops exist on both sides of the transformer. On the primary side, the loop consists of the input capacitor, transformer, and on-chip power transistor, while the transformer, rectifier diodes, and output capacitors form another loop on the secondary side. Just as in the boost circuit, all traces and leads containing large AC currents should be kept short.
2. Separate the low current signal grounds from the power grounds. Use single point grounding or ground plane construction for the best results.
3. Locate the voltage feedback resistors as near the IC as possible to keep the sensitive feedback wiring short. Connect feedback resistors to the low current analog ground.

## Variable Frequency Micropower DC-to-DC Converter

The MC33463 series are micropower step-up switching voltage regulators, specifically designed for handheld and laptop applications, to provide regulated output voltages using a minimum of external parts. A wide choice of output voltages are available. These devices feature a very low quiescent bias current of $4.0 \mu \mathrm{~A}$ typical.

The MC33463H-XXKT1 series features a highly accurate voltage reference, an oscillator, a variable frequency modulation (VFM) controller, a driver transistor (Lx), a comparator and feedback resistive divider.

The MC33463H-XXLT1 is identical to the MC33463H-XXKT1, except that a drive pin (EXT) for an external transistor is provided.

Due to the low bias current specifications, these devices are ideally suited for battery powered computer, consumer, and industrial equipment where an extension of useful battery life is desirable.

## MC33463 Series Features:

- Low Quiescent Bias Current of $4.0 \mu \mathrm{~A}$
- High Output Voltage Accuracy of $\pm 2.5 \%$
- Low Startup Voltage of 0.9 V at 1.0 mA
- Wide Output Voltage Range of 2.5 V to 7.5 V Available
- High Efficiency of $80 \%$ Typical
- Surface Mount Package

## DEFINITIONS

Quiescent Bias Current - Current which is used to operate the switching regulator chip and is not delivered to the load.
Leakage Current - Current drawn through a transistor junction, under a specified collector voltage, when the transistor is off.

## FUNCTIONAL DESCRIPTION

## Introduction

The MC33463 series are monolithic power switching regulators optimized for dc-to-dc converter applications where power drain must be minimized. The combination of features in this series allows the system designer to directly implement step-up, step-down or flyback converters with a small number of external components. Potential applications include low power consumer products and battery powered portable products. Typical application circuits are shown in Figure 17 and Figure 18.

## Operating Description

The MC33463 series converters each operate as a fixed on-time, variable off-time voltage mode ripple regulator. Operation is intended to be in the discontinuous mode, where the inductor current ramps up to a peak value which is greater than or equal to twice the value of the dc input current during the on-time of the transistor switch. During the off-time of the transistor switch, the inductor current ramps down to zero and remains at zero until another switching cycle begins.

Because the output voltage pin is also used as the supply voltage for powering internal circuitry, an external startup circuit is needed in step-down and flyback converter designs to provide initial power to the integrated circuit to begin switching. The startup circuit needed can be three

Figure 16. Startup/Hold Voltage versus Temperature
discrete components, as shown in Figure 19, or a micropower undervoltage sensor, as shown in Figure 20.

## Oscillator

The maximum oscillator frequency, is internally programmed to 100 kHz . The duty ratio of the oscillator is designed for a constant value of 0.75 nominal. Hence the nominal on-time of the power switch is:

$$
t_{\text {on }}=\frac{D}{f_{\mathrm{osc}}}=\frac{0.75}{(100 \mathrm{kHz})}=7.5 \mu \mathrm{~s}
$$

## Feedback Comparator

The output voltage is sensed and fed to a high speed comparator noninverting input through an internal resistive divider. The comparator inverting input is connected to an internally trimmed to 0.7 V reference.
With a voltage mode ripple converter operating under normal conditions, output switch conduction is initiated and terminated by the oscillator, off-time is controlled by the high speed voltage feedback comparator.

## Driver and Output Switch

To aid in system design flexibility and conversion efficiency, two output driver options are provided. The MC33463H-XXKT1 converters have an internal drive transistor which is capable of sinking currents greater than 60 mA into the Lx pin. An internal $\mathrm{V}_{\mathrm{Lx}}$ limiter circuit senses if the Lx pin voltage exceeds 1.0 V during $\mathrm{t}_{\mathrm{on}}$ and turns off the drive transistor. The MC33463H-XXLT1 provides output drive for an external transistor.

## Applications

The following converter applications show the simplicity and flexibility of the converter architecture. Three main converter topologies are demonstrated in Figures 17 through 21.

| L |  | $<\frac{(\mathrm{n})\left(\mathrm{V}_{\text {in }}\right)^{2}\left(\mathrm{t}_{\mathrm{on}}\right)}{\mathrm{P}_{\mathrm{O}}}$ | $<\frac{(n)\left(\mathrm{V}_{\mathrm{in}}\right)^{2}\left(\mathrm{t}_{\mathrm{on}}\right)}{\mathrm{P}_{\mathrm{O}}}$ |
| L(avg) | 10 | $\mathrm{l}_{\text {in }}$ | $\mathrm{l}_{\text {in }}$ |
| $\mathrm{I}_{\mathrm{L}(\mathrm{pk})}$ | $\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {sat }}-\mathrm{V}_{\mathrm{O}}\right)\left(\mathrm{t}_{\text {on }}\right)}{\mathrm{L}}$ | $\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {sat }}\right)\left(\mathrm{t}_{\text {on }}\right)}{\mathrm{L}}$ | $\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {sat }}\right)\left(\mathrm{t}_{\text {on }}\right)}{\mathrm{L}}$ |
| $\mathrm{V}_{\text {ripple(pp) }}$ | $\Delta \mathrm{I}_{\mathrm{L}}\left[\left(\frac{1}{16 f_{\text {OSC }} \mathrm{C}_{\mathrm{O}}}\right)^{2}+(E S R)^{2}\right]^{\frac{1}{2}}$ | $\approx \frac{\left(\mathrm{t}_{\mathrm{on}}\right)\left(\mathrm{I}_{\mathrm{O}}\right)}{\left(\mathrm{C}_{\mathrm{O}}\right)}$ | $\approx \frac{\left(\mathrm{t}_{\mathrm{On}}\right)\left(\mathrm{I}_{\mathrm{O}}\right)}{\left(\mathrm{C}_{\mathrm{O}}\right)}$ |

The following converter design characteristics must be chosen:
$V_{\text {in }}$ - Nominal Operating dc input voltage
$\mathrm{V}_{\mathrm{O}}$ - Desired dc output voltage
Io - Desired dc output current
$\mathrm{V}_{\text {ripple(pp) }}$ - Desired peak-to-peak output ripple voltage. For best performance the ripple voltage should be kept to a low value since it will directly affect line and load regulation. Capacitor $\mathrm{C}_{\mathrm{O}}$ should be a low equivalent series resistance (ESR) electrolytic designed for switching regulator applications.

1. $\mathrm{V}_{\text {sat }}$ - Saturation voltage of the switching transistor.
n -Estimated circuit efficiency.

## MC33466

## Fixed Frequency PWM Micropower DC-to-DC Converter

The MC33466 series are micropower switching voltage regulators, specifically designed for handheld and laptop applications, to provide regulated output voltages using a minimum of external parts. A wide choice of output voltages are available. These devices feature a very low quiescent bias current of $15 \mu \mathrm{~A}$ typical.

The MC33466H-XXJT1 series features a highly accurate voltage reference, an oscillator, a pulse width modulation (PWM) controller, a driver transistor (Lx), an error amplifier and feedback resistive divider.

The MC33466H-XXLT1 is identical to the MC33466H-XXJT1, except that a drive pin (EXT) for an external transistor is provided.

Due to the low bias current specifications, these devices are ideally suited for battery powered computer, consumer, and industrial equipment where an extension of useful battery life is desirable.

## MC33466 Series Features:

- Low Quiescent Bias Current of $15 \mu \mathrm{~A}$
- High Output Voltage Accuracy of $\pm 2.5 \%$
- Low Startup Voltage of 0.9 V at 1.0 mA
- Soft-Start $=500 \mu \mathrm{~s}$
- Surface Mount Package

1. When the Lx switch is turned on, $\mathrm{I}_{\mathrm{Lx}}$ current carried through the $\mathrm{R}_{\mathrm{DS}(o n)}$ of the Lx switch results in $\mathrm{V}_{\mathrm{Lx}}$. When $\mathrm{V}_{\mathrm{Lx}}$ reaches $\mathrm{V}_{\mathrm{LxLim}}$, the Lx switch is turned off by the Lx switch protection circuit.
2. The soft-start circuit turn-on sequence is as follows:
a) $V_{\text {in }}$ is applied.
b) The internal IC $V_{\text {ref }}$ is held at zero for $200 \mu \mathrm{~s}$. During this time, the error amplifier output voltage ramps up to the positive voltage rail.
c) The internal reference steps up to 0.7 V after $200 \mu \mathrm{~s}$ delay has timed out.
d) The error amplifier output voltage integrates down to its steady state value. As the error amplifier output integrates down, the output Lx pin of EXT pin pulse width gradually widens to its steady operating value.

## MC33466

TYPICAL APPLICATIONS

Figure 20. Supply Current versus Input Voltage

## DEFINITIONS

Quiescent Bias Current - Current which is used to operate the switching regulator chip and is not delivered to the load.
Leakage Current - Current drawn through a transistor junction, under a specified collector voltage, when the transistor is off.

## FUNCTIONAL DESCRIPTION

## Introduction

The MC33466 series are monolithic power switching regulators optimized for dc-to-dc converter applications where power drain must be minimized. The combination of features in this series allows the system designer to directly implement step-up, step-down or flyback converters with a small number of external components. Potential applications include low power consumer products and battery powered portable products. Typical application circuits are shown in Figures 22 through 26.

## Operating Description

The MC33466 series converters operate as a fixed frequency voltage mode regulator. Operation is intended to be in the discontinuous mode, where the inductor current ramps up to a peak value which is greater than or equal to twice the value of the dc input current during the on-time of the transistor switch. During the off-time of the transistor switch, the inductor current ramps down to zero and remains at zero until another switching cycle begins.

Because the output voltage pin is also used as the supply voltage for powering internal circuitry, an external startup circuit is needed in step-down converter and flyback designs to provide initial power to the integrated circuit to begin switching. The startup circuit needed can be three discrete components, as shown in Figure 24, or a micropower undervoltage sensor, as shown in Figure 25.

## Oscillator

The oscillator frequency, is internally programmed to 50 kHz for the JT1 suffix and 100 kHz for the LT1 suffix. The timing capacitor $\left(\mathrm{C}_{\mathrm{T}}\right)$ discharge to charge ratio of the oscillator is designed for a maximum duty cycle of $80 \%$ at the Lx or EXT output. During the charge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the PWM control off, disabling the output transistor drive. The oscillator peak and valley thresholds are 0.5 V and ground, respectively.

## Pulse Width Modulator

The Pulse Width Modulator consists of a comparator with the oscillator ramp voltage applied to the inverting input, while the error amplifier output is applied to the noninverting input. Output switch conduction is initiated when the timing capacitor is charged to its peak voltage value. When the timing capacitor ramp discharges to a voltage below the error amplifier output, the comparator resets a latch terminating output transistor drive for the duration of the oscillator ramp period.

## Error Amplifier and Reference

An Error Amplifier is provided which has a nominal 80 dB of voltage gain at dc. Internal compensation components provide poles at $0.25 \mathrm{~Hz}, 30 \mathrm{kHz}$ and 33 kHz . Two zeros are provided at 1.0 kHz and at 2.5 kHz . The output voltage value is set by the internal voltage divider and a 0.7 V reference which is trimmed to an accuracy of $\pm 2.5 \%$. Because the loop compensation components are located within the IC, discontinuous mode operation is recommended for most applications.

## Driver and Output Switch

To aid in system design flexibility and conversion efficiency, two output driver options are provided. The MC33466H-XXJT1 converters have an internal drive transistor which is capable of sinking currents greater than 60 mA into the Lx pin. An internal $\mathrm{V}_{\mathrm{Lx}}$ limiter circuit senses if the Lx pin voltage exceeds 1.0 V during $\mathrm{t}_{\mathrm{on}}$ and turns off the drive transistor. The MC33466H-XXLT1 provides output drive for an external transistor.

## Applications

The following converter applications show the simplicity and flexibility of the converter architecture. Three main converter topologies are demonstrated in Figures 22 through 26.

| $\mathrm{t}_{\text {on }}$ | $\frac{\mathrm{D}}{\mathrm{fs}}$ | $\frac{\mathrm{D}}{\mathrm{fs}}$ | $\frac{\mathrm{D}}{\mathrm{fs}}$ |
| D | $<\frac{\left(\mathrm{V}_{\mathrm{O}}\right)}{\left(\mathrm{V}_{\text {in }}\right)}$ | $<\frac{\left(\mathrm{V}_{\mathrm{O}}-\mathrm{V}_{\mathrm{in}}\right)}{\left(\mathrm{V}_{\mathrm{O}}\right)}$ | $<\frac{v_{O}}{\left[\left(\frac{N s}{N p}\right)\left(v_{\text {in }}\right)+v_{O}\right]}$ |
| L(avg) | 10 | $1{ }_{\text {in }}$ | $\mathrm{l}_{\text {in }}$ |
| $\mathrm{I}_{\mathrm{L}(\mathrm{pk})}$ | $\frac{\left(V_{\text {in }}-V_{0}\right)\left(t_{\text {on }}\right)}{L}$ | $\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {sat }}\left(\mathrm{t}_{\text {on }}\right)\right.}{L}$ | $\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {sat }}\left(\mathrm{t}_{\text {on }}\right)\right.}{\mathrm{L}}$ |
| $\mathrm{V}_{\text {ripple(pp) }}$ |  | $\mathrm{I}_{\mathrm{L}(\mathrm{pk})}\left[\left(\frac{1}{8 f \mathrm{~S}_{\mathrm{O}}}\right)^{2}+(\mathrm{ESR})^{2}\right]^{\frac{1}{2}}$ |  |

The following converter design characteristics must be chosen:
$\mathrm{V}_{\text {in }}$ - Nominal Operating dc input voltage
$\mathrm{V}_{\mathrm{O}}$ - Desired dc output voltage
$\mathrm{I}_{\mathrm{O}}$ - Desired dc output current
$\mathrm{V}_{\text {ripple(pp) }}$ - Desired peak-to-peak output ripple voltage. For best performance the ripple voltage should be kept to a low value since it will directly affect line and load regulation. Capacitor $\mathrm{C}_{\mathrm{o}}$ should be a low equivalent series resistance (ESR) electrolytic designed for switching regulator applications.
$D$ - Operating duty cycle $=t_{\mathrm{on}}(\mathrm{fs})$. This parameter must be chosen to be $<0.5$ for step-up and flyback applications.
NOTES: 1. $\mathrm{V}_{\text {sat }}$ - Saturation voltage of the switching transistor.
2. $\mathrm{I}_{\mathrm{in}}$ - DC input switch.
3. fs - Switching frequency, nominally 50 kHz .
4. $\mathrm{R}_{\mathrm{O}}$ - Load resistance. $\mathrm{R}_{\mathrm{O}}=\mathrm{V}_{\mathrm{O}} / \mathrm{l}_{\mathrm{O}}$.
5. Ns, Np - In flyback applications Ns is the number of turns of the secondary transformer winding; Np is the number of the primary winding turns.

Figure 27. Design Equations

## Design Example - Step-down Application

Required: $\mathrm{V}_{\text {in }}=8.0 \mathrm{~V}$, an output voltage of 3.3 V at 300 mA is desired with an output ripple of less than 300 mVpp .

$$
\mathrm{R}_{\mathrm{O}}=\frac{\mathrm{v}_{\mathrm{O}}}{\mathrm{I}_{\mathrm{O}}}=11 \Omega
$$

1. Because this is a discontinuous mode design, $D<\frac{V_{O}}{V_{i n}}=\frac{3.3}{8}=0.41$. Choose $D=0.33$.
2. $\mathrm{t}_{\mathrm{on}} \approx \frac{\mathrm{D}}{\mathrm{fs}}=\frac{0.33}{(50 \mathrm{kHz})}=6.6 \mu \mathrm{~s}$.
3. $\mathrm{L}<\frac{\left(\mathrm{V}_{\mathrm{in}}-\mathrm{V}_{\mathrm{O}}\right)\left(\mathrm{t}_{\mathrm{on}}\right)}{2 \mathrm{I}_{\mathrm{O}}}=\frac{(8-3.3)(6.6 \mu \mathrm{~s})}{[2(0.3)]}=51.7 \mu \mathrm{H}$.

Choose $\mathrm{L}=47 \mu \mathrm{H}$. Coilcraft part number DO3316P-473.
4. $\mathrm{I}_{\mathrm{L}(\mathrm{pk})}=\frac{\left(\mathrm{V}_{\mathrm{in}}-\mathrm{V}_{\mathrm{O}}\right)\left(\mathrm{t}_{\mathrm{on}}\right)}{\mathrm{L}}=\frac{(8-3.3)(6.6 \mu \mathrm{~s})}{(47 \mu \mathrm{H})}=660 \mathrm{~mA}$.
5. $\mathrm{ESR}<\frac{\mathrm{V}_{\text {ripple(pp) }}}{\mathrm{I}_{\mathrm{L}(\mathrm{pk})}}=\frac{(300 \mathrm{mV})}{(660 \mathrm{~mA})}=0.455 \Omega$.

Choose $\mathrm{C}_{\mathrm{O}}=$ two parallel AVX $330 \mu \mathrm{~F}$ tantalum chip capacitors. Part Number TAJE337M006.
Specified maximum ESR for each is $0.9 \Omega$.
The complete design schematic is shown in Figure 24.

## MC33466

ORDERING INFORMATION

| Device | Output Voltage | Type | Operating Temperature Range | Package | Shipping |
| :---: | :---: | :---: | :---: | :---: | :---: |
| MC33466H-30JT1 | 3.0 | Int. Switch | $\mathrm{T}_{\mathrm{A}}=-30^{\circ}$ to $+80^{\circ} \mathrm{C}$ | SOT-89 | 1000 Tape \& Reel |
| MC33466H-33JT1 | 3.3 |  |  |  |  |
| MC33466H-50JT1 | 5.0 |  |  |  |  |
| MC33466H-30LT1 | 3.0 |  |  |  |  |
| MC33466H-33LT1 | 3.3 | Switch |  |  |  |
| MC33466H-50LT1 | 5.0 | Drive |  |  |  |

Other voltages from 2.5 V to 7.5 V , in 0.1 V increments are available. Consult factory for information.

## NCP1400A

## 100 mA , Fixed Frequency PWM Step-Up Micropower Switching Regulator

The NCP1400A series are micropower step-up DC to DC converters that are specifically designed for powering portable equipment from one or two cell battery packs. These devices are designed to start-up with a cell voltage of 0.8 V and operate down to less than 0.2 V . With only four external components, this series allows a simple means to implement highly efficient converters that are capable of up to 100 mA of output current.

Each device consists of an on-chip fixed frequency oscillator, pulse width modulation controller, phase compensated error amplifier that ensures converter stability with discontinuous mode operation, soft-start, voltage reference, driver, and power MOSFET switch with current limit protection. Additionally, a chip enable feature is provided to power down the converter for extended battery life.

The NCP1400A device series are available in the Thin SOT-23-5 package with six standard regulated output voltages. Additional voltages that range from 1.8 V to 4.9 V in 100 mV steps can be manufactured.

## Features

- Extremely Low Start-Up Voltage of 0.8 V
- Operation Down to Less than 0.2 V
- Only Four External Components for Simple Highly Efficient Converters
- Up to 100 mA Output Current Capability
- Fixed Frequency Pulse Width Modulation Operation
- Phase Compensated Error Amplifier for Stable Converter Operation
- Chip Enable Power Down Capability for Extended Battery Life

## Typical Applications

- Cellular Telephones
- Pagers
- Personal Digital Assistants
- Electronic Games
- Digital Cameras
- Camcorders
- Handheld Instruments

## PIN FUNCTION DESCRIPTION

| Pin \# | Symbol |  |
| :---: | :---: | :--- |
| 1 | CE | Chip Enable Pin <br> (1) The chip is enabled if a voltage equal to or greater than 0.9 V is applied. <br> (2) The chip is disabled if a voltage less than 0.3 V is applied. <br> (3) The chip is enabled if this pin is left floating. |
| 2 | OUT | Output voltage monitor pin and also the power supply pin for the device. |
| 3 | NC | No internal connection to this pin. |
| 4 | GND | Ground pin. |
| 5 | LX | External inductor connection pin to power switch drain. |

## DETAILED OPERATING DESCRIPTION

## Operation

The NCP1400A series are monolithic power switching regulators optimized for applications where power drain must be minimized. These devices operate as fixed frequency, voltage mode boost regulator and is designed to operate in the discontinuous conduction mode. Potential applications include low powered consumer products and battery powered portable products.

The NCP1400A series are low noise fixed frequency voltage-mode PWM DC-DC converters, and consist of soft-start circuit, feedback resistor, reference voltage, oscillator, loop compensation network, PWM control circuit, current limit circuit and power switch. Due to the on-chip feedback resistor and loop compensation network, the system designer can get the regulated output voltage from 1.8 V to 5.0 V with a small number of external components. The quiescent current is typically $32 \mu \mathrm{~A}$ $\left(\mathrm{V}_{\text {OUT }}=2.7 \mathrm{~V}\right)$, and can be further reduced to about $1.5 \mu \mathrm{~A}$ when the chip is disabled $\left(\mathrm{V}_{\mathrm{CE}}<0.3 \mathrm{~V}\right)$.

## Soft Start

There is a soft start circuit in NCP1400A. When power is applied to the device, the soft start circuit pumps up the output voltage to approximately 1.5 V at a fixed duty cycle, the level at which the converter can operate normally. What is more, the start-up capability with heavy loads is also improved.

## Oscillator

The oscillator frequency is internally set to 180 kHz at an accuracy of $\pm 20 \%$ and with low temperature coefficient of $0.11 \% /{ }^{\circ} \mathrm{C}$. Figures 16 and 17 illustrate oscillator frequency versus temperature.

## Regulated Converter Voltage (VOUT)

The Vout is set by an internal feedback resistor network. This is trimmed to a selected voltage from 1.8 V to 5.0 V range in 100 mV steps with an accuracy of $\pm 2.5 \%$.

## Compensation

The device is designed to operate in discontinuous conduction mode. An internal compensation circuit was designed to guarantee stability over the full input/output voltage and full output load range. Stability cannot be guaranteed in continuous conduction mode.

## Current Limit

The NCP1400A series utilizes cycle-by-cycle current limiting as a means of protecting the output switch MOSFET from overstress and preventing the small value inductor from saturation. Current limiting is implemented by monitoring the output MOSFET current build-up during conduction, and upon sensing an overcurrent conduction immediately turning off the switch for the duration of the oscillator cycle.

The voltage across the output MOSFET is monitored and compared against a reference by the VLX limiter. When the threshold is reached, a signal is sent to the PWM controller block to terminate the output switch conduction. The current limit threshold is typically set at 350 mA .

## Enable/Disable Operation

The NCP1400A series offer IC shutdown mode by chip enable pin (CE pin) to reduce current consumption. An internal pull-up resistor tied the CE pin to OUT pin by default, i.e., user can float the pin CE for permanent "On". When voltage at pin CE is equal or greater than 0.9 V , the chip will be enabled, which means the regulator is in normal operation. When voltage at pin CE is less than 0.3 V , the chip is disabled, which means IC is shutdown.
Important: DO NOT apply a voltage between 0.3 V to 0.9 V to pin CE as this voltage will place the IC into an undefined state and the IC may drain excessive current from the supply.

## APPLICATION CIRCUIT INFORMATION

Figure 41. Typical Step-Up Converter Application

## Step-up Converter Design Equations

General step-up DC-DC converter designed to operate in discontinuous conduction mode can be defined by:

| Calculation | Equation |
| :---: | :---: |
| D | $\frac{\mathrm{t}_{\text {on }}}{T}$ |
| $\mathrm{I}_{\mathrm{PK}}$ | $\frac{\mathrm{V}_{\text {in }} \mathrm{t}_{\text {on }}}{\mathrm{L}}$ |
| $\mathrm{I}_{\mathrm{O}}$ | $\frac{\left(\mathrm{V}_{\text {in }}\right)^{2}\left(\mathrm{t}_{\text {on }}\right)^{2 \mathrm{f}}}{2 \mathrm{~L}\left(\mathrm{~V}_{\text {out }}+\mathrm{V}_{\mathrm{F}}-\mathrm{V}_{\text {in }}\right)}$ |

## NOTES:

D - Duty cycle
IPK - Peak inductor current
$\mathrm{I}_{\mathrm{O}}$ - Desired dc output current
$\mathrm{V}_{\text {in }}$ - Nominal operating dc input voltage
$V_{\text {out }}$ - Desired dc output voltage
$V_{F}$ - Diode forward voltage
Assume saturation voltage of the internal FET switch is negligible.

## External Component Selection

## Inductor

Inductance values between $18 \mu \mathrm{H}$ and $27 \mu \mathrm{H}$ are the best suitable values for NCP1400A. In general, smaller inductance values can provide larger peak inductor current and output current capability, and lower conversion efficiency, and vice versa. Select an inductor with smallest possible DCR, usually less than $1.0 \Omega$ to minimize loss. It is necessary to choose an inductor with saturation current greater than the peak current which the inductor will encounter in the application.

## Diode

The diode is the largest source of loss in DC-DC converters. The most importance parameters which affect their efficiency are the forward voltage drop, $\mathrm{V}_{\mathrm{F}}$, and the reverse recovery time, trr. The forward voltage drop creates a loss just by having a voltage across the device while a current flowing through it. The reverse recovery time generates a loss when the diode is reverse biased, and the current appears to actually flow backwards through the diode due to the minority carriers being swept from the $\mathrm{P}-\mathrm{N}$ junction. A schottky diode with the following characteristics is recommended:

Small forward voltage, $\mathrm{V}_{\mathrm{F}}<0.3 \mathrm{~V}$
Small reverse leakage current
Fast reverse recovery time/switching speed
Rated current larger than peak inductor current,

$$
\mathrm{I}_{\text {rated }}>\mathrm{I}_{\mathrm{PK}}
$$

Reverse voltage larger than output voltage,

$$
V_{\text {reverse }}>V_{\text {out }}
$$

## Input Capacitor

The input capacitor can stabilize the input voltage and minimize peak current ripple from the source. The value of the capacitor depends on the impedance of the input source used. Small ESR (Equivalent Series Resistance) Tantalum or ceramic capacitor with value of $10 \mu \mathrm{~F}$ should be suitable.

## Output Capacitor

The output capacitor is used for sustaining the output voltage when the internal MOSFET is switched on and smoothing the ripple voltage. Low ESR capacitor should be used to reduce output ripple voltage. In general, a $47 \mu \mathrm{~F}$ to $68 \mu \mathrm{~F}$ low ESR ( $0.15 \Omega$ to $0.30 \Omega$ ) Tantalum capacitor should be appropriate.

An evaluation board of NCP1400A has been made in the small size of $23 \mathrm{~mm} \times 20 \mathrm{~mm}$ and is shown in Figures 42 and 43. Please contact your ON Semiconductor representative
for availability. The evaluation board schematic diagram, the artwork and the silkscreen of the surface mount PCB are shown below:

Figure 42. NCP1400A PWM Step-up DC-DC Converter Evaluation Board Silkscreen

Figure 43. NCP1400A PWM Step-up DC-DC Converter Evaluation Board Artwork (Component Side)

Components Supplier

| Parts | Supplier | Part Number | Description | Phone |
| :--- | :--- | :--- | :--- | :---: |

## PCB Layout Hints

## Grounding

One point grounding should be used for the output power return ground, the input power return ground, and the device switch ground to reduce noise as shown in Figure 44, e.g.: C2 GND, C1 GND, and U1 GND are connected at one point in the evaluation board. The input ground and output ground traces must be thick enough for current to flow through and for reducing ground bounce.

## Power Signal Traces

Low resistance conducting paths should be used for the power carrying traces to reduce power loss so as to improve
efficiency (short and thick traces for connecting the inductor L can also reduce stray inductance), e.g.: short and thick traces listed below are used in the evaluation board:

1. Trace from TP1 to L1
2. Trace from L1 to Lx pin of U1
3. Trace from L1 to anode pin of D1
4. Trace from cathode pin of D1 to TP2

## Output Capacitor

The output capacitor should be placed close to the output terminals to obtain better smoothing effect on the output ripple.

Figure 44. NCP1400A Evaluation Board Schematic Diagram

## NCP1402

## 200 mA, PFM Step-Up Micropower Switching Regulator

The NCP1402 series are monolithic micropower step-up DC to DC converter that are specially designed for powering portable equipment from one or two cell battery packs.These devices are designed to start-up with a cell voltage of 0.8 V and operate down to less than 0.3 V . With only three external components, this series allow a simple means to implement highly efficient converters that are capable of up to 200 mA of output current at $\mathrm{V}_{\text {in }}=2.0 \mathrm{~V}, \mathrm{~V}_{\text {OUT }}=3.0 \mathrm{~V}$.

Each device consists of an on-chip PFM (Pulse Frequency Modulation) oscillator, PFM controller, PFM comparator, soft-start, voltage reference, feedback resistors, driver, and power MOSFET switch with current limit protection. Additionally, a chip enable feature is provided to power down the converter for extended battery life.

The NCP1402 device series are available in the Thin SOT-23-5 package with five standard regulated output voltages. Additional voltages that range from 1.8 V to 5.0 V in 100 mV steps can be manufactured.

## Features

- Extremely Low Start-Up Voltage of 0.8 V
- Operation Down to Less than 0.3 V
- High Efficiency $85 \%\left(\mathrm{~V}_{\text {in }}=2.0 \mathrm{~V}, \mathrm{~V}_{\text {OUT }}=3.0 \mathrm{~V}, 70 \mathrm{~mA}\right)$
- Low Operating Current of $30 \mu \mathrm{~A}\left(\mathrm{~V}_{\text {OUT }}=1.9 \mathrm{~V}\right)$
- Output Voltage Accuracy $\pm 2.5 \%$
- Low Converter Ripple with Typical 30 mV
- Only Three External Components Are Required
- Chip Enable Power Down Capability for Extended Battery Life
- Micro Miniature Thin SOT-23-5 Packages

## Typical Applications

- Cellular Telephones
- Pagers
- Personal Digital Assistants (PDA)
- Electronic Games
- Portable Audio (MP3)
- Camcorders
- Digital Cameras
- Handheld Instruments

## ORDERING INFORMATION

See detailed ordering and shipping information in the ordering information section on page 1443 of this data sheet.

Figure 1. Typical Step-Up Converter Application

Figure 2. Representative Block Diagram

## PIN FUNCTION DESCRIPTIONS

| Pin \# | Symbol |  |
| :---: | :---: | :--- |
| 1 | CE | Chip Enable pin <br> (1) The chip is enabled if a voltage which is equal to or greater than 0.9 V is applied <br> (2) The chip is disabled if a voltage which is less than 0.3 V is applied <br> (3) The chip will be enabled if it is left floating |
| 2 | OUT | Output voltage monitor pin, also the power supply pin of the device |
| 3 | NC | No internal connection to this pin |
| 4 | GND | Ground pin |
| 5 | LX | External inductor connection pin to power switch drain |

ORDERING INFORMATION

| Device | Output Voltage | Device Marking | Package | Shipping |
| :--- | :---: | :---: | :---: | :---: |
| NCP1402SN19T1 | 1.9 V | DAU |  |  |
| NCP1402SN27T1 | 2.7 V | DAE | SOT23-5 | 3000 Units Per Reel |
| NCP1402SN30T1 | 3.0 V | DAF |  |  |
| NCP1402SN33T1 | 3.3 V | DAG |  |  |
| NCP1402SN50T1 | 5.0 V | DAH |  |  |

NOTE: The ordering information lists five standard output voltage device options. Additional device with output voltage ranging from 1.8 V to 5.0 V in 100 mV increments can be manufactured. Contact your ON Semiconductor representative for availability.

## ABSOLUTE MAXIMUM RATINGS

| Rating | Symbol | Value | Unit |
| :--- | :---: | :---: | :---: |
| Power Supply Voltage (Pin 2) | $\mathrm{V}_{\text {OUT }}$ | 6.0 | V |
| Input/Output Pins <br> LX (Pin 5) <br> LX Peak Sink Current | $\mathrm{V}_{\mathrm{LX}}$ | -0.3 to 6.0 |  |
| CE (Pin 1) | $\mathrm{I}_{\mathrm{LX}}$ | 400 | V |

## NOTES:

1. This device series contains ESD protection and exceeds the following tests:

Human Body Model (HBM) $\pm 2.0$ kV per JEDEC standard: JESD22-A114.
Machine Model (MM) $\pm 200$ V per JEDEC standard: JESD22-A115.
2. The maximum package power dissipation limit must not be exceeded.

$$
P_{D}=\frac{T_{J(\max )}-T_{A}}{R_{\theta J A}}
$$

3. Latch-up Current Maximum Rating: $\pm 150 \mathrm{~mA}$ per JEDEC standard: JESD78.
4. Moisture Sensitivity Level: MSL 1 per IPC/JEDEC standard: J-STD-020A.

ELECTRICAL CHARACTERISTICS (For all values $\mathrm{T}_{\mathrm{A}}=25^{\circ} \mathrm{C}$, unless otherwise noted.)

## DETAILED OPERATING DESCRIPTION

## Operation

The NCP1402 series are monolithic power switching regulators optimized for applications where power drain must be minimized. These devices operate as variable frequency, voltage mode boost regulators and designed to operate in continuous conduction mode. Potential applications include low powered consumer products and battery powered portable products.

The NCP1402 series are low noise variable frequency voltage-mode DC-DC converters, and consist of soft-start circuit, feedback resistor, reference voltage, oscillator, PFM comparator, PFM control circuit, current limit circuit and power switch. Due to the on-chip feedback resistor network, the system designer can get the regulated output voltage from 1.8 V to 5 V with a small number of external components. The operating current is typically $30 \mu \mathrm{~A}$ $\left(\mathrm{V}_{\text {OUT }}=1.9 \mathrm{~V}\right)$, and can be further reduced to about $0.6 \mu \mathrm{~A}$ when the chip is disabled $\left(\mathrm{V}_{\mathrm{CE}}<0.3 \mathrm{~V}\right)$.

The NCP1402 operation can be best understood by examining the block diagram in Figure 2. PFM comparator monitors the output voltage via the feedback resistor. When the feedback voltage is higher than the reference voltage, the power switch is turned off. As the feedback voltage is lower than reference voltage and the power switch has been off for at least a period of minimum off-time decided by PFM oscillator, the power switch is then cycled on for a period of on-time also decided by PFM oscillator, or until current limit signal is asserted. When the power switch is on, current ramps up in the inductor, storing energy in the magnetic field. When the power switch is off, the energy in the magnetic field is transferred to output filter capacitor and the load. The output filter capacitor stores the charge while the inductor current is high, then holds up the output voltage until next switching cycle.

Figure 58. NCP1402SNXXT1 Maximum Output Current vs. Input Voltage

## Soft Start

There is a soft start circuit in NCP1402. When power is applied to the device, the soft start circuit pumps up the output voltage to approximately 1.5 V at a fixed duty cycle, the level at which the converter can operate normally. What is more, the start-up capability with heavy loads is also improved.

## Regulated Converter Voltage ( $\mathrm{V}_{\text {OUT }}$ )

The $\mathrm{V}_{\text {OUT }}$ is set by an internal feedback resistor network. This is trimmed to a selected voltage from 1.8 to 5.0 V range in 100 mV steps with an accuracy of $\pm 2.5 \%$.

## Current Limit

The NCP1402 series utilizes cycle-by-cycle current limiting as a means of protecting the output switch MOSFET from overstress and preventing the small value inductor from saturation. Current limiting is implemented by monitoring the output MOSFET current build-up during conduction, and upon sensing an overcurrent conduction immediately turning off the switch for the duration of the oscillator cycle.

The voltage across the output MOSFET is monitored and compared against a reference by the VLX limiter. When the threshold is reached, a signal is sent to the PFM controller block to terminate the power switch conduction. The current limit threshold is typically set at 350 mA .

## Enable / Disable Operation

The NCP1402 series offer IC shut-down mode by chip enable pin (CE pin) to reduce current consumption. An internal pull-up resistor tied the CE pin to OUT pin by default i.e. user can float the pin CE for permanent "On". When voltage at pin CE is equal or greater than 0.9 V , the chip will be enabled, which means the regulator is in normal operation. When voltage at pin CE is less than 0.3 V , the chip is disabled, which means IC is shutdown.

Important: DO NOT apply a voltage between 0.3 V and 0.9 V to pin CE as this is the CE pin's hyteresis voltage range. Clearly defined output states can only be obtained by applying voltage out of this range.

## APPLICATIONS CIRCUIT INFORMATION

Figure 59. Typical Application Circuit

## Step-up Converter Design Equations

NCP1402 step-up DC-DC converter designed to operate in continuous conduction mode can be defined by:

| Calculation | Equation |
| :---: | :---: |
| L | $\leq \mathrm{M}\left(\frac{\mathrm{V}_{\text {in }}{ }^{2}}{\mathrm{~V}_{\text {OUT }} \text { IOmax }}\right)$ |
| IPK | $\frac{\left(V_{\text {in }}-V_{S}\right)^{t_{0 n}}}{L}+I_{\text {min }}$ |
| 1 min | $\frac{\left(t_{\text {on }}+t_{\text {off }}\right)_{\mathrm{O}}}{t_{\text {off }}}-\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\mathrm{S}}\right) \mathrm{t}_{\mathrm{on}}}{2 \mathrm{~L}}$ |
| $\mathrm{t}_{\text {off }}$ | $\frac{\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\mathrm{S}} \text { ton }^{\left(\mathrm{V}_{\text {OUT }}+\mathrm{V}_{\mathrm{F}}-\mathrm{V}_{\text {in }}\right)}\right.}{\text { ( }}$ |
| $\Delta \mathrm{Q}$ | $\left(\mathrm{L}_{\mathrm{L}}-\mathrm{l}_{\mathrm{O}}\right) \mathrm{t}_{\text {off }}$ |
| $\mathrm{V}_{\text {ripple }}$ | $\approx \frac{\Delta \mathrm{Q}}{\mathrm{COUT}}+(\mathrm{IL}-\mathrm{IO}) \mathrm{ESR}$ |

*NOTES:
lpK - Peak inductor current
$I_{\text {min }}$ - Minimum inductor current
Io - Desired dc output current
Iomax - Desired maximum dc output current
$I_{L}$ - Average inductor current
$V_{\text {in }}$ - Nominal operating dc input voltage
$V_{\text {OUT }}$ - Desired dc output voltage
$V_{F}$ - Diode forward voltage
$V_{S}$ - Saturation voltage of the internal FET switch
$\Delta$ Q - Charge stores in the Cout during charging up
$\mathrm{V}_{\text {ripple }}$ - Output ripple voltage
ESR - Equivalent series resistance of the output capacitor
M - An empirical factor, when $\mathrm{V}_{\text {OUT }} \geq 3.0 \mathrm{~V}$,
$M=8 \times 10^{-6}$, otherwise $M=5.3 \times 10^{-6}$.

## EXTERNAL COMPONENT SELECTION

## Inductor

The NCP1402 is designed to work well with a $47 \mu \mathrm{H}$ inductor in most applications. $47 \mu \mathrm{H}$ is a sufficiently low value to allow the use of a small surface mount coil, but large
enough to maintain low ripple. Low inductance values supply higher output current, but also increase the ripple and reduce efficiency. Note that values below $27 \mu \mathrm{H}$ is not recommended due to NCP1402 switch limitations. Higher inductor values reduce ripple and improve efficiency, but also limit output current.
The inductor should have small DCR, usually less than 1 $\Omega$ to minimize loss. It is necessary to choose an inductor with saturation current greater than the peak current which the inductor will encounter in the application.

## Diode

The diode is the main source of loss in DC-DC converters. The most importance parameters which affect their efficiency are the forward voltage drop, $\mathrm{V}_{\mathrm{F}}$, and the reverse recovery time, $\mathrm{t}_{\mathrm{rr}}$. The forward voltage drop creates a loss just by having a voltage across the device while a current flowing through it. The reverse recovery time generates a loss when the diode is reverse biased, and the current appears to actually flow backwards through the diode due to the minority carriers being swept from the $\mathrm{P}-\mathrm{N}$ junction. A Schottky diode with the following characteristics is recommended:

Small forward voltage, $\mathrm{V}_{\mathrm{F}}<0.3 \mathrm{~V}$
Small reverse leakage current
Fast reverse recovery time/ switching speed
Rated current larger than peak inductor current,
$\mathrm{I}_{\text {rated }}>\mathrm{I}_{\mathrm{PK}}$
Reverse voltage larger than output voltage,
$\mathrm{V}_{\text {reverse }}>\mathrm{V}_{\text {OUT }}$

## Input Capacitor

The input capacitor can stabilize the input voltage and minimize peak current ripple from the source. The value of the capacitor depends on the impedance of the input source used. Small ESR (Equivalent Series Resistance) Tantalum or ceramic capacitor with value of $10 \mu \mathrm{~F}$ should be suitable.

## Output Capacitor

The output capacitor is used for sustaining the output voltage when the internal MOSFET is switched on and smoothing the ripple voltage. Low ESR capacitor should be used to reduce output ripple voltage. In general, a 47 uF to 68 uF low ESR ( $0.15 \Omega$ to $0.30 \Omega$ ) Tantalum capacitor should be appropriate. For applications where space is a critical factor, two parallel 22 uF low profile SMD ceramic capacitors can be used.

An evaluation board of NCP1402 has been made in the size of $23 \mathrm{~mm} \times 20 \mathrm{~mm}$ only, as shown in Figures 60 and 61. Please contact your ON Semiconductor representative for availability. The evaluation board schematic diagram, the artwork and the silkscreen of the surface-mount PCB are shown below:

## PCB Layout Hints

## Grounding

One point grounding should be used for the output power return ground, the input power return ground, and the device switch ground to reduce noise as shown in Figure 62, e.g. : C2 GND, C1 GND, and U1 GND are connected at one point in the evaluation board. The input ground and output ground traces must be thick enough for current to flow through and for reducing ground bounce.

## Power Signal Traces

Low resistance conducting paths should be used for the power carrying traces to reduce power loss so as to improve
efficiency (short and thick traces for connecting the inductor L can also reduce stray inductance), e.g. : short and thick traces listed below are used in the evaluation board:

1. Trace from TP1 to L1
2. Trace from L1 to Lx pin of U1
3. Trace from L1 to anode pin of D1
4. Trace from cathode pin of D1 to TP2

## Output Capacitor

The output capacitor should be placed close to the output terminals to obtain better smoothing effect on the output ripple.

## NCP1410

## 250 mA Sync-Rect PFM Step-Up DC-DC Converter with Low-Battery Detector

NCP1410 is a monolithic micropower high frequency Boost (step-up) voltage switching converter IC specially designed for battery operated hand-held electronic products up to 250 mA loading. It integrates Synchronous Rectifier for improving efficiency as well as eliminating the external Schottky Diode. High switching frequency (up to 600 kHz ) allows low profile inductor and output capacitor being used. Low-Battery Detector, Logic-Controlled Shutdown and Cycle-by-Cycle Current Limit provide value-added features for various battery-operated applications. With all these functions ON, the device quiescent supply current is only $9.0 \mu \mathrm{~A}$ typical. This device is available in space saving compact Micro8 package.

## Features

- High Efficiency up to $92 \%$
- Very Low Device Quiescent Supply Current of $9.0 \mu \mathrm{~A}$ Typical
- Allows use of Small Size Inductor and Capacitor
- Built-in Synchronous Rectifier (PFET) Eliminates One External Schottky Diode
- High Switching Frequency (up to 600 kHz ) Allows Use of Small Size Inductor and Capacitor
- High Accuracy Reference Output, $1.19 \mathrm{~V} \pm 0.6 \%$ @ $25^{\circ} \mathrm{C}$, can supply more than 2.5 mA when $\mathrm{V}_{\text {OUT }} \geq 3.3 \mathrm{~V}$
- 1.0 V Startup at No Load Guaranteed
- Output Voltage from 1.5 V to 5.5 V Adjustable
- Output Current up to $250 \mathrm{~mA} @ \mathrm{~V}_{\text {in }}=2.5 \mathrm{~V}, \mathrm{~V}_{\text {out }}=3.3 \mathrm{~V}$
- Logic-Controlled Shutdown
- Open Drain Low-Battery Detector Output
- 1.0 A Cycle-by-Cycle Current Limit
- Low Profile and Minimum External Parts
- Compact Micro8 Package

## Typical Applications

- Personal Digital Assistant (PDA)
- Handheld Digital Audio Product
- Camcorders and Digital Still Camera
- Hand-held Instrument
- Conversion from One or Two NiMH or NiCd, or One Li-ion Cell to 3.3 V/5.0 V

## DETAILED OPERATION DESCRIPTIONS

NCP1410 is a monolithic micropower high frequency step-up voltage switching converter IC specially designed for battery operated hand-held electronic products up to 250 mA loading. It integrates Synchronous Rectifier for improving efficiency as well as eliminating the external Schottky Diode. High switching frequency (up to 600 kHz ) allows low profile inductor and output capacitor being used. Low-Battery Detector, Logic-Controlled Shutdown and Cycle-by-Cycle Current Limit provide value-added features for various battery-operated application. With all these functions ON, the quiescent supply current is only $9.0 \mu \mathrm{~A}$ typical. This device is available in a compact Micro8 package.

## PFM Regulation Scheme

From the simplified Functional Diagram (Figure 2), the output voltage is divided down and fed back to pin 1 (FB). This voltage goes to the non-inverting input of the PFM comparator whereas the comparator's inverting input is connected to REF. A switching cycle is initiated by the falling edge of the comparator, at the moment, the main switch (M1) is turned ON. After the maximum ON-time (typical $1.4 \mu \mathrm{~S}$ ) elapses or the current limit is reached, M1 is turned OFF, and the synchronous switch (M2) is turned ON. The M1 OFF time is not less than the minimum OFF-time (typical $0.31 \mu \mathrm{~S}$ ), this is to ensure energy transfer from the inductor to the output capacitor. If the regulator is operating at continuous conduction mode (CCM), M2 is turned OFF just before M1 is supposed to be ON again. If the regulator is operating at discontinuous conduction mode (DCM), which means the coil current will decrease to zero before the next cycle, M1 is turned OFF as the coil current is almost reaching zero. The comparator (ZLC) with fixed offset is dedicated to sense the voltage drop across M2 as it is conducting, when the voltage drop is below the offset, the ZLC comparator output goes HIGH, and M2 is turned OFF. Negative feedback of closed loop operation regulates voltage at pin $1(\mathrm{FB})$ equal to the internal voltage reference (1.190 V).

## Synchronous Rectification

Synchronous Rectifier is used to replace Schottky Diode for eliminating the conduction loss contributed by forward voltage of the latter. Synchronous Rectifier is normally realized by powerFET with gate control circuitry which, however, involved relative complicated timing concerns.

As main switch M1 is being turned OFF, if the synchronous switch M2 is just turned ON with M1 not being completed turned OFF, current will be shunt from the output bulk capacitor through M2 and M1 to ground. This power loss lowers overall efficiency. So a certain amount of dead time is introduced to make sure M1 is completely OFF before M 2 is being turned ON .

When the main regulator is operating in CCM, as M2 is being turned OFF, and M1 is just turned ON with M2 not being completed OFF, the above mentioned situation will occur. So dead time is introduced to make sure M2 is completed OFF before M1 is being turned ON.
When the regulator is operating in DCM, as coil current is dropped to zero, M2 is supposed to be OFF. Fail to do so, reverse current will flow from the output bulk capacitor through M2 and then the inductor to the battery input. It causes damage to the battery. So the ZLC comparator comes with fixed offset voltage to switch M2 OFF before any reverse current builds up. However, if M2 is switch OFF too early, large residue coil current flows through the body diode of M2 and increases conduction loss. Therefore, determination on the offset voltage is essential for optimum performance.
With the implementation of synchronous rectification, efficiency can be as high as $92 \%$. For single cell input voltage, use an external Schottky diode such as MBR0520 connected from pin 7 to pin 8 to ensure start-up.

## Cycle-by-Cycle Current Limit

From Figure 2, SENSEFET is applied to sample the coil current as M1 is ON. With that sample current flowing through a sense resistor, sense-voltage is developed. Threshold detector (ILIM) detects whether the sense-voltage is higher than preset level. If it happens, detector output signifies the CONTROL LOGIC to switch OFF M1, and M1 can only be switched ON as next cycle starts after the minimum OFF-time (typical $0.31 \mu \mathrm{~S}$ ). With properly sizing of SENSEFET and sense resistor, the peak coil current limit is set at 1.0 A typically.

## Voltage Reference

The voltage at REF is set typically at +1.190 V . It can output up to 2.5 mA with load regulation $\pm 1.5 \%$, at $\mathrm{V}_{\text {OUT }}$ equal to 3.3 V . If $\mathrm{V}_{\text {OUT }}$ is increased, the REF load capability can also be increased. A bypass capacitor of $0.15 \mu \mathrm{~F}$ is required for proper operation when REF is not loaded. If REF is loaded, $1.0 \mu \mathrm{~F}$ capacitor at REF is needed.

## Shutdown

The IC is shutdown when the voltage at pin 5 ( $\overline{\mathrm{SHDN}}$ ) is pulled lower than 0.3 V . During shutdown, M1 and M2 are both switched OFF, however, the body diode of M2 allows current flow from battery to the output, the IC internal circuit will consume less than $0.05 \mu \mathrm{~A}$ current typically. If the pin 5 voltage is pull higher than 0.6 V , for example, by a resistor connected to VIN, the IC is enabled, and the internal circuit will only consume $9.0 \mu \mathrm{~A}$ current typically from the OUT pin. Refer to Figure 2, the product of $\mathrm{R}_{\text {SHDN }}$ and $\mathrm{C}_{\text {SHDN }}$ must be larger than ( $500 \mathrm{k} \cdot 56 \mathrm{nF}$, i.e. 28 msec ). This is to provide reset pulse for startup as battery is plugged in.

## Low-Battery Detection

A comparator with 30 mV hysteresis is applied to perform the low-battery detection function. When pin 2 (LBI) is at a voltage, which can be defined by a resistor divider from the battery voltage, lower than the internal reference voltage, 1.190 V , the comparator output will cause a 50 Ohm low side switch to be turned ON. It will pull down the voltage at pin 3 (LBO) which has a hundreds kilo-Ohm of pull-high resistance. If the pin 2 voltage is higher than $1.190 \mathrm{~V}+30$ mV , the comparator output will cause the 50 Ohm low side switch to be turned OFF, pin 3 will become high impedance, and its voltage will be pulled high by the external resistor.

## APPLICATIONS INFORMATION

## Output Voltage Setting

The output voltage of the converter is determined by the external feedback network comprised of $\mathrm{R}_{\mathrm{FB} 1}$ and $\mathrm{R}_{\mathrm{FB} 2}$ and the relationship is given by:

$$
\mathrm{V}_{\mathrm{OUT}}=1.190 \mathrm{~V} \times\left(1+\frac{\mathrm{R}_{\mathrm{FB} 1}}{\mathrm{R}_{\mathrm{FB} 2}}\right)
$$

where $R_{F 2}$ and $R_{F 1}$ are the upper and lower feedback resistors respectively.

## Low Battery Detect Level Setting

The Low Battery Detect Voltage of the converter is determined by the external divider network comprised of $\mathrm{R}_{\mathrm{LB} 1}$ and $\mathrm{R}_{\mathrm{LB} 2}$ and the relationship is given by:

$$
\mathrm{V}_{\mathrm{LB}}=1.190 \mathrm{~V} \times\left(1+\frac{R_{\mathrm{LB} 1}}{R_{\mathrm{LB} 2}}\right)
$$

where $\mathrm{R}_{\mathrm{LB} 1}$ and $\mathrm{R}_{\mathrm{LB} 2}$ are the upper and lower divider resistors respectively.

## Inductor Selection

The NCP1410 is tested to produce optimum performance with a $22 \mu \mathrm{H}$ inductor at $\mathrm{V}_{\text {IN }}=3 \mathrm{~V}, \mathrm{~V}_{\text {OUT }}=3.3 \mathrm{~V}$ supplying output current up to 250 mA . For other input/output requirements, inductance in the range $10 \mu \mathrm{H}$ to $47 \mu \mathrm{H}$ can be used according to end application specifications. Selecting an inductor is a compromise between output current capability and tolerable output voltage ripple. Of course, the first thing we need to obey is to keep the peak inductor current below its saturation limit at maximum current and the $\mathrm{I}_{\text {LIM }}$ of the device. In NCP1410, $\mathrm{I}_{\text {LIM }}$ is set at 1 A . As a rule of thumb, low inductance values supply higher output current, but also increase the ripple at output and reducing efficiency, on the other hand, high inductance values can improve output ripple and efficiency, however it also limit the output current capability at the same time. One other parameter of the inductor is its DC resistance, this resistance can introduce unwanted power loss and hence reduce overall efficiency, the basic rule is selecting an inductor with lowest DC resistance within the board space limitation of the end application.

## Capacitors Selection

In all switching mode boost converter applications, both the input and output terminals sees pulsating voltage/current waveforms. The currents flowing into and out of the capacitors multiplying with the Equivalent Series Resistance (ESR) of the capacitor producing ripple voltage at the terminals. During the syn-rect switch off cycle, the charges stored in the output capacitor is used to sustain the output load current. Load current at this period and the ESR combined and reflected as ripple at the output terminals. For all cases, the lower the capacitor ESR, the lower the ripple voltage at output. As a general guide line, low ESR capacitors should be used. Ceramic capacitors have the lowest ESR, but low ESR tantalum capacitors can also be used as a cost effective substitute.

## Optional Startup Schottky Diode for Low Battery Voltage

In general operation, no external Schottky diode is required, however, in case you are intended to operate the device close to 1 V level, a Schottky diode connected between the LX and OUT pins as shown in Figure 27 can help during startup of the converter. The effect of the additional Schottky was shown in Figure 8.

Figure 27. Schottky Device Between LX and OUT Pins

## PCB Layout Recommendations

Good PCB layout plays an important role in switching mode power conversion. Careful PCB layout can help to minimize ground bounce, EMI noise and unwanted feedback that can affect the performance of the converter. Hints in the following paragraphs, can be used as guidelines in most situations.

## Grounding

Star-ground connection should be used to connect the output power return ground, the input power return ground and the device power ground together at one point. All high current running paths must be thick enough for current flowing through and producing insignificant voltage drop along the path. Feedback signal path must be separated with the main current path and sensing directly at the anode of the output capacitor.

## Components Placement

Power components, i.e. input capacitor, inductor and output capacitor, must be placed as close together as possible. All connecting traces must be short, direct and thick. High current flowing and switching paths must be kept away from the feedback (FB, pin 1) terminal to avoid unwanted injection of noise into the feedback path.

## Feedback Network

Feedback of the output voltage must be a separate trace detached from the power path. External feedback network must be placed very close to the feedback (FB, pin 1) pin and sensing the output voltage directly at the anode of the output capacitor.

## TYPICAL APPLICATION CIRCUIT

Figure 28. Typical Application Schematic for 2 Alkaline Cells Supply

## GENERAL DESIGN PROCEDURES

Switching mode converter design is considered as black magic to most engineers, some complicate empirical formulae are available for reference usage. Those formulae are derived form the assumption that the key components, i.e. power inductor and capacitors are available with no tolerance. Practically, its not true, the result is not a matter of how accurate the equations you are using to calculate the component values, the outcome is still somehow away from the optimum point. In below a simple method base on the most basic first order equations to estimate the inductor and capacitor values for NCP1410 operate in Continuous Conduction Mode is introduced. The component value set can be used as a starting point to fine tune the circuit operation. By all means, detail bench testing is needed to get the best performance out of the circuit.

## Design Parameters:

$\mathrm{V}_{\mathrm{IN}}=1.8 \mathrm{~V}$ to 3.0 V , Typical 2.4 V
$\mathrm{V}_{\text {OUT }}=3.3 \mathrm{~V}$
$\mathrm{I}_{\text {OUT }}=200 \mathrm{~mA}(250 \mathrm{~mA}$ max $)$
$\mathrm{V}_{\mathrm{LB}}=2.0 \mathrm{~V}$
$\mathrm{V}_{\text {OUT-RIPPLE }}=40 \mathrm{mV}_{\text {P-P }}$ at $\mathrm{I}_{\text {OUT }}=250 \mathrm{~mA}$
Calculate the feedback network:
Select $\mathrm{R}_{\mathrm{FB} 2}=200 \mathrm{~K}$

$$
\begin{aligned}
& R_{F B 1}=\operatorname{RFB2}\left(\frac{V_{\text {OUT }}}{V_{\text {REF }}}-1\right) \\
& R_{\text {FB1 }}=200 \mathrm{~K}\left(\frac{3.3 \mathrm{~V}}{1.19 \mathrm{~V}}-1\right)=355 \mathrm{~K}
\end{aligned}
$$

Calculate the Low Battery Detect divider:
$\mathrm{V}_{\mathrm{LB}}=2.0 \mathrm{~V}$
Select $\mathrm{R}_{\mathrm{LB} 2}=330 \mathrm{~K}$

$$
\begin{aligned}
& R_{\mathrm{LB} 1}=\mathrm{R}_{\mathrm{LB} 2}\left(\frac{\mathrm{~V}_{\mathrm{LB}}}{\mathrm{~V}_{\mathrm{REF}}}-1\right) \\
& \mathrm{R}_{\mathrm{LB} 1}=330 \mathrm{~K}\left(\frac{2.0 \mathrm{~V}}{1.19 \mathrm{~V}}-1\right)=225 \mathrm{~K}
\end{aligned}
$$

Determine the Steady State Duty Ratio, D for typical $\mathrm{V}_{\mathrm{IN}}$, operation will be optimized around this point:

$$
\begin{gathered}
\frac{V_{\text {OUT }}}{V_{I N}}=\frac{1}{1-D} \\
D=1-\frac{V_{I N}}{V_{\text {OUT }}}=1-\frac{2.4 \mathrm{~V}}{3.3 \mathrm{~V}}=0.273
\end{gathered}
$$

Determine the average inductor current, $\mathrm{I}_{\mathrm{LAVG}}$ at maximum IOUT:

$$
\text { lLAVG }=\frac{\text { IOUT }}{1-D}=\frac{250 \mathrm{~mA}}{1-0.273}=344 \mathrm{~mA}
$$

Determine the peak inductor ripple current, $\mathrm{I}_{\text {RIPPLE-P }}$ and calculate the inductor value:

Assume $\mathrm{I}_{\text {RIPPLE-P }}$ is $20 \%$ of $\mathrm{I}_{\text {LAVG }}$, the inductance of the power inductor can be calculated as in below:

$$
\begin{aligned}
& \text { IRIPPLE-P }=0.20 \times 344 \mathrm{~mA}=68.8 \mathrm{~mA} \\
& \qquad L=\frac{\mathrm{VIN}_{\mathrm{IN}} \times \mathrm{tON}}{2 \mathrm{I}_{\text {RIPPLE }}-\mathrm{P}}=\frac{2.4 \mathrm{~V} \times 0.4 \mu \mathrm{~S}}{2(68.8 \mathrm{~mA})}=24.4 \mu \mathrm{H}
\end{aligned}
$$

Standard value of $22 \mu \mathrm{H}$ is selected for initial trial.
Determine the output voltage ripple, VOUT-RIPPLE and calculate the output capacitor value:
VOUT-RIPPLE $=40 \mathrm{mV}_{\text {P-P }}$ at $\mathrm{I}_{\text {OUT }}=250 \mathrm{~mA}$

$$
\text { COUT }>\frac{\text { IOUT } \times \text { tON }}{\text { VOUT-RIPPLE }- \text { IOUT } \times \text { ESRCOUT }}
$$

where $\mathrm{t}_{\mathrm{ON}}=1.4 \mu \mathrm{~S}$ and $\mathrm{ESR}_{\mathrm{COUT}}=0.1 \Omega$,

$$
\text { COUT }>\frac{250 \mathrm{~mA} \times 0.4 \mu \mathrm{~S}}{40 \mathrm{mV}-250 \mathrm{~mA} \times 0.1 \Omega}=23.33 \mu \mathrm{~F}
$$

From above calculation, you need at least $23.33 \mu \mathrm{~F}$ in order to achieve the specified ripple level at conditions stated. Practically, a one level larger capacitor will be used to accommodate factors not take into account in the calculation, therefore a capacitor value of $33 \mu \mathrm{~F}$ is selected.

