## PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: | :---: |
| DIP-8 | SO-14 |  |  |
| 1 | 1 | COMP | Error amp output, used to compensate error amplifier. |
| 2 | 3 | $V_{\text {FB }}$ | Error amp inverting input. |
| 3 | 5 | Sense | Noninverting input to Current Sense Comparator. |
| 4 | 7 | OSC | Oscillator timing network with Capacitor to Ground, resistor to $\mathrm{V}_{\text {REF }}$. |
| 5 | 8 | GND | Ground. |
|  | 9 | Pwr GND | Output driver Ground. |
| 6 | 10 | $\mathrm{V}_{\text {OUT }}$ | Output drive pin. |
|  | 11 | $\mathrm{V}_{\mathrm{CC}}$ Pwr | Output driver positive supply. |
| 7 | 12 | $\mathrm{V}_{\mathrm{CC}}$ | Positive power supply. |
| 8 | 14 | $\mathrm{V}_{\text {REF }}$ | Output of 5.0 V internal reference. |
|  | 2, 4, 6, 13 | NC | No connection. |

TYPICAL PERFORMANCE CHARACTERISTICS

Figure 2. Oscillator Frequency vs. $\mathbf{C}_{\mathbf{T}}$

Figure 3. Oscillator Duty Cycle vs. $\mathbf{R}_{\mathbf{T}}$

Figure 4. Test Circuit

## CIRCUIT DESCRIPTION

## Undervoltage Lockout

During Undervoltage Lockout (Figure 5), the output driver is biased to a high impedance state. The output should be shunted to ground with a resistor to prevent output leakage current from activating the power switch.

Figure 5. Typical Undervoltage Characteristics

## PWM Waveform

To generate the PWM waveform, the control voltage from the error amplifier is compared to a current sense signal which represents the peak output inductor current (Figure 6). An increase in $\mathrm{V}_{\mathrm{CC}}$ causes the inductor current slope to increase, thus reducing the duty cycle. This is an inherent feed-forward characteristic of current mode control, since the control voltage does not have to change during changes of input supply voltage.

Figure 6. Timing Diagram for Key CS2841B Parameters

When the power supply sees a sudden large output current increase, the control voltage will increase allowing the duty cycle to momentarily increase. Since the duty cycle tends to exceed the maximum allowed to prevent transformer saturation in some power supplies, the internal oscillator waveform provides the maximum duty cycle clamp as programmed by the selection of OSC components.

Timing Parameters

## Sawtooth Mode

## Triangular Mode

Figure 7. Oscillator Timing Network and Parameters

## Setting the Oscillator

Oscillator timing capacitor, $\mathrm{C}_{\mathrm{T}}$, is charged by $\mathrm{V}_{\mathrm{REF}}$ through $\mathrm{R}_{\mathrm{T}}$ and discharged by an internal current source. During the discharge time, the internal clock signal blanks out the output to the Low state, thus providing a user selected maximum duty cycle clamp. Charge and discharge times are determined by the general formulas:

$$
\begin{gathered}
t_{\mathrm{C}}=R_{T} C T \ln \left(\frac{V_{\text {REF }}-V_{\text {lower }}}{V_{\text {REF }}-V_{\text {upper }}}\right) \\
t_{d}=R_{T} C T \ln \left(\frac{V_{\text {REF }}-I_{d} R T-V_{\text {lower }}}{V_{\text {REF }}-I_{d} R T-V_{\text {upper }}}\right)
\end{gathered}
$$

Substituting in typical values for the parameters in the above formulas:
$\mathrm{V}_{\text {REF }}=5.0 \mathrm{~V}$
$\mathrm{V}_{\text {upper }}=2.7 \mathrm{~V}$
$V_{\text {lower }}=1.0 \mathrm{~V}$
$\mathrm{I}_{\mathrm{d}}=8.3 \mathrm{~mA}$
$\mathrm{t}_{\mathrm{C}} \approx 0.5534 \mathrm{R}_{\mathrm{T}} \mathrm{C} T$

The frequency and maximum duty cycle can be determined from the Typical Performance Characteristic graphs.

## Grounding

High peak currents associated with capacitive loads necessitate careful grounding techniques. Timing and bypass capacitors should be connected close to GND pin in a single point ground.

The transistor and $5.0 \mathrm{k} \Omega$ potentiometer are used to sample the oscillator waveform and apply an adjustable ramp to Sense.

$$
t_{d}=R_{T} C_{T} \ln \left(\frac{2.3-0.0083 R_{T}}{4.0-0.0083 R_{T}}\right)
$$

## CS5124, CS5126

## High Performance, Integrated Current Mode PWM Controllers

The CS5124/6 is a fixed frequency current mode controller designed specifically for DC-DC converters found in the telecommunications industry. The CS5124/6 integrates many commonly required current mode power supply features and allows the power supply designer to realize substantial cost and board space savings. The product matrix is as follows:

CS5124: 400 kHz w/VBIAS Pin, 195 mV first current sense threshold.
CS5126: 200 kHz w/SYNC Pin, 335 mV first current sense threshold.
The CS5124/6 integrates the following features: Internal Oscillator, Slope Compensation, Sleep On/Off, Undervoltage Lock Out, Thermal Shutdown, Soft Start Timer, Low Voltage Current Sense for Resistive Sensing, Second Current Threshold for Pulse by Pulse Over Current Protection, a Direct Optocoupler Interface and Leading Edge Current Blanking.

The CS5124/6 has supply range of 7.7 V to 20 V and is available in 8 pin SO narrow package.

## Features

- Line UVLO Monitoring
- Low Current Sense Voltage for Resistive Current Sensing
- External Synchronization to Higher or Lower Frequency Oscillator (CS5126 Only)
- Bias for Start Up Circuitry (CS5124 Only)
- Thermal Shutdown
- Sleep On/Off Pin
- Soft Start Timer
- Leading Edge Blanking
- Direct Optocoupler Interface
- 90 ns Propagation Delay
- 35 ns Driver Rise and Fall Times
- Sleep Mode

Figure 2. Block Diagram

## THEORY OF OPERATION

## Powering the IC

$\mathrm{V}_{\mathrm{CC}}$ can be powered directly from a regulated supply and requires $500 \mu \mathrm{~A}$ of start-up current. The CS5124/6 includes a line bias pin (BIAS) that can be used to control a series pass transistor for operation over a wide input voltage. The BIAS pin will control the gate voltage of an N -channel MOSFET placed between $\mathrm{V}_{\mathrm{IN}}$ and $\mathrm{V}_{\mathrm{CC}}$ to regulate $\mathrm{V}_{\mathrm{CC}}$ at 8.0 V .

## $\mathrm{V}_{\mathrm{Cc}}$ and UVLO Pins

The UVLO pin has three different modes; low power shutdown, Line UVLO, and normal operation. To illustrate how the UVLO pin works; assume that $\mathrm{V}_{\mathrm{IN}}$, as shown in the application schematic, is ramped up starting at 0 V with the UVLO pin open. The SS and ISENSE pins also start at 0 V . While the UVLO is below 1.8 V , the IC will remain in a low current sleep mode and the BIAS pin of the CS5124 is internally clamped to a maximum of 15 V . When the voltage
on the UVLO pin rises to between 1.8 V and 2.6 V the reference for the $\mathrm{V}_{\mathrm{CC}}$ UVLO is enabled and $\mathrm{V}_{\mathrm{CC}}$ is regulated to 8.0 V by the BIAS pin (CS5124 only), but the IC remains in a UVLO state and the output driver does not switch. When the UVLO pin exceeds 2.6 V and the $\mathrm{V}_{\mathrm{CC}}$ pin exceeds 7.7 V , the GATE pin is released from a low state and can begin switching based on the comparison of the I IENSE and $V_{\text {FB }}$ pins. The Soft Start capacitor begins charging from 0 V at $10 \mu \mathrm{~A}$. As the capacitor charges, a buffered version of the capacitor voltage appears on the $\mathrm{V}_{\mathrm{FB}}$ pin and the $\mathrm{V}_{\mathrm{FB}}$ voltage begins to rise. As $\mathrm{V}_{\mathrm{FB}}$ rises the duty cycle increases until the supply comes into regulation.

## Soft Start

Soft Start is accomplished by clamping the $\mathrm{V}_{\mathrm{FB}}$ pin 1.32 V below the SS pin during normal start up and during restart after a fault condition. When the CS5124/6 starts, the Soft

Start capacitor is charged from a $10 \mu \mathrm{~A}$ source from 0 V to 4.9 V. The $\mathrm{V}_{\mathrm{FB}}$ pin follows the Soft Start pin offset by -1.32 V until the supply comes into regulation or until the Soft Start error amp is clamped at $2.9 \mathrm{~V}(2.65 \mathrm{~V}$ for the CS5126). During fault conditions the Soft Start capacitor is discharged at 10 mA .

## Fault Conditions

The CS5124/6 recognizes the following faults: UVLO off, Thermal Shutdown, $\mathrm{V}_{\operatorname{REF}(\mathrm{OK})}$, and Second Current Threshold. Once a fault is recognized, fault latch F2 is set and the IC immediately shuts down the output driver and discharges the Soft Start capacitor. Soft Start will begin only after all faults have been removed and the Soft Start capacitor has been discharged to less than 0.275 V. Each fault will be explained in the following sections.

## Under Voltage Lockout (UVLO)

The UVLO pin is tied to typically the midpoint of a resistive divider between $\mathrm{V}_{\text {IN }}$ and GROUND. During a start up sequence, this pin must be above 2.6 V in order for the IC to begin normal operation. If the IC is running and this pin is pulled below $1.8 \mathrm{~V}, \mathrm{~F} 2$ shuts down the output driver and discharges the Soft Start capacitor in order to insure proper start-up. If the UVLO pin is pulled high again before the Soft Start capacitor discharges, the IC will complete the Soft Start discharge and, if no other faults are present, will immediately restart the power supply. If the UVLO pin stays low, then it will enter either the low current sleep mode or the UVLO state depending on the level of the UVLO pin.

## Thermal Shutdown

If the IC junction temperature exceeds approximately $150^{\circ} \mathrm{C}$ the thermal shutdown circuit sets F2, which shuts down the output driver and discharges the Soft Start capacitor. If no other faults are present the IC will initiate Soft Start when the IC junction temperature has been reduced by $25^{\circ} \mathrm{C}$.

## $\mathbf{V}_{\text {REF(OK) }}$

$\mathrm{V}_{\mathrm{REF}(\mathrm{OK})}$ is an internal monitor that insures the internal regulator is running before any switching occurs. This function does not trip the fault comparator like the other fault functions. To insure that Soft Start will occur at low line conditions the UVLO divider should be set up so that the $\mathrm{V}_{\mathrm{CC}}$ UVLO comparator turns on before the LINE UVLO comparator.

## Second Threshold Comparator

Since the maximum dynamic range of the I IENSE signal in normal operation is 195 mV ( 335 mV for the CS5126), any voltage exceeding this threshold on the I IENSE pin is considered a fault and the PWM cycle is terminated. The 2nd $\mathrm{I}_{\text {COMP }}$ compares the $\mathrm{I}_{\text {SENSE }}$ signal with a 275 mV ( 525 mV for the CS5126) threshold. If the ISENSE voltage exceeds the second threshold, F2 is set, the driver turns off, and the Soft Start capacitor discharges. After the Soft Start capacitor has discharged to less than 0.275 V Soft Start will begin. If the fault condition has been removed the supply will operate normally. If the fault remains the supply will operate in hiccup mode until the fault condition is removed.

## $\mathrm{V}_{\mathrm{FB}}$ Comparator

The $\mathrm{V}_{\mathrm{FB}}$ comparator detects when the output voltage is too high. When the regulated output voltage is too high, the feedback loop will drive $\mathrm{V}_{\mathrm{FB}}$ low. If $\mathrm{V}_{\mathrm{FB}}$ is less than 0.49 V the output of the $\mathrm{V}_{\mathrm{FB}}$ comparator will go high and shut the output driver off.

## Oscillator

The internally trimmed, 400 kHz (CS5124) or 200 kHz (CS5126) provides the slope compensation ramp as well as the pulse for enabling the output driver.

## PWM Comparator and Slope Compensation

The CS5124/6 provides a fixed internal slope compensation ramp that is subtracted from the feedback signal. The PWM comparator compares peak primary current to a portion of the difference of the feedback voltage and slope compensation ramp. The $170 \mathrm{mV} / \mu \mathrm{s}(85 \mathrm{mV} / \mu \mathrm{s}$ for the CS5126) slope compensation ramp is subtracted from the voltage feedback signal internally. The difference signal is then divided by ten (five for the CS5126) before the PWM comparator to provide high noise rejection with a low voltage across the current sense network. (The effective ramp is $21 \mathrm{mV} / \mu \mathrm{s}$ for the CS5124, and $18 \mathrm{mV} / \mu \mathrm{s}$ for the CS5126). A 60 mV ( 125 mV for the CS5126) nominal offset on the positive input to the PWM comparator allows for operation with the $\mathrm{I}_{\text {SENSE }}$ pin at, or even slightly below GND.

A $4.3 \mathrm{k} \Omega$ pull-up resistor internally connected to a 5.0 V nominal reference provides the bias current to for an optocoupler connection to the $\mathrm{V}_{\mathrm{FB}}$ pin.

## APPLICATION INFORMATION

## UVLO and Thermal Shutdown Interaction

The UVLO pin and thermal shutdown circuit share the same internal comparator. During high temperature operation $\left(\mathrm{T}_{\mathrm{J}}>100^{\circ} \mathrm{C}\right)$ the UVLO pin will interact with the thermal shutdown circuit. This interaction increases the turn-on threshold (and hysteresis) of the UVLO circuit. If the UVLO pin shuts down the IC during high temperature operation, higher hysteresis (see hysteresis specification) might be required to enable the IC.

## BIAS Pin (CS5124 Only)

The bias pin can be used to control $\mathrm{V}_{\mathrm{CC}}$ as shown in the main application diagram in Figure 1. In order to provide adequate phase margin for the bias control loop, the pole created by the series pass transistor and the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor should be kept above 10 kHz . The frequency of this pole can be calculated by Formula (1).
Pole Frequency $=\frac{\text { Transconductance of pass Transistor }}{2 \times \pi \times \mathrm{CV}(\mathrm{CC})}$
The Line BIAS pin shows a significant change in the regulated $\mathrm{V}_{\mathrm{CC}}$ voltage when sinking large currents. This will show up as poor line regulation with a low value pull-up resistor. Typical regulated $\mathrm{V}_{\mathrm{CC}}$ vs BIAS pin sink current is shown in Figure 3.

Figure 3. Regulated V $_{\text {Cc }}$ vs. BIAS Sink Current
The BIAS pin and associated components form a high impedance node. Care should be taken during PCB layout to avoid connections that could couple noise into this node.

## Clock Synchronization Pin (CS5126 Only)

The CS5126 can be synchronized to signals ranging from $30 \%$ slower to several times faster than the internal oscillator frequency. If the part is synchronized to a fast signal, maximum duty cycle will be reduced as the frequency increases as shown in Figure 4.

Figure 4. CS5126 Maximum Duty Cycle vs. Frequency (Synchronized Operation)
If the converter is initially free running and a sync signal is applied, the current oscillator cycle will terminate and the oscillator will lock on to the sync signal. The SYNC pin works with a positive edge triggered signal. When the sync signal transitions high the current PWM cycle terminates and a new cycle begins as shown in Figure 5. The typical phase lag between the rising edge of the SYNC signal and the rising edge of the Gate is shown in Figure 6. When this pin is held high or low the internal clock determines the oscillator frequency.

Figure 5. Synchronized Operation

Figure 6. Typical Phase Lag between SYNC and GATE on

## Gate Drive

Rail to rail gate driver operation can be obtained (up to 13.5 V) over a range of MOSFET input capacitance if the gate resistor value is kept low. Figure 5 shows the high gate drive level vs. the series gate resistance with $\mathrm{V}_{\mathrm{CC}}=8.0 \mathrm{~V}$ driving an IRF220.

Figure 7. Gate Drive vs. Gate Resistor Driving an IRF220 ( $\mathrm{V}_{\mathrm{CC}}=8.0 \mathrm{~V}$ )

A large negative $\mathrm{dv} / \mathrm{dt}$ on the power MOSFET drain will couple current into the gate driver through the gate to drain capacitance. If this current is kept within absolute maximum ratings for the GATE pin it will not damage the IC. However if a high negative dv/dt coincides with the start of a PWM duty cycle, there will be small variations in oscillator frequency due to current in the controller substrate. If required, this can be avoided by choosing the transformer ratio and reset circuit so that a high dv/dt does not coincide with the start of a PWM cycle, or by clamping the negative voltage on the GATE pin with a schottky diode

## First Current Sense Threshold

During normal operation the peak primary current is controlled by the level of the $\mathrm{V}_{\mathrm{FB}}$ pin (as determined by the control loop) and the current sense network. Once the signal on the $\mathrm{I}_{\text {SENSE }}$ pin exceeds the level determined by $\mathrm{V}_{\mathrm{FB}}$ pin the PWM cycle terminates. During high output currents the $\mathrm{V}_{\mathrm{FB}}$ pin will rise until it reaches the $\mathrm{V}_{\mathrm{FB}}$ clamp. The first current sense threshold determines the maximum signal allowed on the I ISENSE pin before the PWM cycle is terminated. Under this condition the maximum peak current is determined by the $\mathrm{V}_{\mathrm{FB}}$ Clamp, the slope compensation ramp, the PWM comparator offset voltage and the PWM on time. The nominal first current threshold varies with on time and can be calculated from Formulas (2) \& (3) below.

CS5124
1st Threshold $=\frac{2.9 \mathrm{~V}-170 \mathrm{mV} / \mu \mathrm{s} \times \text { TON }}{10}-60 \mathrm{mV}$
CS5126
1st Threshold $=\frac{2.65 \mathrm{~V}-85 \mathrm{mV} / \mu \mathrm{s} \times \mathrm{T} \mathrm{ON}}{5.0}-125 \mathrm{mV}$

When the output current is high enough for the I ISENSE pin to exceed the first threshold, the PWM cycle terminates early and the converter begins to function more like a current source. The current sense network must be chosen so that the peak current during normal operation does not exceed the first current sense threshold.

## Second Current Sense Threshold

The second threshold is intended to protect the converter from over-heating by switching to a low duty cycle mode when there are abnormally high fast rise currents in the converter. If the second current sense threshold is tripped, the converter will shut off and restart in Soft Start mode until the high current condition is removed. The dead time after a second threshold over-current condition will primarily be determined by the time required to charge the Soft Start cap from 0.275 V nominal to 1.32 V .

The second threshold will only be reached when a high $\mathrm{dv} / \mathrm{dt}$ is present at the current sense pin. The signal must be fast enough to reach the second threshold before the first threshold turns off the driver. This will normally happen if the forward inductor saturates or when there is a shorted load.

Excessive filtering of the current sense signal, a low value current sense resistor, or even an inductor that does not saturate during heavy output currents can prevent the second threshold from being reached. In this case the first current sense threshold will trip during each cycle of high output current conditions. The first threshold will limit output current but some components, especially the output rectifier, can overheat due to higher than normal average output current.

## Slope Compensation

Current mode converters operating at duty cycles in excess of $50 \%$ require an artificial ramp to be added to the current waveform or subtracted from the feedback waveform. For the current loop to be stable the artificial ramp must be equivalent to at least $50 \%$ of the inductor current down slope and is typically chosen between $75 \%$ to $100 \%$ of the inductor down current down slope.
To choose an inductor value such that the internal slope compensation ramp will be equal to a certain fraction of the inductor down current slope use the Formula (4).
$\frac{1}{\text { Internal Ramp }} \times\left(\right.$ V OUT $\left.+\mathrm{V}_{\text {RECTIFIER }}\right) \times \frac{\mathrm{N}_{\text {SECONDARY }}}{\mathrm{NPRIMARY}} \times$
RSENSE $\times$ Slope Value Factor $=$ Inductor Value $(\mathrm{H})$
Calculating the nominal inductor value for an artificial ramp equivalent to $100 \%$ of the current inductor down slope at CS5126 nominal conditions, a 5.0 V output, a $200 \mathrm{~m} \Omega$ current sense resistor and a $4: 1$ transformer ratio yields
$\frac{1}{20 \mathrm{mV} / \mu \mathrm{s}} \times(5.0 \mathrm{~V}+0.3 \mathrm{~V}) \times \frac{1}{4} \times 0.2 \Omega \times 1.0=13.2 \mu \mathrm{H}$

To check that the slope compensation ramp will be greater than $50 \%$ of the inductor down under all conditions, substitute the minimum internal slope compensation value and use 0.5 for the slope compensation value. Then check that the actual inductor value will always be greater than the inductor value calculated.

During synchronized operation of the CS5126 the slope compensation ramp is reduced by $33 \%$. If the CS5126 will be used in synchronized operation, the inductor value should be recalculated to work with the slope compensation ramp reduced to $67 \%$ of the normal value.

## Powering the CS5124/6 from a Transformer Winding

There are numerous ways to power the CS5124/6 from a transformer winding to enable the converter to be operated at high efficiency over a wide input range. Two ways are shown in the application circuits.

The CS5124 application circuit in Figure 1 is a flyback converter that uses a second flyback winding to power $\mathrm{V}_{\mathrm{CC}}$. R 4 improves $\mathrm{V}_{\mathrm{CC}}$ regulation with load changes by snubbing the turn off spike. Once the turn off spike has subsided the voltage of this winding is voltage proportional to the voltage on the main flyback winding. This voltage is regulated because the main winding is clamped by the regulated output voltage.

In the CS5126 application circuit in Figure 8 an extra winding is added to the forward inductor to power $\mathrm{V}_{\mathrm{CC}}$. This winding is phased to conduct during the off time of the forward converter and performs the same function as the flyback winding above.

A flyback winding from a forward transformer can also be used to power $\mathrm{V}_{\mathrm{CC}}$. Ideally the transformer volt-second product of a forward converter would be constant over the range of line voltages and load currents; and the transformer inductance could be chosen to store the required level of energy during each cycle to power $\mathrm{V}_{\mathrm{CC}}$. Even though the flyback energy is not directly regulated it would remain constant. Unfortunately in a real converter there are many non-ideal effects that degrade regulation. Transformer inductance varies, converter frequency varies, energy stored in primary leakage inductance varies with output current, stray transformer capacitances and various parasitics all effect the level of energy available for $\mathrm{V}_{\mathrm{CC}}$. If too little energy is provided to $\mathrm{V}_{\mathrm{CC}}$, the bootstrapping circuit must provide power and efficiency will be reduced. If too much energy is provided $\mathrm{V}_{\mathrm{CC}}$ rises and may damage the controller. If this approach is taken the circuit must be carefully designed and component values must be controlled for good regulation.

MC44603A

## Enhanced Mixed Frequency Mode GreenLine ${ }^{T M}$ PWM Controller: <br> Fixed Frequency, Variable Frequency, Standby Mode

The MC44603A is an enhanced high performance controller that is specifically designed for off-line and dc-to-dc converter applications. This device has the unique ability of automatically changing operating modes if the converter output is overloaded, unloaded, or shorted, offering the designer additional protection for increased system reliability. The MC44603A has several distinguishing features when compared to conventional SMPS controllers. These features consist of a foldback facility for overload protection, a standby mode when the converter output is slightly loaded, a demagnetization detection for reduced switching stresses on transistor and diodes, and a high current totem pole output ideally suited for driving a power MOSFET. It can also be used for driving a bipolar transistor in low power converters ( $<150 \mathrm{~W}$ ). It is optimized to operate in discontinuous mode but can also operate in continuous mode. Its advanced design allows use in current mode or voltage mode control applications.

## Current or Voltage Mode Controller

- Operation up to 250 kHz Output Switching Frequency
- Inherent Feed Forward Compensation
- Latching PWM for Cycle-by-Cycle Current Limiting
- Oscillator with Precise Frequency Control

## High Flexibility

- Externally Programmable Reference Current
- Secondary or Primary Sensing
- Synchronization Facility
- High Current Totem Pole Output
- Undervoltage Lockout with Hysteresis

## Safety/Protection Features

- Overvoltage Protection Against Open Current and Open Voltage Loop
- Protection Against Short Circuit on Oscillator Pin
- Fully Programmable Foldback
- Soft-Start Feature
- Accurate Maximum Duty Cycle Setting
- Demagnetization (Zero Current Detection) Protection
- Internally Trimmed Reference
- Enhanced Output Drive

## GreenLine Controller: Low Power Consumption in Standby Mode

- Low Startup and Operating Current
- Fully Programmable Standby Mode
- Controlled Frequency Reduction in Standby Mode
- Low dV/dT for Low EMI Radiations

GreenLine is a trademark of Motorola, Inc.

PIN FUNCTION DESCRIPTION

| Pin | Name | Description |
| :---: | :---: | :---: |
| 1 | $\mathrm{V}_{\mathrm{CC}}$ | This pin is the positive supply of the IC. The operating voltage range after startup is 9.0 to 14.5 V . |
| 2 | $\mathrm{V}_{\mathrm{C}}$ | The output high state $\left(\mathrm{V}_{\mathrm{OH}}\right)$ is set by the voltage applied to this pin. With a separate connection to the power source, it can reduce the effects of switching noise on the control circuitry. |
| 3 | Output | Peak currents up to 750 mA can be sourced or sunk, suitable for driving either MOSFET or Bipolar transistors. This output pin must be shunted by a Schottky diode, 1N5819 or equivalent. |
| 4 | Gnd | The ground pin is a single return, typically connected back to the power source; it is used as control and power ground. |
| 5 | Foldback Input | The foldback function provides overload protection. Feeding the foldback input with a portion of the $\mathrm{V}_{\mathrm{CC}}$ voltage ( 1.0 V max) establishes on the system control loop a foldback characteristic allowing a smoother startup and sharper overload protection. Above 1.0 V the foldback input is inactive. |
| 6 | Overvoltage Protection | When the overvoltage protection pin receives a voltage greater than 17 V , the device is disabled and requires a complete restart sequence. The overvoltage level is programmable. |
| 7 | Current Sense Input | A voltage proportional to the current flowing into the power switch is connected to this input. The PWM latch uses this information to terminate the conduction of the output buffer when working in a current mode of operation. A maximum level of 1.0 V allows either current or voltage mode operation. |
| 8 | Demagnetization Detection | A voltage delivered by an auxiliary transformer winding provides to the demagnetization pin an indication of the magnetization state of the flyback transformer. A zero voltage detection corresponds to complete core saturation. The demagnetization detection ensures a discontinuous mode of operation. This function can be inhibited by connecting Pin 8 to Gnd. |
| 9 | Synchronization Input | The synchronization input pin can be activated with either a negative pulse going from a level between 0.7 V and 3.7 V to Gnd or a positive pulse going from a level between 0.7 V and 3.7 V up to a level higher than 3.7 V . The oscillator runs free when Pin 9 is connected to Gnd. |
| 10 | $\mathrm{C}_{\text {T }}$ | The normal mode oscillator frequency is programmed by the capacitor $\mathrm{C}_{\mathrm{T}}$ choice together with the $\mathrm{R}_{\text {ref }}$ resistance value. $\mathrm{C}_{\mathrm{T}}$, connected between Pin 10 and Gnd, generates the oscillator sawtooth. |
| 11 | Soft-Start/ $D_{\text {max }} /$ Voltage-Mode | A capacitor, resistor or a voltage source connected to this pin limits the switching duty-cycle. This pin can be used as a voltage mode control input. By connecting Pin 11 to Ground, the MC44603A can be shut down. |
| 12 | RP Standby | A voltage level applied to the $R_{P}$ Standby pin determines the output power level at which the oscillator will turn into the reduced frequency mode of operation (i.e. standby mode). An internal hysteresis comparator allows to return in the normal mode at a higher output power level. |
| 13 | E/A Out | The error amplifier output is made available for loop compensation. |
| 14 | Voltage Feedback | This is the inverting input of the Error Amplifier. It can be connected to the switching power supply output through an optical (or other) feedback loop. |
| 15 | $\mathrm{R}_{\mathrm{F} \text { Standby }}$ | The reduced frequency or standby frequency programming is made by the $\mathrm{R}_{F}$ Standby resistance choice. |
| 16 | $\mathrm{R}_{\text {ref }}$ | $\mathrm{R}_{\text {ref }}$ sets the internal reference current. The internal reference current ranges from $100 \mu \mathrm{~A}$ to $500 \mu \mathrm{~A}$. This requires that $5.0 \mathrm{k} \Omega \leq \mathrm{R}_{\mathrm{ref}} \leq 25 \mathrm{k} \Omega$. |

OPERATING DESCRIPTION

## Error Amplifier

A fully compensated Error Amplifier with access to the inverting input and output is provided. It features a typical dc voltage gain of 70 dB . The noninverting input is internally biased at 2.5 V and is not pinned out. The converter output voltage is typically divided down and monitored by the inverting input. The maximum input bias current with the inverting input at 2.5 V is $-2.0 \mu \mathrm{~A}$. This can cause an output voltage error that is equal to the product of the input bias current and the equivalent input divider source resistance.

The Error Amp output (Pin 13) is provided for external loop compensation. The output voltage is offset by two diode drops $(\approx 1.4 \mathrm{~V})$ and divided by three before it connects to the inverting input of the Current Sense Comparator. This guarantees that no drive pulses appear at the Output (Pin 3) when Pin 13 is at its lowest state ( $\mathrm{V}_{\mathrm{OL}}$ ). The Error Amp minimum feedback resistance is limited by the amplifier's minimum source current $(0.2 \mathrm{~mA})$ and the required output voltage $\left(\mathrm{V}_{\mathrm{OH}}\right)$ to reach the current sense comparator's 1.0 V clamp level:

$$
\mathrm{R}_{\mathrm{f}(\min )} \approx \frac{3.0(1.0 \mathrm{~V})+1.4 \mathrm{~V}}{0.2 \mathrm{~mA}}=22 \mathrm{k} \Omega
$$

## Figure 32. Error Amplifier Compensation

## Current Sense Comparator and PWM Latch

The MC44603A can operate as a current mode controller or as a voltage mode controller. In current mode operation, the MC44603A uses the current sense comparator. The output switch conduction is initiated by the oscillator and terminated when the peak inductor current reaches the threshold level established by the Error Amplifier output
(Pin 13). Thus, the error signal controls the peak inductor current on a cycle-by-cycle basis. The Current Sense Comparator PWM Latch ensures that only a single pulse appears at the Source Output during the appropriate oscillator cycle.

The inductor current is converted to a voltage by inserting the ground referenced sense resistor $\mathrm{R}_{\mathrm{S}}$ in series with the power switch Q1.

This voltage is monitored by the Current Sense Input (Pin 7) and compared to a level derived from the Error Amp output. The peak inductor current under normal operating conditions is controlled by the voltage at Pin 13 where:

$$
\mathrm{I}_{\mathrm{pk}} \approx \frac{\mathrm{~V}(\operatorname{Pin} 13)-1.4 \mathrm{~V}}{3 \mathrm{RS}_{\mathrm{S}}}
$$

The Current Sense Comparator threshold is internally clamped to 1.0 V . Therefore, the maximum peak switch current is:

$$
\operatorname{lpk}(\max ) \approx \frac{1.0 \mathrm{~V}}{\mathrm{R}_{\mathrm{S}}}
$$

Figure 33. Output Totem Pole

Series gate resistor, R2, will dampen any high frequency oscillations caused by the MOSFET input capacitance and any series wiring inductance in the gate-source circuit. Diode $D$ is required if the negative current into the output drive pin exceeds 15 mA .

## Oscillator

The oscillator is a very accurate sawtooth generator that can work either in free mode or in synchronization mode. In this second mode, the oscillator stops in the low state and waits for a demagnetization or a synchronization pulse to start a new charging cycle.

## - The Sawtooth Generation:

In the steady state, the oscillator voltage varies between about 1.6 V and 3.6 V .

The sawtooth is obtained by charging and discharging an external capacitor $\mathrm{C}_{\mathrm{T}}$ (Pin 10), using two distinct current sources $=I_{\text {charge }}$ and $\mathrm{I}_{\text {discharge }}$. In fact, $\mathrm{C}_{\mathrm{T}}$ is permanently connected to the charging current source ( $0.4 \mathrm{I}_{\mathrm{ref}}$ ) and so,
the discharge current source has to be higher than the charge current to be able to decrease the $\mathrm{C}_{\mathrm{T}}$ voltage (refer to Figure 35).

This condition is performed, its value being ( $2.0 \mathrm{I}_{\mathrm{ref}}$ ) in normal working and ( $0.4 \mathrm{I}_{\mathrm{ref}}+0.5 \mathrm{I}_{\mathrm{F} \text { Stby }}$ in standby mode).

Figure 34. Oscillator

Figure 35. Simplified Block Oscillator

Two comparators are used to generate the sawtooth. They compare the $\mathrm{C}_{\mathrm{T}}$ voltage to the oscillator valley $(1.6 \mathrm{~V})$ and peak reference ( 3.6 V ) values. A latch $\left(\mathrm{L}_{\text {disch }}\right)$ memorizes the oscillator state.

In addition to the charge and discharge cycles, a third state can exist. This phase can be produced when, at the end of the discharge phase, the oscillator has to wait for a synchronization or demagnetization pulse before restarting. During this delay, the $\mathrm{C}_{\mathrm{T}}$ voltage must remain equal to the oscillator valley value ( $\simeq 1.6 \mathrm{~V}$ ). So, a third regulated current source $\mathrm{I}_{\text {Regul }}$ controlled by $\mathrm{C}_{\mathrm{OSC}}$ Regul, is connected to $\mathrm{C}_{\mathrm{T}}$ in order to perfectly compensate the ( $0.4 \mathrm{I}_{\mathrm{ref}}$ ) current source that permanently supplies $\mathrm{C}_{\mathrm{T}}$.

The maximum duty cycle is $80 \%$. Indeed, the on-time is allowed only during the oscillator capacitor charge.

Consequently:
$\mathrm{T}_{\text {charge }}=\mathrm{C}_{\mathrm{T}} \times \Delta \mathrm{V} / \mathrm{I}_{\text {charge }}$
$\mathrm{T}_{\text {discharge }}=\mathrm{C}_{\mathrm{T}} \times \Delta \mathrm{V} / \mathrm{I}_{\text {discharge }}$
where:
$\mathrm{T}_{\text {charge }}$ is the oscillator charge time
$\Delta \mathrm{V}$ is the oscillator peak-to-peak value
$\mathrm{I}_{\text {charge }}$ is the oscillator charge current and
$\mathrm{T}_{\text {discharge }}$ is the oscillator discharge time
$\mathrm{I}_{\text {discharge }}$ is the oscillator discharge current
So, as $\mathrm{f}_{\mathrm{S}}=1 /\left(\mathrm{T}_{\text {charge }}+\mathrm{T}_{\text {discharge }}\right)$ when the Regul arrangement is not activated, the operating frequency can be obtained from the graph in Figure 1.
NOTE: The output is disabled by the signal $V_{\text {OSC prot }}$ when $\mathrm{V}_{\mathrm{CT}}$ is lower than 1.0 V (refer to Figure 30).

## Synchronization and Demagnetization Blocks

To enable the output, the L ${ }_{\text {OSC }}$ latch complementary output must be low. Reset is activated by the $\mathrm{L}_{\text {disch }}$ output during the discharge phase. To restart, the L OSC has to be set (refer to Figure 34). To perform this, the demagnetization signal and the synchronization must be low.

## - Synchronization:

The synchronization block consists of two comparators that compare the synchronization signal (external) to 0.7 and 3.7 V (typical values). The comparators' outputs are connected to the input of an AND gate so that the final output of the block should be:

- high when $0.7<$ SYNC $<3.7 \mathrm{~V}$
- low in the other cases.

As a low level is necessary to enable the output, synchronized low level pulses have to be generated on the output of the synchronization block. If synchronization is not required, the Pin 9 must be connected to the ground.

Figure 36. Synchronization

## - Demagnetization:

In flyback applications, a good means to detect magnetic saturation of the transformer core, or demagnetization, consists in using the auxiliary winding voltage. This voltage is:

- negative during the on-time,
- positive during the off-time,
- equal to zero for the dead-time with generally some ringing (refer to Figure 37).
That is why, the MC44603A demagnetization detection consists of a comparator that can compare the auxiliary winding voltage to a reference that is typically equal to 65 mV .

Figure 37. Demagnetization Detection

A diode D has been incorporated to clamp the positive applied voltages while an active clamping system limits the negative voltages to typically -0.33 V . This negative clamp level is sufficient to avoid the substrate diode switching on.
In addition to the comparator, a latch system has been incorporated in order to keep the demagnetization block output level low as soon as a voltage lower than 65 mV is detected and as long as a new restart is produced (high level on the output) (refer to Figure 38). This process prevents ringing on the signal at Pin 8 from disrupting the demagnetization detection. This results in a very accurate demagnetization detection.

The demagnetization block output is also directly connected to the output, disabling it during the demagnetization phase (refer to Figure 33).
NOTE: The demagnetization detection can be inhibited by connecting Pin 8 to the ground.

Figure 38. Demagnetization Block

## Standby

## - Power Losses in a Classical Flyback Structure

Figure 39. Power Losses in a Classical Flyback Structure

In a classical flyback (as depicted in Figure 39), the standby losses mainly consist of the energy waste due to:

- the startup resistor $\mathrm{R}_{\text {startup }} \quad \rightarrow \mathrm{P}_{\text {startup }}$
- the consumption of the IC and the power switch control $\rightarrow P_{\text {control }}$
- the inrush current limitation resistor $\mathrm{R}_{\mathrm{ICL}} \rightarrow \mathrm{P}_{\mathrm{ICL}}$
- the switching losses in the power switch $\rightarrow \mathrm{P}_{\mathrm{SW}}$
- the snubber and clamping network $\quad \rightarrow \mathrm{P}_{\mathrm{SN}-\mathrm{CLN}}$
$P_{\text {startup }}$ is nearly constant and is equal to:

$$
\left(\left(\mathrm{V}_{\mathrm{in}}-\mathrm{V}_{\mathrm{CC}}\right)^{2} / \mathrm{R}_{\text {startup }}\right)
$$

$\mathrm{P}_{\mathrm{ICL}}$ only depends on the current drawn from the mains. Losses can be considered constant. This waste of energy decreases when the standby losses are reduced.
$P_{\text {control }}$ increases when the oscillator frequency is increased (each switching requires some energy to turn on the power switch).
$\mathrm{P}_{\mathrm{SW}}$ and $\mathrm{P}_{\mathrm{SN}-\mathrm{CLN}}$ are proportional to the switching frequency.

Consequently, standby losses can be minimized by decreasing the switching frequency as much as possible.

The MC44603A was designed to operate at a standby frequency lower than the normal working one.

## - Standby Power Calculations with MC44603A

During a switching period, the energy drawn by the transformer during the on-time to be transferred to the output during the off-time, is equal to:

$$
E=\frac{1}{2} \times L \times l_{p k}^{2}
$$

where:

- L is the transformer primary inductor,
$-l_{p k}$ is the inductor peak current.
Input power is labelled $\mathrm{P}_{\mathrm{in}}$ :

$$
P_{\text {in }}=0.5 \times L \times l_{p k}{ }^{2} \times f \text { S }
$$

where $f_{S}$ is the normal working switching frequency.
Also,

$$
\mathrm{I}_{\mathrm{pk}}=\frac{\mathrm{V}_{\mathrm{CS}}}{\mathrm{R}_{\mathrm{S}}}
$$

where $\mathrm{R}_{\mathrm{S}}$ is the resistor used to measure the power switch current.

Thus, the input power is proportional to $\mathrm{V}_{\mathrm{CS}}{ }^{2}\left(\mathrm{~V}_{\mathrm{CS}}\right.$ being the internal current sense comparator input).

That is why the standby detection is performed by creating a $\mathrm{V}_{\mathrm{CS}}$ threshold. An internal current source ( $0.4 \times \mathrm{I}_{\mathrm{ref}}$ ) sets the threshold level by connecting a resistor to Pin 12.
As depicted in Figure 40, the standby comparator noninverting input voltage is typically equal to $\left(3.0 \times \mathrm{V}_{\mathrm{CS}}+\right.$ $\left.V_{F}\right)$ while the inverter input value is $\left(V_{R} P\right.$ Stby $\left.+V_{F}\right)$.

Figure 40. Standby

The $V_{C S}$ threshold level is typically equal to $\left[\left(\mathrm{V}_{\mathrm{R}}\right.\right.$ P Stby $\left.) / 3\right]$ and if the corresponding power threshold is labelled $\mathrm{P}_{\mathrm{thL}}$ :

$$
P_{\text {thL }}=0.5 \times L \times\left(\frac{V_{R} P \text { Stby }}{3.0 R_{S}}\right)^{2} \times \mathrm{fs}
$$

And as:

$$
\begin{array}{r}
V_{R ~ P ~ S t b y}=R_{\text {P Stby }} \times 0.4 \times I_{\text {ref }} \\
=R_{R} P \text { Stby } \times 0.4 \times \frac{V_{\text {ref }}}{R_{\text {ref }}} \\
R_{\text {R Stby }}=\frac{10.6 \times R_{\text {S }} \times R_{\text {ref }}}{V_{\text {ref }}} \times \sqrt{\frac{P_{\text {thL }}}{L \times f S}}
\end{array}
$$

Thus, when the power drawn by the converter decreases, $\mathrm{V}_{\mathrm{CS}}$ decreases and when $\mathrm{V}_{\mathrm{CS}}$ becomes lower than [ $\mathrm{V}_{\text {CS-th }}$ $\mathrm{x}\left(\mathrm{V}_{\mathrm{R}}\right.$ P Stby $\left.) / 3\right]$, the standby mode is activated. This results in an oscillator discharge current reduction in order to increase the oscillator period and to diminish the switching frequency. As it is represented in Figure 40, the ( $0.8 \times \mathrm{I}_{\mathrm{ref}}$ ) current source is disconnected and is replaced by a lower value one ( $0.25 \times \mathrm{I}_{\mathrm{F} \text { Stby }}$ ).
Where: $\mathrm{I}_{\mathrm{F} \text { Stby }}=\mathrm{V}_{\text {ref }} / \mathrm{R}_{\mathrm{F} \text { Stby }}$
In order to prevent undesired mode switching when power is close to the threshold value, a hysteresis that is
proportional to $\mathrm{V}_{\mathrm{R}}$ P Stby is incorporated creating a second $\mathrm{V}_{\mathrm{CS}}$ threshold level that is equal to [2.5 $\times\left(\mathrm{V}_{\mathrm{R}} \mathrm{P}\right.$ Stby $\left.) / 3\right]$. When the standby comparator output is high, a second current source ( $0.6 \mathrm{x}_{\mathrm{ref}}$ ) is connected to Pin 12 .

Finally, the standby mode function can be shown graphically in Figure 41.

Figure 41. Dynamic Mode Change
This curve shows that there are two power threshold levels:

- the low one:

$$
P_{\text {thL }} \text { fixed by } V_{R} \text { P Stby }
$$

- the high one:

$$
\begin{aligned}
& P_{\text {thH }}=(2.5)^{2} \times P_{\text {thL }} \times \frac{\mathrm{f}_{\text {thy }}}{\mathrm{f}_{\mathrm{S}}} \\
& P_{\mathrm{thH}}=6.25 \times \mathrm{P}_{\mathrm{thL}} \times \frac{\mathrm{f}_{\mathrm{Stby}}}{\mathrm{f}_{\mathrm{S}}}
\end{aligned}
$$

## Maximum Duty Cycle and Soft-Start Control

Maximum duty cycle can be limited to values less than $80 \%$ by utilizing the $\mathrm{D}_{\text {max }}$ and soft-start control. As depicted in Figure 42, the Pin 11 voltage is compared to the oscillator sawtooth.

Figure 42. $\mathrm{D}_{\text {max }}$ and Soft-Start

Figure 43. Maximum Duty Cycle Control

Using the internal current source ( $0.4 \mathrm{I}_{\mathrm{ref}}$ ), the Pin 11 voltage can easily be set by connecting a resistor to this pin.

If a capacitor is connected to Pin 11, the voltage increases from 0 to its maximum value progressively (refer to Figure 44), thereby, implementing a soft-start. The soft-start capacitor is discharged internally when the $\mathrm{V}_{\mathrm{CC}}$ (Pin 1) voltage drops below 9.0 V .

Figure 44. Different Possible Uses of Pin 11
If no external component is connected to Pin 11, an internal zener diode clamps the Pin 11 voltage to a value $\mathrm{V}_{\mathrm{Z}}$ that is higher than the oscillator peak value, disabling soft-start and maximum duty cycle limitation.

## Foldback

As depicted in Figures 32 and 48, the foldback input (Pin 5) can be used to reduce the maximum $V_{C S}$ value, providing foldback protection. The foldback arrangement is a programmable peak current limitation.

If the output load is increased, the required converter peak current becomes higher and $\mathrm{V}_{\mathrm{CS}}$ increases until it reaches its maximum value (normally, $\mathrm{V}_{\mathrm{CS} \text { max }}=1.0 \mathrm{~V}$ ).

Then, if the output load keeps on increasing, the system is unable to supply enough energy to maintain the output voltages in regulation. Consequently, the decreasing output can be applied to Pin 5, in order to limit the maximum peak current. In this way, the well known foldback characteristic can be obtained (refer to Figure 45).

Figure 45. Foldback Characteristic

NOTE: Foldback is disabled by connecting Pin 5 to $\mathrm{V}_{\mathrm{CC}}$.

## Overvoltage Protection

The overvoltage arrangement consists of a comparator that compares the Pin 6 voltage to $\mathrm{V}_{\text {ref }}(2.5 \mathrm{~V})$ (refer to Figure 46).

If no external component is connected to Pin 6, the comparator noninverting input voltage is nearly equal to:

$$
\left(\frac{2.0 \mathrm{k} \Omega}{11.6 \mathrm{k} \Omega+2.0 \mathrm{k} \Omega}\right) \times \mathrm{V}_{\mathrm{CC}}
$$

The comparator output is high when:

$$
\begin{gathered}
\left(\frac{2.0 \mathrm{k} \Omega}{11.6 \mathrm{k} \Omega+2.0 \mathrm{k} \Omega}\right) \times \mathrm{V}_{\mathrm{CC}} \geq 2.5 \mathrm{~V} \\
\Leftrightarrow \mathrm{~V}_{\mathrm{CC}} \geq 17 \mathrm{~V}
\end{gathered}
$$

A delay latch $(2.0 \mu \mathrm{~s})$ is incorporated in order to sense overvoltages that last at least $2.0 \mu \mathrm{~s}$.

If this condition is achieved, $\mathrm{V}_{\mathrm{OVP}}$ out, the delay latch output, becomes high. As this level is brought back to the input through an OR gate, $\mathrm{V}_{\text {OVP out }}$ remains high (disabling the IC output) until $\mathrm{V}_{\text {ref }}$ is disabled.

Consequently, when an overvoltage longer than $2.0 \mu \mathrm{~s}$ is detected, the output is disabled until $\mathrm{V}_{\mathrm{CC}}$ is removed and then re-applied.

The $\mathrm{V}_{\mathrm{CC}}$ is connected after $\mathrm{V}_{\text {ref }}$ has reached steady state in order to limit the circuit startup consumption.

The overvoltage section is enabled $5.0 \mu$ s after the regulator has started to allow the reference $\mathrm{V}_{\text {ref }}$ to stabilize.

By connecting an external resistor to Pin 6, the threshold $\mathrm{V}_{\mathrm{CC}}$ level can be changed.

Figure 46. Overvoltage Protection

## Undervoltage Lockout Section

Figure 47. $\mathrm{V}_{\mathrm{CC}}$ Management
As depicted in Figure 47, an undervoltage lockout has been incorporated to garantee that the IC is fully functional before allowing system operation.

This block particularly, produces $\mathrm{V}_{\text {ref }}$ (Pin 16 voltage) and $\mathrm{I}_{\text {ref }}$ that is determined by the resistor $\mathrm{R}_{\text {ref }}$ connected between Pin 16 and the ground:

$$
I_{\text {ref }}=\frac{V_{\text {ref }}}{R_{\text {ref }}} \text { where } V_{\text {ref }}=2.5 \mathrm{~V} \text { (typically) }
$$

Another resistor is connected to the Reference Block: $\mathrm{R}_{\mathrm{F} \text { Stby }}$ that is used to fix the standby frequency.

In addition to this, $\mathrm{V}_{\mathrm{CC}}$ is compared to a second threshold level that is nearly equal to $9.0 \mathrm{~V}\left(\mathrm{~V}_{\text {disable1 }}\right)$. UVLO1 is generated to reset the maximum duty cycle and soft-start block disabling the output stage as soon as $\mathrm{V}_{\mathrm{CC}}$ becomes lower than $\mathrm{V}_{\text {disable1 }}$. In this way, the circuit is reset and made ready for the next startup, before the reference block is disabled (refer to Figure 29). Finally, the upper limit for the minimum normal operating voltage is 9.4 V (maximum value of $\mathrm{V}_{\text {disable1 }}$ ) and so the minimum hysteresis is 4.2 V . $\left(\left(\mathrm{V}_{\text {stup-th }}\right)_{\text {min }}=13.6 \mathrm{~V}\right)$.

The large hysteresis and the low startup current of the MC44603A make it ideally suited for off-line converter applications where efficient bootstrap startup techniques are required.

* Diode D15 is required if the negative current into the output pin exceeds 15 mA .

## MC44604

## High Safety Pulsed Mode Standby GreenLine ${ }^{\text {TM }}$ PWM Controller

The MC44604 is an enhanced high performance controller that is specifically designed for off-line and dc-to-dc converter applications. Its high current totem pole output is ideally suited for driving a power MOSFET.

The MC44604 is an evolution of the MC44603A. Like the MC44603A, the MC44604 has been optimized to operate with universal ac mains voltage from 80 V to 280 V . It also offers enhanced safety and reliable power management thanks to its protection features (foldback, overvoltage detection, soft-start, accurate demagnetization detection).

In addition, the MC44604 offers a new efficient way to reduce the standby operating power by means of a so-called pulsed mode standby operation of the converter, significantly reducing the converter consumption in standby mode.

## Current Mode Controller

- Operation Up to 250 kHz Output Switching Frequency
- Inherent Feed Forward Compensation
- Latching PWM for Cycle-by-Cycle Current Limiting
- Oscillator with Precise Frequency Control

## High Flexibility

- Externally Programmable Reference Current
- Secondary or Primary Sensing
- High Current Totem Pole Output
- Undervoltage Lockout with Hysteresis

## Safety/Protection Features

- Overvoltage Protection Facility Against Open Loop
- Protection Against Short Circuit on Oscillator Pin
- Fully Programmable Foldback
- Soft-Start Feature
- Accurate Maximum Duty Cycle Setting
- Demagnetization (Zero Current Detection) Protection
- Internally Trimmed Reference

## GreenLine ${ }^{T \mathrm{M}}$ Controller $^{\mathrm{TM}}$

- Low Start-Up and Operating Current
- Pulsed Mode Standby for Low Standby Losses
- Low dV/dT for Low EMI

| Pin | Name | Pin Description |
| :---: | :---: | :---: |
| 1 | $\mathrm{V}_{\mathrm{CC}}$ | This pin is the positive supply of the IC. |
| 2 | $\mathrm{V}_{\mathrm{C}}$ | The output high state, $\mathrm{V}_{\mathrm{OH}}$, is set by the voltage applied to this pin. With a separate connection to the power source, it gives the possibility to set by means of an external resistor the output source current at a different value than the sink current. |
| 3 | Output | The output current capability is suited for driving a power MOSFET. A Bipolar transistor can also be driven for low power applications. The maximum on-time of the duty cycle can last up to $80 \%$ of the switching period. |
| 4 | Gnd | The ground pin is a single return typically connected back to the power source, it is used as control and power ground. |
| 5 | Foldback Input | The foldback function ensures an overload protection. Feeding the foldback input with a portion of the $\mathrm{V}_{\mathrm{CC}}$ voltage ( 1 V max) establishes on the system control loop a foldback characteristic allowing a smoother start-up and a sharper overload protection. The foldback action performs an active current sense clamping reduction. Above 1 V the foldback input is no more active. |
| 6 | Overvoltage Protection | When the overvoltage protection pin receives a voltage greater than 17 V the device gets disabled and requires a complete restart sequence. The overvoltage level is programmable. |
| 7 | Current Sense Input | A voltage proportional to the current flowing into the power switch is connected to this input. The PWM latch uses this information to terminate the conduction of the output buffer when operating in current mode. A maximum level of 1 V allows to limit the inductor current either in current or voltage mode of operation. |
| 8 | Demagnetization Detection | A voltage delivered by an auxiliary transformer winding provides to the demagnetization pin an indication of the magnetization state of the flyback energy reservoir. A zero voltage detection corresponds to a complete core demagnetization. The demagnetization detection ensures a discontinuous mode of operation. This function can be inhibited by connecting Pin 8 to GND. |
| 9 | Standby Current Set | Using an external resistor connected to this pin, the standby burst mode peak current can be adjusted. |
| 10 | $\mathrm{C}_{\mathrm{T}}$ | The normal mode oscillator frequency is programmed by the capacitor $\mathrm{C}_{\boldsymbol{T}}$ choice together with the $\mathrm{R}_{\mathrm{ref}}$ resistance value. $\mathrm{C}_{\mathrm{T}}$, connected between pin 10 and GND, generates the oscillator sawtooth. |
| 11 | Soft-Start/D ${ }_{\text {max }} /$ Voltage-Mode | A capacitor or a resistor or a voltage source connected to this pin can temporary or permanently control the effective switching duty-cycle. This pin can be used as a voltage mode control input. By connecting pin 11 to Ground, the MC44604 can be shut down. |
| 12 | Clamp Error Amplifier Input | In normal mode, the current drawn from this pin, is used by the Error Amplifier to perform the regulation. A 4.7 V zener diode clamps the voltage of this pin. |
| 13 | E/A Out | The error amplifier output is made available for loop compensation. |
| 14 | Voltage Feedback | This is the inverting input of the Error Amplifier. It uses a voltage that is built up using the current drawn from the pin 12. |
| 15 | Standby Management | This block is designed to detect the standby mode. It particularly determines if the circuit must work in standby or in normal mode at each start-up. For that, it uses an information given by an external arrangement consisting of an opto-coupler. In standby mode, this block makes the circuit work in the standby configuration, and the current injected in the pin 15 is used to perform the regulation. In normal mode, this pin is internally connected to the pin 12. |
| 16 | $\mathrm{R}_{\text {REF }}$ | The $R_{\text {REF }}$ values fixes the internal reference current which is used to perform the precise oscillator waveform. The current range goes from $100 \mu \mathrm{~A}$ up to $500 \mu \mathrm{~A}$. |

Figure 27. Demagnetization

## Error Amplifier

A fully compensated Error Amplifier with access to the inverting input and output is provided. It features a typical DC voltage gain of 70 dB . The non-inverting input is internally biased at 2.5 V and is not pinned out. The converter output voltage is typically divided down and monitored by the inverting input. The maximum input bias current with the inverting input at 2.5 V is $-2.0 \mu \mathrm{~A}$. This can cause an output voltage error that is equal to the product of the input bias current and the equivalent input divider source resistance.

The Error Amp Output (Pin 13) is provided for external loop compensation. The output voltage is offset by two diodes drops ( $\approx 1.4 \mathrm{~V}$ ) and divided by three before it connects to the inverting input of the Current Sense Comparator. This guarantees that no drive pulses appear at the Source Output (Pin 3) when Pin 13 is at its lowest state $\left(\mathrm{V}_{\mathrm{OL}}\right)$. This occurs when the power supply is operating and the load is removed, or at the beginning of a soft-start interval. The Error Amp minimum feedback resistance is limited by the amplifier's minimum source current $(0.2 \mathrm{~mA})$ and the required output voltage $\left(\mathrm{VOH}_{\mathrm{OH}}\right)$ to reach the current sense comparator's 1.0 V clamp level:

$$
\mathrm{R}_{\mathrm{f}(\text { min })} \approx \frac{3 \cdot 0(1.0 \mathrm{~V})+1.4 \mathrm{~V}}{0.2 \mathrm{~mA}}=22 \mathrm{k} \Omega
$$

Figure 28. Error Amplifier Compensation

In a preferred embodiment, the feedback signal (current) is drawn from the pin 12 that is connected to the pin 15 in normal mode (Note 1). Using a resistor connected on pin 12, this current generates a voltage that is the input signal of the error amplifier arrangement.

Note 1. The error amplifier is not used in the standby mode regulation.

## Current Sense Comparator and PWM Latch

The MC44604 can operate as a current mode controller and/or as a voltage mode controller. In current mode operation, the MC44604 uses the current sense comparator, where the output switch conduction is initiated by the oscillator and terminated when the peak inductor current reaches the threshold level established by the Error Amplifier output (Pin 13). Thus the error signal controls the peak inductor current on a cycle-by-cycle basis. The Current Sense Comparator PWM Latch configuration used ensures that only a single pulse appears at the Source Output during the appropriate oscillator cycle.

The inductor current is converted to a voltage by inserting the ground referenced sense resistor $\mathrm{R}_{\mathrm{S}}$ in series with the power switch Q1.
In normal mode, this voltage is monitored by the Current Sense Input (Pin 7) and compared to a level derived from the Error Amp output. The peak inductor current under normal operating conditions is controlled by the voltage at Pin 13 where:

$$
I_{p k} \approx \frac{V_{(\text {pin13 })}-1.4 \mathrm{~V}}{3 R_{S}}
$$

The Current Sense Comparator threshold is internally clamped to 1.0 V . Therefore the maximum peak switch current is:

$$
I_{\mathrm{pk}(\max )} \approx \frac{1.0 \mathrm{~V}}{\mathrm{R}_{\mathrm{S}}}
$$

Figure 29. Output Totem Pole

## Oscillator

The oscillator is a very accurate sawtooth generator.

## The Sawtooth Generation

In the steady state, the oscillator voltage varies between about 1.6 V and 3.6 V .

Indeed, the sawtooth is obtained by charging and discharging an external capacitor $\mathrm{C}_{\mathrm{T}}$ (Pin 10), using two distinct current sources $=I_{\text {charge }}$ and $\mathrm{I}_{\text {discharge }}$. In fact, $\mathrm{C}_{\mathrm{T}}$ is permanently connected to the charging current source ( $0.4 \mathrm{I}_{\mathrm{ref}}$ ) and so, the discharge current source has to be higher than the charge one to be able to decrease the $\mathrm{C}_{\mathrm{T}}$ voltage. This condition is performed, its value being ( $2 \mathrm{I}_{\mathrm{ref}}$ ).

Two comparators are used to generate the sawtooth. They compare the $\mathrm{C}_{\mathrm{T}}$ voltage to the oscillator valley and peak values. The comparison to the low value enables to detect the end of the discharge phase while the comparison to the high value determines when the charge cycle must be stopped. A latch ( $\mathrm{L}_{\mathrm{DISCH}}$ ) memorizes the oscillator state.

Figure 30. Oscillator
Now, in addition to the charge and discharge cycles, a third state can exist. This phase can be produced when at the end of the discharge phase, the oscillator has to wait for a demagnetization pulse before re-starting. During this delay, the $\mathrm{C}_{\mathrm{T}}$ voltage must remain equal to the oscillator valley value ( $\sim 1.6 \mathrm{~V}$ ). So, a third regulated current source $\mathrm{I}_{\text {REGUL }}$ controlled by $\mathrm{C}_{\text {OSC REGUL }}$, is connected to $\mathrm{C}_{\mathrm{T}}$ in
order to perfectly compensate the ( $0.4 \mathrm{I}_{\mathrm{ref}}$ ) current source that permanently supplies $\mathrm{C}_{\mathrm{T}}$.

On-time is only allowed during the oscillator capacitor charge. So, the maximum duty cycle is $80 \%$. (Note 1 )

The demagnetization condition is taken into account by a second latch ( $\mathrm{L}_{\mathrm{osc}}$ ). (Refer to demagnetization $\S$ for further details.)

## Oscillator Frequency

The oscillator frequency can be deducted using the following equations:

$$
\begin{aligned}
\mathrm{T}_{\text {charge }} & =\mathrm{C}_{\mathrm{T}} \cdot \Delta \mathrm{~V} / \mathrm{I}_{\text {charge }} \\
\mathrm{T}_{\text {discharge }} & =\mathrm{C}_{\mathrm{T}} \cdot \Delta \mathrm{~V} / \mathrm{I}_{\text {discharge }}
\end{aligned}
$$

where:
$\mathrm{T}_{\text {charge }}$ is the oscillator charge time
$\Delta \mathrm{V}$ is the oscillator peak to peak value
$\mathrm{I}_{\text {charge }}$ is the oscillator charge current
and
$\mathrm{T}_{\text {discharge }}$ is the oscillator discharge time
$\mathrm{I}_{\text {discharge }}$ is the oscillator discharge current So, as:
$\mathrm{f}_{\text {osc }}=1 /\left(\mathrm{T}_{\text {charge }}+\mathrm{T}_{\text {discharge }}\right)$ if the REGUL arrangement is not activated, the following equation can be obtained:

$$
\mathrm{f}_{\mathrm{osc}} \sim \frac{0.395}{\mathrm{R}_{\mathrm{ref}} \cdot \mathrm{C}_{\mathrm{T}}}
$$

## Demagnetization Block (Note 2)

To enable the output, the $\mathrm{L}_{\text {osc }}$ latch complementary output must be low. Now, this latch reset is activated by the $\mathrm{L}_{\text {DISCH }}$ output during the discharge phase. So, to restart, the $\mathrm{L}_{\text {osc }}$ has to be set (refer to Figure 30). To perform this, the demagnetization signal must be low.

In a fly-back, a good means to detect the demagnetization consists in using the $\mathrm{V}_{\mathrm{CC}}$ winding voltage. Indeed this voltage is:

- negative during the on-time,
- positive during the off-time,
- equal to zero for the dead-time with generally a ringing (refer to Figure 31).
That is why, the MC44604 demagnetization detection consists of a comparator that can compare the $\mathrm{V}_{\mathrm{CC}}$ winding voltage to a reference that is typically equal to 65 mV .

Note 1 . The output is disabled by the signal $\mathrm{V}_{\text {osc prot }}$ when $\mathrm{V}_{\mathrm{CT}}$ is lower than 1 V. (Refer to Figure 29 and Figure 30.)
Note 2. The demagnetization detection can be inhibited by connecting pin 8 to the ground.

Figure 31. Demagnetization Detection

A diode D has been incorporated to clamp the positive applied voltages while an active clamping system limits the negative voltages to typically -0.33 V . This negative clamp level is sufficient to avoid the substrate diode switching on.

In addition to the comparator, a latch system has been incorporated in order to keep the demagnetization block output level low as soon as a voltage lower than 65 mV is detected and as long as a new restart is produced (high level on the output) (refer to Figure 33). This process avoids that any ringing on the signal used on the pin 8 , disrupts the demagnetization detection. Finally, this method results in a very accurate demagnetization detection.

For a higher safety, the demagnetization block output is also directly connected to the output, disabling it during the demagnetization phase (refer to Figure 29).

Figure 33. $\mathrm{D}_{\text {max }}$ and Soft-Start Block Diagram

## Maximum Duty Cycle and Soft-Start Control

As explained in the paragraph "oscillator", the duty cycle cannot be more than $80 \%$. Now, using the $D_{\max }$ and soft-start control, this duty cycle can be limited to a lower value. Indeed as depicted in Figure 34, the pin 11 voltage is compared to the oscillator sawtooth, so that the MC44604 output should be disabled as soon as the pin 11 level becomes lower than the oscillator voltage (refer to Figure 27 and to Figure 25).

Figure 34. Maximum Duty Cycle Control
Now, using the internal current source $\left(0,4 \mathrm{I}_{\text {ref }}\right)$, the pin 11 voltage can easily be fixed by connecting a resistor to this pin.
If a capacitor is connected to pin 11 (without any resistor or in parallel to a resistor for instance), the pin 11 voltage increases from 0 to its maximum value progressively (refer to Figure 26).

Thus, the allowed maximum duty cycle grows for a delay depending on the capacitor value (and the resistor value when a resistor is connected).

So, this pin can be used to limit the duty cycle during the start-up phase and thus, to perform a soft-start.

Figure 32. Demagnetization Block

Figure 35. Different Possible Uses of Pin 11

In any case (particularly if no external component is connected to pin 11), an internal zener diode ( $\mathrm{D}_{\mathrm{Z}}$, refer to Figure 34) is able to clamp the pin 11 voltage to a value $V_{Z}$ that is higher than the oscillator value and so, that results in no max duty cycle limitation.

As soon as $\mathrm{V}_{\text {disable1 }}$ is detected, a signal UVLO1 is generated until the $\mathrm{V}_{\mathrm{CC}}$ voltage falls down to $\mathrm{V}_{\text {disable2 }}$ (refer to the undervoltage lockout section paragraph). During the delay between the disable 1 and the disable 2, using a transistor controlled by UVLO1, the pin 11 voltage is made equal to zero in order to make the max duty cycle and soft-start arrangement ready to work for the next restart.

In standby mode, this block is inhibited in order not to interfere with the Standby Current Set.

## Protection

The MC44604 can ensure a high converter reliability thanks to the protection it offers.

## Demagnetization Detection (Refer to Demag §) <br> Foldback

As depicted in Figure 28, the foldback input (pin 5) enables to reduce the maximum $\mathrm{V}_{\mathrm{CS}}$ value that would be equal to 1 typically, if there was no foldback action. Finally, the foldback arrangement is a programmable peak current limitation.

Figure 36. Foldback Characteristic
It could be used as a soft-start (by connecting to pin 5, a gradually increasing voltage) but in fact, it has been designed to provide the system with an effective overload protection.

Indeed, as the output load gradually increases, the required converter peak current becomes higher and so,
$\mathrm{V}_{\mathrm{CS}}$ grows up till it reaches its maximum value (normally, $\mathrm{V}_{\mathrm{CS} \max }=1 \mathrm{~V}$ ).

Then if the output load keeps on increasing, the system is not able to supply enough energy to maintain the output regulation. Consequently, the decreasing output can be used to apply a voltage that diminishes to a value lower than 1 V , to pin 5, in order to limit the maximum peak current. In this way, the well known foldback characteristic is obtained (refer to Figure 36).

The foldback action can be inhibited by connecting the pin 5 to $\mathrm{V}_{\mathrm{CC}}$.

## Overvoltage Protection

The overvoltage arrangement consists of a comparator that compares the pin 6 voltage to $\mathrm{V}_{\text {ref }}(2,5 \mathrm{~V})$ (refer to Figure 37).

Figure 37. Overvoltage Protection
If no external component is connected to pin 6 , the comparator non inverting input voltage is nearly equal to:

$$
\left(\frac{2 \mathrm{k} \Omega}{11,6 \mathrm{k} \Omega+2 \mathrm{k} \Omega}\right) \cdot \mathrm{V}_{\mathrm{CC}}
$$

So, the comparator output is high when:

$$
\begin{gathered}
\left(\frac{2 \mathrm{k} \Omega}{11,6 \mathrm{k} \Omega+2 \mathrm{k} \Omega}\right) \cdot \mathrm{V}_{\mathrm{CC}} \geq 2,5 \mathrm{~V} \\
\mathrm{~V}_{\mathrm{CC}} \geq 17 \mathrm{~V}
\end{gathered}
$$

A delay latch $(2 \mu \mathrm{~s})$ is incorporated in order to only take into account the overvoltages that last at least $2 \mu \mathrm{~s}$.
If this condition is achieved, $\mathrm{V}_{\text {OVPout }}$ the delay latch output becomes high and as this level is brought back to the input through an OR gate, V OVPout remains high (and so, the IC output is disabled) until $\mathrm{V}_{\text {ref }}$ is disabled.
Consequently when an overvoltage longer than $2 \mu \mathrm{~s}$ is detected, the output is disabled until a new circuit restart.

The $\mathrm{V}_{\mathrm{CC}}$ is connected when once the circuit has started-up in order to limit the circuit start-up consumption ( T is switched on when once $\mathrm{V}_{\text {ref }}$ has been generated).

The overvoltage section is enabled $5 \mu$ s after the regulator has started to allow the reference $\mathrm{V}_{\text {ref }}$ to stabilize.

By connecting external resistors to pin 6, the threshold $\mathrm{V}_{\mathrm{CC}}$ level can be changed.

Figure 38. $\mathrm{V}_{\mathrm{Cc}}$ Management

## Undervoltage Lockout Section

As depicted in Figure 39, an undervoltage lockout has been incorporated to guarantee that the IC is fully functional before allowing operation of the system.

Indeed, the $\mathrm{V}_{\mathrm{CC}}$ is connected to the non inverting input of a comparator that has an upper threshold equal to $14,5 \mathrm{~V}$ ( $\mathrm{V}_{\text {stup-th }}$ ) and a lower one equal to $7.5 \mathrm{~V}\left(\mathrm{~V}_{\text {disable2 }}\right)$ in normal mode and 14.5 V and 12.5 V in Standby mode (typical values) (Note 1).

This hysteresis comparator enables or disables the reference block that generates the voltage and current sources required by the system.

This block particularly, produces $\mathrm{V}_{\text {ref }}$ (pin 16 voltage) and $I_{r e f}$ that is determined by the resistor $R_{\text {ref }}$ connected between pin 16 and the ground:

$$
I_{\text {ref }}=\frac{V_{\text {ref }}}{R_{\text {ref }}} \text { where } V_{\text {ref }}=2.5 \mathrm{~V} \text { (typically) }
$$

In addition to this, $\mathrm{V}_{\mathrm{CC}}$ is compared to a second threshold level that is nearly equal to $9 \mathrm{~V}\left(\mathrm{~V}_{\text {disable1 }}\right)$ so that in normal mode, a signal UVLO1 is generated to reset the maximum duty cycle and soft-start block and so, to disable the output stage (refer to Max. Duty Cycle and Soft-Start §) as soon as $\mathrm{V}_{\mathrm{CC}}$ becomes lower than $\mathrm{V}_{\text {disable1 }}$. In this way, the circuit is reset and made ready for a next start-up, before the reference block is disabled (refer to Figure 26). In standby, UVLO1 is not active (there is no need to discharge the soft-start capacitor as the soft-start pin is maintained short circuited).
Note 1. In standby the difference between $\mathrm{V}_{\text {disable2 }}$ and $\mathrm{V}_{\text {stup-th }}$ is decreased not to have too low pulsed mode frequencies.

Thus, finally in normal mode, the upper $\mathrm{V}_{\mathrm{cc}}$ limit that enables the output to be active, is 9.4 V (maximum value of $\mathrm{V}_{\text {disable1 }}$ ) and so the minimum hysteresis is 4.2 V . $\left[\left(\mathrm{V}_{\text {stup-th }}\right)_{\min }=13.6 \mathrm{~V}\right]$.
The large hysteresis and the low start-up current of the MC44604 make it ideally suited for off-line converter applications where efficient bootstrap start-up techniques are required.

## Standby Management

The MC44604 has been designed to detect the transitions between the standby and normal mode and to manage each mode in an optimal way.

In standby, the device monitors a pulsed mode that enables to drastically reduce the power consumption.

## Pulsed Mode

The MC44604 standby is preferably associated to a flyback configuration as depicted in Figure 39.

Figure 39. Standby Flyback Configuration

In effect, by this means, all the output regulation levels are divided by the ratio:

where $\mathrm{V}_{\mathrm{HV}}$ is the normal mode high voltage regulation level, $\mathrm{V}_{\text {stby }}$ is the standby $\mu \mathrm{P}$ supply voltage.

For instance, in the case of TV or monitors applications, the output levels (except the $\mu \mathrm{P}$ supply voltage, $\mathrm{V}_{\text {stby }}$ ) are drastically reduced by a ratio in the range of 10 .

Consequently, as the output voltages are reduced, the losses due to the output leakage consumption, are practically eliminated, without having to disconnect the loads.

## Start-up Operations

The choice of the right configuration (normal or standby) is performed at each start-up.

That is why, as explained in the transitions $\S$, at each change of mode, the MC44604 is first turned off so that a new start-up should be performed.

Figure 40. Start-up Operation
At each start-up, the circuit detects if it must work in standby or in normal mode configuration.

To do that, the circuit compares the current $\mathrm{I}_{\mathrm{pin} 15}$ to $\mathrm{I}_{\text {det }}$ so that, if:

- $\mathrm{I}_{\mathrm{pin} 15}>\mathrm{I}_{\text {det }}:$ Standby mode
- $\mathrm{I}_{\mathrm{pin} 15}<\mathrm{I}_{\text {det }}$ : Normal mode

According to the detected mode, the circuit configuration is set (refer to Figure 40).

This detection phase takes place during the first $5 \mu \mathrm{~s}$ of circuit operation in order to have the internal signals well stabilized before the decision is taken.

Figure 41. Standby Pin 15 Arrangement

## Standby Management

The standby operation consists of two main phases:

- the off phase during which the MC44604 is off. During this sequence, the circuit $\mathrm{V}_{\mathrm{cc}}$ is being charged and no energy is transferred to the output.
- the active phase during which the MC44604 is on. At this moment, some power can be drawn from the mains.
During the active phase, the power conversion is controlled so that:
- the normal mode regulation means (error amplifier) and the soft-start are inhibited
- the $\mathrm{V}_{\mathrm{cc}}$ undervoltage lockout $\left(\mathrm{V}_{\text {disable2 }}\right)$ level is increased from 9 V up to 12.5 V . This limitation of the $\mathrm{V}_{\mathrm{cc}}$ hysteresis enables to increase the pulsed mode frequency
- the peak inductor current is forced to be constant and equal to the level programmable by the external resistor $\mathrm{R}_{\text {Ipmax }}$ connected to the pin 9 so that:

$$
I_{\mathrm{pmax}}=\frac{0,4 \times I_{\mathrm{ref}} \times \mathrm{R}_{\text {lpmax }}}{2,6 \times \mathrm{R}_{\mathrm{S}}}
$$

where: $I_{p m a x}$ is the standby inductor peak current, $R_{S}$ is the current sense resistor.

- when the pin 15 current gets higher than the threshold $\mathrm{I}_{\mathrm{reg}}\left(20.5 \times \mathrm{I}_{\mathrm{ref}}\right)$, this operating mode stops and the circuit output is latched off.
So, in fact, the active phase is split into two distinct sequences and finally three phases can be defined (refer to Figure 32):
- the off phase: the MC44604 is off and the $\mathrm{V}_{\text {cc }}$ capacitor is being charged. When the $\mathrm{V}_{\mathrm{cc}}$ gets higher than $V_{\text {stup-th }}$, the circuit turns on and the switching sequence starts
- the switching phase: the circuit is on and forces a constant peak inductor current. This sequence lasts until $\mathrm{I}_{\mathrm{pin} 15}$ gets higher than $\mathrm{I}_{\text {reg }}$
- the latched phase: the circuit is on but the output is disabled. This sequence lasts until the standby $\mathrm{V}_{\mathrm{cc}}$ undervoltage lockout voltage ( 12.5 V ) is reached. A new off phase is then initialized.

Figure 42. Standby Regulation
As a consequence, $\mathrm{V}_{\text {stby }}$ varies between a peak value (obtained at the end of the switching phase) and a valley level (reached at the end of the off phase).

The level of the peak value is controlled by forcing a current higher than $I_{\text {reg }}$ in pin 15 when this level has reached the desired value.

The arrangement in Figure 41 allows to obtain this operation. A zener diode Z is connected so that a current limited by $R_{\text {reg }}$, is drawn by this device, when the $\mu \mathrm{P}$ supply voltage gets higher than $\mathrm{V}_{\mathrm{Z}}$. By this way, the current injected in the pin 15 increases and when this current is detected as higher than $\mathrm{I}_{\text {reg }}$, the output gets disabled until the next start-up (Note 1).

Practically, the pin 15 current can be expressed as follows (when the zener is activated):

$$
\mathrm{I}_{\text {pin15 }}=\mathrm{CTR} \times \frac{\mathrm{V}_{\text {stby }}-\mathrm{V}_{\text {opto }}-\mathrm{V}_{\mathrm{z}}}{R_{\text {reg }}}
$$

where: CTR is the opto coupler gain, $\mathrm{V}_{\text {opto }}$ is opto coupler voltage drop.
So, as the Vstby peak value is obtained when $\left(\mathrm{I}_{\mathrm{pin} 15}=\right.$ $\mathrm{I}_{\text {reg }}$ ), it can be calculated using the following equation:

$$
V_{\text {stby pk }}=V_{z}+V_{\text {opto }}+\frac{R_{\text {reg }} \times I_{\text {reg }}}{\text { CTR }}
$$

Practically, $\mathrm{R}_{\text {reg }}$ is chosen very low (in the range of $10 \Omega$ low resistance just to limit the current when $\mathrm{V}_{\text {stby }} \mathrm{pk}$ gets higher than $\mathrm{V}_{\mathrm{Z}}$ ):

$$
V_{\text {stby pk }} \cong V_{z}+V_{\text {opto }}
$$

Note 1. If the pin 15 current is higher than $\mathrm{I}_{\text {reg }}$ at start-up, the output is just shutdown but not latched. The circuit must
detect a sequence during which $\mathrm{I}_{\mathrm{pin} 15}$ lower than $\mathrm{I}_{\text {reg }}$ before being able to latch gets higher than $\mathrm{V}_{\mathrm{z}}$ ).

## Transitions Between Normal Mode and Standby Mode

 (Refer to Figure 43)The MC44604 detects a transition by comparing the pin 15 current to:

- $\mathrm{I}_{\text {det }}$ (transition standby to normal mode)
- $\mathrm{I}_{\text {init }}$ (transition normal mode to standby)

Each transition detection results in the circuit turning off, so that the device can work in the new mode after the following restart.

## - transition normal mode to standby:

This transition is detected by comparing the $\mathrm{I}_{\mathrm{pin} 15}$ current to the threshold current ( $\mathrm{I}_{\mathrm{init}}$ ).
$\mathrm{I}_{\text {init }}$ is high enough so that the opto coupler current used for the regulation, never exceeds this value.

The arrangement in Figure 41 is well adapted to this mode of operation. The $\mu \mathrm{P}$ initializes the standby mode by turning on the switch T . This results in the C capacitor charge that produces a peak current in the primary side of the opto coupler. C and $\mathrm{R}_{\text {init }}$ must be dimensioned so that the opto coupler primary side generates a pin 15 current higher than $\mathrm{I}_{\text {init }}$ during more than $1 \mu \mathrm{~s}$.

## - transition standby to normal mode:

If the circuit detects that ( $\mathrm{I}_{\mathrm{pin} 15}<\mathrm{I}_{\mathrm{det}}$ ) during standby operation, the circuit is turned off. So, if the normal mode is maintained at the following start-up, the circuit will re-start in a normal mode configuration.

The arrangement in Figure 41 allows to perform this detection. When the $\mu \mathrm{P}$ detects the end of the standby, it turns off the switch T and the opto coupler stops supplying current to the circuit.

The transition stand-by to normal mode occurs while the circuit is off ( $\mathrm{V}_{\mathrm{CC}}$ charge phase)

The transition stand-by to normal mode occurs while the circuit is on (working phase)

Figure 43. Transitions Between Modes

Application Schematic

## MC44605

## High Safety, Latched Mode, GreenLine ${ }^{\text {TM }}$ PWM Controller for (Multi)Synchronized Applications

The MC44605 is a high performance current mode controller that is specifically designed for off-line converters. This circuit has several distinguishing features that make it particularly suitable for multisynchronized monitor applications.

The MC44605 synchronization arrangement enables operation from 16 kHz up to 130 kHz . This product was optimized to operate with universal mains voltage, i.e., from 80 V to 280 V , and its high current totem pole output makes it ideally suited for driving a power MOSFET.

The MC44605 protections enable a well-controlled and safe power management. Four major faults while detected, activate the analogic counter of a disabling block designed to perform a latched circuit output inhibition.

## Current Mode Controller

- Current Mode Operation up to 250 kHz Output Switching Frequency
- Inherent Feed Forward Compensation
- Latching PWM for Cycle-by-Cycle Current Limiting
- Oscillator with Precise Frequency Control
- Externally Programmable Reference Current
- Secondary or Primary Sensing (Availability of Error Amplifier Output)
- Synchronization Facility
- High Current Totem Pole Output
- $\mathrm{V}_{\mathrm{cc}}$ Undervoltage Lockout with Hysteresis
- Low Output dV/dT for Low EMI Radiations
- Low Start-Up and Operating Current

## Safety/Protection Features

- Soft-Start Feature
- Demagnetization (Zero Current Detection) Protection
- Overvoltage Protection Facility against Open Loop
- EHT Overvoltage Protection (E.H.T.OVP): Detection of too High Synchronization Pulses
- Winding Short Circuit Detection (W.S.C.D.)
- Limitation of the Maximum Input Power (M.P.L.): Calculation of Input Power for Overload Protection
- Overheating Detection (O.H.D.): to Prevent the Power Switch from an Excessive Heating
Latched Disabling Mode
- When one of the following faults is detected: EHT overvoltage, Winding Short Circuit (WSCD), a too high input power (M.P.L.), power switch overheating (O.H.D.), an analogic counter is activated
- If the counter is activated for a time that is long enough, the circuit gets definitively disabled. The latch can only be reset by making decrease the $\mathrm{V}_{\mathrm{cc}}$ down to about 3 V , i.e., practically by unplugging or turning off the SMPS.

*Refer to Note 1.
**This consumption is measured while the circuit is inhibited by the Definitive Latch.

1. Adjust $\mathrm{V}_{\mathrm{CC}}$ above the start-up threshold before setting to 12 V . Low duty cycle pulse techniques are used during test to maintain junction temperature as close to ambient as possible.
2. This function can be inhibited by connecting pin 9 to GND. In this case, the synchronization block is inhibited too and the MC44605 works in free mode.

| Pin | Name | Pin Description |
| :---: | :---: | :---: |
| 1 | $\mathrm{V}_{\mathrm{CC}}$ | This pin is the positive supply of the IC. |
| 2 | $\mathrm{V}_{\mathrm{C}}$ | The output high state, $\mathrm{V}_{\mathrm{OH}}$, is set by the voltage applied to this pin. With a separate connection to the power source, it gives the possibility to set by means of an external resistor the output source current at a different value than the sink current. |
| 3 | Output | The output current capability is suited for driving a power MOSFET. |
| 4 | GND | The ground pin is a single return typically connected back to the power source. It is used as control and power ground. |
| 5 | Maximum Power Limitation | This block enables to estimate the input power. When this calculated power is detected as too high, a fault information is sent to the disabling block in order to definitively disable the circuit. |
| 6 | Over-Heating Detection | This block estimates the MOSFET heating. When this calculated heating is too high, the device gets definitively disabled (disabling block action). |
| 7 | Current Sense Input | A voltage proportional to the current flowing into the power switch is connected to this input. The PWM latch uses this information to terminate the conduction of the output buffer. A maximum level of 1 V allows to limit the inductor current. |
| 8 | Demagnetization Detection | A voltage delivered by an auxiliary transformer winding provides to the demagnetization pin an indication of the magnetization state of the flyback energy reservoir. A zero voltage detection corresponds to a complete core demagnetization. The demagnetization detection prevents the oscillator from a re-start and so the circuit from a new conduction phase, if the fly-back is not in a dead-time state. This function can be inhibited by connecting Pin 8 to GND but in this case, there is a minimum off-time typically equal to $3 \mu \mathrm{~s}$. |
| 9 | Synchronization and E.H.T.OVP Input | Activating the synchronization input pin with a pulse higher or equal to the negative threshold (typically -200 mV ) allows the next switching period to be reinitialized. The oscillator is free when connecting Pin 9 to GND. When the E.H.T.OVP pin receives a voltage that is greater than 7.5 V , the disabling block $\mathrm{C}_{\text {ext }}$ capacitor is charged so that the circuit gets definitively disabled if the $\mathrm{C}_{\text {ext }}$ voltage becomes higher than $\mathrm{V}_{\text {ref }}$. This block is incorporated to detect and disable the device when the synchronization pulses are too high. |
| 10 | Oscillator Capacitor $\mathrm{C}_{\boldsymbol{T}}$ | The free mode oscillator frequency is programmed by the capacitor $\mathrm{C}_{\mathrm{T}}$ choice together with the $\mathrm{R}_{\text {ref }}$ resistance value. $\mathrm{C}_{\mathrm{T}}$, connected between pin 10 and GND, generates the oscillator sawtooth. |
| 11 | Soft-Start | A capacitor connected to this pin can temporary reduce the maximum inductor peak current. By this way, a soft-start can be performed. By connecting pin 11 to Ground, the MC44605 is shut down. |
| 12 | $\mathrm{C}_{\text {ext }}$ (Disabling Block) | When a too high synchronization pulse voltage (E.H.T.OVP) or a winding short circuit (WSCD) is detected, the capacitor $\mathrm{C}_{\text {ext }}$ is charged using a current source $\mathrm{I}_{\text {Dis- }}$. In the case of a MPL or OHD fault detection, $\mathrm{C}_{\text {ext }}$ is charged using $\mathrm{I}_{\text {Dis-L. }}$. If the $\mathrm{C}_{\text {ext }}$ capacitor voltage gets higher than $\mathrm{V}_{\text {ref }}$, the circuit is definitively disabled. Then, to restart, the converter must be switched off in order to make $\mathrm{V}_{\mathrm{CC}}$ decrease down to about 0 V . |
| 13 | E/A Output | The error amplifier output is made available for loop compensation. |
| 14 | Voltage Feedback | This is the inverting input of the Error Amplifier. It can be connected to the Switching Mode Power Supply output through an optical (or else) feedback loop or to the subdivided $\mathrm{V}_{\mathrm{CC}}$ voltage in case of primary sensing technic. |
| 15 | Winding Short Circuit Detection Programmation | The W.S.C.D. block is incorporated to detect the transformer Winding Short Circuits. This function is performed by detecting the inductor overcurrents thanks to a comparator which threshold is programmable to be well adapted to any application. |
| 16 | $\mathrm{R}_{\text {ref }}$ | The $\mathrm{R}_{\text {ref }}$ value fixes the internal reference current that is particularly used to perform the precise oscillator waveform. The current range goes from 100 $\mu \mathrm{A}$ up to $500 \mu \mathrm{~A}$. |

## MC44605

## Summary of the Main Design Equations

The following table consists of equations enabling to dimension a multisynchronized SMPS operating in discontinuous mode.

| $\operatorname{Pin}_{\max }=\frac{\text { Pout }_{\max }}{\eta}$ | Pout $_{\text {max }}$ is the maximum power the load may draw in normal working. <br> The maximum input power $\mathrm{Pin}_{\text {max }}$ is easily deducted by dividing Pout ${ }_{\text {max }}$ by the efficiency $(\eta)$. In this kind of application, the efficiency is generally taken equal to $80 \%$. |
| :---: | :---: |
| $\mathrm{Lp}_{\max }=\frac{\left[\frac{\sqrt{2} \cdot \mathrm{Vac}_{\text {min }} \times \mathrm{NVo}}{\sqrt{2} \cdot \mathrm{Vac}_{\text {min }}+\mathrm{NVo}}\right]^{2}}{2 \times \mathrm{Pin}_{\max } \times \mathrm{fsync}_{\max }}$ | The inductor value Lp must be chosen lower than $\mathrm{Lp} \mathrm{p}_{\max }$ or ideally equal to this value (to optimize the application design-in). <br> In effect, if $L p$ was higher than $L p_{\text {max }}$, a synchronized and discontinuous working could not be guaranteed (in some cases, the demagnetization phase would not be finished while a new conduction phase should start to follow the synchronization). |
|  | $\mathrm{Ipk}_{\text {max }}$ is the maximum inductor peak current. This current is obtained when the power to transfer is maximum at the minimum synchronization frequency ( 60 W output, 30 kHz in the proposed application). |
| $\mathrm{d}_{\text {max }}=\frac{\sqrt{\mathrm{Pin}_{\text {max }} \times \mathrm{Lp} \times \text { fsync }_{\text {max }}}}{\mathrm{Vac}_{\text {min }}}$ | $d_{\text {max }}$ is the maximum duty cycle. The duty cycle is maximum at the lowest input voltage when the power demand is maximum while the synchronization frequency also is maximum. |
| $\mathrm{Pon}_{\text {max }}=\frac{1}{3} \times \mathrm{Rds}_{\text {on }} \times \mathrm{lpk}_{\text {max }}{ }^{2} \times \mathrm{d}_{\text {max }}$ | $\mathrm{Pon}_{\text {max }}$ is the maximum Mosfet on-time losses that are proportional to $\mathrm{Ipk}_{\text {max }}, \mathrm{d}_{\text {max }}$ and Rds ${ }_{\text {on }}$ (on-time Mosfet resistor). <br> This conduction losses estimation enables to dimension the power Mosfet. |
| $\left(\mathrm{V}_{\mathrm{DS}}\right) \max =\left(\sqrt{2} \times \mathrm{Vac}_{\text {max }}\right)+(\mathrm{N} \times$ Vout $)$ | $\left(V_{\mathrm{DS}}\right)$ max is the maximum voltage the power switch must be able to face. In fact, this calculation does not take into account the turnings off spikes. So, it is necessary to take a margin of at least about 50 V . |
| $\left(\mathrm{V}_{\mathrm{D}}\right) \max =\left(\sqrt{2} \times \frac{\mathrm{Vac}_{\text {max }}}{\mathrm{N}}\right)+$ Vout | $\left(\mathrm{V}_{\mathrm{D}}\right)$ max is the maximum voltage the high voltage secondary diode must be able to face. Because of the turning off spikes, a margin must also be taken. |
| (ni) $\max =\mathrm{N} \times \mathrm{n}_{\text {Vout }} \times \mathrm{Ipk}_{\max }$ | ( $\mathrm{A}_{\mathrm{L}}$ ) and (ni) are the magnetic parameters. <br> (ni) max must not exceed the ferrite (ni). Otherwise, the transformer may get saturated when the peak current is high. |
| $A_{L}=\frac{L_{P}}{\left(N \times n_{\text {Vout }}\right)^{2}}$ | $\left(A_{L}\right)$ is the ferrite constant that links the primary inductor value to the squared number of primary turns: $L p=A_{L} \times n_{p}{ }^{2}$. |

## Error Amplifier

A fully compensated Error Amplifier with access to the inverting input and output is provided. It features a typical DC voltage gain of 70 dB . The non inverting input is internally biased at 2.5 V and is not pinned out. The converter output voltage is typically divided down and monitored by the inverting input. The maximum input bias current with the inverting input at 2.5 V is $-2.0 \mu \mathrm{~A}$. This can cause an output voltage error that is equal to the product of the input bias current and the equivalent input divider source resistance.

Figure 1. Error Amplifier Compensation

The Error Amp Output (Pin 13) is provided for external loop compensation. The output voltage is offset by two diodes drops ( $\approx 1.4 \mathrm{~V}$ ) and divided by three before it connects to the inverting input of the Current Sense Comparator. This guarantees that no drive pulses appear at the Source Output (Pin 3) when Pin 13 is at its lowest state $\left(\mathrm{V}_{\mathrm{OL}}\right)$. This occurs when the power supply is operating and the load is removed, or at the beginning of a soft-start interval. The Error Amp minimum feedback resistance is limited by the amplifier's minimum source current ( 0.2 mA ) and the required output voltage $\left(\mathrm{V}_{\mathrm{OH}}\right)$ to reach the current sense comparator's 1.0 V clamp level:

$$
\mathrm{R} 1(\mathrm{~min})=\frac{(3 \times 1 \mathrm{~V})+1.4 \mathrm{~V}}{0.2 \mathrm{~mA}}=22 \mathrm{k} \Omega
$$

## Current Sense Comparator and PWM Latch

The MC44605 operates as a current mode controller. The circuit uses a current sense comparator to compare the inductor current to the threshold level established by the Error Amplifier output (Pin 13). When the current reaches the threshold, the current sense comparator terminates the output switch conduction that has been initiated by the oscillator, by resetting the PWM Latch. Thus the error signal controls the peak inductor current on a cycle-by-cycle basis. This configuration ensures that only one single pulse appears at the Source Output during the appropriate oscillator cycle.

Figure 2. Output Totem Pole
The inductor current is converted to a voltage by inserting the ground referenced sense resistor $\mathrm{R}_{\mathrm{S}}$ in series with the power switch Q1.

This voltage is monitored by the Current Sense Input (Pin 7) and compared to a level derived from the Error Amp output. The peak inductor current under normal operating conditions is controlled by the voltage at Pin 13 where:

$$
\mathrm{I}_{\mathrm{pk}} \approx \frac{\mathrm{~V}_{(\mathrm{pin} 13)}-1.4 \mathrm{~V}}{3 \times \mathrm{R}_{\mathrm{S}}}
$$

The Current Sense Comparator threshold is internally clamped to 1.0 V . Therefore the maximum peak switch current is:

$$
\mathrm{I}_{\mathrm{pk}(\max )}=\frac{1 \mathrm{~V}}{\mathrm{R}_{\mathrm{S}}}
$$

## Undervoltage Lockout Section

As depicted in Figure 3, an undervoltage lockout has been incorporated to guarantee that the IC is fully functional before allowing the system working.

In effect, the $\mathrm{V}_{\mathrm{CC}}$ is connected to the non inverting input of a comparator that has an upper threshold equal to $14,5 \mathrm{~V}$ (typical $\mathrm{V}_{\text {stup-th }}$ ) and a lower one equal to 7.5 V (typical $\mathrm{V}_{\text {disable 2). This }}$ hysteresis comparator enables or disables the reference block that generates the voltage and current sources required by the system.

This block particularly, produces $\mathrm{V}_{\text {ref }}$ (pin 16 voltage) and $\mathrm{I}_{\text {ref }}$ that is determined by the resistor $\mathrm{R}_{\text {ref }}$ connected between pin 16 and the ground:

$$
I_{\text {ref }}=\frac{V_{\text {ref }}}{R_{\text {ref }}} \text { where } V_{\text {ref }}=2.5 \mathrm{~V} \text { (typically) }
$$

Figure 3. $\mathrm{V}_{\mathrm{CC}}$ Management
In addition to this, $\mathrm{V}_{\mathrm{CC}}$ is compared to a second threshold level that is nearly equal to $9 \mathrm{~V}\left(\mathrm{~V}_{\text {disable1 }}\right)$ so that a signal UVLO1 is generated to reset the soft start block and so, to disable the output stage (refer to the Soft-Start §) as soon as $\mathrm{V}_{\mathrm{CC}}$ becomes lower than $\mathrm{V}_{\text {disable 1 }}$. In this way, the circuit is reset and made ready for a next start-up, before the reference block is disabled (refer to Figure 3). Thus, finally the upper limit for the minimum normal operating voltage
is 9.4 V (maximum value of $\mathrm{V}_{\text {disable 1 }}$ ) and so the minimum hysteresis is 4.2 V . $\left[\left(\mathrm{V}_{\text {stup-th }}\right)_{\min }=13.6 \mathrm{~V}\right]$.

The large hysteresis and the low start-up current of the MC44605 make it ideally suited for off-line converter applications where efficient bootstrap start-up techniques are required.

## Soft-Start Control Section

The $\mathrm{V}_{\mathrm{cs}}$ value is clamped down to the pin 11 voltage.
So, if a capacitor is connected to this pin, its voltage increases slowly at the start-up (the capacitor is charged by an internal current source $0.4 \mathrm{I}_{\text {ref }}$ ). So, $\mathrm{V}_{\text {cs }}$ is limited during the start-up and then a soft-start is performed.

This pin can be used to inhibit the circuit by applying a voltage that is lower than $\mathrm{V}_{\text {SSinhi }}$ (refer to page 4). Particularly, the MC44605 can be shutdown by connecting the soft-start pin to ground.

As soon as $\mathrm{V}_{\text {dis } 1}$ is detected (that is $\mathrm{V}_{\mathrm{cc}}$ lower than $\mathrm{V}_{\text {disable1 }}$ ), a signal UVLO1 is generated until the $\mathrm{V}_{\mathrm{cc}}$ falls down to $\mathrm{V}_{\mathrm{dis} 2}$ (refer to the undervoltage lockout section §). During the delay between the disable1 and the disable2, using a transistor controlled by UVLO1, the pin 11 voltage is made equal to zero in order to make the soft-start arrangement ready to work for the next re-start.

Figure 4. Soft-Start

## Oscillator Section (Figures 5 \& 5b)

The oscillator and synchronization behavior is represented in Figure 5b.

The MC44605 oscillator achieves four functions:

- it fixes the free mode frequency
- it takes into account the synchronization signal
- it does not allow a new power switch conduction if the flyback is not in a dead-time state when the circuit works in demagnetization mode (pin 8 connected)
- it builds the Sf pulse required by the MPL block

During the operating mode, the oscillator sawtooth can vary between a valley value ( 1.6 V typically) and a peak one (3.6 V typically) and presents three distinct phases:

- the $\mathrm{C}_{\mathrm{T}}$ charge
- the $\mathrm{C}_{\mathrm{T}}$ discharge
- the phase during which the oscillator voltage is maintained equal to its valley value. This happens at the end of a discharge cycle when the synchronization or demagnetization condition does not allow a new $\mathrm{C}_{\mathrm{T}}$ charge phase. During this sequence, $\mathrm{I}_{\text {REGUL }}$ compensates the charge current $\mathrm{I}_{\text {charge }}$.
The oscillator has two working modes:
- a free one when there is no synchronization
- a synchronized one.

In the free working, the oscillator grows up from its valley value to its peak one for the charge phase and when once the peak value is reached, a discharge sequence makes the $\mathrm{C}_{\mathrm{T}}$ voltage decrease down to its valley value. When the decrease phase is finished, a new charge cycle occurs if the demagnetization condition is achieved $\left(\mathrm{V}_{\mathrm{DT}}\right.$ high). Otherwise there is a REGUL phase until $\mathrm{V}_{\text {DT }}$ gets high.

In the synchronized mode, the charge cycle is only allowed when the synchronization signal gets high while a dead time has been detected ( $\mathrm{V}_{\mathrm{DT}}$ high). This charge phase is stopped when the synchronization signal has got low and when the oscillator voltage is higher than $\mathrm{V}_{\mathrm{int}}$, the intermediary voltage level used to generate the calibrated pulse Sf by comparing the $\mathrm{C}_{\mathrm{T}}$ voltage to this threshold. So, when these two conditions are performed, a discharge sequence is set until the oscillator voltage is equal to its valley value. Then, the $\mathrm{C}_{\mathrm{T}}$ voltage is maintained constant thanks to the "REGUL" arrangement until the next synchronization pulse.

In both cases, during the charge phase, a signal $\mathrm{V}_{\mathrm{S}}$ is generated. When Sf becomes high. $\mathrm{V}_{\mathrm{S}}$ gets high and remains in this state until the PWN latch is set of Sf is low. Then, $\mathrm{V}_{\mathrm{S}}$ keeps low until the next Sf high level. This oscillator behavior is obtained using the process described in Figure 5b.

$\square \mathrm{b}$-Synchronized mode

Figure 5b. Oscillator Behavior

In effect, the output of the latch L1 is:

- high during the oscillator capacitor charge and during the REGUL phase
- low for the oscillator capacitor discharge

Now, the latch L2 is set when the L1 output is high and the synchronization condition is performed (that is: sync $=1-$ free mode or synchro signal high state) and during the dead-time ( $\mathrm{V}_{\mathrm{DT}}$ high). So, this latch is set for the $\mathrm{C}_{\mathrm{T}}$ charge.

On the other hand, this latch is reset by the signal used to reset L1. Consequently, it is reset at the end of the charge phase.

So, in any case, $\mathrm{Q}_{\mathrm{L} 2}$ is:

- high during the $\mathrm{C}_{\mathrm{T}}$ charge cycle
- low in the other cases

Thus, this latch enables to obtain a signal that is high for the charge phase and low in the other cases, whatever the mode (synchronized or free) and whatever the synchronization pulses width (higher than the delay necessary for the oscillator to reach its intermediary value or lower than this delay) in the synchronized mode.

That is why:

- the discharge current source must be connected to the oscillator capacitor when $\mathrm{Q}_{\mathrm{L} 1}$ is low. The condition $\left(\mathrm{C}_{\mathrm{T}}\right.$ voltage higher than the valley value) is added to stop the discharge phase as soon as the oscillator voltage is detected as lower than the valley value (without any delay due to the L1 latch propagation time).
- the REGUL current source must be connected when:
- $\mathrm{Q}_{\mathrm{L} 1}$ is high (charge or REGUL phase)
- $\mathrm{Q}_{\mathrm{L} 2}$ is low (the oscillator is not in a charge phase)

On the other hand, the oscillator charge is stopped when:

- the oscillator voltage reaches the peak value in the free mode
- the oscillator voltage is higher than the intermediary value $\left(\mathrm{V}_{\mathrm{int}}\right)$ and the synchronization signal is negative, in the synchronized mode.
Consequently, in any case, $\mathrm{Q}_{\mathrm{L} 2}$ that is high during the oscillator charge phase, is high for the delay during which the oscillator voltage grows from the valley value up to the intermediary one. That is why the signal Sf (refer to the MPL block) that must be high when the oscillator voltage is between the valley value and the intermediary one during the charge phase ( $\mathrm{Q}_{\mathrm{L} 2}$ high), is obtained using an AND gate with the following inputs:
- $\mathrm{Q}_{\mathrm{L} 2}$ ( $\mathrm{Q}_{\mathrm{L} 2}$ high $\Leftrightarrow$ charge phase)
- Coscint (Coscint high $\Leftrightarrow$ the $\mathrm{C}_{\mathrm{T}}$ voltage is lower than the intermediary value).
So, using the output of this AND gate, Sf is obtained.
This signal Sf is connected to a logic block consisting of two AND gates and an OR one. This block aims at supplying a signal VS that:
- gets high as soon as Sf becomes high if the PWM latch output is low
- gets low as soon as the PWM latch is set and then remains low until the next cycle.

Figure 5. Oscillator

## Synchronization Section (Note 1)

The synchronization block consists of a protection arrangement similar to the demagnetization block one (a diode + a negative active clamping system (Note 2)). In addition to this, a high value resistor ( R - about $50 \mathrm{k} \Omega$ ) is incorporated as the pin 9 input is also used by the EHTOVP section.

The signal obtained at the output of this protection arrangement, is compared to a negative threshold ( -200 mV , typically) so that when the synchronization pulse applied to the pin 9 (through a resistor or a resistors divider to adapt this input to the EHTOVP function), is higher than this threshold, the system considers that the synchronization condition is performed (free mode or synchronization signal high level).
Note 1. The synchronization can be inhibited by connecting the pin 9 to the ground. By this means, a free mode is obtained.
Note 2. This negative active clamping system works even if the circuit is off. This feature is really useful as synchronization pulses may be applied while the product is off.

Figure 6. Synchronization

## Demagnetization Section

This block is incorporated to detect the complete core demagnetization in order to prevent the power MOSFET from switching on if the converter is not in a dead time phase. That is why this block inhibits any oscillator re-start as long as the inductor current is not finished (from the beginning of the on-time to the end of the demagnetization phase).

In a fly-back, a good means to detect the demagnetization phase consists in using the $\mathrm{V}_{\mathrm{CC}}$ winding voltage. In effect, this voltage is:

- negative during the on-time,
- positive during the off-time,
- equal to zero for the dead-time with generally a ringing (refer to Figure 7).

Figure 7. Demagnetization Detection

That is why, the MC44605 demagnetization detection consists of a comparator that compares the $\mathrm{V}_{\mathrm{CC}}$ winding voltage to a reference that is typically equal to 65 mV .

A diode D is incorporated to clamp the positive applied voltages while an active clamping system limit the negative voltages to typically -0.33 V . This negative clamp level is high enough to avoid the substrate diode switching on.

A latch system is incorporated to keep the demagnetization block output level low as soon as a voltage lower than 65 mV is detected and as long as a new restart is produced (high level on the output (refer to Figure 8). This process avoids that any ringing on the signal used on the pin 8, disrupts the demagnetization detection (refer to Figure 7). Finally, this method results in a very accurate demagnetization phase detection, and the signal $\mathrm{V}_{\mathrm{DT}}$ drawn from this block is high only for the dead time. Therefore, an oscillator re-start and so, a new power switch conduction is only allowed during the dead-time.

For a higher safety, the $V_{\text {demagout }}$ output of the demagnetization block is also directly connected to the output, to disable it during the demagnetization phase (refer to the block diagram).

The demagnetization detection can be inhibited by connecting pin 8 to the ground but in this case, a timer (about $3 \mu \mathrm{~s}$ ) that is incorporated to set the latch when it can not be set by $\mathrm{V}_{\text {demagout }}$, results in a minimum off-time (refer to Figure 8).

Figure 8. Demagnetization Block

## Overvoltage Protection Section

The overvoltage arrangement compares a portion $\mathrm{V}_{\mathrm{cc}}$ to $\mathrm{V}_{\text {ref }}(2,5 \mathrm{~V})$ (refer to Figure 9). In fact, this threshold corresponds to a $\mathrm{V}_{\mathrm{CC}}$ equal to to 17 V . When the $\mathrm{V}_{\mathrm{cc}}$ is higher than this level, the output is latched off until a new circuit re-start.

Figure 9. Overvoltage Protection

A delay $(2 \mu \mathrm{~s})$ is incorporated in order to avoid any activation due to interferences by only taking into account the overvoltages that last at least $2 \mu \mathrm{~s}$.

The $\mathrm{V}_{\mathrm{CC}}$ is connected when once the circuit has started-up in order to limit the circuit start-up consumption ( T is switched on when once $\mathrm{V}_{\text {ref }}$ has been generated).

The overvoltage section is enabled $5 \mu \mathrm{~s}$ after the regulator has started to allow the reference $\mathrm{V}_{\text {ref }}$ to stabilize.

## E.H.T. Overvoltage Protection Section

This block uses the synchronization input as this section is incorporated to detect too high synchronization pulses and then to activate the device definitive latch in this case.

Figure 10. E.H.T. OVP
This block consists of a high impedance resistors bridge ( R is nearly equal to $50 \mathrm{k} \Omega$ - refer to Figure 10) so that the EHTovp threshold is 7.5 V . So, using an external resistors bridge (r1, r2 $\ll \mathrm{R}$ ), the synchronization pulse level above which the working must be considered as wrong, can be adjusted.

For instance, if this threshold value is required to be equal to $30 \mathrm{~V}, \mathrm{~V}_{\text {pin9 }}$ must be equal to 7.5 V when the synchronization pulse value is 30 V .

So, in this case:

$$
30 \times \frac{r 2}{r 1+r 2}=7.5
$$

Then, the ratio ( $\mathrm{r} 1 / \mathrm{r} 2$ ) can be deducted:

$$
\frac{\mathrm{r} 1}{\mathrm{r} 2}=3
$$

So, as r 1 and r 2 must be negligible in relation to R (about $50 \mathrm{k} \Omega$ ), the couple of resistors can be chosen as follows:

$$
\mathrm{r} 1=3 \mathrm{k} \Omega
$$

and:

$$
\mathrm{r} 2=1 \mathrm{k} \Omega
$$

## Winding Short Circuit Detection Section (WSCD)

The MC44605 being designed to control a Fly-Back SMPS, this block is incorporated to detect a short circuit on a transformer winding or on an output diode (refer to Figure 11).

Figure 11. Winding Short Circuit Fault

In the case of a Winding Short Circuit, the primary inductor $L_{p}$ is short circuited and then the current increase is only controlled by the leakage inductor $\mathrm{L}_{\text {leak }}$.

In current mode, the power switch conduction is stopped when the inductor current is detected as high enough, by the controller. In fact, when the current sense resistor ( $\mathrm{R}_{\mathrm{s}}$ ) voltage gets equal to $\mathrm{V}_{\mathrm{cs}}$, the current sense comparator switches to reset the output.
Now, the circuit has a propagation delay and the power switch needs some time to turn off. Consequently, there is a delay $\delta$ t between the moment at which the $\mathrm{R}_{\mathrm{S}}$ voltage gets equal to $\mathrm{V}_{\mathrm{cs}}$ and the actual current increase stop. So, this results in an overcurrent (refer to Figure 12).

Figure 12. Overcurrent in a WSCD Case

Now, in normal working, this overcurrent $\Delta \mathrm{Ipk}$ is equal to:

$$
\Delta \mathrm{lpk}=\frac{\operatorname{Vin} \times \delta \mathrm{t}}{\mathrm{~L}_{\mathrm{P}}}
$$

where: $\mathrm{V}_{\mathrm{in}}$ is the input voltage (rectified a.c. line)
While in a WSCD case:

$$
(\Delta \mathrm{lpk})_{\mathrm{WSCD}}=\frac{\mathrm{Vin} \times \delta \mathrm{t}}{\mathrm{~L}_{\text {Leak }}}
$$

Consequently, as the leakage inductor value is generally much lower than the primary one (less than 5\% generally), the overcurrent is much higher in the WSCD case. That is why this fault can be detected by detecting the high overcurrents.

So, the WSCD block consists of comparing the sensed current to a reference equal to: $\left(\mathrm{V}_{\mathrm{cs}}+\mathrm{V}_{\text {shift }}\right)$, where $\mathrm{V}_{\text {shift }}$ is a voltage proportional to the current injected in the pin 15 (refer to Figure 13).

Figure 13. WSCD
Now, as the overcurrent level depends on the input voltage $\mathrm{V}_{\mathrm{in}}$, it is preferable to use a $\mathrm{V}_{\text {shift }}$ proportional to this input voltage instead of a constant $\mathrm{V}_{\text {shift }}$. So, the WSCD pin must be connected to $\mathrm{V}_{\text {in }}$ through a resistor that fixes $\mathrm{V}_{\text {shift }}$ by adjusting the current injected in this pin 15.

Finally, when there is a winding short circuit, an overcurrent is detected by the WSCD comparator. The output of this comparator, $\mathrm{V}_{\mathrm{WSCD}}$, is connected to the disabling block (refer to the disabling block §).

## Maximum Power Limitation Section (MPL)

The MPL block is designed to calculate this input power using the following equation:

$$
\operatorname{Pin}=\frac{1}{2} \times L_{P} \times \mathrm{lpk}^{2} \times \mathrm{f}
$$

where: Lp is the inductor value
Ipk is the inductor peak current
f is the switching frequency
As $\mathrm{V}_{\mathrm{cs}}$ is proportional to the inductor peak current ( $\mathrm{V}_{\mathrm{cs}}=\mathrm{R}_{\mathrm{s}} \mathrm{x}$ Ipk), the squared Ipk value is estimated by building a current source proportional to $\mathrm{V}_{\mathrm{cs}}{ }^{2}$. This current is chopped by a calibrated pulse Sf , generated at each new oscillator cycle (refer to Figure 14).
Finally, using an external resistor and capacitor network $\left(\mathrm{R}_{\mathrm{MPL}}, \mathrm{C}_{\mathrm{MPL}}\right)$ on the MPL pin, a voltage $\mathrm{V}_{\text {MPL }}$, proportional to the input power can be obtained.
In effect,

$$
V_{M P L}=R_{M P L} \times k_{M P L} \times V_{c s}{ }^{2} \times \frac{(\mathrm{Sf})}{\mathrm{T}}
$$

where: $\mathrm{k}_{\mathrm{MPL}}$ is the multiplier gain
$(\mathrm{Sf})$ is the width of the calibrated pulse
T is the switching (oscillator) period
Now, as Sf is built comparing the oscillator to a constant level, (Sf) is proportional to $\mathrm{R}_{\text {ref }}$ and $\mathrm{C}_{\mathrm{T}}$ :

$$
(\mathrm{Sf})=\mathrm{k} 1 \times \mathrm{R}_{\mathrm{ref}} \times \mathrm{C}_{\mathrm{T}}
$$

where: k 1 is a constant
On the other hand, $\mathrm{k}_{\mathrm{MPL}}$ that is depending on the reference current source $I_{\text {ref }}$, is proportional to $1 / R_{\text {ref }}$ :

$$
\mathrm{k}_{\mathrm{MPL}}=\mathrm{k} 2 \times \frac{1}{\mathrm{R}_{\mathrm{ref}}}
$$

where: k 2 is a constant
So:

$$
\mathrm{V}_{\mathrm{MPL}}=\mathrm{R}_{\mathrm{MPL}} \times \mathrm{k} 1 \times \mathrm{k} 2 \times \mathrm{Vcs}^{2} \times \mathrm{f} \times \mathrm{C}_{\mathrm{T}}
$$

where: $\mathrm{C}_{\mathrm{T}}$ is the oscillator capacitor
Finally:

$$
\mathrm{V}_{\mathrm{MPL}}=\mathrm{R}_{\mathrm{MPL}} \times \Gamma_{\mathrm{MPL}} \times \mathrm{Vcs}^{2} \times \mathrm{f} \times \mathrm{C}_{\mathrm{T}}
$$

where: $\Gamma_{\text {MPL }}$ is the MPL parameter as defined in the specification. This is a constant equal to the product (k1 x k2).

Now, as:

$$
\operatorname{Pin}=\frac{1}{2} \times L_{P} \times \mathrm{lpk}^{2} \times f
$$

and:

$$
\mathrm{Vcs}=\mathrm{R}_{\mathrm{S}} \times \mathrm{lpk}
$$

So:

$$
\mathrm{V}_{\mathrm{MPL}}=\frac{2 \times \mathrm{R}_{\mathrm{MPL}} \times \Gamma_{\mathrm{MPL}} \times \mathrm{C}_{\mathrm{T}} \times \mathrm{R}_{\mathrm{S}}^{2}}{\mathrm{~L}_{\mathrm{P}}} \times \mathrm{Pin}
$$

A comparator is used to compare $\mathrm{V}_{\mathrm{MPL}}$ to $\mathrm{V}_{\text {ref }}$, the output of which, Dis ${ }_{\text {MPL }}$, is connected to the "definitive inhibition latch" of the disabling block. So, when the calculated power is higher than the threshold, the circuit is definitively disabled (the system considers that there is an overload condition).

Finally, replacing $\mathrm{V}_{\mathrm{MPL}}$ by 2.5 V (the threshold value), the $\mathrm{R}_{\mathrm{MPL}}$ value to be used, can be deducted:

Figure 14. OHD and MPL

## Overheating Detection Section (O.H.D.)

In the MPL block, the converter input power is calculated. In the O.H.D. block, that is the power MOSFET heating which is calculated, using the following equation:

$$
\mathrm{p}_{\mathrm{on}}=\frac{1}{3} \times \mathrm{R}_{\mathrm{dson}} \times \mathrm{Ipk}^{2} \times \mathrm{d}
$$

where: $\mathrm{p}_{\mathrm{on}}$ are the power switch on-time losses
$\mathrm{R}_{\text {dson }}$ is the conduction MOSFET resistor d is the duty cycle

As in the MPL section, the squared Ipk term is estimated by building a current source proportional to $\mathrm{Vcs}^{2}$.

The duty cycle is taken into account thanks to the action on this current source of a "chopper" controlled by the circuit output. By this means, the pin 6 average current is proportional to the squared peak current multiplied to the duty cycle (refer to Figure 14).

So, using an external resistor and capacitor network ( $\mathrm{R}_{\mathrm{OHD}}, \mathrm{C}_{\mathrm{OHD}}$ ) on this pin, a voltage $\mathrm{V}_{\mathrm{OHD}}$, proportional to the conduction losses can be obtained.

Like in the MPL block, this voltage $\mathrm{V}_{\mathrm{OHD}}$, is compared to 2.5 V . If $\mathrm{V}_{\mathrm{OHD}}$ gets higher than this threshold, the disabling block is activated by $\mathrm{Dis}_{\mathrm{OHD}}$ (output of the comparator).

The external resistor $\mathrm{R}_{\mathrm{OHD}}$ choice enables to obtain a calculated $\mathrm{V}_{\mathrm{OHD}}$ equal to 2.5 V when the conduction losses are equal to their maximum value.
In effect,

$$
\mathrm{v}_{\mathrm{OHD}}=\mathrm{R}_{\mathrm{OHD}} \times \mathrm{k}_{\mathrm{OHD}} \times \mathrm{Vcs}^{2} \times \mathrm{d}
$$

where: $\mathrm{k}_{\mathrm{OHD}}$ is the multiplier gain
Now, as $\mathrm{k}_{\mathrm{OHD}}$ that is depending on the reference current source $I_{\text {ref }}$, is proportional to $1 / R_{\text {ref }}$ :

$$
\mathrm{k}_{\mathrm{OHD}}=\mathrm{k} 2 \times \frac{1}{\mathrm{R}_{\mathrm{ref}}}
$$

where: k 2 is a constant
So:

$$
\mathrm{V}_{\mathrm{OHD}}=\mathrm{R}_{\mathrm{OHD}} \times \mathrm{k} 2 \times \frac{\mathrm{Vcs}^{2}}{R_{\text {ref }}} \times \mathrm{d}
$$

Finally:

$$
\mathrm{v}_{\mathrm{OHD}}=\frac{\mathrm{R}_{\mathrm{OHD}} \times \Gamma_{\mathrm{OHD}} \times \mathrm{Vcs}^{2} \times \mathrm{d}}{R_{\mathrm{ref}}}
$$

where: $\Gamma_{\text {OHD }}$ is the OHD parameter as defined in the specification. This is a constant equal to k 2 .
Now, as:

$$
\mathrm{Vcs}=\mathrm{R}_{\mathrm{S}} \times \mathrm{lpk}
$$

So, replacing Vcs and using the $\mathrm{p}_{\mathrm{on}}$ equation:

$$
\mathrm{v}_{\mathrm{OHD}}=\frac{3 \times \mathrm{R}_{\mathrm{OHD}} \times \Gamma_{\mathrm{OHD}} \times \mathrm{R}_{\mathrm{S}}^{2}}{\mathrm{R}_{\mathrm{ref}} \times \mathrm{R}_{\mathrm{dson}}} \times \mathrm{p}_{\mathrm{on}}
$$

So, by choosing the value of $\mathrm{R}_{\mathrm{OHD}}$, the heating corresponding to $\mathrm{V}_{\text {ref }}$ is determined. If the MOSFET dissipation is such that the heating is higher than this threshold, the "definitive inhibition latch" of the Disabling Block is activated and so, the output gets definitively disabled.

Consequently, by replacing $\mathrm{V}_{\mathrm{OHD}}$ by 2.5 V (threshold value) in the last equation, the value $\mathrm{R}_{\mathrm{OHD}}$ to use, can be deducted:

$$
\mathrm{R}_{\mathrm{OHD}}=\frac{2.5 \times \mathrm{R}_{\mathrm{ref}} \times \mathrm{R}_{\mathrm{dson}}}{3 \times \Gamma_{\mathrm{OHD}} \times \mathrm{R}_{\mathrm{S}}^{2} \times\left(\mathrm{p}_{\mathrm{on}}\right)_{\max }}
$$

where: $\left(\mathrm{p}_{\mathrm{on}}\right)_{\max }$ are the maximum on time losses that are acceptable.

## Disabling Block Section

This section consists of a "definitive inhibition latch" (directly supplied by the $\mathrm{V}_{\mathrm{cc}}$ ) that disables the output (the output is forced to zero).

In effect, this block aims at definitively disabling the circuit when one of the following faults is detected:
— a Winding Short Circuit

- too high synchronization pulses
- a too high input power
- a too high power switch (MOSFET) heating

The signals corresponding to these faults are high when a fault is detected (for instance, when the input power is detected as too high, DismPL is high).

When one (or several) of these four faults is detected, a current source charges $\mathrm{C}_{\text {ext }}$ (with a certain duty cycle) and when its voltage becomes higher than $\mathrm{V}_{\text {ref }}$, the definitive inhibition latch is activated. Thus, the circuit gets definitively disabled after a delay depending on $\mathrm{C}_{\text {ext }}$.

According to the detected fault, the current that charges $\mathrm{C}_{\text {ext }}$ is not the same:

The typical values are:

- $260 \mu \mathrm{~A}$ for EHTOVP and WSCD
- $8.5 \mu \mathrm{~A}$ for OHD and MPL
when $R_{r e f}$ is equal to $10 \mathrm{k} \Omega$.

Figure 15. Disabling Block
This latch is reset when the $\mathrm{V}_{\mathrm{cc}}$ falls down to about 3 V . In this case, if a new start up is performed, the circuit will work normally (until this fault or another one is detected).
Practically, to re-start after a fault has shutdown the circuit, the converter must be turned off for a time long enough to enable the $\mathrm{V}_{\mathrm{cc}}$ capacitor discharge (repair time...).
Note: As $V_{\text {WSCD }}$ is generally a really narrow pulse, it is necessary to add a latch and a delay to build a $4 \mu$ s width pulse when $\mathrm{V}_{\text {WSCD }}$ becomes high.

## Application Schematic

65 W output SMPS controlled by the MC44605
Mains input range: 90 Vac <-> 264 Vac
Synchronization range: $\mathbf{3 0} \mathbf{~ k H z ~ < - > ~} 100$ kHz
Orega Transformer ref. G5984-00
(Lp = $195 \mu \mathrm{H}$ )

## CS51021A, CS51022A, CS51023A, CS51024A

## Enhanced Current Mode PWM Controller

The CS51021A/2A/3A/4A Fixed Frequency PWM Current Mode Controller family provides all necessary features required for AC-DC or DC-DC primary side control. Several features are included eliminating the additional components needed to implement them externally. In addition to low start-up current $(75 \mu \mathrm{~A})$ and high frequency operation capability, the CS51021A/2A/3A/4A family includes overvoltage and undervoltage monitoring, externally programmable dual threshold overcurrent protection, current sense leading edge blanking, current slope compensation, accurate duty cycle control and an externally available 5.0 V reference. The CS51021A and CS51023A feature bidirectional synchronization capability, while the CS51022A and CS51024A offer a sleep mode with $100 \mu \mathrm{~A}$ maximum IC current consumption. The CS51021A/2A/3A/4A family is available in a 16 lead narrow body SO package.

| Device | Sleep/Synch | $\mathbf{V}_{\text {CC }}$ Start/Stop |
| :--- | :---: | :---: |
| CS51021A | Synch | $8.25 \mathrm{~V} / 7.7 \mathrm{~V}$ |
| CS51022A | Sleep | $8.25 \mathrm{~V} / 7.7 \mathrm{~V}$ |
| CS51023A | Synch | $13 \mathrm{~V} / 7.7 \mathrm{~V}$ |
| CS51024A | Sleep | $13 \mathrm{~V} / 7.7 \mathrm{~V}$ |

## Features

- $75 \mu \mathrm{~A}$ Max. Startup Current
- Fixed Frequency Current Mode Control
- 1.0 MHz Switching Frequency
- Undervoltage Protection Monitor
- Overvoltage Protection Monitor with Programmable Hysteresis
- Programmable Dual Threshold Overcurrent Protection with Delayed Restart
- Programmable Soft Start
- Accurate Maximum Duty Cycle Limit
- Programmable Slope Compensation
- Leading Edge Current Sense Blanking
- 1.0 A Sink/Source Gate Drive
- Bidirectional Synchronization (CS51021A/3A)
- 50 ns PWM Propagation Delay
- $100 \mu \mathrm{~A}$ Max Sleep Current (CS51022A/4A)

## PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| 16 Lead SO Narrow |  |  |
| 1 | GATE | External power switch driver with 1.0 A peak capability. |
| 2 | $I_{\text {SENSE }}$ | Current sense amplifier input. |
| 3 | SYNC (CS51021A/3A) | Bi-directional synchronization. Locks to the highest frequency. |
| 3 | SLEEP (CS51022A/4A) | Active high chip disable. In sleep mode, $\mathrm{V}_{\text {REF }}$ and GATE are turned off. |
| 4 | SLOPE | Additional slope to the current sense signal. Internal current source charges the external capacitor. |
| 5 | UV | Undervoltage protection monitor. |
| 6 | OV | Overvoltage protection monitor. |
| 7 | $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ | Timing resistor $\mathrm{R}_{\mathrm{T}}$ and capacitor $\mathrm{C}_{\mathrm{T}}$ determine oscillator frequency and maximum duty cycle, $\mathrm{D}_{\text {MAX }}$. |
| 8 | $I_{\text {SET }}$ | Voltage at this pin sets pulse-by-pulse overcurrent threshold, and second threshold ( 1.33 times higher) with Soft Start retrigger (hiccup mode). |
| 9 | $\mathrm{V}_{\mathrm{FB}}$ | Feedback voltage input. Connected to the error amplifier inverting input. |
| 10 | COMP | Error amplifier output. Frequency compensation network is usually connected between COMP and $\mathrm{V}_{\mathrm{FB}}$ pins. |
| 11 | SS | Charging external capacitor restricts error amplifier output voltage during the start or fault conditions (hiccup). |
| 12 | LGND | Logic ground. |

## CIRCUIT DESCRIPTION

Figure 3. Typical Waveforms

## THEORY OF OPERATION

## Powering the IC

The IC has two supply and two ground pins. $\mathrm{V}_{\mathrm{C}}$ and PGND pins provide high speed power drive for the external power switch. $\mathrm{V}_{\mathrm{CC}}$ and LGND pins power the control portion of the IC. The internal logic monitors the supply voltage, $\mathrm{V}_{\mathrm{CC}}$. During abnormal operating conditions, the output is held low. The CS51021A/2A/3A/4A requires only $75 \mu \mathrm{~A}$ of startup current.

## Voltage Feedback

The output voltage is monitored via the $\mathrm{V}_{\mathrm{FB}}$ pin and is compared with the internal 2.5 V reference. The error amplifier output minus one diode drop is divided by 3 and connected to the negative input of the PWM comparator. The positive input of the PWM comparator is connected to the modified current sense signal. The oscillator turns the external power switch on at the beginning of each cycle. When current sense ramp voltage exceeds the reference side of PWM comparator, the output stage latches off. It is turned on again at the beginning of the next oscillator cycle.

## Current Sense and Protection

The current is monitored at the ISENSE pin. The CS51021A/2A/3A/4A has leading edge blanking circuitry that ignores the first 55 ns of each switching period. Blanking is disabled when $\mathrm{V}_{\mathrm{FB}}$ is less than 2.0 V so that the minimum on-time of the controller does not have an additional 55 ns of delay time during fault conditions. For the remaining portion of the switching period, the current sense signal, combined with a fraction of the slope compensation voltage, is applied to the positive input of the PWM comparator where it is compared with the divided by three error amplifier output voltage. The pulse-by-pulse overcurrent protection threshold is set by the voltage at the $\mathrm{I}_{\text {SET }}$ pin. This voltage is passed through the $\mathrm{I}_{\text {SET }}$ Clamp and appears at the non-inverting input of the PWM comparator, limiting its dynamic range according to the following formula:

$$
\begin{aligned}
\text { Overcurrent Threshold }= & 0.8 \times \mathrm{V}_{\mathrm{I}}(\text { SENSE }) \\
& +0.1 \mathrm{~V}+0.1 \mathrm{~V} \text { SLOPE }
\end{aligned}
$$

where
$\mathrm{V}_{\mathrm{I}}($ SENSE $)$ is voltage at the ISENSE pin.
and
VSLOPE is voltage at the SLOPE pin.
During extreme overcurrent or short circuit conditions, the slope of the current sense signal will become much steeper than during normal operation. Due to loop propagation delay, the sensed signal will overshoot the pulse-by-pulse threshold eventually reaching the second overcurrent protection threshold which is 1.33 times higher than the first threshold and is described by the following equation:

$$
\text { 2nd Threshold }=1.33 \times \mathrm{V}_{\mathrm{I}}(\mathrm{SET})
$$

Exceeding the second threshold will reset the Soft Start capacitor $\mathrm{C}_{\mathrm{SS}}$ and reinitiate the Soft Start sequence, repeating for as long as the fault condition persists.

## Soft Start

During power up, when the output filter capacitor is discharged and the output voltage is low, the voltage across the Soft Start capacitor $\left(\mathrm{V}_{\mathrm{SS}}\right)$ controls the duty cycle. An internal current source of $55 \mu \mathrm{~A}$ charges $\mathrm{C}_{\text {SS }}$. The maximum error amplifier output voltage is clamped by the SS Clamp. When the Soft Start capacitor voltage exceeds the error amplifier output voltage, the feedback loop takes over the duty cycle control. The Soft Start time can be estimated with the following formula:

$$
\mathrm{tSS}=9 \times 10^{4} \times \mathrm{CSS}
$$

The Soft Start voltage, $\mathrm{V}_{\mathrm{SS}}$, charges and discharges between 0.25 V and 4.7 V .