## NCP1411

## Sync－Rect PFM Step－Up DC－DC Converter with Low－Battery Detector and Ring－Killer

NCP1411 is a monolithic micropower high frequency Boost （step－up）voltage switching converter IC specially designed for battery operated hand－held electronic products up to 250 mA loading． It integrates Synchronous Rectifier for improving efficiency as well as eliminating the external Schottky Diode．High switching frequency （up to 600 kHz ）allows low profile inductor and output capacitor being used．Low－Battery Detector，Logic－Controlled Shutdown and Cycle－by－Cycle Current Limit provide value－added features for various battery－operated applications．The innovative Ring－Killer circuitry guarantees quiet operation in discontinuous conduction mode．With all these functions ON，the device quiescent supply current is only $9.0 \mu \mathrm{~A}$ typical．This device is available in the space saving compact Micro8 ${ }^{\text {TM }}$ package．

## Features

－High Efficiency，up to $92 \%$
－Very Low Device Quiescent Supply Current of $9.0 \mu \mathrm{~A}$ Typical
－Built－in Synchronous Rectifier（P－FET）Eliminates One External Schottky Diode
－High Switching Frequency（up to 600 kHz ）Allows use of Small Size Inductor
－High Accuracy Reference Output， $1.19 \mathrm{~V} \pm 0.6 \%$＠ $25^{\circ} \mathrm{C}$ ，can supply more than 2.5 mA when $\mathrm{V}_{\text {OUT }} \geq 3.3 \mathrm{~V}$
－Ring－Killer for Quiet Operation in Discontinuous Conduction Mode
－ 1.0 V Startup at No Load Guaranteed
－Output Voltage from 1.5 V to 5.5 V Adjustable
－Output Current up to $250 \mathrm{~mA} @ \mathrm{~V}_{\mathrm{IN}}=2.5 \mathrm{~V}, \mathrm{~V}_{\text {OUT }}=3.3 \mathrm{~V}$
－Logic－Controlled Shutdown
－Open Drain Low－Battery Detector Output
－1．0 A Cycle by Cycle Current Limit
－Low Profile and Minimum External Parts
－Compact Micro8 Package

## Typical Applications

－Personal Digital Assistant（PDA）
－Handheld Digital Audio Product
－Camcorder and Digital Still Camera
－Handheld Instrument
－Conversion from One or Two NiMH or NiCd，or One Li－ion Cell to 3．3 V／5．0 V

## DETAILED OPERATION DESCRIPTIONS

NCP1411 is a monolithic micropower high frequency step-up voltage switching converter IC specially designed for battery operated hand-held electronic products up to 250 mA loading. It integrates Synchronous Rectifier for improving efficiency as well as eliminating the external Schottky Diode. High switching frequency (up to 600 kHz ) allows low profile inductor and output capacitor being used. Low-Battery Detector, Logic-Controlled Shutdown and Cycle-by-Cycle Current Limit provide value-added features for various battery-operated application. With all these functions ON, the quiescent supply current is only $9.0 \mu \mathrm{~A}$ typical. This device is available in a compact Micro8 package.

## PFM Regulation Scheme

From the simplified Functional Diagram (Figure 2), the output voltage is divided down and fed back to pin 1 (FB). This voltage goes to the non-inverting input of the PFM comparator whereas the comparator's inverting input is connected to REF. A switching cycle is initiated by the falling edge of the comparator, at the moment, the main switch (M1) is turned ON. After the maximum ON-time (typical $1.4 \mu \mathrm{~S}$ ) elapses or the current limit is reached, M1 is turned OFF, and the synchronous switch (M2) is turned ON. The M1 OFF time is not less than the minimum OFF-time (typical $0.31 \mu \mathrm{~S}$ ), this is to ensure energy transfer from the inductor to the output capacitor. If the regulator is operating at continuous conduction mode (CCM), M2 is turned OFF just before M1 is supposed to be ON again. If the regulator is operating at discontinuous conduction mode (DCM), which means the coil current will decrease to zero before the next cycle, M1 is turned OFF as the coil current is almost reaching zero. The comparator (ZLC) with fixed offset is dedicated to sense the voltage drop across M2 as it is conducting, when the voltage drop is below the offset, the ZLC comparator output goes HIGH, and M2 is turned OFF. Negative feedback of closed loop operation regulates voltage at pin $1(\mathrm{FB})$ equal to the internal voltage reference (1.190 V).

## Synchronous Rectification

Synchronous Rectifier is used to replace Schottky Diode for eliminating the conduction loss contributed by forward voltage of the latter. Synchronous Rectifier is normally realized by powerFET with gate control circuitry which, however, involved relative complicated timing concerns.

As main switch M1 is being turned OFF, if the synchronous switch M2 is just turned ON with M1 not being completed turned OFF, current will be shunt from the output bulk capacitor through M2 and M1 to ground. This power loss lowers overall efficiency. So a certain amount of dead time is introduced to make sure M1 is completely OFF before M 2 is being turned ON .

When the main regulator is operating in CCM, as M2 is being turned OFF, and M1 is just turned ON with M2 not being completely turned OFF, the above mentioned
situation will occur. So dead time is introduced to make sure M2 is completely turned OFF before M1 is being turned ON.

When the regulator is operating in DCM, as coil current is dropped to zero, M2 is supposed to be OFF. Fail to do so, reverse current will flow from the output bulk capacitor through M2 and then the inductor to the battery input. It causes damage to the battery. So the ZLC comparator comes with fixed offset voltage to switch M2 OFF before any reverse current builds up. However, if M2 is switch OFF too early, large residue coil current flows through the body diode of M2 and increases conduction loss. Therefore, determination on the offset voltage is essential for optimum performance.

With the implementation of synchronous rectification, efficiency can be as high as $92 \%$. For single cell input voltage, use an external schottky diode such as MBR0520 connected from pin 7 to pin 8 to ensure quick start-up.

## Ring-Killer

When the device entered Discontinuous Conduction Mode operation, a typical ringing at LX pin will start while the inductor current just ceased. This ringing is caused primarily by the capacitance and inductance at LX node and the result can produce unwanted EMI problem to the system. In order to eliminate this ringing, an internal damping switch (M3) is implemented to provide a low impedance path to dissipate the residue energy stored in the inductor once the operation entered the Discontinuous Conduction Mode. This feature can improve the EMI problem. The performance of the Ring-Killer switch is shown in Figure 22.

## Cycle-by-Cycle Current Limit

From Figure 2, SenseFET is applied to sample the coil current as M1 is ON. With that sample current flowing through a sense resistor, sense-voltage is developed. Threshold detector (ILIM) detects whether the sense-voltage is higher than preset level. If it happens, detector output signifies the CONTROL LOGIC to switch OFF M1, and M1 can only be switched ON as next cycle starts after the minimum OFF-time (typical $0.31 \mu \mathrm{~S}$ ). With properly sizing of SenseFET and sense resistor, the peak coil current limit is set at 1.0 A typically.

## Voltage Reference

The voltage at REF is set typically at +1.190 V . It can deliver up to 2.5 mA with load regulation $\pm 1.5 \%$, at $\mathrm{V}_{\text {OUT }}$ equal to 3.3 V . If $\mathrm{V}_{\text {OUT }}$ is increased, the REF load capability can also be increased. A bypass capacitor of $0.15 \mu \mathrm{~F}$ is required for proper operation when REF is not loaded. If REF is loaded, $1.0 \mu \mathrm{~F}$ capacitor at REF is needed.

## Shutdown

The IC will shutdown when the voltage at pin 2 (LBI/EN) is pulled lower than 0.3 V . During shutdown, M1 and M2 are both switched OFF, however, the body diode of M2 allows current flow from battery to the output, the IC internal circuit will consume less than $0.05 \mu \mathrm{~A}$ current typically. If the pin

1 voltage raised higher than 0.6 V , the IC will be enabled. The internal circuit will only consume $9.0 \mu \mathrm{~A}$ current typically from the OUT pin. In order to ensure proper startup, a timing capacitor $\mathrm{C}_{\mathrm{EN}}$ as shown in Figure 1 is required to provide the reset pulse during batteries are plugged in. The product of $\mathrm{R}_{\mathrm{LB} 1}$ and $\mathrm{C}_{\mathrm{EN}}$ must be larger than 28 msec .

## Low-Battery Detection

A comparator with 30 mV hysteresis is applied to perform the low-battery detection function. When pin 2 (LBI/EN) is at a voltage, which can be defined by a resistor divider from the battery voltage, lower than the internal reference voltage, 1.190 V , the comparator output will cause a 50 Ohm low side switch to be turned ON. It will pull down the voltage at pin 3 (LBO) which has a hundreds kilo-Ohm of pull-high resistance. If the pin 2 voltage is higher than $1.190 \mathrm{~V}+30 \mathrm{mV}$, the comparator output will cause the 50 Ohm low side switch to be turned OFF, pin 3 will become high impedance, and its voltage will be pulled high.

## APPLICATIONS INFORMATION

## Output Voltage Setting

The output voltage of the converter is determined by the external feedback network comprised of $\mathrm{R}_{\mathrm{FB} 1}$ and $\mathrm{R}_{\mathrm{FB} 2}$ and the relationship is given by:

$$
\mathrm{V}_{\mathrm{OUT}}=1.190 \mathrm{~V} \times\left(1+\frac{\mathrm{R}_{\mathrm{FB} 1}}{\mathrm{R}_{\mathrm{FB} 2}}\right)
$$

where $\mathrm{R}_{\mathrm{FB} 1}$ and $\mathrm{R}_{\mathrm{FB} 2}$ are the upper and lower feedback resistors respectively.

## Low Battery Detect Level Setting

The Low Battery Detect Voltage of the converter is determined by the external divider network comprised of $\mathrm{R}_{\mathrm{LB} 1}$ and $\mathrm{R}_{\mathrm{LB} 2}$ and the relationship is given by:

$$
\mathrm{V} \mathrm{LB}=1.190 \mathrm{~V} \times\left(1+\frac{\mathrm{R}_{\mathrm{LB} 1}}{\mathrm{R}_{\mathrm{LB} 2}}\right)
$$

where $\mathrm{R}_{\mathrm{LB} 1}$ and $\mathrm{R}_{\mathrm{LB} 2}$ are the upper and lower divider resistors respectively.

## Inductor Selection

The NCP1411 is tested to produce optimum performance with a $22 \mu \mathrm{H}$ inductor at $\mathrm{V}_{\mathrm{IN}}=3.0 \mathrm{~V}, \mathrm{~V}_{\text {OUT }}=3.3 \mathrm{~V}$ supplying output current up to 250 mA . For other input/output requirements, inductance in the range $10 \mu \mathrm{H}$ to $47 \mu \mathrm{H}$ can be used according to end application specifications. Selecting an inductor is a compromise between output current capability and tolerable output voltage ripple. Of course, the first thing we need to obey is to keep the peak inductor current below its saturation limit at maximum current and the $\mathrm{I}_{\mathrm{LIM}}$ of the device. In NCP1411, $\mathrm{I}_{\text {LIM }}$ is set at 1.0 A . As a rule of thumb, low inductance values supply higher output current, but also increase the ripple at output and reducing efficiency, on the other hand, high inductance values can improve output ripple and efficiency,
however it also limit the output current capability at the same time. One other parameter of the inductor is its DC resistance, this resistance can introduce unwanted power loss and hence reduce overall efficiency, the basic rule is selecting an inductor with lowest DC resistance within the board space limitation of the end application.

## Capacitors Selection

In all switching mode boost converter applications, both the input and output terminals sees impulsive voltage/current waveforms. The currents flowing into and out of the capacitors multiplying with the Equivalent Series Resistance (ESR) of the capacitor producing ripple voltage at the terminals. During the syn-rect switch off cycle, the charges stored in the output capacitor is used to sustain the output load current. Load current at this period and the ESR combined and reflected as ripple at the output terminal. For all cases, the lower the capacitor ESR, the lower the ripple voltage at output. As a general guide line, low ESR capacitors should be used. Ceramic capacitors have the lowest ESR, but low ESR tantalum capacitors can also be used as a cost effective substitute.

## Optional Startup Schottky Diode for Low Battery Voltage

In general operation, no external schottky diode is required, however, in case you are intended to operate the device close to 1.0 V level, a schottky diode connected between the LX and OUT pins as shown in Figure 27 can help during startup of the converter. The effect of the additional schottky was shown in Figure 8.

Figure 27. PCB Layout Recommendations

## PCB Layout Recommendations

Good PCB layout plays an important role in switching mode power conversion. Careful PCB layout can help to minimize ground bounce, EMI noise and unwanted feedback that can affect the performance of the converter. Hints suggested in below can be used as a guide line in most situations.

## Grounding

Star-ground connection should be used to connect the output power return ground, the input power return ground and the device power ground together at one point. All high
current running paths must be thick enough for current flowing through and producing insignificant voltage drop along the path. Feedback signal path must be separated with the main current path and sensing directly at the anode of the output capacitor.

## Components Placement

Power components, i.e. input capacitor, inductor and output capacitor, must be placed as close together as possible. All connecting traces must be short, direct and
thick. High current flowing and switching paths must be kept away from the feedback ( FB , pin 1) terminal to avoid unwanted injection of noise into the feedback path.

## Feedback Network

Feedback of the output voltage must be a separate trace detached from the power path. External feedback network must be placed very close to the feedback (FB, pin 1) pin and sensing the output voltage directly at the anode of the output capacitor.

Figure 28. Typical Application Schematic for 2 Alkaline Cells Supply

## GENERAL DESIGN PROCEDURES

Switching mode converter design is considered as black magic to most engineers, some complicate empirical formulae are available for reference usage. Those formulae are derived from the assumption that the key components, i.e. power inductor and capacitors are available with no tolerance. Practically, its not true, the result is not a matter of how accurate the equations you are using to calculate the component values, the outcome is still somehow away from the optimum point. In below a simple method base on the most basic first order equations to estimate the inductor and capacitor values for NCP1411 operate in Continuous Conduction Mode is introduced. The component value set can be used as a starting point to fine tune the circuit operation. By all means, detail bench testing is needed to get the best performance out of the circuit.

Design Parameters:

| $\mathrm{V}_{\text {IN }}$ | $=1.8 \mathrm{~V}$ to 3.0 V , Typical 2.4 V |
| :--- | :--- |
| $\mathrm{~V}_{\text {OUT }}$ | $=3.3 \mathrm{~V}$ |
| $\mathrm{I}_{\text {OUT }}$ | $=200 \mathrm{~mA}(250 \mathrm{~mA}$ max $)$ |
| $\mathrm{V}_{\text {LB }}$ | $=2.0 \mathrm{~V}$ |
| $\mathrm{~V}_{\text {OUT-RIPPLE }}$ | $=40 \mathrm{mV} \mathrm{P}_{\text {P-P }}$ at $\mathrm{I}_{\text {OUT }}=250 \mathrm{~mA}$ |

Calculate the feedback network:
Select $\mathrm{R}_{\mathrm{FB} 2}=200 \mathrm{~K}$

$$
\begin{gathered}
\mathrm{R}_{\text {FB1 }}=\mathrm{R}_{\mathrm{FB} 2}\left(\frac{\mathrm{~V}_{\mathrm{OUT}}}{\mathrm{~V}_{\text {REF }}}-1\right) \\
\mathrm{R}_{\mathrm{FB} 1}=200 \mathrm{~K}\left(\frac{3.3 \mathrm{~V}}{1.19 \mathrm{~V}}-1\right)=355 \mathrm{~K}
\end{gathered}
$$

With the feedback resistor divider, additional small capacitor, $\mathrm{C}_{\mathrm{FB} 1}$ in parallel with $\mathrm{R}_{\mathrm{FB} 1}$ is required to ensure stability. The value can be in between 68 pF to 220 pF , the rule is to select the lowest capacitance to ensure stability. Also a small capacitor, $\mathrm{C}_{\mathrm{FB} 2}$ in parallel with $\mathrm{R}_{\mathrm{FB} 2}$ may also be needed to lower the feedback ripple hence improve output regulation. The use of $\mathrm{C}_{\mathrm{FB} 2}$ is a compromise between output ripple level and regulation, so careful selection of the value according to end application requirement is needed. In this example, values for $\mathrm{C}_{\mathrm{FB} 1}$ and $\mathrm{C}_{\mathrm{FB} 2}$ are 150 pF and 220 pF respectively.

Calculate the Low Battery Detect divider:
$\mathrm{V}_{\mathrm{LB}} \quad=2.0 \mathrm{~V}$
Select $R_{\text {LB2 }}=330 \mathrm{~K}$

$$
\begin{gathered}
\mathrm{R}_{\mathrm{LB} 1}=\mathrm{R}_{\mathrm{LB} 2}\left(\frac{\mathrm{~V}_{\mathrm{LB}}}{\mathrm{~V}_{\mathrm{REF}}}-1\right) \\
\mathrm{R}_{\mathrm{LB} 1}=330 \mathrm{~K}\left(\frac{2.0 \mathrm{~V}}{1.19 \mathrm{~V}}-1\right)=225 \mathrm{~K} \\
\mathrm{C}_{\mathrm{EN}}=\frac{28 \mathrm{msec}}{225 \mathrm{~K}}=120 \mathrm{nF}
\end{gathered}
$$

Determine the Steady State Duty Ratio, D for typical $\mathrm{V}_{\text {IN }}$, operation will be optimized around this point:

$$
\begin{gathered}
\frac{\mathrm{V}_{\text {OUT }}}{\mathrm{V}_{\text {IN }}}=\frac{1}{1-\mathrm{D}} \\
\mathrm{D}=1-\frac{\mathrm{VIN}}{\mathrm{~V}_{\text {OUT }}}=1-\frac{2.4 \mathrm{~V}}{3.3 \mathrm{~V}}=0.273
\end{gathered}
$$

Determine the average inductor current, $\mathrm{I}_{\mathrm{LAVG}}$ at maximum IOUT:

$$
\text { l} \mathrm{LAVG}=\frac{\mathrm{IOUT}}{1-\mathrm{D}}=\frac{250 \mathrm{~mA}}{1-0.273}=344 \mathrm{~mA}
$$

Determine the peak inductor ripple current, $\mathrm{I}_{\text {RIPPLE-P }}$ and calculate the inductor value:

Assume $\mathrm{I}_{\text {RIPPLE-P }}$ is $20 \%$ of $\mathrm{I}_{\text {LAVG }}$, the inductance of the power inductor can be calculated as in below:
$\mathrm{I}_{\text {RIPPLE-P }}=0.20 \times 344 \mathrm{~mA}=68.8 \mathrm{~mA}$

$$
\mathrm{L}=\frac{\mathrm{V} \text { IN } \times \operatorname{tON}}{2 \mathrm{I} \mathrm{RIPPLE}-\mathrm{P}}=\frac{2.4 \mathrm{~V} \times 1.4 \mu \mathrm{~S}}{2(68.8 \mathrm{~mA})}=24.4 \mu \mathrm{H}
$$

Standard value of $22 \mu \mathrm{H}$ is selected for initial trial.
Determine the output voltage ripple, VOUT-RIPPLE and calculate the output capacitor value:
$\mathrm{V}_{\text {OUT-RIPPLE }}=40 \mathrm{mV}$ P-P at $\mathrm{I}_{\text {OUT }}=250 \mathrm{~mA}$

$$
\text { COUT } \geq \frac{\text { IOUT } \times \text { tON }}{\text { VOUT }- \text { RIPPLE }- \text { IOUT } \times \text { ESRCOUT }}
$$

where $\mathrm{t}_{\mathrm{ON}}=1.4 \mu \mathrm{~S}$ and $\mathrm{ESR}_{\text {COUT }}=0.1 \Omega$,

$$
\text { COUT } \geq \frac{250 \mathrm{~mA} \times 1.4 \mu \mathrm{~S}}{40 \mathrm{mV}-250 \mathrm{~mA} \times 0.1 \Omega}=23.33 \mu \mathrm{~F}
$$

From above calculation, we need at least $23.33 \mu \mathrm{~F}$ in order to achieve the specified ripple level at conditions stated. Practically, a one level larger capacitor will be used to accommodate factors not take into account in the calculation. So a capacitor value of $33 \mu \mathrm{~F}$ is selected.

## NCP1450A

## PWM Step-up DC-DC Controller

The NCP1450A series are PWM step-up DC-DC switching controller that are specially designed for powering portable equipment from one or two cells battery packs. The NCP1450A series have a driver pin, EXT pin, for connecting to an external transistor. Large output currents can be obtained by connecting a low ON-resistance external power transistor to the EXT pin. With only five external components, this series allows a simple means to implement highly efficient converter for large output current applications.

Each device consists of an on-chip PWM (Pulse Width Modulation) oscillator, PWM controller, phase-compensated error amplifier, soft-start, voltage reference, and driver for driving external power transistor. Additionally, a chip enable feature is provided to power down the converter for extended battery life.

The NCP1450A device series are available in the TSOP-5 package with five standard regulated output voltages. Additional voltages that range from 1.8 V to 5.0 V in 100 mV steps can be manufactured.

## Features

- High Efficiency $86 \%$ at $\mathrm{I}_{\mathrm{O}}=200 \mathrm{~mA}, \mathrm{~V}_{\mathrm{IN}}=2.0 \mathrm{~V}, \mathrm{~V}_{\text {OUT }}=3.0 \mathrm{~V}$

$$
88 \% \text { at } \mathrm{I}_{\mathrm{O}}=400 \mathrm{~mA}, \mathrm{~V}_{\mathrm{IN}}=3.0 \mathrm{~V}, \mathrm{~V}_{\mathrm{OUT}}=5.0 \mathrm{~V}
$$

- Low Start-up Voltage of 0.9 V typical at $\mathrm{I}_{\mathrm{O}}=1.0 \mathrm{~mA}$
- Operation Down to 0.6 V
- Five Standard Voltages: 1.9 V, 2.7 V, 3.0 V, 3.3 V, 5.0 V with High Accuracy $\pm 2.5 \%$
- Low Conversion Ripple
- High Output Current up to 1000 mA (3.0 V version at $\mathrm{V}_{\text {IN }}=2.0 \mathrm{~V}, \mathrm{~L}=10 \mu \mathrm{H}, \mathrm{C}_{\mathrm{OUT}}=220 \mu \mathrm{~F}$ )
- Fixed Frequency Pulse Width Modulation (PWM) at 180 kHz
- Chip Enable Pin with On-chip Pull-up Resistor
- Low Profile and Micro Miniature TSOP-5 Package

## Typical Applications

- Personal Digital Assistant (PDA)
- Electronic Games
- Portable Audio (MP3)
- Digital Still Cameras
- Handheld Instruments

## DETAILED OPERATING DESCRIPTION

## Operation

The NCP1450A series are monolithic power switching controllers optimized for battery powered portable products where large output current is required.

The NCP1450A series are low noise fixed frequency voltage-mode PWM DC-DC controllers, and consist of start-up circuit, feedback resistor divider, reference voltage, oscillator, loop compensation network, PWM control circuit, and low ON resistance driver. Due to the on-chip feedback resistor and loop compensation network, the system designer can get the regulated output voltage from 1.8 V to 5.0 V with 0.1 V stepwise with a small number of external components. The quiescent current is typically $93 \mu \mathrm{~A}\left(\mathrm{~V}_{\text {OUT }}=2.7 \mathrm{~V}, \mathrm{f}_{\text {OSC }}=180 \mathrm{kHz}\right)$, and can be further reduced to about $1.5 \mu \mathrm{~A}$ when the chip is disabled ( $\mathrm{V}_{\mathrm{CE}}<$ 0.3 V ).

The NCP1450A operation can be best understood by referring to the block diagram in Figure 2. The error amplifier monitors the output voltage via the feedback resistor divider by comparing the feedback voltage with the reference voltage. When the feedback voltage is lower than the reference voltage, the error amplifier output will decrease. The error amplifier output is then compared with the oscillator ramp voltage at the PWM controller. When the ramp voltage is higher than the error amplifier output, the high-side driver is turned on and the low-side driver is turned off which will then switch on the external transistor; and vice versa. As the error amplifier output decreases, the high-side driver turn-on time increases and duty cycle increases. When the feedback voltage is higher than the reference voltage, the error amplifier output increases and the duty cycle decreases. When the external power switch is on, the current ramps up in the inductor, storing energy in the magnetic field. When the external power switch is off, the energy stored in the magnetic field is transferred to the output filter capacitor and the load. The output filter capacitor stores the charge while the inductor current is higher than the output current, then sustains the output voltage until the next switching cycle.

As the load current is decreased, the switch transistor turns on for a shorter duty cycle. Under the light load condition, the controller will skip cycles to maintain the output voltage regulation.

## Soft Start

There is a soft start circuit in NCP1450A. When power is applied to the device, the soft start circuit pumps up the output voltage to approximately 1.5 V at a fixed duty cycle, the level at which the controller can operate normally. In addition to that, the start-up capability with heavy loads is also improved.

## Oscillator

The oscillator frequency is internally set to 180 kHz at an accuracy of $\pm 20 \%$ and with low temperature coefficient of $0.11 \% /{ }^{\circ} \mathrm{C}$.

## Regulated Converter Voltage ( $\mathrm{V}_{\text {OUT }}$ )

The $\mathrm{V}_{\text {OUT }}$ is set by an integrated feedback resistor network. This is trimmed to a selected voltage from 1.8 V to 5.0 V range in 100 mV steps with an accuracy of $\pm 2.5 \%$.

## Compensation

The device is designed to operate in continuous conduction mode. An internal compensation circuit was designed to guarantee stability over the full input/output voltage and full output load range.

## Enable/Disable Operation

The NCP1400A series offer IC shut-down mode by chip enable pin (CE pin) to reduce current consumption. An internal pull-up resistor tied the CE pin to OUT pin by default, i.e., user can float the pin CE for permanent "ON". When voltage at pin CE is equal or greater than 0.9 V , the chip will be enabled, which means the controller is in normal operation. When voltage at pin CE is less than 0.3 V , the chip is disabled, which means IC is shutdown.
Important: DO NOT apply a voltage between 0.3 V to 0.9 V to pin CE as this is the CE pin's hysteresis voltage range. Clearly defined output states can only be obtained by applying voltage out of this range.

## APPLICATION CIRCUIT INFORMATION

## Step-up Converter Design Equations

The NCP1450A PWM step-up DC-DC controller is designed to operate in continuous conduction mode and can be defined by the following equations. External components values can be calculated from these equations, however, the optimized value should obtained through experimental results.

| Calculation | Equation |
| :---: | :---: |
| D | $\leq \frac{V_{O U T}+V_{D}-V_{I N}}{V_{O U T}+V_{D}-V_{S}}$ |
| l | $\frac{\mathrm{lO}}{1-\mathrm{D}}$ |
| L | $\frac{\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{S}} \mathrm{D}_{\mathrm{in}}\right.}{2 \mathrm{f}\left(\mathrm{I} \mathrm{~L}-I_{\min }\right)}$ |
| lPK | $\mathrm{LL}+\frac{\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{S}}\right) \mathrm{D}}{2 \mathrm{Lf}}$ |
| $\Delta \mathrm{Q}$ | $\frac{(\mathrm{IL}-\mathrm{IO})(1-\mathrm{D})}{f}$ |
| $V_{\text {PP }}$ | $\approx \frac{\Delta \mathrm{Q}}{\mathrm{COUT}}+(\mathrm{IL}-\mathrm{IO}) \mathrm{ESR}$ |

## NOTES:

D - On-time duty cycle
IL - Average inductor current
IPK - Peak inductor current
$I_{\text {min }}$ - Minimum inductor current
IO - Desired dc output current
$\mathrm{V}_{\mathrm{IN}}$ - Nominal operating dc input voltage
$V_{\text {OUT }}$ - Desired dc output voltage
$V_{D}$ - Diode forward voltage
$\mathrm{V}_{\mathrm{S}}$ - Saturation voltage of the external transistor switch
$\Delta Q \quad$ - Charge stores in the Cout during charging up
ESR - Equivalent series resistance of the output capacitor

## External Component Selection

## Inductor Selection

The NCP1450A is designed to work well with a 6.8 to 12 $\mu \mathrm{H}$ inductors in most applications $10 \mu \mathrm{H}$ is a sufficiently low value to allow the use of a small surface mount coil, but large enough to maintain low ripple. Lower inductance values supply higher output current, but also increase the ripple and reduce efficiency.

Higher inductor values reduce ripple and improve efficiency, but also limit output current.
The inductor should have small DCR , usually less than $1 \Omega$, to minimize loss. It is necessary to choose an inductor with a saturation current greater than the peak current which the inductor will encounter in the application.

## Diode

The diode is the largest source of loss in DC-DC converters. The most importance parameters which affect their efficiency are the forward voltage drop, $\mathrm{V}_{\mathrm{D}}$, and the reverse recovery time, trr. The forward voltage drop creates a loss just by having a voltage across the device while a current flowing through it. The reverse recovery time generates a loss when the diode is reverse biased, and the current appears to actually flow backwards through the diode due to the minority carriers being swept from the $\mathrm{P}-\mathrm{N}$ junction. A Schottky diode with the following characteristics is recommended:

Small forward voltage, $\mathrm{V}_{\mathrm{F}}<0.3 \mathrm{~V}$
Small reverse leakage current
Fast reverse recovery time/switching speed
Rated current larger than peak inductor current,

$$
\mathrm{I}_{\text {rated }}>\mathrm{I}_{\mathrm{PK}}
$$

Reverse voltage larger than output voltage,
$\mathrm{V}_{\text {reverse }}>\mathrm{V}_{\text {OUT }}$

## Input Capacitor

The input capacitor can stabilize the input voltage and minimize peak current ripple from the source. The value of the capacitor depends on the impedance of the input source used. Small ESR (Equivalent Series Resistance) Tantalum or ceramic capacitor with a value of $10 \mu \mathrm{~F}$ should be suitable.

## Output Capacitor

The output capacitor is used for sustaining the output voltage when the external MOSFET or bipolar transistor is switched on and smoothing the ripple voltage. Low ESR capacitor should be used to reduce output ripple voltage. In general, a $100 \mu \mathrm{~F}$ to $220 \mu \mathrm{~F}$ low $\operatorname{ESR}(0.10 \Omega$ to $0.30 \Omega$ ) Tantalum capacitor should be appropriate.

## External Switch Transistor

An enhancement N -channel MOSFET or a bipolar NPN transistor can be used as the external switch transistor.

For enhancement N-channel MOSFET, since enhancement MOSFET is a voltage driven device, it is a more efficient switch than a BJT transistor. However, the MOSFET requires a higher voltage to turn on as compared with BJT transistors. An enhancement N-channel MOSFET can be selected by the following guidelines:

1. Low ON -resistance, $\mathrm{R}_{\mathrm{DS}(o n)}$, typically $<0.1 \Omega$.
2. Low gate threshold voltage, $\mathrm{V}_{\mathrm{GS}(\mathrm{th})}$, must be < $\mathrm{V}_{\text {OUT }}$, typically $<1.5 \mathrm{~V}$, it is especially important for the low $\mathrm{V}_{\text {OUT }}$ device, like $\mathrm{V}_{\text {OUT }}=1.9 \mathrm{~V}$.
3. Rated continuous drain current, $\mathrm{I}_{\mathrm{D}}$, should be larger than the peak inductor current, i.e. $\mathrm{I}_{\mathrm{D}}>\mathrm{I}_{\mathrm{PK}}$.
4. Gate capacitance should be 1200 pF or less.

For bipolar NPN transistor, medium power transistor with continuous collector current typically 1 A to 5 A and $\mathrm{V}_{\mathrm{CE} \text { (sat) }}$ $<0.2 \mathrm{~V}$ should be employed. The driving capability is determined by the DC current gain, $\mathrm{H}_{\mathrm{FE}}$, of the transistor and the base resistor, Rb ; and the controller's EXT pin must be able to supply the necessary driving current.

Rb can be calculated by the following equation:

$$
\begin{gathered}
\mathrm{Rb}=\frac{\mathrm{V}_{\mathrm{OUT}}-0.7}{\mathrm{Ib}}-\frac{0.4}{|\mathrm{IEXTH}|} \\
\mathrm{lb}=\frac{\mathrm{IPK}}{\mathrm{H}_{\mathrm{FE}}}
\end{gathered}
$$

Since the pulse current flows through the transistor, the exact Rb value should be finely tuned by the experiment. Generally, a small Rb value can increase the output current capability, but the efficiency will decrease due to more energy is used to drive the transistor.

Moreover, a speed-up capacitor, Cb , should be connected in parallel with Rb to reduce switching loss and improve efficiency. Cb can be calculated by the equation below:

$$
\mathrm{Cb} \leq \frac{1}{2 \pi \times \mathrm{Rb} \times \mathrm{fOSC} \times 0.7}
$$

It is due to the variation in the characteristics of the transistor used. The calculated value should be used as the initial test value and the optimized value should be obtained by the experiment.

## PCB Layout Hints

## Grounding

One point grounding should be used for the output power return ground, the input power return ground, and the device switch ground to reduce noise. In Figure 73, e.g.: C2 GND, C1 GND, and IC1 GND are connected at one point in the evaluation board. The input ground and output ground traces must be thick enough for current to flow through and for reducing ground bounce.

## Power Signal Traces

Low resistance conducting paths should be used for the power carrying traces to reduce power loss so as to improve
efficiency (short and thick traces for connecting the inductor L can also reduce stray inductance), e.g.: short and thick traces listed below are used in the evaluation board:

1. Trace from TP1 to L1
2. Trace from L1 to anode pin of D1
3. Trace from cathode pin of D1 to TP2

## Output Capacitor

The output capacitor should be placed close to the output terminals to obtain better smoothing effect on the output ripple.

## MINIMUM RECOMMENDED FOOTPRINT FOR SURFACE MOUNTED APPLICATIONS

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to insure proper solder connection
interface between the board and the package. With the correct pad geometry, the packages will self align when subjected to a solder reflow process.

## MC34063A, MC33063A

### 1.5 A, Step-Up/Down/ Inverting Switching Regulators

The MC34063A Series is a monolithic control circuit containing the primary functions required for DC-to-DC converters. These devices consist of an internal temperature compensated reference, comparator, controlled duty cycle oscillator with an active current limit circuit, driver and high current output switch. This series was specifically designed to be incorporated in Step-Down and Step-Up and Voltage-Inverting applications with a minimum number of external components. Refer to Application Notes AN920A/D and AN954/D for additional design information.

- Operation from 3.0 V to 40 V Input
- Low Standby Current
- Current Limiting
- Output Switch Current to 1.5 A
- Output Voltage Adjustable
- Frequency Operation to 100 kHz
- Precision $2 \%$ Reference

This device contains 51 active transistors.

3. $\mathrm{T}_{\text {low }}=0^{\circ} \mathrm{C}$ for MC34063A, $-40^{\circ} \mathrm{C}$ for MC33063A, AV $\quad \mathrm{T}_{\text {high }}=+70^{\circ} \mathrm{C}$ for MC34063A, $+85^{\circ} \mathrm{C}$ for MC33063A,$+125^{\circ} \mathrm{C}$ for MC33063AV 4. Low duty cycle pulse techniques are used during test to maintain junction temperature as close to ambient temperature as possible.
4. If the output switch is driven into hard saturation (non-Darlington configuration) at low switch currents ( $\leq 300 \mathrm{~mA}$ ) and high driver currents ( $\geq 30 \mathrm{~mA}$ ), it may take up to $2.0 \mu \mathrm{~s}$ for it to come out of saturation. This condition will shorten the off time at frequencies $\geq 30 \mathrm{kHz}$, and is magnified at high temperatures. This condition does not occur with a Darlington configuration, since the output switch cannot saturate. If a non-Darlington configuration is used, the following output drive condition is recommended:
Forced $\beta$ of output switch : $\frac{\text { IC output }}{I_{C} \text { driver }-7.0 \mathrm{~mA}^{*}} \geq 10$

* The $100 \Omega$ resistor in the emitter of the driver device requires about 7.0 mA before the output switch conducts.

$V_{\text {sat }}=$ Saturation voltage of the output switch.
$\mathrm{V}_{\mathrm{F}}=$ Forward voltage drop of the output rectifier.
The following power supply characteristics must be chosen:
$\mathrm{V}_{\text {in }}$ - Nominal input voltage.
$\mathrm{V}_{\text {out }}$ - Desired output voltage, $\left|\mathrm{V}_{\text {out }}\right|=1.25\left(1+\frac{\mathrm{R} 2}{\mathrm{R} 1}\right)$
$I_{\text {out }}$ - Desired output current.
$f_{\text {min }}$ - Minimum desired output switching frequency at the selected values of $V_{\text {in }}$ and $I_{O}$.
$\mathrm{V}_{\text {ripple(pp) }}$ - Desired peak-to-peak output ripple voltage. In practice, the calculated capacitor value will need to be increased due to its equivalent series resistance and board layout. The ripple voltage should be kept to a low value since it will directly affect the line and load regulation.
NOTE: For further information refer to Application Note AN920A/D and AN954/D.

### 3.4 A, Step-Up/Down/ Inverting Switching Regulators

The MC34163 series are monolithic power switching regulators that contain the primary functions required for dc-to-dc converters. This series is specifically designed to be incorporated in step-up, step-down, and voltage-inverting applications with a minimum number of external components.

These devices consist of two high gain voltage feedback comparators, temperature compensated reference, controlled duty cycle oscillator, driver with bootstrap capability for increased efficiency, and a high current output switch. Protective features consist of cycle-by-cycle current limiting, and internal thermal shutdown. Also included is a low voltage indicator output designed to interface with microprocessor based systems.

These devices are contained in a 16 pin dual-in-line heat tab plastic package for improved thermal conduction.

- Output Switch Current in Excess of 3.0 A
- Operation from 2.5 V to 40 V Input
- Low Standby Current
- Precision $2 \%$ Reference
- Controlled Duty Cycle Oscillator
- Driver with Bootstrap Capability for Increased Efficiency
- Cycle-by-Cycle Current Limiting
- Internal Thermal Shutdown Protection
- Low Voltage Indicator Output for Direct Microprocessor Interface
- Heat Tab Power Package
- Moisture Sensitivity Level (MSL) Equals 1

## MC34163, MC33163

Figure 19. Representative Block Diagram

Figure 20. Typical Operating Waveforms

## INTRODUCTION

The MC34163 series are monolithic power switching regulators optimized for dc-to-dc converter applications. The combination of features in this series enables the system designer to directly implement step-up, step-down, and voltage-inverting converters with a minimum number of external components. Potential applications include cost sensitive consumer products as well as equipment for the automotive, computer, and industrial markets. A Representative Block Diagram is shown in Figure 19.

## OPERATING DESCRIPTION

The MC34163 operates as a fixed on-time, variable off-time voltage mode ripple regulator. In general, this mode of operation is somewhat analogous to a capacitor charge pump and does not require dominant pole loop compensation for converter stability. The Typical Operating Waveforms are shown in Figure 20. The output voltage waveform shown is for a step-down converter with the ripple and phasing exaggerated for clarity. During initial converter startup, the feedback comparator senses that the output voltage level is below nominal. This causes the output switch to turn on and off at a frequency and duty cycle controlled by the oscillator, thus pumping up the output filter capacitor. When the output voltage level reaches nominal, the feedback comparator sets the latch, immediately terminating switch conduction. The feedback comparator will inhibit the switch until the load current causes the output voltage to fall below nominal. Under these conditions, output switch conduction can be inhibited for a partial oscillator cycle, a partial cycle plus a complete cycle, multiple cycles, or a partial cycle plus multiple cycles.

## Oscillator

The oscillator frequency and on-time of the output switch are programmed by the value selected for timing capacitor $\mathrm{C}_{\mathrm{T}}$. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged and discharged by a 9 to 1 ratio internal current source and sink, generating a negative going sawtooth waveform at Pin 6. As $\mathrm{C}_{\mathrm{T}}$ charges, an internal pulse is generated at the oscillator output. This pulse is connected to the NOR gate center input, preventing output switch conduction, and to the AND gate upper input, allowing the latch to be reset if the comparator output is low. Thus, the output switch is always disabled during ramp-up and can be enabled by the comparator output only at the start of ramp-down. The oscillator peak and valley thresholds are 1.25 V and 0.55 V , respectively, with a charge current of $225 \mu \mathrm{~A}$ and a discharge current of $25 \mu \mathrm{~A}$, yielding a maximum on-time duty cycle of $90 \%$. A reduction of the maximum duty cycle may be required for specific converter configurations. This can be accomplished with the addition
of an external deadtime resistor $\left(\mathrm{R}_{\mathrm{DT}}\right)$ placed across $\mathrm{C}_{\mathrm{T}}$. The resistor increases the discharge current which reduces the on-time of the output switch. A graph of the Output Switch On-Off Time versus Oscillator Timing Capacitance for various values of $\mathrm{R}_{\mathrm{DT}}$ is shown in Figure 2. Note that the maximum output duty cycle, $\mathrm{t}_{\mathrm{on}} / \mathrm{t}_{\text {on }}+\mathrm{t}_{\text {off }}$, remains constant for values of $\mathrm{C}_{\mathrm{T}}$ greater than 0.2 nF . The converter output can be inhibited by clamping $\mathrm{C}_{\mathrm{T}}$ to ground with an external NPN small-signal transistor.

## Feedback and Low Voltage Indicator Comparators

Output voltage control is established by the Feedback comparator. The inverting input is internally biased at 1.25 V and is not pinned out. The converter output voltage is typically divided down with two external resistors and monitored by the high impedance noninverting input at Pin 2. The maximum input bias current is $\pm 0.4 \mu \mathrm{~A}$, which can cause an output voltage error that is equal to the product of the input bias current and the upper divider resistance value. For applications that require 5.0 V , the converter output can be directly connected to the noninverting input at Pin 3. The high impedance input, Pin 2, must be grounded to prevent noise pickup. The internal resistor divider is set for a nominal voltage of 5.05 V . The additional 50 mV compensates for a $1.0 \%$ voltage drop in the cable and connector from the converter output to the load. The Feedback comparator's output state is controlled by the highest voltage applied to either of the two noninverting inputs.
The Low Voltage Indicator (LVI) comparator is designed for use as a reset controller in microprocessor-based systems. The inverting input is internally biased at 1.125 V , which sets the noninverting input thresholds to $90 \%$ of nominal. The LVI comparator has 15 mV of hysteresis to prevent erratic reset operation. The Open Collector output is capable of sinking in excess of 6.0 mA (see Figure 11). An external resistor $\left(\mathrm{R}_{\mathrm{LVI}}\right)$ and capacitor $\left(\mathrm{C}_{\mathrm{DLY}}\right)$ can be used to program a reset delay time ( $\mathrm{t}_{\mathrm{DLY}}$ ) by the formula shown below, where $\mathrm{V}_{\mathrm{th}(\mathrm{MPU})}$ is the microprocessor reset input threshold. Refer to Figure 21.

$$
t_{D L Y}=R_{L V I} C_{D L Y} \ln \left(\frac{1}{1-\frac{V_{\text {th }(M P U)}}{V_{\text {out }}}}\right)
$$

## Current Limit Comparator, Latch and Thermal Shutdown

With a voltage mode ripple converter operating under normal conditions, output switch conduction is initiated by the oscillator and terminated by the Voltage Feedback comparator. Abnormal operating conditions occur when the converter output is overloaded or when feedback voltage sensing is lost. Under these conditions, the Current Limit comparator will protect the Output Switch.

The switch current is converted to a voltage by inserting a fractional ohm resistor, $\mathrm{R}_{\mathrm{SC}}$, in series with $\mathrm{V}_{\mathrm{CC}}$ and output switch transistor $\mathrm{Q}_{2}$. The voltage drop across $\mathrm{R}_{\mathrm{SC}}$ is monitored by the Current Sense comparator. If the voltage drop exceeds 250 mV with respect to $\mathrm{V}_{\mathrm{CC}}$, the comparator will set the latch and terminate output switch conduction on a cycle-by-cycle basis. This Comparator/Latch configuration ensures that the Output Switch has only a single on-time during a given oscillator cycle. The calculation for a value of $\mathrm{R}_{\mathrm{SC}}$ is:

$$
\text { RSC }=\frac{0.25 \mathrm{~V}}{\operatorname{lpk}(\text { Switch })}
$$

Figures 12 and 13 show that the Current Sense comparator threshold is tightly controlled over temperature and has a typical input bias current of $1.0 \mu \mathrm{~A}$. The propagation delay from the comparator input to the Output Switch is typically 200 ns . The parasitic inductance associated with $\mathrm{R}_{\mathrm{SC}}$ and the circuit layout should be minimized. This will prevent unwanted voltage spikes that may falsely trip the Current Limit comparator.

Internal thermal shutdown circuitry is provided to protect the IC in the event that the maximum junction temperature is exceeded. When activated, typically at $170^{\circ} \mathrm{C}$, the Latch is forced into the "Set" state, disabling the Output Switch. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a replacement for proper heatsinking.

## Driver and Output Switch

To aid in system design flexibility and conversion efficiency, the driver current source and collector, and output switch collector and emitter are pinned out separately. This allows the designer the option of driving the output switch into saturation with a selected force gain or driving it near saturation when connected as a Darlington. The output switch has a typical current gain of 70 at 2.5 A and is designed to switch a maximum of 40 V collector to emitter, with up to 3.4 A peak collector current. The minimum value for $\mathrm{R}_{\mathrm{SC}}$ is:

$$
\operatorname{RSC}(\min )=\frac{0.25 \mathrm{~V}}{3.4 \mathrm{~A}}=0.0735 \Omega
$$

When configured for step-down or voltage-inverting applications, as in Figures 21 and 25, the inductor will forward bias the output rectifier when the switch turns off. Rectifiers with a high forward voltage drop or long turn-on delay time should not be used. If the emitter is allowed to go sufficiently negative, collector current will flow, causing
additional device heating and reduced conversion efficiency.

Figure 10 shows that by clamping the emitter to 0.5 V , the collector current will be in the range $10 \mu \mathrm{~A}$ over temperature. A 1N5822 or equivalent Schottky barrier rectifier is recommended to fulfill these requirements.
A bootstrap input is provided to reduce the output switch saturation voltage in step-down and voltage-inverting converter applications. This input is connected through a series resistor and capacitor to the switch emitter and is used to raise the internal 2.0 mA bias current source above $\mathrm{V}_{\mathrm{CC}}$. An internal zener limits the bootstrap input voltage to $\mathrm{V}_{\mathrm{CC}}$ +7.0 V. The capacitor's equivalent series resistance must limit the zener current to less than 100 mA . An additional series resistor may be required when using tantalum or other low ESR capacitors. The equation below is used to calculate a minimum value bootstrap capacitor based on a minimum zener voltage and an upper limit current source.

$$
\mathrm{C}_{\mathrm{B}(\min )}=\mathrm{I} \frac{\Delta \mathrm{t}}{\Delta \mathrm{~V}}=4.0 \mathrm{~mA} \frac{\mathrm{t}_{\mathrm{on}}}{4.0 \mathrm{~V}}=0.001 \mathrm{t} \mathrm{ton}
$$

Parametric operation of the MC34163 is guaranteed over a supply voltage range of 2.5 V to 40 V . When operating below 3.0 V , the Bootstrap Input should be connected to $\mathrm{V}_{\mathrm{CC}}$. Figure 16 shows that functional operation down to 1.7 V at room temperature is possible.

## Package

The MC34163 is contained in a heatsinkable 16-lead plastic dual-in-line package in which the die is mounted on a special heat tab copper alloy lead frame. This tab consists of the four center ground pins that are specifically designed to improve thermal conduction from the die to the circuit board. Figures 17 and 18 show a simple and effective method of utilizing the printed circuit board medium as a heat dissipater by soldering these pins to an adequate area of copper foil. This permits the use of standard layout and mounting practices while having the ability to halve the junction-to-air thermal resistance. These examples are for a symmetrical layout on a single-sided board with two ounce per square foot of copper.

## APPLICATIONS

The following converter applications show the simplicity and flexibility of this circuit architecture. Three main converter topologies are demonstrated with actual test data shown below each of the circuit diagrams.

| Test | Condition | Results |
| :--- | :--- | :--- |
| Line Regulation | $\mathrm{V}_{\text {in }}=8.0 \mathrm{~V}$ to $24 \mathrm{~V}, \mathrm{I}=3.0 \mathrm{~A}$ | $6.0 \mathrm{mV}= \pm 0.06 \%$ |
| Load Regulation | $\mathrm{V}_{\text {in }}=12 \mathrm{~V}, \mathrm{I}_{\mathrm{O}}=0.6 \mathrm{~A}$ to 3.0 A | $2.0 \mathrm{mV}= \pm 0.02 \%$ |
| Output Ripple | $\mathrm{V}_{\text {in }}=12 \mathrm{~V}, \mathrm{I}_{\mathrm{O}}=3.0 \mathrm{~A}$ | 36 mVpp |
| Short Circuit Current | $\mathrm{V}_{\text {in }}=12 \mathrm{~V}, \mathrm{R}_{\mathrm{L}}=0.1 \Omega$ | 3.3 A |
| Efficiency, Without Bootstrap | $\mathrm{V}_{\text {in }}=12 \mathrm{~V}, \mathrm{I}_{\mathrm{O}}=3.0 \mathrm{~A}$ | $76.7 \%$ |
| Efficiency, With Bootstrap | $\mathrm{V}_{\text {in }}=12 \mathrm{~V}, \mathrm{I}_{\mathrm{O}}=3.0 \mathrm{~A}$ | $81.2 \%$ |

| Ipk (Switch) | $\mathrm{L}(\mathrm{avg})+\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2}$ | $\mathrm{L}($ avg $)+\frac{\Delta l_{L}}{2}$ | $\mathrm{L}($ avg $)+\frac{\Delta I_{L}}{2}$ |
| RSC | $\frac{0.25}{\text { lpk (Switch) }}$ | $\frac{0.25}{\text { Ipk (Switch) }}$ | $\frac{0.25}{\text { Ipk (Switch) }}$ |
| L | $\left(\frac{v_{\text {in }}-v_{\text {sat }}-v_{\text {out }}}{\Delta \mathrm{I}_{\mathrm{L}}}\right) \mathrm{t}_{\text {on }}$ | $\left(\frac{v_{\text {in }}-v_{\text {sat }}}{\Delta I_{L}}\right) t_{\text {on }}$ | $\left(\frac{v_{\text {in }}-v_{\text {sat }}}{\Delta \mathrm{I}_{\mathrm{L}}}\right) \mathrm{t}_{\text {on }}$ |
| $\mathrm{V}_{\text {ripple(pp) }}$ | $\Delta \mathrm{IL} \sqrt{\left(\frac{1}{8 \mathrm{CO}_{\mathrm{O}}}\right)^{2}+(\mathrm{ESR})^{2}}$ | $\approx \frac{t_{\text {on }} I_{\text {out }}}{C_{\mathrm{O}}}$ | $\approx \frac{t_{\text {on }} I_{\text {out }}}{C_{\mathrm{O}}}$ |
| Vout | $\mathrm{V}_{\text {ref }}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)$ | $\mathrm{V}_{\text {ref }}\left(\frac{R_{2}}{R_{1}}+1\right)$ | $\mathrm{V}_{\text {ref }}\left(\frac{R_{2}}{R_{1}}+1\right)$ |

The following Converter Characteristics must be chosen:
$V_{\text {in }}$ - Nominal operating input voltage.
$V_{\text {out }}$ - Desired output voltage.
$\mathrm{I}_{\text {out }}$ - Desired output current.
$\Delta_{\mathrm{L}}$ - Desired peak-to-peak inductor ripple current. For maximum output current it is suggested that $\Delta_{\mathrm{L}}$ be chosen to be less

> threshold set by $R_{S C}$. If the design goal is to use a minimum inductance value, let $\Delta_{\mathrm{L}}=2$ ( $\mathrm{L}(\mathrm{avg})$ ). This will proportionally reduce converter output current capability.
> $f$ - Maximum output switch frequency.
> $\mathrm{V}_{\text {ripple(pp) }}$ - Desired peak-to-peak output ripple voltage. For best performance the ripple voltage should be kept to a low value since it will directly affect line and load regulation. Capacitor $\mathrm{C}_{\mathrm{O}}$ should be a low equivalent series resistance (ESR) electrolytic designed for switching regulator applications.

NOTES: 1. $\mathrm{V}_{\text {sat }}$ - Saturation voltage of the output switch, refer to Figures 8 and 9.
2. $\mathrm{V}_{F}$ - Output rectifier forward voltage drop. Typical value for 1 N 5822 Schottky barrier rectifier is 0.5 V .
3. The calculated $\mathrm{t}_{\mathrm{on}} / \mathrm{t}_{\text {off }}$ must not exceed the minimum guaranteed oscillator charge to discharge ratio of 8 , at the minimum operating input voltage.

## MC34166, MC33166

### 3.0 A, Step-Up/Down/ Inverting Switching Regulators

The MC34166, MC33166 series are high performance fixed frequency power switching regulators that contain the primary functions required for dc-to-dc converters. This series was specifically designed to be incorporated in step-down and voltage-inverting configurations with a minimum number of external components and can also be used cost effectively in step-up applications.

These devices consist of an internal temperature compensated reference, fixed frequency oscillator with on-chip timing components, latching pulse width modulator for single pulse metering, high gain error amplifier, and a high current output switch.

Protective features consist of cycle-by-cycle current limiting, undervoltage lockout, and thermal shutdown. Also included is a low power standby mode that reduces power supply current to $36 \mu \mathrm{~A}$.

- Output Switch Current in Excess of 3.0 A
- Fixed Frequency Oscillator ( 72 kHz ) with On-Chip Timing
- Provides 5.05 V Output without External Resistor Divider
- Precision $2 \%$ Reference
- 0\% to $95 \%$ Output Duty Cycle
- Cycle-by-Cycle Current Limiting
- Undervoltage Lockout with Hysteresis
- Internal Thermal Shutdown
- Operation from 7.5 V to 40 V
- Standby Mode Reduces Power Supply Current to $36 \mu \mathrm{~A}$
- Economical 5-Lead TO-220 Package with Two Optional Leadforms
- Also Available in Surface Mount D ${ }^{2}$ PAK Package
- Moisture Sensitivity Level (MSL) Equals 1

## MC34166, MC33166

## INTRODUCTION

The MC34166, MC33166 series are monolithic power switching regulators that are optimized for dc-to-dc converter applications. These devices operate as fixed frequency, voltage mode regulators containing all the active functions required to directly implement step-down and voltage-inverting converters with a minimum number of external components. They can also be used cost effectively in step-up converter applications. Potential markets include automotive, computer, industrial, and cost sensitive consumer products. A description of each section of the device is given below with the representative block diagram shown in Figure 14.

## Oscillator

The oscillator frequency is internally programmed to 72 kHz by capacitor $\mathrm{C}_{\mathrm{T}}$ and a trimmed current source. The charge to discharge ratio is controlled to yield a $95 \%$ maximum duty cycle at the Switch Output. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gate high, disabling the output switch transistor. The nominal oscillator peak and valley thresholds are 4.1 V and 2.3 V respectively.

## Pulse Width Modulator

The Pulse Width Modulator consists of a comparator with the oscillator ramp voltage applied to the noninverting input, while the error amplifier output is applied into the inverting input. Output switch conduction is initiated when $\mathrm{C}_{\mathrm{T}}$ is discharged to the oscillator valley voltage. As $\mathrm{C}_{\mathrm{T}}$ charges to a voltage that exceeds the error amplifier output, the latch resets, terminating output transistor conduction for the duration of the oscillator ramp-up period. This PWM/Latch combination prevents multiple output pulses during a given oscillator clock cycle. Figures 7 and 15 illustrate the switch output duty cycle versus the compensation voltage.

## Current Sense

The MC34166 series utilizes cycle-by-cycle current limiting as a means of protecting the output switch transistor from overstress. Each on-cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch transistor current buildup during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the oscillator ramp-up period.

The collector current is converted to a voltage by an internal trimmed resistor and compared against a reference by the Current Sense comparator. When the current limit threshold is reached, the comparator resets the PWM latch. The current limit threshold is typically set
at 4.3 A. Figure 10 illustrates switch output current limit threshold versus temperature.

## Error Amplifier and Reference

A high gain Error Amplifier is provided with access to the inverting input and output. This amplifier features a typical dc voltage gain of 80 dB , and a unity gain bandwidth of 600 kHz with 70 degrees of phase margin (Figure 4). The noninverting input is biased to the internal 5.05 V reference and is not pinned out. The reference has an accuracy of $\pm 2.0 \%$ at room temperature. To provide 5.0 V at the load, the reference is programmed 50 mV above 5.0 V to compensate for a $1.0 \%$ voltage drop in the cable and connector from the converter output. If the converter design requires an output voltage greater than 5.05 V , resistor $\mathrm{R}_{1}$ must be added to form a divider network at the feedback input as shown in Figures 14 and 19. The equation for determining the output voltage with the divider network is:

$$
\mathrm{V}_{\text {out }}=5.05\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)
$$

External loop compensation is required for converter stability. A simple low-pass filter is formed by connecting a resistor $\left(\mathrm{R}_{2}\right)$ from the regulated output to the inverting input, and a series resistor-capacitor $\left(\mathrm{R}_{\mathrm{F}}, \mathrm{C}_{\mathrm{F}}\right)$ between Pins 1 and 5. The compensation network component values shown in each of the applications circuits were selected to provide stability over the tested operating conditions. The step-down converter (Figure 19) is the easiest to compensate for stability. The step-up (Figure 21) and voltage-inverting (Figure 23) configurations operate as continuous conduction flyback converters, and are more difficult to compensate. The simplest way to optimize the compensation network is to observe the response of the output voltage to a step load change, while adjusting $R_{F}$ and $\mathrm{C}_{\mathrm{F}}$ for critical damping. The final circuit should be verified for stability under four boundary conditions. These conditions are minimum and maximum input voltages, with minimum and maximum loads.

By clamping the voltage on the error amplifier output (Pin 5) to less than 150 mV , the internal circuitry will be placed into a low power standby mode, reducing the power supply current to $36 \mu \mathrm{~A}$ with a 12 V supply voltage. Figure 11 illustrates the standby supply current versus supply voltage.

The Error Amplifier output has a $100 \mu \mathrm{~A}$ current source pull-up that can be used to implement soft-start. Figure 18 shows the current source charging capacitor $\mathrm{C}_{\text {SS }}$ through a series diode. The diode disconnects $\mathrm{C}_{\mathrm{SS}}$ from the feedback loop when the 1.0 M resistor charges it above the operating range of Pin 5.

## MC34166, MC33166

## Switch Output

The output transistor is designed to switch a maximum of 40 V , with a minimum peak collector current of 3.3 A . When configured for step-down or voltage-inverting applications, as in Figures 19 and 23, the inductor will forward bias the output rectifier when the switch turns off. Rectifiers with a high forward voltage drop or long turn-on delay time should not be used. If the emitter is allowed to go sufficiently negative, collector current will flow, causing additional device heating and reduced conversion efficiency. Figure 9 shows that by clamping the emitter to 0.5 V , the collector current will be in the range of $100 \mu \mathrm{~A}$ over temperature. A 1N5822 or equivalent Schottky barrier rectifier is recommended to fulfill these requirements.

## Undervoltage Lockout

An Undervoltage Lockout comparator has been incorporated to guarantee that the integrated circuit is fully
functional before the output stage is enabled. The internal 5.05 V reference is monitored by the comparator which enables the output stage when $\mathrm{V}_{\mathrm{CC}}$ exceeds 5.9 V . To prevent erratic output switching as the threshold is crossed, 0.9 V of hysteresis is provided.

## Thermal Protection

Internal Thermal Shutdown circuitry is provided to protect the integrated circuit in the event that the maximum junction temperature is exceeded. When activated, typically at $170^{\circ} \mathrm{C}$, the latch is forced into a 'reset' state, disabling the output switch. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a substitute for proper heatsinking. The MC34166 is contained in a 5-lead TO-220 type package. The tab of the package is common with the center pin (Pin 3) and is normally connected to ground.

## DESIGN CONSIDERATIONS

Do not attempt to construct a converter on wire-wrap or plug-in prototype boards. Special care should be taken to separate ground paths from signal currents and ground paths from load currents. All high current loops should be kept as short as possible using heavy copper runs to minimize ringing and radiated EMI. For best operation, a
tight component layout is recommended. Capacitors $\mathrm{C}_{\text {IN }}$, $\mathrm{C}_{\mathrm{O}}$, and all feedback components should be placed as close to the IC as physically possible. It is also imperative that the Schottky diode connected to the Switch Output be located as close to the IC as possible.

The Step-Down Converter application is shown in Figure 19. The output switch transistor $Q_{1}$ interrupts the input voltage, generating a squarewave at the LC o filter input. The filter averages the squarewaves, producing a dc output voltage that can be set to any level between $V_{\text {in }}$ and $V_{\text {ref }}$ by controlling the percent conduction time of $Q_{1}$ to that of the total oscillator cycle time. If the converter design requires an output voltage greater than 5.05 V , resistor $\mathrm{R}_{1}$ must be added to form a divider network at the feedback input.

Figure 19. Step-Down Converter

Figure 21 shows that the MC34166 can be configured as a step-up/down converter with the addition of an external power MOSFET. Energy is stored in the inductor during the on-time of transistors $Q_{1}$ and $Q_{2}$. During the off-time, the energy is transferred, with respect to ground, to the output filter capacitor and load. This circuit configuration has two significant advantages over the basic step-up converter circuit. The first advantage is that output short-circuit protection is provided by the MC34166, since $Q_{1}$ is directly in series with $V_{\text {in }}$ and the load. Second, the output voltage can be programmed to be less than $\mathrm{V}_{\text {in }}$. Notice that during the off-time, the inductor forward biases diodes $\mathrm{D}_{1}$ and $\mathrm{D}_{2}$, transferring its energy with respect to ground rather than with respect to $\mathrm{V}_{\text {in }}$. When operating with $\mathrm{V}_{\text {in }}$ greater than 20 V , a gate protection network is required for the MOSFET. The network consists of components $\mathrm{R}_{\mathrm{G}}, \mathrm{D}_{3}$, and $\mathrm{D}_{4}$.

Two potential problems arise when designing the standard voltage-inverting converter with the MC34166. First, the Switch Output emitter is limited to -1.5 V with respect to the ground pin and second, the Error Amplifier's noninverting input is internally committed to the reference and is not pinned out. Both of these problems are resolved by connecting the IC ground pin to the converter's negative output as shown in Figure 23. This keeps the emitter of $Q_{1}$ positive with respect to the ground pin and has the effect of reversing the Error Amplifier inputs. Note that the voltage drop across $\mathrm{R}_{1}$ is equal to 5.05 V when the output is in regulation.

$$
\mathrm{V}_{\mathrm{O} 3}-96 \text { turns of \#28 AWG }
$$

Heatsink $=$ AAVID Engineering Inc. 5903B, or 5930B.
Multiple auxiliary outputs can easily be derived by winding secondaries on the main output inductor to form a transformer. The secondaries must be connected so that the energy is delivered to the auxiliary outputs when the Switch Output turns off. During the OFF time, the voltage across the primary winding is regulated by the feedback loop, yielding a constant Volts/Turn ratio. The number of turns for any given secondary voltage can be calculated by the following equation:

$$
\# \operatorname{TURNS}_{(\mathrm{SEC})}=\frac{\mathrm{V}_{\mathrm{O}(\mathrm{SEC})}+\mathrm{V}_{\mathrm{F}(\mathrm{SEC})}}{\left(\frac{\mathrm{V}_{\mathrm{O}(\mathrm{PRI})}+\mathrm{V}_{\mathrm{F}(\mathrm{PRI})}}{\# \mathrm{TURNS}(\mathrm{PRI})}\right)}
$$

Note that the 12 V winding is stacked on top of the 5.0 V output. This reduces the number of secondary turns and improves lead regulation. For best auxiliary regulation, the auxiliary outputs should be less than $33 \%$ of the total output power.

## MC34166, MC33166

The MC34166 can be used cost effectively in off-line applications even though it is limited to a maximum input voltage of 40 V . Figure 28 shows a simple and efficient method for converting the AC line voltage down to 24 V . This preconverter has a total power rating of 125 W with a conversion efficiency of $90 \%$. Transformer $T_{1}$ provides output isolation from the AC line and isolation between each of the secondaries. The circuit self-oscillates at 50 kHz and is controlled by the saturation characteristics of $\mathrm{T}_{2}$. Multiple MC34166 post regulators can be used to provide accurate independently regulated outputs for a distributed power system.

| $V_{\text {out }}$ | $\mathrm{V}_{\text {ref }}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)$ | $\mathrm{V}_{\text {ref }}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)$ | $\mathrm{V}_{\text {ref }}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)$ |

1. $\mathrm{V}_{\text {sat }}-$ Switch Output source saturation voltage, refer to Figure 8.
2. $\mathrm{V}_{\mathrm{F}}$ - Output rectifier forward voltage drop. Typical value for 1 N5822 Schottky barrier rectifier is 0.5 V .
3. Duty cycle is calculated at the minimum operating input voltage and must not exceed the guaranteed minimum $\mathrm{DC}_{(\max )}$ specification of 0.92 .

The following converter characteristics must be chosen:
$V_{\text {out }}$ - Desired output voltage.
$I_{\text {out }}$ - Desired output current.
$\Delta L_{\mathrm{L}}$ - Desired peak-to-peak inductor ripple current. For maximum output current especially when the duty cycle is greater than 0.5 , it is suggested that $\Delta I_{\mathrm{L}}$ be chosen to be less than $10 \%$ of the average inductor current $I_{\mathrm{L}}$ avg. This will help prevent $\mathrm{I}_{\mathrm{pk}(\text { switch })}$ from reaching the guaranteed minimum current limit threshold of 3.3 A. If the design goal is to use a minimum inductance value, let $\Delta L_{\mathrm{L}}=2\left(\mathrm{I}_{\mathrm{L}}\right.$ avg $)$. This will proportionally reduce the converter's output current capability.
$\mathrm{V}_{\text {ripple }(\mathrm{pp})}$ - Desired peak-to-peak output ripple voltage. For best performance, the ripple voltage should be kept to less than $2 \%$ of $\mathrm{V}_{\text {out }}$. Capacitor $\mathrm{C}_{\mathrm{O}}$ should be a low equivalent series resistance (ESR) electrolytic designed for switching regulator applications.

## MC34167, MC33167

### 5.0 A, Step-Up/Down/ Inverting Switching Regulators

The MC34167, MC33167 series are high performance fixed frequency power switching regulators that contain the primary functions required for dc-to-dc converters. This series was specifically designed to be incorporated in step-down and voltage-inverting configurations with a minimum number of external components and can also be used cost effectively in step-up applications.

These devices consist of an internal temperature compensated reference, fixed frequency oscillator with on-chip timing components, latching pulse width modulator for single pulse metering, high gain error amplifier, and a high current output switch.

Protective features consist of cycle-by-cycle current limiting, undervoltage lockout, and thermal shutdown. Also included is a low power standby mode that reduces power supply current to $36 \mu \mathrm{~A}$.

- Output Switch Current in Excess of 5.0 A
- Fixed Frequency Oscillator ( 72 kHz ) with On-Chip Timing
- Provides 5.05 V Output without External Resistor Divider
- Precision $2 \%$ Reference
- 0\% to $95 \%$ Output Duty Cycle
- Cycle-by-Cycle Current Limiting
- Undervoltage Lockout with Hysteresis
- Internal Thermal Shutdown
- Operation from 7.5 V to 40 V
- Standby Mode Reduces Power Supply Current to $36 \mu \mathrm{~A}$
- Economical 5-Lead TO-220 Package with Two Optional Leadforms
- Also Available in Surface Mount D ${ }^{2}$ PAK Package
- Moisture Sensitivity Level (MSL) Equals 1

## INTRODUCTION

The MC34167, MC33167 series are monolithic power switching regulators that are optimized for dc-to-dc converter applications. These devices operate as fixed frequency, voltage mode regulators containing all the active functions required to directly implement step-down and voltage-inverting converters with a minimum number of external components. They can also be used cost effectively in step-up converter applications. Potential markets include automotive, computer, industrial, and cost sensitive consumer products. A description of each section of the device is given below with the representative block diagram shown in Figure 14.

## Oscillator

The oscillator frequency is internally programmed to 72 kHz by capacitor $\mathrm{C}_{\mathrm{T}}$ and a trimmed current source. The charge to discharge ratio is controlled to yield a $95 \%$ maximum duty cycle at the Switch Output. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gate high, disabling the output switch transistor. The nominal oscillator peak and valley thresholds are 4.1 V and 2.3 V respectively.

## Pulse Width Modulator

The Pulse Width Modulator consists of a comparator with the oscillator ramp voltage applied to the noninverting input, while the error amplifier output is applied into the inverting input. Output switch conduction is initiated when $\mathrm{C}_{\mathrm{T}}$ is discharged to the oscillator valley voltage. As $\mathrm{C}_{\mathrm{T}}$ charges to a voltage that exceeds the error amplifier output, the latch resets, terminating output transistor conduction for the duration of the oscillator ramp-up period. This PWM/Latch combination prevents multiple output pulses during a given oscillator clock cycle. Figures 7 and 15 illustrate the switch output duty cycle versus the compensation voltage.

## Current Sense

The MC34167 series utilizes cycle-by-cycle current limiting as a means of protecting the output switch transistor from overstress. Each on cycle is treated as a separate situation. Current limiting is implemented by monitoring the output switch transistor current buildup during conduction, and upon sensing an overcurrent condition, immediately turning off the switch for the duration of the oscillator ramp-up period.
The collector current is converted to a voltage by an internal trimmed resistor and compared against a reference by the Current Sense comparator. When the current limit threshold is reached, the comparator resets the PWM latch. The current limit threshold is typically set at 6.5 A .

Figure 10 illustrates switch output current limit threshold versus temperature.

## Error Amplifier and Reference

A high gain Error Amplifier is provided with access to the inverting input and output. This amplifier features a typical dc voltage gain of 80 dB , and a unity gain bandwidth of 600 kHz with 70 degrees of phase margin (Figure 4). The noninverting input is biased to the internal 5.05 V reference and is not pinned out. The reference has an accuracy of $\pm 2.0 \%$ at room temperature. To provide 5.0 V at the load, the reference is programmed 50 mV above 5.0 V to compensate for a $1.0 \%$ voltage drop in the cable and connector from the converter output. If the converter design requires an output voltage greater than 5.05 V , resistor $\mathrm{R}_{1}$ must be added to form a divider network at the feedback input as shown in Figures 14 and 19. The equation for determining the output voltage with the divider network is:

$$
\mathrm{V}_{\text {out }}=5.05\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)
$$

External loop compensation is required for converter stability. A simple low-pass filter is formed by connecting a resistor $\left(\mathrm{R}_{2}\right)$ from the regulated output to the inverting input, and a series resistor-capacitor $\left(\mathrm{R}_{\mathrm{F}}, \mathrm{C}_{\mathrm{F}}\right)$ between Pins 1 and 5 . The compensation network component values shown in each of the applications circuits were selected to provide stability over the tested operating conditions. The step-down converter (Figure 19) is the easiest to compensate for stability. The step-up (Figure 21) and voltage-inverting (Figure 23) configurations operate as continuous conduction flyback converters, and are more difficult to compensate. The simplest way to optimize the compensation network is to observe the response of the output voltage to a step load change, while adjusting $R_{F}$ and $\mathrm{C}_{\mathrm{F}}$ for critical damping. The final circuit should be verified for stability under four boundary conditions. These conditions are minimum and maximum input voltages, with minimum and maximum loads.

By clamping the voltage on the error amplifier output (Pin 5) to less than 150 mV , the internal circuitry will be placed into a low power standby mode, reducing the power supply current to $36 \mu \mathrm{~A}$ with a 12 V supply voltage. Figure 11 illustrates the standby supply current versus supply voltage.

The Error Amplifier output has a $100 \mu \mathrm{~A}$ current source pull-up that can be used to implement soft-start. Figure 18 shows the current source charging capacitor $\mathrm{C}_{\text {SS }}$ through a series diode. The diode disconnects $\mathrm{C}_{\mathrm{SS}}$ from the feedback loop when the 1.0 M resistor charges it above the operating range of Pin 5 .

## MC34167, MC33167

## Switch Output

The output transistor is designed to switch a maximum of 40 V , with a minimum peak collector current of 5.5 A . When configured for step-down or voltage-inverting applications, as in Figures 19 and 23, the inductor will forward bias the output rectifier when the switch turns off. Rectifiers with a high forward voltage drop or long turn on delay time should not be used. If the emitter is allowed to go sufficiently negative, collector current will flow, causing additional device heating and reduced conversion efficiency. Figure 9 shows that by clamping the emitter to 0.5 V , the collector current will be in the range of $100 \mu \mathrm{~A}$ over temperature. A 1N5825 or equivalent Schottky barrier rectifier is recommended to fulfill these requirements.

## Undervoltage Lockout

An Undervoltage Lockout comparator has been incorporated to guarantee that the integrated circuit is fully
functional before the output stage is enabled. The internal reference voltage is monitored by the comparator which enables the output stage when $\mathrm{V}_{\mathrm{CC}}$ exceeds 5.9 V . To prevent erratic output switching as the threshold is crossed, 0.9 V of hysteresis is provided.

## Thermal Protection

Internal Thermal Shutdown circuitry is provided to protect the integrated circuit in the event that the maximum junction temperature is exceeded. When activated, typically at $170^{\circ} \mathrm{C}$, the latch is forced into a 'reset' state, disabling the output switch. This feature is provided to prevent catastrophic failures from accidental device overheating. It is not intended to be used as a substitute for proper heatsinking. The MC34167 is contained in a 5-lead TO-220 type package. The tab of the package is common with the center pin ( Pin 3 ) and is normally connected to ground.

## DESIGN CONSIDERATIONS

Do not attempt to construct a converter on wire-wrap or plug-in prototype boards. Special care should be taken to separate ground paths from signal currents and ground paths from load currents. All high current loops should be kept as short as possible using heavy copper runs to minimize ringing and radiated EMI. For best operation, a
tight component layout is recommended. Capacitors $\mathrm{C}_{\mathrm{in}}$, $\mathrm{C}_{\mathrm{O}}$, and all feedback components should be placed as close to the IC as physically possible. It is also imperative that the Schottky diode connected to the Switch Output be located as close to the IC as possible.

The Step-Down Converter application is shown in Figure 19. The output switch transistor $Q_{1}$ interrupts the input voltage, generating a squarewave at the LCo filter input. The filter averages the squarewaves, producing a dc output voltage that can be set to any level between $V_{\text {in }}$ and $V_{\text {ref }}$ by controlling the percent conduction time of $Q_{1}$ to that of the total oscillator cycle time. If the converter design requires an output voltage greater than 5.05 V , resistor $\mathrm{R}_{1}$ must be added to form a divider network at the feedback input.

Figure 21 shows that the MC34167 can be configured as a step-up/down converter with the addition of an external power MOSFET. Energy is stored in the inductor during the ON time of transistors $Q_{1}$ and $Q_{2}$. During the OFF time, the energy is transferred, with respect to ground, to the output filter capacitor and load. This circuit configuration has two significant advantages over the basic step-up converter circuit. The first advantage is that output short circuit protection is provided by the MC34167, since $Q_{1}$ is directly in series with $V_{\text {in }}$ and the load. Second, the output voltage can be programmed to be less than $V_{\text {in }}$. Notice that during the OFF time, the inductor forward biases diodes $D_{1}$ and $D_{2}$, transferring its energy with respect to ground rather than with respect to $\mathrm{V}_{\text {in }}$. When operating with $\mathrm{V}_{\text {in }}$ greater than 20 V , a gate protection network is required for the MOSFET. The network consists of components $R_{G}, D_{3}$, and $D_{4}$.

Two potential problems arise when designing the standard voltage-inverting converter with the MC34167. First, the Switch Output emitter is limited to -1.5 V with respect to the ground pin and second, the Error Amplifier's noninverting input is internally committed to the reference and is not pinned out. Both of these problems are resolved by connecting the IC ground pin to the converter's negative output as shown in Figure 23. This keeps the emitter of $Q_{1}$ positive with respect to the ground pin and has the effect of reversing the Error Amplifier inputs. Note that the voltage drop across $R_{1}$ is equal to 5.05 V when the output is in regulation.

Heatsink = AAVID Engineering Inc. 5903B, or 5930B.
Multiple auxiliary outputs can easily be derived by winding secondaries on the main output inductor to form a transformer. The secondaries must be connected so that the energy is delivered to the auxiliary outputs when the Switch Output turns off. During the OFF time, the voltage across the primary winding is regulated by the feedback loop, yielding a constant Volts/Turn ratio. The number of turns for any given secondary voltage can be calculated by the following equation:

$$
\# \operatorname{TURNS}_{(\mathrm{SEC})}=\frac{\mathrm{V}_{\mathrm{O}(\mathrm{SEC})}+\mathrm{V}_{\mathrm{F}(\mathrm{SEC})}}{\left(\frac{\mathrm{V}_{\mathrm{O}(\mathrm{PRI})}+\mathrm{V}_{\mathrm{F}(\mathrm{PRI})}}{\text { \#TURNS(PRI) }}\right)}
$$

Note that the 12 V winding is stacked on top of the 5.0 V output. This reduces the number of secondary turns and improves lead regulation. For best auxiliary regulation, the auxiliary outputs should be less than $33 \%$ of the total output power.

## MC34167, MC33167

The MC34167 can be used cost effectively in off-line applications even though it is limited to a maximum input voltage of 40 V . Figure 28 shows a simple and efficient method for converting the AC line voltage down to 24 V . This preconverter has a total power rating of 125 W with a conversion efficiency of $90 \%$. Transformer $\mathrm{T}_{1}$ provides output isolation from the AC line and isolation between each of the secondaries. The circuit self-oscillates at 50 kHz and is controlled by the saturation characteristics of $\mathrm{T}_{2}$. Multiple MC34167 post regulators can be used to provide accurate independently regulated outputs for a distributed power system.

1. $\mathrm{V}_{\text {sat }}-$ Switch Output source saturation voltage, refer to Figure 8.
2. $\mathrm{V}_{\mathrm{F}}$ - Output rectifier forward voltage drop. Typical value for 1 N 5822 Schottky barrier rectifier is 0.35 V .
3. Duty cycle is calculated at the minimum operating input voltage and must not exceed the guaranteed minimum $\mathrm{DC}_{(\max )}$ specification of 0.92 .

The following converter characteristics must be chosen:
$V_{\text {out }}$ - Desired output voltage.
$\mathrm{I}_{\text {out }}$ - Desired output current.
$\Delta L_{\mathrm{L}}$ - Desired peak-to-peak inductor ripple current. For maximum output current especially when the duty cycle is greater than 0.5 , it is suggested that $\Delta L_{\mathrm{L}}$ be chosen minimum current limit threshold of 5.5 A. If the design goal is to use a minimum inductance value, let $\Delta I_{\mathrm{L}}=2\left(\mathrm{l}_{\mathrm{L}}\right.$ avg $)$. This will proportionally reduce the converter's output current capability.
$\mathrm{V}_{\text {ripple(pp) }}$ - Desired peak-to-peak output ripple voltage. For best performance, the ripple voltage should be kept to less than $2 \%$ of $\mathrm{V}_{\text {out }}$. Capacitor $\mathrm{C}_{0}$ should be a low equivalent series resistance (ESR) electrolytic designed for switching regulator applications.

## CS51031

## Fast PFET Buck Controller

The CS51031 is a switching controller for use in DC-DC converters. It can be used in the buck topology with a minimum number of external components. The CS51031 consists of a $\mathrm{V}_{\mathrm{CC}}$ monitor for controlling the state of the device, 1.0 A power driver for controlling the gate of a discrete P -channel transistor, fixed frequency oscillator, short circuit protection timer, programmable soft start, precision reference, fast output voltage monitoring comparator, and output stage driver logic with latch.

The high frequency oscillator allows the use of small inductors and output capacitors, minimizing PC board area and systems cost. The programmable soft start reduces current surges at start up. The short circuit protection timer significantly reduces the duty cycle to approximately $1 / 30$ of its cycle during short circuit conditions.

The CS51031 is available in 8 Lead SO and 8 Lead PDIP plastic packages.

## Features

- 1.0 A Totem Pole Output Driver
- High Speed Oscillator (700 kHz max)
- No Stability Compensation Required
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- $2.0 \%$ Precision Reference
- Programmable Soft Start
- Wide Ambient Temperature Range:
- Industrial Grade: $-40^{\circ} \mathrm{C}$ to $85^{\circ} \mathrm{C}$
- Commercial Grade: $0^{\circ} \mathrm{C}$ to $70^{\circ} \mathrm{C}$

| 7 | 7 | CS | Soft start and fault timing capacitor. |
| 8 | 8 | $\mathrm{V}_{\mathrm{C}}$ | Driver supply voltage. |

Figure 2. Block Diagram

## CIRCUIT DESCRIPTION

## THEORY OF OPERATION

## Control Scheme

The CS51031 monitors and the output voltage to determine when to turn on the PFET. If $\mathrm{V}_{\mathrm{FB}}$ falls below the internal reference voltage of 1.25 V during the oscillator's charge cycle, the PFET is turned on and remains on for the
duration of the charge time. The PFET gets turned off and remains off during the oscillator's discharge time with the maximum duty cycle to $80 \%$. It requires 7.0 mV typical, and 20 mV maximum ripple on the $\mathrm{V}_{\mathrm{FB}}$ pin is required to operate. This method of control does not require any loop stability compensation.

## Startup

The CS51031 has an externally programmable soft start feature that allows the output voltage to come up slowly, preventing voltage overshoot on the output.

At startup, the voltage on all pins is zero. As $\mathrm{V}_{\mathrm{CC}}$ rises, the $\mathrm{V}_{\mathrm{C}}$ voltage along with the internal resistor $\mathrm{R}_{\mathrm{G}}$ keeps the PFET off. As $\mathrm{V}_{\mathrm{CC}}$ and $\mathrm{V}_{\mathrm{C}}$ continue to rise, the oscillator capacitor (COSC ) and the Soft Start/Fault Timing capacitor (CS) charges via internal current sources. COSC gets charged by the current source IC and CS gets charged by the $\mathrm{I}_{\mathrm{T}}$ source combination described by:

$$
I_{C S}=I_{T}-\left(\frac{I T}{55}+\frac{I T}{5}\right)
$$

The internal Holdoff Comparator ensures that the external PFET is off until $\mathrm{V}_{\mathrm{CS}}>0.7 \mathrm{~V}$, preventing the GATE flip-flop (F2) from being set. This allows the oscillator to reach its operating frequency before enabling the drive output. Soft start is obtained by clamping the $\mathrm{V}_{\mathrm{FB}}$ comparator's (A6) reference input to approximately $1 / 2$ of the voltage at the CS pin during startup, permitting the control loop and the output voltage to slowly increase. Once the CS pin charges above the Holdoff Comparator trip point of 0.7 V , the low feedback to the $\mathrm{V}_{\mathrm{FB}}$ Comparator sets the GATE flip-flop during CoSC 's charge cycle. Once the GATE flip-flop is set, $\mathrm{V}_{\text {GATE }}$ goes low and turns on the PFET. When $\mathrm{V}_{\mathrm{CS}}$ exceeds 2.4 V , the CS charge sense comparator ( A 4 ) sets the $\mathrm{V}_{\mathrm{FB}}$ comparator reference to 1.25 V completing the startup cycle.

## Lossless Short Circuit Protection

The CS51031 has "lossless" short circuit protection since there is no current sense resistor required. When the voltage at the CS pin (the fault timing capacitor voltage ) reaches 2.5 V during startup, the fault timing circuitry is enabled. During normal operation the CS voltage is 2.6 V . During a short circuit or a transient condition, the output voltage moves lower and the voltage at $\mathrm{V}_{\mathrm{FB}}$ drops. If $\mathrm{V}_{\mathrm{FB}}$ drops below 1.15 V , the output of the fault comparator goes high and the CS51031 goes into a fast discharge mode. The fault timing capacitor, CS , discharges to 2.4 V . If the $\mathrm{V}_{\mathrm{FB}}$ voltage is still below 1.15 V when the CS pin reaches 2.4 V , a valid fault condition has been detected. The slow discharge comparator output goes high and enables gate G5 which sets the slow discharge flip flop. The $\mathrm{V}_{\text {GATE }}$ flip flop resets and the output switch is turned off. The fault timing capacitor is slowly discharged to 1.5 V . The CS51031 then enters a normal startup routine. If the fault is still present when the fault timing capacitor voltage reaches 2.5 V , the fast and slow discharge cycles repeat as shown in figure 3.
If the $\mathrm{V}_{\mathrm{FB}}$ voltage is above 1.15 V when CS reaches 2.4 V a fault condition is not detected, normal operation resumes and CS charges back to 2.6 V . This reduces the chance of erroneously detecting a load transient as a fault condition.

Figure 3. Voltage on Start Capacitor ( $\mathrm{V}_{\mathrm{GS}}$ ), the Gate ( $\mathrm{V}_{\mathrm{GATE}}$ ), and in the Feedback Loop ( $\mathrm{V}_{\mathrm{FB}}$ ), During Startup, Normal and Fault Conditions.

## Buck Regulator Operation

A block diagram of a typical buck regulator is shown in Figure 4. If we assume that the output transistor is initially off, and the system is in discontinuous operation, the inductor current $\mathrm{I}_{\mathrm{L}}$ is zero and the output voltage is at its nominal value. The current drawn by the load is supplied by the output capacitor $\mathrm{C}_{\mathrm{O}}$. When the voltage across $\mathrm{C}_{\mathrm{O}}$ drops below the threshold established by the feedback resistors R1
and R2 and the reference voltage $\mathrm{V}_{\text {REF }}$, the power transistor Q1 switches on and current flows through the inductor to the output. The inductor current rises at a rate determined by $\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right) / \mathrm{L}$. The duty cycle (or "on" time) for the CS51031 is limited to $80 \%$. If output voltage remains higher than nominal during the entire $\mathrm{C}_{\mathrm{OSC}}$ change time, the Q1 does not turn on, skipping the pulse.

Figure 4. Buck Regulator Block Diagram.

## APPLICATIONS INFORMATION

## CS51031 DESIGN EXAMPLE

## Specifications 12 V to 5.0 V, 3.0 A Buck Controller

- $\mathrm{V}_{\mathrm{IN}}=12 \mathrm{~V} \pm 20 \%$ (i.e. 14.4 V max., 12 V nom., 9.6 V min.)
- $\mathrm{V}_{\text {OUT }}=5.0 \mathrm{~V} \pm 2 \%$
- $\mathrm{I}_{\text {OUT }}=0.3 \mathrm{~A}$ to 3.0 A
- Output ripple voltage $<50 \mathrm{mV}$ max.
- Efficiency > 80\%
- $\mathrm{f}_{\mathrm{SW}}=200 \mathrm{kHz}$

## 1) Duty Cycle Estimates

Since the maximum duty cycle D, of the CS51031 is limited to $80 \% \mathrm{~min}$., it is necessary to estimate the duty cycle for the various input conditions over the complete operating range.

The duty cycle for a buck regulator operating in a continuous conduction mode is given by:

$$
\mathrm{D}=\frac{\mathrm{V}_{\mathrm{OUT}}+\mathrm{V}_{\mathrm{F}}}{\mathrm{~V}_{\text {IN }}-\mathrm{V}_{\mathrm{SAT}}}
$$

where:
$\mathrm{V}_{\mathrm{SAT}}=\mathrm{R}_{\mathrm{ds}(\text { on })} \times \mathrm{I}_{\text {OUT }}$ max. and $\mathrm{R}_{\mathrm{ds}(\text { on })}$ is the value at $\mathrm{T}_{\mathrm{J}}$ $100^{\circ} \mathrm{C}$.

If $\mathrm{V}_{\mathrm{F}}=0.60 \mathrm{~V}$ and $\mathrm{V}_{\mathrm{SAT}}=0.60 \mathrm{~V}$ then the above equation becomes:

$$
\begin{aligned}
& D_{M A X}=\frac{5.6}{9.0}=0.62 \\
& D_{M I N}=\frac{5.6}{13.8}=0.40
\end{aligned}
$$

## 2) Switching Frequency and On and Off Time Calculations

Given that $\mathrm{f}_{\mathrm{SW}}=200 \mathrm{kHz}$ and $\mathrm{D}_{\mathrm{MAX}}=0.80$

$$
\begin{gathered}
\mathrm{T}=\frac{1.0}{\mathrm{fSW}}=5.0 \mu \mathrm{~s} \\
\mathrm{TON}(\max )=\mathrm{T} \times \mathrm{DMAX}_{\mathrm{M}}=5.0 \mu \mathrm{~s} \times 0.62 \cong 3.0 \mu \mathrm{~s} \\
\mathrm{TON}(\min )=\mathrm{T} \times \mathrm{DMIN}=5.0 \mu \mathrm{~s} \times 0.40 \cong 2.0 \mu \mathrm{~s} \\
\mathrm{TOFF}(\max )=\mathrm{TON}(\min )=5.0 \mu \mathrm{~s}-2.0 \mu \mathrm{~s}=3.0 \mu \mathrm{~s}
\end{gathered}
$$

## 3) Oscillator Capacitor Selection

The switching frequency is set by COSC, whose value is given by:

$$
\operatorname{COSC} \text { in } \mathrm{pF}=\frac{95 \times 10-6}{\operatorname{FSW}\left(1+\frac{\mathrm{FSW}}{3 \times 10^{6}}-\left(\frac{30 \times 10^{3}}{\mathrm{FSW}}\right)^{2}\right)}
$$

## 4) Inductor Selection

The inductor value is chosen for continuous mode operation down to 0.3 Amps .

The ripple current $\Delta \mathrm{I}=2 \times \mathrm{I}_{\text {OUT }} \mathrm{min}=2 \times 0.3 \mathrm{~A}=0.6 \mathrm{~A}$.
$\mathrm{L}_{\text {min }}=\frac{\left(\mathrm{V}_{\text {OUT }}+\mathrm{V}_{\mathrm{D}}\right) \times \operatorname{TOFF}(\max )}{\Delta \mathrm{I}}=\frac{5.6 \mathrm{~V} \times 3.0 \mu \mathrm{~s}}{0.6 \mathrm{~A}}=28 \mu \mathrm{H}$
This is the minimum value of inductor to keep the ripple current < 0.6 A during normal operation.

A smaller inductor will result in larger ripple current. Ripple current at a minimum off time is

$$
\Delta \mathrm{l}=\frac{\left(\mathrm{V}_{\mathrm{OUT}}+\mathrm{V}_{\mathrm{F}}\right) \times \mathrm{TOFF}(\mathrm{~min})}{\mathrm{L}_{\mathrm{MIN}}}=\frac{5.6 \mathrm{~V} \times 2.0 \mu \mathrm{~s}}{28 \mu \mathrm{H}}=0.4 \mathrm{~A}
$$

The core must not saturate with the maximum expected current, here given by:

$$
\mathrm{ImAX}=\mathrm{IOUT}+\Delta \mathrm{I} / 2=3.0 \mathrm{~A}+0.4 \mathrm{~A} / 2=3.2 \mathrm{~A}
$$

## 5) Output Capacitor

The output capacitor and the inductor form a low pass filter. The output capacitor should have a low ESL and ESR. Low impedance aluminum electrolytic, tantalum or organic semiconductor capacitors are a good choice for an output capacitor. Low impedance aluminum are less expensive. Solid tantalum chip capacitors are available from a number of suppliers and are the best choice for surface mount applications.

The output capacitor limits the output ripple voltage. The CS51031 needs a maximum of 20 mV of output ripple for the feedback comparator to change state. If we assume that all the inductor ripple current flows through the output capacitor and that it is an ideal capacitor (i.e. zero ESR), the minimum capacitance needed to limit the output ripple to 50 mV peak to peak is given by:

$$
\mathrm{C}=\frac{\Delta \mathrm{I}}{8.0 \times \mathrm{fSW} \times \Delta \mathrm{V}}=\frac{0.6 \mathrm{~A}}{8.0 \times\left(200 \times 10^{3} \mathrm{~Hz}\right) \times\left(50 \times 10^{-3} \mathrm{~V}\right)}=7.5 \mu \mathrm{~F}
$$

The minimum ESR needed to limit the output voltage ripple to 50 mV peak to peak is:

$$
\mathrm{ESR}=\frac{\Delta \mathrm{V}}{\Delta \mathrm{l}}=\frac{50 \times 10-3}{0.6 \mathrm{~A}}=83 \mathrm{~m} \Omega
$$

The output capacitor should be chosen so that its ESR is less than $83 \mathrm{~m} \Omega$.

During the minimum off time, the ripple current is 0.4 A and the output voltage ripple will be:

$$
\Delta \mathrm{V}=\mathrm{ESR} \times \Delta \mathrm{I}=83 \mathrm{~m} \Omega \times 0.4=33 \mathrm{mV}
$$

## 6) $V_{F B}$ Divider

$$
\mathrm{V}_{\text {OUT }}=1.25 \mathrm{~V}\left(\frac{\mathrm{R} 1+\mathrm{R} 2}{\mathrm{R} 2}\right)=1.25 \mathrm{~V}\left(\frac{\mathrm{R} 1}{\mathrm{R} 2}+1.0\right)
$$

The input bias current to the comparator is $4.0 \mu \mathrm{~A}$. The resistor divider current should be considerably higher than this to ensure that there is sufficient bias current. If we choose the divider current to be at least 250 times the bias current this permits a divider current of 1 mA and simplifies the calculations.

$$
\frac{5.0 \mathrm{~V}}{1.0 \mathrm{~mA}}=\mathrm{R} 1+\mathrm{R} 2=5.0 \mathrm{~K} \Omega
$$

Let R2 $=1.0 \mathrm{~K}$
Rearranging the divider equation gives:
$R 1=\operatorname{R2}\left(\frac{\mathrm{V}_{\text {OUT }}}{1.25}-1.0\right)=1.0 \mathrm{k} \Omega\left(\frac{5.0 \mathrm{~V}}{1.25}-1.0\right)=3.0 \mathrm{k} \Omega$

## 7) Divider Bypass Capacitor $\mathrm{C}_{\mathrm{RR}}$

Since the feedback resistors divide the output voltage by a factor of 4.0 , i.e. $5.0 \mathrm{~V} / 1.25 \mathrm{~V}=4.0$, it follows that the output ripple is also divided by four. This would require that the output ripple be at least $60 \mathrm{mV}(4.0 \times 15 \mathrm{mV})$ to trip the feedback comparator. We use a capacitor $C_{R R}$ to act as an AC short.
The ripple voltage frequency is equal to the switching frequency so we choose $\mathrm{C}_{\mathrm{RR}}=1.0 \mathrm{nF}$.

## 8) Soft Start and Fault Timing Capacitor CS

CS performs several important functions. First it provides a delay time for load transients so that the IC does not enter a fault mode every time the load changes abruptly. Secondly it disables the fault circuitry during startup, it also provides soft start by clamping the reference voltage during startup, allowing it to rise slowly, and, finally it controls the hiccup short circuit protection circuitry. This reduces the duty cycle to approximately 0.035 during short circuit conditions.

An important consideration in calculating CS is that it's voltage does not reach 2.5 V (the voltage at which the fault detect circuitry is enabled) before $\mathrm{V}_{\mathrm{FB}}$ reaches 1.15 V otherwise the power supply will never start.

If the $\mathrm{V}_{\mathrm{FB}}$ pin reaches 1.15 V , the fault timing comparator will discharge CS and the supply will not start. For the $\mathrm{V}_{\mathrm{FB}}$ voltage to reach 1.15 V the output voltage must be at least $4 \times 1.15=4.6 \mathrm{~V}$.

If we choose an arbitrary startup time of $900 \mu \mathrm{~s}$, the value of CS is:

$$
\begin{gathered}
\text { tstartup }_{=\frac{\mathrm{CS} \times 2.5 \mathrm{~V}}{\text { ICharge }}}^{\mathrm{CS}_{\min }=\frac{900 \mu \mathrm{~s} \times 264 \mu \mathrm{~A}}{2.5 \mathrm{~V}}=950 \mathrm{nF} \cong 0.1 \mu \mathrm{~F}}
\end{gathered}
$$

The fault time is the sum of the slow discharge time the fast discharge time and the recharge time. It is dominated by the slow discharge time.

The first parameter is the slow discharge time, it is the time for the CS capacitor to discharge from 2.4 V to 1.5 V and is given by:

$$
\text { tSlowDischarge }(\mathrm{t})=\frac{\mathrm{CS} \times(2.4 \mathrm{~V}-1.5 \mathrm{~V})}{\text { IDischarge }}
$$

where $\mathrm{I}_{\text {Discharge }}$ is $6.0 \mu \mathrm{~A}$ typical.

$$
\text { tSlowDischarge }(\mathrm{t})=\mathrm{CS} \times 1.5 \times 10^{5}
$$

The fast discharge time occurs when a fault is first detected. The CS capacitor is discharged from 2.5 V to 2.4 V .

$$
\text { tFastDischarge }(\mathrm{t})=\frac{\mathrm{CS} \times(2.5 \mathrm{~V}-2.4 \mathrm{~V})}{\mathrm{I} \text { FastDischarge }}
$$

where $\mathrm{I}_{\text {FastDischarge }}$ is $66 \mu \mathrm{~A}$ typical.

$$
\mathrm{t} \text { FastDischarge }(\mathrm{t})=\mathrm{CS} \times 1515
$$

The recharge time is the time for CS to charge from 1.5 V to 2.5 V .

$$
\text { tCharge }(\mathrm{t})=\frac{\mathrm{CS} \times(2.5 \mathrm{~V}-1.5 \mathrm{~V})}{\mathrm{I}^{\text {Charge }}}
$$

where $I_{\text {Charge }}$ is $264 \mu \mathrm{~A}$ typical.

$$
\text { tCharge }(\mathrm{t})=\mathrm{CS} \times 3787
$$

The fault time is given by:

$$
\begin{gathered}
\text { tFault }=\mathrm{CS} \times\left(3787+1515+1.5 \times 10^{5}\right) \\
\mathrm{t} \text { Fault }=\mathrm{CS} \times\left(1.55 \times 10^{5}\right)
\end{gathered}
$$

For this circuit

$$
\text { tFault }=0.1 \times 10^{-6} \times 1.55 \times 10^{5}=15.5 \mu \mathrm{~s}
$$

A larger value of CS will increase the fault time out time but will also increase the soft start time.

## 9) Input Capacitor

The input capacitor reduces the peak currents drawn from the input supply and reduces the noise and ripple voltage on
the $V_{C C}$ and $V_{C}$ pins. This capacitor must also ensure that the $\mathrm{V}_{\mathrm{CC}}$ remains above the UVLO voltage in the event of an output short circuit. A low ESR capacitor of at least $100 \mu \mathrm{~F}$ is good. A ceramic surface mount capacitor should also be connected between $\mathrm{V}_{\mathrm{CC}}$ and ground to filter high frequency noise.

## 10) MOSFET Selection

The CS51031 drives a P-channel MOSFET. The $\mathrm{V}_{\text {GATE }}$ pin swings from GND to $\mathrm{V}_{\mathrm{C}}$. The type of PFET used depends on the operating conditions but for input voltages below 7.0 V a logic level FET should be used.

A PFET with a continuous drain current $\left(\mathrm{I}_{\mathrm{D}}\right)$ rating greater than the maximum output current is required.
The Gate-to-Source voltage $\mathrm{V}_{\mathrm{GS}}$ and the Drain-to Source Breakdown Voltage should be chosen based on the input supply voltage.

The power dissipation due to the conduction losses is given by:

$$
P_{D}=I_{O U T}{ }^{2} \times R_{D S}(O N) \times D
$$

where

$$
\operatorname{RDS}(O N) \text { is the value at } T J=100^{\circ} \mathrm{C}
$$

The power dissipation of the PFET due to the switching losses is given by:

$$
\mathrm{PD}=0.5 \times \mathrm{V}_{\mathrm{IN}} \times \mathrm{IOUT} \times\left(\mathrm{t}_{\mathrm{r}}\right) \times \mathrm{fSW}
$$

where $t_{r}=$ Rise Time.

## 11) Diode Selection

The flyback or catch diode should be a Schottky diode because of it's fast switching ability and low forward voltage drop. The current rating must be at least equal to the maximum output current. The breakdown voltage should be at least 20 V for this 12 V application.

The diode power dissipation is given by:

$$
P_{D}=I_{O U T} \times V_{D} \times\left(1.0-D_{\text {min }}\right)
$$

## CS51033

## Fast PFET Buck Controller

The CS51033 is a switching controller for use in DC-DC converters. It can be used in the buck topology with a minimum number of external components. The CS51033 consists of a 1.0 A power driver for controlling the gate of a discrete P -channel transistor, fixed frequency oscillator, short circuit protection timer, programmable Soft Start, precision reference, fast output voltage monitoring comparator, and output stage driver logic with latch.

The high frequency oscillator allows the use of small inductors and output capacitors, minimizing PC board area and systems cost. The programmable Soft Start reduces current surges at start up. The short circuit protection timer significantly reduces the PFET duty cycle to approximately $1 / 30$ of its normal cycle during short circuit conditions.

The CS51033 is available in 8 Lead SO and 8 Lead PDIP plastic packages.

## Features

- 1.0 A Totem Pole Output Driver
- High Speed Oscillator (700 kHz max)
- No Stability Compensation Required
- Lossless Short Circuit Protection
- $2.0 \%$ Precision Reference
- Programmable Soft Start
- Wide Ambient Temperature Range:
- Industrial Grade: $-40^{\circ} \mathrm{C}$ to $85^{\circ} \mathrm{C}$
- Commercial Grade: $0^{\circ} \mathrm{C}$ to $70^{\circ} \mathrm{C}$

## THEORY OF OPERATION

## Control Scheme

The CS51033 monitors the output voltage to determine when to turn on the PFET. If $\mathrm{V}_{\mathrm{FB}}$ falls below the internal reference voltage of 1.25 V during the oscillator's charge cycle, the PFET is turned on and remains on for the duration of the charge time. The PFET gets turned off and remains off during the oscillator's discharge cycle time with the maximum duty cycle to $80 \%$. It requires 7.0 mV typical, and 20 mV maximum ripple on the $\mathrm{V}_{\mathrm{FB}}$ pin to operate. This method of control does not require any loop stability compensation.

## Startup

The CS51033 has an externally programmable Soft Start feature that allows the output voltage to come up slowly, preventing voltage overshoot on the output.

At startup, the voltage on all pins is zero. As $\mathrm{V}_{\mathrm{CC}}$ rises, the $\mathrm{V}_{\mathrm{C}}$ voltage along with the internal resistor $\mathrm{R}_{\mathrm{G}}$ keeps the PFET off. As $\mathrm{V}_{\mathrm{CC}}$ and $\mathrm{V}_{\mathrm{C}}$ continue to rise, the oscillator capacitor (COSC) and the Soft Start/Fault Timing capacitor (CS) charges via internal current sources. COSC gets charged by the current source $I_{C}$ and $C S$ gets charged by the $I_{T}$ source combination described by:

$$
I_{C S}=I_{T}-\left(\frac{I T}{55}+\frac{I T}{5}\right)
$$

The internal Holdoff Comparator ensures that the external PFET is off until $\mathrm{V}_{\mathrm{CS}}>0.7 \mathrm{~V}$, preventing the GATE flip-flop (F2) from being set. This allows the oscillator to reach its operating frequency before enabling the drive output. Soft Start is obtained by clamping the $\mathrm{V}_{\mathrm{FB}}$ comparator's (A6) reference input to approximately $1 / 2$ of the voltage at the CS
pin during startup, permitting the control loop and the output voltage to slowly increase. Once the CS pin charges above the Holdoff Comparator trip point of 0.7 V , the low feedback to the $\mathrm{V}_{\mathrm{FB}}$ Comparator sets the GATE flip-flop during CosC's charge cycle. Once the GATE flip-flop is set, $\mathrm{V}_{\text {GATE }}$ goes low and turns on the PFET. When $\mathrm{V}_{\mathrm{CS}}$ exceeds 2.4 V , the CS charge sense comparator ( A 4 ) sets the $\mathrm{V}_{\mathrm{FB}}$ comparator reference to 1.25 V completing the startup cycle.

## Lossless Short Circuit Protection

The CS51033 has "lossless" short circuit protection since there is no current sense resistor required. When the voltage at the CS pin (the fault timing capacitor voltage ) reaches 2.5 V , the fault timing circuitry is enabled. During normal operation the CS voltage is 2.6 V . During a short circuit or a transient condition, the output voltage moves lower and the voltage at $\mathrm{V}_{\mathrm{FB}}$ drops. If $\mathrm{V}_{\mathrm{FB}}$ drops below 1.15 V , the output of the fault comparator goes high and the CS51033 goes into a fast discharge mode. The fault timing capacitor, CS, discharges to 2.4 V . If the $\mathrm{V}_{\mathrm{FB}}$ voltage is still below 1.15 V when the CS pin reaches 2.4 V , a valid fault condition has been detected. The slow discharge comparator output goes high and enables gate G5 which sets the slow discharge flip flop. The $\mathrm{V}_{\text {GATE }}$ flip flop resets and the output switch is turned off. The fault timing capacitor is slowly discharged to 1.5 V . The CS51033 then enters a normal startup routine. If the fault is still present when the fault timing capacitor voltage reaches 2.5 V , the fast and slow discharge cycles repeat as shown in Figure 3.

If the $\mathrm{V}_{\mathrm{FB}}$ voltage is above 1.15 V when CS reaches 2.4 V a fault condition is not detected, normal operation resumes and CS charges back to 2.6 V . This reduces the chance of erroneously detecting a load transient as a fault condition.

Figure 3. Voltage on Start Capacitor ( $\mathrm{V}_{\mathrm{GS}}$ ), the Gate ( $\mathrm{V}_{\mathrm{GATE}}$ ), and in the Feedback Loop ( $\mathrm{V}_{\mathrm{FB}}$ ), During Startup, Normal and Fault Conditions.

## Buck Regulator Operation

A block diagram of a typical buck regulator is shown in Figure 4. If we assume that the output transistor is initially off, and the system is in discontinuous operation, the inductor current $\mathrm{I}_{\mathrm{L}}$ is zero and the output voltage is at its nominal value. The current drawn by the load is supplied by the output capacitor $\mathrm{C}_{\mathrm{O}}$. When the voltage across $\mathrm{C}_{\mathrm{O}}$ drops below the threshold established by the feedback resistors R1
and R2 and the reference voltage $\mathrm{V}_{\text {REF }}$, the power transistor Q1 switches on and current flows through the inductor to the output. The inductor current rises at a rate determined by ( $\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}$ )/Load. The duty cycle (or "on" time) for the CS51033 is limited to $80 \%$. If output voltage remains higher than nominal during the entire CosC change time, the Q1 does not turn on, skipping the pulse.

Figure 4. Buck Regulator Block Diagram.

## Charge Pump Circuit

(Refer to the CS51033 Application Diagram on page 1573).

An external charge pump circuit is necessary when the $V_{C}$ input voltage is below 5.0 V to ensure that there is suffifient gate drive voltage for the external FET. When $\mathrm{V}_{\text {IN }}$ is applied, capacitors C 1 and C 2 will be charged to a diodes drop below $\mathrm{V}_{\text {IN }}$ via diodes D2 and D4, respectively. When the PFET
turns on, it's drain voltage will be approximately equal to $\mathrm{V}_{\mathrm{IN}}$. Since the voltage across C 1 can not change instantaneously, D2 is reverse biased and the anode voltage rises to approximately $2.0 \times 3.3 \mathrm{~V}-\mathrm{VD} 2$. C 1 transfers some of its stored charge C2 via D3. After several cycles there is sufficient gate drive voltage.

## APPLICATIONS INFORMATION

## DESIGNING A POWER SUPPLY WITH THE CS51033

## Specifications

- $\mathrm{V}_{\mathrm{IN}}=3.3 \mathrm{~V} \pm 10 \%$ (i.e. 3.63 V max., 2.97 V min.)
- $\mathrm{V}_{\text {OUT }}=1.5 \mathrm{~V} \pm 2.0 \%$
- $\mathrm{I}_{\text {OUT }}=0.3 \mathrm{~A}$ to 3.0 A
- Output ripple voltage $<33 \mathrm{mV}$.
- $\mathrm{F}_{\mathrm{SW}}=200 \mathrm{kHz}$

## 1) Duty Cycle Estimates

Since the maximum duty cycle D, of the CS51033 is limited to $80 \% \mathrm{~min}$., it is best to estimate the duty cycle for the various input conditions to see that the design will work over the complete operating range.

The duty cycle for a buck regulator operating in a continuous conduction mode is given by:

$$
\mathrm{D}=\frac{\mathrm{V}_{\mathrm{OUT}}+\mathrm{V}_{\mathrm{D}}}{\mathrm{~V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{SAT}}}
$$

where:
$\mathrm{V}_{\mathrm{SAT}}=\mathrm{R}_{\mathrm{DS}(\mathrm{ON})} \times \mathrm{I}_{\mathrm{OUT}}$ Max.

In this case we can assume that $\mathrm{V}_{\mathrm{D}}=0.6 \mathrm{~V}$ and $\mathrm{V}_{\mathrm{SAT}}=$ 0.6 V so the equation reduces to:

$$
\mathrm{D}=\frac{\mathrm{V}_{\mathrm{OUT}}}{\mathrm{~V}_{\mathrm{IN}}}
$$

From this, the maximum duty cycle $\mathrm{D}_{\mathrm{MAX}}$ is $53 \%$, this occurs when $\mathrm{V}_{\mathrm{IN}}$ is at it's minimum while the minimum duty cycle $\mathrm{D}_{\mathrm{MIN}}$ is $0.35 \%$.

## 2) Switching Frequency and On and Off Time Calculations

$\mathrm{F}_{\mathrm{SW}}=200 \mathrm{kHz}$. The switching frequency is determined by CosC, whose value is determined by:

$$
\begin{gathered}
\operatorname{COSC}=\frac{95}{\mathrm{FSW}^{2} \times\left(1-\left(\frac{\mathrm{FSW}}{3 \times 10^{6}}\right)-\left(\frac{30 \times 10^{3}}{\mathrm{FSW}}\right)^{2}\right)} \cong 470 \mathrm{pF} \\
\mathrm{~T}=\frac{1.0}{\mathrm{FSW}}=5.0 \mu \mathrm{~s} \\
\operatorname{TON}(\mathrm{MAX})=5.0 \mu \mathrm{~s} \times 0.53=2.65 \mu \mathrm{~s}
\end{gathered}
$$

$$
\begin{gathered}
\mathrm{TON}(\mathrm{MIN})=5.0 \mu \mathrm{~s} \times 0.35=1.75 \mu \mathrm{~s} \\
\mathrm{TOFF}(\mathrm{MAX})=5.0 \mu \mathrm{~s}-0.7 \mu \mathrm{~s}=4.3 \mu \mathrm{~s}
\end{gathered}
$$

## 3) Inductor Selection

Pick the inductor value to maintain continuous mode operation down to 0.3 Amps.

The ripple current $\Delta \mathrm{I}=2 \times \mathrm{I}$ OUT $(\mathrm{MIN})=2 \times 0.3 \mathrm{~A}=0.6 \mathrm{~A}$.
$\mathrm{L}_{\mathrm{MIN}}=\frac{\mathrm{V}_{\text {OUT }}+\mathrm{V}_{\mathrm{D}} \times \operatorname{TOFF}(\mathrm{MAX})}{\Delta \mathrm{l}}=\frac{2.1 \mathrm{~V} \times 4.3 \mu \mathrm{~s}}{0.6 \mathrm{~A}} \cong 15 \mu \mathrm{H}$
The CS51033 will operate with almost any value of inductor. With larger inductors the ripple current is reduced and the regulator will remain in a continuous conduction mode for lower values of load current. A smaller inductor will result in larger ripple current. The core must not saturate with the maximum expected current, here given by:

$$
\mathrm{I} \mathrm{MAX}=\frac{\mathrm{IOUT}+\Delta \mathrm{I}}{2.0}=3.0 \mathrm{~A}+0.6 \mathrm{~A} / 2.0=3.3 \mathrm{~A}
$$

## 4) Output Capacitor

The output capacitor limits the output ripple voltage. The CS51033 needs a maximum of 15 mV of output ripple for the feedback comparator to change state. If we assume that all the inductor ripple current flows through the output capacitor and that it is an ideal capacitor (i.e. zero ESR), the minimum capacitance needed to limit the output ripple to 50 mV peak to peak is given by:

$$
\begin{aligned}
\mathrm{CO} & =\frac{\Delta \mathrm{l}}{8.0 \times \mathrm{FSW} \times \Delta \mathrm{V}} \\
& =\frac{0.6 \mathrm{~A}}{8.0 \times\left(200 \times 10^{3} \mathrm{~Hz}\right) \times\left(33 \times 10^{-3 \mathrm{~V})} \cong 11.4 \mu \mathrm{~F}\right.}
\end{aligned}
$$

The minimum ESR needed to limit the output voltage ripple to 50 mV peak to peak is:

$$
\mathrm{ESR}=\frac{\Delta \mathrm{V}}{\Delta \mathrm{l}}=\frac{50 \times 10-3}{0.6 \mathrm{~A}}=55 \mathrm{~m} \Omega
$$

The output capacitor should be chosen so that its ESR is at least half of the calculated value and the capacitance is at least ten times the calculated value. It is often advisable to use several capacitors in parallel to reduce ESR.

Low impedance aluminum electrolytic, tantalum or organic semiconductor capacitors are a good choice for an output capacitor. Low impedance aluminum are the cheapest but are not available in surface mount at present. Solid tantalum chip capacitors are available from a number of suppliers and offer the best choice for surface mount applications. The capacitor working voltage should be greater than the output voltage in all cases.

## 5) $\mathrm{V}_{\mathrm{FB}}$ Divider

$$
\mathrm{V}_{\mathrm{OUT}}=1.25 \mathrm{~V}\left(\frac{\mathrm{R} 1+\mathrm{R} 2}{\mathrm{R} 2}\right)=1.25 \mathrm{~V}\left(\frac{\mathrm{R} 1}{\mathrm{R} 2}+1.0\right)
$$

The input bias current to the comparator is $4.0 \mu \mathrm{~A}$. The resistor divider current should be considerably higher than
this to ensure that there is sufficient bias current. If we choose the divider current to be at least 250 times the bias current this gives a divider current of 1.0 mA and simplifies the calculations.

$$
\frac{1.5 \mathrm{~V}}{1.0 \mathrm{~mA}}=\mathrm{R} 1+\mathrm{R} 2=1.5 \mathrm{k} \Omega
$$

Let R2 $=1.0 \mathrm{k}$
Rearranging the divider equation gives:

$$
\mathrm{R} 1=\mathrm{R} 2\left(\frac{\mathrm{~V}_{\mathrm{OUT}}}{1.25}-1.0\right)=1.0 \mathrm{k} \Omega\left(\frac{1.5 \mathrm{~V}}{1.25}\right)=200 \Omega
$$

## 6) Divider Bypass Capacitor CRR $_{\text {R }}$

Since the feedback resistors divide the output voltage by a factor of 4.0 , i.e. $5.0 \mathrm{~V} / 1.25 \mathrm{~V}=4.0$, it follows that the output ripple is also divided by four. This would require that the output ripple be at least $60 \mathrm{mV}(4.0 \times 15 \mathrm{mV})$ to trip the feedback comparator. We use a capacitor $C_{R R}$ to act as an AC short so that the output ripple is not attenuated by the divider network. The ripple voltage frequency is equal to the switching frequency so we choose $C_{R R}$ so that:

$$
X_{C}=\frac{1.0}{2 \pi f C}
$$

is negligible at the switching frequency.
In this case $\mathrm{F}_{\mathrm{SW}}$ is 200 kHz if we allow $\mathrm{X}_{\mathrm{C}}=3.0 \Omega$ then:

$$
C=\frac{1.0}{2 \pi f 3} \cong 0.265 \mu \mathrm{~F}
$$

## 7) Soft Start and Fault Timing Capacitor CS

CS performs several important functions. First it provides a dead time for load transients so that the IC does not enter a fault mode every time the load changes abruptly. Secondly it disables the fault circuitry during startup, it also provides Soft Start by clamping the reference voltage during startup to rise slowly and finally it controls the hiccup short circuit protection circuitry. This function reduces the PFET's duty cycle to $2.0 \%$ of the CS period.

The most important consideration in calculating CS is that it's voltage does not reach 2.5 V (the voltage at which the fault detect circuitry is enabled) before $\mathrm{V}_{\mathrm{FB}}$ reaches 1.15 V otherwise the power supply will never start.

If the $\mathrm{V}_{\mathrm{FB}}$ pin reaches 1.15 V , the fault timing comparator will discharge CS and the supply will not start. For the $\mathrm{V}_{\mathrm{FB}}$ voltage to reach 1.15 V the output voltage must be at least $4 \times 1.15=4.6 \mathrm{~V}$.
If we choose an arbitrary startup time of $200 \mu \mathrm{~s}$, we calculate the value of CS from:

$$
\begin{gathered}
\mathrm{T}=\frac{\mathrm{CS} \times 2.5 \mathrm{~V}}{\mathrm{I} \mathrm{CHARGE}} \\
\mathrm{CS}(\mathrm{MIN})=\frac{200 \mu \mathrm{~s} \times 264 \mu \mathrm{~A}}{2.5 \mathrm{~V}}=0.02 \mu \mathrm{~F}
\end{gathered}
$$

Use $0.1 \mu \mathrm{f}$.

The fault time out time is the sum of the slow discharge time the fast discharge time and the recharge time and is obviously dominated by the slow discharge time.

The first parameter is the slow discharge time, it is the time for the CS capacitor to discharge from 2.4 V to 1.5 V and is given by:

$$
\text { TSLOWDISCHARGE }=\frac{\mathrm{CS} \times(2.4 \mathrm{~V}-1.5 \mathrm{~V})}{\mathrm{I} \text { DISCHARGE }}
$$

where $I_{\text {DISCHARGE }}$ is $6.0 \mu \mathrm{~A}$ typical.

$$
\text { TSLOWDISCHARGE }=\mathrm{CS} \times 1.5 \mathrm{~V} \times 10^{5}
$$

The fast discharge time occurs when a fault is first detected. The CS capacitor is discharged from 2.5 V to 2.4 V .

$$
\text { TFASTDISCHARGE }=\frac{\mathrm{CS} \times(2.5 \mathrm{~V}-2.4 \mathrm{~V})}{\mathrm{I} \text { FASTDISCHARGE }}
$$

where $\mathrm{I}_{\text {FASTDISCHARGE }}$ is $66 \mu \mathrm{~A}$ typical.

$$
\text { TFASTDISCHARGE }=\text { CS } \times 1515
$$

The recharge time is the time for CS to charge from 1.5 V to 2.5 V .

$$
\text { TCHARGE }=\frac{\mathrm{CS} \times(2.5 \mathrm{~V}-1.5 \mathrm{~V})}{\mathrm{I} \mathrm{CHARGE}}
$$

where $I_{\text {CHARGE }}$ is $264 \mu \mathrm{~A}$ typical.

$$
\text { TCHARGE }=\mathrm{CS} \times 3787
$$

The fault time out time is given by:

$$
\begin{gathered}
\mathrm{T}_{\mathrm{FAULT}}=\mathrm{CS} \times\left(3787+1515+1.5 \times 10^{5}\right) \\
\mathrm{T}_{\mathrm{FAULT}}=\mathrm{CS} \times(1.55 \times 105)
\end{gathered}
$$

For this circuit

$$
\mathrm{T}_{\text {FAULT }}=0.1 \times 10^{-6} \times 1.55 \times 10^{5}=0.0155
$$

A larger value of CS will increase the fault time out time but will also increase the Soft Start time.

## 8) Input Capacitor

The input capacitor reduces the peak currents drawn from the input supply and reduces the noise and ripple voltage on
the $\mathrm{V}_{\mathrm{CC}}$ and $\mathrm{V}_{\mathrm{C}}$ pins. This capacitor must also ensure that the $\mathrm{V}_{\mathrm{CC}}$ remains above the UVLO voltage in the event of an output short circuit. $\mathrm{C}_{\text {IN }}$ should be a low ESR capacitor of at least $100 \mu \mathrm{~F}$. A ceramic surface mount capacitor should also be connected between $\mathrm{V}_{\mathrm{CC}}$ and ground to prevent spikes.

## 9) MOSFET Selection

The CS51033 drives a P-channel MOSFET. The $\mathrm{V}_{\text {GATE }}$ pin swings from GND to $\mathrm{V}_{\mathrm{C}}$. The type of PFET used depends on the operating conditions but for input voltages below 7.0 V a logic level FET should be used.

Choose a PFET with a continuous drain current ( $\mathrm{I}_{\mathrm{D}}$ ) rating greater than the maximum output current. $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ should be less than

$$
\operatorname{RDS}<=\frac{0.6 \mathrm{~V}}{\operatorname{lOUT}(\mathrm{MAX})} 167 \mathrm{~m} \Omega
$$

The Gate-to-Source voltage $\mathrm{V}_{\mathrm{GS}}$ and the Drain-to Source Breakdown Voltage should be chosen based on the input supply voltage.

The power dissipation due to the conduction losses is given by:

$$
P_{D}=I_{O U T}{ }^{2} \times \operatorname{RDS}(O N) \times D
$$

The power dissipation due to the switching losses is given by:

$$
\mathrm{PD}_{\mathrm{D}}=0.5 \times \mathrm{V}_{\text {IN }} \times \mathrm{IOUT} \times\left(\mathrm{T}_{\mathrm{R}}{ }^{r}+\mathrm{T}_{\mathrm{F}}\right) \times \mathrm{FSW}
$$

where $T_{R}=$ Rise Time and $T_{F}=$ Fall Time.

## 10) Diode Selection

The flyback or catch diode should be a Schottky diode because of it's fast switching ability and low forward voltage drop. The current rating must be at least equal to the maximum output current. The breakdown voltage should be at least 20 V for this 12 V application.

The diode power dissipation is given by:

$$
\mathrm{PD}_{\mathrm{D}}=\mathrm{IOUT} \times \mathrm{V}_{\mathrm{D}} \times\left(1.0-\mathrm{D}_{\mathrm{MIN}}\right)
$$

## CS51033

## CS5211

## Low Voltage Synchronous Buck Controller

The CS5211 is a low voltage synchronous buck controller. It contains all required circuitry for a synchronous buck converter using external N-Channel MOSFETs. High current internal gate drivers are capable of driving high gate capacitance of low $\mathrm{R}_{\mathrm{DS}(\mathrm{on})}$ NFETs for better efficiency. The $\mathrm{V}^{2 \mathrm{TM}}$ control architecture is used to achieve unmatched transient response, the best overall regulation and the simplest loop compensation. The CS5211 is in a 14-pin package to allow the designer added flexibility.