## Slope Compensation

DC-DC converters with current mode control require a current sense signal with slope compensation to avoid instability at duty cycles greater than $50 \%$. Slope capacitor $\mathrm{C}_{\mathrm{S}}$ is charged by an internal $53 \mu \mathrm{~A}$ current source and is discharged during the oscillator discharge time. The slope compensation voltage is divided by 10 and is added to the current sense voltage, $\mathrm{V}_{\mathrm{I} \text { (SENSE). }}$. The signal applied to the input of the PWM comparator is a combination of these two voltages. The slope compensation, $\mathrm{dV}_{\text {SLOPE }} / \mathrm{dt}$, is calculated using the following formula:

$$
\frac{\mathrm{dV} \mathrm{~V}_{\mathrm{SLOPE}}}{\mathrm{dt}}=0.1 \times \frac{53 \mu \mathrm{~A}}{\mathrm{CS}}
$$

It should be noted that internal capacitance of the IC will cause an error when determining slope compensation capacitance $\mathrm{C}_{\mathrm{S}}$. This error is typically small for large values of $C_{S}$, but increases as $C_{S}$ becomes small and comparable to the internal capacitance. The effect is apparent as a reduction in charging current due to the need to charge the internal capacitance in parallel with $\mathrm{C}_{S}$.Figure 4 shows a typical curve indicating this decrease in available charging current.

Figure 4. The Slope Compensation Pin Charge Current Reduces When a Small Capacitor Is Used.

## Undervoltage (UV) and Overvoltage (OV) Monitor

Two independent comparators monitor OV and UV conditions. A string of three resistors is connected in series between the monitored voltage (usually the input voltage) and ground (see Figure 5). When voltage at the OV pin exceeds 2.5 V , an overvoltage condition is detected and GATE shuts down. An internal $12.5 \mu \mathrm{~A}$ current source turns on and feeds current into the external resistor, $\mathrm{R}_{3}$, creating a hysteresis determined by the value of this resistor (the higher the value, the greater the hysteresis). The hysteresis voltage of the OV monitor is determined by the following formula:

$$
\mathrm{V}_{\mathrm{OV}(\mathrm{HYST})}=12.5 \mu \mathrm{~A} \times \mathrm{R}_{3}
$$

where $R_{3}$ is a resistor connected from the OV pin to ground.
When the monitored voltage is low and the UV pin is less than 1.45 V , GATE shuts down. The UV pin has fixed 75 mV hysteresis.
Both OV and UV conditions are latched until the Soft Start capacitor is discharged. This way, every time a fault condition is detected the controller goes through the power up sequence.

Figure 5. UV/OV Monitor Divider

To calculate the OV?UV resistor divider :

1. Solve for $\mathrm{R}_{3}$, based on OV hysteresis requirements.

$$
\mathrm{R}_{3}=\frac{\mathrm{V}_{\mathrm{OV}(\mathrm{HYST})} \times 2.5 \mathrm{~V}}{\mathrm{~V}_{\mathrm{MAX}} \times 12.5 \mu \mathrm{~A}}
$$

where $\mathrm{V}_{\mathrm{OV} \text { (HYST) }}$ is the desired amount of overvoltage hysteresis, and $\mathrm{V}_{\text {MAX }}$ is the input voltage at which the supply will shut down.
2. Find the total impedance of the divider.

$$
\mathrm{RTOT}_{\mathrm{TO}}=\mathrm{R}_{1}+\mathrm{R}_{2}+\mathrm{R}_{3}=\frac{\mathrm{V}_{\mathrm{MAX}} \times \mathrm{R}_{3}}{2.5}
$$

3. Determine the value of $\mathrm{R}_{2}$ from the UV threshold conditions.

$$
\mathrm{R}_{2}=\frac{1.45 \times \mathrm{RTOT}}{\mathrm{~V}_{\mathrm{MIN}}}-\mathrm{R}_{3}
$$

where $\mathrm{V}_{\mathrm{MIN}}$ is the UV voltage at which the supply will shut down.
4. Calculate $\mathrm{R}_{1}$.

$$
\mathrm{R}_{1}=\mathrm{R}_{\mathrm{TOT}}-\mathrm{R}_{2}-\mathrm{R}_{3}
$$

5. The undervoltage hysteresis is given by :

$$
\mathrm{VUV}(\mathrm{HYST})=\frac{\mathrm{V}_{\mathrm{MIN}} \times 0.075}{1.45}
$$

## $\mathbf{V}_{\text {REF }}$ Monitor

The 5.0 V reference voltage is internally monitored to ensure that it remains within specifications. The monitor, which outputs a fault, can be tripped by two methods:

- If the reference voltage drops below 4.75 V
- If $\mathrm{V}_{\mathrm{CC}}$ falls below the STOP threshold

As indicated in the block diagram, any fault causes the output to stop switching and begins the discharge of the Soft Start capacitor $\mathrm{C}_{\text {SS }}$.

## CS51021A, CS51022A, CS51023A, CS51024A

## Synchronization

A bi-directional synchronization is provided to synchronize several controllers. When SYNC pins are connected together, the converters will lock to the highest switching frequency. The fastest controller becomes the master, producing a $4.3 \mathrm{~V}, 200 \mathrm{~ns}$ pulse train. Only one, the highest frequency SYNC signal, will appear on the SYNC line.

## Sleep

The sleep input is an active high input. The CS51022A/4A is placed in sleep mode when SLEEP is driven high. In sleep mode, the controller and MOSFET are turned off. Connect to GND for normal operation. The sleep mode operates at VCC $\leq 15 \mathrm{~V}$.

## Oscillator and Duty Cycle Limit

The switching frequency is set by $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$ connected to the $\mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}$ pin. $\mathrm{C}_{\mathrm{T}}$ charges and discharges between 3.0 V and 1.5 V .

The maximum duty cycle is set by the ratio of the on time, $\mathrm{t}_{\mathrm{ON}}$, and the whole period, $\mathbf{T}=\mathbf{t}_{\mathbf{O N}}+\mathbf{t}_{\mathbf{O F F}}$. Because the timing capacitor's discharge current is trimmed, the maximum duty cycle is well defined. It is determined by the ratio between the timing resistor $\mathrm{R}_{\mathrm{T}}$ and the timing capacitor $\mathrm{C}_{\mathrm{T}}$. Refer to figures 6 and 7 to select appropriate values for $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$.

$$
\mathrm{fSW}=\frac{1}{\mathrm{TSW}} ; \mathrm{TSW}=\mathrm{t} \mathrm{CH}+\mathrm{tDIS}
$$

## CS5106

## Multi-Feature, Synchronous plus Auxiliary PWM Controller

The CS5106 is a fixed frequency, current mode controller with one single NFET driver and one dual FET, synchronous driver. The synchronous driver allows for increased efficiency of the main isolated power stage and the single driver allows the designer to develop auxiliary supplies for controller power as well as secondary side house keeping. In addition, because the synchronous drivers have programmable FET non-overlap, the CS5106 is an ideal controller for soft-switched converter topologies.

The CS5106 is specifically designed for isolated topologies where speed, flexibility, reduced size and reduced component count are requirements. The controller contains the following features: Undervoltage Shutdown, Overvoltage Shutdown, Programmable Frequency, Programmable Synchronous Non-Overlap Time, Master/Slave Clocking with Frequency Range Detection, Enable, Output Undervoltage Protection with Timer, 20 mA 5.0 V Output, 80 ns PWM propagation delay, and Controlled Hiccup Mode.

The CS5106 has junction temperature and supply ranges of $-40^{\circ} \mathrm{C}$ to $125^{\circ} \mathrm{C}$ and 9.0 V to 16 V respectively and is available in the 24 lead SSOP package.

## Features

- Programmable Fixed Frequency
- Programmable FET Non-Overlap
- Enable Lead
- 12 V Fixed Auxiliary Supply Control
- Under and Overvoltage Shutdown
- Output Undervoltage Protection with Timer
- Master/Slave Clock Sync Capability
- Sync Frequency Range Detection
- 80 ns PWM Propagation Delay
- 20 mA 5.0 V Reference Output
- Small 24 Lead SSOP Package
- Controlled Hiccup Mode

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| SSOP-24 | PIN SYMBOL | FUNCTION |
| 1 | UVSD | Undervoltage shutdown lead. Typically this lead is connected through a resistor divider to the main high voltage $\left(\mathrm{V}_{\mathbb{N}}\right)$ line. If the voltage on this lead is less than 5.0 V then a fault is initiated such that GATE1, GATE2 and GATE2B go low. |
| 2 | OVSD | Overvoltage shutdown lead. Typically this lead is connected through a resistor divider to the main high voltage $\left(\mathrm{V}_{\text {IN }}\right)$ line. If the voltage on this lead exceeds 5.0 V then a fault is initiated such that GATE1, GATE2 and GATE2B go low. |
| 3 | $\mathrm{V}_{\text {SREF }}$ | 5.0 V reference output lead. Capable of 20 mA nominal output. If this lead falls to 4.5 V , a fault is initiated such that GATE1, GATE2 and GATE2B go low. |
| 4 | OAM | Auxiliary error amplifier minus input. This lead is compared to 1.2 V nominal on the auxiliary error amp plus lead and represents the $\mathrm{V}_{S S}$ voltage divided by ten. |
| 5 | OAOUT | Auxiliary error amplifier output lead. Source current $300 \mu \mathrm{~A}$ max. |
| 6 | OUVDELAY | Output undervoltage timing capacitor lead. If the controlled output voltages of either the main or the auxiliary supply are such that either $\mathrm{V}_{\mathrm{FB} 1}$ or $\mathrm{V}_{\mathrm{FB} 2}$ is greater that 4.1 V nominal, then capacitor from OUVDELAY to ground will begin charging. If the over voltage duration is such that the OUVDELAY voltage exceeds 5.0 V , then a fault will be initiated such that GATE1, GATE2 and GATE2B will go low. |
| 7 | ILIM1 | Pulse by pulse over current protection lead for the auxiliary PWM. A voltage exceeding 1.2 V nominal on ILIM1 will cause GATE1 to go low. A voltage exceeding 1.4 V nominal on ILIM1 will cause GATE1 to go low for at least two clock cycles. |
| 8 | RAMP1 | Current Ramp Input Lead for the Auxiliary PWM. A voltage which is linear with respect to current in the primary side of the auxiliary transformer is usually represented on this lead. A voltage exceeding $\mathrm{V}_{\mathrm{FB} 1}-0.13$ on RAMP1 will cause GATE1 to go low. |
| 9 | $\mathrm{V}_{\text {FB1 }}$ | Voltage Feedback Lead for the Auxiliary PWM. A voltage which represents the auxiliary power supply output voltage is fed to this lead. A voltage less than RAMP1+0.13 on $\mathrm{V}_{\mathrm{FB} 1}$ will cause GATE1 to go low. |
| 10 | $\mathrm{V}_{S S}$ | $\mathrm{V}_{S S}$ power/feedback input lead. See $\mathrm{V}_{\mathrm{CC}}$ for description of power operation. In addition, this lead is fed to a divide by ten resistor divider and compared to 1.2 V nominal at the positive side of the error amplifier. |
| 11 | $\mathrm{V}_{\mathrm{CC}}$ | $\mathrm{V}_{\mathrm{CC}}$ power input lead. This input runs off a Zener referenced supply until $\mathrm{V}_{S S}>\mathrm{V}_{\mathrm{CC}}$. Then an internal diode which runs between $\mathrm{V}_{\mathrm{SS}}$ and $\mathrm{V}_{\mathrm{CC}}$ turns on and all main power is derived from $\mathrm{V}_{\mathrm{SS}}$. |
| 12 | GATE1 | Auxiliary PWM gate drive lead. This output normally drives the FET which drives the auxiliary transformer. |
| 13 | GND | Ground lead. |
| 14 | GATE2 | Synchronous PWM gate drive lead. This output normally drives the FET which drives the main transformer. |
| 15 | GATE2B | Synchronous PWM gate drive lead. This output normally drives the FET for the gate drive transformer used for synchronous rectification. |
| 16 | $\mathrm{V}_{\text {FB2 }}$ | Voltage feedback lead for the synchronous PWM. A voltage which represents the main power supply output voltage is fed to this lead. A voltage less than RAMP2 +0.13 on $\mathrm{V}_{\mathrm{FB} 2}$ will cause GATE2 to go low and GATE2B to go high. |
| 17 | RAMP2 | Current ramp input lead for the synchronous PWM. A voltage which is linear with respect to current in the primary side of the main transformer is usually represented on this lead. A voltage exceeding $\mathrm{V}_{\mathrm{FB} 2}-0.13$ on RAMP2 will cause GATE2 to go low and GATE2B to go high. |
| 18 | ILIM2 | Pulse by pulse over current protection lead for the synchronous PWM. A voltage exceeding 1.2 V nominal on $\mathrm{I}_{\text {LIM2 }}$ will cause GATE2 to go low and GATE2B to go high. A voltage exceeding 1.4 V nominal on ILIM2 will cause GATE2 to go low and GATE2B to go high for at least two clock cycles. |
| 19 | DLYSET | GATE2, GATE2B non-overlap time adjustment lead. A $27 \mathrm{k} \Omega$ resistor from DLYSET to ground sets the non-overlap time to 45 ns nominal. |

CS5106

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| SSOP-24 | PIN SYMBOL | FUNCTION |
| 20 | FADJ | Frequency adjustment lead. A $27 \mathrm{k} \Omega$ resistor from FADJ to ground sets the clock frequency to 512 kHz nominal. |
| 21 | SYNCOUT | Clock output lead. This is a $50 \%$ duty cycle, 1.0 V to 5.0 V pulse whose rising edge is in phase with GATE1. This signal can be used to synchronize other power supplies. |
| 22 | $\mathrm{SYNC}_{\mathrm{IN}}$ | Clock synchronization lead. The internal clock frequency can be adjusted $+10 \%,-15 \%$ by the onset of positive edges of an external clock occurring on the $\mathrm{SYNC}_{\mathbb{I N}}$ lead. If the external clock frequency is outside the internal clock frequency by $+25 \%,-35 \%$ the external clock is ignored and the internal clock free runs. |
| 23 | PROGRAM | ENABLE programming input. See ENABLE for programming states. PROGRAM has at least $20 \mu \mathrm{~A}$ min. of available source current. |
| 24 | ENABLE | PWM enable input. If PROGRAM is HIGH then a LOW on ENABLE will allow GATE1, GATE2 and GATE2B to switch. If PROGRAM is LOW then a HIGH on ENABLE will allow GATE1, GATE2 and GATE2B to switch. If ENABLE is left floating, it will pull up to a HIGH level. ENABLE has at least $100 \mu \mathrm{~A}(\mathrm{~min})$ of available source current. |

CS5106

## THEORY OF APPLICATION

## THEORY OF OPERATION

## Powering the IC

The IC has one supply, $\mathrm{V}_{\mathrm{CC}}$, and one Ground lead. If $\mathrm{V}_{\mathrm{SS}}$ is used for a bootstrapped supply the diode between $\mathrm{V}_{\mathrm{SS}}$ and $\mathrm{V}_{\mathrm{CC}}$ is forward biased, and the IC will derive its power from $\mathrm{V}_{\mathrm{SS}}$. The internal logic monitors the supply voltage, $\mathrm{V}_{\mathrm{CC}}$. During abnormal operating conditions, all GATE drivers are held in a low state. The CS5106 requires 1.5 mA nominal of startup current.

## Startup

Assume the part is enabled and there are no over voltage or under voltage faults present. Also, assume that all auxiliary and main regulated output voltages start at 0 V . An 8.0 V , Zener referenced supply is typically applied to $\mathrm{V}_{\mathrm{CC}}$. When $\mathrm{V}_{\mathrm{CC}}$ exceeds 7.5 V , the 5.0 V reference is enabled and the OSC begins switching. If the $\mathrm{V}_{5 \text { REF }}$ lead is not excessively loaded such that $\mathrm{V}_{5 \mathrm{REF}}<4.5 \mathrm{~V}$ nominal, ' $\mathrm{V}_{\text {REF }} \mathrm{OK}$ ' goes 'high' and 'RUN1' will go 'high', releasing GATE1 from its low state. After GATE1 is released, it begins switching according to conditions set by the auxiliary control loop and the auxiliary supply, $\mathrm{V}_{\mathrm{SS}}$ begins to rise. When $V_{S S}>V_{C C}+V(D 1)$, P1 turns on and 'RUN2' goes 'high', releasing GATE2 and GATE2B from their low state. GATE2 and GATE2B begin switching according to conditions set by the main control loop and the main regulated output begins to rise. See startup waveforms in Figure 3.

## Soft Start

Soft Start for the auxiliary power supply is accomplished by placing a capacitor between OAOUT and Ground. The error amplifier has $200 \mu \mathrm{~A}$ of nominal of source current and is ideal for setting up a Soft Start condition for the auxiliary regulator. Care should be taken to make sure that the Soft Start timing requirements are not in conflict with any transient load requirements for the auxiliary supply as large capacitors on OAOUT will slow down the loop response. Also, the Soft Start capacitor must be chosen such that during start or restart, both outputs will come into regulation before the OUVDELAY timer trips. Soft Start for the main supply is accomplished by charging Soft Start capacitor C6 through D5 and R7 at start up. After the main supply has come into regulation C 6 continues to charge and is disconnected from the feedback loop by D8.

Figure 3. Startup Waveforms

## Voltage and Current Ramp PWM Comparator Inputs ( $\mathrm{V}_{\mathrm{FB} 1,2}$ and RAMP1,2 leads)

C10 and C11 are the PWM comparators for the auxiliary and main supplies. The feedback voltage $\left(\mathrm{V}_{\mathrm{FB}}\right)$ is divided by three and compared with a linear, voltage representation of the current in the primary side of the transformer (RAMP). When the output of the feedback comparator goes 'high', a reset signal is sent to the PWM flip-flop and the GATE driver is driven 'low'. A 130 mV offset on the RAMP leads allows the drivers to go to $0 \%$ duty cycle in the presence of light loads.

## Feedback Voltage for GATE1 Driver ( $\mathbf{V}_{\mathrm{FB} 1}$ )

Typically the output of the auxiliary error amplifier (A1) is tied to $\mathrm{V}_{\mathrm{FB} 1}$. The $\mathrm{V}_{\mathrm{SS}}$ output is programmed to 12 V by a 10:1 resistive divider on the negative input of the error amplifier and a fixed 1.2 V reference on the positive input of the error amplifier.

## Pulse by Pulse Over Current Protection and Hiccup Mode (lim1,2 leads)

C 12 and C 13 are the pulse by pulse current limit comparators for the auxiliary and main supplies. When the current in the primary side of the transformer increases such that the voltage across the current sense resistor exceeds 1.2 V nominal, the output of the current limit comparator goes
'high' and a reset signal is sent to the PWM flip-flop and the GATE driver is driven 'low'.

C16 and C17 are the second threshold, pulse by pulse current limit comparators for the auxiliary and main supplies. If the current in the primary side of the transformer increases so quickly that the current sense voltage is not limited by C12 or C13 and the voltage across the current sense resistor exceeds 1.4 V , the second threshold comparator will trip a delay circuit and force the GATE driver stage to go low and stay low for the next two clock cycles.

## Undervoltage and Overvoltage Thresholds

C5 and C8 are the undervoltage and overvoltage detection comparators. Typically, these inputs are tied across the middle resistor in a three resistor divider with the top resistor to $\mathrm{V}_{\text {IN }}$ and bottom resistor to Ground. The under voltage comparator has 200 mV of built in hysteresis with respect to a direct input on the UVSD lead. The under voltage comparator has its positive input referenced to 5.0 V while the over voltage comparator has its negative input referenced to 5.0 V . The output of both comparators are ORed at (G4) with the over current and enable inputs. The output of G4 feeds the input to the fault latch (F2).

## PROGRAM and ENABLE Leads

The PROGRAM lead controls the polarity of the ENABLE lead. If the PROGRAM lead is 'high' or floating, the GATE outputs will go low if the ENABLE input is tied 'high' or floating. If the PROGRAM lead is tied low, the GATE outputs will go low if the ENABLE input is tied 'low'. If the part is then enabled after switching the outputs low, the part will restart according to the procedure outlined in the "Startup" section.

## FAULT Logic

If a $\mathrm{V}_{\text {REF }}$, UVSD or OVSD fault occurs at any time, G4 resets the fault latch (F2). RUN1 goes low and all gate drivers cease switching and return to their 'low' state. When RUN1 goes low, the output of the auxiliary op-amp (A1) discharges the Soft Start capacitor and holds it low while RUN1 is low. If the fault condition is removed before the OUVDELAY timer is tripped, the IC will restart the power supplies when $\mathrm{V}_{\mathrm{SS}}<1.4 \mathrm{~V}$. If the OUVDELAY timer trips, the power supply must be restarted as explained in the following section.

## Output Undervoltage Delay Timer for the Main and Auxiliary Regulated Outputs

C7 and C4 are the output under voltage monitor comparators for the auxiliary and main supplies. If a regulated output drops such that its associated $\mathrm{V}_{\mathrm{FB}}$ voltage exceeds 4.1 V , the output undervoltage monitor comparator goes 'high' and the OUVDELAY capacitor begins charging from 0 V . A timing relation is set up by a $10 \mu \mathrm{~A}$ nominal current source, the OUVDELAY capacitor and a 5.0 V fault threshold at the input of C2 (see Figure 4). If any regulated output drops and stays low for the entire charge time of the OUVDELAY capacitor, a fault is triggered and all GATE drivers will go into a low state.

Once this fault is triggered, the IC will restart the power supplies only if the OUVDELAY fault is reset and ENABLE or UVSD is toggled while $\mathrm{V}_{\mathrm{SS}}<1.4 \mathrm{~V}$. To reset the OUVDELAY fault, both the $\mathrm{V}_{\mathrm{FB}}$ inputs must be less than 4.1 V. In the application circuit shown, $\mathrm{V}_{\mathrm{FB} 1}$ is brought low by OAOUT when RUN1 stops the oscillators. $\mathrm{V}_{\mathrm{FB} 2}$ is brought low when $\mathrm{V}_{\mathrm{AUXP}}$ bleeds down and the $\mathrm{V}_{\mathrm{FB}}$ 2 opto-isolator is no longer powered.

Figure 4. OUVDELAY Time vs. OUVDELAY Capacitance

## FADJ and DLYSET Leads

Amplifier A2 and transistor N3 create a current source follower whose output is FADJ. An external resistor from FADJ to ground completes the loop. The voltage across the resistor is set by a buffered, trimmed, precision reference. In this fashion, an accurate current is created which is used to charge and discharge an internal capacitor thereby creating an oscillator with a tight frequency tolerance. For FADJ resistor value selection, see Figure 5. Transistor N2 is in parallel with N3 and is used to created an independent current across the resistor from DLYSET to ground. This current is used to program the GATE non-overlap delay blocks in the main PWM drivers. For DLYSET resistor value selection, see Figure 6.

Figure 5. SYNC Out Frequency vs. FADJ Resistors

Figure 6. GATE Non-Overlap Time vs. DLYSET Resistance

## Oscillator

The oscillator generates two clock signals which are 180 degrees out of phase with respect to time. One clock signal feeds the main driver and the other feeds the auxiliary driver. Because the drivers are never turned on at the same time, ground noise and supply noise is minimized. The clock signals are actually 100 ns pulse spikes. These spikes create a narrow driver turn-on window. This narrow window prevents the driver from spurious turn on in the middle of a clock cycle. The oscillator can be synchronized by an external clock (slave) or drive the clocks of other controllers (master). See Figure 7 for the relationship between SYNC, CLK, and GATE waveforms.

Figure 7. SYNC, GATE and CLOCK Waveforms

## SYNC $_{\text {IN }}$ and SYNC OUt Leads

Multiple supplies can be synchronized to one supply by using the SYNC leads. The SYNC ${ }_{\text {IN }}$ and SYNCOUT pulses are always 180 degrees out of phase. The SYNC IN input is always in phase with the clock signal for the main driver and the SYNC OUT output is always in phase with the clock signal for the auxiliary driver. If the IC is being used as a slave, the incoming frequency must be within $+10 \%,-20 \%$ of the programmed frequency set by its own FADJ resistor. If the frequency on the $\mathrm{SYNC}_{\text {IN }}$ lead is outside the internal frequency by $+25 \%,-35 \%$, the $\mathrm{SYNC}_{\text {IN }}$ input will be ignored. If the SYNC signal stops while the power supplies are in synchronized operation, the synchronized supplies
will stop and restart free running. If the $\mathrm{SYNC}_{\text {IN }}$ signal drifts out of frequency specification while the power supplies are in synchronized operation, the synchronized supplies will begin to free run without restarting.

## Slope Compensation

DC-DC converters with current mode control require slope compensation to avoid instability at duty cycles greater than $50 \%$. A slope is added to the current sense waveform (or subtracted from the voltage waveform) that is equal to a percentage ( $75 \%$ typical) of the down slope of the inductor current. In the application diagram shown, the bootstrap (flyback) transformer inductance can be chosen so that the duty cycle never exceeds $50 \%$ and therefore does not require slope compensation. The buck indicator in the forward converter would typically be chosen to work in continuous conduction mode with a maximum duty cycle of $50-60 \%$ and would require slope compensation. Slope compensation is accomplished as follows: R9 and C9 form a ramp waveform rising each time GATE 2 turns on. C9 is discharged through D3 to the same level each cycle regardless of duty cycle. R10 and R11 are chosen to control the amount of slope compensation. C10 provides filtering for noise and turn-on spikes. To calculate the required slope compensation, calculate the buck indicator down current and the corresponding voltage slope at the current sense resistor-R12.

The buck inductor down slope is:

$$
\text { Inductor_Slope }=\frac{\mathrm{V}_{\mathrm{OUT}}+\mathrm{V}_{\mathrm{Q} 5}}{\mathrm{~L} 1(\mu \mathrm{H})}\left(\frac{\mathrm{A}}{\mu \mathrm{~S}}\right)
$$

The equivalent down slope at the current sense resistor for this application circuit is:
Slope @ R12 $=$ Inductor_Slope $\times \frac{\mathrm{NST}_{2}}{\text { NPT2 }} \times \frac{\mathrm{NPT} 3}{\mathrm{NST} 3} \times$ R12 $\left(\frac{\mathrm{V}}{\mu \mathrm{S}}\right)$
After choosing R9 and C9 to generate a ramp with a time constant of about 5 times the oscillator period, R10 and R11 can be chosen for the voltage at RAMP2 to be 1.75 of the voltage across R12.

## Synchronous Rectification

Synchronous rectification was chosen to reduce losses in the forward converter. Improvements in efficiency will be most significant in low voltage, medium and high current converters where improvement in conduction loss offsets any added losses for gate drive.

In the application circuit Q4 is turned on and off by the forward transformer. Q5 is turned on and off through pulse transformer T4 and the gate driver formed by Q6 and Q7. Because Q4 and Q5 are driven through different types of components, differences in propagation delay must be considered. The DLYSET resistor should be chosen to avoid shoot-through or excessive off time.

## Gate Drive Capability

All GATE drive outputs have nominal peak currents of 0.5A. See Figures 8 and 9 for typical rise and fall times.

Figure 8. Typical GATE2, 2B Switching Times

## Design Considerations

The circuit board should utilize high frequency layout techniques to avoid pulse width jitter and false triggering of high impedance inputs. Ground plane(s) should be employed. Signal grounds and power grounds should be run separately. Portions of the circuit with high slew rates or current pulses should be segregated from sensitive areas. Shields and decoupling capacitors should be used as required.

Special care should be taken to prevent coupling between the SYNC leads and the surrounding leads. Depending on the circuit board layout and component values, decoupling capacitors or reduction in resistor values might be required to reduce noise pick-up on the FADJ and DLYSET resistors. Decoupling capacitors or active pull-up/down might be required to prevent false triggering of the ENABLE and PROGRAM leads.

## MC34067, MC33067

## High Performance <br> Resonant Mode Controllers

The MC34067/MC33067 are high performance zero voltage switch resonant mode controllers designed for off-line and dc-to-dc converter applications that utilize frequency modulated constant off-time or constant deadtime control. These integrated circuits feature a variable frequency oscillator, a precise retriggerable one-shot timer, temperature compensated reference, high gain wide bandwidth error amplifier, steering flip-flop, and dual high current totem pole outputs ideally suited for driving power MOSFETs.

Also included are protective features consisting of a high speed fault comparator, programmable soft-start circuitry, input undervoltage lockout with selectable thresholds, and reference undervoltage lockout.

These devices are available in dual-in-line and surface mount packages.

- Zero Voltage Switch Resonant Mode Operation
- Variable Frequency Oscillator with a Control Range Exceeding 1000:1
- Precision One-Shot Timer for Controlled Off-Time
- Internally Trimmed Bandgap Reference
- 4.0 MHz Error Amplifier
- Dual High Current Totem Pole Outputs
- Selectable Undervoltage Lockout Thresholds with Hysteresis
- Enable Input
- Programmable Soft-Start Circuitry
- Low Startup Current for Off-Line Operation

## Introduction

As power supply designers have strived to increase power conversion efficiency and reduce passive component size, high frequency resonant mode power converters have emerged as attractive alternatives to conventional pulse-width modulated control. When compared to pulse-width modulated converters, resonant mode control offers several benefits including lower switching losses, higher efficiency, lower EMI emission, and smaller size. A new integrated circuit has been developed to support this trend in power supply design. The MC34067 Resonant Mode Controller is a high performance bipolar IC dedicated to variable frequency power control at frequencies exceeding 1.0 MHz . This integrated circuit provides the features and performance specifically for zero voltage switching resonant mode power supply applications.

The primary purpose of the control chip is to provide a fixed off-time to the gates of external power MOSFETs at a repetition rate regulated by a feedback control loop. Additional features of the IC ensure that system startup and fault conditions are administered in a safe, controlled manner.

A simplified block diagram of the IC is shown on the front page, which identifies the main functional blocks and the block-to-block interconnects. Figure 14 is a detailed functional diagram which accurately represents the internal circuitry. The various functions can be divided into two sections. The first section includes the primary control path which produces precise output pulses at the desired frequency. Included in this section are a variable frequency Oscillator, a One-Shot, a pulse Steering Flip-Flop, a pair of power MOSFET Drivers, and a wide bandwidth Error Amplifier. The second section provides several peripheral support functions including a voltage reference, undervoltage lockout, Soft-Start circuit, and a fault detector.

## Primary Control Path

The output pulse width and repetition rate are regulated through the interaction of the variable frequency Oscillator, One-Shot timer and Error Amplifier. The Oscillator triggers the One-Shot which generates a pulse that is alternately steered to a pair of totem pole output drivers by a toggle Flip-Flop. The Error Amplifier monitors the output of the regulator and modulates the frequency of the Oscillator. High speed Schottky logic is used throughout the primary control channel to minimize delays and enhance high frequency characteristics.

## Oscillator

The characteristics of the variable frequency Oscillator are crucial for precise controller performance at high operating frequencies. In addition to triggering the One-Shot timer and initiating the output deadtime, the oscillator also determines the initial voltage for the one-shot capacitor. The Oscillator is designed to operate at
frequencies exceeding 1.0 MHz . The Error Amplifier can control the oscillator frequency over a 1000:1 frequency range, and both the minimum and maximum frequencies are easily and accurately programmed by the proper selection of external components.

The functional diagram of the Oscillator and One-Shot timer is shown in Figure 16. The oscillator capacitor ( $\mathrm{C}_{\mathrm{OSC}}$ ) is initially charged by transistor Q1. When COSC exceeds the 4.9 V upper threshold of the oscillator comparator, the base of Q1 is pulled low allowing COSC to discharge through the external resistor, ( $\mathrm{R}_{\mathrm{OSC}}$ ), and the oscillator control current, ( $\mathrm{I}_{\mathrm{OSC}}$ ). When the voltage on $\mathrm{C}_{\mathrm{OSC}}$ falls below the comparator's 3.6 V lower threshold, Q1 turns on and again charges Cosc.

Cosc charges from 3.6 V to 5.1 V in less than 50 ns . The high slew rate of COSC and the propagation delay of the comparator make it difficult to control the peak voltage. This accuracy issue is overcome by clamping the base of Q1 through a diode to a voltage reference. The peak voltage of the oscillator waveform is thereby precisely set at 5.1 V .

Figure 16. Oscillator and One-Shot Timer

The frequency of the Oscillator is modulated by varying the current flowing out of the Oscillator Control Current (I $\mathrm{I}_{\mathrm{OSC}}$ ) pin. The $\mathrm{I}_{\text {OSC }}$ pin is the output of a voltage regulator. The input of the voltage regulator is tied to the variable frequency oscillator. The discharge current of the Oscillator increases by increasing the current out of the IOSC pin. Resistor R VFO is used in conjunction with the Error Amp output to change the $\mathrm{I}_{\mathrm{OSC}}$ current. Maximum frequency occurs when the Error Amplifier output is at its low state with a saturation voltage of 0.1 V at 1.0 mA .

The minimum oscillator frequency will result when the IOSC current is zero, and CosC is discharged through the external resistor ( $\mathrm{R}_{\mathrm{OSC}}$ ). This occurs when the Error Amplifier output is at its high state of 2.5 V . The minimum and maximum oscillator frequencies are programmed by the proper selection of resistor $\mathrm{R}_{\mathrm{OSC}}$ and $\mathrm{R}_{\mathrm{VFO}}$. The minimum frequency is programmed by $\mathrm{R}_{\mathrm{OSC}}$ using Equation 1:

$$
\begin{equation*}
\mathrm{R}_{\mathrm{OSC}}=\frac{\frac{1}{f_{(\min )}}-\mathrm{t}_{\text {PD }}}{\mathrm{C}_{\mathrm{OSC}} \ln \left(\frac{5.1}{3.6}\right)}=\frac{\mathrm{t}_{(\mathrm{max})}-70 \mathrm{~ns}}{0.348 \mathrm{C}_{\mathrm{OSC}}} \tag{1}
\end{equation*}
$$

where $t_{P D}$ is the internal propagation delay.
The maximum oscillator frequency is set by the current through resistor $\mathrm{R}_{\mathrm{VFO}}$. The current required to discharge $\mathrm{C}_{\text {OSC }}$ at the maximum oscillator frequency can be calculated by Equation 2:

$$
\begin{equation*}
I_{(\max )}=\operatorname{CoSC}_{\text {OSC }} \frac{5.1-3.6}{\frac{1}{f_{(\max )}}}=1.5 \mathrm{C}_{\text {OSC }^{f}} f_{(\max )} \tag{2}
\end{equation*}
$$

The discharge current through R $_{\text {OSC }}$ must also be known and can be calculated by Equation 3:

$$
\left.\begin{array}{rl}
\mathrm{I}_{\mathrm{OSC}}= & \frac{5.1-3.6}{\mathrm{R}_{\mathrm{OSC}}} \varepsilon  \tag{3}\\
& =\frac{1.5}{\mathrm{R}_{\mathrm{OSC}}} \varepsilon^{\left(-\frac{1}{f_{(\text {min })}}\right.} \mathrm{R}_{\mathrm{OSC}} \mathrm{C}_{\mathrm{OSC}}
\end{array}\right)
$$

Resistor R VFO can now be calculated by Equation 4:

$$
\begin{equation*}
\mathrm{R}_{\text {VFO }}=\frac{2.5-\mathrm{V}_{\text {EAsat }}}{I_{(\max )}-\mathrm{I}_{\mathrm{R}}} \tag{4}
\end{equation*}
$$

## One-Shot Timer

The One-Shot is designed to disable both outputs simultaneously providing a deadtime before either output is enabled. The One-Shot capacitor $\left(\mathrm{C}_{\mathrm{T}}\right)$ is charged concurrently with the oscillator capacitor by transistor Q1, as shown in Figure 16. The one-shot period begins when the oscillator comparator turns off Q 1 , allowing $\mathrm{C}_{\mathrm{T}}$ to discharge. The period ends when resistor $\mathrm{R}_{\mathrm{T}}$ discharges $\mathrm{C}_{\mathrm{T}}$ to the threshold of the One-Shot comparator. The lower threshold of the One-Shot is 3.6 V . By choosing $\mathrm{C}_{\mathrm{T}}, \mathrm{R}_{\mathrm{T}}$ can by solved by Equation 5:

$$
\begin{equation*}
\mathrm{R}_{\mathrm{T}}=\frac{\mathrm{t} O \mathrm{OS}}{\mathrm{C}_{\mathrm{T}} \ln \left(\frac{5.1}{3.6}\right)}=\frac{\mathrm{t}_{\mathrm{OS}}}{0.348 \mathrm{C}_{\mathrm{T}}} \tag{5}
\end{equation*}
$$

Errors in the threshold voltage and propagation delays through the output drivers will affect the One-Shot period. To guarantee accuracy, the output pulse of the control chip is trimmed to within $5 \%$ of 250 ns with nominal values of $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$.

The outputs of the Oscillator and One-Shot comparators are OR'd together to produce the pulse tos, which drives the Flip-Flop and output drivers. The output pulse ( $\mathrm{t}_{\mathrm{OS}}$ ) is initiated by the Oscillator and terminated by the One-Shot comparator. With zero-voltage resonant mode converters, the oscillator discharge time should never be set less than the one-shot period.

## Error Amplifier

A fully accessible high performance Error Amplifier is provided for feedback control of the power supply system. The Error Amplifier is internally compensated and features dc open loop gain greater than 70 dB , input offset voltage of less than 10 mV and a guaranteed minimum gain-bandwidth product of 2.5 MHz . The input common mode range extends from 1.5 V to 5.1 V , which includes the reference voltage.

Figure 17. Error Amplifier and Clamp
When the Error Amplifier output is coupled to the $\mathrm{I}_{\mathrm{OSC}}$ pin by $\mathrm{R}_{\mathrm{VFO}}$, as illustrated in Figure 17, it provides the Oscillator Control Current, IOSC. The output swing of the Error Amplifier is restricted by a clamp circuit to improve its transient recovery time.

## Output Section

The pulse( $\mathrm{t}_{\mathrm{OS}}$ ), generated by the Oscillator and One-Shot timer is gated to dual totem-pole output drives by the Steering Flip-Flop shown in Figure 18. Positive transitions of $\mathrm{t}_{\mathrm{OS}}$ toggle the Flip-Flop, which causes the pulses to alternate between Output A and Output B. The flip-flop is reset by the undervoltage lockout circuit during startup to guarantee that the first pulse appears at Output A.

Figure 18. Steering Flip-Flop and Output Drivers

The totem-pole output drivers are ideally suited for driving power MOSFETs and are capable of sourcing and sinking 1.5 A. Rise and fall times are typically 20 ns when driving a 1.0 nF load. High source/sink capability in a totem-pole driver normally increases the risk of high cross conduction
current during output transitions. The MC34067 utilizes a unique design that virtually eliminates cross conduction, thus controlling the chip power dissipation at high frequencies. A separate power ground pin is provided to isolate the sensitive analog circuitry from large transient currents.

Figure 19. Undervoltage Lockout and Reference

## PERIPHERAL SUPPORT FUNCTIONS

The MC34067 Resonant Controller provides a number of support and protection functions including a precision voltage reference, undervoltage lockout comparators, soft-start circuitry, and a fault detector. These peripheral circuits ensure that the power supply can be turned on and off in a controlled manner and that the system will be quickly disabled when a fault condition occurs.

## Undervoltage Lockout and Voltage Reference

Separate undervoltage lockout comparators sense the input $\mathrm{V}_{\mathrm{CC}}$ voltage and the regulated reference voltage as illustrated in Figure 19. When $\mathrm{V}_{\mathrm{CC}}$ increases to the upper threshold voltage, the $\mathrm{V}_{\mathrm{CC}}$ UVLO comparator enables the Reference Regulator. After the $\mathrm{V}_{\text {ref }}$ output of the Reference Regulator rises to 4.2 V , the $\mathrm{V}_{\text {ref }} \mathrm{UVLO}$ comparator switches the UVLO signal to a logic zero state enabling the primary control path. Reducing $\mathrm{V}_{\mathrm{CC}}$ to the lower threshold voltage causes the $\mathrm{V}_{\mathrm{CC}}$ UVLO comparator to disable the Reference Regulator. The $\mathrm{V}_{\text {ref }}$ UVLO comparator then switches the UVLO output to a logic one state disabling the controller.

The Enable/UVLO Adjust pin allows the power supply designer to select the $\mathrm{V}_{\mathrm{CC}}$ UVLO threshold voltages. When this pin is open, the comparator switches the controller on at 16 V and off at 9.0 V . If this pin is connected to the $\mathrm{V}_{\mathrm{CC}}$ terminal, the upper and lower thresholds are reduced to 9.0 V and 8.6 V , respectively. Forcing the Enable/UVLO Adjust pin low will pull the $\mathrm{V}_{\mathrm{CC}}$ UVLO comparator input low (through an internal diode) turning off the controller.

The Reference Regulator provides a precise 5.1 V reference to internal circuitry and can deliver up to 10 mA to external loads. The reference is trimmed to better than $2 \%$ initial accuracy and includes active short circuit protection.

## Fault Detector

The high speed Fault Comparator illustrated in Figure 20 can protect a power supply from destruction under fault conditions. The Fault Input pin connects to the input of the Fault Comparator. The Fault Comparator output connects to the output drivers. This direct path reduces the propagation delay from the Fault Input to the A and B outputs to typically 70 ns. The Fault Comparator output is also OR'd with the UVLO output from the $\mathrm{V}_{\text {ref }}$ UVLO comparator to produce the logic output labeled "UVLO+Fault". This signal disables the Oscillator and One-Shot by forcing both the $\mathrm{C}_{\text {OSC }}$ and $\mathrm{C}_{\mathrm{T}}$ capacitors to be continually charged.

Figure 20. Fault Detector and Soft-Start

## Soft-Start Circuit

The Soft-Start circuit shown in Figure 20 forces the variable frequency Oscillator to start at the maximum frequency and ramp downward until regulated by the feedback control loop. The external capacitor at the C Soft-Start terminal is initially discharged by the UVLO+Fault signal. The low voltage on the capacitor passes through the Soft-Start Buffer to hold the Error

Amplifier output low. After UVLO+Fault switches to a logic zero, the soft-start capacitor is charged by a $9.0 \mu \mathrm{~A}$ current source. The buffer allows the Error Amplifier output to follow the soft-start capacitor until it is regulated by the Error Amplifier inputs. The soft-start function is generally applicable to controllers operating below resonance and can be disabled by simply opening the $\mathrm{C}_{\text {Soft-Start }}$ terminal.

## APPLICATIONS INFORMATION

The MC34067 is specifically designed for zero voltage switching (ZVS) quasi-resonant converter (QRC) applications. The IC is optimized for double-ended push-pull or bridge type converters operating in continuous conduction mode. Operation of this type of ZVS with resonant properties is similar to standard push-pull or bridge circuits in that the energy is transferred during the transistor on-time. The difference is that a series resonant tank is usually introduced to shape the voltage across the power transistor prior to turn-on. The resonant tank in this topology is not used to deliver energy to the output as is the case with zero current switch topologies. When the power transistor is enabled the voltage across it should already be zero, yielding minimal switching loss. Figure 21 shows a timing diagram for a half-bridge ZVS QRC. An application circuit is shown in Figure 22. The circuit built is a dc to dc half-bridge converter delivering 75 W to the output from a 48 V source.

When building a zero voltage switch (ZVS) circuit, the objective is to waveshape the power transistor's voltage waveform so that the voltage across the transistor is zero when the device is turned on. The purpose of the control IC is to allow a resonant tank to waveshape the voltage across the power transistor while still maintaining regulation. This is accomplished by maintaining a fixed deadtime and by varying the frequency; thus the effective duty cycle is changed.

Primary side resonance can be used with ZVS circuits. In the application circuit, the elements that make the resonant tank are the primary leakage inductance of the transformer $\left(\mathrm{L}_{\mathrm{L}}\right)$ and the average output capacitance ( $\mathrm{C}_{\mathrm{OSS}}$ ) of a power $\operatorname{MOSFET}\left(\mathrm{C}_{\mathrm{R}}\right)$. The desired resonant frequency for the application circuit is calculated by Equation 6:

$$
\begin{equation*}
f_{r}=\frac{1}{2 \pi \sqrt{L_{L}{ }^{2 C_{R}}}} \tag{6}
\end{equation*}
$$

In the application circuit, the operating voltage is low and the value of Coss versus Drain Voltage is known. Because the C COSS of a MOSFET changes with drain voltage, the value of the $C_{R}$ is approximated as the average CoSS of the MOSFET. For the application circuit the average Coss can be calculated by Equation 7:

$$
\begin{equation*}
C_{R}=\sqrt{2} * C_{\text {OSS }} \text { measured at } \frac{1}{2} V_{\text {in }} \tag{7}
\end{equation*}
$$

The MOSFET chosen fixes $\mathrm{C}_{\mathrm{R}}$ and that $\mathrm{L}_{\mathrm{L}}$ is adjusted to achieve the desired resonant frequency.

However, the desired resonant frequency is less critical than the leakage inductance. Figure 21 shows the primary current ramping toward its peak value during the resonant transition. During this time, there is circulating current flowing through the secondary inductance, which effectively makes the primary inductance appear shorted. Therefore, the current through the primary will ramp to its peak value at a rate controlled by the leakage inductance and the applied voltage. Energy is not transferred to the secondary during this stage, because the primary current has not overcome the circulating current in the secondary. The larger the leakage inductance, the longer it takes for the primary current to slew. The practical effect of this is to lower the duty cycle, thus reducing the operating range.

The maximum duty cycle is controlled by the leakage inductance, not by the MC34067. The One-Shot in the MC34067 only assures that the power switch is turned on under a zero voltage condition. Adjust the one-shot period so that the output switch is activated while the primary current is slewing but before the current changes polarity. The resonant stage should then be designed to be as long as the time for the primary current to go to zero amps.

## MAX1720

## Switched Capacitor Voltage Inverter with Shutdown

The MAX1720 is a CMOS charge pump voltage inverter that is designed for operation over an input voltage range of 1.15 V to 5.5 V with an output current capability in excess of 50 mA . The operating current consumption is only $67 \mu \mathrm{~A}$, and a power saving shutdown input is provided to further reduce the current to a mere $0.4 \mu \mathrm{~A}$. The device contains a 12 kHz oscillator that drives four low resistance MOSFET switches, yielding a low output resistance of $26 \Omega$ and a voltage conversion efficiency of $99 \%$. This device requires only two external $10 \mu \mathrm{~F}$ capacitors for a complete inverter making it an ideal solution for numerous battery powered and board level applications. The MAX1720 is available in the space saving TSOP-6 (SOT-23-6) package.

## Features

- Operating Voltage Range of 1.15 V to 5.5 V
- Output Current Capability in Excess of 50 mA
- Low Current Consumption of $67 \mu \mathrm{~A}$
- Power Saving Shutdown Input for a Reduced Current of $0.4 \mu \mathrm{~A}$
- Operation at 12 kHz
- Low Output Resistance of $26 \Omega$
- Space Saving TSOP-6 (SOT-23-6) Package

## Typical Applications

- LCD Panel Bias
- Cellular Telephones
- Pagers
- Personal Digital Assistants
- Electronic Games
- Digital Cameras
- Camcorders
- Hand Held Instruments

## MAX1720

Figure 14. Test Setup/Voltage Inverter

## DETAILED OPERATING DESCRIPTION

The MAX1720 charge pump converter inverts the voltage applied to the $\mathrm{V}_{\text {in }}$ pin. Conversion consists of a two-phase operation (Figure 15). During the first phase, switches $S_{2}$ and $S_{4}$ are open and $S_{1}$ and $S_{3}$ are closed. During this time, $\mathrm{C}_{1}$ charges to the voltage on $\mathrm{V}_{\text {in }}$ and load current is supplied from $C_{2}$. During the second phase, $S_{2}$ and $S_{4}$ are closed, and $S_{1}$ and $S_{3}$ are open. This action connects $C_{1}$ across $C_{2}$, restoring charge to $\mathrm{C}_{2}$.

Figure 15. Ideal Switched Capacitor Charge Pump

## APPLICATIONS INFORMATION

## Output Voltage Considerations

The MAX1720 performs voltage conversion but does not provide regulation. The output voltage will drop in a linear manner with respect to load current. The value of this equivalent output resistance is approximately $26 \Omega$ nominal at $25^{\circ} \mathrm{C}$ with $\mathrm{V}_{\text {in }}=5.0 \mathrm{~V}$. $\mathrm{V}_{\text {out }}$ is approximately -5.0 V at light loads, and drops according to the equation below:

$$
\begin{gathered}
V_{D R O P}=I_{\text {out }} \times R_{\text {out }} \\
V_{\text {out }}=-\left(V_{\text {in }}-V_{\text {DROP }}\right)
\end{gathered}
$$

## Charge Pump Efficiency

The overall power conversion efficiency of the charge pump is affected by four factors:

1. Losses from power consumed by the internal oscillator, switch drive, etc. (which vary with input voltage, temperature and oscillator frequency).
2. I 2 R losses due to the on-resistance of the MOSFET switches on-board the charge pump.
3. Charge pump capacitor losses due to Equivalent Series Resistance (ESR).
4. Losses that occur during charge transfer from the commutation capacitor to the output capacitor when a voltage difference between the two capacitors exists.
Most of the conversion losses are due to factors 2, 3 and 4. These losses are given by Equation 1.

$$
\begin{gather*}
\mathrm{P}_{\text {LOSS }(2,3,4)}=\mathrm{I}_{\text {out }}^{2} \times \mathrm{R}_{\text {out }} \cong \mathrm{I}_{\text {out }}^{2} \times \\
{\left[\frac{1}{\left(\mathrm{f}_{\mathrm{OSC}}\right) \mathrm{C}_{1}}+8 \mathrm{R}_{\text {SWITCH }}+4 \mathrm{ESR}_{\mathrm{C}_{1}}+\mathrm{ESR}_{\mathrm{C}_{2}}\right]} \tag{eq.1}
\end{gather*}
$$

The $1 /\left(\mathrm{f}_{\mathrm{OSC}}\right)\left(\mathrm{C}_{1}\right)$ term in Equation 1 is the effective output resistance of an ideal switched capacitor circuit (Figures 16 and 17).

The losses due to charge transfer above are also shown in Equation 2. The output voltage ripple is given by Equation 3.

$$
\begin{align*}
\mathrm{P}_{\text {LOSS }} & =\left[0.5 \mathrm{C}_{1}\left(\mathrm{~V}_{\text {in }^{2}}-\mathrm{V}_{\text {out }}{ }^{2}\right)\right. \\
& \left.+0.5 \mathrm{C}_{2}\left(\mathrm{~V}_{\text {RIPPLE }}{ }^{2}-2 \mathrm{~V}_{\text {out }} \mathrm{V}_{\text {RIPPLE }}\right)\right] \times \mathrm{f}_{\text {OSC }} \tag{eq.2}
\end{align*}
$$

$V_{\text {RIPPLE }}=\frac{I_{\text {out }}}{\left(\mathrm{f}_{\mathrm{OSC}}\right)\left(\mathrm{C}_{2}\right)}+2\left(\mathrm{I}_{\text {out }}\right)\left(\mathrm{ESR}_{\mathrm{C}_{2}}\right)$

Figure 16. Ideal Switched Capacitor Model

Figure 17. Equivalent Output Resistance

## Capacitor Selection

In order to maintain the lowest output resistance and output ripple voltage, it is recommended that low ESR capacitors be used. Additionally, larger values of $\mathrm{C}_{1}$ will lower the output resistance and larger values of $\mathrm{C}_{2}$ will reduce output voltage ripple. (See Equation 3).

Table 1 shows various values of $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$ with the corresponding output resistance values at $25^{\circ} \mathrm{C}$. Table 2 shows the output voltage ripple for various values of $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$. The data in Tables 1 and 2 was measured not calculated.

## Input Supply Bypassing

The input voltage, $\mathrm{V}_{\text {in }}$ should be capacitively bypassed to reduce AC impedance and minimize noise effects due to the
switching internals in the device. If the device is loaded from $V_{\text {out }}$ to GND, it is recommended that a large value capacitor (at least equal to $\mathrm{C}_{1}$ ) be connected from $\mathrm{V}_{\text {in }}$ to GND. If the device is loaded from $V_{\text {in }}$ to $V_{\text {out }}$, a small $(0.7 \mu \mathrm{~F})$ capacitor between the pins is sufficient.

## Voltage Inverter

The most common application for a charge pump is the voltage inverter (Figure 14). This application uses two or three external capacitors. The $\mathrm{C}_{1}$ (pump capacitor) and $\mathrm{C}_{2}$ (output capacitor) are required. The input bypass capacitor, $\mathrm{C}_{3}$, may be necessary depending on the application. The output is equal to $-\mathrm{V}_{\text {in }}$ plus any voltage drops due to loading. Refer to Tables 1 and 2 for capacitor selection. The test setup used for the majority of the characterization is shown in Figure 14.

## Layout Considerations

As with any switching power supply circuit, good layout practice is recommended. Mount components as close together as possible to minimize stray inductance and capacitance. Also, use a large ground plane to minimize noise leakage into other circuitry.

## Capacitor Resources

Selecting the proper type of capacitor can reduce switching loss. Low ESR capacitors are recommended. The MAX1720 was characterized using the capacitors listed in Table 3. This list identifies low ESR capacitors for the voltage inverter application.

Figure 18. Voltage Inverter

The MAX1720 primary function is a voltage inverter. The device will convert 5.0 V into -5.0 V with light loads. Two capacitors are required for the inverter to function. A third capacitor, the input bypass capacitor, may be required depending on the power source for the inverter. The performance for this device is illustrated below.

Figure 19. Inverter Load Regulation, Output Voltage vs. Output Current

## MAX1720

Figure 20. Cascaded Devices for Increased Negative Output Voltage

Two or more devices can be cascaded for increased output voltage. Under light load conditions, the output voltage is approximately equal to $-\mathrm{V}_{\text {in }}$ times the number of stages. The converter output resistance increases dramatically with each additional stage. This is due to a reduction of input voltage to each successive stage as the converter output is loaded. Note that the ground connection for each successive stage must connect to the negative output of the previous stage. The performance characteristics for a converter consisting of two cascaded devices are shown below.

Figure 29. Tripler Load Regulation, Output Voltage vs. Output Current

Figure 30. Load Regulated Negative Output Voltage

A zener diode can be used with the shutdown input to provide closed loop regulation performance. This significantly reduces the converter's output resistance and dramatically enhances the load regulation. For closed loop operation, the desired regulated output voltage must be lower in magnitude than $-\mathrm{V}_{\mathrm{in}}$. The output will regulate at a level of $-\mathrm{V}_{\mathrm{Z}}+\mathrm{V}_{\mathrm{th}(\overline{\mathrm{SHDN}})}$. Note that the shutdown input voltage threshold is typically $0.5 \mathrm{~V}_{\mathrm{in}}$ and therefore, the regulated output voltage will change proportional to the converter's input. This characteristic will not present a problem when used in applications with constant input voltage. In this case the zener breakdown was measured at $25 \mu \mathrm{~A}$. The performance characteristics for the above converter are shown below. Note that the dashed curve sections represent the converter's open loop performance.

| Curve | $\mathrm{V}_{\text {in }}(\mathrm{V})$ | $\mathrm{V}_{\mathbf{z}}(\mathrm{V})$ | $\mathrm{V}_{\text {out }}(\mathrm{V})$ |

Figure 31. Load Regulation, Output Voltage vs. Output Current

## MAX1720

Figure 32. Line and Load Regulated Negative Output Voltage

An adjustable shunt regulator can be used with the shutdown input to give excellent closed loop regulation performance. The shunt regulator acts as a comparator with a precise input offset voltage which significantly reduces the converter's output resistance and dramatically enhances the line and load regulation. For closed loop operation, the desired regulated output voltage must be lower in magnitude than $-\mathrm{V}_{\mathrm{in}}$. The output will regulate at a level of $-\mathrm{V}_{\text {ref }}\left(\mathrm{R}_{2} / \mathrm{R}_{1}+1\right)$. The adjustable shunt regulator can be from either the TLV431 or TL431 families. The comparator offset or reference voltage is 1.25 V or 2.5 V respectively. The performance characteristics for the converter are shown below. Note that the dashed curve sections represent the converter's open loop performance.

## MAX1720

Figure 35. Paralleling Devices for Increased Negative Output Current
An increase in converter output current capability with a reduction in output resistance can be obtained by paralleling two or more devices. The output current capability is approximately equal to the number of devices paralleled. A single shared output capacitor is sufficient for proper operation but each device does require it's own pump capacitor. Note that the output ripple frequency will be complex since the oscillators are not synchronized. The performance characteristics for a converter consisting of two paralleled devices is shown below.

| Curve | $\mathbf{V}_{\text {in }}(\mathrm{V})$ | $\mathbf{R}_{\text {out }}(\Omega)$ |
| :---: | :---: | :---: |
| $A$ | 5.0 | 14.5 |
| $B$ | 3.0 | 17 |

## MAX1720

Figure 37. External Switch for Increased Negative Output Current

The output current capability of the MAX1720 can be extended beyond 600 mA with the addition of two external switch transistors and two Schottky diodes. The output voltage is approximately equal to $-\mathrm{V}_{\text {in }}$ minus the sum of the base emitter drops of both transistors and the forward voltage of both diodes. The performance characteristics for the converter are shown below. Note that the output resistance is reduced to 0.9 ohms.

Figure 38. Current Boosted Load Regulation, Output Voltage vs. Output Current

Figure 39. Line and Load Regulated Negative Output Voltage with High Current Capability

This converter is a combination of Figures 37 and 32. It provides a line and load regulated output of -2.36 V at up to 450 mA with an input voltage of 5.0 V . The output will regulate at a level of $-\mathrm{V}_{\text {ref }}\left(\mathrm{R}_{2} / \mathrm{R}_{1}+1\right)$. The performance characteristics are shown below. Note, the dashed line is the open loop and the solid line is the closed loop performance.

Figure 40. Current Boosted Load Regulation, Output Voltage vs. Output Current

Figure 41. Current Boosted Line Regulation, Output Voltage vs. Input Voltage

## MAX1720

Figure 42. Positive Output Voltage Doubler with High Current Capability
The MAX1720 can be configured to produce a positive output voltage doubler with current capability in excess of 500 mA . This is accomplished with the addition of two external switch transistors and two Schottky diodes. The output voltage is approximately equal to $2 \mathrm{~V}_{\text {in }}$ minus the sum of the base emitter drops of both transistors and the forward voltage of both diodes. The performance characteristics for the converter is shown below. Note that the output resistance is reduced to 1.9 ohms.

Figure 43. Positive Doubler with Current Boosted Load Regulation, Output Voltage vs. Output Current

## MAX1720

Figure 44. Line and Load Regulated Positive Output Voltage Doubler with High Current Capability
This converter is a combination of Figures 42 and the shunt regulator to close the loop. In this case the anode of the regulator is connected to ground. This convert provides a line and load regulated output of 7.6 V at up to 300 mA with an input voltage of 5.0 V . The output will regulate at a level of $\mathrm{V}_{\text {ref }}\left(\mathrm{R}_{2} / \mathrm{R}_{1}+1\right)$. The open loop configuration is the dashed line and the closed loop is the solid line. The performance characteristics are shown below.

Figure 45. Current Boosted Close Loop Load Regulation, Output Voltage vs. Output Current

Figure 46. Current Boosted Close Loop Line Regulation, Output Voltage vs. Input Voltage

## MAX1720

Figure 47. Negative Input Voltage Splitter

A single device can be used to split a negative input voltage. The output voltage is approximately equal to $-\mathrm{V}_{\text {in }} / 2$. The performance characteristics are shown below. Note that the converter has an output resistance of 10 ohms.

Figure 48. Negative Voltage Splitter Load Regulation, Output Voltage vs. Output Current

## MAX1720

Figure 49. Combination of a Closed Loop Negative Inverter with a Positive Output Voltage Doubler

All of the previously shown converter circuits have only single outputs. Applications requiring multiple outputs can be constructed by incorporating combinations of the former circuits. The converter shown above combines Figures 26 and 32 to form a regulated negative output inverter with a non-regulated positive output doubler. The magnitude of $-\mathrm{V}_{\text {out }}$ is controlled by the resistor values and follows the relationship $-V_{\text {ref }}\left(R_{2} / R_{1}+1\right)$. Since the positive output is not within the feedback loop, its output voltage will increase as the negative output load increases. This cross regulation characteristic is shown in the upper portion of Figure 50. The dashed line is the open loop and the solid line is the closed loop configuration for the load regulation. The load regulation for the positive doubler with a constant load on the $-\mathrm{V}_{\text {out }}$ is shown in Figure 51.

## MAX828, MAX829

## Switched Capacitor Voltage Converter

The MAX828 and MAX829 are CMOS charge pump voltage inverters that are designed for operation over an input voltage range of 1.15 V to 5.5 V with an output current capability in excess of 50 mA . The operating current consumption is only $68 \mu \mathrm{~A}$ for the MAX828 and $118 \mu \mathrm{~A}$ for the MAX829. The devices contain an internal oscillator that operates at 12 kHz for the MAX828 and 35 kHz for the MAX829. The oscillator drives four low resistance MOSFET switches, yielding a low output resistance of $26 \Omega$ and a voltage conversion efficiency of $99.9 \%$. These devices require only two external capacitors, $10 \mu \mathrm{~F}$ for the MAX828 and $3.3 \mu \mathrm{~F}$ for the MAX829, for a complete inverter making it an ideal solution for numerous battery powered and board level applications. The MAX828 and MAX829 are available in the space saving Thin SOT-23-5 package.

## Features

- Operating Voltage Range of 1.15 V to 5.5 V
- Output Current Capability in Excess of 50 mA
- Low Current Consumption of $68 \mu \mathrm{~A}$ (MAX828) or $118 \mu \mathrm{~A}$ (MAX829)
- Operation at 12 kHz (MAX828) or 35 kHz (MAX829)
- Low Output Resistance of $26 \Omega$
- Space Saving Thin SOT-23-5 Package

## Typical Applications

- LCD Panel Bias
- Cellular Telephones
- Pagers
- Personal Digital Assistants
- Electronic Games
- Digital Cameras
- Camcorders
- Hand Held Instruments

This device contains 77 active transistors.

## DETAILED OPERATING DESCRIPTION

The MAX828/829 charge pump converters inverts the voltage applied to the $\mathrm{V}_{\text {in }}$ pin. Conversion consists of a two-phase operation (Figure 21). During the first phase, switches $S_{2}$ and $S_{4}$ are open and $S_{1}$ and $S_{3}$ are closed. During this time, $\mathrm{C}_{1}$ charges to the voltage on $\mathrm{V}_{\text {in }}$ and load current is supplied from $C_{2}$. During the second phase, $S_{2}$ and $S_{4}$ are closed, and $S_{1}$ and $S_{3}$ are open. This action connects $C_{1}$ across $C_{2}$, restoring charge to $C_{2}$.

Figure 21. Ideal Switched Capacitor Charge Pump

## APPLICATIONS INFORMATION

## Output Voltage Considerations

The MAX828/829 performs voltage conversion but does not provide regulation. The output voltage will drop in a linear manner with respect to load current. The value of this equivalent output resistance is approximately $26 \Omega$ nominal at $25^{\circ} \mathrm{C}$ and $\mathrm{V}_{\text {in }}=5.0 \mathrm{~V}$. $\mathrm{V}_{\text {out }}$ is approximately -5.0 V at light loads, and drops according to the equation below:

$$
\begin{gathered}
V_{\text {DROP }}=I_{\text {out }} \times R_{\text {out }} \\
V_{\text {out }}=-\left(V_{\text {in }}-V_{\text {DROP }}\right)
\end{gathered}
$$

## Charge Pump Efficiency

The overall power efficiency of the charge pump is affected by four factors:

1. Losses from power consumed by the internal oscillator, switch drive, etc. (which vary with input voltage, temperature and oscillator frequency).
2. I ${ }^{2}$ R losses due to the on-resistance of the MOSFET switches on-board the charge pump.
3. Charge pump capacitor losses due to Equivalent Series Resistance (ESR).
4. Losses that occur during charge transfer from the commutation capacitor to the output capacitor when a voltage difference between the two capacitors exists.
Most of the conversion losses are due to factors 2, 3 and 4. These losses are given by Equation 1.

$$
\begin{gather*}
\mathrm{P}_{\text {LOSS }(2,3,4)}=\mathrm{I}_{\text {out }}^{2} \times \mathrm{R}_{\text {out }} \cong \mathrm{I}_{\text {out }}{ }^{2} \times \\
{\left[\frac{1}{\left(\mathrm{f}_{\mathrm{OSC}}\right) \mathrm{C}_{1}}+8 \mathrm{R}_{\text {SWITCH }}+4 \mathrm{ESR}_{\mathrm{C}_{1}}+\mathrm{ESR}_{\mathrm{C}_{2}}\right]} \tag{eq.1}
\end{gather*}
$$

The $1 /\left(\mathrm{f}_{\mathrm{OSC}}\right)\left(\mathrm{C}_{1}\right)$ term in Equation 1 is the effective output resistance of an ideal switched capacitor circuit (Figures 22 and 23).

The losses due to charge transfer above are also shown in Equation 2. The output voltage ripple is given by Equation 3.

$$
\begin{align*}
\mathrm{P}_{\text {LOSS }} & =\left[0.5 \mathrm{C}_{1}\left(\mathrm{~V}_{\text {in }^{2}}-\mathrm{V}_{\text {out }}{ }^{2}\right)\right. \\
& \left.+0.5 \mathrm{C}_{2}\left(\mathrm{~V}_{\text {RIPPLE }}{ }^{2}-2 \mathrm{~V}_{\text {out }} \mathrm{V}_{\text {RIPPLE }}\right)\right] \times \mathrm{f} \text { OSC } \tag{eq.2}
\end{align*}
$$

$\mathrm{V}_{\text {RIPPLE }}=\frac{\mathrm{I}_{\text {out }}}{\left(\mathrm{f}_{\mathrm{OSC}}\right)\left(\mathrm{C}_{2}\right)}+2\left(\mathrm{I}_{\text {out }}\right)\left(\mathrm{ESR}_{\mathrm{C}_{2}}\right)$

Figure 22. Ideal Switched Capacitor Model

Figure 23. Equivalent Output Resistance

## Capacitor Selection

In order to maintain the lowest output resistance and output ripple voltage, it is recommended that low ESR capacitors be used. Additionally, larger values of $\mathrm{C}_{1}$ will lower the output resistance and larger values of $\mathrm{C}_{2}$ will reduce output voltage ripple. (See Equation 3).

Table 1 shows various values of $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$ with the corresponding output resistance values at $25^{\circ} \mathrm{C}$. Table 2 shows the output voltage ripple for various values of $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$. The data in Tables 1 and 2 was measured not calculated.

## Input Supply Bypassing

The input voltage, $\mathrm{V}_{\text {in }}$ should be capacitively bypassed to reduce AC impedance and minimize noise effects due to the switching internals in the device. If the device is loaded from $V_{\text {out }}$ to GND, it is recommended that a large value capacitor (at least equal to $\mathrm{C}_{1}$ ) be connected from $\mathrm{V}_{\text {in }}$ to GND. If the device is loaded from $\mathrm{V}_{\text {in }}$ to $\mathrm{V}_{\text {out }}$ a small $(0.7 \mu \mathrm{~F})$ capacitor between the pins is sufficient.

## Voltage Inverter

The most common application for a charge pump is the voltage inverter (Figure 20). This application uses two or three external capacitors. The capacitors $\mathrm{C}_{1}$ (pump capacitor) and $\mathrm{C}_{2}$ (output capacitor) are required. The input bypass capacitor $\mathrm{C}_{3}$, may be necessary depending on the application. The output is equal to $-\mathrm{V}_{\text {in }}$ plus any voltage drops due to loading. Refer to Tables 1 and 2 for capacitor selection. The test setup used for the majority of the characterization is shown in Figure 20.

## Layout Considerations

As with any switching power supply circuit, good layout practice is recommended. Mount components as close together as possible to minimize stray inductance and capacitance. Also use a large ground plane to minimize noise leakage into other circuitry.

## Capacitor Resources

Selecting the proper type of capacitor can reduce switching loss. Low ESR capacitors are recommended. The MAX828 and MAX829 were characterized using the capacitors listed in Table 3. This list identifies low ESR capacitors for the voltage inverter application.

MAX828: Capacitors $=10 \mu \mathrm{~F}$
MAX829: Capacitors $=3.3 \mu \mathrm{~F}$
Figure 24. Voltage Inverter

The MAX828 / 829 primary function is a voltage inverter. The device will convert 5.0 V into -5.0 V with light loads. Two capacitors are required for the inverter to function. A third capacitor, the input bypass capacitor, may be required depending on the power source for the inverter. The performance for this device is illustrated below.

## MAX828, MAX829

Figure 27. Cascade Devices for Increased Negative Output Voltage

Two or more devices can be cascaded for increased output voltage. Under light load conditions, the output voltage is approximately equal to $-\mathrm{V}_{\text {in }}$ times the number of stages. The converter output resistance increases dramatically with each additional stage. This is due to a reduction of input voltage to each successive stage as the converter output is loaded. Note that the ground connection for each successive stage must connect to the negative output of the previous stage. The performance characteristics for a converter consisting of two cascaded devices are shown below.

Figure 42. Paralleling Devices for Increased Negative Output Current

An increase in converter output current capability with a reduction in output resistance can be obtained by paralleling two or more devices. The output current capability is approximately equal to the number of devices paralleled. A single shared output capacitor is sufficient for proper operation but each device does require it's own pump capacitor. Note that the output ripple frequency will be complex since the oscillators are not synchronized. The output resistance is approximately equal to the output resistance of one device divided by the total number of devices paralleled. The performance characteristics for a converter consisting of two paralleled devices is shown below.

| C | 5.0 | 14.4 |
| D | 3.0 | 17.3 |

Figure 45. External Switch for Increased Negative Output Current

The output current capability of the MAX828 and MAX829 can be extended beyond 600 mA with the addition of two external switch transistors and two Schottky diodes. The output voltage is approximately equal to $-\mathrm{V}_{\mathrm{in}}$ minus the sum of the base emitter drops of both transistors and the forward voltage of both diodes. The performance characteristics for the converter are shown below. Note that the output resistance is reduced to 0.9 and 1.0 ohms for the 828 and 829 respectively.

Figure 46. Current Boosted Load Regulation, Output Voltage vs. Output Current MAX828

Figure 47. Current Boosted Load Regulation, Output Voltage vs. Output Current MAX829

Figure 48. Positive Output Voltage Doubler with High Current Capability

The MAX828 / 829 can be configured to produce a positive output voltage doubler with current capability in excess of 500 mA . This is accomplished with the addition of two external switch transistors and two Schottky diodes. The output voltage is approximately equal to $2 \mathrm{~V}_{\text {in }}$ minus the sum of the base emitter drops of both transistors and the forward voltage of both diodes. The performance characteristics for the converter are shown below. Note that the output resistance is reduced to 1.8 ohms.

Figure 49. Positive Doubler with Current Boosted Load Regulation, Output Voltage vs. Output Current, MAX828

Figure 50. Positive Doubler with Current Boosted Load Regulation, Output Voltage vs. Output Current, MAX829

Figure 51. A Positive Doubler, with a Negative Inverter
All of the previously shown converter circuits have only single outputs. Applications requiring multiple outputs can be constructed by incorporating combinations of the former circuits. The converter shown above combines Figures 24 and 36 to form a negative output inverter with a positive output doubler. Different combinations of load regulation are shown below. In Figures 52 and 53 the positive doubler has a constant $\mathrm{I}_{\mathrm{out}}=15 \mathrm{~mA}$ while the negative inverter has the variable load. In Figures 54 and 55 the negative inverter has the constant $\mathrm{I}_{\mathrm{out}}=15 \mathrm{~mA}$ and the positive doubler has the variable load.

| Thin SOT-23-5 | 8 mm | 4 mm | 3000 | 7 inches |

## CS5150H

## CPU 4-Bit Synchronous Buck Controller

The CS5150H is a 4-bit synchronous dual N -Channel buck controller. It is designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. The regulator operates using a proprietary control method, which allows a 100 ns response time to load transients. The CS5150H is designed to operate over a $4.25-20 \mathrm{~V}$ range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V or 12 V as the main supply for conversion.

The CS5150H is specifically designed to power Pentium ${ }^{\circledR}$ Pro processors and other high performance core logic. It includes the following features: on board, 4-bit DAC, short circuit protection, $1.0 \%$ output tolerance, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The CS5150H is upward compatible with the 5-bit CS5155H, allowing the mother board designer the capability of using either the CS5150H or the CS5155H with no change in layout. The CS5150H is available in 16 pin surface mount.

## Features

- Dual N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 4-Bit DAC
- Upward Compatible with 5-Bit CS5155H/CS5156H
- 30 ns Gate Rise/Fall Times
- $1.0 \%$ DAC Accuracy
- 5.0 V \& 12 V Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- 25 ns FET Nonoverlap Time
- Adaptive Voltage Positioning
- $\mathrm{V}^{2 \mathrm{Tm}}$ Control Topology
- Current Sharing
- Overvoltage Protection

PIN CONNECTIONS

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| 16 Lead SO Narrow |  |  |
| 1, 2, 3, 4 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID3 }}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V providing logic ones if left open. The DAC range is 2.14 V to 3.54 V with 100 mV increments. $\mathrm{V}_{\text {IDO }}-\mathrm{V}_{\text {ID3 }}$ select the desired DAC output voltage. Leaving all 4 DAC input pins open results in a DAC output voltage of 1.244 V , allowing for adjustable output voltage, using a traditional resistor divider. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND in conjunction with internal $60 \mu \mathrm{~A}$ current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 6 | NC | No Connection. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $\mathrm{V}_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Boosted power for the high side gate driver. |
| 10 | $\mathrm{V}_{\text {GATE(H) }}$ | High FET driver pin capable of 1.5 A peak switching current. Internal circuit prevents $\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}$ and $\mathrm{V}_{\mathrm{GATE}(\mathrm{L})}$ from being in high state simultaneously. |
| 11 | PGND | High current ground for the IC. The MOSFET drivers are referenced to this pin. Input capacitor ground and the source of lower FET should be tied to this pin. |
| 12 | $\mathrm{V}_{\text {GATE(L) }}$ | Low FET driver pin capable of 1.5 A peak switching current. |
| 13 | $\mathrm{V}_{\mathrm{CC} 1}$ | Input power for the IC and low side gate driver. |
| 14 | LGND | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $V_{F B}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## $\mathrm{V}^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. V ${ }^{2}$ Control Diagram

The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5150H uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $30 \mu \mathrm{~s}$ timer, minimizing stress to the power components.

## Programmable Output

The CS5150H is designed to provide two methods for programming the output voltage of the power supply. A four bit on board digital to analog converter (DAC) is used to program the output voltage from 2.14 V to 3.54 V in 100 mV steps, depending on the digital input code. If all four bits are left open, the CS5150H enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{FFB}}$ pins, as in traditional controllers. The CS5150H is specifically designed to be upwards compatible with the CS5155H, which uses a five bit DAC code.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 3.9 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the $\operatorname{GATE}(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.

If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE(H) pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.
When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the C CoFF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.
The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP
capacitor charging to its final value. Its voltage is limited by the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

## Normal Operation

During normal operation, switch off time is constant and set by the C OFF capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The CS5150H V ${ }^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

Overall load transient response is further improved through a feature called "adaptive voltage positioning". This technique pre-positions the output capacitor's voltage to reduce total output voltage excursions during changes in load.

Holding tolerance to $1.0 \%$ allows the error amplifier's reference voltage to be targeted +40 mV high without compromising DC accuracy. A "droop resistor", implemented through a PC board trace, connects the error amplifier's feedback pin $\left(\mathrm{V}_{\mathrm{FB}}\right)$ to the output capacitors and load and carries the output current. With no load, there is no DC drop across this resistor, producing an output voltage tracking the error amplifier's, including the +40 mV offset. When the full load current is delivered, an 80 mV drop is developed across this resistor. This results in output voltage being offset -40 mV low.

The result of adaptive voltage positioning is that additional margin is provided for a load transient before reaching the output voltage specification limits. When load current suddenly increases from its minimum level, the output capacitor is pre-positioned +40 mV . Conversely, when load current suddenly decreases from its maximum
level, the output capacitor is pre-positioned -40 mV (see Figures 9, 10, and 11). For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.
If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $\mathrm{V}_{\mathrm{C} 1}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 3.75 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 3.70 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs ( $\mathrm{V}_{\mathrm{FFB}}<1.0$ V ), the $\mathrm{V}_{\mathrm{FFB}}$ low comparator sets the FAULT latch. This causes the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=$ $3.3 \%$ ), while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board
traces than occurs with constant NO TAGcurrent limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Figure 12. CS5150H Demonstration Board Hiccup Mode Short Circuit Protection. Gate Pulses are Delivered While the Soft Start Capacitor Charges, and Cease During Discharge

Figure 13. Startup with Regulator Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 14 and 15). The regulator will remain in this state until the overvoltage
condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function.

Trace 1- Regulator Output Voltage ( $1.0 \mathrm{~V} / \mathrm{div}$.)
Figure 15. OVP Response to an Input-to-Output Short Circuit by Pulling the Input Voltage to Ground

## External Output Enable Circuit

On/off control of the regulator can be implemented through the addition of two additional discrete components (see Figure 16). This circuit operates by pulling the Soft Start pin high, and the $\mathrm{V}_{\mathrm{FFB}}$ pin low, emulating a short circuit condition.

Figure 16. Implementing Shutdown with the CS5150H

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 17). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
\text { VPower Good }=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $\mathrm{V}_{\text {Power Good }}$.

## Selecting External Components

The CS5150H can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and utilize logic level MOSFETs. A charge pump may be easily implemented to permit use of standard MOSFETs or support 5.0 V or 12 V only systems (maximum of 20 V ). Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the MOSFET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the MOSFET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC} 1}=\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;

$$
\mathrm{VGATE}(\mathrm{H})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}, \mathrm{VGATE}(\mathrm{~L})=12 \mathrm{~V}
$$

Figure 19. CS5150H Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is RDS $_{\mathrm{ON}}$, which effects regulator efficiency and MOSFET thermal management requirements.

The power dissipated by the MOSFETs may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\mathrm{ILOAD}^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:

$$
\text { Power }=\mathrm{I}_{\text {LOAD }}{ }^{2} \times \text { RDSON } \times(1-\text { duty cycle })
$$

Duty Cycle =

$$
\frac{\text { VOUT }+(\text { LLOAD } \times \text { RDSON OF SYNCH FET })}{\left[\begin{array}{l}
\text { VIN }+(\mathrm{ILOAD} \times \text { RDSON OF SYNCH FET }) \\
-(\mathrm{ILOAD} \times \text { RDSON OF SWITCH FET })
\end{array}\right]}
$$

## Off Time Capacitor (Coff)

The C CFF timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

When the $\mathrm{V}_{\text {FFB }}$ pin is less than 1.0 V , the current charging the $\mathrm{C}_{\text {OFF }}$ capacitor is reduced. The extended off time can be calculated as follows:

$$
\text { TOFF }=\text { COFF } \times 24,242.5
$$

Off time will be determined by either the $\mathrm{T}_{\mathrm{OFF}}$ time, or the time out timer, whichever is longer.
(see Figure 19.)

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the COFF timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous MOSFET

A Schottky diode may be placed in parallel with the synchronous MOSFET to conduct the inductor current upon turn off of the switching MOSFET to improve efficiency. The CS5150H reference circuit does not use this device due to its excellent design. Instead, the body diode of the synchronous MOSFET is utilized to reduce cost and conducts the inductor current. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense (see Figure 8, channel 2). The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=\mathrm{V}_{\mathrm{BD}} \times$ LLOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the CS5150H demonstration board as shown in Figure 8;
Power $=1.6 \mathrm{~V} \times 13 \mathrm{~A} \times 100 \mathrm{~ns} \times 233 \mathrm{kHz}=0.48 \mathrm{~W}$
This is only $1.3 \%$ of the 36.4 W being delivered to the load.

## "Droop" Resistor for Adaptive Voltage Positioning

Adaptive voltage positioning is used to reduce output voltage excursions during abrupt changes in load current. Regulator output voltage is offset +40 mV when the regulator is unloaded, and -40 mV at full load. This results in increased margin before encountering minimum and maximum transient voltage limits, allowing use of less capacitance on the regulator output (see Figure 9).

To implement adaptive voltage positioning, a "droop" resistor must be connected between the output inductor and output capacitors and load. This is normally implemented by a PC board trace of the following value:

$$
\mathrm{RDROOP}=\frac{80 \mathrm{mV}}{\operatorname{l} \mathrm{MAX}}
$$

Adaptive voltage positioning can be disabled for improved $D C$ regulation by connecting the $V_{F B}$ pin directly to the load using a separate, non-load current carrying circuit trace.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to
provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:
Thermal Impedance $=\frac{\text { TJUNCTION }(\text { MAX })-\text { TAMBIENT }}{\text { Power }}$
A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 20. Filter Components

Figure 21. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGND).
2. Connect pin 11 (PGND) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGND).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGND).
6. To implement adaptive voltage positioning, connect both slow and fast feedback pins $16\left(\mathrm{~V}_{\mathrm{FB}}\right)$ and 8 $\left(\mathrm{V}_{\mathrm{FFB}}\right)$ to the regulator output right at the inductor terminal. Connect inductor to the output capacitors via a trace with the following resistance:

$$
\text { RTRACE }=\frac{80 \mathrm{mV}}{\mathrm{I}_{\mathrm{MAX}}}
$$

This causes the output voltage to be +40 mV with no load, and -40 mV with a full load, improving regulator transient response. This trace must be wide enough to carry the full output current. (Typical trace is 1.0 inch long, 0.17 inch wide). Care should be taken to minimize any additional losses after the feedback connection point to maximize regulation.
7. If DC regulation is to be optimized (at the expense of degraded transient regulation), adaptive voltage positioning can be disabled by connecting to $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
8. Place 5.0 V input capacitors close to the switching MOSFET and synchronous MOSFET.

Route gate drive signals $\mathrm{V}_{\text {GATE(H) }}$ (pin 10) and $\mathrm{V}_{\text {GATE(L) }}$ (pin 12 when used) with traces that are a minimum of 0.025 inches wide.

## CS5151H

## CPU 4-Bit Nonsynchronous Buck Controller

The CS5151H is a 4-bit nonsynchronous N-Channel buck controller. It is designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. The regulator operates using a proprietary control method, which allows a 100 ns response time to load transients. The CS5151H is designed to operate over a $4.25-20 \mathrm{~V}$ range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V or 12 V as the main supply for conversion.

The CS5151H is specifically designed to power Pentium ${ }^{\circledR}$ processors with $\mathrm{MMX}^{\mathrm{TM}}$ Technology and other high performance core logic. It includes the following features: on board, 4-bit DAC, short circuit protection, $1.0 \%$ output tolerance, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The CS5151H is upwards compatible with the 5-bit CS5156H, allowing the mother board designer the capability of using either the CS5151H or the CS5156H with no change in layout. The CS5151H is available in 16 pin surface mount package.

## Features

- N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 4-Bit DAC
- Upward Compatible with 5-Bit CS5155H/CS5156H
- 30 ns Gate Rise/Fall Times
- $1.0 \%$ DAC Accuracy
- 5.0 V \& 12 V Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- Adaptive Voltage Positioning
- $\mathrm{V}^{2 \mathrm{Tm}}$ Control Topology
- Current Sharing
- Overvoltage Protection

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| 16 Lead SO Narrow |  |  |
| 1, 2, 3, 4 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID3 }}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V providing logic ones if left open. The DAC range is 2.14 V to 3.54 V with 100 mV increments. $\mathrm{V}_{\text {IDO }}-\mathrm{V}_{\text {ID3 }}$ select the desired DAC output voltage. Leaving all 4 DAC input pins open results in a DAC output voltage of 1.244 V , allowing for adjustable output voltage, using a traditional resistor divider. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND in conjunction with internal $60 \mu \mathrm{~A}$ current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 6, 12 | NC | No Connection. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $\mathrm{V}_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Boosted power for the gate driver. |
| 10 | $\mathrm{V}_{\text {GATE }}$ | MOSFET driver pin capable of 1.5 A peak switching current. |
| 11 | PGND | High current ground for the IC. The MOSFET driver is referenced to this pin. Input capacitor ground and the anode of the Schottky diode should be tied to this pin. |
| 13 | $\mathrm{V}_{\mathrm{CC} 1}$ | Input power for the IC. |
| 14 | LGND | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $V_{\text {FB }}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## $\mathrm{V}^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. V ${ }^{2}$ Control Diagram

The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5151H uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $30 \mu \mathrm{~s}$ timer, minimizing stress to the power components.

## Programmable Output

The CS5151H is designed to provide two methods for programming the output voltage of the power supply. A four bit on board digital to analog converter (DAC) is used to program the output voltage from 2.14 V to 3.54 V in 100 mV steps, depending on the digital input code. If all four bits are left open, the CS5151H enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{FFB}}$ pins, as in traditional controllers. The CS5151H is specifically designed to be upwards compatible with the CS5156H, which uses a five bit DAC code.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 3.9 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the GATE output is activated, and the Soft Start capacitor begins charging. The GATE output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.
If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE pin drives low for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. Then, the GATE pin will drive high, and the cycle repeats.

When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the C CoFF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.
The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP capacitor charging to its final value. Its voltage is limited by
the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

## Normal Operation

During normal operation, switch off time is constant and set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The CS5151H V ${ }^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

Overall load transient response is further improved through a feature called "adaptive voltage positioning". This technique pre-positions the output capacitor's voltage to reduce total output voltage excursions during changes in load.

Holding tolerance to $1.0 \%$ allows the error amplifier's reference voltage to be targeted +40 mV high without compromising DC accuracy. A "droop resistor", implemented through a PC board trace, connects the error amplifier's feedback pin $\left(\mathrm{V}_{\mathrm{FB}}\right)$ to the output capacitors and load and carries the output current. With no load, there is no DC drop across this resistor, producing an output voltage tracking the error amplifier's, including the +40 mV offset. When the full load current is delivered, an 80 mV drop is developed across this resistor. This results in output voltage being offset -40 mV low.

The result of adaptive voltage positioning is that additional margin is provided for a load transient before reaching the output voltage specification limits. When load current suddenly increases from its minimum level, the output capacitor is pre-positioned +40 mV . Conversely, when load current suddenly decreases from its maximum
level, the output capacitor is pre-positioned -40 mV (see Figures 9, 10, and 11). For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.
If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $\mathrm{V}_{\mathrm{C} 1}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 3.75 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 3.70 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs ( $\mathrm{V}_{\mathrm{FFB}}<1.0 \mathrm{~V}$ ), the $\mathrm{V}_{\mathrm{FFB}}$ low comparator sets the FAULT latch. This causes the MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=$ $3.3 \%$ ), while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board
traces than occurs with constant current limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Figure 12. CS5151H Demonstration Board Hiccup Mode Short Circuit Protection. Gate Pulses are Delivered While the Soft Start Capacitor Charges, and Cease During Discharge

Figure 13. Startup with Regulator Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the MOSFET to shut off, disconnecting the regulator from it's input voltage.

## External Output Enable Circuit

On/off control of the regulator can be implemented through two additional discrete components (see Figure 14).

This circuit operates by pulling the Soft Start pin high, and the $\mathrm{V}_{\mathrm{FFB}}$ pin low, emulating a short circuit condition.

Figure 14. Implementing Shutdown with the CS5151H

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 15). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
V_{\text {Power Good }}=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $V_{\text {Power Good }}$.

## Selecting External Components

The CS5151H can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and use logic level MOSFETs. A charge pump may be easily implemented to permit use of standard MOSFETs or support 5.0 V or 12 V only systems (maximum of 20 V ). Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the MOSFET gates depends on the application circuit used. The gate driver output is specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of its bias supply when in the high state. In practice, the MOSFET gate will be driven rail to rail due to overshoot caused by the capacitive load it presents to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC} 1}=$ $\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;

$$
\mathrm{V}_{\mathrm{GATE}}=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}
$$

(see Figure 17.)

Figure 17. CS5151H Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is RDS $_{\text {ON }}$, which effects regulator efficiency and MOSFET thermal management requirements.

The power dissipated by the MOSFET and the Schottky diode may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\text { LLOAD }^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Schottky diode:

$$
\text { Power }=\text { VFORWARD } \times \text { ILOAD } \times(1-\text { duty cycle })
$$

Duty Cycle =
VOUT + VFORWARD
$\overline{\mathrm{V}_{\text {IN }}}+\mathrm{V}_{\text {FORWARD }}-($ ILOAD $\times$ RDSON OF SYNCH FET) $)$

## Off Time Capacitor (Coff)

The C Coff timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

When the $\mathrm{V}_{\text {FFB }}$ pin is less than 1.0 V , the current charging the $\mathrm{C}_{\mathrm{OFF}}$ capacitor is reduced. The extended off time can be calculated as follows:

$$
\text { TOFF }=\text { COFF } \times 24,242.5
$$

Off time will be determined by either the $\mathrm{T}_{\mathrm{OFF}}$ time, or the time out timer, whichever is longer.

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\mathrm{OFF}}$ timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:
Period $=\frac{1}{\text { switching frequency }}$
"Droop" Resistor for Adaptive Voltage Positioning
Adaptive voltage positioning is used to reduce output voltage excursions during abrupt changes in load current. Regulator output voltage is offset +40 mV when the regulator is unloaded, and -40 mV at full load. This results in increased margin before encountering minimum and maximum transient voltage limits, allowing use of less capacitance on the regulator output (see Figure 9).

To implement adaptive voltage positioning, a "droop" resistor must be connected between the output inductor and output capacitors and load. This is normally implemented by a PC board trace of the following value:

$$
\text { RDROOP }=\frac{80 \mathrm{mV}}{\mathrm{I} \mathrm{MAX}}
$$

Adaptive voltage positioning can be disabled for improved DC regulation by connecting the $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load using a separate, non-load current carrying circuit trace.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:
Thermal Impedance $=\frac{\text { TJUNCTION(MAX) }- \text { TAMBIENT }}{\text { Power }}$
A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 18. Filter Components

Figure 19. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGND).
2. Connect pin 11 (PGND) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGND).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGND).
6. To implement adaptive voltage positioning, connect both slow and fast feedback pins $16\left(\mathrm{~V}_{\mathrm{FB}}\right)$ and 8 $\left(\mathrm{V}_{\mathrm{FFB}}\right)$ to the regulator output right at the inductor terminal. Connect inductor to the output capacitors via a trace with the following resistance:

$$
\text { RTRACE }=\frac{80 \mathrm{mV}}{\mathrm{I}_{\mathrm{MAX}}}
$$

This causes the output voltage to be +40 mV with no load, and -40 mV with a full load, improving regulator transient response. This trace must be wide enough to carry the full output current. (Typical trace is 1.0 inch long, 0.17 inch wide). Care should be taken to minimize any additional losses after the feedback connection point to maximize regulation.
7. If DC regulation is to be optimized (at the expense of degraded transient regulation), adaptive voltage positioning can be disabled by connecting to $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
8. Place 5.0 V input capacitors close to the switching MOSFET.

Route gate drive signals $\mathrm{V}_{\text {GATE }}$ (pin 10) with a trace that is a minimum of 0.025 inches wide.

## CS5155H

## CPU 5-Bit Synchronous Buck Controller

The CS5155H is a 5 -bit synchronous dual N -Channel buck controller. It is designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. The regulator operates using a proprietary control method, which allows a 100 ns response time to load transients. The CS5155H is designed to operate over a $4.25-20 \mathrm{~V}$ range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V or 12 V as the main supply for conversion.

The CS5155H is specifically designed to power Pentium ${ }^{\circledR}$ II processors and other high performance core logic. It includes the following features: on board, 5-bit DAC, short circuit protection, $1.0 \%$ output tolerance, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The CS5155H is backwards compatible with the 4-bit CS5150, allowing the mother board designer the capability of using either the CS5150 or the CS5155H with no change in layout. The CS5155H is available in 16 pin surface mount packages.

## Features

- Dual N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 5-Bit DAC
- Backward Compatible with 4-Bit CS5150H/CS5151H
- 30 ns Gate Rise/Fall Times
- $1.0 \%$ DAC Accuracy
- 5.0 V \& 12 V Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- 25 ns FET Nonoverlap Time
- Adaptive Voltage Positioning
- $\mathrm{V}^{2 \mathrm{Tm}}$ Control Topology
- Current Sharing
- Overvoltage Protection

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| SO-16 | PIN SYMBOL | FUNCTION |
| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID } 4}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V providing logic ones if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is High (logic one), the DAC range is 2.14 V to 3.54 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is Low (logic zero), the DAC range is 1.34 V to 2.09 V with 50 mV increments. $\mathrm{V}_{\text {IDO }}-\mathrm{V}_{\text {ID4 }}$ select the desired DAC output voltage. Leaving all 5 DAC input pins open results in a DAC output voltage of 1.244 V , allowing for adjustable output voltage, using a traditional resistor divider. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND in conjunction with internal $60 \mu \mathrm{~A}$ current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $\mathrm{V}_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Boosted power for the high side gate driver. |
| 10 | $\mathrm{V}_{\text {GATE(H) }}$ | High FET driver pin capable of 1.5 A peak switching current. Internal circuit prevents $\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}$ and $\mathrm{V}_{\mathrm{GATE}(\mathrm{L})}$ from being in high state simultaneously. |
| 11 | PGND | High current ground for the IC. The MOSFET driver is referenced to this pin. Input capacitor ground and the source of lower FET should be tied to this pin. |
| 12 | $\mathrm{V}_{\text {GATE(L) }}$ | Low FET driver pin capable of 1.5 A peak switching current. |
| 13 | $\mathrm{V}_{\text {CC1 }}$ | Input power for the IC and low side gate driver. |
| 14 | LGND | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $V_{F B}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## $\mathrm{V}^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. V ${ }^{2}$ Control Diagram

The $V^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5155H uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $30 \mu \mathrm{~s}$ timer, minimizing stress to the power components.

## Programmable Output

The CS5155H is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.14 V to 3.54 V in 100 mV steps, the second is 1.34 V to 2.09 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS5155H enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{FFB}}$ pins, as in traditional controllers. The CS5155H is specifically designed to be backwards compatible with the CS5150, which uses a four bit DAC code.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 3.9 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the GATE $(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.

If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE(H) pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.
When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the C CoFF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.
The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP
capacitor charging to its final value. Its voltage is limited by the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

## Normal Operation

During normal operation, switch off time is constant and set by the C OFF capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The CS5155H V ${ }^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

Overall load transient response is further improved through a feature called "adaptive voltage positioning". This technique pre-positions the output capacitor's voltage to reduce total output voltage excursions during changes in load.

Holding tolerance to $1.0 \%$ allows the error amplifier's reference voltage to be targeted +40 mV high without compromising DC accuracy. A "droop resistor", implemented through a PC board trace, connects the error amplifier's feedback pin $\left(\mathrm{V}_{\mathrm{FB}}\right)$ to the output capacitors and load and carries the output current. With no load, there is no DC drop across this resistor, producing an output voltage tracking the error amplifier's, including the +40 mV offset. When the full load current is delivered, an 80 mV drop is developed across this resistor. This results in output voltage being offset -40 mV low.

The result of adaptive voltage positioning is that additional margin is provided for a load transient before reaching the output voltage specification limits. When load current suddenly increases from its minimum level, the output capacitor is pre-positioned +40 mV . Conversely, when load current suddenly decreases from its maximum
level, the output capacitor is pre-positioned -40 mV (see Figures 9, 10, and 11). For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.
If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $\mathrm{V}_{\mathrm{C} 1}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 3.75 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 3.70 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs ( $\mathrm{V}_{\mathrm{FFB}}<1.0 \mathrm{~V}$ ), the $\mathrm{V}_{\mathrm{FFB}}$ low comparator sets the FAULT latch. This causes the MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=$ $3.3 \%$ ), while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board
traces than occurs with constant current limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Figure 13. Startup with Regulator Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 14 and 15 ). The regulator will remain in this state until the overvoltage
condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function.

Trace 4-5.0 V from PC Power Supply (2.0 V/div.)
Trace 1- Regulator Output Voltage (1.0 V/div.)
Figure 15. OVP Response to an Input-to-Output Short Circuit by Pulling the Input Voltage to Ground

## External Output Enable Circuit

On/off control of the regulator can be implemented through the addition of two additional discrete components (see Figure 16). This circuit operates by pulling the Soft Start pin high, and the $\mathrm{V}_{\mathrm{FFB}}$ pin low, emulating a short circuit condition.

Figure 16. Implementing Shutdown with the CS5155H

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 17). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
\text { VPower Good }=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $\mathrm{V}_{\text {Power Good }}$.

## Selecting External Components

The CS5155H can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and use logic level MOSFETs. A charge pump may be easily implemented to support 5.0 V or 12 V only systems (maximum of 20 V ). Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the MOSFET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the MOSFET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC} 1}=\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;

$$
\operatorname{VGATE}(\mathrm{H})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}, \mathrm{VGATE}(\mathrm{~L})=12 \mathrm{~V}
$$

Figure 19. CS5155H Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is RDS $_{\mathrm{ON}}$, which effects regulator efficiency and MOSFET thermal management requirements.

The power dissipated by the MOSFETs may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\mathrm{ILOAD}^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:

$$
\text { Power }=\mathrm{I}_{\text {LOAD }}{ }^{2} \times \text { RDSON } \times(1-\text { duty cycle })
$$

Duty Cycle =

$$
\frac{\text { VOUT }+(\text { LLOAD } \times \text { RDSON OF SYNCH FET })}{\left[\begin{array}{l}
\text { VIN }+(\text { ILOAD } \times \text { RDSON OF SYNCH FET }) \\
-(\text { ILOAD } \times \text { RDSON OF SWITCH FET })
\end{array}\right]}
$$

## Off Time Capacitor (Coff)

The C CFF timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

When the $\mathrm{V}_{\text {FFB }}$ pin is less than 1.0 V , the current charging the $\mathrm{C}_{\text {OFF }}$ capacitor is reduced. The extended off time can be calculated as follows:

$$
\text { TOFF }=\text { COFF } \times 24,242.5
$$

Off time will be determined by either the $\mathrm{T}_{\mathrm{OFF}}$ time, or the time out timer, whichever is longer.
(see Figure 19.)

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\text {OFF }}$ timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous MOSFET

A Schottky diode may be placed in parallel with the synchronous MOSFET to conduct the inductor current upon turn off of the switching MOSFET to improve efficiency. The CS5155H reference circuit does not use this device due to it's excellent design. Instead, the body diode of the synchronous MOSFET is utilized to reduce cost and conducts the inductor current. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense (see Figure 8, channel 2). The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=V_{B D} \times$ LLOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the CS5155H demonstration board as shown in Figure 8;
Power $=1.6 \mathrm{~V} \times 13 \mathrm{~A} \times 100 \mathrm{~ns} \times 233 \mathrm{kHz}=0.48 \mathrm{~W}$
This is only $1.3 \%$ of the 36.4 W being delivered to the load.

## "Droop" Resistor for Adaptive Voltage Positioning

Adaptive voltage positioning is used to reduce output voltage excursions during abrupt changes in load current. Regulator output voltage is offset +40 mV when the regulator is unloaded, and -40 mV at full load. This results in increased margin before encountering minimum and maximum transient voltage limits, allowing use of less capacitance on the regulator output (see Figure 9).

To implement adaptive voltage positioning, a "droop" resistor must be connected between the output inductor and output capacitors and load. This is normally implemented by a PC board trace of the following value:

$$
\text { RDROOP }=\frac{80 \mathrm{mV}}{\mathrm{I}_{\mathrm{MAX}}}
$$

Adaptive voltage positioning can be disabled for improved $D C$ regulation by connecting the $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load using a separate, non-load current carrying circuit trace.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to
provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:
Thermal Impedance $=\frac{\left.\text { TJUNCTION }^{\text {MAX }}\right)- \text { TAMBIENT }}{\text { Power }}$
A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 20. Filter Components

Figure 21. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGND).
2. Connect pin 11 (PGND) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGND).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGND).
6. To implement adaptive voltage positioning, connect both slow and fast feedback pins $16\left(\mathrm{~V}_{\mathrm{FB}}\right)$ and 8 $\left(\mathrm{V}_{\mathrm{FFB}}\right)$ to the regulator output right at the inductor terminal. Connect inductor to the output capacitors via a trace with the following resistance:

$$
\text { RTRACE }=\frac{80 \mathrm{mV}}{\mathrm{I}_{\mathrm{MAX}}}
$$

This causes the output voltage to be +40 mV with no load, and -40 mV with a full load, improving regulator transient response. This trace must be wide enough to carry the full output current. (Typical trace is 1.0 inch long, 0.17 inch wide). Care should be taken to minimize any additional losses after the feedback connection point to maximize regulation.
7. If DC regulation is to be optimized (at the expense of degraded transient regulation), adaptive voltage positioning can be disabled by connecting to $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
8. Place 5.0 V input capacitors close to the switching MOSFET and synchronous MOSFET.

Route gate drive signals $\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}$ (pin 10) and $\mathrm{V}_{\text {GATE(L) }}$ (pin 12 when used) with a trace that are a minimum of 0.025 inches wide.

## CS5156H

## CPU 5-Bit Nonsynchronous Buck Controller

The CS5156H is a 5 -bit nonsynchronous N-Channel buck controller. It is designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. The regulator operates using a proprietary control method, which allows a 100 ns response time to load transients. The CS5156H is designed to operate over a $4.25-20 \mathrm{~V}$ range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V or 12 V as the main supply for conversion.

The CS5156H is specifically designed to power Pentium ${ }^{\circledR}$ II processors and other high performance core logic. It includes the following features: on board, 5-bit DAC, short circuit protection, $1.0 \%$ output tolerance, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The CS5156H is backwards compatible with the 4-bit CS5151, allowing the mother board designer the capability of using either the CS5151 or the CS5156H with no change in layout. The CS5156H is available in 16 pin surface mount packages.

## Features

- N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 5-Bit DAC
- Backward Compatible with 4-Bit CS5150H/CS5151H
- 30 ns Gate Rise/Fall Times
- $1.0 \%$ DAC Accuracy
- 5.0 V \& 12 V Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- Adaptive Voltage Positioning
- $\mathrm{V}^{2 \mathrm{Tm}}$ Control Topology
- Current Sharing
- Overvoltage Protection

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| SO-16 |  |  |
| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID } 4}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V providing logic ones if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is High (logic one), the DAC range is 2.14 V to 3.54 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is Low (logic zero), the DAC range is 1.34 V to 2.09 V with 50 mV increments. $\mathrm{V}_{\text {IDO }}-\mathrm{V}_{\text {ID4 }}$ select the desired DAC output voltage. Leaving all 5 DAC input pins open results in a DAC output voltage of 1.244 V , allowing for adjustable output voltage, using a traditional resistor divider. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND in conjunction with internal $60 \mu \mathrm{~A}$ current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $\mathrm{V}_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\text {CC2 }}$ | Boosted power for the gate driver. |
| 10 | $\mathrm{V}_{\text {GATE }}$ | MOSFET driver pin capable of 1.5 A peak switching current. |
| 11 | PGND | High current ground for the IC. The MOSFET driver is referenced to this pin. Input capacitor ground and the anode of the Schottky diode should be tied to this pin. |
| 12 | NC | No connection. |
| 13 | $\mathrm{V}_{\mathrm{CC} 1}$ | Input power for the IC. |
| 14 | LGND | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $V_{\text {FB }}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## $\mathrm{V}^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. ${ }^{2}$ ºntrol Diagram

The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5156H uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $30 \mu \mathrm{~s}$ timer, minimizing stress to the power components.

## Programmable Output

The CS5156H is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.14 V to 3.54 V in 100 mV steps, the second is 1.34 V to 2.09 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS5156H enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{FFB}}$ pins, as in traditional controllers. The CS5156H is specifically designed to be backwards compatible with the CS5151H, which uses a four bit DAC code.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 3.9 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the GATE output is activated, and the Soft Start capacitor begins charging. The GATE output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.
If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE pin drives low for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. Then, the GATE pin will drive high, and the cycle repeats.

When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the C $\mathrm{C}_{\mathrm{OFF}}$ capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.

The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP capacitor charging to its final value. Its voltage is limited by
the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

## Normal Operation

During normal operation, switch off time is constant and set by the C CopF capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The CS5156H V ${ }^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

Overall load transient response is further improved through a feature called "adaptive voltage positioning". This technique pre-positions the output capacitor's voltage to reduce total output voltage excursions during changes in load.

Holding tolerance to $1.0 \%$ allows the error amplifier's reference voltage to be targeted +40 mV high without compromising DC accuracy. A "droop resistor", implemented through a PC board trace, connects the error amplifier's feedback pin $\left(\mathrm{V}_{\mathrm{FB}}\right)$ to the output capacitors and load and carries the output current. With no load, there is no DC drop across this resistor, producing an output voltage tracking the error amplifier's, including the +40 mV offset. When the full load current is delivered, an 80 mV drop is developed across this resistor. This results in output voltage being offset -40 mV low.

The result of adaptive voltage positioning is that additional margin is provided for a load transient before reaching the output voltage specification limits. When load current suddenly increases from its minimum level, the output capacitor is pre-positioned +40 mV . Conversely, when load current suddenly decreases from its maximum
level, the output capacitor is pre-positioned -40 mV (see Figures 9, 10, and 11). For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.
If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $\mathrm{V}_{\mathrm{C} 1}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 3.75 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 3.70 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs ( $\mathrm{V}_{\mathrm{FFB}}<1.0 \mathrm{~V}$ ), the $\mathrm{V}_{\mathrm{FFB}}$ low comparator sets the FAULT latch. This causes the MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=$ $3.3 \%$ ), while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board
traces than occurs with constant current limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Figure 12. CS5156H Demonstration Board Hiccup Mode Short Circuit Protection. Gate Pulses are Delivered While the Soft Start Capacitor Charges, and Cease During Discharge

Figure 13. Startup with Regulator Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage.

## External Output Enable Circuit

On/off control of the regulator can be implemented through the addition of two additional discrete components
(see Figure 14). This circuit operates by pulling the Soft Start pin high, and the $\mathrm{V}_{\mathrm{FFB}}$ pin low, emulating a short circuit condition.

Figure 14. Implementing Shutdown with the CS5156H

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 15). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
V_{\text {Power Good }}=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $V_{\text {Power Good }}$.

## Selecting External Components

The CS5156H can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and use logic level MOSFETs. A charge pump may be easily implemented to permit use of standard MOSFETs or support 5.0 V or 12 V only systems (maximum of 20 V ). Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the MOSFET gates depends on the application circuit used. The gate driver output is specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of its bias supply when in the high state. In practice, the MOSFET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC} 1}=$ $\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;

$$
\text { VGATE }=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}
$$

(see Figure 17.)

Figure 17. CS5156H Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is $\mathrm{RDS}_{\mathrm{ON}}$, which effects regulator efficiency and MOSFET thermal management requirements.

The power dissipated by the MOSFETs and the Schottky diode may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\text { LLOAD }^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Schottky diode:

$$
\text { Power }=\text { VFORWARD } \times \text { ILOAD } \times(1-\text { duty cycle })
$$

Duty Cycle =
VOUT + VFORWARD
$\overline{\mathrm{V}_{\text {IN }}}+\mathrm{V}_{\text {FORWARD }}-($ ILOAD $\times$ RDSON OF SYNCH FET) $)$

## Off Time Capacitor (Coff)

The C CFF timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

When the $\mathrm{V}_{\text {FFB }}$ pin is less than 1.0 V , the current charging the $\mathrm{C}_{\mathrm{OFF}}$ capacitor is reduced. The extended off time can be calculated as follows:

$$
\text { TOFF }=\text { COFF } \times 24,242.5
$$

Off time will be determined by either the $\mathrm{T}_{\mathrm{OFF}}$ time, or the time out timer, whichever is longer.

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\mathrm{OFF}}$ timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:
Period $=\frac{1}{\text { switching frequency }}$
"Droop" Resistor for Adaptive Voltage Positioning
Adaptive voltage positioning is used to reduce output voltage excursions during abrupt changes in load current. Regulator output voltage is offset +40 mV when the regulator is unloaded, and -40 mV at full load. This results in increased margin before encountering minimum and maximum transient voltage limits, allowing use of less capacitance on the regulator output (see Figure 9).
To implement adaptive voltage positioning, a "droop" resistor must be connected between the output inductor and output capacitors and load. This is normally implemented by a PC board trace of the following value:

$$
\text { RDROOP }=\frac{80 \mathrm{mV}}{\mathrm{I} \mathrm{MAX}}
$$

Adaptive voltage positioning can be disabled for improved DC regulation by connecting the $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load using a separate, non-load current carrying circuit trace.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:
Thermal Impedance $=\frac{\text { TJUNCTION(MAX) }- \text { TAMBIENT }}{\text { Power }}$
A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 18. Filter Components

Figure 19. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGND).
2. Connect pin 11 (PGND) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGND).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGND).
6. To implement adaptive voltage positioning, connect both slow and fast feedback pins $16\left(\mathrm{~V}_{\mathrm{FB}}\right)$ and 8 $\left(\mathrm{V}_{\mathrm{FFB}}\right)$ to the regulator output right at the inductor terminal. Connect inductor to the output capacitors via a trace with the following resistance:

$$
\text { RTRACE }=\frac{80 \mathrm{mV}}{\mathrm{I}_{\mathrm{MAX}}}
$$

This causes the output voltage to be +40 mV with no load, and -40 mV with a full load, improving regulator transient response. This trace must be wide enough to carry the full output current. (Typical trace is 1.0 inch long, 0.17 inch wide). Care should be taken to minimize any additional losses after the feedback connection point to maximize regulation.
7. If DC regulation is to be optimized (at the expense of degraded transient regulation), adaptive voltage positioning can be disabled by connecting to $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
8. Place 5.0 V input capacitors close to the switching MOSFET.

Route gate drive signals $\mathrm{V}_{\text {GATE }}$ (pin 10) with a trace that is a minimum of 0.025 inches wide.

## CS5161, CS5161H

## CPU 5-Bit Synchronous Buck Controller

The CS5161/5161H are 5-bit synchronous dual N-Channel buck controllers designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. They operate using a proprietary control method which allows a 100 ns response time to load transients. The CS5161 is designed to operate over a $9-16 \mathrm{~V}$ range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V as the main supply for conversion.

The CS5161H operates from a 12 V input as the main supply for conversion using a discrete charge pump circuit to provide up to 20 V for $\mathrm{V}_{\mathrm{CC} 2}$ and high side gate drive.

The CS5161/5161H are specifically designed to power Pentium ${ }^{\circledR}$ III processors and other high performance core logic. They include the following features: on board 5-bit DAC, short circuit protection, $1.0 \%$ output tolerance, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The CS5161/5161H are available in 16 pin surface mount packages.

## Features

- Dual N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 5-Bit DAC
- Backward Compatible with CS515X Family
- 30 ns Gate Rise/Fall Times
- $1.0 \%$ DAC Accuracy
- $5.0 \mathrm{~V} \& 12 \mathrm{~V}$ Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- 50 ns FET Nonoverlap Time
- $V^{2 \mathrm{TM}}$ Control Topology
- Current Sharing
- Overvoltage Protection

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| 16 Lead SO Narrow |  |  |
| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {ID0 }}-\mathrm{V}_{\text {ID4 }}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V providing logic ones if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is High (logic one), the DAC range is 2.10 V to 3.50 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is Low (logic zero), the DAC range is 1.30 V to 2.05 V with 50 mV increments. $\mathrm{V}_{\text {ID0 }}-\mathrm{V}_{\text {ID4 }}$ select the desired DAC output voltage. Leaving all 5 DAC input pins open results in a DAC output voltage of 1.2440 V , allowing for adjustable output voltage, using a traditional resistor divider. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGnd in conjunction with internal $60 \mu \mathrm{~A}$ current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 7 | CofF | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $V_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Boosted power for the high side gate driver. |
| 10 | $\mathrm{V}_{\text {GATE }}(\mathrm{H})$ | High FET driver pin capable of 1.5 A peak switching current. Internal circuit prevents $\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}$ and $\mathrm{V}_{\mathrm{GATE}(\mathrm{L})}$ from being in high state simultaneously. |
| 11 | PGnd | High current ground for the IC. The MOSFET drivers are referenced to this pin. Input capacitor ground and the source of lower FET should be tied to this pin. |
| 12 | $\mathrm{V}_{\text {GATE(L) }}$ | Low FET driver pin capable of 1.5 A peak switching current. |
| 13 | $\mathrm{V}_{\mathrm{CC} 1}$ | Input power for the IC and low side gate driver. |
| 14 | LGnd | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $\mathrm{V}_{\mathrm{FB}}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## V $^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. V ${ }^{2}$ Control Diagram

The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5161/5161H uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the C CoFF capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $30 \mu \mathrm{~s}$ timer, minimizing stress to the power components.

## Programmable Output

The CS5161/5161H is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.10 V to 3.50 V in 100 mV steps, the second is 1.30 V to 2.05 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS5161/5161H enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{FFB}}$ pins, as in traditional controllers.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 9.05 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the $\operatorname{GATE}(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.

If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE(H) pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.
When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the C CoFF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.
The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP

## CS5161, CS5161H

capacitor charging to its final value. Its voltage is limited by the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

## Normal Operation

During normal operation, switch off time is constant and set by the C OFF capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The CS5161/5161H V ${ }^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.

If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $V_{\text {CC1 }}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 8.70 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 8.55 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs ( $\mathrm{V}_{\mathrm{FFB}}<1.0 \mathrm{~V}$ ), the $\mathrm{V}_{\mathrm{FFB}}$ low comparator sets the FAULT
latch. This causes the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=3.3 \%)$, while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board traces than occurs with constant current limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Figure 13. CS5161/5161H Startup with Regulator Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 14 and 15). The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function.

Figure 14. CS5161/5161H OVP Response to an Input-to-Output Short Circuit by Immediately
Providing 0\% Duty Cycle, Crow-Barring the Input Voltage to Ground

Figure 15. CS5161/5161H OVP Response to an Input-to-Output Short Circuit by Pulling the Input Voltage to Ground

## External Output Enable Circuit

On/off control of the regulator can be implemented through the addition of two additional discrete components (see Figure 16). This circuit operates by pulling the Soft Start pin high, and the $\mathrm{V}_{\text {FFB }}$ pin low, emulating a short circuit condition.

Figure 16. Implementing Shutdown with the CS5161/5161H

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 17). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
V_{\text {Power Good }}=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $V_{\text {Power Good. }}$

## Slope Compensation

The $\mathrm{V}^{2}$ control method uses a ramp signal, generated by the ESR of the output capacitors, that is proportional to the ripple current through the inductor. To maintain regulation, the $\mathrm{V}^{2}$ control loop monitors this ramp signal, through the PWM comparator, and terminates the switch on-time.
The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope presented to the PWM comparator, due to the very low ESR, can lead to pulse width jitter and variation caused by both random or synchronous noise.

Adding slope compensation to the control loop, avoids erratic operation of the PWM circuit, particularly at lower duty cycles and higher frequencies, where there is not enough ramp signal, and provides a more stable switchpoint.
The scheme that prevents that switching noise prematurely triggers the PWM circuit consists of adding a positive voltage slope to the output of the Error Amplifier (COMP pin) during an off-time cycle.

The circuit that implements this function is shown in Figure 19.

Figure 19. Small RC Filter Provides the Proper Voltage Ramp at the Beginning of each On-Time Cycle
The ramp waveform is generated through a small RC filter that provides the proper voltage ramp at the beginning of each on-time cycle. The resistors R1 and R2 in the circuit of Figure 14 form a voltage divider from the GATE(L) output, superimposing a small artificial ramp on the output of the error amplifier. It is important that the series combination $\mathrm{R} 1 / \mathrm{R} 2$ is high enough in resistance not to load down and negatively affect the slew rate on the GATE(L) pin.

## Selecting External Components

The CS5161/5161H can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and utilize logic level MOSFETs. Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the MOSFET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the MOSFET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC} 1}=\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;

$$
\operatorname{VGATE}(\mathrm{H})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}, \mathrm{VGATE}(\mathrm{~L})=12 \mathrm{~V}
$$

(see Figure 20.)

Figure 20. CS5161/5161H Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is RDS $_{\text {ON }}$, which effects regulator efficiency and MOSFET thermal management requirements.

The power dissipated by the MOSFETs may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\mathrm{ILOAD}^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:

$$
\text { Power }=\mathrm{I}_{\mathrm{LOAD}}{ }^{2} \times \text { RDSON } \times(1-\text { duty cycle })
$$

Duty Cycle =

$$
\frac{\text { VOUT }+(\text { LLOAD } \times \text { RDSON OF SYNCH FET })}{\left[\begin{array}{l}
\text { VIN }+(\text { ILOAD } \times \text { RDSON OF SYNCH FET }) \\
-(\text { LLOAD } \times \text { RDSON OF SWITCH FET })
\end{array}\right]}
$$

## Off Time Capacitor (COFF)

The C CFF timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\text {OFF }}$ timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous MOSFET

A Schottky diode may be placed in parallel with the synchronous MOSFET to conduct the inductor current upon turn off of the switching MOSFET to improve efficiency. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense (see Figure 8, channel 2). The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=V_{B D} \times I$ LOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the CS5161/5161H demonstration board as shown in Figure 8;

$$
\text { Power }=1.6 \mathrm{~V} \times 13 \mathrm{~A} \times 100 \mathrm{~ns} \times 233 \mathrm{kHz}=0.48 \mathrm{~W}
$$

This is only $1.3 \%$ of the 36.4 W being delivered to the load.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:

Thermal Impedance $=\frac{\text { TJUNCTION(MAX) }- \text { TAMBIENT }}{\text { Power }}$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 21. Filter Components

Figure 22. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGnd).
2. Connect pin 11 (PGnd) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGnd).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGnd).
6. Connect the $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
7. Place 5.0 V input capacitors close to the switching MOSFET and synchronous MOSFET.
Route gate drive signals $\mathrm{V}_{\text {GATE(H) }}$ (pin 10) and $\mathrm{V}_{\text {GATE(L) }}$ (pin 12 when used) with traces that are a minimum of 0.025 inches wide.

## CS5165H

## 5-Bit Synchronous CPU Buck Controller

The CS5156H synchronous 5-bit NFET buck controller is optimized to manage the power of the next generation Pentium II processors. It's $V^{2 \mathrm{TM}}$ control architecture delivers the fastest transient response ( 100 ns ), and best overall voltage regulation in the industry today. It's feature rich design gives end users the maximum flexibility to implement the best price/performance solutions for their end products.

The CS5156H has been carefully crafted to maximize performance and protect the processor during operation. It has a 5-bit DAC on board that holds a $\pm 1.0 \%$ tolerance over temperature. Its on board programmable Soft Start insures a control start up, and the FET nonoverlap circuitry ensures that both FETs do not conduct simultaneously.

The on board oscillator can be programmed up to 1.0 MHz to give the designer maximum flexibility in choosing external components and setting systems costs.

The CS5156H protects the processor during potentially catastrophic events like overvoltage (OVP) and short circuit. The OVP feature is part of the $\mathrm{V}^{2}$ architecture and does not require any additional components. During short circuit, the controller pulses the MOSFETs in a "hiccup" mode ( $3.0 \%$ duty cycle) until the fault is removed. With this method, the MOSFETs do not overheat or self destruct.

The CS5156H is designed for use in both single processor desktop and multiprocessor workstation and server applications. The IC can be powered from either single or dual $5.0 \mathrm{~V}, 12 \mathrm{~V}$ power supplies. The CS5156H's current sharing capability allows the designer to build multiple parallel and redundant power solutions for multiprocessor systems.

The CS5156H contains other control and protection features such as Power Good, ENABLE, and adaptive voltage positioning. It is available in a 16 lead SOIC wide body package.

## Features

- $\mathrm{V}^{2}$ Control Topology
- 100 ns Controller Transient Response
- Excess of 1.0 MHz Operation
- 5-Bit DAC with $1.0 \%$ Tolerance
- Power Good Output With Internal Delay
- Enable Input Provides Micropower Shutdown Mode
- 5.0 V \& 12 V Operation Using Either Dual or Single Supplies
- Adaptive Voltage Positioning
- Remote Sense Capability
- Current Sharing Capability
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- Hiccup Mode Short Circuit Protection
- Overvoltage Protection (OVP)
- Programmable Soft Start
- 150 ns PWM Blanking
- 65 ns FET Nonoverlap Time
- 40 ns Gate Rise and Fall Times (3.3 nF Load)

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| SO-16L | PIN SYMBOL | FUNCTION |
| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {ID0 }}-\mathrm{V}_{\text {ID4 }}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is high (logic one), the Error Amp reference range is 2.14 V to 3.45 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is low (logic zero), the Error Amp reference voltage 1.34 V to 2.09 V with 50 mV increments. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND sets the Soft Start and fault timing. |
| 7 | COFF | Off-Time Capacitor Pin. A capacitor from this pin to LGND sets both the normal and extended off time. |
| 8 | ENABLE | Output Enable Input. This pin is internally pulled up to 1.8 V . A logic Low ( $<0.8 \mathrm{~V}$ ) on this pin disables operation and places the CS5156H into a low current sleep mode. |
| 9 | $\mathrm{V}_{\mathrm{CC}}$ | Input Power Supply Pin. |
| 10 | GATE(H) | High Side Switch FET driver pin. |
| 11 | PGND | High current ground for the GATE(H) and GATE(L) pins. |
| 12 | GATE(L) | Low Side Synchronous FET driver pin. |
| 13 | PWRGD | Power Good Output. Open collector output drives low when $\mathrm{V}_{\mathrm{FB}}$ is out of regulation. Active when ENABLE input is low. |
| 14 | LGND | Reference ground. All control circuits are referenced to this pin. |
| 15 | COMP | Error Amp output. PWM Comparator reference input. A capacitor to LGND provides Error Amp compensation. |
| 16 | $\mathrm{V}_{\mathrm{FB}}$ | Error Amp, PWM Comparator, and Low $\mathrm{V}_{\text {FB }}$ Comparator feedback input. |

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## $\mathrm{V}^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 9. $\mathbf{V}^{2}$ Control Diagram
The $\mathrm{V}^{2}$ control method is illustrated in Figure 9. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop.

The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.
Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $V^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5156H uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the C CFF capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.
Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.
Switch on time is limited by an internal $30 \mu \mathrm{~s}$ (typical) timer, minimizing stress to the power components.

## Programmable Output

The CS5156H is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.14 V to 3.54 V in 100 mV steps, the second is 1.34 V to 2.09 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS5156H enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ pin, as in traditional controllers. The CS5156H is specifically designed to meet or exceed Intel's Pentium II specifications.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC}}$ supply pin exceeds the 3.95 V monitor threshold, the Soft Start and GATE pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC}}$ pin exceeds the monitor threshold, the GATE $(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.

If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE(H) pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.

When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the CofF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.

The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP capacitor charging to its final value. Its voltage is limited by the Soft Start COMP clamp and the voltage on the Soft Start pin.

## Power Supply Sequencing

The CS5156H offers inherent protection from undefined start up conditions, regardless of the 12 V and 5.0 V supply power up sequencing. The turn on slew rates of the 12 V and 5.0 V power supplies can be varied over wide ranges without affecting the output voltage or causing detrimental effects to the buck regulator.

## Normal Operation

During normal operation, switch off time is constant and set by the C CofF capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working and the ESR of the output capacitors (see Figures 13 and 14).

## Transient Response

The CS5156H V ${ }^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

Overall load transient response is further improved through a feature called "Adaptive Voltage Positioning". This technique pre-positions the output capacitors voltage to reduce total output voltage excursions during changes in load.

Holding tolerance to $1.0 \%$ allows the error amplifiers reference voltage to be targeted +40 mV high without compromising DC accuracy. A "Droop Resistor", implemented through a PC board trace, connects the Error Amps feedback pin $\left(\mathrm{V}_{\mathrm{FB}}\right)$ to the output capacitors and load and carries the output current. With no load, there is no DC drop across this resistor, producing an output voltage tracking the Error amps, including the +40 mV offset. When the full load current is delivered, an 80 mV drop is developed across this resistor. This results in output voltage being offset -40 mV low.

The result of Adaptive Voltage Positioning is that additional margin is provided for a load transient before reaching the output voltage specification limits. When load
current suddenly increases from its minimum level, the output capacitor is pre-positioned +40 mV . Conversely, when load current suddenly decreases from its maximum level, the output capacitor is pre-positioned -40 mV (see Figures 15, 16, and 17). For best Transient Response, a combination of a number of high frequency and bulk output capacitors are usually used.

If the Maximum On-Time is exceeded while responding to a sudden increase in Load current, a normal off-time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs the $\mathrm{V}_{\mathrm{FB}}$ low comparator sets the FAULT latch. This causes the top FET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=$ $3.3 \%$ ), while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).
This protection feature results in less stress to the regulator components, input power supply, and PC board traces than occurs with constant current limit protection (see Figures 18 and 19).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 20 and 21 ). The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to
implement the OVP function. If a dedicated OVP output is required, it can be implemented using the circuit in Figure 22. In this figure the OVP signal will go high (overvoltage condition), if the output voltage ( $\mathrm{V}_{\mathrm{CORE}}$ ) exceeds $20 \%$ of the voltage set by the particular DAC code and provided that PWRGD is low. It is also required that the overvoltage condition be present for at least the PWRGD delay time for the OVP signal to be activated. The resistor values shown in Figure 22 are for $\mathrm{V}_{\mathrm{DAC}}=+2.8 \mathrm{~V}(\mathrm{DAC}=10111)$. The $\mathrm{V}_{\mathrm{OVP}}$ (overvoltage trip-point) can be set using the following equation:

$$
\mathrm{V}_{\mathrm{OVP}}=\mathrm{V}_{\mathrm{BEQ}}\left(1+\frac{\mathrm{R} 2}{\mathrm{R1}}\right)
$$

Figure 22. Circuit To Implement A Dedicated OVP Output Using The CS5156H

## Output Enable Circuit

The Enable pin (pin 8) is used to enable or disable the regulator output voltage, and is consistent with TTL DC specifications. It is internally pulled-up. If pulled low (below 0.8 V ), the output voltage is disabled. At the same time the Power Good and Soft Start pins are pulled low, so that when normal operation resumes power-up of the CS5156H goes through the Soft Start sequence. Upon pulling the Enable pin low, the internal IC bias is completely shut off, resulting in total shutdown of the Controller IC.

## Power Good Circuit

The Power Good pin (pin 13) is an open-collector signal consistent with TTL DC specifications. It is externally pulled-up, and is pulled low (below 0.3 V ) when the regulator output voltage typically exceeds $\pm 8.5 \%$ of the
nominal output voltage. Maximum output voltage deviation before Power Good is pulled low is $\pm 12 \%$.

Trace 2- PWRGD (2.0 V/div.)
Trace 4- V
Figure 23. PWRGD Signal Becomes Logic High as $V_{\text {OUT }}$ Enters -8.5\% of Lower PWRGD Threshold, $\mathrm{V}_{\text {OUT }}=+\mathbf{2 . 8 4} \mathrm{V}(\mathrm{DAC}=10111)$

Figure 24. Power Good Response to an Out of Regulation Condition
Figure 24 shows the relationship between the regulated output voltage $\mathrm{V}_{\mathrm{FB}}$ and the Power Good signal. To prevent Power Good from interrupting the CPU unnecessarily, the CS5156H has a built-in delay to prevent noise at the $\mathrm{V}_{\mathrm{FB}}$ pin from toggling Power Good. The internal time delay is designed to take about $75 \mu$ s for Power Good to go low and $65 \mu$ s for it to recover. This allows the Power Good signal to be completely insensitive to out of regulation conditions that are present for a duration less than the built in delay (see Figure 25).

It is therefore required that the output voltage attains an out of regulation or in regulation level for at least the built-in delay time duration before the Power Good signal can change state.

Trace 2- PWRGD (2.0 V/div.)
Trace 4- VFB ( $1.0 \mathrm{~V} /$ div.)
Figure 25. Power Good is Insensitive to Out of Regulation Conditions that are Present for a Duration Less Than the Built In Delay

## Selecting External Components

The CS5156H buck regulator can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard FETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and utilize logic level FETs. A charge pump may be easily implemented to permit use of standard FET's or support 5.0 V or 12 V only systems (maximum of 20 V ). Multiple FET's may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the FET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the FET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC}}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided:

$$
\begin{gathered}
\mathrm{VGS}_{\mathrm{GS}}(\mathrm{TOP})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V} \\
\mathrm{VGS}(\mathrm{BOTTOM})=12 \mathrm{~V}
\end{gathered}
$$

(see Figure 26)

Figure 26. Gate Drive Waveforms Depicting Rail to Rail Swing

Trace $1=\operatorname{GATE}(\mathrm{H})(5.0 \mathrm{~V} /$ div. $)$
Trace $2=\operatorname{GATE}(\mathrm{L})(5.0 \mathrm{~V} /$ div. $)$
Figure 27. Normal Operation Showing the Guaranteed Non-Overlap Time Between the High and Low-Side MOSFET Gate Drives, I LOAD $=14 \mathrm{~A}$
The CS5156H provides adaptive control of the external NFET conduction times by guaranteeing a typical 65 ns non-overlap between the upper and lower MOSFET gate drive pulses. This feature eliminates the potentially catastrophic effect of "shoot-through current", a condition during which both FETs conduct causing them to overheat, self-destruct, and possibly inflict irreversible damage to the processor.
The most important aspect of FET performance is $\mathrm{RDS}_{\mathrm{ON}}$, which effects regulator efficiency and FET thermal management requirements.

The power dissipated by the MOSFETs may be estimated as follows:

Switching MOSFET:

$$
\text { Power }=I_{\text {LOAD }}{ }^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:

$$
\text { Power }=\text { LLOAD }{ }^{2} \times \text { RDSON } \times(1-\text { duty cycle })
$$

Duty Cycle =

$$
\frac{\mathrm{V}_{\text {OUT }}+(\mathrm{ILOAD} \times \text { RDSON OF SYNCH FET })}{\left[\begin{array}{l}
\mathrm{V}_{\text {IN }}+(\mathrm{ILOAD} \times \mathrm{RDSON} \text { OF SYNCH FET }) \\
-(\mathrm{ILOAD} \times \mathrm{RDSON} \text { OF SWITCH FET })
\end{array}\right]}
$$

## Off Time Capacitor (Coff)

The Coff timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\text {OFF }}$ timing capacitor:

$$
\mathrm{C}_{\mathrm{OFF}}=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous FET

For synchronous operation, a Schottky diode may be placed in parallel with the synchronous FET to conduct the inductor current upon turn off of the switching FET to improve efficiency. The CS5156H reference circuit does not use this device due to it's excellent design. Instead, the body diode of the synchronous FET is utilized to reduce cost and conducts the inductor current. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense. The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=V_{B D} \times$ LIOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the CS5156H demonstration board:

$$
\text { Power }=1.6 \mathrm{~V} \times 14.2 \mathrm{~A} \times 100 \mathrm{~ns} \times 200 \mathrm{kHz}=0.45 \mathrm{~W}
$$

This is only $1.1 \%$ of the 40 W being delivered to the load.

## "Droop" Resistor for Adaptive Voltage Positioning

Adaptive voltage positioning is used to help keep the output voltage within specification during load transients. To implement adaptive voltage positioning a "Droop Resistor" must be connected between the output inductor and output capacitors and load. This resistor carries the full load current and should be chosen so that both DC and AC tolerance limits are met. An embedded PC trace resistor has the distinct advantage of near zero cost implementation. However, this droop resistor can vary due to three reasons: 1) the sheet resistivity variation causes the thickness of the PCB layer to vary. 2) the mismatch of L/W, and 3) temperature variation.

1. Sheet Resistivity for one ounce copper, the thickness variation typically 1.15 mil to 1.35 mil . Therefore the error due to sheet resistivity is:

$$
\frac{1.35-1.15}{1.25}=16 \%
$$

2. Mismatch due to $\mathbf{L} / \mathbf{W}$. The variation in $\mathrm{L} / \mathrm{W}$ is governed by variations due to the PCB manufacturing process that affect the geometry and the power dissipation capability of the droop resistor. The error due to $\mathrm{L} / \mathrm{W}$ mismatch is typically $1.0 \%$.
3. Thermal Considerations. Due to $I^{2} \times R$ power losses the surface temperature of the droop resistor will increase causing the resistance to increase. Also, the ambient temperature variation will contribute to the increase of the resistance, according to the formula:

$$
R=R_{20}\left[1+\alpha_{20}(T-20)\right]
$$

where:
$\mathrm{R}_{20}=$ resistance at $20^{\circ} \mathrm{C}$
$\alpha=\frac{0.00393}{{ }^{\circ} \mathrm{C}}$
$\mathrm{T}=$ operating temperature
$\mathrm{R}=$ desired droop resistor value
For temperature $\mathrm{T}=50^{\circ} \mathrm{C}$, the $\% \mathrm{R}$ change $=12 \%$
Droop Resistor Tolerance
Tolerance due to sheet resistivity variation $16 \%$
Tolerance due to L/W error $1.0 \%$
Tolerance due to temperature variation $12 \%$
Total tolerance for droop resistor $29 \%$
In order to determine the droop resistor value the nominal voltage drop across it at full load has to be calculated. This voltage drop has to be such that the output voltage full load is above the minimum DC tolerance spec.

Example: for a 300 MHz PentiumII, the DC accuracy spec is $2.74<\mathrm{V}_{\mathrm{CC}(\text { CORE })}<2.9 \mathrm{~V}$, and the AC accuracy spec is $2.67 \mathrm{~V}<\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}<2.93 \mathrm{~V}$. The CS5156H DAC output voltage is $+2.812 \mathrm{~V}<\mathrm{V}_{\text {DAC }}<+2.868 \mathrm{~V}$. In order not to exceed the DC accuracy spec, the voltage drop developed across the resistor must be calculated as follows:

$$
\begin{aligned}
\mathrm{V}_{\text {DROOP }}(\mathrm{TYP}) & =\frac{\left[\mathrm{V}_{\mathrm{DAC}}(\mathrm{MIN})-\mathrm{V}_{\mathrm{DC}} \text { PENTIUMII(MIN) }\right]}{1+\mathrm{RDROOP}_{\mathrm{D}}(\text { TOLERANCE })} \\
& =\frac{2.812 \mathrm{~V}-2.74 \mathrm{~V}}{1.3}=56 \mathrm{mV}
\end{aligned}
$$

With the CS5156H DAC accuracy being $1.0 \%$, the internal error amplifier's reference voltage is trimmed so that the output voltage will be 40 mV high at no load. With no load, there is no DC drop across the resistor, producing an output voltage tracking the error amplifier output voltage, including the offset. When the full load current is delivered, a drop of -56 mV is developed across the resistor. Therefore,
the regulator output is pre-positioned at 40 mV above the nominal output voltage before a load turn-on. The total voltage drop due to a load step is $\Delta \mathrm{V}-40 \mathrm{mV}$ and the deviation from the nominal output voltage is 40 mV smaller than it would be if there was no droop resistor. Similarly at full load the regulator output is pre-positioned at 16 mV below the nominal voltage before a load turn-off. The total voltage increase due to a load turn-off is $\Delta \mathrm{V}-16 \mathrm{mV}$ and the deviation from the nominal output voltage is 16 mV smaller than it would be if there was no droop resistor. This is because the output capacitors are pre-charged to value that is either 40 mV above the nominal output voltage before a load turn-on or, 16 mV below the nominal output voltage before a load turn-off (see Figure 15).

Obviously, the larger the voltage drop across the droop resistor ( the larger the resistance), the worse the DC and load regulation, but the better the AC transient response.

## Design Rules for Using a Droop Resistor

The basic equation for laying an embedded resistor is:

$$
R_{A R}=\rho \times \frac{L}{A} \text { or } R=\rho \times \frac{L}{(W \times t)}
$$

where:
$\mathrm{A}=\mathrm{W} \times \mathrm{t}=$ cross-sectional area
$\rho=$ the copper resistivity $(\mu \Omega-$ mil $)$
$\mathrm{L}=$ length (mils)
$\mathrm{W}=$ width (mils)
$\mathrm{t}=$ thickness (mils)
For most PCBs the copper thickness, t , is $35 \mu \mathrm{~m}(1.37$ mils) for one ounce copper. $\rho=717.86 \mu \Omega$-mil

For a Pentium II load of 14.2 A the resistance needed to create a 56 mV drop at full load is:

$$
\text { Response Droop }=\frac{56 \mathrm{mV}}{\mathrm{IOUT}}=\frac{56 \mathrm{mV}}{14.2 \mathrm{~A}}=3.9 \mathrm{~m} \Omega
$$

The resistivity of the copper will drift with the temperature according to the following guidelines:

$$
\begin{gathered}
\Delta R=12 \% @ T_{A}=+50^{\circ} \mathrm{C} \\
\Delta R=34 \% @ T_{A}=+100^{\circ} \mathrm{C}
\end{gathered}
$$

## Droop Resistor Width Calculations

The droop resistor must have the ability to handle the load current and therefore requires a minimum width which is calculated as follows (assume one ounce copper thickness):

$$
W=\frac{\mathrm{L} O A D}{0.05}
$$

where:
$\mathrm{W}=$ minimum width (in mils) required for proper power dissipation, and $\mathrm{I}_{\text {LOAD }}$ Load Current Amps.

The Pentium ${ }^{\circledR}$ II maximum load current is 14.2 A Therefore:

$$
\mathrm{W}=\frac{14.2 \mathrm{~A}}{0.05}=284 \mathrm{mils}=0.7213 \mathrm{~cm}
$$

Droop Resistor Length Calculation

$$
\begin{aligned}
\mathrm{L} & =\frac{\mathrm{R}_{\mathrm{DROOP}} \times \mathrm{W} \times \mathrm{t}}{\rho} \\
& =\frac{0.0039 \times 284 \times 1.37}{717.86}=2113 \mathrm{mil}=5.36 \mathrm{~cm}
\end{aligned}
$$

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## Inductor Ripple Current

$$
\text { Ripple Current }=\frac{\left[\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{V}_{\mathrm{OUT}}\right]}{\left(\text { Switching Frequency } \times \mathrm{L} \times \mathrm{V}_{\text {IN }}\right)}
$$

Example: $\mathrm{V}_{\mathrm{IN}}=+5.0 \mathrm{~V}, \mathrm{~V}_{\mathrm{OUT}}=+2.8 \mathrm{~V}, \mathrm{I}_{\mathrm{LOAD}}=14.2 \mathrm{~A}$, $\mathrm{L}=1.2 \mu \mathrm{H}$, Freq $=200 \mathrm{kHz}$

$$
\text { Ripple Current }=\frac{[(5.0 \mathrm{~V}-2.8 \mathrm{~V}) \times 2.8 \mathrm{~V}]}{[200 \mathrm{kHz} \times 1.2 \mu \mathrm{H} \times 5.0 \mathrm{~V}]}=5.1 \mathrm{~A}
$$

## Output Ripple Voltage

VRIPPLE $=$ Inductor Ripple Current $\times$ Output Capacitor ESR
Example:
$\mathrm{V}_{\text {IN }}=+5.0 \mathrm{~V}, \mathrm{~V}_{\text {OUT }}=+2.8 \mathrm{~V}, \mathrm{I}_{\text {LOAD }}=14.2 \mathrm{~A}, \mathrm{~L}=1.2 \mu \mathrm{H}$, Switching Frequency $=200 \mathrm{kHz}$
Output Ripple Voltage $=5.1 \mathrm{~A} \times$ Output Capacitor ESR (from manufacturer's specs)

ESR of Output Capacitors to limit Output Voltage Spikes

$$
\mathrm{ESR}=\frac{\Delta \mathrm{V} \text { OUT }}{\Delta \mathrm{I} \mathrm{OUT}}
$$

This applies for current spikes that are faster than regulator response time. Printed Circuit Board resistance will add to the ESR of the output capacitors.

In order to limit spikes to 100 mV for a 14.2 A Load Step, $\mathrm{ESR}=0.1 / 14.2=0.007 \Omega$

## Inductor Peak Current

Peak Current $=$ Maximum Load Current $+\left(\frac{\text { Ripple Current }}{2}\right)$
Example: $\mathrm{V}_{\mathrm{IN}}=+5.0 \mathrm{~V}, \mathrm{~V}_{\mathrm{OUT}}=+2.8 \mathrm{~V}, \mathrm{I}_{\mathrm{LOAD}}=14.2 \mathrm{~A}$, $\mathrm{L}=1.2 \mu \mathrm{H}$, Freq $=200 \mathrm{kHz}$

$$
\text { Peak Current }=14.2 \mathrm{~A}+(5.1 / 2)=16.75 \mathrm{~A}
$$

A key consideration is that the inductor must be able to deliver the Peak Current at the switching frequency without saturating.

## Response Time to Load Increase

(limited by Inductor value unless Maximum On-Time is exceeded)

$$
\text { Response Time }=\frac{\mathrm{L} \times \Delta \mathrm{I} \mathrm{OUT}}{\left(\mathrm{~V} \mathrm{~V}-\mathrm{V}_{\mathrm{OUT}}\right)}
$$

Example: $\mathrm{V}_{\mathrm{IN}}=+5.0 \mathrm{~V}, \mathrm{~V}_{\mathrm{OUT}}=+2.8 \mathrm{~V}, \mathrm{~L}=1.2 \mu \mathrm{H}, 14.2 \mathrm{~A}$ change in Load Current

$$
\text { Response Time }=\frac{1.2 \mu \mathrm{H} \times 14.2 \mathrm{~A}}{(5.0 \mathrm{~V}-2.8 \mathrm{~V})}=7.7 \mu \mathrm{~s}
$$

## Response Time to Load Decrease

(limited by Inductor value)

$$
\text { Response Time }=\frac{\mathrm{L} \times \text { Change in IOUT }}{\text { VOUT }}
$$

Example: $\mathrm{V}_{\text {OUT }}=+2.8 \mathrm{~V}, 14.2$ A change in Load Current, $\mathrm{L}=1.2 \mu \mathrm{H}$

$$
\text { Response Time }=\frac{1.2 \mu \mathrm{H} \times 14.2 \mathrm{~A}}{2.8 \mathrm{~V}}=6.1 \mu \mathrm{~s}
$$

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:

$$
\text { Thermal Impedance }=\frac{T_{J(M A X)}-T_{A M B I E N T}}{\text { Power }}
$$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter
and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

## Layout Guidelines

When laying out the CPU buck regulator on a printed circuit board, the following checklist should be used to ensure proper operation of the CS5156H.

1. Rapid changes in voltage across parasitic capacitors and abrupt changes in current in parasitic inductors are major concerns for a good layout.
2. Keep high currents out of logic grounds.
3. Avoid ground loops as they pick up noise. Use star or single point grounding. The source of the lower (synchronous FET) is an ideal point where the input and output GND planes can be connected.
4. For double-sided PCBs a single large ground plane is not recommended, since there is little control of where currents flow and the large surface area can act as an antenna.
5. Even though double sided PCBs are usually sufficient for a good layout, four-layer PCBs are the optimum approach to reducing susceptibility to noise. Use the two internal layers as the +5.0 V and GND planes, and the top and bottom layers for the vias.
6. Keep the inductor switching node small by placing the output inductor, switching and synchronous FETs close together.
7. The FET gate traces to the IC must be as short, straight, and wide as possible. Ideally, the IC has to be placed right next to the FETs.
8. Use fewer, but larger output capacitors, keep the capacitors clustered, and use multiple layer traces with heavy copper to keep the parasitic resistance low.
9. Place the switching FET as close to the +5.0 V input capacitors as possible.
10. Place the output capacitors as close to the load as possible.
11. Place the $\mathrm{V}_{\mathrm{FB}}$ filter resistor in series with the $\mathrm{V}_{\mathrm{FB}}$ pin (pin 16) right at the pin.
12. Place the $\mathrm{V}_{\mathrm{FB}}$ filter capacitor right at the $\mathrm{V}_{\mathrm{FB}}$ pin (pin 16).
13. The "Droop" Resistor (embedded PCB trace) has to be wide enough to carry the full load current.
14. Place the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor as close as possible to the $\mathrm{V}_{\mathrm{CC}}$ pin.

## CS5166H

## 5-Bit Synchronous CPU Controller with Power Good and Current Limit

The CS5166H is a synchronous dual NFET buck controller. It is designed to power the core logic of the latest high performance CPUs. It uses $\mathrm{V}^{2 \mathrm{TM}}$ control method to achieve the fastest possible transient response and best overall regulation. It incorporates many additional features required to ensure the proper operation and protection of the CPU and power system. The CS5166H provides the industry's most highly integrated solution, minimizing external component count, total solution size, and cost.

The CS5166H is specifically designed to power Intel's Pentium ${ }^{\circledR}$ II processor and includes the following features: 5-bit DAC with $1.0 \%$ tolerance, Power Good output, adjustable hiccup mode overcurrent protection, $\mathrm{V}_{\mathrm{CC}}$ monitor, Soft Start, adaptive voltage positioning, overvoltage protection, remote sense and current sharing capability.

The CS5166H will operate over a 4.15 to 20 V range using either single or dual input voltage and is available in a 16 lead wide body surface mount package.

## Features

- $\mathrm{V}^{2}$ Control Topology
- Dual N-Channel Design
- 125 ns Controller Transient Response
- Excess of 1.0 MHz Operation
- 5-Bit DAC with $1.0 \%$ Tolerance
- Power Good Output With Internal Delay
- Adjustable Hiccup Mode Overcurrent Protection
- Complete Pentium II System Requires Just 21 Components
- 5.0 V \& 12 V Operation Using Either Dual or Single Supplies
- Adaptive Voltage Positioning
- Remote Sense Capability
- Current Sharing Capability
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- Overvoltage Protection (OVP)
- Programmable Soft Start
- 200 ns PWM Blanking
- 65 ns FET Nonoverlap Time
- 40 ns Gate Rise and Fall Times (3.3 nF Load)

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| SO-16L | PIN SYMBOL | FUNCTION |
| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {ID0 }}-\mathrm{V}_{\text {ID4 }}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID }}$ is high (logic one), the Error Amp reference range is 2.125 V to 3.525 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is low (logic zero), the Error Amp reference voltage is 1.325 V to 2.075 V with 50 mV increments. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND sets the Soft Start and fault timing. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | Off-Time Capacitor Pin. A capacitor from this pin to LGND sets both the normal and extended off time. |
| 8 | ISENSE | Current Sense Comparator Inverting Input. |
| 9 | $\mathrm{V}_{\mathrm{CC}}$ | Input Power Supply Pin. |
| 10 | GATE(H) | High Side Switch FET driver pin. |
| 11 | PGND | High current ground for the GATE $(\mathrm{H})$ and GATE $(\mathrm{L})$ pins. |
| 12 | GATE(L) | Low Side Synchronous FET driver pin. |
| 13 | PWRGD | Power Good Output. Open collector output drives low when $\mathrm{V}_{\mathrm{FB}}$ is out of regulation. |
| 14 | LGND | Reference ground. All control circuits are referenced to this pin. |
| 15 | COMP | Error Amp output. PWM Comparator reference input. A capacitor to LGND provides Error Amp compensation. |
| 16 | $\mathrm{V}_{\mathrm{FB}}$ | Error Amp, PWM Comparator feedback input, Current Sense Comparator Non-Inverting input, and PWRGD Comparator input. |

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## $\mathrm{V}^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 9. ${ }^{2}$ Control Diagram
The $V^{2}$ control method is illustrated in Figure 9. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved,
since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.
The Bode plot in Figure 10 shows the gain and phase margin of the CS5166H single pole feedback loop and demonstrates the overall stability of the CS5166H-based regulator.

Figure 10. Feedback Loop Bode Plot
Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation.
A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5166H uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the CofF capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.
Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $30 \mu$ s (typical) timer, minimizing stress to the power components.

## Programmable Output

The CS5166H is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.125 V to 3.525 V in 100 mV steps, the second is 1.325 V to 2.075 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS5166H enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ pin, as in traditional controllers. The CS5166H is specifically designed to meet or exceed Intel's Pentium II specifications.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC}}$ supply pin exceeds the 3.95 V monitor threshold, the Soft Start and GATE pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC}}$ pin exceeds the monitor threshold, the GATE $(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.

If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE(H) pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.

When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the C CoFF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.

The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP capacitor charging to its final value. Its voltage is limited by the Soft Start COMP clamp and the voltage on the Soft Start pin.

## Normal Operation

During normal operation, switch off time is constant and set by the C CofF capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working and the ESR of the output capacitors (see Figures 14 and 15).

Figure 14. Normal Operation Showing Output Inductor Ripple Current and Output Voltage Ripple, 0.5 A Load, $\mathrm{V}_{\text {OUT }}=+2.825 \mathrm{~V}(\mathrm{DAC}=10111)$

## Transient Response

The CS5166H V ${ }^{2}$ control loop's 150 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

Overall load transient response is further improved through a feature called "Adaptive Voltage Positioning". This technique pre-positions the output capacitors voltage to reduce total output voltage excursions during changes in load.

Holding tolerance to $1.0 \%$ allows the error amplifiers reference voltage to be targeted +25 mV high without compromising DC accuracy. A "Droop Resistor", implemented through a PC board trace, connects the Error Amps feedback pin ( $\mathrm{V}_{\mathrm{FB}}$ ) to the output capacitors and load and carries the output current. With no load, there is no DC drop across this resistor, producing an output voltage tracking the Error amps, including the +25 mV offset. When the full load current is delivered, an 50 mV drop is developed across this resistor. This results in output voltage being offset -25 mV low.

The result of Adaptive Voltage Positioning is that additional margin is provided for a load transient before
reaching the output voltage specification limits. When load current suddenly increases from its minimum level, the output capacitor is pre-positioned +25 mV . Conversely, when load current suddenly decreases from its maximum level, the output capacitor is pre-positioned -25 mV (see Figures 16, 17, and 18). For best Transient Response, a combination of a number of high frequency and bulk output capacitors are usually used.

If the Maximum On-Time is exceeded while responding to a sudden increase in Load current, a normal off-time occurs to prevent saturation of the output inductor.

## Power Supply Sequencing

The CS5166H offers inherent protection from undefined start up conditions, regardless of the 12 V and 5.0 V supply power up sequencing. The turn on slew rates of the 12 V and 5.0 V power supplies can be varied over wide ranges without affecting the output voltage or causing detrimental effects to the buck regulator.

## PROTECTION AND MONITORING FEATURES

## Overcurrent Protection

A loss-less hiccup mode current limit protection feature is provided, requiring only the Soft Start capacitor to implement. The CS5166H provides overcurrent protection by sensing the current through a "Droop" resistor, using an internal current sense comparator. The comparator compares this voltage drop to an internal reference voltage of 76 mV (typical).

If the voltage drop across the "Droop" resistor exceeds this threshold, the current sense comparator allows the fault latch to be set. This causes the regulator to stop switching. During this overcurrent condition, the CS5166H stays off for the time it takes the Soft Start capacitor to slowly discharge by a $2.0 \mu \mathrm{~A}$ current source until it reaches its lower 0.7 V threshold.

At that time the regulator attempts to restart normally by delivering short gate pulses to both FET's. The CS5166H will operate initially in its extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a 60 mA charge current. The gates will switch on while
the Soft Start capacitor is charged to its upper 2.7 V threshold. During an overload condition the Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=3.3 \%)$, while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ) when $\mathrm{V}_{\mathrm{FB}}$ is less than 1.0 V . The Soft Start hiccup pulses last for a 3.0 ms period at the end of which the duty cycle repeats if a fault is detected, otherwise normal operation resumes.

The protection scheme minimizes thermal stress to the regulator components, input power supply, and PC board traces, as the overcurrent condition persists. Upon removal of the overload, the fault latch is cleared, allowing normal operation to resume. The current limit trip point can be adjusted through an external resistor, providing the user with the current limit set-point flexibility.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top

MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 21 and 22 ). The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function. If a dedicated OVP output is required, it can be implemented using the circuit in Figure 23. In this figure the OVP signal will go high (overvoltage condition), if the output voltage ( $\mathrm{V}_{\mathrm{CORE}}$ ) exceeds $20 \%$ of the voltage set by the particular DAC code and provided that PWRGD is low. It is also required that the overvoltage condition be present for at least the PWRGD delay time for the OVP signal to be activated. The resistor values shown in Figure 23 are for $\mathrm{V}_{\mathrm{DAC}}=+2.8 \mathrm{~V}(\mathrm{DAC}=10111)$. The $\mathrm{V}_{\mathrm{OVP}}$ (overvoltage trip-point) can be set using the following equation:

$$
\mathrm{V}_{\mathrm{OVP}}=\mathrm{V}_{\mathrm{BEQ}}\left(1+\frac{\mathrm{R} 2}{\mathrm{R} 1}\right)
$$

## Power Good Circuit

The Power Good pin (pin 13) is an open-collector signal consistent with TTL DC specifications. It is externally pulled-up, and is pulled low (below 0.3 V ) when the regulator output voltage typically exceeds $\pm 8.5 \%$ of the nominal output voltage. Maximum output voltage deviation before Power Good is pulled low is $\pm 12 \%$.

Trace $4-\mathrm{V}_{\mathrm{FB}}$ ( $1.0 \mathrm{~V} /$ div.)
Figure 25. Power Good Response to an Out of Regulation Condition
Figure 25 shows the relationship between the regulated output voltage $\mathrm{V}_{\mathrm{FB}}$ and the Power Good signal. To prevent Power Good from interrupting the CPU unnecessarily, the CS5166H has a built-in delay to prevent noise at the $V_{\text {FB }}$ pin from toggling Power Good. The internal time delay is designed to take about $75 \mu$ s for Power Good to go low and $65 \mu \mathrm{~s}$ for it to recover. This allows the Power Good signal to be completely insensitive to out of regulation conditions that are present for a duration less than the built in delay (see Figure 26).
It is therefore required that the output voltage attains an out of regulation or in regulation level for at least the built-in delay time duration before the Power Good signal can change state.

Trace 4- $\mathrm{V}_{\mathrm{FB}}$ (1.0 V/div.)
Figure 26. Power Good is Insensitive to Out of Regulation Conditions that are Present for a Duration Less Than the Built In Delay

## External Output Enable Circuit

On/off control of the regulator can be implemented through the addition of two additional discrete components (see Figure ). This circuit operates by pulling the Soft Start pin high, and the I SENSE pin low, emulating a current limit condition.

Figure 27. Implementing Shutdown with the CS5166H

## Selecting External Components

The CS5166H buck regulator can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard FETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and utilize logic level FETs. A charge pump may be easily implemented to permit use of standard FET's or support 5.0 V or 12 V only systems (maximum of 20 V ). Multiple FET's may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the FET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the FET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC}}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided:

$$
\begin{gathered}
\mathrm{VGS}_{\mathrm{GS}}(\mathrm{TOP})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V} \\
\mathrm{VGS}(\mathrm{BOTTOM})=12 \mathrm{~V}
\end{gathered}
$$

(see Figure 28)

Figure 28. Gate Drive Waveforms Depicting Rail to Rail Swing

Trace $1=\operatorname{GATE}(\mathrm{H})(5.0 \mathrm{~V} /$ div. $)$
Trace $2=$ GATE(L) (5.0 V/div.)
Figure 29. Normal Operation Showing the Guaranteed Non-Overlap Time Between the High and Low-Side MOSFET Gate Drives, I LOAD = 14 A
The CS5166H provides adaptive control of the external NFET conduction times by guaranteeing a typical 65 ns non-overlap (as seen in Figure 29) between the upper and lower MOSFET gate drive pulses. This feature eliminates the potentially catastrophic effect of "shoot-through current", a condition during which both FETs conduct causing them to overheat, self-destruct, and possibly inflict irreversible damage to the processor.

The most important aspect of FET performance is RDS $_{\text {ON }}$, which effects regulator efficiency and FET thermal management requirements.

The power dissipated by the MOSFETs may be estimated as follows:

Switching MOSFET:

$$
\text { Power }=\text { ILOAD }{ }^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:

$$
\begin{aligned}
& \text { Power }=\text { ILOAD }^{2} \times \text { RDSON } \times(1-\text { duty cycle }) \\
& \text { Duty Cycle }= \\
& \frac{\text { VOUT }+(\text { ILOAD } \times \text { RDSON OF SYNCH FET })}{\left[\begin{array}{l}
\text { VIN }+(\text { ILOAD } \times \text { RDSON OF SYNCH FET }) \\
-(\text { ILOAD } \times \text { RDSON OF SWITCH FET })
\end{array}\right]}
\end{aligned}
$$

## Off Time Capacitor (COFF)

The $\mathrm{C}_{\mathrm{OFF}}$ timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the CofF timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous FET

For synchronous operation, a Schottky diode may be placed in parallel with the synchronous FET to conduct the inductor current upon turn off of the switching FET to improve efficiency. The CS5166H reference circuit does not use this device due to it's excellent design. Instead, the body diode of the synchronous FET is utilized to reduce cost and conducts the inductor current. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense. The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=V_{B D} \times$ LLOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the CS5166H demonstration board:

$$
\text { Power }=1.6 \mathrm{~V} \times 14.2 \mathrm{~A} \times 100 \mathrm{~ns} \times 200 \mathrm{kHz}=0.45 \mathrm{~W}
$$

This is only $1.1 \%$ of the 40 W being delivered to the load.

## "Droop" Resistor for Adaptive Voltage Positioning

Adaptive voltage positioning is used to help keep the output voltage within specification during load transients. To implement adaptive voltage positioning a "Droop Resistor" must be connected between the output inductor
and output capacitors and load. This resistor carries the full load current and should be chosen so that both DC and AC tolerance limits are met. An embedded PC trace resistor has the distinct advantage of near zero cost implementation. However, this droop resistor can vary due to three reasons: 1) the sheet resistivity variation causes the thickness of the PCB layer to vary. 2) the mismatch of L/W, and 3) temperature variation.

1. Sheet Resistivity for one ounce copper, the thickness variation typically 1.15 mil to 1.35 mil . Therefore the error due to sheet resistivity is:

$$
\frac{1.35-1.15}{1.25}=16 \%
$$

2. Mismatch due to $L / W$. The variation in $L / W$ is governed by variations due to the PCB manufacturing process that affect the geometry and the power dissipation capability of the droop resistor. The error due to $\mathrm{L} / \mathrm{W}$ mismatch is typically $1.0 \%$.
3. Thermal Considerations. Due to $\mathrm{I}^{2} \times \mathrm{R}$ power losses the surface temperature of the droop resistor will increase causing the resistance to increase. Also, the ambient temperature variation will contribute to the increase of the resistance, according to the formula:

$$
R=R_{20}\left[1+\alpha_{20}(T-20)\right]
$$

where:
$\mathrm{R}_{20}=$ resistance at $20^{\circ} \mathrm{C}$
$\alpha=\frac{0.00393}{{ }^{\circ} \mathrm{C}}$

$$
\mathrm{T}=\text { operating temperature }
$$

$\mathrm{R}=$ desired droop resistor value
For temperature $\mathrm{T}=50^{\circ} \mathrm{C}$, the $\% \mathrm{R}$ change $=12 \%$

## Droop Resistor Tolerance

Tolerance due to sheet resistivity variation $16 \%$
Tolerance due to L/W error $1.0 \%$
Tolerance due to temperature variation $12 \%$
Total tolerance for droop resistor 29\%
In order to determine the droop resistor value the nominal voltage drop across it at full load has to be calculated. This voltage drop has to be such that the output voltage full load is above the minimum DC tolerance spec.

$$
\mathrm{V}_{\mathrm{DROOP}}(\mathrm{TYP})=\frac{\left[\mathrm{V}_{\mathrm{DAC}}(\mathrm{MIN})-\mathrm{V}_{\mathrm{DC}}(\mathrm{MIN})\right]}{1+\mathrm{RDROOP}^{(T O L E R A N C E)}}
$$

Example: for a 300 MHz PentiumII, the DC accuracy spec is $2.74<\mathrm{V}_{\mathrm{CC}(\text { CORE })}<2.9 \mathrm{~V}$, and the AC accuracy spec is $2.67 \mathrm{~V}<\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}<2.93 \mathrm{~V}$. The CS5166H DAC output voltage is $+2.796 \mathrm{~V}<\mathrm{V}_{\mathrm{DAC}}<+2.853 \mathrm{~V}$. In order not to exceed the DC accuracy spec, the voltage drop developed across the resistor must be calculated as follows:

$$
\begin{aligned}
\mathrm{V}_{\text {DROOP(TYP) }} & =\frac{\left[\mathrm{V}_{\mathrm{DAC}(\mathrm{MIN})}-\mathrm{V}_{\mathrm{DC}}\right. \text { PENTIUMII(MIN)] }}{1+\mathrm{RDROOP}(\mathrm{TOLERANCE})} \\
& =\frac{2.796 \mathrm{~V}-2.74 \mathrm{~V}}{1.3}=43 \mathrm{mV}
\end{aligned}
$$

With the CS5166H DAC accuracy being $1.0 \%$, the internal error amplifier's reference voltage is trimmed so that the output voltage will be 25 mV high at no load. With no load, there is no DC drop across the resistor, producing an output voltage tracking the error amplifier output voltage, including the offset. When the full load current is delivered, a drop of -43 mV is developed across the resistor. Therefore, the regulator output is pre-positioned at 25 mV above the nominal output voltage before a load turn-on. The total voltage drop due to a load step is $\Delta \mathrm{V}-25 \mathrm{mV}$ and the
deviation from the nominal output voltage is 25 mV smaller than it would be if there was no droop resistor. Similarly at full load the regulator output is pre-positioned at 18 mV below the nominal voltage before a load turn-off. The total voltage increase due to a load turn-off is $\Delta \mathrm{V}-18 \mathrm{mV}$ and the deviation from the nominal output voltage is 18 mV smaller than it would be if there was no droop resistor. This is because the output capacitors are pre-charged to value that is either 25 mV above the nominal output voltage before a load turn-on or, 18 mV below the nominal output voltage before a load turn-off (see Figure 16).
Obviously, the larger the voltage drop across the droop resistor (the larger the resistance), the worse the DC and load regulation, but the better the AC transient response.

Figure 30. Circuit Used to Determine the Voltage Across the Droop Resistor that will Trip the Internal Current Sense Comparator

## Current Limit Setpoint Calculations

The following is the design equations used to set the current limit trip point by determining the value of the embedded PCB trace used as a current sensing element.

The current limit setpoint has to be higher than the normal full load current. Attention has to be paid to the current rating of the external power components as these are the first to fail during an overload condition. The MOSFET continuous and pulsed drain current rating at a given case temperature has to be accounted for when setting the current limit trip point. For example the IRL 3103S ( $\mathrm{D}^{2}$ PAK) MOSFET has a continuous drain current rating of 45 A at $\mathrm{V}_{\mathrm{GS}}=10 \mathrm{~V}$ and $\mathrm{T}_{\mathrm{C}}=100^{\circ} \mathrm{C}$. Temperature curves on MOSFET manufacturers' data sheets allow the designer to determine the MOSFET drain current at a particular $\mathrm{V}_{\mathrm{GS}}$ and $\mathrm{T}_{\mathrm{J}}$ (junction temperature). This, in turn, will assist the designer to set a proper current limit, without causing device breakdown during an overload condition.

For 300 MHz Pentium II CPU the full load is 14.2 A . The internal current sense comparator current limit voltage
limits are: $55 \mathrm{mV}<\mathrm{V}_{\mathrm{TH}}<130 \mathrm{mV}$. Also, there is a $29 \%$ total variation in $\mathrm{R}_{\text {SENSE }}$ as discussed in the previous section.

We select the value of the current sensing element (embedded PCB trace) for the minimum current limit setpoint:

$$
\begin{gathered}
\operatorname{RSENSE}(\mathrm{MAX})=\frac{\mathrm{V}_{\mathrm{TH}(\mathrm{MIN})} \mathrm{I} \mathrm{CL}(\mathrm{MIN})}{\mathrm{R}} \Rightarrow \mathrm{RSENSE} \times 1.29=\frac{55 \mathrm{mV}}{14.2 \mathrm{~A}} \Rightarrow \\
\text { RSENSE } \times 1.29=3.87 \mathrm{~m} \Omega \Rightarrow \text { RSENSE }=3.0 \mathrm{~m} \Omega
\end{gathered}
$$

We calculate the range of load currents that will cause the internal current sense comparator to detect and overload condition.

From the overcurrent detection data section on page 2095. Nominal Current Limit Setpoint

$$
\begin{gathered}
\mathrm{V}_{\mathrm{TH}(\mathrm{TYP})}=76 \mathrm{mV} \\
\mathrm{I}_{\mathrm{CL}(\mathrm{NOM})}=\frac{\mathrm{V}_{\mathrm{TH}(\mathrm{TYP})}}{\operatorname{RSENSE}(\mathrm{NOM})}
\end{gathered}
$$

Maximum Current Limit Setpoint

$$
\begin{aligned}
& \text { Therefore, } \operatorname{ICL}(\mathrm{NOM})=\frac{76 \mathrm{mV}}{3.0 \mathrm{~m} \Omega}=25.3 \\
& \mathrm{~V}_{\mathrm{TH}(\mathrm{MAX})}=110 \mathrm{mV}
\end{aligned}
$$

Therefore,
$\operatorname{ICL}(\mathrm{MAX})=$
$\frac{110 \mathrm{mV}}{\operatorname{RSENSE}_{(M I N)}}=\frac{110 \mathrm{mV}}{\text { RSENSE } \times 0.71}=\frac{110 \mathrm{mV}}{3.0 \mathrm{~m} \Omega \times 0.71}=51.6 \mathrm{~A}$
Therefore, the range of load currents that will cause the internal current sense comparator to detect an overload condition through a $3.0 \mathrm{~m} \Omega$ embedded PCB trace is: 14.2 A $<\mathrm{I}_{\mathrm{CL}}<51.6 \mathrm{~A}$, with 25.3 A being the nominal overload condition.

There may be applications whose layout will require the use of two extra filter components, a $510 \Omega$ resistor in series with the $\mathrm{I}_{\text {SENSE }}$ pin, and a $0.1 \mu \mathrm{~F}$ capacitor between the $I_{\text {SENSE }}$ and $\mathrm{V}_{\text {FB }}$ pins. These are needed for proper current limit operation and the resistor value is layout dependent.

This series resistor affects the calculation of the current limit setpoint, and has to be taken into account when determining an effective current limit.

The calculations below show how the current limit setpoint is determined when this $510 \Omega$ is taken into consideration.
$\mathrm{V}_{\text {TRIP }}=\mathrm{V}_{\mathrm{TH}}+\left(\mathrm{I}_{\text {SENSE }} \times \mathrm{R}_{\text {ISENSE }}\right)-\left(\mathrm{R}_{\mathrm{FB}} \times \mathrm{I}_{\mathrm{FB}}\right)$
Where:
$\mathrm{V}_{\text {TRIP }}=$ voltage across the droop resistor that trips the $\mathrm{I}_{\text {SENSE }}$ comparator.
$\mathrm{V}_{\mathrm{TH}}=$ internal $\mathrm{I}_{\text {SENSE }}$ comparator threshold
$\mathrm{I}_{\text {SENSE }}=\mathrm{I}_{\text {SENSE }}$ bias current
$\mathrm{R}_{\text {ISENSE }}=\mathrm{I}_{\text {SENSE }}$ pin $510 \Omega$ filter resistor
$\mathrm{R}_{\mathrm{FB}}=\mathrm{V}_{\mathrm{FB}}$ pin 3.3 k filter resistor
$\mathrm{I}_{\mathrm{FB}}=\mathrm{V}_{\mathrm{FB}}$ bias current
Minimum current sense resistor (droop resistor) voltage drop required for current limit when $\mathrm{R}_{\text {ISENSE }}$ is used

$$
\begin{aligned}
\mathrm{V}_{\mathrm{TRIP}(\mathrm{MIN})} & =55 \mathrm{mV}+(13 \mu \mathrm{~A} \times 510)-(3.3 \mathrm{k} \times 1.0 \mu \mathrm{~A}) \\
& =55 \mathrm{mV}+6.6 \mathrm{mV}-3.3 \mathrm{mV}=58.3 \mathrm{mV}
\end{aligned}
$$

Nominal current sense resistor (droop resistor) voltage drop required for current limit when $\mathrm{R}_{\text {ISENSE }}$ is used

$$
\begin{aligned}
\mathrm{V} \text { TRIP(NOM) } & =76 \mathrm{mV}+(30 \mu \mathrm{~A} \times 510)-(3.3 \mathrm{k} \times 0.1 \mu \mathrm{~A}) \\
& =76 \mathrm{mV}+15.3 \mathrm{mV}-0.33 \mathrm{mV}=90.97 \mathrm{mV}
\end{aligned}
$$

Maximum current sense resistor (droop resistor) voltage drop required for current limit when $\mathrm{R}_{\text {ISENSE }}$ is used

$$
\begin{aligned}
\mathrm{V} \operatorname{TRIP}(\mathrm{NOM}) & =110 \mathrm{mV}+(50 \mu \mathrm{~A} \times 510) \\
& =110 \mathrm{mV}+25.5 \mathrm{mV}=135.5 \mathrm{mV}
\end{aligned}
$$

The value of $\mathrm{R}_{\text {SENSE }}$ (current sense PCB trace) is then calculated:

$$
\begin{gathered}
\operatorname{RSENSE}(\mathrm{MAX})=\frac{58.3 \mathrm{mV}}{14.2 \mathrm{~A}}=4.1 \mathrm{~m} \Omega \\
\operatorname{RSENSE}(\mathrm{NOM})=\frac{\operatorname{RSENSE}(\mathrm{MAX})}{1.29}=\frac{4.1 \mathrm{~m} \Omega \mathrm{~m}}{1.29}=3.18 \mathrm{~m} \Omega
\end{gathered}
$$

The range of load currents that will cause the internal current sense comparator to detect an overload condition is as follows:
Nominal Current Limit Setpoint

$$
\operatorname{ICL}(\mathrm{NOM})=\frac{\mathrm{V}_{\operatorname{TRIP}(\mathrm{NOM})}}{\operatorname{RSENSE}(\mathrm{NOM})}
$$

Therefore,

$$
\mathrm{ICL}(\mathrm{NOM})=\frac{90.97 \mathrm{mV}}{3.18 \mathrm{~m} \Omega}=28.6 \mathrm{~A}
$$

## Maximum Current Limit Setpoint

$$
\mathrm{I}_{\mathrm{CL}(\mathrm{MAX})}=\frac{\mathrm{V} \operatorname{TRIP}(\mathrm{MAX})}{\operatorname{RSENSE}(\mathrm{MAX})}
$$

Therefore,

$$
\mathrm{ICL}(\mathrm{MAX})=\frac{135 \mathrm{mV}}{3.18 \mathrm{~m} \Omega \times 0.71}=60 \mathrm{~A}
$$

Therefore, the range of load currents that will cause the internal current sense comparator to detect an overload condition through a $3.0 \mathrm{~m} \Omega$ embedded PCB trace is: 14.2 A < ICL 60 A, with 28.6 A being the nominal overload condition.

## Design Rules for Using a Droop Resistor

The basic equation for laying an embedded resistor is:

$$
R_{A R}=\rho \times \frac{L}{A} \text { or } R=\rho \times \frac{L}{(W \times t)}
$$

where:

$$
\begin{aligned}
& A=W \times t=\text { cross-sectional area } \\
& \rho=\text { the copper resistivity }(\mu \Omega-\text { mil }) \\
& L=\text { length (mils) } \\
& W=\text { width (mils) } \\
& t=\text { thickness (mils) }
\end{aligned}
$$

For most PCBs the copper thickness, t , is $35 \mu \mathrm{~m}(1.37$ mils) for one ounce copper. $\rho=717.86 \mu \Omega-$ mil

For a Pentium II load of 14.2 A the resistance needed to create a 43 mV drop at full load is:

$$
\text { Response Droop }=\frac{43 \mathrm{mV}}{\mathrm{IOUT}}=\frac{43 \mathrm{mV}}{14.2 \mathrm{~A}}=3.0 \mathrm{~m} \Omega
$$

The resistivity of the copper will drift with the temperature according to the following guidelines:

$$
\begin{gathered}
\Delta R=12 \% @ T_{A}=+50^{\circ} \mathrm{C} \\
\Delta R=34 \% @ T_{A}=+100^{\circ} \mathrm{C}
\end{gathered}
$$

Figure 31. Current Sharing of a 2.8 V/30 A Power Supply Using Two CS5166H Synchronous Buck Regulators

## Droop Resistor Width Calculations

The droop resistor must have the ability to handle the load current and therefore requires a minimum width which is calculated as follows (assume one ounce copper thickness):

$$
W=\frac{\mathrm{L} \text { LOAD }}{0.05}
$$

where:
$\mathrm{W}=$ minimum width (in mils) required for proper power dissipation, and $\mathrm{I}_{\text {LOAD }}$ Load Current Amps.

The Pentium II maximum load current is 14.2 A . Therefore:

$$
\mathrm{W}=\frac{14.2 \mathrm{~A}}{0.05}=284 \mathrm{mils}=0.7213 \mathrm{~cm}
$$

Droop Resistor Length Calculation

$$
\begin{aligned}
\mathrm{L} & =\frac{\mathrm{RDROOP} \times \mathrm{W} \times \mathrm{t}}{\rho} \\
& =\frac{0.0030 \times 284 \times 1.37}{717.86}=1626 \mathrm{mil}=4.13 \mathrm{~cm}
\end{aligned}
$$

## Implementing Current Sharing Using the "Droop Resistor"

In addition to improving load transient performance, the CS5166H V ${ }^{2}$ control method allows the droop resistor to provide the additional capability to easily implement current sharing. Figure 31 shows a simplified schematic of two current sharing synchronous buck regulators. Each buck
regulator's droop resistor is terminated at the load. The PWM control signal from each Error Amp is connected together, causing the inner PWM loop to regulate to a common voltage. Since the voltage at each resistor terminal is the same, this configuration results in equal voltage being applied across each matched droop resistor. The result is equal current flowing through each buck regulator. An additional benefit is that synchronization to a common switching frequency tends to be achieved because each regulator shares a common PWM ramp signal.

In practice, each buck regulator will regulate to a slightly different output voltage due to mismatching of the PWM comparators, slope of the PWM ramp (output voltage ripple), and propagation delays. At light loads, the results can be very poor current sharing. With zero output current, some regulators may be sourcing current while others may be sinking current.

This results in additional power dissipation and lower efficiency than would be obtained by a single regulator. This is usually not an issue since efficiency is most important when a supply is fully loaded.

This effect is similar to the difference in efficiency between synchronous and non-synchronous buck regulators. Synchronous buck regulators have lower efficiency at light loads because inductor current is always continuous, flowing from the load to ground during switch off-time through the synchronous rectifier. Under full load conditions, the synchronous design is more efficient due to the lower voltage drop across the synchronous rectifier. Likewise, the efficiency of droop sharing regulators will be lower at light loads due to the continuous current flow in the droop resistors. Efficiency at heavy loads tends to be higher due to reduced $\mathrm{I}^{2} \mathrm{R}$ losses.

The output current of each regulator can be calculated from:

$$
\mathrm{I}_{\mathrm{N}}=\frac{(\mathrm{VOUT}(\mathrm{~N})-\mathrm{VOUT})}{\operatorname{RDROOP}(\mathrm{N})}
$$

where: $\mathrm{V}_{\mathrm{OUT}(\mathrm{N})}$ and $\mathrm{R}_{\mathrm{DROOP}(\mathrm{N})}$ are the output voltage and droop resistance of a particular regulator and $\mathrm{V}_{\text {OUT }}$ is the system output voltage. Output current is the sum of each regulator's current:

$$
\text { IOUT }=\mathrm{I} 1+\mathrm{I} 2+\ldots+\mathrm{IN}
$$

Current sharing improves with increasing load current. The increasing voltage drop across the droop resistor due to increasing load current eventually swamps out the differences in regulator output voltages. If a large enough voltage can be developed across the droop resistors, current sharing accuracy will be determined solely by their matching. To realize the benefits of current sharing, it is not
necessary to obtain perfect matching. Keeping output currents within $\pm 10 \%$ is usually acceptable.
For microprocessor applications, the value of the droop resistor must be selected to optimize adaptive voltage positioning, current sharing, current limit and efficiency. Current sharing is realized by simply connecting the COMP pins of the respective buck regulators, as shown in Figure 31.

Figure 32 shows operation with no load. In this case, there is insufficient output voltage ripple across the droop resistor to produce complete synchronization. Duty Cycle is close to the theoretical $56 \%\left(\mathrm{~V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{IN}}\right)$ resulting in a switching frequency of approximately 275 kHz .
Figure 34 shows operation with a 30 Amp load. Synchronization between the two regulators is now obtained due to increased ripple voltage. Increases losses cause the $\mathrm{V}^{2}$ control loop to increase on-time to compensate. This results in a larger duty cycle and a corresponding decrease in switching frequency to 233 kHz .

Figure 33. 15 A Load Transient Waveforms

Trace 1 = Output voltage ripple.
Trace 2 = Buck regulator \#1 inductor switching node.
Trace 3 = Buck regulator \#2 inductor switching node.
Figure 34. 30 A Load Waveforms
Figure 33 shows supply response to a 15 A load step with a $30 \mathrm{~A} / \mu \mathrm{s}$ slew rate. The $\mathrm{V}^{2}$ control loop immediately forces the duty cycle to $100 \%$, ramping the current in both inductors up. A voltage spike of 136 mV due to output capacitor impedance occurs. The inductive component of the spike due to ESL recovers within several microseconds. The resistive component due to ESR decreases as inductor current replaces capacitor current.

The benefit of adaptive voltage positioning in reducing the voltage spike can readily be seen. The difference in DC voltage and duty cycle can also be observed. This particular transient occurred near the beginning of regulator off time, resulting in a longer recovery time and increased voltage spike.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## Inductor Ripple Current

$$
\text { Ripple Current }=\frac{\left[\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{V}_{\mathrm{OUT}}\right]}{\left(\text { Switching Frequency } \times \mathrm{L} \times \mathrm{V}_{\mathrm{IN}}\right)}
$$

Example: $\mathrm{V}_{\mathrm{IN}}=+5.0 \mathrm{~V}, \mathrm{~V}_{\mathrm{OUT}}=+2.8 \mathrm{~V}, \mathrm{I}_{\mathrm{LOAD}}=14.2 \mathrm{~A}$, $\mathrm{L}=1.2 \mu \mathrm{H}$, Freq $=200 \mathrm{kHz}$

$$
\text { Ripple Current }=\frac{[(5.0 \mathrm{~V}-2.8 \mathrm{~V}) \times 2.8 \mathrm{~V}]}{[200 \mathrm{kHz} \times 1.2 \mu \mathrm{H} \times 5.0 \mathrm{~V}]}=5.1 \mathrm{~A}
$$

## Output Ripple Voltage

VRIPPLE $=$ Inductor Ripple Current $\times$ Output Capacitor ESR

## Example:

$\mathrm{V}_{\text {IN }}=+5.0 \mathrm{~V}, \mathrm{~V}_{\text {OUT }}=+2.8 \mathrm{~V}, \mathrm{I}_{\mathrm{LOAD}}=14.2 \mathrm{~A}, \mathrm{~L}=1.2 \mu \mathrm{H}$, Switching Frequency $=200 \mathrm{kHz}$

Output Ripple Voltage $=5.1 \mathrm{~A} \times$ Output Capacitor ESR (from manufacturer's specs)

ESR of Output Capacitors to limit Output Voltage Spikes

$$
\mathrm{ESR}=\frac{\Delta \mathrm{V} \mathrm{OUT}}{\Delta \mathrm{I} \mathrm{OUT}}
$$

This applies for current spikes that are faster than regulator response time. Printed Circuit Board resistance will add to the ESR of the output capacitors.

In order to limit spikes to 100 mV for a 14.2 A Load Step, $\mathrm{ESR}=0.1 / 14.2=0.007 \Omega$

## Inductor Peak Current

Peak Current $=$ Maximum Load Current $+\left(\frac{\text { Ripple Current }}{2}\right)$
Example: $\mathrm{V}_{\mathrm{IN}}=+5.0 \mathrm{~V}, \mathrm{~V}_{\mathrm{OUT}}=+2.8 \mathrm{~V}, \mathrm{I}_{\mathrm{LOAD}}=14.2 \mathrm{~A}$, $\mathrm{L}=1.2 \mu \mathrm{H}$, Freq $=200 \mathrm{kHz}$

$$
\text { Peak Current }=14.2 \mathrm{~A}+(5.1 / 2)=16.75 \mathrm{~A}
$$

A key consideration is that the inductor must be able to deliver the Peak Current at the switching frequency without saturating.

## Response Time to Load Increase

(limited by Inductor value unless Maximum On-Time is exceeded)

$$
\text { Response Time }=\frac{\mathrm{L} \times \Delta \mathrm{l} \text { OUT }}{\left(\mathrm{V} \mathrm{~V}, ~-\mathrm{V}_{\mathrm{OUT}}\right)}
$$

Example: $\mathrm{V}_{\mathrm{IN}}=+5.0 \mathrm{~V}, \mathrm{~V}_{\text {OUT }}=+2.8 \mathrm{~V}, \mathrm{~L}=1.2 \mu \mathrm{H}, 14.2 \mathrm{~A}$ change in Load Current

$$
\text { Response Time }=\frac{1.2 \mu \mathrm{H} \times 14.2 \mathrm{~A}}{(5.0 \mathrm{~V}-2.8 \mathrm{~V})}=7.7 \mu \mathrm{~s}
$$

## Response Time to Load Decrease

(limited by Inductor value)

$$
\text { Response Time }=\frac{\mathrm{L} \times \text { Change in IOUT }}{\text { VOUT }}
$$

Example: $\mathrm{V}_{\text {OUT }}=+2.8 \mathrm{~V}, 14.2$ A change in Load Current, $\mathrm{L}=1.2 \mu \mathrm{H}$

$$
\text { Response Time }=\frac{1.2 \mu \mathrm{H} \times 14.2 \mathrm{~A}}{2.8 \mathrm{~V}}=6.1 \mu \mathrm{~s}
$$

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:

$$
\text { Thermal Impedance }=\frac{\mathrm{T}_{\mathrm{J}}(\mathrm{MAX})-\mathrm{T}_{\mathrm{A}}}{\text { Power }}
$$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 35. Filter Components

Figure 36. Input Filter

## Layout Guidelines

When laying out the CPU buck regulator on a printed circuit board, the following checklist should be used to ensure proper operation of the CS5166H.

1. Rapid changes in voltage across parasitic capacitors and abrupt changes in current in parasitic inductors are major concerns for a good layout.
2. Keep high currents out of sensitive ground connections. Avoid connecting the IC GND (LGND) between the source of the lower FET and the input capacitor GND.
3. Avoid ground loops as they pick up noise. Use star or single point grounding.
4. For high power buck regulators on double-sided PCBs a single large ground plane (usually the bottom) is recommended.
5. Even though double sided PCBs are usually sufficient for a good layout, four-layer PCBs are the optimum approach to reducing susceptibility to noise. Use the two internal layers as the +5.0 V and GND planes, the top layer for the power connections and component vias, and the bottom layer for the noise sensitive traces.
6. Keep the inductor switching node small by placing the output inductor, switching and synchronous FETs close together.
7. The FET gate traces to the IC must be as short, straight, and wide as possible. Ideally, the IC has to be placed right next to the FETs.
8. Use fewer, but larger output capacitors, keep the capacitors clustered, and use multiple layer traces with heavy copper to keep the parasitic resistance low.
9. Place the switching FET as close to the +5.0 V input capacitors as possible.
10. Place the output capacitors as close to the load as possible.
11. Place the $\mathrm{V}_{\mathrm{FB}}$ filter resistor in series with the $\mathrm{V}_{\mathrm{FB}}$ pin (pin 16) right at the pin.
12. Place the $\mathrm{V}_{\mathrm{FB}}$ filter capacitor right at the $\mathrm{V}_{\mathrm{FB}}$ pin (pin 16).
13. The "Droop" Resistor (embedded PCB trace) has to be wide enough to carry the full load current.
14. Place the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor as close as possible to the $\mathrm{V}_{\mathrm{CC}}$ pin and connect it to the PGND pin of the IC. Connect the PGND pin directly to the GND plane.
15. Create a subground (local GND) plane preferably on the PCB top layer and under the IC controller. Connect all logic capacitor returns and the LGND pin of the IC to this place. Connect the subground plane to the main GND plane using a minimum of four (4) vias.

## CS51312

## Synchronous CPU Buck Controller for 12 V Only Applications

The CS51312 is a synchronous dual NFET Buck Regulator Controller. It is designed to power the core logic of the latest high performance CPUs and ASICs from a single 12 V input. It uses the $\mathrm{V}^{2 \mathrm{TM}}$ control method to achieve the fastest possible transient response and best overall regulation. It incorporates many additional features required to ensure the proper operation and protection of the CPU and Power system. The CS51312 provides the industry's most highly integrated solution, minimizing external component count, total solution size, and cost.

The CS51312 is specifically designed to power Intel's Pentium® II processor and includes the following features: 5-bit DAC with $1.2 \%$ tolerance, Power-Good output, overcurrent hiccup mode protection, overvoltage protection, $\mathrm{V}_{\mathrm{CC}}$ monitor, Soft Start, adaptive voltage positioning, adaptive FET non-overlap time, and remote sense. The CS51312 will operate over a 9.0 V to $20 \mathrm{~V}\left(\mathrm{~V}_{\mathrm{CC} 2}\right)$ range using either single or dual input voltage and is available in 16 lead narrow body surface mount package.

## Features

- Synchronous Switching Regulator Controller for CPU VCORE
- Dual N-Channel MOSFET Synchronous Buck Design
- $\mathrm{V}^{2}$ Control Topology
- 200 ns Transient Loop Response
- 5-Bit DAC with $1.2 \%$ Tolerance
- Hiccup Mode Overcurrent Protection
- 40 ns Gate Rise and Fall Times (3.3nF Load)
- 65 ns Adaptive FET Non-Overlap Time
- Adaptive Voltage Positioning
- Power Good Output Monitors Regulator Output
- 5.0 V/12 V or $12 \mathrm{~V}-$ Only Operation
- $\mathrm{V}_{\mathrm{CC}}$ Monitor Provides Undervoltage Lockout
- OVP Output Monitors Regulator Output
- Multifunctional COMP Pin Provides ENABLE, Soft Start, and Hiccup Timing in Addition to Control Loop Compensation

## PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| SO-16 | PIN SYMBOL | FUNCTION |
| 1, 2, 3, 4, 5 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID } 4}$ | Voltage ID DAC inputs. These pins are internally pulled up to 5.65 V if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is high (logic one), the Error Amp reference range is 2.125 V to 3.525 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is low (logic zero), the Error Amp reference voltage is 1.325 V to 2.075 V with 50 mV increments. |
| 6 | $V_{F B}$ | Error amp inverting input, PWM comparator non-inverting input, current limit comparator non-inverting input, PWRGD and OVP comparator input. |
| 7 | Vout | Current limit comparator inverting input. |
| 8 | $\mathrm{V}_{\mathrm{CC} 1}$ | Input power supply pin for the internal circuitry and low side gate driver. Decouple with filter capacitor to GND. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Input power supply pin for the high side gate driver. Decouple with filter capacitor to GND. |
| 10 | GATE(H) | High side switch FET driver pin. |
| 11 | GND | Ground pin and IC substrate connection. |
| 12 | GATE(L) | Low side synchronous FET driver pin. |
| 13 | OVP | Overvoltage protection pin. Drives high when overvoltage condition is detected on $V_{F B}$. |
| 14 | PWRGD | Power Good Output. Open collector output drives low when $\mathrm{V}_{\mathrm{FB}}$ is out of regulation. |
| 15 | $\mathrm{C}_{\text {OFF }}$ | Off-Time Capacitor pin. A capacitor from this pin to GND sets the off time for the regulator. |
| 16 | COMP | Error amp output. PWM comparator inverting input. A capacitor on this pin provides error amp compensation, and determines the Soft Start and hiccup timing. Pulling COMP below $1.1 \mathrm{~V}(\mathrm{typ})$ turns off both GATE drivers and shuts down the regulator. |

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## V $^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

The $\mathrm{V}^{2}$ control method is illustrated in Figure 8. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

Figure 8. $\mathbf{V}^{2}$ Control Diagram
A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop.

The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.
Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation.
A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off-Time

To minimize transient response, the CS51312 uses a Constant Off-Time method to control the rate of output pulses. During normal operation, the Off-Time of the high side switch is terminated after a fixed period, set by the C OFF capacitor. Every time the $\mathrm{V}_{\mathrm{FB}}$ pin exceeds the COMP pin voltage an Off-Time is initiated. To maintain regulation, the $\mathrm{V}^{2}$ Control Loop varies switch On-Time. The PWM comparator monitors the output voltage ramp, and terminates the switch On-Time.
Constant Off-Time provides a number of advantages. Switch Duty Cycle can be adjusted from 0 to $100 \%$ on a pulse-by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ Duty Cycle operation can be maintained for extended periods of time in response to Load or Line transients.

## Programmable Output

The CS51312 is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.125 V to 3.525 V in 100 mV steps, the second is 1.325 V to 2.075 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS51312 enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ pin, as in traditional controllers. The CS51312 is specifically designed to meet or exceed Intel's Pentium II specifications.

## Error Amplifier

The COMP pin is the output of the error amplifier. A capacitor to GND compensates the error amplifier loop.

Additionally, the built in offset on the PWM Comparator non-inverting input provides the hiccup timing for the Overcurrent Protection, Soft Start function, and regulator output enable.

## $\mathrm{V}_{\mathrm{CC} 2}$ Charge Pump

In order to fully turn on the high side NFET, a voltage greater than the input voltage must be applied to $\mathrm{V}_{\mathrm{CC} 2}$ to bias the GATE(H) driver. Referring to the application diagram on page 2120; a simple charge pump circuit can be implemented for this purpose through capacitor C6, resistor R1, and diodes D1 and D2. The input voltage, less the drop in D1 is stored in C6 during the off-time period. When the high-side FET turns on, it drives the inductor switching node and C6 high causing Schottky diode D1 to reverse bias. The charge stored in C 6 is transferred to $\mathrm{V}_{\mathrm{CC} 2}$ through R1. Zener diode D 2 clamps the $\mathrm{V}_{\mathrm{CC} 2}$ voltage to 18 V to prevent the $\mathrm{V}_{\mathrm{CC} 2}$ from exceeding its 20 V Max rating (see Figure 9).

Figure 9. $\mathrm{V}_{\mathrm{CC} 2}$ Charge Pump Operation ( $1.0 \mu \mathrm{~s} / \mathrm{div}$ )

## Startup

The CS51312 provides a controlled startup of regulator output voltage and features Programmable Soft Start implemented through the Error Amp and external Compensation Capacitor. This feature, combined with overcurrent protection, prevents stress to the regulator power components and overshoot of the output voltage during startup.

As Power is applied to the regulator, the CS51312 Undervoltage Lockout circuit (UVL) monitors the ICs supply voltage ( $\mathrm{V}_{\mathrm{CC} 1}$ ) which is typically connected to the +12 V input. The UVL circuit prevents the NFET gates from being activated until $\mathrm{V}_{\mathrm{CC} 1}$ exceeds the 8.4 V (typ) threshold. Hysteresis of 300 mV (typ) is provided for noise immunity.

The Error Amp Capacitor connected to the COMP pin is charged by a $30 \mu \mathrm{~A}$ current source. This capacitor must be charged to 1.1 V (typ) so that it exceeds the PWM comparator's offset before the $\mathrm{V}^{2}$ PWM control loop permits switching to occur.
When $\mathrm{V}_{\mathrm{CC} 1}$ has exceeded 8.4 V and COMP has charged to 1.1 V , the upper Gate driver ( $\operatorname{GATE}(\mathrm{H})$ ) is activated, turning on the upper FET. This causes current to flow through the output inductor and into the output capacitors and load according to the following equation:

$$
\mathrm{I}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \frac{\mathrm{T}}{\mathrm{~L}}
$$

GATE(H) and the upper NFET remain on and inductor current ramps up until the initial pulse is terminated by either the PWM control loop or the overcurrent protection. This initial surge of in-rush current minimizes startup time, but avoids overstressing of the regulator's power components.
The PWM comparator will terminate the initial pulse if the regulator output exceeds the voltage on the COMP pin plus the 1.1 V PWM comparator offset prior to the drop across the current sense resistor exceeding the current limit threshold. In this case, the PWM control loop has achieved regulation and the initial pulse is then followed by a constant off time as programmed by the C $\mathrm{C}_{\text {OFF }}$ capacitor. The COMP capacitor will continue to slowly charge and the regulator output voltage will follow it, less the 1.1 V PWM offset, until it achieves the voltage programmed by the DAC's VID input. The Error Amp will then source or sink current to the COMP cap as required to maintain the correct regulator DC output voltage. Since the rate of increase of the COMP pin voltage is typically set much slower than the regulator's slew capability, inrush current, output voltage, and duty cycle all gradually increase from zero. (See Figures 10 and 11).

Channel 1 - Regulator Input Voltage and $\mathrm{V}_{\mathrm{CC} 1}$ (10 V/div)
Channel 2 - COMP (2.0 V/div)
Channel 3 - Regulator Output Voltage (1.0 V/div)
Figure 10. Normal Startup ( $5.0 \mathrm{~ms} / \mathrm{div}$ )

Channel 1 - VCC2 (10 V/div)
Channel 2 - GATE(H) (10 V/div)
Channel 3 - Inductor Switching Node (10 V/div)
Channel 4 - Regulator Output Voltage ( $2.0 \mathrm{~V} / \mathrm{div}$ )
Figure 11. Normal Startup Showing Initial Pulse Followed by Soft Start ( $5.0 \mu \mathrm{~s} / \mathrm{div}$ )

If the voltage across the Current Sense resistor generates a voltage difference between the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ pins that exceeds the OVC Comparator Offset Voltage ( 86 mV typical), the Fault latch is set. This causes the COMP pin to be quickly discharged, turning off $\operatorname{GATE}(\mathrm{H})$ and the upper NFET since the voltage on the COMP pin is now less than the 1.1 V PWM comparator offset. The Fault latch is reset when the voltage on the COMP decreases below the discharge threshold voltage ( 0.25 V typical). The COMP capacitor will again begin to charge, and when it exceeds the 1.1 V PWM comparator offset, the regulator output will Soft Start normally (see Figure 12).

Channel 1 - Regulator Output Voltage (1.0 V/div)
Channel 2 - COMP Pin (1.0 V/div)
Channel 3 - $\mathrm{V}_{\mathrm{CC}}$ ( $10 \mathrm{~V} / \mathrm{div}$ )
Figure 12. Startup with COMP Pre-Charged to 2.0 V ( $2.0 \mathrm{~ms} / \mathrm{div}$ )

When driving large capacitive loads, the COMP must charge slowly enough to avoid tripping the CS51312 overcurrent protection. The following equation can be used to ensure unconditional startup:

$$
\frac{\text { ICHG }}{\text { CCOMP }}<\frac{\text { ILIM }- \text { ILOAD }^{\text {COUT }}}{}
$$

where:
$\mathrm{I}_{\mathrm{CHG}}=$ COMP Source Current ( $30 \mu \mathrm{~A}$ typical);
$\mathrm{C}_{\text {COMP }}=$ COMP Capacitor value ( $0.1 \mu \mathrm{~F}$ typical);
$\mathrm{I}_{\text {LIM }}=$ Current Limit Threshold;
$\mathrm{I}_{\text {LOAD }}=$ Load Current during startup;
CouT $=$ Total Output Capacitance.

## Normal Operation

During normal operation, Switch Off-Time is constant and set by the C CofF capacitor. Switch On-Time is adjusted by the $\mathrm{V}^{2}$ Control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current and the ESR of the output capacitors

## Transient Response

The CS51312 V ${ }^{2}$ Control Loop's 200 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse-by-pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

Overall load transient response is further improved through a feature called "Adaptive Voltage Positioning". This technique pre-positions the output capacitors voltage to reduce total output voltage excursions during changes in load.

Holding tolerance to $1.0 \%$ allows the error amplifiers reference voltage to be targeted +25 mV high without compromising DC accuracy. A "Droop Resistor" connects the Error Amps feedback pin $\left(\mathrm{V}_{\mathrm{FB}}\right)$ to the output capacitors and load and carries the output current. With no load, there is no DC drop across this resistor, producing an output voltage tracking the Error amps, including the +25 mV offset. When the full load current is delivered, a 50 mV drop is developed across this resistor. This results in output voltage being offset -25 mV low.
The benefit of Adaptive Voltage Positioning is that additional margin is provided for a load transient before reaching the output voltage specification limits. When load current suddenly increases from its minimum level, the output capacitor is pre-positioned +25 mV . Conversely, when load current suddenly decreases from its maximum level, the output capacitor is pre-positioned -25 mV . For
best Transient Response, a combination of a number of high frequency and bulk output capacitors are usually used.

## PROTECTION AND MONITORING FEATURES

## Overcurrent Protection

A hiccup mode current limit protection feature is provided, requiring only the COMP capacitor to implement. The CS51312 provides overcurrent protection by sensing the current through a "Droop" resistor, using an internal current sense comparator. The comparator compares the voltage drop through the "Droop" resistor to an internal reference voltage of 86 mV (typical).

If the voltage drop across the "Droop" resistor exceeds this threshold, the current sense comparator allows the fault latch to be set. This causes the regulator to stop switching.

During this over current condition, the CS51312 stays off for the time it takes the COMP pin capacitor to discharge to its lower 0.25 V threshold. As soon as the COMP pin reaches 0.25 V , the Fault latch is reset (no overcurrent condition present) and the COMP pin is charged with a $30 \mu \mathrm{~A}$ current source to a voltage 1.1 V greater than the $\mathrm{V}_{\mathrm{FB}}$ voltage. Only at this point the regulator attempts to restart normally by delivering short gate pulses to both FETs. This protection scheme minimizes thermal stress to the regulator components, input power supply, and PC board traces, as the over current condition persists. Upon removal of the overload, the fault latch is cleared, allowing normal operation to resume.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 200 ns , causing the top MOSFET to shut off, disconnecting the regulator from its input voltage. This results in a "crowbar" action to clamp the output voltage and prevents damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. Additionally, a dedicated Overvoltage protection (OVP) output pin (pin 13) is provided in the CS51312. The OVP signal will go high (overvoltage condition), if the output voltage ( $\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}$ ) exceeds the regulation voltage by $8.5 \%$ of the voltage set by the particular DAC code. The OVP pin can source up to 25 mA of current that can be used to drive an SCR to crowbar the power supply.

## Power Good Circuit

The Power Good pin (pin 14) is an open-collector signal consistent with TTL DC specifications. It is externally pulled up, and is pulled low (below 0.3 V ) when the regulator output voltage typically exceeds $\pm 8.5 \%$ of the nominal output voltage. Maximum output voltage deviation before Power Good is pulled low is $\pm 12 \%$.

## Output Enable

On/off control of the regulator outputs can be implemented by pulling the COMP pins low. It is required to pull the COMP pins below the 1.1 V PWM comparator offset voltage in order to disable switching on the GATE drivers.

## Adaptive FET Non-Overlap

The CS51312 includes circuitry to prevent the simultaneous conduction of both the high and low side NFETs. This is necessary to prevent efficiency reducing "shoot-through" current from flowing from the input voltage to ground through the two NFETs. Prior to either GATE(H) or GATE(L) driving high, the other GATE must reach its low state. Since GATE rise and fall times vary with loading, this results in a variable delay from the start of turn-off until the start of turn-on (see Figure 13).

Channel 1 - GATE(H) (5.0 V/div)
Channel 2 - GATE(L) (5.0 V/div)
Channel 3 - Inductor Switching Node ( $10 \mathrm{~V} /$ div)
Figure 13. Adaptive FET Non-Overlap (100 ns/div)

## CS51312-BASED $V_{\text {CC(CORE) }}$ BUCK REGULATOR DESIGN EXAMPLE

## Step 1: Definition of the Design Specifications

The output voltage tolerance can be affected by any or all of the following reasons:

1. buck regulator output voltage setpoint accuracy;
2. output voltage change due to discharging or charging of the bulk decoupling capacitors during a load current transient;
3. output voltage change due to the ESR and ESL of the bulk and high frequency decoupling capacitors, circuit traces, and vias;
4. output voltage ripple and noise.

Budgeting the tolerance is left up to the designer who must take into account all of the above effects and provide an output voltage that will meet the specified tolerance at the load.

The designer must also ensure that the regulator component temperatures are kept within the manufacturer's specified ratings at full load and maximum ambient temperature.

## Step 2: Selection of the Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the regulator output voltage. Key specifications for output capacitors are their ESR (Equivalent Series Resistance), and ESL (Equivalent Series Inductance). For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

In order to determine the number of output capacitors the maximum voltage transient allowed during load transitions has to be specified. The output capacitors must hold the output voltage within these limits since the inductor current can not change with the required slew rate. The output capacitors must therefore have a very low ESL and ESR.

The voltage change during the load current transient is:

$$
\Delta \mathrm{V}_{\mathrm{OUT}}=\Delta \mathrm{I} \mathrm{OUT} \times\left(\frac{\mathrm{ESL}}{\Delta \mathrm{t}}+\mathrm{ESR}+\frac{\mathrm{tTR}}{\mathrm{COUT}}\right)
$$

where:
$\Delta \mathrm{I}_{\mathrm{OUT}} / \Delta \mathrm{t}=$ load current slew rate;
$\Delta \mathrm{I}_{\text {OUT }}=$ load transient;
$\Delta \mathrm{t}=$ load transient duration time;
$\mathrm{ESL}=$ Maximum allowable ESL including capacitors,
circuit traces, and vias;
ESR = Maximum allowable ESR including capacitors and circuit traces;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time.
The designer has to independently assign values for the change in output voltage due to ESR, ESL, and output capacitor discharging or charging. Empirical data indicates that most of the output voltage change (droop or spike depending on the load current transition) results from the total output capacitor ESR.

The maximum allowable ESR can then be determined according to the formula

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESR}}}{\Delta \mathrm{I}_{\mathrm{OUT}}}
$$

where $\Delta \mathrm{V}_{\mathrm{ESR}}=$ change in output voltage due to ESR (assigned by the designer).

Once the maximum allowable ESR is determined, the number of output capacitors can be found by using the formula

$$
\text { Number of capacitors }=\frac{\text { ESRCAP }}{\text { ESR }}
$$

where:
$E S R_{C A P}=$ maximum ESR per capacitor (specified in manufacturer's data sheet);
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR.

The actual output voltage deviation due to ESR can then be verified and compared to the value assigned by the designer:

$$
\Delta \mathrm{V}_{\mathrm{ESR}}=\Delta \mathrm{I} \text { OUT } \times \mathrm{ESR}_{\mathrm{MAX}}
$$

Similarly, the maximum allowable ESL is calculated from the following formula:

$$
\mathrm{ESL}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESL}} \times \Delta \mathrm{t}}{\Delta \mathrm{I}}
$$

where:
$\Delta \mathrm{I} / \Delta \mathrm{T}=$ load current slew rate (as high as $20 \mathrm{~A} / \mu \mathrm{s}$ );
$\Delta \mathrm{V}_{\mathrm{ESL}}=$ change in output voltage due to ESL.
The actual maximum allowable ESL can be determined by using the equation:

$$
\text { ESLMAX }=\frac{E S L C A P}{\text { Number of output capacitors }}
$$

where $\mathrm{ESL}_{\mathrm{CAP}}=$ maximum ESL per capacitor (it is estimated that a $10 \times 12 \mathrm{~mm}$ Aluminum Electrolytic capacitor has approximately 4.0 nH of package inductance).
The actual output voltage deviation due to the actual maximum ESL can then be verified:

$$
\Delta \mathrm{V}_{\mathrm{ESL}}=\frac{\mathrm{ESL}}{\mathrm{MAX} \times \Delta \mathrm{I}}
$$

The designer now must determine the change in output voltage due to output capacitor discharge during the transient:

$$
\Delta \mathrm{V}_{\mathrm{CAP}}=\frac{\Delta \mathrm{l} \times \Delta \mathrm{t} \mathrm{TR}}{\mathrm{COUT}}
$$

where:
$\Delta \mathrm{t}_{\mathrm{TR}}=$ the output voltage transient response time (assigned by the designer);
$\Delta \mathrm{V}_{\mathrm{CAP}}=$ output voltage deviation due to output capacitor discharge;
$\Delta \mathrm{I}=$ Load step.
The total change in output voltage as a result of a load current transient can be verified by the following formula:

$$
\Delta \mathrm{V}_{\mathrm{OUT}}=\Delta \mathrm{V}_{\mathrm{ESR}}+\Delta \mathrm{V}_{\mathrm{ESL}}+\Delta \mathrm{V}_{\mathrm{CAP}}
$$

## Step 3: Selection of the Duty Cycle, Switching Frequency, Switch On-Time (Ton) and Switch Off-Time (TOfF)

The duty cycle of a buck converter (including parasitic losses) is given by the formula:

$$
\text { Duty Cycle }=\mathrm{D}=\frac{\mathrm{V}_{\mathrm{OUT}}+\left(\mathrm{V}_{\mathrm{HFET}}+\mathrm{V}_{\mathrm{L}}+\mathrm{V}_{\mathrm{DROOP}}\right)}{\mathrm{V}_{\mathrm{IN}}+\mathrm{V}_{\mathrm{LFET}}-\mathrm{V}_{\mathrm{HFET}}-\mathrm{V}_{\mathrm{L}}}
$$

where:
$\mathrm{V}_{\text {OUT }}=$ buck regulator output voltage;
$\mathrm{V}_{\mathrm{HFET}}=$ high side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$;
$\mathrm{V}_{\mathrm{L}}=$ output inductor voltage drop due to inductor wire DC resistance;
$\mathrm{V}_{\text {DROOP }}=$ droop $($ current sense) resistor voltage drop;
$\mathrm{V}_{\mathrm{IN}}=$ buck regulator input voltage;
$\mathrm{V}_{\mathrm{LFET}}=$ low side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$.

## Step3a: Calculation of Switch On-Time

The Switch On-Time (time during which the switching MOSFET in a synchronous buck topology is conducting) is determined by:

$$
\text { TON }=\frac{\text { Duty Cycle }}{\text { FSW }}
$$

where $\mathrm{F}_{\text {SW }}=$ regulator switching frequency selected by the designer.

Higher operating frequencies allow the use of smaller inductor and capacitor values. Nevertheless, it is common to select lower frequency operation because a higher frequency results in lower efficiency due to MOSFET gate charge losses. Additionally, the use of smaller inductors at higher frequencies results in higher ripple current, higher output voltage ripple, and lower efficiency at light load currents.

## Step 3b: Calculation of Switch Off-Time

The Switch Off-Time (time during which the switching MOSFET is not conducting) can be determined by:

$$
\text { TOFF }=\frac{1.0}{\mathrm{FSW}}-\mathrm{TON}
$$

The $\mathrm{C}_{\mathrm{OFF}}$ capacitor value has to be selected in order to set the Off-Time, $\mathrm{T}_{\text {OFF }}$, above:

$$
\text { COFF }=\frac{\text { Period } \times(1.0-\mathrm{D})}{3980}
$$

where:
3980 is a characteristic factor of the CS51312;
D = Duty Cycle.

## Step 4: Selection of the Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response. There are many factors to consider in selecting the inductor including cost, efficiency, EMI and ease of manufacture. The inductor must be able to handle the peak current at the switching frequency without saturating, and the copper resistance in the winding should be kept as low as possible to minimize resistive power loss. There are a variety of materials and types of magnetic cores that could be used for this application. Among them are ferrites, molypermalloy cores (MPP), amorphous and powdered iron cores. Powdered iron cores are very commonly used. Powdered iron cores are very suitable due to their high saturation flux density and have low loss at high frequencies, a distributed gap and exhibit very low EMI.

The inductor value can be determined by:

$$
\mathrm{L}=\frac{\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{tTR}}{\Delta \mathrm{I}}
$$

where:
$\mathrm{V}_{\mathrm{IN}}=$ input voltage;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time (assigned by the designer);
$\Delta \mathrm{I}=$ load transient.
The inductor ripple current can then be determined:

$$
\Delta \mathrm{I}_{\mathrm{L}}=\frac{\mathrm{VOUT} \times \mathrm{TOFF}}{\mathrm{~L}}
$$

where:
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{T}_{\mathrm{OFF}}=$ switch Off-Time;
$\mathrm{L}=$ inductor value.
The designer can now verify if the number of output capacitors from Step 2 will provide an acceptable output voltage ripple ( $1.0 \%$ of output voltage is common). The formula below is used:

$$
\Delta \mathrm{l}_{\mathrm{L}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\mathrm{ESR} \mathrm{MAX}^{2}}
$$

Rearranging we have:

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\Delta \mathrm{I}_{\mathrm{L}}}
$$

where
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR ;
$\Delta \mathrm{V}_{\text {OUT }}=1.0 \% \times \mathrm{V}_{\text {OUT }}=$ maximum allowable output voltage ripple ( budgeted by the designer );
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage .
The number of output capacitors is determined by:

$$
\text { Number of capacitors }=\frac{\mathrm{ESR}_{\mathrm{CAP}}}{\mathrm{ESR}_{\mathrm{MAX}}}
$$

where $\mathrm{ESR}_{\mathrm{CAP}}=$ maximum ESR per capacitor (specified in manufacturer's data sheet).

The designer must also verify that the inductor value yields reasonable inductor peak and valley currents (the inductor current is a triangular waveform):

$$
\mathrm{I}(\mathrm{PEAK})=\mathrm{IOUT}+\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2.0}
$$

where:
$\mathrm{I}_{\mathrm{L}(\mathrm{PEAK})}=$ inductor peak current;
$\mathrm{I}_{\text {OUT }}=$ load current;
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current.

$$
\mathrm{IL}(\mathrm{VALLEY})=\mathrm{IOUT}-\frac{\Delta \mathrm{IL}}{2.0}
$$

where $\mathrm{I}_{\mathrm{L}(\mathrm{VALLEY})}=$ inductor valley current .

## Step 5: Selection of the Input Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines. A key specification for input capacitors is their ripple current rating. The input capacitor should also be able to handle the input RMS current $\mathrm{I}_{\mathrm{IN}(\mathrm{RMS})}$.

The combination of the input capacitors $\mathrm{C}_{\text {IN }}$ discharges during the on-time.

The input capacitor discharge current is given by:
ICINDIS(RMS) =

$$
\sqrt{\frac{\left(\begin{array}{l}
\mathrm{IL}(\mathrm{PEAK})^{2} \\
+(\mathrm{IL}(\mathrm{PEAK}) \times \operatorname{IL}(\mathrm{VALLEY})) \\
+\mathrm{IL}(\mathrm{VALLEY})^{2}
\end{array}\right.}{} \sqrt{3.0}}
$$

where:
$\mathrm{I}_{\mathrm{CINDIS}(\mathrm{RMS})}=$ input capacitor discharge current;
$\mathrm{I}_{\mathrm{L}(\text { PEAK })}=$ inductor peak current;
$\mathrm{I}_{\mathrm{L}(\text { VALLEY })}=$ inductor valley current.
$\mathrm{C}_{\text {IN }}$ charges during the off-time, the average current through the capacitor over one switching cycle is zero:

$$
\operatorname{ICIN}(C H)=\operatorname{ICIN}(D I S) \times \frac{D}{1.0-D}
$$

where:
$\mathrm{I}_{\mathrm{CIN}(\mathrm{CH})}=$ input capacitor charge current;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{DIS})}=$ input capacitor discharge current;
D = Duty Cycle.
The total Input RMS current is:

$$
\operatorname{ICIN}(\mathrm{RMS})=\sqrt{\begin{array}{l}
\left(\mathrm{I} \mathrm{CIN}(\mathrm{DIS})^{2} \times \mathrm{D}\right) \\
+\left(\mathrm{I} \mathrm{CIN}(\mathrm{CH})^{2} \times(1.0-\mathrm{D})\right)
\end{array}}
$$

The number of input capacitors required is then determined by:

$$
\mathrm{N}_{\mathrm{CIN}}=\frac{\mathrm{I} \mathrm{CIN}(\mathrm{RMS})}{\mathrm{I}_{\mathrm{RIPPLE}}}
$$

where:
$\mathrm{N}_{\mathrm{CIN}}=$ number of input capacitors;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{RMS})}=$ total input RMS current;
$\mathrm{I}_{\text {RIPPLE }}=$ input capacitor ripple current rating (specified in manufacturer's data sheets).

The total input capacitor ESR needs to be determined in order to calculate the power dissipation of the input capacitors:

$$
\mathrm{ESR}_{\mathrm{CIN}}=\frac{\mathrm{ESR} \mathrm{CAP}}{\mathrm{~N}_{\mathrm{CIN}}}
$$

where:
$\mathrm{ESR}_{\mathrm{CIN}}=$ total input capacitor ESR;
$\mathrm{ESR}_{\mathrm{CAP}}=$ maximum ESR per capacitor (specified in manufacturer's data sheets);
$\mathrm{N}_{\mathrm{CIN}}=$ number of input capacitors.
Once the total ESR of the input capacitors is known, the input capacitor ripple voltage can be determined using the formula:

$$
\mathrm{V}_{\mathrm{CIN}(\mathrm{RMS})}=\operatorname{ICIN(RMS)} \times \mathrm{ESR}_{\mathrm{CIN}}
$$

where:
$\mathrm{V}_{\mathrm{CIN}(\mathrm{RMS})}=$ input capacitor RMS voltage;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{RMS})}=$ total input RMS current;
$\mathrm{ESR}_{\mathrm{CIN}}=$ total input capacitor ESR.
The designer must determine the input capacitor power loss in order to ensure there isn't excessive power dissipation through these components. The following formula is used:

$$
\operatorname{PCIN}(\mathrm{RMS})=\operatorname{ICIN}(\mathrm{RMS})^{2} \times \mathrm{ESRCIN}
$$

where:
$\mathrm{P}_{\mathrm{CIN}(\mathrm{RMS})}=$ input capacitor RMS power dissipation;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{RMS})}=$ total input RMS current;
$\mathrm{ESR}_{\mathrm{CIN}}=$ total input capacitor ESR .

## Step 6: Selection of the Input Inductor

A common requirement is that the buck controller must not disturb the input voltage. One method of achieving this is by using an input inductor and a bypass capacitor. The input inductor isolates the supply from the noise generated in the switching portion of the buck regulator and also limits the inrush current into the input capacitors upon power up. The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients. The worst case is when the load changes from no load to full load (load step), a condition under which the highest voltage change across the input capacitors is also seen by the input inductor. The inductor successfully blocks the ripple current while placing the transient current requirements on the input bypass capacitor bank, which has to initially support the sudden load change.

The minimum inductance value for the input inductor is therefore:

$$
\mathrm{L}_{\mathrm{IN}}=\frac{\Delta \mathrm{V}}{(\mathrm{dl} / \mathrm{dt}) \mathrm{MAX}}
$$

where:
$\mathrm{L}_{\mathrm{IN}}=$ input inductor value;
$\Delta \mathrm{V}=$ voltage seen by the input inductor during a full load swing;
$(\mathrm{dI} / \mathrm{dt})_{\mathrm{MAX}}=$ maximum allowable input current slew rate.
The designer must select the LC filter pole frequency so that at least 40 dB attenuation is obtained at the regulator switching frequency. The LC filter is a double-pole network with a slope of -2.0 , a roll-off rate of $-40 \mathrm{~dB} / \mathrm{dec}$, and a corner frequency:

$$
\mathrm{f}_{\mathrm{C}}=\frac{1.0}{2.0 \pi \sqrt{\mathrm{LC}}}
$$

where:
$\mathrm{L}=$ input inductor;
$\mathrm{C}=$ input capacitor(s).

## Step 7: Selection of the Switching FET FET Basics

The use of the MOSFET as a power switch is propelled by two reasons: 1) Its very high input impedance; and 2) Its very fast switching times. The electrical characteristics of a MOSFET are considered to be those of a perfect switch.

Control and drive circuitry power is therefore reduced. Because the input impedance is so high, it is voltage driven. The input of the MOSFET acts as if it were a small capacitor, which the driving circuit must charge at turn on. The lower the drive impedance, the higher the rate of rise of $\mathrm{V}_{\mathrm{GS}}$, and the faster the turn-on time. Power dissipation in the switching MOSFET consists of 1) conduction losses, 2) leakage losses, 3) turn-on switching losses, 4) turn-off switching losses, and 5) gate-transitions losses. The latter three losses are proportional to frequency. For the conducting power dissipation rms values of current and resistance are used for true power calculations. The fast switching speed of the MOSFET makes it indispensable for high-frequency power supply applications. Not only are switching power losses minimized, but also the maximum usable switching frequency is considerably higher. Switching time is independent of temperature. Also, at higher frequencies, the use of smaller and lighter components (transformer, filter choke, filter capacitor) reduces overall component cost while using less space for more efficient packaging at lower weight.

The MOSFET has purely capacitive input impedance. No DC current is required. It is important to keep in mind the drain current of the FET has a negative temperature coefficient. Increase in temperature causes higher on-resistance and greater leakage current. $\mathrm{V}_{\mathrm{DS}(\mathrm{ON})}$ should be low to minimize power dissipation at a given $\mathrm{I}_{\mathrm{D}}$, and $\mathrm{V}_{\mathrm{GS}}$ should be high to accomplish this. MOSFET switching times are determined by device capacitance, stray capacitance, and the impedance of the gate drive circuit. Thus the gate driving circuit must have high momentary peak current sourcing and sinking capability for switching the MOSFET. The input capacitance, output capacitance and reverse-transfer capacitance also increase with increased device current rating.

Two considerations complicate the task of estimating switching times. First, since the magnitude of the input capacitance, $\mathrm{C}_{\mathrm{ISS}}$, varies with $\mathrm{V}_{\mathrm{DS}}$, the RC time constant determined by the gate-drive impedance and $\mathrm{C}_{\text {ISS }}$ changes during the switching cycle. Consequently, computation of the rise time of the gate voltage by using a specific gate-drive impedance and input capacitance yields only a rough estimate. The second consideration is the effect of the "Miller" capacitance, $\mathrm{C}_{\text {RSS }}$, which is referred to as $\mathrm{C}_{\text {DG }}$ in the following discussion. For example, when a device is on, $\mathrm{V}_{\mathrm{DS}(\mathrm{ON})}$ is fairly small and $\mathrm{V}_{\mathrm{GS}}$ is about $12 \mathrm{~V} . \mathrm{C}_{\mathrm{DG}}$ is charged to $\mathrm{V}_{\mathrm{DS}(\mathrm{ON})}-\mathrm{V}_{\mathrm{GS}}$, which is a negative potential if the drain is considered the positive electrode. When the drain is "off", $\mathrm{C}_{\mathrm{DG}}$ is charged to quite a different potential. In this case the voltage across $C_{D G}$ is a positive value since the potential from gate-to-source is near zero volts and $\mathrm{V}_{\mathrm{DS}}$ is essentially the drain supply voltage. During turn-on and turn-off, these large swings in gate-to-drain voltage tax the current sourcing and sinking capabilities of the gate drive. In addition to charging and discharging $\mathrm{C}_{\mathrm{GS}}$, the gate drive must also supply the displacement current required by
$\mathrm{C}_{\mathrm{DG}}\left(\mathrm{I}_{\text {GATE }}=\mathrm{C}_{\mathrm{DG}} \mathrm{dV}_{\mathrm{DG}} / \mathrm{dt}\right)$. Unless the gate-drive impedance is very low, the $\mathrm{V}_{\mathrm{GS}}$ waveform commonly plateaus during rapid changes in the drain-to-source voltage.
The most important aspect of FET performance is the Static Drain-To-Source On-Resistance ( $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ ), which effects regulator efficiency and FET thermal management requirements. The On-Resistance determines the amount of current a FET can handle without excessive power dissipation that may cause overheating and potentially catastrophic failure. As the drain current rises, especially above the continuous rating, the On-Resistance also increases. Its positive temperature coefficient is between $+0.6 \% / \mathrm{C}$ and $+0.85 \% / \mathrm{C}$. The higher the On-Resistance the larger the conduction loss is. Additionally, the FET gate charge should be low in order to minimize switching losses and reduce power dissipation.
Both logic level and standard FETs can be used.
Voltage applied to the FET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the FET gates will be driven rail-to-rail due to overshoot caused by the capacitive load they present to the controller IC.

## Step 7a: Selection of the Switching (Upper) FET

The designer must ensure that the total power dissipation in the FET switch does not cause the power component's junction temperature to exceed $150^{\circ} \mathrm{C}$.

The maximum RMS current through the switch can be determined by the following formula:

$$
\begin{aligned}
& \operatorname{IRMS}(H)= \\
& \sqrt{\frac{\left(\begin{array}{l}
\operatorname{lL}(\mathrm{PEAK})^{2} \\
+(\mathrm{IL}(P E A K) \\
+\operatorname{IL}(V A L L E Y)^{2}
\end{array}\right.}{3.0}}
\end{aligned}
$$

where:
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{I}_{\mathrm{L}(\mathrm{PEAK})}=$ inductor peak current;
$\mathrm{I}_{\mathrm{L}(\text { VALLEY })}=$ inductor valley current;
D = Duty Cycle.
Once the RMS current through the switch is known, the switching MOSFET conduction losses can be calculated:

$$
\operatorname{PRMS}(\mathrm{H})=\operatorname{IRMS}(\mathrm{H})^{2} \times \operatorname{RDS}(\mathrm{ON})
$$

where:
$\mathrm{P}_{\mathrm{RMS}(\mathrm{H})}=$ switching MOSFET conduction losses;
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=\mathrm{FET}$ drain-to-source on-resistance
The upper MOSFET switching losses are caused during MOSFET switch-on and switch-off and can be determined by using the following formula:

$$
\begin{aligned}
\mathrm{PSWH} & =\mathrm{PSWH}(\mathrm{ON})+\mathrm{PSWH}(\mathrm{OFF}) \\
& =\frac{\mathrm{V}_{\mathrm{IN}} \times \mathrm{IOUT} \times(\mathrm{tRISE}+\mathrm{tFALL})}{6.0 \mathrm{~T}}
\end{aligned}
$$

where:
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{OFF})}=$ upper MOSFET switch-off losses;
$\mathrm{V}_{\mathrm{IN}}=$ input voltage;
IOUT $=$ load current;
$\mathrm{t}_{\text {RISE }}=$ MOSFET rise time (from FET manufacturer's switching characteristics performance curve);
$\mathrm{t}_{\text {FALL }}=$ MOSFET fall time (from FET manufacturer's switching characteristics performance curve);
$\mathrm{T}=1 / \mathrm{F}_{\mathrm{SW}}=$ period.
The total power dissipation in the switching MOSFET can then be calculated as:
PHFET(TOTAL) $=$ PRMSH $+\operatorname{PSWH}(O N)+$ PSWH $(O F F)$
where:
$\mathrm{P}_{\text {HFET(TOTAL) }}=$ total switching (upper) MOSFET losses;
$\mathrm{P}_{\text {RMSH }}=$ upper MOSFET switch conduction Losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{OFF})}=$ upper MOSFET switch-off losses.
Once the total power dissipation in the switching FET is known, the maximum FET switch junction temperature can be calculated:

$$
T_{J}=T_{A}+\left(\text { PhFET }(T O T A L) \times R_{\theta J A}\right)
$$

where:
$\mathrm{T}_{\mathrm{J}}=\mathrm{FET}$ junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$\mathrm{P}_{\text {HFET(TOTAL) }}=$ total switching (upper) FET losses;
$\mathrm{R}_{\theta \mathrm{JA}}=$ upper FET junction-to-ambient thermal resistance.

## Step 7b: Selection of the Synchronous (Lower) FET

The switch conduction losses for the lower FET can be calculated as follows:

$$
\begin{aligned}
\mathrm{PRMSL} & =\mathrm{IRMS}^{2} \times \mathrm{RDS}(\mathrm{ON}) \\
& =(\mathrm{IOUT} \times \sqrt{(1.0-\mathrm{D})})^{2} \times \mathrm{RDS}(\mathrm{ON})
\end{aligned}
$$

where:
$\mathrm{P}_{\mathrm{RMSL}}=$ lower MOSFET conduction losses;
$\mathrm{I}_{\text {OUT }}=$ load current;
D = Duty Cycle;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=$ lower FET drain-to-source on-resistance.
The synchronous MOSFET has no switching losses, except for losses in the internal body diode, because it turns on into near zero voltage conditions. The MOSFET body diode will conduct during the non-overlap time and the resulting power dissipation (neglecting reverse recovery losses) can be calculated as follows:

$$
\text { PSWL }=V_{S D} \times \operatorname{lLOAD} \times \text { non-overlap time } \times \text { FSW }
$$

where:
$\mathrm{P}_{\text {SWL }}=$ lower FET switching losses;
$\mathrm{V}_{\mathrm{SD}}=$ lower FET source-to-drain voltage;
$\mathrm{I}_{\text {LOAD }}=$ load current
Non-overlap time $=$ GATE(L)-to-GATE(H) or GATE(H)-to-GATE(L) delay (from CS51312 data sheet Electrical Characteristics section);
$\mathrm{F}_{\text {SW }}=$ switching frequency .
The total power dissipation in the synchronous (lower) MOSFET can then be calculated as:
PLFET(TOTAL) = PRMSL + PSWL
where:
$P_{\text {LFET }}($ TOTAL $) ~=~ S y n c h r o n o u s ~(l o w e r) ~ F E T ~ t o t a l ~ l o s s e s ; ~ ; ~$
$\mathrm{P}_{\text {RMSL }}=$ Switch Conduction Losses;
$P_{\text {SWL }}=$ Switching losses.
Once the total power dissipation in the synchronous FET is known the maximum FET switch junction temperature can be calculated:

$$
T_{J}=T_{A}+\left(P_{L F E T}(T O T A L) \times R_{\theta J A}\right)
$$

where:
$\mathrm{T}_{\mathrm{J}}=$ MOSFET junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$\mathrm{P}_{\text {LFET }}($ TOTAL $) ~=~ t o t a l ~ s y n c h r o n o u s ~(l o w e r) ~ F E T ~ l o s s e s ; ~ ; ~$
$\mathrm{R}_{\theta \mathrm{JA}}=$ lower FET junction-to-ambient thermal resistance.

## Step 8: Control IC Power Dissipation

The power dissipation of the IC varies with the MOSFETs used, $\mathrm{V}_{\mathrm{CC}}$, and the CS51312 operating frequency. The average MOSFET gate charge current typically dominates the control IC power dissipation.

The IC power dissipation is determined by the formula:

$$
\text { PCONTROLIC }=\operatorname{ICC1} \mathrm{V}_{\mathrm{CC} 1}+\operatorname{PGATE}(\mathrm{H})+\mathrm{PGATE}(\mathrm{~L})
$$

where:
$\mathrm{P}_{\text {CONTROLIC }}=$ control IC power dissipation;
$\mathrm{I}_{\mathrm{CC} 1}=\mathrm{IC}$ quiescent supply current;
$\mathrm{V}_{\mathrm{CC} 1}=\mathrm{IC}$ supply voltage;
$\mathrm{P}_{\text {GATE(H) }}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{P}_{\mathrm{GATE}(\mathrm{L})}=$ lower MOSFET gate driver (IC) losses.

The upper (switching) MOSFET gate driver (IC) losses are:

$$
\operatorname{PGATE}(\mathrm{H})=\mathrm{Q}_{\mathrm{GATE}}(\mathrm{H}) \times \mathrm{F}_{S W} \times \mathrm{V}_{\mathrm{GATE}}(\mathrm{H})
$$

where:
$\mathrm{P}_{\text {GATE(H) }}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\mathrm{GATE}(\mathrm{H})}=$ total upper MOSFET gate charge;
$\mathrm{F}_{\text {SW }}=$ switching frequency;
$\mathrm{V}_{\text {GATE }}(\mathrm{H})=$ upper MOSFET gate voltage.
The lower (synchronous) MOSFET gate driver (IC) losses are:

$$
\operatorname{PGATE}(\mathrm{L})=\text { QGATE }^{\text {G }} \text { L) } \times \text { FSW } \times \mathrm{V}_{\text {GATE }}(\mathrm{L})
$$

where:
$\mathrm{P}_{\text {GATE(L) }}=$ lower MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\mathrm{GATE}(\mathrm{L})}=$ total lower MOSFET gate charge;
$\mathrm{F}_{\mathrm{SW}}=$ switching frequency;
$\mathrm{V}_{\text {GATE(L) }}=$ lower MOSFET gate voltage.
The junction temperature of the control IC is primarily a function of the PCB layout, since most of the heat is removed through the traces connected to the pins of the IC.

## Step 9: Slope Compensation

Voltage regulators for today's advanced processors are expected to meet very stringent load transient requirements. One of the key factors in achieving tight dynamic voltage regulation is low ESR at the CPU input supply pins. Low ESR at the regulator output results in low output voltage ripple. The consequence is, however, that there's very little voltage ramp at the control IC feedback pin ( $\mathrm{V}_{\mathrm{FB}}$ ) and regulator sensitivity to noise and loop instability are two undesirable effects that can surface. The performance of the CS51312-based CPU $\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}$ regulator is improved when a fixed amount of slope compensation is added to the output of the PWM Error Amplifier (COMP pin) during the regulator Off-Time. Referring to Figure 14, the amount of voltage ramp at the COMP pin is dependent on the gate voltage of the lower (synchronous) FET and the value of resistor divider formed by R1and R2.

$$
\mathrm{V}_{\text {SLOPECOMP }}=\mathrm{V}_{\operatorname{GATE}}(\mathrm{L}) \times\left(\frac{\mathrm{R} 2}{\mathrm{R} 1+\mathrm{R} 2}\right) \times\left(1.0-\mathrm{e}^{\frac{-t}{\tau}}\right)
$$

where:
$\mathrm{V}_{\text {SLOPECOMP }}=$ amount of slope added;
$\mathrm{V}_{\text {GATE(L) }}=$ lower MOSFET gate voltage;
$\mathrm{R} 1, \mathrm{R} 2=$ voltage divider resistors;
$\mathrm{t}=\mathrm{t}_{\text {OFF }}$ (switch off-time);
$\tau=\mathrm{RC}$ constant determined by C 1 and the parallel combination of R1, R2 (Figure 14), neglecting the low driver output impedance.

Figure 14. Small RC Filter Provides the Proper Voltage Ramp at the Beginning of Each On-Time Cycle

The artificial voltage ramp created by the slope compensation scheme results in improved control loop stability provided that the RC filter time constant is smaller than the off-time cycle duration (time during which the lower MOSFET is conducting). It is important that the series combination of R1 and R2 is high enough in resistance to avoid loading the GATE(L) pin.

## Step 10: Selection of Current Limit Filter Components

In some applications, the current limit comparator may falsely trigger due to noise, load transients, or high inductor ripple currents. A filter circuit such as the one shown in Figure 15 can be added to prevent this. The RC time constant of this filter is equal to $\left(\mathrm{R}_{\mathrm{FB}}+\mathrm{R}_{\mathrm{OUT}}\right) \times \mathrm{C}_{\text {SENSE }}$. Increasing the RC time constant will reduce the sensitivity of the circuit, but increase the time required to detect an overcurrent condition. The value of $\mathrm{R}_{\mathrm{FB}}+\mathrm{R}_{\mathrm{OUT}}$ should be kept to $510 \Omega$ or lower to avoid significant DC offsets due to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ bias currents.

Figure 15. Current Limit Filter Circuit

## "DROOP" RESISTOR FOR ADAPTIVE VOLTAGE POSITIONING AND CURRENT LIMIT

Adaptive voltage positioning is used to help keep the output voltage within specification during load transients. To implement adaptive voltage positioning a "Droop Resistor" must be connected between the output inductor and output capacitors and load. This resistor carries the full load current and should be chosen so that both DC and AC tolerance limits are met.

In order to determine the droop resistor value the nominal voltage drop across it at full load has to be calculated. This voltage drop has to be such that the output voltage at full load is above the minimum DC tolerance spec:

$$
V_{D R O O P}(T Y P)=\frac{V_{D A C}(M I N)-V_{D C}(M I N)}{1.0+R_{D R O O P}(T O L E R A N C E)}
$$

## Current Limit

The current limit setpoint has to be higher than the normal full load current. Attention has to be paid to the current rating of the external power components as these are the first to fail during an overload condition. The MOSFET continuous and pulsed drain current rating at a given case temperature has to be accounted for when setting the current limit trip point.

## Nominal Current Limit Setpoint

From the overcurrent detection data in the electrical characteristics table:

$$
\begin{gathered}
\mathrm{V}_{\mathrm{TH}}(\mathrm{TYP})=86 \mathrm{mV} \\
\mathrm{I}_{\mathrm{CL}(\mathrm{NOM})}=\frac{\mathrm{V}_{\mathrm{TH}(\mathrm{TYP})}}{\operatorname{RSENSE}(\mathrm{NOM})}
\end{gathered}
$$

## Design Rules for Using a Droop Resistor

The basic equation for laying an embedded resistor is:

$$
R_{A R}=\rho \times \frac{L}{A} \text { or } R=\rho \times \frac{L}{(W \times t)}
$$

where:
$\mathrm{A}=\mathrm{W} \times \mathrm{t}=$ cross-sectional area;
$\rho=$ the copper resistivity ( $\mu \Omega-$ mil $)$;
$\mathrm{L}=$ length (mils);
$\mathrm{W}=$ width (mils);
$\mathrm{t}=$ thickness (mils).
An embedded PC trace resistor has the distinct advantage of near zero cost implementation. However, this droop resistor can vary due to three reasons: 1) the sheet resistivity variation caused by variation in the thickness of the PCB layer; 2) the mismatch of $\mathrm{L} / \mathrm{W}$; and 3) temperature variation.

## 1) Sheet Resistivity

For one ounce copper, the thickness variation is typically 1.26 mil to 1.48 mil . Therefore the error due to sheet resistivity is:

$$
\frac{1.48-1.26}{1.37}= \pm 8.0 \%
$$

## 2) Mismatch Due to L/W

The variation in $\mathrm{L} / \mathrm{W}$ is governed by variations due to the PCB manufacturing process. The error due to L/W mismatch is typically $1.0 \%$.

## 3) Thermal Considerations

Due to $I^{2} \times R$ power losses the surface temperature of the droop resistor will increase causing the resistance to increase. Also, the ambient temperature variation will contribute to the increase of the resistance, according to the formula:

$$
R=R_{20}\left[1.0+\alpha_{20}(T-20)\right]
$$

where:
$\mathrm{R}_{20}=$ resistance at $20^{\circ} \mathrm{C}$;
$\alpha=0.00393 /{ }^{\circ} \mathrm{C}$
$\mathrm{T}=$ operating temperature;
$\mathrm{R}=$ desired droop resistor value.
For temperature $\mathrm{T}=50^{\circ} \mathrm{C}$, the $\% \mathrm{R}$ change $=12 \%$.

## Droop Resistor Tolerance

Tolerance due to sheet resistivity variation $\pm 8.0 \%$
Tolerance due to L/W error $1.0 \%$
Tolerance due to temperature variation $12 \%$
Total tolerance for droop resistor $21 \%$

## Droop Resistor Length, Width, and Thickness

The minimum width and thickness of the droop resistor should primarily be determined on the basis of the current-carrying capacity required, and the maximum permissible droop resistor temperature rise. PCB manufacturer design charts can be used in determining current-carrying capacity and sizes of etched copper conductors for various temperature rises above ambient.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:

$$
\text { Thermal Impedance }=\frac{T_{\mathrm{J}(\mathrm{MAX})}-\mathrm{T}_{\mathrm{A}}}{\text { Power }}
$$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI MANAGEMENT

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for
compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

## LAYOUT GUIDELINES

When laying out the CPU buck regulator on a printed circuit board, the following checklist should be used to ensure proper operation of the CS51312.

1. Rapid changes in voltage across parasitic capacitors and abrupt changes in current in parasitic inductors are major concerns for a good layout.
2. Keep high currents out of sensitive ground connections.
3. Avoid ground loops as they pick up noise. Use star or single point grounding.
4. For high power buck regulators on double-sided PCBs a single ground plane (usually the bottom) is recommended.
5. Even though double sided PCBs are usually sufficient for a good layout, four-layer PCBs are the optimum approach to reducing susceptibility to noise. Use the two internal layers as the power and GND planes, the top layer for power connections and component vias, and the bottom layer for the noise sensitive traces.
6. Keep the inductor switching node small by placing the output inductor, switching and synchronous FETs close together.
7. The MOSFET gate traces to the IC must be as short, straight, and wide as possible.
8. Use fewer, but larger output capacitors, keep the capacitors clustered, and use multiple layer traces with heavy copper to keep the parasitic resistance low.
9. Place the switching MOSFET as close to the +5.0 V input capacitors as possible.
10. Place the output capacitors as close to the load as possible.
11. Place the $\mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{OUT}}$ filter resistors $(510 \Omega)$ in series with the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ pins as close as possible to the pins.
12. Place the C Coff and COMP capacitors as close as possible to the $\mathrm{C}_{\mathrm{OFF}}$ and COMP pins.
13. Place the current limit filter capacitor between the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{OUT}}$ pins, as close as possible to the pins.
14. Connect the filter components of the following pins: $\mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{OUT}}, \mathrm{C}_{\mathrm{OFF}}$, and COMP to the GND pin with a single trace, and connect this local GND trace to the output capacitor GND.
15. The "Droop" Resistor (embedded PCB trace) has to be wide enough to carry the full load current.
16. Place the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor as close as possible to the IC.

## CS5157H

## CPU 5-Bit Synchronous Buck Controller

The CS5157H is a 5 -bit synchronous dual N -Channel buck controller. It is designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. The regulator operates using a proprietary control method, which allows a 100 ns response time to load transients. The CS5157H is designed to operate over a $4.25-20 \mathrm{~V}$ range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V or 12 V as the main supply for conversion.

The CS5157H is specifically designed to power Pentium ${ }^{\circledR}$ II processors and other high performance core logic. It includes the following features: on board, 5-bit DAC, short circuit protection, $1.0 \%$ output tolerance, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The CS5157H is available in 16 pin surface mount.

## Features

- Dual N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 5-Bit DAC
- 30 ns Gate Rise/Fall Times
- $1.0 \%$ DAC Accuracy
- 5.0 V \& 12 V Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- 25 ns FET Nonoverlap Time
- $\mathrm{V}^{2 \mathrm{Tm}}$ Control Topology
- Current Sharing
- Overvoltage Protection

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| SO-16 | PIN SYMBOL | FUNCTION |
| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID } 4}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V providing logic ones if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is High (logic one), the DAC range is 2.10 V to 3.50 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is Low (logic zero), the DAC range is 1.30 V to 2.05 V with 50 mV increments. $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID4 }}$ select the desired DAC output voltage. Leaving all 5 DAC input pins open results in a DAC output voltage of 1.2440 V , allowing for adjustable output voltage, using a traditional resistor divider. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND in conjunction with internal $60 \mu \mathrm{~A}$ current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $\mathrm{V}_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Boosted power for the high side gate driver. |
| 10 | $\mathrm{V}_{\text {GATE(H) }}$ | High FET driver pin capable of 1.5 A peak switching current. Internal circuit prevents $\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}$ and $\mathrm{V}_{\mathrm{GATE}(\mathrm{L})}$ from being in high state simultaneously. |
| 11 | PGND | High current ground for the IC. The MOSFET driver is referenced to this pin. Input capacitor ground and the source of lower FET should be tied to this pin. |
| 12 | $\mathrm{V}_{\text {GATE(L) }}$ | Low FET driver pin capable of 1.5 A peak switching current. |
| 13 | $\mathrm{V}_{\text {CC1 }}$ | Input power for the IC and low side gate driver. |
| 14 | LGND | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $V_{F B}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## $\mathrm{V}^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. V ${ }^{2}$ Control Diagram

The $V^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5157H uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $25 \mu$ s timer, minimizing stress to the power components.

## Programmable Output

The CS5157H is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.10 V to 3.50 V in 100 mV steps, the second is 1.30 V to 2.05 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS5157H enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{FFB}}$ pins, as in traditional controllers.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 3.9 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the GATE $(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.

If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE $(\mathrm{H})$ pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.

When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the COFF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.
The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP capacitor charging to its final value. Its voltage is limited by
the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

## Normal Operation

During normal operation, switch off time is constant and set by the C CopF capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The CS5157H V ${ }^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.

If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $V_{\text {CC1 }}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 3.75 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 3.70 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs ( $\mathrm{V}_{\mathrm{FFB}}<1.0 \mathrm{~V}$ ), the $\mathrm{V}_{\text {FFB }}$ low comparator sets the FAULT latch. This causes the MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=$ $3.3 \%$ ), while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board traces than occurs with constant current limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Trace 2- Inductor Switching Node (2.0 V/div.)
Figure 13. Startup with Regulator Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 14 and 15 ). The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function.

Trace 4-5.0 V from PC Power Supply (2.0 V/div.)
Trace 1 - Regulator Output Voltage (1.0 V/div.)
Figure 15. OVP Response to an Input-to-Output Short Circuit by Pulling the Input Voltage to Ground

## External Output Enable Circuit

On/off control of the regulator can be implemented through the addition of two additional discrete components (see Figure 16). This circuit operates by pulling the Soft Start pin high, and the $\mathrm{V}_{\mathrm{FFB}}$ pin low, emulating a short circuit condition.

Figure 16. Implementing Shutdown with the CS5157H

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 17). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
V_{\text {Power Good }}=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $V_{\text {Power }}$ Good.

Figure 17. Implementing Power Good with the CS5157H

## Selecting External Components

The CS5157H can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and utilize logic level MOSFETs. Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the MOSFET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the MOSFET gates will be driven rail to rail due to overshoot caused by the
capacitive load they present to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC} 1}=\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;

$$
\operatorname{VGATE}(\mathrm{H})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}, \mathrm{VGATE}(\mathrm{~L})=12 \mathrm{~V}
$$

(see Figure 19.)

Figure 19. CS5157H Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is $\mathrm{RDS}_{\mathrm{ON}}$, which effects regulator efficiency and MOSFET thermal management requirements.

The power dissipated by the MOSFETs may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\text { LLOAD }^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:

$$
\text { Power }=\text { LLOAD }{ }^{2} \times \text { RDSON } \times(1-\text { duty cycle })
$$

Duty Cycle =
VOUT + (ILOAD $\times$ RDSON OF SYNCH FET) $\left[\begin{array}{l}\text { VIN }+(\text { ILOAD } \times \text { RDSON OF SYNCH FET }) \\ -(\text { LLOAD } \times \text { RDSON OF SWITCH FET })\end{array}\right]$

## Off Time Capacitor (Coff)

The Coff timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

When the $\mathrm{V}_{\mathrm{FFB}}$ pin is less than 1.0 V , the current charging the $\mathrm{C}_{\text {OFF }}$ capacitor is reduced. The extended off time can be calculated as follows:

$$
\text { TOFF }=\text { COFF } \times 24,242.5
$$

Off time will be determined by either the $\mathrm{T}_{\text {OFF }}$ time, or the time out timer, whichever is longer.

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\text {OFF }}$ timing capacitor:

$$
\text { CoFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous MOSFET

A Schottky diode may be placed in parallel with the synchronous MOSFET to conduct the inductor current upon turn off of the switching MOSFET to improve efficiency. The CS5157H reference circuit does not use this device due to it's excellent design. Instead, the body diode of the synchronous MOSFET is utilized to reduce cost and conducts the inductor current. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense (see Figure 8, channel 2). The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=\mathrm{V}_{\mathrm{BD}} \times$ ILOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the CS5157H demonstration board as shown in Figure 8;

$$
\text { Power }=1.6 \mathrm{~V} \times 13 \mathrm{~A} \times 100 \mathrm{~ns} \times 233 \mathrm{kHz}=0.48 \mathrm{~W}
$$

This is only $1.3 \%$ of the 36.4 W being delivered to the load.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal
impedance (junction to ambient) required to meet this requirement can be calculated as follows:

Thermal Impedance $=\frac{\text { TJUNCTION(MAX) }- \text { TAMBIENT }}{\text { Power }}$
A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 20. Filter Components

Figure 21. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGND).
2. Connect pin 11 (PGND) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGND).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGND).
6. Connect the $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
7. Place 5.0 V input capacitors close to the switching MOSFET and synchronous MOSFET.
Route gate drive signals $\mathrm{V}_{\text {GATE(H) }}$ (pin 10) and $\mathrm{V}_{\mathrm{GATE}(\mathrm{L})}$ (pin 12 when used) with traces that are a minimum of 0.025 inches wide.

## CS5158

## CPU 5-Bit Synchronous Buck Controller

The CS5158 is a 5-bit synchronous dual N-Channel buck controller. It is designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. The regulator operates using a proprietary control method, which allows a 100 ns response time to load transients. The CS5158 is designed to operate over a $4.25-16 \mathrm{~V}$ range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V as the main supply for conversion.

The CS5158 is specifically designed to power Pentium ${ }^{\circledR}$ II processors and other high performance core logic. It includes the following features: on board, 5-bit DAC, short circuit protection, $0.8 \%$ output tolerance for the 01111 DAC code ( 1.3 V ) and $1.0 \%$ for the remaining DAC codes, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The CS5158 is available in 16 pin surface mount.

## Features

- Dual N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 5-Bit DAC
- 30 ns Gate Rise/Fall Times
- $0.8 \%$ Accuracy for the 01111 DAC Code and $1.0 \%$ for the Remaining DAC Codes
- $5.0 \mathrm{~V} \& 12 \mathrm{~V}$ Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- 25 ns FET Nonoverlap Time
- $V^{2 \mathrm{Tm}}$ Control Topology
- Current Sharing
- Overvoltage Protection

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| SO-16 |  |  |
| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID }}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V providing logic ones if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is High (logic one), the DAC range is 2.10 V to 3.50 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is Low (logic zero), the DAC range is 1.30 V to 2.05 V with 50 mV increments. $\mathrm{V}_{\text {IDO }}-\mathrm{V}_{\text {ID4 }}$ select the desired DAC output voltage. Leaving all 5 DAC input pins open results in a DAC output voltage of 1.2440 V , allowing for adjustable output voltage, using a traditional resistor divider. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND in conjunction with internal $60 \mu \mathrm{~A}$ current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $\mathrm{V}_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Boosted power for the high side gate driver. |
| 10 | $\mathrm{V}_{\text {GATE(H) }}$ | High FET driver pin capable of 1.5 A peak switching current. Internal circuit prevents $\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}$ and $\mathrm{V}_{\mathrm{GATE}(\mathrm{L})}$ from being in high state simultaneously. |
| 11 | PGND | High current ground for the IC. The MOSFET driver is referenced to this pin. Input capacitor ground and the source of lower FET should be tied to this pin. |
| 12 | $\mathrm{V}_{\text {GATE(L) }}$ | Low FET driver pin capable of 1.5 A peak switching current. |
| 13 | $\mathrm{V}_{\mathrm{CC} 1}$ | Input power for the IC and low side gate driver. |
| 14 | LGND | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $V_{\text {FB }}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## V $^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. V ${ }^{\mathbf{2}}$ Control Diagram

The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5158 uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $30 \mu \mathrm{~s}$ timer, minimizing stress to the power components.

## Programmable Output

The CS5158 is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.10 V to 3.50 V in 100 mV steps, the second is 1.30 V to 2.05 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS5158 enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{FFB}}$ pins, as in traditional controllers.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 3.9 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the GATE $(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.
If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE $(\mathrm{H})$ pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.

When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the COFF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.

The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP capacitor charging to its final value. Its voltage is limited by
the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

## Normal Operation

During normal operation, switch off time is constant and set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The CS5158 V ${ }^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.

If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $V_{\text {CC1 }}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 3.75 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 3.70 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs ( $\mathrm{V}_{\mathrm{FFB}}<1.0 \mathrm{~V}$ ), the $\mathrm{V}_{\text {FFB }}$ low comparator sets the FAULT latch. This causes the MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=$ $3.3 \%$ ), while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board traces than occurs with constant current limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Figure 12. CS5158 Demonstration Board Hiccup Mode Short Circuit Protection. Gate Pulses are Delivered While the Soft Start Capacitor Charges, and Cease During Discharge

Figure 13. Startup with Regulator Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 14 and 15 ). The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function.

Figure 14. OVP Response to an Input-to-Output Short Circuit by Immediately Providing 0\% Duty Cycle, Crow-Barring the Input Voltage to Ground

Figure 15. OVP Response to an Input-to-Output Short Circuit by Pulling the Input Voltage to Ground

## External Output Enable Circuit

On/off control of the regulator can be implemented through the addition of two additional discrete components (see Figure 16). This circuit operates by pulling the Soft Start pin high, and the $\mathrm{V}_{\mathrm{FFB}}$ pin low, emulating a short circuit condition.

Figure 16. Implementing Shutdown with the CS5158

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 17). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
V_{\text {Power Good }}=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $V_{\text {Power }}$ Good .

## Selecting External Components

The CS5158 can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and utilize logic level MOSFETs. Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.
Voltage applied to the MOSFET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the MOSFET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the
typical application where $\mathrm{V}_{\mathrm{CC} 1}=\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;

$$
\operatorname{VGATE}(\mathrm{H})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}, \mathrm{VGATE}(\mathrm{~L})=12 \mathrm{~V}
$$

(see Figure 19.)

Figure 19. CS5158 Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is $\mathrm{RDS}_{\mathrm{ON}}$, which effects regulator efficiency and MOSFET thermal management requirements.

The power dissipated by the MOSFETs may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\text { ILOAD }^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:

$$
\text { Power }=\operatorname{ILOAD}{ }^{2} \times \text { RDSON } \times(1-\text { duty cycle })
$$

Duty Cycle =

$$
\frac{\mathrm{V}_{\text {OUT }}+(\mathrm{lLOAD} \times \text { RDSON OF SYNCH FET })}{\left[\begin{array}{l}
\mathrm{V}_{\text {IN }}+(\mathrm{ILOAD} \times \mathrm{RDS} \text { ON OF SYNCH FET }) \\
-(\mathrm{ILOAD} \times \text { RDSON OF SWITCH FET })
\end{array}\right]}
$$

## Off Time Capacitor (COFF)

The Coff timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

When the $\mathrm{V}_{\mathrm{FFB}}$ pin is less than 1.0 V , the current charging the $\mathrm{C}_{\mathrm{OFF}}$ capacitor is reduced. The extended off time can be calculated as follows:

$$
\text { TOFF }=\text { COFF } \times 24,242.5
$$

Off time will be determined by either the $\mathrm{T}_{\mathrm{OFF}}$ time, or the time out timer, whichever is longer.

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\mathrm{OFF}}$ timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous MOSFET

A Schottky diode may be placed in parallel with the synchronous MOSFET to conduct the inductor current upon turn off of the switching MOSFET to improve efficiency. The CS5158 reference circuit does not use this device due to it's excellent design. Instead, the body diode of the synchronous MOSFET is utilized to reduce cost and conducts the inductor current. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense (see Figure 8, channel 2). The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=\mathrm{V}_{\mathrm{BD}} \times$ ILOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the CS5158 demonstration board as shown in Figure 8;

$$
\text { Power }=1.6 \mathrm{~V} \times 13 \mathrm{~A} \times 100 \mathrm{~ns} \times 233 \mathrm{kHz}=0.48 \mathrm{~W}
$$

This is only $1.3 \%$ of the 36.4 W being delivered to the load.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:
Thermal Impedance $=\frac{\text { TJUNCTION }(M A X)-\text { TAMBIENT }}{\text { Power }}$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 20. Filter Components

Figure 21. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGND).
2. Connect pin 11 (PGND) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGND).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGND).
6. Connect the $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
7. Place 5.0 V input capacitors close to the switching MOSFET and synchronous MOSFET.
Route gate drive signals $\mathrm{V}_{\text {GATE(H) }}$ (pin 10) and $\mathrm{V}_{\text {GATE(L) }}$ (pin 12 when used) with traces that are a minimum of 0.025 inches wide.

## CS5159

## CPU 5-Bit Synchronous Buck Controller

The CS5159 is a 5 -bit synchronous dual N-Channel buck controller. It is designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. The regulator operates using a proprietary control method, which allows a 100 ns response time to load transients. The CS5159 is designed to operate over a $4.25-16 \mathrm{~V}$ range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V or 12 V as the main supply for conversion.

The CS5159 is specifically designed to power Pentium ${ }^{\circledR}$ II processors and other high performance core logic. It includes the following features: on board, 5-bit DAC, short circuit protection, $1.0 \%$ output tolerance, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The CS5159 is available in 16 pin surface mount.

## Features

- Dual N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 5-Bit DAC
- Backward Compatible with Adjustable CS5157
- 30 ns Gate Rise/Fall Times
- $1.0 \%$ DAC Accuracy
- $5.0 \mathrm{~V} \& 12 \mathrm{~V}$ Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- 25 ns FET Nonoverlap Time
- $\mathrm{V}^{2 \mathrm{Tm}}$ Control Topology
- Current Sharing
- Overvoltage Protection

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| SO-16 |  |  |
| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID4 }}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V providing logic ones if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is High (logic one), the DAC range is 2.10 V to 3.50 V with 100 mV increments. When $\mathrm{V}_{\text {ID } 4}$ is Low (logic zero), the DAC range is 1.30 V to 2.05 V with 50 mV increments. $\mathrm{V}_{\text {IDO }}-\mathrm{V}_{\text {ID4 }}$ select the desired DAC output voltage. Leaving all 5 DAC input pins open results in a DAC output voltage of 1.2440 V , allowing for adjustable output voltage, using a traditional resistor divider. |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGND in conjunction with internal $60 \mu$ A current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $\mathrm{V}_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Boosted power for the high side gate driver. |
| 10 | $\mathrm{V}_{\text {GATE(H) }}$ | High FET driver pin capable of 1.5 A peak switching current. Internal circuit prevents $\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}$ and $\mathrm{V}_{\mathrm{GATE}(\mathrm{L})}$ from being in high state simultaneously. |
| 11 | PGND | High current ground for the IC. The MOSFET driver is referenced to this pin. Input capacitor ground and the source of lower FET should be tied to this pin. |
| 12 | $\mathrm{V}_{\text {GATE(L) }}$ | Low FET driver pin capable of 1.5 A peak switching current. |
| 13 | $\mathrm{V}_{\mathrm{CC} 1}$ | Input power for the IC and low side gate driver. |
| 14 | LGND | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $V_{F B}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## $\mathrm{V}^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. ${ }^{2}$ Control Diagram

The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5159 uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $25 \mu$ s timer, minimizing stress to the power components.

## Programmable Output

The CS5159 is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.10 V to 3.50 V in 100 mV steps, the second is 1.30 V to 2.05 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS5159 enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{FFB}}$ pins, as in traditional controllers.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 3.9 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the GATE $(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.
If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE $(\mathrm{H})$ pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.
When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the COFF capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.

The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP capacitor charging to its final value. Its voltage is limited by
the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

## Normal Operation

During normal operation, switch off time is constant and set by the C CopF capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The CS5159 $\mathrm{V}^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.

If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $V_{\text {CC1 }}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 3.75 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 3.70 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs ( $\mathrm{V}_{\mathrm{FFB}}<1.0 \mathrm{~V}$ ), the $\mathrm{V}_{\text {FFB }}$ low comparator sets the FAULT latch. This causes the MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=$ $3.3 \%$ ), while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board traces than occurs with constant current limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Figure 13. Startup with Regulator Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 14 and 15 ). The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function.

Figure 14. OVP Response to an Input-to-Output Short Circuit by Immediately Providing 0\% Duty Cycle, Crow-Barring the Input Voltage to Ground

Figure 15. OVP Response to an Input-to-Output Short Circuit by Pulling the Input Voltage to Ground

## External Output Enable Circuit

On/off control of the regulator can be implemented through the addition of two additional discrete components (see Figure 16). This circuit operates by pulling the Soft Start pin high, and the $\mathrm{V}_{\text {FFB }}$ pin low, emulating a short circuit condition.

Figure 16. Implementing Shutdown with the CS5159

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 17). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
V_{\text {Power Good }}=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $V_{\text {Power Good }}$.

## Selecting External Components

The CS5159 can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and utilize logic level MOSFETs. Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.
Voltage applied to the MOSFET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the MOSFET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the
typical application where $\mathrm{V}_{\mathrm{CC} 1}=\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;

$$
\operatorname{VGATE}(\mathrm{H})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}, \mathrm{VGATE}(\mathrm{~L})=12 \mathrm{~V}
$$

(see Figure 19.)

Figure 19. CS5159 Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is RDS $_{\text {ON }}$, which effects regulator efficiency and MOSFET thermal management requirements.