The CS5211 provides overcurrent protection, undervoltage lockout, Soft Start and built in adaptive nonoverlap. The CS5211 also provides adjustable fixed frequency range of 150 kHz to 750 kHz . This gives the designer more flexibility to make efficiency and component size compromises. The CS5211 will operate over a 4.5 V to 14 V range using either single of dual input voltage.

## Features

- Switching Regulator Controller
- N-Channel Synchronous Buck Design
- $\mathrm{V}^{2}$ Control Topology
- 200 ns Transient Response
- Programmable Fixed Frequency of $150 \mathrm{kHz}-750 \mathrm{kHz}$
- $1.0 \mathrm{~V} 1.5 \%$ Internal Reference
- Lossless Inductor Sensing Overcurrent Protection
- Hiccup Mode Short Circuit Protection
- Programmable Soft Start
- 40 ns GATE Rise and Fall Times (3.3 nF Load)
- 70 ns Adaptive FET Nonoverlap Time
- Differential Remote Sense Capability
- System Power Management
- 5.0 V or 12 V Operation
- Undervoltage Lockout
- On/Off Control Through Use of the COMP Pin

ORDERING INFORMATION
See detailed ordering and shipping information in the package dimensions section on page 1594 of this data sheet.

## PACKAGE PIN DESCRIPTION

| PIN NO. | PIN SYMBOL | FUNCTION |
| :---: | :---: | :--- |
| 1 | GATE(H) | High Side Switch FET driver pin. Capable of delivering peak currents of 1.0 A. |
| 2 | BST | Power supply input for the high side driver. |
| 3 | LGND | Reference ground. All control circuits are referenced to this pin. IC substrate connection. |
| 4 | V $_{\text {FFB }}$ | Input for the PWM comparator. |
| 5 | VFB $^{\text {COMP }}$ | Error amplifier input. |
| 6 | SGND | Error Amp output. PWM Comparator reference input. A capacitor to LGND provides error amp <br> compensation. |
| 7 | Internal reference is connected to this ground. Connect directly at the load for ground remote <br> sensing. |  |
| 8 | VCC | A resistor from this pin to SGND sets switching frequency. |
| 10 | IS- | Input Power Supply Pin. It supplies power to control circuitry. A 0.1 $\mu$ F Decoupling cap is rec- <br> ommended. |
| 11 | Vegative input for overcurrent comparator. |  |
| 12 | GATE(L) | Positive input for overcurrent comparator. |
| 13 | PGND | High Current ground for the GATE(H) and GATE(L) pins. |
| 14 |  |  |

Figure 2. Block Diagram

## THEORY OF OPERATION

## $V^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variations in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. $\mathrm{V}^{\mathbf{2}}$ Control Block Diagram
The $V^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of the change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in the inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an effect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this "slow" feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulations are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variations, since both line and load affect the ramp signal.

## Constant Frequency Operation

The CS5211 uses a constant frequency, trailing edge modulation architecture for generating PWM signal. During normal operation, the oscillator generates a narrow pulse at the beginning of each switching cycle to turn on the main switch. The main switch will be turned off when the ramp signal intersects with the output of the error amplifier (COMP pin voltage). Therefore, the switch duty cycle can be modified to regulate the output voltage to the desired value as line and load conditions change.
The major advantage of constant frequency operation is that the component selections, especially the magnetic component design, become very easy. The oscillator frequency of CS5211 is programmable from 150 kHz to 750 kHz using an external resistor connected from the R OSC pin to ground.

## Start-Up

If there are no fault conditions and the fault latch is reset, the error amplifier will start charging the COMP pin capacitor after the CS5211 is powered up. The output of the error amplifier (COMP voltage) will ramp up linearly. The COMP capacitance and the source current of the error amplifier determine the slew rate of COMP voltage. The output of the error amplifier is connected internally to the inverting input of the PWM comparator and it is compared with the $\mathrm{V}_{\text {FFB }}$ pin voltage plus 0.5 V offset at the non-inverting input of the PWM comparator. Since $\mathrm{V}_{\mathrm{FFB}}$ voltage is zero before the start-up, the PWM comparator output will stay high until the COMP pin voltage hits 0.5 V . There is no switching action while the PWM comparator output is high.
After the COMP voltage exceeds the 0.5 V offset, the output of PWM comparator toggles and releases the PWM latch. The narrow pulse generated by the oscillator at the beginning of the next oscillator cycle will set the latch so that the main switch can be turned on and the regulator output voltage ramps up. When the output voltage achieves a level set by the COMP voltage, the main switch will be turned off. The $\mathrm{V}^{2}$ control loop will adjust the main switch duty cycle as required to ensure the regulator output voltage tracks the

COMP voltage. Since the COMP voltage increases gradually, the Soft-Start can be achieved. The start-up period ends when the output voltage reaches the level set by the external resistor divider.

## Output Enable

Since there can be no switching until the COMP pin exceeds the 0.5 V offset built into the PWM comparator, the COMP pin can also be used for an enable function. Hold the COMP pin below 0.4 V with an open collector circuit to disable the output. When the COMP pin is released to enable start-up, the user must ensure there is no leakage current from the enable circuit into COMP. During normal operation the COMP output is driven with only $5.0 \mu \mathrm{~A}$ to $30 \mu \mathrm{~A}$ internally.

## Hiccup Mode Overcurrent Protection

Under normal load conditions, the voltage across the IS+ and IS- pins is less than the 60 mV overcurrent threshold. If the threshold is exceeded, the overcurrent fault latch is set, the high side gate driver is forced low, and the COMP pin is discharged with $5.0 \mu \mathrm{~A}$. There is no switching until the COMP voltage drops below a 0.25 V threshold. Then, the fault latch is cleared and a soft-start is initiated. The low effective duty cycle during hiccup overcurrent greatly reduces component stress for an extended fault.

## Inductor Current Sensing

Besides using a current sense resistor to sense inductor current, CS5211 provides the users with the possibility of using loss-less inductor sensing technique. This sensing technique utilizes the Equivalent Series Resistance (ESR) of the inductor to sense the current. The output current is sensed through an RC network in parallel with the inductor as shown in Figure 4. The voltage across the small capacitor is then fed to the OC comparator.

Figure 4. Inductor Current Sensing

If the values of R and C are chosen such that:

$$
\frac{L}{R_{L}}=R C
$$

Then the voltage across the capacitor C will be:

$$
V_{C}=R_{L} I_{L}
$$

Therefore, if the time constant of the RC network is equal to that of the inductor, the voltage across the capacitor is proportional to the inductor current by a factor of the inductor ESR. In practice, the user should ensure that under all component tolerances, the RC time constant is larger than the $\mathrm{L} / \mathrm{R}$ time constant. This will keep the high frequency gain for $\mathrm{V}_{\mathrm{C}}(\mathrm{s}) / \mathrm{I}_{\mathrm{L}}(\mathrm{s})$ less than the low frequency gain, and avoid unnecessary OCP tripping during short duration overcurrent situations.

Compared with conventional resistor sensing, the inductor ESR current sensing technique is lossless, but is not as accurate due to variation in the ESR from inductor to inductor and over temperature. For typical inductor ESR, the $0.39 \% /{ }^{\circ} \mathrm{C}$ positive temperature coefficient will reduce the current limit at high temperature, and will help prevent thermal runaway, but will force an increased design target at room temperature. This technique can be more accurate than using a PCB trace, since PCB copper thickness can vary $10-20 \%$, compared to $1 \%$ variation in wire diameter thickness typical of inductors.

## Remote Voltage Sensing

The CS5211 has the capability to sense the voltage when the load is located far away from the regulator. The SGND pin is dedicated to the differential remote sensing. The negative remote sense line is connected to SGND pin directly, while the positive remote sense line is usually connected to the top of the feedback voltage divider. To prevent over-voltage condition caused by open remote sense lines, the divider should also be locally connected to the output of the regulator through a low value resistor. That resistor is used to compensate for the voltage drop across the output power cables.

## APPLICATIONS AND COMPONENT SELECTION

## Inductor Component Selection

The output inductor may be the most critical component in the converter because it will directly effect the choice of other components and dictate both the steady-state and transient performance of the converter. When selecting an inductor the designer must consider factors such as DC current, peak current, output voltage ripple, core material, magnetic saturation, temperature, physical size, and cost (usually the primary concern).

In general, the output inductance value should be as low and physically small as possible to provide the best transient response and minimum cost. If a large inductance value is used, the converter will not respond quickly to rapid changes in the load current. On the other hand, too low an inductance value will result in very large ripple currents in the power components (MOSFETs, capacitors, etc) resulting in increased dissipation and lower converter efficiency. Also, increased ripple currents will force the designer to use higher rated MOSFETs, oversize the thermal solution, and use more, higher rated input and output capacitors - the converter cost will be adversely effected.

One method of calculating an output inductor value is to size the inductor to produce a specified maximum ripple current in the inductor. Lower ripple currents will result in less core and MOSFET losses and higher converter efficiency. The following equation may be used to calculate the minimum inductor value to produce a given maximum ripple current ( $\alpha \bullet \mathrm{I}_{\mathrm{O}, \mathrm{MAX}}$ ). The inductor value calculated by this equation is a minimum because values less than this will produce more ripple current than desired. Conversely, higher inductor values will result in less than the maximum ripple current.

$$
\text { LoMIN }=(\text { Vin }- \text { Vout }) \cdot \text { Vout } /(\alpha \cdot \text { IO,MAX } \cdot \text { Vin } \cdot \text { fSW })
$$

$\alpha$ is the ripple current as a percentage of the maximum output current ( $\alpha=0.15$ for $\pm 15 \%, \alpha=0.25$ for $\pm 25 \%$, etc) and $f_{s w}$ is the switching frequency. If the minimum inductor value is used, the inductor current will swing $\pm \alpha / 2 \%$ about Iout. Therefore, the inductor must be designed or selected such that it will not saturate with a peak current of $(1+\alpha / 2)$

- IO,MAX.

Power dissipation in the inductor can now be calculated from the RMS current level. The RMS of the AC component of the inductor is given by the following relationship:

$$
I_{A C}=\frac{I P P}{\sqrt{12}}
$$

where IPP $=\alpha \bullet \mathrm{I}_{\mathrm{O}, \mathrm{MAX}}$.
The total $\mathrm{I}_{\mathrm{RMS}}$ of the current will be calculated from:

$$
\mathrm{I}_{\mathrm{RMS}}=\sqrt{\mathrm{IOUT}}{ }^{2}+\mathrm{I}_{\mathrm{AC}}{ }^{2}
$$

The power dissipation for the inductor can be determined from:

$$
\mathrm{P}=\mathrm{I}_{\mathrm{RMS}}{ }^{2} \times \mathrm{R}_{\mathrm{L}}
$$

## Input Capacitor Selection and Considerations

The input capacitor is used to reduce the current surges caused by conduction of current of the top pass transistor charging the PWM inductor.

The input current is pulsing at the switching frequency going from 0 to peak current in the inductor. The duty factor will be a function of the ratio of the input to output voltage and of the efficiency.

$$
D F=\frac{V_{\mathrm{O}}}{\mathrm{~V}_{\mathrm{I}}} \times \frac{1}{E f f}
$$

The RMS value of the ripple into the input capacitors can now be calculated:

$$
\operatorname{IIN}(\mathrm{RMS})=\operatorname{IOUT} \sqrt{D F-D F^{2}}
$$

The input RMS is maximum at $50 \% \mathrm{DF}$, so selection of the possible duty factor closest to $50 \%$ will give the worst case dissipation in the capacitors. The power dissipation of the input capacitors can be calculated by multiplying the square of the RMS current by the ESR of the capacitor.

## Output Capacitor

The output capacitor filters output inductor ripple current and provides low impedance for load current changes. The effect of the capacitance for handling the power supply induced ripple will be discussed here. Effects of load transient behavior can be considered separately.
The principle consideration for the output capacitor is the ripple current induced by the switches through the inductor. This ripple current was calculated as $\mathrm{I}_{\mathrm{AC}}$ in the above discussion of the inductor. This ripple component will induce heating in the capacitor by a factor of the RMS current squared multiplied by the ESR of the output capacitor section. It will also create output ripple voltage.

The ripple voltage will be a vector summation of the ripple current times the ESR of the capacitor, plus the ripple current integrating in the capacitor, and the rate of change in current times the total series inductance of the capacitor and connections.
The inductor ripple current acting against the ESR of the output capacitor is the major contributor to the output ripple voltage. This fact can be used as a criterion to select the output capacitor.

$$
V_{P P}=I P P \times C_{E S R}
$$

The power dissipation in the output capacitor can be calculated from:

$$
P=I_{A C}{ }^{2} \times C_{E S R}
$$

where:
$\mathrm{I}_{\mathrm{AC}}=\mathrm{AC}$ RMS of the inductor
$\mathrm{C}_{\text {ESR }}=$ Effective series resistance of the output capacitor network.

## MOSFET \& Heatsink Selection

Power dissipation, package size, and thermal solution drive MOSFET selection. To adequately size the heat sink, the design must first predict the MOSFET power dissipation. Once the dissipation is known, the heat sink thermal impedance can be calculated to prevent the specified maximum case or junction temperatures from being exceeded at the highest ambient temperature. Power dissipation has two primary contributors: conduction losses and switching losses. The control or upper MOSFET will display both switching and conduction losses. The synchronous or lower MOSFET will exhibit only conduction losses because it switches into nearly zero voltage. However, the body diode in the synchronous MOSFET will suffer diode losses during the non-overlap time of the gate drivers.

For the upper or control MOSFET, the power dissipation can be approximated from:

$$
\begin{aligned}
& \text { Pd,CONTROL }=\left(\text { IRMS,CNTL }{ }^{2} \cdot \operatorname{RDS}(o n)\right) \\
& +\left(\mathrm{L}_{\mathrm{L}, \mathrm{MAX}} \cdot \mathrm{Q}_{\text {switch }} / \mathrm{Ig} \cdot \mathrm{~V}_{\mathrm{IN}} \cdot \mathrm{fs}^{2}\right) \\
& +\left(Q_{\text {oss }} / 2 \cdot V_{\text {IN }} \cdot f S W\right)+\left(V_{\text {IN }} \cdot Q_{R R} \cdot f S W\right)
\end{aligned}
$$

The first term represents the conduction or IR losses when the MOSFET is ON while the second term represents the switching losses. The third term is the losses associated with the control and synchronous MOSFET output charge when the control MOSFET turns ON. The output losses are caused by both the control and synchronous MOSFET but are dissipated only in the control FET. The fourth term is the loss due to the reverse recovery time of the body diode in the synchronous MOSFET. The first two terms are usually adequate to predict the majority of the losses.

Where $\mathrm{I}_{\mathrm{RMS}, \mathrm{CNTL}}$ is the RMS value of the trapezoidal current in the control MOSFET:

$$
\begin{aligned}
I_{R M S, C N T L}=\sqrt{D} & \cdot\left[\left(I_{\text {Lo }}, M A X^{2}+I_{\text {Lo }}, M A X \cdot I_{\text {Lo }}, \mathrm{MIN}\right.\right. \\
& \left.+I_{\left.\mathrm{Lo}, \mathrm{MIN}^{2}\right) / 3}\right]^{1 / 2}
\end{aligned}
$$

$\mathrm{I}_{\text {Lo,MAX }}$ is the maximum output inductor current:

$$
\mathrm{I}_{\mathrm{Lo}, \mathrm{MAX}}=\mathrm{I} \mathrm{O}, \mathrm{MAX} / 2+\Delta \mathrm{I}_{\mathrm{Lo}} / 2
$$

$\mathrm{I}_{\text {Lo,MIN }}$ is the minimum output inductor current:

$$
\mathrm{I} \mathrm{Lo}, \mathrm{MIN}=\mathrm{I}, \mathrm{MAX} / 2-\Delta \mathrm{I} \mathrm{Lo} / 2
$$

$\mathrm{I}_{\mathrm{O}, \text { MAX }}$ is the maximum converter output current.
D is the duty cycle of the converter:
D = VOUT/VIN
$\Delta \mathrm{I}_{\mathrm{Lo}}$ is the peak-to-peak ripple current in the output inductor of value Lo:

$$
\Delta \mathrm{I}_{\mathrm{Lo}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \cdot \mathrm{D} /(\mathrm{Lo} \cdot \mathrm{fSW})
$$

$\mathrm{R}_{\mathrm{DS}(\mathrm{on})}$ is the ON resistance of the MOSFET at the applied gate drive voltage.

Qswitch is the post gate threshold portion of the gate-to-source charge plus the gate-to-drain charge. This
may be specified in the data sheet or approximated from the gate-charge curve as shown in the Figure 5.

$$
Q_{\text {switch }}=Q_{g s 2}+Q_{g d}
$$

Figure 5. MOSFET Switching Characteristics
$\mathrm{I}_{\mathrm{g}}$ is the output current from the gate driver IC.
$\mathrm{V}_{\text {IN }}$ is the input voltage to the converter.
$\mathrm{f}_{\text {sw }}$ is the switching frequency of the converter.
$\mathrm{Q}_{\mathrm{G}}$ is the MOSFET total gate charge to obtain $\mathrm{R}_{\mathrm{DS}(\text { on })}$. Commonly specified in the data sheet.
$\mathrm{V}_{\mathrm{g}}$ is the gate drive voltage.
$\mathrm{Q}_{\mathrm{RR}}$ is the reverse recovery charge of the lower MOSFET.
$\mathrm{Q}_{\text {oss }}$ is the MOSFET output charge specified in the data sheet.
For the lower or synchronous MOSFET, the power dissipation can be approximated from:

$$
\begin{aligned}
& \text { PD,SYNCH }=\left(I_{R M S}, S Y N C H^{2} \cdot \operatorname{RDS}(o n)\right) \\
& \quad+\left(\text { Vf }_{\text {diode }} \cdot \mathrm{IO}_{\mathrm{O}}, \mathrm{MAX} / 2 \cdot \mathrm{t} \text { _nonoverlap } \cdot \mathrm{fSW}\right)
\end{aligned}
$$

The first term represents the conduction or IR losses when the MOSFET is ON and the second term represents the diode losses that occur during the gate non-overlap time.

All terms were defined in the previous discussion for the control MOSFET with the exception of:

$$
\begin{aligned}
& \text { IRMS,SYNCH }=\sqrt{1-\mathrm{D}} \\
& \quad \cdot\left[\left(\text { ILo }_{\text {Lo }}\right.\right. \text { MAX }
\end{aligned}
$$

where:
$\mathrm{Vf}_{\text {diode }}$ is the forward voltage of the MOSFET's intrinsic diode at the converter output current.
t _nonoverlap is the non-overlap time between the upper and lower gate drivers to prevent cross conduction. This time is usually specified in the data sheet for the control IC.
When the MOSFET power dissipations are known, the designer can calculate the required thermal impedance to maintain a specified junction temperature at the worst case ambient operating temperature

$$
\theta \mathrm{T}<\left(\mathrm{T}_{\mathrm{J}}-\mathrm{T}_{\mathrm{A}}\right) / \mathrm{P}_{\mathrm{D}}
$$

where;
$\theta_{\mathrm{T}}$ is the total thermal impedance $\left(\theta_{\mathrm{JC}}+\theta_{\mathrm{SA}}\right)$.
$\theta_{\mathrm{JC}}$ is the junction-to-case thermal impedance of the MOSFET.
$\theta_{\mathrm{SA}}$ is the sink-to-ambient thermal impedance of the heatsink assuming direct mounting of the MOSFET (no thermal "pad" is used).
$\mathrm{T}_{\mathrm{J}}$ is the specified maximum allowed junction temperature.
$\mathrm{T}_{\mathrm{A}}$ is the worst case ambient operating temperature.
For TO-220 and TO-263 packages, standard FR-4 copper clad circuit boards will have approximate thermal resistances $\left(\theta_{\mathrm{SA}}\right)$ as shown below:

| Pad Size <br> (in $^{2} / \mathrm{mm}^{2}$ ) | Single-Sided <br> $\mathbf{1}$ oz. Copper |
| :---: | :---: |
| $0.5 / 323$ | $60-65^{\circ} \mathrm{C} / \mathrm{W}$ |
| $0.75 / 484$ | $55-60^{\circ} \mathrm{C} / \mathrm{W}$ |
| $1.0 / 645$ | $50-55^{\circ} \mathrm{C} / \mathrm{W}$ |
| $1.5 / 968$ | $45-50^{\circ} \mathrm{C} / \mathrm{W}$ |
| $2.0 / 1290$ | $38-42^{\circ} \mathrm{C} / \mathrm{W}$ |
| $2.5 / 1612$ | $33-37^{\circ} \mathrm{C} / \mathrm{W}$ |

As with any power design, proper laboratory testing should be performed to insure the design will dissipate the required power under worst case operating conditions. Variables considered during testing should include maximum ambient temperature, minimum airflow, maximum input voltage, maximum loading, and component variations (i.e. worst case MOSFET $\mathrm{R}_{\mathrm{DS}(o n)}$ ). Also, the inductors and capacitors share the MOSFET's heatsinks and will add heat and raise the temperature of the circuit board and MOSFET. For any new design, its advisable to have as much heatsink area as possible - all too often new designs are found to be too hot and require re-design to add heatsinking.

## Compensation Capacitor Selection

The nominal output current capability of the error amp is $30 \mu \mathrm{~A}$. This current charging the capacitor on the COMP pin is used as soft start for the converter. The COMP pin is going to ramp up to a voltage level that is within 70 mV of what $\mathrm{V}_{\mathrm{FFB}}$ is going to be when in regulation. This is the voltage that will determine the soft start. Therefore, the COMP capacitor can be established by the following relationship:

$$
\mathrm{C}=30 \mu \mathrm{~A} \times \frac{\text { soft start }}{\mathrm{V}_{\mathrm{FFB}}(\mathrm{REG})}
$$

where:
soft start = output ramp-up time
$\mathrm{V}_{\mathrm{FFB}(\mathrm{REG})}=\mathrm{V}_{\mathrm{FFB}}$ voltage when in regulation
$30 \mu \mathrm{~A}=$ COMP output current, typ.

The COMP output current range is given in the data sheet and will affect the ramp-up time. The value of the capacitor on the COMP pin will have an effect on the loop response and the transient response of the converter. Transient response can be enhanced by the addition of a parallel combination of a resistor and capacitor between the COMP pin and the comp capacitor.

## $\mathrm{R}_{\text {osc }}$ Selection

The switching frequency is programmed by selecting the resistor connected between the R $_{\text {OSC }}$ pin and SGND (pin 7). The grounded side of this resistor should be directly connected to the SGND pin, without any other currents flowing between the bottom of the resistor and the pin. Also, avoid running any noisy signals under the resistor, since injected noise could cause frequency jitter. The graph in Figure 6 shows the required resistance to program the frequency. Below 500 kHz , the following formula is accurate:

$$
R=13500 / \mathrm{f} S W+6 \mathrm{k} \Omega
$$

where $\mathrm{f}_{\mathrm{SW}}$ is the switching frequency in kHz .

Figure 6. Frequency vs. Rosc

## Differential Remote Sense Operation

The ability to implement fully differential remote sense is provided by the CS5211. The positive remote sense is implemented by bringing the output remote sense connection to the positive load connection. A low value resistor is connected from Vout to the feedback point at the regulator to provide feedback in the instance when the remote sense point is not connected.
The negative remote sense connection is provided by connecting the SGND of the CS5211 to the negative of the load return. Again, a low value resistor should be connected between SGND and LGND at the regulator to provide feedback in the instance when the remote sense point is not connected. The maximum voltage differential between the three grounds for this part is 200 mV .

## Feedback Divider Selection

The feedback voltage measured at $\mathrm{V}_{\mathrm{FB}}$ during normal regulation will be 1.0 V . This voltage is compared to an internal 1.0 V reference and is used to regulate the output voltage. The bias current into the error amplifier is $1.0 \mu \mathrm{~A}$ max, so select the resistor values so that this current does not add an excessive offset voltage.

## $V_{\text {FFB }}$ Feedback Selection

To take full advantage of the $\mathrm{V}^{2}$ control scheme, a small amount of output ripple must be fed back to the $V_{\text {FFB }}$ pin, typically 50 mV . For most application, this requirement is simple to achieve and the $V_{\mathrm{FFB}}$ can be connected directly to the $\mathrm{V}_{\mathrm{FB}}$ pin. There are some application that have to meet stringent load transient requirements. One of the key factor in achieving tight dynamic voltage regulation is low ESR. Low ESR at the regulator output results in low output voltage ripple. This situation could result in increase noise sensitivity and a potential for loop instability. In applications where the output ripple is not sufficient, the performance of the CS5211 can be improved by adding a fixed amount external ramp compensation to the $\mathrm{V}_{\mathrm{FFB}}$ pin. Refer to Figure 7, the amount of ramp at the $\mathrm{V}_{\mathrm{FFB}}$ pin depends on the switch node Voltage, Feedback Voltage, R1 and C2.

$$
\text { Vramp }=\left(V s w-V_{F B}\right) \times \operatorname{ton} /(R 1 \times C 2)
$$

where:
Vramp = amount of ramp needed;
Vsw = switch note voltage;
$\mathrm{V}_{\mathrm{FB}}=$ voltage feedback, 1 V ;
ton $=$ switch on-time.
To minimize the lost in efficiency R1 resistance should be large, typically 100 k or larger. With R1 chosen, C2 can be determined by the following;

$$
\mathrm{C} 2=\left(\mathrm{Vsw}-\mathrm{V}_{\mathrm{FB}}\right) \times \text { ton } /(\mathrm{R} 1 \times \mathrm{Vramp})
$$

C 1 is used as a bypass capacitor and its value should be equal to or greater than C 2 .

Figure 7. Small RC Filter Providing the Proper Voltage Ramp at the Beginning of Each On-Time Cycle

## Maximum Frequency Operation

The minimum pulse width may limit the maximum operating frequency. The duty factor, given by the output/input voltage ratio, multiplied by the period determines the pulse width during normal operation. This pulse width must be greater than 200 ns , or duty cycle jitter could become excessive. For low pulse widths below 300 ns , external slope compensation should be added to the $\mathrm{V}_{\mathrm{FFB}}$ pin to increase the PWM ramp signal and improve stability. 50 mV of added ramp at the $\mathrm{V}_{\mathrm{FFB}}$ pin is typically enough.

## Current Sense Component Selection

The current limit threshold is set by sensing a 60 mV voltage differential between the IS+ and IS- pins. Referring to Figure 8, the time constant of the R2,C1 filter should be set larger than the L/R1 time constant under worst case tolerances, to prevent overshoot in the sensed voltage and tripping the current limit too low. Resistor R3 of value equal to R2 is added for bias current cancellation. R2 and R3 should not be made too large, to reduce errors from bias current offsets. For typical L/R time constants, a $0.1 \mu \mathrm{~F}$ capacitor for C 1 will allow R 2 to be between 1.0 k and $10 \mathrm{k} \Omega$.
The current limit without R4 and R5, which are optional, is given by $60 \mathrm{mV} / \mathrm{R} 1$, where R 1 is the internal resistance of the inductor, obtained from the manufacturer. The addition of R5 can be used to decrease the current limit to a value given by:

$$
\mathrm{I} \text { LIM }=\left(60 \mathrm{mV}-\left(\mathrm{V}_{\text {OUT }} \times \mathrm{R} 3 /(\mathrm{R} 3+\mathrm{R} 5)\right) / R 1\right.
$$

where $\mathrm{V}_{\text {OUT }}$ is the output voltage.
Similiarly, omitting R5 and adding R4 will increase the current limit to a value given by:

$$
\mathrm{I} \mathrm{LIM}=60 \mathrm{mV} / \mathrm{R} 1 \times(1+\mathrm{R} 2 / \mathrm{R} 4)
$$

Essentially, R4 or R5 are used to increase or decrease the inductor voltage drop which corresponds to 60 mV at the IS+ and IS- pins.

Figure 8. Current Limit

## Boost Component Selection for Upper FET Gate Drive

The boost (BST) pin provides for application of a higher voltage to drive the upper FET. This voltage may be provided by a fixed higher voltage or it may be generated with a boost capacitor and charging diode, as shown in Figure 10. The voltage in the boost configuration would be
the summation of the voltage from the charging diode and the output voltage swing. Care must be taken to keep the peak voltage with respect to ground less than 20 V peak. The capacitor should be large enough to drive the capacitance of the top FET.

## NCP1570

## Low Voltage Synchronous Buck Controller

The NCP1570 is a low voltage buck controller. It provides the control for a DC-DC power solution producing an output voltage as low as 0.985 V over a wide current range. The NCP1570-based solution is powered from 12 V with the output derived from a 5 V supply. It contains all required circuitry for a synchronous NFET buck regulator using the $\mathrm{V}^{2 \mathrm{TM}}$ control method to achieve the fastest possible transient response and best overall regulation. The NCP1570 operates at a fixed internal 200 kHz frequency and is packaged in an SO-8.

The NCP1570 provides undervoltage lockout protection, Soft Start, Power Good with delay, and built-in adaptive non-overlap.

## Features

- $0.985 \mathrm{~V} \pm 1.0 \%$ Reference
- $\mathrm{V}^{2}$ Control Topology
- 200 ns Transient Response
- Programmable Soft Start
- Power Good
- Programmable Power Good Delay
- 40 ns Gate Rise and Fall Times (3.3 nF Load)
- 50 ns Adaptive FET Non-Overlap Time
- Fixed 200 kHz Oscillator Frequency
- Undervoltage Lockout
- On/Off Control Through Use of the COMP Pin
- Overvoltage Protection through Synchronous MOSFETs
- Synchronous N-Channel Buck Design
- Dual Supply, 12 V Control, 5 V Power Source

## APPLICATION INFORMATION

## THEORY OF OPERATION

The NCP1570 is a simple, synchronous, fixed-frequency, low-voltage buck controller using the $\mathrm{V}^{2}$ control method. It provides a programmable-delay Power Good function to indicate when the output voltage is out of regulation.

## $V^{2}$ Control Method

The $\mathrm{V}^{2}$ control method uses a ramp signal generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. The $\mathrm{V}^{2}$ method differs from traditional techniques such as voltage mode control, which generates an artificial ramp, and current mode control, which generates a ramp using the inductor current.

Figure 21. $\mathbf{V}^{2}$ Control with Slope Compensation

The $\mathrm{V}^{2}$ control method is illustrated in Figure 21. The output voltage generates both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output, regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, allowing the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A variation in line voltage changes the current ramp in the inductor, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since any variation in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme offers the same advantages in line transient response.

A variation in load current will affect the output voltage, modifying the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. The comparator response time and the transition speed of the main switch determine the load transient response. Unlike traditional control methods, the reaction
time to the output load step is not related to the crossover frequency of the error signal loop.
The error signal loop can have a low crossover frequency, since the transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent control loops. A voltage mode controller relies on the change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains a fixed error signal during line transients, since the slope of the ramp signal changes in this case. However, regulation of load transients still requires a change in the error signal. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope in the output ripple can lead to pulse width jitter and variation caused by both random and synchronous noise. A ramp waveform generated in the oscillator is added to the ramp signal from the output voltage to provide the proper voltage ramp at the beginning of each switching cycle. This slope compensation increases the noise immunity, particularly at duty cycles above $50 \%$.

## Start Up

The NCP1570 features a programmable Soft Start function, which is implemented through the error amplifier and the external compensation capacitor. This feature prevents stress to the power components and limits output voltage overshoot during start-up. As power is applied to the regulator, the NCP1570 undervoltage lockout circuit (UVL) monitors the IC's supply voltage ( $\mathrm{V}_{\mathrm{CC}}$ ). The UVL circuit prevents the MOSFET gates from switching until $\mathrm{V}_{\mathrm{CC}}$ exceeds the 8.5 V threshold. A hysteresis function of 1.0 V improves noise immunity. The compensation capacitor connected to the COMP pin is charged by a $30 \mu \mathrm{~A}$ current source. When the capacitor voltage exceeds the 0.5 V offset of the PWM comparator, the PWM control loop will allow switching to occur. The upper gate driver GATE(H) is activated turning on the upper MOSFET. The current then ramps up through the main inductor and linearly powers the output capacitors and load. When the regulator output voltage exceeds the COMP pin voltage minus the 0.5 V

PWM comparator offset threshold and the artificial ramp, the PWM comparator terminates the initial pulse.

Figure 22. Idealized Waveforms

## Normal Operation

During normal operation, the duty cycle of the gate drivers remains approximately constant as the $\mathrm{V}^{2}$ control loop maintains the regulated output voltage under steady state conditions. Variations in supply line or output load conditions will result in changes in duty cycle to maintain regulation.

## Gate Charge Effect on Switching Times

When using the onboard gate drivers, the gate charge has an important effect on the switching times of the FETs. A finite amount of time is required to charge the effective capacitor seen at the gate of the FET. Therefore, the rise and fall times rise linearly with increased capacitive loading.

## Transient Response

The 200 ns reaction time of the control loop provides fast transient response to any variations in input voltage and output current. Pulse-by-pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitors during the time required to slew the inductor current. For better transient response, several high frequency and bulk output capacitors are usually used.

## Overvoltage Protection

Overvoltage protection is provided as a result of the normal operation of the $\mathrm{V}^{2}$ control method and requires no additional external components. The control loop responds to an overvoltage condition within 200 ns , turning off the upper MOSFET and disconnecting the regulator from its input voltage. This results in a crowbar action to clamp the output voltage, preventing damage to the load. The regulator remains in this state until the overvoltage condition ceases.

## Power Good

The PWRGD pin is asserted when the output voltage is within regulation limits. Sensing for the PWRGD pin is achieved through the $\mathrm{V}_{\mathrm{FB}}$ pin. When the output voltage is rising, PWRGD goes high at $90 \%$ of the designed output voltage. When the output voltage is falling, PWRGD goes
low at $70 \%$ of the designed output voltage. PWRGD is an open-collector output and should be externally pulled to logic high through a resistor to limit current to no more than 20 mA . Figure 23 shows the hysteretic nature of the PWRGD pin's operation.

Figure 23. PWRGD Assertion

## Selection of the Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the regulator output voltage. Key specifications for output capacitors are their ESR (Equivalent Series Resistance), and ESL (Equivalent Series Inductance). For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.
In order to determine the number of output capacitors the maximum voltage transient allowed during load transitions has to be specified. The output capacitors must hold the output voltage within these limits since the inductor current can not change with the required slew rate. The output capacitors must therefore have a very low ESL and ESR.
The voltage change during the load current transient is:

$$
\Delta \mathrm{V}_{\mathrm{OUT}}=\Delta \mathrm{I}_{\mathrm{OUT}} \times\left(\frac{\mathrm{ESL}}{\Delta \mathrm{t}}+\mathrm{ESR}+\frac{\mathrm{t} T \mathrm{R}}{\mathrm{COUT}}\right)
$$

where:
$\Delta \mathrm{I}_{\text {OUT }} / \Delta \mathrm{t}=$ load current slew rate;
$\Delta \mathrm{I}_{\text {OUT }}=$ load transient;
$\Delta t=$ load transient duration time;
$\mathrm{ESL}=$ Maximum allowable ESL including capacitors, circuit traces, and vias;
$\mathrm{ESR}=$ Maximum allowable ESR including capacitors and circuit traces;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time.
The designer has to independently assign values for the change in output voltage due to ESR, ESL, and output capacitor discharging or charging. Empirical data indicates that most of the output voltage change (droop or spike depending on the load current transition) results from the total output capacitor ESR.

The maximum allowable ESR can then be determined according to the formula:

$$
\text { ESRMAX }=\frac{\Delta V_{\text {ESR }}}{\Delta \mathrm{I}_{\text {OUT }}}
$$

where:
$\Delta \mathrm{V}_{\mathrm{ESR}}=$ change in output voltage due to ESR (assigned by the designer)
Once the maximum allowable ESR is determined, the number of output capacitors can be found by using the formula:

$$
\text { Number of capacitors }=\frac{\text { ESRCAP }}{\text { ESRMAX }}
$$

where:
$E S R_{C A P}=$ maximum ESR per capacitor (specified in manufacturer's data sheet).
$E S R_{M A X}=$ maximum allowable ESR.
The actual output voltage deviation due to ESR can then be verified and compared to the value assigned by the designer:

$$
\Delta \mathrm{V}_{\mathrm{ESR}}=\Delta \mathrm{I} \text { OUT } \times \mathrm{ESR}_{\mathrm{MAX}}
$$

Similarly, the maximum allowable ESL is calculated from the following formula:

$$
\text { ESLMAX }=\frac{\Delta V_{E S L} \times \Delta t}{\Delta l}
$$

## Selection of the Input Inductor

A common requirement is that the buck controller must not disturb the input voltage. One method of achieving this is by using an input inductor and a bypass capacitor. The input inductor isolates the supply from the noise generated in the switching portion of the buck regulator and also limits the inrush current into the input capacitors upon power up. The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients. The worst case is when the load changes from no load to full load (load step), a condition under which the highest voltage change across the input capacitors is also seen by the input inductor. The inductor successfully blocks the ripple current while placing the transient current requirements on the input bypass capacitor bank, which has to initially support the sudden load change.

The minimum inductance value for the input inductor is therefore:

$$
\operatorname{LIN}=\frac{\Delta V}{(\mathrm{dl} / \mathrm{dt}) \mathrm{MAX}}
$$

where:
$\mathrm{L}_{\mathrm{IN}}=$ input inductor value;
$\Delta \mathrm{V}=$ voltage seen by the input inductor during a full load swing;
$(\mathrm{dI} / \mathrm{dt})_{\mathrm{MAX}}=$ maximum allowable input current slew rate.
The designer must select the LC filter pole frequency so that at least 40 dB attenuation is obtained at the regulator switching frequency. The LC filter is a double-pole network with a slope of -2.0 , a roll-off rate of $-40 \mathrm{~dB} / \mathrm{dec}$, and a corner frequency:

$$
\mathrm{f}_{\mathrm{C}}=\frac{1}{2 \pi \times \sqrt{\mathrm{LC}}}
$$

where:
$\mathrm{L}=$ input inductor;
$\mathrm{C}=$ input capacitor( s ).

## Selection of the Output Inductor

There are many factors to consider when choosing the output inductor. Maximum load current, core and winding losses, ripple current, short circuit current, saturation characteristics, component height and cost are all variables that the designer should consider. However, the most important consideration may be the effect inductor value has on transient response.
The amount of overshoot or undershoot exhibited during a current transient is defined as the product of the current step and the output filter capacitor ESR. Choosing the inductor value appropriately can minimize the amount of energy that must be transferred from the inductor to the capacitor or vice-versa. In the subsequent paragraphs, we will determine the minimum value of inductance required for our system and consider the trade-off of ripple current vs. transient response.
In order to choose the minimum value of inductance, input voltage, output voltage and output current must be known. Most computer applications use reasonably well regulated bulk power supplies so that, while the equations below specify $\mathrm{V}_{\mathrm{IN}(\mathrm{MAX})}$ or $\mathrm{V}_{\text {IN(MIN) }}$, it is possible to use the nominal value of $\mathrm{V}_{\text {IN }}$ in these calculations with little error.
Current in the inductor while operating in the continuous current mode is defined as the load current plus ripple current.

$$
\mathrm{IL}=\mathrm{ILOAD}+\mathrm{IRIPPLE}
$$

The ripple current waveform is triangular, and the current is a function of voltage across the inductor, switch FET on-time and the inductor value. FET on-time can be defined as the product of duty cycle and switch frequency, and duty cycle can be defined as a ratio of $V_{\text {OUT }}$ to $V_{\text {IN }}$. Thus,

$$
\text { IRIPPLE }=\frac{\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{(\mathrm{foSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}\right)}
$$

Peak inductor current is defined as the load current plus half of the peak current. Peak current must be less than the maximum rated FET switch current, and must also be less than the inductor saturation current. Thus, the maximum output current can be defined as:
$\operatorname{IOUT}(\mathrm{MAX})=\operatorname{ISWITCH}(\mathrm{MAX})-\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MAX})-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{(2)(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}(\mathrm{MAX})\right)}$
Since the maximum output current must be less than the maximum switch current, the minimum inductance required can be determined.

$$
L_{(\text {MIN })}=\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{(\mathrm{fOSC})\left(\operatorname{ISWITCH}(\mathrm{MAX})\left(\mathrm{V}_{\text {IN }(\text { MIN })}\right)\right.}
$$

This equation identifies the value of inductor that will provide the full rated switch current as inductor ripple current, and will usually result in inefficient system operation. The system will sink current away from the load during some portion of the duty cycle unless load current is greater than half of the rated switch current. Some value larger than the minimum inductance must be used to ensure the converter does not sink current. Choosing larger values of inductor will reduce the ripple current, and inductor value can be designed to accommodate a particular value of ripple current by replacing $\mathrm{I}_{\text {SWITCH(MAX) }}$ with a desired value of IRIPPLE:

$$
\left.\mathrm{L}_{(\text {RIPPLE }}\right)=\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})-\mathrm{V}_{\mathrm{OUT}}\right) \mathrm{V}_{\mathrm{OUT}}}{(\mathrm{fOSC})(\mathrm{IRIPPLE})\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})\right)}
$$

However, reducing the ripple current will cause transient response times to increase. The response times for both increasing and decreasing current steps are shown below.

$$
\begin{aligned}
& \text { TRESPONSE(INCREASING) }=\frac{(\mathrm{L})(\Delta \text { IOUT })}{\left(\mathrm{V}_{\text {IN }}-\text { VOUT }\right)} \\
& \text { TRESPONSE(DECREASING })^{(\mathrm{L})\left(\Delta \text { IOUT }^{\prime}\right)} \frac{\left(\mathrm{V}_{\text {OUT }}\right)}{}
\end{aligned}
$$

Inductor value selection also depends on how much output ripple voltage the system can tolerate. Output ripple voltage is defined as the product of the output ripple current and the output filter capacitor ESR.

Thus, output ripple voltage can be calculated as:
$\mathrm{V}_{\text {RIPPLE }}=\left(\mathrm{ESR}_{\mathrm{C}}\right)(\operatorname{IRIPPLE})=\frac{\left(\mathrm{ESR}_{\mathrm{C}}\right)\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}\right)}$
Finally, we should consider power dissipation in the output inductors. Power dissipation is proportional to the square of inductor current:

$$
\mathrm{P}_{\mathrm{D}}=\left(\mathrm{I}_{\mathrm{L}}^{2}\right)\left(\mathrm{ESR}_{\mathrm{L}}\right)
$$

The temperature rise of the inductor relative to the air surrounding it is defined as the product of power dissipation and thermal resistance to ambient:

$$
\Delta \mathrm{T}(\text { inductor })=(\mathrm{Ra})\left(\mathrm{P}_{\mathrm{D}}\right)
$$

Ra for an inductor designed to conduct 20 A to 30 A is approximately $45^{\circ} \mathrm{C} / \mathrm{W}$. The inductor temperature is given as:

$$
\mathrm{T} \text { (inductor) }=\Delta \mathrm{T} \text { (inductor) }+ \text { Tambient }
$$

## $V_{\text {cc }}$ Bypass Filtering

A small RC filter should be added between module $\mathrm{V}_{\mathrm{CC}}$ and the $\mathrm{V}_{\mathrm{CC}}$ input to the IC. A $10 \Omega$ resistor and a $0.1 \mu \mathrm{~F}$ capacitor should be sufficient to ensure the controller IC does not operate erratically due to injected noise.

## Input Filter Capacitors

The input filter capacitors provide a charge reservoir that minimizes supply voltage variations due to changes in current flowing through the switch FETs. These capacitors must be chosen primarily for ripple current rating.

Figure 24.
Consider the schematic shown in Figure 24. The average current flowing in the input inductor $\mathrm{L}_{\mathrm{IN}}$ for any given output current is:

$$
\operatorname{IIN}(\mathrm{AVE})=\operatorname{IOUT} \times \frac{\mathrm{V}_{\text {OUT }}}{\mathrm{V}_{\text {IN }}}
$$

Input capacitor current is positive into the capacitor when the switch FETs are off, and negative out of the capacitor when the switch FETs are on. When the switches are off, $\mathrm{I}_{\text {IN(AVE) }}$ flows into the capacitor. When the switches are on, capacitor current is equal to the per-phase output current minus $\mathrm{I}_{\mathrm{IN}(\mathrm{AVE})}$. If we ignore the small current variation due to the output ripple current, we can approximate the input capacitor current waveform as a square wave. We can then calculate the RMS input capacitor ripple current:
$\operatorname{IRMS}($ CIN $)=\sqrt{\begin{array}{l}I_{\text {IN(AVE) }}^{2}+\frac{V_{\text {OUT }}}{V_{\text {IN }}} \\ \times\left[(\operatorname{IOUT} \text { per phase }-\operatorname{IIN(AVE)})^{2}-I_{\text {IN(AVE }}^{2}\right]\end{array}}$
The input capacitance must be designed to conduct the worst case input ripple current. This will require several capacitors in parallel. In addition to the worst case current, attention must be paid to the capacitor manufacturer's derating for operation over temperature.

As an example, let us define the input capacitance for a 5 V to 3.3 V conversion at 10 A at an ambient temperature of $60^{\circ} \mathrm{C}$. A droop voltage of 90 mV to 1.61 V and efficiency of $80 \%$ is assumed. Average input current in the input filter inductor is:

$$
\operatorname{IIN}(A V E)=(10 \mathrm{~A})(3.3 \mathrm{~V} / 5 \mathrm{~V})=6.6 \mathrm{~A}
$$

Input capacitor RMS ripple current is then

$$
\begin{aligned}
\operatorname{IIN}(\mathrm{RMS}) & =\sqrt{\begin{array}{l}
6.6^{2}+\frac{3.3 \mathrm{~V}}{5 \mathrm{~V}} \\
\times\left[(10 \mathrm{~A}-6.6 \mathrm{~A})^{2}-6.6 \mathrm{~A}^{2}\right]
\end{array}} \\
& =4.74 \mathrm{~A}
\end{aligned}
$$

If we consider a Rubycon MBZ series capacitor, the ripple current rating for a $6.3 \mathrm{~V}, 1800 \mathrm{nF}$ capacitor is 2000 mA at 100 kHz and $105^{\circ} \mathrm{C}$. We determine the number of input capacitors by dividing the ripple current by the per-capacitor current rating:

$$
\text { Number of capacitors }=4.74 \mathrm{~A} / 2.0 \mathrm{~A}=2.3
$$

A total of at least 3 capacitors in parallel must be used to meet the input capacitor ripple current requirements.

## Output Switch FETs

Output switch FETs must be chosen carefully, since their properties vary widely from manufacturer to manufacturer. The NCP1570 system is designed assuming that n -channel FETs will be used. The FET characteristics of most concern are the gate charge/gate-source threshold voltage, gate capacitance, on-resistance, current rating and the thermal capability of the package.

The onboard FET driver has a limited drive capability. If the switch FET has a high gate charge, the amount of time the FET stays in its ohmic region during the turn-on and turn-off transitions is larger than that of a low gate charge FET, with the result that the high gate charge FET will consume more power. Similarly, a low on-resistance FET will dissipate less power than will a higher on-resistance FET at a given current. Thus, low gate charge and low $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ will result in higher efficiency and will reduce generated heat.

It can be advantageous to use multiple switch FETs to reduce power consumption. By placing a number of FETs in parallel, the effective $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ is reduced, thus reducing the ohmic power loss. However, placing FETs in parallel increases the gate capacitance so that switching losses increase. As long as adding another parallel FET reduces the ohmic power loss more than the switching losses increase, there is some advantage to doing so. However, at some point the law of diminishing returns will take hold, and a marginal increase in efficiency may not be worth the board area required to add the extra FET. Additionally, as more FETs are used, the limited drive capability of the FET driver will have to charge a larger gate capacitance, resulting in increased gate voltage rise and fall times. This will affect the amount of time the FET operates in its ohmic region and will increase power dissipation.

The following equations can be used to calculate power dissipation in the switch FETs.

For ohmic power losses due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ :

$$
\begin{gathered}
\mathrm{PON}(\mathrm{TOP})=\frac{\left(\mathrm{RDS}(\mathrm{ON})(\mathrm{TOP})(\mathrm{I} \mathrm{RMS}(\mathrm{TOP}))^{2}\right.}{(\text { number of topside FETs })} \\
\mathrm{PON}(\mathrm{BOTTOM})=\frac{\left(\mathrm{RDS}(\mathrm{ON})(\mathrm{BOTTOM})(\mathrm{I} M \mathrm{RM}(\mathrm{BOTTOM}))^{2}\right.}{(\text { number of bottom }- \text { side FETs })}
\end{gathered}
$$

where:
$\mathrm{n}=$ number of phases.
Note that $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ increases with temperature. It is good practice to use the value of $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ at the FET's maximum junction temperature in the calculations shown above.

$$
\begin{aligned}
& I_{R M S}(T O P)=\sqrt{I_{P K}^{2}-\left(I_{P K}\right)\left(I_{\text {RIPPLE }}\right)+\frac{D}{3} I_{\text {RIPPLE }}^{2}} \\
& \operatorname{IRMS}(\text { BOTTOM })=I_{\text {PK }}^{2}-(\text { IPKIRIPPLE })+\frac{(1-D)}{3} I_{\text {RIPPLE }}^{2} \\
& \text { IRIPPLE }=\frac{\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right)\left(\mathrm{V}_{\mathrm{OUT}}\right)}{(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\mathrm{IN}}\right)}
\end{aligned}
$$

$$
\text { IPEAK }=\text { ILOAD }+\frac{\text { IRIPPLE }}{2}=\frac{\text { IOUT }}{3}+\frac{\text { IRIPPLE }}{2}
$$

where:
D = Duty cycle.
For switching power losses:

$$
\mathrm{PD}=\mathrm{nCV}{ }^{2}(\mathrm{fOSC})
$$

where:
$\mathrm{n}=$ number of switch FETs (either top or bottom),
$\mathrm{C}=\mathrm{FET}$ gate capacitance,
$\mathrm{V}=$ maximum gate drive voltage (usually $\mathrm{V}_{\mathrm{CC}}$ ),
$\mathrm{f}_{\mathrm{OSC}}=$ switching frequency.

## Layout Considerations

1. The fast response time of $\mathrm{V}^{2}$ technology increases the IC's sensitivity to noise on the $\mathrm{V}_{\mathrm{FB}}$ line. Fortunately, a simple RC filter, formed by the feedback network and a small capacitor $(100 \mathrm{pF}$ works well, shown below as C6) placed between $\mathrm{V}_{\mathrm{FB}}$ and GND, filters out most noise and provides a system practically immune to jitter. This capacitor should be located as close as possible to the IC.
2. The COMP capacitor (shown below as C13) should be connected via its own path to the IC ground. The COMP capacitor is sensitive to the intermittent ground drops caused by switching currents. A separate ground path will reduce the potential for jitter.
3. The $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor $(0.1 \mu \mathrm{~F}$ or greater, shown below as C 4 ) should be located as close as possible to the IC. This capacitor's connection to GND must be as short as possible. The $10 \Omega$ resistor (shown below as R3) should be placed close to the $\mathrm{V}_{\mathrm{CC}}$ pin.
4. The IC should not be placed in the path of switching currents. If a ground plane is used, care should be taken by the designer to ensure that the IC is not located over a ground or other current return path.

Figure 25.

## NCP1571

## Low Voltage Synchronous Buck Controller

The NCP1571 is a low voltage buck controller. It provides the control for a DC-DC power solution producing an output voltage as low as 0.980 V over a wide current range. The NCP1571-based solution is powered from 12 V with the output derived from a $2-7 \mathrm{~V}$ supply. It contains all required circuitry for a synchronous NFET buck regulator using the $\mathrm{V}^{2 \mathrm{TM}}$ control method to achieve the fastest possible transient response and best overall regulation. NCP1571 operates at a fixed internal 200 kHz frequency and is packaged in an SO-8.

This device provides undervoltage lockout protection, Soft Start, Power Good with delay, and built-in adaptive non-overlap. During undervoltage lockout, the NCP1571 controller allows the power supply output to drift down, allowing the load time to shut off. This operation distinguishes the NCP1571 from other parts in its family.

## Features

- $0.980 \mathrm{~V} \pm 1.0 \%$ Reference Voltage
- $\mathrm{V}^{2}$ Control Topology
- 200 ns Transient Response
- Programmable Soft Start
- Power Good
- Programmable Power Good Delay
- 40 ns Gate Rise and Fall Times (3.3 nF Load)
- Adaptive FET Non-Overlap Time
- Fixed 200 kHz Oscillator Frequency
- Undervoltage Lockout Holds Both Gate Outputs Low
- On/Off Control Through Use of the COMP Pin

## APPLICATION INFORMATION

## THEORY OF OPERATION

The NCP1571 is a simple, synchronous, fixed-frequency, low-voltage buck controller using the $\mathrm{V}^{2}$ control method. It provides a programmable-delay Power Good function to indicate when the output voltage is out of regulation.

## $V^{2}$ Control Method

The $\mathrm{V}^{2}$ control method uses a ramp signal generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. The $\mathrm{V}^{2}$ method differs from traditional techniques such as voltage mode control, which generates an artificial ramp, and current mode control, which generates a ramp using the inductor current.

Figure 21. ${ }^{2}$ Control with Slope Compensation

The $\mathrm{V}^{2}$ control method is illustrated in Figure 21. The output voltage generates both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output, regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, allowing the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A variation in line voltage changes the current ramp in the inductor, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since any variation in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme offers the same advantages in line transient response.

A variation in load current will affect the output voltage, modifying the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. The comparator response time and the transition speed of the main switch determine the load transient response. Unlike traditional control methods, the reaction
time to the output load step is not related to the crossover frequency of the error signal loop.
The error signal loop can have a low crossover frequency, since the transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent control loops. A voltage mode controller relies on the change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains a fixed error signal during line transients, since the slope of the ramp signal changes in this case. However, regulation of load transients still requires a change in the error signal. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.
The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope in the output ripple can lead to pulse width jitter and variation caused by both random and synchronous noise. A ramp waveform generated in the oscillator is added to the ramp signal from the output voltage to provide the proper voltage ramp at the beginning of each switching cycle. This slope compensation increases the noise immunity, particularly at duty cycles above $50 \%$.

## Start Up

The NCP1571 features a programmable Soft Start function, which is implemented through the error amplifier and the external compensation capacitor. This feature prevents stress to the power components and limits output voltage overshoot during start-up. As power is applied to the regulator, the NCP1571 undervoltage lockout circuit (UVL) monitors the IC's supply voltage ( $\mathrm{V}_{\mathrm{CC}}$ ). The UVL circuit holds both gate outputs low until $\mathrm{V}_{\mathrm{CC}}$ exceeds the 8.5 V threshold. A hysteresis function of 1.0 V improves noise immunity. The compensation capacitor connected to the COMP pin is charged by a $30 \mu \mathrm{~A}$ current source. When the capacitor voltage exceeds the 0.5 V offset of the PWM comparator, the PWM control loop will allow switching to occur. The upper gate driver GATE(H) is activated, turning on the upper MOSFET. The current ramps up through the main inductor and linearly powers the output capacitors and load. When the regulator output voltage exceeds the COMP pin voltage minus the 0.5 V PWM comparator offset
threshold and the artificial ramp, the PWM comparator terminates the initial pulse.

Figure 22. Idealized Waveforms

## Normal Operation

During normal operation, the duty cycle of the gate drivers remains approximately constant as the $\mathrm{V}^{2}$ control loop maintains the regulated output voltage under steady state conditions. Variations in supply line or output load conditions will result in changes in duty cycle to maintain regulation.

## Input Supplies

The NCP1571 can be used in applications where a 12 V supply is available along with a lower voltage supply. Often the lower voltage supply is 5 V , but it can be any voltage less than the 12 V supply minus the required gate drive voltage of the top MOSFET. The greater the difference between the two voltages, the better the efficiency due to increasing $\mathrm{V}_{\mathrm{GS}}$ available to turn on the upper MOSFET. In order to maintain power supply stability, the lower supply voltage should be at least 1.5 times the desired voltage.

A lower supply voltage between $2-7 \mathrm{~V}$ is recommended.

## Gate Charge Effect on Switching Times

When using the onboard gate drivers, the gate charge has an important effect on the switching times of the FETs. A finite amount of time is required to charge the effective capacitor seen at the gate of the FET. Therefore, the rise and fall times rise linearly with increased capacitive loading.

## Transient Response

The 200 ns reaction time of the control loop provides fast transient response to any variations in input voltage and output current. Pulse-by-pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitors during the time required to slew the inductor current. For better transient response, several high frequency and bulk output capacitors are usually used.

## Overvoltage Protection

Overvoltage protection is provided as a result of the normal operation of the $\mathrm{V}^{2}$ control method and requires no additional external components. The control loop responds
to an overvoltage condition within 200 ns , turning off the upper MOSFET and disconnecting the regulator from its input voltage. This results in a crowbar action to clamp the output voltage, preventing damage to the load. The regulator remains in this state until the overvoltage condition ceases.

## Power Good

The PWRGD pin is asserted when the output voltage is within regulation limits. Sensing for the PWRGD pin is achieved through the $\mathrm{V}_{\mathrm{FB}}$ pin. When the output voltage is rising, PWRGD goes high at $90 \%$ of the designed output voltage. When the output voltage is falling, PWRGD goes low at $70 \%$ of the designed output voltage. PWRGD is an open-collector output and should be externally pulled to logic high through a resistor to limit current to no more than 20 mA . Figure 23 shows the hysteretic nature of the PWRGD pin's operation.

Figure 23. PWRGD Assertion

## Shutdown

When the input voltage connected to $\mathrm{V}_{\mathrm{CC}}$ falls through the lower threshold of the UVLO comparator, a fault latch is set. The fault latch provides a signal that forces both GATE(H) and GATE(L) into their logic low state, producing a high-impedance output at the converter switch node. At the same time, the latch also turns on two transistors which pull down on the COMP and PGDELAY pins, quickly discharging their external capacitors, and allowing PWRGD to fall.

## CONVERTER DESIGN

## Selection of the Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the regulator output voltage. Key specifications for output capacitors are their ESR (Equivalent Series Resistance), and ESL (Equivalent Series Inductance). For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.
In order to determine the number of output capacitors the maximum voltage transient allowed during load transitions has to be specified. The output capacitors must hold the
output voltage within these limits since the inductor current can not change with the required slew rate. The output capacitors must therefore have a very low ESL and ESR.

The voltage change during the load current transient is:

$$
\Delta \mathrm{V}_{\mathrm{OUT}}=\Delta \mathrm{I} \mathrm{OUT} \times\left(\frac{\mathrm{ESL}}{\Delta \mathrm{t}}+\mathrm{ESR}+\frac{\mathrm{t} \mathrm{TR}}{\mathrm{COUT}}\right)
$$

where:
$\Delta \mathrm{I}_{\text {OUT }} / \Delta \mathrm{t}=$ load current slew rate;
$\Delta \mathrm{I}_{\text {OUT }}=$ load transient;
$\Delta t=$ load transient duration time;
ESL = Maximum allowable ESL including capacitors, circuit traces, and vias;
ESR $=$ Maximum allowable ESR including capacitors and circuit traces;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time.
The designer has to independently assign values for the change in output voltage due to ESR, ESL, and output capacitor discharging or charging. Empirical data indicates that most of the output voltage change (droop or spike depending on the load current transition) results from the total output capacitor ESR.

The maximum allowable ESR can then be determined according to the formula:

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESR}}}{\Delta \mathrm{I}_{\mathrm{OUT}}}
$$

where:
$\Delta \mathrm{V}_{\mathrm{ESR}}=$ change in output voltage due to ESR (assigned by the designer)
Once the maximum allowable ESR is determined, the number of output capacitors can be found by using the formula:

$$
\text { Number of capacitors }=\frac{\text { ESRCAP }}{\text { ESRMAX }}
$$

where:
$E S R_{C A P}=$ maximum $E S R$ per capacitor (specified in manufacturer's data sheet).
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR.
The actual output voltage deviation due to ESR can then be verified and compared to the value assigned by the designer:

$$
\Delta \mathrm{V}_{\mathrm{ESR}}=\Delta \mathrm{I}_{\mathrm{OUT}} \times \mathrm{ESR}_{\mathrm{MAX}}
$$

Similarly, the maximum allowable ESL is calculated from the following formula:

$$
\mathrm{ESL}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESL}} \times \Delta \mathrm{t}}{\Delta \mathrm{l}}
$$

## Selection of the Input Inductor

A common requirement is that the buck controller must not disturb the input voltage. One method of achieving this is by using an input inductor and a bypass capacitor. The input inductor isolates the supply from the noise generated in the switching portion of the buck regulator and also limits the inrush current into the input capacitors upon power up.

The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients. The worst case is when the load changes from no load to full load (load step), a condition under which the highest voltage change across the input capacitors is also seen by the input inductor. The inductor successfully blocks the ripple current while placing the transient current requirements on the input bypass capacitor bank, which has to initially support the sudden load change.