The power dissipated by the MOSFETs may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\text { ILOAD }^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:

$$
\text { Power }=\operatorname{ILOAD}{ }^{2} \times \text { RDSON } \times(1-\text { duty cycle })
$$

Duty Cycle =

$$
\frac{\mathrm{V}_{\text {OUT }}+(\mathrm{lLOAD} \times \text { RDSON OF SYNCH FET })}{\left[\begin{array}{l}
\mathrm{V}_{\text {IN }}+(\mathrm{ILOAD} \times \mathrm{RDS} \text { ON OF SYNCH FET }) \\
-(\mathrm{ILOAD} \times \text { RDSON OF SWITCH FET })
\end{array}\right]}
$$

## Off Time Capacitor (COFF)

The Coff timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { COFF } \times 4848.5
$$

When the $\mathrm{V}_{\mathrm{FFB}}$ pin is less than 1.0 V , the current charging the $\mathrm{C}_{\mathrm{OFF}}$ capacitor is reduced. The extended off time can be calculated as follows:

$$
\text { TOFF }=\text { COFF } \times 24,242.5
$$

Off time will be determined by either the $\mathrm{T}_{\mathrm{OFF}}$ time, or the time out timer, whichever is longer.

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\mathrm{OFF}}$ timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous MOSFET

A Schottky diode may be placed in parallel with the synchronous MOSFET to conduct the inductor current upon turn off of the switching MOSFET to improve efficiency. The CS5159 reference circuit does not use this device due to it's excellent design. Instead, the body diode of the synchronous MOSFET is utilized to reduce cost and conducts the inductor current. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense (see Figure 8, channel 2). The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=\mathrm{V}_{\mathrm{BD}} \times$ ILOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the CS5159 demonstration board as shown in Figure 8;

$$
\text { Power }=1.6 \mathrm{~V} \times 13 \mathrm{~A} \times 100 \mathrm{~ns} \times 233 \mathrm{kHz}=0.48 \mathrm{~W}
$$

This is only $1.3 \%$ of the 36.4 W being delivered to the load.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:
Thermal Impedance $=\frac{\text { TJUNCTION }(M A X)-\text { TAMBIENT }}{\text { Power }}$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 20. Filter Components

Figure 21. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGND).
2. Connect pin 11 (PGND) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGND).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGND).
6. Connect the $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
7. Place 5.0 V input capacitors close to the switching MOSFET and synchronous MOSFET.
Route gate drive signals $\mathrm{V}_{\text {GATE(H) }}$ (pin 10) and $\mathrm{V}_{\text {GATE(L) }}$ (pin 12 when used) with traces that are a minimum of 0.025 inches wide.

## CS5160

## CPU 5-Bit Synchronous Buck Controller

The CS5160 is a 5 -bit synchronous dual N -Channel buck controllers designed to provide unprecedented transient response for today's demanding high-density, high-speed logic. It operates using a proprietary control method which allows a 100 ns response time to load transients. The CS5160 is designed to operate over a 9-16 V range $\left(\mathrm{V}_{\mathrm{CC}}\right)$ using 12 V to power the IC and 5.0 V as the main supply for conversion.

The CS5160 is specifically designed to power Pentium® III processors and other high performance core logic. They include the following features: on board 5-bit DAC, short circuit protection, $1.0 \%$ output tolerance, $\mathrm{V}_{\mathrm{CC}}$ monitor, and programmable Soft Start capability. The CS5160 is available in a 16 pin surface mount package.

## Features

- Dual N-Channel Design
- Excess of 1.0 MHz Operation
- 100 ns Transient Response
- 5-Bit DAC
- Backward Compatible with CS515X Family
- 30 ns Gate Rise/Fall Times
- $0.8 \%$ DAC Accuracy for the 01111 DAC Code
- 5.0 V \& 12 V Operation
- Remote Sense
- Programmable Soft Start
- Lossless Short Circuit Protection
- $\mathrm{V}_{\mathrm{CC}}$ Monitor
- $\mathrm{V}^{2 \mathrm{Tm}}$ Control Topology
- Overvoltage Protection

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| 16 Lead SO Narrow |  |  |

| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {IDO }}-\mathrm{V}_{\text {ID }}$ | Voltage ID DAC input pins. These pins are internally pulled up to 5.0 V providing logic ones if left open. $\mathrm{V}_{\text {ID4 }}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is High (logic one), the DAC range is 2.10 V to 3.50 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is Low (logic zero), the DAC range is 1.30 V to 2.05 V with 50 mV increments. $\mathrm{V}_{\text {IDO }}-\mathrm{V}_{\text {ID4 }}$ select the desired DAC output voltage. Leaving all 5 DAC input pins open results in a DAC output voltage of 1.2440 V , allowing for adjustable output voltage, using a traditional resistor divider. |
| :---: | :---: | :---: |
| 5 | SS | Soft Start Pin. A capacitor from this pin to LGnd in conjunction with internal $60 \mu \mathrm{~A}$ current source provides Soft Start function for the controller. This pin disables fault detect function during Soft Start. When a fault is detected, the Soft Start capacitor is slowly discharged by internal $2.0 \mu \mathrm{~A}$ current source setting the time out before trying to restart the IC. Charge/discharge current ratio of 30 sets the duty cycle for the IC when the regulator output is shorted. |
| 7 | $\mathrm{C}_{\text {OFF }}$ | A capacitor from this pin to ground sets the time duration for the on board one shot, which is used for the constant off time architecture. |
| 8 | $\mathrm{V}_{\text {FFB }}$ | Fast feedback connection to the PWM comparator. This pin is connected to the regulator output. The inner feedback loop terminates on time. |
| 9 | $\mathrm{V}_{\mathrm{CC} 2}$ | Boosted power for the high side gate driver. |
| 10 | $\mathrm{V}_{\text {GATE(H) }}$ | High FET driver pin capable of 1.5 A peak switching current. Internal circuit prevents $\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}$ and $\mathrm{V}_{\mathrm{GATE}(\mathrm{L})}$ from being in high state simultaneously. |
| 11 | PGnd | High current ground for the IC. The MOSFET drivers are referenced to this pin. Input capacitor ground and the source of lower FET should be tied to this pin. |
| 12 | $\mathrm{V}_{\text {GATE(L) }}$ | Low FET driver pin capable of 1.5 A peak switching current. |
| 13 | $\mathrm{V}_{\mathrm{CC} 1}$ | Input power for the IC and low side gate driver. |
| 14 | LGnd | Signal ground for the IC. All control circuits are referenced to this pin. |
| 15 | COMP | Error amplifier compensation pin. A capacitor to ground should be provided externally to compensate the amplifier. |
| 16 | $V_{\text {FB }}$ | Error amplifier DC feedback input. This is the master voltage feedback which sets the output voltage. This pin can be connected directly to the output or a remote sense trace. |

Figure 2. Block Diagram

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## V $^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

Figure 3. V ${ }^{2}$ Control Diagram

The $\mathrm{V}^{2}$ control method is illustrated in Figure 3. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off Time

To maximize transient response, the CS5160 uses a constant off time method to control the rate of output pulses. During normal operation, the off time of the high side switch is terminated after a fixed period, set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. To maintain regulation, the $\mathrm{V}^{2}$ control loop varies switch on time. The PWM comparator monitors the output voltage ramp, and terminates the switch on time.

Constant off time provides a number of advantages. Switch duty cycle can be adjusted from 0 to $100 \%$ on a pulse by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ duty cycle operation can be maintained for extended periods of time in response to load or line transients. PWM slope compensation to avoid sub-harmonic oscillations at high duty cycles is avoided.

Switch on time is limited by an internal $30 \mu \mathrm{~s}$ timer, minimizing stress to the power components.

## Programmable Output

The CS5160 is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.10 V to 3.50 V in 100 mV steps, the second is 1.30 V to 2.05 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS5160 enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{FFB}}$ pins, as in traditional controllers.

## Start Up

Until the voltage on the $\mathrm{V}_{\mathrm{CC} 1}$ supply pin exceeds the 9.05 V monitor threshold, the Soft Start and gate pins are held low. The FAULT latch is reset (no Fault condition). The output of the error amplifier (COMP) is pulled up to 1.0 V by the comparator clamp. When the $\mathrm{V}_{\mathrm{CC} 1}$ pin exceeds the monitor threshold, the GATE $(\mathrm{H})$ output is activated, and the Soft Start capacitor begins charging. The GATE(H) output will remain on, enabling the NFET switch, until terminated by either the PWM comparator, or the maximum on time timer.

If the maximum on time is exceeded before the regulator output voltage achieves the 1.0 V level, the pulse is terminated. The GATE(H) pin drives low, and the GATE(L) pin drives high for the duration of the extended off time. This time is set by the time out timer and is approximately equal to the maximum on time, resulting in a $50 \%$ duty cycle. The GATE(L) pin will then drive low, the GATE(H) pin will drive high, and the cycle repeats.

When regulator output voltage achieves the 1.0 V level present at the COMP pin, regulation has been achieved and normal off time will ensue. The PWM comparator terminates the switch on time, with off time set by the C $\mathrm{C}_{\mathrm{OFF}}$ capacitor. The $\mathrm{V}^{2}$ control loop will adjust switch duty cycle as required to ensure the regulator output voltage tracks the output of the error amplifier.
The Soft Start and COMP capacitors will charge to their final levels, providing a controlled turn on of the regulator output. Regulator turn on time is determined by the COMP capacitor charging to its final value. Its voltage is limited by
the Soft Start COMP clamp and the voltage on the Soft Start pin (see Figures 4 and 5).

Trace 2- Inductor Switching Node ( $5.0 \mathrm{~V} /$ div.)
Figure 6. CS5160 Enable Startup Waveforms

## Normal Operation

During normal operation, switch off time is constant and set by the $\mathrm{C}_{\mathrm{OFF}}$ capacitor. Switch on time is adjusted by the $\mathrm{V}^{2}$ control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current working into the ESR of the output capacitors (see Figures 7 and 8).

## Transient Response

The CS5160 $\mathrm{V}^{2}$ control loop's 100 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse by pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

For best transient response, a combination of a number of high frequency and bulk output capacitors are usually used.

If the maximum on time is exceeded while responding to a sudden increase in load current, a normal off time occurs to prevent saturation of the output inductor.

## PROTECTION AND MONITORING FEATURES

## $V_{\text {CC1 }}$ Monitor

To maintain predictable startup and shutdown characteristics an internal $\mathrm{V}_{\mathrm{CC} 1}$ monitor circuit is used to prevent the part from operating below 8.95 V minimum startup. The $\mathrm{V}_{\mathrm{CC} 1}$ monitor comparator provides hysteresis and guarantees a 8.80 V minimum shutdown threshold.

## Short Circuit Protection

A lossless hiccup mode short circuit protection feature is provided, requiring only the Soft Start capacitor to implement. If a short circuit condition occurs $\left(\mathrm{V}_{\mathrm{FFB}}<1.0 \mathrm{~V}\right)$, the $\mathrm{V}_{\mathrm{FFB}}$ low comparator sets the FAULT
latch. This causes the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The Soft Start capacitor is then slowly discharged by a $2.0 \mu \mathrm{~A}$ current source until it reaches it's lower 0.7 V threshold. The regulator will then attempt to restart normally, operating in it's extended off time mode with a $50 \%$ duty cycle, while the Soft Start capacitor is charged with a $60 \mu \mathrm{~A}$ charge current.

If the short circuit condition persists, the regulator output will not achieve the 1.0 V low $\mathrm{V}_{\mathrm{FFB}}$ comparator threshold before the Soft Start capacitor is charged to it's upper 2.5 V threshold. If this happens the cycle will repeat itself until the short is removed. The Soft Start charge/discharge current ratio sets the duty cycle for the pulses $(2.0 \mu \mathrm{~A} / 60 \mu \mathrm{~A}=3.3 \%)$, while actual duty cycle is half that due to the extended off time mode ( $1.65 \%$ ).

This protection feature results in less stress to the regulator components, input power supply, and PC board traces than occurs with constant current limit protection (see Figures 12 and 13).

If the short circuit condition is removed, output voltage will rise above the 1.0 V level, preventing the FAULT latch from being set, allowing normal operation to resume.

Figure 12. CS5160 Hiccup Mode Short Circuit Protection. Gate Pulses are Delivered While the Soft Start Capacitor Charges, and Cease During Discharge

Figure 13. CS5160 Startup with Regulator
Output Shorted

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 100 ns , causing the top MOSFET to shut off, disconnecting the regulator from it's input voltage. The bottom MOSFET is then activated, resulting in a "crowbar" action to clamp the output voltage and prevent damage to the load (see Figures 14 and 15). The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function.

Figure 15. CS5160 OVP Response to an Input-to-Output Short Circuit by Pulling the Input Voltage to Ground

## External Output Enable Circuit

On/off control of the regulator can be implemented through the addition of two additional discrete components (see Figure 14). This circuit operates by pulling the Soft Start pin high, and the $\mathrm{V}_{\text {FFB }}$ pin low, emulating a short circuit condition.

Figure 16. Implementing Shutdown with the CS5160

## External Power Good Circuit

An optional Power Good signal can be generated through the use of four additional external components (see Figure 17). The threshold voltage of the Power Good signal can be adjusted per the following equation:

$$
V_{\text {Power Good }}=\frac{(\mathrm{R} 1+\mathrm{R} 2) \times 0.65 \mathrm{~V}}{\mathrm{R} 2}
$$

This circuit provides an open collector output that drives the Power Good output to ground for regulator voltages less than $V_{\text {Power Good }}$.

Trace 2- Power Good Signal (2.0 V/div.)
Figure 18. CS5160 During Power Up. Power Good Signal is Activated when Output Voltage Reaches 1.70 V

## Slope Compensation

The $\mathrm{V}^{2}$ control method uses a ramp signal, generated by the ESR of the output capacitors, that is proportional to the ripple current through the inductor. To maintain regulation, the $\mathrm{V}^{2}$ control loop monitors this ramp signal, through the PWM comparator, and terminates the switch on-time.
The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope presented to the PWM comparator, due to the very low ESR, can lead to pulse width jitter and variation caused by both random or synchronous noise.
Adding slope compensation to the control loop, avoids erratic operation of the PWM circuit, particularly at lower duty cycles and higher frequencies, where there is not enough ramp signal, and provides a more stable switchpoint.
The scheme that prevents that switching noise prematurely triggers the PWM circuit consists of adding a positive voltage slope to the output of the Error Amplifier (COMP pin) during an off-time cycle.

The circuit that implements this function is shown in Figure 19.

Figure 19. Small RC Filter Provides the Proper Voltage Ramp at the Beginning of each On-Time Cycle
The ramp waveform is generated through a small RC filter that provides the proper voltage ramp at the beginning of each on-time cycle. The resistors R1 and R2 in the circuit of Figure 14 form a voltage divider from the GATE(L) output, superimposing a small artificial ramp on the output of the error amplifier. It is important that the series combination $\mathrm{R} 1 / \mathrm{R} 2$ is high enough in resistance not to load down and negatively affect the slew rate on the GATE(L) pin.

## Selecting External Components

The CS5160 can be used with a wide range of external power components to optimize the cost and performance of a particular design. The following information can be used as general guidelines to assist in their selection.

## NFET Power Transistors

Both logic level and standard MOSFETs can be used. The reference designs derive gate drive from the 12 V supply which is generally available in most computer systems and utilize logic level MOSFETs. Multiple MOSFETs may be paralleled to reduce losses and improve efficiency and thermal management.

Voltage applied to the MOSFET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the MOSFET gates will be driven rail to rail due to overshoot caused by the capacitive load they present to the controller IC. For the typical application where $\mathrm{V}_{\mathrm{CC} 1}=\mathrm{V}_{\mathrm{CC} 2}=12 \mathrm{~V}$ and 5.0 V is used as the source for the regulator output current, the following gate drive is provided;

$$
\operatorname{VGATE}(\mathrm{H})=12 \mathrm{~V}-5.0 \mathrm{~V}=7.0 \mathrm{~V}, \mathrm{VGATE}(\mathrm{~L})=12 \mathrm{~V}
$$

(see Figure 20.)

Figure 20. CS5160 Gate Drive Waveforms Depicting Rail to Rail Swing
The most important aspect of MOSFET performance is RDS $_{\mathrm{ON}}$, which effects regulator efficiency and MOSFET thermal management requirements.
The power dissipated by the MOSFETs may be estimated as follows;

Switching MOSFET:

$$
\text { Power }=\operatorname{lLOAD}^{2} \times \text { RDSON } \times \text { duty cycle }
$$

Synchronous MOSFET:

$$
\text { Power }=\mathrm{I}_{\mathrm{LOAD}}{ }^{2} \times \text { RDSON } \times(1-\text { duty cycle })
$$

Duty Cycle =

$$
\frac{\text { VOUT }+(\text { LLOAD } \times \text { RDSON OF SYNCH FET })}{\left[\begin{array}{l}
\text { VIN }+(\text { ILOAD } \times \text { RDSON OF SYNCH FET }) \\
-(\text { ILOAD } \times \text { RDSON OF SWITCH FET })
\end{array}\right]}
$$

## Off Time Capacitor (Coff)

The C CFF timing capacitor sets the regulator off time:

$$
\text { TOFF }=\text { CofF } \times 4848.5
$$

The preceding equations for duty cycle can also be used to calculate the regulator switching frequency and select the $\mathrm{C}_{\text {OFF }}$ timing capacitor:

$$
\text { COFF }=\frac{\text { Perioid } \times(1-\text { duty cycle })}{4848.5}
$$

where:

$$
\text { Period }=\frac{1}{\text { switching frequency }}
$$

## Schottky Diode for Synchronous MOSFET

A Schottky diode may be placed in parallel with the synchronous MOSFET to conduct the inductor current upon turn off of the switching MOSFET to improve efficiency. For a design operating at 200 kHz or so, the low non-overlap time combined with Schottky forward recovery time may make the benefits of this device not worth the additional expense (see Figure 8, channel 2). The power dissipation in the synchronous MOSFET due to body diode conduction can be estimated by the following equation:
Power $=\mathrm{V}_{\mathrm{BD}} \times$ ILOAD $\times$ conduction time $\times$ switching frequency
Where $\mathrm{V}_{\mathrm{BD}}=$ the forward drop of the MOSFET body diode. For the CS5160 demonstration board as shown in Figure 8;
Power $=1.6 \mathrm{~V} \times 13 \mathrm{~A} \times 100 \mathrm{~ns} \times 233 \mathrm{kHz}=0.48 \mathrm{~W}$
This is only $1.3 \%$ of the 36.4 W being delivered to the load.

## Input and Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines and regulator output voltage. Key specifications for input capacitors are their ripple rating, while ESR is important for output capacitors. For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

## Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs and Diodes

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:
Thermal Impedance $=\frac{\text { TJUNCTION } \text { MAX })- \text { TAMBIENT }}{\text { Power }}$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI Management

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

Figure 21. Filter Components

Figure 22. Input Filter

## Layout Guidelines

1. Place 12 V filter capacitor next to the IC and connect capacitor ground to pin 11 (PGnd).
2. Connect pin 11 (PGnd) with a separate trace to the ground terminals of the 5.0 V input capacitors.
3. Place fast feedback filter capacitor next to pin $8\left(\mathrm{~V}_{\mathrm{FFB}}\right)$ and connect it's ground terminal with a separate, wide trace directly to pin 14 (LGnd).
4. Connect the ground terminals of the Compensation capacitor directly to the ground of the fast feedback filter capacitor to prevent common mode noise from effecting the PWM comparator.
5. Place the output filter capacitor(s) as close to the load as possible and connect the ground terminal to pin 14 (LGnd).
6. Connect the $\mathrm{V}_{\mathrm{FB}}$ pin directly to the load with a separate trace (remote sense).
7. Place 5.0 V input capacitors close to the switching MOSFET and synchronous MOSFET.
Route gate drive signals $\mathrm{V}_{\text {GATE(H) }}$ (pin 10) and $\mathrm{V}_{\text {GATE(L) }}$ (pin 12 when used) with traces that are a minimum of 0.025 inches wide.

## CS51311

## Synchronous CPU <br> Buck Controller for 12 V and 5.0 V Applications

The CS51311 is a synchronous dual NFET Buck Regulator Controller. It is designed to power the core logic of the latest high performance CPUs. It uses the $\mathrm{V}^{2 \mathrm{TM}}$ control method to achieve the fastest possible transient response and best overall regulation. It incorporates many additional features required to ensure the proper operation and protection of the CPU and Power system. The CS51311 provides the industry's most highly integrated solution, minimizing external component count, total solution size, and cost.

The CS51311 is specifically designed to power Intel's Pentium ${ }^{\circledR}$ II processor and includes the following features: 5-bit DAC with $1.2 \%$ tolerance, Power Good output, overcurrent hiccup mode protection, $\mathrm{V}_{\mathrm{CC}}$ monitor, soft start, adaptive voltage positioning, adaptive FET non-overlap time, and remote sense. The CS51311 will operate over an 8.4 V to 14 V range and is available in 14 lead narrow body surface mount package.

## Features

- Synchronous Switching Regulator Controller for CPU VCORE
- Dual N-Channel MOSFET Synchronous Buck Design
- $\mathrm{V}^{2}$ Control Topology
- 200 ns Transient Loop Response
- 5-Bit DAC with $1.2 \%$ Tolerance
- Hiccup Mode Overcurrent Protection
- 40 ns Gate Rise and Fall Times (3.3 nF Load)
- 65 ns Adaptive FET Non-Overlap Time
- Adaptive Voltage Positioning
- Power Good Output Monitors Regulator Output
- $\mathrm{V}_{\mathrm{CC}}$ Monitor Provides Undervoltage Lockout
- Enable Through Use of the COMP Pin

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## V $^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

The $\mathrm{V}^{2}$ control method is illustrated in Figure 8. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

Figure 8. $\mathbf{V}^{2}$ Control Diagram
A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop.

The main purpose of this "slow" feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.
Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation.
A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off-Time

To minimize transient response, the CS51311 uses a Constant Off-Time method to control the rate of output pulses. During normal operation, the Off-Time of the high side switch is terminated after a fixed period, set by the CofF capacitor. Every time the $\mathrm{V}_{\mathrm{FB}}$ pin exceeds the COMP pin voltage an Off-Time is initiated. To maintain regulation, the $\mathrm{V}^{2}$ Control Loop varies switch On-Time. The PWM comparator monitors the output voltage ramp, and terminates the switch On-Time.
Constant Off-Time provides a number of advantages. Switch Duty Cycle can be adjusted from 0 to $100 \%$ on a pulse-by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ Duty Cycle operation can be maintained for extended periods of time in response to Load or Line transients.

## Programmable Output

The CS51311 is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.125 V to 3.525 V in 100 mV steps, the second is 1.325 V to 2.075 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS51311 enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ pin, as in traditional controllers. The CS51311 is specifically designed to meet or exceed Intel's Pentium II specifications.

## Error Amplifier

An inherent benefit of the $\mathrm{V}^{2}$ control topology is that there is no large bandwidth requirement on the error amplifier
design. The reaction time to an output load step has no relation to the crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this "slow" feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered. The COMP pin is the output of the error amplifier and a capacitor to GND compensates the error amplifier loop. Additionally, through the built-in offset on the PWM Comparator non-inverting input, the COMP pin provides the hiccup timing for the Overcurrent Protection, the Soft Start function that minimizes inrush currents during regulator power-up and switcher output enable.

## Startup

The CS51311 provides a controlled startup of regulator output voltage and features Programmable Soft Start implemented through the Error Amp and external Compensation Capacitor. This feature, combined with overcurrent protection, prevents stress to the regulator power components and overshoot of the output voltage during startup.

As power is applied to the regulator, the CS51311 Undervoltage Lockout circuit (UVL) monitors the IC's supply voltage ( $\mathrm{V}_{\mathrm{CC}}$ ) which is typically connected to the +12 V output of the AC-DC power supply. The UVL circuit prevents the NFET gates from being activated until $\mathrm{V}_{\mathrm{CC}}$ exceeds the 8.4 V (typ) threshold. Hysteresis of 300 mV (typ) is provided for noise immunity. The Error Amp Capacitor connected to the COMP pin is charged by a $30 \mu \mathrm{~A}$ current source. This capacitor must be charged to 1.1 V (typ) so that it exceeds the PWM comparator's offset before the $\mathrm{V}^{2}$ PWM control loop permits switching to occur.

When $\mathrm{V}_{\mathrm{CC}}$ has exceeded 8.4 V and COMP has charged to 1.1 V, the upper Gate driver (GATE(H)) is activated, turning on the upper FET. This causes current to flow through the output inductor and into the output capacitors and load according to the following equation:

$$
I=\left(V_{I N}-V_{O U T}\right) \times \frac{T}{L}
$$

GATE(H) and the upper NFET remain on and inductor current ramps up until the initial pulse is terminated by either the PWM control loop or the overcurrent protection. This initial surge of in-rush current minimizes startup time, but avoids overstressing of the regulator's power components.

The PWM comparator will terminate the initial pulse if the regulator output exceeds the voltage on the COMP pin plus the 1.1 V PWM comparator offset prior to the drop across the current sense resistor exceeding the current limit threshold. In this case, the PWM control loop has achieved regulation and the initial pulse is then followed by a constant off time as programmed by the Coff capacitor. The COMP
capacitor will continue to slowly charge and the regulator output voltage will follow it, less the 1.1 V PWM offset, until it achieves the voltage programmed by the DAC's VID input. The Error Amp will then source or sink current to the COMP cap as required to maintain the correct regulator DC output voltage. Since the rate of increase of the COMP pin voltage is typically set much slower than the regulator's slew capability, inrush current, output voltage, and duty cycle all gradually increase from zero. (See Figures 9, 10, and 11).

Channel 3 - V CC ( $10 \mathrm{~V} /$ div)
Channel 4 - Regulator Input Voltage ( $5.0 \mathrm{~V} / \mathrm{div}$ )
Figure 11. Pulse-By-Pulse Regulation During Soft Start ( $2.0 \mu \mathrm{~s} / \mathrm{div}$ )

If the voltage across the Current Sense resistor generates a voltage difference between the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ pins that exceeds the OVC Comparator Offset Voltage ( 86 mV typical), the Fault latch is set. This causes the COMP pin to be quickly discharged, turning off GATE $(\mathrm{H})$ and the upper NFET since the voltage on the COMP pin is now less than the 1.1 V PWM comparator offset. The Fault latch is reset when the voltage on the COMP decreases below the discharge threshold voltage ( 0.25 V typical). The COMP capacitor will again begin to charge, and when it exceeds the 1.1 V PWM comparator offset, the regulator output will Soft Start normally (see Figure 12).

Figure 12. Startup with COMP Pre-Charge to 2.0 V ( $2.0 \mathrm{~ms} / \mathrm{div}$ )

Because the start-up circuit depends on the current sense function, a current sense resistor should always be used.

When driving large capacitive loads, the COMP must charge slowly enough to avoid tripping the CS51311 overcurrent protection. The following equation can be used to ensure unconditional startup:

$$
\frac{I_{\mathrm{CHG}}}{\mathrm{CCOMP}}<\frac{\mathrm{I}_{\mathrm{LIM}}-\mathrm{I}_{\mathrm{LOAD}}}{\mathrm{COUT}}
$$

where:
$\mathrm{I}_{\mathrm{CHG}}=$ COMP Source Current ( $30 \mu \mathrm{~A}$ typical);
$\mathrm{C}_{\text {COMP }}=$ COMP Capacitor value ( $0.1 \mu \mathrm{~F}$ typical);
$\mathrm{I}_{\text {LIM }}=$ Current Limit Threshold;
$\mathrm{I}_{\text {LOAD }}=$ Load Current during startup;
Cout $=$ Total Output Capacitance .

## Normal Operation

During normal operation, Switch Off-Time is constant and set by the C CofF capacitor. Switch On-Time is adjusted by the $\mathrm{V}^{2}$ Control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current and the ESR of the output capacitors

## Transient Response

The CS51311 V ${ }^{2}$ Control Loop's 200 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse-by-pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

Overall load transient response is further improved through a feature called "Adaptive Voltage Positioning". This technique pre-positions the output capacitors voltage to reduce total output voltage excursions during changes in load.

Holding tolerance to $1.0 \%$ allows the error amplifiers reference voltage to be targeted +25 mV high without compromising DC accuracy. A "Droop Resistor," implemented through a PC board trace, connects the Error Amps feedback pin ( $\mathrm{V}_{\mathrm{FB}}$ ) to the output capacitors and load and carries the output current. With no load, there is no DC drop across this resistor, producing an output voltage tracking the Error amps, including the +25 mV offset. When the full load current is delivered, a 50 mV drop is developed across this resistor. This results in output voltage being offset -25 mV low.

The result of Adaptive Voltage Positioning is that additional margin is provided for a load transient before reaching the output voltage specification limits. When load current suddenly increases from its minimum level, the output capacitor is pre-positioned +25 mV . Conversely, when load current suddenly decreases from its maximum level, the output capacitor is pre-positioned -25 mV . For
best Transient Response, a combination of a number of high frequency and bulk output capacitors are usually used.

## Slope Compensation

The $\mathrm{V}^{2}$ control method uses a ramp signal, generated by the ESR of the output capacitors, that is proportional to the ripple current through the inductor. To maintain regulation, the $\mathrm{V}^{2}$ control loop monitors this ramp signal, through the PWM comparator, and terminates the switch on-time.

The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope presented to the PWM comparator, due to the very low ESR, can lead to pulse width jitter and variation caused by both random or synchronous noise.

Adding slope compensation to the control loop, avoids erratic operation of the PWM circuit, particularly at lower duty cycles and higher frequencies, where there is not enough ramp signal, and provides a more stable switchpoint.

The scheme that prevents that switching noise prematurely triggers the PWM circuit consists of adding a positive voltage slope to the output of the Error Amplifier (COMP pin) during an off-time cycle.

The circuit that implements this function is shown in Figure 13.

Figure 13. Small RC Filter Provides the Proper Voltage Ramp at the Beginning of Each On-Time Cycle

The ramp waveform is generated through a small RC filter that provides the proper voltage ramp at the beginning of each on-time cycle. The resistors R1 and R2 in the circuit of Figure 13 form a voltage divider from the GATE(L) output, superimposing a small artificial ramp on the output of the error amplifier. It is important that the series combination $\mathrm{R} 1 / \mathrm{R} 2$ is high enough in resistance not to load down and negatively affect the slew rate on the GATE(L) pin.

## PROTECTION AND MONITORING FEATURES

## Overcurrent Protection

A loss-less hiccup mode current limit protection feature is provided, requiring only the COMP capacitor to implement. The CS51311 provides overcurrent protection by sensing the current through a "Droop" resistor, using an internal current sense comparator. The comparator
compares the voltage drop through the "Droop" resistor to an internal reference voltage of 86 mV (typical).

If the voltage drop across the "Droop" resistor exceeds this threshold, the current sense comparator allows the fault latch to be set. This causes the regulator to stop switching.

During this overcurrent condition, the CS51311 stays off for the time it takes the COMP pin capacitor to discharge to its lower 0.25 V threshold. As soon as the COMP pin reaches 0.25 V , the Fault latch is reset (no overcurrent condition present) and the COMP pin is charged with a $30 \mu \mathrm{~A}$ current source to a voltage 1.1 V greater than the $\mathrm{V}_{\mathrm{FB}}$ voltage. Only at this point the regulator attempts to restart normally by delivering short gate pulses to both FETS. The CS51311 will operate initially with a duty cycle whose value depends on how low the $\mathrm{V}_{\mathrm{FB}}$ voltage was during the overcurrent condition (whether hiccup mode was due to excessive current or hard short). This protection scheme minimizes thermal stress to the regulator components, input power supply, and PC board traces, as the overcurrent condition persists. Upon removal of the overload, the fault latch is cleared, allowing normal operation to resume.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 200 ns , causing the top MOSFET to shut off, disconnecting the regulator from its input voltage. This results in a "crowbar" action to clamp the output voltage and prevents damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. The bottom FET and board trace must be properly designed to implement the OVP function.

## Power Good Circuit

The Power Good pin (pin 12) is an open-collector signal consistent with TTL DC specifications. It is externally pulled up, and is pulled low (below 0.3 V ) when the regulator output voltage typically exceeds $\pm 8.5 \%$ of the nominal output voltage. Maximum output voltage deviation before Power Good is pulled low is $\pm 12 \%$.

## Output Enable

On/off control of the regulator outputs can be implemented by pulling the COMP pins low. It is required to pull the COMP pins below the 1.1 V PWM comparator offset voltage in order to disable switching on the GATE drivers.

## CS51311-BASED $\mathrm{V}_{\mathrm{CC}(\text { (CORE) }}$ BUCK REGULATOR DESIGN PROCEDURE

## Step 1: Definition of the Design Specifications

In computer motherboard applications the input voltage comes from the "silver box" power supply. $5.0 \mathrm{~V} \pm 5.0 \%$ is
used for conversion to output voltage, and $12 \mathrm{~V} \pm 5.0 \%$ is used for the external NFET gate voltage and circuit bias. The CPU V ${ }_{\text {CC(CORE) }}$ tolerance can be affected by any or all of the following reasons:

1. buck regulator output voltage setpoint accuracy;
2. output voltage change due to discharging or charging of the bulk decoupling capacitors during a load current transient;
3. output voltage change due to the ESR and ESL of the bulk and high frequency decoupling capacitors, circuit traces, and vias;
4. output voltage ripple and noise.

Budgeting the tolerance is left up to the designer who must take into account all of the above effects and provide a $\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}$ that will meet the specified tolerance at the CPU's inputs.

The designer must also ensure that the regulator component junction temperatures are kept within the manufacturer's specified ratings at full load and maximum ambient temperature. As computer motherboards become increasingly complex, regulator size also becomes important, as there is less space available for the CPU power supply.

## Step 2: Selection of the Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the regulator output voltage. Key specifications for output capacitors are their ESR (Equivalent Series Resistance), and ESL (Equivalent Series Inductance). For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

In order to determine the number of output capacitors the maximum voltage transient allowed during load transitions has to be specified. The output capacitors must hold the output voltage within these limits since the inductor current can not change with the required slew rate. The output capacitors must therefore have a very low ESL and ESR.

The voltage change during the load current transient is:

$$
\Delta \mathrm{V}_{\mathrm{OUT}}=\Delta \mathrm{I} \mathrm{OUT} \times\left(\frac{\mathrm{ESL}}{\Delta \mathrm{t}}+\mathrm{ESR}+\frac{\mathrm{tTR}}{\mathrm{COUT}}\right)
$$

where:
$\Delta \mathrm{I}_{\mathrm{OUT}} / \Delta \mathrm{t}=$ load current slew rate;
$\Delta \mathrm{I}_{\text {OUT }}=$ load transient;
$\Delta t=$ load transient duration time;
$\mathrm{ESL}=$ Maximum allowable ESL including capacitors, circuit traces, and vias;
$\mathrm{ESR}=$ Maximum allowable ESR including capacitors and circuit traces;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time.
The designer has to independently assign values for the change in output voltage due to ESR, ESL, and output capacitor discharging or charging. Empirical data indicates that most of the output voltage change (droop or spike
depending on the load current transition) results from the total output capacitor ESR.

The maximum allowable ESR can then be determined according to the formula

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESR}}}{\Delta \mathrm{I} \mathrm{OUT}}
$$

where $\Delta \mathrm{V}_{\mathrm{ESR}}=$ change in output voltage due to ESR (assigned by the designer).

Once the maximum allowable ESR is determined, the number of output capacitors can be found by using the formula

$$
\text { Number of capacitors }=\frac{\text { ESRCAP }}{\text { ESRMAX }}
$$

where:
$\mathrm{ESR}_{\mathrm{CAP}}=$ maximum ESR per capacitor (specified in manufacturer's data sheet);
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR.
The actual output voltage deviation due to ESR can then be verified and compared to the value assigned by the designer:

$$
\Delta \mathrm{V}_{\mathrm{ESR}}=\Delta \mathrm{I} \text { OUT } \times \mathrm{ESR}_{\mathrm{MAX}}
$$

Similarly, the maximum allowable ESL is calculated from the following formula:

$$
\mathrm{ESLMAX}=\frac{\Delta \mathrm{V}_{\mathrm{ESL}} \times \Delta \mathrm{t}}{\Delta \mathrm{I}}
$$

where:
$\Delta \mathrm{I} / \Delta \mathrm{T}=$ load current slew rate (as high as $20 \mathrm{~A} / \mu \mathrm{s}$ );
$\Delta \mathrm{V}_{\mathrm{ESL}}=$ change in output voltage due to ESL.
The actual maximum allowable ESL can be determined by using the equation:

$$
\text { ESLMAX }=\frac{\text { ESLCAP }}{\text { Number of output capacitors }}
$$

where $\mathrm{ESL}_{\mathrm{CAP}}=$ maximum ESL per capacitor (it is estimated that a $10 \times 12 \mathrm{~mm}$ Aluminum Electrolytic capacitor has approximately 4.0 nH of package inductance).

The actual output voltage deviation due to the actual maximum ESL can then be verified:

$$
\Delta \mathrm{V}_{\mathrm{ESL}}=\frac{\mathrm{ESLMAX} \times \Delta \mathrm{I}}{\Delta \mathrm{t}}
$$

The designer now must determine the change in output voltage due to output capacitor discharge during the transient:

$$
\Delta \mathrm{V}_{\mathrm{CAP}}=\frac{\Delta \mathrm{l} \times \Delta \mathrm{t} \mathrm{TR}}{\mathrm{COUT}}
$$

where:
$\Delta \mathrm{t}_{\mathrm{TR}}=$ the output voltage transient response time (assigned by the designer);
$\Delta \mathrm{V}_{\mathrm{CAP}}=$ output voltage deviation due to output capacitor discharge;
$\Delta \mathrm{I}=$ Load step .

The total change in output voltage as a result of a load current transient can be verified by the following formula:

$$
\Delta \mathrm{V}_{\text {OUT }}=\Delta \mathrm{V}_{\mathrm{ESR}}+\Delta \mathrm{V}_{\mathrm{ESL}}+\Delta \mathrm{V}_{\mathrm{CAP}}
$$

## Step 3: Selection of the Duty Cycle, Switching Frequency, Switch On-Time (TON) and Switch Off-Time (TOfF)

The duty cycle of a buck converter (including parasitic losses) is given by the formula:

$$
\text { Duty Cycle }=\mathrm{D}=\frac{\mathrm{V}_{\mathrm{OUT}}+\left(\mathrm{V}_{\mathrm{HFET}}+\mathrm{V}_{\mathrm{L}}+\mathrm{V}_{\mathrm{DROOP}}\right)}{\mathrm{V}_{\mathrm{IN}}+\mathrm{V}_{\mathrm{LFET}}-\mathrm{V}_{\mathrm{HFET}}-\mathrm{V}_{\mathrm{L}}}
$$

where:
$\mathrm{V}_{\text {OUT }}=$ buck regulator output voltage;
$\mathrm{V}_{\text {HFET }}=$ high side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$;
$\mathrm{V}_{\mathrm{L}}=$ output inductor voltage drop due to inductor wire DC resistance;
$\mathrm{V}_{\text {DROOP }}=$ droop (current sense) resistor voltage drop;
$\mathrm{V}_{\mathrm{IN}}=$ buck regulator input voltage;
$\mathrm{V}_{\mathrm{LFET}}=$ low side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$.

## Step3a: Calculation of Switch On-Time

The Switch On-Time (time during which the switching MOSFET in a synchronous buck topology is conducting) is determined by:

$$
\text { TON }=\frac{\text { Duty Cycle }}{\text { FSW }}
$$

where $\mathrm{F}_{\mathrm{SW}}=$ regulator switching frequency selected by the designer.

Higher operating frequencies allow the use of smaller inductor and capacitor values. Nevertheless, it is common to select lower frequency operation because a higher frequency results in lower efficiency due to MOSFET gate charge losses. Additionally, the use of smaller inductors at higher frequencies results in higher ripple current, higher output voltage ripple, and lower efficiency at light load currents.

## Step 3b: Calculation of Switch Off-Time

The Switch Off-Time (time during which the switching MOSFET is not conducting) can be determined by:

$$
\text { TOFF }=\frac{1.0}{\text { FSW }}-\mathrm{TON}
$$

The $\mathrm{C}_{\mathrm{OFF}}$ capacitor value has to be selected in order to set the Off-Time, $\mathrm{T}_{\text {OfF }}$, above:

$$
\text { COFF }=\frac{\text { Period } \times(1.0-\mathrm{D})}{3980}
$$

where:
3980 is a characteristic factor of the CS51311;
D = Duty Cycle.

## Step 4: Selection of the Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but
degrade transient response. There are many factors to consider in selecting the inductor including cost, efficiency, EMI and ease of manufacture. The inductor must be able to handle the peak current at the switching frequency without saturating, and the copper resistance in the winding should be kept as low as possible to minimize resistive power loss. There are a variety of materials and types of magnetic cores that could be used for this application. Among them are ferrites, molypermalloy cores (MPP), amorphous and powdered iron cores. Powdered iron cores are very commonly used. Powdered iron cores are very suitable due to their high saturation flux density and have low loss at high frequencies, a distributed gap and exhibit very low EMI.

The inductor value can be determined by:

$$
\mathrm{L}=\frac{\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{t} \mathrm{TR}}{\Delta \mathrm{I}}
$$

where:
$\mathrm{V}_{\text {IN }}=$ input voltage;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time (assigned by the designer);
$\Delta \mathrm{I}=$ load transient.
The inductor ripple current can then be determined:

$$
\Delta \mathrm{I}_{\mathrm{L}}=\frac{\mathrm{V}_{\mathrm{OUT}} \times \mathrm{T}_{\mathrm{OFF}}}{\mathrm{~L}}
$$

where:
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{T}_{\mathrm{OFF}}=$ switch Off-Time;
$\mathrm{L}=$ inductor value.
The designer can now verify if the number of output capacitors from Step 2 will provide an acceptable output voltage ripple ( $1.0 \%$ of output voltage is common). The formula below is used:

$$
\Delta \mathrm{I}_{\mathrm{L}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\mathrm{ESR} \mathrm{MAX}^{2}}
$$

Rearranging we have:

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\Delta \mathrm{l}}
$$

where
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR ;
$\Delta \mathrm{V}_{\text {OUT }}=1.0 \% \times \mathrm{V}_{\text {OUT }}=$ maximum allowable output voltage ripple ( budgeted by the designer );
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage .
The number of output capacitors is determined by:

$$
\text { Number of capacitors }=\frac{\text { ESRCAP }}{\text { ESRMAX }}
$$

where $\mathrm{ESR}_{\mathrm{CAP}}=$ maximum ESR per capacitor (specified in manufacturer's data sheet).

The designer must also verify that the inductor value yields reasonable inductor peak and valley currents (the inductor current is a triangular waveform):

$$
\mathrm{I}(\mathrm{PEAK})=\mathrm{IOUT}+\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2.0}
$$

where:
$\mathrm{I}_{\mathrm{L}(\text { PEAK })}=$ inductor peak current;
I OUT $=$ load current;
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current.

$$
\mathrm{IL}(\mathrm{VALLEY})=\mathrm{IOUT}-\frac{\Delta \mathrm{I}}{2.0}
$$

where $\mathrm{I}_{\mathrm{L}(\text { VALLEY })}=$ inductor valley current.
Given the requirements of an application such as a buck converter, it is found that a toroid powdered iron core is quite suitable due to its low cost, low core losses at the switching frequency, and low EMI.

## Step 5: Selection of the Input Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines. A key specification for input capacitors is their ripple current rating. The input capacitor should also be able to handle the input RMS current $\mathrm{I}_{\text {IN(RMS) }}$.

The combination of the input capacitors $\mathrm{C}_{\mathrm{IN}}$ discharges during the on-time.

The input capacitor discharge current is given by:
ICINDIS(RMS) $=$

$$
\sqrt{\frac{\left(\begin{array}{l}
\mathrm{IL}(\mathrm{PEAK})^{2} \\
+(\mathrm{IL}(\mathrm{PEAK}) \times \mathrm{L}(\mathrm{VALLEY})) \\
+\mathrm{IL}(\mathrm{VALLEY})^{2}
\end{array}\right.}{3.0}}
$$

where:
$\mathrm{I}_{\mathrm{CINDIS}(\mathrm{RMS})}=$ input capacitor discharge current;
$\mathrm{I}_{\mathrm{L}(\text { PEAK })}=$ inductor peak current;
$\mathrm{I}_{\mathrm{L}(\text { VALLEY })}=$ inductor valley current.
$\mathrm{C}_{\mathrm{IN}}$ charges during the off-time, the average current through the capacitor over one switching cycle is zero:

$$
\operatorname{ICIN}(C H)=\operatorname{ICIN}(D I S) \times \frac{D}{1.0-D}
$$

where:
$\mathrm{I}_{\mathrm{CIN}(\mathrm{CH})}=$ input capacitor charge current;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{DIS})}=$ input capacitor discharge current;
D = Duty Cycle .
The total Input RMS current is:

$$
\mathrm{I} \mathrm{CIN}(\mathrm{RMS})=\sqrt{\begin{array}{l}
\left(\mathrm{I} \mathrm{CIN}(\mathrm{DIS})^{2} \times \mathrm{D}\right) \\
+\left(\operatorname{ICIN}(\mathrm{CH})^{2} \times(1.0-\mathrm{D})\right)
\end{array}}
$$

The number of input capacitors required is then determined by:

$$
N_{\mathrm{CIN}}=\frac{\mathrm{I} \mathrm{I} \operatorname{IN}(\mathrm{RMS})}{\mathrm{I}_{\mathrm{RIPPLE}}}
$$

where:
$\mathrm{N}_{\mathrm{CIN}}=$ number of input capacitors;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{RMS})}=$ total input RMS current;
$\mathrm{I}_{\text {RIPPLE }}=$ input capacitor ripple current rating (specified in manufacturer's data sheets).

The total input capacitor ESR needs to be determined in order to calculate the power dissipation of the input capacitors:

$$
\mathrm{ESR}_{\mathrm{CIN}}=\frac{\mathrm{ESR} \mathrm{CAP}}{\mathrm{~N}_{\mathrm{CIN}}}
$$

where:
$\mathrm{ESR}_{\mathrm{CIN}}=$ total input capacitor ESR;
$\mathrm{ESR}_{\mathrm{CAP}}=$ maximum ESR per capacitor (specified in manufacturer's data sheets);
$\mathrm{N}_{\mathrm{CIN}}=$ number of input capacitors.
Once the total ESR of the input capacitors is known, the input capacitor ripple voltage can be determined using the formula:

$$
\mathrm{V}_{\mathrm{CIN}(\mathrm{RMS})}=\operatorname{I} \mathrm{CIN}(\mathrm{RMS}) \times \mathrm{ESR}_{\mathrm{CIN}}
$$

where:
$\mathrm{V}_{\mathrm{CIN}(\mathrm{RMS})}=$ input capacitor RMS voltage;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{RMS})}=$ total input RMS current;
$\mathrm{ESR}_{\mathrm{CIN}}=$ total input capacitor ESR.
The designer must determine the input capacitor power loss in order to ensure there isn't excessive power dissipation through these components. The following formula is used:

$$
\operatorname{PCIN}(\mathrm{RMS})=\operatorname{ICIN}(\mathrm{RMS})^{2} \times \mathrm{ESR}_{\mathrm{CIN}}
$$

where:
$\mathrm{P}_{\mathrm{CIN}(\mathrm{RMS})}=$ input capacitor RMS power dissipation;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{RMS})}=$ total input RMS current;
$\mathrm{ESR}_{\mathrm{CIN}}=$ total input capacitor ESR .

## Step 6: Selection of the Input Inductor

A CPU switching regulator, such as the one in a buck topology, must not disturb the primary +5.0 V supply. One method of achieving this is by using an input inductor and a bypass capacitor. The input inductor isolates the +5.0 V supply from the noise generated in the switching portion of the microprocessor buck regulator and also limits the inrush current into the input capacitors upon power up. The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients. The worst case is when the CPU load changes from no load to full load (load step), a condition under which the highest voltage change across the input capacitors is also seen by the input inductor. The inductor successfully blocks the ripple current while placing the transient current requirements on the input
bypass capacitor bank, which has to initially support the sudden load change.

The minimum inductance value for the input inductor is therefore:

$$
\mathrm{LIN}=\frac{\Delta \mathrm{V}}{(\mathrm{dl} / \mathrm{dt}) \mathrm{MAX}}
$$

where:
$\mathrm{L}_{\mathrm{IN}}=$ input inductor value;
$\Delta \mathrm{V}=$ voltage seen by the input inductor during a full load swing;
$(\mathrm{dI} / \mathrm{dt})_{\text {MAX }}=$ maximum allowable input current slew rate ( $0.1 \mathrm{~A} / \mu$ s for a Pentium II power supply).

The designer must select the LC filter pole frequency so that at least 40 dB attenuation is obtained at the regulator switching frequency. The LC filter is a double-pole network with a slope of -2 , a roll-off rate of $-40 \mathrm{~dB} / \mathrm{dec}$, and a corner frequency:

$$
\mathrm{f}_{\mathrm{C}}=\frac{1.0}{2.0 \pi \sqrt{\mathrm{LC}}}
$$

where:
$\mathrm{L}=$ input inductor;
$\mathrm{C}=$ input capacitor(s).

## Step 7: Selection of the Switching FET FET Basics

The use of the MOSFET as a power switch is propelled by two reasons: 1) Its very high input impedance; and 2) Its very fast switching times. The electrical characteristics of a MOSFET are considered to be those of a perfect switch. Control and drive circuitry power is therefore reduced. Because the input impedance is so high, it is voltage driven. The input of the MOSFET acts as if it were a small capacitor, which the driving circuit must charge at turn on. The lower the drive impedance, the higher the rate of rise of $\mathrm{V}_{\mathrm{GS}}$, and the faster the turn-on time. Power dissipation in the switching MOSFET consists of 1) conduction losses, 2) leakage losses, 3) turn-on switching losses, 4) turn-off switching losses, and 5) gate-transitions losses. The latter three losses are proportional to frequency. For the conducting power dissipation rms values of current and resistance are used for true power calculations. The fast switching speed of the MOSFET makes it indispensable for high-frequency power supply applications. Not only are switching power losses minimized, but also the maximum usable switching frequency is considerably higher. Switching time is independent of temperature. Also, at higher frequencies, the use of smaller and lighter components (transformer, filter choke, filter capacitor) reduces overall component cost while using less space for more efficient packaging at lower weight.

The MOSFET has purely capacitive input impedance. No DC current is required. It is important to keep in mind the drain current of the FET has a negative temperature coefficient. Increase in temperature causes higher on-resistance and greater leakage current. For switching
circuits, $\mathrm{V}_{\mathrm{DS}(\mathrm{ON})}$ should be low to minimize power dissipation at a given ID, and $\mathrm{V}_{\mathrm{GS}}$ should be high to accomplish this. MOSFET switching times are determined by device capacitance, stray capacitance, and the impedance of the gate drive circuit. Thus the gate driving circuit must have high momentary peak current sourcing and sinking capability for switching the MOSFET. The input capacitance, output capacitance and reverse-transfer capacitance also increase with increased device current rating.

Two considerations complicate the task of estimating switching times. First, since the magnitude of the input capacitance, $\mathrm{C}_{\text {ISS }}$, varies with $\mathrm{V}_{\mathrm{DS}}$, the RC time constant determined by the gate-drive impedance and $\mathrm{C}_{\text {ISS }}$ changes during the switching cycle. Consequently, computation of the rise time of the gate voltage by using a specific gate-drive impedance and input capacitance yields only a rough estimate. The second consideration is the effect of the "Miller" capacitance, $\mathrm{C}_{\text {RSS }}$, which is referred to as $\mathrm{C}_{\mathrm{DG}}$ in the following discussion. For example, when a device is on, $\mathrm{V}_{\mathrm{DS}(\mathrm{ON})}$ is fairly small and $\mathrm{V}_{\mathrm{GS}}$ is about $12 \mathrm{~V} . \mathrm{C}_{\mathrm{DG}}$ is charged to $\mathrm{V}_{\mathrm{DS}(\mathrm{ON})}-\mathrm{V}_{\mathrm{GS}}$, which is a negative potential if the drain is considered the positive electrode. When the drain is "off", $\mathrm{C}_{\mathrm{DG}}$ is charged to quite a different potential. In this case the voltage across $C_{D G}$ is a positive value since the potential from gate-to-source is near zero volts and $\mathrm{V}_{\mathrm{DS}}$ is essentially the drain supply voltage. During turn-on and turn-off, these large swings in gate-to-drain voltage tax the current sourcing and sinking capabilities of the gate drive. In addition to charging and discharging $\mathrm{C}_{\mathrm{GS}}$, the gate drive must also supply the displacement current required by $C_{D G}\left(I_{\mathrm{GATE}}=C_{\mathrm{DG}} \mathrm{dV}_{\mathrm{DG}} / \mathrm{dt}\right)$. Unless the gate-drive impedance is very low, the $\mathrm{V}_{\mathrm{GS}}$ waveform commonly plateaus during rapid changes in the drain-to-source voltage.

The most important aspect of FET performance is the Static Drain-To-Source On-Resistance ( $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ ), which effects regulator efficiency and FET thermal management requirements. The On-Resistance determines the amount of current a FET can handle without excessive power dissipation that may cause overheating and potentially catastrophic failure. As the drain current rises, especially above the continuous rating, the On-Resistance also increases. Its positive temperature coefficient is between $+0.6 \% / \mathrm{C}$ and $+0.85 \% / \mathrm{C}$. The higher the On-Resistance the larger the conduction loss is. Additionally, the FET gate charge should be low in order to minimize switching losses and reduce power dissipation.

Both logic level and standard FETs can be used. The reference designs derive gate drive from the 12 V supply, which is generally available in most computer systems and utilizes logic level FETs.

Voltage applied to the FET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias
supplies when in the high state. In practice, the FET gates will be driven rail-to-rail due to overshoot caused by the capacitive load they present to the controller IC.

## Step 7a: Selection of the Switching (Upper) FET

The designer must ensure that the total power dissipation in the FET switch does not cause the power component's junction temperature to exceed $150^{\circ} \mathrm{C}$.

The maximum RMS current through the switch can be determined by the following formula:
IRMS(H) =

where:
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{I}_{\mathrm{L}(\text { PEAK })}=$ inductor peak current;
$\mathrm{I}_{\mathrm{L}(\mathrm{VALLEY})}=$ inductor valley current;
D = Duty Cycle.
Once the RMS current through the switch is known, the switching MOSFET conduction losses can be calculated:

$$
\operatorname{PRMS}(\mathrm{H})=\operatorname{IRMS}(\mathrm{H})^{2} \times \operatorname{RDS}(\mathrm{ON})
$$

where:
$\mathrm{P}_{\mathrm{RMS}(\mathrm{H})}=$ switching MOSFET conduction losses;
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=\mathrm{FET}$ drain-to-source on-resistance
The upper MOSFET switching losses are caused during MOSFET switch-on and switch-off and can be determined by using the following formula:

$$
\begin{aligned}
\mathrm{PSWH} & =\mathrm{PSWH}_{\text {SWN }}(\mathrm{ON}+\mathrm{PSWH}(\mathrm{OFF}) \\
& =\frac{\mathrm{V}_{\mathrm{IN}} \times \mathrm{IOUT} \times(\mathrm{tRISE}+\mathrm{tFALL})}{6.0 \mathrm{~T}}
\end{aligned}
$$

where:
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{OFF})}=$ upper MOSFET switch-off losses;
$\mathrm{V}_{\text {IN }}=$ input voltage;
IOUT $=$ load current;
$\mathrm{t}_{\text {RISE }}=$ MOSFET rise time (from FET manufacturer's switching characteristics performance curve);
$\mathrm{t}_{\mathrm{FALL}}=$ MOSFET fall time (from FET manufacturer's switching characteristics performance curve);
$\mathrm{T}=1 / \mathrm{F}_{\mathrm{SW}}=$ period.
The total power dissipation in the switching MOSFET can then be calculated as:
PHFET $($ TOTAL $)=$ PRMSH $+\operatorname{PSWH}(O N)+\operatorname{PSWH}(O F F)$
where:
$\mathrm{P}_{\text {HFET(TOTAL) }}=$ total switching (upper) MOSFET losses;
$\mathrm{P}_{\text {RMSH }}=$ upper MOSFET switch conduction Losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{OFF})}=$ upper MOSFET switch-off losses.
Once the total power dissipation in the switching FET is known, the maximum FET switch junction temperature can be calculated:

$$
T_{J}=T_{A}+\left(P_{H F E T}(T O T A L) \times R_{\theta J A}\right)
$$

where:
$\mathrm{T}_{\mathrm{J}}=\mathrm{FET}$ junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$\mathrm{P}_{\text {HFET(TOTAL) }}=$ total switching (upper) FET losses;
$\mathrm{R}_{\theta \mathrm{JA}}=$ upper FET junction-to-ambient thermal resistance.

## Step 7b: Selection of the Synchronous (Lower) FET

The switch conduction losses for the lower FET can be calculated as follows:

$$
\begin{aligned}
\mathrm{PRMSL} & =\mathrm{IRMS}^{2} \times \operatorname{RDS}(\mathrm{ON}) \\
& =(\mathrm{IOUT} \times \sqrt{(1.0-\mathrm{D})})^{2} \times \operatorname{RDS}(\mathrm{ON})
\end{aligned}
$$

where:
$\mathrm{P}_{\text {RMSL }}=$ lower MOSFET conduction losses;
IOUT = load current;
D = Duty Cycle;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=$ lower FET drain-to-source on-resistance.
The synchronous MOSFET has no switching losses, except for losses in the internal body diode, because it turns on into near zero voltage conditions. The MOSFET body diode will conduct during the non-overlap time and the resulting power dissipation (neglecting reverse recovery losses) can be calculated as follows:

$$
P_{S W L}=V_{S D} \times I_{\text {LOAD }} \times \text { non-overlap time } \times \mathrm{F}_{S W}
$$

where:
$\mathrm{P}_{\text {SWL }}=$ lower FET switching losses;
$\mathrm{V}_{\mathrm{SD}}=$ lower FET source-to-drain voltage;
$\mathrm{I}_{\text {LOAD }}=$ load current
Non-overlap time $=\operatorname{GATE}(\mathrm{L})-$ to-GATE(H) or GATE(H)-to-GATE(L) delay (from CS51311 data sheet Electrical Characteristics section);
$\mathrm{F}_{\text {SW }}=$ switching frequency.
The total power dissipation in the synchronous (lower) MOSFET can then be calculated as:

$$
\text { PLFET }(\text { TOTAL })=\text { PRMSL }+ \text { PSWL }
$$

where:
$\mathrm{P}_{\text {LFET(TOTAL) }}=$ Synchronous (lower) FET total losses;
$P_{\text {RMSL }}=$ Switch Conduction Losses;
$\mathrm{P}_{\text {SWL }}=$ Switching losses.
Once the total power dissipation in the synchronous FET is known the maximum FET switch junction temperature can be calculated:

$$
T_{J}=T_{A}+\left(\text { PLFET }(T O T A L) \times R_{\theta J A}\right)
$$

where:
$\mathrm{T}_{\mathrm{J}}=$ MOSFET junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$\left.\mathrm{P}_{\text {LFET }(\text { TOTAL }}\right)=$ total synchronous (lower) FET losses;
$\mathrm{R}_{\text {OJA }}=$ lower FET junction-to-ambient thermal resistance.

## Step 8: Control IC Power Dissipation

The power dissipation of the IC varies with the MOSFETs used, $\mathrm{V}_{\mathrm{CC}}$, and the CS51311 operating frequency. The average MOSFET gate charge current typically dominates the control IC power dissipation.

The IC power dissipation is determined by the formula:
PCONTROLIC $=I_{C C} V_{C C}+\operatorname{PGATE}(H)+\operatorname{PGATE}(L)$
where:
$\mathrm{P}_{\text {CONTROLIC }}=$ control IC power dissipation;
$\mathrm{I}_{\mathrm{CC}}=\mathrm{IC}$ quiescent supply current;
$\mathrm{V}_{\mathrm{CC}}=\mathrm{IC}$ supply voltage;
$\mathrm{P}_{\text {GATE(H) }}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{P}_{\text {GATE }(\mathrm{L})}=$ lower MOSFET gate driver (IC) losses.
The upper (switching) MOSFET gate driver (IC) losses are:

$$
\operatorname{PGATE}(\mathrm{H})=\operatorname{QGATE}_{(H)} \times \operatorname{FSW} \times \operatorname{VGATE}(\mathrm{H})
$$

where:
$\mathrm{P}_{\text {GATE(H) }}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\mathrm{GATE}(\mathrm{H})}=$ total upper MOSFET gate charge;
$\mathrm{F}_{\mathrm{SW}}=$ switching frequency;
$\mathrm{V}_{\text {GATE(H) }}=$ upper MOSFET gate voltage.
The lower (synchronous) MOSFET gate driver (IC) losses are:

$$
\operatorname{PGATE}(\mathrm{L})=\text { QGATE }^{\text {GL }} \mathbf{L} \times \text { FSW } \times \mathrm{V}_{\text {GATE }}(\mathrm{L})
$$

where:
$\mathrm{P}_{\text {GATE(L) }}=$ lower MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\mathrm{GATE}(\mathrm{L})}=$ total lower MOSFET gate charge;
$\mathrm{F}_{\text {SW }}=$ switching frequency;
$\mathrm{V}_{\text {GATE(L) }}=$ lower MOSFET gate voltage.
The junction temperature of the control IC is primarily a function of the PCB layout, since most of the heat is removed through the traces connected to the pins of the IC.

## Step 9: Slope Compensation

Voltage regulators for today's advanced processors are expected to meet very stringent load transient requirements. One of the key factors in achieving tight dynamic voltage regulation is low ESR at the CPU input supply pins. Low ESR at the regulator output results in low output voltage ripple. The consequence is, however, that there's very little voltage ramp at the control IC feedback pin ( $\mathrm{V}_{\mathrm{FB}}$ ) and regulator sensitivity to noise and loop instability are two undesirable effects that can surface. The performance of the CS51311-based CPU $\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}$ regulator is improved when a fixed amount of slope compensation is added to the output of the PWM Error Amplifier (COMP pin) during the regulator Off-Time. Referring to Figure 13, the amount of voltage ramp at the COMP pin is dependent on the gate voltage of the lower (synchronous) FET and the value of resistor divider formed by R1 and R2.
$\mathrm{V}_{\text {SLOPECOMP }}=\mathrm{V}_{\text {GATE }}(\mathrm{L}) \times\left(\frac{\mathrm{R} 2}{\mathrm{R} 1+\mathrm{R} 2}\right) \times\left(1.0-\mathrm{e}^{\frac{-\mathrm{t}}{\tau}}\right)$
where:
$\mathrm{V}_{\text {SLOPECOMP }}=$ amount of slope added;
$\mathrm{V}_{\text {GATE(L) }}=$ lower MOSFET gate voltage;
$\mathrm{R} 1, \mathrm{R} 2=$ voltage divider resistors;
$\mathrm{t}=\mathrm{t}_{\text {OFF }}$ (switch off-time);
$\tau=\mathrm{RC}$ constant determined by C 1 and the parallel combination of R1, R2 (Figure 13), neglecting the low driver output impedance

The artificial voltage ramp created by the slope compensation scheme results in improved control loop stability provided that the RC filter time constant is smaller than the off-time cycle duration (time during which the lower MOSFET is conducting).

## Step 10: Selection of Current Limit Filter Components

The current limit filter is implemented by a $0.1 \mu \mathrm{~F}$ ceramic capacitor across and two $510 \Omega$ resistors in series with the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ current limit comparator input pins. They provide a time constant $\tau=\mathrm{RC}=100 \mu \mathrm{~s}$, which enables the circuit to filter out noise and be immune to false triggering, caused by sudden and fast load changes. These load transients can have slew rates as high as $20 \mathrm{~A} / \mu \mathrm{s}$.

## "DROOP" RESISTOR FOR ADAPTIVE VOLTAGE POSITIONING AND CURRENT LIMIT

Adaptive voltage positioning is used to help keep the output voltage within specification during load transients. To implement adaptive voltage positioning a "Droop Resistor" must be connected between the output inductor and output capacitors and load. This resistor carries the full load current and should be chosen so that both DC and AC tolerance limits are met. An embedded PC trace resistor has the distinct advantage of near zero cost implementation. However, this droop resistor can vary due to three reasons: 1) the sheet resistivity variation caused by variation in the thickness of the PCB layer; 2) the mismatch of $\mathrm{L} / \mathrm{W}$; and 3) temperature variation.

## 1) Sheet Resistivity

For one ounce copper, the thickness variation is typically 1.26 mil to 1.48 mil . Therefore the error due to sheet resistivity is:

$$
\frac{1.48-1.26}{1.37}= \pm 8.0 \%
$$

## 2) Mismatch Due to L/W

The variation in $\mathrm{L} / \mathrm{W}$ is governed by variations due to the PCB manufacturing process. The error due to L/W mismatch is typically $1.0 \%$.

## 3) Thermal Considerations

Due to $\mathrm{I}^{2} \times \mathrm{R}$ power losses the surface temperature of the droop resistor will increase causing the resistance to increase. Also, the ambient temperature variation will
contribute to the increase of the resistance, according to the formula:

$$
R=R_{20}\left[1.0+\alpha_{20}(T-20)\right]
$$

where:
$\mathrm{R}_{20}=$ resistance at $20^{\circ} \mathrm{C}$;
$\alpha=0.00393 /{ }^{\circ} \mathrm{C}$
$\mathrm{T}=$ operating temperature;
$\mathrm{R}=$ desired droop resistor value.
For temperature $\mathrm{T}=50^{\circ} \mathrm{C}$, the $\% \mathrm{R}$ change $=12 \%$.

## Droop Resistor Tolerance

Tolerance due to sheet resistivity variation $\pm 8.0 \%$
Tolerance due to L/W error $1.0 \%$
Tolerance due to temperature variation $12 \%$
Total tolerance for droop resistor $21 \%$
In order to determine the droop resistor value the nominal voltage drop across it at full load has to be calculated. This voltage drop has to be such that the output voltage at full load is above the minimum DC tolerance spec:

$$
\mathrm{V}_{\mathrm{DROOP}(\mathrm{TYP})}=\frac{\mathrm{V}_{\mathrm{DAC}(\mathrm{MIN})}-\mathrm{V}_{\mathrm{DC}}(\mathrm{MIN})}{1.0+\mathrm{R}_{\mathrm{DROOP}}(\text { TOLERANCE })}
$$

Example: for a 450 MHz Pentium II, the DC accuracy spec is $1.93<\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}<2.07 \mathrm{~V}$, and the AC accuracy spec is $1.9 \mathrm{~V}<\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}<2.1 \mathrm{~V}$. The CS51311 DAC output voltage is $+2.001 \mathrm{~V}<\mathrm{V}_{\mathrm{DAC}}<+2.049 \mathrm{~V}$. In order not to exceed the DC accuracy spec, the voltage drop developed across the resistor must be calculated as follows:

$$
\begin{aligned}
\mathrm{VDROOP}_{\mathrm{DR}}(\mathrm{TYP}) & =\frac{\left(\mathrm{V}_{\mathrm{DAC}}(\mathrm{MIN})-\mathrm{V}_{\mathrm{DC}}(\mathrm{MIN})\right)}{1.0+\mathrm{R}_{\mathrm{DROOP}}(\mathrm{TOLERANCE})} \\
& =\frac{+2.001 \mathrm{~V}-1.93 \mathrm{~V}}{1.21}=71 \mathrm{mV}
\end{aligned}
$$

With the CS51311 DAC accuracy being $1.0 \%$, the internal error amplifier's reference voltage is trimmed so that the output voltage will be 25 mV high at no load. With no load, there is no DC drop across the resistor, producing an output voltage tracking the error amplifier output voltage, including the offset. When the full load current is delivered, a drop of -50 mV is developed across the resistor. Therefore, the regulator output is pre-positioned at 25 mV above the nominal output voltage before a load turn-on. The total voltage drop due to a load step is $\Delta \mathrm{V}-25 \mathrm{mV}$ and the deviation from the nominal output voltage is 25 mV smaller than it would be if there was no droop resistor. Similarly at full load the regulator output is pre-positioned at 25 mV below the nominal voltage before a load turn-off. the total voltage increase due to a load turn-off is $\Delta \mathrm{V}-25 \mathrm{mV}$ and the deviation from the nominal output voltage is 25 mV smaller than it would be if there was no droop resistor. This is because the output capacitors are pre-charged to a value that is either 25 mV above the nominal output voltage before a load turn-on or, 25 mV below the nominal output voltage before a load turn-off .

Obviously, the larger the voltage drop across the droop resistor (the larger the resistance), the worse the DC and load regulation, but the better the AC transient response.

## Current Limit

The current limit setpoint has to be higher than the normal full load current. Attention has to be paid to the current rating of the external power components as these are the first to fail during an overload condition. The MOSFET continuous and pulsed drain current rating at a given case temperature has to be accounted for when setting the current limit trip point.
Temperature curves on MOSFET manufacturers' data sheets allow the designer to determine the MOSFET drain current at a particular VGS and TJ (junction temperature). This, in turn, will assist the designer to set a proper current limit, without causing device breakdown during an overload condition.
Let's assume the full CPU load is 16 A . The internal current sense comparator current limit voltage limits are: $77 \mathrm{mV}<\mathrm{V}_{\mathrm{TH}}<101 \mathrm{mV}$. Also, there is a $21 \%$ total variation in $\mathrm{R}_{\text {SENSE }}$ as discussed in the previous section.
We compute the value of the current sensing element (embedded PCB trace) for the minimum current limit setpoint:

$$
\begin{gathered}
\operatorname{RSENSE}(\mathrm{MIN})=\operatorname{RSENSE}(\mathrm{TYP}) \times 0.79 \\
\operatorname{RSENSE}(\mathrm{MAX})=\operatorname{RSENSE}(\mathrm{TYP}) \times 1.21 \\
\operatorname{RSENSE}(\mathrm{MAX})=\frac{\mathrm{V}_{\mathrm{TH}(\mathrm{MIN})}^{\mathrm{I}(\mathrm{MIN})}=\frac{77 \mathrm{mV}}{16 \mathrm{~A}}=4.8 \mathrm{~m} \Omega}{}
\end{gathered}
$$

We select,

$$
\text { RSENSE(TYP) }=3.3 \mathrm{~m} \Omega
$$

We calculate the range of load currents that will cause the internal current sense comparator to detect an overload condition.

## Nominal Current Limit Setpoint

From the overcurrent detection data in the electrical characteristics table:

$$
\begin{gathered}
\mathrm{V}_{\mathrm{TH}(\mathrm{TYP})}=86 \mathrm{mV} \\
\mathrm{ICL}(\mathrm{NOM})=\frac{\mathrm{V}_{\mathrm{TH}(\mathrm{TYP})}}{\operatorname{RSENSE}(\mathrm{NOM})}=\frac{86 \mathrm{mV}}{3.3 \mathrm{~m} \Omega}=26 \mathrm{~A}
\end{gathered}
$$

## Maximum Current Limit Setpoint

From the overcurrent detection data in the electrical characteristics table:

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{TH}}(\mathrm{MAX})=101 \mathrm{mV} \\
& \mathrm{I}_{\mathrm{CL}(\mathrm{MAX})}= \frac{\mathrm{V}_{\mathrm{TH}(\mathrm{MAX})}}{\operatorname{RSENSE}(\mathrm{MIN})}=\frac{\mathrm{V}_{\mathrm{TH}(\mathrm{MAX})}}{\operatorname{RSENSE}(\mathrm{NOM}) \times 0.79} \\
&=\frac{101 \mathrm{mV}}{3.3 \mathrm{~m} \Omega \times 0.79}=38.7 \mathrm{~A}
\end{aligned}
$$

Therefore, the range of load currents that will cause the internal current sense comparator to detect an overload condition through a $3.3 \mathrm{~m} \Omega$ embedded PCB trace is: 19.3 A $<\mathrm{I}_{\mathrm{CL}}<38.7 \mathrm{~A}$, with 26 A being the nominal overload condition.

## Design Rules for Using a Droop Resistor

The basic equation for laying an embedded resistor is:

$$
R_{A R}=\rho \times \frac{L}{A} \text { or } R=\rho \times \frac{L}{(W \times t)}
$$

where:
$\mathrm{A}=\mathrm{W} \times \mathrm{t}=$ cross-sectional area;
$\rho=$ the copper resistivity ( $\mu \Omega$-mil);
$\mathrm{L}=$ length (mils);
$\mathrm{W}=$ width (mils);
$\mathrm{t}=$ thickness (mils).
For most PCBs the copper thickness, t , is $35 \mu \mathrm{~m}$ (1.37 mils) for one ounce copper; $\rho=717.86 \mu \Omega-$ mil.

For a CPU load of 16 A the resistance needed to create a 50 mV drop at full load is:

$$
\text { RDROOP }=\frac{50 \mathrm{mV}}{\mathrm{IOUT}}=\frac{50 \mathrm{mV}}{16 \mathrm{~A}}=3.1 \mathrm{~m} \Omega
$$

The resistivity of the copper will drift with the temperature according to the following guidelines:

$$
\begin{aligned}
& \Delta R=12 \% @ T_{A}=+50^{\circ} \mathrm{C} \\
& \Delta R=34 \% @ T_{A}=+100^{\circ} \mathrm{C}
\end{aligned}
$$

## Droop Resistor Length, Width, and Thickness

The minimum width and thickness of the droop resistor should primarily be determined on the basis of the current-carrying capacity required, and the maximum permissible droop resistor temperature rise. PCB manufacturer design charts can be used in determining current-carrying capacity and sizes of etched copper conductors for various temperature rises above ambient.

For single conductor applications, such as the use of the droop resistor, PCB design charts show that for a droop resistor with a required current-carrying capacity of 16 A , and a $45^{\circ} \mathrm{C}$ temperature rise above ambient, the recommended cross section is $275 \mathrm{mil}^{2}$.

$$
\mathrm{W} \times \mathrm{t}=275 \mathrm{mil}{ }^{2}
$$

where:
$\mathrm{W}=$ droop resistor width;
$\mathrm{t}=$ droop resistor thickness.
For 1 oz . copper, $\mathrm{t}=1.37 \mathrm{mils}$, therefore $\mathrm{W}=201 \mathrm{mils}=$ 0.201 in.

$$
R=\rho \times \frac{L}{W \times t}
$$

where:
$\mathrm{R}=$ droop resistor value;
$\rho=0.71786 \mathrm{~m} \Omega-\mathrm{mil}$ ( 1 oz. copper);
$\mathrm{L}=$ droop resistor length;
$\mathrm{W}=$ droop resistor width.

$$
\begin{gathered}
\text { RDROOP }=3.3 \mathrm{~m} \Omega \\
3.3 \mathrm{~m} \Omega=0.71786 \mathrm{~m} \Omega-\mathrm{mil} \times \frac{\mathrm{L}}{201 \mathrm{mils} \times 1.37 \mathrm{mils}}
\end{gathered}
$$

Hence, $\mathrm{L}=1265$ mils $=1.265$ in.
In layouts where it is impractical to lay out a droop resistor in a straight line 1265 mils long, the embedded PCB trace can be "snaked" to fit within the available space.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:

$$
\text { Thermal Impedance }=\frac{T_{J}(\mathrm{MAX})-\mathrm{T}_{\mathrm{A}}}{\text { Power }}
$$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI MANAGEMENT

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

## LAYOUT GUIDELINES

When laying out the CPU buck regulator on a printed circuit board, the following checklist should be used to ensure proper operation of the CS51311.

1. Rapid changes in voltage across parasitic capacitors and abrupt changes in current in parasitic inductors are major concerns for a good layout.
2. Keep high currents out of sensitive ground connections.
3. Avoid ground loops as they pick up noise. Use star or single point grounding.
4. For high power buck regulators on double-sided PCBs a single ground plane (usually the bottom) is recommended.
5. Even though double sided PCBs are usually sufficient for a good layout, four-layer PCBs are the optimum approach to reducing susceptibility to noise. Use the two internal layers as the power and GND planes, the top layer for power connections and component vias, and the bottom layer for the noise sensitive traces.
6. Keep the inductor switching node small by placing the output inductor, switching and synchronous FETs close together.
7. The MOSFET gate traces to the IC must be as short, straight, and wide as possible.
8. Use fewer, but larger output capacitors, keep the capacitors clustered, and use multiple layer traces with heavy copper to keep the parasitic resistance low.
9. Place the switching MOSFET as close to the +5.0 V input capacitors as possible.
10. Place the output capacitors as close to the load as possible.
11. Place the $\mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{OUT}}$ filter resistors $(510 \Omega)$ in series with the $V_{\text {FB }}$ and $V_{\text {OUT }}$ pins as close as possible to the pins.
12. Place the Coff and COMP capacitors as close as possible to the $\mathrm{C}_{\mathrm{OFF}}$ and COMP pins.
13. Place the current limit filter capacitor between the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ pins, as close as possible to the pins.
14. Connect the filter components of the following pins: $\mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{OUT}}, \mathrm{C}_{\mathrm{OFF}}$, and COMP to the GND pin with a single trace, and connect this local GND trace to the output capacitor GND.
15. The "Droop" Resistor (embedded PCB trace) has to be wide enough to carry the full load current.
16. Place the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor as close as possible to the IC.

PACKAGE THERMAL DATA

## Synchronous Rectification DC/DC Converter Programmable Integrated Controller

The MC33470 is a digitally programmable switching voltage regulator, specifically designed for Microprocessor supply, Voltage Regulator Module and general purpose applications, to provide a high power regulated output voltage using a minimum of external parts. A 5-bit digital-to-analog converter defines the dc output voltage.

This product has three additional features. The first is a pair of high speed comparators which monitor the output voltage and expedite the circuit response to load current changes. The second feature is a soft start circuit which establishes a controlled response when input power is applied and when recovering from external circuit fault conditions. The third feature is two output drivers which provide synchronous rectification for optimum efficiency.

This product is ideally suited for computer, consumer, and industrial equipment where accuracy, efficiency and optimum regulation performance is desirable.

MC33470 Features:

- 5-Bit Digital-to-Analog Converter Allows Digital Control of Output Voltage
- High Speed Response to Transient Load Conditions
- Output Enable Pin Provides On/Off Control
- Programmable Soft Start Control
- High Current Output Drives for Synchronous Rectification
- Internally Trimmed Reference with Low Temperature Coefficient
- Programmable Overcurrent Protection
- Overvoltage Fault Indication
- Functionally Similar to the LTC1553

## OPERATING DESCRIPTION

The MC33470 is a monolithic, fixed frequency power switching regulator specifically designed for dc-to-dc converter applications which provide a precise supply voltage for state of the art processors. The MC33470 operates as fixed frequency, voltage mode regulator containing all the active functions required to directly implement digitally programmable step-down synchronous rectification with a minimum number of external components.

## Oscillator

The oscillator frequency is internally programmed to 300 kHz . The charge to discharge ratio is controlled to yield a $95 \%$ maximum duty cycle at the switch outputs. During the fall time of the internal sawtooth waveform, the oscillator generates an internal blanking pulse that disables the G1 output switching MOSFET. The internal sawtooth waveform has a nominal peak voltage of 2.5 V and a valley voltage of 1.5 V .

## Pulse Width Modulator

The pulse width modulator consists of a comparator with the oscillator ramp voltage applied to the noninverting input, while the error amplifier output is applied to the inverting input. Output switch conduction is initiated when the ramp waveform is discharged to the valley voltage. As the ramp voltage increases to a voltage that exceeds the error amplifier output, the latch resets, terminating output G1 MOSFET conduction, and turning on output G2 MOSFET,
for the duration of the oscillator ramp. This PWM/latch combination prevents multiple output pulses during a given oscillator cycle.

The sense voltage input at Pin 6 is applied to the noninverting inputs of a pair of high speed comparators. The high speed comparators' inverting inputs are tied $0.96 \times \mathrm{V}_{\text {ref }}$ and $1.04 \mathrm{x}_{\text {ref }}$, respectively, to provide an optimum response to load changes. When load transients which cause the output voltage to fall outside a $\pm 4 \%$ regulation window occur, the high speed comparators override the PWM comparator to force a zero or maximum duty cycle operating condition until the output voltage is once again within the linear window.
When voltages are initially provided to the supply pins, $\mathrm{V}_{\mathrm{CC}}$ and $\mathrm{P}_{\mathrm{V}_{\mathrm{CC}}}$, undervoltage lockout circuits monitor each of the supply voltage levels. Both G1 and G2 output pins are held low until the $\mathrm{V}_{\mathrm{CC}}$ pin voltage exceeds 4.0 V and the $\mathrm{P}_{\mathrm{V}_{\mathrm{CC}}}$ pin voltage exceeds 9.0 V .

## Error Amplifier and Voltage Reference

The error amplifier is a transconductance type amplifier, having a nominal transconductance of $800 \mu \mathrm{mho}$. The transconductance has a negative temperature coefficient. Typical transconductance is $868 \mu \mathrm{mho}$ at $0^{\circ} \mathrm{C}$ and $620 \mu \mathrm{mho}$ at $125^{\circ} \mathrm{C}$ junction temperature. The amplifier has a cascode output stage which provides a typical $3.0 \mathrm{Mega-Ohms}$ of
impedance. The typical error amplifier dc voltage gain is 67 dB .

External loop compensation is required for converter stability. Compensation components may be connected from the compensation pin to ground. The error amplifier input is tied to the sense pin which also has an internal $20 \mu \mathrm{~A}$ current source to ground. The current source is intended to provide a 24 mV offset when an external 1.2 k resistor is placed between the output voltage and the sense pin. The 24 mV offset voltage is intended to allow a greater dynamic load regulation range within a given specified tolerance for the output voltage. The offset may be increased by increasing the resistor value. The offset can be eliminated by connecting the sense pin directly to the regulated output voltage.

The voltage reference consists of an internal, low temperature coefficient, reference circuit with an added offset voltage. The offset voltage level is the output of the digital-to-analog converter. Control bits VID0 through VID4 control the amount of offset voltage which sets the value of the voltage reference, as shown in Table 1. The VID0-4 input bits each have internal 10 k pullup resistances. Therefore, the reference voltage, and the output voltage, may be programmed by connecting the VID pins to ground for logic " 0 " or by an open for a logic " 1 ". Typically, a logic " 1 " will be recognized by a voltage $>0.67 \times \mathrm{V}_{\mathrm{CC}}$. A logic " 0 " is a voltage $<\mathrm{V}_{\mathrm{CC}} / 3$.

## MOSFET Switch Outputs

The output MOSFETs are designed to switch a maximum of 18 V , with a peak drain current of 2.0 A . Both G1 and G2 output drives are designed to switch N -channel MOSFETs. Output drive controls to G1 and G2 are phased to prevent cross conduction of the internal IC output stages. Output dead time is typically 100 nanoseconds between G1 and G2 in order to minimize cross conduction of the external switching MOSFETs.

## Current Limit and Soft-Start Controls

The soft-start circuit is used both for initial power application and during current limit operation. A single external capacitor and an internal $10 \mu \mathrm{~A}$ current source control the rate of voltage increase at the error amplifier output, establishing the circuit turn on time. The G1 output will increase from zero duty cycle as the voltage across the soft-start capacitor increases beyond about 0.5 V . When the soft-start capacitor voltage has reached about 1.5 V , normal duty cycle operation of G1 will be allowed.

An overcurrent condition is detected by the current limit amplifier. The current limit amplifier is activated whenever the G1 output is high. The current limit amplifier compares the voltage drop across the external MOSFET driven by G1,
as measured at the $\mathrm{I}_{\mathrm{FB}}$ pin, with the voltage at the $\mathrm{I}_{\max }$ pin. Because the $I_{\text {max }}$ pin draws $190 \mu \mathrm{~A}$ of input current, the overcurrent threshold is programmed by an external resistor. Referring to Figure 13, the current limit resistor value can be determined from the following equation:

$$
\mathrm{R} 1=\frac{\left[\left(\mathrm{I}_{\mathrm{L}(\max )}\right)\left(\mathrm{R}_{\mathrm{DS}(\mathrm{on})}\right)\right]}{\left(\mathrm{I}_{\max }\right)}
$$

where:

$$
\begin{gathered}
\mathrm{I}_{\mathrm{L}(\max )}=\frac{\mathrm{I}_{\mathrm{O}}+\mathrm{I}_{\text {ripple }}}{2} \\
\mathrm{I}_{\mathrm{O}}=\text { Maximum load current } \\
\mathrm{I}_{\text {ripple }}=\text { Inductor peak to peak ripple current }
\end{gathered}
$$

## OUTEN Input and OT Output Pins

On and off control of the MC33470 may be implemented with the OUTEN pin. A logic " 1 " applied the OUTEN pin, where a logic " 1 " is above 2.0 V , will allow normal operation of the MC33470. The OUTEN pin also has multiple thresholds to provide over temperature protection. An negative temperature coefficient thermistor can be connected to the OUTEN pin, as shown in Figure 15. Together with $\mathrm{R}_{\mathrm{S}}$, a voltage divider is formed. The divider voltage will decrease as the thermistor temperature increases. Therefore, the thermistor should be mounted to the hottest part on the circuit board. When the OUTEN voltage drops below 2.0 V typically, the MC33470 OT pin open collector output will switch from a logic " 1 " to a logic " 0 ", providing a warning to the system. If the OUTEN voltage drops below 1.7 V, both G1 and G2 output driver pins are latched to a logic " 0 " state.

Figure 15. OUTEN/OT Overtemperature Function

## APPLICATIONS INFORMATION

## Design Example

Given the following requirements, design a switching dc-to-dc converter:

$$
\begin{aligned}
\mathrm{V}_{\mathrm{CC}} & =5.0 \mathrm{~V} \\
\mathrm{~V}_{\mathrm{CCP}} & =12 \mathrm{~V} \\
\text { VID4-0 bits } & =10111-\text { Output Voltage }=2.8 \mathrm{~V} \\
\text { Output current } & =0.3 \mathrm{~A} \text { to } 14 \mathrm{~A}
\end{aligned}
$$

Efficiency $\geq 80 \%$ at full load
Output ripple voltage $\approx 1 \%$ of output voltage

1. Choose power MOSFETs.

In order to meet the efficiency requirement, MOSFETs should be chosen which have a low value of $\mathrm{R}_{\mathrm{DS}}$ (on). However, the threshold voltage rating of the MOSFET must also be greater than 1.5 V , to prevent turn on of the synchronous rectifier MOSFETs due to dv/dt coupling through the Miller capacitance of the MOSFET drain-to-source junction. Figure 16 shows the gate voltage transient due to this effect.

In this design, choose two parallel MMSF3300 MOSFETs for both the main switch and the synchronous rectifier to maximize efficiency.
2. $\mathrm{D} \approx \mathrm{V}_{\mathrm{O}} / \mathrm{V}_{\text {in }}=2.8 / 5.0=0.56$
3. Inductor selection

In order to maintain continuous mode operation at $10 \%$ of full load current, the minimum value of the inductor will be:
$\mathrm{L}_{\text {min }}=\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\mathrm{O}}\right)(\mathrm{DTs}) /\left(2 \mathrm{I}_{\mathrm{O} \text { min }}\right)$

$$
=(5-2.8)(0.56 \times 3.3 \mu \mathrm{~s}) /(2 \times 1.4 \mathrm{~A})=1.45 \mu \mathrm{H}
$$

Coilcraft's U6904, or an equivalent, provides a surface mount $1.5 \mu \mathrm{H}$ choke which is rated for for full load current.
4. Output capacitor selection
$\mathrm{V}_{\text {ripple }} \approx \Delta \mathrm{I}_{\mathrm{L}} \times \mathrm{ESR}$, where ESR is the equivalent series resistance of the output capacitance. Therefore:
$\mathrm{ESR}_{\text {max }}=\mathrm{V}_{\text {ripple }} / \Delta \mathrm{I}_{\mathrm{L}}=0.01 \times 2.8 \mathrm{~V} / 1.4 \mathrm{~A}=0.02 \Omega$ maximum

The AVX TPS series of tantalum chip capacitors may be chosen. Or OSCON capacitors may be used if leaded parts are acceptable. In this case, the output capacitance consists of two parallel $820 \mu \mathrm{~F}, 4.0 \mathrm{~V}$ capacitors. Each capacitor has a maximum specified ESR of $0.012 \Omega$.
5. Input Filter

As with all buck converters, input current is drawn in pulses. In this case, the current pulses may be 14 A peak. If a $1.5 \mu \mathrm{H}$ choke is used, two parallel OSCON $150 \mu \mathrm{~F}, 16 \mathrm{~V}$ capacitors will provide a filter cutoff frequency of 7.5 kHz .
6. Feedback Loop Compensation

The corner frequency of the output filter with $\mathrm{L}=1.5 \mu \mathrm{H}$ and $\mathrm{C}_{\mathrm{o}}=1640 \mu \mathrm{~F}$ is 3.2 kHz . In addition, the ESR of each output capacitor creates a zero at:
$\mathrm{f}_{\mathrm{z}}=1 /(2 \pi \mathrm{C}$ ESR $)=1 /(2 \pi \times 820 \mu \mathrm{~F} \times 0.012)=16.2 \mathrm{kHz}$
The dc gain of the PWM is: Gain $=\mathrm{V}_{\mathrm{in}} / \mathrm{V}_{\mathrm{pp}}=5 / 1=5.0$. Where $\mathrm{V}_{\mathrm{pp}}$ is the peak-to-peak sawtooth voltage across the internal timing capacitor. In order to make the feedback loop as responsive as possible to load changes, choose the unity gain frequency to be $10 \%$ of the switching frequency, or 30 kHz . Plotting the PWM gain over frequency, at a frequency of 30 kHz the gain is about $-16.5 \mathrm{~dB}=0.15$. Therefore, to have a 30 kHz unity gain loop, the error amplifier gain at 30 kHz should be $1 / 0.15=6.7$. Choose a design phase margin for the loop of $60^{\circ}$. Also, choose the error amp type to be an integrator for best dc regulation performance. The phase boost needed by the error amplifier is then $60^{\circ}$ for the desired phase margin. Then, the following calculations can be made:

$$
\begin{aligned}
& \mathrm{k}=\tan \left[\text { Boost } / 2+45^{\circ}\right]=\tan [60 / 2+45]=3.73 \\
& \text { Error Amp zero freq }=\mathrm{f}_{\mathrm{c}} / \mathrm{K}=30 \mathrm{kHz} / 3.73=8.0 \mathrm{kHz} \\
& \text { Error Amp pole freq }=\mathrm{K}_{\mathrm{fc}}=3.73 \times 30 \mathrm{kHz}=112 \mathrm{kHz} \\
& \mathrm{R} 2=\text { Error Amp Gain } / \mathrm{G}_{\mathrm{m}}=6.7 / 800 \mu=8.375 \mathrm{k}-\text { use an } \\
& \quad 8.2 \mathrm{k} \text { standard value } \\
& \begin{aligned}
\mathrm{C} 16 & =1 /\left(2 \pi \mathrm{R} 2 \mathrm{f}_{\mathrm{z}}\right)=1 /(2 \pi \times 8.2 \mathrm{k} \times 8.0 \mathrm{kHz}) \\
& =2426 \mathrm{pF}-\text { use } 2200 \mathrm{pF} \\
\mathrm{C} 17= & 1 /\left(2 \pi \mathrm{R} 2 \mathrm{f}_{\mathrm{p}}\right)=1 /(2 \pi \times 8.2 \mathrm{kx} 112 \mathrm{kHz}) \\
& =173 \mathrm{pF}-\text { use } 100 \mathrm{pF}
\end{aligned}
\end{aligned}
$$

The complete design is shown in Figure 13. The PC board top and bottom views are shown in Figures 17 and 18.

Figure 16. Voltage Coupling Through Miller Capacitance

PIN FUNCTION DESCRIPTION

| Pin | Name | Description |
| :---: | :---: | :---: |
| 1 | G2 | This is a high current dual totem pole output Gate Drive for the Lower, or rectifier, N -channel MOSFET. Its output swings from ground to $\mathrm{P}_{\mathrm{Vcc}}$. During initial power application, both G 2 and G 1 are held low until both $\mathrm{V}_{\mathrm{CC}}$ and $\mathrm{P}_{\mathrm{VCC}}$ have reached proper levels. |
| 2 | $\mathrm{P}_{\mathrm{V}} \mathrm{CC}$ | This is a separate power source connection for driving N-channel MOSFETs from the G1 and G2 outputs. It may be connected to 12 V . |
| 3 | $\mathrm{P}_{\text {Gnd }}$ | This is a separate power ground return that is connected back to the power source. It is used to reduce the effects of switching transient noise on the control circuitry. |
| 4 | $\mathrm{A}_{\text {Gnd }}$ | This pin is the ground for the control circuitry. |
| 5 | $\mathrm{V}_{\mathrm{CC}}$ | This pin is the positive supply of the control IC. |
| 6 | Sense | This pin is used for feedback from the output of the power supply. It has a $20 \mu \mathrm{~A}$ current source to ground which can be used to provide offset in the converter output voltage. |
| 7 | $I_{\text {max }}$ | This pin sets the current limit threshold. $190 \mu \mathrm{~A}$ must be sourced into the pin. The external resistor is determined from the following equation: $\mathrm{R}=\left(\left[\mathrm{R}_{\mathrm{DS}(o n)}\right][\mathrm{LIMM}] /[190 \mu \mathrm{~A}]\right)$ |
| 8 | $\mathrm{I}_{\text {FB }}$ | This pin has two functions. First, it provides cycle-by-cycle current limiting. Second, if the current is excessive, this pin will reinitiate a soft-start cycle. If the voltage at the $I_{\text {FB }}$ pin drops below the voltage at the $I_{\max }$ pin when G 1 is on, the controller will go into current limit. The current limit circuit can be disabled by floating the $I_{\max }$ pin and shorting the $\mathrm{I}_{\mathrm{FB}}$ pin to $\mathrm{V}_{\mathrm{CC}}$. |
| 9 | SS | This is the soft-start pin. A capacitor at this pin, in conjunction with a $10 \mu \mathrm{~A}$ internal current source, sets the soft-start time. During moderate overload (current limit with $\mathrm{V}_{\mathrm{O}}>50 \%$ of the set value), the soft-start capacitor will be discharged by an internal $90 \mu \mathrm{~A}$ current source in order to reduce the duty cycle of G1. During hard current limit (current limit with $\mathrm{V}_{\mathrm{O}}<50 \%$ of set value), the soft-start capacitor will be discharged by a 64 mA current source. |
| 10 | Comp | This pin is provided for compensating the error amp for poles and zeros encountered in the power supply system, mostly the output LC filter. |
| 11 | $\overline{\text { OT }}$ | This is the over temperature fault pin. $\overline{\mathrm{OT}}$ is an open drain output that will be pulled low if the OUTEN pin is less than 2.0 V . |
| 12 | Fault | This pin indicates a fault condition. Fault is an open drain output that switches low if $\mathrm{V}_{\mathrm{O}}$ exceeds $115 \%$ of its set value. Once triggered, the controller will remain in this state until the power supply is recycled or the OUTEN pin is toggled. |
| 13 | $P_{\text {wrgd }}$ | This pin is an open drain output which indicates that $\mathrm{V}_{\mathrm{O}}$ is properly regulated. A high level on $P_{\text {wrgd }}$ indicates that $V_{O}$ is within $\pm 4 \%$ of its set value for more than $400 \mu \mathrm{~s}$. $\mathrm{P}_{\text {wrgd }}$ will switch low if $V_{O}$ is outside $\pm 4 \%$ for more than $100 \mu \mathrm{~s}$. |
| 14 | VID4 | Voltage ID pin. This CMOS-compatible input programs the output voltage as shown in Table 2. This pin has an internal 10 k pull-up resistor to $\mathrm{V}_{\mathrm{CC}}$. |
| 15 | VID3 | Voltage ID pin. This CMOS-compatible input programs the output voltage as shown in Table 2. This pin has an internal 10 k pull-up resistor to $\mathrm{V}_{\mathrm{CC}}$. |
| 16 | VID2 | Voltage ID pin. This CMOS-compatible input programs the output voltage as shown in Table 2. This pin has an internal 10 k pull-up resistor to $\mathrm{V}_{\mathrm{CC}}$. |
| 17 | VID1 | Voltage ID pin. This CMOS-compatible input programs the output voltage as shown in Table 2. This pin has an internal 10 k pull-up resistor to $\mathrm{V}_{\mathrm{CC}}$. |
| 18 | VIDO | Voltage ID pin. This CMOS-compatible input programs the output voltage as shown in Table 2. This pin has an internal 10 k pull-up resistor to $\mathrm{V}_{\mathrm{CC}}$. |
| 19 | OUTEN | This is the on/off control pin. A CMOS-compatible logic "1" allows the controller to operate. This pin can also be used as a temperature sensor to trigger the OT pin (when OUTEN drops below 2.0 V OT pulls low). When OUTEN drops below 1.7 V for longer than $50 \mu \mathrm{~s}$, the controller will shut down. |
| 20 | G1 | This is a high current dual totem pole output Gate Drive for the Upper, or switching, N-channel MOSFET. Its output swings from ground to $\mathrm{P}_{\mathrm{Vcc}}$. During initial power application, both G 2 and G 1 are held low until both $\mathrm{V}_{\mathrm{CC}}$ and $\mathrm{P}_{\mathrm{Vcc}}$ have reached proper levels. |

## CS51313

## Synchronous CPU <br> Buck Controller Capable of Implementing Multiple Linear Regulators

The CS51313 is a synchronous dual NFET Buck Regulator Controller. It is designed to power the core logic of the latest high performance CPUs. It uses the $\mathrm{V}^{2 \mathrm{TM}}$ control method to achieve the fastest possible transient response and best overall regulation. It incorporates many additional features required to ensure the proper operation and protection of the CPU and Power system. The CS51313 provides the industry's most highly integrated solution, minimizing external component count, total solution size, and cost.

The CS51313 is specifically designed to power Intel's Pentium® II processor and includes the following features: 5-bit DAC with $1.2 \%$ tolerance, Power Good output, overcurrent hiccup mode protection, overvoltage protection, $\mathrm{V}_{\mathrm{CC}}$ monitor, Soft Start, adaptive voltage positioning and adaptive FET non-overlap time. A precision reference trimmed to $1.0 \%$ is also externally available for use by other regulators. The CS51313 will operate over an 8.4 V to 14 V range and is available in 16 lead narrow body surface mount package.

## Features

- Synchronous Switching Regulator Controller for CPU VCORE
- Dual N-Channel MOSFET Synchronous Buck Design
- $\mathrm{V}^{2}$ Control Topology
- 200 ns Transient Loop Response
- 5-Bit DAC with $1.2 \%$ Tolerance
- Hiccup Mode Overcurrent Protection
- 40 ns Gate Rise and Fall Times (3.3 nF Load)
- 65 ns Adaptive FET Non-Overlap Time
- Adaptive Voltage Positioning
- Power Good Output Monitors Regulator Output
- $V_{\text {CC }}$ Monitor Provides Undervoltage Lockout
- OVP Output Monitors Regulator Output
- Enable Through Use of the COMP Pin
- +1.23 V Reference Voltage Available Externally

| :---: | :---: | :---: |
| SO-16 | PIN SYMBOL | FUNCTION |
| 1, 2, 3, 4, 6 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID } 4}$ | Voltage ID DAC inputs. These pins are internally pulled up to 5.65 V if left open. $\mathrm{V}_{\text {ID4 } 4}$ selects the DAC range. When $\mathrm{V}_{\text {ID4 }}$ is high (logic one), the Error Amp reference range is 2.125 V to 3.525 V with 100 mV increments. When $\mathrm{V}_{\text {ID4 }}$ is low (logic zero), the Error Amp reference voltage is 1.325 V to 2.075 V with 50 mV increments. |
| 5 | $\mathrm{V}_{\text {REF }}$ | Bandgap Reference Voltage. It can be used to generate other regulated output voltages. |
| 7 | $\mathrm{V}_{\mathrm{FB}}$ | Error amp inverting input, PWM comparator non-inverting input, current limit comparator non-inverting input, PWRGD and OVP comparator input. |
| 8 | $\mathrm{V}_{\text {OUT }}$ | Current limit comparator inverting input. |
| 9 | $\mathrm{V}_{\mathrm{CC}}$ | Input power supply pin for the internal circuitry. Decouple with filter capacitor to GND. |
| 10 | GATE(H) | High side switch FET driver pin. |
| 11 | GND | Ground pin. |
| 12 | GATE(L) | Low side synchronous FET driver pin. |
| 13 | OVP | Overvoltage protection pin. Goes high when overvoltage condition is detected on $\mathrm{V}_{\mathrm{FB}}$. |
| 14 | PWRGD | Power Good Output. Open collector output drives low when $\mathrm{V}_{\mathrm{FB}}$ is out of regulation. |
| 15 | $\mathrm{C}_{\text {OFF }}$ | Off-Time Capacitor pin. A capacitor from this pin to GND sets the off time for the regulator. |
| 16 | COMP | Error amp output. PWM comparator inverting input. A capacitor to GND provides error amp compensation. |

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## V $^{2}$ Control Method

The $\mathrm{V}^{2}$ method of control uses a ramp signal that is generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the value of the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. This control scheme differs from traditional techniques such as voltage mode, which generates an artificial ramp, and current mode, which generates a ramp from inductor current.

The $\mathrm{V}^{2}$ control method is illustrated in Figure 8. The output voltage is used to generate both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, which allows the control circuit to drive the main switch to $0 \%$ or $100 \%$ duty cycle as required.

Figure 8. ${ }^{2}$ Control Diagram

A change in line voltage changes the current ramp in the inductor, affecting the ramp signal, which causes the $\mathrm{V}^{2}$ control scheme to compensate the duty cycle. Since the change in inductor current modifies the ramp signal, as in current mode control, the $\mathrm{V}^{2}$ control scheme has the same advantages in line transient response.

A change in load current will have an affect on the output voltage, altering the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. Load transient response is determined only by the comparator response time and the transition speed of the main switch. The reaction time to an output load step has no relation to the crossover frequency of the error signal loop, as in traditional control methods.

The error signal loop can have a low crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.
Line and load regulation are drastically improved because there are two independent voltage loops. A voltage mode controller relies on a change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation.
A current mode controller maintains fixed error signal under deviation in the line voltage, since the slope of the ramp signal changes, but still relies on a change in the error signal for a deviation in load. The $\mathrm{V}^{2}$ method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

## Constant Off-Time

To minimize transient response, the CS51313 uses a Constant Off-Time method to control the rate of output pulses. During normal operation, the Off-Time of the high side switch is terminated after a fixed period, set by the Coff capacitor. Every time the $\mathrm{V}_{\mathrm{FB}}$ pin exceeds the COMP pin voltage an Off-Time is initiated. To maintain regulation, the $\mathrm{V}^{2}$ Control Loop varies switch On-Time. The PWM comparator monitors the output voltage ramp, and terminates the switch On-Time.
Constant Off-Time provides a number of advantages. Switch Duty Cycle can be adjusted from 0 to $100 \%$ on a pulse-by pulse basis when responding to transient conditions. Both $0 \%$ and $100 \%$ Duty Cycle operation can be maintained for extended periods of time in response to Load or Line transients.

## Programmable Output

The CS51313 is designed to provide two methods for programming the output voltage of the power supply. A five bit on board digital to analog converter (DAC) is used to program the output voltage within two different ranges. The first range is 2.125 V to 3.525 V in 100 mV steps, the second is 1.325 V to 2.075 V in 50 mV steps, depending on the digital input code. If all five bits are left open, the CS51313 enters adjust mode. In adjust mode, the designer can choose any output voltage by using resistor divider feedback to the $\mathrm{V}_{\mathrm{FB}}$ pin, as in traditional controllers. The CS51313 is specifically designed to meet or exceed Intel's Pentium II specifications.

## Error Amplifier

An inherent benefit of the $\mathrm{V}^{2}$ control topology is that there is no large bandwidth requirement on the error amplifier design. The reaction time to an output load step has no relation to the crossover frequency, since transient response is handled by the ramp signal loop. The main purpose of this "slow" feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered. The COMP pin is the output of the error amplifier and a capacitor to GND compensates the error amplifier loop. Additionally, through the built-in offset on the PWM Comparator non-inverting input, the COMP pin provides the hiccup timing for the Overcurrent Protection, the Soft Start function that minimizes inrush currents during regulator power-up and switcher output enable.

## Reference Voltage

The CS51313 has a precision reference trimmed to $1.5 \%$ over temperature, which is externally available for use by other power supplies on the motherboard. For instance, the $\mathrm{V}_{\text {REF }}$ pin can be used to configure an LDO controller that drives either a MOSFET or a bipolar transistor. The compensation criteria on this LDO controller is set by the dynamic performance requirement on the overall power supply. The following circuit demonstrates the typical connections required to implement an LDO controller using the CS51313 $\mathrm{V}_{\text {REF }}$ pin.

Figure 9. $\mathrm{V}_{\text {REF }}$ Used in an N-FET LDO Regulator
The applications diagram shows a pair of linear regulators for $\mathrm{V}_{\text {GTL }}$ and $\mathrm{V}_{\text {CLOCK. }}$. The $1.23 \mathrm{~V}_{\mathrm{REF}}$ of the CS51313 is used as the reference for both regulators. The feedback resistors determine the output voltage for each regulator. In this case, it will be $1.5 \mathrm{~V} @ 3.0 \mathrm{~A}$ for $\mathrm{V}_{\mathrm{GTL}}$ and $2.5 \mathrm{~V} @$ 1.0 A for $\mathrm{V}_{\text {Clock. }}$. In Figure 9 the ratio of resistor R1 to resistor R 2 is $\left(\mathrm{V}_{\text {OUT }} / \mathrm{V}_{\text {ReF }}\right)-1$, where $\mathrm{V}_{\text {OUT }}=1.5 \mathrm{~V}$ and $\mathrm{V}_{\text {REF }}=1.23 \mathrm{~V}$. The same formula can be used to determine the ratio of the feedback resistors needed to implement a 2.5 V linear regulator $\left(\mathrm{V}_{\text {Out }}=2.5 \mathrm{~V}\right)$. To negate the bias
current of the operational amplifier, a resistor with a value equal to the parallel combination of the feedback resistors ( $\mathrm{R} 1 / / \mathrm{R} 2$ ) is connected in series with the non-inverting input of this operational amplifier. R2 sets the minimum output current, ( $\left.\mathrm{I}_{\mathrm{MIN}}=\mathrm{V}_{\mathrm{REF}} / \mathrm{R} 2\right)$.
The pass transistor must be able to dissipate the power adequately while keeping the junction temperature below the maximum specified by the manufacturer. For example, with $\mathrm{V}_{\mathrm{GTL}}$ output of 1.5 V , input voltage of 3.3 V , and output DC current of 3.0 A , the pass transistor dissipates $(3.3 \mathrm{~V}-$ $1.5 \mathrm{~V}) \times 3.0 \mathrm{~A}=5.4 \mathrm{~W}$.

Sufficient output capacitance must be added to ensure that the output voltage remains within specification during transient loading. For example, the GTL bus load can ramp from 0 to 2.7 A at a rate of $8 \mathrm{~A} / \mu \mathrm{s}$. The designer needs to verify that the circuit will meet these requirements using the transistor and operational amplifier chosen.

## Startup

The CS51313 provides a controlled startup of regulator output voltage and features Programmable Soft Start implemented through the Error Amp and external Compensation Capacitor. This feature, combined with overcurrent protection, prevents stress to the regulator power components and overshoot of the output voltage during startup.

As power is applied to the regulator, the CS51313 Undervoltage Lockout circuit (UVL) monitors the IC's supply voltage $\left(\mathrm{V}_{\mathrm{CC}}\right)$ which is typically connected to the +12 V output of the AC-DC power supply. The UVL circuit prevents the NFET gates from being activated until $\mathrm{V}_{\mathrm{CC}}$ exceeds the 8.4 V (typ) threshold. Hysteresis of 300 mV (typ) is provided for noise immunity. The Error Amp Capacitor connected to the COMP pin is charged by a $30 \mu \mathrm{~A}$ current source. This capacitor must be charged to 1.1 V (typ) so that it exceeds the PWM comparator's offset before the $\mathrm{V}^{2} \mathrm{PWM}$ control loop permits switching to occur.

When $\mathrm{V}_{\mathrm{CC}}$ has exceeded 8.4 V and COMP has charged to 1.1 V, the upper Gate driver $(\operatorname{GATE}(\mathrm{H}))$ is activated, turning on the upper FET. This causes current to flow through the output inductor and into the output capacitors and load according to the following equation:

$$
I=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \frac{\mathrm{T}}{\mathrm{~L}}
$$

GATE(H) and the upper NFET remain on and inductor current ramps up until the initial pulse is terminated by either the PWM control loop or the overcurrent protection. This initial surge of in-rush current minimizes startup time, but avoids overstressing of the regulator's power components.

The PWM comparator will terminate the initial pulse if the regulator output exceeds the voltage on the COMP pin plus the 1.1 V PWM comparator offset before the voltage drop across the current sense resistor exceeds the current limit threshold voltage. In this case, the PWM control loop has achieved regulation and the initial pulse is then followed by a constant off time as programmed by the Coff capacitor.

The COMP capacitor will continue to slowly charge and the regulator output voltage will follow it, less the 1.1 V PWM offset, until it achieves the voltage programmed by the DAC's VID input. The Error Amp will then source or sink current to the COMP cap as required to maintain the correct regulator DC output voltage. Since the rate of increase of the COMP pin voltage is typically set much slower than the regulator's slew capability, inrush current, output voltage, and duty cycle all gradually increase from zero. (See Figures 10,11 , and 12).

Figure 10. Normal Startup ( $\mathbf{2 . 0} \mathbf{~ m s} / \mathrm{div}$ )

Channel 1 - Regulator Output Voltage ( $0.2 \mathrm{~V} / \mathrm{div}$ )
Channel 2 - Inductor Switching Node ( $5.0 \mathrm{~V} / \mathrm{div}$ )
Channel 3 - VCC (10 V/div)
Channel 4 - Regulator Input Voltage ( $5.0 \mathrm{~V} / \mathrm{div}$ )
Figure 11. Normal Startup Showing Initial Pulse Followed by Soft Start ( $20 \mu \mathrm{~s} / \mathrm{div}$ )

Channel 1 - Regulator Output Voltage ( $0.2 \mathrm{~V} /$ div)
Channel 2 - Inductor Switching Node (5.0 V/div)
Channel 3 - V CC ( $10 \mathrm{~V} /$ div)
Channel 4 - Regulator Input Voltage (5.0 V/div)
Figure 12. Pulse-By-Pulse Regulation During Soft Start ( $2.0 \mu \mathrm{~s} / \mathrm{div}$ )

If the voltage across the Current Sense resistor generates a voltage difference between the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ pins that exceeds the OVC Comparator Offset Voltage ( 86 mV typical), the Fault latch is set. This causes the COMP pin to be quickly discharged, turning off GATE $(\mathrm{H})$ and the upper NFET since the voltage on the COMP pin is now less than the 1.1 V PWM comparator offset. The Fault latch is reset when the voltage on the COMP decreases below the discharge threshold voltage ( 0.25 V typical). The COMP capacitor will again begin to charge, and when it exceeds the 1.1 V PWM comparator offset, the regulator output will Soft Start normally (see Figure 13).

Channel 1 - Regulator Output Voltage ( $1.0 \mathrm{~V} / \mathrm{div}$ )
Channel 2 - COMP Pin (1.0 V/div)
Channel 3 - $\mathrm{V}_{\mathrm{CC}}$ ( $10 \mathrm{~V} /$ div)
Channel 4 - Regulator Input Voltage (5.0 V/div)
Figure 13. Startup with COMP Pre-Charge to 2.0 V ( $2.0 \mathrm{~ms} / \mathrm{div}$ )

Because the start-up circuitry depends on the current sense function, a current sense resistor should always be used.

When driving large capacitive loads, the COMP must charge slowly enough to avoid tripping the CS51313 overcurrent protection. The following equation can be used to ensure unconditional startup:

$$
\frac{I_{C H G}}{\mathrm{C}_{\mathrm{COMP}}}<\frac{\mathrm{ILIM}-\mathrm{I}_{\mathrm{LOAD}}}{\mathrm{COUT}}
$$

where:
$\mathrm{I}_{\mathrm{CHG}}=$ COMP Source Current ( $30 \mu \mathrm{~A}$ typical);
$\mathrm{C}_{\text {COMP }}=$ COMP Capacitor value ( $0.1 \mu \mathrm{~F}$ typical);
$\mathrm{I}_{\text {LIM }}=$ Current Limit Threshold;
$\mathrm{I}_{\text {LOAD }}=$ Load Current during startup;
Cout $=$ Total Output Capacitance .

## Normal Operation

During normal operation, Switch Off-Time is constant and set by the C OFF capacitor. Switch On-Time is adjusted by the $\mathrm{V}^{2}$ Control loop to maintain regulation. This results in changes in regulator switching frequency, duty cycle, and output ripple in response to changes in load and line. Output voltage ripple will be determined by inductor ripple current and the ESR of the output capacitors

## Transient Response

The CS51313 V ${ }^{2}$ Control Loop's 200 ns reaction time provides unprecedented transient response to changes in input voltage or output current. Pulse-by-pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitor(s) during the time required to slew the inductor current.

Overall load transient response is further improved through a feature called "Adaptive Voltage Positioning." This technique pre-positions the output voltage to reduce total output voltage excursions during changes in load.

Holding tolerance to $1.0 \%$ allows the error amplifiers reference voltage to be targeted +25 mV high without compromising DC accuracy. A "Droop Resistor," implemented through a PC board trace, connects the Error Amps feedback pin ( $\mathrm{V}_{\mathrm{FB}}$ ) to the output capacitors and load and carries the output current. With no load, there is no DC drop across this resistor, producing an output voltage tracking the Error amps, including the +25 mV offset. When the full load current is delivered, a 50 mV drop is developed across this resistor. This results in output voltage being offset -25 mV low.

The result of Adaptive Voltage Positioning is that additional margin is provided for a load transient before reaching the output voltage specification limits. When load current suddenly increases from its minimum level, the output is pre-positioned +25 mV . Conversely, when load current suddenly decreases from its maximum level, the output is pre-positioned -25 mV . For best Transient

Response, a combination of a number of high frequency and bulk output capacitors are usually used.

## Slope Compensation

The $\mathrm{V}^{2}$ control method uses a ramp signal, generated by the ESR of the output capacitors, that is proportional to the ripple current through the inductor. To maintain regulation, the $\mathrm{V}^{2}$ control loop monitors this ramp signal, through the PWM comparator, and terminates the switch on-time.

The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope presented to the PWM comparator, due to the very low ESR, can lead to pulse width jitter and variation caused by both random or synchronous noise.

Adding slope compensation to the control loop, avoids erratic operation of the PWM circuit, particularly at lower duty cycles and higher frequencies, where there is not enough ramp signal, and provides a more stable switchpoint.

The scheme that prevents that switching noise prematurely triggers the PWM circuit consists of adding a positive voltage slope to the output of the Error Amplifier (COMP pin) during an off-time cycle.

The circuit that implements this function is shown in Figure 14.

Figure 14. Small RC Filter Provides the Proper Voltage Ramp at the Beginning of Each On-Time Cycle

The ramp waveform is generated through a small RC filter that provides the proper voltage ramp at the beginning of each on-time cycle. The resistors R1 and R2 in the circuit of Figure 14 form a voltage divider from the GATE(L) output, superimposing a small artificial ramp on the output of the error amplifier. It is important that the series combination $\mathrm{R} 1 / \mathrm{R} 2$ is high enough in resistance not to load down and negatively affect the slew rate on the GATE(L) pin.

## PROTECTION AND MONITORING FEATURES

## Overcurrent Protection

A loss-less hiccup mode current limit protection feature is provided, requiring only the COMP capacitor to implement. The CS51313 provides overcurrent protection by sensing the current through a "Droop" resistor, using an internal current sense comparator. The comparator
compares the voltage drop across the "Droop" resistor to an internal reference voltage of 86 mV (typical).

If the voltage drop across the "Droop" resistor exceeds this threshold, the current sense comparator allows the fault latch to be set. This causes the regulator to stop switching.

During this over current condition, the CS51313 stays off for the time it takes the COMP pin capacitor to discharge to its lower 0.25 V threshold. As soon as the COMP pin reaches 0.25 V , the Fault latch is reset (no overcurrent condition present) and the COMP pin is charged with a $30 \mu \mathrm{~A}$ current source to a voltage 1.1 V greater than the $\mathrm{V}_{\mathrm{FB}}$ voltage. Only at this point the regulator attempts to restart normally. The CS51313 will operate initially with a duty cycle whose value depends on how low the $\mathrm{V}_{\mathrm{FB}}$ voltage was during the overcurrent condition (whether hiccup mode was due to excessive current or hard short). This protection scheme minimizes thermal stress to the regulator components, input power supply, and PC board traces, as the over current condition persists. Upon removal of the overload, the fault latch is cleared, allowing normal operation to resume.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as result of the normal operation of the $\mathrm{V}^{2}$ control topology and requires no additional external components. The control loop responds to an overvoltage condition within 200 ns , causing the top MOSFET to shut off, disconnecting the regulator from its input voltage. This results in a "crowbar" action to clamp the output voltage and prevents damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low. Additionally, a dedicated Overvoltage protection (OVP) output pin (pin 13) is provided in the CS51313. The OVP signal will go high (overvoltage condition), if the output voltage ( $\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}$ ) exceeds the regulation voltage by $8.5 \%$ of the voltage set by the particular DAC code. The OVP pin can source up to 25 mA of current that can be used to drive an SCR to crowbar the power supply.

## Power Good Circuit

The Power Good pin (pin 14) is an open-collector signal consistent with TTL DC specifications. It is externally pulled up, and is pulled low (below 0.3 V ) when the regulator output voltage typically exceeds $\pm 8.5 \%$ of the nominal output voltage. Maximum output voltage deviation before Power Good is pulled low is $\pm 12 \%$.

## Output Enable

On/off control of the regulator outputs can be implemented by pulling the COMP pins low. It is required to pull the COMP pins below the 1.1 V PWM comparator offset voltage in order to disable switching on the GATE drivers.

## CS51313-BASED V CC(CORE) $^{\text {BUCK REGULATOR }}$ DESIGN EXAMPLE

## Step 1: Definition of the Design Specifications

In computer motherboard applications the input voltage comes from the "silver box" power supply. $5.0 \mathrm{~V} \pm 5.0 \%$ is used for conversion to output voltage, and $12 \mathrm{~V} \pm 5.0 \%$ is used for the external NFET gate voltage and circuit bias. The CPU $\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}$ tolerance can be affected by any or all of the following reasons:
1.buck regulator output voltage setpoint accuracy;
2.output voltage change due to discharging or charging of the bulk decoupling capacitors during a load current transient;
3.output voltage change due to the ESR and ESL of the bulk and high frequency decoupling capacitors, circuit traces, and vias;
4.output voltage ripple and noise.

Budgeting the tolerance is left up to the designer who must take into account all of the above effects and provide a $\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}$ that will meet the specified tolerance at the CPU's inputs.
The designer must also ensure that the regulator component junction temperatures are kept within the manufacturer's specified ratings at full load and maximum ambient temperature. As computer motherboards become increasingly complex, regulator size also becomes important, as there is less space available for the CPU power supply.

## Step 2: Selection of the Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the regulator output voltage. Key specifications for output capacitors are their ESR (Equivalent Series Resistance), and ESL (Equivalent Series Inductance). For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.
In order to determine the number of output capacitors the maximum voltage transient allowed during load transitions has to be specified. The output capacitors must hold the output voltage within these limits since the inductor current can not change with the required slew rate. The output capacitors must therefore have a very low ESL and ESR.

The voltage change during the load current transient is:

$$
\Delta \mathrm{V}_{\mathrm{OUT}}=\Delta \mathrm{I} \text { OUT } \times\left(\frac{\mathrm{ESL}}{\Delta \mathrm{t}}+\mathrm{ESR}+\frac{\mathrm{tTR}}{\mathrm{COUT}}\right)
$$

where:
$\Delta \mathrm{I}_{\text {OUT }} / \Delta \mathrm{t}=$ load current slew rate;
$\Delta \mathrm{I}_{\text {OUT }}=$ load transient;
$\Delta \mathrm{t}=$ load transient duration time;
$\mathrm{ESL}=$ Maximum allowable ESL including capacitors, circuit traces, and vias;
ESR = Maximum allowable ESR including capacitors and circuit traces;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time.
The designer has to independently assign values for the change in output voltage due to ESR, ESL, and output capacitor discharging or charging. Empirical data indicates that most of the output voltage change (droop or spike depending on the load current transition) results from the total output capacitor ESR.

The maximum allowable ESR can then be determined according to the formula

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESR}}}{\Delta \mathrm{I}_{\mathrm{OUT}}}
$$

where $\Delta \mathrm{V}_{\mathrm{ESR}}=$ change in output voltage due to ESR (assigned by the designer).

Once the maximum allowable ESR is determined, the number of output capacitors can be found by using the formula

$$
\text { Number of capacitors }=\frac{\text { ESRCAP }}{\text { ESRMAX }}
$$

where:
$E S R_{\text {CAP }}=$ maximum ESR per capacitor (specified in manufacturer's data sheet);
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR.
The actual output voltage deviation due to ESR can then be verified and compared to the value assigned by the designer:

$$
\Delta \mathrm{V}_{\mathrm{ESR}}=\Delta \mathrm{l} \text { OUT } \times \mathrm{ESR}_{\mathrm{MAX}}
$$

Similarly, the maximum allowable ESL is calculated from the following formula:

$$
\mathrm{ESL}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{ESL}} \times \Delta \mathrm{t}}{\Delta \mathrm{l}}
$$

where:
$\Delta \mathrm{I} / \Delta \mathrm{T}=$ load current slew rate (as high as $20 \mathrm{~A} / \mu \mathrm{s}$ );
$\Delta \mathrm{V}_{\mathrm{ESL}}=$ change in output voltage due to ESL .
The actual maximum allowable ESL can be determined by using the equation:

$$
\text { ESL MAX }=\frac{\text { ESLCAP }}{\text { Number of output capacitors }}
$$

where $\mathrm{ESL}_{\mathrm{CAP}}=$ maximum ESL per capacitor (it is estimated that a $10 \times 12 \mathrm{~mm}$ Aluminum Electrolytic capacitor has approximately 4.0 nH of package inductance).

The actual output voltage deviation due to the actual maximum ESL can then be verified:

$$
\Delta \mathrm{V}_{\mathrm{ESL}}=\frac{\mathrm{ESL}}{\mathrm{MAX} \times \Delta \mathrm{I}} \text { }
$$

The designer now must determine the change in output voltage due to output capacitor discharge during the transient:

$$
\Delta \mathrm{V}_{\mathrm{CAP}}=\frac{\Delta \mathrm{I} \times \Delta \mathrm{t} \mathrm{TR}}{\mathrm{COUT}}
$$

where:
$\Delta \mathrm{t}_{\mathrm{TR}}=$ the output voltage transient response time (assigned by the designer);
$\Delta \mathrm{V}_{\mathrm{CAP}}=$ output voltage deviation due to output capacitor discharge;
$\Delta \mathrm{I}=$ Load step.
The total change in output voltage as a result of a load current transient can be verified by the following formula:

$$
\Delta \mathrm{V}_{\mathrm{OUT}}=\Delta \mathrm{V}_{\mathrm{ESR}}+\Delta \mathrm{V}_{\mathrm{ESL}}+\Delta \mathrm{V}_{\mathrm{CAP}}
$$

## Step 3: Selection of the Duty Cycle, Switching Frequency, Switch On-Time ( $\mathrm{T}_{\mathrm{ON}}$ ) and Switch Off-Time (TOFF)

The duty cycle of a buck converter (including parasitic losses) is given by the formula:

$$
\text { Duty Cycle }=\mathrm{D}=\frac{\mathrm{V}_{\mathrm{OUT}}+\left(\mathrm{V}_{\mathrm{HFET}}+\mathrm{V}_{\mathrm{L}}+\mathrm{V}_{\mathrm{DROOP}}\right)}{\mathrm{V}_{\mathrm{IN}}+\mathrm{V}_{\mathrm{LFET}}-\mathrm{V}_{\mathrm{HFET}}-\mathrm{V}_{\mathrm{L}}}
$$

where:
$\mathrm{V}_{\text {OUT }}=$ buck regulator output voltage;
$\mathrm{V}_{\text {HFET }}=$ high side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$;
$\mathrm{V}_{\mathrm{L}}=$ output inductor voltage drop due to inductor wire DC resistance;
$\mathrm{V}_{\text {DROOP }}=$ droop (current sense) resistor voltage drop;
$\mathrm{V}_{\mathrm{IN}}=$ buck regulator input voltage;
$\mathrm{V}_{\mathrm{LFET}}=$ low side FET voltage drop due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$.

## Step3a: Calculation of Switch On-Time

The Switch On-Time (time during which the switching MOSFET in a synchronous buck topology is conducting) is determined by:

$$
\text { TON }=\frac{\text { Duty Cycle }}{\text { FSW }}
$$

where $\mathrm{F}_{\mathrm{SW}}=$ regulator switching frequency selected by the designer.

Higher operating frequencies allow the use of smaller inductor and capacitor values. Nevertheless, it is common to select lower frequency operation because a higher frequency results in lower efficiency due to MOSFET gate charge losses. Additionally, the use of smaller inductors at higher frequencies results in higher ripple current, higher output voltage ripple, and lower efficiency at light load currents.

## Step 3b: Calculation of Switch Off-Time

The Switch Off-Time (time during which the switching MOSFET is not conducting) can be determined by:

$$
\text { TOFF }=\frac{1.0}{\text { FSW }}-\mathrm{TON}
$$

The C CoFF capacitor value has to be selected in order to set the Off-Time, $\mathrm{T}_{\text {OFF }}$, above:

$$
\text { COFF }=\frac{\text { Period } \times(1.0-D)}{3980}
$$

where:
3980 is a characteristic factor of the CS51313; D = Duty Cycle .

## Step 4: Selection of the Output Inductor

The inductor should be selected based on its inductance, current capability, and DC resistance. Increasing the inductor value will decrease output voltage ripple, but degrade transient response. There are many factors to consider in selecting the inductor including cost, efficiency, EMI and ease of manufacture. The inductor must be able to handle the peak current at the switching frequency without saturating, and the copper resistance in the winding should be kept as low as possible to minimize resistive power loss. There are a variety of materials and types of magnetic cores that could be used for this application. Among them are ferrites, molypermalloy cores (MPP), amorphous and powdered iron cores. Powdered iron cores are very commonly used. Powdered iron cores are very suitable due to their high saturation flux density and have low loss at high frequencies, a distributed gap and exhibit very low EMI.

The inductor value can be determined by:

$$
\mathrm{L}=\frac{\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{t} \mathrm{TR}}{\Delta \mathrm{I}}
$$

where:
$\mathrm{V}_{\mathrm{IN}}=$ input voltage;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{t}_{\mathrm{TR}}=$ output voltage transient response time (assigned by the designer);
$\Delta \mathrm{I}=$ load transient.
The inductor ripple current can then be determined:

$$
\Delta \mathrm{I}_{\mathrm{L}}=\frac{\mathrm{V} \mathrm{OUT} \times \mathrm{TOFF}}{\mathrm{~L}}
$$

where:
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage;
$\mathrm{T}_{\mathrm{OFF}}=$ switch Off-Time;
$\mathrm{L}=$ inductor value.
The designer can now verify if the number of output capacitors from Step 2 will provide an acceptable output voltage ripple ( $1.0 \%$ of output voltage is common). The formula below is used:

$$
\Delta l_{\mathrm{L}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\mathrm{ESR} \mathrm{MAX}^{2}}
$$

Rearranging we have:

$$
\mathrm{ESR}_{\mathrm{MAX}}=\frac{\Delta \mathrm{V}_{\mathrm{OUT}}}{\Delta \mathrm{I}_{\mathrm{L}}}
$$

where
$\mathrm{ESR}_{\mathrm{MAX}}=$ maximum allowable ESR;
$\Delta \mathrm{V}_{\text {OUT }}=1.0 \% \times \mathrm{V}_{\text {OUT }}=$ maximum allowable output voltage ripple ( budgeted by the designer );
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current;
$\mathrm{V}_{\text {OUT }}=$ output voltage.

The number of output capacitors is determined by:

$$
\text { Number of capacitors }=\frac{\text { ESRCAP }}{\text { ESRMAX }}
$$

where $\mathrm{ESR}_{\mathrm{CAP}}=$ maximum ESR per capacitor (specified in manufacturer's data sheet).
The designer must also verify that the inductor value yields reasonable inductor peak and valley currents (the inductor current is a triangular waveform):

$$
\mathrm{IL}(\mathrm{PEAK})=\mathrm{IOUT}+\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2.0}
$$

where:
$\mathrm{I}_{\mathrm{L}(\text { PEAK })}=$ inductor peak current;
$\mathrm{I}_{\text {OUT }}=$ load current;
$\Delta \mathrm{I}_{\mathrm{L}}=$ inductor ripple current.

$$
\mathrm{IL}(\text { VALLEY })=\mathrm{IOUT}-\frac{\Delta \mathrm{I}_{\mathrm{L}}}{2.0}
$$

where $\mathrm{I}_{\mathrm{L}(\text { VALLEY })}=$ inductor valley current.
Given the requirements of an application such as a buck converter, it is found that a toroid powdered iron core is quite suitable due to its low cost, low core losses at the switching frequency, and low EMI.

## Step 5: Selection of the Input Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the input supply lines. A key specification for input capacitors is their ripple current rating. The input capacitor should also be able to handle the input RMS current $\mathrm{I}_{\mathrm{IN}(\mathrm{RMS})}$.
The combination of the input capacitors $\mathrm{C}_{\text {IN }}$ discharges during the on-time.
The input capacitor discharge current is given by:

$$
\begin{aligned}
& \operatorname{ICINDIS(RMS)}= \\
& \sqrt{\frac{\left(\begin{array}{l}
\mathrm{I}(\mathrm{PEAK})^{2} \\
+\left(I_{L(P E A K)} \times I_{L(V A L L E Y)}\right) \\
+\mathrm{I}_{\mathrm{L}(\mathrm{VALLEY})^{2}}
\end{array}\right) \times \mathrm{D}}{3.0}}
\end{aligned}
$$

where:
$\mathrm{I}_{\mathrm{CINDIS}(\mathrm{RMS})}=$ input capacitor discharge current;
$\mathrm{I}_{\mathrm{L}(\mathrm{PEAK})}=$ inductor peak current;
$\mathrm{I}_{\mathrm{L}(\text { VALLEY })}=$ inductor valley current.
$\mathrm{C}_{\mathrm{IN}}$ charges during the off-time, the average current through the capacitor over one switching cycle is zero:

$$
\operatorname{ICIN}(C H)=\operatorname{ICIN}(\mathrm{DIS}) \times \frac{D}{1.0-\mathrm{D}}
$$

where:
$\mathrm{I}_{\mathrm{CIN}(\mathrm{CH})}=$ input capacitor charge current;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{DIS})}=$ input capacitor discharge current;
D = Duty Cycle.
The total Input RMS current is:

$$
\operatorname{ICIN(RMS)}=\sqrt{\begin{array}{l}
\left(\mathrm{ICIN}(\mathrm{DIS})^{2} \times \mathrm{D}\right) \\
+\left(\mathrm{ICIN}(\mathrm{CH})^{2} \times(1.0-\mathrm{D})\right)
\end{array}}
$$

The number of input capacitors required is then determined by:

$$
\mathrm{N}_{\mathrm{CIN}}=\frac{\mathrm{ICIN(RMS)}}{\operatorname{IRIPPLE}}
$$

where:
$\mathrm{N}_{\text {CIN }}=$ number of input capacitors;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{RMS})}=$ total input RMS current;
$\mathrm{I}_{\text {RIPPLE }}=$ input capacitor ripple current rating (specified in manufacturer's data sheets).

The total input capacitor ESR needs to be determined in order to calculate the power dissipation of the input capacitors:

$$
\mathrm{ESR}_{\mathrm{CIN}}=\frac{\mathrm{ESR} \mathrm{CAP}}{\mathrm{~N}_{\mathrm{CIN}}}
$$

where:
$\mathrm{ESR}_{\mathrm{CIN}}=$ total input capacitor ESR;
$E S R_{\text {CAP }}=$ maximum ESR per capacitor (specified in manufacturer's data sheets);
$\mathrm{N}_{\mathrm{CIN}}=$ number of input capacitors.
Once the total ESR of the input capacitors is known, the input capacitor ripple voltage can be determined using the formula:

$$
\mathrm{V}_{\mathrm{CIN}(\mathrm{RMS})}=\operatorname{ICIN(RMS)} \times \mathrm{ESR}_{\mathrm{CIN}}
$$

where:
$\mathrm{V}_{\mathrm{CIN}(\mathrm{RMS})}=$ input capacitor RMS voltage;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{RMS})}=$ total input RMS current;
$\mathrm{ESR}_{\mathrm{CIN}}=$ total input capacitor ESR.
The designer must determine the input capacitor power loss in order to ensure there isn't excessive power dissipation through these components. The following formula is used:

$$
\operatorname{PCIN}(\mathrm{RMS})=\operatorname{ICIN}(\mathrm{RMS})^{2} \times \operatorname{ESRCIN}
$$

where:
$\mathrm{P}_{\mathrm{CIN}(\mathrm{RMS})}=$ input capacitor RMS power dissipation;
$\mathrm{I}_{\mathrm{CIN}(\mathrm{RMS})}=$ total input RMS current;
$\mathrm{ESR}_{\mathrm{CIN}}=$ total input capacitor ESR.

## Step 6: Selection of the Input Inductor

A CPU switching regulator, such as the one in a buck topology, must not disturb the primary +5.0 V supply. One method of achieving this is by using an input inductor and a bypass capacitor. The input inductor isolates the +5.0 V supply from the noise generated in the switching portion of the microprocessor buck regulator and also limits the inrush current into the input capacitors upon power up. The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients. The worst case is when the CPU load changes from no load to full load (load step), a condition under which the highest voltage
change across the input capacitors is also seen by the input inductor. The inductor successfully blocks the ripple current while placing the transient current requirements on the input bypass capacitor bank, which has to initially support the sudden load change.
The minimum inductance value for the input inductor is therefore:

$$
\operatorname{LIN}=\frac{\Delta V}{(\mathrm{~d} / / \mathrm{dt}) \mathrm{MAX}}
$$

where:
$\mathrm{L}_{\mathrm{IN}}=$ input inductor value;
$\Delta \mathrm{V}=$ voltage seen by the input inductor during a full load swing;
$(\mathrm{dI} / \mathrm{dt})_{\mathrm{MAX}}=$ maximum allowable input current slew rate ( $0.1 \mathrm{~A} / \mu \mathrm{s}$ for a Pentium II power supply).
The designer must select the LC filter pole frequency so that at least 40 dB attenuation is obtained at the regulator switching frequency. The LC filter is a double-pole network with a slope of -2 , a roll-off rate of $-40 \mathrm{~dB} / \mathrm{dec}$, and a corner frequency:

$$
\mathrm{f}_{\mathrm{C}}=\frac{1.0}{2.0 \pi \sqrt{\mathrm{LC}}}
$$

where:
$\mathrm{L}=$ input inductor;
$\mathrm{C}=$ input capacitor(s).

## Step 7: Selection of the Switching FET FET Basics

The use of the MOSFET as a power switch is propelled by two reasons: 1) Its very high input impedance; and 2) Its very fast switching times. The electrical characteristics of a MOSFET are considered to be those of a perfect switch. Control and drive circuitry power is therefore reduced. Because the input impedance is so high, it is voltage driven. The input of the MOSFET acts as if it were a small capacitor, which the driving circuit must charge at turn on. The lower the drive impedance, the higher the rate of rise of $\mathrm{V}_{\mathrm{GS}}$, and the faster the turn-on time. Power dissipation in the switching MOSFET consists of 1) conduction losses, 2) leakage losses, 3 ) turn-on switching losses, 4) turn-off switching losses, and 5) gate-transitions losses. The latter three losses are proportional to frequency. For the conducting power dissipation rms values of current and resistance are used for true power calculations. The fast switching speed of the MOSFET makes it indispensable for high-frequency power supply applications. Not only are switching power losses minimized, but also the maximum usable switching frequency is considerably higher. Switching time is independent of temperature. Also, at higher frequencies, the use of smaller and lighter components (transformer, filter choke, filter capacitor) reduces overall component cost while using less space for more efficient packaging at lower weight.
The MOSFET has purely capacitive input impedance. No DC current is required. It is important to keep in mind the
drain current of the FET has a negative temperature coefficient. Increase in temperature causes higher on-resistance and greater leakage current. For switching circuits, $\mathrm{V}_{\mathrm{DS}(\mathrm{ON})}$ should be low to minimize power dissipation at a given ID , and $\mathrm{V}_{\mathrm{GS}}$ should be high to accomplish this. MOSFET switching times are determined by device capacitance, stray capacitance, and the impedance of the gate drive circuit. Thus the gate driving circuit must have high momentary peak current sourcing and sinking capability for switching the MOSFET. The input capacitance, output capacitance and reverse-transfer capacitance also increase with increased device current rating.

Two considerations complicate the task of estimating switching times. First, since the magnitude of the input capacitance, $\mathrm{C}_{\mathrm{ISS}}$, varies with $\mathrm{V}_{\mathrm{DS}}$, the RC time constant determined by the gate-drive impedance and $\mathrm{C}_{\text {ISS }}$ changes during the switching cycle. Consequently, computation of the rise time of the gate voltage by using a specific gate-drive impedance and input capacitance yields only a rough estimate. The second consideration is the effect of the "Miller" capacitance, $\mathrm{C}_{\text {RSS }}$, which is referred to as $\mathrm{C}_{\mathrm{DG}}$ in the following discussion. For example, when a device is on, $\mathrm{V}_{\mathrm{DS}(\mathrm{ON})}$ is fairly small and $\mathrm{V}_{\mathrm{GS}}$ is about $12 \mathrm{~V} . \mathrm{C}_{\mathrm{DG}}$ is charged to $\mathrm{V}_{\mathrm{DS}(\mathrm{ON})}-\mathrm{V}_{\mathrm{GS}}$, which is a negative potential if the drain is considered the positive electrode. When the drain is "off," $\mathrm{C}_{\mathrm{DG}}$ is charged to quite a different potential. In this case the voltage across $C_{D G}$ is a positive value since the potential from gate-to-source is near zero volts and $\mathrm{V}_{\mathrm{DS}}$ is essentially the drain supply voltage. During turn-on and turn-off, these large swings in gate-to-drain voltage tax the current sourcing and sinking capabilities of the gate drive. In addition to charging and discharging $\mathrm{C}_{\mathrm{GS}}$, the gate drive must also supply the displacement current required by $C_{\text {DG }}\left(I_{\text {GATE }}=C_{\text {DG }} \mathrm{dV}_{\mathrm{DG}} / \mathrm{dt}\right)$. Unless the gate-drive impedance is very low, the $\mathrm{V}_{\mathrm{GS}}$ waveform commonly plateaus during rapid changes in the drain-to-source voltage.

The most important aspect of FET performance is the Static Drain-To-Source On-Resistance ( $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ ), which effects regulator efficiency and FET thermal management requirements. The On-Resistance determines the amount of current a FET can handle without excessive power dissipation that may cause overheating and potentially catastrophic failure. As the drain current rises, especially above the continuous rating, the On-Resistance also increases. Its positive temperature coefficient is between $+0.6 \% / \mathrm{C}$ and $+0.85 \% / \mathrm{C}$. The higher the On-Resistance the larger the conduction loss is. Additionally, the FET gate charge should be low in order to minimize switching losses and reduce power dissipation.

Both logic level and standard FETs can be used. The reference designs derive gate drive from the 12 V supply, which is generally available in most computer systems and utilizes logic level FETs.

Voltage applied to the FET gates depends on the application circuit used. Both upper and lower gate driver outputs are specified to drive to within 1.5 V of ground when in the low state and to within 2.0 V of their respective bias supplies when in the high state. In practice, the FET gates will be driven rail-to-rail due to overshoot caused by the capacitive load they present to the controller IC.

## Step 7a: Selection of the Switching (Upper) FET

The designer must ensure that the total power dissipation in the FET switch does not cause the power component's junction temperature to exceed $150^{\circ} \mathrm{C}$.

The maximum RMS current through the switch can be determined by the following formula:

$$
\operatorname{IRMS}(\mathrm{H})=
$$

where:
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{I}_{\mathrm{L}(\text { PEAK })}=$ inductor peak current;
$\mathrm{I}_{\mathrm{L}(\mathrm{VALLEY})}=$ inductor valley current;
D = Duty Cycle.
Once the RMS current through the switch is known, the switching MOSFET conduction losses can be calculated:

$$
\mathrm{P}_{\mathrm{RMS}(\mathrm{H})}=\operatorname{IRMS}(\mathrm{H})^{2} \times \mathrm{RDS}_{\mathrm{DS}(\mathrm{ON})}
$$

where:
$\mathrm{P}_{\mathrm{RMS}(\mathrm{H})}=$ switching MOSFET conduction losses;
$\mathrm{I}_{\mathrm{RMS}(\mathrm{H})}=$ maximum switching MOSFET RMS current;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=\mathrm{FET}$ drain-to-source on-resistance
The upper MOSFET switching losses are caused during MOSFET switch-on and switch-off and can be determined by using the following formula:

$$
\begin{aligned}
\mathrm{PSWH} & =\mathrm{PSWH}(\mathrm{ON})+\mathrm{PSWH}_{\mathrm{SW}}(\mathrm{OFF}) \\
& =\frac{\mathrm{V}_{\mathrm{IN}} \times \mathrm{IOUT} \times\left(\mathrm{t} \text { RISE }+\mathrm{t}_{\mathrm{OALL}}\right)}{6.0 \mathrm{~T}}
\end{aligned}
$$

where:
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{OFF})}=$ upper MOSFET switch-off losses;
$\mathrm{V}_{\text {IN }}=$ input voltage;
IOUT = load current;
$\mathrm{t}_{\text {RISE }}=$ MOSFET rise time (from FET manufacturer's switching characteristics performance curve);
$\mathrm{t}_{\text {FALL }}=$ MOSFET fall time (from FET manufacturer's switching characteristics performance curve);
$\mathrm{T}=1 / \mathrm{F}_{\mathrm{SW}}=$ period.
The total power dissipation in the switching MOSFET can then be calculated as:

PhFET $($ TOTAL $)=$ PRMSH + PSWH $(O N)+$ PSWH $(O F F)$
where:
$\mathrm{P}_{\text {HFET(TOTAL) }}=$ total switching (upper) MOSFET losses; $P_{\text {RMSH }}=$ upper MOSFET switch conduction Losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{ON})}=$ upper MOSFET switch-on losses;
$\mathrm{P}_{\mathrm{SWH}(\mathrm{OFF})}=$ upper MOSFET switch-off losses.
Once the total power dissipation in the switching FET is known, the maximum FET switch junction temperature can be calculated:

$$
T_{J}=T_{A}+\left(\operatorname{PHFET}(T O T A L) \times R_{\theta J A}\right)
$$

where:
$\mathrm{T}_{\mathrm{J}}=\mathrm{FET}$ junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$\mathrm{P}_{\mathrm{HFET}(\mathrm{TOTAL})}=$ total switching (upper) FET losses;
$\mathrm{R}_{\theta \mathrm{JIA}}=$ upper FET junction-to-ambient thermal resistance.

## Step 7b: Selection of the Synchronous (Lower) FET

The switch conduction losses for the lower FET can be calculated as follows:

$$
\begin{aligned}
\mathrm{PRMSL} & =\mathrm{I}_{\mathrm{RMS}^{2}} \times \mathrm{RDS}(\mathrm{ON}) \\
& =(\mathrm{IOUT} \times \sqrt{(1.0-\mathrm{D})})^{2} \times \mathrm{RDS}(\mathrm{ON})
\end{aligned}
$$

where:
$\mathrm{P}_{\text {RMSL }}=$ lower MOSFET conduction losses;
Iout = load current;
D = Duty Cycle;
$\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}=$ lower FET drain-to-source on-resistance.
The synchronous MOSFET has no switching losses, except for losses in the internal body diode, because it turns on into near zero voltage conditions. The MOSFET body diode will conduct during the non-overlap time and the resulting power dissipation (neglecting reverse recovery losses) can be calculated as follows:

$$
\text { PSWL }=V_{S D} \times \text { ILOAD } \times \text { non-overlap time } \times \text { FSW }
$$

where:
$\mathrm{P}_{\mathrm{SWL}}=$ lower FET switching losses;
$\mathrm{V}_{\mathrm{SD}}=$ lower FET source-to-drain voltage;
$\mathrm{I}_{\text {LOAD }}=$ load current
Non-overlap time $=$ GATE(L)-to-GATE(H) or GATE(H)-to-GATE(L) delay (from CS51313 data sheet Electrical Characteristics section);
$\mathrm{F}_{\mathrm{SW}}=$ switching frequency.
The total power dissipation in the synchronous (lower) MOSFET can then be calculated as:

$$
\text { PLFET(TOTAL) }=\text { PRMSL }+ \text { PSWL }
$$

where:
$\mathrm{P}_{\text {LFET(TOTAL) }}=$ Synchronous (lower) FET total losses;
$\mathrm{P}_{\text {RMSL }}=$ Switch Conduction Losses;
$P_{\text {SWL }}=$ Switching losses.
Once the total power dissipation in the synchronous FET is known the maximum FET switch junction temperature can be calculated:

$$
\mathrm{T}_{\mathrm{J}}=\mathrm{T}_{\mathrm{A}}+\left(\text { PLFET }(\mathrm{TOTAL}) \times \mathrm{R}_{\theta \mathrm{JA}}\right)
$$

where:
$\mathrm{T}_{\mathrm{J}}=$ MOSFET junction temperature;
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature;
$\mathrm{P}_{\text {LFET(TOTAL) }}=$ total synchronous (lower) FET losses;
$\mathrm{R}_{\theta J \mathrm{~A}}=$ lower FET junction-to-ambient thermal resistance.

## Step 8: Control IC Power Dissipation

The power dissipation of the IC varies with the MOSFETs used, $\mathrm{V}_{\mathrm{CC}}$, and the CS51313 operating frequency. The average MOSFET gate charge current typically dominates the control IC power dissipation.
The IC power dissipation is determined by the formula:

$$
\text { PCONTROLIC }=\operatorname{ICCVCC}+\operatorname{PGATE}(\mathrm{H})+\operatorname{PGATE}(\mathrm{L})
$$

where:
$\mathrm{P}_{\text {CONTROLIC }}=$ control IC power dissipation;
$\mathrm{I}_{\mathrm{CC}}=\mathrm{IC}$ quiescent supply current;
$\mathrm{V}_{\mathrm{CC}}=$ IC supply voltage;
$\mathrm{P}_{\mathrm{GATE}(\mathrm{H})}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{P}_{\text {GATE(L) }}=$ lower MOSFET gate driver (IC) losses.
The upper (switching) MOSFET gate driver (IC) losses are:

$$
\operatorname{PGATE}(H)=Q_{\operatorname{GATE}(H)} \times \mathrm{FSW} \times \mathrm{V}_{\operatorname{GATE}(\mathrm{H})}
$$

where:
$\mathrm{P}_{\mathrm{GATE}(\mathrm{H})}=$ upper MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\text {GATE(H) }}=$ total upper MOSFET gate charge;
$\mathrm{F}_{\text {SW }}=$ switching frequency;
$\mathrm{V}_{\mathrm{GATE}(\mathrm{H})}=$ upper MOSFET gate voltage.
The lower (synchronous) MOSFET gate driver (IC) losses are:

$$
\operatorname{PGATE}(\mathrm{L})=Q_{G A T E}(\mathrm{~L}) \times \mathrm{FSW}_{\mathrm{SW}} \times \mathrm{V}_{\mathrm{GATE}}(\mathrm{~L})
$$

where:
$\mathrm{P}_{\mathrm{GATE}(\mathrm{L})}=$ lower MOSFET gate driver (IC) losses;
$\mathrm{Q}_{\mathrm{GATE}(\mathrm{L})}=$ total lower MOSFET gate charge;
$\mathrm{F}_{\text {SW }}=$ switching frequency;
$\mathrm{V}_{\text {GATE(L) }}=$ lower MOSFET gate voltage.
The junction temperature of the control IC is primarily a function of the PCB layout, since most of the heat is removed through the traces connected to the pins of the IC.

## Step 9: Slope Compensation

Voltage regulators for today's advanced processors are expected to meet very stringent load transient requirements. One of the key factors in achieving tight dynamic voltage regulation is low ESR at the CPU input supply pins. Low ESR at the regulator output results in low output voltage ripple. The consequence is, however, that there's very little voltage ramp at the control IC feedback pin ( $\mathrm{V}_{\mathrm{FB}}$ ) and regulator sensitivity to noise and loop instability are two undesirable effects that can surface. The performance of the CS51313-based CPU V ${ }_{\text {CC(CORE) }}$ regulator is improved when a fixed amount of slope compensation is added to the
output of the PWM Error Amplifier (COMP pin) during the regulator Off-Time. Referring to Figure 14, the amount of voltage ramp at the COMP pin is dependent on the gate voltage of the lower (synchronous) FET and the value of resistor divider formed by R1and R2.

$$
\mathrm{V}_{\text {SLOPECOMP }}=\mathrm{V}_{\mathrm{GATE}}(\mathrm{~L}) \times\left(\frac{\mathrm{R} 2}{\mathrm{R} 1+\mathrm{R} 2}\right) \times\left(1.0-\mathrm{e}^{\frac{-\mathrm{t}}{\tau}}\right)
$$

where:
$\mathrm{V}_{\text {SLOPECOMP }}=$ amount of slope added;
$\mathrm{V}_{\text {GATE(L) }}=$ lower MOSFET gate voltage;
$\mathrm{R} 1, \mathrm{R} 2=$ voltage divider resistors;
$\mathrm{t}=\mathrm{t}_{\text {OFF }}$ (switch off-time);
$\tau=\mathrm{RC}$ constant determined by C 1 and the parallel combination of R1, R2 (Figure 14), neglecting the low driver output impedance

The artificial voltage ramp created by the slope compensation scheme results in improved control loop stability provided that the RC filter time constant is smaller than the off-time cycle duration (time during which the lower MOSFET is conducting).

## Step 10: Selection of Current Limit Filter Components

The current limit filter is implemented by a $0.1 \mu \mathrm{~F}$ ceramic capacitor across and two $510 \Omega$ resistors in series with the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ current limit comparator input pins. They provide a time constant $\tau=\mathrm{RC}=100 \mu \mathrm{~s}$, which enables the circuit to filter out noise and be immune to false triggering, caused by sudden and fast load changes. These load transients can have slew rates as high as $20 \mathrm{~A} / \mu \mathrm{s}$.

## "DROOP" RESISTOR FOR ADAPTIVE VOLTAGE POSITIONING AND CURRENT LIMIT

Adaptive voltage positioning is used to help keep the output voltage within specification during load transients. To implement adaptive voltage positioning a "Droop Resistor" must be connected between the output inductor and output capacitors and load. This resistor carries the full load current and should be chosen so that both DC and AC tolerance limits are met. An embedded PC trace resistor has the distinct advantage of near zero cost implementation. However, this droop resistor can vary due to three reasons: 1) the sheet resistivity variation caused by variation in the thickness of the PCB layer; 2) the mismatch of L/W; and 3) temperature variation.

## 1) Sheet Resistivity

For one ounce copper, the thickness variation is typically 1.26 mil to 1.48 mil. Therefore the error due to sheet resistivity is:

$$
\frac{1.48-1.26}{1.37}= \pm 8.0 \%
$$

## 2) Mismatch Due to L/W

The variation in $\mathrm{L} / \mathrm{W}$ is governed by variations due to the PCB manufacturing process. The error due to $\mathrm{L} / \mathrm{W}$ mismatch is typically $1.0 \%$.

## 3) Thermal Considerations

Due to $I^{2} \times R$ power losses the surface temperature of the droop resistor will increase causing the resistance to increase. Also, the ambient temperature variation will contribute to the increase of the resistance, according to the formula:

$$
R=R_{20}\left[1.0+\alpha_{20}(T-20)\right]
$$

where:
$\mathrm{R}_{20}=$ resistance at $20^{\circ} \mathrm{C}$;
$\alpha=0.00393 /{ }^{\circ} \mathrm{C}$
$\mathrm{T}=$ operating temperature;
$\mathrm{R}=$ desired droop resistor value.
For temperature $\mathrm{T}=50^{\circ} \mathrm{C}$, the $\% \mathrm{R}$ change $=12 \%$.

## Droop Resistor Tolerance

Tolerance due to sheet resistivity variation $\pm 8.0 \%$
Tolerance due to L/W error $1.0 \%$
Tolerance due to temperature variation $12 \%$
Total tolerance for droop resistor $21 \%$
In order to determine the droop resistor value the nominal voltage drop across it at full load has to be calculated. This voltage drop has to be such that the output voltage at full load is above the minimum DC tolerance spec:

$$
\mathrm{V}_{\mathrm{DROOP}}(\mathrm{TYP})=\frac{\mathrm{V}_{\mathrm{DAC}}(\mathrm{MIN})-\mathrm{V}_{\mathrm{DC}}(\mathrm{MIN})}{1.0+\mathrm{RDROOP}(\text { TOLERANCE })}
$$

Example: for a 450 MHz Pentium II, the DC accuracy spec is $1.93<\mathrm{V}_{\mathrm{CC}(\text { CORE })}<2.07 \mathrm{~V}$, and the AC accuracy spec is $1.9 \mathrm{~V}<\mathrm{V}_{\mathrm{CC}(\mathrm{CORE})}<2.1 \mathrm{~V}$. The CS51313 DAC output voltage is $+2.001 \mathrm{~V}<\mathrm{V}_{\mathrm{DAC}}<+2.049 \mathrm{~V}$. In order not to exceed the DC accuracy spec, the voltage drop developed across the resistor must be calculated as follows:

$$
\begin{aligned}
\mathrm{VDROOP}_{\text {(TYP })} & =\frac{\left(\mathrm{V} \operatorname{DAC}(\mathrm{MIN})-\mathrm{VDC}_{\mathrm{DIN}}\right)}{1.0+\mathrm{R}_{\mathrm{DROOP}}(\mathrm{TOLERANCE})} \\
& =\frac{+2.001 \mathrm{~V}-1.93 \mathrm{~V}}{1.21}=71 \mathrm{mV}
\end{aligned}
$$

With the CS51313 DAC accuracy being $1.0 \%$, the internal error amplifier's reference voltage is trimmed so that the output voltage will be 25 mV high at no load. With no load, there is no DC drop across the resistor, producing an output voltage tracking the error amplifier output voltage, including the offset. When the full load current is delivered, a drop of -50 mV is developed across the resistor. Therefore, the regulator output is pre-positioned at 25 mV above the nominal output voltage before a load turn-on. The total voltage drop due to a load step is $\Delta \mathrm{V}-25 \mathrm{mV}$ and the deviation from the nominal output voltage is 25 mV smaller than it would be if there was no droop resistor. Similarly at full load the regulator output is pre-positioned at 25 mV below the nominal voltage before a load turn-off. the total voltage increase due to a load turn-off is $\Delta \mathrm{V}-25 \mathrm{mV}$ and the deviation from the nominal output voltage is 25 mV smaller than it would be if there was no droop resistor. This is because the output capacitors are pre-charged to a value that is either 25 mV above the nominal output voltage before
a load turn-on or, 25 mV below the nominal output voltage before a load turn-off .

Obviously, the larger the voltage drop across the droop resistor (the larger the resistance), the worse the DC and load regulation, but the better the AC transient response.

## Current Limit

The current limit setpoint has to be higher than the normal full load current. Attention has to be paid to the current rating of the external power components as these are the first to fail during an overload condition. The MOSFET continuous and pulsed drain current rating at a given case temperature has to be accounted for when setting the current limit trip point.

Temperature curves on MOSFET manufacturers' data sheets allow the designer to determine the MOSFET drain current at a particular VGS and TJ (junction temperature). This, in turn, will assist the designer to set a proper current limit, without causing device breakdown during an overload condition.

Let's assume the full CPU load is 16A. The internal current sense comparator current limit voltage limits are: $77 \mathrm{mV}<\mathrm{V}_{\mathrm{TH}}<101 \mathrm{mV}$. Also, there is a $21 \%$ total variation in $\mathrm{R}_{\text {SENSE }}$ as discussed in the previous section.

We compute the value of the current sensing element (embedded PCB trace) for the minimum current limit setpoint:

$$
\begin{gathered}
\operatorname{RSENSE}(\mathrm{MIN})=\operatorname{RSENSE}(\mathrm{TYP}) \times 0.79 \\
\operatorname{RSENSE}(\mathrm{MAX})=\operatorname{RSENSE}(\mathrm{TYP}) \times 1.21 \\
\operatorname{RSENSE}^{(\mathrm{MAX})}=\frac{\mathrm{V}_{\mathrm{TH}(\mathrm{MIN})}}{\mathrm{ICL}(\mathrm{MIN})}=\frac{77 \mathrm{mV}}{16 \mathrm{~A}}=4.8 \mathrm{~m} \Omega
\end{gathered}
$$

We select,

$$
\text { RSENSE(TYP) }=3.3 \mathrm{~m} \Omega
$$

We calculate the range of load currents that will cause the internal current sense comparator to detect an overload condition.

## Nominal Current Limit Setpoint

From the overcurrent detection data in the electrical characteristics table:

$$
\begin{gathered}
\mathrm{V}_{\mathrm{TH}(\mathrm{TYP})}=86 \mathrm{mV} \\
\mathrm{I}_{\mathrm{CL}(\mathrm{NOM})}=\frac{\mathrm{V}_{\mathrm{TH}(\mathrm{TYP})}}{\operatorname{RSENSE}(\mathrm{NOM})}=\frac{86 \mathrm{mV}}{3.3 \mathrm{~m} \Omega}=26 \mathrm{~A}
\end{gathered}
$$

## Maximum Current Limit Setpoint

From the overcurrent detection data in the electrical characteristics table:

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{TH}}(\mathrm{MAX})=101 \mathrm{mV} \\
& \mathrm{I}_{\mathrm{CL}(\mathrm{MAX})}= \frac{\mathrm{V}_{\mathrm{TH}(\mathrm{MAX})}}{\operatorname{RSENSE}(\mathrm{MIN})}=\frac{\mathrm{V}_{\mathrm{TH}(\mathrm{MAX})}}{\operatorname{RSENSE}(\mathrm{NOM}) \times 0.79} \\
&=\frac{101 \mathrm{mV}}{3.3 \mathrm{~m} \Omega \times 0.79}=38.7 \mathrm{~A}
\end{aligned}
$$

Therefore, the range of load currents that will cause the internal current sense comparator to detect an overload condition through a $3.3 \mathrm{~m} \Omega$ embedded PCB trace is: 19.3 A $<\mathrm{I}_{\mathrm{CL}}<38.7 \mathrm{~A}$, with 26 A being the nominal overload condition.

## Design Rules for Using a Droop Resistor

The basic equation for laying an embedded resistor is:

$$
R_{A R}=\rho \times \frac{L}{A} \text { or } R=\rho \times \frac{L}{(W \times t)}
$$

where:
$\mathrm{A}=\mathrm{W} \times \mathrm{t}=$ cross-sectional area;
$\rho=$ the copper resistivity ( $\mu \Omega$-mil);
$\mathrm{L}=$ length (mils);
$\mathrm{W}=$ width (mils);
$\mathrm{t}=$ thickness (mils).
For most PCBs the copper thickness, t , is $35 \mu \mathrm{~m}(1.37$ mils) for one ounce copper; $\rho=717.86 \mu \Omega-$ mil.

For a CPU load of 16 A the resistance needed to create a 50 mV drop at full load is:

$$
\text { RDROOP }=\frac{50 \mathrm{mV}}{\mathrm{IOUT}}=\frac{50 \mathrm{mV}}{16 \mathrm{~A}}=3.1 \mathrm{~m} \Omega
$$

The resistivity of the copper will drift with the temperature according to the following guidelines:

$$
\begin{aligned}
& \Delta R=12 \% @ T_{A}=+50^{\circ} \mathrm{C} \\
& \Delta R=34 \% @ T_{A}=+100^{\circ} \mathrm{C}
\end{aligned}
$$

## Droop Resistor Length, Width, and Thickness

The minimum width and thickness of the droop resistor should primarily be determined on the basis of the current-carrying capacity required, and the maximum permissible droop resistor temperature rise. PCB manufacturer design charts can be used in determining current-carrying capacity and sizes of etched copper conductors for various temperature rises above ambient.

For single conductor applications, such as the use of the droop resistor, PCB design charts show that for a droop resistor with a required current-carrying capacity of 16 A , and a $45^{\circ} \mathrm{C}$ temperature rise above ambient, the recommended cross section is $275 \mathrm{mil}^{2}$.

$$
\mathrm{W} \times \mathrm{t}=275 \mathrm{mil} 2
$$

where:
$\mathrm{W}=$ droop resistor width;
$\mathrm{t}=$ droop resistor thickness.
For 1 oz . copper, $\mathrm{t}=1.37 \mathrm{mils}$, therefore $\mathrm{W}=201 \mathrm{mils}=$ 0.201 in .

$$
R=\rho \times \frac{L}{W \times t}
$$

where:
$\mathrm{R}=$ droop resistor value;
$\rho=0.71786 \mathrm{~m} \Omega-\mathrm{mil}(1 \mathrm{oz}$. copper);
$\mathrm{L}=$ droop resistor length;
$\mathrm{W}=$ droop resistor width.

$$
\begin{gathered}
\text { RDROOP }=3.3 \mathrm{~m} \Omega \\
3.3 \mathrm{~m} \Omega=0.71786 \mathrm{~m} \Omega-\mathrm{mil} \times \frac{\mathrm{L}}{201 \mathrm{mils} \times 1.37 \mathrm{mils}}
\end{gathered}
$$

Hence, $L=1265$ mils $=1.265$ in.
In layouts where it is impractical to lay out a droop resistor in a straight line 1265 mils long, the embedded PCB trace can be "snaked" to fit within the available space.

## THERMAL MANAGEMENT

## Thermal Considerations for Power MOSFETs

In order to maintain good reliability, the junction temperature of the semiconductor components should be kept to a maximum of $150^{\circ} \mathrm{C}$ or lower. The thermal impedance (junction to ambient) required to meet this requirement can be calculated as follows:

$$
\text { Thermal Impedance }=\frac{\mathrm{T}_{\mathrm{J}}(\mathrm{MAX})-\mathrm{T}_{\mathrm{A}}}{\text { Power }}
$$

A heatsink may be added to TO-220 components to reduce their thermal impedance. A number of PC board layout techniques such as thermal vias and additional copper foil area can be used to improve the power handling capability of surface mount components.

## EMI MANAGEMENT

As a consequence of large currents being turned on and off at high frequency, switching regulators generate noise as a consequence of their normal operation. When designing for compliance with EMI/EMC regulations, additional components may be added to reduce noise emissions. These components are not required for regulator operation and experimental results may allow them to be eliminated. The input filter inductor may not be required because bulk filter and bypass capacitors, as well as other loads located on the board will tend to reduce regulator di/dt effects on the circuit board and input power supply. Placement of the power component to minimize routing distance will also help to reduce emissions.

## LAYOUT GUIDELINES

When laying out the CPU buck regulator on a printed circuit board, the following checklist should be used to ensure proper operation of the CS51313.
1.Rapid changes in voltage across parasitic capacitors and abrupt changes in current in parasitic inductors are major concerns for a good layout.
2. Keep high currents out of sensitive ground connections.
3.Avoid ground loops as they pick up noise. Use star or single point grounding.
4.For high power buck regulators on double-sided PCBs a single ground plane (usually the bottom) is recommended.
5.Even though double sided PCBs are usually sufficient for a good layout, four-layer PCBs are the optimum approach to reducing susceptibility to noise. Use the two internal layers as the power and GND planes, the top layer for power connections and component vias, and the bottom layer for the noise sensitive traces.
6.Keep the inductor switching node small by placing the output inductor, switching and synchronous FETs close together.
7.The MOSFET gate traces to the IC must be as short, straight, and wide as possible.
8.Use fewer, but larger output capacitors, keep the capacitors clustered, and use multiple layer traces with heavy copper to keep the parasitic resistance low.
9.Place the switching MOSFET as close to the +5.0 V input capacitors as possible.
10. Place the output capacitors as close to the load as possible.
11. Place the $\mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{OUT}}$ filter resistors $(510 \Omega)$ in series with the $V_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ pins as close as possible to the pins.
12. Place the CofF and COMP capacitors as close as possible to the $\mathrm{C}_{\mathrm{OFF}}$ and COMP pins.
13. Place the current limit filter capacitor between the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$ pins, as close as possible to the pins.
14. Connect the filter components of the following pins: $\mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{OUT}}, \mathrm{C}_{\mathrm{OFF}}$, and COMP to the GND pin with a single trace, and connect this local GND trace to the output capacitor GND.
15. The "Droop" Resistor (embedded PCB trace) has to be wide enough to carry the full load current.
16. Place the $\mathrm{V}_{\mathrm{CC}}$ bypass capacitor as close as possible to the IC.

## CS5301

## Three-Phase <br> Buck Controller with Integrated Gate Drivers and Power Good

The CS5301 is a three-phase step down controller which incorporates all control functions required to power high performance processors and high current power supplies. Proprietary multi-phase architecture guarantees balanced load current distribution and reduces overall solution cost in high current applications. Enhanced V ${ }^{2 T M}$ control architecture provides the fastest possible transient response, excellent overall regulation, and ease of use.

The CS5301 multi-phase architecture reduces output voltage and input current ripple, allowing for a significant reduction in inductor values and a corresponding increase in inductor current slew rate. This approach allows a considerable reduction in input and output capacitor requirements, as well as reducing overall solution size and cost.

## Features

- Enhanced $\mathrm{V}^{2}$ Control Method
- 5-Bit DAC with 1\% Accuracy
- Adjustable Output Voltage Positioning
- 6 On-Board Gate Drivers
- 200 kHz to 800 kHz Operation Set by Resistor
- Current Sensed through Buck Inductors, Sense Resistors, or V-S Control
- Hiccup Mode Current Limit
- Individual Current Limits for Each Phase
- On-Board Current Sense Amplifiers
- $3.3 \mathrm{~V}, 1.0 \mathrm{~mA}$ Reference Output
- 5.0 V and/or 12 V Operation
- On/Off Control (through COMP Pin)
- Power Good Output

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| 32 Lead SO Wide | PIN SYMBOL | FUNCTION |
| 1 | COMP | Output of the error amplifier and input for the PWM comparators. |
| 2 | $\mathrm{V}_{\mathrm{FB}}$ | Voltage Feedback Pin. To use Adaptive Voltage Positioning (AVP) select an offset voltage at light load and connect a resistor between $V_{F B}$ and $V_{\text {OUT }}$. The input bias current of the $V_{F B}$ pin and the resistor value determine output voltage offset for zero output current. Short $\mathrm{V}_{\mathrm{FB}}$ to $\mathrm{V}_{\mathrm{OUT}}$ for no AVP. |
| 3 | $\mathrm{V}_{\text {DRP }}$ | Current sense output for AVP. The offset of this pin above the DAC voltage is proportional to the output current. Connect a resistor from this pin to $\mathrm{V}_{\mathrm{FB}}$ to set amount AVP or leave this pin open for no AVP. |
| 4-6 | CS1-CS3 | Current sense inputs. Connect current sense network for the corresponding phase to each input. |
| 7 | $\mathrm{CS}_{\text {REF }}$ | Reference for current sense amplifiers. To balance input offset voltages between the inverting and noninverting inputs of the Current Sense Amplifiers, connect a resistor between CS REF and the output voltage. The value should be $1 / 3$ of the value of the resistors connected to the CSx pins. |
| 8 | PWRGD | Power Good Output. Open collector output goes low when $\mathrm{CS}_{\text {REF }}$ is out of regulation. |
| 9-13 | $\mathrm{V}_{\text {ID4 }}-\mathrm{V}_{\text {ID0 }}$ | Voltage ID DAC inputs. These pins are internally pulled up to 3.3 V if left open. |
| 14 | PWRGDS | Power Good Sense. Connect to Output. |
| 15 | ILIM | Sets threshold for current limit. Connect to reference through a resistive divider. |
| 16 | REF | Reference output. Decouple with $0.1 \mu \mathrm{~F}$ to LGND. |
| 17 | LGND | Return for internal control circuits and IC substrate connection. |
| 18 | $\mathrm{V}_{\text {CCH3 }}$ | Power for GATE(H)3. |
| 19 | Gate(H)3 | High side driver \#3. |
| 20 | GND3 | Return for \#3 drivers. |
| 21 | Gate(L)3 | Low side driver \#3. |
| 22 | $\mathrm{V}_{\text {CCL23 }}$ | Power for GATE(L)2 and GATE(L)3. |
| 23 | Gate(L)2 | Low side driver \#2. |
| 24 | GND2 | Return for \#2 driver. |
| 25 | Gate(H)2 | High side driver \#2. |
| 26 | $\mathrm{V}_{\mathrm{CCH} 12}$ | Power for GATE(H)1 and GATE(H)2. UVLO Sense for High Side Driver supply connects to this pin. |
| 27 | Gate(H)1 | High side driver \#1. |
| 28 | GND1 | Return \#1 drivers. |
| 29 | Gate(L)1 | Low side driver \#1. |
| 30 | $\mathrm{V}_{\text {CCL1 }}$ | Power for GATE(L)1. |
| 31 | $\mathrm{V}_{\mathrm{CCL}}$ | Power for internal control circuits and UVLO Sense for Logic. |
| 32 | Rosc | A resistor from this pin to ground sets operating frequency and $V_{F B}$ bias current. |

## APPLICATIONS INFORMATION

## FIXED FREQUENCY MULTI-PHASE CONTROL

In a multi-phase converter, multiple converters are connected in parallel and are switched on at different times. This reduces output current from the individual converters and increases the apparent ripple frequency. Because several converters are connected in parallel, output current can ramp up or down faster than a single converter (with the same value output inductor) and heat is spread among multiple components.

The CS5301 uses a three-phase, fixed frequency, Enhanced $\mathrm{V}^{2}$ architecture. Each phase is delayed $120^{\circ}$ from the previous phase. Normally GATE(H) transitions high at the beginning of each oscillator cycle. Inductor current ramps up until the combination of the current sense signal and the output ripple trip the PWM comparator and bring GATE(H) low. Once GATE $(\mathrm{H})$ goes low, it will remain low until the beginning of the next oscillator cycle. While $\operatorname{GATE}(\mathrm{H})$ is high, the enhanced $\mathrm{V}^{2}$ loop will respond to line and load transients. Once GATE $(\mathrm{H})$ is low, the loop will not respond again until the beginning of the next cycle. Therefore, constant frequency Enhanced $\mathrm{V}^{2}$ will typically respond within $1 / 3$ of the off-time for a three-phase converter.

The Enhanced $\mathrm{V}^{2}$ architecture measures and adjusts current in each phase. An additional input $\left(\mathrm{CS}_{\mathrm{x}}\right)$ for inductor current information has been added to the $\mathrm{V}^{2}$ loop for each phase as shown in Figure 9.

Figure 9. Enhanced V ${ }^{2}$ Feedback and Current Sense Scheme

The inductor current is measured across $\mathrm{R}_{\mathrm{S}}$, amplified by CSA and summed with the OFFSET and Output Voltage at the non-inverting input of the PWM comparator. The inductor current provides the PWM ramp and as inductor current increases the voltage on the positive pin of the PWM
comparator rises and terminates the PWM cycle. If the inductor starts the cycle with a higher current, the PWM cycle will terminate earlier providing negative feedback. The CS5301 provides a CS $_{\mathrm{x}}$ input for each phase, but the $\mathrm{CS}_{\mathrm{REF}}, \mathrm{V}_{\mathrm{FB}}$ and COMP inputs are common to all phases. Current sharing is accomplished by referencing all phases to the same $\mathrm{V}_{\mathrm{FB}}$ and COMP pins, so that a phase with a larger current signal will turn off earlier than phases with a smaller current signal.
Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. If the COMP pin is held steady and the inductor current changes, there must also be a change in the output voltage. Or, in a closed loop configuration when the output current changes, the COMP pin must move to keep the same output voltage. The required change in the output voltage or COMP pin depends on the scaling of the current feedback signal and is calculated as

$$
\Delta V=\operatorname{RS} \times \text { CSA Gain } \times \Delta I
$$

The single-phase power stage output impedance is:
Single Stage Impedance $=\Delta \mathrm{V} / \Delta \mathrm{I}=\mathrm{RS} \times$ CSA Gain.
The multi-phase power stage output impedance is the single-phase output impedance divided by the number of phases. The output impedance of the power stage determines how the converter will respond during the first few $\mu$ s of a transient before the feedback loop has repositioned the COMP pin.

The peak output current of each phase can also be calculated from;

$$
I_{\text {pkout }}(\text { per phase })=\frac{\mathrm{V}_{\mathrm{COMP}}-\mathrm{V}_{\mathrm{FB}}-\mathrm{V}_{\mathrm{OFFSET}}}{\mathrm{R}_{\mathrm{S}} \times \mathrm{CSA} \text { Gain }}
$$

Figure 10 shows the step response of a single phase with the COMP pin at a fixed level. Before T1 the converter is in normal steady state operation. The inductor current provides the PWM ramp through the Current Share Amplifier. The PWM cycle ends when the sum of the current signal, voltage signal and OFFSET exceed the level of the COMP pin. At T1 the output current increases and the output voltage sags. The next PWM cycle begins and the cycle continues longer than previously while the current signal increases enough to make up for the lower voltage at the $\mathrm{V}_{\mathrm{FB}}$ pin and the cycle ends at T2. After T2 the output voltage remains lower than at light load and the current signal level is raised so that the sum of the current and voltage signal is the same as with the original load. In a closed loop system the COMP pin would move higher to restore the output voltage to the original level.

Figure 10. Open Loop Operation

## Inductive Current Sensing

For lossless sensing, current can be sensed across the inductor as shown in Figure 11. In the diagram L is the output inductance and $\mathrm{R}_{\mathrm{L}}$ is the inherent inductor resistance. To compensate the current sense signal the values of R1 and C 1 are chosen so that $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} 1 \times \mathrm{C} 1$. If this criteria is met the current sense signal will be the same shape as the inductor current, the voltage signal at $\mathrm{CS}_{\mathrm{x}}$ will represent the instantaneous value of inductor current and the circuit can be analyzed as if a sense resistor of value $R_{L}$ was used as a sense resistor ( $\mathrm{R}_{\mathrm{S}}$ ).

Figure 11. Lossless Inductive Current Sensing with Enhanced $\mathbf{V}^{2}$
When choosing or designing inductors for use with inductive sensing tolerances and temperature effects should be considered. Cores with a low permeability material or a large gap will usually have minimal inductance change with temperature and load. Copper magnet wire has a temperature coefficient of $0.39 \%$ per ${ }^{\circ} \mathrm{C}$. The increase in winding resistance at higher temperatures should be
considered when setting the $\mathrm{I}_{\text {LIM }}$ threshold. If a more accurate current sense is required than inductive sensing can provide, current can be sensed through a resistor as shown in Figure 9.

## Current Sharing Accuracy

PCB traces that carry inductor current can be used as part of the current sense resistance depending on where the current sense signal is picked off. For accurate current sharing, the current sense inputs should sense the current at the same point for each phase and the connection to the $\mathrm{CS}_{\text {REF }}$ should be made so that no phase is favored. (In some cases, especially with inductive sensing, resistance of the pcb can be useful for increasing the current sense resistance.) The total current sense resistance used for calculations must include any pcb trace between the $\mathrm{CS}_{\mathrm{x}}$ inputs and the $\mathrm{CS}_{\text {REF }}$ input that carries inductor current.

Current Sense Amplifier Input Mismatch and the value of the current sense element will determine the accuracy of current sharing between phases. The worst case Current Sense Amplifier Input Mismatch is 5.0 mV and will typically be within 3.0 mV . The difference in peak currents between phases will be the CSA Input Mismatch divided by the current sense resistance. If all current sense elements are of equal resistance a 3.0 mV mismatch with a $2.0 \mathrm{~m} \Omega$ sense resistance will produce a 1.5 A difference in current between phases.

## Operation at > 50\% Duty Cycle

For operation at duty cycles above $50 \%$ Enhanced V ${ }^{2}$ will exhibit subharmonic oscillation unless a compensation ramp is added to each phase. A circuit like the one on the left side of Figure 12 can be added to each current sense network to implement slope compensation. The value of R1 can be varied to adjust the ramp size.

Figure 12. External Slope Compensation Circuit

## Ramp Size and Current Sensing

Because the current ramp is used for both the PWM ramp and to sense current, the inductor and sense resistor values will be constrained. A small ramp will provide a quick transient response by minimizing the difference over which the COMP pin must travel between light and heavy loads, but a steady state ramp of 25 mV -p or greater is typically required to prevent pulse skipping and minimize pulse width jitter. For resistive current sensing, the combination of the inductor and sense resistor values must be chosen to provide a large enough steady state ramp. For large inductor values the sense resistor value must also be increased.

For inductive current sensing, the RC network must meet the requirement of $L / R_{L}=R \times C$ to accurately sense the $A C$ and DC components of the current the signal. Again the values for L and $\mathrm{R}_{\mathrm{L}}$ will be constrained in order to provide a large enough steady state ramp with a compensated current sense signal. A smaller $L$, or a larger $R_{L}$ than optimum might be required. But unlike resistive sensing, with inductive sensing, small adjustments can be made easily with the values of R and C to increase the ramp size if needed.

If RC is chosen to be smaller (faster) than $\mathrm{L} / \mathrm{R}_{\mathrm{L}}$, the AC portion of the current sensing signal will be scaled larger than the DC portion. This will provide a larger steady state ramp, but circuit performance will be affected and must be evaluated carefully. The current signal will overshoot during transients and settle at the rate determined by $\mathrm{R} \times \mathrm{C}$. It will eventually settle to the correct DC level, but the error will decay with the time constant of $\mathrm{R} \times \mathrm{C}$. If this error is excessive it will effect transient response, adaptive positioning and current limit. During transients the COMP pin will be required to overshoot along with the current signal in order to maintain the output voltage. The $\mathrm{V}_{\mathrm{DRP}}$ pin will also overshoot during transients and possibly slow the response. Single phase overcurrent will trip earlier than it would if compensated correctly and hiccup mode current limit will have a lower threshold for fast rise step loads than for slowly rising output currents.

The waveforms in Figure 13 show a simulation of the current sense signal and the actual inductor current during a positive step in load current with values of $\mathrm{L}=500 \mathrm{nH}$, $\mathrm{R}_{\mathrm{L}}=1.6 \mathrm{~m} \Omega, \mathrm{R} 1=20 \mathrm{k}$ and $\mathrm{C} 1=.01 \mu \mathrm{~F}$. For ideal current signal compensation the value of R1 should be $31 \mathrm{k} \Omega$. Due to the faster than ideal RC time constant there is an overshoot of $50 \%$ and the overshoot decays with a $200 \mu \mathrm{~s}$ time constant. With this compensation the $\mathrm{I}_{\text {LIM }}$ pin threshold must be set more than $50 \%$ above the full load current to avoid triggering hiccup mode during a large output load step.

Figure 13. Inductive Sensing waveform during a Step with Fast RC Time Constant ( $50 \mu \mathrm{~s} / \mathrm{div}$ )

## Current Limit

Two levels of overcurrent protection are provided. Any time the voltage on a Current Sense pin exceeds CS REF by more than the Single Phase Pulse by Pulse Current Limit, the PWM comparator for that phase is turned off. This provides fast peak current protection for individual phases. The outputs of all the currents are also summed and filtered to compare an averaged current signal to the voltage on the $\mathrm{I}_{\text {LIM }}$ pin. If this voltage is exceeded, the fault latch trips and the Soft Start capacitor is discharged by a $5.0 \mu \mathrm{~A}$ source until the COMP pin reaches 0.2 V . Then Soft Start begins. The converter will continue to operate in this mode until the fault condition is corrected.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as a result of the normal operation of the Enhanced $\mathrm{V}^{2}$ control topology with synchronous rectifiers. The control loop responds to an overvoltage condition within 400 ns , causing the top MOSFET's to shut off and the synchronous MOSFET's to turn on. This results in a "crowbar" action to clamp the output voltage and prevent damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low.

## UVLO

The CS5301 has undervoltage lockout functions connected to two pins. One intended for the logic and low-side drivers with a 4.5 V turn-on threshold is connected to the $\mathrm{V}_{\mathrm{CCL}}$ pin. A second for the high side drivers has a 3.5 V threshold and is connected to the $\mathrm{V}_{\mathrm{CCH} 12} \mathrm{pin}$.

The UVLO threshold for the high side drivers was chosen at a low value to allow for flexibility in the part. In many applications this function will be disabled or will only check that the applicable supply is on - not that is at a high enough voltage to run the converter.

For the 12 VIN converter (see Figure 1) the UVLO pin for the high side driver is pulled up by the 5.0 V supply (through two diode drops) and the function is not used. The diode between the COMP pin and the 12 V supply holds the COMP pin near GND and prevents start-up while the 12 V supply is off. In an application where a higher UVLO threshold is necessary a circuit like the one in Figure 15 will lock out the converter until the 12 V supply exceeds 8.0 V .

## VID Codes and Power Good

The internal VID and DACOUT levels are set up so that the reference for the control loop is nominally 125 mV below the VID code (see the block diagram). The nominal lower Power Good threshold is $2.5 \%$ below the DACout level. The nominal upper Power Good threshold is fixed at 2.0 V for all VID codes. This scheme is intended to select the VID level as the maximum output voltage and the DAC OUT level as the minimum output voltage.

## TRANSIENT RESPONSE AND ADAPTIVE POSITIONING

For applications with fast transient currents the output filter is frequently sized larger than ripple currents require in order to reduce voltage excursions during transients. Adaptive voltage positioning can reduce peak-peak output voltage deviations during load transients and allow for a smaller output filter. The output voltage can be set higher at light loads to reduce output voltage sag when the load current is stepped up and set lower during heavy loads to reduce overshoot when the load current is stepped up. For low current applications a droop resistor can provide fast accurate adaptive positioning. However, at high currents the loss in a droop resistor becomes excessive. For example; in a 50 A converter a $1.0 \mathrm{~m} \Omega$ resistor to provide a 50 mV change in output voltage between no load and full load would dissipate 2.5 Watts.

Lossless adaptive positioning is an alternative to using a droop resistor, but must respond quickly to changes in load current. Figure 14 shows how adaptive positioning works. The waveform labeled normal shows a converter without adaptive positioning. On the left, the output voltage sags when the output current is stepped up and later overshoots when current is stepped back down. With fast (ideal) adaptive positioning the peak to peak excursions are cut in half. In the slow adaptive positioning waveform the output
voltage is not repositioned quickly enough after current is stepped up and the upper limit is exceeded.

Figure 14. Adaptive Positioning
The CS5301 uses two methods to provide fast and accurate adaptive positioning. For low frequency positioning the VFB and VDRP pins are used to adjust the output voltage with varying load currents. For high frequency positioning, the current sense input pins can be used to control the power stage output impedance. The transition between fast and slow positioning is adjusted by the error amp compensation.

The CS5301 can be configured to adjust the output voltage based on the output current of the converter, as shown in Figure 1.
To set the no-load positioning, a resistor (R9) is placed between the output voltage and $\mathrm{V}_{\mathrm{FB}}$ pin. The $\mathrm{V}_{\mathrm{FB}}$ bias current will develop a voltage across the resistor to decrease the output voltage. The $\mathrm{V}_{\mathrm{FB}}$ bias current is dependent on the value of $\mathrm{R}_{\text {ROSC }}$, as shown in Figure 4.
During no load conditions the $\mathrm{V}_{\mathrm{DRP}}$ pin is at the same voltage as the $\mathrm{V}_{\mathrm{FB}}$ pin, so none of the $\mathrm{V}_{\mathrm{FB}}$ bias current flows through the $\mathrm{V}_{\mathrm{DRP}}$ resistor (R8). When output current increases the $\mathrm{V}_{\text {DRP }}$ pin increases proportionally and the $\mathrm{V}_{\mathrm{DRP}}$ pin current offsets the $\mathrm{V}_{\mathrm{FB}}$ bias current and causes the output voltage to further decrease.
The $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{DRP}}$ pins take care of the slower and DC voltage positioning. The first few $\mu$ s are controlled primarily by the ESR and ESL of the output filter. The transition between fast and slow positioning is controlled by the ramp size and the error amp compensation. If the ramp size is too large or the error amp too slow there will be a long transition to the final voltage after a transient. This will be most apparent with lower capacitance output filters.

Note: Large levels of adaptive positioning can cause pulse width jitter.

## Error Amp Compensation

The transconductance error amplifier can be configured to provide both a slow soft-start and a fast transient response. C 4 in Figure 1 controls soft-start. A $0.1 \mu \mathrm{~F}$ capacitor with the $30 \mu \mathrm{~A}$ error amplifier output capability will allow the output to ramp up at $0.3 \mathrm{~V} / \mathrm{ms}$ or 1.5 V in 5.0 ms .

R 10 is connected in series with C 4 to allow the error amplifier to slew quickly over a narrow range during load transients. Here the $30 \mu \mathrm{~A}$ error amplifier output capability
works against $10 \mathrm{k} \Omega$ (R10) to limit the window of fast slewing to 300 mV - enough to allow for fast transients, but not enough to interfere with soft-start. This window will be noticeable as a step in the COMP pin voltage at startup. The size of this step must be kept smaller than the Channel Startup Offset (nominally 0.4 V ) for proper soft-start operation. If adaptive positioning is used the R9 and R8 form a divider with the $\mathrm{V}_{\mathrm{DRP}}$ end held at the DAC voltage during startup, which effectively makes the Channel Startup Offset larger.

C12 is included for error amp stability. A capacitive load is required on the error amp output. Use of values less than 1.0 nF may result in error amp oscillation of several MHz .

C 11 and the parallel resistance of the $\mathrm{V}_{\mathrm{FB}}$ resistor (R9) and the $\mathrm{V}_{\mathrm{DRP}}$ resistor (R8) are used to roll off the error amp gain. The gain is rolled off at high enough frequency to give a quick transient response, but low enough to cross zero dB well below the switching frequency to minimize ripple and noise on the COMP pin.

Figure 15. External UVLO Circuit

## Layout Guidelines

With the fast rise, high output currents of microprocessor applications, parasitic inductance and resistance should be considered when laying out the power, filter and feedback signal sections of the board. Typically, a multi-layer board with at least one ground plane is recommended. If the layout is such that high currents can exist in the ground plane underneath the controller or control circuitry, the ground plane can be slotted to reroute the currents away from the controller. The slots should typically not be placed between the controller and the output voltage or in the return path of the gate drive. Additional power and ground planes or islands can be added as required for a particular layout.

Output filter components should be placed on wide planes connected directly to the load to minimize resistive drops during heavy loads and inductive drops and ringing during transients. If required, the planes for the output voltage and return can be interleaved to minimize inductance between the filter and load.

Voltage feedback should be taken from a point of the output or the output filter that doesn't favor any one phase.

If the feedback connection is closer to one inductor than the others the ripple associated with that phase may appear larger than the ripple associated with the other phases and poor current sharing can result.

The current sense signal is typically tens of milli-volts. Noise pick-up should be avoided wherever possible. Current feedback traces should be routed away from noisy areas such as switch nodes and gate drive signals. The paths should be matched as well as possible. It is especially important that all current sense signals be picked off at similar points for accurate current sharing. If the current signal is taken from a place other than directly at the inductor any additional resistance between the pick-off point and the inductor appears as part of the inherent inductor resistance and should be considered in design calculations. Capacitors for the current feedback networks should be placed as close to the current sense pins as practical.

## DESIGN PROCEDURE

## Current Sensing, Power Stage and Output Filter Components

1. Choose the output filter components to meet peak transient requirements. The formula below can be used to provide an approximate starting point for capacitor choice, but will be inadequate to calculate actual values.

$$
\Delta \mathrm{V} \text { PEAK }=(\Delta \mathrm{I} / \Delta \mathrm{T}) \times \mathrm{ESL}+\Delta \mathrm{I} \times \mathrm{ESR}
$$

Ideally the output filter should be simulated with models including ESR, ESL, circuit board parasitics and delays due to switching frequency and converter response. Typically both bulk capacitance (electrolytic, Oscon, etc.,) and low impedance capacitance (ceramic chip) will be required. The bulk capacitance provides "hold up" during the converter response. The low impedance capacitance reduces steady state ripple and bypasses the bulk capacitance during slewing of output current.
2. For inductive current sensing (only) choose the current sense network RC to provide a 25 mV minimum ramp during steady state operation.

$$
R=\left(V_{\text {IN }}-V_{\text {OUT }}\right) \times \frac{V_{\text {OUT }} / V_{I N}}{f \times C \times 25 \mathrm{mV}}
$$

Then choose the inductor value and inherent resistance to satisfy $L / R_{L}=R \times C$.
For ideal current sense compensation the ratio of L and $R_{L}$ is fixed, so the values of $L$ and $R_{L}$ will be a compromise typically with the maximum value $\mathrm{R}_{\mathrm{L}}$ limited by conduction losses or inductor temperature rise and the minimum value of $L$ limited by ripple current.
3. For resistive current sensing choose $L$ and $R_{S}$ to provide a steady state ramp greater than 25 mV .

$$
\mathrm{L} / \mathrm{R}_{\mathrm{S}}=\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\mathrm{OUT}}\right) \times \frac{\mathrm{V}_{\mathrm{OUT} /} / \mathrm{V}_{\text {IN }}}{\mathrm{f} \times 25 \mathrm{mV}}
$$

Again the ratio of $L$ and $R_{L}$ is fixed and the values of L and $\mathrm{R}_{\mathrm{S}}$ will be a compromise.
4. Calculate the high frequency output impedance (ConverterZ) of the converter during transients. This is the impedance of the Output filter ESR in parallel with the power stage output impedance (PwrstgZ) and will indicate how far from the original level ( $\Delta \mathrm{VR}$ ) the output voltage will typically recover to within one switching cycle. For a good transient response $\Delta \mathrm{VR}$ should be less than the peak output voltage overshoot or undershoot.

$$
\begin{array}{r}
\Delta \mathrm{VR}=\text { ConverterZ } \times \text { IOUT } \\
\text { ConverterZ }=\frac{\text { PwrstgZ } \times \text { ESR }}{\text { PwrstgZ }+ \text { ESR }}
\end{array}
$$

where:

$$
\text { PwrstgZ }=\text { RS } \times \text { CSA Gain } / 3
$$

Multiply the converterZ by the output current step size to calculate where the output voltage should recover to within the first switching cycle after a transient. If the ConverterZ is higher than the value required to recover to where the adaptive positioning is set the remainder of the recovery will be controlled by the error amp compensation and will typically recover in 10-20 $\mu \mathrm{s}$.

$$
\Delta \mathrm{VR}=\Delta \mathrm{l} \text { OUT } \times \text { ConverterZ }
$$

Make sure that $\Delta \mathrm{VR}$ is less than the expected peak transient for a good transient response.
5. Adjust L and $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ as required to meet the best combination of transient response, steady state output voltage ripple and pulse width jitter.

## Current Limit

When the sum of the Current Sense amplifiers ( $\mathrm{V}_{\text {ITOTAL }}$ ) exceeds the voltage on the $\mathrm{I}_{\text {LIM }}$ pin the part will enter hiccup mode. For inductive sensing the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the inductor resistance (or current sense resistor) at max temperature and max current. To set the level of the $\mathrm{I}_{\text {LIM }}$ pin:
6. $\mathrm{VILIM}_{\mathrm{IL}}=\mathrm{R} \times \operatorname{IOUT}(\mathrm{LIM}) \times \mathrm{CS}$ to ILIM Gain
where:

$$
\mathrm{R} \text { is } \mathrm{R}_{\mathrm{L}} \text { or } \mathrm{R}_{\mathrm{S}}
$$

$\mathrm{I}_{\mathrm{OUT}(\mathrm{LIM})}$ is the current limit threshold.
For the overcurrent to work properly the inductor time constant (L/R) should be $\leq$ the Current sense RC. If the RC is too fast, during step loads the current waveform will appear larger than it is (typically for a few hundred $\mu \mathrm{s}$ ) and may trip the current limit at a level lower than the DC limit.

## Adaptive Positioning

7. To set the amount of voltage positioning above the DAC setting at no load connect a resistor ( $\mathrm{R}_{\mathrm{VFB}}$ ) between the output voltage and the $\mathrm{V}_{\mathrm{FB}}$ pin. Choose $R_{\text {VFB }}$ as;

$$
\text { RVFB }=\text { NL Position/VFB Bias Current }
$$

See Figure 4 for $\mathrm{V}_{\mathrm{FB}}$ Bias Current.
8. To set the difference in output voltage between no load and full load, connect a resistor (RVDRP) between the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pins. $\mathrm{R}_{\mathrm{VDRP}}$ can be calculated in two steps. First calculate the difference between the $\mathrm{V}_{\text {DRP }}$ and $\mathrm{V}_{\mathrm{FB}}$ pin at full load. (The $\mathrm{V}_{\mathrm{FB}}$ voltage should be the same as the DAC voltage during closed loop operation.) Then choose the $\mathrm{R}_{\mathrm{VDRP}}$ to source enough current across $\mathrm{R}_{\mathrm{VFB}}$ for the desired change in output voltage.

$$
\Delta V_{V D R P}=\mathrm{R} \times \mathrm{IOUT} \times \mathrm{CS} \text { to } \mathrm{V}_{\mathrm{DRP}} \text { Gain }
$$

where:
$\mathrm{R}=\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ for one phase;
IOUT is the full load output current.

$$
\begin{gathered}
\mathrm{RVDRP}=\Delta \mathrm{V}_{\mathrm{VDRP}} \times \mathrm{RV}(\mathrm{FB}) / \Delta \mathrm{V}_{\mathrm{OUT}} \\
\text { DESIGN EXAMPLE }
\end{gathered}
$$

Choose the component values for lossless current sensing, adaptive positioning and current limit for a $250 \mathrm{kHz}, 1.55 \mathrm{~V}$, 60 A converter. The VID code is set to 1.6 V . Adaptive positioning is set for 100 mV above DACOUT (or 25 mV below VID) at no load and 75 mV below the no load position with a 60 A load. The peak output voltage transient should be less than 100 mV during a 60 A step current. The overcurrent limit is nominally 75 A .

## Current Sensing, Power Stage and Output Filter Components

1. Assume $1.5 \mathrm{~m} \Omega$ of output filter ESR.
2. Choose $\mathrm{C}=0.01 \mu \mathrm{~F}$

$$
\begin{aligned}
& R=\left(V_{\text {IN }}-V_{\text {OUT }}\right) \times \frac{V_{\text {OUT }} / V_{I N}}{f \times C \times 25 \mathrm{mV}} \\
&=(12-1.55) \times \frac{1.55 / 12}{250 \mathrm{k} \times 0.01 \mu \mathrm{~F} \times 25 \mathrm{mV}} \\
&=21.5 \mathrm{k} \Omega \Rightarrow C h o o s e 20 \mathrm{k} \Omega \\
& \mathrm{~L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} \times \mathrm{C}=20 \mathrm{k} \Omega \times 0.01 \mu \mathrm{~F}=200 \mu \mathrm{~s} \\
& \mathrm{Choose} \mathrm{R}_{\mathrm{L}}=2.0 \mathrm{~m} \Omega \\
& \mathrm{~L}=\mathrm{R}_{\mathrm{L}} \times \mathrm{R} \times \mathrm{C}=2.0 \mathrm{~m} \Omega \times 200 \mu \mathrm{~s}=400 \mathrm{nH}
\end{aligned}
$$

3. $\mathrm{n} / \mathrm{a}$
4. PwrstgZ $=R_{L} \times$ CSA Gain $/ 3$

$$
=2.0 \mathrm{~m} \Omega \times 4.2 / 3.0=2.8 \mathrm{~m} \Omega
$$

$$
\begin{aligned}
\text { ConverterZ } & =\frac{\text { PwrstgZ } \times \text { ESR }}{\text { PwrstgZ }+ \text { ESR }} \\
& =\frac{2.8 \mathrm{~m} \Omega \times 1.5 \mathrm{~m} \mathrm{\Omega}}{2.8 \mathrm{~m} \Omega+1.5 \mathrm{~m} \Omega} \cong 1.0 \mathrm{~m} \Omega
\end{aligned}
$$

$$
\Delta \mathrm{VR}=\text { ConverterZ } \times \text { IOUT }
$$

$$
=1.0 \mathrm{~m} \Omega \times 60 \mathrm{~A}=60 \mathrm{mV}
$$

5. $\mathrm{n} / \mathrm{a}$

## Current Limit

6. $\mathrm{V}_{\mathrm{ILIM}}=\mathrm{R}_{\mathrm{L}} \times \mathrm{IOUT}^{(\mathrm{LIM})}$

$$
\begin{aligned}
& \times \text { CS to ILIM Gain } \\
= & 2.0 \mathrm{~m} \Omega \times 75 \mathrm{~A} \times 6.5 \\
= & 975 \mathrm{mV}
\end{aligned}
$$

Adaptive Positioning
7. RVFB $=$ NL Position/VFB Bias Current

$$
=100 \mathrm{mV} / 6.0 \mu \mathrm{~A}=16.7 \mathrm{k} \Omega
$$

$$
\text { 8. } \begin{aligned}
\Delta V_{\text {DRP }}= & R_{\mathrm{L}} \times \text { IOUT } \\
& \times \text { Current Sense to VDRP Gain } \\
= & 2.0 \mathrm{~m} \Omega \times 60 \mathrm{~A} \times 3.1 \\
= & 372 \mathrm{mV} \\
\text { RVDRP }= & \Delta V_{\mathrm{DRP}} \times \text { RVFB } / \Delta \mathrm{V}_{\mathrm{OUT}} \\
= & 372 \mathrm{mV} \times 16.7 \mathrm{k} \Omega / 75 \mathrm{mV} \\
= & 82 \mathrm{k} \Omega
\end{aligned}
$$

## CS5302

## Two-Phase Buck Controller with Integrated Gate Drivers and 4-Bit DAC

The CS5302 is a two-phase step down controller which incorporates all control functions required to power high performance processors and high current power supplies. Proprietary multi-phase architecture guarantees balanced load current distribution and reduces overall solution cost in high current applications. Enhanced V ${ }^{2 T M}$ control architecture provides the fastest possible transient response, excellent overall regulation, and ease of use.

The CS5302 multi-phase architecture reduces output voltage and input current ripple, allowing for a significant reduction in inductor values and a corresponding increase in inductor current slew rate. This approach allows a considerable reduction in input and output capacitor requirements, as well as reducing overall solution size and cost.

## Features

- Enhanced $\mathrm{V}^{2}$ Control Method
- 4-Bit DAC with $1 \%$ Accuracy
- Adjustable Output Voltage Positioning
- 4 On-Board Gate Drivers
- 200 kHz to 800 kHz Operation Set by Resistor
- Current Sensed through Buck Inductors, Sense Resistors, or V-S Control
- Hiccup Mode Current Limit
- Individual Current Limits for Each Phase
- On-Board Current Sense Amplifiers
- 3.3 V, 1.0 mA Reference Output
- On/Off Control (through Soft Start Pin)
- Power Good Output with Internal Delay

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| 28 Lead SO Wide | PIN SYMBOL | FUNCTION |
| 1 | COMP | Output of the error amplifier and input for the PWM comparators. |
| 2 | $V_{\text {FB }}$ | Voltage Feedback Pin. To use Adaptive Voltage Positioning (AVP) select an offset voltage at light load and connect a resistor between $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$. The input bias current of the $\mathrm{V}_{\mathrm{FB}}$ pin and the resistor value determine output voltage offset for zero output current. Short $\mathrm{V}_{\mathrm{FB}}$ to $\mathrm{V}_{\mathrm{OUT}}$ for no AVP. |
| 3 | $\mathrm{V}_{\text {DRP }}$ | Current sense output for AVP. The offset of this pin above the DAC voltage is proportional to the output current. Connect a resistor from this pin to $\mathrm{V}_{\mathrm{FB}}$ to set amount AVP or leave this pin open for no AVP. |
| 4-5 | CS1-CS2 | Current sense inputs. Connect current sense network for the corresponding phase to each input. |
| 6 | $C S_{\text {REF }}$ | Reference for current sense amplifiers and input for Power Good comparators. To balance input offset voltages between the inverting and non-inverting inputs of the current sense amplifiers, connect a resistor between $\mathrm{CS}_{\text {REF }}$ and the output voltage. The value should be $2 / 5$ of the value of the resistors connected to the CSx pins. |
| 7 | PWRGD | Power Good Output. Open collector output goes low when $\mathrm{CS}_{\text {REF }}$ is out of regulation. |

PACKAGE PIN DESCRIPTION (continued)

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| 28 Lead SO Wide | PIN SYMBOL | FUNCTION |
| 8 | N/C | No connection. |
| 9-12 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID }}$ | Voltage ID DAC inputs. These pins are internally pulled up to 3.3 V if left open. |
| 13 | ILIM | Sets threshold for current limit. Connect to reference through a resistive divider. |
| 14 | REF | Reference output. Decouple with $0.1 \mu \mathrm{~F}$ to LGND. |
| 15 | $\mathrm{V}_{\mathrm{CCH} 2}$ | Power for GATE(H)2. |
| 16 | Gate(H)2 | High side driver \#2. |
| 17 | GND2 | Return for \#2 driver. |
| 18 | Gate(L)2 | Low side driver \#2. |
| 19 | $\mathrm{V}_{\text {CCL2 }}$ | Power for GATE(L)2. |
| 20 | SS | Soft Start capacitor pin. The Soft Start capacitor controls both Soft Start time and hiccup mode frequency. The COMP pin is clamped below Soft Start during Start-Up and hiccup mode. |
| 21 | LGND | Return for internal control circuits and IC substrate connection. |
| 22 | $\mathrm{V}_{\mathrm{CCH} 1}$ | Power for GATE(H)1. UVLO Sense for High Side Driver supply connects to this pin. |
| 23 | Gate(H)1 | High side driver \#1. |
| 24 | GND1 | Return \#1 drivers. |
| 25 | Gate(L)1 | Low side driver \#1. |
| 26 | $\mathrm{V}_{\text {CCL1 }}$ | Power for GATE(L)1. |
| 27 | $\mathrm{V}_{\text {CCL }}$ | Power for internal control circuits. UVLO Sense for Logic connects to this pin. |
| 28 | Rosc | A resistor from this pin to ground sets operating frequency and $\mathrm{V}_{\mathrm{FB}}$ bias current. |

## APPLICATIONS INFORMATION

## FIXED FREQUENCY MULTI-PHASE CONTROL

In a multi-phase converter, multiple converters are connected in parallel and are switched on at different times. This reduces output current from the individual converters and increases the apparent ripple frequency. Because several converters are connected in parallel, output current can ramp up or down faster than a single converter (with the same value output inductor) and heat is spread among multiple components.

The CS5302 uses a two-phase, fixed frequency, Enhanced V ${ }^{2}$ architecture. Each phase is delayed $180^{\circ}$ from the previous phase. Normally GATE(H) transitions high at the beginning of each oscillator cycle. Inductor current ramps up until the combination of the current sense signal and the output ripple trip the PWM comparator and bring GATE(H) low. Once GATE(H) goes low, it will remain low until the beginning of the next oscillator cycle. While $\operatorname{GATE}(\mathrm{H})$ is high, the enhanced $\mathrm{V}^{2}$ loop will respond to line and load transients. Once GATE $(\mathrm{H})$ is low, the loop will not respond again until the beginning of the next cycle. Therefore, constant frequency Enhanced $\mathrm{V}^{2}$ will typically respond within the off-time of the converter.

The Enhanced $\mathrm{V}^{2}$ architecture measures and adjusts current in each phase. An additional input ( Cx ) for inductor current information has been added to the $\mathrm{V}^{2}$ loop for each phase as shown in Figure 9.

Figure 9. Enhanced V ${ }^{2}$ Feedback and Current Sense Scheme

The inductor current is measured across $\mathrm{R}_{\mathrm{S}}$, amplified by CSA and summed with the OFFSET and Output Voltage at the non-inverting input of the PWM comparator. The inductor current provides the PWM ramp and as inductor current increases the voltage on the positive pin of the PWM comparator rises and terminates the PWM cycle. If the inductor starts the cycle with a higher current, the PWM
cycle will terminate earlier providing negative feedback. The CS5302 provides a Cx input for each phase, but the $\mathrm{CS}_{\mathrm{REF}}, \mathrm{V}_{\mathrm{FB}}$ and COMP inputs are common to all phases. Current sharing is accomplished by referencing all phases to the same $\mathrm{V}_{\mathrm{FB}}$ and COMP pins, so that a phase with a larger current signal will turn off earlier than phases with a smaller current signal.
Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. When the average output current is zero, the COMP pin will be only $1 / 2$ of the steady state ramp height plus the OFFSET above the output voltage. If the COMP pin is held steady and the inductor current changes, there must also be a change in the output voltage. Or, in a closed loop configuration when the output current changes, the COMP pin must move to keep the same output voltage. The required change in the output voltage or COMP pin depends on the scaling of the current feedback signal and is calculated as

$$
\Delta \mathrm{V}=\mathrm{RS} \times \mathrm{CSA} \text { Gain } \times \Delta \mathrm{I}
$$

The single-phase power stage output impedance is:
Single Stage Impedance $=\Delta \mathrm{V} / \Delta \mathrm{I}=\mathrm{R}_{\mathrm{S}} \times$ CSA Gain.
The multi-phase power stage output impedance is the single-phase output impedance divided by the number of phases. The output impedance of the power stage determines how the converter will respond during the first few $\mu$ s of a transient before the feedback loop has repositioned the COMP pin.

The peak output current of each phase can also be calculated from;

$$
I_{\text {pkout }}(\text { per phase })=\frac{\mathrm{V}_{\mathrm{COMP}}-\mathrm{V}_{\mathrm{FB}}-\mathrm{V}_{\text {OFFSET }}}{\mathrm{R}_{\mathrm{S}} \times \mathrm{CSA} \text { Gain }}
$$

Figure 10 shows the step response of a single phase with the COMP pin at a fixed level. Before T1 the converter is in normal steady state operation. The inductor current provides the PWM ramp through the Current Sense Amplifier. The PWM cycle ends when the sum of the current signal, voltage signal and OFFSET exceed the level of the COMP pin. At T1 the output current increases and the output voltage sags. The next PWM cycle begins and the cycle continues longer than previously while the current signal increases enough to make up for the lower voltage at the $\mathrm{V}_{\mathrm{FB}}$ pin and the cycle ends at T2. After T2 the output voltage remains lower than at light load and the current signal level is raised so that the sum of the current and voltage signal is the same as with the original load. In a closed loop system the COMP pin would move higher to restore the output voltage to the original level.

Figure 10. Open Loop Operation

## Inductive Current Sensing

For lossless sensing, current can be sensed across the inductor as shown in Figure 11. In the diagram $L$ is the output inductance and $\mathrm{R}_{\mathrm{L}}$ is the inherent inductor resistance. To compensate the current sense signal the values of R1 and C1 are chosen so that $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} 1 \times \mathrm{C} 1$. If this criteria is met the current sense signal will be the same shape as the inductor current, the voltage signal at Cx will represent the instantaneous value of inductor current and the circuit can be analyzed as if a sense resistor of value $R_{L}$ was used as a sense resistor $\left(\mathrm{R}_{\mathrm{S}}\right)$.

Figure 11. Lossless Inductive Current Sensing with Enhanced $\mathbf{V}^{2}$
When choosing or designing inductors for use with inductive sensing tolerances and temperature, effects should be considered. Cores with a low permeability material or a large gap will usually have minimal inductance change with temperature and load. Copper magnet wire has a temperature coefficient of $0.39 \%$ per ${ }^{\circ} \mathrm{C}$. The increase in winding resistance at higher temperatures should be
considered when setting the $\mathrm{I}_{\text {LIM }}$ threshold. If a more accurate current sense is required than inductive sensing can provide, current can be sensed through a resistor as shown in Figure 9.

## Current Sharing Accuracy

PCB traces that carry inductor current can be used as part of the current sense resistance depending on where the current sense signal is picked off. For accurate current sharing, the current sense inputs should sense the current at the same point for each phase and the connection to the $\mathrm{CS}_{\text {REF }}$ should be made so that no phase is favored. (In some cases, especially with inductive sensing, resistance of the pcb can be useful for increasing the current sense resistance.) The total current sense resistance used for calculations must include any pcb trace between the CS inputs and the $\mathrm{CS}_{\text {REF }}$ input that carries inductor current.

Current Sense Amplifier Input Mismatch and the value of the current sense element will determine the accuracy of current sharing between phases. The worst case Current Sense Amplifier Input Mismatch is 5.0 mV and will typically be within 3.0 mV . The difference in peak currents between phases will be the CSA Input Mismatch divided by the current sense resistance. If all current sense elements are of equal resistance a 3.0 mV mismatch with a $2.0 \mathrm{~m} \Omega$ sense resistance will produce a 1.5 A difference in current between phases.

## Operation at > 50\% Duty Cycle

For operation at duty cycles above $50 \%$ Enhanced $V^{2}$ will exhibit subharmonic oscillation unless a compensation ramp is added to each phase. A circuit like the one on the left side of Figure 12 can be added to each current sense network to implement slope compensation. The value of R1 can be varied to adjust the ramp size.

Figure 12. External Slope Compensation Circuit

## Ramp Size and Current Sensing

Because the current ramp is used for both the PWM ramp and to sense current, the inductor and sense resistor values will be constrained. A small ramp will provide a quick transient response by minimizing the difference over which the COMP pin must travel between light and heavy loads, but a steady state ramp of 25 mV -p or greater is typically required to prevent pulse skipping and minimize pulse width jitter. For resistive current sensing, the combination of the inductor and sense resistor values must be chosen to provide a large enough steady state ramp. For large inductor values the sense resistor value must also be increased.

For inductive current sensing, the RC network must meet the requirement of $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} \times \mathrm{C}$ to accurately sense the AC and DC components of the current the signal. Again the values for L and $\mathrm{R}_{\mathrm{L}}$ will be constrained in order to provide a large enough steady state ramp with a compensated current sense signal. A smaller $L$, or a larger $R_{L}$ than optimum might be required. But unlike resistive sensing, with inductive sensing, small adjustments can be made easily with the values of R and C to increase the ramp size if needed.

If RC is chosen to be smaller (faster) than $\mathrm{L} / \mathrm{R}_{\mathrm{L}}$, the AC portion of the current sensing signal will be scaled larger than the DC portion. This will provide a larger steady state ramp, but circuit performance will be affected and must be evaluated carefully. The current signal will overshoot during transients and settle at the rate determined by $\mathrm{R} \times \mathrm{C}$. It will eventually settle to the correct DC level, but the error will decay with the time constant of $\mathrm{R} \times \mathrm{C}$. If this error is excessive it will effect transient response, adaptive positioning and current limit. During transients the COMP pin will be required to overshoot along with the current signal in order to maintain the output voltage. The $V_{\text {DRP }}$ pin will also overshoot during transients and possibly slow the response. Single phase overcurrent will trip earlier than it would if compensated correctly and hiccup mode current limit will have a lower threshold for fast rise step loads than for slowly rising output currents.

The waveforms in Figure 13 show a simulation of the current sense signal and the actual inductor current during a positive step in load current with values of $\mathrm{L}=500 \mathrm{nH}$, $\mathrm{R}_{\mathrm{L}}=1.6 \mathrm{~m} \Omega, \mathrm{R} 1=20 \mathrm{k}$ and $\mathrm{C} 1=.01 \mu \mathrm{~F}$. For ideal current signal compensation the value of R 1 should be $31 \mathrm{k} \Omega$. Due to the faster than ideal RC time constant there is an overshoot of $50 \%$ and the overshoot decays with a $200 \mu \mathrm{~s}$ time constant. With this compensation the $\mathrm{I}_{\mathrm{LIM}}$ pin threshold must be set more than $50 \%$ above the full load current to avoid triggering hiccup mode during a large output load step.

Figure 13. Inductive Sensing waveform during a Step with Fast RC Time Constant ( $50 \mu \mathrm{~s} / \mathrm{div}$ )

## Current Limit

Two levels of overcurrent protection are provided. Any time the voltage on a Current Sense pin exceeds CS $_{\text {REF }}$ by more than the Single Phase Pulse by Pulse Current Limit, the PWM comparator for that phase is turned off. This provides fast peak current protection for individual phases. The outputs of all the currents are also summed and filtered to compare an averaged current signal to the voltage on the I $_{\text {LIM }}$ pin. If this voltage is exceeded, the fault latch trips and the Soft Start capacitor is discharged by a $7.5 \mu \mathrm{~A}$ source until the COMP pin reaches 0.2 V . Then Soft Start begins. The converter will continue to operate in this mode until the fault condition is corrected.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as a result of the normal operation of the Enhanced $\mathrm{V}^{2}$ control topology with synchronous rectifiers. The control loop responds to an overvoltage condition within 400 ns , causing the top MOSFET's to shut off and the synchronous MOSFET's to turn on. This results in a "crowbar" action to clamp the output voltage and prevent damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low.

## Transient Response and Adaptive Positioning

For applications with fast transient currents the output filter is frequently sized larger than ripple currents require in
order to reduce voltage excursions during transients. Adaptive voltage positioning can reduce peak-peak output voltage deviations during load transients and allow for a smaller output filter. The output voltage can be set higher than nominal at light loads to reduce output voltage sag when the load current is stepped up and set lower than nominal during heavy loads to reduce overshoot when the load current is stepped up. For low current applications a droop resistor can provide fast accurate adaptive positioning. However, at high currents the loss in a droop resistor becomes excessive. For example; in a 50 A converter a $1.0 \mathrm{~m} \Omega$ resistor to provide a 50 mV change in output voltage between no load and full load would dissipate 2.5 Watts.

Lossless adaptive positioning is an alternative to using a droop resistor, but must respond quickly to changes in load current. Figure 14 shows how adaptive positioning works. The waveform labeled normal shows a converter without adaptive positioning. On the left, the output voltage sags when the output current is stepped up and later overshoots when current is stepped back down. With fast (ideal) adaptive positioning the peak to peak excursions are cut in half. In the slow adaptive positioning waveform the output voltage is not repositioned quickly enough after current is stepped up and the upper limit is exceeded.

Figure 14. Adaptive Positioning
The CS5302 can be configured to adjust the output voltage based on the output current of the converter. (Refer to the application diagram on page 2278.)

To set the no-load positioning, a resistor is placed between the output voltage and $\mathrm{V}_{\mathrm{FB}}$ pin. The $\mathrm{V}_{\mathrm{FB}}$ bias current will develop a voltage across the resistor to increase the output voltage. The $\mathrm{V}_{\mathrm{FB}}$ bias current is dependent on the value of $\mathrm{R}_{\mathrm{OSC}}$. See Figure 4.

During no load conditions the $\mathrm{V}_{\text {DRP }}$ pin is at the same voltage as the $\mathrm{V}_{\mathrm{FB}}$ pin, so none of the $\mathrm{V}_{\mathrm{FB}}$ bias current flows through the $\mathrm{V}_{\mathrm{DRP}}$ resistor. When output current increases the $V_{\text {DRP }}$ pin increases proportionally and the $V_{\text {DRP }}$ pin current offsets the $\mathrm{V}_{\mathrm{FB}}$ bias current and causes the output voltage to decrease.

The $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{DRP}}$ pins take care of the slower and DC voltage positioning. The first few $\mu \mathrm{s}$ are controlled primarily by the ESR and ESL of the output filter. The transition between fast and slow positioning is controlled by the ramp size and the error amp compensation. If the ramp size is too large or the error amp too slow there will be a long transition
to the final voltage after a transient. This will be most apparent with lower capacitance output filters.

Note: Large levels of adaptive positioning can cause pulse width jitter.

## Error Amp Compensation

The transconductance error amplifier requires a capacitor between the COMP pin and GND. Use of values less than 1 nF may result in error amp oscillation of several MHz .

The capacitor between the COMP pin and the inverting error amplifier input and the parallel resistance of the $\mathrm{V}_{\mathrm{FB}}$ resistor and the $\mathrm{V}_{\mathrm{DRP}}$ resistor are used to roll off the error amp gain. The gain is rolled off at a high enough frequency to give a quick transient response, but low enough to cross zero dB well below the switching frequency to minimize ripple and noise on the COMP pin.

## UVLO

The CS5302 has undervoltage lockout functions connected to two pins. One, intended for the logic and low-side drivers, with a 4.4 V turn-on threshold is connected to the $\mathrm{V}_{\mathrm{CCL}}$ pin. A second, intended for the high side drivers, powered from 12 V has a 9.0 V threshold is connected to the $\mathrm{V}_{\mathrm{CCH} 1}$ pin.
Both thresholds must be exceeded for the converter to start.

## Soft Start and Hiccup Mode

A capacitor between the Soft Start pin and GND controls Soft Start and hiccup mode slopes. A $0.1 \mu \mathrm{~F}$ capacitor with the $30 \mu \mathrm{~A}$ charge current will allow the output to ramp up at $0.3 \mathrm{~V} / \mathrm{ms}$ or 1.5 V in 5.0 ms at start-up.

When a fault is detected due to overcurrent or UVLO the converter will enter a low duty cycle hiccup mode. During hiccup mode the converter will not switch from the time a fault is detected until the Soft Start capacitor has discharged below the Soft Start Discharge Threshold and then charged back up above the Channel Start Up Offset.

The Soft Start pin will disable the converter when pulled below 0.3 V .

## Layout Guidelines

With the fast rise, high output currents of microprocessor applications, parasitic inductance and resistance should be considered when laying out the power, filter and feedback signal sections of the board. Typically, a multi-layer board with at least one ground plane is recommended. If the layout is such that high currents can exist in the ground plane underneath the controller or control circuitry, the ground plane can be slotted to reroute the currents away from the controller. The slots should typically not be placed between the controller and the output voltage or in the return path of the gate drive. Additional power and ground planes or islands can be added as required for a particular layout.

Gate drives experience high di/dt during switching and the inductance of gate drive traces should be minimized. Gate
drive traces should be kept as short and wide as practical and should have a return path directly below the gate trace.

Output filter components should be placed on wide planes connected directly to the load to minimize resistive drops during heavy loads and inductive drops and ringing during transients. If required, the planes for the output voltage and return can be interleaved to minimize inductance between the filter and load.

Voltage feedback should be taken from a point of the output or the output filter that doesn't favor any one phase. If the feedback connection is closer to one inductor than the others the ripple associated with that phase may appear larger than the ripple associated with the other phases and poor current sharing can result.

The current sense signal is typically tens of milli-volts. Noise pick-up should be avoided wherever possible. Current feedback traces should be routed away from noisy areas such as switch nodes and gate drive signals. The paths should be matched as well as possible. It is especially important that all current sense signals be picked off at similar points for accurate current sharing. If the current signal is taken from a place other than directly at the inductor any additional resistance between the pick-off point and the inductor appears as part of the inherent inductor resistance and should be considered in design calculations. Capacitors for the current feedback networks should be placed as close to the current sense pins as practical.

## DESIGN PROCEDURE

## Current Sensing, Power Stage and Output Filter Components

1. Choose the output filter components to meet peak transient requirements. The formula below can be used to provide an approximate starting point for capacitor choice, but will be inadequate to calculate actual values.

$$
\Delta V_{\text {PEAK }}=(\Delta \mathrm{I} / \Delta \mathrm{T}) \times \mathrm{ESL}+\Delta \mathrm{I} \times \mathrm{ESR}
$$

Ideally the output filter should be simulated with models including ESR, ESL, circuit board parasitics and delays due to switching frequency and converter response. Typically both bulk capacitance (electrolytic, Oscon, etc.,) and low impedance capacitance (ceramic chip) will be required. The bulk capacitance provides "hold up" during the converter response. The low impedance capacitance reduces steady state ripple and bypasses the bulk capacitance during slewing of output current.
2. For inductive current sensing (only) choose the current sense network RC to provide a 25 mV minimum ramp during steady state operation.

$$
\mathrm{R}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \frac{\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\text {IN }}}{\mathrm{F} \times \mathrm{C} \times 25 \mathrm{mV}}
$$

Then choose the inductor value and inherent resistance to satisfy $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} \times \mathrm{C}$.

For ideal current sense compensation the ratio of $L$ and $R_{L}$ is fixed, so the values of $L$ and $R_{L}$ will be a compromise typically with the maximum value $\mathrm{R}_{\mathrm{L}}$ limited by conduction losses or inductor temperature rise and the minimum value of L limited by ripple current.
3. For resistive current sensing choose L and $\mathrm{R}_{\mathrm{S}}$ to provide a steady state ramp greater than 25 mV .

$$
\mathrm{L} / \mathrm{RS}_{\mathrm{S}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{TON} / 25 \mathrm{mV}
$$

Again the ratio of $L$ and $R_{L}$ is fixed and the values of L and $\mathrm{R}_{\mathrm{S}}$ will be a compromise.
4. Calculate the high frequency output impedance (ConverterZ) of the converter during transients. This is the impedance of the Output filter ESR in parallel with the power stage output impedance (PwrstgZ) and will indicate how far from the original level ( $\Delta \mathrm{VR}$ ) the output voltage will typically recover to within one switching cycle. For a good transient response $\Delta \mathrm{VR}$ should be less than the peak output voltage overshoot or undershoot.

$$
\begin{array}{r}
\Delta \mathrm{VR}=\text { ConverterZ } \times \mathrm{ESR} \\
\text { ConverterZ }=\frac{\text { PwrstgZ } \times \mathrm{ESR}}{\text { PwrstgZ }+\mathrm{ESR}}
\end{array}
$$

where:

$$
\text { PwrstgZ }=R_{S} \times \text { CSA Gain } / 3.0
$$

Multiply the converterZ by the output current step size to calculate where the output voltage should recover to within the first switching cycle after a transient. If the ConverterZ is higher than the value required to recover to where the adaptive positioning is set the remainder of the recovery will be controlled by the error amp compensation and will typically recover in $10-20 \mu \mathrm{~s}$.

$$
\Delta \mathrm{VR}=\Delta \mathrm{l} \mathrm{OUT} \times \text { ConverterZ }
$$

Make sure that $\Delta \mathrm{VR}$ is less than the expected peak transient for a good transient response.
5. Adjust L and $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ as required to meet the best combination of transient response, steady state output voltage ripple and pulse width jitter.

## Current Limit

When the sum of the Current Sense amplifiers (VITOtaL) exceeds the voltage on the $\mathrm{I}_{\text {LIM }}$ pin the part will enter hiccup mode. For inductive sensing the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the inductor resistance (or current sense resistor) at max temperature and max current. To set the level of the $\mathrm{I}_{\text {LIM }}$ pin:
6. $\mathrm{V}_{\mathrm{I}(\mathrm{LIM})}=\mathrm{R} \times \operatorname{lOUT}(\mathrm{LIM}) \times \mathrm{CS}$ to ILIM Gain
where: R is $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$; $\mathrm{I}_{\mathrm{OUT}(\mathrm{LIM})}$ is the current limit threshold.
For the overcurrent to work properly the inductor time constant $(L / R)$ should be $\leq$ the Current sense RC.

If the RC is too fast, during step loads the current waveform will appear larger than it is (typically for a few hundred $\mu \mathrm{s}$ ) and may trip the current limit at a level lower than the DC limit.

## Adaptive Positioning

7. To set the amount of voltage positioning below the DAC setting at no load connect a resistor $\left(\mathrm{R}_{\mathrm{V}(\mathrm{FB})}\right)$ between the output voltage and the $\mathrm{V}_{\mathrm{FB}}$ pin. Choose $\mathrm{R}_{\mathrm{V}(\mathrm{FB})}$ as;

$$
\mathrm{R}_{\mathrm{V}(\mathrm{FB})}=\mathrm{NL} \text { Position } / \mathrm{V}_{\mathrm{FB}} \text { Bias Current }
$$

See Figure 4 for $V_{F B}$ Bias Current.
8. To set the difference in output voltage between no load and full load, connect a resistor $\left(\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}\right)$ between the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pins. $\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}$ can be calculated in two steps. First calculate the difference between the $\mathrm{V}_{\text {DRP }}$ and $\mathrm{V}_{\mathrm{FB}}$ pin at full load. (The $\mathrm{V}_{\mathrm{FB}}$ voltage should be the same as the DAC voltage during closed loop operation.) Then choose the $\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}$ to source enough current across $\mathrm{R}_{\mathrm{V}}(\mathrm{FB})$ for the desired change in output voltage.

$$
\Delta \mathrm{V} V(\mathrm{DRP})=\mathrm{I} \text { OUTFL } \times \mathrm{R} \times \mathrm{CS} \text { to } \mathrm{V} \text { DRP Gain }
$$

where:
$\mathrm{R}=\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ for one phase;
$\mathrm{I}_{\mathrm{OUTFL}}$ is the full load output current.

$$
\mathrm{RV}(\mathrm{DRP})=\Delta \mathrm{V}_{\mathrm{DRP}} \times \mathrm{RV}_{\mathrm{V}(\mathrm{FB})} / \Delta \mathrm{V}_{\mathrm{OUT}}
$$

## Calculate Input Filter Capacitor Current Ripple

The procedure below assumes that phases do not overlap and output inductor ripple current $(\mathrm{P}-\mathrm{P})$ is less than the average output current of one phase.
9. Calculate Input Current
$\mathrm{I}_{\mathrm{IN}}=\frac{\mathrm{V}_{\mathrm{OUT}} \times \mathrm{IOUT}_{\mathrm{OU}}}{\left(\text { Efficiency } \times \mathrm{V}_{\mathrm{IN}}\right)}$
10. Calculate Duty Cycle (per phase).

Duty Cycle $=\frac{\text { VOUT }}{\left(\text { Efficiency } \times \mathrm{V}_{\mathrm{IN}}\right)}$
11. Calculate Apparent Duty Cycle.

## Apparent Duty Cycle $=$ Duty Cycle $\times$ \# of Phases

12. Calculate Input Filter Capacitor Ripple Current. Use the chart in Figure 15 to calculate the normalized ripple current ( $\mathrm{K}_{\mathrm{RMS}}$ ) based on the reciprocal of Apparent Duty Cycle. Then multiply the input current by $K_{\text {RMS }}$ to obtain the Input Filter Capacitor Ripple Current.
Ripple $($ RMS $)=I_{I N} \times K_{R M S}$

Figure 15. Normalized Input Filter Capacitor Ripple Current

DESIGN EXAMPLE
Choose the component values for a 5.0 V to $1.6 \mathrm{~V}, 35 \mathrm{~A}$ converter with lossless current sensing, adaptive positioning and a 45 A current limit. The adaptive positioning is chosen 30 mV above the nominal $\mathrm{V}_{\text {OUT }}$ at no load and 40 mV below the no-load position with 35 A out. The peak output voltage transient is 70 mV max during a 32 A step current.

## Current Sensing, Power Stage and Output Filter Components

1. Assume $1.5 \mathrm{~m} \Omega$ of output filter ESR.
2. 

$$
\begin{aligned}
& \mathrm{R}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \frac{\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{IN}}}{\mathrm{~F} \times \mathrm{C} \times 25 \mathrm{mV}} \\
&=(5.0-1.6) \times \frac{1.6 / 5.0}{250 \mathrm{k} \times 0.01 \mu \mathrm{~F} \times 25 \mathrm{mV}} \\
&=17.4 \mathrm{k} \Omega \\
& \mathrm{~L} / \mathrm{R}_{\mathrm{L}}=.01 \mu \mathrm{~F} \times 17.47 \mathrm{k} \Omega=174 \mu \mathrm{~s} \\
& \mathrm{Choose} \mathrm{R}_{\mathrm{L}}=2.0 \mathrm{~m} \Omega \\
& \mathrm{~L}=2.0 \mathrm{~m} \Omega \times 174 \mu \mathrm{~s}=348 \mathrm{nH} \\
& \text { 3. } \mathrm{n} / \mathrm{a} \\
& \text { 4. }
\end{aligned}
$$

$$
\begin{aligned}
\text { PwrstgZ } & =R_{L} \times C S A \text { Gain } / 2.0 \\
& =2.0 \mathrm{~m} \Omega \times 3.15 / 2.0=3.1 \mathrm{~m} \Omega \\
\text { ConverterZ } & =\frac{\text { PwrstgZ } \times \mathrm{ESR}}{\text { PwrstgZ }+\mathrm{ESR}} \\
& =\frac{3.1 \mathrm{~m} \Omega \times 1.5 \mathrm{~m} \Omega}{3.1 \mathrm{~m} \Omega+1.5 \mathrm{~m} \Omega} \cong 1.0 \mathrm{~m} \Omega
\end{aligned}
$$

$$
\Delta \mathrm{VR}=1.0 \mathrm{~m} \Omega \times 32 \mathrm{~A}=32 \mathrm{mV}
$$

5. $\mathrm{n} / \mathrm{a}$

## Current Limit

6. 

$\mathrm{V}_{\mathrm{I}}(\mathrm{LIM})=\mathrm{R}_{\mathrm{L}} \times \operatorname{IOUT}(\mathrm{LIM})$ $\times$ CS to LLIM Gain
$=2.0 \mathrm{~m} \Omega \times 45 \mathrm{~A} \times 6.25$
$=562 \mathrm{mV}$

## Adaptive Positioning

7. 

RV(FB) $=$ NL Position/VFB Bias Current $=30 \mathrm{mV} / 6.0 \mu \mathrm{~A}=5.0 \mathrm{k} \Omega$
8.
$\Delta \mathrm{V}_{\mathrm{DRP}}=\mathrm{R}_{\mathrm{L}} \times$ IOUT
$\times$ Current Sense to VDRP Gain

$$
=2.0 \mathrm{~m} \Omega \times 35 \mathrm{~A} \times 3.0
$$

$$
=210 \mathrm{mV}
$$

$\mathrm{RV}(\mathrm{DRP})=\Delta \mathrm{V}_{\mathrm{DRP}} \times \mathrm{RV}(\mathrm{FB}) / \Delta \mathrm{V}_{\mathrm{OUT}}$ $=210 \mathrm{mV} \times 5.0 \mathrm{k} \Omega / 40 \mathrm{mV}$ $=26 \mathrm{k} \Omega$
9.
$\mathrm{I}_{\mathrm{IN}}=1.52 \mathrm{~V} \times \frac{41 \mathrm{~A}}{0.85 \times 12 \mathrm{~V} \mathrm{~N}}=6.1 \mathrm{~A}$
10.

Duty Cycle $=\frac{1.52 \mathrm{~V}}{0.85 \times 12 \mathrm{VIN}}=0.15$
11.

Apparent Duty Cycle $=0.15 \times 2.0=0.3$
12.

RMS ripple $=6.1 \mathrm{~A} \times 1.5=9.2 \mathrm{~A}$

## CS5303

## Three-Phase Buck Controller with Integrated Gate Drivers

The CS5303 is a three-phase step down controller which incorporates all control functions required to power high performance processors and high current power supplies. Proprietary multi-phase architecture guarantees balanced load current distribution and reduces overall solution cost in high current applications. Enhanced $\mathrm{V}^{2 \mathrm{TM}}$ control architecture provides the fastest possible transient response, excellent overall regulation, and ease of use.

The CS5303 multi-phase architecture reduces output voltage and input current ripple, allowing for a significant reduction in inductor values and a corresponding increase in inductor current slew rate. This approach allows a considerable reduction in input and output capacitor requirements, as well as reducing overall solution size and cost.

## Features

- Enhanced $\mathrm{V}^{2}$ Control Method
- 5-Bit DAC with $1.0 \%$ Accuracy
- Adjustable Output Voltage Positioning
- 6 On-Board Gate Drivers
- 200 kHz to 800 kHz Operation Set by Resistor
- Current Sensed through Buck Inductors, Sense Resistors, or V-S Control
- Hiccup Mode Current Limit
- Individual Current Limits for Each Phase
- On-Board Current Sense Amplifiers
- $3.3 \mathrm{~V}, 1.0 \mathrm{~mA}$ Reference Output
- 5.0 V and/or 12 V Operation
- On/Off Control (through COMP Pin)

Figure 1. Application Diagram, 12 V to 1.5 V, 60 A Converter

## ABSOLUTE MAXIMUM RATINGS*

|  | Rating | Value |
| :--- | :---: | :---: |
| Operating Junction Temperature | Unit |  |
| Lead Temperature Soldering: : | 150 | ${ }^{\circ} \mathrm{C}$ |
| Storage Temperature Range (SMD styles only) (Note 1 ) | 230 peak, | ${ }^{\circ}{ }^{\circ} \mathrm{C}$ |
| ESD Susceptibility (Human Body Model) | -65 to +150 | ${ }^{\circ}{ }^{\circ} \mathrm{C}$ |

1. 60 second maximum above $183^{\circ} \mathrm{C}$.
*The maximum package power dissipation must be observed.

## ABSOLUTE MAXIMUM RATINGS

| Pin Name | Pin Symbol | $\mathbf{V}_{\text {MAX }}$ | $\mathbf{V}_{\text {MIN }}$ | $\mathbf{I}_{\text {SOURCE }}$ | $\mathbf{I}_{\text {SINK }}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Power for logic and Gate(L)1 | $\mathrm{V}_{\text {CCLL1 }}$ | 16 V | -0.3 V | $\mathrm{~N} / \mathrm{A}$ | $1.5 \mathrm{~A}, 1.0 \mu \mathrm{~s} 200 \mathrm{~mA} \mathrm{DC}$ |
| Power for Gate(L)2 and Gate(L)3 | $\mathrm{V}_{\text {CCL23 }}$ | 16 V | -0.3 V | $\mathrm{~N} / \mathrm{A}$ | $1.5 \mathrm{~A}, 1.0 \mu \mathrm{~s} 200 \mathrm{~mA} \mathrm{DC}$ |
| Power for Gate(H)1 and Gate(H)2 | $\mathrm{V}_{\text {CCH12 }}$ | 20 V | -0.3 V | $\mathrm{~N} / \mathrm{A}$ | $1.5 \mathrm{~A}, 1.0 \mu \mathrm{~s} 200 \mathrm{~mA} \mathrm{DC}$ |
| Power Gate(H)3 | $\mathrm{V}_{\text {CCH3 }}$ | 20 V | -0.3 V | $\mathrm{~N} / \mathrm{A}$ | $1.5 \mathrm{~A}, 1.0 \mu \mathrm{~s} 200 \mathrm{~mA} \mathrm{DC}$ |

## ABSOLUTE MAXIMUM RATINGS (continued)

| Pin Name | Pin Symbol | $\mathrm{V}_{\text {MAX }}$ | $\mathrm{V}_{\text {MIN }}$ | Isource | $\mathrm{I}_{\text {SINK }}$ |

## PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| 28 Lead SO Wide | PIN SYMBOL | FUNCTION |
| 1 | COMP | Output of the error amplifier and input for the PWM comparators. |
| 2 | $V_{\text {FB }}$ | Voltage Feedback Pin. To use Adaptive Voltage Positioning (AVP) select an offset voltage at light load and connect a resistor between $V_{F B}$ and $V_{\text {OUT }}$. The input bias current of the $\mathrm{V}_{\mathrm{FB}}$ pin and the resistor value determine output voltage offset for zero output current. Short $\mathrm{V}_{\mathrm{FB}}$ to $\mathrm{V}_{\text {OUT }}$ for no AVP. |
| 3 | $\mathrm{V}_{\text {DRP }}$ | Current sense output for AVP. The offset of this pin above the DAC voltage is proportional to the output current. Connect a resistor from this pin to $\mathrm{V}_{\mathrm{FB}}$ to set amount AVP or leave this pin open for no AVP. |
| 4-6 | CS1-CS3 | Current sense amplifier inputs. Connect current sense network for the corresponding phase to each input. |
| 7 | $\mathrm{CS}_{\text {REF }}$ | Reference for current sense amplifiers. To balance input offset voltages between the inverting and noninverting inputs of the current sense amplifiers, connect a resistor between CS REF and the output voltage. The value should be $1 / 3$ of the value of the resistors connected to the CSx pins. |
| 8-12 | VID4-VID0 | Voltage ID DAC inputs. These pins are internally pulled up to 3.3 V if left open. |
| 13 | ILIM | Sets threshold for current limit. Connect to reference through a resistive divider. |

PACKAGE PIN DESCRIPTION (continued)

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| 28 Lead SO Wide | PIN SYMBOL | FUNCTION |
| 14 | REF | Reference output. Decouple with $0.1 \mu \mathrm{~F}$ to GndL2 |
| 15 | $\mathrm{V}_{\mathrm{CCH} 3}$ | Power for Gate(H)3. |
| 16 | Gate(H)3 | High side driver \#3. |
| 17 | Gnd3 | Return for \#3 drivers. |
| 18 | Gate(L)3 | Low side driver \#3. |
| 19 | $\mathrm{V}_{\text {CCL23 }}$ | Power for Gate(L)2 and Gate(L)3. |
| 20 | Gate(L)2 | Low side driver \#2. |
| 21 | GndL2 | Return for \#2 driver, internal control circuits and IC substrate connection. |
| 22 | Gate(H)2 | High side driver \#2. |
| 23 | $\mathrm{V}_{\mathrm{CCH} 12}$ | Power for Gate(H)1 and Gate(H)2. UVLO Sense for High Side Driver supply connects to this pin. |
| 24 | Gate(H)1 | High side driver \#1. |
| 25 | Gnd1 | Return for \#1 drivers. |
| 26 | Gate(L)1 | Low side driver \#1. |
| 27 | $\mathrm{V}_{\text {CCLL } 1}$ | Power for internal control circuits and Gate(L)1. UVLO Sense for Logic and Low Side Driver supply connects to this pin. |
| 28 | Rosc | A resistor from this pin to ground sets operating frequency and $\mathrm{V}_{\mathrm{FB}}$ bias current. |

## APPLICATIONS INFORMATION

## FIXED FREQUENCY MULTI-PHASE CONTROL

In a multi-phase converter, multiple converters are connected in parallel and are switched on at different times. This reduces output current from the individual converters and increases the apparent ripple frequency. Because several converters are connected in parallel, output current can ramp up or down faster than a single converter (with the same value output inductor) and heat is spread among multiple components.

The CS5303 uses a three-phase, fixed frequency, enhanced $\mathrm{V}^{2}$ architecture. Each phase is delayed $120^{\circ}$ from the previous phase. Normally GATE(H) transitions high at the beginning of each oscillator cycle. Inductor current ramps up until the combination of the current sense signal and the output ripple trip the PWM comparator and bring GATE(H) low. Once GATE(H) goes low, it will remain low until the beginning of the next oscillator cycle. While $\operatorname{GATE}(\mathrm{H})$ is high, the enhanced $\mathrm{V}^{2}$ loop will respond to line and load transients. Once GATE $(\mathrm{H})$ is low, the loop will not respond again until the beginning of the next cycle. Therefore, constant frequency enhanced $\mathrm{V}^{2}$ will typically respond within the off-time of the converter.

The enhanced $\mathrm{V}^{2}$ architecture measures and adjusts current in each phase. An additional input ( $\mathrm{C}_{\mathrm{X}}$ ) for inductor current information has been added to the $\mathrm{V}^{2}$ loop for each phase as shown in Figure 9.

Figure 9. Enhanced V ${ }^{2}$ Feedback and Current Sense Scheme

The inductor current is measured across $\mathrm{R}_{\mathrm{S}}$, amplified by CSA and summed with the OFFSET and Output Voltage at the non-inverting input of the PWM comparator. The inductor current provides the PWM ramp and as inductor current increases the voltage on the positive pin of the pwm
comparator rises and terminates the pwm cycle. If the inductor starts the cycle with a higher current the PWM cycle will terminate earlier providing negative feedback. The CS5303 provides a $\mathrm{C}_{\mathrm{X}}$ input for each phase, but the $\mathrm{CS}_{\mathrm{REF}}, \mathrm{V}_{\mathrm{FB}}$ and COMP inputs are common to all phases. Current sharing is accomplished by referencing all phases to the same $\mathrm{V}_{\mathrm{FB}}$ and COMP pins, so that a phase with a larger current signal will turn off earlier than phases with a smaller current signal.

Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. If the COMP pin is held steady and the inductor current changes there must also be a change in the output voltage. Or, in a closed loop configuration when the output current changes, the COMP pin must move to keep the same output voltage. The required change in the output voltage or COMP pin depends on the scaling of the current feedback signal and is calculated as

$$
\Delta \mathrm{V}=\mathrm{RS} \times \mathrm{CSA} \text { Gain } \times \Delta \mathrm{I}
$$

The single-phase power stage output impedance is;
Single Stage Impedance $=\Delta \mathrm{V} / \Delta \mathrm{I}=\mathrm{RS} \times$ CSA Gain.
The multi-phase power stage output impedance is the single-phase output impedance divided by the number of phases. The output impedance of the power stage determines how the converter will respond during the first few $\mu$ s of a transient before the feedback loop has repositioned the COMP pin.

The peak output current of each phase can also be calculated from;

$$
\text { Ipkout }(\text { per phase })=\frac{V_{C O M P}-V_{F B}-V_{O F F S E T}}{R_{S} \times C S A} \text { Gain }
$$

Figure 10 shows the step response of a single phase with the COMP pin at a fixed level. Before T1 the converter is in normal steady state operation. The inductor current provides the pwm ramp through the Current Share Amplifier. The pwm cycle ends when the sum of the current signal, voltage signal and OFFSET exceed the level of the COMP pin. At T1 the output current increases and the output voltage sags. The next pwm cycle begins and the cycle continues longer than previously while the current signal increases enough to make up for the lower voltage at the $\mathrm{V}_{\mathrm{FB}}$ pin and the cycle ends at T2. After T2 the output voltage remains lower than at light load and the current signal level is raised so that the sum of the current and voltage signal is the same as with the original load. In a closed loop system the COMP pin would move higher to restore the output voltage to the original level.

Figure 10. Open Loop Operation

## Inductive Current Sensing

For lossless sensing current can be sensed across the inductor as shown below in Figure 11. In the diagram L is the output inductance and $\mathrm{R}_{\mathrm{L}}$ is the inherent inductor resistance. To compensate the current sense signal the values of R1 and C 1 are chosen so that $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} 1 \times \mathrm{C} 1$. If this criteria is met the current sense signal will be the same shape as the inductor current, the voltage signal at Cx will represent the instantaneous value of inductor current and the circuit can be analyzed as if a sense resistor of value $R_{L}$ was used as a sense resistor $\left(\mathrm{R}_{\mathrm{S}}\right)$.

Figure 11. Lossless Inductive Current Sensing with Enhanced V ${ }^{2}$
When choosing or designing inductors for use with inductive sensing, tolerances and temperature effects should be considered. Cores with a low permeability material or a large gap will usually have minimal inductance change with temperature and load. Copper magnet wire has a temperature coefficient of $0.39 \%$ per ${ }^{\circ} \mathrm{C}$. The increase in winding resistance at higher temperatures should be
considered when setting the $\mathrm{I}_{\text {LIM }}$ threshold. If a more accurate current sense is required than inductive sensing can provide, current can be sensed through a resistor as shown in Figure 9.

## Current Sharing Accuracy

PCB traces that carry inductor current can be used as part of the current sense resistance depending on where the current sense signal is picked off. For accurate current sharing, the current sense inputs should sense the current at the same point for each phase and the connection to the $\mathrm{CS}_{\text {REF }}$ should be made so that no phase is favored. (In some cases, especially with inductive sensing, resistance of the pcb can be useful for increasing the current sense resistance.) The total current sense resistance used for calculations must include any pcb trace between the CS inputs and the $\mathrm{CS}_{\text {REF }}$ input that carries inductor current.

Current Sense Amplifier Input Mismatch and the value of the current sense element will determine the accuracy of current sharing between phases. The worst case Current Sense Amplifier Input Mismatch is 5 mV and will typically be within 3 mV . The difference in peak currents between phases will be the CSA Input Mismatch divided by the current sense resistance. If all current sense elements are of equal resistance a 3 mV mismatch with a $2 \mathrm{~m} \Omega$ sense resistance will produce a 1.5 A difference in current between phases.

## Operation at > 50\% Duty Cycle

For operation at duty cycles above $50 \%$ Enhanced V ${ }^{2}$ will exhibit subharmonic oscillation unless a compensation ramp is added to each phase. A circuit like the one on the left side of Figure 12 can be added to each current sense network to implement slope compensation. The value of R1 can be varied to adjust the ramp size.

Figure 12. External Slope Compensation Circuit

## Ramp Size and Current Sensing

Because the current ramp is used for both the PWM ramp and to sense current, the inductor and sense resistor values will be constrained. A small ramp will provide a quick transient response by minimizing the difference over which the COMP pin must travel between light and heavy loads, but a steady state ramp of $25 \mathrm{mV}_{\mathrm{P}-\mathrm{P}}$ or greater is typically required to prevent pulse skipping and minimize pulse width jitter. For resistive current sensing the combination of the inductor and sense resistor values must be chosen to provide a large enough steady state ramp. For large inductor values the sense resistor value must also be increased.

For inductive current sensing the RC network must meet the requirement of $L / R_{L}=R \times C$ to accurately sense the $A C$ and DC components of the current the signal. Again the values for L and $\mathrm{R}_{\mathrm{L}}$ will be constrained in order to provide a large enough steady state ramp with a compensated current sense signal. A smaller $L$, or a larger $R_{L}$ than optimum might be required. But unlike resistive sensing, with inductive sensing small adjustments can be made easily with the values of R and C to increase the ramp size if needed.

If RC is chosen to be smaller (faster) than $\mathrm{L} / \mathrm{R}_{\mathrm{L}}$, the AC portion of the current sensing signal will be scaled larger than the DC portion. This will provide a larger steady state ramp, but circuit performance will be affected and must be evaluated carefully. The current signal will overshoot during transients and settle at the rate determined by $\mathrm{R} \times \mathrm{C}$. It will eventually settle to the correct DC level, but the error will decay with the time constant of $\mathrm{R} \times \mathrm{C}$. If this error is excessive it will effect transient response, adaptive positioning and current limit. During transients the COMP pin will be required to overshoot along with the current signal in order to maintain the output voltage. The $\mathrm{V}_{\mathrm{DRP}}$ pin will also overshoot during transients and possibly slow the response. Single phase overcurrent will trip earlier than it would if compensated correctly and hiccup mode current limit will have a lower threshold for fast rise step loads than for slowly rising output currents.

The waveforms in Figure 13 show a simulation of the current sense signal and the actual inductor current during a positive step in load current with values of $\mathrm{L}=500 \mathrm{nH}$, $\mathrm{R}_{\mathrm{L}}=1.6 \mathrm{~m} \Omega, \mathrm{R} 1=20 \mathrm{k}$ and $\mathrm{C} 1=.01 \mu \mathrm{~F}$. For ideal current signal compensation the value of R1 should be $31 \mathrm{k} \Omega$. Due to the faster than ideal RC time constant there is an overshoot of $50 \%$ and the overshoot decays with a $200 \mu \mathrm{~s}$ time constant. With this compensation the $\mathrm{I}_{\text {LIM }}$ pin threshold must be set more than $50 \%$ above the full load current to avoid triggering hiccup mode during a large output load step.

Figure 13. Inductive Sensing waveform during a Step with Fast RC Time Constant ( $50 \mathrm{\mu s} / \mathrm{div}$ )

## Current Limit

Two levels of overcurrent protection are provided. Any time the voltage on a Current Sense pin exceeds CS REF by more than the Single Phase Pulse by Pulse Current Limit, the pwm comparator for that phase is turned off. This provides fast peak current protection for individual phases. The outputs of all the currents are also summed and filtered to compare an averaged current signal to the voltage on the I $_{\text {LIM }}$ pin. If this voltage is exceeded, the fault latch trips and the SS capacitor is discharged by a $5 \mu \mathrm{~A}$ source until the COMP pin reaches 0.2 V . Then soft-start begins. The converter will continue to operate in this mode until the fault condition is corrected.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as a result of the normal operation of the enhanced $\mathrm{V}^{2}$ control topology with synchronous rectifiers. The control loop responds to an overvoltage condition within 400 ns , causing the top MOSFET's to shut off, and the synchronous MOSFET's to turn on. This results in a "crowbar" action to clamp the output voltage and prevents damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low.

## Transient Response and Adaptive Positioning

For applications with fast transient currents the output filter is frequently sized larger than ripple currents require in
order to reduce voltage excursions during transients. Adaptive voltage positioning can reduce peak-peak output voltage deviations during load transients and allow for a smaller output filter. The output voltage can be set higher at light loads to reduce output voltage sag when the load current is stepped up and set lower during heavy loads to reduce overshoot when the load current is stepped up. For low current applications a droop resistor can provide fast accurate adaptive positioning. However at high currents, the loss in a droop resistor becomes excessive. For example; in a 50 A converter a $1 \mathrm{~m} \Omega$ resistor to provide a 50 mV change in output voltage between no load and full load would dissipate 2.5 Watts.

Lossless adaptive positioning is an alternative to using a droop resistor, but must respond quickly to changes in load current. Figure 14 shows how adaptive positioning works. The waveform labeled normal shows a converter without adaptive positioning. On the left, the output voltage sags when the output current is stepped up and later overshoots when current is stepped back down. With fast (ideal) adaptive positioning the peak to peak excursions are cut in half. In the slow adaptive positioning waveform the output voltage is not repositioned quickly enough after current is stepped up and the upper limit is exceeded.

Figure 14. Adaptive Positioning
The CS5303 uses two methods to provide fast and accurate adaptive positioning. For low frequency positioning the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{DRP}}$ pins are used to adjust the output voltage with varying load currents. For high frequency positioning, the current sense input pins can be used to control the power stage output impedance. The transition between fast and slow positioning is adjusted by the error amp compensation.

The CS5303 can be configured to adjust the output voltage based on the output current of the converter. The adaptive positioning circuit is designed to select the DAC setting as the maximum output voltage. (Refer to Application Diagram on page 2294.)

To set the no-load positioning a resistor (R9) is placed between the output voltage and $\mathrm{V}_{\mathrm{FB}}$ pin. The $\mathrm{V}_{\mathrm{FB}}$ bias current will develop a voltage across the resistor to decrease the output voltage. The $\mathrm{V}_{\mathrm{FB}}$ bias current is dependent on the value of ROSC. See Figure 4 on the datasheet.

During no load conditions the $\mathrm{V}_{\text {DRP }}$ pin is at the same voltage as the $\mathrm{V}_{\mathrm{FB}}$ pin, so none of the $\mathrm{V}_{\mathrm{FB}}$ bias current flows through the $\mathrm{V}_{\mathrm{DRP}}$ resistor (R8). When output current
increases the $\mathrm{V}_{\mathrm{DRP}}$ pin increases proportionally and the $\mathrm{V}_{\text {DRP }}$ pin current offsets the $\mathrm{V}_{\mathrm{FB}}$ bias current and causes the output voltage to further decrease.

The $V_{\text {FB }}$ and $V_{\text {DRP }}$ pins take care of the slower and DC voltage positioning. The first few $\mu \mathrm{s}$ are controlled primarily by the ESR and ESL of the output filter. The transition between fast and slow positioning is controlled by the ramp size and the error amp compensation. If the ramp size is too large or the error amp too slow there will be a long transition to the final voltage after a transient. This will be most apparent with lower capacitance output filters.

Note: Large levels of adaptive positioning can cause pulse width jitter.

## Error Amp Compensation

The transconductance error amplifier can be configured to provide both a slow soft-start and a fast transient response. C4 in the main applications diagram controls soft-start. A $0.1 \mu \mathrm{~F}$ capacitor with the $30 \mu \mathrm{~A}$ error amplifier output capability will allow the output to ramp up at $0.3 \mathrm{~V} / \mathrm{ms}$ or 1.5 V in 5 ms .

R10 is connected in series with C 4 to allow the error amplifier to slew quickly over a narrow range during load transients. Here the $30 \mu \mathrm{~A}$ error amplifier output capability works against $10 \mathrm{k} \Omega$ (R10) to limit the window of fast slewing too 300 mV - enough to allow for fast transients, but not enough to interfere with soft-start. This window will be noticeable as a step in the COMP pin voltage at start-up. The size of this step must be kept smaller than the Channel Start-Up Offset (nominally 0.4 V ) for proper soft-start operation. If adaptive positioning is used the R9 and R8 form a divider with the $\mathrm{V}_{\mathrm{DRP}}$ end held at the DAC voltage during start-up, which effectively makes the Channel Start-Up Offset larger.
C12 is included for error amp stability. A capacitive load is required on the error amp output. Use of values less than 1 nF may result in error amp oscillation of several MHz .
C 11 and the parallel resistance of the $\mathrm{V}_{\mathrm{FB}}$ resistor (R9) and the $\mathrm{V}_{\mathrm{DRP}}$ resistor (R8) are used to roll off the error amp gain. The gain is rolled off at a high enough frequency to give a quick transient response, but low enough to cross zero dB well below the switching frequency to minimize ripple and noise on the COMP pin.

## UVLO

The CS5303 has undervoltage lockout functions connected to two pins. One intended for the logic and low-side drivers with a 4.4 V turn-on threshold is connected to the $\mathrm{V}_{\text {CCLL1 }}$ pin. A second for the high side drivers has a 2 V threshold and is connected to the $\mathrm{V}_{\mathrm{CCH} 12}$ pin.

The UVLO threshold for the high side drivers was chosen at a low value to allow for flexibility in the part and an input voltage as low as 3.3 V. In many applications this will be disabled or will only check that the applicable supply is on - not that it is at a high enough voltage to run the converter.

For the $12 \mathrm{~V}_{\text {IN }}$ converter in the application diagram on page 2294 the UVLO pin for the high side driver is pulled up by the 5 V supply (through two diode drops) and the function is not used. The diode between the COMP pin and the 12 V supply holds the COMP pin near Gnd and prevents start-up while the 12 V supply is off. In an application where a higher UVLO threshold is necessary a circuit like the one in Figure 15 will lock out the converter until the 12 V supply exceeds 9 V .

Figure 15. External UVLO Circuit

## Layout Guidelines

With the fast rise, high output currents of microprocessor applications parasitic inductance and resistance should be considered when laying out the power, filter and feedback signal sections of the board. Typically a multi-layer board with at least one ground plane is recommended. If the layout is such that high currents can exist in the ground plane underneath the controller or control circuitry, the ground plane can be slotted to reroute the currents away from the controller. The slots should typically not be placed between the controller and the output voltage or in the return path of the gate drive. Additional power and ground planes or islands can be added as required for a particular layout.

Output filter components should be placed on wide planes connected directly to the load to minimize resistive drops during heavy loads and inductive drops and ringing during transients. If required, the planes for the output voltage and return can be interleaved to minimize inductance between the filter and load.

Voltage feedback should be taken from a point of the output or the output filter that doesn't favor any one phase. If the feedback connection is closer to one inductor than the others the ripple associated with that phase may appear larger than the ripple associated with the other phases and poor current sharing can result.

The current sense signal is typically tens of milli-volts. Noise pick-up should be avoided wherever possible. Current feedback traces should be routed away from noisy areas such as switch nodes and gate drive signals. The paths should be matched as well as possible. It is especially important that all current sense signals be picked off at similar points for accurate current sharing. If the current signal is taken from a place other than directly at the inductor
any additional resistance between the pick-off point and the inductor appears as part of the inherent inductor resistance and should be considered in design calculations. Capacitors for the current feedback networks should be placed as close to the current sense pins as practical.