The minimum inductance value for the input inductor is therefore:

$$
\mathrm{L}_{\mathrm{IN}}=\frac{\Delta \mathrm{V}}{(\mathrm{dl} / \mathrm{dt}) \mathrm{MAX}}
$$

where:
$\mathrm{L}_{\mathrm{IN}}=$ input inductor value;
$\Delta \mathrm{V}=$ voltage seen by the input inductor during a full load swing;
$(\mathrm{dI} / \mathrm{dt})_{\mathrm{MAX}}=$ maximum allowable input current slew rate.
The designer must select the LC filter pole frequency so that at least 40 dB attenuation is obtained at the regulator switching frequency. The LC filter is a double-pole network with a slope of -2.0 , a roll-off rate of $-40 \mathrm{~dB} / \mathrm{dec}$, and a corner frequency:

$$
\mathrm{f}_{\mathrm{C}}=\frac{1}{2 \pi \times \sqrt{\mathrm{LC}}}
$$

where:
$\mathrm{L}=$ input inductor;
$\mathrm{C}=$ input capacitor(s).

## Selection of the Output Inductor

There are many factors to consider when choosing the output inductor. Maximum load current, core and winding losses, ripple current, short circuit current, saturation characteristics, component height and cost are all variables that the designer should consider. However, the most important consideration may be the effect inductor value has on transient response.

The amount of overshoot or undershoot exhibited during a current transient is defined as the product of the current step and the output filter capacitor ESR. Choosing the inductor value appropriately can minimize the amount of energy that must be transferred from the inductor to the capacitor or vice-versa. In the subsequent paragraphs, we will determine the minimum value of inductance required for our system and consider the trade-off of ripple current vs. transient response.

In order to choose the minimum value of inductance, input voltage, output voltage and output current must be known. Most computer applications use reasonably well regulated bulk power supplies so that, while the equations below specify $\mathrm{V}_{\text {IN(MAX) }}$ or $\mathrm{V}_{\mathrm{IN}(\mathrm{MIN})}$, it is possible to use the nominal value of $\mathrm{V}_{\text {IN }}$ in these calculations with little error.

Current in the inductor while operating in the continuous current mode is defined as the load current plus ripple current.

$$
\mathrm{IL}=\mathrm{I} \mathrm{LOAD}+\mathrm{I} \text { RIPPLE }
$$

The ripple current waveform is triangular, and the current is a function of voltage across the inductor, switch FET on-time and the inductor value. FET on-time can be defined as the product of duty cycle and switch frequency, and duty cycle can be defined as a ratio of $\mathrm{V}_{\text {OUT }}$ to $\mathrm{V}_{\text {IN }}$. Thus,

$$
\text { IRIPPLE }=\frac{\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}\right)}
$$

Peak inductor current is defined as the load current plus half of the peak current. Peak current must be less than the maximum rated FET switch current, and must also be less than the inductor saturation current. Thus, the maximum output current can be defined as:
$\operatorname{IOUT}(\mathrm{MAX})=\operatorname{ISWITCH}(\mathrm{MAX})-\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MAX})-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{(2)(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}(\mathrm{MAX})\right)}$
Since the maximum output current must be less than the maximum switch current, the minimum inductance required can be determined.

$$
L_{(M I N)}=\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})-\mathrm{V}_{\mathrm{OUT}}\right) \mathrm{V}_{\mathrm{OUT}}}{(\mathrm{fOSC})(\operatorname{ISWITCH}(\mathrm{MAX}))\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})\right)}
$$

This equation identifies the value of inductor that will provide the full rated switch current as inductor ripple current, and will usually result in inefficient system operation. The system will sink current away from the load during some portion of the duty cycle unless load current is greater than half of the rated switch current. Some value larger than the minimum inductance must be used to ensure the converter does not sink current. Choosing larger values of inductor will reduce the ripple current, and inductor value can be designed to accommodate a particular value of ripple current by replacing $\mathrm{I}_{\text {SWITCH(MAX) }}$ with a desired value of I $_{\text {RIPPLE }}:$

$$
L_{(\text {RIPPLE })}=\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{(\mathrm{fOSC})(\operatorname{IRIPPLE})\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})\right)}
$$

However, reducing the ripple current will cause transient response times to increase. The response times for both increasing and decreasing current steps are shown below.

$$
\begin{aligned}
& \text { TRESPONSE(INCREASING) }=\frac{(\mathrm{L})(\Delta \text { IOUT })}{\left(\mathrm{V}_{\text {IN }}-\text { VOUT }^{\prime}\right)} \\
& \text { TRESPONSE(DECREASING })=\frac{(\mathrm{L})(\text { (IIOUT })}{\left(\text { VOUT }^{\prime}\right)}
\end{aligned}
$$

Inductor value selection also depends on how much output ripple voltage the system can tolerate. Output ripple voltage is defined as the product of the output ripple current and the output filter capacitor ESR.

Thus, output ripple voltage can be calculated as:
$\mathrm{V}_{\text {RIPPLE }}=($ ESRC $)(\operatorname{IRIPPLE})=\frac{\left(E_{R} C\right)\left(V_{\text {IN }}-V_{\text {OUT }}\right) V_{\text {OUT }}}{(\mathrm{fOSC})(L)\left(\mathrm{V}_{\text {IN }}\right)}$

Finally, we should consider power dissipation in the output inductors. Power dissipation is proportional to the square of inductor current:

$$
P_{D}=\left(I_{L}^{2}\right)\left(E S R_{L}\right)
$$

The temperature rise of the inductor relative to the air surrounding it is defined as the product of power dissipation and thermal resistance to ambient:

$$
\Delta \mathrm{T}(\text { inductor })=(\mathrm{Ra})\left(\mathrm{P}_{\mathrm{D}}\right)
$$

Ra for an inductor designed to conduct 20 A to 30 A is approximately $45^{\circ} \mathrm{C} / \mathrm{W}$. The inductor temperature is given as:

$$
\mathrm{T} \text { (inductor) }=\Delta \mathrm{T} \text { (inductor) }+ \text { Tambient }
$$

## $\mathrm{V}_{\mathrm{Cc}}$ Bypass Filtering

A small RC filter should be added between module $\mathrm{V}_{\mathrm{CC}}$ and the $\mathrm{V}_{\mathrm{CC}}$ input to the IC. A $10 \Omega$ resistor and a $0.47 \mu \mathrm{~F}$ capacitor should be sufficient to ensure the controller IC does not operate erratically due to injected noise, and will also supply reserve charge for the onboard gate drivers.

## Input Filter Capacitors

The input filter capacitors provide a charge reservoir that minimizes supply voltage variations due to changes in current flowing through the switch FETs. These capacitors must be chosen primarily for ripple current rating.

Figure 24.
Consider the schematic shown in Figure 24. The average current flowing in the input inductor $\mathrm{L}_{\mathrm{IN}}$ for any given output current is:

$$
\operatorname{IIN}(A V E)=\operatorname{IOUT} \times \frac{V_{\text {OUT }}}{V_{\text {IN }}}
$$

Input capacitor current is positive into the capacitor when the switch FETs are off, and negative out of the capacitor when the switch FETs are on. When the switches are off, $\mathrm{I}_{\text {IN(AVE) }}$ flows into the capacitor. When the switches are on, capacitor current is equal to the per-phase output current minus $\mathrm{I}_{\mathrm{IN}(\mathrm{AVE}) \text {. }}$ If we ignore the small current variation due to the output ripple current, we can approximate the input capacitor current waveform as a square wave. We can then calculate the RMS input capacitor ripple current:
$I_{\text {RMS }(C I N)}=\sqrt{\begin{array}{l}I_{\text {INAVE }}^{2}+\frac{V_{\text {OUT }}}{V_{\text {II }}} \\ \left.\times[\text { IOUT per phase }-\operatorname{IIN(AVE)})^{2}-I_{\operatorname{INAVE})}^{2}\right]\end{array}}$
The input capacitance must be designed to conduct the worst case input ripple current. This will require several capacitors in parallel. In addition to the worst case current, attention must be paid to the capacitor manufacturer's derating for operation over temperature.

As an example, let us define the input capacitance for a 5 V to 3.3 V conversion at 10 A at an ambient temperature of $60^{\circ} \mathrm{C}$. Efficiency of $80 \%$ is assumed. Average input current in the input filter inductor is:

$$
\operatorname{IIN}(\mathrm{AVE})=(10 \mathrm{~A})(3.3 \mathrm{~V} / 5 \mathrm{~V})=6.6 \mathrm{~A}
$$

Input capacitor RMS ripple current is then

$$
\begin{aligned}
\operatorname{IIN}(\mathrm{RMS}) & =\sqrt{\begin{array}{l}
6.6^{2}+\frac{3.3 \mathrm{~V}}{5 \mathrm{~V}} \\
\times\left[(10 \mathrm{~A}-6.6 \mathrm{~A})^{2}-6.6 \mathrm{~A}^{2}\right]
\end{array}} \\
& =4.74 \mathrm{~A}
\end{aligned}
$$

If we consider a Rubycon MBZ series capacitor, the ripple current rating for a $6.3 \mathrm{~V}, 1800 \mathrm{nF}$ capacitor is 2000 mA at 100 kHz and $105^{\circ} \mathrm{C}$. We determine the number of input capacitors by dividing the ripple current by the per-capacitor current rating:

Number of capacitors $=4.74 \mathrm{~A} / 2.0 \mathrm{~A}=2.3$
A total of at least 3 capacitors in parallel must be used to meet the input capacitor ripple current requirements.

## Output Switch FETs

Output switch FETs must be chosen carefully, since their properties vary widely from manufacturer to manufacturer. The NCP1571 system is designed assuming that n -channel FETs will be used. The FET characteristics of most concern are the gate charge/gate-source threshold voltage, gate capacitance, on-resistance, current rating and the thermal capability of the package.

The onboard FET driver has a limited drive capability. If the switch FET has a high gate charge, the amount of time the FET stays in its ohmic region during the turn-on and turn-off transitions is larger than that of a low gate charge FET, with the result that the high gate charge FET will consume more power. Similarly, a low on-resistance FET will dissipate less power than will a higher on-resistance FET at a given current. Thus, low gate charge and low $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ will result in higher efficiency and will reduce generated heat.

It can be advantageous to use multiple switch FETs to reduce power consumption. By placing a number of FETs in parallel, the effective $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ is reduced, thus reducing the ohmic power loss. However, placing FETs in parallel increases the gate capacitance so that switching losses increase. As long as adding another parallel FET reduces the ohmic power loss more than the switching losses increase,
there is some advantage to doing so. However, at some point the law of diminishing returns will take hold, and a marginal increase in efficiency may not be worth the board area required to add the extra FET. Additionally, as more FETs are used, the limited drive capability of the FET driver will have to charge a larger gate capacitance, resulting in increased gate voltage rise and fall times. This will affect the amount of time the FET operates in its ohmic region and will increase power dissipation.
The following equations can be used to calculate power dissipation in the switch FETs.
For ohmic power losses due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ :

$$
\begin{gathered}
\mathrm{PON}(\mathrm{TOP})=\frac{\left(\mathrm{RDS}(\mathrm{ON})(\mathrm{TOP})(\mathrm{IRMS}(\mathrm{TOP}))^{2}\right.}{(\text { number of topside FETs })} \\
\mathrm{PON}(\mathrm{BOTTOM})=\frac{\left(\mathrm{RDS}(\mathrm{ON})(\text { BOTTOM })(\text { (RMS }(\mathrm{BOTTOM}))^{2}\right.}{(\text { number of bottom-side FETs })}
\end{gathered}
$$

where:
$\mathrm{n}=$ number of phases.
Note that $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ increases with temperature. It is good practice to use the value of $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ at the FET's maximum junction temperature in the calculations shown above.

$$
\begin{aligned}
& I_{R M S}(T O P)=\sqrt{I_{\text {PK }}^{2}-(I P K)\left(I_{\text {RIPPLE }}\right)+\frac{D}{3} I_{\text {RIPPLE }}^{2}} \\
& \operatorname{IRMS}(\text { BOTTOM })=I_{\text {PK }}^{2}-(\text { IPKIRIPPLE })+\frac{(1-\mathrm{D})}{3} I_{\text {RIPPLE }}^{2} \\
& { }_{\text {IRIPPLE }}=\frac{\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right)\left(\mathrm{V}_{\text {OUT }}\right)}{(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}\right)} \\
& I_{\text {IPEAK }}=\text { ILOAD }^{\text {I }} \frac{\text { IRIPPLE }}{2}=\frac{\text { IOUT }}{3}+\frac{\text { IRIPPLE }}{2}
\end{aligned}
$$

where:
D = Duty cycle.
For switching power losses:

$$
\mathrm{P}_{\mathrm{D}}=\mathrm{nCV}{ }^{2}(\mathrm{fOSC})
$$

where:
$\mathrm{n}=$ number of switch FETs (either top or bottom),
$\mathrm{C}=\mathrm{FET}$ gate capacitance,
$\mathrm{V}=$ maximum gate drive voltage (usually $\mathrm{V}_{\mathrm{CC}}$ ),
$f_{\text {OSC }}=$ switching frequency .

## Layout Considerations

1. The fast response time of $\mathrm{V}^{2}$ technology increases the IC's sensitivity to noise on the $\mathrm{V}_{\mathrm{FB}}$ line. Fortunately, a simple RC filter, formed by the feedback network and a small capacitor ( 100 pF works well, shown below as C6) placed between $\mathrm{V}_{\mathrm{FB}}$ and GND, filters out most noise and provides a system practically immune to jitter. This capacitor should be located as close as possible to the IC.
2. The COMP capacitor (shown below as C13) should be connected via its own path to the IC ground. The COMP capacitor is sensitive to the
intermittent ground drops caused by switching currents. A separate ground path will reduce the potential for jitter.
3. The $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor $(0.1 \mu \mathrm{~F}$ or greater, shown below as C 4 ) should be located as close as possible to the IC. This capacitor's connection to GND must be as short as possible. The $10 \Omega$ resistor (shown below as R3) should be placed close to the $\mathrm{V}_{\mathrm{CC}}$ pin.
4. The IC should not be placed in the path of switching currents. If a ground plane is used, care should be taken by the designer to ensure that the IC is not located over a ground or other current return path.

Figure 25.

## NCP5162

## General Purpose Synchronous Buck Controller

The NCP5162 is a synchronous dual N -Channel buck controller designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. It operates using a proprietary control method which allows a 100 ns response time to load transients. The NCP5162 is designed to operate over a 9-16 V range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V as the main supply for conversion.

The NCP5162 is specifically designed for high performance core logic. It includes the following features: $0.8 \%$ output tolerance, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The NCP5162 is available in a 16 pin surface mount package.

## Features

- Dual N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 2.0 A Gate Drivers
- 1.02 V Reference Voltage with $0.8 \%$ Tolerance
- 5.0 V \& 12 V Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- $\mathrm{V}^{2 \mathrm{Tm}}$ Control Topology
- Overvoltage Protection

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| SO-16 |  |  |
| 1 | Disable | This pin is internally pulled down to ground through a resistor, providing a logic 0 if left open. When pulled to $\mathrm{V}_{\mathrm{CC}}$, The output gate drivers are pulled low, powering off the external output stage. At the same time the Soft Start capacitor is slowly discharged by an internal $2.0 \mu \mathrm{~A}$ current source, setting the time out before the IC is restarted. |
| $2,3,4,6$ | NC | No connection. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND in conjunction with internal $60 \mu \mathrm{~A}$ current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $\mathrm{V}_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Boosted power for the high side gate driver. |
| 10 | $\mathrm{V}_{\text {GATE }}(\mathrm{H})$ | High FET driver pin capable of 3.0 A peak switching current. Internal circuit prevents $\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}$ and $\mathrm{V}_{\mathrm{GATE}}(\mathrm{L})$ from being in high state simultaneously. |
| 11 | PGND | High current ground for the IC. The MOSFET drivers are referenced to this pin. Input capacitor ground and the source of lower FET should be tied to this pin. |
| 12 | $\mathrm{V}_{\text {GATE(L) }}$ | Low FET driver pin capable of 3.0 A peak switching current. |
| 13 | $\mathrm{V}_{\mathrm{CC} 1}$ | Input power for the IC and low side gate driver. |
| 14 | LGND | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $\mathrm{V}_{\mathrm{FB}}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## V $^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. ${ }^{2}$ Control Diagram

The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the NCP5162 uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on
time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.
Switch on time is limited by an internal $30 \mu$ s timer, minimizing stress to the power components.

## Programmable Output

The NCP5162 has a 1.0 V reference voltage at the non-inverting input of the error amplifier, and the output voltage is programmed by connecting resistor divider feedback to the $V_{F B}$ and $V_{F F B}$ pins.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 8.95 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the GATE $(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.

If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE(H) pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.
When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the COFF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.

The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP capacitor charging to its final value. Its voltage is limited by the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

## Normal Operation

During normal operation, switch off time is constant and set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The NCP5162 $\mathrm{V}^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.

If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $V_{\text {CC1 }}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 8.95 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 8.80 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs ( $\mathrm{V}_{\mathrm{FFB}}<1.0 \mathrm{~V}$ ), the $\mathrm{V}_{\mathrm{FFB}}$ low comparator sets the FAULT latch. This causes the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=3.3 \%)$, while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board traces than occurs with constant current limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Figure 13. NCP5162 Startup with Regulator Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 14 and 15). The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function.

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 16). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
V_{\text {Power Good }}=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $V_{\text {Power Good }}$.

## Slope Compensation

The $\mathrm{V}^{2}$ control method uses a ramp signal, generated by the ESR of the output capacitors, that is proportional to the ripple current through the inductor. To maintain regulation, the $\mathrm{V}^{2}$ control loop monitors this ramp signal, through the PWM comparator, and terminates the switch on-time.
The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope presented to the PWM comparator, due to the very low ESR, can lead to pulse width jitter and variation caused by both random or synchronous noise.

Adding slope compensation to the control loop, avoids erratic operation of the PWM circuit, particularly at lower duty cycles and higher frequencies, where there is not enough ramp signal, and provides a more stable switchpoint.

The scheme that prevents that switching noise prematurely triggers the PWM circuit consists of adding a positive voltage slope to the output of the Error Amplifier (COMP pin) during an off-time cycle.

The circuit that implements this function is shown in Figure 18.

Figure 18. Small RC Filter Provides the Proper Voltage Ramp at the Beginning of each On-Time Cycle
The ramp waveform is generated through a small RC filter that provides the proper voltage ramp at the beginning of each on-time cycle. The resistors R1 and R2 in the circuit of Figure 18 form a voltage divider from the GATE(L) output, superimposing a small artificial ramp on the output of the error amplifier. It is important that the series combination $\mathrm{R} 1 / \mathrm{R} 2$ is high enough in resistance not to load down and negatively affect the slew rate on the GATE(L) pin.

## Selecting External Components

The NCP5162 can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and utilize logic level MOSFETs. Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the MOSFET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias
supplies when in the high state. In practice, the MOSFET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC} 1}=\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;
$\mathrm{V}_{\mathrm{GATE}}(\mathrm{H})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}, \mathrm{VGATE}(\mathrm{L})=12 \mathrm{~V}$
The gate drive waveforms are shown in Figure 19.

Figure 19. NCP5162 Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is RDS $_{\mathrm{ON}}$, which effects regulator efficiency and MOSFET thermal management requirements.

The power dissipated by the MOSFETs may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\mathrm{ILOAD}^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:
Power $=$ LLOAD $^{2} \times$ RDSON $\times(1-$ duty cycle $)$
Duty Cycle =

$$
\frac{\text { VOUT }+(\text { ILOAD } \times \text { RDSON OF SYNCH FET })}{\left[\begin{array}{l}
\text { VIN }+(\text { ILOAD } \times \text { RDSON OF SYNCH FET }) \\
-(\text { ILOAD } \times \text { RDSON OF SWITCH FET })
\end{array}\right]}
$$

## Off Time Capacitor (Coff)

The Coff timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\text {OFF }}$ timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous MOSFET

A Schottky diode may be placed in parallel with the synchronous MOSFET to conduct the inductor current upon turn off of the switching MOSFET to improve efficiency. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense (see Figure 8, channel 2). The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=\mathrm{V}_{\mathrm{BD}} \times$ ILOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the NCP5162 demonstration board as shown in Figure 8;
Power $=1.6 \mathrm{~V} \times 13 \mathrm{~A} \times 100 \mathrm{~ns} \times 233 \mathrm{kHz}=0.48 \mathrm{~W}$
This is only $1.3 \%$ of the 36.4 W being delivered to the load.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:

$$
\text { Thermal Impedance }=\frac{T_{J U N C T I O N(M A X)}-\text { TAMBIENT }^{\text {Power }}}{}
$$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 20. Filter Components

Figure 21. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGND).
2. Connect pin 11 (PGND) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGND).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGND).
6. Connect the $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
7. Place 5.0 V input capacitors close to the switching MOSFET and synchronous MOSFET.
Route gate drive signals $\mathrm{V}_{\operatorname{GATE}(\mathrm{H})}$ (pin 10) and $\mathrm{V}_{\text {GATE(L) }}$ (pin 12 when used) with traces that are a minimum of 0.025 inches wide.

Figure 22. Layout Guidelines

## CS5421

## Dual Out-of-Phase Synchronous Buck Controller with Remote Sense

The CS5421 is a dual N -channel synchronous buck regulator controller. It contains all the circuitry required for two independent buck regulators and utilizes the $\mathrm{V}^{2 \mathrm{TM}}$ control method to achieve the fastest possible transient response and best overall regulation, while using the least number of external components. The CS5421 features out-of-phase synchronization between the channels, reducing the input filter requirement. The CS5421 also provides undervoltage lockout, Soft Start, built in adaptive FET non-overlap and remote sense capability. The part is available in a 16 Lead SO Narrow package allowing the designer to minimize solution size.

## Features

- $\mathrm{V}^{2}$ Control Topology
- 150 ns Transient Response
- Programmable Soft Start
- 25 ns Gate Rise and Fall Times (with 1.0 nF load)
- 40 ns Adaptive FET Nonoverlap Time
- 100\% Duty Cycle for Enhanced Transient Response
- Internal Slope Compensation
- $1.0 \mathrm{~V} 0.8 \%$ and $2.0 \%$ Error Amplifier References
- 150 kHz to 750 kHz Programmable Frequency Operation
- Switching Frequency Set by Single Resistor
- Out-Of-Phase Synchronization Between the Channels Reduces the Input Filter Requirement
- Undervoltage Lockout
- On/Off Control Through Use of the COMP Pins

| 10 | $\mathrm{V}_{\text {FB2 }}$ | Error amplifier inverting input for channel 2. |
| 11 | $\mathrm{V}_{\text {FFB2 }}$ | Input for the channel 2 PWM comparator. |
| 12 | Rosc | A resistor from this pin to ground sets switching frequency. |
| 13 | $V_{\text {cc }}$ | Input Power supply pin. |
| 14 | PGND2 | High Current ground for the GATE(H)2 and GATE(L)2 pins. |
| 15 | GATE(L)2 | Low Side Synchronous FET driver pin for the channel 2 FET. |
| 16 | GATE(H)2 | High Side Switch FET driver pin for the channel 2 FET. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

The CS5421 is a dual power supply controller that utilizes the $\mathrm{V}^{2}$ control method. Two synchronous $\mathrm{V}^{2}$ buck regulators can be built using a single controller. The fixed-frequency architecture, driven from a common oscillator, ensures a $180^{\circ}$ phase differential between channels.

## $V^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. The $\mathrm{V}^{2}$ method differs from traditional techniques such as voltage mode control, which generates an artificial ramp, and current mode control, which generates a ramp using the inductor current.

Figure 3. ${ }^{2}$ Control with Slope Compensation
The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage generates both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output, regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, allowing the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A variation in line voltage changes the current ramp in the inductor, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since any variation in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme offers the same advantages in line transient response.

A variation in load current will affect the output voltage, modifying the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. The comparator response time and the transition speed of the main switch determine the load transient response. Unlike traditional control methods, the reaction
time to the output load step is not related to the crossover frequency of the error signal loop.
The error signal loop can have a low crossover frequency, since the transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation is drastically improved because there are two independent control loops. A voltage mode controller relies on the change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulations. A current mode controller maintains a fixed error signal during line transients, since the slope of the ramp signal changes in this case. However, regulation of load transients still requires a change in the error signal. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.
The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope in the output ripple can lead to pulse width jitter and variation caused by both random and synchronous noise. A ramp waveform generated in the oscillator is added to the ramp signal from the output voltage to provide the proper voltage ramp at the beginning of each switching cycle. This slope compensation increases the noise immunity particularly at higher duty cycle (above 50\%).

## Startup

The CS5421 features a programmable Soft Start function, which is implemented through the Error Amplifier and the external Compensation Capacitor. This feature prevents stress to the power components and overshoot of the output voltage during start-up. As power is applied to the regulator, the CS5421 Undervoltage Lockout circuit (UVL) monitors the IC's supply voltage $\left(\mathrm{V}_{\mathrm{CC}}\right)$. The UVL circuit prevents the MOSFET gates from switching until $\mathrm{V}_{\mathrm{CC}}$ exceeds the 8.6 V threshold. A hysteresis function of 800 mV improves noise immunity. The Compensation Capacitor connected to the COMP pin is charged by a $30 \mu \mathrm{~A}$ current source. When the capacitor voltage exceeds the 0.4 V offset of the PWM comparator, the PWM control loop will allow switching to occur. The upper gate driver GATE $(\mathrm{H})$ is activated turning on the upper MOSFET. The current then ramps up through the main inductor and linearly powers the output capacitors and load. When the regulator output voltage exceeds the COMP pin voltage minus the 0.4 V PWM comparator offset
threshold and the artificial ramp, the PWM comparator terminates the initial pulse.

Figure 4. Idealized Waveforms

## Normal Operation

During normal operation, the duty cycle of the gate drivers remains approximately constant as the $\mathrm{V}^{2}$ control loop maintains the regulated output voltage under steady state conditions. Variations in supply line or output load conditions will result in changes in duty cycle to maintain regulation.

## Gate Charge Effect on Switching Times

When using the onboard gate drivers, the gate charge has an important effect on the switching times of the FETs. A finite amount of time is required to charge the effective capacitor seen at the gate of the FET. Therefore, the rise and fall times rise linearly with increased capacitive loading, according to the following graphs.

Figure 5. Average Rise and Fall Times

## Transient Response

The 200 ns reaction time of the control loop provides fast transient response to any variations in input voltage and output current. Pulse-by-pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitors during the time required to slew the inductor
current. For better transient response, several high frequency and bulk output capacitors are usually used.

## Out-of-Phase Synchronization

In out-of-phase synchronization, the turn-on of the second channel is delayed by half the switching cycle. This delay is supervised by the oscillator, which supplies a clock signal to the second channel which is $180^{\circ}$ out of phase with the clock signal of the first channel.
The advantages of out-of-phase synchronization are many. Since the input current pulses are interleaved with one another, the overlap time is reduced. The effect of this overlap reduction is to reduce the input filter requirement, allowing the use of smaller components. In addition, since peak current occurs during a shorter time period, emitted EMI is also reduced, thereby reducing shielding requirements.

## Overvoltage Protection

Overvoltage Protection (OVP) is provided as a result of the normal operation of the $\mathrm{V}^{2}$ control method and requires no additional external components. The control loop responds to an overvoltage condition within 200 ns , turning off the upper MOSFET and disconnecting the regulator from its input voltage. This results in a crowbar action to clamp the output voltage preventing damage to the load. The regulator remains in this state until the overvoltage condition ceases.

## Remote Sense

When the load is far away from the regulator, the long feedback traces can cause additional voltage drop and induce noise which affects the accuracy of voltage regulation. A separate signal ground is provided to improve the noise immunity of remote voltage sensing. The 1.0 V reference voltage of the error amplifiers is directly referenced to this ground and no large currents flow through this ground during normal operation. The noise immunity and regulation accuracy can be improved significantly.

## Output Enable

On/Off control of the regulator outputs can be implemented by pulling the COMP pins low. The COMP pins must be driven below the 0.4 V PWM comparator offset voltage in order to disable the switching of the GATE drivers.

## DESIGN GUIDELINES

## Definition of the design specifications

The output voltage tolerance can be affected by any or all of the following reasons:

1. buck regulator output voltage setpoint accuracy;
2. output voltage change due to discharging or charging of the bulk decoupling capacitors during a load current transient;
3. output voltage change due to the ESR and ESL of the bulk and high frequency decoupling capacitors, circuit traces, and vias;
4. output voltage ripple and noise.

Budgeting the tolerance is left up to the designer who must take into account all of the above effects and provide an output voltage that will meet the specified tolerance at the load.

The designer must also ensure that the regulator component temperatures are kept within the manufacturer's specified ratings at full load and maximum ambient temperature.

## Selecting Feedback Divider Resistors

Figure 6. Selecting Feedback Divider Resistors
The feedback pins $\left(\mathrm{V}_{\mathrm{FB} 1(2)}\right)$ are connected to externalresistor dividers to set the output voltages. The error amplifier is referenced to 1.0 V and the output voltage is determined by selecting resistor divider values. Resistor R1 is selected based on a design trade-off between efficiency and output voltage accuracy. The output voltage error can be estimated due to the bias current of the error amplifier neglecting resistor tolerance:

$$
\text { Error\% }=\frac{1 \times 10^{-6} \times \mathrm{R} 1}{1.0} \times 100 \%
$$

R2 can be sized after R1 has been determined:

$$
\mathrm{R} 2=\mathrm{R} 1\left(\frac{\mathrm{~V} \text { OUT }}{1.0}-1.0\right)
$$

## Calculating Duty Cycle

The duty cycle of a buck converter (including parasitic losses) is given by the formula:

$$
\text { Duty Cycle }=\mathrm{D}=\frac{\mathrm{V}_{\mathrm{OUT}}+\left(\mathrm{V}_{\mathrm{HFET}}+\mathrm{V}_{\mathrm{L}}\right)}{\mathrm{V}_{\mathrm{IN}}+\mathrm{V}_{\mathrm{LFE}}-\mathrm{V}_{\mathrm{HFET}}-\mathrm{V}_{\mathrm{L}}}
$$

where:
$\mathrm{V}_{\text {OUT }}=$ buck regulator output voltage;
$\mathrm{V}_{\text {HFET }}=$ high side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$;
$\mathrm{V}_{\mathrm{L}}=$ output inductor voltage drop due to inductor wire DC resistance;
$\mathrm{V}_{\mathrm{IN}}=$ buck regulator input voltage;
$\mathrm{V}_{\mathrm{LFET}}=$ low side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$.

Figure 7. Switching Frequency

## Selecting the Switching Frequency

Selecting the switching frequency is a trade-off between component size and power losses. Operation at higher switching frequencies allows the use of smaller inductor and capacitor values. Nevertheless, it is common to select lower frequency operation because a higher frequency results in lower efficiency due to MOSFET gate charge losses. Additionally, the use of smaller inductors at higher frequencies results in higher ripple current, higher output voltage ripple, and lower efficiency at light load currents.

The value of the oscillator resistor is designed to be linearly related to the switching period. If the designer prefers not to use Figure 7 to select the necessary resistor, the following equation quite accurately predicts the proper resistance for room temperature conditions.

$$
\text { ROSC }=\frac{21700-\mathrm{fSW}}{2.31 \mathrm{fSW}}
$$

where:
$\mathrm{R}_{\mathrm{OSC}}=$ oscillator resistor in $\mathrm{k} \Omega$;
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency in kHz .

## Selection of the Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response. There are many factors to consider in selecting the inductor including cost, efficiency, EMI and ease of manufacture. The inductor must be able to handle the peak current at the switching frequency without saturating, and the copper resistance in the winding should be kept as low as possible to minimize resistive power loss.

There are a variety of materials and types of magnetic cores that could be used for this application. Among them are ferrites, molypermalloy cores (MPP), amorphous and powdered iron cores. Powdered iron cores are very commonly used. Powdered iron cores are very suitable due
to its high saturation flux density and have low loss at high frequencies, a distributed gap and exhibit very low EMI.

The minimum value of inductance which prevents inductor saturation or exceeding the rated FET current can be calculated as follows:

$$
\mathrm{L}_{\mathrm{MIN}}=\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})-\mathrm{V}_{\mathrm{OUT}}\right) \mathrm{V}_{\mathrm{OUT}}}{\mathrm{fSW} \times \mathrm{V}_{\text {IN }}(\mathrm{MIN}) \times \operatorname{ISW}(\mathrm{MAX})}
$$

where:
$\mathrm{L}_{\mathrm{MIN}}=$ minimum inductance value;
$\mathrm{V}_{\mathrm{IN}(\mathrm{MIN})}=$ minimum design input voltage;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency;
$\mathrm{I}_{\mathrm{SW}(\mathrm{MAX})}$ - maximum design switch current.
The inductor ripple current can then be determined:

$$
\Delta_{\mathrm{L}}=\frac{\mathrm{VOUT} \times(1.0-\mathrm{D})}{\mathrm{L} \times \mathrm{fSW}}
$$

where:
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{L}=$ inductor value;
$\mathrm{D}=$ duty cycle.
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency
The designer can now verify if the number of output capacitors will provide an acceptable output voltage ripple ( $1.0 \%$ of output voltage is common). The formula below is used:

$$
\Delta \mathrm{I}_{\mathrm{L}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\mathrm{ESR}_{\mathrm{MAX}}}
$$

Rearranging we have:

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\Delta \mathrm{I}_{\mathrm{L}}}
$$

where:
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR;
$\Delta \mathrm{V}_{\text {OUT }}=1.0 \% \times \mathrm{V}_{\text {OUT }}=$ maximum allowable output voltage ripple ( budgeted by the designer );
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage.
The number of output capacitors is determined by:

$$
\text { Number of capacitors }=\frac{\mathrm{ESR} \mathrm{CAP}}{\mathrm{ESR}} \mathrm{MAX}
$$

where:
$E S R_{\text {CAP }}=$ maximum ESR per capacitor (specified in manufacturer's data sheet).
The designer must also verify that the inductor value yields reasonable inductor peak and valley currents (the inductor current is a triangular waveform):

$$
\mathrm{I}(\mathrm{PEAK})=\mathrm{IOUT}+\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2.0}
$$

where:
$\mathrm{I}_{\mathrm{L}(\mathrm{PEAK})}=$ inductor peak current;
IOUT $=$ load current;
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current.

$$
\mathrm{IL}(\mathrm{VALLEY})=\mathrm{IOUT}-\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2.0}
$$

where:
$\mathrm{I}_{\mathrm{L}(\text { VALLEY })}=$ inductor valley current.

## Selection of the Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the regulator output voltage. Key specifications for output capacitors are their ESR (Equivalent Series Resistance), and ESL (Equivalent Series Inductance). For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

In order to determine the number of output capacitors the maximum voltage transient allowed during load transitions has to be specified. The output capacitors must hold the output voltage within these limits since the inductor current can not change with the required slew rate. The output capacitors must therefore have a very low ESL and ESR.

The voltage change during the load current transient is:

$$
\Delta \mathrm{V}_{\mathrm{OUT}}=\Delta \mathrm{I} \mathrm{OUT} \times\left(\frac{\mathrm{ESL}}{\Delta \mathrm{t}}+\mathrm{ESR}+\frac{\mathrm{tTR}}{\mathrm{COUT}}\right)
$$

where:
$\Delta \mathrm{I}_{\text {OUT }} / \Delta \mathrm{t}=$ load current slew rate;
$\Delta \mathrm{I}_{\text {OUT }}=$ load transient;
$\Delta \mathrm{t}=$ load transient duration time;
$\mathrm{ESL}=$ Maximum allowable ESL including capacitors, circuit traces, and vias;
ESR $=$ Maximum allowable ESR including capacitors and circuit traces;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time.
The designer has to independently assign values for the change in output voltage due to ESR, ESL, and output capacitor discharging or charging. Empirical data indicates that most of the output voltage change (droop or spike depending on the load current transition) results from the total output capacitor ESR.

The maximum allowable ESR can then be determined according to the formula:

$$
\mathrm{ESR}_{\text {MAX }}=\frac{\Delta \mathrm{V}_{\mathrm{ESR}}}{\Delta \mathrm{I} \text { OUT }}
$$

where:
$\Delta \mathrm{V}_{\mathrm{ESR}}=$ change in output voltage due to ESR (assigned by the designer)
Once the maximum allowable ESR is determined, the number of output capacitors can be found by using the formula:

$$
\text { Number of capacitors }=\frac{\text { ESRCAP }}{\text { ESRMAX }}
$$

where:
$\mathrm{ESR}_{\mathrm{CAP}}=$ maximum ESR per capacitor (specified in manufacturer's data sheet).
$\mathrm{ESR}=$ maximum allowable ESR.

The actual output voltage deviation due to ESR can then be verified and compared to the value assigned by the designer:

$$
\Delta \mathrm{V}_{\mathrm{ESR}}=\Delta \mathrm{I} \text { OUT } \times \text { ESRMAX }
$$

Similarly, the maximum allowable ESL is calculated from the following formula:

$$
\mathrm{ESL}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESL}} \times \Delta \mathrm{t}}{\Delta \mathrm{I}}
$$

## Selection of the Input Inductor

A common requirement is that the buck controller must not disturb the input voltage. One method of achieving this is by using an input inductor and a bypass capacitor. The input inductor isolates the supply from the noise generated in the switching portion of the buck regulator and also limits the inrush current into the input capacitors upon power up. The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients. The worst case is when the load changes from no load to full load (load step), a condition under which the highest voltage change across the input capacitors is also seen by the input inductor. The inductor successfully blocks the ripple current while placing the transient current requirements on the input bypass capacitor bank, which has to initially support the sudden load change.

The minimum inductance value for the input inductor is therefore:

$$
\operatorname{LIN}=\frac{\Delta V}{(\mathrm{dl} / \mathrm{dt}) \mathrm{MAX}}
$$

where:
$\mathrm{L}_{\mathrm{IN}}=$ input inductor value;
$\Delta \mathrm{V}=$ voltage seen by the input inductor during a full load swing;
$(\mathrm{dI} / \mathrm{dt})_{\mathrm{MAX}}=$ maximum allowable input current slew rate.
The designer must select the LC filter pole frequency so that at least 40 dB attenuation is obtained at the regulator switching frequency. The LC filter is a double-pole network with a slope of -2 , a roll-off rate of $-40 \mathrm{~dB} / \mathrm{dec}$, and a corner frequency:

$$
\mathrm{ff}_{\mathrm{C}}=\frac{1.0}{2 \pi \times \sqrt{\mathrm{LC}}}
$$

where:
$\mathrm{L}=$ input inductor;
$\mathrm{C}=$ input capacitor(s).

## SELECTION OF THE POWER FET

## FET Basics

The use of the MOSFET as a power switch is propelled by two reasons: 1) Its very high input impedance; and 2) Its very fast switching times. The electrical characteristics of a MOSFET are considered to be those of a perfect switch. Control and drive circuitry power is therefore reduced. Because the input impedance is so high, it is voltage driven.

The input of the MOSFET acts as if it were a small capacitor, which the driving circuit must charge at turn on. The lower the drive impedance, the higher the rate of rise of $\mathrm{V}_{\mathrm{GS}}$, and the faster the turn-on time. Power dissipation in the switching MOSFET consists of 1) conduction losses, 2) leakage losses, 3) turn-on switching losses, 4) turn-off switching losses, and 5) gate-transitions losses. The latter three losses are proportional to frequency.

The most important aspect of FET performance is the Static Drain-To-Source On-Resistance ( $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ ), which effects regulator efficiency and FET thermal management requirements. The On-Resistance determines the amount of current a FET can handle without excessive power dissipation that may cause overheating and potentially catastrophic failure. As the drain current rises, especially above the continuous rating, the On-Resistance also increases. Its positive temperature coefficient is between $+0.6 \% /{ }^{\circ} \mathrm{C}$ and $+0.85 \% /{ }^{\circ} \mathrm{C}$. The higher the On-Resistance the larger the conduction loss is. Additionally, the FET gate charge should be low in order to minimize switching losses and reduce power dissipation.

Both logic level and standard FETs can be used.
Voltage applied to the FET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the FET gates will be driven rail-to-rail due to overshoot caused by the capacitive load they present to the controller IC.

## Selection of the Switching (Upper) FET

The designer must ensure that the total power dissipation in the FET switch does not cause the power component's junction temperature to exceed $150^{\circ} \mathrm{C}$.

The maximum RMS current through the switch can be determined by the following formula:

$$
\operatorname{IRMS}(\mathrm{H})=\sqrt{\frac{\left[\begin{array}{l}
\mathrm{IL}(\mathrm{PEAK})^{2}+(\mathrm{IL}(\mathrm{PEAK}) \times \mathrm{I}(\mathrm{VALLEY})) \\
+\mathrm{I}(\mathrm{VALLEY})^{2} \times \mathrm{D}
\end{array}\right]}{3.0}}
$$

where:
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{I}_{\mathrm{L}(\text { PEAK })}=$ inductor peak current;
$\mathrm{I}_{\mathrm{L}(\text { VALLEY })}=$ inductor valley current;
D = duty cycle.
Once the RMS current through the switch is known, the switching MOSFET conduction losses can be calculated:

$$
\operatorname{PRMS}(\mathrm{H})=\operatorname{IRMS}(\mathrm{H})^{2} \times \operatorname{RDS}(\mathrm{ON})
$$

where:
$\mathrm{P}_{\text {RMS }}(\mathrm{H})=$ switching MOSFET conduction losses;
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=\mathrm{FET}$ drain-to-source on-resistance

The upper MOSFET switching losses are caused during MOSFET switch-on and switch-off and can be determined by using the following formula:

$$
\begin{aligned}
\mathrm{PSWH} & =\operatorname{PSWH}(\mathrm{ON})+\mathrm{PSWH}(\mathrm{OFF}) \\
& =\frac{\mathrm{V}_{\text {IN }} \times \operatorname{IOUT} \times(\mathrm{tRISE}+\mathrm{tFALL})}{6.0 \mathrm{~T}}
\end{aligned}
$$

where:
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{OFF})}=$ upper MOSFET switch-off losses;
$\mathrm{V}_{\mathrm{IN}}=$ input voltage;
$\mathrm{I}_{\text {OUT }}=$ load current;
$t_{\text {RISE }}=$ MOSFET rise time (from FET manufacturer's
switching characteristics performance curve);
$\mathrm{t}_{\text {FALL }}=$ MOSFET fall time (from FET manufacturer's
switching characteristics performance curve);
$\mathrm{T}=1 / \mathrm{f}_{\mathrm{SW}}=$ period.
The total power dissipation in the switching MOSFET can then be calculated as:

$$
\text { PHFET(TOTAL) }=\text { PRMS }(\mathrm{H})+\mathrm{PSWH}(\mathrm{ON})+\mathrm{PSWH}(\mathrm{OFF})
$$

where:
$\mathrm{P}_{\text {HFET(TOTAL) }}=$ total switching (upper) MOSFET losses;
$\mathrm{P}_{\text {RMS }}(\mathrm{H})=$ upper MOSFET switch conduction Losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{OFF})}=$ upper MOSFET switch-off losses;
Once the total power dissipation in the switching FET is known, the maximum FET switch junction temperature can be calculated:

$$
\mathrm{T}_{\mathrm{J}}=\mathrm{T}_{\mathrm{A}}+\left[\mathrm{PHFET}(\mathrm{TOTAL}) \times \mathrm{R}_{\Theta} \mathrm{JA}\right]
$$

where:
$\mathrm{T}_{\mathrm{J}}=\mathrm{FET}$ junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$\mathrm{P}_{\text {HFET(TOTAL) }}=$ total switching (upper) FET losses;
$\mathrm{R}_{\Theta \mathrm{JA}}=$ upper FET junction-to-ambient thermal resistance.

## Selection of the Synchronous (Lower) FET

The switch conduction losses for the lower FET can be calculated as follows:

$$
\begin{aligned}
\operatorname{PRMS}(\mathrm{L}) & =\mathrm{I}_{\mathrm{RMS}^{2}} \times \mathrm{R}_{\mathrm{DS}(\mathrm{ON})} \\
& =[\mathrm{IOUT} \times \sqrt{(1.0-\mathrm{D})}]^{2} \times \mathrm{RDS}(\mathrm{ON})
\end{aligned}
$$

where:
$\mathrm{P}_{\text {RMS(L) }}=$ lower MOSFET conduction losses;
$\mathrm{I}_{\text {OUT }}=$ load current;
D = Duty Cycle;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=$ lower FET drain-to-source on-resistance.
The synchronous MOSFET has no switching losses, except for losses in the internal body diode, because it turns on into near zero voltage conditions. The MOSFET body diode will conduct during the non-overlap time and the resulting power dissipation (neglecting reverse recovery losses) can be calculated as follows:

$$
\text { PSWL }=V_{S D} \times \operatorname{ILOAD} \times \text { non-overlap time } \times f \text { SW }
$$

where:
$\mathrm{P}_{\text {SWL }}=$ lower FET switching losses;
$\mathrm{V}_{\mathrm{SD}}=$ lower FET source-to-drain voltage;
$\mathrm{I}_{\text {LOAD }}=$ load current;
Non-overlap time $=\operatorname{GATE}(\mathrm{L})$-to-GATE(H) or GATE(H)-to-GATE(L) delay (from CS5421 data sheet Electrical Characteristics section);
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency.
The total power dissipation in the synchronous (lower) MOSFET can then be calculated as:

$$
\text { PLFET(TOTAL) }=\text { PRMS(L) }+ \text { PSWL }
$$

where:
$P_{\text {LFET(TOTAL) }}=$ Synchronous (lower) FET total losses;
$\mathrm{P}_{\mathrm{RMS}(\mathrm{L})}=$ Switch Conduction Losses;
$\mathrm{P}_{\text {SWL }}=$ Switching losses.
Once the total power dissipation in the synchronous FET is known the maximum FET switch junction temperature can be calculated:

$$
\mathrm{T}_{\mathrm{J}}=\mathrm{T}_{\mathrm{A}}+\left[\mathrm{PLFET}(\mathrm{TOTAL}) \times \mathrm{R}_{\Theta J A}\right]
$$

where:
$\mathrm{T}_{\mathrm{J}}=$ MOSFET junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$\left.\mathrm{P}_{\text {LFET }(\text { TOTAL }}\right)=$ total synchronous (lower) FET losses;
$\mathrm{R}_{\Theta \mathrm{JA}}=$ lower FET junction-to-ambient thermal resistance.

## Control IC Power Dissipation

The power dissipation of the IC varies with the MOSFETs used, $\mathrm{V}_{\mathrm{CC}}$, and the CS5421 operating frequency. The average MOSFET gate charge current typically dominates the control IC power dissipation.

The IC power dissipation is determined by the formula:

$$
\begin{aligned}
\operatorname{PCONTROL}(\mathrm{IC}) & =\operatorname{ICC1} \mathrm{V}_{\mathrm{CC} 1}+\operatorname{PGATE}(\mathrm{H}) 1 \\
& +\operatorname{PGATE}(\mathrm{L}) 1+\operatorname{PGATE}(\mathrm{H}) 2+\operatorname{PGATE}(\mathrm{L}) 2
\end{aligned}
$$

where:
$\mathrm{P}_{\text {CONTROL(IC) }}=$ control IC power dissipation;
$\mathrm{I}_{\mathrm{CC} 1}=\mathrm{IC}$ quiescent supply current;
$\mathrm{V}_{\mathrm{CC} 1}=\mathrm{IC}$ supply voltage;
$\mathrm{P}_{\text {GATE(H) }}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{P}_{\text {GATE(L) }}=$ lower MOSFET gate driver (IC) losses.
The upper (switching) MOSFET gate driver (IC) losses are:

$$
\operatorname{PGATE}(\mathrm{H})=\operatorname{QGATE}(\mathrm{H}) \times \mathrm{fSW} \times \mathrm{V}_{\mathrm{CC}}
$$

where:
$\mathrm{P}_{\text {GATE(H) }}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\mathrm{GATE}(\mathrm{H})}=$ total upper MOSFET gate charge at $\mathrm{V}_{\mathrm{CC}}$;
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency;
The lower (synchronous) MOSFET gate driver (IC) losses are:

$$
\operatorname{PGATE}(\mathrm{L})=\operatorname{QGATE}_{\mathrm{G}}(\mathrm{~L}) \times \mathrm{fSW} \times \mathrm{V}_{\mathrm{GATE}}(\mathrm{~L})
$$

where:
$\mathrm{P}_{\mathrm{GATE}(\mathrm{L})}=$ lower MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\mathrm{GATE}(\mathrm{L})}=$ total lower MOSFET gate charge at $\mathrm{V}_{\mathrm{CC}}$;
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency;
The junction temperature of the control IC is primarily a function of the PCB layout, since most of the heat is removed through the traces connected to the pins of the IC.

## Adding External Slope Compensation

Today's voltage regulators are expected to meet very stringent load transient requirements. One of the key factors in achieving tight dynamic voltage regulation is low ESR. Low ESR at the regulator output results in low output voltage ripple. The consequence is, however, that very little voltage ramp exists at the control IC feedback pin ( $\mathrm{V}_{\mathrm{FB}}$ ), resulting in increased regulator sensitivity to noise and the potential for loop instability. In applications where the internal slope compensation is insufficient, the performance of the CS5421-based regulator can be improved through the addition of a fixed amount of external slope compensation at the output of the PWM Error Amplifier (the COMP pin) during the regulator off-time. Referring to Figure 7, the amount of voltage ramp at the COMP pin is dependent on the gate voltage of the lower (synchronous) FET and the value of resistor divider formed by R1 and R2.
$\mathrm{V}_{\text {SLOPECOMP }}=\mathrm{V}_{\text {GATE }}(\mathrm{L}) \times\left(\frac{\mathrm{R} 2}{\mathrm{R} 1+\mathrm{R} 2}\right) \times\left(1.0-\mathrm{e}^{\frac{-\mathrm{t}}{\tau}}\right)$
where:
$\mathrm{V}_{\text {SLOPECOMP }}=$ amount of slope added;
$\mathrm{V}_{\mathrm{GATE}(\mathrm{L})}=$ lower MOSFET gate voltage;
R1, R2 = voltage divider resistors;
$\mathrm{t}=\mathrm{t}_{\mathrm{ON}}$ or $\mathrm{t}_{\text {OFF }}$ (switch off-time);
$\tau=\mathrm{RC}$ constant determined by C 1 and the parallel combination of R1, R 2 neglecting the low driver output impedance.
The artificial voltage ramp created by the slope compensation scheme results in improved control loop stability provided that the RC filter time constant is smaller than the off-time cycle duration (time during which the lower MOSFET is conducting). It is important that the series combination of R1 and R2 is high enough in resistance to avoid loading the GATE(L) pin.

Figure 8. Small RC Filter Provides the Proper Voltage Ramp at the Beginning of Each On-Time Cycle

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFET

As the plastic packaging of a semiconductor will deteriorate at high temperatures, it is necessary to limit the junction temperature of the control IC and power MOSFETs to maintain high reliability. Most semiconductor devices have a maximum junction temperature of $150^{\circ} \mathrm{C}$, and manufacturers recommend operating their products at lower temperatures if at all possible.
Power dissipation in a semiconductor devices results in the generation of heat in the pin junctions at the surface of the chip. This heat is transferred to the surface of the IC package, but a thermal gradient exists due to the resistive properties of the package molding compound. The magnitude of the thermal gradient is expressed in manufacturer's data sheets as $\Theta_{\mathrm{JA}}$, or junction-to-air thermal resistance. The on-chip junction temperature can be calculated if $\Theta_{\mathrm{JA}}$, the air temperature at the surface of the IC, and the on-chip power dissipation are known.

$$
T_{J}=T_{A}+(P D \Theta J A)
$$

where:
TJ = IC or FET junction temperature (in degrees C);
TA = ambient temperature (in degrees C);
$\mathrm{PD}=$ power dissipated by part in question (in watts);
$\Theta_{\mathrm{JA}}=$ junction-to-ambient thermal resistance (in degrees C per watt).
The value for $\Theta_{\mathrm{JA}}$ can be found in the Absolute Maximum Ratings table on page 1637 of this datasheet. Note that this value is different for every package style and every manufacturer.
The junction temperature should be calculated for all semiconductor devices as a part of the design phase in order to ensure that the devices are operated below the manufacturer's maximum junction temperature specification. If any component's temperature exceeds the manufacturer's maximum temperature, some form of heatsink will be required.

Heatsinking improves the thermal performance of any component. Adding a heatsink will reduce the magnitude of $\Theta_{\mathrm{JA}}$ by providing a larger surface area for the transfer of heat from the component to the surrounding air. Typical heatsinking techniques include the use of commercial heatsinks for devices in TO-220 packages, or printed circuit board techniques such as thermal bias and large copper foil areas for surface mount packages.
When choosing a heatsink, it is important to realize that $\Theta_{\mathrm{JA}}$ is comprised of several components:

$$
\Theta_{\mathrm{JA}}=\Theta_{\mathrm{JC}}+\Theta_{\mathrm{CS}}+\Theta_{\mathrm{SA}}
$$

where:
$\Theta_{\mathrm{JC}}=$ the junction-to-case thermal resistance (in degrees C per watt);
$\Theta_{\mathrm{CS}}=$ the case-to-sink thermal resistance (in degrees C per watt);
$\Theta_{\mathrm{SA}}=$ the sink-to-ambient thermal resistance (in degrees C per watt).
The value for $\Theta_{\mathrm{JC}}$ is included in the component manufacturer's data sheets. Its value is dependent on the mold compound and lead frames used in assembly of the semiconductor device in question.
$\Theta_{\mathrm{CS}}$ is the thermal impedance from the surface of the case to the heatsink. This component of the thermal resistance is dependent on the roughness of the heatsink and component as well as on the pressure applied between the two. $\Theta_{\mathrm{CS}}$ can be reduced by using thermal pads or by applying a thin layer of thermal grease between the case and the heatsink. Such materials reduce the air gap normally found between the heatsink and the case and provide a better path for thermal energy. Values of $\Theta_{\mathrm{CS}}$ are found in catalogs published by manufacturers of heatsinks and thermal compounds.

Finally, $\Theta_{\mathrm{SA}}$ is the thermal impedance from the heatsink to the ambient environment. $\Theta_{\mathrm{SA}}$ is the important parameter when selecting a heatsink. Low values of $\Theta_{\mathrm{SA}}$ allow increased power dissipation without exceeding the maximum junction temperature of the component. Values of $\Theta_{\text {SA }}$ are found in catalogs published by heatsink manufacturers.

The basic equation for selecting a heatsink is:

$$
P=\frac{T J-T_{A}}{\Theta J C+\Theta C S+\Theta S A}
$$

where:
$\mathrm{P}_{\mathrm{D}}=$ power dissipated by part in question (in watts);
$\mathrm{T}_{\mathrm{J}}=\mathrm{IC}$ or FET junction temperature (in degrees C );
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature (in degrees C );
$\Theta_{\mathrm{JC}}=$ the junction-to-case thermal resistance (in degrees C per watt);
$\Theta_{\mathrm{CS}}=$ the case-to-sink thermal resistance (in degrees C per watt);
$\Theta_{\mathrm{SA}}=$ the sink-to-ambient thermal resistance (in degrees C per watt).
The choice of heatsink is dependent on the value of $\Theta_{\text {SA }}$ required to keep the calculated junction temperature at the given level of power dissipation below the component manufacturer's maximum junction temperature.

## EMI MANAGEMENT

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The
input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

## LAYOUT GUIDELINES

When laying out the CPU buck regulator on a printed circuit board, the following checklist should be used to ensure proper operation of the CS5421.

1. Rapid changes in voltage across parasitic capacitors and abrupt changes in current in parasitic inductors are major concerns for a good layout.
2. Keep high currents out of sensitive ground connections.
3. Avoid ground loops as they pick up noise. Use star or single point grounding.
4. For high power buck regulators on double-sided PCB's a single ground plane (usually the bottom) is recommended.
5. Even though double sided PCB's are usually sufficient for a good layout, four-layer PCB's are the optimum approach to reducing susceptibility to noise. Use the two internal layers as the power and GND planes, the top layer for power connections and component vias, and the bottom layers for the noise sensitive traces.
6. Keep the inductor switching node small by placing the output inductor, switching and synchronous FETs close together.
7. The MOSFET gate traces to the IC must be short, straight, and wide as possible.
8. Use fewer, but larger output capacitors, keep the capacitors clustered, and use multiple layer traces with heavy copper to keep the parasitic resistance low.
9. Place the switching MOSFET as close to the +5.0 V input capacitors as possible.
10. Place the output capacitors as close to the load as possible.
11. Place the COMP capacitor as close as possible to the COMP pin.
12. Connect the filter components of the following pins: $\mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{OUT}}$, and COMP to the GND pin with a single trace, and connect this local GND trace to the output capacitor GND.
13. Place the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitors as close as possible to the IC.

## CS5422

## Dual Out-of-Phase <br> Synchronous <br> Buck Controller with Current Limit

The CS5422 is a dual N -channel synchronous buck regulator controller. It contains all the circuitry required for two independent buck regulators and utilizes the $\mathrm{V}^{2 \mathrm{TM}}$ control method to achieve the fastest possible transient response and best overall regulation, while using the least number of external components. The CS5422 features out-of-phase synchronization between the channels, reducing the input filter requirement. The CS5422 also provides undervoltage lockout, Soft Start, built in adaptive FET non-overlap and hiccup mode overcurrent protection. The part is available in a 16 Lead SO Narrow or 24 Lead Fused SO Wide package allowing the designer to minimize solution size.

## Features

- $\mathrm{V}^{2}$ Control Topology
- Hiccup Mode Overcurrent Protection
- 150 ns Transient Response
- Programmable Soft Start
- 100\% Duty Cycle for Enhanced Transient Response
- 150 kHz to 600 kHz Programmable Frequency Operation
- Switching Frequency Set by Single Resistor
- Out-Of-Phase Synchronization Between the Channels Reduces the Input Filter Requirement
- Undervoltage Lockout
- Internally Fused Leads available in 24 Lead SO Wide Package

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

The CS5422 is a dual power supply controller that utilizes the $\mathrm{V}^{2}$ control method. Two synchronous $\mathrm{V}^{2}$ buck regulators can be built using a single controller. The fixed-frequency architecture, driven from a common oscillator, ensures a $180^{\circ}$ phase differential between channels.

## $\mathrm{V}^{2}$ Control Method

The $V^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. The $\mathrm{V}^{2}$ method differs from traditional techniques such as voltage mode control, which generates an artificial ramp, and current mode control, which generates a ramp using the inductor current.

Figure 3. ${ }^{\mathbf{2}}$ Control with Slope Compensation
The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage generates both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output, regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, allowing the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A variation in line voltage changes the current ramp in the inductor, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since any variation in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme offers the same advantages in line transient response.

A variation in load current will affect the output voltage, modifying the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. The comparator response time and the transition speed of the main switch determine the load transient response. Unlike traditional control methods, the reaction
time to the output load step is not related to the crossover frequency of the error signal loop.

The error signal loop can have a low crossover frequency, since the transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation is drastically improved because there are two independent control loops. A voltage mode controller relies on the change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulations. A current mode controller maintains a fixed error signal during line transients, since the slope of the ramp signal changes in this case. However, regulation of load transients still requires a change in the error signal. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.
The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope in the output ripple can lead to pulse width jitter and variation caused by both random and synchronous noise. A ramp waveform generated in the oscillator is added to the ramp signal from the output voltage to provide the proper voltage ramp at the beginning of each switching cycle. This slope compensation increases the noise immunity particularly at higher duty cycle (above 50\%).

## Start Up

The CS5422 features a programmable Soft Start function, which is implemented through the Error Amplifier and the external Compensation Capacitor. This feature prevents stress to the power components and overshoot of the output voltage during start-up. As power is applied to the regulator, the CS5422 Undervoltage Lockout circuit (UVL) monitors the IC's supply voltage ( $\mathrm{V}_{\mathrm{CC}}$ ). The UVL circuit prevents the MOSFET gates from switching until $\mathrm{V}_{\mathrm{CC}}$ exceeds the 8.6 V threshold. A hysteresis function of 800 mV improves noise immunity. The Compensation Capacitor connected to the COMP pin is charged by a $30 \mu \mathrm{~A}$ current source. When the capacitor voltage exceeds the 0.45 V offset of the PWM comparator, the PWM control loop will allow switching to occur. The upper gate driver GATE $(\mathrm{H})$ is activated turning on the upper MOSFET. The current then ramps up through the main inductor and linearly powers the output capacitors and load. When the regulator output voltage exceeds the

COMP pin voltage minus the 0.45 V PWM comparator offset threshold and the artificial ramp, the PWM comparator terminates the initial pulse.

Figure 4. Idealized Waveforms

## Normal Operation

During normal operation, the duty cycle of the gate drivers remains approximately constant as the $\mathrm{V}^{2}$ control loop maintains the regulated output voltage under steady state conditions. Variations in supply line or output load conditions will result in changes in duty cycle to maintain regulation.

## Gate Charge Effect on Switching Times

When using the onboard gate drivers, the gate charge has an important effect on the switching times of the FETs. A finite amount of time is required to charge the effective capacitor seen at the gate of the FET. Therefore, the rise and fall times rise linearly with increased capacitive loading, according to the following graphs.

Figure 5. Average Rise and Fall Times

## Transient Response

The 150 ns reaction time of the control loop provides fast transient response to any variations in input voltage and output current. Pulse-by-pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required
level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitors during the time required to slew the inductor current. For better transient response, several high frequency and bulk output capacitors are usually used.