## DESIGN PROCEDURE

## Current Sensing, Power Stage and Output Filter Components

1. Choose the output filter components to meet peak transient requirements. The formula below can be used to provide an approximate starting point for capacitor choice, but will be inadequate to calculate actual values.

$$
\Delta \mathrm{V}_{\mathrm{PEAK}}=(\Delta \mathrm{I} / \Delta \mathrm{T}) \times \mathrm{ESL}+\Delta \mathrm{I} \times \mathrm{ESR}
$$

Ideally the output filter should be simulated with models including ESR, ESL, circuit board parasitics and delays due to switching frequency and converter response. Typically both bulk capacitance (electrolytic, Oscon, etc,) and low impedance capacitance (ceramic chip) will be required. The bulk capacitance provides "hold up" during the converter response. The low impedance capacitance reduces steady state ripple and bypasses the bulk capacitance during slewing of output current.
2. For inductive current sensing (only) choose the current sense network RC to provide a 25 mV minimum ramp during steady state operation.

$$
\mathrm{R}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \frac{\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{IN}}}{\mathrm{~F} \times \mathrm{C} \times 25 \mathrm{mV}}
$$

Then choose the inductor value and inherent resistance to satisfy $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} \times \mathrm{C}$.
For ideal current sense compensation the ratio of L and $R_{L}$ is fixed, so the values of $L$ and $R_{L}$ will be a compromise typically with the maximum value $R_{L}$ limited by conduction losses or inductor temperature rise and the minimum value of $L$ limited by ripple current.
3. For resistive current sensing choose $L$ and $R_{S}$ to provide a steady state ramp greater than 25 mV .

$$
\mathrm{L} / \mathrm{RS}_{\mathrm{S}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{T} \mathrm{ON} / 25 \mathrm{mV}
$$

Again the ratio of L and $\mathrm{R}_{\mathrm{L}}$ is fixed and the values of L and $\mathrm{R}_{\mathrm{S}}$ will be a compromise.
4. Calculate the high frequency output impedance (ConverterZ) of the converter during transients. This is the impedance of the Output filter ESR in parallel with the power stage output impedance (PwrstgZ) and will indicate how far from the original level ( $\Delta \mathrm{VR}$ ) the output voltage will typically recover to within one switching cycle. For a good transient response $\Delta \mathrm{VR}$ should be less than the peak output voltage overshoot or undershoot.

$$
\begin{array}{r}
\Delta V R=\text { ConverterZ } \times \text { ESR } \\
\text { ConverterZ }=\frac{\text { PwrstgZ } \times \text { ESR }}{\text { PwrstgZ }+ \text { ESR }}
\end{array}
$$

where:

$$
\text { PwrstgZ }=\text { RS } \times \text { CSA Gain } / 3
$$

Multiply the converterZ by the output current step size to calculate where the output voltage should recover to within the first switching cycle after a transient. If the ConverterZ is higher than the value required to recover to where the adaptive positioning is set the remainder of the recovery will be controlled by the error amp compensation and will typically recover in $10-20 \mu \mathrm{~s}$.

$$
\Delta \mathrm{VR}=\Delta \mathrm{I} \mathrm{OUT} \times \text { ConverterZ }
$$

Make sure that $\Delta \mathrm{VR}$ is less than the expected peak transient for a good transient response.
5. Adjust L and $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ as required to meet the best combination of transient response, steady state output voltage ripple and pulse width jitter.

## Current Limit

When the sum of the Current Sense amplifiers ( $\mathrm{V}_{\text {ITOTAL }}$ ) exceeds the voltage on the $\mathrm{I}_{\text {LIM }}$ pin the part will enter hiccup mode. For inductive sensing the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the inductor resistance (or current sense resistor) at max temperature and max current. To set the level of the $I_{\text {LIM }}$ pin:
6. $\mathrm{V}_{\mathrm{I}(\mathrm{LIM})}=\mathrm{R} \times \operatorname{IOUT}(\mathrm{LIM}) \times \mathrm{CS}$ to ILIM Gain
where:
R is $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$;
$\mathrm{I}_{\mathrm{OUT}(\mathrm{LIM})}$ is the current limit threshold.
For the overcurrent to work properly the inductor time constant (L/R) should be $\leq$ the Current sense RC. If the RC is too fast, during step loads the current waveform will appear larger than it is (typically for a few hundred $\mu \mathrm{s}$ ) and may trip the current limit at a level lower than the DC limit.

## Adaptive Positioning

7. To set the amount of voltage positioning below the DAC setting at no load connect a resistor $\left(\mathrm{R}_{\mathrm{V}}(\mathrm{FB})\right)$ between the output voltage and the $\mathrm{V}_{\mathrm{FB}}$ pin. Choose $\mathrm{R}_{\mathrm{V}}(\mathrm{FB})$ as:

$$
R \mathrm{~V}(\mathrm{FB})=\mathrm{NL} \text { Position/VFB Bias Current }
$$

See Figure 4 for $\mathrm{V}_{\mathrm{FB}}$ Bias Current.
8. To set the difference in output voltage between no load and full load, connect a resistor ( $\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}$ ) between the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pins. $\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}$ can be calculated in two steps. First calculate the difference between the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pin at full load. (The $\mathrm{V}_{\mathrm{FB}}$ voltage should be the same as the DAC voltage during closed loop operation.) Then choose the $\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}$ to source enough current across $\mathrm{R}_{\mathrm{V}}(\mathrm{FB})$ for the desired change in output voltage.

$$
\Delta \mathrm{V}_{\mathrm{V}(\mathrm{DRP})}=\mathrm{I}_{\mathrm{OUTFL}} \times \mathrm{R} \times \mathrm{CS} \text { to } \mathrm{V}_{\mathrm{DRP}} \text { Gain }
$$

where:
$R=R_{L}$ or $R_{S}$ for one phase;
$\mathrm{I}_{\text {OUTFL }}$ is the full load output current.

$$
\mathrm{RV}(\mathrm{DRP})=\Delta \mathrm{V}_{\mathrm{DRP}} \times \mathrm{RV}(\mathrm{FB}) / \Delta \mathrm{V}_{\mathrm{OUT}}
$$

## DESIGN EXAMPLE

Choose the component values for lossless current sensing, adaptive positioning and current limit for a 60 A converter. The adaptive positioning is chosen 50 mV below the maximum V position with 60 A out. The peak output voltage transient is 100 mV max during a 60 A step current. The overcurrent limit is nominally 75 A .

## Current Sensing, Power Stage and Output Filter Components

1. Assume $1.5 \mathrm{~m} \Omega$ of output filter ESR.

$$
\begin{aligned}
& \text { 2. } \mathrm{R}=\left(\mathrm{V} \text { IN }-\mathrm{V}_{\text {OUT }}\right) \times\left(\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{IN}}\right) /(\mathrm{F} \times \mathrm{C} \times 25 \mathrm{mV}) \\
& =(12-1.5) \times(1.5 / 12) /(250 \mathrm{k} \times .01 \mu \mathrm{~F} \times 25 \mathrm{mV}) \\
& =21 \mathrm{k} \Omega \Rightarrow \text { Choose } 20 \mathrm{k} \Omega \\
& \mathrm{~L} / \mathrm{R}_{\mathrm{L}}=.01 \mu \mathrm{~F} \times 20 \mathrm{k} \Omega=200 \mu \mathrm{~s} \\
& \text { Choose } R_{L}=2 \mathrm{~m} \Omega \\
& \mathrm{~L}=2 \mathrm{~m} \Omega \times 200 \mu \mathrm{~s}=400 \mathrm{nH} \\
& \text { 3. } \mathrm{n} / \mathrm{a} \\
& \text { 4. PwrstgZ }=R_{L} \times \text { CSA Gain } / 3 \\
& =1.5 \mathrm{~m} \Omega \times 4.2 / 3=2.1 \mathrm{~m} \Omega \\
& \text { ConverterZ }=\frac{\text { PwrstgZ } \times \text { ESR }}{\text { PwrstgZ }+ \text { ESR }} \\
& =\frac{2.8 \mathrm{~m} \Omega \times 1.5 \mathrm{~m} \Omega}{2.8 \mathrm{~m} \Omega+1.5 \mathrm{~m} \Omega} \cong 1 \mathrm{~m} \Omega \\
& \Delta \mathrm{VR}=1.2 \mathrm{~m} \Omega \times 60 \mathrm{~A}=60 \mathrm{mV}
\end{aligned}
$$

5. n/a

## Current Limit

6. $\begin{aligned} \mathrm{V}_{\mathrm{I}(\mathrm{LIM})} & =\mathrm{R}_{\mathrm{L}} \times \operatorname{IOUT}(\mathrm{LIM}) \times \mathrm{CS} \text { to ILIM Gain } \\ & =1.5 \mathrm{~m} \Omega \times 75 \mathrm{~A} \times 6.5=731 \mathrm{mV}\end{aligned}$

## Adaptive Positioning

7. $\mathrm{RV}(\mathrm{FB})=$ NL Position $/ \mathrm{V}$ FB Bias Current

$$
=50 \mathrm{mV} / 19 \mu \mathrm{~A}=2.63 \mathrm{k} \Omega
$$

## CS5305

## Three-Phase Synchronous Switching Step-Down Controller with Single Wire Current Sharing

The CS5305 provides a low-cost, single-controller solution for the low-voltage, high-current power needs of next-generation workstation and server processors. This IC provides high accuracy and the industry's fastest transient response, reducing the need for large banks of output capacitors and providing the most compact, reliable, and economical power supply.

Since each phase's output voltage and current feed back to develop the PWM ramp signal (enhanced $\mathrm{V}^{2 \mathrm{TM}}$ control), the CS5305 shares output current accurately between phases. Accurate current sharing means that the power supply design does not need to use power components rated to handle mismatched current per phase. The enhanced $\mathrm{V}^{2}$ control compensates for variations in both line and load.

The IC's built-in single wire current sharing capability allows easy paralleling of multiple Voltage Regulator Modules (VRMs) based on the CS5305. The paralleled VRMs use a shared bus to provide high current and high reliability to multiple microprocessor workstations or servers.

The CS5305 meets VRM 9.x specifications with its Power Good, Enable, Differential Remote Sense, and single-wire Current Share features. The product fits server and workstation VRMs, and can be used to power Embedded Processors. The IC provides the simplest, lowest-cost solution for any low voltage, high current power supply.

## Features

- Enhanced $V^{2}$ Control Method
- VRM 9.x Compatible VID Codes
- Lossless Inductor Current Sensing
- Single Wire Active Current Sharing Between Converters
- Auto Master-Slave Current Share Control Method
- Programmable 200 to 800 kHz Switching Frequency
- Programmable Adaptive Voltage Positioning
- Differential Remote Sense
- Pulse-by-Pulse Current Limit
- Master Hiccup Overcurrent Protection through Single

Wire Share Bus

- 5-Bit DAC with $1 \%$ Tolerance
- ENABL Input
- VRM 9.x-Compliant Power Good Output
- Active Current Sharing During Soft Start

## PACKAGE PIN DESCRIPTION

| Package Pin Number |  |  |  |
| :---: | :---: | :---: | :---: |
| SO-28L | Pin Symbol | Pin Name | Function |
| 1 | OCSET | Over-Current Set | Resistor divider from R RSC to GND programs the threshold of the hiccup over-current protection. |
| 2 | Rosc | Oscillator Frequency Adjust | Resistance to GND programs the oscillator frequency. It also programs the $\mathrm{V}_{\mathrm{FB}}$ bias current shown in Figure 5. |
| 3 | ENABL | Enable Input | TTL-Compatible logic input with $50 \mathrm{k} \Omega$ internal pull-up resistor to 3.3 V . A logic low puts the IC in FAULT mode. |
| 4-6 | CS1-3 | Current Sense Inputs | Non-inverting inputs to the current sense amplifiers. |
| 7 | $\mathrm{CS}_{\text {REF }}$ | Current Sense Reference | Inverting input to the current sense amplifiers, and fast feedback input to the PWM comparator. |
| 8 | $\mathrm{I}_{\text {FB }}$ | Share Current Amp Inverting Input | Inverting input to share current amp. Connect resistor divider between $\mathrm{I}_{\mathrm{OUT}}, \mathrm{I}_{\mathrm{FB}}$, and IC GND pin 28 to program Share Current Amp gain. |
| 9 | IOUT | Share Current Amp Output | Share current amplifier output and input to share adjust amplifier. |
| 10 | SHARE | Share Bus | Connect with other modules for single-wire current sharing. |
| 11 | SCOMP | Share Compensation | Connect compensation network to stabilize share loop. |
| 12 | $\mathrm{V}_{\text {DRP }}$ | Current Sense Output for AVP | The offset of this pin above the DAC voltage is proportional to the output current. Connect a resistor from this pin to $\mathrm{V}_{\mathrm{FB}}$ to program the AVP voltage or leave this pin open for no AVP. |
| 13 | $V_{\text {FB }}$ | Voltage Feedback | Error Amp inverting input. Input bias current used to program AVP light load offset via resistor connected to converter output voltage. Short $\mathrm{V}_{\mathrm{FB}}$ to the converter output voltage for no AVP. |
| 14 | COMP | Error Amp Output and PWM Comparator Input | Provides loop compensation. Also used to control Softstart and Fault timing. |
| 15 | PWRGD | Power Good Output | Open collector output goes low when $\mathrm{V}_{\mathrm{FB}}$ is out of regulation. User must externally limit current into this pin to less than 20 mA . |
| 16-20 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID }}$ | Voltage ID DAC Inputs | Programs Output Voltage. $50 \mathrm{k} \Omega$ internal pull-up resistors to 3.3 V . |
| 21 | PWRGDS | Power Good Sense | Provides remote output voltage sensing. |
| 22 | SGND | Reference Ground | Ground connection for the DAC. Provides remote sensing of ground at the load. |
| 23 | $\mathrm{V}_{\mathrm{Cc}}$ | Supply Input | IC Power Supply Input. |
| 24 | DRVON | Driver Enable | Logic High enables outputs of compatible MOSFET Driver ICs. Low turns all MOSFETs OFF. Pin driven from internal $5.5 \mathrm{~V} ; 70 \mathrm{k} \Omega$ internal resistor to GND. |
| 25-27 | GATE 3-1 | FET Driver Outputs | PWM Signal Input to external MOSFET Gate Driver ICs. |
| 28 | GND | Ground | IC Power Supply Return; connected to IC substrate. |

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## Fixed Frequency Multi-phase Control

Multi-phase CPU controllers include the necessary control circuitry to implement several buck converters in parallel. These converters are configured to turn on at different times. This allows much higher output current than could be provided by a single converter. The apparent ripple frequency is increased and so output current can ramp up or down faster than a single converter with the same value of output inductor. Heat is also spread among multiple components.

The CS5305 uses a fixed frequency, Enhanced V ${ }^{2}$ architecture. Each phase is delayed by approximately $120^{\circ}$ from the previous phase. The GATE output for each channel changes to a logic high at the beginning of its oscillator cycle. Inductor current ramps up until the combination of the current sense signal and the output ripple trip the PWM comparator, at which time the GATE output changes to a logic low. Once low, the GATE output remains low until the next oscillator cycle begins, and the control loop will not respond until that time. The Enhanced $V^{2}$ control loop will respond to line and load transients while the GATE output is high. Enhanced V ${ }^{2}$ control will respond within the off time of the converter.

Figure 27.
The Enhanced $\mathrm{V}^{2}$ architecture measures and adjusts current in each phase. An additional input (CSx pin) provides current information for each output phase to the control loop as shown in Figure 27. Inductor current is measured across capacitor Ccsx. The voltage across this capacitor is equal to the product of the output current and the inductor ESR if these components are chosen such that $(\operatorname{Ccsx})(\operatorname{Rcsx})=(\mathrm{L}) / \mathrm{ESR}_{\mathrm{L}}$. This signal is buffered by the current sense amplifier (unity gain in the CS5305) and summed with an offset voltage before it is presented as input to non-inverting input of the PWM comparator. Inductor current provides the PWM ramp. As inductor current
increases, the voltage at the positive input to the PWM comparator rises and terminates the PWM cycle. If the inductor starts the next cycle with higher current, the PWM cycle terminates earlier, thus providing negative feedback. A CSx input is provided for each channel, but the $\mathrm{CS}_{\text {REF }}$, $\mathrm{V}_{\mathrm{FB}}$ and COMP inputs are common to all phases. Current sharing between phases is accomplished by referencing all phases to the same error amplifier. Any phase with a larger current signal will turn off earlier than the channels with a lower current signal.
Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. In the absence of any load current, the COMP pin voltage will be equal to the sum of the output voltage, the offset voltage and half of the steady-state ramp voltage. (At no load, the output ripple current's positive and negative contributions are equal, and the DC averaged voltage is equal to half the ripple voltage.) If the COMP pin is held steady and the inductor current is forced to change, the output voltage will also change. In a closed-loop situation, changing the inductor current will force the COMP voltage to change so the output voltage can remain the same. The change in COMP voltage depends on the scaling of the current feedback signal, and can be defined as:

## $\Delta \mathrm{V}_{\mathrm{COMP}}=(\mathrm{ESRL})($ Current Sense Gain $)(\Delta \mathrm{I}$ PHASE $)$

Since the current sense gain for this loop is unity, this equation reduces to:

$$
\Delta \mathrm{V}_{\mathrm{COMP}}=\left(\mathrm{ESR}_{\mathrm{L}}\right)(\Delta \mathrm{IPHASE})
$$

and so the single-phase power stage output impedance is:

$$
\Delta \mathrm{V}_{\mathrm{COMP}} / \Delta \mathrm{IPHASE}=\mathrm{ESR} \mathrm{~L}
$$

The CS5305 has three phases, so the total power stage output impedance is then $\mathrm{ESR}_{\mathrm{L}} / 3$.

## Lossless Inductive Current Sensing

Current can be sensed across the inductor as shown in Figure 27. The output inductor is designated L and the inductor's equivalent series resistance is designated $\mathrm{ESR}_{\mathrm{L}}$. In the ideal case, the values of Rcsx and Ccsx are chosen such that $\left(\mathrm{L} / \mathrm{ESR}_{\mathrm{L}}\right)=(\operatorname{Rcsx})(\mathrm{Ccsx})$. If this criterion is met, the current sense signal will have the same shape as the inductor current, and the circuit can be analyzed as if a sense resistor with value equal to $\mathrm{ESR}_{\mathrm{L}}$ was placed in series with the inductor. However, these components also determine the ramp signal that is used to prevent pulse skipping and duty cycle jitter. Choosing (Rcsx)(Ccsx) < (L/ESR ${ }_{L}$ ) will result in the AC portion of the current sense signal being scaled more than the DC portion. This results in a larger ramp signal, but the current signal will overshoot during transients. This will affect transient response, adaptive voltage positioning and current limit. The COMP pin voltage will overshoot along with the current signal in order to maintain the output voltage. The COMP voltage will
eventually find the correct level for regulation, but the error will decay with the time constant $(\operatorname{Rcsx})(\mathrm{Ccsx})$. The $\mathrm{V}_{\mathrm{DRP}}$ voltage will also overshoot and response will be slowed, since the current signal is a component of that voltage. The single phase current limit will trip earlier since the current signal appears larger than it should be, and the module current limit will have a lower threshold for fast transients than it will for slow transients. Additional external components in the droop circuit and in the error amp compensation will correct this condition. Details are provided in the data sheet section on choosing external components.

## Adaptive Voltage Positioning

Adaptive voltage positioning is a technique used to reduce peak-to-peak output deviations during output current transients. The output voltage is set higher than nominal at light loads to reduce output voltage sag when load current is suddenly increased. Similarly, output voltage is set lower than nominal at heavy loads to reduce overshoot when load current suddenly decreases. The CS5305 implements adaptive voltage positioning by placing a resistor divider between $\mathrm{V}_{\text {DRP }}$ and $\mathrm{V}_{\text {OUT }}$. The center tap of the divider connects to $\mathrm{V}_{\mathrm{FB}}$. These resistors, along with two or three other external components, implement a lossless droop voltage function.

Past implementations of adaptive voltage positioning used a droop resistor. This resistor was placed in series between the regulation point of the output voltage and the load. Increasing the current to the load caused the voltage at the load to droop below the regulation point. The amount of droop was equal to the change in current multiplied by the droop resistor value. This method was acceptable for low values of output current, where the droop resistor provided a minimal change in voltage without dissipating a great deal of power. Higher output current levels and tighter droop voltage requirements in today's microprocessors have rendered this droop resistor technique unusable. The lossless technique solves these problems.

The AVP function addresses DC and slow transient output voltage positioning. Response during the first few hundreds of nanoseconds of a transient are addressed primarily by the power stage output impedance, and the ESR and ESL of the output filter. The ramp size and the error amplifier compensation control the transition between these two regions. If ramp size is too large or the error amp is too slow, there will be a long transition to the final voltage after a transient. This will be most apparent if the output capacitance is low.

Figure 28 shows how adaptive positioning works. The waveform labeled "normal" shows output voltage for a converter without adaptive voltage positioning. The voltage sags when current steps up, returns to its nominal value and then overshoots when the current load is decreased. Using a slow adaptive positioning circuit can actually worsen performance. The slow adaptive positioning waveform above shows the output voltage sag, but the voltage recovers to its initial value before the adaptive positioning circuit
becomes active. When the load decreases, the overshoot causes the output voltage to exceed the upper limit. The fast adaptive positioning waveform shows how AVP can reduce transient voltage requirements by about one half compared to a "normal" converter.

Figure 28. Adaptive Positioning

## Current Limit

The CS5305 features two separate current limit circuits. First, the per-phase current limit terminates topside switch conduction in a phase if the voltage between any CSx pin and $\mathrm{CS}_{\text {REF }}$ exceeds a typical value of 90 mV . This provides fast peak current protection for individual phases. In addition, the output current signals for all three phases are summed and filtered to provide an average module current signal. This signal is compared to a voltage that is user-programmable. If this voltage is exceeded, the fault latch is set and the COMP capacitor is discharged by a $5 \mu \mathrm{~A}$ current sink until the COMP voltage falls below 0.2 V . The soft-start cycle begins when this threshold is reached, and the converter will operate in hiccup-mode until the overcurrent condition is cleared.

## Error Amplifier

The CS5305 uses the Enhanced $\mathrm{V}^{2}$ control method to offer the fastest and most accurate regulation available. One of the features of this control method is ease of error amplifier compensation. A single capacitor placed from the COMP pin to ground is sufficient to adequately stabilize the error amplifier.

Figure 29. Error Amplifier Frequency Response with No Compensation

Figure 30. Error Amplifier Frequency Response with $0.1 \mu \mathrm{~F}$ Capacitor

## Soft Start/Hiccup Mode

At initial power-up, the COMP voltage is zero. The total COMP capacitance will begin to charge with a typical current of $30 \mu \mathrm{~A}$. (There may be more than one capacitor connected between COMP and ground depending on the adaptive voltage positioning compensation.) All GATE outputs are held low until the COMP voltage reaches 0.6 V . Once this threshold is reached, the GATE outputs are released to operate normally. In hiccup-mode, this will result in GATE pulses being generated until the module overcurrent condition reoccurs, and the discharge/Soft Start cycle begins anew.

## Undervoltage Lockout

The CS5305 includes an under-voltage lockout circuit. This circuit disables the output drivers until $\mathrm{V}_{\mathrm{CC}}$ applied to the IC reaches a typical value of 9 V . The GATE outputs are disabled when $\mathrm{V}_{\mathrm{CC}}$ drops below 8 V typical.

## Enable

The CS5305 has a dedicated enable pin, in accordance with the latest VRM specifications. This pin is internally pulled up to a 3.3 V rail through a blocking diode and a $50 \mathrm{k} \Omega$ resistor. The blocking diode allows external pull up to a bias voltage greater than 3.3 V but below 13 V .

## Fault Protection Logic

The CS5305 is equipped with sophisticated fault-detection and protection circuitry to ensure proper operation in a paralleled VRM environment. In such an environment, any one of several distinct failures could not only destroy the VRM that sees the fault, but also those VRMs that are connected in parallel with the faulted VRM.
Table 1 describes the fault logic circuitry, shown below in Figure 31.

Figure 31. Fault Logic Circuitry

Table 1. Description of Fault Logic

| Fault Modes | Stop Switching | DRVON Level | PWRGD <br> Level | SHARE | Controller Off | COMP Pin Characteristics | Reset Method |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Under Voltage Lockout | yes | low | low via Power Good window comparator | n/a | no | $-5.0 \mu \mathrm{~A}$ | Comp < 0.2 V |
| VID $=11111$ | yes | low | low via Power Good window comparator | n/a | no | $-5.0 \mu \mathrm{~A}$ | Comp < 0.2 V |
| Enable Low | yes | Iow | low | n/a | no | $-5.0 \mu \mathrm{~A}$ | Comp<0.2 V |
| Module Over Current (set by OCSET) | yes | low | Iow via Power Good window comparator | > 3.8 V | no | $-5.0 \mu \mathrm{~A}$ | Comp < 0.2 V |
| Phase Over Current (0.33 V limit) | terminate pulse | high | n/a | n/a | no | not affected | not affected |
| External Share Fault (SHARE > 3.8 V ) | yes | low | Iow via Power Good window comparator | $\mathrm{n} / \mathrm{a}$ | no | -2.5 mA | remove external 3.8 V from SHARE |
| PWRGDS out of window range | no | high | low | n/a | no | not affected | not affected |

## Gate Outputs

The CS5305 is designed to operate with external gate drivers. Accordingly, the gate outputs are capable of driving a 100 pF load with typical rise and fall time of 15 ns .

## DRVON

When the CS5305 is used with DRVON-compatible gate drivers, the ability of the system to survive a fault in a paralleled environment is greatly increased. The DRVON signal tells the gate drivers to shut off both FETs while entering a fault condition. This action takes the faulted VRM "out of the picture," allowing the system to operate until the bad module can be replaced.

## Digital to Analog Converter (DAC)

The output voltage of the CS5305 module is set by means of a $5-\mathrm{bit}, 1 \% \mathrm{DAC}$. The DAC pins are internally pulled up to a 3.3 V rail through a blocking diode and a set of $50 \mathrm{k} \Omega$ resistors. The blocking diode allows external pull up to a bias voltage greater than 3.3 V and less than 13 V .

The output of the DAC is described in the Electrical Characteristics section of the datasheet. These outputs are consistent with the latest VRM specifications. The DAC produces an output voltage 125 mV lower than the VID code would indicate in order to produce an accurate PWRGD output. The relationship between the VID code and the DAC code is described by Figure 32 shown below. The shaded area shows the acceptable range of output voltages.

In order to produce a workable VRM using the CS5305, the designer is expected to use AVP as described earlier to position the output voltage above the DAC output, resulting in an output voltage somewhere in the middle of the acceptable range.

Figure 32. VRM 9.0 Output Voltage Accuracy Requirements

The latest VRM specifications require a module to turn its output off in the event of a 11111 VID code. When the DAC
sees such a code, the GATE pins stop switching and go low. The DRVON signal also goes low, which turns off all FETs on the module if the FET driver has an enable input. This condition is described in Table 1.

## PWRGD

According to the latest VRM specifications, the PWRGD signal is to be asserted when the output voltage is within a window defined by the VID code, as shown in Figure 33.

Figure 33. PWRGD Assertion Window
In addition, certain fault modes must cause PWRGD to go low to signal the system board that a VRM fault has occurred. In that sense, the PWRGD signal operates as a "VRM BAD" signal. These fault modes, as shown in Table 1 above, are ENABL low and CSx out of window.

When the ENABL pin is pulled low, PWRGD is pulled low to indicate that the VRM is off. DRVON is pulled low to turn both FETs off if the FET driver has an enable input.
The logic circuitry inside the chip sets PWRGD low only after a delay period has been passed. A "power bad" event does not cause PWRGD to go low unless it is sustained through the delay time, typically $200 \mu \mathrm{~s}$. If the anomaly disappears before the end of the delay, the PWRGD output will never be set low.
In order to use the PWRGD pin as specified, the user is advised to connect external resistors as necessary to limit the current into this pin to 4 mA or less.

## Share Bus

VRM 9.x specifications require that a single-wire share bus be provided from each module. This bus allows output current information to be communicated between modules such that the total load current is shared equally by each module. The CS5305 employs a proprietary share algorithm called direct duty cycle control. A block diagram is provided in Figure 34.

Figure 34.

Direct duty cycle control utilizes a master-slave approach to current sharing. At any given current load, one module will have a higher share bus voltage than the other modules. This module acts as the master. It conveys output current information to the other modules via the share bus. This information is buffered and provided to the PWM comparators, thus directly controlling duty cycle for the slave modules.

The share current sense amplifier allows the user to customize the share bus transconductance. Current sense information is provided to the non-inverting input from the $3.7 \times$ current sense amplifier from each phase. This provides a representation of the total module current. An external resistor divider between IOUT and ground, center-tapped at $\mathrm{I}_{\mathrm{FB}}$ programs the share bus voltage for a particular current level.

The share bus amplifier serves as a buffer and places the IOUT voltage on the SHARE pin. Note there is a diode in the schematic between the share bus amplifier and the SHARE pin. This is an "ideal" diode, and indicates that the share bus amplifier does not have current sink capability. This allows the share bus to be driven by the module with the highest share bus voltage. A 30 mV offset voltage provides noise immunity to ensure that any given module does not cycle between master and slave in a random fashion. It also guarantees that the master module is not driving duty cycle from the share bus. For the master module, the IOUT and SHARE voltages will be equal. In this case, the 30 mV offset holds the share adjust amplifier inactive, and the PWM channel is controlled in the normal manner. The offset voltage results in a current error between the master and slave modules, but this error is small compared to the current share tolerance found in the VRM 9.x specifications.

The share adjust amplifier takes the share bus voltage and directly drives the PWM comparators of all slave modules as previously described. The SCOMP pin provides a connection point for a compensation capacitor for the share adjust amplifier.

## CHOOSING EXTERNAL COMPONENTS FOR THE CS5305

## $R_{\text {OCSET }}$ and $R_{\text {OSC }}$

The $\mathrm{R}_{\text {OSC }}$ lead of the CS5305 provides a fixed 1 V reference to the user. A resistive divider is connected from $\mathrm{R}_{\mathrm{OSC}}$ to ground as shown in Figure 35. The center tap of the divider is connected to the OCSET lead. The total resistance from the $\mathrm{R}_{\text {OSC }}$ lead to ground programs the oscillator frequency for the converter according to the chart in Figure 36.
The resistive divider also sets a voltage on the OCSET lead. This voltage programs the module overcurrent trip point. The module overcurrent comparator, or OC Comparator, uses the OCSET lead voltage as the reference against which the module output current signal is compared. The output current of each phase is given as $\left(\mathrm{V}_{\mathrm{CSx}}-\mathrm{V}_{\text {CSREF }}\right)$ divided by the equivalent series resistance of the inductor. The voltage information $\left(\mathrm{V}_{\mathrm{CSx}}-\mathrm{V}_{\mathrm{CSREF}}\right)$ is gained up by a factor of 3.7 and summed for all three phases at the non-inverting input of the OC Comparator. The fault latch is set if the module overcurrent limit is exceeded. This results in "hiccup-mode" operation until the overcurrent condition is cleared.

Figure 35.

Figure 36. Fosc vs. R1 + ROCSET
Additionally, the total value of resistance between R $\mathrm{R}_{\mathrm{OSC}}$ and ground also programs the $\mathrm{V}_{\mathrm{FB}}$ pin bias current. $\mathrm{V}_{\mathrm{FB}}$ bias current is equal to 0.333 V divided by the total resistance from Rosc to ground. This current is used to generate the droop function in the adaptive voltage positioning circuitry and is discussed further in that section.

## Current Sense Components

Current sense components are chosen for two reasons. First, the value of $\mathrm{R}_{\mathrm{CSx}}$ and $\mathrm{C}_{\mathrm{CSx}}$ should be chosen to meet the criterion:

$$
\left(\mathrm{R}_{\mathrm{CSx}}\right)\left(\mathrm{C}_{\mathrm{CSx}}\right) \geq(\mathrm{L}) /\left(\mathrm{ESRL}_{\mathrm{L}}\right)
$$

where L is the inductor value and $\mathrm{ESR}_{\mathrm{L}}$ is the inductor equivalent series resistance. Meeting this criterion will ensure that the module overcurrent limit is not exceeded during current transients. Second, $\mathrm{R}_{\mathrm{CSx}}$ and $\mathrm{C}_{\mathrm{CSx}}$ should be chosen to add a small amount of ramp to the system. This will provide stable, jitter-free operation. The amount of ramp voltage required depends on several factors: supply voltage, output voltage (DAC code), switching frequency and board layout all affect the amount of artificial ramp required to some degree. The power supply designer should be aware that choosing the value of artificial ramp is a trade-off. As artificial ramp amplitude increases, the system becomes less prone to duty cycle jitter, but transient response will suffer. Adding 20 mV of artificial ramp is a good compromise and can be used to start design.

The current sense ramp is generated from the square wave obtained at the switching node of each phase by using an RC filter. The RC filter components for the CSx leads should be chosen to satisfy the following formula:

$$
R_{\mathrm{CSx}} \mathrm{CcSx}_{\mathrm{C}} \leq \frac{\left(\mathrm{V}_{\text {OUT }}\right)\left(1-\left(\mathrm{V}_{\text {OUT }} / \mathrm{V}_{\mathrm{CC}}\right)\right)}{(\mathrm{fOSC})\left(\mathrm{V}_{\text {RAMP }}\right)}
$$

Choose a convenient standard value for $\mathrm{C}_{\mathrm{CSx}}$ and solve for the value of $\mathrm{R}_{\mathrm{CSx}}$. Each of the three output phases requires its own RC combination.
An RC filter is also required for the $\mathrm{CS}_{\text {REF }}$ connection. This filter may use the same value of capacitance identified
for the CS1, CS2 and CS3 leads, but the value of resistance should be one third that of $\mathrm{R}_{\mathrm{CSx}}$ :

```
RCSREF = RCSx/3
```

This change is necessary to compensate for the difference in bias current between the $\mathrm{CS}_{\text {REF }}$ lead and each CSx lead. The schematic in Figure 37 shows the connection of these components.

Figure 37.

## Share Bus Components

Five external components are required to implement the module-to-module current share function. These components set the current sense load line, provide the share bus pull-down and compensate the share adjust amplifier.
The share current sense amplifier monitors the total module current and provides a DC voltage output proportional to that current. The share sense amplifier gain is programmable and allows the user to set the share bus transconductance. It is important that all modules in a system have a share current load line that approximates that of all the other modules to ensure accurate module-to-module current sharing. Let us arbitrarily set the share bus maximum voltage for full load at 2 V . If a module is designed to provide 81 A at full load, the module share transconductance should be $81 \mathrm{~A} / 2 \mathrm{~V}$ or $40.5 \mathrm{~A} / \mathrm{V}$. Two resistors and a capacitor set the share current sense amplifier gain. The resistors set the DC gain while the capacitor provides a zero to minimize errors due to noise.
The total module current is measured as described in the section dealing with the OCSET current limit function. That is, each phase within a module generates a voltage between the CSx and $\mathrm{CS}_{\mathrm{REF}}$ leads that is proportional to the current flow in the output inductor and the inductor's ESR:

$$
V_{C S x}-V_{C S R E F}=\left(I_{L}\right)\left(E S R_{L}\right)
$$

This signal is amplified by a factor of 3.7 for each phase and then summed for all three phases. This signal is provided as input to the share current sense amplifier. If we assume that all three phases are sharing current equally within a single module, the input to the share current sense amplifier can be expressed as:

$$
\begin{aligned}
\mathrm{V}_{\mathrm{IN}}(\mathrm{SENSE}) & =11.1\left(\mathrm{~V}_{\mathrm{CS}}-\mathrm{V}_{\mathrm{CSREF}}\right) \\
& =11.1\left(\mathrm{I}_{\mathrm{L}}\right)\left(\mathrm{ESR}_{\mathrm{L}}\right)=3.7\left(\mathrm{IOUT}^{(\mathrm{ESR}} \mathrm{L}\right)
\end{aligned}
$$

If we set $\mathrm{I}_{\mathrm{L}}$ equal to the maximum per phase current at full load, and if we know the value of ESR for our inductors, we
can calculate the required share current sense amplifier gain as:

$$
\operatorname{AV}(\text { SHARESENSE })=\frac{\text { share maximimum voltage }}{\operatorname{VIN}^{(S E N S E)}}
$$

As an example, let us again consider the case for a module providing full load current of 81 A . Each output phase is conducting 27 A . If we assume $\mathrm{ESR}=1.5 \mathrm{~m} \Omega$ then input to the share current sense amplifier is $(11.1)(27 \mathrm{~A})(1.5 \mathrm{~m} \Omega)=$ 0.45 V . The required share current sense amplifier gain is then $2 \mathrm{~V} / 0.45 \mathrm{~V}=4.44$.

Figure 38.
From the schematic in Figure 38, we derive the DC gain as:

$$
\operatorname{AV}(\text { SHARESENSE })=4.44=\left(\mathrm{RIOUT}^{2} / \mathrm{RIFB}\right)+1
$$

This specifies that $\mathrm{R}_{\text {IOUT }}$ should be 3.44 times greater than $\mathrm{R}_{\text {IFB }}$.

Another important consideration is the type of resistor selected for $\mathrm{R}_{\mathrm{IFB}}$. The thermal performance of $\mathrm{R}_{\mathrm{IFB}}$ must match that of whatever sense element is being used to monitor module current. Inductive sensing has been shown to be reasonably accurate, but copper's thermal coefficient of resistivity is approximately +4000 parts per million per ${ }^{\circ} \mathrm{C}$ ( $0.4 \%$ per ${ }^{\circ} \mathrm{C}$ ). In order to maintain accurate control of the share bus over temperature, $\mathrm{R}_{\mathrm{IFB}}$ must have a similar thermal coefficient. This requires a positive temperature coefficient element such as the KOA-Speer LT73. If a standard sense resistor is used in series between the inductor and the load, there is no need to use special resistors for sensing, but efficiency will suffer due to power dissipation in the sense resistor.

As regards the value of $\mathrm{C}_{\text {IOUT }}$, it should be noted that the complete transfer function for the share current sense amplifier in Figure 38 is:

$$
A V(S H A R E S E N S E)=\frac{R_{I O U T}}{R_{\operatorname{IFB}}\left(1+s C_{I O U T} R_{I O U T}\right)}+1
$$

$\mathrm{C}_{\text {IOUT }}$ causes the gain for high frequency noise to decrease, thus quieting the share bus.

The share resistor provides a passive pull-down on the SHARE lead. This allows the share bus voltage to be pulled all the way down to ground. The share resistor is selected to satisfy a number of criteria. First, the resistor cannot be made too small. The SHARE lead source current is guaranteed to be above 1 mA and must be capable of driving the SHARE
lead voltage to 3 V . The share bus of one module serves as master to all and drives the total resistance of all SHARE leads. Thus, the total impedance of all share resistors should be made greater than or equal to $3 \mathrm{k} \Omega$. That is,

$$
3 \mathrm{k} \Omega \geq \text { RSHARE } / \mathrm{N}
$$

where N is the maximum number of modules that can be placed in parallel as defined by the designer. As an example, if ten is the maximum number of modules that may be paralleled, then the minimum value of $\mathrm{R}_{\text {SHARE }}$ should be $30 \mathrm{k} \Omega$.

The share resistor should also not be made too large, since this is the only pull-down on the SHARE lead. Transient response of the share bus is limited by the RC time constant of the share resistance and any parasitic capacitance found on the SHARE line between modules.

## Droop Components

The CS5305 offers adaptive voltage positioning. This feature allows the output voltage to be set at different levels according to the amount of current being provided by the module. The output voltage is somewhat higher than nominal under no load or light load conditions and somewhat lower than nominal under heavy load conditions. Both set points must fall within the Power Good window. The adaptive positioning allows for overshoot and undershoot conditions that occur during load current transients and results in a reduction in the peak-to-peak $\mathrm{V}_{\text {OUT }}$ voltage excursion during load current transients.

Three components are required to implement DC adaptive voltage positioning. Resistor $\mathrm{R}_{\mathrm{FB}}$ is connected between the module $\mathrm{V}_{\mathrm{OUT}}$ (SENSE)+ lead and the $\mathrm{V}_{\mathrm{FB}}$ lead. Resistor $\mathrm{R}_{\mathrm{DRP}}$ is connected between the $\mathrm{V}_{\text {DRP }}$ lead and $\mathrm{V}_{\mathrm{FB}}$ lead. Resistor $\mathrm{R}_{\text {VSENSE }}$ is connected between the $\mathrm{V}_{\text {OUT(SENSE)+ }}$ lead and the module $\mathrm{V}_{\text {OUt }}$ lead. These connections are shown in Figure 39.

Figure 39.
The first step in choosing these components is to select the appropriate no-load and full-load output voltage set points for the particular DAC code being used. Additionally, the values of $\mathrm{R}_{\text {OSC }}$ and $\mathrm{R}_{\text {OCSET }}$ should be known, as should ESR of the output inductors and the full-load output current.

Figure 40.
As was previously noted, the total value of resistance between the $\mathrm{R}_{\text {OSC }}$ pin and ground sets the $\mathrm{V}_{\mathrm{FB}}$ lead bias current according to:

$$
\mathrm{I}\left(\mathrm{~V}_{\mathrm{FB}}\right)=0.333 \mathrm{~V} /(\mathrm{ROSC}+\mathrm{ROCSET})
$$

Referring to Figure 40, the $\mathrm{V}_{\text {DRP }}$ lead voltage is equal to the DAC voltage plus the current sense information. Under no load conditions, the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pin voltages are equal, and the entire $\mathrm{V}_{\mathrm{FB}}$ bias current flows between $\mathrm{V}_{\text {OUT(SENSE)+ }}$ and $\mathrm{V}_{\mathrm{FB}}$ through $\mathrm{R}_{\mathrm{FB}}$. Because the $\mathrm{V}_{\mathrm{FB}}$ bias current sinks into $\mathrm{V}_{\mathrm{FB}}$, the output voltage is forced to be higher than the DAC voltage, and so the value of $\mathrm{R}_{\mathrm{FB}}$ can be calculated as:

$$
\mathrm{R}_{\mathrm{FB}}=\left(\mathrm{V}_{\text {OUT }} \text { no load set point }-\mathrm{V}_{\mathrm{DAC}}\right) / \mathrm{I}\left(\mathrm{~V}_{\mathrm{FB}}\right)
$$

With $R_{F B}$ chosen, we can now select the value of $R_{\text {DRP }}$. If we again refer to Figure 40, we can use Kirchoff's Current Law at the $\mathrm{V}_{\mathrm{FB}}$ node to find that the value of $\mathrm{R}_{\mathrm{DRP}}$ is defined as:

$$
R_{D R P}=\frac{(\text { full load current })(3.7)\left(\mathrm{ESR}_{\mathrm{L}}\right)\left(\mathrm{R}_{\mathrm{FB}}\right)}{\left(\mathrm{R}_{\mathrm{FB}}\right)\left(\mathrm{I}\left(\mathrm{~V}_{\mathrm{FB}}\right)\right)+\left(\mathrm{V}(\mathrm{DAC})-\mathrm{V}_{\mathrm{OUT}} \text { full load set point }\right)}
$$

$\mathrm{R}_{\text {VSENSE }}$ is used to ensure that a connection between $\mathrm{V}_{\text {OUT }}$ and $\mathrm{V}_{\text {OUT(SENSE) }}$ always exists. This ensures that the module will operate correctly in the event that the $\mathrm{V}_{\text {OUT(SENSE) }}$ connection is broken. The module-to-load interface and the number of modules placed in parallel determine the value of RVSENSE. The CS5305 is specified to operate correctly with up to 55 mV dropped across the module connector. It is assumed that the maximum current allowed to flow in this connection to the load is 1 mA .

$$
\text { RVSENSE }=55 \mathrm{mV} /(1 \mathrm{~mA} / \mathrm{N})
$$

where:
$\mathrm{N}=$ the number of modules to be paralleled.
If four modules are to be paralleled, each contributes a maximum of $250 \mu \mathrm{~A}$ to this connection, and so $\mathrm{R}_{\text {VSENSE }}=$ $55 \mathrm{mV} / 250 \mu \mathrm{~A}=220 \Omega$. This component is placed to ensure the VRM module will regulate correctly if the module $\mathrm{V}_{\text {OUT(SENSE)+ }}$ connection to the load is opened.

The transient droop performance should be checked next. Performance should be verified using the transient test tool typically provided in a microprocessor development kit. True transient performance can be masked even at test frequencies as low as 2 kHz . It should be possible to modify
the test tool so a function generator can drive it. Using lower frequency (approximately 100 Hz ) and lower duty cycle $(10 \%)$ allow the designer to better observe the true settling behavior of the VRM module.

It may be necessary to add some filtering components to the droop voltage divider. These components cause the AC and DC gain from the current sense circuitry to match and allow the user to tailor the droop output voltage performance.
There are two methods for tuning droop performance. The first is illustrated in Figure 41. In this case, capacitors CDRP and $C_{F B}$ are placed in parallel with $R_{D R P}$ and $R_{F B}$. A third capacitor $\mathrm{C}_{\mathrm{DRCMP}}$ is connected between the COMP and $\mathrm{V}_{\text {DRP }}$ leads. The first two capacitors correct any gain errors introduced in the selection of current sense components Rcsx and Ccsx. Values for these components are defined as:

$$
C_{F B}=L /\left(\left(R_{F B}\right)\left(E S R_{L}\right)\right)
$$

and

$$
C_{D R P}=\left(\left(C_{C S x}\right)\left(R_{C S x}\right)\right) / R_{D R P}
$$

The capacitor between $V_{\text {DRP }}$ and COMP allows the user to fine-tune the transition between "fast" AVP and the slower positioning set by resistors $\mathrm{R}_{\mathrm{DRP}}$ and $\mathrm{R}_{\mathrm{FB}}$. This capacitor may or may not be required and is empirically chosen based on the fine-tuning procedure described below. A value of 1 nF is recommended as an initial value.

Figure 41.
Set up the circuit to be tested with a DVM and oscilloscope to the output. Have the scope set to DC input and set its offset so a resolution of at least $100 \mathrm{mV} / \mathrm{div}$ is used and the output is visible on the screen.
Using a DVM, measure the output voltage with no load. If this value differs from the expected value, adjust $\mathrm{R}_{\mathrm{FB}}$ until the nominal value is reached. Once this is set, mark this DC level on the scope with a cursor.
Next, measure the output voltage with full DC load. If this value deviates from the expected value, adjust $R_{\text {DRP }}$ until the nominal value is reached. Once this is set, mark this DC level on the scope with another cursor.

Figure 42.

Using the transient test tool, set up a current load step from low current ( 1 A ) to maximum load at the slew rate being designed for. Set the current step at about 100 Hz with a duty cycle of $10 \%$. Converter response should be similar to that shown in Figure 42.

Next, determine if there is a "bump" (trace 4 or trace 5) in the output. Adjust $\mathrm{C}_{\text {COMP }}$ and $\mathrm{C}_{\text {DRCMP }}$ to flatten out this bump. If the "bump" is negative (trace 5), make C ${ }_{\text {DRCMP }}$ slightly larger and $\mathrm{C}_{\text {COMP }}$ slightly smaller. If you see a positive "bump" (trace 4), make CDRCMP slightly smaller and $\mathrm{C}_{\text {COMP }}$ slightly larger. If performance is better without $\mathrm{C}_{\text {DRCMP }}$, just make C1 larger.

Once the bump is removed, look to see if the "pulse step" magnitude is larger or smaller than the DC level (trace 2 or trace 3). Make $\mathrm{C}_{\mathrm{FB}}$ slightly larger if the AC gain (trace 3 ) is too large or slightly smaller if the AC gain (trace 2) is too small. Once the output response resembles the "optimal" trace (trace 1), the controller has been optimized for the design from a static and dynamic response.

If the output appears to be jittering slightly prior to optimizing transient response, make the previous adjustments first, since they may solve the problem. If the problem persists, decreasing the value of Rcsx across the inductor will increase ramp amplitude, and jitter performance should improve with increased ramp.

The second method uses a capacitor to "square up" the COMP waveform and a series resistor and capacitor to tune the $\mathrm{V}_{\mathrm{DRP}}$ waveform. These components are chosen empirically based on observations of COMP and $V_{\text {DRP }}$ performance.

First, set the test tool for a load current transient from no load (1 A) to full load and observe the COMP waveform.

The COMP waveform should ideally be flat, or at worst decrease slightly during a current increase transient. The principle at work here is that the increase in current sense information will generate a voltage that should exactly cancel the droop voltage, and thus the COMP capacitor voltage should not change. In reality, it is unlikely that every manufactured module can be built to perfectly compensate the droop voltage, and so the COMP voltage should exhibit a small amplitude square wave during transient conditions. If the COMP voltage is decreasing gradually, the current sense information is too small to fully compensate for the droop voltage, and the designer should add a capacitor between $\mathrm{V}_{\text {OUT }}$ and COMP. This capacitor is chosen empirically, with 1 nF a good starting point. This capacitor will pull the COMP pin down initially and "square up" the COMP waveform as shown in Figure 43.

Figure 43.

In a similar manner, if the current information is too large, the COMP voltage will rise to compensate. Again, a square wave is preferable to a slow change in the COMP voltage, and placing a capacitor between $\mathrm{V}_{\mathrm{DRP}}$ and COMP will "square up" the COMP waveform as shown in Figure 44.

Figure 44.
Once the COMP waveform has been squared up, it is necessary to check the $\mathrm{V}_{\mathrm{DRP}}$ waveform. The $\mathrm{V}_{\mathrm{DRP}}$ waveform is dependent on the choice of ramp components. If these components have been chosen such that $\left(\mathrm{R}_{\mathrm{CSx}}\right)\left(\mathrm{C}_{\mathrm{CSx}}\right)=\mathrm{L} / \mathrm{ESR}_{\mathrm{L}}$, the $\mathrm{V}_{\text {DRP }}$ waveform should be a square wave that matches the current step. At this point, the V VUT waveform should also be a square wave and transient performance should be optimized.

If $\left(\mathrm{R}_{\mathrm{CSx}}\right)\left(\mathrm{C}_{\mathrm{CSx}}\right)<\mathrm{L} / \mathrm{ESR}_{\mathrm{L}}$, the $\mathrm{V}_{\mathrm{DRP}}$ waveform will be faster than current step. The $V_{\text {DRP }}$ voltage will exhibit a fast rise followed by an exponential droop down to a DC level, as shown in Figure 45. This waveform has the effect of telling the system that transient current signals are larger than the true current. Response will be slowed, and $\mathrm{V}_{\text {OUT }}$ will overshoot until the error amplifier "catches up". In this case, it is desirable to push the $\mathrm{V}_{\mathrm{FB}}$ pin down, so that COMP voltage is forced up and duty cycle is reduced slightly. This is done by placing a series RC filter across resistor $\mathrm{R}_{\mathrm{FB}}$.

Figure 45.
If $\left(\mathrm{R}_{\mathrm{CSx}}\right)\left(\mathrm{C}_{\mathrm{CSx}}\right)>\mathrm{L} / \mathrm{ESR}_{\mathrm{L}}$, the $\mathrm{V}_{\mathrm{DRP}}$ waveform will be slower than the current step. $\mathrm{V}_{\text {DRP }}$ will exhibit an initial spike, but the voltage will then exponentially rise toward its correct DC level, as shown in Figure 46. This waveform effectively tells the system that the current signal is smaller than the true current, and response will be faster than optimal. $V_{\text {OUT }}$ will then undershoot. In this case, forcing
$\mathrm{V}_{\mathrm{FB}}$ up so COMP voltage decreases results in increasing output duty cycle. The series RC filter is now located in parallel with $\mathrm{R}_{\mathrm{DRP}}$.

Figure 46.
These components are chosen empirically. The fastest way to optimize the design is to start with a 1 nF capacitor and a $500 \mathrm{k} \Omega$ potentiometer and "dial in" performance.

## Error Amplifier Compensation

Error amplifier compensation is very simple using the enhanced $\mathrm{V}^{2}$ control architecture. A single $0.1 \mu \mathrm{~F}$ capacitor from the COMP lead to ground is usually sufficient. As an alternative, a resistor and capacitor in series between COMP and ground may improve output voltage positioning during current transients. The resistance will speed up the effective slew rate of the error amplifier output.
The COMP capacitor also provides soft start and hiccup-mode timing. At start-up, the COMP capacitance must charge from ground through a typical channel start-up offset of 0.6 V before the GATE outputs are allowed to begin switching. The COMP capacitance includes both the COMP capacitor and any droop compensation capacitance that may be connected to the COMP pin. The typical soft start time can then be approximated as:

$$
\text { TSOFT-START(ms) = } 20 \text { CCOMP(TOTAL) }(\mu \mathrm{F})
$$

Hiccup timing has a similar equation. During hiccup-mode, the COMP voltage traverses between the fault reset threshold (approximately 0.2 V ) and the channel start-up offset voltage. When the fault circuitry becomes active, the COMP capacitor is discharged with a $5 \mu \mathrm{~A}$ current until the fault reset threshold is reached. The time this initial discharge takes is variable depending on the COMP voltage when the fault occurred. Once the reset threshold is reached, the COMP capacitor is charged with the $30 \mu \mathrm{~A}$ current until the start-up offset voltage is reached. The GATE outputs will begin to pulse, quickly ramping the inductor current. The fault circuitry can then re-detect the fault condition some number of GATE pulses later if it is still present. Thus, the period of the fault hiccup mode is approximately defined as:

$$
\mathrm{THICCUP}(\mathrm{~ms})=93.3 \mathrm{C} \operatorname{COMP}(\mathrm{TOTAL})(\mu \mathrm{F})
$$

Period is only approximately defined since the number of GATE pulses between restart and redetection of a fault condition is unpredictable.

## Inductors

There are many factors to consider when choosing the output inductors. Maximum load current, core and winding losses, ripple current, short circuit current, saturation characteristics, component height and cost are all variables that the designer should consider. However, the most important consideration in designing for the VRM 9.x specifications may be the effect inductor value has on transient response.

The amount of overshoot or undershoot exhibited during a current transient is defined as the product of the current step and the output filter capacitor ESR. To some degree, adaptive voltage positioning is used to "pre-position" the output voltage so the voltage step during a current transient will not cause the output voltage to exceed the Power Good window. However, adaptive positioning will not completely eliminate the overshoot or undershoot conditions, and choosing the inductor value appropriately can minimize the amount of energy that must be transferred from the inductor to the capacitor or vice-versa. In the subsequent paragraphs, we will determine the minimum value of inductance required for our system and consider the trade-off of ripple current vs. transient response.

In order to choose the minimum value of inductance, input voltage, output voltage and output current must be known. Most computer applications use reasonably well regulated bulk power supplies so that, while the equations below specify $\mathrm{V}_{\text {IN(MAX) }}$ or $\mathrm{V}_{\text {IN(MIN) }}$, it is possible to use the nominal value of $\mathrm{V}_{\mathrm{IN}}$ in these calculations with little error.

Current in the inductor while operating in the continuous current mode is defined as the load current plus ripple current.

$$
\mathrm{I}_{\mathrm{L}}=\mathrm{I}_{\mathrm{LOAD}}+\mathrm{I}_{\text {RIPPLE }}
$$

The ripple current waveform is triangular, and the current is a function of voltage across the inductor, switch FET on-time and the inductor value. FET on-time can be defined as the product of duty cycle and switch frequency, and duty cycle can be defined as a ratio of $\mathrm{V}_{\text {OUT }}$ to $\mathrm{V}_{\text {IN }}$. Thus,

$$
\text { IRIPPLE }=\frac{\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}\right)}
$$

Peak inductor current is defined as the load current plus half of the peak current. Peak current must be less than the maximum rated FET switch current, and must also be less than the inductor saturation current. Thus, the maximum output current for a single phase can be defined as:
$\operatorname{IOUT}(\mathrm{MAX})=\operatorname{ISWITCH}(\mathrm{MAX})-\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MAX})-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{(2)(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}(\mathrm{MAX})\right)}$

Since the maximum output current must be less than the maximum switch current, the minimum inductance required for a single phase can be determined.

$$
\mathrm{L}_{(\mathrm{MIN})}=\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})-\mathrm{V}_{\mathrm{OUT}}\right) \mathrm{V}_{\mathrm{OUT}}}{(\mathrm{fOSC})(\mathrm{ISWITCH}(\mathrm{MAX}))\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})\right)}
$$

This equation identifies the value of inductor that will provide the full rated switch current as inductor ripple current, and will usually result in inefficient system operation. The system will sink current away from the load during some portion of the duty cycle unless load current is greater than half of the rated switch current. Some value larger than the minimum inductance must be used to ensure the converter does not sink current. Choosing larger values of inductor will reduce the ripple current, and inductor value can be designed to accommodate a particular value of ripple current by replacing $\mathrm{I}_{\text {SWITCH(MAX) }}$ with a desired value of I RIPPLE:

$$
\mathrm{L}_{(\mathrm{RIPPLE})}=\frac{\left(\mathrm{V}_{\text {IN }}(\mathrm{MIN})-\mathrm{V}_{\mathrm{OUT}}\right) \mathrm{V}_{\mathrm{OUT}}}{(\mathrm{fOSC})(\mathrm{IRIPPLE})\left(\mathrm{V}_{\mathrm{IN}(\mathrm{MIN})}\right)}
$$

However, reducing the ripple current will cause transient response times to increase. The response times for both increasing and decreasing current steps are shown below.

$$
\begin{aligned}
& \text { TRESPONSE(INCREASING) }=\frac{(\mathrm{L})\left(\Delta \mathrm{I}_{\mathrm{OUT}}\right)}{\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right)} \\
& \text { TRESPONSE }^{\text {DECREASING })}=\frac{(\mathrm{L})\left(\Delta \mathrm{I}_{\mathrm{OUT}}\right)}{\left(\mathrm{V}_{\mathrm{OUT}}\right)}
\end{aligned}
$$

Inductor value selection also depends on how much output ripple voltage the system can tolerate. Output ripple voltage is defined as the product of the output ripple current and the output filter capacitor ESR. However, since the CS5305 has three paralleled phases, the net effect is that the switching frequency as seen by the output capacitance is tripled relative to the CS5305 operating frequency. This is because each phase switches in sequence and the ripple currents in each phase are superimposed on the output capacitance. This is illustrated graphically in Figures 45 and 46.

Thus, output ripple voltage can be calculated as:
$\mathrm{V}_{\text {RIPPLE }}=\left(\mathrm{ESR}_{\mathrm{C}}\right)(\operatorname{IRIPPLE})=\frac{\left(\mathrm{ESRC}_{\mathrm{C}}\right)\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right) \mathrm{V}_{\text {OUT }}}{3(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}\right)}$
It is also important to note that the maximum value of inductor ESR is limited by the single-phase pulse-by-pulse current limit. The specified minimum value for this parameter is 80 mV , so the maximum inductor ESR is:
$E S R_{L(M A X)}$ (in ohms) $=\frac{(0.08 \mathrm{~V})}{(\text { single phase current limit value in Amps) }}$

Figure 47.
Finally, we should consider power dissipation in the output inductors. Power dissipation is proportional to the square of inductor current:

$$
P \mathrm{D}=\left(\mathrm{I}_{\mathrm{PHASE}}^{2}\right)\left(E S R_{\mathrm{L}}\right)
$$

The temperature rise of the inductor relative to the air surrounding it is defined as the product of power dissipation and thermal resistance to ambient:

$$
\Delta \mathrm{T}(\text { inductor })=(\mathrm{Ra})(\mathrm{PD})
$$

Ra for an inductor designed to conduct 20 A to 30 A is approximately $45^{\circ} \mathrm{C} / \mathrm{W}$. The inductor temperature is given as:

$$
\mathrm{T} \text { (inductor) }=\Delta \mathrm{T} \text { (inductor) }+ \text { Tambient }
$$

## Output Filter Capacitors

Each microprocessor manufacturer specifies output filter capacitors for the motherboards. In addition, the designer may need to add some output capacitance on the VRM module. These added output capacitors would serve to reduce the noise floor and help ensure jitter-free operation. If needed, one or two ceramic capacitors should be sufficient. They should have a 4 WVDC rating. Large amounts of bulk capacitance placed on the VRM module are not useful, since the impedance of the VRM connector exists between the module and the load. Low equivalent series resistance is important since output ripple voltage and response to output current transients are largely dependent on this parasitic parameter.

## $\mathrm{V}_{\mathrm{Cc}}$ Bypass Filtering

A small RC filter should be added between module $\mathrm{V}_{\mathrm{CC}}$ and the $\mathrm{V}_{\mathrm{CC}}$ input to the CS5305. A $10 \Omega$ resistor and a $0.1 \mu \mathrm{~F}$ capacitor should be sufficient to ensure the controller IC does not operate erratically due to injected noise.

## Module Input Filter Capacitors

The input filter capacitors for the VRM module provide a charge reservoir that minimizes supply voltage variations due to changes in current flowing through the switch FETs. These capacitors must be chosen primarily for ripple current rating.

Figure 48.
Consider the schematic shown in Figure 48. The average current flowing in the input inductor $\mathrm{L}_{\mathrm{IN}}$ for any given output current is:

$$
\begin{aligned}
\mathrm{I} \mathrm{~N}(\mathrm{AVE}) & =(\mathrm{I} \mathrm{OUT})(\mathrm{V} \text { OUT } / \mathrm{V} \text { IN }) \\
& =(\mathrm{IOUT} \text { per phase })(\mathrm{n})(\mathrm{D})
\end{aligned}
$$

where:
$\mathrm{D}=$ duty cycle,
$\mathrm{n}=$ number of phases.
Input capacitor current is positive into the capacitor when the switch FETs are off, and negative out of the capacitor when the switch FETs are on. When the switches are off, $\mathrm{I}_{\text {IN(AVE) }}$ flows into the capacitor. When the switches are on, capacitor current is equal to the per-phase output current minus $\mathrm{I}_{\mathrm{IN}(\mathrm{AVE})}$. If we ignore the small current variation due to the output ripple current, we can approximate the input capacitor current waveform as a square wave. We can then calculate the RMS input capacitor ripple current:

The input capacitance must be designed to conduct the worst case input ripple current. This will require several capacitors in parallel. In addition to the worst case current, attention must be paid to the capacitor manufacturer's derating for operation over temperature.

As an example, let us define the input capacitance for a 12 V to 1.7 V conversion at 81 A , or 27 A per phase at an ambient temperature of $60^{\circ} \mathrm{C}$. A droop voltage of 90 mV to 1.61 V and efficiency of $80 \%$ is assumed. Average input current in the input filter inductor is:

$$
\mathrm{I}_{\mathrm{I}} \mathrm{~N}(\mathrm{AVE})=\frac{(27 \mathrm{~A})(3 \text { phases })(1.61 \mathrm{~V} / 12 \mathrm{~V})}{80 \%}=10.868 \mathrm{~A}
$$

Input capacitor RMS ripple current is then

$$
\begin{aligned}
\operatorname{IIN}(\mathrm{RMS}) & =\sqrt{\begin{array}{l}
10.868^{2}+\frac{1.61 \mathrm{~V}}{12 \mathrm{~V}} \times 3 \\
\times\left[(27 \mathrm{~A}-10.868 \mathrm{~A})^{2}-10.868 \mathrm{~A}^{2}\right]
\end{array}} \\
& =13.347 \mathrm{~A}
\end{aligned}
$$

If we consider a Sanyo SP series capacitor, the ripple current rating for a 16 SPS 100 M capacitor is 2820 mA at 100 kHz and $45^{\circ} \mathrm{C}$. The derating factor is 0.85 for operation up to $65^{\circ} \mathrm{C}$, resulting in an effective ripple current rating of 2397 mA . We determine the number of input capacitors by dividing the ripple current by the per-capacitor current rating:

Number of capacitors $=13.347 \mathrm{~A} / 2.397 \mathrm{~A}=5.52$
A total of at least 6 capacitors in parallel must be used to meet the input capacitor ripple current requirements.

## Output Switch FETs

Output switch FETs must be chosen carefully, since their properties vary widely from manufacturer to manufacturer. The CS5305 system is designed assuming that a FET driver IC and $n$-channel FETs will be used. The FET characteristics of most concern are the gate charge/gate-source threshold voltage, gate capacitance, on-resistance, current rating and the thermal capability of the package.

FET driver ICs have a limited drive capability. If the switch FET has a high gate charge, the amount of time the FET stays in its ohmic region during the turn-on and turn-off transitions is larger than that of a low gate charge FET, with the result that the high gate charge FET will consume more power. Similarly, a low on-resistance FET will dissipate less power than will a higher on-resistance FET at a given current. Thus, low gate charge and low $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ will result in higher module efficiency and will reduce heat being generated by the VRM module.

It can be advantageous to use multiple switch FETs to reduce power consumption. By placing a number of FETs in
parallel, the effective $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ is reduced, thus reducing the ohmic power loss. However, placing FETs in parallel increases the gate capacitance so that switching losses increase. As long as adding another parallel FET reduces the ohmic power loss more than the switching losses increase, there is some advantage to doing so. However, at some point the law of diminishing returns will take hold, and a marginal increase in efficiency may not be worth the board area required to add the extra FET. Additionally, as more FETs are used, the limited drive capability of the FET driver will have to charge a larger gate capacitance, resulting in increased gate voltage rise and fall times. This will affect the amount of time the FET operates in its ohmic region and will increase power dissipation.

The following equations can be used to calculate power dissipation in the switch FETs.

For ohmic power losses due to $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ :

$$
\begin{aligned}
\mathrm{PON}(\mathrm{TOP}) & =\frac{(\mathrm{RDS}(\mathrm{ON})(\mathrm{TOP}))(\mathrm{I} M \mathrm{RM}(\mathrm{TOP}))^{2}(\mathrm{n})}{(\text { number of topside FETs per phase })} \\
\mathrm{PON}(\mathrm{BOTTOM}) & =\frac{\left(\mathrm{RDS}(\mathrm{ON})(\mathrm{BOTTOM})(\mathrm{IRMS}(\mathrm{BOTTOM}))^{2}(\mathrm{n})\right.}{(\text { number of bottom-side FETs per phase })}
\end{aligned}
$$

where:
$\mathrm{n}=$ number of phases.
Note that $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ increases with temperature. It is good practice to use the value of $\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ at the FET's maximum junction temperature in the calculations shown above.

$$
\begin{aligned}
& I_{R M S}(T O P)=\sqrt{I_{\text {PK }}^{2}-(I P K)\left(I_{R I P P L E}\right)+\frac{D}{3} I_{\text {RIPPLE }}^{2}} \\
& \operatorname{IRMS}(\text { BOTTOM })=I_{\text {PK }}^{2}-(\text { IPKIRIPPLE })+\frac{(1-\mathrm{D})}{3} I_{\text {RIPPLE }}^{2} \\
& \mathrm{I}_{\text {RIPPLE }}=\frac{\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right)\left(\mathrm{V}_{\text {OUT }}\right)}{(\mathrm{fOSC})(\mathrm{L})\left(\mathrm{V}_{\text {IN }}\right)} \\
& \text { IPEAK }=I_{\text {LOAD }}+\frac{\text { IRIPPLE }^{2}}{2}=\frac{\text { IOUT }}{3}+\frac{\text { IRIPPLE }}{2}
\end{aligned}
$$

where:
D = Duty cycle.
For switching power losses:

$$
\mathrm{PD}=\mathrm{nCV} 2(\mathrm{fOSC})
$$

where:
$\mathrm{n}=$ number of switch FETs (either top or bottom) per phase,
$\mathrm{C}=\mathrm{FET}$ gate capacitance,
$\mathrm{V}=$ maximum gate drive voltage (usually $\mathrm{V}_{\mathrm{CC}}$ ),
$\mathrm{f}_{\mathrm{OSC}}=$ switching frequency.

## External FET Driver

The CS5305 is designed such that an external FET driver IC is required. The GATE pin outputs are designed to drive a 100 pF load, and do not have sufficient drive capability to directly drive the gates of switch FETs. The GATE outputs have a typical output high voltage of 2.5 V , so the turn-on threshold of the FET driver should be approximately 2 V . The GATE outputs are also phased such that the FET driver IC should turn on the topside $n$-channel FET when the GATE output goes high. The bottom-side n-channel FET should be on when the GATE output is below the FET driver IC turn-on threshold.

Additionally, the CS5305 provides a signal called DRVON that can be connected to the ENABLE pin of FET drivers that offer an enable feature. If the FET driver's ENABLE input is high, the FET driver output is determined by the GATE input, and the switch FETs are driven according to the conditions described above. If the FET driver's ENABLE input is low, all switch FETs are turned off and no current is conducted to the load. This DRVON signal is a logic output from the CS5305. DRVON goes high when all internal functions of the CS5305 are operating correctly and the IC is not in fault mode. A table of the DRVON logic may be found in the Theory of Operation section.

Choosing a FET driver IC with an enable feature significantly improves system reliability, since a faulty module is essentially disconnected from the load.

## SGND Resistor

The module-to-load interface and the number of modules placed in parallel determine the value of $\mathrm{R}_{\text {SGND }}$. The CS5305 is specified to operate correctly with up to 55 mV dropped across the module connector. It is assumed that the maximum current allowed to flow in this connection to the load is 1 mA .

$$
\mathrm{RSGND}=55 \mathrm{mV} /(1 \mathrm{~mA} / \mathrm{N})
$$

where:
$\mathrm{N}=$ the number of VRM modules to be paralleled.
If four modules are to be paralleled, each contributes a maximum of $250 \mu \mathrm{~A}$ to this connection, and so,

$$
\text { RSGND }=55 \mathrm{mV} / 250 \mu \mathrm{~A}=220 \Omega
$$

This component is placed to ensure the VRM module will regulate correctly if the module $\mathrm{V}_{\text {OUT(SENSE)- }}$ connection to the load is opened.

## Layout Considerations

Enhanced $V^{2}$ performs best under dynamic load conditions if current ramp is kept small. However, this may lead to pulse-width jitter or pulse skipping, particularly as the ambient noise level at the control circuit increases. This is a complicated design trade-off that can not be mathematically characterized, and it is crucial to have a "quiet" layout. Following the design/layout guidelines below will provide the best system performance. Refer to Figure 50 for a layout example and to page 2312 for the associated schematic. Numbers in parentheses refer to IC pin numbers. Component names refer to the reference designators for the application schematic.
1.Noise across the PWM comparator inputs needs to be low or pulse width jitter will occur. Referring to the block diagram, the $\mathrm{CS}_{\text {REF }}$ pin (7) and the COMP pin (14) present external information to the PWM comparator. Any differential signal across these pins is expressed directly across the PWM comparator, which may cause pulse-width jitter or pulse skipping. The solution is to provide a dedicated Kelvin connection for sensing the VRM's V ${ }_{\text {OUT-. }}$ The IC's GND pin (28) and COMP capacitance need a dedicated sense line to $\mathrm{V}_{\text {OUT }}$, in effect making the IC and COMP capacitance $V_{\text {OUT-ground-referenced. }}$ This is desirable since the fast feedback path through $\mathrm{CS}_{\text {REF }}$ is connected to $\mathrm{V}_{\text {OUT+ }}$ and is therefore also Vout-ground-referenced. Furthermore, a ground strip under the IC is desirable since the COMP pin is located at the opposite corner of the IC from the GND pin. This ground strip further reduces the ambient noise level of the CS5305 along with providing a good connection from COMP return to GND and VOUT-. Following this guideline will provide the most system improvement from a layout standpoint.

Figure 49.
2.Differential noise across the PWM comparator can be further reduced if the $\mathrm{V}_{\text {OUT+ }}$ and $\mathrm{V}_{\text {OUT- }}$ sense lines going to $\mathrm{CS}_{\text {REF }}$ and GND are paralleled to minimize loop area. $V_{\text {OUT+ }}$ ripple information provided to the PWM comparator via the CS $_{\text {REF }}$ pin needs to be symmetric for all three phases or poor current sharing between phases will occur. This can be accomplished by placing the $V_{\text {OUT+ }}$ and $V_{\text {OUT- }}$ sense locations symmetrically with respect to the three output inductors. See Figure 49.
3.Frequency jitter could occur if the $\mathrm{R}_{\mathrm{OSC}}$ pin (2) and OCSET pin (1) components are not properly located. Most layouts will have two resistors in series from $\mathrm{R}_{\text {OSC }}$ to GND. Keep these two components as close as possible to the IC and ensure a short ground connection to the IC GND. Provision for a small cap ( 1000 pF or less) from $\mathrm{R}_{\mathrm{OSC}}$ to GND can be placed although this is rarely needed. If the $\mathrm{R}_{\text {OSC }}$ capacitor value is too large, the $\mathrm{R}_{\mathrm{OSC}}$ voltage reference will oscillate.
4.The $\mathrm{V}_{\mathrm{CC}}$ (23) bypass capacitor ( $0.1 \mu \mathrm{~F}$ or greater) should be located as close as possible to the IC. This capacitor's connection to GND must be as short as possible. The most effective way to implement this tight component placement is to via the GATE1, 2,3 and DRVON runs to internal layers right at the IC pins.
5.The switch nodes of all three phases must be sensed for inductive current sensing. Care should be given to how this information is brought to the CS5305. Switch node voltages should not be routed underneath or near the IC; however, the resistors in the RC filter of CS1, 2, 3 must be reasonably close to their associated capacitors so noise pick-up on the CS1, 2, 3 pins is minimized. The best solution is to locate the RC filter capacitors close to the CS1, 2, 3 pins and to place the respective resistors off to the side of the IC.
6.A positive temperature coefficient thermistor can be used for R11 (see Share Bus section) to compensate for thermal variation in the inductor ESR. This
component should be placed near the one of the inductors to achieve the best thermal coupling, and so the best current sharing performance. Remote placement with respect to the IC requires dedicated parallel runs of GND and $\mathrm{I}_{\mathrm{FB}}$ to reduce share bus noise sensitivity.

## Thermal Considerations

Typically, the controller IC and the FET gate drivers do not dissipate significant amounts of power, and do not contribute greatly to module power dissipation. The main components of concern are the switch FETs and the inductors.

We have already reviewed the power calculations for these components, but we haven't related them to a thermal solution. Standards exist limiting the maximum VRM printed circuit board temperature $\left(105^{\circ} \mathrm{C}\right.$ is common), and thus power dissipation becomes a thermal consideration in addition to playing a part in overall module efficiency.

Power dissipation on the VRM results in heat radiation to the surrounding air. Power dissipated by the components is conducted to the PCB. The PCB acts as a heat sink and provides a larger surface area for heat exchange to the surrounding air. The PCB temperature is dependent on total PCB power dissipation, the surface area of the PCB available to act as a heat sink, the ambient temperature of the surrounding air and the thermal resistance to ambient of the PCB.

While it is possible to model power dissipation on the PCB for efficiency purposes, it is very difficult to accurately model thermal performance. In particular, thermal resistance to ambient of the PCB varies widely. This parameter depends on many factors: board shape, size and material; copper weight; amount of exposed copper; insulating characteristics of the solder mask layers; air flow properties (amount, direction, PCB orientation to the airflow); and even whether a particular component is "hidden" behind others. In reality, modeling PCB resistance to ambient is highly complex and the best way to guarantee thermal performance is to actually build prototypes and measure it directly.

Figure 50. Sample Layout

## Additional Information

Several additional resources are available to make system design with the CS5305 a simpler task. The power supply designer is invited to obtain the following documents and files from ON Semiconductor.
1.AND8045/D, "Enhanced $V^{2}$ Multiphase SMPS for Microprocessor." This application note provides details on the theory of operation, selection of components, layout practices and thermal management strategies necessary to design power supplies with the CS5305 controller.
2."Excel Spreadsheet Method for Choosing CS5305 External Components". This Excel spreadsheet that can be used to generate a first-pass schematic design for VRM 9.x designs based on user input, and is available from the factory.
3."Excel Spreadsheet Method for CS5305 Power Budget Optimization". This Excel spreadsheet that can be used to calculate power dissipation in all the high-power dissipation components (including metal traces). This allows the design to be optimized for power/thermal management, and is available from the factory.

## CS5307

## Advance Information <br> Four-Phase <br> Buck CPU Controller

Multiphase controllers provide fast, accurate regulation with the control features required to power the next generation of processors in workstation and server applications. Combined with external gate drivers and power components, such controllers implement a compact, highly integrated buck converter. Enhanced $\mathrm{V}^{2 \mathrm{TM}}$ control inherently compensates for variations in both line and load. Current sharing between phases is achieved by Peak Current Sharing.

The CS5307 includes Power Good with a programmable lower threshold.

Applications include Embedded Processor Power and low voltage/high current power supplies.

## Features

- Switching Regulator Controller
- Four-Phase Operation
- Loss-Less Current Sensing
- Enhanced V ${ }^{2}$ Control Method Provides Excellent Regulation and Fast Transient Response
- Programmable 200 to 800 kHz Switching Frequency (Per Phase)
- Pulse-by-Pulse 0 to 100\% Adjustment of Duty Cycle as Required to Maintain Regulation
- Programmable Adaptive Voltage Positioning Reduces Output Capacitor Requirements
- Implements Converters Capable of Supplying Up to 25 A Per Phase of Low Voltage Output Current
- Programmable Soft Start
- Current Sharing
- Current Sharing Within 10\% Between Phases
- Protection Features
- Pulse-by-Pulse Current Limit for Each Phase
- Programmable Hiccup Overcurrent Protection
- All "1" DAC Code Fault
- Processor Overvoltage Protection through Bottom MOSFETs
- Undervoltage Lockout
- System Power Management
- 5-Bit DAC With 1.0\% Tolerance Compatible with Latest VRM Specifications
- Power Good Output
- Programmable Power Good Lower Threshold

This document contains information on a new product. Specifications and information herein are subject to change without notice.

## PACKAGE PIN DESCRIPTION

| Pin Number |  |  |  |
| :---: | :---: | :---: | :---: |
| SO-24L | Pin Symbol | Pin Name | Function |
| 1 | GND | Ground | IC power supply return. Connected to IC substrate. |
| 2 | OCSET | Overcurrent Set | Resistor divider from Rosc to GND. Programs the threshold of the hiccup overcurrent protection. |
| 3 | Rosc | Oscillator Frequency Adjust | Rosc is a regulated 1.0 V output and programs the oscillator frequency with a resistor to GND. |
| 4-7 | CS1-CS4 | Current Sense Inputs | Non-inverting inputs to the current sense amplifiers. |
| 8 | $\mathrm{CS}_{\text {REF }}$ | Current Sense Reference | Inverting input to the current sense amplifiers and reference for Power Good. |
| 9 | $V_{\text {DRP }}$ | Current Sense Amp Output | Compensates for IR droop. A resistor from $V_{\text {DRP }}$ to FB programs the amount of Adaptive Voltage Positioning. Omitting this resistor defeats the AVP function. |
| 10 | $V_{F B}$ | Voltage Feedback | Error Amplitude inverting input. Input bias current is used to program AVP light load offset via a resistor connected to the converter output voltage. |
| 11 | COMP | Error Amp Output and PWM Comparator Input | Provides loop compensation and is clamped by SS. |
| 12 | SS | Soft Start | Controls fault timing and startup. |
| 13 | PWRGD | Power Good Output | Open collector output, which is "low" when the converter output is out of regulation. |
| 14 | PWRGDS | Power Good Sense | A resistor divider from VOUT to GND programs the Power Good lower threshold. |
| 15-19 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID }}$ | DAC $V_{\text {ID }}$ Inputs | TTL compatible logic input used to program the converter output voltage. Internal 50 k pull-up resistors are provided to 3.3 V . All high generates fault. |
| 20-23 | GATE4-1 | Channel Outputs | PWM outputs to drive FET driver IC. |
| 24 | $\mathrm{V}_{\mathrm{CC}}$ | Supply Input | IC bias input. |

## APPLICATIONS INFORMATION

## Overview

The CS5307 DC/DC controller from ON Semiconductor was developed using the Enhanced $\mathrm{V}^{2}$ topology to meet requirements of low voltage, high current loads with fast transient requirements. Enhanced $V^{2}$ combines the original $\mathrm{V}^{2}$ topology with peak current-mode control for fast transient response and current sensing capability. The addition of an internal PWM ramp and implementation of fast-feedback directly from Vcore has improved transient response and simplified design. The CS5307 includes Power Good (PWRGD), providing a highly integrated solution to simplify design, minimize circuit board area, and reduce overall system cost.

Two advantages of a multi-phase converter over a single-phase converter are current sharing and increased apparent output frequency. Current sharing allows the designer to use less inductance in each phase than would be required in a single-phase converter. The smaller inductor will produce larger ripple currents but the total per phase power dissipation is reduced because the RMS current is lower. Transient response is improved because the control loop will measure and adjust the current faster in a smaller output inductor. Increased apparent output frequency is desirable because the off- time and the ripple voltage of the two-phase converter will be less than that of a single-phase converter.

## Fixed Frequency Multi-Phase Control

In a multi-phase converter, multiple converters are connected in parallel and are switched on at different times. This reduces output current from the individual converters and increases the apparent ripple frequency. Because several converters are connected in parallel, output current can ramp up or down faster than a single converter (with the same value output inductor) and heat is spread among multiple components.

The CS5307 controller uses four-phase, fixed-frequency, Enhanced $\mathrm{V}^{2}$ architecture to measure and control currents in
individual phases. Each phase is delayed $90^{\circ}$ from the previous phase. Normally, GATEx transitions to a high voltage at the beginning of each oscillator cycle. Inductor current ramps up until the combination of the current sense signal, the internal ramp and the output voltage ripple trip the PWM comparator and bring GATEx low. Once GATEx goes low, it will remain low until the beginning of the next oscillator cycle. While GATEx is high, the Enhanced V ${ }^{2}$ loop will respond to line and load variations. On the other hand, once GATEx is low, the loop can not respond until the beginning of the next PWM cycle. Therefore, constant frequency Enhanced $V^{2}$ will typically respond to disturbances within the off-time of the converter.
The Enhanced $V^{2}$ architecture measures and adjusts the output current in each phase. An additional input (CSx) for inductor current information has been added to the $\mathrm{V}^{2}$ loop for each phase as shown in Figure 3. The triangular inductor current is measured differentially across RS, amplified by CSA and summed with the Channel Startup Offset, the Internal Ramp, and the Output Voltage at the non-inverting input of the PWM comparator. The purpose of the Internal Ramp is to compensate for propagation delays in the CS5307. This provides greater design flexibility by allowing smaller external ramps, lower minimum pulse widths, higher frequency operation, and PWM duty cycles above $50 \%$ without external slope compensation. As the sum of the inductor current and the internal ramp increase, the voltage on the positive pin of the PWM comparator rises and terminates the PWM cycle. If the inductor starts a cycle with higher current, the PWM cycle will terminate earlier providing negative feedback. The CS5307 provides a CSx input for each phase, but the $\mathrm{CS}_{\text {REF }}$ and COMP inputs are common to all phases. Current sharing is accomplished by referencing all phases to the same CS $_{\text {REF }}$ and COMP pins, so that a phase with a larger current signal will turn off earlier than a phase with a smaller current signal.

Figure 3. Enhanced V ${ }^{2}$ Control Employing Resistive Current Sensing and Additional Internal Ramp

Enhanced $\mathrm{V}^{2}$ responds to disturbances in $\mathrm{V}_{\text {CORE }}$ by employing both "slow" and "fast" voltage regulation. The internal error amplifier performs the slow regulation. Depending on the gain and frequency compensation set by the amplifier's external components, the error amplifier will typically begin to ramp its output to react to changes in the output voltage in 1-2 PWM cycles. Fast voltage feedback is implemented by a direct connection from Vcore to the non-inverting pin of the PWM comparator via the summation with the inductor current, internal ramp, and Offset. A rapid increase in output current will produce a negative offset at Vcore and at the output of the summer. This will cause the PWM duty cycle to increase almost instantly. Fast feedback will typically adjust the PWM duty-cycle in 1 PWM cycle.
As shown in Figure 3, an internal ramp (nominally 90 mV at a $50 \%$ duty cycle) is added to the inductor current ramp at the positive terminal of the PWM comparator. This additional ramp compensates for propagation time delays from the current sense amplifier (CSA), the PWM comparator, and the MOSFET gate drivers. As a result, the minimum ON time of the controller is reduced and lower duty-cycles may be achieved at higher frequencies. Also, the additional ramp reduces the reliance on the inductor current ramp and allows greater flexibility when choosing the output inductor and the $\mathrm{R}_{\mathrm{CSx}} \mathrm{C}_{\mathrm{CSx}}$ time constant of the feedback components from $\mathrm{V}_{\text {CORE }}$ to the CSn pin.

Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. When the average output current is zero, the COMP pin will be:

$$
\begin{aligned}
\text { VCOMP }= & \text { VOUT @ } 0 \text { A + Channel_Startup_Offset } \\
& + \text { Int_Ramp }+ \text { GCSA } \cdot \text { Ext_Ramp } / 2
\end{aligned}
$$

Int_Ramp is the "partial" internal ramp value at the corresponding duty cycle, Ext_Ramp is the peak-to-peak external steady-state ramp at 0 A, $\mathrm{G}_{\mathrm{CSA}}$ is the Current Sense Amplifier Gain (nominally 3 V/V), and the Channel Startup Offset is typically 0.60 V . The magnitude of the Ext_Ramp can be calculated from:

$$
\text { Ext_Ramp }=\mathrm{D} \cdot\left(\mathrm{~V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) /\left(\mathrm{RCSn}^{2} \cdot \mathrm{CCSn} \cdot \mathrm{fSW}\right)
$$

For example, if $\mathrm{V}_{\text {Out }}$ at 0 A is set to 1.700 V with AVP and the input voltage is 12.0 V , the duty cycle ( D ) will be $1.700 / 12.0$ or $14.2 \%$. Int_Ramp will be $90 \mathrm{mV} / 50 \bullet 14.2 \%$ $=26 \mathrm{mV}$. Realistic values for $\mathrm{R}_{\mathrm{CSn}}, \mathrm{C}_{\mathrm{CSn}}$ and $\mathrm{f}_{\mathrm{Sw}}$ are $10 \mathrm{k} \Omega$, $0.015 \mu \mathrm{~F}$, and 650 kHz - using these and the previously mentioned formula, Ext_Ramp will be 15.0 mV .

$$
\begin{aligned}
\mathrm{V} \text { COMP }= & 1.700 \mathrm{~V}+0.60 \mathrm{~V}+26 \mathrm{mV} \\
& +3 \mathrm{~V} / \mathrm{V} \cdot 15.0 \mathrm{mV} / 2 \\
= & 2.348 \mathrm{Vdc}
\end{aligned}
$$

If the COMP pin is held steady and the inductor current changes, there must also be a change in the output voltage. Or, in a closed loop configuration when the output current
changes, the COMP pin must move to keep the same output voltage. The required change in the output voltage or COMP pin depends on the scaling of the current feedback signal and is calculated as:

$$
\Delta \mathrm{V}=\mathrm{RS} \cdot \mathrm{GCSA} \cdot \Delta \mathrm{I} \mathrm{OUT}
$$

The single-phase power stage output impedance is:

$$
\text { Single Stage Impedance }=\Delta \mathrm{V}_{\mathrm{OUT}} / \Delta \mathrm{I} \mathrm{OUT}=\mathrm{RS} \cdot \mathrm{GCSA}
$$

The total output impedance will be the single stage impedance divided by 4 .

The multi-phase power stage output impedance is the single-phase output impedance divided by the number of phases. The output impedance of the power stage determines how the converter will respond during the first few microseconds of a transient before the feedback loop has repositioned the COMP pin.

The peak output current can be calculated from:

Figure 4. Open Loop Operation
Figure 4 shows the step response of the COMP pin at a fixed level. Before T1 the converter is in normal steady state operation. The inductor current provides a portion of the PWM ramp through the Current Sense Amplifier. The PWM cycle ends when the sum of the current ramp, the "partial" internal ramp voltage signal and Offset exceed the level of the COMP pin. At T1 the output current increases and the output voltage sags. The next PWM cycle begins and the cycle continues longer than previously while the current signal increases enough to make up for the lower voltage at the $\mathrm{V}_{\mathrm{FB}}$ pin and the cycle ends at T 2 . After T 2 the output voltage remains lower than at light load and the average current signal level (CSx output) is raised so that the sum of the current and voltage signal is the same as with the original load. In a closed loop system the COMP pin would move higher to restore the output voltage to the original level.

Figure 5. Enhanced ${ }^{2}$ Control Employing Lossless Inductive Current Sensing and Internal Ramp

## Inductive Current Sensing

For lossless sensing, current can be sensed across the inductor as shown in Figure 5. In the diagram, L is the output inductance and $\mathrm{R}_{\mathrm{L}}$ is the inherent inductor resistance. To compensate the current sense signal, the values of $\mathrm{R}_{\mathrm{CSx}}$ and $\mathrm{C}_{\mathrm{CSx}}$ are chosen so that $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R}_{\mathrm{CSn}} \bullet \mathrm{C}_{\mathrm{CSn}}$. If this criteria is met, the current sense signal will be the same shape as the inductor current and the voltage signal at CSx will represent the instantaneous value of inductor current. Also, the circuit can be analyzed as if a sense resistor of value $\mathrm{R}_{\mathrm{L}}$ was used as a sense resistor $\left(\mathrm{R}_{\mathrm{S}}\right)$.

When choosing or designing inductors for use with inductive sensing, tolerances and temperature effects should be considered. Cores with a low permeability material or a large gap will usually have minimal inductance change with temperature and load. Copper magnet wire has a temperature coefficient of $0.39 \%$ per ${ }^{\circ} \mathrm{C}$. The increase in winding resistance at higher temperatures should be considered when setting the OCSET threshold. If a more accurate current sense is required than inductive sensing can provide, current can be sensed through a resistor as shown in Figure 3.

## Current Sharing Accuracy

Printed circuit board (PCB) traces that carry inductor current can be used as part of the current sense resistance depending on where the current sense signal is picked off. For accurate current sharing, the current sense inputs should sense the current at relatively the same point for each phase and the connection to the $\mathrm{CS}_{\mathrm{REF}}$ pin should be made so that no phase is favored. In some cases, especially with inductive sensing, resistance of the PCB can be useful for increasing the current sense resistance. The total current sense resistance used for calculations must include any PCB trace resistance between the CSx input and the $\mathrm{CS}_{\text {REF }}$ input that carries inductor current.

Current Sense Amplifier (CSA) input mismatch and the value of the current sense component will determine the accuracy of the current sharing between phases. The worst case Current Sense Amplifier input mismatch is $\pm 5.0 \mathrm{mV}$ and will typically be within 3.0 mV . The difference in peak currents between phases will be the CSA input mismatch divided by the current sense resistance. If all current sense components are of equal resistance a 3.0 mV mismatch with a $2.0 \mathrm{~m} \Omega$ sense resistance will produce a 1.5 A difference in current between phases.

## External Ramp Size and Current Sensing

The internal ramp allows flexibility of current sense time constant. Typically, the current sense $\mathrm{R}_{\mathrm{CSx}} \mathrm{C}_{\mathrm{CSx}}$ time constant should be equal to or slightly slower than the inductor's time constant. If RC is chosen to be smaller (faster) than $\mathrm{L} / \mathrm{R}_{\mathrm{L}}$, the AC or transient portion of the current sensing signal will be scaled larger than the DC portion. This will provide a larger steady state ramp, but circuit performance will be affected and must be evaluated carefully. The current signal will overshoot during transients and settle at the rate determined by $\mathrm{R}_{\mathrm{CSx}} \bullet \mathrm{C}_{\mathrm{CSx}}$. It will eventually settle to the correct DC level, but the error will decay with the time constant of $\mathrm{R}_{\mathrm{CSx}} \bullet \mathrm{C}_{\mathrm{CSx}}$. If this error is excessive it will effect transient response, adaptive positioning and current limit. During a positive current transient, the COMP pin will be required to undershoot in response to the current signal in order to maintain the output voltage. Similarly, the $\mathrm{V}_{\text {DRP }}$ signal will overshoot which will produce too much transient droop in the output voltage. The single phase pulse-by-pulse overcurrent protection will trip earlier than it would if compensated correctly and hiccup mode current limit will have a lower threshold for fast rising step loads than for slowly rising output currents.
The waveforms in Figure 6 show a simulation of the current sense signal and the actual inductor current during a
positive step in load current with values of $\mathrm{L}=500 \mathrm{nH}, \mathrm{R}_{\mathrm{L}}$ $=1.6 \mathrm{~m} \Omega, \mathrm{R}_{\mathrm{CSx}}=20 \mathrm{k}$ and $\mathrm{C}_{\mathrm{CSx}}=.01 \mu \mathrm{~F}$. In this case, ideal current signal compensation would require $\mathrm{R}_{\mathrm{CSx}}$ to be $31 \mathrm{k} \Omega$. Due to the faster than ideal RC time constant there is an overshoot of $50 \%$ and the overshoot decays with a $200 \mu \mathrm{~s}$ time constant. With this compensation the OCSET pin threshold must be set more than $50 \%$ above the full load current to avoid triggering hiccup mode during a large output load step.

Figure 6. Inductive Sensing Waveform During a Load Step with Fast RC Time Constant ( $50 \mu \mathrm{~s} / \mathrm{div}$ )

## Transient Response and Adaptive Voltage Positioning

For applications with fast transient currents the output filter is frequently sized larger than ripple currents require in order to reduce voltage excursions during load transients. Adaptive voltage positioning can reduce peak-peak output voltage deviations during load transients and allow for a smaller output filter. The output voltage can be set higher than nominal at light loads to reduce output voltage sag when the load current is applied. Similarly, the output voltage can be set lower than nominal during heavy loads to reduce overshoot when the load current is removed. For low current applications a droop resistor can provide fast accurate adaptive positioning. However, at high currents the loss in a droop resistor becomes excessive. For example, in a 50 A converter a $1 \mathrm{~m} \Omega$ resistor would provide a 50 mV change in output voltage between no load and full load and would dissipate 2.5 W .
Lossless adaptive voltage positioning (AVP) is an alternative to using a droop resistor, but it must respond to changes in load current. Figure 7 shows how AVP works. The waveform labeled normal shows a converter without AVP. On the left, the output voltage sags when the output current is stepped up and later overshoots when current is stepped back down. With fast (ideal) AVP the peak to peak
excursions are cut in half. In the slow AVP waveform the output voltage is not repositioned quickly enough after current is stepped up and the upper limit is exceeded.

Figure 7. Adaptive Voltage Positioning
The controller can be configured to adjust the output voltage based on the output current of the converter. (Refer to the application diagram in Figure 1). To set the no-load positioning, a resistor is placed between the output voltage and $\mathrm{V}_{\mathrm{FB}}$ pin. The $\mathrm{V}_{\mathrm{FB}}$ bias current will develop a voltage across the resistor to adjust the no-load output voltage. The $\mathrm{V}_{\mathrm{FB}}$ bias current is dependent on the value of $\mathrm{R}_{\mathrm{OSC}}$ as shown in the datasheets.

During no load conditions the $\mathrm{V}_{\mathrm{DRP}}$ pin is at the same voltage as the $\mathrm{V}_{\mathrm{FB}}$ pin, so none of the $\mathrm{V}_{\mathrm{FB}}$ bias current flows through the $\mathrm{V}_{\mathrm{DRP}}$ resistor. When output current increases the $V_{\text {DRP }}$ pin increases proportionally and the $V_{\text {DRP }}$ pin current offsets the $\mathrm{V}_{\mathrm{FB}}$ bias current and causes the output voltage to decrease.

The response during the first few microseconds of a load transient are controlled primarily by power stage output impedance and the ESR and ESL of the output filter. The transition between fast and slow positioning is controlled by the total ramp size and the error amp compensation. If the ramp size is too large or the error amp too slow there will be a long transition to the final voltage after a transient. This will be most apparent with lower capacitance output filters.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as a result of the normal operation of the Enhanced $\mathrm{V}^{2}$ control topology with synchronous rectifiers. The control loop responds to an overvoltage condition within 40 ns , causing the GATEx output to shut OFF. The (external) MOSFET driver should react normally to turn off the top MOSFET and turn on the bottom MOSFET. This results in a "crowbar" action to clamp the output voltage and prevent damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low.

## Power Good

According to the latest specifications, the Power Good (PWRGD) signal must be asserted when the output voltage is within a window defined by the VID code, as shown in Figure 8.

Figure 8. PWRGD Assertion Window
The PWRGDS pin is provided to allow the PWRGD comparators to accurately sense the output voltage. The effect of the PWRGD lower threshold can be modified using a resistor divider from the output to PWRGDS to ground, as shown in Figure 9, below.

Figure 9. Adjusting the PWRGD Threshold
Since the internally set thresholds for PWRGDS are VID/2 for the lower threshold and a fixed 1.975V for the upper threshold, a simple equation can be provided to assist the designer in selecting a resistor divider to provide the desired PWRGD performance.

$$
\begin{aligned}
& V_{\text {LOWER }}=\frac{V_{V I D}}{2} \cdot \frac{R_{1}+R_{2}}{R_{1}} \\
& V_{\text {UPPER }}=1.975 \mathrm{~V}
\end{aligned}
$$

The logic circuitry inside the chip sets PWRGD low only after a delay period has been passed. A "power bad" event does not cause PWRGD to go low unless it is sustained through the delay time of $500 \mu \mathrm{~s}$. If the anomaly disappears before the end of the delay, the PWRGD output will never be set low.

In order to use the PWRGD pin as specified, the user is advised to connect external resistors as necessary to limit the current into this pin to 4 mA or less.

## Undervoltage Lockout

The CS5307 includes an undervoltage lockout circuit. This circuit keeps the IC's output drivers low until $\mathrm{V}_{\mathrm{CC}}$ applied to the IC reaches 9 V . The GATE outputs are disabled when $\mathrm{V}_{\mathrm{CC}}$ drops below 8 V .

## Soft Start and Hiccup Mode

At initial power-up, both SS and COMP voltages are zero. The total SS capacitance will begin to charge with a current of $160 \mu \mathrm{~A}$. The error amplifier directly charges the COMP capacitance. An internal clamp ensures that the COMP pin voltage will always be less than the voltage at the SS pin, ensuring proper start-up behavior. All GATE outputs are held low until the COMP voltage reaches 0.6 V . Once this threshold is reached, the GATE outputs are released to operate normally. In hiccup-mode, the internal fault latch will initiate a $5 \mu \mathrm{~A}$ discharge current on the SS pin, and the internal clamp will discharge the capacitor connected to the COMP pin at a similar rate. This performance will result in GATE pulses being generated until the overcurrent condition reoccurs, and the discharge/soft start cycle begins anew.

## Current Limit

Two levels of over-current protection are provided. First, if the voltage on the Current Sense pins (either CS1 or CS2) exceeds $\mathrm{CS}_{\text {REF }}$ by more than a fixed threshold (Single Pulse Current Limit), the PWM comparator is turned off. This provides fast peak current protection for individual phases. Second, the individual phase currents are summed and low-pass filtered to compare an averaged current signal to a user adjustable voltage on the OCSET pin. If the OCSET voltage is exceeded, the fault latch trips and the Soft Start capacitor discharges until the Soft Start pin reaches 0.3 V . Then Soft Start begins. The converter will continue to operate in a low current hiccup mode until the fault condition is corrected.

## Fault Protection Logic

The CS5307 includes fault protection circuitry to prevent harmful modes of operation from occurring. The fault logic is described in Table 1.

Table 1. Fault Protection Logic

| Fault Modes | Stop Switching | SS Pin Characteristics | Reset Method |
| :--- | :---: | :---: | :---: |
| Undervoltage Lockout | Yes | $-5.0 \mu \mathrm{~A}$ | SS $<0.3 \mathrm{~V}$ |
| VID-11111 | Yes | $-5.0 \mu \mathrm{~A}$ | Change VID Code |
| Phase Over Current <br> $(0.33 ~ V ~ L i m i t) ~$ | No | Not Affected | Automatic |

## Gate Outputs

The CS5307 is designed to operate with external gate drivers. Accordingly, the gate outputs are capable of driving a 100 pF load with typical rise and fall times of 15 ns .

## Digital to Analog Converter (DAC)

The output voltage of the CS5307 is set by means of a 5 -bit, $1 \%$ DAC. The DAC pins are internally pulled up to a 3.3 V rail through a blocking diode and a set of $50 \mathrm{k} \Omega$ resistors. The blocking diode allows external pull up to a bias voltage greater than 3.3 V and less than 13 V .

The output of the DAC is described in the Electrical Characteristics section of the data sheet. These outputs are
consistent with the latest VRM and processor specifications. The DAC output is equal to the VID code specification.

In order to produce a workable power supply using the CS5307, the designer is expected to use AVP as described earlier to position the output voltage above the DAC output, resulting in an output voltage somewhere in the middle of the acceptable range.

The latest VRM and processor specifications require a power supply to turn its output off in the event of a 11111 VID code. When the DAC sees such a code, the GATE pins stop switching and go low. This condition is described in Table 1.

## CS5308

## Two－Phase PWM Controller with Integrated Gate Drivers for VRM 8.5

The CS5308 is a second－generation，two－phase step down controller that incorporates all control functions required to power next generation processors．Proprietary multi－phase architecture guarantees balanced load current distribution and reduces overall solution cost in high current applications．Enhanced V ${ }^{2 \mathrm{TM}}$ control architecture provides the fastest possible transient response，excellent overall regulation，and ease of use．The CS5308 is a second generation PWM controller because it optimizes transient response by combining traditional Enhanced $\mathrm{V}^{2}$ with an internal PWM ramp and fast－feedback directly from $\mathrm{V}_{\text {CORE }}$ to the internal PWM comparator． These enhancements provide greater design flexibility，facilitate use and reduce output voltage jitter．

The multi－phase architecture reduces input and output filter ripple， allowing for a significant reduction in filter size and inductor values with a corresponding increase in the output inductor current slew rate． This approach allows a considerable reduction in input and output capacitor requirements，as well as reducing overall solution size and cost．

The CS5308 includes VTT monitoring and timing，VTT Power Good（VTT ${ }_{\text {PGD }}$ ），Power Good（PWRGD），and internal MOSFET gate drivers to provide a＂fully integrated solution＂to simplify design， minimize circuit board area，and reduce overall system cost．

## Features

－Enhanced $V^{2}$ Control Method
－Internal PWM Ramp
－Fast－Feedback Directly from $V_{\text {CORE }}$
－5－Bit DAC with $1 \%$ Tolerance
－Adjustable Output Voltage Positioning
－ 200 kHz to 800 kHz Operation Set by Resistor
－Current Sensed through Sense Resistors or Output Inductors
－Adjustable Hiccup Mode Current Limit
－Overvoltage Protection through Synchronous MOSFETs
－Individual Current Limits for Each Phase
－On－Board Current Share Amplifiers
－ $3.3 \mathrm{~V}, 1.0 \mathrm{~mA}$ Reference Output
－VTT Monitoring and VTT Power Good（VTT ${ }_{\text {PGD }}$ ）
－V CORE Power Good
－On／Off Control（through COMP Pin）
－Improved Noise Immunity

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| 28 Lead SO Wide | PIN SYMBOL | FUNCTION |
| 1 | COMP | Output of the error amplifier and input for the PWM comparators. |
| 2 | $\mathrm{V}_{\mathrm{FB}}$ | Voltage Feedback Pin. To use Adaptive Voltage Positioning, set the light load offset voltage by connecting a resistor between $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {OUT }}$. The resistor and the $\mathrm{V}_{\text {FB }}$ bias current determine the offset. For no adaptive positioning connect $\mathrm{V}_{\mathrm{FB}}$ directly to $\mathrm{V}_{\mathrm{OUT}}$. |
| 3 | $\mathrm{V}_{\text {DRP }}$ | Current sense output for Adaptive Voltage Positioning (AVP). The offset of this pin above the DAC voltage is proportional to the output current. Connect a resistor from this pin to $\mathrm{V}_{\mathrm{FB}}$ to set the amount of AVP or leave this pin open for no AVP. This pin's maximum working voltage is 2.3 Vdc . |
| 4 | REF | Reference output. Decouple to LGND with $0.1 \mu \mathrm{~F}$. |
| 5 | ILIM | Sets threshold for current limit. Connect to reference through a resistive divider. This pin's maximum working voltage is 1.3 Vdc . |
| 6-10 | VID Pins | Voltage ID DAC inputs. These pins are internally pulled up to 3.3 V if left open. |
| 11 | PWRGD | Power Good Output. Open collector output goes low when $\mathrm{CS}_{\text {REF }}$ is out of regulation. |
| 12 | CS ${ }_{\text {REF }}$ | Reference for current sense amplifiers, input to the Power Good comparators, and fast feedback connection to the PWM comparator. Connect this pin to the output voltage through a resistor equal to $1 / 5$ th the value of the current sense resistors. The input voltage to this pin must not exceed the maximum VID (DAC) setting by more than 100 mV . |
| 13, 14 | CS1-CS2 | Current Sense inputs. Connect Current Sense network for the corresponding phase to each input. The input voltages to these pins must be kept within 105 mV of $\mathrm{CS}_{\text {REF }}$ or pulse-by-pulse current limit will be triggered. |
| 15 | VTT | VTT sense input. The voltage on this pin must be higher than the VTT threshold (nominally 1.05 V ) or switching will not occur. |
| 16 | $\mathrm{VTT}_{\text {CT }}$ | 1.0 ms timer for VTT Power Good. |
| 17 | VTTP $_{\text {GD }}$ | VTT Power Good output. Open collector, pulls down when VTT < 1.03 V . |
| 18 | $\mathrm{V}_{\mathrm{CCH} 2}$ | Power for channel 2 high side gate driver. |
| 19, 20 | GATE(H)2, GATE(L)2 | High and low side gate drivers for channels 1 and 2. |
| 21 | $\mathrm{V}_{\text {CCL12 }}$ | Power for both low side gate drivers. |
| 22 | PGND | Return for all gate drivers. |
| 23, 24 | GATE(L)1, GATE(H)1 | Low and high side gate drivers for channels 1 and 2. |
| 25 | $\mathrm{V}_{\mathrm{CCH} 1}$ | Power for channel 1 high side gate driver. |
| 26 | $\mathrm{V}_{\mathrm{CCL}}$ | Power for logic. UVLO Sense for supply connects to this pin. |
| 27 | LGND | Ground for internal control circuits and the IC substrate connection. |
| 28 | Rosc | A resistor from this pin to ground sets operating frequency. |

## APPLICATIONS INFORMATION

## Overview

The CS5308 DC/DC controller from ON Semiconductor was developed using the Enhanced $\mathrm{V}^{2}$ topology to meet requirements of low voltage, high current loads with fast transient requirements. Enhanced $\mathrm{V}^{2}$ combines the original $\mathrm{V}^{2}$ topology with peak current-mode control for fast transient response and current sensing capability. The addition of an internal PWM ramp and implementation of fast-feedback directly from $V_{\text {CORE }}$ has improved transient response and simplified design. The CS5308 includes VTT monitoring, $\mathrm{VTT}_{\mathrm{PGD}}$, PWRGD, and MOSFET gate drivers to provide a "fully integrated solution" to simplify design, minimize circuit board area, and reduce overall system cost.

Two advantages of a multi-phase converter over a single-phase converter are current sharing and increased apparent output frequency. Current sharing allows the designer to use less inductance in each phase than would be required in a single-phase converter. The smaller inductor will produce larger ripple currents but the total per phase power dissipation is reduced because the RMS current is lower. Transient response is improved because the control loop will measure and adjust the current faster in a smaller output inductor. Increased apparent output frequency is desirable because the off-time and the ripple voltage of the two-phase converter will be less than that of a single-phase converter.

## Fixed Frequency Multi-Phase Control

In a multi-phase converter, multiple converters are connected in parallel and are switched on at different times. This reduces output current from the individual converters and increases the apparent ripple frequency. Because several converters are connected in parallel, output current can ramp up or down faster than a single converter (with the same value output inductor) and heat is spread among multiple components.

The CS5308 controller uses two-phase, fixed frequency, Enhanced $\mathrm{V}^{2}$ architecture to measure and control currents in
individual phases. Each phase is delayed $180^{\circ}$ from the previous phase. Normally, GATE(H) transitions to a high voltage at the beginning of each oscillator cycle. Inductor current ramps up until the combination of the current sense signal, the internal ramp and the output voltage ripple trip the PWM comparator and bring GATE(H) low. Once GATE(H) goes low, it will remain low until the beginning of the next oscillator cycle. While $\operatorname{GATE}(\mathrm{H})$ is high, the Enhanced $\mathrm{V}^{2}$ loop will respond to line and load variations. On the other hand, once $\operatorname{GATE}(\mathrm{H})$ is low, the loop can not respond until the beginning of the next PWM cycle. Therefore, constant frequency Enhanced $\mathrm{V}^{2}$ will typically respond to disturbances within the off-time of the converter.
The Enhanced $V^{2}$ architecture measures and adjusts the output current in each phase. An additional input ( CSn ) for inductor current information has been added to the $\mathrm{V}^{2 \mathrm{TM}}$ loop for each phase as shown in Figure 9. The triangular inductor current is measured differentially across $\mathrm{R}_{\mathrm{S}}$, amplified by CSA and summed with the Channel Startup Offset, the Internal Ramp, and the Output Voltage at the non-inverting input of the PWM comparator. The purpose of the Internal Ramp is to compensate for propagation delays in the CS5308. This provides greater design flexibility by allowing smaller external ramps, lower minimum pulse widths, higher frequency operation, and PWM duty cycles above $50 \%$ without external slope compensation. As the sum of the inductor current and the internal ramp increase, the voltage on the positive pin of the PWM comparator rises and terminates the PWM cycle. If the inductor starts a cycle with higher current, the PWM cycle will terminate earlier providing negative feedback. The CS5308 provides a CSn input for each phase, but the $\mathrm{CS}_{\text {REF }}$ and COMP inputs are common to all phases. Current sharing is accomplished by referencing all phases to the same $\mathrm{CS}_{\text {REF }}$ and COMP pins, so that a phase with a larger current signal will turn off earlier than a phase with a smaller current signal.

Figure 9. Enhanced V ${ }^{2}$ Control Employing Resistive Current Sensing and Additional Internal Ramp

Enhanced $\mathrm{V}^{2}$ responds to disturbances in $\mathrm{V}_{\text {CORE }}$ by employing both "slow" and "fast" voltage regulation. The internal error amplifier performs the slow regulation. Depending on the gain and frequency compensation set by the amplifier's external components, the error amplifier will typically begin to ramp its output to react to changes in the output voltage in 1-2 PWM cycles. Fast voltage feedback is implemented by a direct connection from $\mathrm{V}_{\text {CORE }}$ to the non-inverting pin of the PWM comparator via the summation with the inductor current, internal ramp, and OFFSET. A rapid increase in load current will produce a negative offset at $\mathrm{V}_{\text {CORE }}$ and at the output of the summer. This will cause the PWM duty cycle to increase almost instantly. Fast feedback will typically adjust the PWM duty-cycle in one PWM cycle.
As shown in Figure 9, a "partial" internal ramp (nominally 125 mV at a $50 \%$ duty cycle) is added to the inductor current ramp at the positive terminal of the PWM comparator. This additional ramp compensates for propagation time delays from the current sense amplifier (CSA), the PWM comparator, and the MOSFET gate drivers. As a result, the minimum ON time of the controller is reduced and lower duty cycles may be achieved at higher frequencies. Also, the additional ramp reduces the reliance on the inductor current ramp and allows greater flexibility when choosing the output inductor and the $\mathrm{R}_{\mathrm{CSn}} \mathrm{C}_{\mathrm{CSn}}(\mathrm{n}=1$ or 2 ) time constant of the feedback components from $\mathrm{V}_{\text {CORE }}$ to the CSn pin.
Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. When the average output current is zero, the COMP pin will be:

$$
\begin{aligned}
\text { VCOMP }= & \text { VOUT @ } 0 \text { A }+ \text { Channel_Startup_Offset } \\
& + \text { Int_Ramp }+ \text { GCSA } \cdot \text { Ext_Ramp } / 2
\end{aligned}
$$

Int_Ramp is the "partial" internal ramp value at the corresponding duty cycle, Ext_Ramp is the peak-to-peak external steady-state ramp at 0 A, $\mathrm{G}_{\mathrm{CSA}}$ is the Current Sense Amplifier Gain (nominally $3.5 \mathrm{~V} / \mathrm{V}$ ), and the Channel Startup Offset is typically 0.40 V . The magnitude of the Ext_Ramp can be calculated from:

$$
\text { Ext_Ramp }=\mathrm{D} \cdot\left(\mathrm{~V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) /\left(\mathrm{R}_{\mathrm{CSn}} \cdot \mathrm{C}_{\mathrm{CSn}} \cdot \mathrm{fSW}\right)
$$

For example, if $\mathrm{V}_{\text {Out }}$ at 0 A is set to 1.745 V with AVP and the input voltage is 5.0 V , the duty cycle (D) will be $1.745 / 5.0$ or $35 \%$. Int_Ramp will be $125 \mathrm{mV} \bullet 35 / 50=87.5 \mathrm{mV}$. Realistic values for $\mathrm{R}_{\mathrm{CSn}}, \mathrm{C}_{\mathrm{CSn}}$ and $\mathrm{f}_{\text {Sw }}$ are $60 \mathrm{k} \Omega, 0.01 \mu \mathrm{~F}$, and 300 kHz - using these Ext_Ramp will be 6.3 mV .

$$
\begin{aligned}
\mathrm{V}_{\mathrm{COMP}}= & 1.745 \mathrm{~V}+0.40 \mathrm{~V}+87.5 \mathrm{mV} \\
& +3.5 \mathrm{~V} / \mathrm{V} \cdot 6.3 \mathrm{mV} / 2 \\
= & 2.244 \mathrm{Vdc}
\end{aligned}
$$

If the COMP pin is held steady and the inductor current changes, there must also be a change in the output voltage.

Or, in a closed loop configuration when the output current changes, the COMP pin must move to keep the same output voltage. The required change in the output voltage or COMP pin depends on the scaling of the current feedback signal and is calculated as:

$$
\Delta \mathrm{V}=\mathrm{R} \cdot \mathrm{G} \cdot \mathrm{CSA} \cdot \Delta \mathrm{I} \text { OUT }
$$

The single-phase power stage output impedance is:

$$
\text { Single Stage Impedance }=\Delta \mathrm{V}_{\mathrm{OUT}} / \Delta \mathrm{I} \mathrm{OUT}=\mathrm{RS} \cdot \mathrm{GCSA}
$$

The multi-phase power stage output impedance is the single-phase output impedance divided by the number of phases. The output impedance of the power stage determines how the converter will respond during the first few microseconds of a transient before the feedback loop has repositioned the COMP pin.

The peak output current can be calculated from:
IOUT,PEAK $=\left(V_{\text {COMP }}-\right.$ VOUT - Offset $) /\left(\mathrm{RS}_{\text {S }} \cdot \mathrm{GCSA}\right)$
Figure 10 shows the step response of the COMP pin at a fixed level. Before T1 the converter is in normal steady state operation. The inductor current provides a portion of the PWM ramp through the Current Sense Amplifier. The PWM cycle ends when the sum of the current ramp, the "partial" internal ramp voltage signal and Offset exceed the level of the COMP pin. At T1 the output current increases and the output voltage sags. The next PWM cycle begins and the cycle continues longer than previously while the current signal increases enough to make up for the lower voltage at the $\mathrm{V}_{\mathrm{FB}}$ pin and the cycle ends at T2. After T2 the output voltage remains lower than at light load and the average current signal level (CSn output) is raised so that the sum of the current and voltage signal is the same as with the original load. In a closed loop system the COMP pin would move higher to restore the output voltage to the original level.

Figure 10. Open Loop Operation

Figure 11. Enhanced V² Control Employing Lossless Inductive Current Sensing and Internal Ramp

## Inductive Current Sensing

For lossless sensing, current can be sensed across the inductor as shown in Figure 11. In the diagram, L is the output inductance and $\mathrm{R}_{\mathrm{L}}$ is the inherent inductor resistance. To compensate the current sense signal, the values of $\mathrm{R}_{\mathrm{CSn}}$ and $\mathrm{C}_{\mathrm{CSn}}$ are chosen so that $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R}_{\mathrm{CSn}} \bullet \mathrm{C}_{\mathrm{CSn}}$. If this criteria is met, the current sense signal will be the same shape as the inductor current and the voltage signal at CSn will represent the instantaneous value of inductor current. Also, the circuit can be analyzed as if a sense resistor of value $R_{L}$ was used as a sense resistor ( $\mathrm{R}_{\mathrm{S}}$ ).

When choosing or designing inductors for use with inductive sensing, tolerances and temperature effects should be considered. Cores with a low permeability material or a large gap will usually have minimal inductance change with temperature and load. Copper magnet wire has a temperature coefficient of $0.39 \%$ per ${ }^{\circ} \mathrm{C}$. The increase in winding resistance at higher temperatures should be considered when setting the $\mathrm{I}_{\text {LIM }}$ threshold. If a more accurate current sense is required than inductive sensing can provide, current can be sensed through a resistor as shown in Figure 9.

## Current Sharing Accuracy

Printed circuit board (PCB) traces that carry inductor current can be used as part of the current sense resistance depending on where the current sense signal is picked off. For accurate current sharing, the current sense inputs should sense the current at relatively the same point for each phase and the connection to the $\mathrm{CS}_{\mathrm{REF}}$ pin should be made so that no phase is favored. In some cases, especially with inductive sensing, resistance of the PCB can be useful for increasing the current sense resistance. The total current sense resistance used for calculations must include any PCB trace resistance between the CSn input and the $\mathrm{CS}_{\text {REF }}$ input that carries inductor current.

Current Sense Amplifier (CSA) input mismatch and the value of the current sense component will determine the accuracy of the current sharing between phases. The worst case Current Sense Amplifier input mismatch is $\pm 5.0 \mathrm{mV}$ and will typically be within 3.0 mV . The difference in peak currents between phases will be the CSA input mismatch divided by the current sense resistance. If all current sense components are of equal resistance a 3.0 mV mismatch with a $2.0 \mathrm{~m} \Omega$ sense resistance will produce a 1.5 A difference in current between phases.

## External Ramp Size and Current Sensing

The internal ramp allows flexibility of current sense time constant. Typically, the current sense $\mathrm{R}_{\mathrm{CSn}} \mathrm{C}_{\mathrm{CSn}}$ time constant ( $\mathrm{n}=1$ or 2 ) should be equal to or slower than the inductor's time constant. If RC is chosen to be smaller (faster) than $\mathrm{L} / \mathrm{R}_{\mathrm{L}}$, the AC or transient portion of the current sensing signal will be scaled larger than the DC portion. This will provide a larger steady state ramp, but circuit performance will be affected and must be evaluated carefully. The current signal will overshoot during transients and settle at the rate determined by $\mathrm{R}_{\mathrm{CSn}} \bullet \mathrm{C}_{\mathrm{CSn}}$. It will eventually settle to the correct DC level, but the error will decay with the time constant of $\mathrm{R}_{\mathrm{CSn}} \bullet \mathrm{C}_{\mathrm{CSn}}$. If this error is excessive it will effect transient response, adaptive positioning and current limit. During a positive current transient, the COMP pin will be required to overshoot in response to the current signal in order to maintain the output voltage. Similarly, the $\mathrm{V}_{\text {DRP }}$ signal will overshoot which will produce too much transient droop in the output voltage. Single phase overcurrent will trip earlier than it would if compensated correctly and hiccup mode current limit will have a lower threshold for fast rise step loads than for slowly rising output currents.
The waveforms in Figure 12 show a simulation of the current sense signal and the actual inductor current during
a positive step in load current with values of $\mathrm{L}=500 \mathrm{nH}$, $\mathrm{R}_{\mathrm{L}}=1.6 \mathrm{~m} \Omega, \mathrm{R}_{\mathrm{CSn}}=20 \mathrm{k}$ and $\mathrm{C}_{\mathrm{CSn}}=0.01 \mu \mathrm{~F}$. For ideal current signal compensation the value of $\mathrm{R}_{\mathrm{CSn}}$ should be 31 $\mathrm{k} \Omega$. Due to the faster than ideal RC time constant there is an overshoot of $50 \%$ and the overshoot decays with a $200 \mu$ s time constant. With this compensation the $\mathrm{I}_{\text {LIM }}$ pin threshold must be set more than $50 \%$ above the full load current to avoid triggering hiccup mode during a large output load step.

Figure 12. Inductive Sensing Waveform During a Load Step with Fast RC Time Constant ( $50 \mu \mathrm{~s} / \mathrm{div}$ )

## Current Limit

Two levels of over-current protection are provided. First, if the voltage on the Current Sense pins (either CS1 or CS2) exceeds CS $_{\text {REF }}$ by more than a fixed threshold (Single Pulse Current Limit), the PWM comparator is turned off. This provides fast peak current protection for individual phases. Second, the individual phase currents are summed and low-pass filtered to compare an averaged current signal to a user adjustable voltage on the $\mathrm{I}_{\text {LIM }}$ pin. If the $\mathrm{I}_{\text {LIM }}$ voltage is exceeded, the fault latch trips and the Soft Start capacitor is discharged until the COMP pin reaches 0.27 V . Then Soft Start begins. The converter will continue to operate in a low current hiccup mode until the fault condition is corrected.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as a result of the normal operation of the Enhanced $\mathrm{V}^{2}$ control topology with synchronous rectifiers. The control loop responds to an overvoltage condition within 400 ns , causing the top MOSFET to shut OFF and the synchronous (lower) MOSFET to turn ON. This results in a "crowbar" action to clamp the output voltage and prevent damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low.

## Transient Response and Adaptive Positioning

For applications with fast transient currents the output filter is frequently sized larger than ripple currents require in order to reduce voltage excursions during load transients. Adaptive voltage positioning can reduce peak-peak output voltage deviations during load transients and allow for a smaller output filter. The output voltage can be set higher than nominal at light loads to reduce output voltage sag when the load current is applied. Similarly, the output voltage can be set lower than nominal during heavy loads to reduce overshoot when the load current is removed. For low current applications a droop resistor can provide fast accurate adaptive positioning. However, at high currents the loss in a droop resistor becomes excessive. For example; in a 50 A converter a $1 \mathrm{~m} \Omega$ resistor to provide a 50 mV change in output voltage between no load and full load would dissipate 2.5 Watts.

Lossless adaptive positioning is an alternative to using a droop resistor, but must respond to changes in load current. Figure 13 shows how adaptive positioning works. The waveform labeled normal shows a converter without adaptive positioning. On the left, the output voltage sags when the output current is stepped up and later overshoots when current is stepped back down. With fast (ideal) adaptive positioning the peak to peak excursions are cut in half. In the slow adaptive positioning waveform the output voltage is not repositioned quickly enough after current is stepped up and the upper limit is exceeded.

Figure 13. Adaptive Positioning
The controller can be configured to adjust the output voltage based on the output current of the converter. (Refer to the application diagram in Figure 1.) To set the no-load positioning, a resistor is placed between the output voltage and $\mathrm{V}_{\mathrm{FB}}$ pin. The $\mathrm{V}_{\mathrm{FB}}$ bias current will develop a voltage across the resistor to adjust the no-load output voltage. The $\mathrm{V}_{\mathrm{FB}}$ bias current is dependent on the value of $\mathrm{R}_{\mathrm{OSC}}$ as shown in the data sheets.

During no-load conditions the $\mathrm{V}_{\mathrm{DRP}}$ pin is at the same voltage as the $\mathrm{V}_{\mathrm{FB}}$ pin, so none of the $\mathrm{V}_{\mathrm{FB}}$ bias current flows through the $\mathrm{V}_{\mathrm{DRP}}$ resistor. When output current increases the $\mathrm{V}_{\text {DRP }}$ pin increases proportionally and the $\mathrm{V}_{\text {DRP }}$ pin current offsets the $\mathrm{V}_{\mathrm{FB}}$ bias current and causes the output voltage to decrease.

The response during the first few microseconds of a load transient are controlled primarily by power stage output impedance and the ESR and ESL of the output filter. The transition between fast and slow positioning is controlled by the total ramp size and the error amp compensation. If the current signal is too large or the error amp too slow there will be a long transition to the final voltage after a transient. This will be most apparent with lower capacitance output filters.

## Error Amp Compensation \& Tuning

The transconductance error amplifier requires a capacitor ( $\mathrm{C}_{\mathrm{CMP} 2}$ in the Applications Diagram) between the COMP pin and GND for two reasons. First, this capacitor stabilizes the transconductance error amplifier. Values less than a few nF may cause oscillations of the COMP voltage. These oscillations will increase the output voltage jitter. Second, this capacitor sets the Soft Start time when power is applied to the converter or the converter is enabled. The internal error amplifier will source approximately $30 \mu \mathrm{~A}$ during Soft Start and no switching will occur until the COMP voltage exceeds the Channel Startup Offset (nominally 0.4 V ). The COMP voltage will ramp up to the value shown previously (repeated here for convenience):

$$
\begin{aligned}
\text { VCOMP }= & \text { VOUT @ } 0 \text { A }+ \text { Channel_Startup_Offset } \\
& + \text { Int_Ramp }+ \text { GCSA } \cdot \text { Ext_Ramp } / 2
\end{aligned}
$$

The RC network between the COMP pin and the Soft Start capacitor ( $\mathrm{R}_{\mathrm{CMP1}}$ and $\mathrm{C}_{\mathrm{CMP1}}$ ) allows the COMP voltage to slew quickly during transient loading of the converter. Without this network the error amplifier would have to drive the large Soft Start/Stability capacitor directly, which would drastically limit the slew rate of the COMP voltage. The $\mathrm{R}_{\mathrm{CMP1}} / \mathrm{C}_{\mathrm{CMP} 1}$ network allows the COMP voltage to undergo a step change in voltage of approximately $\mathrm{R}_{\mathrm{CMP} 1} \bullet \mathrm{I}_{\mathrm{COMP}}$.

The capacitor ( $\mathrm{C}_{\mathrm{AMP}}$ ) between the COMP pin and the inverting error amplifier input (the $\mathrm{V}_{\mathrm{FB}} \mathrm{pin}$ ) and the parallel combination of the resistors $\mathrm{R}_{\mathrm{FBK} 1}$ and $\mathrm{R}_{\mathrm{DRP} 1}$ determine the bandwidth of the error amplifier. The gain of the error amplifier crosses 0 dB at a high enough frequency to give a quick transient response, but well below the switching frequency to minimize ripple and noise on the COMP pin. A capacitor in parallel with the $\mathrm{V}_{\mathrm{FB}}$ resistor $\left(\mathrm{C}_{\mathrm{FBK} 2}\right)$ adds a zero to boost phase near the crossover frequency to improve loop stability.

Setting-up and tuning the error amplifier is a three step process. First, the no-load and full-load adaptive voltage positioning (AVP) are set using $\mathrm{R}_{\mathrm{FBK} 1}$ and $\mathrm{R}_{\mathrm{DRP} 1}$, respectively. Second, the current sense time constant and error amplifier gain are adjusted with $\mathrm{R}_{\mathrm{CSn}}$ and $\mathrm{C}_{\mathrm{AMP}}$ while monitoring $V_{\text {OUT }}$ during transient loading. Lastly, the peak-to-peak voltage ripple on the COMP pin is examined when the converter is fully loaded to insure low output voltage jitter. The details of this process are covered in the Design Procedure section.

## Undervoltage Lockout (UVLO)

The controller has undervoltage lockout functions connected to two pins. One, intended for the logic and low-side drivers, with approximately a 4.2 V turn-on threshold is connected to the $\mathrm{V}_{\mathrm{CC}}$ pin. A second, for the high side drivers, with approximately an 8.25 V threshold, is connected to the $\mathrm{V}_{\mathrm{CCH}}$ pin.

The UVLO threshold for the high side drivers varies with the part type. In many applications this function will be disabled or will only check that the applicable supply is on - not that is at a high enough voltage to run the converter. See individual data sheets for more information on UVLO.

## Soft Start Enable, and Hiccup Mode

A capacitor between the COMP pin and GND controls Soft Start and hiccup mode slopes. A $0.1 \mu \mathrm{~F}$ capacitor with the $30 \mu \mathrm{~A}$ charge current will allow the output to ramp up at $0.3 \mathrm{~V} / \mathrm{ms}$ or 1.5 V in 5 ms at start-up.

When a fault is detected due to an overcurrent condition the converter will enter a low duty cycle hiccup mode. During hiccup mode the converter will not switch from the time a fault is detected until the Soft Start capacitor has discharged below the Soft Start Discharge Threshold and then charged back up above the Channel Start Up Offset.

The COMP pin will disable the converter when pulled below 0.27 V

## VTT Monitoring \& VTT Power Good (VTT ${ }_{\text {PGD }}$ )

The CS5308 includes VTT monitoring, delay timing and an open-collector VTT Power Good ( $\mathrm{VTT}_{\mathrm{PGD}}$ ) output. A comparator with a threshold of approximately 1.05 V monitors VTT. At power-up, VTT PGD is held low and is released a short time after VTT crosses the 1.05 V threshold. The time between VTT stabilizing and the release of $\mathrm{VTT}_{\mathrm{PGD}}$ is set by a capacitor ( $\mathrm{C}_{\mathrm{VTT}}$ ) at the open-collector $\mathrm{VTT}_{\mathrm{CT}}$ pin. The voltage at the $\mathrm{VTT}_{\mathrm{CT}}$ pin will ramp from its $\mathrm{V}_{\mathrm{CE}(\mathrm{sat})}$ voltage, approximately 0.25 V , to 1 V before $\mathrm{VTT}_{\mathrm{PGD}}$ is pulled HIGH. The $\mathrm{VTT}_{\mathrm{CT}}$ charging current and $\mathrm{C}_{\text {VTT }}$ set the $\mathrm{VTT}_{\text {PGD }}$ delay time. The delay time can be calculated using:

$$
\text { TD,VTT = (1 V - } 0.25 \mathrm{~V}) \cdot \mathrm{CVTT} / \mathrm{VTT} \mathrm{CT} \text { _Current. }
$$

The $\mathrm{VTT}_{\mathrm{CT}}$ charging current is dependent on the selection of the oscillator frequency. See Figure 3 for a representation of oscillator frequency and charging current versus $\mathrm{R}_{\text {OSC }}$ value.