## Out-of-Phase Synchronization

In out-of-phase synchronization, the turn-on of the second channel is delayed by half the switching cycle. This delay is supervised by the oscillator, which supplies a clock signal to the second channel which is $180^{\circ}$ out of phase with the clock signal of the first channel.

The advantages of out-of-phase synchronization are many. Since the input current pulses are interleaved with one another, the overlap time is reduced. The effect of this overlap reduction is to reduce the input filter requirement, allowing the use of smaller components. In addition, since peak current occurs during a shorter time period, emitted EMI is also reduced, thereby reducing shielding requirements.

## Overvoltage Protection

Overvoltage Protection (OVP) is provided as a result of the normal operation of the $\mathrm{V}^{2}$ control method and requires no additional external components. The control loop responds to an overvoltage condition within 150 ns , turning off the upper MOSFET and disconnecting the regulator from its input voltage. This results in a crowbar action to clamp the output voltage preventing damage to the load. The regulator remains in this state until the overvoltage condition ceases.

## Hiccup Overcurrent Protection

A lossless hiccup mode short circuit protection feature is provided on the chip. The only external component required is the COMP1 capacitor. Any overcurrent condition results in the immediate shutdown of both output phases.

A comparator between the IS+ and IS- on each output phase detects a short circuit when the voltage difference between the two pins exceeds 70 mV and sets the fault latch. The fault latch immediately turns off the error amplifier and discharges both COMP capacitors. The capacitor connected to COMP1 is discharged through a $5.0 \mu \mathrm{~A}$ current sink in order to provide timing for the reset cycle. When COMP1 has fallen below 0.25 V , a comparator resets the fault latch and error amplifier 1 begins to charge COMP1 with a $30 \mu \mathrm{~A}$ source current. When COMP1 exceeds the feedback voltage plus the PWM Comparator offset voltage, the normal switching cycle will resume.

If the short circuit condition persists through the restart cycle, the overcurrent reset cycle will repeat itself until the short circuit is removed, resulting in small hiccup output pulses while the COMP capacitor charges, as shown in Figure 6.

Figure 6. Hiccup Overcurrent Protection

## Output Enable

On/Off control of the regulator outputs can be implemented by pulling the COMP pins low. The COMP pins must be driven below the 0.45 V PWM comparator offset voltage in order to disable the switching of the GATE drivers.

## DESIGN GUIDELINES

## Definition of the design specifications

The output voltage tolerance can be affected by any or all of the following reasons:

1. buck regulator output voltage setpoint accuracy;
2. output voltage change due to discharging or charging of the bulk decoupling capacitors during a load current transient;
3. output voltage change due to the ESR and ESL of the bulk and high frequency decoupling capacitors, circuit traces, and vias;
4. output voltage ripple and noise.

Budgeting the tolerance is left up to the designer who must take into account all of the above effects and provide an output voltage that will meet the specified tolerance at the load.

The designer must also ensure that the regulator component temperatures are kept within the manufacturer's specified ratings at full load and maximum ambient temperature.

## Selecting Feedback Divider Resistors

Figure 7. Selecting Feedback Divider Resistors
The feedback pins ( $\mathrm{V}_{\mathrm{FB} 1(2)}$ ) are connected to external resistor dividers to set the output voltages. The error amplifier is referenced to 1.0 V and the output voltage is determined by selecting resistor divider values. Resistor R1 is selected based on a design trade-off between efficiency and output voltage accuracy. The output voltage error can be estimated due to the bias current of the error amplifier neglecting resistor tolerance:

$$
\text { Error } \%=\frac{1 \times 10^{-6} \times \mathrm{R} 1}{1} \times 100 \%
$$

R2 can be sized after R1 has been determined:

$$
\mathrm{R} 2=\mathrm{R} 1\left(\frac{\mathrm{VOUT}}{1}-1\right)
$$

## Calculating Duty Cycle

The duty cycle of a buck converter (including parasitic losses) is given by the formula:

$$
\text { Duty Cycle }=\mathrm{D}=\frac{\mathrm{V}_{\mathrm{OUT}}+\left(\mathrm{V}_{\mathrm{HFET}}+\mathrm{V}_{\mathrm{L}}\right)}{\mathrm{V}_{\mathrm{IN}}+\mathrm{V}_{\mathrm{LFET}}-\mathrm{V}_{\mathrm{HFET}}-\mathrm{V}_{\mathrm{L}}}
$$

where:
$\mathrm{V}_{\text {OUT }}=$ buck regulator output voltage;
$\mathrm{V}_{\mathrm{HFET}}=$ high side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$;
$\mathrm{V}_{\mathrm{L}}=$ output inductor voltage drop due to inductor wire DC resistance;
$\mathrm{V}_{\mathrm{IN}}=$ buck regulator input voltage;
$\mathrm{V}_{\mathrm{LFET}}=$ low side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$.

## Selecting the Switching Frequency

Selecting the switching frequency is a trade-off between component size and power losses. Operation at higher switching frequencies allows the use of smaller inductor and capacitor values. Nevertheless, it is common to select lower
frequency operation because a higher frequency results in lower efficiency due to MOSFET gate charge losses. Additionally, the use of smaller inductors at higher frequencies results in higher ripple current, higher output voltage ripple, and lower efficiency at light load currents.

The value of the oscillator resistor is designed to be linearly related to the switching period. If the designer prefers not to use Figure 8 to select the necessary resistor, the following equation quite accurately predicts the proper resistance for room temperature conditions.

$$
\text { ROSC }=\frac{21700-f(S W}{2.31 \mathrm{fSW}}
$$

where:
$\mathrm{R}_{\mathrm{OSC}}=$ oscillator resistor in $\mathrm{k} \Omega$;
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency in kHz .

Figure 8. Switching Frequency

## Selection of the Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response. There are many factors to consider in selecting the inductor including cost, efficiency, EMI and ease of manufacture. The inductor must be able to handle the peak current at the switching frequency without saturating, and the copper resistance in the winding should be kept as low as possible to minimize resistive power loss.

There are a variety of materials and types of magnetic cores that could be used for this application. Among them are ferrites, molypermalloy cores (MPP), amorphous and powdered iron cores. Powdered iron cores are very commonly used. Powdered iron cores are very suitable due to its high saturation flux density and have low loss at high frequencies, a distributed gap and exhibit very low EMI.

The minimum value of inductance which prevents inductor saturation or exceeding the rated FET current can be calculated as follows:

$$
\mathrm{L}_{\mathrm{MIN}}=\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})-\mathrm{V}_{\mathrm{OUT}}\right) \mathrm{V}_{\mathrm{OUT}}}{\mathrm{fSW} \times \mathrm{V}_{\text {IN }}(\mathrm{MIN}) \times \operatorname{ISW}(\mathrm{MAX})}
$$

where:
$\mathrm{L}_{\mathrm{MIN}}=$ minimum inductance value;
$\mathrm{V}_{\mathrm{IN}(\mathrm{MIN})}=$ minimum design input voltage;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency;
$\mathrm{I}_{\text {SW (MAX) }}$ - maximum design switch current.
The inductor ripple current can then be determined:

$$
\Delta \mathrm{I}_{\mathrm{L}}=\frac{\mathrm{V}_{\mathrm{OUT}} \times(1-\mathrm{D})}{\mathrm{L} \times \mathrm{f} \mathrm{SW}}
$$

where:
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{L}=$ inductor value;
$\mathrm{D}=$ duty cycle.
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency
The designer can now verify if the number of output capacitors will provide an acceptable output voltage ripple ( $1.0 \%$ of output voltage is common). The formula below is used:

$$
\Delta \mathrm{I}_{\mathrm{L}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\mathrm{ESR} \mathrm{MAX}^{2}}
$$

Rearranging we have:

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\Delta \mathrm{I}_{\mathrm{L}}}
$$

where:
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR ;
$\Delta \mathrm{V}_{\text {OUT }}=1.0 \% \times \mathrm{V}_{\text {OUT }}=$ maximum allowable output voltage ripple ( budgeted by the designer );
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage.
The number of output capacitors is determined by:

$$
\text { Number of capacitors }=\frac{\text { ESRCAP }}{\text { ESRMAX }}
$$

where:
$E S R_{\text {CAP }}=$ maximum ESR per capacitor (specified in manufacturer's data sheet).
The designer must also verify that the inductor value yields reasonable inductor peak and valley currents (the inductor current is a triangular waveform):

$$
\mathrm{I}(\mathrm{PEAK})=\mathrm{I} O U T+\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2}
$$

where:
$\mathrm{I}_{\mathrm{L}(\mathrm{PEAK})}=$ inductor peak current;
$\mathrm{I}_{\text {OUT }}=$ load current;
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current.

$$
\mathrm{IL}(\mathrm{VALLEY})=\mathrm{IOUT}-\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2}
$$

where:
$\mathrm{I}_{\mathrm{L}(\mathrm{VALLEY})}=$ inductor valley current.

## Selection of the Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the regulator output voltage. Key specifications for output capacitors are their ESR (Equivalent Series Resistance), and ESL (Equivalent Series Inductance). For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

In order to determine the number of output capacitors the maximum voltage transient allowed during load transitions has to be specified. The output capacitors must hold the output voltage within these limits since the inductor current can not change with the required slew rate. The output capacitors must therefore have a very low ESL and ESR.

The voltage change during the load current transient is:

$$
\Delta \mathrm{V}_{\mathrm{OUT}}=\Delta \mathrm{I} \mathrm{OUT} \times\left(\frac{\mathrm{ESL}}{\Delta \mathrm{t}}+\mathrm{ESR}+\frac{\mathrm{t} \mathrm{TR}}{\mathrm{COUT}}\right)
$$

where:
$\Delta \mathrm{I}_{\text {OUT }} / \Delta \mathrm{t}=$ load current slew rate;
$\Delta \mathrm{I}_{\text {OUT }}=$ load transient;
$\Delta \mathrm{t}=$ load transient duration time;
$\mathrm{ESL}=$ Maximum allowable ESL including capacitors, circuit traces, and vias;
$\mathrm{ESR}=$ Maximum allowable ESR including capacitors and circuit traces;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time.
The designer has to independently assign values for the change in output voltage due to ESR, ESL, and output capacitor discharging or charging. Empirical data indicates that most of the output voltage change (droop or spike depending on the load current transition) results from the total output capacitor ESR.

The maximum allowable ESR can then be determined according to the formula:

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESR}}}{\Delta \mathrm{I}_{\mathrm{OUT}}}
$$

where:
$\Delta \mathrm{V}_{\mathrm{ESR}}=$ change in output voltage due to ESR (assigned by the designer)
Once the maximum allowable ESR is determined, the number of output capacitors can be found by using the formula:

$$
\text { Number of capacitors }=\frac{\mathrm{ESR}_{\mathrm{CAP}}}{\mathrm{ESR} \text { MAX }}
$$

where:
$\mathrm{ESR}_{\mathrm{CAP}}=$ maximum ESR per capacitor (specified in manufacturer's data sheet).
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR.
The actual output voltage deviation due to ESR can then be verified and compared to the value assigned by the designer:

$$
\Delta \mathrm{V}_{\mathrm{ESR}}=\Delta \mathrm{I} \text { OUT } \times \text { ESRMAX }
$$

Similarly, the maximum allowable ESL is calculated from the following formula:

$$
\mathrm{ESL}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESL}} \times \Delta \mathrm{t}}{\Delta \mathrm{I}}
$$

## Selection of the Input Inductor

A common requirement is that the buck controller must not disturb the input voltage. One method of achieving this is by using an input inductor and a bypass capacitor. The input inductor isolates the supply from the noise generated in the switching portion of the buck regulator and also limits the inrush current into the input capacitors upon power up. The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients. The worst case is when the load changes from no load to full load (load step), a condition under which the highest voltage change across the input capacitors is also seen by the input inductor. The inductor successfully blocks the ripple current while placing the transient current requirements on the input bypass capacitor bank, which has to initially support the sudden load change.
The minimum inductance value for the input inductor is therefore:

$$
\mathrm{L}_{\mathrm{IN}}=\frac{\Delta \mathrm{V}}{(\mathrm{dl} / \mathrm{dt}) \mathrm{MAX}}
$$

where:
$\mathrm{L}_{\mathrm{IN}}=$ input inductor value;
$\Delta \mathrm{V}=$ voltage seen by the input inductor during a full load swing;
$(\mathrm{dI} / \mathrm{dt})_{\mathrm{MAX}}=$ maximum allowable input current slew rate.
The designer must select the LC filter pole frequency so that at least 40 dB attenuation is obtained at the regulator switching frequency. The LC filter is a double-pole network with a slope of -2.0 , a roll-off rate of $-40 \mathrm{~dB} / \mathrm{dec}$, and a corner frequency:

$$
\mathrm{f}_{\mathrm{C}}=\frac{1}{2 \pi \times \sqrt{\mathrm{LC}}}
$$

where:
$\mathrm{L}=$ input inductor;
$\mathrm{C}=$ input capacitor(s).

## SELECTION OF THE POWER FET

## FET Basics

The use of the MOSFET as a power switch is propelled by two reasons: 1) Its very high input impedance; and 2) Its very fast switching times. The electrical characteristics of a MOSFET are considered to be those of a perfect switch. Control and drive circuitry power is therefore reduced. Because the input impedance is so high, it is voltage driven. The input of the MOSFET acts as if it were a small capacitor, which the driving circuit must charge at turn on. The lower the drive impedance, the higher the rate of rise of $\mathrm{V}_{\mathrm{GS}}$, and the faster the turn-on time. Power dissipation in the
switching MOSFET consists of 1) conduction losses, 2) leakage losses, 3) turn-on switching losses, 4) turn-off switching losses, and 5) gate-transitions losses. The latter three losses are proportional to frequency.

The most important aspect of FET performance is the Static Drain-To-Source On-Resistance ( $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ ), which affects regulator efficiency and FET thermal management requirements. The On-Resistance determines the amount of current a FET can handle without excessive power dissipation that may cause overheating and potentially catastrophic failure. As the drain current rises, especially above the continuous rating, the On-Resistance also increases. Its positive temperature coefficient is between $+0.6 \% /{ }^{\circ} \mathrm{C}$ and $+0.85 \% /{ }^{\circ} \mathrm{C}$. The higher the On-Resistance the larger the conduction loss is. Additionally, the FET gate charge should be low in order to minimize switching losses and reduce power dissipation.

Both logic level and standard FETs can be used.
Voltage applied to the FET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the FET gates will be driven rail-to-rail due to overshoot caused by the capacitive load they present to the controller IC.

## Selection of the Switching (Upper) FET

The designer must ensure that the total power dissipation in the FET switch does not cause the power component's junction temperature to exceed $150^{\circ} \mathrm{C}$.

The maximum RMS current through the switch can be determined by the following formula:

$$
\operatorname{IRMS}(\mathrm{H})=\sqrt{\frac{\left[\begin{array}{l}
\mathrm{IL}(\mathrm{PEAK})^{2}+(\mathrm{IL}(\mathrm{PEAK}) \times \mathrm{I}(\mathrm{VALLEY})) \\
+\mathrm{IL}(\mathrm{VALLEY})^{2} \times \mathrm{D}
\end{array}\right]}{3}}
$$

where:
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{I}_{\mathrm{L}(\mathrm{PEAK})}=$ inductor peak current;
$\mathrm{I}_{\mathrm{L}(\mathrm{VALLEY})}=$ inductor valley current;
D = duty cycle.
Once the RMS current through the switch is known, the switching MOSFET conduction losses can be calculated:

$$
\operatorname{PRMS}(\mathrm{H})=\operatorname{IRMS}(\mathrm{H})^{2} \times \operatorname{RDS}(\mathrm{ON})
$$

where:
$\mathrm{P}_{\mathrm{RMS}(\mathrm{H})}=$ switching MOSFET conduction losses;
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=$ FET drain-to-source on-resistance
The upper MOSFET switching losses are caused during
MOSFET switch-on and switch-off and can be determined by using the following formula:

$$
\begin{aligned}
\mathrm{PSWH} & =\mathrm{PSWH}(\mathrm{ON})+\mathrm{PSWH}(\mathrm{OFF}) \\
& =\frac{\mathrm{VIN}^{2} \times \mathrm{IOUT} \times(\mathrm{tRISE}+\mathrm{tFALL})}{6 \mathrm{~T}}
\end{aligned}
$$

where:
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}}(\mathrm{OFF})=$ upper MOSFET switch-off losses;
$\mathrm{V}_{\text {IN }}=$ input voltage;
$\mathrm{I}_{\text {OUT }}=$ load current;
$t_{\text {RISE }}=$ MOSFET rise time (from FET manufacturer's switching characteristics performance curve);
$\mathrm{t}_{\mathrm{FALL}}=$ MOSFET fall time (from FET manufacturer's switching characteristics performance curve);
$\mathrm{T}=1 / \mathrm{f}_{\mathrm{SW}}=$ period.
The total power dissipation in the switching MOSFET can then be calculated as:
PHFET(TOTAL) $=\operatorname{PRMS}(\mathrm{H})+\operatorname{PSWH}(\mathrm{ON})+\mathrm{PSWH}(\mathrm{OFF})$
where:
$\mathrm{P}_{\text {HFET(TOTAL) }}=$ total switching (upper) MOSFET losses;
$\mathrm{P}_{\text {RMS }(\mathrm{H})}=$ upper MOSFET switch conduction Losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}}^{(\text {OFF })}$ = upper MOSFET switch-off losses;
Once the total power dissipation in the switching FET is known, the maximum FET switch junction temperature can be calculated:

$$
T_{J}=T_{A}+\left[\operatorname{PHFET}(T O T A L) \times R_{\Theta J A}\right]
$$

where:
$\mathrm{T}_{\mathrm{J}}=\mathrm{FET}$ junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$\mathrm{P}_{\text {HFET(TOTAL) }}=$ total switching (upper) FET losses;
$\mathrm{R}_{\Theta \mathrm{JA}}=$ upper FET junction-to-ambient thermal resistance.

## Selection of the Synchronous (Lower) FET

The switch conduction losses for the lower FET can be calculated as follows:

$$
\begin{aligned}
\operatorname{PRMS}(\mathrm{L}) & =\mathrm{I}_{\mathrm{RMS}}{ }^{2} \times \mathrm{RDS}(\mathrm{ON}) \\
& =[\mathrm{IOUT} \times \sqrt{(1-\mathrm{D})}]^{2} \times \mathrm{R} \mathrm{DS}(\mathrm{ON})
\end{aligned}
$$

where:
$\mathrm{P}_{\mathrm{RMS}(\mathrm{L})}=$ lower MOSFET conduction losses;
IOUT = load current;
D = Duty Cycle;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=$ lower FET drain-to-source on-resistance.
The synchronous MOSFET has no switching losses, except for losses in the internal body diode, because it turns on into near zero voltage conditions. The MOSFET body diode will conduct during the non-overlap time and the resulting power dissipation (neglecting reverse recovery losses) can be calculated as follows:

$$
\text { PSWL }=\mathrm{V}_{\mathrm{SD}} \times \mathrm{I}_{\mathrm{LOAD}} \times \text { non-overlap time } \times \mathrm{fSW}
$$

where:
$\mathrm{P}_{\text {SWL }}=$ lower FET switching losses;
$\mathrm{V}_{\mathrm{SD}}=$ lower FET source-to-drain voltage;
$\mathrm{I}_{\text {LOAD }}=$ load current;
Non-overlap time $=\operatorname{GATE}(\mathrm{L})$-to-GATE(H) or GATE(H)-to-GATE(L) delay (from CS5422 data sheet Electrical Characteristics section);
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency.
The total power dissipation in the synchronous (lower) MOSFET can then be calculated as:

$$
\text { PLFET(TOTAL) }=\operatorname{PRMS}(\mathrm{L})+\operatorname{PSWL}
$$

where:
$P_{\text {LFET (TOTAL) }}=$ Synchronous (lower) FET total losses;
$P_{\text {RMS(L) }}=$ Switch Conduction Losses;
$P_{\text {SWL }}=$ Switching losses.
Once the total power dissipation in the synchronous FET is known the maximum FET switch junction temperature can be calculated:

$$
\mathrm{T}_{\mathrm{J}}=\mathrm{T}_{\mathrm{A}}+\left[\text { PLFET }(\mathrm{TOTAL}) \times \mathrm{R}_{\Theta \mathrm{JA}}\right]
$$

where:
$\mathrm{T}_{\mathrm{J}}=$ MOSFET junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$P_{\text {LFET(TOTAL) }}=$ total synchronous (lower) FET losses;
$\mathrm{R}_{\Theta \mathrm{JA}}=$ lower FET junction-to-ambient thermal resistance.

## Control IC Power Dissipation

The power dissipation of the IC varies with the MOSFETs used, $\mathrm{V}_{\mathrm{CC}}$, and the CS5422 operating frequency. The average MOSFET gate charge current typically dominates the control IC power dissipation.

The IC power dissipation is determined by the formula:

$$
\begin{aligned}
\operatorname{PCONTROL}(\mathrm{IC}) & =\operatorname{ICC1} \mathrm{V}_{\mathrm{CC} 1}+\operatorname{IBST} \mathrm{V}_{\mathrm{BST}}+\operatorname{PGATE}(\mathrm{H}) 1 \\
& +\operatorname{PGATE}(\mathrm{L}) 1+\operatorname{PGATE}(\mathrm{H}) 2+\operatorname{PGATE}(\mathrm{L}) 2
\end{aligned}
$$

where:
$\mathrm{P}_{\text {CONTROL(IC) }}=$ control IC power dissipation;
$\mathrm{I}_{\mathrm{CC} 1}=\mathrm{IC}$ quiescent supply current;
$\mathrm{V}_{\mathrm{CC} 1}=\mathrm{IC}$ supply voltage;
$\mathrm{P}_{\text {GATE(H) }}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{P}_{\text {GATE }(\mathrm{L})}=$ lower MOSFET gate driver (IC) losses.
The upper (switching) MOSFET gate driver (IC) losses are:

$$
\left.\operatorname{PGATE}(\mathrm{H})=\text { QGATE }^{\mathrm{P}} \mathrm{H}\right) \times \mathrm{fSW} \times \mathrm{V}_{\mathrm{BST}}
$$

where:
$\mathrm{P}_{\text {GATE(H) }}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\mathrm{GATE}(\mathrm{H})}=$ total upper MOSFET gate charge at $\mathrm{V}_{\mathrm{CC}}$;
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency;
The lower (synchronous) MOSFET gate driver (IC) losses are:

$$
\operatorname{PGATE}(\mathrm{L})=\mathrm{Q}_{\mathrm{GATE}}(\mathrm{~L}) \times \mathrm{fSW} \times \mathrm{V}_{\mathrm{CC}}
$$

where:
$\mathrm{P}_{\text {GATE(L) }}=$ lower MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\mathrm{GATE}(\mathrm{L})}=$ total lower MOSFET gate charge at $\mathrm{V}_{\mathrm{CC}}$;
$\mathrm{f}_{\mathrm{SW}}=$ switching frequency;

The junction temperature of the control IC is primarily a function of the PCB layout, since most of the heat is removed through the traces connected to the pins of the IC.

## Current Sensing

The current supplied to the load can be sensed easily using the IS+ and IS- pins for the output. These pins sense a voltage, proportional to the output current, and compare it to a fixed internal voltage threshold. When the differential voltage exceeds 70 mV , the internal overcurrrent protection system goes into hiccup mode. Two methods for sensing the current are available.
Sense Resistor. A sense resistor can be added in series with the inductor. When the voltage drop across the sense resistor exceeds the internal voltage threshold of 70 mV , a fault condition is set.
The sense resistor is selected according to:

$$
\text { RSENSE }=\frac{0.070 \mathrm{~V}}{\text { ILIMIT }}
$$

In a high current supply, the sense resistor will be a very low value, typically less than $10 \mathrm{~m} \Omega$. Such a resistor can be either a discrete component or a PCB trace. The resistance value of a discrete component can be more precise than a PCB trace, but the cost is also greater.

Setting the current limit using an external sense resistor is very precise because all the values can be designed to specific tolerances. However, the disadvantage of using a sense resistor is its additional constant power loss and heat generation.
Inductor ESR. Another means of sensing current is to use the intrinsic resistance of the inductor. A model of an inductor reveals that the windings of an inductor have an effective series resistance (ESR).

The voltage drop across the inductor ESR can be measured with a simple parallel circuit: an RC integrator. If the value of $\mathrm{R}_{\mathrm{S} 1}$ and C are chosen such that:

$$
\frac{L}{E S R}=R_{S 1} C
$$

then the voltage measured across the capacitor C will be:

$$
\mathrm{V}_{\mathrm{C}}=\mathrm{ESR} \times \mathrm{ILIM}
$$

Selecting Components. Select the capacitor C first. A value of $0.1 \mu \mathrm{~F}$ is recommended. The value of $\mathrm{R}_{\mathrm{S} 1}$ can be selected according to:

$$
\mathrm{RS}_{1}=\frac{1}{\mathrm{ESR} \times \mathrm{C}}
$$

Typical values for inductor ESR range in the low m; consult manufacturer's datasheet for specific details.

Selection of components at these values will result in a current limit of:

Figure 9. Inductor ESR Current Sensing
Given an ESR value of $3.5 \mathrm{~m} \Omega$, the current limit becomes 20 A . If an increased current limit is required, a resistor divider can be added.

The advantages of setting the current limit by using the winding resistance of the inductor are that efficiency is maximized and heat generation is minimized. The tolerance of the inductor ESR must be factored into the design of the current limit. Finally, one or two more components are required for this approach than with resistor sensing.

## Adding External Slope Compensation

Today's voltage regulators are expected to meet very stringent load transient requirements. One of the key factors in achieving tight dynamic voltage regulation is low ESR. Low ESR at the regulator output results in low output voltage ripple. The consequence is, however, that very little voltage ramp exists at the control IC feedback pin ( $\mathrm{V}_{\mathrm{FB}}$ ), resulting in increased regulator sensitivity to noise and the potential for loop instability. In applications where the internal slope compensation is insufficient, the performance of the CS5422-based regulator can be improved through the addition of a fixed amount of external slope compensation at the output of the PWM Error Amplifier (the COMP pin) during the regulator off-time. Referring to Figure 8, the amount of voltage ramp at the COMP pin is dependent on the gate voltage of the lower (synchronous) FET and the value of resistor divider formed by R1 and R2.
$\mathrm{V}_{\text {SLOPECOMP }}=\mathrm{V}_{\text {GATE }}(\mathrm{L}) \times\left(\frac{\mathrm{R} 2}{\mathrm{R} 1+\mathrm{R} 2}\right) \times\left(1-\mathrm{e}^{\frac{-\mathrm{t}}{\tau}}\right)$
where:
$\mathrm{V}_{\text {SLOPECOMP }}=$ amount of slope added;
$\mathrm{V}_{\text {GATE(L) }}=$ lower MOSFET gate voltage;
R1, R2 = voltage divider resistors;
$\mathrm{t}=\mathrm{t}_{\mathrm{ON}}$ or $\mathrm{t}_{\mathrm{OFF}}$ (switch off-time);
$\tau=\mathrm{RC}$ constant determined by C 1 and the parallel combination of R1, R2 neglecting the low driver output impedance.

Figure 10. Small RC Filter Provides the Proper Voltage Ramp at the Beginning of Each On-Time Cycle
The artificial voltage ramp created by the slope compensation scheme results in improved control loop stability provided that the RC filter time constant is smaller than the off-time cycle duration (time during which the lower MOSFET is conducting). It is important that the series combination of R1 and R2 is high enough in resistance to avoid loading the GATE(L) pin. Also, C1 should be very small (less than a few nF ) to avoid heating the part.

## EMI MANAGEMENT

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

## LAYOUT GUIDELINES

When laying out the CPU buck regulator on a printed circuit board, the following checklist should be used to ensure proper operation of the CS5422.

1. Rapid changes in voltage across parasitic capacitors and abrupt changes in current in parasitic inductors are major concerns for a good layout.
2. Keep high currents out of sensitive ground connections.
3. Avoid ground loops as they pick up noise. Use star or single point grounding.
4. For high power buck regulators on double-sided PCB's a single ground plane (usually the bottom) is recommended.
5. Even though double sided PCB's are usually sufficient for a good layout, four-layer PCB's are the
optimum approach to reducing susceptibility to noise. Use the two internal layers as the power and GND planes, the top layer for power connections and component vias, and the bottom layers for the noise sensitive traces.
6. Keep the inductor switching node small by placing the output inductor, switching and synchronous FETs close together.
7. The MOSFET gate traces to the IC must be short, straight, and wide as possible.
8. Use fewer, but larger output capacitors, keep the capacitors clustered, and use multiple layer traces with heavy copper to keep the parasitic resistance low.
9. Place the switching MOSFET as close to the input capacitors as possible.
10. Place the output capacitors as close to the load as possible.
11. Place the COMP capacitor as close as possible to the COMP pin.
12. Connect the filter components of the following pins: $\mathrm{R}_{\mathrm{OSC}}, \mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{OUT}}$, and COMP to the GND pin with a single trace, and connect this local GND trace to the output capacitor GND.
13. Place the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitors as close as possible to the IC.
14. Place the $\mathrm{R}_{\text {OSC }}$ resistor as close as possible to the $\mathrm{R}_{\mathrm{OSC}} \mathrm{pin}$.
15. Include provisions for $100-100 \mathrm{pF}$ capacitor across each resistor of the feedback network to improve noise immunity and add COMP.
16. Assign the output with lower duty cycle to channel 2, which has better noise immunity.

## MC34060A, MC33060A

## Fixed Frequency, PWM, Voltage Mode Single Ended Controllers

The MC34060A is a low cost fixed frequency, pulse width modulation control circuit designed primarily for single-ended SWITCHMODE ${ }^{T M}$ power supply control.

The MC34060A is specified over the commercial operating temperature range of $0^{\circ}$ to $+70^{\circ} \mathrm{C}$, and the MC33060A is specified over an automotive temperature range of $-40^{\circ}$ to $+85^{\circ} \mathrm{C}$.

- Complete Pulse Width Modulation Control Circuitry
- On-Chip Oscillator with Master or Slave Operation
- On-Chip Error Amplifiers
- On-Chip 5.0 V Reference, 1.5\% Accuracy
- Adjustable Dead-Time Control
- Uncommitted Output Transistor Rated to 200 mA Source or Sink
- Undervoltage Lockout

Figure 1. Block Diagram

## Description

The MC34060A is a fixed-frequency pulse width modulation control circuit, incorporating the primary building blocks required for the control of a switching power supply (see Figure 1). An internal-linear sawtooth oscillator is frequency-programmable by two external components, $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. The approximate oscillator frequency is determined by:

$$
f_{\mathrm{osc}} \cong \frac{1.2}{R_{T} \cdot C_{T}}
$$

For more information refer to Figure 3.

Figure 2. Timing Diagram

## MC34060A, MC33060A

## APPLICATIONS INFORMATION

The control signals are external inputs that can be fed into the dead-time control, the error amplifier inputs, or the feed-back input. The dead-time control comparator has an effective 120 mV input offset which limits the minimum output dead time to approximately the first $4 \%$ of the sawtooth-cycle time. This would result in a maximum duty cycle of $96 \%$. Additional dead time may be imposed on the output by setting the dead time-control input to a fixed voltage, ranging between 0 V to 3.3 V .

The pulse width modulator comparator provides a means for the error amplifiers to adjust the output pulse width from the maximum percent on-time, established by the dead time control input, down to zero, as the voltage at the feedback
pin varies from 0.5 V to 3.5 V . Both error amplifiers have a common mode input range from -0.3 V to $\left(\mathrm{V}_{\mathrm{CC}}-2.0 \mathrm{~V}\right)$, and may be used to sense power supply output voltage and current. The error-amplifier outputs are active high and are ORed together at the noninverting input of the pulse-width modulator comparator. With this configuration, the amplifier that demands minimum output on time, dominates control of the loop.
The MC34060A has an internal 5.0 V reference capable of sourcing up to 10 mA of load currents for external bias circuits. The reference has an internal accuracy of $\pm 5 \%$ with a typical thermal drift of less than 50 mV over an operating temperature range of $0^{\circ}$ to $+70^{\circ} \mathrm{C}$.

## MC34023, MC33023

## High Speed Single-Ended PWM Controller

The MC34023 series are high speed, fixed frequency, single-ended pulse width modulator controllers optimized for high frequency operation. They are specifically designed for Off-Line and DC-to-DC converter applications offering the designer a cost-effective solution with minimal external components. These integrated circuits feature an oscillator, a temperature compensated reference, a wide bandwidth error amplifier, a high speed current sensing comparator, and a high current totem pole output ideally suited for driving a power MOSFET.

Also included are protective features consisting of input and reference undervoltage lockouts each with hysteresis, cycle-by-cycle current limiting, and a latch for single pulse metering.

The flexibility of this series allows it to be easily configured for either current mode or voltage mode control.

- 50 ns Propagation Delay to Output
- High Current Totem Pole Output
- Wide Bandwidth Error Amplifier
- Fully-Latched Logic with Double Pulse Suppression
- Latching PWM for Cycle-By-Cycle Current Limiting
- Soft-Start Control with Latched Overcurrent Reset
- Input Undervoltage Lockout with Hysteresis
- Low Start-Up Current (500 $\mu \mathrm{A}$ Typ)
- Internally Trimmed Reference with Undervoltage Lockout
- $90 \%$ Maximum Duty Cycle (Externally Adjustable)
- Precision Trimmed Oscillator
- Voltage or Current Mode Operation to 1.0 MHz
- Functionally Similar to the UC3823

This device contains 176 active transistors.

## MC34023, MC33023

Figure 19. Representative Block Diagram

Figure 20. Current Limit Operating Waveforms

## OPERATING DESCRIPTION

The MC33023 and MC34023 series are high speed, fixed frequency, single-ended pulse width modulator controllers optimized for high frequency operation. They are specifically designed for Off-Line and DC-to-DC converter applications offering the designer a cost effective solution with minimal external components. A representative block diagram is shown in Figure 19.

## Oscillator

The oscillator frequency is programmed by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. The $\mathrm{R}_{\mathrm{T}}$ pin is set to a temperature compensated 3.0 V . By selecting the value of $\mathrm{R}_{\mathrm{T}}$, the charge current is set through a current mirror for the timing capacitor $\mathrm{C}_{\mathrm{T}}$. This charge current runs continuously through $\mathrm{C}_{\mathrm{T}}$. The discharge current is ratioed to be 10 times the charge current, which yields the maximum duty cycle of $90 \% . \mathrm{C}_{\mathrm{T}}$ is charged to 2.8 V and discharged to 1.0 V . During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that resets the PWM Latch and, inhibits the outputs. The threshold voltage on the oscillator comparator is trimmed to guarantee an oscillator accuracy of $5.0 \%$ at $25^{\circ} \mathrm{C}$.

Additional dead time can be added by externally increasing the charge current to $\mathrm{C}_{\mathrm{T}}$ as shown in Figure 24. This changes the charge to discharge ratio of $\mathrm{C}_{\mathrm{T}}$ which is set internally to $\mathrm{I}_{\text {charge }} / 10 \mathrm{I}_{\text {charge. }}$. The new charge to discharge ratio will be:

$$
\% \text { Deadtime }=\frac{\text { I additional }+I_{\text {charge }}}{10\left(I_{\text {charge }}\right)}
$$

A bidirectional clock pin is provided for synchronization or for master/slave operation. As a master, the clock pin provides a positive output pulse during the discharge of $\mathrm{C}_{\mathrm{T}}$. As a slave, the clock pin is an input that resets the PWM latch and blanks the drive output, but does not discharge $\mathrm{C}_{\mathrm{T}}$. Therefore, the oscillator is not synchronized by driving the clock pin alone. Figures 28, 29 and 30 provide suggested synchronization.

## Error Amplifier

A fully compensated Error Amplifier is provided. It features a typical DC voltage gain of 95 dB and a gain bandwidth product of 8.3 MHz with 75 degrees of phase margin (Figure 4). Typical application circuits will have the noninverting input tied to the reference. The inverting input will typically be connected to a feedback voltage generated from the output of the switching power supply. Both inputs have a common mode voltage $\left(\mathrm{V}_{\mathrm{CM}}\right)$ input range of 1.5 V to 5.5 V. The Error Amplifier Output is provided for external loop compensation.

## Soft-Start Latch

Soft-Start is accomplished in conjunction with an external capacitor. The Soft-Start capacitor is charged by an internal $9.0 \mu \mathrm{~A}$ current source. This capacitor clamps the
output of the error amplifier to less than its normal output voltage, thus limiting the duty cycle. The time it takes for a capacitor to reach full charge is given by:

$$
t \approx\left(4.5 \cdot 10^{5}\right) C_{\text {Soft-Start }}
$$

A Soft-Start latch is incorporated to prevent erratic operation of this circuitry. Two conditions can cause the Soft-Start circuit to latch so that the Soft-Start capacitor stays discharged. The first condition is activation of an undervoltage lockout of either $\mathrm{V}_{\mathrm{CC}}$ or $\mathrm{V}_{\text {ref }}$. The second condition is when current sense input exceeds 1.4 V . Since this latch is "set dominant", it cannot be reset until either of these signals is removed and, the voltage at $\mathrm{C}_{\text {Soft-Start }}$ is less than 0.5 V .

## PWM Comparator and Latch

A PWM circuit typically compares an error voltage with a ramp signal. The outcome of this comparison determines the state of the output. In voltage mode operation the ramp signal is the voltage ramp of the timing capacitor. In current mode operation the ramp signal is the voltage ramp induced in a current sensing element. The ramp input of the PWM comparator is pinned out so that the user can decide which mode of operation best suits the application requirements. The ramp input has a 1.25 V offset such that whenever the voltage at this pin exceeds the error amplifier output voltage minus 1.25 V , the PWM comparator will cause the PWM latch to set, disabling the outputs. Once the PWM latch is set, only a blanking pulse by the oscillator can reset it, thus initiating the next cycle.

## Current Limiting and Shutdown

A pin is provided to perform current limiting and shutdown operations. Two comparators are connected to the input of this pin. The reference voltage for the current limit comparator is not set internally. A pin is provided so the user can set the voltage. When the voltage at the current limit input pin exceeds the externally set voltage, the PWM latch is set, disabling the output. In this way cycle-by-cycle current limiting is accomplished. If a current limit resistor is used in series with the power devices, the value of the resistor is found by:

$$
\mathrm{R}_{\text {Sense }}=\frac{\mathrm{I}_{\text {Limit Reference Voltage }}}{\mathrm{I}_{\mathrm{pk}} \text { (switch) }}
$$

If the voltage at this pin exceeds 1.4 V , the second comparator is activated. This comparator sets a latch which, in turn, causes the soft start capacitor to be discharged. In this way a "hiccup" mode of recovery is possible in the case of output short circuits. If a current limit resistor is used in series with the output devices, the peak current at which the controller will enter a "hiccup" mode is given by:

$$
I_{\text {shutdown }}=\frac{1.4 \mathrm{~V}}{\mathrm{R}_{\text {Sense }}}
$$

## Undervoltage Lockout

There are two undervoltage lockout circuits within the IC. The first senses $\mathrm{V}_{\mathrm{CC}}$ and the second $\mathrm{V}_{\text {ref }}$. During power-up, $\mathrm{V}_{\mathrm{CC}}$ must exceed 9.2 V and $\mathrm{V}_{\text {ref }}$ must exceed 4.2 V before the outputs can be enabled and the Soft-Start latch released. If $\mathrm{V}_{\mathrm{CC}}$ falls below 8.4 V or $\mathrm{V}_{\text {ref }}$ falls below 3.6 V , the outputs are disabled and the Soft-Start latch is activated. When the UVLO is active, the part is in a low current standby mode allowing the IC to have an off-line bootstrap start-up circuit. Typical start-up current is $500 \mu \mathrm{~A}$.

## Output

The MC34023 has a high current totem pole output specifically designed for direct drive of power MOSFETs. It is capable of up to $\pm 2.0$ A peak drive current with a typical rise and fall time of 30 ns driving a 1.0 nF load.

Separate pins for $\mathrm{V}_{\mathrm{C}}$ and Power Ground are provided. With proper implementation, a significant reduction of switching transient noise imposed on the control circuitry is possible. The separate $\mathrm{V}_{\mathrm{C}}$ supply input also allows the designer added flexibility in tailoring the drive voltage independent of $\mathrm{V}_{\mathrm{CC}}$.

## Reference

A 5.1 V bandgap reference is pinned out and is trimmed to an initial accuracy of $\pm 1.0 \%$ at $25^{\circ} \mathrm{C}$. This reference has short circuit protection and can source in excess of 10 mA for powering additional control system circuitry.

## Design Considerations

Do not attempt to construct the converter on wire-wrap or plug-in prototype boards. With high frequency, high power, switching power supplies it is imperative to have separate current loops for the signal paths and for the power paths. The printed circuit layout should contain a ground plane with low current signal and high current switch and output grounds returning on separate paths back to the input filter capacitor. Shown in Figure 36 is a printed circuit layout of the application circuit. Note how the power and ground traces are run. All bypass capacitors and snubbers should be connected as close as possible to the specific part in question. The PC board lead lengths must be less than 0.5 inches for effective bypassing for snubbing.

## Instabilities

In current mode control, an instability can be encountered at any given duty cycle. The instability is caused by the
current feedback loop. It has been shown that the instability is caused by a double pole at half the switching frequency. If an external ramp $\left(\mathrm{S}_{\mathrm{e}}\right)$ is added to the on-time ramp $\left(\mathrm{S}_{\mathrm{n}}\right)$ of the current-sense waveform, stability can be achieved.

One must be careful not to add too much ramp compensation. If too much is added the system will start to perform like a voltage mode regulator. All benefits of current mode control will be lost. Figure 26 is an example of one way in which external ramp compensation can be implemented.

Figure 21. Ramp Compensation
A simple equation can be used to calculate the amount of external ramp slope necessary to add that will achieve stability in the current loop. For the following equations, the calculated values for the application circuit in Figure 35 are also shown.

$$
S_{e}=\frac{V_{O}}{L}\left(\frac{N_{S}}{N_{P}}\right)\left(R_{S}\right) A_{i}
$$

$$

## MC34023, MC33023

PIN FUNCTION DESCRIPTION

| Pin |  | Description |
| :---: | :---: | :---: |
| DIP/SOIC | Function |  |
| 1 | Error Amp Inverting Input | This pin is usually used for feedback from the output of the power supply. |
| 2 | Error Amp Noninverting Input | This pin is used to provide a reference in which an error signal can be produced on the output of the error amp. Usually this is connected to $\mathrm{V}_{\text {ref }}$, however an external reference can also be used. |
| 3 | Error Amp Output | This pin is provided for compensating the error amp for poles and zeros encountered in the power supply system, mostly the output LC filter. |
| 4 | Clock | This is a bidirectional pin used for synchronization. |
| 5 | $\mathrm{R}_{\mathrm{T}}$ | The value of $\mathrm{R}_{\mathrm{T}}$ sets the charge current through timing Capacitor, $\mathrm{C}_{\mathrm{T}}$. |
| 6 | $\mathrm{C}_{\mathrm{T}}$ | In conjunction with $\mathrm{R}_{\mathrm{T}}$, the timing Capacitor sets the switching frequency. |
| 7 | Ramp Input | For voltage mode operation this pin is connected to $\mathrm{C}_{\mathrm{T}}$. For current mode operation this pin is connected through a filter to the current sensing element. |
| 8 | Soft-Start | A capacitor at this pin sets the Soft-Start time. |
| 9 | Current Limit/ Shutdown | This pin has two functions. First, it provides cycle-by-cycle current limiting. Second, if the current is excessive, this pin will reinitiate a Soft-Start cycle. |
| 10 | Ground | This pin is the ground for the control circuitry. |
| 11 | Current Limit Reference Input | This pin voltage sets the threshold for cycle-by-cycle current limiting. |
| 12 | Power Ground | This is a separate power ground return that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry. |
| 13 | $\mathrm{V}_{\mathrm{C}}$ | This is a separate power source connection for the outputs that is connected back to the power source input. With a separate power source connection, it can reduce the effects of switching transient noise on the control circuitry. |
| 14 | Output | This is a high current totem pole output. |
| 15 | $\mathrm{V}_{\mathrm{CC}}$ | This pin is the positive supply of the control IC. |
| 16 | $\mathrm{V}_{\text {ref }}$ | This is a 5.1 V reference. It is usually connected to the noninverting input of the error amplifier. |

In voltage mode operation, the control range on the output of the Error Amplifier from 0\% to $90 \%$ duty cycle is from 2.25 V to 4.05 V .

Figure 22. Voltage Mode Operation

In current mode control, an RC filter should be placed at the ramp input to filter the leading edge spike caused by turn-on of a power MOSFET.

Figure 23. Current Mode Operation

The addition of an RC filter will eliminate instability caused by the leading edge spike on the current waveform. This sense signal can also be used at the ramp input pin for current mode control. For ramp compensation it is necessary to know the gain of the current feedback loop. If a transformer is used, the gain can be calculated by:

$$
A_{i}=\frac{R_{\text {Sense }}}{\text { turns ratio }}
$$

Figure 24. Resistive Current Sensing

The addition of an RC filter will eliminate instability caused by the leading edge spike on the current waveform. This sense signal can also be used at the ramp input pin for current mode control. For ramp compensation it is necessary to know the gain of the current feedback loop. The gain can be calculated by:

$$
A_{i}=\frac{R_{w}}{\text { turns ratio }}
$$

Figure 25. Primary Side Current Sensing

This method of slope compensation is easy to implement, however, it is noise sensitive. Capacitor $\mathrm{C}_{1}$ provides AC coupling. The oscillator signal is added to the current signal by a voltage divider consisting of resistors $R_{1}$ and $R_{2}$.

Figure 26A. Slope Compensation (Noise Sensitive)

When only one output is used, this method of slope compensation can be used and it is relatively noise immune. Resistor $R_{M}$ and capacitor $C_{M}$ provide the added slope necessary. By choosing $R_{M}$ and $C_{M}$ with a larger time constant than the switching frequency, you can assume that its charge is linear. First choose $C_{M}$, then $R_{M}$ can be adjusted to achieve the required slope. The diode provides a reset pulse at the ramp input at the end of every cycle. The charge current $l_{M}$ can be calculated by $I_{M}=C_{M} S_{e}$. Then $R_{M}$ can be calculated by $R_{M}=V_{C C} / l_{M}$.

Figure 26B. Slope Compensation (Noise Immune)

Additional dead time can be added by the addition of a dead time resistor from $V_{\text {ref }}$ to $\mathrm{C}_{\mathrm{T}}$. See text on Oscillator section for more information.

The sync pulse fed into the clock pin must be at least 3.9 V . $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\boldsymbol{T}}$ need to be set $10 \%$ slower than the sync frequency. This circuit is also used in Voltage Mode operation for master/slave operation. The clock signal would be coming from the master which is set at the desired operating frequency, while the slave is set $10 \%$ slower.

Figure 27. Dead Time Addition

Figure 28. External Clock Synchronization

Figure 29. Current Mode Master/Slave Operation Over Short Distances

Figure 30. Synchronization Over Long Distances

In voltage mode operation, the maximum duty cycle can be clamped. By the addition of a PNP transistor to buffer the clamp voltage, the Soft-Start current is not affected by $\mathrm{R}_{1}$.

$$
\text { The new equation for Soft-Start is } \quad t \approx \frac{\mathrm{~V}_{\text {clamp }}+0.6}{9.0 \mu \mathrm{~A}}\left(\mathrm{C}_{\mathrm{SS}}\right)
$$

In current mode operation, this circuit will limit the maximum voltage allowed at the ramp input to end a cycle.

Figure 31. Buffered Maximum Clamp Level

A series gate resistor may be needed to dampen high frequency parasitic oscillation caused by the MOSFET's input capacitance and any series wiring inductance in the gate-source circuit. The series resistor will also decrease the MOSFET switching speed. A Schottky diode can reduce the driver's power dissipation due to excessive ringing, by preventing the output pin from being driven below ground. The Schottky diode also prevents substrate injection when the output pin is driven below ground.

Figure 33. MOSFET Parasitic Oscillations

The totem pole output can furnish negative base current for enhanced transistor turn-off, with the addition of the capacitor in series with the base.

Figure 32. Bipolar Transistor Drive

The totem pole output can easily drive pulse transformers. A Schottky diode is recommended when driving inductive loads at high frequencies. The diode can reduce the driver's power dissipation due to excessive ringing, by preventing the output pin from being driven below ground.

## CS51220

## Feed Forward Voltage Mode PWM Controller with Programmable Synchronization

CS51220 is a single output PWM Controller with switching frequency up to 500 kHz . The feed forward voltage mode control provides excellent line regulation for wide input range. This PWM controller has a synchronization output allowing programmable phase delay. For overcurrent protection, the "soft hiccup" technique effectively limits the output current with maximum flexibility. In addition, this device includes such features as: soft start, pulse-by-pulse current limit, programmable foldback current limit, volt-second clamping, maximum duty cycle, overvoltage and undervoltage protection, and synchronization input. The CS51220 is available in 16 SO narrow surface mount package.

## Features

- Constant Frequency Feed Forward Voltage Mode Control
- Programmable Pulse by Pulse Overcurrent Limit
- Programmable Foldback Overcurrent Limit with Delay
- Soft Hiccup Overcurrent Protection with Programmable Foldback
- Frequency Synchronization Output with Programmable Phase Delay
- Synchronization Input to Higher or Lower Frequency
- Direct Connection to External Opto Isolators
- Logic Gate Output Signal
- Accurate Volt-Second Clamping
- Programmable Soft Start
- Logic Input to Disable IC
- Line Overvoltage and Undervoltage Monitoring
- 3.3 V 3\% Reference Voltage Output

## PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| 16 Lead SO Narrow | PIN SYMBOL | FUNCTION |
| 1 | $\mathrm{V}_{\mathrm{O}}$ | Logic output connecting to external gate driver. |
| 2 | GND | Ground. |
| 3 | $\mathrm{V}_{\mathrm{CC}}$ | Supply Voltage. |
| 4 | $\mathrm{V}_{\text {REF }}$ | 3.3 V reference voltage output. |
| 5 | $I_{\text {SET }}$ | Voltage at this pin sets pulse-by-pulse overcurrent threshold. When the ISENSE exceeds ISET for a sustained period of time, a sink current is generated at this pin. Along with external resistors, this current provides a foldback overcurrent threshold. The sink current is disabled periodically for restart. |
| 6 | IsENSE | Current sense input for overcurrent protection. |
| 7 | OV | Overvoltage protection monitor. |
| 8 | UV | Undervoltage protection monitor. |
| 9 | $\mathrm{C}_{\text {T }}$ | Timing capacitor $\mathrm{C}_{T}$ determines oscillator frequency. |
| 10 | SYNCI | By applying sync pulses to this pin, the IC can be synchronized to frequencies ranging from $25 \%$ slower to several times faster than the internal oscillator frequency. |
| 11 | DISABLE | Disable mode input pin. A voltage greater than 3.0 V turns off the whole IC. |
| 12 | FF | Feed forward input for PWM ramp. This pin allows external connection to make the ramp adjustable to the input line. |
| 13 | COMP | This pin carries feedback error signal from an external amplifier. Internally, it connects to the PWM controller. |
| 14 | SS | A capacitor is connected to this pin for Soft Start and soft hiccup timing. |
| 15 | $V_{S D}$ | The voltage at this pin programs the delay of the SYNCO output in reference to the internal oscillator. |
| 16 | SYNCO | Sync output. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## Feed Forward Voltage Mode Control

Conventional voltage mode control uses a fixed ramp signal for pulse width modulation, typically utilizing the oscillator output as the ramp signal. Since the only feedback signal comes from the output, this results in inferior line regulation and audio susceptibility. A significant improvement in line regulation and line transient response can be achieved using Feed Forward Voltage Mode Control, implemented using the CS51220 controller.

The enhancement comes from generating the ramp signal using a pull-up resistor from the FF pin to the line voltage and a capacitor to ground. The slope of the ramp then depends on the line voltage. At the start of each switch cycle, the capacitor connected to the FF pin is charged through the resistor connected to the input voltage. Meanwhile, the $\mathrm{V}_{\mathrm{O}}$ pin goes high to turn on a power mosfet through an external gate driver. When the rising FF pin exceeds the COMP input pin, as driven through the regulation feedback loop, $\mathrm{V}_{\mathrm{O}}$ goes low and turns off the external switch. Simultaneously, the FF capacitor is quickly discharged and set for the next switching cycle.

Overall, both input and output voltages control the dynamics of the duty cycle. As illustrated in Figure 3, with a fixed input voltage the output voltage is regulated solely by the error amplifier. For example, an elevated output voltage pulls down the COMP pin through an external error amplifier. This in turn causes duty cycle to decrease. On the another hand, if the input voltage varies, the slope of the FF pin ramp reacts correspondingly and immediately. As an example shown in Figure 4, when the input voltage goes up, the slope of the ramp signal increases, which reduces duty cycle and counteracts the change. For line variations, feed forward control requires less response from the error amplifier, which improves the transient speed and DC regulation.

Figure 3. Pulse Width Modulated by the Output Voltage with a Constant Input Voltage

Figure 4. Pulse Width Modulated by the Input Voltage with a Constant Output Voltage

The feed forward feature can also be employed for volt-second clamp, which limits the maximum product of input voltage and switch on time. This clamp is used in circuits, such as forward and flyback converters, to prevent the transformer from saturating. Calculations used in the design of the volt-second clamp are presented in the Design Guidelines section on page 1706 .

## $\mathrm{V}_{\mathrm{Cc}}$ Power Up and Fault Conditions

During power up, an undervoltage lockout comparator monitors $\mathrm{V}_{\mathrm{CC}}$ and disables $\mathrm{V}_{\mathrm{REF}}$, (which in turn disables the entire IC), until the $\mathrm{V}_{\mathrm{CC}}$ voltage reaches its start threshold. Hysteresis prevents "chattering" caused by the source impedance of the $\mathrm{V}_{\mathrm{CC}}$ supply. $\mathrm{V}_{\text {REF }}$ can also be disabled using the Disable input pin, which is active high. An internal pull-down resistor ensures the IC will start up if the Disable pin is allowed to float. In $\mathrm{V}_{\mathrm{CC}}$ or Disable lockout mode, the output stage is held low by the output pull-down resistance.

After $\mathrm{V}_{\text {REF }}$ turns on, there are three conditions that can cause fault mode:
10. The $3.3 \mathrm{~V} \mathrm{~V}_{\mathrm{REF}}$ is below regulation,
11. The OV pin rises above overvoltage threshold, or
12. The UV pin falls below undervoltage threshold.

Fault detection will cause the $\mathrm{V}_{\mathrm{O}}$ output to go low and the SS pin to discharge. The UV and OV inputs are typically used to monitor the input line voltage. The undervoltage comparator has a built-in hysteresis voltage, while the hysteresis for the OV comparator is programmable through a current sourced from the pin when above the threshold, and the equivalent external resistance. The fault condition can only be reset after the SS pin has been completely discharged and all faults have been removed.

After a fault is removed or upon initial startup, the SS pin charges at a rate determined by an internal charge current and an external capacitor. The rising voltage on the SS pin will override the regulation feedback voltage on the COMP pin and clamp the duty cycle, helping to reduce any in-rush current during startup. The duration of the Soft Start is typically set with a capacitor from $0.01 \mu \mathrm{~F}$ to $0.1 \mu \mathrm{~F}$.

## Overcurrent Protection

The CS51220 uses the "soft hiccup" technique to provide an adjustable and predictable overcurrent limit. By choosing external component values the designer can select pulse-by-pulse current limit, soft hiccup current limit or hard hiccup limit.

Normal pulse-by-pulse current limit can be obtained by selecting the $\mathrm{I}_{\text {SET }}$ resistor values for a low Thevenin
resistance to the $\mathrm{I}_{\text {SET }}$ pin. However with normal pulse-by-pulse current limit, the secondary currents during short circuits may be several times the maximum output current.

Soft hiccup limit can be obtained by setting the $\mathrm{I}_{\text {SET }}$ resistor values for a higher thevenin resistance. During overcurrent conditions, the $\mathrm{I}_{\text {SET }}$ level will fold back, after a short delay, to reduce the pulse by pulse threshold. If desired, the short circuit current can be chosen to be equal to or even less than the maximum output current. During soft hiccup the circuit will periodically disable the foldback and attempt to restart.

Hard hiccup limit can be obtained by setting the $\mathrm{I}_{\text {SET }}$ resistor values so that the ISET pin is held below 200 mV during foldback. During overcurrent conditions, the $I_{\text {SET }}$ level will fold back, after a short delay, preventing any gate pulses. When the SS capacitor is completely discharged, the circuit will attempt restart. This configuration provides the lowest power dissipation during short outputs.

The circuit functions can be best described by discussing the block diagram and illustrations of expected waveforms. Actual waveforms, values and circuit configurations from a design will be used. The design is from the 5.0 V supply of a dual synchronized converter.

The current is monitored with a voltage at the $I_{\text {SENSE }}$ pin. The ISENSE signal is slightly attenuated DC shifted by 200 mV , and is compared with the threshold voltage programmed by the voltage at the $I_{\text {SET }}$ pin. If the current signal reaches the threshold voltage, the overcurrent comparator resets the $\mathrm{V}_{\mathrm{O}}$ latch and terminates the $\mathrm{V}_{\mathrm{O}}$ pulse. The overcurrent comparator has a maximum common mode input voltage of 1.8 V . However, an $\mathrm{I}_{\text {SET }}$ voltage below 1.0 V is desirable for reducing the comparator's propagation delay. During initial turnon of the power supply, normal pulse-by-pulse overcurrent control is used to protect the power supply switches. This is accomplished by comparing the voltage at the ISENSE input to the voltage at the $\mathrm{I}_{\text {SET }} \mathrm{pin}$ and using this to limit the duty factor of $\mathrm{V}_{\mathrm{O}}$, the gate drive signal. This current limit control is maintained until the SS voltage reaches 2.9 V .

The block diagram of the soft hiccup circuit is shown in Figure 5. When overcurrent occurs and the SS is above 2.9 V , the OC pulses set the OC latch. The output of the OC latch turns on the OC delay discharge current to ramp down the SS voltage. This SS discharge ramp down is at a rate of $50 \mu \mathrm{~A}$ while the SS voltage is above 2.8 V . The level between 2.9 V and 2.8 V is called the hiccup delay discharge voltage. The time to cross this voltage creates a short delay. This delay is useful so that a quick transient overcurrent condition can be controlled and still allow the supply to return immediately to normal operation. After reaching the hiccup delay discharge voltage, the SS current is reduced to $5.0 \mu \mathrm{~A}$ and the $\mathrm{I}_{\mathrm{SET}}$ foldback current is turned on at $15 \mu \mathrm{~A}$. It is the $\mathrm{I}_{\mathrm{SET}}$ foldback current that adjusts the $\mathrm{I}_{\text {SET }}$ level to establish a new lower I ${ }_{\text {SENSE }}$ current limit level. See Figure 6 for details.

Figure 5. The Block Diagram of the Soft Hiccup Operation

A circuit monitors the OC pulses. If the OC pulses cease for $50 \mu \mathrm{~s}$, the $\mathrm{NOt}-$ OverCurrent (NOOC) signal is generated. This NOOC signal resets the OC Latch and allows the SS capacitor to charge back up allowing the output to reestablish regulation.

For an equivalent circuit shown in Figure 6, the $\mathrm{I}_{\text {SET }}$ current reduces the overcurrent threshold and sets the new threshold at

$$
\mathrm{V}_{\mathrm{I}}(\mathrm{SET})=(3.3-\mathrm{ISET} \times \mathrm{R} 1) \times \frac{\mathrm{R} 2}{(\mathrm{R} 1+\mathrm{R} 2)}
$$

Figure 6. The Voltage Divider Used at the ISET Pin Allows the ISET Foldback Current to Reduce the Overcurrent Threshold

The NOOC or SS low ( $\mathrm{V}_{\mathrm{SS}}<0.3 \mathrm{~V}$ ) signal can reset OC latch at any time. This event turns off I IET foldback and allows the recharging of the SS capacitor. Therefore, the IC allows the power supply to restart periodically or after the overcurrent condition is cleared. The OC latch can not be set until the SS capacitor is fully charged.

To implement "hard hiccup" which disables the $\mathrm{V}_{\mathrm{O}}$ completely when the SS voltage is ramping down, select a resistor value greater than $3.3 \mathrm{~V} / \mathrm{I}_{\text {SET }}$ for R1 in Figure 6, and saturate the internal $\mathrm{I}_{\mathrm{SET}}$ current source. Since the saturation voltage is less than the DC shift applied to the I IENSE signal, the OC comparator output is always high and in turn keeps the $\mathrm{V}_{\mathrm{O}}$ low. Figure 7 demonstrates the interactions among the voltage of SS, I ISET and internal signal OC. Figure 8 further describes the specifications associated with the soft hiccup. The ratio among the charge time, delay time and discharge time is given at the bottom of Figure 8.

Figure 7. Illustrative Waveforms of the Soft Hiccup Operation

Figure 8. The SS Pin Voltage Under Ramp Up and Overcurrent Condition and Associated Specifications.

The effect of the soft hiccup can be observed in Figure 9, which shows the output voltage as load increases. The output is maintained at the regulation value of 5.0 V until it goes into current limit. At the point of overcurrent inception (A), the current limit level changes to a lower level (B). The switchback to a lower current limit level can be seen as the bottom curve in Figure 9.