If either VTT or VTT $_{\text {PGD }}$ are held LOW, the internal Fault latch will be SET, the controller will stop switching, and $V_{\text {CORE }}$ will be zero.

## Power Good (PWRGD)

The open-collector Power Good (PWRGD) pin is driven by a "window-comparator" monitoring VCORE. This comparator will transition HIGH if $\mathrm{V}_{\text {CORE }}$ is within $\pm 12 \%$ of the nominal VID setting. After a $50 \mu \mathrm{~s}$ delay, the comparators output will saturate the open-collector output transistor and the PWRGD pin will be pulled LOW.

## Layout Guidelines

With the fast rise, high output currents of microprocessor applications, parasitic inductance and resistance should be considered when laying out the power, filter and feedback signal sections of the board. Typically, a multi-layer board with at least one ground plane is recommended. If the layout is such that high currents can exist in the ground plane underneath the controller or control circuitry, the ground plane can be slotted to route the currents away from the controller. The slots should typically not be placed between the controller and the output voltage or in the return path of the gate drive. Additional power and ground planes or islands can be added as required for a particular layout.

Gate drives experience high di/dt during switching and the inductance of gate drive traces should be minimized. Gate drive traces should be kept as short and wide as practical and should have a return path directly below the gate trace.

Output filter components should be placed on wide planes connected directly to the load to minimize resistive drops during heavy loads and inductive drops and ringing during transients. If required, the planes for the output voltage and return can be interleaved to minimize inductance between the filter and load.

The current sense signals are typically tens of milli-volts. Noise pick-up should be avoided wherever possible. Current feedback traces should be routed away from noisy areas such as the switch node and gate drive signals. If the current signals are taken from a location other than directly at the inductor any additional resistance between the pick-off point and the inductor appears as part of the inherent inductor resistances and should be considered in design calculations. The capacitors for the current feedback networks should be placed as close to the current sense pins as practical. After placing the CS5308 control IC, follow these guidelines to optimize the layout and routing:

1. Place the $1 \mu \mathrm{~F}$ power-supply bypass (ceramic) capacitors close to their associated pins: $\mathrm{V}_{\mathrm{CCL}}$, $\mathrm{V}_{\mathrm{CCH} 1}, \mathrm{~V}_{\mathrm{CCH} 2}, \mathrm{~V}_{\mathrm{CCL} 12}$.
2. Place the MOSFETs to minimize the length of the Gate traces. Orient the MOSFETs such that the Drain connections are away from the controller and the Gate connections are closest to the controller.
3. Place the components associated with the internal error amplifier ( $\mathrm{R}_{\mathrm{FBK} 1}, \mathrm{C}_{\mathrm{FBK} 2}, \mathrm{C}_{\mathrm{AMP}}, \mathrm{R}_{\mathrm{CMP} 1}$, $\mathrm{C}_{\mathrm{CMP} 1}, \mathrm{C}_{\mathrm{CMP} 2}, \mathrm{R}_{\mathrm{DRP} 1}$ ) to minimize the trace lengths to the pins $\mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{DRP}}$ and COMP.
4. Place the current sense components ( $\mathrm{R}_{\mathrm{CS} 1}, \mathrm{R}_{\mathrm{CS} 2}$, $\mathrm{C}_{\mathrm{CS} 1}, \mathrm{C}_{\mathrm{CS} 2}, \mathrm{R}_{\mathrm{CSREF}}, \mathrm{C}_{\mathrm{CSREF}}$ ) near the CS1, CS2, and $C_{\text {REF }}$ pins.
5. Place the frequency setting resistor ( $\mathrm{R}_{\mathrm{OSC}}$ ) close to the $\mathrm{R}_{\text {OSC }}$ pin. The $\mathrm{R}_{\text {OSC }}$ pin is very sensitive to noise. Route noisy traces, such as the SWNODEs and GATE traces, away from the $\mathrm{R}_{\mathrm{OSC}}$ pin and resistor.
6. Place the VTT timing capacitor ( $\mathrm{C}_{\mathrm{VTT}}$ ) and pull-up resistor $\left(\mathrm{R}_{\mathrm{VTT}}\right)$ near the $\mathrm{VTT}_{\mathrm{CT}}$ and $\mathrm{VTT}_{\mathrm{PGD}}$ pins.
7. Place the MOSFETs and output inductors to reduce the size of the noisy SWNODEs. There is a trade-off between reducing the size of the SWNODEs for noise reduction and providing adequate heat-sinking for the synchronous MOSFETs.
8. Place the input inductor and input capacitor(s) near the Drain of the control (upper) MOSFETs. There is a trade-off between reducing the size of this node to save board area and providing adequate heat-sinking for the control MOSFETs.
9. Place the output capacitors (electrolytic and ceramic) close to the processor socket or output connector.
10. The trace from the SWNODEs to the current sense components will be very noisy. Route this away from more sensitive, low-level traces. The Ground layer can be used to help isolate this trace.
11. The Gate traces are very noisy. Route these away from more sensitive, low-level traces. Keep each Gate signal on one layer and insure that there is an uninterrupted return path directly below the Gate trace. The Ground layer can be used to help isolate these traces.
12. Don't "daisy chain" connections to Ground from one via. Allow each connection to Ground to have its own via as close to the component as possible.
13. Use a slot in the ground plane from the bulk output capacitors back to the input power connector to prevent high currents from flowing beneath the control IC. This slot should extend length-wise under the control IC and separate the connections to "signal ground" and "power ground." Examples of signal ground include the capacitors at COMP, $\mathrm{CS}_{\mathrm{REF}}, \mathrm{REF}$, and $\mathrm{VTT}_{\mathrm{CT}}$, the resistors at $\mathrm{R}_{\mathrm{OSC}}$ and $\mathrm{I}_{\mathrm{LIM}}$, and the LGND pin to the controller. Examples of power ground include the capacitors to $\mathrm{V}_{\mathrm{CCH} 1}$, $\mathrm{V}_{\mathrm{CCH} 2}$ and $\mathrm{V}_{\mathrm{CCL} 12}$, the Source of the synchronous MOSFETs, and the PGND pin to the controller.
14. The $\mathrm{CS}_{\text {REF }}$ sense point should be equidistant between the output inductors to equalize the PCB resistance added to the current sense paths. This will insure acceptable current sharing. Also, route the $\mathrm{CS}_{\text {REF }}$ connection away from noisy traces such as the SWNODEs and GATE traces. If noise from the SWNODEs or GATE signals capacitively couples to the $\mathrm{CS}_{\text {REF }}$ trace the external ramps will be very noise and voltage jitter will result.
15. Ideally, the SWNODEs are exactly the same shape and the current sense points (connections to $\mathrm{R}_{\mathrm{CS} 1}$ and $\mathrm{R}_{\mathrm{CS} 2}$ ) are made at identical locations to equalize the PCB resistance added to the current sense paths. This will help to insure acceptable current sharing.
16. Place the $0.1 \mu \mathrm{~F}$ ceramic capacitors, $\mathrm{C}_{\mathrm{Q} 1}$ and $\mathrm{C}_{\mathrm{Q} 2}$, close to the drains of the MOSFETs Q1 and Q2, respectively.

## Design Procedure

## 1. Output Capacitor Selection

The output capacitors filter the current from the output inductor and provide a low impedance for transient load current changes. Typically, microprocessor applications will require both bulk (electrolytic, tantalum) and low impedance, high frequency (ceramic) types of capacitors. The bulk capacitors provide "hold up" during transient loading. The low impedance capacitors reduce steady-state ripple and bypass the bulk capacitance when the output current changes very quickly. The microprocessor manufacturers usually specify a minimum number of ceramic capacitors. The designer must determine the number of bulk capacitors.

Choose the number of bulk output capacitors to meet the peak transient requirements. The formula below can be used to provide a starting point for the minimum number of bulk capacitors ( $\mathrm{N}_{\text {OUT,MIN }}$ ):

$$
\begin{equation*}
\text { NOUT,MIN }=\text { ESR per capacitor } \cdot \frac{\Delta \mathrm{I}, \mathrm{MAX}}{\Delta \mathrm{~V}_{\mathrm{O}, \mathrm{MAX}}} \tag{1}
\end{equation*}
$$

In reality, both the ESR and ESL of the bulk capacitors determine the voltage change during a load transient according to:
$\Delta \mathrm{V}_{\mathrm{O}, \mathrm{MAX}}=\left(\Delta \mathrm{I}_{\mathrm{O}, \mathrm{MAX}} / \Delta \mathrm{t}\right) \cdot \mathrm{ESL}+\Delta \mathrm{I}_{\mathrm{O}, \mathrm{MAX}} \cdot \mathrm{ESR}$
Unfortunately, capacitor manufacturers do not specify the ESL of their components and the inductance added by the PCB traces is highly dependent on the layout and routing. Therefore, it is necessary to start a design with slightly more than the minimum number of bulk capacitors and perform transient testing or careful modeling/simulation to determine the final number of bulk capacitors.

## 2. Output Inductor Selection

The output inductor may be the most critical component in the converter because it will directly effect the choice of other components and dictate both the steady-state and transient performance of the converter. When selecting an inductor the designer must consider factors such as DC current, peak current, output voltage ripple, core material, magnetic saturation, temperature, physical size, and cost (usually the primary concern).

In general, the output inductance value should be as low and physically small as possible to provide the best transient response and minimum cost. If a large inductance value is used, the converter will not respond quickly to rapid changes in the load current. On the other hand, too low an inductance value will result in very large ripple currents in the power components (MOSFETs, capacitors, etc.) resulting in increased dissipation and lower converter efficiency. Also, increased ripple currents will force the designer to use higher rated MOSFETs, oversize the thermal solution, and use more, higher rated input and output capacitors - the converter cost will be adversely effected.

One method of calculating an output inductor value is to size the inductor to produce a specified maximum ripple current in the inductor. Lower ripple currents will result in less core and MOSFET losses and higher converter efficiency. Equation 3 may be used to calculate the minimum inductor value to produce a given maximum ripple current ( $\alpha$ ) per phase. The inductor value calculated by this equation is a minimum because values less than this will produce more ripple current than desired. Conversely, higher inductor values will result in less than the maximum ripple current.

$$
\begin{equation*}
\text { LOMIN }=\frac{\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\mathrm{OUT}}\right) \cdot \mathrm{V}_{\text {OUT }}}{\left(\alpha \cdot \mathrm{I}_{\mathrm{O}, \mathrm{MAX}} \cdot \mathrm{~V}_{\mathrm{IN}} \cdot \mathrm{fSW}\right)} \tag{3}
\end{equation*}
$$

$\alpha$ is the ripple current as a percentage of the maximum output current per phase ( $\alpha=0.15$ for $\pm 15 \%, \alpha=0.25$ for $\pm 25 \%$, etc.). If the minimum inductor value is used, the inductor current will swing $\pm \alpha \%$ about its value at the center ( $1 / 2$ the DC output current for a two-phase converter). Therefore, for a two-phase converter, the inductor must be designed or selected such that it will not saturate with a peak current of $(1+\alpha) \bullet \mathrm{I}_{\mathrm{O}, \mathrm{MAX}} / 2$.
The maximum inductor value is limited by the transient response of the converter. If the converter is to have a fast transient response then the inductor should be made as small as possible. If the inductor is too large its current will change too slowly, the output voltage will droop excessively, more bulk capacitors will be required, and the converter cost will be increased. For a given inductor value, its interesting to determine the times required to increase or decrease the current.

For increasing current:

$$
\begin{equation*}
\Delta \mathrm{t} \mathrm{INC}=\mathrm{Lo} \cdot \Delta \mathrm{I}_{\mathrm{O}} /\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \tag{3.1}
\end{equation*}
$$

For decreasing current:

$$
\begin{equation*}
\Delta \mathrm{tDEC}=\mathrm{Lo} \cdot \Delta \mathrm{IO} /(\mathrm{VOUT}) \tag{3.2}
\end{equation*}
$$

For typical processor applications with output voltages less than half the input voltage, the current will be increased much more quickly than it can be decreased. It may be more difficult for the converter to stay within the regulation limits when the load is removed than when it is applied - excessive overshoot may result.

The output voltage ripple can be calculated using the output inductor value derived in this Section (Lomin), the number of output capacitors ( $\mathrm{N}_{\text {OUT,MIN }}$ ) and the per capacitor ESR determined in the previous Section:

$$
\begin{align*}
& \text { VOUT,P-P }=(\text { ESR per cap } / \text { NOUT,MIN }) \cdot  \tag{4}\\
& \quad\{(\text { VIN }- \text { \#Phases } \cdot \text { VOUT }) \cdot \mathrm{D} /(\text { LoMIN } \cdot \text { fSW })\}
\end{align*}
$$

This formula assumes steady-state conditions with no more than one phase on at any time. The second term in Equation 4 is the total ripple current seen by the output capacitors. The total output ripple current is the "time
summation" of the two individual phase currents that are 180 degrees out-of-phase. As the inductor current in one phase ramps upward, current in the other phase ramps downward and provides a canceling of currents during part of the switching cycle. Therefore, the total output ripple current and voltage are reduced in a multi-phase converter.

## 3. Input Capacitor Selection

The choice and number of input capacitors is primarily determined by their voltage and ripple current ratings. The designer must choose capacitors that will support the worst case input voltage with adequate margin. To calculate the number of input capacitors one must first determine the total RMS input ripple current. To this end, begin by calculating the average input current to the converter:

$$
\begin{equation*}
\mathrm{I} \mathrm{IN}, \mathrm{AVG}=\mathrm{IO}, \mathrm{MAX} \cdot \mathrm{D} / \eta \tag{5}
\end{equation*}
$$

where:
D is the duty cycle of the converter, $\mathrm{D}=\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{IN}}$; $\eta$ is the specified minimum efficiency;
$\mathrm{I}_{\mathrm{O}, \text { MAX }}$ is the maximum converter output current.
The input capacitors will discharge when the control FET is ON and charge when the control FET is OFF as shown in Figure 14.

Figure 14. Input Capacitor Current for a Two-Phase Converter

The following equations will determine the maximum and minimum currents delivered by the input capacitors:

$$
\begin{align*}
\mathrm{IC}, \mathrm{MAX} & =\mathrm{I} \mathrm{LO}, \mathrm{MAX} / \eta-\mathrm{I} \mathrm{IN}, \mathrm{AVG}  \tag{6}\\
\mathrm{IC}, \mathrm{MIN} & =\mathrm{I} \mathrm{LO}, \mathrm{MIN} / \eta-\mathrm{I} \mathrm{IN}, \mathrm{AVG} \tag{7}
\end{align*}
$$

$\mathrm{I}_{\text {Lo,MAX }}$ is the maximum output inductor current:

$$
\begin{equation*}
\mathrm{I}_{\mathrm{Lo}, \mathrm{MAX}}=\mathrm{I} \mathrm{O}, \mathrm{MAX} / 2+\Delta \mathrm{I}_{\mathrm{Lo}} / 2 \tag{8}
\end{equation*}
$$

$\mathrm{I}_{\mathrm{Lo}, \mathrm{MIN}}$ is the minimum output inductor current:

$$
\begin{equation*}
\mathrm{I} \mathrm{Lo}, \mathrm{MIN}=\mathrm{I}, \mathrm{MAX} / 2-\Delta \mathrm{I} \mathrm{Lo} / 2 \tag{9}
\end{equation*}
$$

$\Delta \mathrm{I}_{\mathrm{Lo}}$ is the peak-to-peak ripple current in the output inductor of value Lo:

$$
\begin{equation*}
\Delta \mathrm{I}_{\mathrm{Lo}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \cdot \mathrm{D} /(\mathrm{Lo} \cdot \mathrm{fSW}) \tag{10}
\end{equation*}
$$

For the two-phase converter, the input capacitor(s) RMS current is then:

$$
\begin{align*}
& \mathrm{I}_{\mathrm{CIN}} \mathrm{RMS}=\left[2 \mathrm { D } \cdot \left(\mathrm{IC}, \mathrm{MIN}^{2}+\mathrm{I}_{\mathrm{C}, \mathrm{MIN} \cdot \Delta \mathrm{I}} \mathrm{I}, \mathrm{IN}\right.\right.  \tag{11}\\
& \left.\left.+\Delta_{C}, I^{2} / 3\right)+I_{I N}, A V G^{2} \cdot(1-2 D)\right]^{1 / 2}
\end{align*}
$$

Select the number of input capacitors $\left(\mathrm{N}_{\mathrm{IN}}\right)$ to provide the RMS input current ( $\mathrm{I}_{\mathrm{CIN}, \mathrm{RMS}}$ ) based on the RMS ripple current rating per capacitor ( $\mathrm{I}_{\text {RMS,RATED }}$ ):
NIN = ICIN,RMS/IRMS,RATED

For a two-phase converter with perfect efficiency ( $\eta=1$ ), the worst case input ripple-current will occur when the converter is operating at a $25 \%$ duty cycle. At this operating point, the parallel combination of input capacitors must support an RMS ripple current equal to $25 \%$ of the converter's DC output current. At other duty cycles, the ripple-current will be less. For example, at a duty cycle of either $10 \%$ or $40 \%$, the two-phase input ripple-current will be approximately $20 \%$ of the converter's DC output current.
In general, capacitor manufacturers require derating to the specified ripple-current based on the ambient temperature. More capacitors will be required because of the current derating. The designer should be cognizant of the ESR of the input capacitors. The input capacitor power loss can be calculated from:

$$
\begin{equation*}
\text { PCIN }=\text { ICIN,RMS }{ }^{2} \cdot \text { ESR_per_capacitor/NIN } \tag{13}
\end{equation*}
$$

Low ESR capacitors are recommended to minimize losses and reduce capacitor heating. The life of an electrolytic capacitor is reduced $50 \%$ for every $10^{\circ} \mathrm{C}$ rise in the capacitor's temperature.

## 4. Input Inductor Selection

The use of an inductor between the input capacitors and the power source will accomplish two objectives. First, it will isolate the voltage source and the system from the noise generated in the switching supply. Second, it will limit the inrush current into the input capacitors at power up. Large inrush currents will reduce the expected life of the input capacitors. The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients.

Figure 15. Calculating the Input Inductance

The worst case input current slew rate will occur during the first few PWM cycles immediately after a step-load change is applied as shown in Figure 15. When the load is applied, the output voltage is pulled down very quickly. Current through the output inductors will not change instantaneously so the initial transient load current must be conducted by the output capacitors. The output voltage will step downward depending on the magnitude of the output current ( $\mathrm{I}_{\mathrm{O}, \mathrm{MAX}}$ ), the per capacitor ESR of the output capacitors ( $\mathrm{ESR}_{\mathrm{OUT}}$ ), and the number of the output capacitors $\left(\mathrm{N}_{\text {OUT }}\right)$ as shown in Figure . Assuming the load current is shared equally between the two phases, the output voltage at full, transient load will be:

$$
\begin{aligned}
& \text { VOUT,FULL-LOAD }= \\
& \text { VOUT,NO-LOAD }-(\mathrm{IO}, \mathrm{MAX} / 2) \cdot \text { ESROUT/NOUT }
\end{aligned}
$$

When the control MOSFET (Q1 in Figure 15) turns ON, the input voltage will be applied to the opposite terminal of the output inductor (the SWNODE). At that instant, the voltage across the output inductor can be calculated as:

$$
\begin{align*}
\Delta \mathrm{V}_{\text {Lo }}= & \mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }, \text { FULL-LOAD }}  \tag{15}\\
= & \mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT,NO-LOAD }} \\
& +(\mathrm{IO}, \mathrm{MAX} / 2) \cdot \text { ESROUT }^{2} \text { NOUT }
\end{align*}
$$

The differential voltage across the output inductor will cause its current to increase linearly with time. The slew rate of this current can be calculated from:

$$
\begin{equation*}
\mathrm{dl} \mathrm{Lo} / \mathrm{dt}=\Delta \mathrm{V}_{\mathrm{Lo}} / \mathrm{Lo} \tag{16}
\end{equation*}
$$

Current changes slowly in the input inductor so the input capacitors must initially deliver the vast majority of the input current. The amount of voltage drop across the input capacitors $\left(\Delta \mathrm{V}_{\mathrm{Ci}}\right)$ is determined by the number of input capacitors $\left(\mathrm{N}_{\mathrm{IN}}\right)$, their per capacitor ESR $\left(\mathrm{ESR}_{\mathrm{IN}}\right)$, and the current in the output inductor according to:

$$
\begin{align*}
\Delta \mathrm{V}_{\mathrm{Ci}} & =\mathrm{ESR}_{\mathrm{IN}} / \mathrm{N}_{\mathrm{IN}} \cdot \mathrm{dl}_{\mathrm{Lo}} / \mathrm{dt} \cdot \mathrm{tON}  \tag{17}\\
& =\mathrm{ESR} \mathrm{IN}_{\mathrm{N}} / \mathrm{N}_{\mathrm{IN}} \cdot \mathrm{dl}_{\mathrm{Lo}} / \mathrm{dt} \cdot \mathrm{D} / \mathrm{fSW}
\end{align*}
$$

Before the load is applied, the voltage across the input inductor $\left(\mathrm{V}_{\mathrm{Li}}\right)$ is very small - the input capacitors charge to the input voltage, $\mathrm{V}_{\mathrm{IN}}$. After the load is applied the voltage drop across the input capacitors, $\Delta \mathrm{V}_{\mathrm{Ci}}$, appears across the input inductor as well. Knowing this, the minimum value of the input inductor can be calculated from:

$$
\begin{align*}
\mathrm{Li}_{\mathrm{MIN}} & =\mathrm{V}_{\mathrm{Li}} / \mathrm{dl}_{\mathrm{IN}} / \mathrm{dt}_{\mathrm{MAX}}  \tag{18}\\
& =\Delta \mathrm{V}_{\mathrm{Ci}} / \mathrm{dl}_{\mathrm{IN}} / \mathrm{dt}_{\mathrm{MAX}}
\end{align*}
$$

$\mathrm{dI}_{\mathrm{IN}} / \mathrm{dt}_{\text {MAX }}$ is the maximum allowable input current slew rate (specified as $0.1 \mathrm{~A} / \mu$ s or $0.1 \times 10^{6} \mathrm{~A} / \mathrm{s}$ for VRM 8.5).

The input inductance value calculated from Equation 18 is relatively conservative. It assumes the supply voltage is very "stiff" and does not account for any parasitic elements that will limit $\mathrm{dI} / \mathrm{dt}$ such as stray inductance. Also, the ESR values of the capacitors specified by the manufacturer's data sheets are worst case high limits. In reality input voltage "sag," lower capacitor ESRs, and stray inductance will help reduce the slew rate of the input current.

As with the output inductor, the input inductor must support the maximum current without saturating the magnetic. Also, for an inexpensive iron powder core, such as the -26 or -52 from Micrometals, the inductance "swing" with DC bias must be taken into account - inductance will decrease as the DC input current increases. At the maximum input current, the inductance must not decrease below the minimum value or the $\mathrm{dI} / \mathrm{dt}$ will be higher than expected.

## 5. MOSFET \& Heatsink Selection

Power dissipation, package size, and thermal solution drive MOSFET selection. To adequately size the heat sink, the design must first predict the MOSFET power dissipation. Once the dissipation is known, the heat sink
thermal impedance can be calculated to prevent the specified maximum case or junction temperatures from being exceeded at the highest ambient temperature. Power dissipation has two primary contributors: conduction losses and switching losses. The control or upper MOSFET will display both switching and conduction losses. The synchronous or lower MOSFET will exhibit only conduction losses because it switches into nearly zero voltage. However, the body diode in the synchronous MOSFET will suffer diode losses during the non-overlap time of the gate drivers.

For the upper or control MOSFET, the power dissipation can be approximated from:

$$
\begin{align*}
& P_{D, C O N T R O L}=\left(\operatorname{IRMS}, C N T L{ }^{2} \cdot R_{D S}(o n)\right)  \tag{19}\\
& +\left(\mathrm{L}_{\mathrm{Lo}, \mathrm{MAX}} \cdot \mathrm{Q}_{\text {switch }} / \mathrm{I}_{\mathrm{g}} \cdot \mathrm{~V}_{\text {IN }} \cdot \mathrm{f}_{\mathrm{SW}}\right) \\
& +\left(Q_{\mathrm{Oss}} / 2 \cdot \mathrm{~V}_{\mathrm{IN}} \cdot \mathrm{fs}_{\mathrm{S}}\right)+\left(\mathrm{V}_{\mathrm{IN}} \cdot \mathrm{Q}_{\mathrm{RR}} \cdot \mathrm{f}_{\mathrm{SW}}\right)
\end{align*}
$$

The first term represents the conduction or IR losses when the MOSFET is ON while the second term represents the switching losses. The third term is the losses associated with the control and synchronous MOSFET output charge when the control MOSFET turns ON. The output losses are caused by both the control and synchronous MOSFET but are dissipated only in the control FET. The fourth term is the loss due to the reverse recovery time of the body diode in the synchronous MOSFET. The first two terms are usually adequate to predict the majority of the losses.

Where $\mathrm{I}_{\mathrm{RMS}, \mathrm{CNTL}}$ is the RMS value of the trapezoidal current in the control MOSFET:

IRMS,CNTL $=\sqrt{D}$

$\mathrm{I}_{\text {Lo,MAX }}$ is the maximum output inductor current:

$$
\begin{equation*}
\mathrm{ILo}_{\mathrm{Lo}, \mathrm{MAX}}=\mathrm{IO}, \mathrm{MAX} / 2+\Delta \mathrm{I}_{\mathrm{Lo}} / 2 \tag{21}
\end{equation*}
$$

$\mathrm{I}_{\mathrm{Lo}, \mathrm{MIN}}$ is the minimum output inductor current:

$$
\begin{equation*}
\mathrm{I} \mathrm{Lo}, \mathrm{MIN}=\mathrm{I} \mathrm{O}, \mathrm{MAX} / 2-\Delta \mathrm{I} \mathrm{Lo} / 2 \tag{22}
\end{equation*}
$$

$\mathrm{I}_{\mathrm{O}, \text { MAX }}$ is the maximum converter output current.
D is the duty cycle of the converter:

$$
\begin{equation*}
\mathrm{D}=\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{IN}} \tag{23}
\end{equation*}
$$

$\Delta \mathrm{I}_{\mathrm{Lo}}$ is the peak-to-peak ripple current in the output inductor of value $L_{0}$ :

$$
\begin{equation*}
\Delta \mathrm{I}_{\mathrm{Lo}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \cdot \mathrm{D} /(\mathrm{Lo} \cdot \mathrm{fSW}) \tag{24}
\end{equation*}
$$

$\mathrm{R}_{\mathrm{DS}(\text { on) }}$ is the ON resistance of the MOSFET at the applied gate drive voltage.
$Q_{\text {switch }}$ is the post gate threshold portion of the gate-to-source charge plus the gate-to-drain charge. This
may be specified in the data sheet or approximated from the gate-charge curve as shown in the Figure 16.

$$
\begin{equation*}
Q_{s w i t c h}=Q_{g s 2}+Q_{g d} \tag{25}
\end{equation*}
$$

Figure 16. MOSFET Switching Characteristics
$\mathrm{I}_{\mathrm{g}}$ is the output current from the gate driver IC.
$\mathrm{V}_{\mathrm{IN}}$ is the input voltage to the converter.
$\mathrm{f}_{\text {sw }}$ is the switching frequency of the converter.
$\mathrm{Q}_{\mathrm{G}}$ is the MOSFET total gate charge to obtain $\mathrm{R}_{\mathrm{DS}(\text { on })}$. Commonly specified in the data sheet.
$\mathrm{V}_{\mathrm{g}}$ is the gate drive voltage.
$\mathrm{Q}_{\mathrm{RR}}$ is the reverse recovery charge of the lower MOSFET.
$\mathrm{Q}_{\text {oss }}$ is the MOSFET output charge specified in the data sheet.
For the lower or synchronous MOSFET, the power dissipation can be approximated from:

$$
\begin{align*}
& \text { PD,SYNCH }=\left(I_{R M S}, S Y N C H^{2} \cdot \operatorname{RDS}(o n)\right) \\
& \quad+\left(\text { Vf }_{\text {diode }} \cdot \mathrm{IO}_{\mathrm{O}}, \mathrm{MAX} / 2 \cdot \mathrm{t} \text { _nonoverlap } \cdot \mathrm{fSW}\right) \tag{26}
\end{align*}
$$

The first term represents the conduction or IR losses when the MOSFET is ON and the second term represents the diode losses that occur during the gate non-overlap time.
All terms were defined in the previous discussion for the control MOSFET with the exception of:

$$
\begin{align*}
& \text { IRMS,SYNCH }=\sqrt{1-\mathrm{D}}  \tag{27}\\
& \cdot\left[\left(\text { ILo }_{\text {Lo }}\right.\right. \text { MAX }
\end{align*}
$$

where:
$\mathrm{Vf}_{\text {diode }}$ is the forward voltage of the MOSFET's intrinsic diode at the converter output current.
t _nonoverlap is the non-overlap time between the upper and lower gate drivers to prevent cross conduction. This time is usually specified in the data sheet for the control IC.

Figure 17. AVP Circuitry at No-Load

When the MOSFET power dissipations are known, the designer can calculate the required thermal impedance to maintain a specified junction temperature at the worst case ambient operating temperature

$$
\begin{equation*}
\theta \mathrm{T}<(\mathrm{T} \mathrm{~J}-\mathrm{T} \mathrm{~A}) / \mathrm{PD}_{\mathrm{D}} \tag{28}
\end{equation*}
$$

where:
$\theta_{\mathrm{T}}$ is the total thermal impedance $\left(\theta_{\mathrm{JC}}+\theta_{\mathrm{SA}}\right)$;
$\theta_{\mathrm{JC}}$ is the junction-to-case thermal impedance of the MOSFET;
$\theta_{\mathrm{SA}}$ is the sink-to-ambient thermal impedance of the heatsink assuming direct mounting of the MOSFET (no thermal "pad" is used);
$\mathrm{T}_{\mathrm{J}}$ is the specified maximum allowed junction temperature;
$\mathrm{T}_{\mathrm{A}}$ is the worst case ambient operating temperature.
For TO-220 and TO-263 packages, standard FR-4 copper clad circuit boards will have approximate thermal resistances $\left(\theta_{\mathrm{SA}}\right)$ as shown below:

| Pad Size <br> $\left(\right.$ in $^{2} / \mathrm{mm}^{2}$ ) | Single-Sided <br> 1 oz. Copper |
| :---: | :---: |
| $0.50 / 323$ | $60-65^{\circ} \mathrm{C} / \mathrm{W}$ |
| $0.75 / 484$ | $55-60^{\circ} \mathrm{C} / \mathrm{W}$ |
| $1.00 / 645$ | $50-55^{\circ} \mathrm{C} / \mathrm{W}$ |
| $1.50 / 968$ | $45-50^{\circ} \mathrm{C} / \mathrm{W}$ |

As with any power design, proper laboratory testing should be performed to insure the design will dissipate the required power under worst case operating conditions. Variables considered during testing should include maximum ambient temperature, minimum airflow, maximum input voltage, maximum loading, and component variations (i.e., worst case MOSFET $\mathrm{R}_{\mathrm{DS}(\mathrm{on})}$ ). Also, the inductors and capacitors share the MOSFET's heatsinks and will add heat and raise the temperature of the circuit board
and MOSFET. For any new design, its advisable to have as much heatsink area as possible - all too often new designs are found to be too hot and require re-design to add heatsinking.

## 6. Adaptive Voltage Positioning

There are two resistors that determine the Adaptive Voltage Positioning: $\mathrm{R}_{\text {VFBK }}$ and $\mathrm{R}_{\text {DRP }}$. R RFBK establishes the no-load "high" voltage position and $\mathrm{R}_{\mathrm{DRP}}$ determines the full-load "droop" voltage.
Resistor $\mathrm{R}_{\mathrm{VFBK}}$ is connected between $\mathrm{V}_{\text {CORE }}$ and the $\mathrm{V}_{\mathrm{FB}}$ pin of the controller. At no load, this resistor will conduct the internal bias current of the $\mathrm{V}_{\mathrm{FB}}$ pin and develop a voltage drop from $V_{\text {CORE }}$ to the $V_{\text {FB }}$ pin. Because the error amplifier regulates $\mathrm{V}_{\mathrm{FB}}$ to the DAC setting, the output voltage, $\mathrm{V}_{\mathrm{CORE}}$, will be higher by the amount IBIAS $\mathrm{VFB} \bullet \mathrm{R}_{\mathrm{VFBK}}$. This condition is shown in Figure 17.

To calculate $\mathrm{R}_{\mathrm{VFBK}}$ the designer must specify the no-load voltage increase above the VID setting ( $\Delta \mathrm{V}_{\text {NO-LOAD }}$ ) and determine the $\mathrm{V}_{\mathrm{FB}}$ bias current. Usually, the no-load voltage increase is specified in the design guide for the processor that is available from the manufacturer. The $\mathrm{V}_{\mathrm{FB}}$ bias current is determined by the value of the resistor from $\mathrm{R}_{\text {OSC }}$ to ground (see Figure in the data sheet for a graph of IBIAS ${ }_{V F B}$ versus R_OSC). The value of $\mathrm{R}_{\mathrm{VFBK}}$ can then be calculated:

$$
\begin{equation*}
\text { RVFBK }=\Delta \mathrm{V}_{\text {NO-LOAD }} / \mathrm{IBIASVFB} \tag{29}
\end{equation*}
$$

Resistor $\mathrm{R}_{\mathrm{DRP}}$ is connected between the $\mathrm{V}_{\mathrm{DRP}}$ and the $\mathrm{V}_{\mathrm{FB}}$ pins. At no-load, the $\mathrm{V}_{\mathrm{DRP}}$ and the $\mathrm{V}_{\mathrm{FB}}$ pins will both be at the DAC voltage so this resistor will conduct zero current. However, at full-load, the voltage at the $\mathrm{V}_{\mathrm{DRP}}$ pin will increase proportional to the output inductor's current while $\mathrm{V}_{\mathrm{FB}}$ will still be regulated to the DAC voltage. Current will be conducted from $\mathrm{V}_{\mathrm{DRP}}$ to $\mathrm{V}_{\mathrm{FB}}$ by $\mathrm{R}_{\mathrm{DRP}}$. This current will be large enough to supply the $\mathrm{V}_{\mathrm{FB}}$ bias current and cause a voltage drop from $\mathrm{V}_{\mathrm{FB}}$ to $\mathrm{V}_{\text {CORE }}$ across $\mathrm{R}_{\mathrm{FBK}}$ - the converter's output voltage will be reduced. This condition is shown in Figure 18.

Figure 18. AVP Circuitry at Full-Load

To determine the value of $R_{D R P}$ the designer must specify the full-load voltage reduction from the VID (DAC) setting ( $\Delta \mathrm{V}_{\text {OUT,FULL-LOAD }}$ ) and predict the voltage increase at the $V_{\text {DRP }}$ pin at full-load. Usually, the full-load voltage reduction is specified in the design guide for the processor that is available from the manufacturer. To predict the voltage increase at the $\mathrm{V}_{\text {DRP }}$ pin at full-load ( $\Delta \mathrm{V}_{\mathrm{DRP}}$ ), the designer must consider the output inductor's resistance $\left(\mathrm{R}_{\mathrm{L}}\right)$, the PCB trace resistance between the current sense points ( $\mathrm{R}_{\mathrm{PCB}}$ ), and the controller IC's gain from the current sense to the $\mathrm{V}_{\text {DRP }}$ pin $\left(\mathrm{G}_{\mathrm{VDRP}}\right)$ :

$$
\begin{equation*}
\Delta V_{D R P}=I O, M A X \cdot\left(R_{L}+R P C B\right) \cdot G V D R P \tag{30}
\end{equation*}
$$

The value of $\mathrm{R}_{\mathrm{DRP}}$ can then be calculated:
RDRP $=\frac{\Delta V_{\text {DRP }}}{\left(\mathrm{IBIASVFB}+\Delta \mathrm{V}_{\text {OUT }}, F U L L-L O A D / R V F B K\right)}$
$\Delta \mathrm{V}_{\text {OUT,FULL-LOAD }}$ is the full-load voltage reduction from the VID (DAC) setting. $\Delta$ VOUT,FULL-LOAD is not the voltage change from the no-load AVP setting.

## 7. Current Sensing

For inductive current sensing, choose the current sense network ( $\mathrm{R}_{\mathrm{CSn}}, \mathrm{C}_{\mathrm{CSn}}, \mathrm{n}=1$ or 2 ) to satisfy

$$
\begin{equation*}
\mathrm{RCSn}_{\mathrm{CS}} \cdot \mathrm{CCSn}_{\mathrm{CS}}=\mathrm{Lo} /\left(\mathrm{R}_{\mathrm{L}}+\mathrm{RPCB}\right) \tag{32}
\end{equation*}
$$

For resistive current sensing, choose the current sense network ( $\mathrm{R}_{\mathrm{CSn}}, \mathrm{C}_{\mathrm{CSn}}, \mathrm{n}=1$ or 2 ) to satisfy

$$
\begin{equation*}
\mathrm{R}_{\mathrm{CSn}} \cdot \mathrm{C}_{\mathrm{CSn}}=\mathrm{Lo} /\left(\mathrm{R}_{\text {Sense }}\right) \tag{33}
\end{equation*}
$$

This will provide an adequate starting point for $\mathrm{R}_{\mathrm{CSn}}$ and $\mathrm{C}_{\mathrm{CSn}}$. After the converter is constructed, the value of $\mathrm{R}_{\mathrm{CSn}}$ (and/or $\mathrm{C}_{\mathrm{CSn}}$ ) should be fine-tuned in the lab by observing the $\mathrm{V}_{\text {DRP }}$ signal during a step change in load current. Tune
the $\mathrm{R}_{\mathrm{CSn}} \bullet \mathrm{C}_{\mathrm{CSn}}$ network to provide a "square-wave" at the $\mathrm{V}_{\text {DRP }}$ output pin with maximum rise time and minimal overshoot as shown in Figure 21.

Figure 19. V DRP Tuning Waveforms. The RC Time Constant of the Current Sense Network Is Too Long (Slow): $\mathrm{V}_{\text {DRP }}$ and $\mathrm{V}_{\text {OUT }}$ Respond Too Slowly.

Figure 20. V ${ }_{\text {DRP }}$ Tuning Waveforms. The RC Time Constant of the Current Sense Network Is Too Short (Fast): V

Figure 21. V ${ }_{\text {DRP }}$ Tuning Waveforms. The RC Time Constant of the Current Sense Network Is Optimal: $\mathrm{V}_{\text {DRP }}$ and $\mathrm{V}_{\text {OUT }}$ Respond to the Load Current Quickly Without Overshooting.

## 8. Error Amplifier Tuning

After the steady-state (static) AVP has been set and the current sense network has been optimized the Error Amplifier must be tuned. Basically, the gain of the Error Amplifier should be adjusted to provide an acceptable transient response by increasing or decreasing the Error Amplifier's feedback capacitor ( $\mathrm{C}_{\text {AMP }}$ in the Applications Diagram). The bandwidth of the control loop will vary directly with the gain of the error amplifier.

Figure 22. The Value of $\mathrm{C}_{\text {AMP }}$ Is Too High and the Loop Gain/Bandwidth Too Low. COMP Slews Too Slowly Which Results in Overshoot in Vout.

If $\mathrm{C}_{\mathrm{AMP}}$ is too large the loop gain/bandwidth will be low, the COMP pin will slew too slowly, and the output voltage will overshoot as shown in Figure 22. On the other hand, if $\mathrm{C}_{\text {AMP }}$ is too small the loop gain/bandwidth will be high, the COMP pin will slew very quickly and overshoot. Integrator "wind up" is the cause of the overshoot. In this case the output voltage will transition more slowly because COMP
spikes upward as shown in Figure 23. Too much loop gain/bandwidth increase the risk of instability. In general, one should use the lowest loop gain/bandwidth as possible to achieve acceptable transient response - this will insure good stability. If $\mathrm{C}_{\mathrm{AMP}}$ is optimal the COMP pin will slew quickly but not overshoot and the output voltage will monotonically settle as shown in Figure 24.

Figure 23. The Value of $\mathrm{C}_{\mathrm{AMP}}$ Is Too Low and the Loop Gain/Bandwidth Too High. COMP Moves Too Quickly, Which Is Evident from the Small Spike in Its Voltage When the Load Is Applied or Removed. The Output Voltage Transitions More Slowly Because of the COMP Spike.

Figure 24. The Value of $\mathrm{C}_{\text {AMP }}$ Is Optimal. COMP Slews Quickly Without Spiking or Ringing. V Overshoot and Monotonically Settles to Its Final Value.

After the control loop is tuned to provide an acceptable transient response the steady-state voltage ripple on the COMP pin should be examined. When the converter is operating at full, steady-state load, the peak-to-peak voltage ripple on the COMP pin should be less than $20 \mathrm{mV}_{\mathrm{PP}}$ as shown in Figure 25. Less than 10 mV PP is ideal. Excessive ripple on the COMP pin will contribute to output voltage jitter.

Figure 25. At Full-Load (28 A) the Peak-to-Peak Voltage Ripple on the COMP Pin Should Be Less than $\mathbf{2 0} \mathbf{~ m V}$ for a Well-Tuned/Stable Controller. Higher COMP Voltage Ripple Will Contribute to Output Voltage Jitter.

## 9. Current Limit Setting

When the output of the current sense amplifier (CO1 or CO 2 in the block diagram) exceeds the voltage on the $\mathrm{I}_{\mathrm{LIM}}$ pin the part will enter hiccup mode. For inductive sensing, the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the inductor's maximum resistance ( $\mathrm{R}_{\mathrm{LMAX}}$ ). The design must consider the inductor's resistance increase due to current heating and ambient temperature rise. Also, depending on the current sense points, the circuit board may add additional resistance. In general, the temperature coefficient of copper is $+0.39 \%$ per ${ }^{\circ} \mathrm{C}$. If using a current sense resistor ( $\mathrm{R}_{\text {SENSE }}$ ), the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the maximum value of the sense resistor. To set the level of the $\mathrm{I}_{\text {LIM }}$ pin:

$$
\begin{equation*}
\text { VILIM }=(\mathrm{IOUT}, \mathrm{LIM}+\Delta \mathrm{I} \mathrm{Lo} / 2) \cdot \mathrm{R} \cdot \mathrm{GILIM} \tag{34}
\end{equation*}
$$

where:
IOUT,LIM is the current limit threshold of the converter;
$\Delta \mathrm{I}_{\mathrm{Lo}} / 2$ is half the inductor ripple current;
$R$ is either ( $\mathrm{R}_{\text {LMAX }}+\mathrm{R}_{\mathrm{PCB}}$ ) or $\mathrm{R}_{\text {SENSE; }}$
$\mathrm{G}_{\text {ILIM }}$ is the current sense to $\mathrm{I}_{\text {LIM }}$ gain.
For the overcurrent protection to work properly, the current sense time constant (RC) should be slightly larger than the $\mathrm{R}_{\mathrm{L}}$ time constant. If the RC time constant is too fast, during step load changes the sensed current waveform will appear larger than the actual inductor current and will probably trip the current limit at a lower level than expected.

## 10. PWM Comparator Input Voltage

The voltage at the positive input terminal of the PWM comparator (see Figure 9 or 11) is limited by the internal voltage supply of the controller ( 3.3 V ), the size of the internal ramp, and the magnitude of the channel startup offset voltage. To prevent the PWM comparator from saturating, the differential input voltage from $\mathrm{CS}_{\text {REF }}$ to CSn ( $\mathrm{n}=1$ or 2 ) must satisfy the following equation:
VCSREF,MAX $+\mathrm{V}_{\text {COn }}, \mathrm{MAX}+310 \mathrm{mV} \cdot \mathrm{D} \leq 2.45 \mathrm{~V}$
where:

> VCSREF,MAX = Max VID Setting w/ AVP @ Full Load
$\mathrm{V}_{\text {COn }}$ MAX $=\left[\mathrm{V}_{\text {CSn }}-\mathrm{V}_{\text {CSREF }}\right] \cdot$ GCSA,MAX $=(\mathrm{IO}, \mathrm{MAX} / 2+\Delta \mathrm{I} \mathrm{Lo} / 2) \cdot \mathrm{R}_{\text {MAX }}$

- GcsA,MAX
RMAX = RSENSE or (RL,MAX + RPCB,MAX)

## 11. $\mathrm{VTT}_{\mathrm{PGD}}$ Delay Time Setting

The $\mathrm{VTT}_{\mathrm{PGD}}$ signal is pulled LOW a predetermined delay time ( $\mathrm{T}_{\mathrm{D}, \mathrm{VTT}}$ ) after the VTT voltage crosses the VTT Threshold. The $\mathrm{VTT}_{\mathrm{CT}}$ charge current and the capacitor value from the $\mathrm{VTT}_{\mathrm{CT}}$ pin to ground $\left(\mathrm{C}_{\mathrm{VTT}}\right)$ determine the $\mathrm{T}_{\mathrm{D}, \mathrm{VTT}}$ delay time. However, the choice of oscillator frequency and the value of $\mathrm{R}_{\mathrm{OSC}}$ set the $\mathrm{VTT}_{\mathrm{CT}}$ charge current as shown in Figure 4. Therefore, delay time is simply set by the value of $\mathrm{C}_{\mathrm{VTT}}$ according to the following equation:

$$
\begin{equation*}
\text { TD,VTT }=(1 \mathrm{~V}-0.25 \mathrm{~V}) \cdot \mathrm{CVTT} / \mathrm{VTT} \mathrm{CT} \_ \text {Current } \tag{36}
\end{equation*}
$$

## 12. Soft Start Time

The Soft Start time ( $\mathrm{T}_{\mathrm{SS}}$ ) can be calculated from:
TSS $=\left(\right.$ VCOMP $\left.-R_{C M P 1} \cdot I_{C O M P}\right) \cdot$ CCMP2/ICOMP
where:

$$
\begin{aligned}
\text { VCOMP }= & \text { VOUT @ } 0 \text { A }+ \text { Channel_Startup_Offset } \\
& + \text { Int_Ramp }+ \text { GCSA } \cdot \text { Ext_Ramp } / 2
\end{aligned}
$$

$\mathrm{I}_{\text {COMP }}$ is the COMP source current from the data sheet.

## Design Example

## Typical Design Requirements:

$\mathrm{V}_{\mathrm{IN}}=5.0 \mathrm{Vdc}$
$\mathrm{V}_{\text {OUT }}=1.70 \mathrm{Vdc}$ (nominal)
$V_{\text {OUT,RIPPLE }}=10 \mathrm{~m}_{\text {PP }} \max$
VID Range: $1.050 \mathrm{Vdc}-1.825 \mathrm{Vdc}$
$\mathrm{I}_{\mathrm{O}, \mathrm{MAX}}=28 \mathrm{~A}$ at full-load
$\mathrm{I}_{\text {OUT,LIM }}=33 \mathrm{~A}$ min at $50^{\circ} \mathrm{C}$ (shutdown threshold)
$\mathrm{dI}_{\text {IN }} / \mathrm{dt}=0.1 \mathrm{~A} / \mathrm{Hs}^{\max }$
$\mathrm{f}_{\mathrm{SW}}=335 \mathrm{kHz}$
$\eta=81 \%$ minimum
$\mathrm{T}_{\mathrm{A}, \mathrm{MAX}}=60^{\circ} \mathrm{C}$
$\mathrm{T}_{\mathrm{J}, \mathrm{MAX}}=115^{\circ} \mathrm{C}$
$\mathrm{T}_{\mathrm{D}, \mathrm{VTT}}=2.5 \mathrm{~ms}$ (VTT $\mathrm{VGGD}_{\mathrm{PG}}$ delay time)
$\mathrm{T}_{\mathrm{SS}}=6.5 \mathrm{~ms}$ (Soft Start time)
$\Delta \mathrm{V}_{\text {OUT }}$ at no-load (static) $=$
+45 mV from VID setting $=1.745 \mathrm{Vdc}$
$\Delta \mathrm{V}_{\text {OUT }}$ at full-load (static) $=$
-45 mV from VID setting $=1.655 \mathrm{Vdc}$
$\Delta \mathrm{V}_{\text {OUT }}$ at full-load (transient) $=$
-90 mV from VID setting $=1.610 \mathrm{Vdc}$

## 1. Output Capacitor Selection

First, choose a low-cost, low-ESR output capacitor such as the Rubycon 6.3ZA1000M10X16: $6.3 \mathrm{~V}, 1000 \mu \mathrm{~F}, 1.65$ ARMS , $24 \mathrm{~m} \Omega, 10 \times 16 \mathrm{~mm}$. Calculate the minimum number of output capacitors:

$$
\begin{align*}
\text { NOUT,MIN } & =\text { ESR per capacitor } \cdot \frac{\Delta \mathrm{I}_{\mathrm{O}, \mathrm{MAX}}}{\Delta \mathrm{~V}, \mathrm{MAX}}  \tag{1}\\
& =24 \mathrm{~m} \Omega \cdot 28 \mathrm{~A} /(1.745 \mathrm{~V}-1.610 \mathrm{~V}) \\
& =4.987 \text { or } 5 \text { capacitors minimum }(5000 \mu \mathrm{~F})
\end{align*}
$$

## 2. Output Inductor Selection

Calculate the minimum output inductance at $\mathrm{I}_{\mathrm{O}, \mathrm{MAX}}$ according to Equation 3 with $\pm 20 \%$ inductor ripple current ( $\alpha=0.20$ ):

$$
\begin{align*}
\text { LOMIN } & =\frac{\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right) \cdot \mathrm{VOUT}^{\left(\alpha \cdot \mathrm{IO}_{\mathrm{OAX}} \cdot \mathrm{~V}_{\text {IN }} \cdot \mathrm{fSW}\right)}}{}  \tag{3}\\
& =\frac{(5 \mathrm{~V}-1.655 \mathrm{~V}) \cdot 1.655 \mathrm{~V}}{(0.2 \cdot 28 \mathrm{~A} \cdot 5 \mathrm{~V} \cdot 335 \mathrm{kHz})} \\
& =590 \mathrm{nH}
\end{align*}
$$

To save cost, we choose the inexpensive T50-52 core from Micrometals: $33 \mathrm{nH} / \mathrm{N}^{2}, 3.19 \mathrm{~cm} . / t \mathrm{urn}$. At 14 A per phase the permeability of this core will be approximately $80 \%$ of the permeability at 0 A . Therefore, at 0 A we must achieve at least $590 \mathrm{nH} / 0.8$ or 738 nH . Using four turns results in only 528 nH , so we must use five turns of \#16AWG bifilar ( $2 \mathrm{~m} \Omega / \mathrm{ft}$.) to produce 825 nH . This inductor is available as part number CTX22-15401 from Coiltronics.

Use Equation 4 to insure the output voltage ripple will satisfy the design goal with the minimum number of capacitors and the nominal output inductance:

```
VOUT,P-P \(=(\) ESR per cap / NOUT,MIN) .
    \(\left\{\left(\mathrm{VIN}_{\mathrm{IN}}\right.\right.\) - \#Phases \(\left.\cdot \mathrm{V}_{\text {OUT }}\right) \cdot \mathrm{D} /(\) Lomin \(\cdot\) fsw \(\left.)\right\}\)
\(=(24 \mathrm{~m} \Omega / 5)\).
    \(\{(5.0 \mathrm{~V}-2 \cdot 1.7 \mathrm{~V}) \cdot(1.7 \mathrm{~V} / 5.0 \mathrm{~V}) /(825 \mathrm{nH} \cdot 335 \mathrm{kHz})\}\)
\(=(4.8 \mathrm{mQ}) \cdot\{1.97 \mathrm{~A}\}\)
\(=9.45 \mathrm{mV}\)
```

The output voltage ripple will be decreased when output capacitors are added to satisfy transient loading requirements.
We will need the nominal and worst case inductor resistances for subsequent calculations:

$$
\begin{aligned}
R_{\mathrm{L}} & =5 \text { turns } \cdot 3.19 \mathrm{~cm} / \text { turn } \cdot 0.03218 \mathrm{ft} / \mathrm{cm} \cdot 2 \mathrm{~m} \Omega / \mathrm{ft} \\
& =1.03 \mathrm{~m} \Omega
\end{aligned}
$$

The inductor resistance will be maximized when the inductor is "hot" due to the load current and the ambient temperature is high. Assuming a $40^{\circ} \mathrm{C}$ temperature rise of the inductor at full-load and a $25^{\circ} \mathrm{C}$ ambient temperature rise we can calculate:

$$
\begin{aligned}
\mathrm{R}_{\mathrm{L}, \mathrm{MAX}} & =1.03 \mathrm{~m} \Omega \cdot\left[1+0.39 \% /{ }^{\circ} \mathrm{C} \cdot\left(40^{\circ} \mathrm{C}+25^{\circ} \mathrm{C}\right)\right] \\
& =1.29 \mathrm{~m} \Omega
\end{aligned}
$$

## 3. Input Capacitor Selection

Use Equation 5 to determine the average input current to the converter:

$$
\begin{align*}
\mathrm{I}_{\mathrm{I}, \mathrm{AVG}} & =\mathrm{I}_{\mathrm{O}, \mathrm{MAX} \cdot \mathrm{D} / \eta}  \tag{5}\\
& =28 \mathrm{~A} \cdot(1.655 \mathrm{~V} / 5.0 \mathrm{~V}) / 0.81=11.44 \mathrm{~A}
\end{align*}
$$

Next, use Equations 6 to 10:

$$
\begin{align*}
\Delta \mathrm{L}_{\mathrm{Lo}} & =\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V} \text { OUT }\right) \cdot \mathrm{D} /(\mathrm{Lo} \cdot \mathrm{fSW}) \\
& =(5 \mathrm{~V}-1.655 \mathrm{~V}) \cdot \frac{(1.655 \mathrm{~V} / 5.0 \mathrm{~V})}{(825 \mathrm{nH} \cdot 335 \mathrm{kHz})}  \tag{10}\\
& =4.00 \mathrm{App}
\end{align*}
$$

$$
\begin{equation*}
\mathrm{I} \text { Lo,MAX }=\mathrm{I} \mathrm{O}, \mathrm{MAX} / 2+\Delta \mathrm{I} \mathrm{Lo} / 2 \tag{8}
\end{equation*}
$$

$$
=28 \mathrm{~A} / 2+4 \mathrm{App} / 2=16 \mathrm{~A}
$$

$$
\mathrm{ILo}, \mathrm{MIN}=\mathrm{I}, \mathrm{MAX} / 2-\Delta \mathrm{I}_{\mathrm{Lo}} / 2
$$

$$
\begin{equation*}
=28 \mathrm{~A} / 2-4 \mathrm{App} / 2=12 \mathrm{~A} \tag{9}
\end{equation*}
$$

$$
\begin{equation*}
\mathrm{IC}, \mathrm{MAX}=\mathrm{I} \mathrm{Lo}, \mathrm{MAX} / \eta-\mathrm{I} \mathrm{IN}, \mathrm{AVG} \tag{6}
\end{equation*}
$$

$$
=16 \mathrm{~A} / 0.81-11.44 \mathrm{~A}=8.3 \mathrm{~A}
$$

$$
\begin{equation*}
\mathrm{I}_{\mathrm{C}, \mathrm{MIN}}=\mathrm{I} \mathrm{Lo}, \mathrm{MIN} / \eta-\mathrm{I} \mathrm{IN}, \mathrm{AVG} \tag{7}
\end{equation*}
$$

$$
=12 \mathrm{~A} / 0.81-11.44 \mathrm{~A}=3.3 \mathrm{~A}
$$

For the two-phase converter, the input capacitor(s) RMS current is then (Note: $\mathrm{D}=1.655 \mathrm{~V} / 5 \mathrm{~V}=0.331$ ):

$$
\begin{aligned}
\mathrm{I}_{\mathrm{IIN}, \mathrm{RMS}}= & {\left[2 \mathrm { D } \cdot \left(\mathrm{I}_{\mathrm{C}, \mathrm{MIN}^{2}+\mathrm{I}_{\mathrm{C}, \mathrm{MIN} \cdot \Delta \mathrm{I}, \mathrm{IN}}}\right.\right.} \\
& +\Delta \mathrm{I}_{\left.\mathrm{C}, \mathrm{IN}^{2} / 3\right)+\mathrm{I}_{\left.\mathrm{IN}, \mathrm{AVG}^{2} \cdot(1-2 \mathrm{D})\right]^{1 / 2}}^{=}}\left[0.662 \cdot\left(3.3^{2}+3.3 \cdot 5+5^{2} / 3\right)+11.44^{2}\right. \\
& \cdot(1-0.662)]^{1 / 2} \\
= & 8.94 \text { ARMS }
\end{aligned}
$$

At this point, the designer must decide between saving board space by using higher-rated/more costly capacitors or saving cost by using more lower-rated/less costly capacitors. To save board space, we choose the SP (Oscon) series capacitors by Sanyo: $680 \mu \mathrm{~F}, 6.3 \mathrm{~V}, 4.84 \mathrm{~A}_{\text {RMS }}, 13 \mathrm{~m} \Omega$ $10 \times 10.5 \mathrm{~mm}$. We need approximately $8.94 \mathrm{~A} / 4.84 \mathrm{~A}=1.84$ or $\mathrm{N}_{\mathrm{IN}}=2$ capacitors on the input for a conservative design.

## 4. Input Inductor Selection

The input inductor must limit the input current slew rate to less than $0.1 \mathrm{~A} / \mu \mathrm{s}$ during a load transient from 0 to 28 A . A conservative value will be calculated assuming the minimum number of output capacitors ( $\mathrm{N}_{\text {OUT }}=5$ ), two input capacitors ( $\mathrm{N}_{\mathrm{IN}}=2$ ), worst case ESR values for both the input and output capacitors, and a maximum duty cycle $\left(\mathrm{D}=\left(1.825 \mathrm{~V}+45 \mathrm{mV}_{\mathrm{AVP}}\right) / 5.0 \mathrm{~V}_{\mathrm{IN}}=0.374\right)$.

First, use Equation 15 to calculate the voltage across the output inductor due to the 28 A load current being shared equally between the two phases:

$$
\begin{align*}
\Delta \mathrm{V}_{\mathrm{Lo}}= & \mathrm{V}_{\text {IN }}-\mathrm{V}_{\mathrm{OUT}, \mathrm{NO}-\mathrm{LOAD}}  \tag{15}\\
& +(\mathrm{IO}, \mathrm{MAX} / 2) \cdot \mathrm{ESROUT} / \mathrm{NOUT} \\
= & 5.0 \mathrm{~V}-1.87 \mathrm{~V}+14 \mathrm{~A} \cdot 23 \mathrm{~m} \Omega / 5 \\
= & 3.194 \mathrm{~V}
\end{align*}
$$

Second, use Equation 16 to determine the rate of current increase in the output inductor:

$$
\begin{align*}
\mathrm{dl} \text { Lo } / \mathrm{dt} & =\Delta \mathrm{V}_{\mathrm{Lo}} / \mathrm{Lo}  \tag{16}\\
& =3.194 \mathrm{~V} / 825 \mathrm{nH}=3.872 \mathrm{~V} / \mu \mathrm{s}
\end{align*}
$$

Finally, use Equations 17 and 18 to calculate the minimum input inductance value:

$$
\begin{align*}
\Delta \mathrm{V}_{\mathrm{Ci}} & =\mathrm{ESR} \mathrm{IN} / \mathrm{N} \text { IN } \cdot \mathrm{dl}_{\mathrm{Lo}} / \mathrm{dt} \cdot \mathrm{D} / \mathrm{fSW}  \tag{17}\\
& =13 \mathrm{~m} \Omega / 2 \cdot 3.872 \mu \mathrm{~s} \cdot 0.374 / 335 \mathrm{kHz} \\
& =28.1 \mathrm{mV} \\
& \begin{aligned}
\mathrm{Li} \mathrm{MIN} & =\Delta \mathrm{V}_{\mathrm{Ci}} / \mathrm{dl}_{\mathrm{IN}} / \mathrm{dt}_{\mathrm{MAX}} \\
& =28.1 \mathrm{mV} / 0.1 \mathrm{~A} / \mu \mathrm{s}=281 \mathrm{nH}
\end{aligned} \tag{18}
\end{align*}
$$

We choose the small, cost effective T30-26 core from Micrometals ( $33.5 \mathrm{nH} / \mathrm{N}^{2}$ ) with \#16 AWG. We need at least
2.89 or 3 turns to achieve the minimum inductance value. With three turns the input inductor will be:

$$
\mathrm{Li}_{\mathrm{i}}=3^{2} \cdot 33.5 \mathrm{nH} / \mathrm{N}^{2}=301 \mathrm{nH}
$$

This inductor is available as part number CTX15-14771 from Coiltronics.

Figure 26. CS5308 Circuitry With Only 5 Rubycon Output Capacitors, 2 Oscon Input Capacitors and a 300 nH Input Inductor. The $\mathrm{dl}_{\mathrm{IN}} / \mathrm{dt}$ of the Input Current ( $0.064 \mathrm{~A} / \mathrm{us}$ ) Is Much Lower Than
Expected (0.1 A/us) Because of Input Voltage Drop and Lower Real ESRs Than Specified in the Capacitors' Data Sheets.

## 5. MOSFET \& Heatsink Selection

The NTB75N03-06 from ON Semiconductor is chosen for both the control and synchronous MOSFET due to its low $\mathrm{R}_{\mathrm{DS}(\mathrm{on})}$ and low gate-charge requirements. The following parameters are derived from the NTB75N03-06 data sheet:

$$
\begin{aligned}
& \mathrm{R}_{\mathrm{DS}(\mathrm{on})}=5.3 \mathrm{~m} \Omega \\
& \mathrm{Q}_{\mathrm{SW} \text { sitch }}=29 \mathrm{nC} \\
& \mathrm{Q}_{\mathrm{G}}=52 \mathrm{nC} \\
& \mathrm{Q}_{\mathrm{RR}}=23 \mathrm{nC} \\
& \mathrm{Q}_{\mathrm{OS}}=35 \mathrm{nC} \text { (approx.) } \\
& \mathrm{Vf}_{\text {diode }}=0.76 \mathrm{~V} @ 15 \mathrm{~A} \\
& \theta_{\mathrm{JC}}=1.0^{\circ} \mathrm{C} / \mathrm{W} \\
& \mathrm{CS} 5308 \text { Parameters: } \\
& \mathrm{i}_{\mathrm{G}}=1 \mathrm{~A} \\
& \mathrm{~V}_{\mathrm{G}}=10 \mathrm{~V} \\
& \text { t_nonoverlap }=65 \mathrm{~ns}
\end{aligned}
$$

The RMS value of the current in the control MOSFET is calculated from Equation 20 and the previously derived values for $\mathrm{D}, \mathrm{I}_{\text {LMAX }}$, and $\mathrm{I}_{\text {LMIN }}$ at the converter's maximum output current:

$$
\begin{align*}
& \mathrm{IRMS}_{\mathrm{CNTL}}= \sqrt{\mathrm{D}} \cdot\left[\left(\mathrm{ILO}_{\mathrm{LO}} \mathrm{MAX}^{2}+\mathrm{ILO}_{\mathrm{LO}} \mathrm{MAX} \cdot \mathrm{ILo}_{\mathrm{LO}, \mathrm{MIN}}{ }^{(20)}\right.\right.  \tag{20}\\
&+{\left.\left.\mathrm{ILO}, \mathrm{MIN}^{2}\right) / 3\right]^{1 / 2}}^{=} \\
& 0.575 \cdot\left[\left(16^{2}+16 \cdot 12+12^{2}\right) / 3\right]^{1 / 2} \\
&= 8.08 \text { ARMS }
\end{align*}
$$

control MOSFET:

$$
\begin{align*}
& \text { PD,CONTROL }=(\text { IRMS,CNTL } 2 \cdot R \text { DS(on) })  \tag{19}\\
& +\left(\text { Lo,MAX } \cdot \mathrm{Q}_{\text {switch }} / \mathrm{I}_{\mathrm{g}} \cdot \mathrm{~V}_{\text {IN }} \cdot \mathrm{f}_{\mathrm{SW}}\right) \\
& +\left(Q_{\text {Oss }} / 2 \cdot V_{I N} \cdot f_{S W}\right)+\left(V_{\text {IN }} \cdot Q_{R R} \cdot f_{S W}\right) \\
& =\left(8.08^{2} \text { ARMS } \cdot 5.3 \mathrm{~m} \Omega\right) \\
& +(16 \mathrm{~A} \cdot 29 \mathrm{nC} / 1 \mathrm{~A} \cdot 5 \mathrm{~V} \cdot 335 \mathrm{kHz}) \\
& +(35 \mathrm{nC} / 2 \cdot 5 \mathrm{~V} \cdot 335 \mathrm{kHz}) \\
& +(5 \mathrm{~V} \cdot 23 \mathrm{nC} \cdot 335 \mathrm{kHz}) \\
& =0.346 \mathrm{~W}+0.78 \mathrm{~W}+0.03 \mathrm{~W}+0.04 \mathrm{~W} \\
& =1.2 \mathrm{~W}
\end{align*}
$$

The RMS value of the current in the synchronous MOSFET is calculated from Equation 27 and the previously derived values for D , $\mathrm{I}_{\mathrm{Lo}, \mathrm{MAX}}$, and $\mathrm{I}_{\mathrm{Lo}, \mathrm{MIN}}$ at the converter's maximum output current:

$$
\begin{aligned}
& \text { IRMS,SYNCH }=\sqrt{1-\mathrm{D}}
\end{aligned}
$$

$$
\begin{aligned}
& =\sqrt{0.669} \cdot\left[\left(16^{2}+16 \cdot 12+12^{2}\right) / 3\right]^{1 / 2} \\
& =11.5 \text { ARMS }
\end{aligned}
$$

Equation 26 is used to calculate the power dissipation of the synchronous MOSFET:

$$
\begin{align*}
& \mathrm{P}_{\mathrm{D}, \mathrm{SYNCH}}=\left(\mathrm{IRMS}, \mathrm{SYNCH}{ }^{2} \cdot \mathrm{RDS}_{\text {(on) }}\right)  \tag{26}\\
& +\left(\mathrm{Vf}_{\text {diode }} \cdot \mathrm{IO}_{\mathrm{O}} \mathrm{MAX} / 2 \cdot \mathrm{t} \text { nonoverlap } \cdot \mathrm{f} \mathrm{SW}\right) \\
& =\left(11.5^{2} \text { ARMS } \cdot 5.3 \mathrm{~m} \Omega\right) \\
& +(0.76 \mathrm{~V} \cdot 28 \mathrm{~A} / 2 \cdot 65 \mathrm{~ns} \cdot 335 \mathrm{kHz}) \\
& =0.70 \mathrm{~W}+0.23 \mathrm{~W}=0.93 \mathrm{~W}
\end{align*}
$$

Equation 28 is used to calculate the heat sink thermal impedances necessary to maintain less than the specified maximum junction temperatures at $60^{\circ} \mathrm{C}$ ambient:
${ }^{\theta} \mathrm{CNTL}<\left(115-60^{\circ} \mathrm{C}\right) / 1.2 \mathrm{~W}-1.0^{\circ} \mathrm{C} / \mathrm{W}=46^{\circ} \mathrm{C} / \mathrm{W}$
${ }^{\theta}$ SYNCH $<\left(115-60^{\circ} \mathrm{C}\right) / 0.93 \mathrm{~W}-1.0^{\circ} \mathrm{C} / \mathrm{W}=59^{\circ} \mathrm{C} / \mathrm{W}$
If board area permits, a cost effective heatsink could be formed by using a TO-263 mounting pad of at least 1.0$1.5 \mathrm{in}^{2}$ per MOSFET on a single-sided, 1 oz . copper PCB (or 0.5 to $0.75 \mathrm{in}^{2}$ on each side of a two-sided board). If board space must be conserved, AAVID offers clip-on heatsinks for TO-220 thru-hole packages. Examples of these
heatsinks include \#577002 $\left(1^{\prime \prime} \times 0.75^{\prime \prime} \times 0.25^{\prime \prime}, 39^{\circ} \mathrm{C} / \mathrm{W}\right.$ at $1 \mathrm{~W})$ and \#591302 ( $0.75^{\prime \prime} \times 0.5^{\prime \prime} \times 0.5^{\prime \prime}, 34^{\circ} \mathrm{C} / \mathrm{W}$ at 1 W )

## 6. Adaptive Voltage Positioning

First, to achieve the 335 kHz switching frequency, use Figure 3 to determine that a $39 \mathrm{k} \Omega$ resistor is needed for $\mathrm{R}_{\mathrm{OSC}}$. Then, use Figure 4 to find the $\mathrm{V}_{\mathrm{FB}}$ bias current at the corresponding value of R RSC. In this example, the $39 \mathrm{k} \Omega$ $\mathrm{R}_{\mathrm{OSC}}$ resistor results in a $\mathrm{V}_{\mathrm{FB}}$ bias current of approximately $7.0 \mu \mathrm{~A}$. Knowing the $\mathrm{V}_{\mathrm{FB}}$ bias current, one can calculate the required values for $\mathrm{R}_{\mathrm{VFBK}}$ and $\mathrm{R}_{\mathrm{DRP}}$ using Equations 29 through 31.
The no-load position is easily set using Equation 29:

$$
\begin{align*}
\text { RVFBK } & =\Delta \mathrm{V}_{\mathrm{NO}}-\text { LOAD/IBIASVFB }  \tag{29}\\
& =+45 \mathrm{mV} / 7.0 \mu \mathrm{~A} \\
& =6.49 \mathrm{k} \Omega
\end{align*}
$$

For inductive current sensing, the designer must calculate the inductor's resistance ( $\mathrm{R}_{\mathrm{L}}$ ) and approximate any resistance added by the circuit board ( $\mathrm{R}_{\mathrm{PCB}}$ ). We found the inductor's nominal resistance in Section $2(1.03 \mathrm{~m} \Omega)$. In this example, we approximate $0.75 \mathrm{~m} \Omega$ for the circuit board resistance ( $\mathrm{R}_{\mathrm{PCB}}$ ). With this information, Equation 30 can be used to calculate the increase at the $V_{\text {DRP }}$ pin at full load;

$$
\begin{aligned}
\Delta \mathrm{V}_{\mathrm{DRP}} & =\mathrm{I} 0, \mathrm{MAX} \cdot\left(\mathrm{RL}_{\mathrm{L}}+\mathrm{RPCB}^{2}\right) \cdot \operatorname{GVDRP} \\
& =28 \mathrm{~A} \cdot(1.03 \mathrm{~m} \Omega+0.75 \mathrm{~m} \Omega) \cdot 3.2 \mathrm{~V} / \mathrm{V} \\
& =159 \mathrm{mV}
\end{aligned}
$$

$\mathrm{R}_{\mathrm{DRP}}$ can then be calculated from Equation 31:

$$
\begin{align*}
\mathrm{RDRP} & =\frac{\Delta \mathrm{V}_{\mathrm{DRP}}}{(\mathrm{IBIASVFB}+\Delta \mathrm{VOUT}, \mathrm{FULL-LOAD} / \mathrm{RVFBK})}  \tag{31}\\
& =159 \mathrm{mV} /(7.0 \mu \mathrm{~A}+45 \mathrm{mV} / 6.49 \mathrm{k} \Omega) \\
& =11.5 \mathrm{k} \Omega
\end{align*}
$$

## 7. Current Sensing

Choose the current sense network $\left(\mathrm{R}_{\mathrm{CSn}}, \mathrm{C}_{\mathrm{CSn}}, \mathrm{n}=1\right.$ or 2$)$ to satisfy

$$
\begin{equation*}
\mathrm{RCSn}_{\mathrm{CS}} \cdot \mathrm{C}_{\mathrm{CSn}}=\mathrm{Lo} /\left(\mathrm{R}_{\mathrm{L}}+\mathrm{RPCB}^{2}\right) \tag{30}
\end{equation*}
$$

The component values determined thus far are $\mathrm{L}_{\mathrm{o}}=825 \mathrm{nH}$, $R_{L}=1.03 \mathrm{~m} \Omega$ and $R_{P C B}=0.75 \mathrm{~m} \Omega$. We choose a convenient value for $\mathrm{C}_{\mathrm{CS} 1}(0.01 \mu \mathrm{~F})$ and solve for $\mathrm{R}_{\mathrm{CS} 1}$ :

$$
\begin{aligned}
\mathrm{RCSn} & =825 \mathrm{nH} /(1.03 \mathrm{~m} \Omega+0.75 \mathrm{~m} \Omega) / 0.01 \mu \mathrm{~F} \\
& =46 \mathrm{k} \Omega \text { or } 50 \mathrm{k} \Omega \text { when rounded up. }
\end{aligned}
$$

After the circuit is constructed, the values of $\mathrm{R}_{\mathrm{CSn}}$ and/or $\mathrm{C}_{\mathrm{CSn}}$ should be tuned to provide a "square-wave" at $\mathrm{V}_{\mathrm{DRP}}$ with minimal overshoot and fast rise time due to a step change in load current as shown in Figures 19-21. Based on experience, the starting value for $\mathrm{R}_{\mathrm{CSn}}$ is probably too low
and will need to be increased to provide a current sense signal similar to those in Figure 21.

Equation 30 will be most accurate for higher quality iron powder core materials such as the -2 or -8 from Micrometals. The permeability of these more expensive cores is relatively constant versus DC current, AC flux density and frequency. Less expensive core materials (such as the -52 from Micrometals) change their characteristics versus DC current, AC flux density, and frequency. The less expensive materials may yield acceptable converter performance if the current sense time constant is set approximatley $2 \times$ longer than anticipated. For example, use approximately twice the resistance $\left(\mathrm{R}_{\mathrm{CSn}}\right)$ or twice the capacitance $\left(\mathrm{C}_{\mathrm{CSn}}\right)$ when using the less expensive core material. If we use -52 material for this design, the value of $\mathrm{R}_{\mathrm{CSn}}$ should be increased to $2 \times 50 \mathrm{k} \Omega$ or $100 \mathrm{k} \Omega$.

## 8. Error Amplifier Tuning

The error amplifier is tuned by adjusting $\mathrm{C}_{\mathrm{AMP}}$ to provide an acceptable full-load transient response as shown in Figures $22-24$. After a value for $\mathrm{C}_{\mathrm{AMP}}$ is chosen, the peak-to-peak voltage ripple on the COMP pin is examined under full-load to insure less than $20 \mathrm{mV}_{\mathrm{PP}}$ as shown in Figure 25.

## 9. Current Limit Setting

The maximum inductor resistance, the maximum PCB resistance, and the maximum current-sense gain as shown in Equation 34 determine the current limit. The maximum current, $\mathrm{I}_{\text {OUT,LIM, }}$ was specified in the design requirements. The maximum inductor resistance occurs at full-load and the highest ambient temperature. This value was found in the "Output Inductor Section" ( $1.58 \mathrm{~m} \Omega$ ). The PCB resistance increases due to the change in ambient temperature:

$$
\begin{aligned}
\mathrm{RPCB}_{\mathrm{MAX}}= & 0.75 \mathrm{~m} \Omega \cdot\left(1+0.39 \% /{ }^{\circ} \mathrm{C} \cdot(60-25)^{\circ} \mathrm{C}\right) \\
= & 0.85 \mathrm{~m} \Omega \\
\mathrm{~V}_{\text {ILIM }}= & \left(\mathrm{I}_{\mathrm{OUT}, \mathrm{LIM}}+\Delta_{\mathrm{L}} / 2\right) \cdot\left(\mathrm{R}_{\mathrm{LMAX}}+\mathrm{RPCB}^{2}, \mathrm{MAX}\right) \\
& \cdot \mathrm{GILIM}^{=} \\
= & (33 \mathrm{~A}+4.0 \mathrm{~A} / 2) \cdot(1.29 \mathrm{~m} \Omega+0.85 \mathrm{~m} \Omega) \\
& \cdot 6.5 \mathrm{~V} / \mathrm{V} \\
= & 0.486 \mathrm{Vdc}
\end{aligned}
$$

Set the voltage at the $\mathrm{I}_{\text {LIM }}$ pin using a resistor divider from the 3.3 V reference output as shown in Figure 27. If the resistor from $\mathrm{I}_{\text {LIM }}$ to GND is chosen as $1 \mathrm{k}\left(\mathrm{R}_{\mathrm{LIM} 2}\right)$, the resistor from $\mathrm{I}_{\mathrm{LIM}}$ to 3.3 V can be calculated from:

$$
\begin{aligned}
\mathrm{R}_{\text {LIM } 1} & =\left(\mathrm{V}_{\text {REF }}-\mathrm{V}_{\text {ILIM }}\right) /\left(\mathrm{V}_{\text {ILIM }} / \mathrm{R}_{\text {LIM } 2}\right) \\
& =(3.3 \mathrm{~V}-0.486 \mathrm{~V}) /(0.486 \mathrm{~V} / 1 \mathrm{k} \Omega) \\
& =5790 \Omega \text { or } 5.76 \mathrm{k} \Omega
\end{aligned}
$$

Figure 27. Setting the Current Limit

## 10. PWM Comparator Input Voltage

Use Equation 35 to check the voltage level to the positive pin of the internal PWM comparators to insure the design will not saturate the comparator at maximum DAC output voltage with $1 \%$ error, AVP at full-load, $100 \%$ duty cycle (D $=1)$, and maximum internal ramp ( 310 mV at $100 \%$ duty-cycle):

$$
\begin{align*}
& \text { VCSREF,MAX = Max VID Setting w/ AVP @ Full-Load } \\
& =1.01 \cdot 1.825 \mathrm{~V}-45 \mathrm{mV}=1.80 \mathrm{~V} \\
& \text { VCOn,MAX } \\
& =(\mathrm{IO}, \mathrm{MAX} / 2+\Delta \mathrm{L} \text { Lo/2 }) \cdot \mathrm{R}_{\mathrm{MAX}} \cdot \operatorname{GCSA}, \mathrm{MAX} \\
& =(28 \mathrm{~A} / 2+4.0 \mathrm{~A} / 2) \cdot(1.29 \mathrm{~m} \Omega+0.82 \mathrm{~m} \Omega) \\
& \text {-3.95 V/V } \\
& =0.133 \mathrm{~V} \\
& \mathrm{~V}_{\text {CSREF, }} \text { MAX }+\mathrm{V}_{\text {COn,MAX }}+310 \mathrm{mV} \cdot \mathrm{D}  \tag{35}\\
& =1.80 \mathrm{~V}+0.133 \mathrm{~V}+310 \mathrm{mV} \\
& =2.243 \mathrm{~V}
\end{align*}
$$

This value is acceptable because it is below the specified maximum of 2.45 V .

## 11. $\mathrm{VTT}_{\mathrm{PGD}}$ Delay Time Setting

To obtain the 335 kHz switching frequency the value of $\mathrm{R}_{\text {OSC }}$ was set to $39 \mathrm{k} \Omega$ in Section 6 . Figure 4 must be used to determine the value of the $\mathrm{VTT}_{\mathrm{CT}}$ Charge Current at this $\mathrm{R}_{\mathrm{OSC}}$ value. In this example, the $39 \mathrm{k} \Omega \mathrm{R}_{\mathrm{OSC}}$ resistor results in a $\mathrm{VTT}_{\mathrm{CT}}$ Charge Current of approximately $26 \mu \mathrm{~A}$. Using Equation 34 and solving for $\mathrm{C}_{\mathrm{VtT}}$ :

$$
\begin{align*}
& \mathrm{T}_{\mathrm{D}, \mathrm{VTT}}=(1 \mathrm{~V}-0.25 \mathrm{~V}) \cdot \mathrm{CVTT}_{\mathrm{V}} / \mathrm{VTT} \mathrm{CT} \text { _Current }  \tag{34}\\
& \mathrm{CVTT}=\mathrm{T}_{\mathrm{D}, \mathrm{VTT}} \cdot \mathrm{VTT} \mathrm{CT} \_ \text {Current } / 0.75 \mathrm{~V} \\
&=2.5 \mathrm{~ms} \cdot 26 \mu \mathrm{~A} / 0.75 \mathrm{~V} \\
&=0.086 \mu \mathrm{~F} \text { or } 0.1 \mu \mathrm{~F}
\end{align*}
$$

## 12. Soft Start Time

To set the Soft Start time we first approximate the COMP voltage at a duty-cycle of $\mathrm{D}=1.745 \mathrm{~V} / 5 \mathrm{~V}=0.349$ :

$$
\begin{aligned}
\mathrm{V}_{\text {COMP }}= & \text { VOUT @ } 0 \mathrm{~A}+\text { Channel_Startup_Offset } \\
& + \text { Int_Ramp } \\
= & 1.745 \mathrm{~V}+0.40 \mathrm{~V}+250 \mathrm{mV} \cdot 0.349 \\
= & 2.232 \mathrm{~V}
\end{aligned}
$$

We then choose a convenient value for $\mathrm{R}_{\mathrm{CMP1}}(5.62 \mathrm{k} \Omega$ ) and solve Equation 37 for $\mathrm{C}_{\mathrm{CMP}}$ :

$$
\begin{aligned}
\mathrm{C} C M P 2 & =\mathrm{TSS} \cdot \frac{\mathrm{ICOMP}}{\left(\mathrm{VCOMP}-\mathrm{RCMP}_{\mathrm{CM}} \cdot \mathrm{ICOMP}\right)} \\
& =6.5 \mathrm{~ms} \cdot \frac{30 \mu \mathrm{~A}}{(2.232 \mathrm{~V}-5.62 \mathrm{k} \Omega \cdot 30 \mu \mathrm{~A})} \\
& =0.0945 \mu \mathrm{~F} \text { or } 0.1 \mu \mathrm{~F}
\end{aligned}
$$

Figure 28. Timing Diagram, VTT Power Good

## CS5322

## Two-Phase Buck Controller with Integrated Gate Drivers and 5-Bit DAC

The CS5322 is a two-phase step down controller which incorporates all control functions required to power high performance processors and high current power supplies. Proprietary multi-phase architecture guarantees balanced load current distribution and reduces overall solution cost in high current applications. Enhanced V ${ }^{2 T M}$ control architecture provides the fastest possible transient response, excellent overall regulation, and ease of use.

The CS5322 multi-phase architecture reduces output voltage and input current ripple, allowing for a significant reduction in inductor values and a corresponding increase in inductor current slew rate. This approach allows a considerable reduction in input and output capacitor requirements, as well as reducing overall solution size and cost.

## Features

- Enhanced $\mathrm{V}^{2}$ Control Method
- 5-Bit DAC with $1.0 \%$ Accuracy
- Adjustable Output Voltage Positioning
- 4 On-Board Gate Drivers
- 200 kHz to 800 kHz Operation Set by Resistor
- Current Sensed through Buck Inductors, Sense Resistors, or V-S Control
- Hiccup Mode Current Limit
- Individual Current Limits for Each Phase
- On-Board Current Sense Amplifiers
- $3.3 \mathrm{~V}, 1.0 \mathrm{~mA}$ Reference Output
- 5.0 V and/or 12 V Operation
- On/Off Control (through Soft Start Pin)
- Power Good Output with Internal Delay

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| SO-28L |  |  |
| 1 | COMP | Output of the error amplifier and input for the PWM comparators. |
| 2 | $V_{\text {FB }}$ | Voltage Feedback Pin. To use Adaptive Voltage Positioning (AVP) select an offset voltage at light load and connect a resistor between $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{OUT}}$. The input current of the $\mathrm{V}_{\mathrm{FB}}$ pin and the resistor value determine output voltage offset for zero output current. Short $\mathrm{V}_{\mathrm{FB}}$ to $\mathrm{V}_{\mathrm{OUT}}$ for no AVP. |
| 3 | $\mathrm{V}_{\text {DRP }}$ | Current sense output for AVP. The offset of this pin above the DAC voltage is proportional to the output current. Connect a resistor from this pin to $\mathrm{V}_{\mathrm{FB}}$ to set amount AVP or leave this pin open for no AVP. |
| 4-5 | CS1-CS2 | Current sense inputs. Connect current sense network for the corresponding phase to each input. |
| 6 | CS REF | Reference for Current Sense Amplifiers. To balance input offset voltages between the inverting and noninverting inputs of the Current Sense Amplifiers, connect a resistor between CS REF and the output voltage. The value should be $1 / 3$ of the value of the resistors connected to the CSx pins. |
| 7 | PWRGD | Power Good Output. Open collector output goes low when $\mathrm{CS}_{\text {REF }}$ is out of regulation. |
| 8-12 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID }}$ | Voltage ID DAC inputs. These pins are internally pulled up to 3.3 V if left open. |
| 13 | ILIM | Sets threshold for current limit. Connect to reference through a resistive divider. |
| 14 | REF | Reference output. Decouple with $0.1 \mu \mathrm{~F}$ to LGND. |
| 15 | $\mathrm{V}_{\mathrm{CCH} 2}$ | Power for GATE(H)2. |
| 16 | GATE(H)2 | High side driver \#2. |
| 17 | GND2 | Return for \#2 driver. |
| 18 | GATE(L)2 | Low side driver \#2. |

PACKAGE PIN DESCRIPTION (continued)

## APPLICATIONS INFORMATION

## FIXED FREQUENCY MULTI-PHASE CONTROL

In a multi-phase converter, multiple converters are connected in parallel and are switched on at different times. This reduces output current from the individual converters and increases the apparent ripple frequency. Because several converters are connected in parallel, output current can ramp up or down faster than a single converter (with the same value output inductor) and heat is spread among multiple components.

The CS5322 uses a two-phase, fixed frequency, Enhanced V ${ }^{2}$ architecture. Each phase is delayed $180^{\circ}$ from the previous phase. Normally Gate(H) transitions high at the beginning of each oscillator cycle. Inductor current ramps up until the combination of the current sense signal and the output ripple trip the PWM comparator and bring Gate(H) low. Once Gate $(\mathrm{H})$ goes low, it will remain low until the beginning of the next oscillator cycle. While Gate(H) is high, the enhanced $\mathrm{V}^{2}$ loop will respond to line and load transients. Once Gate $(\mathrm{H})$ is low, the loop will not respond again until the beginning of the next cycle. Therefore, constant frequency Enhanced $V^{2}$ will typically respond within the off-time of the converter.

The Enhanced $\mathrm{V}^{2}$ architecture measures and adjusts current in each phase. An additional input ( Cx ) for inductor current information has been added to the $\mathrm{V}^{2}$ loop for each phase as shown in Figure 9.

Figure 9. Enhanced V ${ }^{2}$ Feedback and Current Sense Scheme

The inductor current is measured across $\mathrm{R}_{\mathrm{S}}$, amplified by CSA and summed with the OFFSET and Output Voltage at the non-inverting input of the PWM comparator. The inductor current provides the PWM ramp and as inductor current increases the voltage on the positive pin of the PWM comparator rises and terminates the PWM cycle. If the inductor starts the cycle with a higher current, the PWM
cycle will terminate earlier providing negative feedback. The CS5322 provides a Cx input for each phase, but the $\mathrm{CS}_{\mathrm{REF}}, \mathrm{V}_{\mathrm{FB}}$ and COMP inputs are common to all phases. Current sharing is accomplished by referencing all phases to the same $\mathrm{V}_{\mathrm{FB}}$ and COMP pins, so that a phase with a larger current signal will turn off earlier than phases with a smaller current signal.

Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. When the average output current is zero, the COMP pin will be only $1 / 2$ of the steady state ramp height plus the OFFSET above the output voltage. If the COMP pin is held steady and the inductor current changes, there must also be a change in the output voltage. Or, in a closed loop configuration when the output current changes, the COMP pin must move to keep the same output voltage. The required change in the output voltage or COMP pin depends on the scaling of the current feedback signal and is calculated as

$$
\Delta \mathrm{V}=\mathrm{RS} \times \mathrm{CSA} \text { Gain } \times \Delta \mathrm{I}
$$

The single-phase power stage output impedance is:
Single Stage Impedance $=\Delta \mathrm{V} / \Delta \mathrm{I}=\mathrm{R}_{\mathrm{S}} \times$ CSA Gain.
The multi-phase power stage output impedance is the single-phase output impedance divided by the number of phases. The output impedance of the power stage determines how the converter will respond during the first few $\mu$ s of a transient before the feedback loop has repositioned the COMP pin.

The peak output current of each phase can also be calculated from;

$$
I_{\text {pkout }}(\text { per phase })=\frac{\mathrm{V}_{\mathrm{COMP}}-\mathrm{V}_{\mathrm{FB}}-\mathrm{V}_{\text {OFFSET }}}{\mathrm{R}_{\mathrm{S}} \times \mathrm{CSA} \text { Gain }}
$$

Figure 10 shows the step response of a single phase with the COMP pin at a fixed level. Before T1 the converter is in normal steady state operation. The inductor current provides the PWM ramp through the Current Sense Amplifier. The PWM cycle ends when the sum of the current signal, voltage signal and OFFSET exceed the level of the COMP pin. At T1 the output current increases and the output voltage sags. The next PWM cycle begins and the cycle continues longer than previously while the current signal increases enough to make up for the lower voltage at the $\mathrm{V}_{\mathrm{FB}}$ pin and the cycle ends at T2. After T2 the output voltage remains lower than at light load and the current signal level is raised so that the sum of the current and voltage signal is the same as with the original load. In a closed loop system the COMP pin would move higher to restore the output voltage to the original level.

Figure 10. Open Loop Operation

## Inductive Current Sensing

For lossless sensing, current can be sensed across the inductor as shown in Figure 11. In the diagram L is the output inductance and $\mathrm{R}_{\mathrm{L}}$ is the inherent inductor resistance. To compensate the current sense signal the values of R 1 and C 1 are chosen so that $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} 1 \times \mathrm{C} 1$. If this criteria is met the current sense signal will be the same shape as the inductor current, the voltage signal at Cx will represent the instantaneous value of inductor current and the circuit can be analyzed as if a sense resistor of value $R_{L}$ was used as a sense resistor $\left(\mathrm{R}_{\mathrm{S}}\right)$.

Figure 11. Lossless Inductive Current Sensing with Enhanced V ${ }^{2}$
When choosing or designing inductors for use with inductive sensing tolerances and temperature, effects should be considered. Cores with a low permeability material or a large gap will usually have minimal inductance change with temperature and load. Copper magnet wire has a temperature coefficient of $0.39 \%$ per ${ }^{\circ} \mathrm{C}$. The increase in winding resistance at higher temperatures should be
considered when setting the $\mathrm{I}_{\text {LIM }}$ threshold. If a more accurate current sense is required than inductive sensing can provide, current can be sensed through a resistor as shown in Figure 9.

## Current Sharing Accuracy

PCB traces that carry inductor current can be used as part of the current sense resistance depending on where the current sense signal is picked off. For accurate current sharing, the current sense inputs should sense the current at the same point for each phase and the connection to the $\mathrm{CS}_{\text {REF }}$ should be made so that no phase is favored. (In some cases, especially with inductive sensing, resistance of the pcb can be useful for increasing the current sense resistance.) The total current sense resistance used for calculations must include any pcb trace between the CS inputs and the $\mathrm{CS}_{\text {REF }}$ input that carries inductor current.

Current Sense Amplifier Input Mismatch and the value of the current sense element will determine the accuracy of current sharing between phases. The worst case Current Sense Amplifier Input Mismatch is 5.0 mV and will typically be within 3.0 mV . The difference in peak currents between phases will be the CSA Input Mismatch divided by the current sense resistance. If all current sense elements are of equal resistance a 3.0 mV mismatch with a $2.0 \mathrm{~m} \Omega$ sense resistance will produce a 1.5 A difference in current between phases.

## Operation at > 50\% Duty Cycle

For operation at duty cycles above $50 \%$ Enhanced V ${ }^{2}$ will exhibit subharmonic oscillation unless a compensation ramp is added to each phase. A circuit like the one on the left side of Figure 12 can be added to each current sense network to implement slope compensation. The value of R1 can be varied to adjust the ramp size.

Figure 12. External Slope Compensation Circuit

## Ramp Size and Current Sensing

Because the current ramp is used for both the PWM ramp and to sense current, the inductor and sense resistor values will be constrained. A small ramp will provide a quick transient response by minimizing the difference over which the COMP pin must travel between light and heavy loads, but a steady state ramp of 25 mV -p or greater is typically required to prevent pulse skipping and minimize pulse width jitter. For resistive current sensing, the combination of the inductor and sense resistor values must be chosen to provide a large enough steady state ramp. For large inductor values the sense resistor value must also be increased.

For inductive current sensing, the RC network must meet the requirement of $L / R_{L}=R \times C$ to accurately sense the $A C$ and DC components of the current the signal. Again the values for L and $\mathrm{R}_{\mathrm{L}}$ will be constrained in order to provide a large enough steady state ramp with a compensated current sense signal. A smaller $L$, or a larger $R_{L}$ than optimum might be required. But unlike resistive sensing, with inductive sensing, small adjustments can be made easily with the values of R and C to increase the ramp size if needed.

If RC is chosen to be smaller (faster) than $\mathrm{L} / \mathrm{R}_{\mathrm{L}}$, the AC portion of the current sensing signal will be scaled larger than the DC portion. This will provide a larger steady state ramp, but circuit performance will be affected and must be evaluated carefully. The current signal will overshoot during transients and settle at the rate determined by $\mathrm{R} \times \mathrm{C}$. It will eventually settle to the correct DC level, but the error will decay with the time constant of $\mathrm{R} \times \mathrm{C}$. If this error is excessive it will effect transient response, adaptive positioning and current limit. During transients the COMP pin will be required to overshoot along with the current signal in order to maintain the output voltage. The $\mathrm{V}_{\mathrm{DRP}}$ pin will also overshoot during transients and possibly slow the response. Single phase overcurrent will trip earlier than it would if compensated correctly and hiccup mode current limit will have a lower threshold for fast rise step loads than for slowly rising output currents.

The waveforms in Figure 13 show a simulation of the current sense signal and the actual inductor current during a positive step in load current with values of $\mathrm{L}=500 \mathrm{nH}, \mathrm{R}_{\mathrm{L}}$ $=1.6 \mathrm{~m} \Omega, \mathrm{R} 1=20 \mathrm{k}$ and $\mathrm{C} 1=.01 \mu \mathrm{~F}$. For ideal current signal compensation the value of R1 should be $31 \mathrm{k} \Omega$. Due to the faster than ideal RC time constant there is an overshoot of $50 \%$ and the overshoot decays with a $200 \mu$ s time constant. With this compensation the $\mathrm{I}_{\text {LIM }}$ pin threshold must be set more than $50 \%$ above the full load current to avoid triggering hiccup mode during a large output load step.

Figure 13. Inductive Sensing waveform during a Step with Fast RC Time Constant ( $50 \mu \mathrm{~s} / \mathrm{div}$ )

## Current Limit

Two levels of overcurrent protection are provided. Any time the voltage on a Current Sense pin exceeds CS $_{\text {REF }}$ by more than the Single Phase Pulse by Pulse Current Limit, the PWM comparator for that phase is turned off. This provides fast peak current protection for individual phases. The outputs of all the currents are also summed and filtered to compare an averaged current signal to the voltage on the $\mathrm{I}_{\text {LIM }}$ pin. If this voltage is exceeded, the fault latch trips and the Soft Start capacitor is discharged by a $7.5 \mu \mathrm{~A}$ source until the COMP pin reaches 0.2 V . Then Soft Start begins. The converter will continue to operate in this mode until the fault condition is corrected.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as a result of the normal operation of the Enhanced $V^{2}$ control topology with synchronous rectifiers. The control loop responds to an overvoltage condition within 400 ns , causing the top MOSFET's to shut off and the synchronous MOSFET's to turn on. This results in a "crowbar" action to clamp the output voltage and prevent damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low.

## Transient Response and Adaptive Positioning

For applications with fast transient currents the output filter is frequently sized larger than ripple currents require in order to reduce voltage excursions during transients. Adaptive voltage positioning can reduce peak-peak output voltage deviations during load transients and allow for a smaller output filter. The output voltage can be set higher than nominal at light loads to reduce output voltage sag when the load current is stepped up and set lower than nominal during heavy loads to reduce overshoot when the load current is stepped up. For low current applications a droop resistor can provide fast accurate adaptive positioning. However, at high currents the loss in a droop resistor becomes excessive. For example; in a 50 A converter a $1.0 \mathrm{~m} \Omega$ resistor to provide a 50 mV change in output voltage between no load and full load would dissipate 2.5 Watts.

Lossless adaptive positioning is an alternative to using a droop resistor, but must respond quickly to changes in load current. Figure 14 shows how adaptive positioning works. The waveform labeled normal shows a converter without adaptive positioning. On the left, the output voltage sags when the output current is stepped up and later overshoots when current is stepped back down. With fast (ideal) adaptive positioning the peak to peak excursions are cut in half. In the slow adaptive positioning waveform the output voltage is not repositioned quickly enough after current is stepped up and the upper limit is exceeded.

Figure 14. Adaptive Positioning
The CS5322 can be configured to adjust the output voltage based on the output current of the converter. (Refer to the application diagram on page 2387)

To set the no-load positioning, a resistor is placed between the output voltage and $\mathrm{V}_{\mathrm{FB}}$ pin. The $\mathrm{V}_{\mathrm{FB}}$ bias current will develop a voltage across the resistor to increase the output voltage. The $\mathrm{V}_{\mathrm{FB}}$ bias current is dependent on the value of $\mathrm{R}_{\text {OSC }}$. See Figure 4.

During no load conditions the $\mathrm{V}_{\text {DRP }}$ pin is at the same voltage as the $\mathrm{V}_{\mathrm{FB}}$ pin, so none of the $\mathrm{V}_{\mathrm{FB}}$ bias current flows through the $\mathrm{V}_{\mathrm{DRP}}$ resistor. When output current increases the $\mathrm{V}_{\text {DRP }}$ pin increases proportionally and the $\mathrm{V}_{\text {DRP }}$ pin current offsets the $\mathrm{V}_{\mathrm{FB}}$ bias current and causes the output voltage to decrease.

The $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\text {DRP }}$ pins take care of the slower and DC voltage positioning. The first few $\mu$ s are controlled primarily by the ESR and ESL of the output filter. The transition between fast and slow positioning is controlled by the ramp
size and the error amp compensation. If the ramp size is too large or the error amp too slow there will be a long transition to the final voltage after a transient. This will be most apparent with lower capacitance output filters.
Note: Large levels of adaptive positioning can cause pulse width jitter.

## Error Amp Compensation

The transconductance error amplifier requires a capacitor between the COMP pin and GND. Use of values less than 1 nF may result in error amp oscillation of several MHz .
The capacitor between the COMP pin and the inverting error amplifier input and the parallel resistance of the $\mathrm{V}_{\mathrm{FB}}$ resistor and the $\mathrm{V}_{\mathrm{DRP}}$ resistor are used to roll off the error amp gain. The gain is rolled off at a high enough frequency to give a quick transient response, but low enough to cross zero dB well below the switching frequency to minimize ripple and noise on the COMP pin.

## UVLO

The CS5322 has undervoltage lockout functions connected to two pins. One, intended for the logic and low-side drivers, with a 4.4 V turn-on threshold is connected to the $\mathrm{V}_{\mathrm{CCL}}$ pin. A second, for the high side drivers, has a 2.0 V threshold and is connected to the $\mathrm{V}_{\mathrm{CCH}} 1$ pin.
The UVLO threshold for the high side drivers was chosen at a low value to allow for flexibility in the part and an input voltage as low as 3.3 V. In many applications this will be disabled or will only check that the applicable supply is on - not that is at a high enough voltage to run the converter.

For the $12 \mathrm{~V}_{\text {IN }}$ converter in the application diagram on page 2387, the UVLO pin for the high side driver is pulled up by the 5.0 V supply (through two diode drops) and the function is not used. The diode between the Soft Start pin near GND and prevents start-up while the 12 V supply is off. In an application where a higher UVLO threshold is necessary a circuit like the one in Figure 15 will lock out the converter until the 12 V supply exceeds 9 V .

Figure 15. External UVLO Circuit

## Soft Start and Hiccup Mode

A capacitor between the Soft Start pin and GND controls Soft Start and hiccup mode slopes. A $0.1 \mu \mathrm{~F}$ capacitor with
the $30 \mu \mathrm{~A}$ charge current will allow the output to ramp up at $0.3 \mathrm{~V} / \mathrm{ms}$ or 1.5 V in 5.0 ms at start-up.

When a fault is detected due to overcurrent or UVLO the converter will enter a low duty cycle hiccup mode. During hiccup mode the converter will not switch from the time a fault is detected until the Soft Start capacitor has discharged below the Soft Start Discharge Threshold and then charged back up above the Channel Start Up Offset.

The Soft Start pin will disable the converter when pulled below 0.3 V .

## Layout Guidelines

With the fast rise, high output currents of microprocessor applications, parasitic inductance and resistance should be considered when laying out the power, filter and feedback signal sections of the board. Typically, a multi-layer board with at least one ground plane is recommended. If the layout is such that high currents can exist in the ground plane underneath the controller or control circuitry, the ground plane can be slotted to reroute the currents away from the controller. The slots should typically not be placed between the controller and the output voltage or in the return path of the gate drive. Additional power and ground planes or islands can be added as required for a particular layout.

Gate drives experience high di/dt during switching and the inductance of gate drive traces should be minimized. Gate drive traces should be kept as short and wide as practical and should have a return path directly below the gate trace.

Output filter components should be placed on wide planes connected directly to the load to minimize resistive drops during heavy loads and inductive drops and ringing during transients. If required, the planes for the output voltage and return can be interleaved to minimize inductance between the filter and load.

Voltage feedback should be taken from a point of the output or the output filter that doesn't favor any one phase. If the feedback connection is closer to one inductor than the others the ripple associated with that phase may appear larger than the ripple associated with the other phases and poor current sharing can result.

The current sense signal is typically tens of milli-volts. Noise pick-up should be avoided wherever possible. Current feedback traces should be routed away from noisy areas such as switch nodes and gate drive signals. The paths should be matched as well as possible. It is especially important that all current sense signals be picked off at similar points for accurate current sharing. If the current signal is taken from a place other than directly at the inductor any additional resistance between the pick-off point and the inductor appears as part of the inherent inductor resistance and should be considered in design calculations. Capacitors for the current feedback networks should be placed as close to the current sense pins as practical.

## DESIGN PROCEDURE

## Current Sensing, Power Stage and Output Filter Components

1. Choose the output filter components to meet peak transient requirements. The formula below can be used to provide an approximate starting point for capacitor choice, but will be inadequate to calculate actual values.

$$
\Delta \mathrm{V}_{\mathrm{PEAK}}=(\Delta \mathrm{I} / \Delta \mathrm{T}) \times \mathrm{ESL}+\Delta \mathrm{I} \times \mathrm{ESR}
$$

Ideally the output filter should be simulated with models including ESR, ESL, circuit board parasitics and delays due to switching frequency and converter response. Typically both bulk capacitance (electrolytic, Oscon, etc.,) and low impedance capacitance (ceramic chip) will be required. The bulk capacitance provides "hold up" during the converter response. The low impedance capacitance reduces steady state ripple and bypasses the bulk capacitance during slewing of output current.
2. For inductive current sensing (only) choose the current sense network RC to provide a 25 mV minimum ramp during steady state operation.

$$
\mathrm{R}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \frac{\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{IN}}}{\mathrm{~F} \times \mathrm{C} \times 25 \mathrm{mV}}
$$

Then choose the inductor value and inherent resistance to satisfy $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} \times \mathrm{C}$.
For ideal current sense compensation the ratio of $L$ and $R_{L}$ is fixed, so the values of $L$ and $R_{L}$ will be a compromise typically with the maximum value $\mathrm{R}_{\mathrm{L}}$ limited by conduction losses or inductor temperature rise and the minimum value of L limited by ripple current.
3. For resistive current sensing choose $L$ and $R_{S}$ to provide a steady state ramp greater than 25 mV .

$$
\mathrm{L} / \mathrm{RS}_{\mathrm{S}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{T} \mathrm{ON} / 25 \mathrm{mV}
$$

Again the ratio of $L$ and $R_{L}$ is fixed and the values of L and $\mathrm{R}_{\mathrm{S}}$ will be a compromise.
4. Calculate the high frequency output impedance (ConverterZ) of the converter during transients. This is the impedance of the Output filter ESR in parallel with the power stage output impedance (PwrstgZ) and will indicate how far from the original level ( $\Delta \mathrm{VR}$ ) the output voltage will typically recover to within one switching cycle. For a good transient response $\Delta \mathrm{VR}$ should be less than the peak output voltage overshoot or undershoot.

$$
\begin{array}{r}
\Delta V R=\text { ConverterZ } \times \text { ESR } \\
\text { ConverterZ }=\frac{\text { PwrstgZ } \times \text { ESR }}{\text { PwrstgZ }+E S R}
\end{array}
$$

where:

$$
\text { PwrstgZ }=\text { RS } \times \text { CSA Gain/2.0 }
$$

Multiply the converterZ by the output current step size to calculate where the output voltage should recover to within the first switching cycle after a transient. If the ConverterZ is higher than the value required to recover to where the adaptive positioning is set the remainder of the recovery will be controlled by the error amp compensation and will typically recover in $10-20 \mu \mathrm{~s}$.

$$
\Delta \mathrm{VR}=\Delta \mathrm{l} \text { OUT } \times \text { ConverterZ }
$$

Make sure that $\Delta \mathrm{VR}$ is less than the expected peak transient for a good transient response.
5. Adjust L and $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ as required to meet the best combination of transient response, steady state output voltage ripple and pulse width jitter.

## Current Limit

When the sum of the Current Sense amplifiers ( $\mathrm{V}_{\text {ITOTAL }}$ ) exceeds the voltage on the $\mathrm{I}_{\text {LIM }}$ pin the part will enter hiccup mode. For inductive sensing the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the inductor resistance (or current sense resistor) at max temperature and max current. To set the level of the $I_{\text {LIM }}$ pin:
6. $\mathrm{V}_{\mathrm{I}(\mathrm{LIM})}=\mathrm{R} \times \operatorname{IOUT}(\mathrm{LIM}) \times \mathrm{CS}$ to ILIM Gain
where:

$$
\mathrm{R} \text { is } \mathrm{R}_{\mathrm{L}} \text { or } \mathrm{R}_{\mathrm{S}}
$$

$\mathrm{I}_{\mathrm{OUT}(\mathrm{LIM})}$ is the current limit threshold.
For the overcurrent to work properly the inductor time constant (L/R) should be $\leq$ the Current sense RC. If the RC is too fast, during step loads the current waveform will appear larger than it is (typically for a few hundred $\mu \mathrm{s}$ ) and may trip the current limit at a level lower than the DC limit.

## Adaptive Positioning

7. To set the amount of voltage positioning below the DAC setting at no load connect a resistor $\left(\mathrm{R}_{\mathrm{V}(\mathrm{FB})}\right)$ between the output voltage and the $\mathrm{V}_{\mathrm{FB}}$ pin. Choose $\mathrm{R}_{\mathrm{V}(\mathrm{FB})}$ as;

$$
R V(F B)=N L \text { Position } / V F B \text { Bias Current }
$$

See Figure 4 for $V_{F B}$ Bias Current.
8. To set the difference in output voltage between no load and full load, connect a resistor $\left(\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}\right)$ between the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pins. $\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}$ can be calculated in two steps. First calculate the difference between the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pin at full load. (The $\mathrm{V}_{\mathrm{FB}}$ voltage should be the same as the DAC voltage during
closed loop operation.) Then choose the $\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}$ to source enough current across $\mathrm{R}_{\mathrm{V}}(\mathrm{FB})$ for the desired change in output voltage.

$$
\Delta \mathrm{V} V(\mathrm{DRP})=\mathrm{IOUTFL} \times \mathrm{R} \times \mathrm{CS} \text { to } \mathrm{V}_{\mathrm{DRP}} \text { Gain }
$$

where:
$\mathrm{R}=\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ for one phase;
IOUTFL is the full load output current.

$$
\mathrm{RV}(\mathrm{DRP})=\Delta \mathrm{V}_{\mathrm{DRP}} \times \operatorname{RV}(\mathrm{FB}) / \Delta \mathrm{VOUT}_{\mathrm{OU}}
$$

## Calculate Input Filter Capacitor Current Ripple

The procedure below assumes that phases do not overlap and output inductor ripple current $(\mathrm{P}-\mathrm{P})$ is less than the average output current of one phase.
9. Calculate Input Current
$\mathrm{I}_{\mathrm{IN}}=\frac{\mathrm{V}_{\text {OUT }} \times \mathrm{IOUT}}{\left(\text { Efficiency } \times \mathrm{V}_{\text {IN }}\right)}$
10. Calculate Duty Cycle (per phase).

Duty Cycle $=\frac{\mathrm{VOUT}^{\left(\text {Efficiency } \times \mathrm{V}_{\mathrm{IN}}\right)}}{\left(\begin{array}{ll}\end{array}\right)}$
11. Calculate Apparent Duty Cycle.

## Apparent Duty Cycle $=$ Duty Cycle $\times \#$ of Phases

12. Calculate Input Filter Capacitor Ripple Current. Use the chart in Figure 16 to calculate the normalized ripple current ( $\mathrm{K}_{\mathrm{RMS}}$ ) based on the reciprocal of Apparent Duty Cycle. Then multiply the input current by $K_{\text {RMS }}$ to obtain the Input Filter Capacitor Ripple Current.

Figure 16. Normalized Input Filter Capacitor Ripple Current

## DESIGN EXAMPLE

Choose the component values for a 12 V to $1.6 \mathrm{~V}, 35 \mathrm{~A}$ converter with lossless current sensing, adaptive positioning and a 45 A current limit. The adaptive positioning is chosen 30 mV above the nominal $\mathrm{V}_{\text {OUT }}$ at no load and 40 mV below the no-load position with 35 A out. The peak output voltage transient is 70 mV max during a 32 A step current.

## Current Sensing, Power Stage and

## Output Filter Components

1. Assume $1.5 \mathrm{~m} \Omega$ of output filter ESR.
2. 

$$
\begin{aligned}
& \mathrm{R}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \frac{\mathrm{V}_{\mathrm{OUT}} / \mathrm{V} \mathrm{IN}}{\mathrm{~F} \times \mathrm{C} \times 25 \mathrm{mV}} \\
&=(12-1.6) \times \frac{1.6 / 12}{250 \mathrm{k} \times 0.01 \mu \mathrm{~F} \times 25 \mathrm{mV}} \\
&=22 \mathrm{k} \Omega \\
& \mathrm{~L} / \mathrm{R}_{\mathrm{L}}=.01 \mu \mathrm{~F} \times 20 \mathrm{k} \Omega=200 \mu \mathrm{~s} \\
& \mathrm{Choose} \mathrm{R} \\
& \mathrm{~L}=2.0 \mathrm{~m} \Omega \\
& 2.0 \mathrm{~m} \Omega \times 200 \mu \mathrm{~s}=400 \mathrm{nH} \\
& \text { 4. } \mathrm{n} / \mathrm{a}
\end{aligned}
$$

$$
\begin{aligned}
\text { PwrstgZ } & =R_{L} \times \text { CSA Gain } / 2.0 \\
& =2.0 \mathrm{~m} \Omega \times 3.15 / 2.0=3.1 \mathrm{~m} \Omega
\end{aligned}
$$

ConverterZ $=\frac{\text { PwrstgZ } \times \text { ESR }}{\text { PwrstgZ }+ \text { ESR }}$

$$
=\frac{3.1 \mathrm{~m} \Omega \times 1.5 \mathrm{~m} \Omega}{3.1 \mathrm{~m} \Omega+1.5 \mathrm{~m} \Omega} \cong 1.0 \mathrm{~m} \Omega
$$

$\Delta V R=1.0 \mathrm{~m} \Omega \times 32 \mathrm{~A}=32 \mathrm{mV}$
5. $\mathrm{n} / \mathrm{a}$

## Current Limit

6. 

$$
\begin{aligned}
\mathrm{V}_{\mathrm{I}(\mathrm{LIM})=}= & \mathrm{R}_{\mathrm{L}} \times \operatorname{IOUT}(\mathrm{LIM}) \\
& \times \mathrm{CS} \text { to ILIM Gain } \\
= & 2.0 \mathrm{~m} \times 45 \mathrm{~A} \times 6.25 \\
= & 562 \mathrm{mV}
\end{aligned}
$$

## Adaptive Positioning

7. 

$$
R V(F B)=\text { NL Position } / V_{F B} \text { Bias Current }
$$

$$
=30 \mathrm{mV} / 6.0 \mu \mathrm{~A}=5.0 \mathrm{k} \Omega
$$

8. 

$$
\begin{aligned}
\Delta V \mathrm{DRP}= & \mathrm{R}_{\mathrm{L}} \times \text { IOUT } \\
& \times \text { Current Sense to VDRP Gain } \\
= & 2.0 \mathrm{~m} \Omega \times 35 \mathrm{~A} \times 3.0 \\
= & 210 \mathrm{mV} \\
\mathrm{RV}(\mathrm{DRP}) & =\Delta \mathrm{V} \mathrm{DRP} \times \mathrm{RV}(\mathrm{FB}) / \Delta \mathrm{V} \text { OUT } \\
= & 210 \mathrm{mV} \times 5.0 \mathrm{k} \Omega / 40 \mathrm{mV} \\
= & 26 \mathrm{k} \Omega
\end{aligned}
$$

9. 

$\mathrm{I}_{\mathrm{IN}}=1.52 \mathrm{~V} \times \frac{41 \mathrm{~A}}{0.85 \times 12 \mathrm{~V} \mathrm{IN}}=6.1 \mathrm{~A}$
10.

Duty Cycle $=\frac{1.52 \mathrm{~V}}{0.85 \times 12 \mathrm{VIN}}=0.15$
11.

Apparent Duty Cycle $=0.15 \times 2.0=0.3$
12.

RMS ripple $=6.1 \mathrm{~A} \times 1.5=9.2 \mathrm{~A}$

Figure 17. 5.0 V only to $1.6 \mathrm{~V}, 35 \mathrm{~A}$

## NCP5322A

## Two-Phase Buck Controller with Integrated Gate Drivers and 5-Bit DAC

The NCP5322A is a second-generation, two-phase step down controller which incorporates all control functions required to power high performance processors and high current power supplies. Proprietary multi-phase architecture guarantees balanced load current distribution and reduces overall solution cost in high current applications. Enhanced $V^{2 T M}$ control architecture provides the fastest possible transient response, excellent overall regulation, and ease of use. The NCP5322A is a second-generation PWM controller because it optimizes transient response by combining traditional Enhanced $\mathrm{V}^{2}$ with an internal PWM ramp and fast-feedback directly from $V_{\text {CORE }}$ to the internal PWM comparator. These enhancements provide greater design flexibility, facilitate use and reduce output voltage jitter.

The NCP5322A multi-phase architecture reduces output voltage and input current ripple, allowing for a significant reduction in filter size and inductor values with a corresponding increase in inductor current slew rate. This approach allows a considerable reduction in input and output capacitor requirements, as well as reducing overall solution size and cost.

## Features

- Enhanced $V^{2}$ Control Method with Internal Ramp
- Internal PWM Ramp
- Fast-Feedback Directly from $V_{\text {CORE }}$
- 5-Bit DAC with $1.0 \%$ Accuracy
- Adjustable Output Voltage Positioning
- 4 On-Board Gate Drivers
- 200 kHz to 800 kHz Operation Set by Resistor
- Current Sensed through Buck Inductors or Sense Resistors
- Hiccup Mode Current Limit
- Individual Current Limits for Each Phase
- On-Board Current Sense Amplifiers
- $3.3 \mathrm{~V}, 1.0 \mathrm{~mA}$ Reference Output
- 5.0 V and/or 12 V Operation
- On/Off Control (through Soft Start Pin)
- Power Good Output with Internal Delay

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| SO-28L |  |  |
| 1 | COMP | Output of the error amplifier and input for the PWM comparators. |
| 2 | $V_{\text {FB }}$ | Voltage Feedback Pin. To use Adaptive Voltage Positioning (AVP) select an offset voltage at light load and connect a resistor between $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{OUT}}$. The input current of the $\mathrm{V}_{\mathrm{FB}}$ pin and the resistor value determine output voltage offset for zero output current. Short $\mathrm{V}_{\mathrm{FB}}$ to $\mathrm{V}_{\mathrm{OUT}}$ for no AVP. |
| 3 | $\mathrm{V}_{\text {DRP }}$ | Current sense output for AVP. The offset of this pin above the DAC voltage is proportional to the output current. Connect a resistor from this pin to $\mathrm{V}_{\mathrm{FB}}$ to set amount AVP or leave this pin open for no AVP. This pin's maximum working voltage is 2.3 Vdc. |
| 4-5 | CS1-CS2 | Current sense inputs. Connect current sense network for the corresponding phase to each input. The input voltages to these pins must be kept within 105 mV of $\mathrm{CS}_{\text {REF }}$ or pulse-by-pulse current limit will be tripped. |
| 6 | $\mathrm{CS}_{\text {REF }}$ | Reference for Current Sense Amplifiers, input to the Power Good comparators, and fast feedback connection to the PWM comparator. To balance input offset voltages between the inverting and noninverting inputs of the Current Sense Amplifiers, connect a resistor between CS $_{\text {REF }}$ and the output voltage. The value should be $1 / 3$ of the value of the resistors connected to the CSx pins. The input voltage to this pin must not exceed the maximum DAC (VID) setting by more than 100 mV or the internal PWM comparator may saturate. |
| 7 | PWRGD | Power Good Output. Open collector output goes low when $\mathrm{CS}_{\text {REF }}\left(\mathrm{V}_{\text {OUT }}\right)$ is out of regulation. |
| 8-12 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {ID }}$ | Voltage ID DAC inputs. These pins are internally pulled up to 3.3 V if left open. |

## PACKAGE PIN DESCRIPTION (continued)

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| SO-28L | PIN SYMBOL | FUNCTION |
| 13 | ILIM | Sets threshold for current limit. Connect to reference through a resistive divider. This pin's maximum working voltage is 1.3 Vdc . |
| 14 | REF | Reference output. Decouple with $0.1 \mu \mathrm{~F}$ to LGND. |
| 15 | $\mathrm{V}_{\mathrm{CCH} 2}$ | Power for GATE(H)2. |
| 16 | GATE(H)2 | High side driver \#2. |
| 17 | GND2 | Return for \#2 drivers. |
| 18 | GATE(L)2 | Low side driver \#2. |
| 19 | $\mathrm{V}_{\text {CCL2 }}$ | Power for GATE(L)2. |
| 20 | SS | Soft Start capacitor pin. The Soft Start capacitor controls both Soft Start time and hiccup mode frequency. The COMP pin is clamped below Soft Start during Start-Up and hiccup mode. |
| 21 | LGND | Return for internal control circuits and IC substrate connection. |
| 22 | $\mathrm{V}_{\mathrm{CCH} 1}$ | Power for GATE(H)1. UVLO Sense for High Side Driver supply connects to this pin. |
| 23 | GATE(H)1 | High side driver \#1. |
| 24 | GND1 | Return \#1 drivers. |
| 25 | GATE(L) 1 | Low side driver \#1. |
| 26 | $\mathrm{V}_{\text {CCL1 }}$ | Power for GATE(L)1. |
| 27 | $\mathrm{V}_{\text {CCL }}$ | Power for internal control circuits. UVLO Sense for Logic connects to this pin. |
| 28 | Rosc | A resistor from this pin to ground sets operating frequency and $\mathrm{V}_{\mathrm{FB}}$ bias current. |

## APPLICATIONS INFORMATION

## Overview

The NCP5322A DC/DC controller from ON Semiconductor was developed using the Enhanced $V^{2}$ topology to meet requirements of low voltage, high current loads with fast transient requirements. Enhanced $V^{2}$ combines the original $\mathrm{V}^{2}$ topology with peak current-mode control for fast transient response and current sensing capability. The addition of an internal PWM ramp and implementation of fast-feedback directly from $V_{\text {CORE }}$ has improved transient response and simplified design. The NCP5322A includes Power Good (PWRGD) and MOSFET gate drivers to provide a "fully integrated solution" to simplify design, minimize circuit board area, and reduce overall system cost.

Two advantages of a multi-phase converter over a single-phase converter are current sharing and increased apparent output frequency. Current sharing allows the designer to use less inductance in each phase than would be required in a single-phase converter. The smaller inductor will produce larger ripple currents but the total per phase power dissipation is reduced because the RMS current is lower. Transient response is improved because the control loop will measure and adjust the current faster in a smaller output inductor. Increased apparent output frequency is desirable because the off time and the ripple voltage of the two-phase converter will be less than that of a single-phase converter.

## Fixed Frequency Multi-Phase Control

In a multi-phase converter, multiple converters are connected in parallel and are switched on at different times. This reduces output current from the individual converters and increases the apparent ripple frequency. Because several converters are connected in parallel, output current can ramp up or down faster than a single converter (with the same value output inductor) and heat is spread among multiple components.

The NCP5322A controller uses two-phase, fixed frequency, Enhanced $\mathrm{V}^{2}$ architecture to measure and control
currents in individual phases. Each phase is delayed $180^{\circ}$ from the previous phase. Normally, GATE(H) transitions to a high voltage at the beginning of each oscillator cycle. Inductor current ramps up until the combination of the current sense signal, the internal ramp and the output voltage ripple trip the PWM comparator and bring $\operatorname{GATE}(\mathrm{H})$ low. Once GATE(H) goes low, it will remain low until the beginning of the next oscillator cycle. While GATE(H) is high, the Enhanced $\mathrm{V}^{2}$ loop will respond to line and load variations. On the other hand, once $\operatorname{GATE}(\mathrm{H})$ is low, the loop can not respond until the beginning of the next PWM cycle. Therefore, constant frequency Enhanced $\mathrm{V}^{2}$ will typically respond to disturbances within the off-time of the converter.
The Enhanced $V^{2}$ architecture measures and adjusts the output current in each phase. An additional input (CSn) for inductor current information has been added to the $\mathrm{V}^{2}$ loop for each phase as shown in Figure 10. The triangular inductor current is measured differentially across RS, amplified by CSA and summed with the Channel Startup Offset, the Internal Ramp, and the Output Voltage at the non-inverting input of the PWM comparator. The purpose of the Internal Ramp is to compensate for propagation delays in the NCP5322A. This provides greater design flexibility by allowing smaller external ramps, lower minimum pulse widths, higher frequency operation, and PWM duty cycles above $50 \%$ without external slope compensation. As the sum of the inductor current and the internal ramp increase, the voltage on the positive pin of the PWM comparator rises and terminates the PWM cycle. If the inductor starts a cycle with higher current, the PWM cycle will terminate earlier providing negative feedback. The NCP5322A provides a CSn input for each phase, but the $\mathrm{CS}_{\text {REF }}$ and COMP inputs are common to all phases. Current sharing is accomplished by referencing all phases to the same $\mathrm{CS}_{\text {REF }}$ and COMP pins, so that a phase with a larger current signal will turn off earlier than a phase with a smaller current signal.

Figure 10. Enhanced $V^{2}$ Control Employing Resistive Current Sensing and Additional Internal Ramp

Enhanced $\mathrm{V}^{2}$ responds to disturbances in $\mathrm{V}_{\text {CORE }}$ by employing both "slow" and "fast" voltage regulation. The internal error amplifier performs the slow regulation. Depending on the gain and frequency compensation set by the amplifier's external components, the error amplifier will typically begin to ramp its output to react to changes in the output voltage in 1-2 PWM cycles. Fast voltage feedback is implemented by a direct connection from $\mathrm{V}_{\text {CORE }}$ to the non-inverting pin of the PWM comparator via the summation with the inductor current, internal ramp, and Offset. A rapid increase in load current will produce a negative offset at $\mathrm{V}_{\text {CORE }}$ and at the output of the summer. This will cause the PWM duty cycle to increase almost instantly. Fast feedback will typically adjust the PWM duty cycle in 1 PWM cycle.

As shown in Figure 10, an internal ramp (nominally 125 mV at a $50 \%$ duty cycle) is added to the inductor current ramp at the positive terminal of the PWM comparator. This additional ramp compensates for propagation time delays from the current sense amplifier (CSA), the PWM comparator, and the MOSFET gate drivers. As a result, the minimum ON time of the controller is reduced and lower duty cycles may be achieved at higher frequencies. Also, the additional ramp reduces the reliance on the inductor current ramp and allows greater flexibility when choosing the output inductor and the $\mathrm{R}_{\mathrm{CSn}} \mathrm{C}_{\mathrm{CSn}}$ ( $\mathrm{n}=1$ or 2 ) time constant of the feedback components from $\mathrm{V}_{\text {CORE }}$ to the CSn pin.

Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. When the average output current is zero, the COMP pin will be:

$$
\begin{aligned}
\text { VCOMP }= & \text { VOUT @ } 0 \text { A + Channel_Startup_Offset } \\
& + \text { Int_Ramp }+ \text { GCSA } \cdot \text { Ext_Ramp } / 2
\end{aligned}
$$

Int_Ramp is the "partial" internal ramp value at the corresponding duty cycle, Ext_Ramp is the peak-to-peak external steady-state ramp at 0 A, $G_{\text {CSA }}$ is the Current Sense Amplifier Gain (nominally $3.5 \mathrm{~V} / \mathrm{V}$ ), and the Channel Startup Offset is typically 0.40 V . The magnitude of the Ext_Ramp can be calculated from:

$$
\text { Ext_Ramp }=\mathrm{D} \cdot\left(\mathrm{~V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) /\left(\mathrm{RCSn}^{2} \cdot \mathrm{C} \mathrm{CSn} \cdot \mathrm{fSW}\right)
$$

For example, if $\mathrm{V}_{\text {Out }}$ at 0 A is set to 1.630 V with AVP and the input voltage is 12.0 V , the duty cycle ( D ) will be $1.630 / 12.0$ or $13.6 \%$. Int_Ramp will be $125 \mathrm{mV} \bullet 13.6 / 50=$ 34 mV . Realistic values for $\mathrm{R}_{\mathrm{CSn}}, \mathrm{C}_{\mathrm{CSn}}$ and $\mathrm{f}_{\mathrm{SW}}$ are $60 \mathrm{k} \Omega$ $0.01 \mu \mathrm{~F}$, and 220 kHz - using these and the previously mentioned formula, Ext_Ramp will be 10.6 mV .

$$
\begin{aligned}
\mathrm{V} \text { COMP }= & 1.630 \mathrm{~V}+0.40 \mathrm{~V}+34 \mathrm{mV} \\
& +3.5 \mathrm{~V} / \mathrm{V} \cdot 10.6 \mathrm{mV} / 2 \\
= & 2.083 \mathrm{Vdc}
\end{aligned}
$$

If the COMP pin is held steady and the inductor current changes, there must also be a change in the output voltage.

Or, in a closed loop configuration when the output current changes, the COMP pin must move to keep the same output voltage. The required change in the output voltage or COMP pin depends on the scaling of the current feedback signal and is calculated as:

$$
\Delta \mathrm{V}=\mathrm{RS} \cdot \mathrm{G} \text { CSA } \cdot \Delta \mathrm{I} \text { OUT }
$$

The single-phase power stage output impedance is:

$$
\text { Single Stage Impedance }=\Delta \mathrm{V}_{\mathrm{OUT}} / \Delta \mathrm{I} \text { OUT }=\mathrm{RS} \cdot \mathrm{GCSA}
$$

The multi-phase power stage output impedance is the single-phase output impedance divided by the number of phases. The output impedance of the power stage determines how the converter will respond during the first few microseconds of a transient before the feedback loop has repositioned the COMP pin.