Figure 9. Overcurrent In a 5.0 V Output Converter Using Soft Hiccup
A typical overload scenario is shown in Figure 10. The top trace is the voltage on the Soft Start (SS) pin. The initial high discharge rate can be seen transitioning to a 40 ms discharge period. During this period the $\mathrm{I}_{\text {SET }}$ establishes a lower current limit level. The bottom trace shows the output current. The initial current spike is the output capacitors discharging. The next level around 4.0 A is the short circuit current level set by the $\mathrm{I}_{\text {SET }}$ current. The output then turns off allowing the current to reduce to a level that does not cause overcurrent pulses. This releases the SS pin to ramp back up. During ramp up, the output is still shorted as noted by the 8.0 A current level. When SS reaches the 2.9 V level, the short is again recognized and $\mathrm{I}_{\mathrm{SET}}$ is turned back on shifting the short circuit current level.

Figure 10. Over-Load Current and Soft Start Waveforms

The middle trace is a digitizing 'scope trace of the current sense line. The scope interprets the voltages as an average voltage. This voltage is actually a narrow duty cycle peak voltage representing the peak current level in the switching transistor. The actual peak voltages can be seen in the Figure 11. The peaks are 0.85 V at full load, reducing to 0.6 V peak at the reduced short circuit level. The 1.1 V peak is the full short circuit current while SS ramps back up. The 0.32 V level is the normal load resistance, while $\mathrm{I}_{\text {SET }}$ is still on. The 1.0 V surge is created by ramp up into a normal 5.0 A load and followed by the 0.85 V at normal load.

Figure 11. Over-Load Current and Isense Voltage

## Oscillator and Synchronization

The switching frequency is programmable through a capacitor connected to the $\mathrm{C}_{\mathrm{T}}$ pin. When the $\mathrm{C}_{\mathrm{T}}$ pin voltage reaches peak voltage ( 2.0 V ), the internal discharge current discharges the $\mathrm{C}_{\mathrm{T}}$ capacitor and $\mathrm{V}_{\mathrm{O}}$ stays low. When the $\mathrm{C}_{\mathrm{T}}$ voltage declines to valley voltage ( 0.9 V ), the current source toggles to charge current and ramps up the $\mathrm{C}_{\mathrm{T}}$ pin. This starts a new switching cycle. The duty cycle of the oscillator determines the maximum PWM duty cycle.

The switching frequency of the IC can be synchronized to an external frequency presented to the SYNCI pin. When pulses with amplitude over SYNCI input threshold are detected, the $\mathrm{C}_{\mathrm{T}}$ pin immediately ramps down the external capacitor and the $\mathrm{V}_{\mathrm{O}}$ pin is forced low. A new switching cycle begins when the $\mathrm{C}_{\mathrm{T}}$ pin reaches valley voltage. During synchronization, the oscillator charge current is reduced by $80 \mu \mathrm{~A}$, while discharge current is increased by $80 \mu \mathrm{~A}$. This effectively slows down the internal oscillator to avoid any race condition with the sync frequency. As a result, the sync frequency can be either higher or lower than the internal oscillator frequency. CS51220 is able to synchronize up to 500 kHz and down to $25 \%$ below $\mathrm{C}_{\mathrm{T}}$ frequency. The maximum duty cycle clamp is raised to $92 \%$ in synchronization mode. The original oscillator frequency is restored upon the removal of sync pulses.

Figure 12. Synchronization Input Timing
Figure 12 shows the sync input from one CS51220 into another. The delay between receiving the sync input and the start of the next switching cycle is 423 ns . This delay must be taken into account when establishing the total delay between two regulators.

The SYNCO pin provides outgoing synchronization pulses whose delay can be programmed by setting the voltage on the $\mathrm{V}_{\mathrm{SD}}$ pin. The feature allows two converters to run at interleaved phases. This implementation significantly reduces the input ripple, and thus the number of input capacitors. The phase delay is achieved by turning on SYNCO output only after the $\mathrm{C}_{\mathrm{T}}$ pin voltage reaches the $\mathrm{V}_{\mathrm{SD}}$ voltage. Therefore, the phase delay varies linearly with the $\mathrm{V}_{\mathrm{SD}}$ voltage. The SYNCO output is reset during the falling edge of the $\mathrm{C}_{\mathrm{T}} \mathrm{pin}$. For minimum phase delay ( $\sim 240 \mathrm{~ns}$ ), tie the $\mathrm{V}_{\mathrm{SD}}$ pin to the ground. To entirely disable the SYNCO output, connect the $\mathrm{V}_{\mathrm{SD}}$ pin to $\mathrm{V}_{\text {REF }}$.

The waveform in Figure 13 shows the $\mathrm{C}_{\mathrm{T}}$ ramp crossing the $\mathrm{V}_{\mathrm{SD}}$ voltage set at 1.41 V .

Figure 13. Synchronization Output Timing
The delay from the point of crossing to the output of the sync signal is 240 ns . The time for the sync out voltage is measured at the +2.0 V level, which is the level that triggers the next CS51220.

The desired effect on the input ripple is illustrated in Figure 14. This is the input current for two power converters operating from a 36 V line.

Figure 14. Input Current Ripple with Different Overlap Conditions

The top waveform in Figure 14 is the input current with the two supplies operating out of phase. The next down shows the same supplies but with both conduction times occurring simultaneously. The greatly increased ripple current can be observed. The last two waveforms are the two converters shown individually when operating out of phase.

## DESIGN GUIDELINES

## Program Volt-Second Clamp

Feed forward voltage mode control provides the volt-second clamp which clamps the product of the line voltage and switch on time. For the circuit shown in Figure 15, the charging current of the $\mathrm{C}_{\mathrm{FF}}$ can be considered as a constant current equal to $\mathrm{V}_{\mathrm{IN}} / \mathrm{R}_{\mathrm{FF}}$, provided $\mathrm{V}_{\mathrm{IN}}$ is much greater than the FF pin voltage. Then the volt-second clamp provided by CS51220 is given by

$$
\mathrm{V}_{\text {IN }} \mathrm{TON}(\mathrm{MAX})=1.0 \mathrm{RFF}_{\mathrm{FFF}}
$$

Figure 15. An RC Network Provides Both Volt-Second Clamp and Feed Forward Control

Select the time constant of the FF pin RC network to provide desirable volt-second clamp.

## Program Oscillator Frequency

CS51220 requires an external capacitor to program the oscillator frequency. The internally trimmed charge/discharge current determines the maximum duty cycle. The capacitor for a required switching frequency $f_{S}$ can be calculated by:

$$
C T=\frac{13400}{f S}-95
$$

where:
$\mathrm{C}_{\mathrm{T}}=$ Timing capacitance is in pF
$\mathrm{f}_{\mathrm{S}}=$ Switching frequency is in kHz
Figure 16 shows the relationship of $\mathrm{C}_{\mathrm{T}}$ and $\mathrm{f}_{\mathrm{S}}$.

Figure 16. Operating Frequency

## Synchronized Dual Converters with Soft Hiccup and Feed Forward

The circuits shown in Figures 17 and 18 illustrate typical applications for a dual output supply using independent but synchronized converters. These circuits demonstrate the use of the soft hiccup, feed forward, volt-second control and synchronization features of the CS51220.
In Figure 17, the feed forward circuit has a volt-second constant of $82 \mathrm{~V} / \mu \mathrm{s}$. This would limit the duty factor to 0.51 at 48 V input. With a turns ratio of $4: 1$ on the power transformer and 48 V input, a duty factor of 0.46 is required for 5.0 V output. This converter serves as the master synchronization generator. The voltage on the $\mathrm{V}_{\text {SD }}$ pin establishes the delay as it is compared to the ramp generated on the $\mathrm{C}_{\mathrm{T}}$ pin.

Adjustable synchronization allows the conduction time for the two converters to be adjusted so that they are not on at the same time. This greatly reduces the ripple current from the 48 V source.
In Figure 18, the feed forward circuit has a volt-second constant of $63 \mathrm{~V} / \mu \mathrm{s}$. This would limit the duty factor to 0.39 at 48 V input. With a turns ratio of $4: 1$ on the power transformer and 48 V input, a duty factor of 0.33 is required for 3.3 V output.

## Advance Information

Full Featured Voltage Mode PWM Controller

The NCP1560 PWM controller contains all of the features and flexibility needed to implement voltage-mode control for modern high performance power converters. This device cost effectively reduces system part count with the inclusion of a high-voltage start-up regulator that operates over a wide input range of 33 V to 150 V. The NCP1560 provides two control outputs, OUT1 which controls the main PWM switch and OUT2 with adjustable over-lap delay, which can control a synchronous rectifier. Other distinctive features include: two mode over-current protection, line under/over voltage lockout, fast line feed-forward, soft-start and a maximum duty cycle clamp.

## Features

- Internal High Voltage Start-up Regulator
- Dual Control Outputs with Adjustable Over-Lap Delay
- Single Resistor Oscillator Frequency Setting
- Fast Line Feed-Forward
- Line Under/Over Voltage Lockout
- Dual Mode Over-Current Protection
- Programmable Maximum Duty Cycle Control
- Maximum Duty Cycle Proportional to Line Voltage
- Programmable Soft-Start
- Precision Reference

## Typical Applications

- Telecommunication Power Converters
- Industrial Power Converters
- High Voltage Power Modules
- +42 V Automotive Systems
- Control Driven Synchronous Rectifier Power Converters

## PIN DESCRIPTION

| Pin | Name | Description | Application Information |
| :---: | :---: | :---: | :---: |
| 1 | Vin | Source Input Voltage | Input range: 33 V to 150 V . |
| 2 | UV_OV | Input Undervoltage and Overvoltage shutdown. | An external divider from the power converter source input must be scaled $>1.49$ volts and $<3.60$ volts over the operational range. |
| 3 | TP_Ramp | Test point provided for the Feed Forward Ramp signal. | Internally this signal is compared to Vea. |
| 4 | FF_SET | An external resistor between Vin and this pin adjusts the amplitude of the FF_Ramp in proportion to Vin and R. | By varying the PWM ramp amplitude in proportion to the line voltage changes in loop bandwidth resulting from line voltage changes are eliminated. |
| 5 | CS | Current Sense input | If CS exceeds 0.5 volt the outputs will go into a Cycle by Cycle current limit. If CS exceeds 0.6 volts the outputs will be disabled for a period determined by the Current Sense Fault Timer. A softstart will follow at the conclusion of the fault timer. |
| 6 | C_SKIP_SET | An external capacitor sets the shutdown period after 0.6 V CS event. | An external capacitor sets the shutdown period. Range: $68 \mathrm{pF}=12 \mu \mathrm{~s}, 6800 \mathrm{pF}=1.2 \mathrm{~ms}$ |
| 7 | RT | A single external resistor between this pin and GND sets the fixed oscillator frequency. | Resistance Range $68 \mathrm{~K}=500 \mathrm{KHz}$ $390 \mathrm{~K}=100 \mathrm{KHz}$ |
| 8 | MAX_DUTY_SET | An external resistor between this pin and GND sets the maximum allowable Duty cycle. | Resistance Range 0 Ohms $=60 \%$ Open $=80 \%$ given the FF_Ramp of 2.0 V peak (low line). |
| 9 | SS | Softstart control | An external capacitor and the internal $6.0 \mu \mathrm{~A}$ current source, set the softstart ramp. The capacitor voltage sets a maximum duty cycle clamp from 0 to 2.0 volts ( 0 to $100 \%$ Duty). |
| 10 | Vea | Input from an external error amplifier. | There is no error amplifier included within this controller. The error amplifier is typically secondary side referenced while the controller is primary side referenced. |
| 11 | 5.0 V_REF | Precision 5.0 volt reference output. | Maximum output current: 10 mA . |
| 12 | Td_Set | An external resistor between Vref and this pin sets the leading edge and trailing edge time delay between OUT1 and OUT2. | Time delay (Td) <br> Rd open $=250 \mathrm{nS}$ (Max Delay) <br> Rd $(60 \mathrm{~K})=25 \mathrm{nS}$ (Min Delay) |
| 13 | OUT2 | Output of the PWM controller with leading edge and a trailing edge time delay of (Td). | OUT2 can be used to drive a synchronous rectifier. |
| 14 | GND | Return |  |
| 15 | OUT1 | Output of the PWM controller. | OUT1 main PWM output. |
| 16 | AUX | Auxiliary bias power. Upon turn-on an internal current source supplies bias power. An external slave winding then continues supplying bias power. | An internal current source supplies 12 mA until Vaux reaches 11 volts. An external capacitor is required to holdup Vaux above 7.0 volts while the converter starts. Typically an external slave winding then provides power to the control circuits. |

MAXIMUM RATINGS (Notes 1 \& 2)

| Rating | Symbol | Value | Unit |
| :--- | :---: | :---: | :---: |
| Vin to GND | $\mathrm{V}_{\text {in }}$ | 150 | V |
| Vaux to GND | $\mathrm{V}_{\text {aux }}$ | 16 | V |
| All Other Inputs to GND | - | - | V |
| 5.0 V Reference Output Current | $\mathrm{I}_{\text {REF }}$ | 10 | mA |
| OUT1, OUT2 Output Current | $\mathrm{I}_{\text {OUT1 }}, \mathrm{I}_{\mathrm{OUT} 2}$ | 20 | mA |

## DETAILED OPERATING DESCRIPTION

The NCP1560 PWM controller contains all of the features and flexibility needed for implementation of voltage-mode control for modern high performance power converters. This device cost effectively reduces system part count with the inclusion of a high-voltage start-up regulator. The NCP1560 provides two control outputs, OUT1 which controls the main PWM switch and OUT2 with adjustable over-lap delay, which can control a synchronous rectifier switch. Other distinctive features include: two mode over-current protection, line under/over voltage lockout, fast line feed-forward, soft-start and a maximum duty cycle clamp. The Functional Block Diagram is shown in Figure 1.

The NCP1560 is designed for Voltage-Mode Control converters. The features included in the NCP1560 enable all of the advantages of Current-Mode Control, fast line feed-forward, and cycle by cycle current limit. It eliminates the disadvantages of low power jitter, slope compensation and noise susceptibility. Finally the dual outputs of the NCP1560 allow for optimum control of a synchronous rectifier switch.

## High Voltage Start-up Regulator

The NCP1560 contains an internal high voltage current source. This current source is set to 12 mA . When the line voltage is in range, the current source is enabled and sources current into an external capacitor connected to the Vaux pin. When the voltage on the Vaux pin reaches 11 V the controller outputs are enabled and the internal current source is disabled. The Vaux voltage will then transition to the converter self bias voltage. The start-up regulator will remain off until the Vaux voltage falls below 7.0 V. At that time the outputs will be disabled until the Vaux pin again reaches 11 V . The external Vaux capacitor must be sized such that the self-bias will maintain a Vaux voltage greater than 7.0 V during initial start-up. During a fault mode when the converter self bias is inactive, external current draw on the Vaux line should be limited as to not exceed the maximum power dissipation of the controller.

## Input Under/Over Voltage Shutdown

The NCP1560 contains a line under/over voltage shut down circuit. An external voltage divider sets the operational range of the converter. The divider must be set for a voltage at the under/over voltage pin to be greater than 1.49 V and less than 3.60 V . If the Under voltage threshold is not met, all functions of the controller are disabled except the bias (Vaux) regulator and the controller will be in a low power state, $<500 \mu \mathrm{~A}$. If the Over voltage threshold is exceeded, OUT1 and OUT2 will be disabled and the softstart capacitor will be discharged.

The under/over voltage pin can also be used to implement a remote enable/disable function. By shorting the over/under pin to ground, the converter can be disabled. The internal bias regulator will continue to operate varying between 7.0 and 11 volts. All other functions will be disabled.

## Reference

The NCP1560 provides a precision reference output of 5 volts. This output should be locally bypassed with a $0.1 \mu \mathrm{~F}$ ceramic capacitor. The maximum current available from this output is 10 mA .

## Current Limit

The NCP1560 contains two levels of over current protection. If the voltage on the CS pin exceeds 0.5 volt the present cycle is terminated and the outputs are disabled. If the voltage on the CS pin exceeds 0.6 volts, the controller will disable the outputs, enable the Cycle Skip Timer and discharge the softstart capacitor. The outputs will remain disabled until the Cycle Skip Timer completes, then a softstart will commence. The duration of the Current Sense Fault Timer is set by an external capacitor. The range of capacitor (time set) is $68 \mathrm{pF}(12 \mu \mathrm{~s})$ to $6800 \mathrm{pF}(1.2 \mathrm{mS})$. A complete softstart will commence after the current sense fault timer completes.

## Oscillator and Ramp Feed-Forward

The NCP1560 oscillator is set by a single external resistor connected between the RT pin and return. Internally there are two ramp voltages generated by the oscillator. The OSC_Ramp is a fixed amplitude ramp of 0 to 1.5 volts. This ramp is used for the softstart comparator and as a basis for the Feed Forward ramp (FF_Ramp). The amplitude of the FF ramp varies in proportion to the voltage on the FF_SET pin. The FF_Ramp is used for the PWM comparator and the Max Duty Cycle comparator. The amplitude of the FF_Ramp is normally set to vary from 1.5 to 3.0 volts for a corresponding $2: 1$ change in line voltage. An external resistor between the FF_SET pin and the line sets the proportion to which the ramp amplitude changes with line voltage.

## Maximum Duty Cycle

A dedicated internal comparator limits the maximum output duty cycle. The Feedforward ramp is compared to a fixed voltage configured by the Max Duty Cycle pin. Since the amplitude of the Feedforward ramp increases with increasing line voltage the maximum duty cycle will then decrease with increasing line voltage, which is a desirable feature. If the Max Duty Cycle pin is left open the voltage present at the Max Duty Cycle comparator will be 1.6 volts, which will correspond to a maximum duty cycle of $80 \%$ when the FF_Ramp amplitude is at 2.0 volts. If the Max Duty Cycle pin is shorted to return the voltage present at the Max Duty Cycle comparator will be 1.2 volts, which will correspond to a maximum duty cycle of $60 \%$ when the FF_Ramp amplitude is 2.0 volts. If the Max Duty Cycle pin is connected to Vref, the maximum duty cycle feature will be disabled and the maximum duty cycle will approach $100 \%$. If the FF_Ramp amplitude increases to 4.0 volts as a result of the line increasing the maximum duty cycle will
then decrease to $40 \%$ or $30 \%$, respectively, depending upon the Maximum Duty Set pin configuration.

## PWM Comparator

The PWM comparator compares the Feedforward ramp to the voltage presented at the Vea pin. There is a 0.65 V (diode) offset between the Vea pin and the PWM comparator. The output of an external error amplifier generally drives the Vea pin. The comparator polarity is such that 0.65 volts or less on the Vea pin will cause a Zero duty cycle.

## Softstart

The softstart feature allows the converter to gradually reach the initial steady state operating point, thus reducing start-up stresses and surges. Upon power on, a $6.0 \mu \mathrm{~A}$ current is sourced out of the softstart pin into an external capacitor. The capacitor voltage will begin to ramp up. The voltage on the softstart pin is compared to a 2.0 V Oscillator Ramp signal and will act to reduce the maximum duty cycle until the capacitor voltage ramps up. In the event of a fault, line under/over voltage or current cycle skip, the softstart pin will discharge the external capacitor and disable the output drivers. When the fault condition is no longer present a softstart will be exercised again.

## OUT1, OUT2 and Time Delay

The NCP1560 provides two in-phase outputs, OUT1 and OUT2. However, OUT2 always precedes OUT1 at any low to high transition and OUT1 always precedes OUT2 at any high to low transition. The leading and trailing time delays are equal and set by the Time Delay pin. An open circuit on the Time Delay pin will cause the maximum delay of 500 nS . A 60 K resistor between the Time Delay pin and $5.0 \mathrm{~V} \_$REF will cause the minimum delay of 50 nS . Generally, OUT1 controls the main switching element. OUT2 once inverted can drive the free-wheeling synchronous rectifier switching element.

## Thermal Protection

Internal Thermal Shutdown circuitry is provided to protect the integrated circuit in the event the maximum junction temperature is exceeded. When activated, typically at 150 degrees Celsius, the controller is forced into a low power reset state, disabling the output drivers and the bias regulator. This feature is provided to prevent catastrophic failures from accidental device overheating.

## TL494

## SWITCHMODETM Pulse Width Modulation Control Circuit

The TL494 is a fixed frequency, pulse width modulation control circuit designed primarily for SWITCHMODE power supply control.

- Complete Pulse Width Modulation Control Circuitry
- On-Chip Oscillator with Master or Slave Operation
- On-Chip Error Amplifiers
- On-Chip 5.0 V Reference
- Adjustable Deadtime Control
- Uncommitted Output Transistors Rated to 500 mA Source or Sink
- Output Control for Push-Pull or Single-Ended Operation
- Undervoltage Lockout

## APPLICATIONS INFORMATION

## Description

The TL494 is a fixed-frequency pulse width modulation control circuit, incorporating the primary building blocks required for the control of a switching power supply. (See Figure 1.) An internal-linear sawtooth oscillator is frequency- programmable by two external components, $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. The approximate oscillator frequency is determined by:

$$
\mathrm{f}_{\mathrm{osc}} \approx \frac{1.1}{\mathrm{R}_{\mathrm{T}} \cdot \mathrm{C}_{\mathrm{T}}}
$$

For more information refer to Figure 3.

Output pulse width modulation is accomplished by comparison of the positive sawtooth waveform across capacitor $\mathrm{C}_{\mathrm{T}}$ to either of two control signals. The NOR gates, which drive output transistors Q1 and Q2, are enabled only when the flip-flop clock-input line is in its low state. This happens only during that portion of time when the sawtooth voltage is greater than the control signals. Therefore, an increase in control-signal amplitude causes a corresponding linear decrease of output pulse width. (Refer to the Timing Diagram shown in Figure 2.)

The control signals are external inputs that can be fed into the deadtime control, the error amplifier inputs, or the feedback input. The deadtime control comparator has an effective 120 mV input offset which limits the minimum output deadtime to approximately the first $4 \%$ of the sawtooth-cycle time. This would result in a maximum duty cycle on a given output of $96 \%$ with the output control grounded, and $48 \%$ with it connected to the reference line. Additional deadtime may be imposed on the output by setting the deadtime-control input to a fixed voltage, ranging between 0 V to 3.3 V .

Functional Table

| Input/Output <br> Controls | Output Function | $\frac{\mathbf{f}_{\text {out }}}{\mathbf{f}_{\text {osc }}}=$ |
| :---: | :--- | :---: |
| Grounded | Single-ended PWM @ Q1 and Q2 | 1.0 |
| @ $\mathrm{V}_{\text {ref }}$ | Push-pull Operation | 0.5 |

The pulse width modulator comparator provides a means for the error amplifiers to adjust the output pulse width from the maximum percent on-time, established by the deadtime control input, down to zero, as the voltage at the feedback pin varies from 0.5 V to 3.5 V . Both error amplifiers have a
common mode input range from -0.3 V to $\left(\mathrm{V}_{\mathrm{CC}}-2 \mathrm{~V}\right)$, and may be used to sense power-supply output voltage and current. The error-amplifier outputs are active high and are ORed together at the noninverting input of the pulse-width modulator comparator. With this configuration, the amplifier that demands minimum output on time, dominates control of the loop.
When capacitor $\mathrm{C}_{\mathrm{T}}$ is discharged, a positive pulse is generated on the output of the deadtime comparator, which clocks the pulse-steering flip-flop and inhibits the output transistors, Q1 and Q2. With the output-control connected to the reference line, the pulse-steering flip-flop directs the modulated pulses to each of the two output transistors alternately for push-pull operation. The output frequency is equal to half that of the oscillator. Output drive can also be taken from Q1 or Q2, when single-ended operation with a maximum on-time of less than $50 \%$ is required. This is desirable when the output transformer has a ringback winding with a catch diode used for snubbing. When higher output-drive currents are required for single-ended operation, Q1 and Q2 may be connected in parallel, and the output-mode pin must be tied to ground to disable the flip-flop. The output frequency will now be equal to that of the oscillator.

The TL494 has an internal 5.0 V reference capable of sourcing up to 10 mA of load current for external bias circuits. The reference has an internal accuracy of $\pm 5.0 \%$ with a typical thermal drift of less than 50 mV over an operating temperature range of $0^{\circ}$ to $70^{\circ} \mathrm{C}$.

## APPLICATIONS INFORMATION

## Description

The TL594 is a fixed-frequency pulse width modulation control circuit, incorporating the primary building blocks required for the control of a switching power supply. (See Figure 1.) An internal-linear sawtooth oscillator is frequency- programmable by two external components, $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. The approximate oscillator frequency is determined by:

$$
\mathrm{f}_{\mathrm{osc}} \approx \frac{1.1}{\mathrm{R}_{\mathrm{T}} \cdot \mathrm{C}_{T}}
$$

For more information refer to Figure 3.
Output pulse width modulation is accomplished by comparison of the positive sawtooth waveform across capacitor $\mathrm{C}_{\mathrm{T}}$ to either of two control signals. The NOR gates, which drive output transistors Q1 and Q2, are enabled only when the flip-flop clock-input line is in its low state. This happens only during that portion of time when the sawtooth voltage is greater than the control signals. Therefore, an increase in control-signal amplitude causes a corresponding linear decrease of output pulse width. (Refer to the Timing Diagram shown in Figure 2.)

The control signals are external inputs that can be fed into the deadtime control, the error amplifier inputs, or the feedback input. The deadtime control comparator has an effective 120 mV input offset which limits the minimum output deadtime to approximately the first $4 \%$ of the sawtooth-cycle time. This would result in a maximum duty cycle on a given output of $96 \%$ with the output control grounded, and $48 \%$ with it connected to the reference line. Additional deadtime may be imposed on the output by setting the deadtime-control input to a fixed voltage, ranging between 0 V to 3.3 V .
The pulse width modulator comparator provides a means for the error amplifiers to adjust the output pulse width from the maximum percent on-time, established by the deadtime control input, down to zero, as the voltage at the feedback

Figure 3. Oscillator Frequency versus Timing Resistance
pin varies from 0.5 V to 3.5 V . Both error amplifiers have a common-mode input range from -0.3 V to $\left(\mathrm{V}_{\mathrm{CC}}-2 \mathrm{~V}\right)$, and may be used to sense power-supply output voltage and current. The error-amplifier outputs are active high and are ORed together at the noninverting input of the pulse-width modulator comparator. With this configuration, the amplifier that demands minimum output on time, dominates control of the loop.

Functional Table

| Input/Output <br> Controls | Output Function | $\frac{\mathbf{f}_{\text {out }}}{\mathbf{f}_{\text {osc }}}=$ |
| :---: | :--- | :---: |
| Grounded | Single-ended PWM @ Q1 and Q2 | 1.0 |
| $@ \mathrm{~V}_{\text {ref }}$ | Push-pull Operation | 0.5 |

When capacitor $\mathrm{C}_{\mathrm{T}}$ is discharged, a positive pulse is generated on the output of the deadtime comparator, which clocks the pulse-steering flip-flop and inhibits the output transistors, Q1 and Q2. With the output-control connected to the reference line, the pulse-steering flip-flop directs the modulated pulses to each of the two output transistors alternately for push-pull operation. The output frequency is equal to half that of the oscillator. Output drive can also be taken from Q1 or Q2, when single-ended operation with a maximum on-time of less than $50 \%$ is required. This is desirable when the output transformer has a ringback winding with a catch diode used for snubbing. When higher output-drive currents are required for single-ended operation, Q1 and Q2 may be connected in parallel, and the output-mode pin must be tied to ground to disable the flip-flop. The output frequency will now be equal to that of the oscillator.
The TL594 has an internal 5.0 V reference capable of sourcing up to 10 mA of load current for external bias circuits. The reference has an internal accuracy of $\pm 1.5 \%$ with a typical thermal drift of less than 50 mV over an operating temperature range of $0^{\circ}$ to $70^{\circ} \mathrm{C}$.

## SG3525A

## Pulse Width <br> Modulator Control Circuit

The SG3525A pulse width modulator control circuit offers improved performance and lower external parts count when implemented for controlling all types of switching power supplies. The on-chip +5.1 V reference is trimmed to $\pm 1 \%$ and the error amplifier has an input common-mode voltage range that includes the reference voltage, thus eliminating the need for external divider resistors. A sync input to the oscillator enables multiple units to be slaved or a single unit to be synchronized to an external system clock. A wide range of deadtime can be programmed by a single resistor connected between the $\mathrm{C}_{\mathrm{T}}$ and Discharge pins. This device also features built-in soft-start circuitry, requiring only an external timing capacitor. A shutdown pin controls both the soft-start circuitry and the output stages, providing instantaneous turn off through the PWM latch with pulsed shutdown, as well as soft-start recycle with longer shutdown commands. The under voltage lockout inhibits the outputs and the changing of the soft-start capacitor when $\mathrm{V}_{\mathrm{CC}}$ is below nominal. The output stages are totem-pole design capable of sinking and sourcing in excess of 200 mA . The output stage of the SG3525A features NOR logic resulting in a low output for an off-state.

- 8.0 V to 35 V Operation
- $5.1 \mathrm{~V} \pm 1.0 \%$ Trimmed Reference
- 100 Hz to 400 kHz Oscillator Range
- Separate Oscillator Sync Pin
- Adjustable Deadtime Control
- Input Undervoltage Lockout
- Latching PWM to Prevent Multiple Pulses
- Pulse-by-Pulse Shutdown
- Dual Source/Sink Outputs: $\pm 400 \mathrm{~mA}$ Peak

## APPLICATION INFORMATION

## Shutdown Options (See Block Diagram, front page)

Since both the compensation and soft-start terminals (Pins 9 and 8) have current source pull-ups, either can readily accept a pull-down signal which only has to sink a maximum of $100 \mu \mathrm{~A}$ to turn off the outputs. This is subject to the added requirement of discharging whatever external capacitance may be attached to these pins.

An alternate approach is the use of the shutdown circuitry of Pin 10 which has been improved to enhance the available shutdown options. Activating this circuit by applying a positive signal on Pin 10 performs two functions: the PWM
latch is immediately set providing the fastest turn-off signal to the outputs; and a $150 \mu \mathrm{~A}$ current sink begins to discharge the external soft-start capacitor. If the shutdown command is short, the PWM signal is terminated without significant discharge of the soft-start capacitor, thus, allowing, for example, a convenient implementation of pulse-by-pulse current limiting. Holding Pin 10 high for a longer duration, however, will ultimately discharge this external capacitor, recycling slow turn-on upon release.

Pin 10 should not be left floating as noise pickup could conceivably interrupt normal operation.

Figure 7. Oscillator Schematic

Figure 8. Error Amplifier Schematic

Figure 9. Output Circuit
(1/2 Circuit Shown)

For single-ended supplies, the driver outputs are grounded. The $\mathrm{V}_{\mathrm{C}}$ terminal is switched to ground by the totem-pole source transistors on alternate oscillator cycles.

Figure 10. Single-Ended Supply

The low source impedance of the output drivers provides rapid charging of power FET input capacitance while minimizing external components.

Figure 12. Driving Power FETS

In conventional push-pull bipolar designs, forward base drive is controlled by R1-R3. Rapid turn-off times for the power devices are achieved with speed-up capacitors C 1 and C 2 .

Figure 11. Push-Pull Configuration

Low power transformers can be driven directly by the SG3525A. Automatic reset occurs during deadtime, when both ends of the primary winding are switched to ground.

Figure 13. Driving Transformers in a Half-Bridge Configuration

## CS3524A

## Voltage Mode <br> PWM Control Circuit with 200 mA Output Drivers

The CS3524A PWM control circuit retains the same versatile architecture of the industry standard CS3524 (SG3524) while adding substantial improvements.

The CS3524 is pin-compatible with "non-A" versions, and in most applications can be directly interchanged. The CS3524A, however, eliminates many of the design restrictions which had previously required additional external circuitry.

The CS3524A includes a precision 5.0 V reference trimmed to $\pm 1 \%$ accuracy (eliminating the need for potentiometer adjustments), an error amplifier with an output voltage swing extending to 5.0 V , and a current sense amplifier useful in either the ground or power supply output lines. The uncommitted $60 \mathrm{~V}, 200 \mathrm{~mA}$ NPN output pair greatly enhances the output drive capability.

The CS3524A features an undervoltage lockout circuit which disables all internal circuitry (except the reference) until the input voltage has risen to 8.0 V . This holds standby current low until turn-on, and greatly simplifies the design of low power, off-line supplies. The turn-on circuit has approximately 600 mV of hysteresis for jitter free activation.

Other improvements include a PWM latch that insures freedom from multiple pulsing within a period, even in noisy environments; logic to eliminate double pulsing on a single output, a 200 ns external shutdown capability, and automatic thermal protection from excessive chip temperature. The oscillator circuit is usable to 500 kHz and is easier to synchronize with an external clock pulse.

## Features

- Precision Reference Internally Trimmed to $\pm 1 \%$
- Current Limit
- Undervoltage Lockout
- Start-Up Supply Current < 4.0 mA
- Output to 200 mA
- 60 V Output Capability
- Wide Common-Mode Input Range for Error and Current Limit Amplifiers
- PWM Latch Insures Single Pulse per Period
- Double Pulse Suppression
- 200 ns Shutdown
- Guaranteed Frequency
- Thermal Shutdown

Figure 10. Output Saturation Voltage vs. Output Current Over Temperature

Figure 11. Open Loop Test Circuit

Note: The CS3524A should be able to be tested in any 3524 test circuit with two possible exceptions:

1. The higher gain-bandwidth of the current limit amplifier in the CS3524A may cause oscillations in an uncompensated 3524 test circuit.
2. The effect of the shutdown cannot be seen at the compensation terminal, but must be observed at the outputs.

## CS51221

## Enhanced Voltage Mode PWM Controller

The CS51221 fixed frequency feed forward voltage mode PWM controller contains all of the features necessary for basic voltage mode operation. This PWM controller has been optimized for high frequency primary side control operation. In addition, this device includes such features as: Soft Start, accurate duty cycle limit control, less than $50 \mu \mathrm{~A}$ startup current, over and under voltage protection, and bidirectional synchronization. The CS51221 is available in a 16 lead SO narrow surface mount package.

## Features

- 1.0 MHz Frequency Capability
- Fixed Frequency Voltage Mode Operation, with Feed Forward
- Thermal Shutdown
- Undervoltage Lock-Out
- Accurate Programmable Max Duty Cycle Limit
- 1.0 A Sink/Source Gate Drive
- Programmable Pulse-By-Pulse Overcurrent Protection
- Leading Edge Current Sense Blanking
- 75 ns Shutdown Propagation Delay
- Programmable Soft Start
- Undervoltage Protection
- Overvoltage Protection with Programmable Hysteresis
- Bidirectional Synchronization
- 25 ns GATE Rise and Fall Time (1.0 nF Load)
- 3.3 V 3\% Reference Voltage Output

## PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| SO-16 | PIN SYMBOL | FUNCTION |
| 1 | GATE | External power switch driver with 1.0 A peak capability. Rail to rail output occurs when the capacitive load is between 470 pF and 10 nF . |
| 2 | $I_{\text {SENSE }}$ | Current sense comparator input. |
| 3 | SYNC | Bidirectional synchronization. Locks to highest frequency. |
| 4 | FF | PWM ramp. |
| 5 | UV | Undervoltage protection monitor. |
| 6 | OV | Overvoltage protection monitor. |
| 7 | $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ | Timing resistor $\mathrm{R}_{\mathrm{T}}$ and capacitor $\mathrm{C}_{\mathrm{T}}$ determine oscillator frequency and maximum duty cycle, $\mathrm{D}_{\mathrm{MAX}}$. |
| 8 | $\mathrm{I}_{\text {SET }}$ | Voltage at this pin sets pulse-by-pulse overcurrent threshold. |
| 9 | $V_{F B}$ | Feedback voltage input. Connected to the error amplifier inverting input. |
| 10 | COMP | Error amplifier output. |
| 11 | SS | Charging external capacitor restricts error amplifier output voltage during the power up or fault conditions. |
| 12 | LGND | Logic ground. |
| 13 | $\mathrm{V}_{\text {REF }}$ | 3.3 V reference voltage output. Decoupling capacitor can be selected from $0.01 \mu \mathrm{~F}$ to $10 \mu \mathrm{~F}$. |
| 14 | $\mathrm{V}_{\mathrm{CC}}$ | Logic supply voltage. |
| 15 | PGND | Output power stage ground. |
| 16 | $\mathrm{V}_{\mathrm{C}}$ | Output power stage supply voltage. |

Figure 2. Block Diagram

## APPLICATION INFORMATION

## THEORY OF OPERATION

## Feed Forward Voltage Mode Control

In conventional voltage mode control, the ramp signal has fixed rising and falling slope. The feedback signal is derived solely from the output voltage. Consequently, voltage mode control has inferior line regulation and audio susceptibility.

Feed forward voltage mode control derives the ramp signal from the input line, as shown in Figure 3. Therefore, the ramp of the slope varies with the input voltage. At the start of each switch cycle, the capacitor connected to the FF pin is charged through a resistor connected to the input voltage. Meanwhile, the Gate output is turned on to drive an external power switching device. When the FF pin voltage reaches the error amplifier output $\mathrm{V}_{\text {COMP }}$, the PWM comparator turns off the Gate, which in turn opens the external switch. Simultaneously, the FF capacitor is quickly discharged to 0.3 V .

Overall, the dynamics of the duty cycle are controlled by both input and output voltages. As illustrated in Figure 4, with a fixed input voltage the output voltage is regulated solely by the error amplifier. For example, an elevated output voltage reduces $\mathrm{V}_{\text {COMP }}$ which in turn causes duty cycle to decrease. However, if the input voltage varies, the slope of the ramp signal will react immediately which provides a much improved line transient response. As an example shown in Figure 5, when the input voltage goes up, the rising edge of the ramp signal increases which reduces duty cycle to counteract the change.

Figure 3. Feed Forward Voltage Mode Control
The feed forward feature can also be employed to provide a volt-second clamp, which limits the maximum product of input voltage and turn on time. This clamp is used in circuits, such as Forward and Flyback converter, to prevent the transformer from saturating. Calculations used in the design
of the volt-second clamp are presented in the Design Guidelines section.

Figure 4. Pulse Width Modulated by Output Current with Constant Input Voltage

Figure 5. Pulse Width Modulated by Input Voltage with Constant Output Current

## Powering the IC \& UVL

The Under Voltage Lockout (UVL) comparator has two voltage references; the start and stop thresholds. During power-up, the UVL comparator disables $\mathrm{V}_{\text {REF }}$ (which in-turn disables the entire IC) until the controller reaches its $\mathrm{V}_{\mathrm{CC}}$ start threshold. During power-down, the UVL comparator allows the controller to operate until the $\mathrm{V}_{\mathrm{CC}}$ stop threshold is reached. The CS51221 requires only $50 \mu \mathrm{~A}$ during startup. The output stage is held at a low impedance state in lock out mode.
During power up and fault conditions, the soft-start clamps the Comp pin voltage and limits the duty cycle. The power up transition tends to generate temporary duty cycles
much greater than the steady state value due to the low output voltage. Consequently, excessive current stresses often take place in the system. Soft Start technique alleviates this problem by gradually releasing the clamp on the duty cycle to eliminate the in-rush current. The duration of the Soft Start can be programmed through a capacitance connected to the SS pin. The constant charging current to the SS pin is $50 \mu \mathrm{~A}$ (typ).

The $\mathrm{V}_{\text {REF }}$ (ok) comparator monitors the $3.3 \mathrm{~V} \mathrm{~V}_{\text {REF }}$ output and latches a fault condition if $\mathrm{V}_{\text {REF }}$ falls below 3.1 V . The fault condition may also be triggered when the OV pin voltage rises above 2.0 V or the UV pin voltage falls below 1.0 V . The under-voltage comparator has a built-in hysteresis of 75 mV (typ). The hysteresis for the OV comparator is programmable through a resistor connected to the OV pin. When an OV condition is detected, the over-voltage hysteresis current of $12.5 \mu \mathrm{~A}$ (typ) is sourced from the pin.

In Figure 6, the fault condition is triggered by pulling the UV pin to the ground. Immediately, the SS capacitor is discharged with $5.0 \mu \mathrm{~A}$ of current (typ) and the GATE output is disabled until the SS voltage reaches the discharge voltage of 0.3 V (typ). The IC starts the Soft Start transition again if the fault condition has recovered as shown in Figure 6. However, if the fault condition persists, the SS voltage will stay at 0.1 V until the removal of the fault condition.

Figure 6. The Fault Condition Is Triggered when the UV Pin Voltage Falls Below 1.0 V. The Soft Start Capacitor Is Discharged and the GATE Output Is Disabled. CH2: Envelop of GATE Output, CH3: SS Pin with $0.01 \mu$ F Capacitor, CH4: UV Pin

## Current Sense and Over Current Protection

The current can be monitored by the $\mathrm{I}_{\text {SENSE }}$ pin to achieve pulse by pulse current limit. Various techniques, such as a using current sense resistor or current transformer, can be adopted to derive current signals. The voltage of the ISET pin
sets the threshold for maximum current. As shown in Figure 7, when the I current limit comparator will reset the GATE latch flip-flop to terminate the GATE pulse.

Figure 7. The GATE Output Is Terminated When the I ISENSE Pin Voltage Reaches the Threshold Set By the $I_{\text {SET }}$ Pin. CH2: I ISENSE Pin, CH4: I CH3: GATE Pin

The current sense signal is prone to leading edge spikes caused by the switching transition. A RC low-pass filter is usually applied to the current signals to avoid premature triggering. However, the low pass filter will inevitably change the shape of the current pulse and also add cost. The CS51221 uses leading edge blanking circuitry that blocks out the first 150 ns (typ) of each current pulse. This removes the leading edge spikes without altering the current waveform. The blanking is disabled during Soft Start and when the $\mathrm{V}_{\text {COMP }}$ is saturated high so that the minimum on-time of the controller does not have the additional blanking period. The max SS detect comparator keeps the blanking function disabled until SS charges fully. The output of the max Duty Cycle detector goes high when the error amplifier output gets saturated high, indicating that the output voltage has fallen well below its regulation point and the power supply may be under load stress.

## Oscillator and Synchronization

The switching frequency is programmable through a RC network connected to the $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ Pin. As shown in Figure 8, when the $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ pin reaches 2.0 V , the capacitor is discharged by a 1.0 mA current source and the Gate signal is disabled. When the $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ pin decreases to 1.0 V , the Gate output is turned on and the discharge current is removed to let the $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ pin ramp up. This begins a new switching cycle. The $\mathrm{C}_{\mathrm{T}}$ charging time over the switch period sets the maximum duty cycle clamp which is programmable through the $\mathrm{R}_{\mathrm{T}}$ value as shown in the Design Guidelines. At the beginning
of each switching cycle, the SYNC pin generates a 2.5 V , 320 nS (typ) pulse. This pulse can be utilized to synchronize other power supplies.

Figure 8. The SYNC Pin Generates a Sync Pulse at the Beginning of Each Switching Cycle. CH2: GATE Pin, CH3: $\mathbf{R}_{\mathbf{T}} \mathrm{C}_{\mathrm{T}}, \mathrm{CH} 4$ : SYNC Pin

An external pulse signal can feed to the bidirectional SYNC pin to synchronize the switch frequency. For reliable operation, the sync frequency should be approximately $20 \%$ higher than free running IC frequency. As show in Figure 9, when the SYNC pin is triggered by an incoming signal, the IC immediately discharges $\mathrm{C}_{\mathrm{T}}$. The GATE signal is turned on once the $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ pin reaches the valley voltage. Because of the steep falling edge, this valley voltage falls below the regular 1.0 V threshold. However, the $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ pin voltage is then quickly raised by a clamp. When the $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ pin reaches the 0.95 V (typ) Valley Clamp Voltage, the clamp is disconnected after a brief delay and $\mathrm{C}_{\mathrm{T}}$ is charged through $\mathrm{R}_{\mathrm{T}}$.

Figure 9. Operation with External Sync. CH2: SYNC Pin, CH3: GATE Pin, $\mathbf{C H} 4$ : $\mathbf{R}_{\mathbf{T}} \mathbf{C}_{\mathbf{T}}$ Pin

## DESIGN GUIDELINES

## Switch Frequency and Maximum Duty Cycle Calculations

Oscillator timing capacitor, $\mathrm{C}_{\mathrm{T}}$, is charged by $\mathrm{V}_{\mathrm{REF}}$ through $\mathrm{R}_{\mathrm{T}}$ and discharged by an internal current source. During the discharge time, the internal clock signal sets the Gate output to the low state, thus providing a user selectable maximum duty cycle clamp. Charge and discharge times are determined by following general formulas;

$$
\begin{gathered}
t_{C}=R_{T} C_{T} \ln \left(\frac{\left(V_{R E F}-V_{V A L L E Y}\right)}{\left(V_{R E F}-V_{P E A K}\right)}\right) \\
t_{d}=R_{T} C T \ln \left(\frac{\left(V_{R E F}-V_{\text {PEAK }}-I_{d} R T\right)}{\left(V_{R E F}-V_{V A L L E Y}-I_{d} R_{T}\right)}\right)
\end{gathered}
$$

where:
$\mathrm{t}_{\mathrm{C}}=$ charging time;
$\mathrm{t}_{\mathrm{d}}=$ discharging time;
$\mathrm{V}_{\text {VALLEY }}=$ valley voltage of the oscillator;
$\mathrm{V}_{\text {PEAK }}=$ peak voltage of the oscillator.
Substituting in typical values for the parameters in the above formulas, $\mathrm{V}_{\text {REF }}=3.3 \mathrm{~V}, \mathrm{~V}_{\text {VALLEY }}=1.0 \mathrm{~V}, \mathrm{~V}_{\text {PEAK }}=$ $2.0 \mathrm{~V}, \mathrm{I}_{\mathrm{d}}=1.0 \mathrm{~mA}$ :

$$
\begin{gathered}
\mathrm{t}_{\mathrm{C}}=0.57 \mathrm{R}_{\mathrm{T}} \mathrm{C} T \\
\mathrm{t}_{\mathrm{d}}=\mathrm{R}_{\mathrm{T}} \mathrm{C} T \ln \left(\frac{1.3-0.001 \mathrm{R}_{\mathrm{T}}}{2.3-0.001 \mathrm{RT}}\right) \\
\mathrm{D}_{\text {max }}=\frac{0.57}{0.57+\ln \left(\frac{1.3-0.001 \mathrm{RT} T}{2.3-0.001 \mathrm{R}_{\mathrm{T}}}\right)}
\end{gathered}
$$

It is noticed from the equation that for the oscillator to function properly, $\mathrm{R}_{\mathrm{T}}$ has to be greater than 2.3 k .

Figure 10. Typical Performance Characteristics, Oscillator Frequency vs. $\mathrm{C}_{\mathbf{T}}$

## Select RC for Feed Forward Ramp

If the line voltage is much greater than the FF pin Peak Voltage, the charge current can be treated as a constant and is equal to $\mathrm{V}_{\mathrm{IN}} / \mathrm{R}$. Therefore, the volt-second value is determined by:

$$
\mathrm{V}_{\mathrm{IN}} \times \mathrm{T}_{\mathrm{ON}}=\left(\mathrm{V}_{\mathrm{COMP}}-\mathrm{V}_{\mathrm{FF}(\mathrm{~d})}\right) \times \mathrm{R} \times \mathrm{C}
$$

where:
$\mathrm{V}_{\text {COMP }}=$ COMP pin voltage;
$\mathrm{V}_{\mathrm{FF}(\mathrm{d})}=\mathrm{FF}$ pin discharge voltage.
As shown in the equation, the volt-second clamp is set by the $\mathrm{V}_{\mathrm{COMP}}$ clamp voltage which is equal to 1.8 V . In Forward or Flyback circuits, the volt-second clamp value is designed to prevent transformers from saturation.

In a buck or forward converter, volt-second is equal to

$$
\mathrm{V}_{\mathrm{IN}} \times \mathrm{T}_{\mathrm{ON}}=\left(\frac{\mathrm{V}_{\mathrm{OUT}} \times \mathrm{TS}_{\mathrm{S}}}{\mathrm{n}}\right)
$$

$\mathrm{n}=$ transformer turns ratio, which is a constant determined by the regulated output voltage, switching period and transformer turns ration (use 1.0 for buck converter). It is interesting to notice from the aforementioned two equations that during steady state, $\mathrm{V}_{\text {COMP }}$ doesn't change for input voltage variations. This intuitively explains why FF voltage mode control has superior line regulation and line transient response. Knowing the nominal value of $\mathrm{V}_{\mathrm{IN}}$ and $\mathrm{T}_{\mathrm{ON}}$, one can also select the value of RC to place $\mathrm{V}_{\mathrm{COMP}}$ at the center of its dynamic range.

## Select Feedback Voltage Divider

As shown in Figure 12, the voltage divider output feeds to the FB pin, which connects to the inverting input of the error amplifier. The non-inverting input of the error amplifier is connected to a 1.27 V (typ) reference voltage. The FB pin has an input current which has to be considered for accurate DC outputs. The following equation can be used to calculate the R1 and R2 value

$$
\left(\frac{\mathrm{R} 2}{\mathrm{R} 1+\mathrm{R} 2}\right) \mathrm{V}_{\mathrm{OUT}}=1.27-\nabla
$$

Figure 11. Typical Performance Characteristics, Oscillator Duty Cycle vs. $\mathbf{R}_{\mathbf{T}}$
where $\nabla$ is the correction factor due to the existence of the FB pin input current Ier.

$$
\nabla=(\mathrm{Ri}+\mathrm{R} 1 / / \mathrm{R} 2) \mathrm{ler}
$$

$\mathrm{Ri}=\mathrm{DC}$ resistance between the FB pin and the voltage divider output.

Ier $=\mathrm{V}_{\mathrm{FB}}$ input current, $1.3 \mu \mathrm{~A}$ typical.

Figure 12. The Design of Feedback Voltage Divider Has to Consider the Error Amplifier Input Current

## Design Voltage Dividers for OV and UV Detection

In Figure 13, the voltage divider uses three resistors in series to set OV and UV threshold seen from the input voltage. The values of the resistors can be calculated from the following three equations, where the third equation is derived from OV hysteresis requirement.

$$
\begin{gather*}
\mathrm{V}_{\mathrm{IN}(\mathrm{LOW})} \times\left(\frac{\mathrm{R} 2+\mathrm{R} 3}{\mathrm{R} 2+\mathrm{R} 3+\mathrm{R} 1}\right)=1.0 \mathrm{~V}  \tag{A}\\
\mathrm{~V}_{\mathrm{IN}(\mathrm{HIGH})} \times\left(\frac{\mathrm{R} 3}{\mathrm{R} 2+\mathrm{R} 3+\mathrm{R} 1}\right)=2.0 \mathrm{~V}  \tag{B}\\
12.5 \mu \mathrm{~A} \times(\mathrm{R} 1+\mathrm{R} 2)=\mathrm{V}_{\mathrm{HYST}} \tag{C}
\end{gather*}
$$

where:

## CS51221

$\mathrm{V}_{\mathrm{IN}(\mathrm{LOW})}, \mathrm{V}_{\mathrm{IN}(\mathrm{HIGH})}=$ input voltage OV and UV threshold;
$\mathrm{V}_{\text {HYST }}=\mathrm{OV}$ hysteresis seen at $\mathrm{V}_{\text {IN }}$
It is self-evident from equation $A$ and $B$ that to use this design, $\mathrm{V}_{\text {IN(HIGH) }}$ has to be two times greater than $\mathrm{V}_{\text {IN(LOW). }}$. Otherwise, two voltage dividers have to be used to program OV and UV separately.

Figure 13. OV/UV Monitor Divider

## CS51227

## Enhanced Voltage Mode PWM Controller

The CS51227 is a fixed frequency, single output PWM controller using feed forward voltage mode control. Feed forward control provides superior line regulation and line transient response. This PWM controller has been optimized for high frequency primary side control operation. It has undervoltage lockout with 4.7 V start up voltage and $75 \mu \mathrm{~A}$ start up current. One external capacitor can program the switching frequency up to 1.0 MHz . The protection features include pulse-by-pulse current limit with leading edge blanking and thermal shutdown. The CS51227 is available in 8 lead SO narrow surface mount package.

## Features

- 1.0 MHz Frequency Capability
- 4.7 V Start-Up Voltage
- Fixed Frequency Voltage Mode Operation with Feed Forward
- Undervoltage Lockout
- $75 \mu \mathrm{~A}$ Start-Up Current
- Thermal Shutdown
- 1.0 A Sink/Source Gate Drive
- Pulse-By-Pulse Current Limit with Leading Edge Blanking
- 50 ns GATE Rise and Fall Time (1.0 nF Load)
- Maximum Duty Cycle Over 85\%
- Programmable Volt-Second Clamp

## THEORY OF APPLICATION

## THEORY OF OPERATION

## Feed Forward Voltage Mode Control

In conventional voltage mode control, the ramp signal is fixed and often generated by the oscillator. The output voltage is the only feedback path for regulation against load and line variations. Feed forward voltage mode uses the ramp signal driven by the input line, as shown in Figure 3. Therefore, the ramp signal responds immediately to line change. At the start of each switch cycle, the FF pin capacitor is charged up through a resistor connected to the input line. Meanwhile, the Gate output is turned on to drive an external power switching device. When the FF pin voltage reaches the error amplifier output $\mathrm{V}_{\mathrm{COMP}}$, the PWM comparator turns off the Gate and the FF pin capacitor is quickly discharged by an internal current source.

Figure 3. Feed Forward Voltage Mode Control

Figure 4. Pulse Width Modulated By Output Current With Constant Input Voltage

Overall, the dynamics of the duty cycle are controlled by both input and output voltages. As shown in Figure 4, an elevated output voltage reduces $\mathrm{V}_{\text {COMP }}$ through the error amplifier. This in turn decreases the duty cycle and corrects the deviation of the output voltage. For line variation, the ramp signal responds immediately, which provides much improved line transient response. The delay associated with the power stage and feedback path has been totally avoided. As an example, shown in Figure 5, when the input line goes up, the slope of the ramp signal increases, reducing duty cycle to counteract the change.

Figure 5. Pulse Width Modulated By Input Voltage With Constant Output Voltage

The feed forward feature can also be employed to implement volt-second clamping, which limits the maximum product of input voltage and turn on time. This clamp is used in circuits, such as Forward and Flyback converters, to prevent the transformer from saturating. The calculation for volt-second clamping is presented in the Design Guidelines section.

## Powering the IC \& UVL

The internal logic monitors the supply voltage to ensure the controller has enough operating headroom. The $\mathrm{V}_{\text {REF }}$ block provides power to the controller's logic. The $\mathrm{V}_{\text {REF(OK) }}$ comparator monitors the internal $3.3 \mathrm{~V} \mathrm{~V}_{\text {REF }}$ line and flags a fault if $\mathrm{V}_{\text {REF }}$ falls below 3.1 V .
The Undervoltage Lockout (UVL) comparator has two voltage references; the start and stop thresholds. During power-up, the UVL comparator disables $\mathrm{V}_{\text {REF }}$ (which in-turn disables the entire IC) until the controller reaches its $\mathrm{V}_{\mathrm{CC}}$ start threshold. During power-down, the UVL comparator allows the controller to operate until the $\mathrm{V}_{\mathrm{CC}}$ stop threshold is reached. The CS51227 requires only $50 \mu \mathrm{~A}$ during startup. During low $\mathrm{V}_{\mathrm{CC}}$ and abnormal operation conditions, the output stage is held at a low level, low impedance state.

## Current Sense and Over Current Protection

The I pulse current limit. When the ISENSE pin voltage exceeds the internal threshold ( 0.3 V typical), the current limit comparator immediately turns off the Gate signal. The Gate will then stay off for the remainder of the cycle. Various techniques, such as using current sensing resistor or current transformer, are widely adopted to generate the current signal.
The current sense signal is prone to leading edge spikes caused by switching transitions. A RC low-pass filter can effectively reduce the spikes and avoid premature triggering. However, the low pass filter will inevitably change the shape of the current pulse and also add cost. The CS51227 has built-in leading edge blanking circuitry that blocks out the first 150 ns (typ) of each current pulse. This feature removes the leading edge spikes without altering the current waveform. Blanking is disabled when the COMP pin voltage exceeds 3.0 V (typ). This feature reduces the minimum duty cycle during an output short or overload condition.

## DESIGN GUIDELINES

## Programming Oscillator Frequency

The switching frequency is set by the capacitor connected to the $\mathrm{C}_{\mathrm{T}}$ pin. The $\mathrm{C}_{\mathrm{T}}$ pin voltage oscillates between 1.0 V and 2.0 V . The ratio of the charge and discharge currents sets the maximum duty cycle to be $90 \%$. Use the following equation to select $\mathrm{C}_{\mathrm{T}}$,

$$
\mathrm{C}_{\top}=\frac{9.027 \times 107}{\mathrm{f}_{\mathrm{S}}}
$$

where:
$\mathrm{fs}=$ Switching frequency
$\mathrm{C}_{\mathrm{T}}=$ Capacitance in pF

When $\mathrm{C}_{\mathrm{T}}$ is less than 100 pF , parasitic capacitance associated with the $\mathrm{C}_{\mathrm{T}}$ pin starts to impact frequency accuracy. Figure 6 shows typical oscillator frequency vs. $\mathrm{C}_{\mathrm{T}}$ value.

Figure 6. Typical Performance Characteristics: Oscillator Frequency vs. $\mathrm{C}_{\boldsymbol{T}}$

## Component Selection for Feed Forward Ramp

FF discharge voltage and FF maximum voltage limit the maximum voltage rise on the FF pin to 1.5 V typical. This provides the volt-second clamp feature when the FF pin is driven by the input line. If the line voltage is much greater than the FF pin voltage, the charge current is approximately equal to $\mathrm{V}_{\mathrm{IN}} / \mathrm{R}$ where R is the resistor connecting the FF pin and input line. The voltage second clamp then has the form of:

$$
\mathrm{V}_{\mathrm{IN}} \times \mathrm{T}_{\mathrm{ON}}=1.5 \times \mathrm{R} \times \mathrm{C}_{\mathrm{FF}}
$$

One can select $\mathrm{RC}_{\mathrm{FF}}$ to prevent magnetic devices from saturating.

In a buck or forward converter, the error amplifier output $\mathrm{V}_{\text {COMP }}$ is equal to:

$$
\mathrm{V}_{\mathrm{COMP}}=\frac{\mathrm{V}_{\mathrm{OUT}} \times \mathrm{TS}}{\mathrm{~N} \times \mathrm{R} \times \mathrm{C}_{\mathrm{FF}}}+0.3 \mathrm{~V}
$$

where:
$\mathrm{N}=$ Transformer turns ratio (use 1 for buck converter)
$\mathrm{T}_{\mathrm{S}}=$ Switching period
This equation shows that the error amplifier output is independent of the input voltage. Therefore, the system does not rely on the error amplifier to respond to line variations. This excludes the delay associated with the error amplifier. The line regulation is also greatly improved because both
error amplifier and ramp signal can contribute to DC regulation.

## Select Feedback Voltage Divider

As shown in Figure 7, the voltage divider output feeds the FB pin which connects to the inverting input of the error amplifier. The non-inverting input of the error amplifier is connected to a 1.263 V reference voltage. The FB pin has an input current which has to be taken into account for accurate output voltage programming. The following equation can be used to calculate the R1 and R2 value:

$$
\frac{\mathrm{R} 2}{\mathrm{R} 1+\mathrm{R} 2} \times \mathrm{V}_{\mathrm{OUT}}=1.263-\nabla
$$

where $\nabla$ is the correction factor

$$
\nabla=(R i+R 1 / / R 2) \times \operatorname{ler}
$$

$\mathrm{Ri}=\mathrm{DC}$ resistance between the FB pin and the voltage divider output, as shown in Figure 7.
Ier $=\mathrm{FB}$ pin input current, $1.3 \mu \mathrm{~A}$ typical.

Figure 7. The Feedback Voltage Divider Design Has to Consider the Error Amplifier Input Current

## Thermal Management

The CS51227 will enter thermal shutdown when the junction (die surface) temperature exceeds $150^{\circ} \mathrm{C}$, typical. $10^{\circ} \mathrm{C}$ typical thermal hysteresis will prevent part cycling, or a "chattering" startup near the shutdown temperature. Junction temperature is a function of the ambient temperature, thermal resistance of the die and package, and the power dissipated by the package and leads.

PACKAGE THERMAL DATA

| Parameter |  | SO-8 | Unit |
| :--- | :---: | :---: | :---: |
| $R_{\text {©JC }}$ | Typical | 45 | ${ }^{\circ} \mathrm{C} / \mathrm{W}$ |
| $R_{\text {©JA }}$ | Typical | 165 | ${ }^{\circ} \mathrm{C} / \mathrm{W}$ |

## MC34025, MC33025

## High Speed Double-Ended PWM Controller

The MC34025 series are high speed, fixed frequency, double-ended pulse width modulator controllers optimized for high frequency operation. They are specifically designed for Off-Line and DC-to-DC converter applications offering the designer a cost effective solution with minimal external components. These integrated circuits feature an oscillator, a temperature compensated reference, a wide bandwidth error amplifier, a high speed current sensing comparator, steering flip-flop, and dual high current totem pole outputs ideally suited for driving power MOSFETs.

Also included are protective features consisting of input and reference undervoltage lockouts each with hysteresis, cycle-by-cycle current limiting, and a latch for single pulse metering.

The flexibility of this series allows it to be easily configured for either current mode or voltage mode control.

- 50 ns Propagation Delay to Outputs
- Dual High Current Totem Pole Outputs
- Wide Bandwidth Error Amplifier
- Fully-Latched Logic with Double Pulse Suppression
- Latching PWM for Cycle-By-Cycle Current Limiting
- Soft-Start Control with Latched Overcurrent Reset
- Input Undervoltage Lockout with Hysteresis
- Low Start-Up Current (500 $\mu \mathrm{A}$ Typ)
- Internally Trimmed Reference with Undervoltage Lockout
- $90 \%$ Maximum Duty Cycle (Externally Adjustable)
- Precision Trimmed Oscillator
- Voltage or Current Mode Operation to 1.0 MHz
- Functionally Similar to the UC3825

Figure 20. Current Limit Operating Waveforms

The MC33025 and MC34025 series are high speed, fixed frequency, double-ended pulse width modulator controllers optimized for high frequency operation. They are specifically designed for Off-Line and DC-to-DC converter applications offering the designer a cost effective solution with minimal external components. A representative block diagram is shown in Figure 19.

## Oscillator

The oscillator frequency is programmed by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. The $\mathrm{R}_{\mathrm{T}}$ pin is set to a temperature compensated 3.0 V . By selecting the value of $\mathrm{R}_{\mathrm{T}}$, the charge current is set through a current mirror for the timing capacitor $\mathrm{C}_{\mathrm{T}}$. This charge current runs continuously through $\mathrm{C}_{\mathrm{T}}$. The discharge current is ratioed to be 10 times the charge current, which yields the maximum duty cycle of $90 \%$. $\mathrm{C}_{\mathrm{T}}$ is charged to 2.8 V and discharged to 1.0 V . During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that resets the PWM Latch, inhibits the outputs, and toggles the steering flip-flop. The threshold voltages on the oscillator comparator is trimmed to guarantee an oscillator accuracy of $5.0 \%$ at $25^{\circ} \mathrm{C}$.

Additional dead time can be added by externally increasing the charge current to $\mathrm{C}_{\mathrm{T}}$ as shown in Figure 24. This changes the charge to discharge ratio of $\mathrm{C}_{\mathrm{T}}$ which is set internally to $\mathrm{I}_{\text {charge }} / 10 \mathrm{I}_{\text {charge }}$. The new charge to discharge ratio will be:

$$
\% \text { Deadtime }=\frac{I_{\text {additional }}+I_{\text {charge }}}{10\left(I_{\text {charge }}\right)}
$$

A bidirectional clock pin is provided for synchronization or for master/slave operation. As a master, the clock pin provides a positive output pulse during the discharge of $\mathrm{C}_{\mathrm{T}}$. As a slave, the clock pin is an input that resets the PWM latch and blanks the drive output, but does not discharge $\mathrm{C}_{\mathrm{T}}$. Therefore, the oscillator is not synchronized by driving the clock pin alone. Figures 30 and 31 provide suggested synchronization.

## Error Amplifier

A fully compensated Error Amplifier is provided. It features a typical DC voltage gain of 95 dB and a gain bandwidth product of 8.3 MHz with 75 degrees of phase margin (Figure 4). Typical application circuits will have the noninverting input tied to the reference. The inverting input will typically be connected to a feedback voltage generated from the output of the switching power supply. Both inputs have a Common Mode Voltage ( $\mathrm{V}_{\mathrm{CM}}$ ) input range of 1.5 V to 5.5 V . The Error Amplifier Output is provided for external loop compensation.

## Soft-Start Latch

Soft-Start is accomplished in conjunction with an external capacitor. The soft start capacitor is charged by an internal $9.0 \mu \mathrm{~A}$ current source. This capacitor clamps the output of the error amplifier to less than its normal output voltage, thus limiting the duty cycle.
The time it takes for a capacitor to reach full charge is given by:

$$
t \approx\left(4.5 \cdot 10^{5}\right) C_{\text {Soft-Start }}
$$

A Soft-Start latch is incorporated to prevent erratic operation of this circuitry. Two conditions can cause the Soft-Start circuit to latch so that the Soft-Start capacitor stays discharged. The first condition is activation of an undervoltage lockout of either $\mathrm{V}_{\mathrm{CC}}$ or $\mathrm{V}_{\text {ref }}$. The second condition is when current sense input exceeds 1.4 V . Since this latch is "set dominant", it cannot be reset until either of these signals is removed, and the voltage at $\mathrm{C}_{\text {Soft-Start }}$ is less than 0.5 V .

## PWM Comparator and Latch

A PWM circuit typically compares an error voltage with a ramp signal. The outcome of this comparison determines the state of the output. In voltage mode operation the ramp signal is the voltage ramp of the timing capacitor. In current mode operation the ramp signal is the voltage ramp induced in a current sensing element. The ramp input of the PWM comparator is pinned out so that the user can decide which mode of operation best suits the application requirements. The ramp input has a 1.25 V offset such that whenever the voltage at this pin exceeds the Error Amplifier Output voltage minus 1.25 V , the PWM comparator will cause the PWM latch to set, disabling the outputs. Once the PWM latch is set, only a blanking pulse by the oscillator can reset it, thus initiating the next cycle.
A toggle flip flop connected to the output of the PWM latch controls which output is active. The flip flop is pulsed by an OR gate that gets its inputs from the oscillator clock and the output of the PWM latch. A pulse from either one will cause the flip flop to enable the other output.

## Current Limiting and Shutdown

A pin is provided to perform current limiting and shutdown operations. Two comparators are connected to the input of this pin. When the voltage at this pin exceeds 1.0 V , one of the comparators is activated. The output of this comparator sets the PWM latch, which disables the output. In this way cycle-by-cycle current limiting is accomplished. If a current limit resistor is used in series with the power devices, the value of the resistor is found by:

$$
\mathrm{R}_{\text {Sense }}=\frac{1.0 \mathrm{~V}}{\mathrm{I}_{\mathrm{pk}}(\text { switch })}
$$

If the voltage at this pin exceeds 1.4 V , the second comparator is activated. This comparator sets a latch which, in turn, causes the Soft-Start capacitor to be discharged. In this way a "hiccup" mode of recovery is possible in the case of output short circuits. If a current limit resistor is used in series with the output devices, the peak current at which the controller will enter a "hiccup" mode is given by:

$$
I_{\text {shutdown }}=\frac{1.4 \mathrm{~V}}{\mathrm{R}_{\text {Sense }}}
$$

## Undervoltage Lockout

There are two undervoltage lockout circuits within the IC. The first senses $\mathrm{V}_{\mathrm{CC}}$ and the second $\mathrm{V}_{\text {ref }}$. During power-up, $\mathrm{V}_{\mathrm{CC}}$ must exceed 9.2 V and $\mathrm{V}_{\text {ref }}$ must exceed 4.2 V before the outputs can be enabled and the Soft-Start latch released. If $\mathrm{V}_{\mathrm{CC}}$ falls below 8.4 V or $\mathrm{V}_{\text {ref }}$ falls below 3.6 V , the outputs are disabled and the Soft-Start latch is activated. When the UVLO is active, the part is in a low current standby mode allowing the IC to have an off-line bootstrap start-up circuit. Typical start-up current is $500 \mu \mathrm{~A}$.

## Output

The MC34025 has two high current totem pole outputs specifically designed for direct drive of power MOSFETs. They are capable of up to $\pm 2.0$ A peak drive current with a typical rise and fall time of 30 ns driving a 1.0 nF load.

Separate pins for $\mathrm{V}_{\mathrm{C}}$ and Power Ground are provided. With proper implementation, a significant reduction of switching transient noise imposed on the control circuitry is possible. The separate $\mathrm{V}_{\mathrm{C}}$ supply input also allows the designer added flexibility in tailoring the drive voltage independent of $\mathrm{V}_{\mathrm{CC}}$.

## Reference

A 5.1 V bandgap reference is pinned out and is trimmed to an initial accuracy of $\pm 1.0 \%$ at $25^{\circ} \mathrm{C}$. This reference has short circuit protection and can source in excess of 10 mA for powering additional control system circuitry.

## Design Considerations

Do not attempt to construct the converter on wire-wrap or plug-in prototype boards. With high frequency, high power, switching power supplies it is imperative to have separate current loops for the signal paths and for the power paths. The printed circuit layout should contain a ground plane with low current signal and high current switch and output grounds returning on separate paths back to the input filter capacitor. All bypass capacitors
and snubbers should be connected as close as possible to the specific part in question. The PC board lead lengths must be less than 0.5 inches for effective bypassing or snubbing.

## Instabilities

In current mode control, an instability can be encountered at any given duty cycle. The instability is caused by the current feedback loop. It has been shown that the instability is caused by a double pole at half the switching frequency. If an external ramp $\left(\mathrm{S}_{\mathrm{e}}\right)$ is added to the on-time $\operatorname{ramp}\left(\mathrm{S}_{\mathrm{n}}\right)$ of the current-sense waveform, stability can be achieved (see Figure 21).

One must be careful not to add too much ramp compensation. If too much is added, the system will start to perform like a voltage mode regulator. All benefits of current mode control will be lost. Figures 29A and 29B show examples of two different ways in which external ramp compensation can be implemented.

Figure 21. Ramp Compensation
A simple equation can be used to calculate the amount of external ramp necessary to add that will achieve stability in the current loop. For the following equations, the calculated values for the application circuit in Figure 37 are also shown.

$$
\mathrm{Se}=\frac{\mathrm{V}_{\mathrm{O}}}{\mathrm{~L}}\left(\frac{\mathrm{~N}_{\mathrm{S}}}{\mathrm{~N}_{\mathrm{P}}}\right)\left(\mathrm{R}_{\mathrm{S}}\right) A_{\mathrm{i}}
$$

$$

\end{aligned}
$$

## MC34025, MC33025

PIN FUNCTION DESCRIPTION

| Pin No. | Function | Description |
| :---: | :---: | :---: |
| DIP/SOIC |  |  |
| 1 | Error Amp Inverting Input | This pin is usually used for feedback from the output of the power supply. |
| 2 | Error Amp Noninverting Input | This pin is used to provide a reference in which an error signal can be produced on the output of the error amp. Usually this is connected to $\mathrm{V}_{\text {ref }}$, however an external reference can also be used. |
| 3 | Error Amp Output | This pin is provided for compensating the error amp for poles and zeros encountered in the power supply system, mostly the output LC filter. |
| 4 | Clock | This is a bidirectional pin used for synchronization. |
| 5 | $\mathrm{R}_{\mathrm{T}}$ | The value of $\mathrm{R}_{\mathrm{T}}$ sets the charge current through timing Capacitor, $\mathrm{C}_{\mathrm{T}}$. |
| 6 | $\mathrm{C}_{\mathrm{T}}$ | In conjunction with $\mathrm{R}_{\mathrm{T}}$, the timing Capacitor sets the switching frequency. Because this part is a push-pull output, each output runs at one-half the frequency set at this pin. |
| 7 | Ramp Input | For voltage mode operation this pin is connected to $\mathrm{C}_{\mathrm{T}}$. For current mode operation this pin is connected through a filter to the current sensing element. |
| 8 | Soft-Start | A capacitor at this pin sets the Soft-Start time. |
| 9 | Current Limit/Shutdown | This pin has two functions. First, it provides cycle-by-cycle current limiting. Second, if the current is excessive, this pin will reinitiate a Soft-Start cycle. |
| 10 | Ground | This pin is the ground for the control circuitry. |
| 11 | Output A | This is a high current totem pole output. |
| 12 | Power Ground | This is a separate power ground return that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry. |
| 13 | $\mathrm{V}_{\mathrm{C}}$ | This is a separate power source connection for the outputs that is connected back to the power source input. With a separate power source connection, it can reduce the effects of switching transient noise on the control circuitry. |
| 14 | Output B | This is a high current totem pole output. |
| 15 | $\mathrm{V}_{\text {CC }}$ | This pin is the positive supply of the control IC. |
| 16 | $\mathrm{V}_{\text {ref }}$ | This is a 5.1 V reference. It is usually connected to the noninverting input of the error amplifier. |

In voltage mode operation, the control range on the output of the Error Amplifier from 0\% to $90 \%$ duty cycle is from 2.25 V to 4.05 V .

Figure 22. Voltage Mode Operation

In current mode control, an RC filter should be placed at the ramp input to filter the leading edge spike caused by turn-on of a power MOSFET.

Figure 23. Current Mode Operation

Additional dead time can be added by the addition of a dead time resistor from $\mathrm{V}_{\text {ref }}$ to $\mathrm{C}_{\mathrm{T}}$. See text on oscillator section for more information.

Figure 24. Dead Time Addition

The sync pulse fed into the clock pin must be at least 3.9 V . $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\top}$ need to be set $10 \%$ slower than the sync frequency. This circuit is also used in voltage mode operation for master/slave operation. The clock signal would be coming from the master which is set at the desired operating frequency, while the slave is set $10 \%$ slower.

Figure 25. External Clock Synchronization

The addition of an RC filter will eliminate instability caused by the leading edge spike on the current waveform. This sense signal can also be used at the ramp input pin for current mode control. For ramp compensation it is necessary to know the gain of the current feedback loop. If a transformer is used, the gain can be calculated by:

$$
A_{i}=\frac{R_{\text {Sense }}}{\text { turns ratio }}
$$

Figure 26. Resistive Current Sensing

Figure 27. Primary Side Current Sensing
The addition of an RC filter will eliminate instability caused by the leading edge spike on the current waveform. This sense signal can also be used at the ramp input pin for current mode control. For ramp compensation it is necessary to know the gain of the current feedback loop. The gain can be calculated by:

$$
A_{i}=\frac{\mathrm{R}_{\mathrm{w}}}{\text { turns ratio }}
$$

## MC34025, MC33025

This method of slope compensation is easy to implement, however, it is noise sensitive. Capacitor $\mathrm{C}_{1}$ provides $A C$ coupling. The oscillator signal is added to the current signal by a voltage divider consisting of resistors $R_{1}$ and $R_{2}$.

Figure 29A. Slope Compensation (Noise Sensitive)

When only one output is used, this method of slope compensation can be used and it is relatively noise immune. Resistor $R_{M}$ and capacitor $\mathrm{C}_{\mathrm{M}}$ provide the added slope necessary. By choosing $\mathrm{R}_{\mathrm{M}}$ and $\mathrm{C}_{\mathrm{M}}$ with a larger time constant than the switching frequency, you can assume that its charge is linear. First choose $C_{M}$, then $R_{M}$ can be adjusted to achieve the required slope. The diode provides a reset pulse at the ramp input at the end of every cycle. The charge current $I_{M}$ can be calculated by $I_{M}=C_{M} S_{e}$. Then $R_{M}$ can be calculated by $\mathrm{R}_{\mathrm{M}}=\mathrm{V}_{\mathrm{CC}} / \mathrm{I}_{\mathrm{M}}$.

Figure 29B. Slope Compensation (Noise Immune)

Figure 30. Current Mode Master/Slave Operation Over Short Distances

## MC34025, MC33025

Figure 31. Synchronization Over Long Distances

In voltage mode operation, the maximum duty cycle can be clamped. By the addition of a PNP transistor to buffer the clamp voltage, the Soft-Start current is not affected by $\mathrm{R}_{1}$.

$$
\text { The new equation for Soft-Start is } \quad t \approx \frac{V_{\text {clamp }}+0.6}{9.0 \mu \mathrm{~A}}\left(\mathrm{C}_{\mathrm{SS}}\right)
$$

In current mode operation, this circuit will limit the maximum voltage allowed at the ramp input to end a cycle.

Figure 32. Buffered Maximum Clamp Level

Figure 34. Isolated MOSFET Drive

The totem pole output can furnish negative base current for enhanced transistor turn-off, with the addition of the capacitor in series with the base.

Figure 33. Bipolar Transistor Drive

Figure 35. Direct Transformer Drive

The totem pole output can easily drive pulse transformers. A Schottky diode is recommended when driving inductive loads at high frequencies. The diode can reduce the driver's power dissipation due to excessive ringing, by preventing the output pin from being driven below ground.

A series gate resistor may be needed to damp high frequency parasitic oscillation caused by a MOSFET's input capacitance and any series wiring inductance in the gate-source circuit. The series resistor will also decrease the MOSFET's switching speed. A Schottky diode can reduce the driver's power dissipation due to excessive ringing, by preventing the output pin from being driven below ground. The Schottky diode also prevents substrate injection when the output pin is driven below ground.

## UC3842A, UC3843A, UC2842A, UC2843A

## High Performance Current Mode Controllers

The UC3842A, UC3843A series of high performance fixed frequency current mode controllers are specifically designed for off-line and dc-to-dc converter applications offering the designer a cost effective solution with minimal external components. These integrated circuits feature a trimmed oscillator for precise duty cycle control, a temperature compensated reference, high gain error amplifier, current sensing comparator, and a high current totem pole output ideally suited for driving a power MOSFET.

Also included are protective features consisting of input and reference undervoltage lockouts each with hysteresis, cycle-by-cycle current limiting, programmable output deadtime, and a latch for single pulse metering.

These devices are available in an 8-pin dual-in-line plastic package as well as the 14 -pin plastic surface mount (SO-14). The SO-14 package has separate power and ground pins for the totem pole output stage.

The UCX842A has UYLO thresholds of 16 V (on) and 10 V (off), ideally suited for off-line converters. The UCX843A is tailored for lower voltage applications having UVLO thresholds of 8.5 V (on) and 7.6 V (off).

- Trimmed Oscillator Discharge Current for Precise Duty Cycle Control
- Current Mode Operation to 500 kHz
- Automatic Feed Forward Compensation
- Latching PWM for Cycle-By-Cycle Current Limiting
- Internally Trimmed Reference with Undervoltage Lockout
- High Current Totem Pole Output
- Undervoltage Lockout with Hysteresis
- Low Startup and Operating Current
- Direct Interface with ON Semiconductor SENSEFET Products

Figure 19. Timing Diagram

The UC3842A, UC3843A series are high performance, fixed frequency, current mode controllers. They are specifically designed for Off-Line and dc-to-dc converter applications offering the designer a cost effective solution with minimal external components. A representative block diagram is shown in Figure 18.

## Oscillator

The oscillator frequency is programmed by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged from the 5.0 V reference through resistor $\mathrm{R}_{\mathrm{T}}$ to approximately 2.8 V and discharged to 1.2 V by an internal current sink. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates and internal blanking pulse that holds the center input of the NOR gate high. This causes the Output to be in a low state, thus producing a controlled amount of output deadtime. Figure 2 shows $\mathrm{R}_{\mathrm{T}}$ versus Oscillator Frequency and Figure 3, Output Deadtime versus Frequency, both for given values of $C_{T}$. Note that many values of $R_{T}$ and $C_{T}$ will give the same oscillator frequency but only one combination will yield a specific output deadtime at a given frequency. The oscillator thresholds are temperature compensated, and the discharge current is trimmed and guaranteed to within $\pm 10 \%$ at $\mathrm{T}_{\mathrm{J}}=25^{\circ} \mathrm{C}$. These internal circuit refinements minimize variations of oscillator frequency and maximum output duty cycle. The results are shown in Figures 4 and 5.

In many noise sensitive applications it may be desirable to frequency-lock the converter to an external system clock. This can be accomplished by applying a clock signal to the circuit shown in Figure 21. For reliable locking, the free-running oscillator frequency should be set about $10 \%$ less than the clock frequency. A method for multi unit synchronization is shown in Figure 22. By tailoring the clock waveform, accurate Output duty cycle clamping can be achieved.

## Error Amplifier

A fully compensated Error Amplifier with access to the inverting input and output is provided. It features a typical dc voltage gain of 90 dB , and a unity gain bandwidth of 1.0 MHz with 57 degrees of phase margin (Figure 8). The noninverting input is internally biased at 2.5 V and is not pinned out. The converter output voltage is typically divided down and monitored by the inverting input. The maximum input bias current is $-2.0 \mu \mathrm{~A}$ which can cause an output voltage error that is equal to the product of the input bias current and the equivalent input divider source resistance.

The Error Amp Output (Pin 1) is provide for external loop compensation (Figure 31). The output voltage is offset by two diode drops ( $\approx 1.4 \mathrm{~V}$ ) and divided by three before it connects to the inverting input of the Current Sense Comparator. This guarantees that no drive pulses appear at the Output (Pin 6) when Pin 1 is at its lowest state ( $\mathrm{V}_{\mathrm{OL}}$ ). This occurs when the power supply is operating and the load
is removed, or at the beginning of a soft-start interval (Figures 24, 25). The Error Amp minimum feedback resistance is limited by the amplifier's source current $(0.5 \mathrm{~mA})$ and the required output voltage $\left(\mathrm{V}_{\mathrm{OH}}\right)$ to reach the comparator's 1.0 V clamp level:

$$
\mathrm{R}_{\mathrm{f}(\min )} \approx \frac{3.0(1.0 \mathrm{~V})+1.4 \mathrm{~V}}{0.5 \mathrm{~mA}}=8800 \Omega
$$

## Current Sense Comparator and PWM Latch

The UC3842A, UC3843A operate as a current mode controller, whereby output switch conduction is initiated by the oscillator and terminated when the peak inductor current reaches the threshold level established by the Error Amplifier Output/Compensation (Pin1). Thus the error signal controls the peak inductor current on a cycle-by-cycle basis. The current Sense Comparator PWM Latch configuration used ensures that only a single pulse appears at the Output during any given oscillator cycle. The inductor current is converted to a voltage by inserting the ground referenced sense resistor $\mathrm{R}_{\mathrm{S}}$ in series with the source of output switch Q 1 . This voltage is monitored by the Current Sense Input (Pin 3) and compared a level derived from the Error Amp Output. The peak inductor current under normal operating conditions is controlled by the voltage at pin 1 where:

$$
\mathrm{I}_{\mathrm{pk}}=\frac{\mathrm{V}_{(\operatorname{Pin} 1)}-1.4 \mathrm{~V}}{3 \mathrm{R}_{\mathrm{S}}}
$$

Abnormal operating conditions occur when the power supply output is overloaded or if output voltage sensing is lost. Under these conditions, the Current Sense Comparator threshold will be internally clamped to 1.0 V . Therefore the maximum peak switch current is:

$$
\mathrm{I}_{\mathrm{pk}(\max )}=\frac{1.0 \mathrm{~V}}{\mathrm{R}_{\mathrm{S}}}
$$

When designing a high power switching regulator it becomes desirable to reduce the internal clamp voltage in order to keep the power dissipation of $\mathrm{R}_{\mathrm{S}}$ to a reasonable level. A simple method to adjust this voltage is shown in Figure 23. The two external diodes are used to compensate the internal diodes yielding a constant clamp voltage over temperature. Erratic operation due to noise pickup can result if there is an excessive reduction of the $\mathrm{I}_{\mathrm{pk}(\max )}$ clamp voltage.

A narrow spike on the leading edge of the current waveform can usually be observed and may cause the power supply to exhibit an instability when the output is lightly loaded. This spike is due to the power transformer interwinding capacitance and output rectifier recovery time. The addition of an RC filter on the Current Sense Input with a time constant that approximates the spike duration will usually eliminate the instability; refer to Figure 27.

PIN FUNCTION DESCRIPTION

| Pin |  | Function | Description |
| :---: | :---: | :---: | :---: |
| 8-Pin | 14-Pin |  |  |
| 1 | 1 | Compensation | This pin is Error Amplifier output and is made available for loop compensation. |
| 2 | 3 | Voltage Feedback | This is the inverting input of the Error Amplifier. It is normally connected to the switching power supply output through a resistor divider. |
| 3 | 5 | Current Sense | A voltage proportional to inductor current is connected to this input. The PWM uses this information to terminate the output switch conduction. |
| 4 | 7 | $\mathrm{R}_{T} / \mathrm{C}_{\mathrm{T}}$ | The Oscillator frequency and maximum Output duty cycle are programmed by connecting resistor $\mathrm{R}_{\mathrm{T}}$ to $\mathrm{V}_{\text {ref }}$ and capacitor $\mathrm{C}_{\mathrm{T}}$ to ground. Operation to 500 kHz is possible. |
| 5 | - | Gnd | This pin is the combined control circuitry and power ground (8-pin package only). |
| 6 | 10 | Output | This output directly drives the gate of a power MOSFET. Peak currents up to 1.0 A are sourced and sunk by this pin. |
| 7 | 12 | $\mathrm{V}_{\mathrm{CC}}$ | This pin is the positive supply of the control IC. |
| 8 | 14 | $\mathrm{V}_{\text {ref }}$ | This is the reference output. It provides charging current for capacitor $\mathrm{C}_{\boldsymbol{T}}$ through resistor $\mathrm{R}_{\mathrm{T}}$. |
| - | 8 | Power Ground | This pin is a separate power ground return (14-pin package only) that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry. |
| - | 11 | $\mathrm{V}_{\mathrm{C}}$ | The Output high state $\left(\mathrm{V}_{\mathrm{OH}}\right)$ is set by the voltage applied to this pin (14-pin package only). With a separate power source connection, it can reduce the effects of switching transient noise on the control circuitry. |
| - | 9 | Gnd | This pin is the control circuitry ground return (14-pin package only) and is connected back to the power source ground. |
| - | 2,4,6,13 | NC | No connection (14-pin package only). These pins are not internally connected. |

## Undervoltage Lockout

Two undervoltage lockout comparators have been incorporated to guarantee that the IC is fully functional before the output stage is enabled. The positive power supply terminal $\left(\mathrm{V}_{\mathrm{CC}}\right)$ and the reference output $\left(\mathrm{V}_{\text {ref }}\right)$ are each monitored by separate comparators. Each has built-in hysteresis to prevent erratic output behavior as their respective thresholds are crossed. The $\mathrm{V}_{\mathrm{CC}}$ comparator upper and lower thresholds are $16 \mathrm{~V} / 10 \mathrm{~V}$ for the UCX842A, and $8.4 \mathrm{~V} / 7.6 \mathrm{~V}$ for the UCX843A. The $\mathrm{V}_{\text {ref }}$ comparator upper and lower thresholds are $3.6 \mathrm{~V} / 3.4 \mathrm{~V}$. The large hysteresis and low startup current of the UCX842A makes it ideally suited in off-line converter applications where efficient bootstrap startup techniques are required (Figure 34). The UCX843A is intended for lower voltage dc to dc converter applications. A 36 V zener is connected as a shunt regulator form $\mathrm{V}_{\mathrm{CC}}$ to ground. Its purpose is to protect the IC from excessive voltage that can occur during system startup. The minimum operating voltage for the UCX842A is 11 V and 8.2 V for the UCX843A.

## Output

These devices contain a single totem pole output stage that was specifically designed for direct drive of power MOSFETs. It is capable of up to $\pm 1.0 \mathrm{~A}$ peak drive current
and has a typical rise and fall time of 50 ns with a 1.0 nF load. Additional internal circuitry has been added to keep the Output in a sinking mode whenever an undervoltage lockout is active. This characteristic eliminates the need for an external pull-down resistor.
The SO-14 surface mount package provides separate pins for $\mathrm{V}_{\mathrm{C}}$ (output supply) and Power Ground. Proper implementation will significantly reduce the level of switching transient noise imposed on the control circuitry. This becomes particularly useful when reducing the $\mathrm{I}_{\mathrm{pk}(\max )}$ clamp level. The separate $\mathrm{V}_{\mathrm{C}}$ supply input allows the designer added flexibility in tailoring the drive voltage independent of $\mathrm{V}_{\mathrm{CC}}$. A zener clamp is typically connected to this input when driving power MOSFETs in systems where $\mathrm{V}_{\mathrm{CC}}$ is greater than 20 V . Figure 26 shows proper power and control ground connections in a current sensing power MOSFET application.

## Reference

The 5.0 V bandgap reference is trimmed to $\pm 1.0 \%$ tolerance at $\mathrm{T}_{\mathrm{J}}=25^{\circ} \mathrm{C}$ on the UC284XA, and $\pm 2.0 \%$ on the UC384XA. Its primary purpose is to supply charging current to the oscillator timing capacitor. The reference has short circuit protection and is capable of providing in excess of 20 mA for powering additional control system circuitry.

## DESIGN CONSIDERATIONS

Do not attempt to construct the converter on wire-wrap or plug-in prototype boards. High Frequency circuit layout techniques are imperative to prevent pulsewidth jitter. This is usually caused by excessive noise pick-up imposed on the Current Sense or Voltage Feedback inputs. Noise immunity can be improved by lowering circuit impedances at these points. The printed circuit layout should contain a ground plane with low-current signal and high-current switch and output grounds returning on separate paths back to the input filter capacitor. Ceramic bypass capacitors $(0.1 \mu \mathrm{~F})$ connected directly to $\mathrm{V}_{\mathrm{CC}}, \mathrm{V}_{\mathrm{C}}$, and $\mathrm{V}_{\text {ref }}$ may be required depending upon circuit layout. This provides a low impedance path for filtering the high frequency noise. All high current loops should be kept as short as possible using heavy copper runs to minimize radiated EMI. The Error Amp compensation circuitry and the converter output voltage divider should be located close to the IC and as far as possible from the power switch and other noise generating components.

Current mode converters can exhibit subharmonic oscillations when operating at a duty cycle greater than $50 \%$ with continuous inductor current. This instability is independent of the regulators closed-loop characteristics and is caused by the simultaneous operating conditions of fixed frequency and peak current detecting. Figure 20A shows the phenomenon graphically. At $\mathrm{t}_{0}$, switch conduction begins, causing the inductor current to rise at a slope of $m_{1}$. This slope is a function of the input voltage divided by the inductance. At $t_{1}$, the Current Sense Input reaches the threshold established by the control voltage. This causes the switch to turn off and the current to decay at a slope of $\mathrm{m}_{2}$ until the next oscillator cycle. The unstable condition can be shown if a pertubation is added to the control voltage, resulting in a small $\Delta \mathrm{I}$ (dashed line). With a fixed oscillator period, the current decay time is reduced, and the minimum current at switch turn-on $\left(\mathrm{t}_{2}\right)$ is increased by $\Delta \mathrm{I}+\Delta \mathrm{I} \mathrm{m} 2 / \mathrm{m} 1$. The minimum current at the next cycle
( $\mathrm{t}_{3}$ ) decreases to $\left(\Delta \mathrm{I}+{ }_{\Delta} \mathrm{I} \mathrm{m}_{2} / \mathrm{m}_{1}\right)\left(\mathrm{m}_{2} / \mathrm{m}_{1}\right)$. This pertubation is multiplied by $\mathrm{m}_{2} \cdot \mathrm{~m}_{1}$ on each succeeding cycle, alternately increasing and decreasing the inductor current at switch turn-on. Several oscillator cycles may be required before the inductor current reaches zero causing the process to commence again. If $\mathrm{m}_{2} / \mathrm{m}_{1}$ is greater than 1 , the converter will be unstable. Figure 20B shows that by adding an artificial ramp that is synchronized with the PWM clock to the control voltage, the $\Delta \mathrm{I}$ pertubation will decrease to zero on succeeding cycles. This compensation ramp ( $\mathrm{m}_{3}$ ) must have a slope equal to or slightly greater than $m_{2} / 2$ for stability. With $\mathrm{m}_{2} / 2$ slope compensation, the average inductor current follows the control voltage yielding true current mode operation. The compensating ramp can be derived from the oscillator and added to either the Voltage Feedback or Current Sense inputs (Figure 33).

## High Performance Current Mode Controllers

The UC3842B, UC3843B series are high performance fixed frequency current mode controllers. They are specifically designed for Off-Line and dc-to-dc converter applications offering the designer a cost-effective solution with minimal external components. These integrated circuits feature a trimmed oscillator for precise duty cycle control, a temperature compensated reference, high gain error amplifier, current sensing comparator, and a high current totem pole output ideally suited for driving a power MOSFET.

Also included are protective features consisting of input and reference undervoltage lockouts each with hysteresis, cycle-by-cycle current limiting, programmable output deadtime, and a latch for single pulse metering.

These devices are available in an 8-pin dual-in-line and surface mount (SO-8) plastic package as well as the 14 -pin plastic surface mount (SO-14). The SO-14 package has separate power and ground pins for the totem pole output stage.

The UCX842B has UVLO thresholds of 16 V (on) and 10 V (off), ideally suited for off-line converters. The UCX843B is tailored for lower voltage applications having UVLO thresholds of 8.5 V (on) and 7.6 V (off).

- Trimmed Oscillator for Precise Frequency Control
- Oscillator Frequency Guaranteed at 250 kHz
- Current Mode Operation to 500 kHz
- Automatic Feed Forward Compensation
- Latching PWM for Cycle-By-Cycle Current Limiting
- Internally Trimmed Reference with Undervoltage Lockout
- High Current Totem Pole Output
- Undervoltage Lockout with Hysteresis
- Low Startup and Operating Current

PIN FUNCTION DESCRIPTION

| Pin |  | Function |  |
| :---: | :---: | :---: | :--- |
| 8-Pin | $\mathbf{1 4 - P i n}$ |  |  |

## OPERATING DESCRIPTION

The UC3842B, UC3843B series are high performance, fixed frequency, current mode controllers. They are specifically designed for Off-Line and dc-to-dc converter applications offering the designer a cost-effective solution with minimal external components. A representative block diagram is shown in Figure 18.

## Oscillator

The oscillator frequency is programmed by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged from the 5.0 V reference through resistor $\mathrm{R}_{\mathrm{T}}$ to approximately 2.8 V and discharged to 1.2 V by an internal current sink. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the center input of the NOR gate high. This causes the Output to be in a low state, thus producing a controlled amount of output deadtime. Figure 2 shows $\mathrm{R}_{\mathrm{T}}$ versus Oscillator Frequency and Figure 3, Output Deadtime versus Frequency, both for given values of $\mathrm{C}_{\mathrm{T}}$. Note that many values of $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$ will give the same oscillator frequency but only one combination will yield a specific output deadtime at a given frequency. The oscillator thresholds are temperature compensated to within $\pm 6 \%$ at 50 kHz . Also because of industry trends moving the UC384X into higher and higher frequency applications, the UC384XB is guaranteed to within $\pm 10 \%$ at 250 kHz . These internal circuit refinements minimize variations of oscillator frequency and maximum output duty cycle. The results are shown in Figures 4 and 5.

In many noise-sensitive applications it may be desirable to frequency-lock the converter to an external system clock. This can be accomplished by applying a clock signal to the circuit shown in Figure 21. For reliable locking, the free-running oscillator frequency should be set about $10 \%$ less than the clock frequency. A method for multi-unit synchronization is shown in Figure 22. By tailoring the clock waveform, accurate Output duty cycle clamping can be achieved.

## Error Amplifier

A fully compensated Error Amplifier with access to the inverting input and output is provided. It features a typical dc voltage gain of 90 dB , and a unity gain bandwidth of 1.0 MHz with 57 degrees of phase margin (Figure 8). The non-inverting input is internally biased at 2.5 V and is not pinned out. The converter output voltage is typically divided down and monitored by the inverting input. The maximum input bias current is $-2.0 \mu \mathrm{~A}$ which can cause an output voltage error that is equal to the product of the input bias current and the equivalent input divider source resistance.

The Error Amp Output (Pin 1) is provided for external loop compensation (Figure 32). The output voltage is offset by two diode drops ( $\approx 1.4 \mathrm{~V}$ ) and divided by three before it connects to the non-inverting input of the Current Sense Comparator. This guarantees that no drive pulses appear at the Output (Pin 6) when pin 1 is at its lowest state $\left(\mathrm{V}_{\mathrm{OL}}\right)$.

This occurs when the power supply is operating and the load is removed, or at the beginning of a soft-start interval (Figures 24, 25). The Error Amp minimum feedback resistance is limited by the amplifier's source current $(0.5 \mathrm{~mA})$ and the required output voltage $\left(\mathrm{V}_{\mathrm{OH}}\right)$ to reach the comparator's 1.0 V clamp level:

$$
\mathrm{R}_{\mathrm{f}(\min )} \approx \frac{3.0(1.0 \mathrm{~V})+1.4 \mathrm{~V}}{0.5 \mathrm{~mA}}=8800 \Omega
$$

## Current Sense Comparator and PWM Latch

The UC3842B, UC3843B operate as a current mode controller, whereby output switch conduction is initiated by the oscillator and terminated when the peak inductor current reaches the threshold level established by the Error Amplifier Output/Compensation (Pin 1). Thus the error signal controls the peak inductor current on a cycle-by-cycle basis. The Current Sense Comparator PWM Latch configuration used ensures that only a single pulse appears at the Output during any given oscillator cycle. The inductor current is converted to a voltage by inserting the ground-referenced sense resistor $\mathrm{R}_{\mathrm{S}}$ in series with the source of output switch Q1. This voltage is monitored by the Current Sense Input (Pin 3) and compared to a level derived from the Error Amp Output. The peak inductor current under normal operating conditions is controlled by the voltage at pin 1 where:

$$
\mathrm{I}_{\mathrm{pk}}=\frac{\mathrm{V}_{(\mathrm{Pin} 1)}-1.4 \mathrm{~V}}{3 \mathrm{R}_{\mathrm{S}}}
$$

Abnormal operating conditions occur when the power supply output is overloaded or if output voltage sensing is lost. Under these conditions, the Current Sense Comparator threshold will be internally clamped to 1.0 V . Therefore the maximum peak switch current is:

$$
\mathrm{I}_{\mathrm{pk}(\max )}=\frac{1.0 \mathrm{~V}}{\mathrm{R}_{\mathrm{S}}}
$$

When designing a high power switching regulator it becomes desirable to reduce the internal clamp voltage in order to keep the power dissipation of $\mathrm{R}_{\mathrm{S}}$ to a reasonable level. A simple method to adjust this voltage is shown in Figure 23. The two external diodes are used to compensate the internal diodes, yielding a constant clamp voltage over temperature. Erratic operation due to noise pickup can result if there is an excessive reduction of the $\mathrm{I}_{\mathrm{pk}(\max )}$ clamp voltage.
A narrow spike on the leading edge of the current waveform can usually be observed and may cause the power supply to exhibit an instability when the output is lightly loaded. This spike is due to the power transformer interwinding capacitance and output rectifier recovery time. The addition of an RC filter on the Current Sense Input with a time constant that approximates the spike duration will usually eliminate the instability (refer to Figure 27).

Figure 18. Representative Block Diagram

Figure 19. Timing Diagram

## Undervoltage Lockout

Two undervoltage lockout comparators have been incorporated to guarantee that the IC is fully functional before the output stage is enabled. The positive power supply terminal $\left(\mathrm{V}_{\mathrm{CC}}\right)$ and the reference output $\left(\mathrm{V}_{\text {ref }}\right)$ are each monitored by separate comparators. Each has built-in hysteresis to prevent erratic output behavior as their respective thresholds are crossed. The $\mathrm{V}_{\mathrm{CC}}$ comparator upper and lower thresholds are $16 \mathrm{~V} / 10 \mathrm{~V}$ for the UCX842B, and $8.4 \mathrm{~V} / 7.6 \mathrm{~V}$ for the UCX843B. The $\mathrm{V}_{\text {ref }}$ comparator upper and lower thresholds are $3.6 \mathrm{~V} / 3.4 \mathrm{~V}$. The large hysteresis and low startup current of the UCX842B makes it ideally suited in off-line converter applications where efficient bootstrap startup techniques are required (Figure 34). The UCX843B is intended for lower voltage dc-to-dc converter applications. A 36 V zener is connected as a shunt regulator from $\mathrm{V}_{\mathrm{CC}}$ to ground. Its purpose is to protect the IC from excessive voltage that can occur during system startup. The minimum operating voltage $\left(\mathrm{V}_{\mathrm{CC}}\right)$ for the UCX842B is 11 V and 8.2 V for the UCX843B.

These devices contain a single totem pole output stage that was specifically designed for direct drive of power MOSFETs. It is capable of up to $\pm 1.0$ A peak drive current and has a typical rise and fall time of 50 ns with a 1.0 nF load. Additional internal circuitry has been added to keep the Output in a sinking mode whenever an undervoltage lockout is active. This characteristic eliminates the need for an external pull-down resistor.

The SO-14 surface mount package provides separate pins for $\mathrm{V}_{\mathrm{C}}$ (output supply) and Power Ground. Proper implementation will significantly reduce the level of switching transient noise imposed on the control circuitry. This becomes particularly useful when reducing the $\mathrm{I}_{\mathrm{pk}(\max )}$ clamp level. The separate $\mathrm{V}_{\mathrm{C}}$ supply input allows the designer added flexibility in tailoring the drive voltage independent of $\mathrm{V}_{\mathrm{CC}}$. A zener clamp is typically connected to this input when driving power MOSFETs in systems where $\mathrm{V}_{\mathrm{CC}}$ is greater than 20 V . Figure 26 shows proper power and control ground connections in a current-sensing power MOSFET application.

## Reference

The 5.0 V bandgap reference is trimmed to $\pm 1.0 \%$ tolerance at $\mathrm{T}_{\mathrm{J}}=25^{\circ} \mathrm{C}$ on the UC284XB, and $\pm 2.0 \%$ on the UC384XB. Its primary purpose is to supply charging current to the oscillator timing capacitor. The reference has shortcircuit protection and is capable of providing in excess of 20 mA for powering additional control system circuitry.

## Design Considerations

Do not attempt to construct the converter on wire-wrap or plug-in prototype boards. High frequency circuit layout techniques are imperative to prevent pulse-width jitter. This is usually caused by excessive noise pick-up imposed on the Current Sense or Voltage Feedback inputs. Noise immunity can be improved by lowering circuit impedances at these points. The printed circuit layout should contain a ground plane with low-current signal and high-current switch and output grounds returning on separate paths back to the input filter capacitor. Ceramic bypass capacitors $(0.1 \mu \mathrm{~F})$ connected directly to $\mathrm{V}_{\mathrm{CC}}, \mathrm{V}_{\mathrm{C}}$, and $\mathrm{V}_{\text {ref }}$ may be required depending upon circuit layout. This provides a low impedance path for filtering the high frequency noise. All high current loops should be kept as short as possible using heavy copper runs to minimize radiated EMI. The Error Amp compensation circuitry and the converter output voltage divider should be located close to the IC and as far as possible from the power switch and other noise-generating components.

Current mode converters can exhibit subharmonic oscillations when operating at a duty cycle greater than $50 \%$ with continuous inductor current. This instability is independent of the regulator's closed loop characteristics and is caused by the simultaneous operating conditions of fixed frequency and peak current detecting. Figure 20A shows the phenomenon graphically. At $t_{0}$, switch conduction begins, causing the inductor current to rise at a slope of $\mathrm{m}_{1}$. This slope is a function of the input voltage divided by the inductance. At $t_{1}$, the Current Sense Input reaches the threshold established by the control voltage. This causes the switch to turn off and the current to decay at a slope of $\mathrm{m}_{2}$, until the next oscillator cycle. The unstable condition can be shown if a perturbation is added to the control voltage, resulting in a small $\Delta \mathrm{I}$ (dashed line). With a fixed oscillator period, the current decay time is reduced, and the minimum current at switch turn-on $\left(\mathrm{t}_{2}\right)$ is increased by $\Delta \mathrm{I}+\Delta \mathrm{I} \mathrm{m}_{2} / \mathrm{m}_{1}$. The minimum current at the next cycle $\left(\mathrm{t}_{3}\right)$ decreases to $\left(\Delta \mathrm{I}+\Delta \mathrm{I} \mathrm{m}_{2} / \mathrm{m}_{1}\right)\left(\mathrm{m}_{2} / \mathrm{m}_{1}\right)$. This perturbation is multiplied by $\mathrm{m}_{2} / \mathrm{m}_{1}$ on each succeeding cycle, alternately increasing and decreasing the inductor current at switch turn-on. Several oscillator cycles may be required before the inductor current reaches zero causing the process to commence again. If $\mathrm{m}_{2} / \mathrm{m}_{1}$ is greater than 1 , the converter will be unstable. Figure 20B shows that by adding an artificial ramp that is synchronized with the PWM clock to the control voltage, the $\Delta \mathrm{I}$ perturbation will decrease to zero on succeeding cycles. This compensating ramp ( $\mathrm{m}_{3}$ ) must have a slope equal to or slightly greater than $\mathrm{m}_{2} / 2$ for stability. With $\mathrm{m}_{2} / 2$ slope compensation, the average inductor current follows the control voltage, yielding true current mode operation. The compensating ramp can be derived from the oscillator and added to either the Voltage Feedback or Current Sense inputs (Figure 33).

Figure 23. Adjustable Reduction of Clamp Level

Figure 24. Soft-Start Circuit

Virtually lossless current sensing can be achieved with the implementation of a SENSEFET power switch. For proper operation during over-current conditions, a reduction of the $\mathrm{I}_{\mathrm{pk}(\max )}$ clamp level must be implemented. Refer to Figures 23 and 25.

## UC3844B, UC3845B, UC2844B, UC2845B

## High Performance Current Mode Controllers

The UC3844B, UC3845B series are high performance fixed frequency current mode controllers. They are specifically designed for Off-Line and dc-to-dc converter applications offering the designer a cost-effective solution with minimal external components. These integrated circuits feature an oscillator, a temperature compensated reference, high gain error amplifier, current sensing comparator, and a high current totem pole output ideally suited for driving a power MOSFET.

Also included are protective features consisting of input and reference undervoltage lockouts each with hysteresis, cycle-by-cycle current limiting, a latch for single pulse metering, and a flip-flop which blanks the output off every other oscillator cycle, allowing output deadtimes to be programmed from $50 \%$ to $70 \%$.

These devices are available in an 8 -pin dual-in-line and surface mount (SO-8) plastic package as well as the $14-$ pin plastic surface mount (SO-14). The SO-14 package has separate power and ground pins for the totem pole output stage.

The UCX844B has UVLO thresholds of 16 V (on) and 10 V (off), ideally suited for off-line converters. The UCX845B is tailored for lower voltage applications having UVLO thresholds of 8.5 V (on) and 7.6 V (off).

- Trimmed Oscillator for Precise Frequency Control
- Oscillator Frequency Guaranteed at 250 kHz
- Current Mode Operation to 500 kHz Output Switching Frequency
- Output Deadtime Adjustable from 50\% to 70\%
- Automatic Feed Forward Compensation
- Latching PWM for Cycle-By-Cycle Current Limiting
- Internally Trimmed Reference with Undervoltage Lockout
- High Current Totem Pole Output
- Undervoltage Lockout with Hysteresis
- Low Startup and Operating Current

Pin numbers in parenthesis are for the D suffix $\mathrm{SO}-14$ package.

PIN FUNCTION DESCRIPTION

| Pin |  | Function | Description |
| :---: | :---: | :---: | :---: |
| 8-Pin | 14-Pin |  |  |
| 1 | 1 | Compensation | This pin is the Error Amplifier output and is made available for loop compensation. |
| 2 | 3 | Voltage Feedback | This is the inverting input of the Error Amplifier. It is normally connected to the switching power supply output through a resistor divider. |
| 3 | 5 | Current Sense | A voltage proportional to inductor current is connected to this input. The PWM uses this information to terminate the output switch conduction. |
| 4 | 7 | $\mathrm{R}_{T} / \mathrm{C}_{T}$ | The Oscillator frequency and maximum Output duty cycle are programmed by connecting resistor $\mathrm{R}_{\mathrm{T}}$ to $\mathrm{V}_{\text {ref }}$ and capacitor $\mathrm{C}_{\mathrm{T}}$ to ground. Oscillator operation to 1.0 kHz is possible. |
| 5 |  | Gnd | This pin is the combined control circuitry and power ground. |
| 6 | 10 | Output | This output directly drives the gate of a power MOSFET. Peak currents up to 1.0 A are sourced and sunk by this pin. The output switches at one-half the oscillator frequency. |
| 7 | 12 | $\mathrm{V}_{\mathrm{CC}}$ | This pin is the positive supply of the control IC. |
| 8 | 14 | $\mathrm{V}_{\text {ref }}$ | This is the reference output. It provides charging current for capacitor $\mathrm{C}_{\boldsymbol{T}}$ through resistor $\mathrm{R}_{\mathrm{T}}$. |
|  | 8 | Power Ground | This pin is a separate power ground return that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry. |
|  | 11 | $\mathrm{V}_{\mathrm{c}}$ | The Output high state $\left(\mathrm{V}_{\mathrm{OH}}\right)$ is set by the voltage applied to this pin. With a separate power source connection, it can reduce the effects of switching transient noise on the control circuitry |
|  | 9 | Gnd | This pin is the control circuitry ground return and is connected back to the power source ground. |
|  | 2,4,6,13 | NC | No connection. These pins are not internally connected. |

The UC3844B, UC3845B series are high performance, fixed frequency, current mode controllers. They are specifically designed for Off-Line and dc-to-dc converter applications offering the designer a cost-effective solution with minimal external components. A representative block diagram is shown in Figure 16.

## Oscillator

The oscillator frequency is programmed by the values selected for the timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged from the 5.0 V reference through resistor $\mathrm{R}_{\mathrm{T}}$ to approximately 2.8 V and discharged to 1.2 V by an internal current sink. During the discharge of $\mathrm{C}_{\mathrm{T}}$, the oscillator generates an internal blanking pulse that holds the center input of the NOR gate high. This causes the Output to be in a low state, thus producing a controlled amount of output deadtime. An internal flip-flop has been incorporated in the UCX844/5B which blanks the output off every other clock cycle by holding one of the inputs of the NOR gate high. This in combination with the $\mathrm{C}_{\mathrm{T}}$ discharge period yields output deadtimes programmable from $50 \%$ to $70 \%$. Figure 2 shows $\mathrm{R}_{\mathrm{T}}$ versus Oscillator Frequency and Figure 3, Output Deadtime versus Frequency, both for given values of $\mathrm{C}_{\mathrm{T}}$. Note that many values of $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$ will give the same oscillator frequency but only one combination will yield a specific output deadtime at a given frequency. The oscillator thresholds are temperature compensated to within $\pm 6 \%$ at 50 kHz . Also, because of industry trends moving the UC384X into higher and higher frequency applications, the UC384XB is guaranteed to within $\pm 10 \%$ at 250 kHz .

In many noise-sensitive applications it may be desirable to frequency-lock the converter to an external system clock. This can be accomplished by applying a clock signal to the circuit shown in Figure 18. For reliable locking, the free-running oscillator frequency should be set about $10 \%$ less than the clock frequency. A method for multi-unit synchronization is shown in Figure 19. By tailoring the clock waveform, accurate Output duty cycle clamping can be achieved to realize output deadtimes of greater than $70 \%$.

## Error Amplifier

A fully compensated Error Amplifier with access to the inverting input and output is provided. It features a typical dc voltage gain of 90 dB , and a unity gain bandwidth of 1.0 MHz with 57 degrees of phase margin (Figure 6). The non-inverting input is internally biased at 2.5 V and is not pinned out. The converter output voltage is typically divided down and monitored by the inverting input. The maximum input bias current is $-2.0 \mu \mathrm{~A}$ which can cause an output voltage error that is equal to the product of the input bias current and the equivalent input divider source resistance.

The Error Amp Output (Pin 1) is provided for external loop compensation (Figure 29). The output voltage is offset by two diode drops ( $\approx 1.4 \mathrm{~V}$ ) and divided by three before it connects to the inverting input of the Current Sense

Comparator. This guarantees that no drive pulses appear at the Output (Pin 6) when Pin 1 is at its lowest state ( $\mathrm{V}_{\mathrm{OL}}$ ). This occurs when the power supply is operating and the load is removed, or at the beginning of a soft-start interval (Figures 21, 22). The Error Amp minimum feedback resistance is limited by the amplifier's source current $(0.5 \mathrm{~mA})$ and the required output voltage $\left(\mathrm{V}_{\mathrm{OH}}\right)$ to reach the comparator's 1.0 V clamp level:

$$
\mathrm{R}_{\mathrm{f}(\min )} \approx \frac{3.0(1.0 \mathrm{~V})+1.4 \mathrm{~V}}{0.5 \mathrm{~mA}}=8800 \Omega
$$

## Current Sense Comparator and PWM Latch

The UC3844B, UC3845B operate as a current mode controller, whereby output switch conduction is initiated by the oscillator and terminated when the peak inductor current reaches the threshold level established by the Error Amplifier Output/Compensation (Pin 1). Thus the error signal controls the peak inductor current on a cycle-by-cycle basis. The Current Sense Comparator PWM Latch configuration used ensures that only a single pulse appears at the Output during any given oscillator cycle. The inductor current is converted to a voltage by inserting the ground-referenced sense resistor $\mathrm{R}_{\mathrm{S}}$ in series with the source of output switch Q1. This voltage is monitored by the Current Sense Input (Pin 3) and compared to a level derived from the Error Amp Output. The peak inductor current under normal operating conditions is controlled by the voltage at Pin 1 where:

$$
I_{\mathrm{pk}}=\frac{\mathrm{V}_{(\operatorname{Pin} 1)}-1.4 \mathrm{~V}}{3 \mathrm{R}_{\mathrm{S}}}
$$

Abnormal operating conditions occur when the power supply output is overloaded or if output voltage sensing is lost. Under these conditions, the Current Sense Comparator threshold will be internally clamped to 1.0 V . Therefore the maximum peak switch current is:

$$
\mathrm{I}_{\mathrm{pk}(\max )}=\frac{1.0 \mathrm{~V}}{\mathrm{R}_{\mathrm{S}}}
$$

When designing a high power switching regulator it becomes desirable to reduce the internal clamp voltage in order to keep the power dissipation of $\mathrm{R}_{\mathrm{S}}$ to a reasonable level. A simple method to adjust this voltage is shown in Figure 20. The two external diodes are used to compensate the internal diodes, yielding a constant clamp voltage over temperature. Erratic operation due to noise pickup can result if there is an excessive reduction of the $\mathrm{I}_{\mathrm{pk}(\max )}$ clamp voltage.

A narrow spike on the leading edge of the current waveform can usually be observed and may cause the power supply to exhibit an instability when the output is lightly loaded. This spike is due to the power transformer interwinding capacitance and output rectifier recovery time. The addition of an RC filter on the Current Sense Input with a time constant that approximates the spike duration will usually eliminate the instability (refer to Figure 24).

## Undervoltage Lockout

Two undervoltage lockout comparators have been incorporated to guarantee that the IC is fully functional before the output stage is enabled. The positive power supply terminal $\left(\mathrm{V}_{\mathrm{CC}}\right)$ and the reference output $\left(\mathrm{V}_{\text {ref }}\right)$ are each monitored by separate comparators. Each has built-in hysteresis to prevent erratic output behavior as their respective thresholds are crossed. The $\mathrm{V}_{\mathrm{CC}}$ comparator upper and lower thresholds are $16 \mathrm{~V} / 10 \mathrm{~V}$ for the UCX844B, and $8.4 \mathrm{~V} / 7.6 \mathrm{~V}$ for the UCX845B. The $\mathrm{V}_{\text {ref }}$ comparator upper and lower thresholds are $3.6 \mathrm{~V} / 3.4 \mathrm{~V}$. The large hysteresis and low startup current of the UCX844B makes it ideally suited in off-line converter applications where efficient bootstrap startup techniques are required (Figure 30). The UCX845B is intended for lower voltage dc-to-dc converter applications. A 36 V zener is connected as a shunt regulator from $\mathrm{V}_{\mathrm{CC}}$ to ground. Its purpose is to protect the IC from excessive voltage that can occur during system startup. The minimum operating voltage for the UCX844B is 11 V and 8.2 V for the UCX845B.

## Output

These devices contain a single totem pole output stage that was specifically designed for direct drive of power MOSFETs. It is capable of up to $\pm 1.0$ A peak drive current and has a typical rise and fall time of 50 ns with a 1.0 nF load. Additional internal circuitry has been added to keep the Output in a sinking mode whenever an undervoltage lockout is active. This characteristic eliminates the need for an external pull-down resistor.

The SO-14 surface mount package provides separate pins for $\mathrm{V}_{\mathrm{C}}$ (output supply) and Power Ground. Proper implementation will significantly reduce the level of switching transient noise imposed on the control circuitry. This becomes particularly useful when reducing the $\mathrm{I}_{\mathrm{pk}(\max )}$ clamp level. The separate $\mathrm{V}_{\mathrm{C}}$ supply input allows the
designer added flexibility in tailoring the drive voltage independent of $\mathrm{V}_{\mathrm{CC}}$. A zener clamp is typically connected to this input when driving power MOSFETs in systems where $\mathrm{V}_{\mathrm{CC}}$ is greater than 20 V . Figure 23 shows proper power and control ground connections in a current-sensing power MOSFET application.

## Reference

The 5.0 V bandgap reference is trimmed to $\pm 1.0 \%$ tolerance at $\mathrm{T}_{\mathrm{J}}=25^{\circ} \mathrm{C}$ on the UC284XB, and $\pm 2.0 \%$ on the UC384XB. Its primary purpose is to supply charging current to the oscillator timing capacitor. The reference has short-circuit protection and is capable of providing in excess of 20 mA for powering additional control system circuitry.

## Design Considerations

Do not attempt to construct the converter on wire-wrap or plug-in prototype boards. High frequency circuit layout techniques are imperative to prevent pulse-width jitter. This is usually caused by excessive noise pick-up imposed on the Current Sense or Voltage Feedback inputs. Noise immunity can be improved by lowering circuit impedances at these points. The printed circuit layout should contain a ground plane with low-current signal and high-current switch and output grounds returning on separate paths back to the input filter capacitor. Ceramic bypass capacitors $(0.1 \mu \mathrm{~F})$ connected directly to $\mathrm{V}_{\mathrm{CC}}, \mathrm{V}_{\mathrm{C}}$, and $\mathrm{V}_{\text {ref }}$ may be required depending upon circuit layout. This provides a low impedance path for filtering the high frequency noise. All high current loops should be kept as short as possible using heavy copper runs to minimize radiated EMI. The Error Amp compensation circuitry and the converter output voltage divider should be located close to the IC and as far as possible from the power switch and other noise-generating components.

The diode clamp is required if the Sync amplitude is large enough to cause the bottom side of $\mathrm{C}_{\boldsymbol{T}}$ to go more than 300 mV below ground.

## CS2841B

## Automotive Current Mode PWM Control Circuit

The CS2841B provides all the necessary features to implement off-line fixed frequency current-mode control with a minimum number of external components.

The CS2841B (a variation of the CS2843A) is designed specifically for use in automotive operation. The low start threshold voltage of 8.0 V (typ), and the ability to survive 40 V automotive load dump transients are important for automotive subsystem designs. The CS2841 series has a history of quality and reliability in automotive applications.

The CS2841B incorporates a precision temperature-controlled oscillator with an internally trimmed discharge current to minimize variations in frequency. Duty-cycles greater than $50 \%$ are also possible. On board logic ensures that $\mathrm{V}_{\mathrm{REF}}$ is stabilized before the output stage is enabled. Ion implant resistors provide tighter control of undervoltage lockout.

## Features

- Optimized for Off-Line Control
- Internally Trimmed Temperature Compensated Oscillator
- Maximum Duty-Cycle Clamp
- $\mathrm{V}_{\text {REF }}$ Stabilized Before Output Stage Enabled
- Low Start-Up Current
- Pulse-By-Pulse Current Limiting
- Improved Undervoltage Lockout
- Double Pulse Suppression
- 1.0 \% Trimmed Bandgap Reference
- High Current Totem Pole Output

| Input Bias Current | $\mathrm{V}_{\text {Sense }}=0 \mathrm{~V}$ | - | -2.0 | -10 | $\mu \mathrm{~A}$ |
| Delay to Output | $\mathrm{T}_{J}=25^{\circ} \mathrm{C}$. Note 4 | - | 150 | 300 | ns |

3. Adjust $\mathrm{V}_{\mathrm{CC}}$ above the start threshold before setting at 15 V .
4. These parameters, although guaranteed, are not $100 \%$ tested in production.
5. Parameter measured at trip point of latch with $\mathrm{V}_{\mathrm{FB}}=0$.
6. Gain defined as:

$$
\mathrm{A}=\frac{\Delta \mathrm{V}_{\text {COMP }}}{\Delta \mathrm{V}_{\text {Sense }}} ; 0 \leq \mathrm{V}_{\text {Sense }} \leq 0.8 \mathrm{~V}
$$

ELECTRICAL CHARACTERISTICS (continued) $\left(-40^{\circ} \mathrm{C} \leq \mathrm{T}_{\mathrm{A}} \leq 85^{\circ} \mathrm{C}, \mathrm{R}_{\mathrm{T}}=680 \mathrm{k} \Omega, \mathrm{C}_{\mathrm{T}}=0.022 \mu \mathrm{~F}\right.$ for Triangular Mode, $\mathrm{V}_{\mathrm{CC}}=15 \mathrm{~V}$ (Note 3), $\mathrm{R}_{\mathrm{T}}=10 \mathrm{k} \Omega, \mathrm{C}_{\mathrm{T}}=3.3 \mathrm{nF}$ for Sawtooth Mode (see Figure 7); unless otherwise specified.)