The peak output current can be calculated from:
IOUT,PEAK $=\left(V_{\text {COMP }}-V_{\text {OUT }}-\right.$ Offset $) /\left(\mathrm{RS}_{\text {S }} \cdot \mathrm{GCSA}\right)$
Figure 11 shows the step response of the COMP pin at a fixed level. Before T1 the converter is in normal steady state operation. The inductor current provides a portion of the PWM ramp through the Current Sense Amplifier. The PWM cycle ends when the sum of the current ramp, the "partial" internal ramp voltage signal and Offset exceed the level of the COMP pin. At T1 the output current increases and the output voltage sags. The next PWM cycle begins and the cycle continues longer than previously while the current signal increases enough to make up for the lower voltage at the $\mathrm{V}_{\mathrm{FB}}$ pin and the cycle ends at T2. After T2 the output voltage remains lower than at light load and the average current signal level (CSn output) is raised so that the sum of the current and voltage signal is the same as with the original load. In a closed loop system the COMP pin would move higher to restore the output voltage to the original level.

Figure 11. Open Loop Operation

Figure 12. Enhanced V ${ }^{2}$ Control Employing Lossless Inductive Current Sensing and Internal Ramp

## Inductive Current Sensing

For lossless sensing, current can be sensed across the inductor as shown in Figure 12. In the diagram, L is the output inductance and $\mathrm{R}_{\mathrm{L}}$ is the inherent inductor resistance. To compensate the current sense signal, the values of $\mathrm{R}_{\mathrm{CSn}}$ and $\mathrm{C}_{\mathrm{CSn}}$ are chosen so that $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R}_{\mathrm{CSn}} \bullet \mathrm{C}_{\mathrm{CSn}}$. If this criteria is met, the current sense signal will be the same shape as the inductor current and the voltage signal at CSn will represent the instantaneous value of inductor current. Also, the circuit can be analyzed as if a sense resistor of value $R_{L}$ was used as a sense resistor ( $\mathrm{R}_{\mathrm{S}}$ ).

When choosing or designing inductors for use with inductive sensing, tolerances and temperature effects should be considered. Cores with a low permeability material or a large gap will usually have minimal inductance change with temperature and load. Copper magnet wire has a temperature coefficient of $0.39 \%$ per ${ }^{\circ} \mathrm{C}$. The increase in winding resistance at higher temperatures should be considered when setting the $\mathrm{I}_{\text {LIM }}$ threshold. If a more accurate current sense is required than inductive sensing can provide, current can be sensed through a resistor as shown in Figure 10.

## Current Sharing Accuracy

Printed circuit board (PCB) traces that carry inductor current can be used as part of the current sense resistance depending on where the current sense signal is picked off. For accurate current sharing, the current sense inputs should sense the current at relatively the same point for each phase and the connection to the $\mathrm{CS}_{\text {REF }}$ pin should be made so that no phase is favored. In some cases, especially with inductive sensing, resistance of the PCB can be useful for increasing the current sense resistance. The total current sense resistance used for calculations must include any PCB trace resistance between the CSn input and the $\mathrm{CS}_{\mathrm{REF}}$ input that carries inductor current.

Current Sense Amplifier (CSA) input mismatch and the value of the current sense component will determine the accuracy of the current sharing between phases. The worst case Current Sense Amplifier input mismatch is $\pm 5.0 \mathrm{mV}$ and will typically be within 3.0 mV . The difference in peak currents between phases will be the CSA input mismatch divided by the current sense resistance. If all current sense components are of equal resistance a 3.0 mV mismatch with a $2.0 \mathrm{~m} \Omega$ sense resistance will produce a 1.5 A difference in current between phases.

## External Ramp Size and Current Sensing

The internal ramp allows flexibility of current sense time constant. Typically, the current sense $\mathrm{R}_{\mathrm{CSn}} \cdot \mathrm{C}_{\mathrm{CSn}}$ time constant ( $\mathrm{n}=1$ or 2 ) should be equal to or slower than the inductor's time constant. If RC is chosen to be smaller (faster) than $\mathrm{L} / \mathrm{R}_{\mathrm{L}}$, the AC or transient portion of the current sensing signal will be scaled larger than the DC portion. This will provide a larger steady state ramp, but circuit performance will be affected and must be evaluated carefully. The current signal will overshoot during transients and settle at the rate determined by $\mathrm{R}_{\mathrm{CSn}} \bullet \mathrm{C}_{\mathrm{CSn}}$. It will eventually settle to the correct DC level, but the error will decay with the time constant of $\mathrm{R}_{\mathrm{CSn}} \bullet \mathrm{C}_{\mathrm{CSn}}$. If this error is excessive it will effect transient response, adaptive positioning and current limit. During a positive current transient, the COMP pin will be required to undershoot in response to the current signal in order to maintain the output voltage. Similarly, the $\mathrm{V}_{\text {DRP }}$ signal will overshoot which will produce too much transient droop in the output voltage. Single phase overcurrent will trip earlier than it would if compensated correctly and hiccup mode current limit will have a lower threshold for fast rise step loads than for slowly rising output currents.
The waveforms in Figure 13 show a simulation of the current sense signal and the actual inductor current during a
positive step in load current with values of $\mathrm{L}=500 \mathrm{nH}, \mathrm{R}_{\mathrm{L}}$ $=1.6 \mathrm{~m} \Omega, \mathrm{R}_{\mathrm{CSn}}=20 \mathrm{k}$ and $\mathrm{C}_{\mathrm{CSn}}=0.01 \mu \mathrm{~F}$. For ideal current signal compensation the value of $\mathrm{R}_{\mathrm{CSn}}$ should be $31 \mathrm{k} \Omega$. Due to the faster than ideal RC time constant there is an overshoot of $50 \%$ and the overshoot decays with a $200 \mu \mathrm{~s}$ time constant. With this compensation the $\mathrm{I}_{\text {LIM }}$ pin threshold must be set more than $50 \%$ above the full load current to avoid triggering hiccup mode during a large output load step.

Figure 13. Inductive Sensing Waveform During a Load Step with Fast RC Time Constant ( $50 \mu \mathrm{~s} / \mathrm{div}$ )

## Current Limit

Two levels of overcurrent protection are provided. First, if the voltage on the Current Sense pins (either CS1 or CS2) exceeds CS $_{\text {REF }}$ by more than a fixed threshold (Single Pulse Current Limit), the PWM comparator is turned off. This provides fast peak current protection for individual phases. Second, the individual phase currents are summed and low-pass filtered to compare an averaged current signal to a user adjustable voltage on the $\mathrm{I}_{\text {LIM }}$ pin. If the $\mathrm{I}_{\text {LIM }}$ voltage is exceeded, the fault latch trips and the Soft Start capacitor is discharged until the Soft-Start pin reaches 0.27 V . Then Soft Start begins. The converter will continue to operate in a low current hiccup mode until the fault condition is corrected.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as a result of the normal operation of the Enhanced $\mathrm{V}^{2}$ control topology with synchronous rectifiers. The control loop responds to an overvoltage condition within 400 ns , causing the top MOSFET to shut OFF and the synchronous (lower) MOSFET to turn ON. This results in a "crowbar" action to clamp the output voltage and prevent damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low.

## Transient Response and Adaptive Positioning

For applications with fast transient currents the output filter is frequently sized larger than ripple currents require in order to reduce voltage excursions during load transients. Adaptive voltage positioning can reduce peak-to-peak output voltage deviations during load transients and allow for a smaller output filter. The output voltage can be set higher than nominal at light loads to reduce output voltage sag when the load current is applied. Similarly, the output voltage can be set lower than nominal during heavy loads to reduce overshoot when the load current is removed. For low current applications a droop resistor can provide fast accurate adaptive positioning. However, at high currents the loss in a droop resistor becomes excessive. For example; in a 50 A converter a $1 \mathrm{~m} \Omega$ resistor to provide a 50 mV change in output voltage between no load and full load would dissipate 2.5 Watts.

Lossless adaptive positioning is an alternative to using a droop resistor, but must respond to changes in load current. Figure 14 shows how adaptive positioning works. The waveform labeled normal shows a converter without adaptive positioning. On the left, the output voltage sags when the output current is stepped up and later overshoots when current is stepped back down. With fast (ideal) adaptive positioning the peak to peak excursions are cut in half. In the slow adaptive positioning waveform the output voltage is not repositioned quickly enough after current is stepped up and the upper limit is exceeded.

Figure 14. Adaptive Positioning
The controller can be configured to adjust the output voltage based on the output current of the converter. (Refer to the application diagram in Figure 1). To set the no-load positioning, a resistor is placed between the output voltage and $\mathrm{V}_{\mathrm{FB}}$ pin. The $\mathrm{V}_{\mathrm{FB}}$ bias current will develop a voltage across the resistor to adjust the no-load output voltage. The $\mathrm{V}_{\mathrm{FB}}$ bias current is dependent on the value of $\mathrm{R}_{\mathrm{OSC}}$ as shown in the datasheet.

During no load conditions the $\mathrm{V}_{\text {DRP }}$ pin is at the same voltage as the $\mathrm{V}_{\mathrm{FB}}$ pin, so none of the $\mathrm{V}_{\mathrm{FB}}$ bias current flows through the $\mathrm{V}_{\mathrm{DRP}}$ resistor. When output current increases the $\mathrm{V}_{\mathrm{DRP}}$ pin increases proportionally and the $\mathrm{V}_{\mathrm{DRP}}$ pin current offsets the $\mathrm{V}_{\mathrm{FB}}$ bias current and causes the output voltage to decrease.

The response during the first few microseconds of a load transient are controlled primarily by power stage output impedance and the ESR and ESL of the output filter. The
transition between fast and slow positioning is controlled by the total ramp size and the error amp compensation. If the current signal size is too large or the error amp too slow there will be a long transition to the final voltage after a transient. This will be most apparent with lower capacitance output filters.

## Error Amp Compensation \& Tuning

The transconductance error amplifier requires a capacitor ( $\mathrm{C}_{\mathrm{CMP1}}$ in the Applications Diagram) between the COMP pin and GND. This capacitor stabilizes the transconductance error amplifier. Values less than 1 nF may cause oscillations of the COMP voltage. These oscillations will increase the output voltage jitter.

The capacitor ( $\mathrm{C}_{\mathrm{AMP}}$ ) between the COMP pin and the inverting error amplifier input (the $\mathrm{V}_{\mathrm{FB}} \mathrm{pin}$ ) and the parallel combination of the resistors $\mathrm{R}_{\mathrm{FBK} 1}$ and $\mathrm{R}_{\mathrm{DRP} 1}$ determine the bandwidth of the error amplifier. The gain of the error amplifier crosses 0 dB at a high enough frequency to give a quick transient response, but well below the switching frequency to minimize ripple and noise on the COMP pin. A capacitor in parallel with the $\mathrm{V}_{\mathrm{FB}}$ resistor $\left(\mathrm{C}_{\mathrm{FBK} 2}\right)$ adds a zero to boost phase near the crossover frequency to improve loop stability.

Setting-up and tuning the error amplifier is a three step process. First, the no-load and full-load adaptive voltage positioning (AVP) are set using $\mathrm{R}_{\mathrm{FBK} 1}$ and $\mathrm{R}_{\mathrm{DRP} 1}$, respectively. Second, the current sense time constant and error amplifier gain are adjusted with $\mathrm{R}_{\mathrm{CSn}}$ and $\mathrm{C}_{\mathrm{AMP}}$ while monitoring $V_{\text {OUT }}$ during transient loading. Lastly, the peak-to-peak voltage ripple on the COMP pin is examined when the converter is fully loaded to insure low output voltage jitter. The details of this process are covered in the Design Procedure section.

## Undervoltage Lockout (UVLO)

The controller has undervoltage lockout functions connected to two pins. One, intended for the logic and low-side drivers, with approximately a 4.2 V turn-on threshold is connected to the $\mathrm{V}_{\mathrm{CCL}}$ pin. A second, for the high side drivers, with approximately a 1.875 V threshold, is connected to the $\mathrm{V}_{\mathrm{CCH} 1}$ pin.

The UVLO threshold for the high side drivers varies with the part type. In many applications this function will be disabled or will only check that the applicable supply is on - not that is at a high enough voltage to run the converter. See individual datasheets for more information on UVLO.

## Soft Start Enable, and Hiccup Mode

A capacitor between the Soft Start pin and GND controls Soft Start and Hiccup mode slopes. A $0.1 \mu \mathrm{~F}$ capacitor with the $30 \mu \mathrm{~A}$ charge current will allow the output to ramp up at $0.3 \mathrm{~V} / \mathrm{ms}$ or 1.6 V in 5.3 ms at start-up.

When a fault is detected due to an overcurrent condition the converter will enter a low duty cycle hiccup mode. During hiccup mode the converter will not switch from the time a fault is detected until the Soft Start capacitor has
discharged below the Soft Start Discharge Threshold and then charged back up above the Channel Start Up Offset.

The Soft Start pin will disable the converter when pulled below the maximum Soft Start Discharge Threshold (nominally 0.27 V ).

## Power Good (PWRGD)

The open-collector Power Good (PWRGD) pin is driven by a "window-comparator" monitoring V CORE. This comparator will transition HIGH if $\mathrm{V}_{\text {CORE }}$ is within $\pm 12 \%$ of the nominal VID setting. After a $120 \mu \mathrm{~s}$ delay, the comparators output will saturate the open-collector output transistor and the PWRGD pin will be pulled LOW.

## Layout Guidelines

With the fast rise, high output currents of microprocessor applications, parasitic inductance and resistance should be considered when laying out the power, filter and feedback signal sections of the board. Typically, a multi-layer board with at least one ground plane is recommended. If the layout is such that high currents can exist in the ground plane underneath the controller or control circuitry, the ground plane can be slotted to route the currents away from the controller. The slots should typically not be placed between the controller and the output voltage or in the return path of the gate drive. Additional power and ground planes or islands can be added as required for a particular layout.

Gate drives experience high di/dt during switching and the inductance of gate drive traces should be minimized. Gate drive traces should be kept as short and wide as practical and should have a return path directly below the gate trace.

Output filter components should be placed on wide planes connected directly to the load to minimize resistive drops during heavy loads and inductive drops and ringing during transients. If required, the planes for the output voltage and return can be interleaved to minimize inductance between the filter and load.
The current sense signals are typically tens of milli-volts. Noise pick-up should be avoided wherever possible. Current feedback traces should be routed away from noisy areas such as the switch node and gate drive signals. If the current signals are taken from a location other than directly at the inductor any additional resistance between the pick-off point and the inductor appears as part of the inherent inductor resistances and should be considered in design calculations. The capacitors for the current feedback networks should be placed as close to the current sense pins as practical. After placing the NCP5322A control IC, follow these guidelines to optimize the layout and routing:

1. Place the $1 \mu \mathrm{~F}$ power supply bypass (ceramic) capacitors close to their associated pins: $\mathrm{V}_{\mathrm{CCL}}$, $\mathrm{V}_{\mathrm{CCH} 1}$ (and/or $\mathrm{V}_{\mathrm{CCH} 2}$ ), $\mathrm{V}_{\mathrm{CCL} 1}$ (and/or $\mathrm{V}_{\mathrm{CCL} 2}$ ).
2. Place the MOSFETs to minimize the length of the Gate traces. Orient the MOSFETs such that the Drain connections are away from the controller and the Gate connections are closest to the controller.
3. Place the components associated with the internal error amplifier ( $\mathrm{R}_{\mathrm{FBK} 1}, \mathrm{C}_{\mathrm{FBK} 2}, \mathrm{C}_{\mathrm{AMP}}, \mathrm{R}_{\mathrm{CMP} 1}$, $\mathrm{C}_{\mathrm{CMP} 1}, \mathrm{R}_{\mathrm{DRP} 1}$ ) to minimize the trace lengths to the pins $\mathrm{V}_{\mathrm{FB}}, \mathrm{V}_{\mathrm{DRP}}$ and COMP.
4. Place the current sense components $\left(\mathrm{R}_{\mathrm{CS} 1}, \mathrm{R}_{\mathrm{CS} 2}\right.$, $\mathrm{C}_{\mathrm{CS} 1}, \mathrm{C}_{\mathrm{CS} 2}, \mathrm{R}_{\mathrm{CSREF}}, \mathrm{C}_{\text {CSREF }}$ near the CS1, CS2, and $\mathrm{CS}_{\text {REF }}$ pins.
5. Place the frequency setting resistor ( $\mathrm{R}_{\mathrm{OSC}}$ ) close to the $\mathrm{R}_{\text {OSC }}$ pin. The $\mathrm{R}_{\text {OSC }}$ pin is very sensitive to noise. Route noisy traces, such as the SWNODEs and GATE traces, away from the $\mathrm{R}_{\text {OSC }}$ pin and resistor.
6. Place the Soft Start capacitor $\left(\mathrm{C}_{\mathrm{SS}}\right)$ near the Soft Start pin.
7. Place the MOSFETs and output inductors to reduce the size of the noisy SWNODEs. There is a tradeoff between reducing the size of the SWNODEs for noise reduction and providing adequate heat-sinking for the synchronous MOSFETs.
8. Place the input inductor and input capacitor(s) near the Drain of the control (upper) MOSFETs. There is a trade-off between reducing the size of this node to save board area and providing adequate heat-sinking for the control MOSFETs.
9. Place the output capacitors (electrolytic and ceramic) close to the processor socket or output connector.
10. The trace from the SWNODEs to the current sense components ( $\mathrm{R}_{\mathrm{CS} 1}, \mathrm{R}_{\mathrm{CS} 2}$ ) will be very noisy. Route this away from more sensitive, low-level traces. The Ground layer can be used to help isolate this trace.
11. The Gate traces are very noisy. Route these away from more sensitive, low-level traces. Keep each Gate signal on one layer and insure that there is an uninterrupted return path directly below the Gate trace. The Ground layer can be used to help isolate these traces.
12. Don't "daisy chain" connections to Ground from one via. Allow each connection to Ground to have its own via as close to the component as possible.
13. Use a slot in the ground plane from the bulk output capacitors back to the input power connector to prevent high currents from flowing beneath the control IC. This slot should extend length-wise under the control IC and separate the connections to "signal ground" and "power ground." Examples of signal ground include the capacitors at COMP, CS $_{\text {REF }}$, Soft-Start (SS), $\mathrm{V}_{\mathrm{CCL}}$, and REF, the resistors at $\mathrm{R}_{\mathrm{OSC}}$ and $\mathrm{I}_{\mathrm{LIM}}$, and the LGND pin to the controller. Examples of power ground include the capacitors to $\mathrm{V}_{\mathrm{CCH} 1}$ (and/or $\mathrm{V}_{\mathrm{CCH} 2}$ ) and $\mathrm{V}_{\mathrm{CCL} 1}$ (and/or $\mathrm{V}_{\mathrm{CCL} 2}$ ), the Source of the synchronous MOSFET, and the GND1 and GND2 pins of the controller.
14. The $\mathrm{CS}_{\text {REF }}$ sense point should be equidistant between the output inductors to equalize the PCB
resistance added to the current sense paths. This will insure acceptable current sharing. Also, route the $\mathrm{CS}_{\text {REF }}$ connection away from noisy traces such as the SWNODEs and GATE traces. If noise from the SWNODEs or GATE signals capacitively couples to the $\mathrm{CS}_{\text {REF }}$ trace the external ramps will be very noisy and voltage jitter will result.
15. Ideally, the SWNODEs are exactly the same shape and the current sense points (connections to $\mathrm{R}_{\mathrm{CS} 1}$ and $\mathrm{R}_{\mathrm{CS} 2}$ ) are made at identical locations to equalize the PCB resistance added to the current sense paths. This will help to insure acceptable current sharing.
16. Place the $0.1 \mu \mathrm{~F}$ ceramic capacitors, $\mathrm{C}_{\mathrm{Q} 1}$ and $\mathrm{C}_{\mathrm{Q} 2}$, close to the drains of the MOSFETs Q1 and Q2, respectively.

## Design Procedure

## 1. Output Capacitor Selection

The output capacitors filter the current from the output inductor and provide a low impedance for transient load current changes. Typically, microprocessor applications will require both bulk (electrolytic, tantalum) and low impedance, high frequency (ceramic) types of capacitors. The bulk capacitors provide "hold up" during transient loading. The low impedance capacitors reduce steady-state ripple and bypass the bulk capacitance when the output current changes very quickly. The microprocessor manufacturers usually specify a minimum number of ceramic capacitors. The designer must determine the number of bulk capacitors.

Choose the number of bulk output capacitors to meet the peak transient requirements. The formula below can be used to provide a starting point for the minimum number of bulk capacitors ( $\mathrm{N}_{\text {OUT,MIN }}$ ):

$$
\begin{equation*}
\text { NOUT,MIN }=\text { ESR per capacitor } \cdot \frac{\Delta \mathrm{I}_{\mathrm{O}, \mathrm{MAX}}}{\Delta \mathrm{~V}_{\mathrm{O}, \mathrm{MAX}}} \tag{1}
\end{equation*}
$$

In reality, both the ESR and ESL of the bulk capacitors determine the voltage change during a load transient according to:
$\Delta \mathrm{V}_{\mathrm{O}, \mathrm{MAX}}=\left(\Delta \mathrm{I}_{\mathrm{O}, \mathrm{MAX}} / \Delta \mathrm{t}\right) \cdot \mathrm{ESL}+\Delta \mathrm{I}_{\mathrm{O}, \mathrm{MAX}} \cdot \mathrm{ESR}$
Unfortunately, capacitor manufacturers do not specify the ESL of their components and the inductance added by the PCB traces is highly dependent on the layout and routing. Therefore, it is necessary to start a design with slightly more than the minimum number of bulk capacitors and perform transient testing or careful modeling/simulation to determine the final number of bulk capacitors.

## 2. Output Inductor Selection

The output inductor may be the most critical component in the converter because it will directly effect the choice of other components and dictate both the steady-state and
transient performance of the converter. When selecting an inductor the designer must consider factors such as DC current, peak current, output voltage ripple, core material, magnetic saturation, temperature, physical size, and cost (usually the primary concern).

In general, the output inductance value should be as low and physically small as possible to provide the best transient response and minimum cost. If a large inductance value is used, the converter will not respond quickly to rapid changes in the load current. On the other hand, too low an inductance value will result in very large ripple currents in the power components (MOSFETs, capacitors, etc) resulting in increased dissipation and lower converter efficiency. Also, increased ripple currents will force the designer to use higher rated MOSFETs, oversize the thermal solution, and use more, higher rated input and output capacitors - the converter cost will be adversely effected.

One method of calculating an output inductor value is to size the inductor to produce a specified maximum ripple current in the inductor. Lower ripple currents will result in less core and MOSFET losses and higher converter efficiency. Equation 3 may be used to calculate the minimum inductor value to produce a given maximum ripple current $(\alpha)$ per phase. The inductor value calculated by this equation is a minimum because values less than this will produce more ripple current than desired. Conversely, higher inductor values will result in less than the maximum ripple current.

$$
\begin{equation*}
\text { LOMIN }=\frac{\left(V_{\text {IN }}-V_{\text {OUT }}\right) \cdot V_{\text {OUT }}}{\left(\alpha \cdot I_{O, M A X ~} \cdot \mathrm{~V}_{\text {IN }} \cdot \mathrm{fS}^{2}\right)} \tag{3}
\end{equation*}
$$

$\alpha$ is the ripple current as a percentage of the maximum output current per phase ( $\alpha=0.15$ for $\pm 15 \%, \alpha=0.25$ for $\pm 25 \%$, etc). If the minimum inductor value is used, the inductor current will swing $\pm \alpha \%$ about its value at the center ( $1 / 2$ the DC output current for a two-phase converter). Therefore, for a two-phase converter, the inductor must be designed or selected such that it will not saturate with a peak current of $(1+\alpha) \bullet I_{O, M A X} / 2$.

The maximum inductor value is limited by the transient response of the converter. If the converter is to have a fast transient response then the inductor should be made as small as possible. If the inductor is too large its current will change too slowly, the output voltage will droop excessively, more bulk capacitors will be required, and the converter cost will be increased. For a given inductor value, its interesting to determine the times required to increase or decrease the current.

For increasing current:

$$
\begin{equation*}
\Delta \mathrm{t} \operatorname{INC}=\mathrm{Lo} \cdot \Delta \mathrm{I} \mathrm{O} /\left(\mathrm{V} \text { IN }-\mathrm{V}_{\mathrm{OUT}}\right) \tag{3.1}
\end{equation*}
$$

For decreasing current:

$$
\begin{equation*}
\Delta \mathrm{t} \mathrm{DEC}=\mathrm{Lo} \cdot \Delta \mathrm{I}_{\mathrm{O}} /\left(\mathrm{V}_{\mathrm{OUT}}\right) \tag{3.2}
\end{equation*}
$$

For typical processor applications with output voltages less than half the input voltage, the current will be increased much more quickly than it can be decreased. It may be more
difficult for the converter to stay within the regulation limits when the load is removed than when it is applied - excessive overshoot may result.

The output voltage ripple can be calculated using the output inductor value derived in this Section (Lomin), the number of output capacitors (NOUT,MIN) and the per capacitor ESR determined in the previous Section:

$$
\begin{align*}
& \text { VOUT,P-P }=(\text { ESR per cap } / \text { NOUT,MIN }) \cdot  \tag{4}\\
& \{(\text { VIN }- \text { \#Phases } \cdot \text { VOUT }) \cdot \mathrm{D} /(\text { LoMIN } \cdot \text { fSW })\}
\end{align*}
$$

This formula assumes steady-state conditions with no more than one phase on at any time. The second term in Equation 4 is the total ripple current seen by the output capacitors. The total output ripple current is the "time summation" of the two individual phase currents that are 180 degrees out-of-phase. As the inductor current in one phase ramps upward, current in the other phase ramps downward and provides a canceling of currents during part of the switching cycle. Therefore, the total output ripple current and voltage are reduced in a multi-phase converter.

## 3. Input Capacitor Selection

The choice and number of input capacitors is primarily determined by their voltage and ripple current ratings. The designer must choose capacitors that will support the worst case input voltage with adequate margin. To calculate the number of input capacitors one must first determine the total RMS input ripple current. To this end, begin by calculating the average input current to the converter:

$$
\begin{equation*}
I_{I N, A V G}=I O, M A X \cdot D / \eta \tag{5}
\end{equation*}
$$

where:
D is the duty cycle of the converter, $\mathrm{D}=\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{IN}}$. $\eta$ is the specified minimum efficiency.
$\mathrm{I}_{\mathrm{O}, \text { MAX }}$ is the maximum converter output current.
The input capacitors will discharge when the control FET is ON and charge when the control FET is OFF as shown in Figure 15.

Figure 15. Input Capacitor Current for a Two-Phase Converter

The following equations will determine the maximum and minimum currents delivered by the input capacitors:

$$
\begin{align*}
\mathrm{I}_{\mathrm{C}, \mathrm{MAX}} & =\mathrm{I}_{\mathrm{Lo}}, \mathrm{MAX} / \eta-\mathrm{I}_{\mathrm{IN}, \mathrm{AVG}}  \tag{6}\\
\mathrm{I}_{\mathrm{C}, \mathrm{MIN}} & =\mathrm{I}_{\mathrm{Lo}, \mathrm{MIN} / \eta}-\mathrm{I}_{\mathrm{IN}, \mathrm{AVG}} \tag{7}
\end{align*}
$$

$\mathrm{I}_{\text {Lo,MAX }}$ is the maximum output inductor current:

$$
\begin{equation*}
\mathrm{I} \mathrm{Lo}, \mathrm{MAX}=\mathrm{I}, \mathrm{MAX} / 2+\Delta \mathrm{I}_{\mathrm{Lo}} / 2 \tag{8}
\end{equation*}
$$

$\mathrm{I}_{\text {Lo,MIN }}$ is the minimum output inductor current:

$$
\begin{equation*}
\mathrm{ILO}, \mathrm{MIN}=\mathrm{I}, \mathrm{MAX} / 2-\Delta \mathrm{I} \mathrm{Lo} / 2 \tag{9}
\end{equation*}
$$

$\Delta \mathrm{I}_{\text {Lo }}$ is the peak-to-peak ripple current in the output inductor of value Lo:

$$
\begin{equation*}
\Delta_{\mathrm{Lo}}=\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right) \cdot \mathrm{D} /\left(\mathrm{Lo} \cdot \mathrm{f}_{\mathrm{SW}}\right) \tag{10}
\end{equation*}
$$

For the two-phase converter, the input capacitor(s) RMS current is then:

$$
\begin{align*}
\mathrm{ICIN}, \mathrm{RMS}= & {\left[2 \mathrm { D } \cdot \left(\mathrm{IC}, \mathrm{MIN}^{2}+\mathrm{I}_{\mathrm{C}, \mathrm{MIN} \cdot \Delta \mathrm{IC}, \mathrm{IN}}\right.\right.}  \tag{11}\\
& +\Delta \mathrm{I}_{\left.\left.\mathrm{C}, \mathrm{IN}^{2} / 3\right)+\mathrm{IIN}_{2}, \mathrm{AVG}^{2} \cdot(1-2 \mathrm{D})\right]^{1 / 2}}
\end{align*}
$$

Select the number of input capacitors ( $\mathrm{N}_{\text {IN }}$ ) to provide the RMS input current ( $\mathrm{I}_{\mathrm{CIN}, \mathrm{RMS}}$ ) based on the RMS ripple current rating per capacitor ( $\mathrm{I}_{\text {RMS,RATED }}$ ):
NIN = ICIN,RMS/IRMS,RATED

For a two-phase converter with perfect efficiency ( $\eta=1$ ), the worst case input ripple-current will occur when the converter is operating at a $25 \%$ duty cycle. At this operating point, the parallel combination of input capacitors must support an RMS ripple current equal to $25 \%$ of the converter's DC output current. At other duty cycles, the ripple-current will be less. For example, at a duty cycle of either $10 \%$ or $40 \%$, the two-phase input ripple-current will be approximately $20 \%$ of the converter's DC output current.

In general, capacitor manufacturers require derating to the specified ripple-current based on the ambient temperature. More capacitors will be required because of the current
derating. The designer should be cognizant of the ESR of the input capacitors. The input capacitor power loss can be calculated from:

$$
\begin{equation*}
\text { PCIN }=\text { ICIN,RMS }{ }^{2} \cdot \text { ESR_per_capacitor/NIN } \tag{13}
\end{equation*}
$$

Low ESR capacitors are recommended to minimize losses and reduce capacitor heating. The life of an electrolytic capacitor is reduced $50 \%$ for every $10^{\circ} \mathrm{C}$ rise in the capacitor's temperature.

## 4. Input Inductor Selection

The use of an inductor between the input capacitors and the power source will accomplish two objectives. First, it will isolate the voltage source and the system from the noise generated in the switching supply. Second, it will limit the inrush current into the input capacitors at power up. Large inrush currents will reduce the expected life of the input capacitors. The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients.
The worst case input current slew rate will occur during the first few PWM cycles immediately after a step-load change is applied as shown in Figure 16. When the load is applied, the output voltage is pulled down very quickly. Current through the output inductors will not change instantaneously so the initial transient load current must be conducted by the output capacitors. The output voltage will step downward depending on the magnitude of the output current ( $\mathrm{I}_{\mathrm{O}, \mathrm{MAX}}$ ), the per capacitor ESR of the output capacitors (ESR OUT ), and the number of the output capacitors ( $\mathrm{N}_{\text {OUT }}$ ) as shown in Figure 16. Assuming the load current is shared equally between the two phases, the output voltage at full, transient load will be:

$$
\begin{aligned}
& \text { VOUT,FULL-LOAD }= \\
& \text { VOUT,NO-LOAD - (IO,MAX/2) } \cdot \text { ESROUT/NOUT }
\end{aligned}
$$

Figure 16. Calculating the Input Inductance

When the control MOSFET (Q1 in Figure 16) turns ON, the input voltage will be applied to the opposite terminal of the output inductor (the SWNODE). At that instant, the voltage across the output inductor can be calculated as:

$$
\begin{align*}
\Delta V_{\text {Lo }}= & V_{I N}-V_{\text {OUT }, \text { FULL-LOAD }}  \tag{15}\\
= & V_{I N}-V_{O U T, N O-L O A D} \\
& +\left(I_{O, M A X / 2)}\right) \cdot \text { ESROUT/NOUT }
\end{align*}
$$

The differential voltage across the output inductor will cause its current to increase linearly with time. The slew rate of this current can be calculated from:

$$
\begin{equation*}
\mathrm{dl}_{\mathrm{Lo}} / \mathrm{dt}=\Delta \mathrm{V}_{\mathrm{Lo}} / \mathrm{Lo} \tag{16}
\end{equation*}
$$

Current changes slowly in the input inductor so the input capacitors must initially deliver the vast majority of the input current. The amount of voltage drop across the input capacitors $\left(\Delta \mathrm{V}_{\mathrm{Ci}}\right)$ is determined by the number of input capacitors $\left(\mathrm{N}_{\mathrm{IN}}\right)$, their per capacitor ESR $\left(\mathrm{ESR}_{\mathrm{IN}}\right)$, and the current in the output inductor according to:

$$
\begin{align*}
\Delta \mathrm{V}_{\mathrm{Ci}} & =\mathrm{ESR}_{\mathrm{IN}} / \mathrm{N}_{\mathrm{IN}} \cdot \mathrm{dl}_{\mathrm{Lo}} / \mathrm{dt} \cdot \mathrm{tON}  \tag{17}\\
& =\mathrm{ESR}_{\mathrm{IN}} / \mathrm{N}_{\mathrm{IN}} \cdot \mathrm{dl}_{\mathrm{Lo}} / \mathrm{dt}^{2} \cdot \mathrm{D} / \mathrm{f} \mathrm{SW}
\end{align*}
$$

Before the load is applied, the voltage across the input inductor $\left(\mathrm{V}_{\mathrm{Li}}\right)$ is very small - the input capacitors charge to the input voltage, $\mathrm{V}_{\mathrm{IN}}$. After the load is applied the voltage drop across the input capacitors, $\Delta \mathrm{V}_{\mathrm{Ci}}$, appears across the input inductor as well. Knowing this, the minimum value of the input inductor can be calculated from:

$$
\begin{align*}
& \text { Limin }=\mathrm{V}_{\mathrm{Li}} / \text { dIIN/dtMAX }  \tag{18}\\
& =\Delta \mathrm{V}_{\mathrm{Ci}} / \mathrm{dlin}_{\mathrm{I}} / \mathrm{dt}_{\mathrm{MAX}}
\end{align*}
$$

$\mathrm{dI}_{\mathrm{IN}} / \mathrm{dt}_{\text {MAX }}$ is the maximum allowable input current slew rate.

The input inductance value calculated from Equation 18 is relatively conservative. It assumes the supply voltage is very "stiff" and does not account for any parasitic elements that will limit dI/dt such as stray inductance. Also, the ESR values of the capacitors specified by the manufacturer's data sheets are worst case high limits. In reality input voltage "sag," lower capacitor ESRs, and stray inductance will help reduce the slew rate of the input current.

As with the output inductor, the input inductor must support the maximum current without saturating the magnetic. Also, for an inexpensive iron powder core, such as the -26 or -52 from Micrometals, the inductance "swing" with DC bias must be taken into account - inductance will decrease as the DC input current increases. At the maximum input current, the inductance must not decrease below the minimum value or the $\mathrm{dI} / \mathrm{dt}$ will be higher than expected.

## 5. MOSFET \& Heatsink Selection

Power dissipation, package size, and thermal solution drive MOSFET selection. To adequately size the heat sink, the design must first predict the MOSFET power dissipation.

Once the dissipation is known, the heat sink thermal impedance can be calculated to prevent the specified maximum case or junction temperatures from being exceeded at the highest ambient temperature. Power dissipation has two primary contributors: conduction losses and switching losses. The control or upper MOSFET will display both switching and conduction losses. The synchronous or lower MOSFET will exhibit only conduction losses because it switches into nearly zero voltage. However, the body diode in the synchronous MOSFET will suffer diode losses during the non-overlap time of the gate drivers.
For the upper or control MOSFET, the power dissipation can be approximated from:

$$
\begin{align*}
& \text { PD, } \mathrm{CONTROL}=\left(\mathrm{I}_{\mathrm{RMS}, \mathrm{CNTL}}{ }^{2} \cdot \mathrm{R}_{\mathrm{DS}}(\mathrm{on})\right)  \tag{19}\\
& \quad+\left(\mathrm{I}_{\mathrm{Lo}, \mathrm{MAX}} \cdot \mathrm{Q}_{\mathrm{Switch}} / \mathrm{I}_{\mathrm{g}} \cdot \mathrm{~V}_{\mathrm{IN}} \cdot \mathrm{fSW}\right) \\
& \quad+\left(\mathrm{Q}_{\mathrm{OSS}} / 2 \cdot \mathrm{~V}_{\mathrm{IN}} \cdot \mathrm{f}_{\mathrm{SW}}\right)+\left(\mathrm{V}_{\mathrm{IN}} \cdot \mathrm{Q}_{\mathrm{RR}} \cdot \mathrm{fSW}\right)
\end{align*}
$$

The first term represents the conduction or IR losses when the MOSFET is ON while the second term represents the switching losses. The third term is the losses associated with the control and synchronous MOSFET output charge when the control MOSFET turns ON. The output losses are caused by both the control and synchronous MOSFET but are dissipated only in the control FET. The fourth term is the loss due to the reverse recovery time of the body diode in the synchronous MOSFET. The first two terms are usually adequate to predict the majority of the losses.

Where $\mathrm{I}_{\mathrm{RMS}, \mathrm{CNTL}}$ is the RMS value of the trapezoidal current in the control MOSFET:

$$
\begin{align*}
& \left.\left.+ \text { Lo oMIN }^{2}\right) / 3\right]^{1 / 2} \tag{20}
\end{align*}
$$

$\mathrm{I}_{\text {Lo,MAX }}$ is the maximum output inductor current:

$$
\begin{equation*}
\mathrm{I}_{\mathrm{Lo}, \mathrm{MAX}}=\mathrm{I}_{\mathrm{O}, \mathrm{MAX}} / 2+\Delta \mathrm{I}_{\mathrm{Lo}} / 2 \tag{21}
\end{equation*}
$$

$\mathrm{I}_{\text {Lo,MIN }}$ is the minimum output inductor current:

$$
\begin{equation*}
\mathrm{I} \mathrm{Lo}, \mathrm{MIN}=\mathrm{IO}, \mathrm{MAX} / 2-\Delta \mathrm{I} \mathrm{Lo} / 2 \tag{22}
\end{equation*}
$$

$\mathrm{I}_{\mathrm{O}, \text { MAX }}$ is the maximum converter output current.
D is the duty cycle of the converter:

$$
\begin{equation*}
\mathrm{D}=\mathrm{V}_{\mathrm{OUT}} / \mathrm{V}_{\mathrm{IN}} \tag{23}
\end{equation*}
$$

$\Delta \mathrm{I}_{\mathrm{Lo}}$ is the peak-to-peak ripple current in the output inductor of value Lo:

$$
\begin{equation*}
\Delta \mathrm{I}_{\mathrm{Lo}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \cdot \mathrm{D} /(\mathrm{Lo} \cdot \mathrm{fSW}) \tag{24}
\end{equation*}
$$

$\mathrm{R}_{\mathrm{DS} \text { (on) }}$ is the ON resistance of the MOSFET at the applied gate drive voltage.
$\mathrm{Q}_{\text {switch }}$ is the post gate threshold portion of the gate-to-source charge plus the gate-to-drain charge. This may be specified in the data sheet or approximated from the gate-charge curve as shown in the Figure 17.

$$
\begin{equation*}
\mathrm{Q}_{\mathrm{switch}}=\mathrm{Q}_{\mathrm{gs} 2}+\mathrm{Q}_{\mathrm{gd}} \tag{25}
\end{equation*}
$$

Figure 17. MOSFET Switching Characteristics
$\mathrm{I}_{\mathrm{g}}$ is the output current from the gate driver IC.
$\mathrm{V}_{\text {IN }}$ is the input voltage to the converter.
$f_{\text {sw }}$ is the switching frequency of the converter.
$\mathrm{Q}_{\mathrm{G}}$ is the MOSFET total gate charge to obtain $\mathrm{R}_{\mathrm{DS}(\mathrm{on})}$.
Commonly specified in the data sheet.
$\mathrm{V}_{\mathrm{g}}$ is the gate drive voltage.
$\mathrm{Q}_{\mathrm{RR}}$ is the reverse recovery charge of the lower MOSFET.
$\mathrm{Q}_{\text {oss }}$ is the MOSFET output charge specified in the data sheet.
For the lower or synchronous MOSFET, the power dissipation can be approximated from:

$$
\begin{align*}
& \text { PD,SYNCH }=\left(\mathrm{IRMS}_{\mathrm{RM}, \mathrm{SYNCH}}{ }^{2} \cdot \mathrm{RDS}_{\mathrm{DS}(\text { on })}\right. \\
& \quad+\left(\mathrm{Vf}_{\text {diode }} \cdot \mathrm{I}_{\mathrm{O}, \mathrm{MAX} / 2 \cdot \mathrm{t} \text { nonoverlap } \cdot \mathrm{fSW})}\right. \tag{26}
\end{align*}
$$

The first term represents the conduction or IR losses when the MOSFET is ON and the second term represents the diode losses that occur during the gate non-overlap time.

All terms were defined in the previous discussion for the control MOSFET with the exception of:

$$
\begin{aligned}
& \text { IRMS, SYNCH }=[(1-\mathrm{D}) \\
& \cdot\left(\mathrm{ILo}_{\mathrm{Lo}}, \mathrm{MAX}\right.
\end{aligned}
$$

where:
$\mathrm{Vf}_{\text {diode }}$ is the forward voltage of the MOSFET's intrinsic diode at the converter output current.
t _nonoverlap is the non-overlap time between the upper and lower gate drivers to prevent cross conduction. This time is usually specified in the data sheet for the control IC.
When the MOSFET power dissipations are known, the designer can calculate the required thermal impedance to maintain a specified junction temperature at the worst case ambient operating temperature

$$
\begin{equation*}
\theta \mathrm{T}<(\mathrm{T} \mathrm{~J}-\mathrm{T} \mathrm{~A}) / \mathrm{PD} \tag{28}
\end{equation*}
$$

where;
$\theta_{\mathrm{T}}$ is the total thermal impedance $\left(\theta_{\mathrm{JC}}+\theta_{\mathrm{SA}}\right)$.
$\theta_{\mathrm{JC}}$ is the junction-to-case thermal impedance of the MOSFET.
$\theta_{\mathrm{SA}}$ is the sink-to-ambient thermal impedance of the heatsink assuming direct mounting of the MOSFET (no thermal "pad" is used).
$\mathrm{T}_{\mathrm{J}}$ is the specified maximum allowed junction temperature.
$\mathrm{T}_{\mathrm{A}}$ is the worst case ambient operating temperature.
For TO-220 and TO-263 packages, standard FR-4 copper clad circuit boards will have approximate thermal resistances $\left(\theta_{\mathrm{SA}}\right)$ as shown below:

| Pad Size <br> (in $^{2} / \mathrm{mm}^{2}$ ) | Single-Sided <br> $\mathbf{1 ~ o z . ~ C o p p e r ~}$ |
| :---: | :---: |
| $0.5 / 323$ | $60-65^{\circ} \mathrm{C} / \mathrm{W}$ |
| $0.75 / 484$ | $55-60^{\circ} \mathrm{C} / \mathrm{W}$ |
| $1.0 / 645$ | $50-55^{\circ} \mathrm{C} / \mathrm{W}$ |
| $1.5 / 968$ | $45-50^{\circ} \mathrm{C} / \mathrm{W}$ |
| $2.0 / 1290$ | $38-42^{\circ} \mathrm{C} / \mathrm{W}$ |
| $2.5 / 1612$ | $33-37^{\circ} \mathrm{C} / \mathrm{W}$ |

As with any power design, proper laboratory testing should be performed to insure the design will dissipate the required power under worst case operating conditions. Variables considered during testing should include maximum ambient temperature, minimum airflow, maximum input voltage, maximum loading, and component variations (i.e. worst case MOSFET $\mathrm{R}_{\mathrm{DS}(\mathrm{on})}$ ). Also, the inductors and capacitors share the MOSFET's heatsinks and will add heat and raise the temperature of the circuit board and MOSFET. For any new design, its advisable to have as much heatsink area as possible - all too often new designs are found to be too hot and require re-design to add heatsinking.

## 6. Adaptive Voltage Positioning

There are two resistors that determine the Adaptive Voltage Positioning: $\mathrm{R}_{\mathrm{FBK} 1}$ and $\mathrm{R}_{\mathrm{DRP}} . \mathrm{R}_{\mathrm{FBK} 1}$ establishes the no-load "high" voltage position and $\mathrm{R}_{\mathrm{DRP}}$ determines the full-load "droop" voltage.

Resistor $\mathrm{R}_{\mathrm{FBK} 1}$ is connected between $\mathrm{V}_{\mathrm{CORE}}$ and the $\mathrm{V}_{\mathrm{FB}}$ pin of the controller. At no load, this resistor will conduct the internal bias current of the $\mathrm{V}_{\mathrm{FB}}$ pin and develop a voltage drop from $V_{\text {CORE }}$ to the $V_{\text {FB }}$ pin. Because the error amplifier regulates $\mathrm{V}_{\mathrm{FB}}$ to the DAC setting, the output voltage, $\mathrm{V}_{\mathrm{CORE}}$, will be higher by the amount IBIAS $\mathrm{VFB}^{\bullet} \mathrm{R}_{\mathrm{FBK} 1}$. This condition is shown in Figure 18.

To calculate $\mathrm{R}_{\text {FBK1 }}$ the designer must specify the no-load voltage increase above the VID setting ( $\Delta \mathrm{V}_{\text {NO-LOAD }}$ ) and determine the $\mathrm{V}_{\mathrm{FB}}$ bias current. Usually, the no-load voltage increase is specified in the design guide for the processor that is available from the manufacturer. The $\mathrm{V}_{\mathrm{FB}}$ bias current is determined by the value of the resistor from $\mathrm{R}_{\text {OSC }}$ to ground (see Figure 5 in the data sheet for a graph of IBIAS $_{\text {VFB }}$ versus $\mathrm{R}_{\mathrm{OSC}}$ ). The value of $\mathrm{R}_{\mathrm{FBK} 1}$ can then be calculated:

Figure 18. AVP Circuitry at No-Load

$$
\begin{equation*}
\mathrm{R}_{\mathrm{FBK} 1}=\Delta \mathrm{V}_{\text {NO-LOAD }} / \mathrm{IBIASVFB} \tag{29}
\end{equation*}
$$

Resistor $\mathrm{R}_{\mathrm{DRP}}$ is connected between the $\mathrm{V}_{\mathrm{DRP}}$ and the $\mathrm{V}_{\mathrm{FB}}$ pins. At no-load, the $\mathrm{V}_{\mathrm{DRP}}$ and the $\mathrm{V}_{\mathrm{FB}}$ pins will both be at the DAC voltage so this resistor will conduct zero current. However, at full-load, the voltage at the $\mathrm{V}_{\text {DRP }}$ pin will increase proportional to the output inductor's current while $\mathrm{V}_{\mathrm{FB}}$ will still be regulated to the DAC voltage. Current will be conducted from $V_{D R P}$ to $V_{F B}$ by $R_{D R P}$. This current will be large enough to supply the $\mathrm{V}_{\mathrm{FB}}$ bias current and cause a voltage drop from $\mathrm{V}_{\mathrm{FB}}$ to Vcore across $\mathrm{R}_{\mathrm{FBK}}$ - the converter's output voltage will be reduced. This condition is shown in Figure 19.

To determine the value of $\mathrm{R}_{\mathrm{DRP}}$ the designer must specify the full-load voltage reduction from the VID (DAC) setting ( $\Delta \mathrm{V}_{\text {OUT,FULL-LOAD }}$ ) and predict the voltage increase at the $\mathrm{V}_{\text {DRP }}$ pin at full-load. Usually, the full-load voltage reduction is specified in the design guide for the processor that is available from the manufacturer. To predict the voltage increase at the $\mathrm{V}_{\text {DRP }}$ pin at full-load ( $\Delta \mathrm{V}_{\text {DRP }}$ ), the designer must consider the output inductor's resistance
$\left(R_{L}\right)$, the PCB trace resistance between the current sense points ( $\mathrm{R}_{\mathrm{PCB}}$ ), and the controller IC's gain from the current sense to the $\mathrm{V}_{\text {DRP }}$ pin $\left(\mathrm{G}_{\mathrm{VDRP}}\right)$ :

$$
\begin{equation*}
\Delta V_{D R P}=I_{O, M A X} \cdot\left(R_{L}+R_{P C B}\right) \cdot G V D R P \tag{30}
\end{equation*}
$$

The value of $\mathrm{R}_{\mathrm{DRP}}$ can then be calculated:
$\operatorname{RDRP}=\frac{\Delta V_{\text {DRP }}}{\left(\text { IBIASVFB }+\Delta \mathrm{V}_{\text {OUT }}, \text { FULL-LOAD } / R_{F B K 1}\right)}$
$\Delta \mathrm{V}_{\text {OUT,FULL-LOAD }}$ is the full-load voltage reduction from the VID (DAC) setting. $\Delta \mathrm{V}_{\text {OUT,FULL-LOAD }}$ is not the voltage change from the no-load AVP setting.

## 7. Current Sensing

For inductive current sensing, choose the current sense network ( $\mathrm{R}_{\mathrm{CSn}}, \mathrm{C}_{\mathrm{CSn}}, \mathrm{n}=1$ or 2 ) to satisfy

$$
\begin{equation*}
\mathrm{R}_{\mathrm{CSn}} \cdot \mathrm{CCSn}=\mathrm{Lo} /\left(\mathrm{R}_{\mathrm{L}}+\mathrm{RPCB}\right) \tag{32}
\end{equation*}
$$

Figure 19. AVP Circuitry at Full-Load

Figure 20. V Constant of the Current Sense Network Is Too Long (Slow): $\mathrm{V}_{\text {DRP }}$ and $\mathrm{V}_{\text {OUT }}$ Respond Too Slowly.

Figure 21. V Constant of the Current Sense Network Is Too Short (Fast): $\mathrm{V}_{\text {DRP }}$ and $\mathrm{V}_{\text {OUT }}$ Both Overshoot.

Figure 22. V ${ }_{\text {DRP }}$ Tuning Waveforms. The RC Time Constant of the Current Sense Network Is Optimal: $\mathrm{V}_{\text {DRP }}$ and $\mathrm{V}_{\text {OUT }}$ Respond to the Load Current Quickly Without Overshooting.

For resistive current sensing, choose the current sense network ( $\mathrm{R}_{\mathrm{CSn}}, \mathrm{C}_{\mathrm{CSn}}, \mathrm{n}=1$ or 2 ) to satisfy

$$
\begin{equation*}
\mathrm{R}_{\mathrm{CSn}} \cdot \mathrm{C}_{\mathrm{CSn}}=\mathrm{Lo} /\left(\mathrm{R}_{\text {sense }}\right) \tag{33}
\end{equation*}
$$

This will provide an adequate starting point for $\mathrm{R}_{\mathrm{CSn}}$ and $\mathrm{C}_{\mathrm{CSn}}$. After the converter is constructed, the value of $\mathrm{R}_{\mathrm{CSn}}$ (and/or $\mathrm{C}_{\mathrm{CSn}}$ ) should be fine-tuned in the lab by observing the $\mathrm{V}_{\text {DRP }}$ signal during a step change in load current. The $\mathrm{R}_{\mathrm{CSn}}-\mathrm{C}_{\mathrm{CSn}}$ network should be tuned to provide a "square-wave" at the $V_{\text {DRP }}$ output pin with maximum rise time and minimal overshoot as shown in Figure 22.

Equation 32 will be most accurate for better iron powder core material (such as the -8 from Micrometals). This material is very consistent with DC current and frequency. Less expensive core materials (such as the -52 from Micrometals) change their characteristics with DC current, AC flux density, and frequency. This material will yield acceptable converter performance if the current sense time constant is set lower (longer) than anticipated. As a rule of thumb, use approximately twice the resistance $\left(\mathrm{R}_{\mathrm{CSn}}\right)$ or twice the capacitance $\left(\mathrm{C}_{\mathrm{CSn}}\right)$ when using the less expensive core material.

## 8. Error Amplifier Tuning

After the steady-state (static) AVP has been set and the current sense network has been optimized the Error Amplifier must be tuned. Basically, the gain of the Error Amplifier should be adjusted to provide an acceptable transient response by increasing or decreasing the Error Amplifier's feedback capacitor ( $\mathrm{C}_{\text {AMP }}$ in the Applications Diagram). The bandwidth of the control loop will vary directly with the gain of the error amplifier.

Figure 23. The Value of $\mathrm{C}_{\text {AMP }}$ Is Too High and the Loop Gain/Bandwidth Too Low. COMP Slews Too Slowly Which Results in Overshoot in $\mathrm{V}_{\text {OUT }}$.

If $\mathrm{C}_{\text {AMP }}$ is too large the loop gain/bandwidth will be low, the COMP pin will slew too slowly, and the output voltage will overshoot as shown in Figure 23. On the other hand, if $\mathrm{C}_{\mathrm{AMP}}$ is too small the loop gain/bandwidth will be high, the COMP pin will slew very quickly and overshoot. Integrator
"wind up" is the cause of the overshoot. In this case the output voltage will transition more slowly because COMP spikes upward as shown in Figure 24. Too much loop gain/bandwidth increase the risk of instability. In general, one should use the lowest loop gain/bandwidth as possible to achieve acceptable transient response - this will insure good stability. If $\mathrm{C}_{\mathrm{AMP}}$ is optimal the COMP pin will slew quickly but not overshoot and the output voltage will monotonically settle as shown in Figure 25.

After the control loop is tuned to provide an acceptable transient response the steady-state voltage ripple on the COMP pin should be examined. When the converter is operating at full, steady-state load, the peak-to-peak voltage ripple on the COMP pin should be less than $20 \mathrm{mV}_{\mathrm{PP}}$ as shown in Figure 26. Less than $10 \mathrm{mV}_{\mathrm{PP}}$ is ideal. Excessive ripple on the COMP pin will contribute to output voltage jitter.

Figure 24. The Value of $\mathrm{C}_{\mathrm{AMP}}$ Is Too Low and the Loop Gain/Bandwidth Too High. COMP Moves Too Quickly, Which Is Evident from the Small Spike in Its Voltage When the Load Is Applied or Removed. The Output Voltage Transitions More Slowly Because of the COMP Spike.

Figure 25. The Value of $\mathrm{C}_{\text {AMP }}$ Is Optimal. COMP Slews Quickly Without Spiking or Ringing. $\mathrm{V}_{\text {OUT }}$ Does Not Overshoot and Monotonically Settles to Its Final Value.

Figure 26. At Full-Load (28 A) the Peak-to-Peak Voltage Ripple on the COMP Pin Should Be Less than 20 mV for a Well-Tuned/Stable Controller. Higher COMP Voltage Ripple Will Contribute to Output Voltage Jitter.

## 9. Current Limit Setting

When the output of the current sense amplifier (CO1 or CO 2 in the block diagram) exceeds the voltage on the $\mathrm{I}_{\mathrm{LIM}}$ pin the part will enter hiccup mode. For inductive sensing, the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the inductor's maximum resistance ( $\mathrm{R}_{\text {LMAX }}$ ). The design must consider the inductor's resistance increase due to current heating and ambient temperature rise. Also, depending on the current sense points, the circuit board may add additional resistance. In general, the temperature coefficient of copper is $+0.393 \%$ per ${ }^{\circ} \mathrm{C}$. If using a current sense resistor ( $\mathrm{R}_{\text {SENSE }}$ ), the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the maximum value of the sense resistor. To set the level of the $\mathrm{I}_{\text {LIM }}$ pin:

$$
\begin{equation*}
\text { VILIM }=(\mathrm{IOUT}, \mathrm{LIM}+\Delta \mathrm{I} \mathrm{Lo} / 2) \cdot \mathrm{R} \cdot \mathrm{GILIM} \tag{34}
\end{equation*}
$$

where:
IOUT,LIM is the current limit threshold of the converter;
$\Delta \mathrm{I}_{\mathrm{Lo}} / 2$ is half the inductor ripple current;
R is either ( $\mathrm{R}_{\mathrm{LMAX}}+\mathrm{R}_{\mathrm{PCB}}$ ) or $\mathrm{R}_{\text {SENSE }}$;
$\mathrm{G}_{\text {ILIM }}$ is the current sense to $\mathrm{I}_{\text {LIM }}$ gain.
For the overcurrent protection to work properly, the current sense time constant (RC) should be slightly larger than the RL time constant. If the RC time constant is too fast, during step load changes the sensed current waveform will appear larger than the actual inductor current and will probably trip the current limit at a lower level than expected.

## 10. PWM Comparator Input Voltage

The voltage at the positive input terminal of the PWM comparator (see Figure 10 or 12) is limited by the internal voltage supply of the controller ( 3.3 V ), the size of the internal ramp, and the magnitude of the channel startup offset voltage. To prevent the PWM comparator from saturating, the differential input voltage from $\mathrm{CS}_{\text {REF }}$ to CSn ( $\mathrm{n}=1$ or 2 ) must satisfy the following equation:
$V_{C S R E F}, \mathrm{MAX}+\mathrm{V}_{\text {COn }}, \mathrm{MAX}+310 \mathrm{mV} \cdot \mathrm{D} \leq 2.45 \mathrm{~V}$
where:
VCSREF,MAX = Max VID Setting w/ AVP @ Full Load
$\mathrm{V}_{\text {COn, MAX }}=\left[\mathrm{V}_{\text {CSn }}-\mathrm{V}_{\text {CSREF }}\right] \cdot \mathrm{GCSA}, \mathrm{MAX}$
$=\left(\mathrm{IO}, \mathrm{MAX} / 2+\mathrm{I}_{\mathrm{Lo}} / 2\right) \cdot \mathrm{R}_{\text {MAX }}$

- GCSA,MAX
$R_{\text {MAX }}=R_{\text {SENSE }}$ or ( $\mathrm{R}_{\mathrm{L}, \mathrm{MAX}}+\mathrm{RPCB}, \mathrm{MAX}$ )

## 11. Soft Start Time

If the Soft Start time is defined from the instant the Soft Start pin is released (i.e. the converter is enabled) to when the output reaches the VID setting with AVP then the Soft Start time ( $\mathrm{t}_{\mathrm{SS}}$ ) can be calculated from:

$$
\begin{equation*}
\text { TSS }=\text { VCOMP } \cdot \mathrm{CSS} / \mathrm{ISS} \tag{36}
\end{equation*}
$$

where:

$$
\begin{aligned}
\text { V COMP }^{=} & \text {VOUT @ } 0 \text { A + Channel_Startup_Offset } \\
& + \text { Int_Ramp }+ \text { GCSA } \cdot \text { Ext_Ramp } / 2
\end{aligned}
$$

$\mathrm{C}_{\mathrm{SS}}$ is the capacitor from the Soft-Start pin to LGND;
Ext_Ramp = D • $\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) /\left(\mathrm{R}_{\mathrm{CSn}} \bullet \mathrm{C}_{\mathrm{CSn}} \bullet \mathrm{f}_{\mathrm{SW}}\right)$;
$\mathrm{I}_{\mathrm{SS}}$ is the Soft-Start charge current from the data sheet.

## Design Example

## Typical Design Requirements:

$\mathrm{V}_{\mathrm{IN}}=12.0 \mathrm{Vdc}$
$\mathrm{V}_{\text {OUT }}=1.60 \mathrm{Vdc}$ (nominal)
$\mathrm{V}_{\text {OUT,RIPPLE }}<10 \mathrm{mV}_{\text {PP }} \max$
VID Range: 1.100 Vdc -1.850 Vdc
$\mathrm{I}_{\mathrm{O}, \mathrm{MAX}}=45 \mathrm{~A}$ at full-load
$\mathrm{I}_{\text {OUT,LIM }}=52 \mathrm{~A} \mathrm{~min}$ at $55^{\circ} \mathrm{C}$ (shutdown threshold)
$\mathrm{dI}_{\mathrm{IN}} / \mathrm{dt}=0.50 \mathrm{~A} / \mu \mathrm{s} \max$
$\mathrm{f}_{\mathrm{SW}}=220 \mathrm{kHz}$
$\eta=81 \%$ min at full-load
$\mathrm{T}_{\mathrm{A}, \mathrm{MAX}}=60^{\circ} \mathrm{C}$
$\mathrm{T}_{\mathrm{J}, \mathrm{MAX}}=125^{\circ} \mathrm{C}$
$\mathrm{t}_{\mathrm{SS}}<10.0 \mathrm{~ms}$ (Soft Start time)
$\Delta \mathrm{V}_{\text {OUT }}$ at no-load (static) $=$
+30 mV from VID setting $=1.630 \mathrm{Vdc}$
$\Delta \mathrm{V}_{\text {OUT }}$ at full-load (static) $=$
-35 mV from VID setting $=1.565 \mathrm{Vdc}$
$\Delta \mathrm{V}_{\text {OUT }}$ at full-load (transient) $=$
-65 mV from VID setting $=1.540 \mathrm{Vdc}$

## 1. Output Capacitor Selection

First, choose a low-cost, low-ESR output capacitor such as the Rubycon 16MBZ1500M10X20: $16 \mathrm{~V}, 1500 \mu \mathrm{~F}$, 2.55 A $_{\text {RMS }}, 13 \mathrm{~m} \Omega, 10 \times 20 \mathrm{~mm}$. Calculate the minimum number of output capacitors:

$$
\begin{align*}
\text { NOUT,MIN } & =\text { ESR per capacitor } \cdot \frac{\Delta \mathrm{I}_{\mathrm{O}, \mathrm{MAX}}}{\Delta \mathrm{~V}_{\mathrm{O}, \mathrm{MAX}}}  \tag{1}\\
& =13 \mathrm{~m} \Omega \cdot 45 \mathrm{~A} /(1.630 \mathrm{~V}-1.540 \mathrm{~V}) \\
& =6.5 \text { or } 7 \text { capacitors minimum }(10,500 \mu \mathrm{~F})
\end{align*}
$$

## 2. Output Inductor Selection

Calculate the minimum output inductance at $I_{O, M A X}$ according to Equation 4 with $\pm 20 \%$ inductor ripple current ( $\alpha=0.20$ ):

$$
\begin{align*}
\text { LoMIN } & =\frac{\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\mathrm{OUT}}\right) \cdot \mathrm{V}_{\text {OUT }}}{\left(\alpha \cdot \mathrm{I}_{\left.\mathrm{O}, \mathrm{MAX} \cdot \mathrm{VIN}^{2} \cdot \mathrm{fSW}\right)}\right.}  \tag{3}\\
& =\frac{(12 \mathrm{~V}-1.565 \mathrm{~V}) \cdot 1.565 \mathrm{~V}}{(0.2 \cdot 45 \mathrm{~A} \cdot 12 \mathrm{~V} \cdot 220 \mathrm{kHz})} \\
& =687 \mathrm{nH}
\end{align*}
$$

To save cost, we choose the inexpensive T50-52B core from Micrometals: $43.5 \mathrm{nH} / \mathrm{N}^{2}, 3.19 \mathrm{~cm} /$ turn. According to the Micrometals catalog, at 22.5 A (per phase) the permeability of this core will be approximately $70 \%$ of the permeability at 0 A . Therefore, at 0 A we must achieve at least $687 \mathrm{nH} / 0.7$ or 981 nH . Using five turns of \#16AWG bifilar ( $2 \mathrm{~m} \Omega / \mathrm{ft}$ ) will produce $1.1 \mu \mathrm{H}$.

Use Equation 4 to insure the output voltage ripple will satisfy the design goal with the minimum number of capacitors and the nominal output inductance:

```
VOUT,P-P \(=(\) ESR per cap \(/\) NOUT,MIN) \(\cdot\)
    \(\left\{\left(\mathrm{V}_{\text {IN }}-\right.\right.\) \#Phases \(\left.\cdot \mathrm{V}_{\text {OUT }}\right) \cdot \mathrm{D} /(\) LoMIN \(\cdot \mathrm{f}\) SW \(\left.)\right\}\)
\(=(13 \mathrm{~m} \Omega / 7)\).
    \(\{(5.0 \mathrm{~V}-2 \cdot 1.6 \mathrm{~V}) \cdot(1.6 \mathrm{~V} / 5.0 \mathrm{~V}) /(1.1 \mu \mathrm{H} \cdot 220 \mathrm{kHz})\}\)
\(=(1.86 \mathrm{~m} \Omega) \cdot\{2.38 \mathrm{~A}\}\)
\(=4.43 \mathrm{mV}\)
```

The output voltage ripple will be decreased when output capacitors are added to satisfy transient loading requirements.

We will need the nominal and worst case inductor resistances for subsequent calculations:

$$
\begin{aligned}
R_{\mathrm{L}} & =5 \text { turns } \cdot 3.19 \mathrm{~cm} / \text { turn } \cdot 0.03218 \mathrm{ft} / \mathrm{cm} \cdot 2 \mathrm{~m} \Omega / \mathrm{ft} \\
& =1.03 \mathrm{~m} \Omega
\end{aligned}
$$

The inductor resistance will be maximized when the inductor is "hot" due to the load current and the ambient temperature is high. Assuming a $40^{\circ} \mathrm{C}$ temperature rise of the inductor at full-load and a $35^{\circ} \mathrm{C}$ ambient temperature rise we can calculate:

$$
\begin{aligned}
\mathrm{RL}, \mathrm{MAX} & =1.03 \mathrm{~m} \Omega \cdot\left[1+0.39 \% /{ }^{\circ} \mathrm{C} \cdot\left(40^{\circ} \mathrm{C}+35^{\circ} \mathrm{C}\right)\right] \\
& =1.33 \mathrm{~m} \Omega
\end{aligned}
$$

The output inductance at full-load will be:

$$
\mathrm{Lo}=0.70 \times 1.1 \mu \mathrm{H}=770 \mathrm{nH}
$$

## 3. Input Capacitor Selection

Use Equation 5 to determine the average input current to the converter at full-load;

$$
\begin{align*}
\mathrm{I}_{\mathrm{I}, \mathrm{AVG}} & =\mathrm{I}, \mathrm{MAX} \cdot \mathrm{D} / \eta  \tag{5}\\
& =45 \mathrm{~A} \cdot(1.565 \mathrm{~V} / 12 \mathrm{~V}) / 0.81=5.87 \mathrm{~A}
\end{align*}
$$

Next, use Equations 6 to 10 with the full-load inductance value of 770 nH :

$$
\begin{align*}
& \Delta \mathrm{I}_{\mathrm{Lo}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \cdot \mathrm{D} /(\mathrm{Lo} \cdot \mathrm{fSW}) \\
& =(12 \mathrm{~V}-1.565 \mathrm{~V}) \cdot \frac{(1.565 \mathrm{~V} / 12 \mathrm{~V})}{(770 \mathrm{nH} \cdot 220 \mathrm{kHz})}  \tag{10}\\
& =8.03 \mathrm{App} \\
& \mathrm{I}_{\mathrm{Lo}}, \mathrm{MAX}=\mathrm{I}_{\mathrm{O}, \mathrm{MAX}} / 2+\Delta \mathrm{I}_{\mathrm{Lo}} / 2  \tag{8}\\
& =45 \mathrm{~A} / 2+8.03 \mathrm{App} / 2=26.5 \mathrm{~A} \\
& \mathrm{I}_{\mathrm{Lo}}, \mathrm{MIN}=\mathrm{I} \mathrm{O}, \mathrm{MAX} / 2-\Delta \mathrm{I} \mathrm{Lo} / 2 \\
& =45 \mathrm{~A} / 2-8.03 \mathrm{App} / 2=18.5 \mathrm{~A}  \tag{9}\\
& \mathrm{I}_{\mathrm{C}}, \mathrm{MAX}=\mathrm{I}_{\mathrm{Lo}}, \mathrm{MAX} / \eta-\mathrm{I}_{\mathrm{IN}, \mathrm{AVG}}  \tag{6}\\
& =26.5 \mathrm{~A} / 0.81-5.87 \mathrm{~A}=20.63 \mathrm{~A} \\
& \mathrm{I}_{\mathrm{C}} \mathrm{MIN}=\mathrm{I} \mathrm{Lo}, \mathrm{MIN} / \eta-\mathrm{IIN}, \mathrm{AVG}  \tag{7}\\
& =18.5 \mathrm{~A} / 0.81-5.87 \mathrm{~A}=12.63 \mathrm{~A}
\end{align*}
$$

For the two-phase converter, the input capacitor(s) RMS current at full-load is then (Note: $\mathrm{D}=1.565 \mathrm{~V} / 12 \mathrm{~V}=0.13$ ):

$$
\begin{align*}
\mathrm{I} \mathrm{CIN}, R \mathrm{RMS}= & {\left[2 \mathrm { D } \cdot \left(\mathrm{IC}, \mathrm{MIN}^{2}+\mathrm{I}_{\mathrm{C}, \mathrm{MIN} \cdot \Delta \mathrm{I}_{\mathrm{C}}, \mathrm{IN}}\right.\right.}  \tag{11}\\
& +\Delta \mathrm{I}_{\left.\mathrm{C}, \mathrm{IN}^{2} / 3\right)+\mathrm{I}_{\left.\mathrm{IN}, \mathrm{AVG}^{2} \cdot(1-2 \mathrm{D})\right]^{1 / 2}}}=\left[0.26 \cdot\left(12.63^{2}+12.63 \cdot 8.00+8.00^{2} / 3\right)\right. \\
& \left.+5.87^{2} \cdot(1-0.26)\right]^{1 / 2} \\
= & 9.69 \text { ARMS }
\end{align*}
$$

At this point, the designer must decide between saving board space by using higher-rated/more costly capacitors or saving cost by using more lower-rated/less costly capacitors. To save board space, we choose the SP (Oscon) series capacitors by Sanyo. Part number 16SP270: $270 \mu \mathrm{~F}$, $16 \mathrm{~V}, 4.4 \mathrm{~A}_{\mathrm{RMS}}, 18 \mathrm{~m} \Omega, 10 \times 10.5 \mathrm{~mm}$. This design will require $9.69 \mathrm{~A} / 4.4 \mathrm{~A}=2.2$ or $\mathrm{N}_{\mathrm{IN}}=3$ capacitors on the input for a conservative design.

## 4. Input Inductor Selection

The input inductor must limit the input current slew rate to less than $0.5 \mathrm{~A} / \mu \mathrm{s}$ during a load transient from 0 to 45 A . A conservative value will be calculated assuming the minimum number of output capacitors ( $\mathrm{N}_{\text {OUT }}=7$ ), three input capacitors ( $\mathrm{N}_{\mathrm{IN}}=3$ ), worst case ESR values for both the input and output capacitors, and a maximum duty cycle $\left(\mathrm{D}=\left(1.850 \mathrm{~V}+30 \mathrm{mV}_{\mathrm{AVP}}\right) / 12.0 \mathrm{~V}_{\mathrm{IN}}=0.157\right)$.

Figure 27. Actual DC/DC Converter Circuitry With the Calculated Input Inductor and Minimum Filtering Components. The Measured Slew-Rate ( $\mathrm{dl}_{\mathrm{IN}} / \mathrm{dt}$ ) of the Input Current ( $0.064 \mathrm{~A} / \mu \mathrm{s}$ ) Is Much Lower Than Expected ( $0.1 \mathrm{~A} / \mu \mathrm{s}$ ) Because of Input Voltage Drop, Parasitic Inductance, and Lower Real ESRs Than Specified in the Capacitors' Data Sheets.

First, use Equation 15 to calculate the voltage across the output inductor due to the 45 A load current being shared equally between the two phases:

$$
\begin{align*}
\Delta \mathrm{V}_{\mathrm{Lo}}= & \mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}, \mathrm{NO}-\mathrm{LOAD}}  \tag{15}\\
& +(\mathrm{IO}, \mathrm{MAX} / 2) \cdot \mathrm{ESR} \mathrm{OUT} / \mathrm{NOUT} \\
= & 12 \mathrm{~V}-1.85 \mathrm{~V}+45 \mathrm{~A} / 2 \cdot 13 \mathrm{~m} \Omega / 7 \\
= & 10.19 \mathrm{~V}
\end{align*}
$$

Second, use Equation 16 to determine the rate of current increase in the output inductor when the load is first applied (i.e. Lo has not changed much due to the DC current):

$$
\begin{align*}
\mathrm{dl}_{\mathrm{Lo}} / \mathrm{dt} & =\Delta \mathrm{V}_{\mathrm{Lo}} / \mathrm{Lo}  \tag{16}\\
& =10.19 \mathrm{~V} / 1.1 \mu \mathrm{H}=9.26 \mathrm{~V} / \mu \mathrm{s}
\end{align*}
$$

Finally, use Equations 17 and 18 to calculate the minimum input inductance value:

$$
\begin{align*}
\Delta \mathrm{V}_{\mathrm{Ci}} & =\mathrm{ESRIN} / \mathrm{N}_{\mathrm{IN}} \cdot \mathrm{dl}_{\mathrm{Lo}} / \mathrm{dt} \cdot \mathrm{D} / \mathrm{fSW}  \tag{17}\\
& =18 \mathrm{~m} \Omega / 3 \cdot 9.26 \mathrm{~V} / \mu \mathrm{s} \cdot 0.157 / 220 \mathrm{kHz} \\
& =39.7 \mathrm{mV} \\
\mathrm{LiMIN} & =\Delta \mathrm{V}_{\mathrm{Ci}} / \mathrm{dl}_{\mathrm{IN}} / \mathrm{dtMAX}_{\mathrm{MA}}  \tag{18}\\
& =39.7 \mathrm{mV} / 0.50 \mathrm{~A} / \mu \mathrm{s}=80 \mathrm{nH}
\end{align*}
$$

Next, choose the small, cost effective T30-26 core from Micrometals ( $33.5 \mathrm{nH} / \mathrm{N}^{2}$ ) with \#16 AWG. The design requires only 1.54 turns to achieve the minimum inductance value. Allow for inductance "swing" at full-load by using three turns. The input inductor's value will be:

$$
\mathrm{L}_{\mathrm{i}}=3^{2} \cdot 33.5 \mathrm{nH} / \mathrm{N}^{2}=301 \mathrm{nH}
$$

This inductor is available as part number CTX15-14771 from Coiltronics.

## 5. MOSFET \& Heatsink Selection

The IPB05N03L from Infineon is chosen for both the control and synchronous MOSFET due to its low $\mathrm{R}_{\mathrm{DS}(\mathrm{on})}$ and low gate-charge requirements. The following parameters are derived from the IPB05N03L data sheet:

$$
\begin{aligned}
& \mathrm{Rds}_{\mathrm{ON}}=3.9 \mathrm{~m} \Omega @ 10 \mathrm{~V} \\
& \mathrm{Q}_{\mathrm{SWITCH}}=25 \mathrm{nC} \\
& \mathrm{Q}_{\mathrm{RR}}=45 \mathrm{nC} \\
& \mathrm{Q}_{\mathrm{OSS}}=35 \mathrm{nC} \\
& \mathrm{Vf}_{\text {diode }}=0.86 \mathrm{~V} @ 25 \mathrm{~A} \\
& \theta_{\mathrm{JC}}=1.0^{\circ} \mathrm{C} / \mathrm{W}
\end{aligned}
$$

## NCP5322A Parameters:

$$
\mathrm{i}_{\mathrm{G}}=1.5 \mathrm{~A}
$$

$\mathrm{V}_{\mathrm{G}}=10 \mathrm{~V}$
t_nonoverlap $=65 \mathrm{~ns}$
The RMS value of the current in the control MOSFET is calculated from Equation 20 and the previously derived values for $\mathrm{D}, \mathrm{I}_{\text {LMAX }}$, and $\mathrm{I}_{\text {LMIN }}$ at the converter's maximum output current:

$$
\begin{align*}
& \mathrm{I}_{\mathrm{RMS}, \mathrm{CNTL}}= {[\mathrm{D} \cdot}  \tag{20}\\
&\left(\mathrm{ILo}_{\mathrm{Lo}, \mathrm{MAX}}{ }^{2}+\mathrm{I}_{\mathrm{Lo}}, \mathrm{MAX} \cdot \mathrm{I}_{\mathrm{Lo}, \mathrm{MIN}}\right. \\
& \quad+\mathrm{ILo}_{\left.\left.\mathrm{Lo}, \mathrm{MIN}^{2}\right) / 3\right]^{1 / 2}} \\
&=0.36 \cdot\left[\left(26.5^{2}+26.5 \cdot 18.5+18.5^{2}\right) / 3\right]^{1 / 2} \\
&= 8.15 \text { ARMS }
\end{align*}
$$

Equation 19 is used to calculate the power dissipation of the control MOSFET:

$$
\begin{aligned}
& \text { PD,CONTROL }=\left(\mathrm{I}_{\mathrm{RMS}, \mathrm{CNTL}}{ }^{2} \cdot \mathrm{R}_{\mathrm{DS}}(\mathrm{on})\right) \\
&+\left(\mathrm{ILo}_{\mathrm{M}} \mathrm{MAX} \cdot \mathrm{Q}_{\left.\mathrm{Switch} / \mathrm{I}_{\mathrm{g}} \cdot \mathrm{VIN} \cdot \mathrm{fSW}\right)}\right. \\
&+\left(\mathrm{Q}_{\mathrm{OSS}} / 2 \cdot \mathrm{~V}_{\mathrm{IN}} \cdot \mathrm{fSW}\right)+\left(\mathrm{V}_{\mathrm{IN}} \cdot \mathrm{Q}_{\mathrm{RR}} \cdot \mathrm{fSW}\right) \\
&=\left(8.15^{2} \mathrm{ARMS} \cdot 3.9 \mathrm{~m} \Omega\right) \\
&+(26.5 \mathrm{~A} \cdot 25 \mathrm{nC} / 1.5 \mathrm{~A} \cdot 12 \mathrm{~V} \cdot 220 \mathrm{kHz}) \\
&+(35 \mathrm{nC} / 2 \cdot 12 \mathrm{~V} \cdot 220 \mathrm{kHz}) \\
&+(12 \mathrm{~V} \cdot 45 \mathrm{nC} \cdot 220 \mathrm{kHz}) \\
&= 0.26 \mathrm{~W}+1.17 \mathrm{~W}+0.05 \mathrm{~W}+0.12 \mathrm{~W} \\
&= 1.60 \mathrm{~W}
\end{aligned}
$$

The RMS value of the current in the synchronous MOSFET is calculated from Equation 27 and the previously derived values for $\mathrm{D}, \mathrm{I}_{\mathrm{Lo}, \mathrm{MAX}}$, and $\mathrm{I}_{\mathrm{Lo}, \mathrm{MIN}}$ at the converter's maximum output current:

$$
\begin{aligned}
& \text { IRMS,SYNCH }=[(1-D) \cdot
\end{aligned}
$$

$$
\begin{aligned}
& =\left[(1-0.13) \cdot\left(26.5^{2}+26.5 \cdot 18.5+18.5^{2}\right) / 3\right]^{1 / 2} \\
& =21.1 \text { ARMS }
\end{aligned}
$$

Equation 26 is used to calculate the power dissipation of the synchronous MOSFET:

$$
\begin{align*}
\mathrm{PD}, \mathrm{SYNCH}= & \left(\mathrm{I}_{\mathrm{RMS}, \mathrm{SYNCH}}\right.  \tag{26}\\
& +\mathrm{RDS}(\mathrm{on})) \\
= & \left(21.1^{2} \mathrm{ARf} \text { diode } \cdot \mathrm{IO}_{\mathrm{RMS}} \cdot \mathrm{MAX} / 2 \cdot \mathrm{t} .9 \mathrm{~m} \Omega\right) \\
& +(0.86 \mathrm{~V} \cdot 45 \mathrm{~A} / 2 \cdot 65 \mathrm{~ns} \cdot 220 \mathrm{kHz}) \\
= & 1.74 \mathrm{~W}+0.28 \mathrm{~W}=2.02 \mathrm{~W}
\end{align*}
$$

Equation 28 is used to calculate the heat sink thermal impedances necessary to maintain less than the specified maximum junction temperatures at $60^{\circ} \mathrm{C}$ ambient:

$$
\begin{aligned}
& \theta \mathrm{CNTL}<\left(125-60^{\circ} \mathrm{C}\right) / 1.6 \mathrm{~W}-1.0^{\circ} \mathrm{C} / \mathrm{W}=40^{\circ} \mathrm{C} / \mathrm{W} \\
& \theta \text { SYNCH }<\left(125-60^{\circ} \mathrm{C}\right) / 2.02 \mathrm{~W}-1.0^{\circ} \mathrm{C} / \mathrm{W}=31^{\circ} \mathrm{C} / \mathrm{W}
\end{aligned}
$$

If board area permits, a cost effective heatsink could be formed by using a TO-263 mounting pad of at least $1.5 \mathrm{in}^{2}$ for the upper MOSFET and $2.5 \mathrm{in}^{2}$ for the lower MOSFET on a single-sided, 1 oz . copper PCB. The total required pad area would be slightly less if the area were divided evenly between top and bottom layers with multiple thermal vias joining the two areas. To conserve board space, AAVID offers clip-on heatsinks for TO-220 thru-hole packages. Examples of these heatsinks include \#577002 ( $1^{\prime \prime} \times 0.75^{\prime \prime} \times$ $0.25^{\prime \prime}, 33^{\circ} \mathrm{C} / \mathrm{W}$ at 2 W$)$ and \#591302 ( $0.75^{\prime \prime} \times 0.5^{\prime \prime} \times 0.5^{\prime \prime}$, $29^{\circ} \mathrm{C} / \mathrm{W}$ at 2 W ).

## 6. Adaptive Voltage Positioning

First, to achieve the 220 kHz switching frequency, use Figure 4 to determine that a $65 \mathrm{k} \Omega$ resistor is needed for $\mathrm{R}_{\mathrm{OSC}}$. Then, use Figure 5 to find the $\mathrm{V}_{\mathrm{FB}}$ bias current at the corresponding value of $\mathrm{R}_{\mathrm{OSC}}$. In this example, the $65 \mathrm{k} \Omega$ $\mathrm{R}_{\mathrm{OSC}}$ resistor results in a $\mathrm{V}_{\mathrm{FB}}$ bias current of approximately $5.0 \mu \mathrm{~A}$. Knowing the $\mathrm{V}_{\mathrm{FB}}$ bias current, one can calculate the required values for $\mathrm{R}_{\mathrm{FBK} 1}$ and $\mathrm{R}_{\mathrm{DRP}}$ using Equations 29 through 31.
The no-load position is easily set using Equation 29:

$$
\begin{align*}
\text { RFBK1 } & =\Delta \mathrm{V}_{\text {NO }}-\text { LOAD/IBIASVFB }  \tag{29}\\
& =+30 \mathrm{mV} / 5.0 \mu \mathrm{~A} \\
& =6.04 \mathrm{k} \Omega
\end{align*}
$$

For inductive current sensing, the designer must calculate the inductor's resistance $\left(\mathrm{R}_{\mathrm{L}}\right)$ and approximate any resistance added by the circuit board ( $\mathrm{R}_{\mathrm{PCB}}$ ). We found the inductor's nominal resistance in Section $2(0.82 \mathrm{~m} \Omega)$. In this example, we approximate $0.50 \mathrm{~m} \Omega$ for the circuit board resistance ( $\mathrm{R}_{\mathrm{PCB}}$ ). With this information, Equation 30 can be used to calculate the increase at the $\mathrm{V}_{\text {DRP }}$ pin at full load:

$$
\begin{aligned}
\Delta \mathrm{V}_{\mathrm{DRP}} & =\mathrm{I}_{\mathrm{O}}, \mathrm{MAX} \cdot\left(\mathrm{R}_{\mathrm{L}}+\mathrm{RPCB}\right) \cdot \mathrm{GVDRP} \\
& =45 \mathrm{~A} \cdot(1.03 \mathrm{~m} \Omega+0.50 \mathrm{~m} \Omega) \cdot 3.3 \mathrm{~V} / \mathrm{V} \\
& =227 \mathrm{mV}
\end{aligned}
$$

$\mathrm{R}_{\mathrm{DRP1}}$ can then be calculated from Equation 31:

$$
\begin{aligned}
\mathrm{R}_{\mathrm{DRP}} & =\frac{\Delta \mathrm{V} \text { DRP }}{\left(\mathrm{IBIASVFB}+\Delta \mathrm{V}_{\mathrm{OUT}, \mathrm{FULL}-\mathrm{LOAD} / \mathrm{RFBK} 1)}\right)} \\
& =227 \mathrm{mV} /(5.0 \mu \mathrm{~A}+35 \mathrm{mV} / 6.04 \mathrm{k} \Omega) \\
& =21.0 \mathrm{k} \Omega
\end{aligned}
$$

## 7. Current Sensing

Choose the current sense network $\left(\mathrm{R}_{\mathrm{CSn}}, \mathrm{C}_{\mathrm{CSn}}, \mathrm{n}=1\right.$ or 2$)$ to satisfy:

$$
\begin{equation*}
\mathrm{R}_{\mathrm{CSn}} \cdot \mathrm{C}_{\mathrm{CS}}=\mathrm{Lo} /\left(\mathrm{R}_{\mathrm{L}}+\mathrm{RPCB}\right) \tag{32}
\end{equation*}
$$

Equation 32 will be most accurate for better iron powder core material (such as the -8 from Micrometals). This material is very consistent with DC current and frequency. Less expensive core materials (such as the -52 from Micrometals) change their characteristics with DC current, AC flux density, and frequency. This material will yield acceptable converter performance if the current sense time constant is set lower (longer) than anticipated. As a rule of thumb, use approximately twice the resistance $\left(\mathrm{R}_{\mathrm{CSn}}\right)$ or twice the capacitance $\left(\mathrm{C}_{\mathrm{CSn}}\right)$ when using the less expensive core material.

The component values determined thus far are $L o=1.1 \mu \mathrm{H}$, $\mathrm{R}_{\mathrm{L}}=1.03 \mathrm{~m} \Omega$, and $\mathrm{R}_{\mathrm{PCB}}=0.50 \mathrm{~m} \Omega$. We choose a convenient value for $\mathrm{C}_{\mathrm{CS} 1}(0.01 \mu \mathrm{~F})$ and solve for $\mathrm{R}_{\mathrm{CS} 1}$;

$$
\begin{aligned}
\mathrm{R}_{\mathrm{CSn}} & =1.1 \mu \mathrm{H} /(1.03 \mathrm{~m} \Omega+0.50 \mathrm{~m} \Omega) / 0.01 \mu \mathrm{~F} \\
& =71 \mathrm{k} \Omega
\end{aligned}
$$

Equation 32 will be most accurate for higher quality iron powder core materials such as the -2 or -8 from Micrometals. The permeability of these more expensive cores is relatively constant versus DC current, AC flux density and frequency. Less expensive core materials (such as the -52 from Micrometals) change their characteristics versus DC current, AC flux density, and frequency. The less expensive materials may yield acceptable converter performance if the current sense time constant is set approximately $1 \times-2 \times$ longer than anticipated. For example, use up to twice the resistance $\left(\mathrm{R}_{\mathrm{CSn}}\right)$ or twice the capacitance $\left(\mathrm{C}_{\mathrm{CSn}}\right)$ when using the less expensive core material. If we use -52 material for this design, the value of $\mathrm{R}_{\mathrm{CSn}}$ may need to be increased to $2 \times 71 \mathrm{k} \Omega$ or $142 \mathrm{k} \Omega$.

After the circuit is constructed, the values of $\mathrm{R}_{\mathrm{CSn}}$ and/or $\mathrm{C}_{\mathrm{CSn}}$ should be tuned to provide a "square-wave" at $\mathrm{V}_{\mathrm{DRP}}$ with minimal overshoot and fast rise time due to a step change in load current as shown in Figures 20-22.

## 8. Error Amplifier Tuning

The error amplifier is tuned by adjusting $\mathrm{C}_{\mathrm{AMP}}$ to provide an acceptable full-load transient response as shown in Figures 23-25. After a value for $\mathrm{C}_{\mathrm{AMP}}$ is chosen, the peak-to-peak voltage ripple on the COMP pin is examined under full-load to insure less than $20 \mathrm{mV}_{\mathrm{PP}}$ as shown in Figure 26.

## 9. Current Limit Setting

The maximum inductor resistance, the maximum PCB resistance, and the maximum current-sense gain as shown in Equation 34 determine the current limit. The maximum current, IOUT,LIM, was specified in the design requirements. The maximum inductor resistance occurs at full-load and the highest ambient temperature. This value was found in the "Output Inductor Section" ( $1.06 \mathrm{~m} \Omega$ ). This analysis assumes the PCB resistance only increases due to the change in ambient temperature. Component heating will also increase the PCB temperature but quantifying this effect is difficult. Lab testing should be used to "fine tune" the overcurrent threshold.

$$
\begin{aligned}
\mathrm{RPCB}, \mathrm{MAX}= & 0.50 \mathrm{~m} \Omega \cdot\left(1+0.39 \% /{ }^{\circ} \mathrm{C} \cdot(60-25)^{\circ} \mathrm{C}\right) \\
= & 0.57 \mathrm{~m} \Omega \\
\mathrm{~V}_{\text {ILIM }}= & \left(\mathrm{l} \text { OUT,LIM }+\Delta \mathrm{L}_{\mathrm{Lo}} / 2\right) \cdot\left(\mathrm{R}_{\mathrm{LMAX}}+\mathrm{RPCB}^{2}, \mathrm{MAX}\right) \\
& \cdot \mathrm{GILIM} \\
= & (52 \mathrm{~A}+8.03 \mathrm{~A} / 2) \cdot(1.33 \mathrm{~m} \Omega+0.57 \mathrm{~m} \Omega) \\
& \cdot 6.75 \mathrm{~V} / \mathrm{V} \\
= & 0.718 \mathrm{Vdc}
\end{aligned}
$$

Set the voltage at the $\mathrm{I}_{\text {LIM }}$ pin using a resistor divider from the 3.3 V reference output as shown in Figure 28. If the resistor from $\mathrm{I}_{\mathrm{LIM}}$ to GND is chosen as $1 \mathrm{k}\left(\mathrm{R}_{\mathrm{LIM}}\right)$, the resistor from $\mathrm{I}_{\text {LIM }}$ to 3.3 V can be calculated from:

$$
\begin{aligned}
\mathrm{R}_{\mathrm{LIM} 1} & =\left(\mathrm{V}_{\text {REF }}-\mathrm{V} \text { ILIM }\right) /\left(\mathrm{V} \text { ILIM } / \mathrm{R}_{\text {LIM }}\right) \\
& =(3.3 \mathrm{~V}-0.718 \mathrm{~V}) /(0.718 \mathrm{~V} / 1 \mathrm{k} \Omega) \\
& =3596 \Omega \text { or } 3.57 \mathrm{k} \Omega
\end{aligned}
$$

Figure 28. Setting the Current Limit

## 10. PWM Comparator Input Voltage

Use Equation 35 to check the voltage level to the positive pin of the internal PWM comparators. The design should not saturate the PWM comparator at maximum DAC output voltage ( $+1 \%$ error), AVP at full-load, $100 \%$ duty cycle (D $=1$ ), and worst-case maximum internal ramp ( 310 mV at $100 \%$ duty cycle):

$$
\begin{aligned}
\text { VCSREF,MAX } & =\text { Max VID Setting w/AVP @ Full-Load } \\
& =1.01 \cdot 1.850 \mathrm{~V}-30 \mathrm{mV}=1.834 \mathrm{~V}
\end{aligned}
$$

$$
\begin{align*}
& \mathrm{VCOn}, \mathrm{MAX} \\
&=\left(\mathrm{IO}, \mathrm{MAX} / 2+\Delta \mathrm{I}_{\mathrm{Lo}} / 2\right) \cdot \mathrm{RMAX} \cdot \mathrm{GCSA}, \mathrm{MAX} \\
&=(52 \mathrm{~A} / 2+8.03 \mathrm{~A} / 2) \cdot(1.33 \mathrm{~m} \Omega+0.57 \mathrm{~m} \Omega) \\
& \cdot 3.90 \mathrm{~V} / \mathrm{V} \\
&= 0.222 \mathrm{~V} \\
& \mathrm{~V} \tag{35}
\end{align*}
$$

This value is acceptable because it below the specified maximum of 2.45 V .

## 11. Soft Start Time

To set the Soft Start time, first calculate the external ramp size at a duty-cycle of $\mathrm{D}=1.630 \mathrm{~V} / 12 \mathrm{~V}=0.135$ :

$$
\begin{aligned}
\text { Ext_Ramp } & =\mathrm{D} \cdot \frac{\left(\mathrm{~V}_{\text {IN }}-\mathrm{V}_{\mathrm{OUT}}\right)}{\left(\mathrm{RCSn} \cdot \mathrm{C}_{\mathrm{CSn}} \cdot \mathrm{fSW}\right)} \\
& =0.135 \cdot \frac{(12 \mathrm{~V}-1.630 \mathrm{~V})}{60 \mathrm{k} \Omega \cdot 0.01 \mathrm{~F} \cdot 220 \mathrm{kHz})} \\
& =11 \mathrm{mV}
\end{aligned}
$$

Then calculate the steady-state COMP voltage:

$$
\begin{aligned}
\text { VCOMP }= & \text { VOUT @ } 0 \mathrm{~A}+\text { Channel_Startup_Offset } \\
& + \text { Int_Ramp }+ \text { GCSA } \cdot \text { Ext_Ramp } / 2 \\
= & 1.630 \mathrm{~V}+0.40 \mathrm{~V}+0.135 \cdot 250 \mathrm{mV} \\
& +3.5 \mathrm{~V} / \mathrm{V} \cdot 11 \mathrm{mV} / 2 \\
= & 2.083 \mathrm{~V}
\end{aligned}
$$

Then choose a convenient value for the Soft-Start time ( 7.5 ms ) and solve Equation 37 for the Soft-Start capacitor, $\mathrm{C}_{\mathrm{SS}}$ :

$$
\begin{align*}
\text { CSS } & =\mathrm{tSS} \cdot \text { ISS } / \mathrm{V}_{\mathrm{COMP}}  \tag{37}\\
& =7.5 \mathrm{~ms} \cdot 30 \mu \mathrm{~A} / 2.083 \mathrm{~V} \\
& =0.108 \mu \mathrm{~F} \text { or } 0.1 \mu \mathrm{~F}
\end{align*}
$$

$I_{\text {SS }}$ is the Soft-Start charge current from the data sheet.

## CS5323

## Three-Phase Buck Controller with 5-Bit DAC

The CS5323 is a three-phase step down controller that incorporates all control functions required to power next generation processors. Proprietary multi-phase architecture guarantees balanced load current distribution and reduces overall solution cost in high current applications. Enhanced $V^{2 T M}$ control architecture provides the fastest possible transient response, excellent overall regulation, and ease of use.

The multi-phase architecture reduces input and output filter ripple, allowing for a reduction in filter size and inductor values with a corresponding increase in the output inductor current slew rate.

## Features

- Enhanced $\mathrm{V}^{2}$ Control Method
- 5-Bit DAC with $1.0 \%$ Tolerance
- Adjustable Output Voltage Positioning
- Programmable Frequency Set by Single Resistor
- 200 kHz to 800 kHz Operation (Per Phase)
- Current Sensed through Sense Resistors, or Buck Inductors
- Adjustable Current Sense Threshold
- Hiccup Mode Current Limit
- Over-Voltage Protection through Synchronous MOSFET's
- Individual Current Limits for Each Phase
- On-Board Current Sense Amplifiers
- $3.3 \mathrm{~V}, 1.0 \mathrm{~mA}$ Reference Output
- 5.0 V and/or 12 V Operation
- On/Off Control (through COMP Pin)

## APPLICATIONS INFORMATION

## FIXED FREQUENCY MULTI-PHASE CONTROL

In a multi-phase converter, multiple converters are connected in parallel and are switched on at different times. This reduces output current from the individual converters and increases the apparent ripple frequency. Because several converters are connected in parallel, output current can ramp up or down faster than a single converter (with the same value output inductor) and heat is spread among multiple components.

The CS5323 uses a three-phase, fixed frequency, enhanced $\mathrm{V}^{2}$ architecture. Each phase is delayed $120^{\circ}$ from the previous phase. Normally the GATE transitions high at the beginning of each oscillator cycle. Inductor current ramps up until the combination of the current sense signal and the output ripple trip the PWM comparator and bring the GATE low. Once the GATE goes low, it will remain low until the beginning of the next oscillator cycle. While the GATE is high, the enhanced $\mathrm{V}^{2}$ loop will respond to line and load transients. Once the GATE is low, the loop will not respond again until the beginning of the next cycle. Therefore, constant frequency, enhanced $\mathrm{V}^{2}$ will typically respond within the off-time of the converter.

The enhanced $\mathrm{V}^{2}$ architecture measures and adjusts current in each phase. An additional input ( $\mathrm{C}_{\mathrm{X}}$ ) for inductor current information has been added to the $\mathrm{V}^{2}$ loop for each phase as shown in Figure 5.

Figure 5. Enhanced V ${ }^{2}$ Feedback and Current Sense Scheme

The inductor current is measured across $\mathrm{R}_{\mathrm{S}}$, amplified by CSA and summed with the OFFSET and Output Voltage at the non-inverting input of the PWM comparator. The inductor current provides the PWM ramp and as inductor current increases the voltage on the positive pin of the pwm
comparator rises and terminates the pwm cycle. If the inductor starts the cycle with a higher current the PWM cycle will terminate earlier providing negative feedback. The CS5323 provides a $\mathrm{C}_{\mathrm{X}}$ input for each phase, but the $\mathrm{CS}_{\mathrm{REF}}, \mathrm{V}_{\mathrm{FB}}$ and COMP inputs are common to all phases. Current sharing is accomplished by referencing all phases to the same $\mathrm{V}_{\mathrm{FB}}$ and COMP pins, so that a phase with a larger current signal will turn off earlier than phases with a smaller current signal.

Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. If the COMP pin is held steady and the inductor current changes there must also be a change in the output voltage. Or, in a closed loop configuration when the output current changes, the COMP pin must move to keep the same output voltage. The required change in the output voltage or COMP pin depends on the scaling of the current feedback signal and is calculated as

$$
\Delta \mathrm{V}=\mathrm{RS} \times \mathrm{CSA} \text { Gain } \times \Delta \mathrm{I}
$$

The single-phase power stage output impedance is;
Single Stage Impedance $=\Delta \mathrm{V} / \Delta \mathrm{I}=\mathrm{RS} \times$ CSA Gain.
The multi-phase power stage output impedance is the single-phase output impedance divided by the number of phases. The output impedance of the power stage determines how the converter will respond during the first few $\mu$ s of a transient before the feedback loop has repositioned the COMP pin.

The peak output current of each phase can also be calculated from;

$$
\text { Ipkout }(\text { per phase })=\frac{V_{\mathrm{COMP}}-\mathrm{V}_{\mathrm{FB}}-\mathrm{V}_{\mathrm{OFFSET}}}{\mathrm{R}_{\mathrm{S}} \times \mathrm{CSA} \text { Gain }}
$$

Figure 6 shows the step response of a single phase with the COMP pin at a fixed level. Before T1 the converter is in normal steady state operation. The inductor current provides the pwm ramp through the Current Share Amplifier. The pwm cycle ends when the sum of the current signal, voltage signal and OFFSET exceed the level of the COMP pin. At T1 the output current increases and the output voltage sags. The next pwm cycle begins and the cycle continues longer than previously while the current signal increases enough to make up for the lower voltage at the $\mathrm{V}_{\mathrm{FB}}$ pin and the cycle ends at T2. After T2 the output voltage remains lower than at light load and the current signal level is raised so that the sum of the current and voltage signal is the same as with the original load. In a closed loop system the COMP pin would move higher to restore the output voltage to the original level.

Figure 6. Open Loop Operation

## Inductive Current Sensing

For lossless sensing current can be sensed across the inductor as shown below in Figure 7. In the diagram, L is the output inductance and $\mathrm{R}_{\mathrm{L}}$ is the inherent inductor resistance. To compensate the current sense signal the values of R1 and C 1 are chosen so that $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} 1 \times \mathrm{C} 1$. If this criteria is met the current sense signal will be the same shape as the inductor current, the voltage signal at $C x$ will represent the instantaneous value of inductor current and the circuit can be analyzed as if a sense resistor of value $R_{L}$ was used as a sense resistor $\left(\mathrm{R}_{\mathrm{S}}\right)$.

Figure 7. Lossless Inductive Current Sensing with Enhanced ${ }^{2}{ }^{2}$
When choosing or designing inductors for use with inductive sensing, tolerances and temperature effects should be considered. Cores with a low permeability material or a large gap will usually have minimal inductance change with temperature and load. Copper magnet wire has a temperature coefficient of $0.39 \%$ per ${ }^{\circ} \mathrm{C}$. The increase in winding resistance at higher temperatures should be
considered when setting the $\mathrm{I}_{\text {LIM }}$ threshold. If a more accurate current sense is required than inductive sensing can provide, current can be sensed through a resistor as shown in Figure 5.

## Current Sharing Accuracy

PCB traces that carry inductor current can be used as part of the current sense resistance depending on where the current sense signal is picked off. For accurate current sharing, the current sense inputs should sense the current at the same point for each phase and the connection to the $\mathrm{CS}_{\text {REF }}$ should be made so that no phase is favored. (In some cases, especially with inductive sensing, resistance of the pcb can be useful for increasing the current sense resistance.) The total current sense resistance used for calculations must include any pcb trace between the CS inputs and the $\mathrm{CS}_{\text {REF }}$ input that carries inductor current.

Current Sense Amplifier Input Mismatch and the value of the current sense element will determine the accuracy of current sharing between phases. The worst case Current Sense Amplifier Input Mismatch is 5 mV and will typically be within 3 mV . The difference in peak currents between phases will be the CSA Input Mismatch divided by the current sense resistance. If all current sense elements are of equal resistance a 3 mV mismatch with a $2 \mathrm{~m} \Omega$ sense resistance will produce a 1.5 A difference in current between phases.

## Operation at > 50\% Duty Cycle

For operation at duty cycles above $50 \%$ Enhanced V ${ }^{2}$ will exhibit subharmonic oscillation unless a compensation ramp is added to each phase. A circuit like the one on the left side of Figure 8 can be added to each current sense network to implement slope compensation. The value of R1 can be varied to adjust the ramp size.

Figure 8. External Slope Compensation Circuit

## Ramp Size and Current Sensing

Because the current ramp is used for both the PWM ramp and to sense current, the inductor and sense resistor values will be constrained. A small ramp will provide a quick transient response by minimizing the difference over which the COMP pin must travel between light and heavy loads, but a steady state ramp of $25 \mathrm{mV}_{\mathrm{P}-\mathrm{P}}$ or greater is typically required to prevent pulse skipping and minimize pulse width jitter. For resistive current sensing the combination of the inductor and sense resistor values must be chosen to provide a large enough steady state ramp. For large inductor values the sense resistor value must also be increased.

For inductive current sensing the RC network must meet the requirement of $L / R_{L}=R \times C$ to accurately sense the $A C$ and DC components of the current the signal. Again the values for L and $\mathrm{R}_{\mathrm{L}}$ will be constrained in order to provide a large enough steady state ramp with a compensated current sense signal. A smaller $L$, or a larger $R_{L}$ than optimum might be required. But unlike resistive sensing, with inductive sensing small adjustments can be made easily with the values of R and C to increase the ramp size if needed.

If RC is chosen to be smaller (faster) than $\mathrm{L} / \mathrm{R}_{\mathrm{L}}$, the AC portion of the current sensing signal will be scaled larger than the DC portion. This will provide a larger steady state ramp, but circuit performance will be affected and must be evaluated carefully. The current signal will overshoot during transients and settle at the rate determined by $\mathrm{R} \times \mathrm{C}$. It will eventually settle to the correct DC level, but the error will decay with the time constant of $\mathrm{R} \times \mathrm{C}$. If this error is excessive it will effect transient response, adaptive positioning and current limit. During transients the COMP pin will be required to overshoot along with the current signal in order to maintain the output voltage. The $\mathrm{V}_{\mathrm{DRP}}$ pin will also overshoot during transients and possibly slow the response. Single phase overcurrent will trip earlier than it would if compensated correctly and hiccup mode current limit will have a lower threshold for fast rise step loads than for slowly rising output currents.

The waveforms in Figure 9 show a simulation of the current sense signal and the actual inductor current during a positive step in load current with values of $\mathrm{L}=500 \mathrm{nH}$, $\mathrm{R}_{\mathrm{L}}=1.6 \mathrm{~m} \Omega, \mathrm{R} 1=20 \mathrm{k}$ and $\mathrm{C} 1=.01 \mu \mathrm{~F}$. For ideal current signal compensation the value of R1 should be $31 \mathrm{k} \Omega$. Due to the faster than ideal RC time constant there is an overshoot of $50 \%$ and the overshoot decays with a $200 \mu \mathrm{~s}$ time constant. With this compensation the $\mathrm{I}_{\text {LIM }}$ pin threshold must be set more than $50 \%$ above the full load current to avoid triggering hiccup mode during a large output load step.

Figure 9. Inductive Sensing waveform during a Step with Fast RC Time Constant ( $50 \mathrm{us} / \mathrm{div}$ )

## Current Limit

Two levels of overcurrent protection are provided. Any time the voltage on a Current Sense pin exceeds CS $_{\text {REF }}$ by more than the Single Phase Pulse by Pulse Current Limit, the pwm comparator for that phase is turned off. This provides fast peak current protection for individual phases. The outputs of all the currents are also summed and filtered to compare an averaged current signal to the voltage on the $\mathrm{I}_{\text {LIM }}$ pin. If this voltage is exceeded, the fault latch trips and the SS capacitor is discharged by a $5 \mu \mathrm{~A}$ source until the COMP pin reaches 0.2 V . Then soft-start begins. The converter will continue to operate in this mode until the fault condition is corrected.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as a result of the normal operation of the enhanced $\mathrm{V}^{2}$ control topology with synchronous rectifiers. The control loop responds to an overvoltage condition within 400 ns , causing the top MOSFET's to shut off, and the synchronous MOSFET's to turn on. This results in a "crowbar" action to clamp the output voltage and prevents damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low.

## Transient Response and Adaptive Positioning

For applications with fast transient currents the output filter is frequently sized larger than ripple currents require in
order to reduce voltage excursions during transients. Adaptive voltage positioning can reduce peak-peak output voltage deviations during load transients and allow for a smaller output filter. The output voltage can be set higher at light loads to reduce output voltage sag when the load current is stepped up and set lower during heavy loads to reduce overshoot when the load current is stepped up. For low current applications a droop resistor can provide fast accurate adaptive positioning. However at high currents, the loss in a droop resistor becomes excessive. For example; in a 50 A converter a $1 \mathrm{~m} \Omega$ resistor to provide a 50 mV change in output voltage between no load and full load would dissipate 2.5 Watts.

Lossless adaptive positioning is an alternative to using a droop resistor, but must respond quickly to changes in load current. Figure 10 shows how adaptive positioning works. The waveform labeled normal shows a converter without adaptive positioning. On the left, the output voltage sags when the output current is stepped up and later overshoots when current is stepped back down. With fast (ideal) adaptive positioning the peak to peak excursions are cut in half. In the slow adaptive positioning waveform the output voltage is not repositioned quickly enough after current is stepped up and the upper limit is exceeded.

Figure 10. Adaptive Positioning
The CS5323 uses two methods to provide fast and accurate adaptive positioning. For low frequency positioning the $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{DRP}}$ pins are used to adjust the output voltage with varying load currents. For high frequency positioning, the current sense input pins can be used to control the power stage output impedance. The transition between fast and slow positioning is adjusted by the error amp compensation.

The CS5323 can be configured to adjust the output voltage based on the output current of the converter. The adaptive positioning circuit is designed to select the DAC setting as the maximum output voltage. (Refer to Figure 1 on page 2436.)

To set the no-load positioning a resistor (R9) is placed between the output voltage and $\mathrm{V}_{\mathrm{FB}}$ pin. The $\mathrm{V}_{\mathrm{FB}}$ bias current will develop a voltage across the resistor to decrease the output voltage. The $\mathrm{V}_{\mathrm{FB}}$ bias current is dependent on the value of ROSC. See Figure 4 on the datasheet.

During no load conditions the $\mathrm{V}_{\text {DRP }}$ pin is at the same voltage as the $\mathrm{V}_{\mathrm{FB}}$ pin, so none of the $\mathrm{V}_{\mathrm{FB}}$ bias current flows through the $\mathrm{V}_{\mathrm{DRP}}$ resistor (R6). When output current
increases the $\mathrm{V}_{\text {DRP }}$ pin increases proportionally and the $\mathrm{V}_{\mathrm{DRP}}$ pin current offsets the $\mathrm{V}_{\mathrm{FB}}$ bias current and causes the output voltage to further decrease.

The $V_{F B}$ and $V_{\text {DRP }}$ pins take care of the slower and DC voltage positioning. The first few $\mu \mathrm{s}$ are controlled primarily by the ESR and ESL of the output filter. The transition between fast and slow positioning is controlled by the ramp size and the error amp compensation. If the ramp size is too large or the error amp too slow there will be a long transition to the final voltage after a transient. This will be most apparent with lower capacitance output filters.

Note: Large levels of adaptive positioning can cause pulse width jitter.

## Error Amp Compensation

The transconductance error amplifier can be configured to provide both a slow soft-start and a fast transient response. C 4 in the main applications diagram controls soft-start. A $0.1 \mu \mathrm{~F}$ capacitor with the $30 \mu \mathrm{~A}$ error amplifier output capability will allow the output to ramp up at $0.3 \mathrm{~V} / \mathrm{ms}$ or 1.5 V in 5 ms .

R 10 is connected in series with C 4 to allow the error amplifier to slew quickly over a narrow range during load transients. Here the $30 \mu \mathrm{~A}$ error amplifier output capability works against $8 \mathrm{k} \Omega$ (R10) to limit the window of fast slewing too 240 mV - enough to allow for fast transients, but not enough to interfere with soft-start. This window will be noticeable as a step in the COMP pin voltage at start-up. The size of this step must be kept smaller than the Channel Start-Up Offset (nominally 0.4 V ) for proper soft-start operation. If adaptive positioning is used the R9 and R8 form a divider with the $\mathrm{V}_{\mathrm{DRP}}$ end held at the DAC voltage during start-up, which effectively makes the Channel Start-Up Offset larger.

C12 is included for error amp stability. A capacitive load is required on the error amp output. Use of values less than 1 nF may result in error amp oscillation of several MHz .

C 11 and the parallel resistance of the $\mathrm{V}_{\mathrm{FB}}$ resistor (R9) and the $V_{\text {DRP }}$ resistor (R6) are used to roll off the error amp gain. C28 adds a zero to the error amp response to boost the phase near the crossover frequency.

## UVLO

The CS5323 has one undervoltage lockout function connected to the $\mathrm{V}_{\mathrm{CC}}$ pin. In applications where the converter is powered from multiple voltages, additional UVLO protection might be required if the voltage powering the controller can turn on before other voltages.

For the $12 \mathrm{~V}_{\text {IN }}$ converter in Figure 1, the CS5323 UVLO function monitors the 5.0 V supply. If the 5.0 V supply comes up before the 12 V supply, the COMP pin will rise until it reaches the upper rail or until the 12 V supply comes up and the converter comes into regulation. If the delay between the 5.0 V and 12 V supplies is too long, soft-start will be compromised. A diode connected from the 12 V supply to the COMP pin can hold the COMP pin down until the 12 V supply starts to come up. Or, if a higher UVLO
threshold is needed, a circuit like the one in Figure 11 will lock out the converter until the 12 V supply reaches about 7.0 V.

Figure 11. External UVLO Circuit

## Remote Sense

In some applications that require remote output voltage sensing, there are conditions when the path of the feedback signal can be broken. In a voltage regulator module (VRM) the remote voltage feedback sense point is typically off the module. If the module is powered apart from the intended application, the feedback will be left open. On a motherboard, the feedback path might be broken when the processor socket is left open. Without the feedback connection the output voltage is likely to exceed the intended voltage. To protect the circuit from overvoltage conditions, a resistor can be connected between the local output voltage and the remote sense line as shown in Figure 12.

Figure 12. Remote Sense Connection

## Layout Guidelines

With the fast rise, high output currents of microprocessor applications parasitic inductance and resistance should be considered when laying out the power, filter and feedback signal sections of the board. Typically a multi-layer board with at least one ground plane is recommended. If the layout is such that high currents can exist in the ground plane underneath the controller or control circuitry, the ground plane can be slotted to reroute the currents away from the
controller. The slots should typically not be placed between the controller and the output voltage or in the return path of the gate drive. Additional power and ground planes or islands can be added as required for a particular layout.

Output filter components should be placed on wide planes connected directly to the load to minimize resistive drops during heavy loads and inductive drops and ringing during transients. If required, the planes for the output voltage and return can be interleaved to minimize inductance between the filter and load.
Voltage feedback should be taken from a point of the output or the output filter that doesn't favor any one phase. If the feedback connection is closer to one inductor than the others the ripple associated with that phase may appear larger than the ripple associated with the other phases and poor current sharing can result.
The current sense signal is typically tens of milli-volts. Noise pick-up should be avoided wherever possible. Current feedback traces should be routed away from noisy areas such as switch nodes and gate drive signals. The paths should be matched as well as possible. It is especially important that all current sense signals be picked off at similar points for accurate current sharing. If the current signal is taken from a place other than directly at the inductor any additional resistance between the pick-off point and the inductor appears as part of the inherent inductor resistance and should be considered in design calculations. Capacitors for the current feedback networks should be placed as close to the current sense pins as practical.

## DESIGN PROCEDURE

## Current Sensing, Power Stage and Output Filter Components

1. Choose the output filter components to meet peak transient requirements. The formula below can be used to provide an approximate starting point for capacitor choice, but will be inadequate to calculate actual values.

$$
\Delta \mathrm{V}_{\mathrm{PEAK}}=(\Delta \mathrm{I} / \Delta \mathrm{T}) \times \mathrm{ESL}+\Delta \mathrm{I} \times \mathrm{ESR}
$$

Ideally the output filter should be simulated with models including ESR, ESL, circuit board parasitics and delays due to switching frequency and converter response. Typically both bulk capacitance (electrolytic, Oscon, etc,) and low impedance capacitance (ceramic chip) will be required. The bulk capacitance provides "hold up" during the converter response. The low impedance capacitance reduces steady state ripple and bypasses the bulk capacitance during slewing of output current.
2. For inductive current sensing (only) choose the current sense network RC to provide a 25 mV minimum ramp during steady state operation.

$$
\mathrm{R}=\left(\mathrm{V}_{\text {IN }}-\mathrm{V}_{\text {OUT }}\right) \times \frac{\mathrm{V}_{\text {OUT }} / \mathrm{V}_{\text {IN }}}{\mathrm{F} \times \mathrm{C} \times 25 \mathrm{mV}}
$$

Then choose the inductor value and inherent resistance to satisfy $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} \times \mathrm{C}$.
For ideal current sense compensation the ratio of $L$ and $R_{L}$ is fixed, so the values of $L$ and $R_{L}$ will be a compromise typically with the maximum value $\mathrm{R}_{\mathrm{L}}$ limited by conduction losses or inductor temperature rise and the minimum value of $L$ limited by ripple current.
3. For resistive current sensing choose $L$ and $R_{S}$ to provide a steady state ramp greater than 25 mV .

$$
\mathrm{L} / \mathrm{RS}_{\mathrm{S}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{TON} / 25 \mathrm{mV}
$$

Again the ratio of L and $\mathrm{R}_{\mathrm{L}}$ is fixed and the values of L and $\mathrm{R}_{\mathrm{S}}$ will be a compromise.
4. Calculate the high frequency output impedance (ConverterZ) of the converter during transients. This is the impedance of the Output filter ESR in parallel with the power stage output impedance (PwrstgZ) and will indicate how far from the original level $(\Delta \mathrm{VR})$ the output voltage will typically recover to within one switching cycle. For a good transient response $\Delta \mathrm{VR}$ should be less than the peak output voltage overshoot or undershoot.

$$
\begin{array}{r}
\Delta V R=\text { ConverterZ } \times \text { ESR } \\
\text { ConverterZ }=\frac{\text { PwrstgZ } \times \text { ESR }}{\text { PwrstgZ }+ \text { ESR }}
\end{array}
$$

where:

$$
\text { PwrstgZ }=\text { RS } \times \text { CSA Gain } / 3
$$

Multiply the converterZ by the output current step size to calculate where the output voltage should recover to within the first switching cycle after a transient. If the ConverterZ is higher than the value required to recover to where the adaptive positioning is set the remainder of the recovery will be controlled by the error amp compensation and will typically recover in $10-20 \mu \mathrm{~s}$.

$$
\Delta \mathrm{VR}=\Delta \mathrm{I} \mathrm{OUT} \times \text { ConverterZ }
$$

Make sure that $\Delta \mathrm{VR}$ is less than the expected peak transient for a good transient response.
5. Adjust L and $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ as required to meet the best combination of transient response, steady state output voltage ripple and pulse width jitter.

## Current Limit

When the sum of the Current Sense amplifiers ( $\mathrm{V}_{\text {ITOTAL }}$ ) exceeds the voltage on the $\mathrm{I}_{\text {LIM }}$ pin the part will enter hiccup mode. For inductive sensing the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the inductor resistance (or current sense resistor) at max temperature and max current. To set the level of the $I_{\text {LIM }}$ pin:
6. $\mathrm{V}_{\mathrm{I}(\mathrm{LIM})}=\mathrm{R} \times \operatorname{IOUT}(\mathrm{LIM}) \times \mathrm{CS}$ to ILIM Gain
where:
R is $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$;
$I_{\text {OUT(LIM) }}$ is the current limit threshold.
For the overcurrent to work properly the inductor time constant $(\mathrm{L} / \mathrm{R})$ should be $\leq$ the Current sense RC. If the RC is too fast, during step loads the current waveform will appear larger than it is (typically for a few hundred $\mu \mathrm{s}$ ) and may trip the current limit at a level lower than the DC limit.

## Adaptive Positioning

7. To set the amount of voltage positioning below the DAC setting at no load connect a resistor ( $\mathrm{R}_{\mathrm{V}}(\mathrm{FB})$ ) between the output voltage and the $\mathrm{V}_{\mathrm{FB}}$ pin. Choose $\mathrm{R}_{\mathrm{V}}(\mathrm{FB})$ as;

$$
R V(F B)=N L \text { Position } / V_{F B} \text { Bias Current }
$$

See Figure 4 for $V_{F B}$ Bias Current.
8. To set the difference in output voltage between no load and full load, connect a resistor $\left(\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}\right)$ between the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pins. $\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}$ can be calculated in two steps. First calculate the difference between the $\mathrm{V}_{\mathrm{DRP}}$ and $V_{F B}$ pin at full load. (The $V_{F B}$ voltage should be the same as the DAC voltage during closed loop operation.) Then choose the $\mathrm{R}_{V(\mathrm{DRP})}$ to source enough current across $\mathrm{R}_{\mathrm{V}}(\mathrm{FB})$ for the desired change in output voltage.

$$
\Delta V_{V}(D R P)=I O U T F L \times R \times C S \text { to } V_{D R P} \text { Gain }
$$

where:
$\mathrm{R}=\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ for one phase;
$I_{O U T F L}$ is the full load output current.

$$
\mathrm{RV}(\mathrm{DRP})=\Delta \mathrm{V}_{\mathrm{DRP}} \times \operatorname{RV}(\mathrm{FB}) / \Delta \mathrm{V}_{\mathrm{OUT}}
$$

## Calculate Input Filter Capacitor Current Ripple

The procedure below assumes that phases do not overlap and output inductor ripple current $(\mathrm{P}-\mathrm{P})$ is less than the average output current of one phase.
9. Calculate Input Current
$\mathrm{I}_{\mathrm{I}}=\frac{\mathrm{V}_{\text {OUT }} \times \mathrm{I}_{\mathrm{OUT}}}{\left(\text { Efficiency } \times \mathrm{V}_{\mathrm{IN}}\right)}$
10. Calculate Duty Cycle (per phase).

Duty Cycle $=\frac{\text { VOUT }}{\left(\text { Efficiency } \times \mathrm{V}_{\text {IN }}\right)}$
11. Calculate Apparent Duty Cycle.

## Apparent Duty Cycle $=$ Duty Cycle $\times \#$ of Phases

12. Calculate Input Filter Capacitor Ripple Current. Use the chart in Figure 13 to calculate the normalized ripple current ( $\mathrm{K}_{\mathrm{RMS}}$ ) based on the reciprocal of Apparent Duty Cycle. Then multiply the input current by $K_{\text {RMS }}$ to obtain the Input Filter Capacitor Ripple Current.

Ripple $(\mathrm{RMS})=\mathrm{I}_{\mathrm{I}} \times \mathrm{K}_{\mathrm{RMS}}$

Figure 13. Normalized Input Filter Capacitor Ripple Current

## DESIGN EXAMPLE

Choose the component values for lossless current sensing, adaptive positioning and current limit for a 12 V to 1.5 V 60 A converter. The adaptive positioning is chosen 20 mV below the maximum $\mathrm{V}_{\text {OUT }}$ at no load and 70 mV below the no-load position with 60 A out. The peak output voltage transient is 100 mV max during a 60 A step current. The overcurrent limit is nominally 75 A .

## Current Sensing, Power Stage and Output Filter Components

1. Assume $1.5 \mathrm{~m} \Omega$ of output filter ESR.
2. $\mathrm{R}=\left(\mathrm{VIN}-\mathrm{V}_{\mathrm{OUT}}\right) \times\left(\mathrm{V}_{\mathrm{OUT}} / \mathrm{VIN}_{\mathrm{IN}}\right) /(\mathrm{F} \times \mathrm{C} \times 25 \mathrm{mV})$

$$
=(12-1.5) \times(1.5 / 12) /(250 \mathrm{k} \times .01 \mu \mathrm{~F} \times 25 \mathrm{mV})
$$

$$
=21 \mathrm{k} \Omega \Rightarrow \text { Choose } 20 \mathrm{k} \Omega
$$

$\mathrm{L} / \mathrm{R}_{\mathrm{L}}=.01 \mu \mathrm{~F} \times 20 \mathrm{k} \Omega=200 \mu \mathrm{~s}$
Choose RL $=2.0 \mathrm{~m} \Omega$
$\mathrm{L}=2 \mathrm{~m} \Omega \times 200 \mu \mathrm{~s}=400 \mathrm{nH}$
3. $n / a$
4. PwrstgZ $=R_{L} \times$ CSA Gain $/ 3$

$$
=1.5 \mathrm{~m} \Omega \times 4.2 / 3=2.1 \mathrm{~m} \Omega
$$

$$
\begin{aligned}
\text { ConverterZ } & =\frac{\text { Pwrstg } Z \times \mathrm{ESR}}{\text { PwrstgZ }+\mathrm{ESR}} \\
& =\frac{2.8 \mathrm{~m} \Omega \times 1.5 \mathrm{~m} \Omega}{2.8 \mathrm{~m} \Omega+1.5 \mathrm{~m} \Omega} \cong 1.0 \mathrm{~m} \Omega
\end{aligned}
$$

$$
\Delta \mathrm{VR}=1.0 \mathrm{~m} \Omega \times 60 \mathrm{~A}=60 \mathrm{mV}
$$

5. n/a

## Current Limit

$$
\text { 6. } \begin{aligned}
\mathrm{V}_{\mathrm{I}(\mathrm{LIM})} & =R_{\mathrm{L}} \times \operatorname{IOUT}(\mathrm{LIM}) \times \mathrm{CS} \text { to ILIM Gain } \\
& =1.5 \mathrm{~m} \Omega \times 75 \mathrm{~A} \times 6.5=731 \mathrm{mV}
\end{aligned}
$$

## Adaptive Positioning

9. $\mathrm{I}_{\mathrm{I}} \mathrm{N}=\frac{1.6 \mathrm{~V} \times 60 \mathrm{~A}}{\left(0.85 \times 12 \mathrm{~V}_{\mathrm{IN}}\right)}=9.4 \mathrm{~A}$
10. Duty Cycle $=\frac{1.6 \mathrm{~V}}{\left(0.85 \times 12 \mathrm{~V}_{\mathrm{IN}}\right)}=0.16$
11. Apparent Duty Cycle $=0.16 \times 3.0=0.48$
12. RMS ripple is $9.4 \mathrm{~A} \times 1.0=9.4 \mathrm{~A}$

$$
\begin{aligned}
& \text { 7. } \mathrm{RV}_{\mathrm{V}}(\mathrm{FB})=\mathrm{NL} \text { Position } / \mathrm{V}_{\mathrm{FB}} \text { Bias Current } \\
& =20 \mathrm{mV} / 19 \mu \mathrm{~A} \cong 1.00 \mathrm{k} \Omega \\
& \text { 8. } \Delta V_{\text {DRP }}=\text { RL } \times \text { IOUT } \times \text { Current Sense to VDRP Gain } \\
& =2 \mathrm{~m} \Omega \times 60 \mathrm{~A} \times 3=360 \mathrm{mV} \\
& R V(D R P)=\Delta V_{D R P} \times R V(F B) / \Delta V O U T \\
& =360 \mathrm{mV} \times 1.00 \mathrm{k} \Omega / 50 \mathrm{mV}=7.2 \mathrm{k} \Omega
\end{aligned}
$$

## CS5332

## Two-Phase Buck Controller with Integrated Gate Drivers for VRM 9.0

The CS5332 is a two-phase step down controller which incorporates all control functions required to power high performance processors and high current power supplies. Proprietary multi-phase architecture guarantees balanced load current distribution and reduces overall solution cost in high current applications. Enhanced V ${ }^{2 T M}$ control architecture provides the fastest possible transient response, excellent overall regulation, and ease of use.

The CS5332 multi-phase architecture reduces output voltage and input current ripple, allowing for a significant reduction in inductor values and a corresponding increase in inductor current slew rate. This approach allows a considerable reduction in input and output capacitor requirements, as well as reducing overall solution size and cost.

## Features

- Enhanced $\mathrm{V}^{2}$ Control Method
- VRM 9.0 Compatible 5-Bit DAC with $1.0 \%$ Accuracy
- Adjustable Output Voltage Positioning
- 4 On-Board GATE Drivers
- 200 kHz to 800 kHz Operation Set by Resistor
- Current Sensed through Buck Inductors, or Sense Resistors
- Hiccup Mode Current Limit
- Individual Current Limits for Each Phase
- On-Board Current Sense Amplifiers
- $3.3 \mathrm{~V}, 1.0 \mathrm{~mA}$ Reference Output
- 5.0 V and/or 12 V Operation
- On/Off Control (through Soft Start Pin)
- Power Good Output with Internal Delay

PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  |  |
| :---: | :---: | :---: |
| 28 Lead SO Wide | PIN SYMBOL | FUNCTION |
| 1 | COMP | Output of the error amplifier and input for the PWM comparators. |
| 2 | $V_{\text {FB }}$ | Voltage Feedback Pin. To use Adaptive Voltage Positioning (AVP) select an offset voltage at light load and connect a resistor between $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{OUT}}$. The input current of the $\mathrm{V}_{\mathrm{FB}}$ pin and the resistor value determine output voltage offset for zero output current. Short $\mathrm{V}_{\mathrm{FB}}$ to $\mathrm{V}_{\mathrm{OUT}}$ for no AVP. |
| 3 | $\mathrm{V}_{\text {DRP }}$ | Current sense output for AVP. The offset of this pin above the DAC voltage is proportional to the output current. Connect a resistor from this pin to $V_{F B}$ to set amount AVP or leave this pin open for no AVP. |
| 4-5 | CS1-CS2 | Current sense inputs. Connect current sense network for the corresponding phase to each input. |
| 6 | $C S_{\text {REF }}$ | Reference for current sense amplifiers and input for Power Good comparators. To balance input offset voltages between the inverting and non-inverting inputs of the current sense amplifiers, connect a resistor between CS $_{\text {REF }}$ and the output voltage. The value should be $2 / 5$ of the value of the resistors connected to the CSx pins. |
| 7 | PWRGD | Power-Good Output. Open collector output goes low when the $\mathrm{CS}_{\text {REF }}$ is out of regulation. |
| 8-12 | $\mathrm{V}_{\text {ID }}-\mathrm{V}_{\text {IDO }}$ | Voltage ID DAC inputs. These pins are internally pulled up to 3.3 V if left open. |
| 13 | ILIM | Sets threshold for current limit. Connect to reference through a resistive divider. |
| 14 | REF | Reference output. Decouple with $0.1 \mu \mathrm{~F}$ to LGND |
| 15 | $\mathrm{V}_{\mathrm{CCH} 2}$ | Power for GATE(H)2. |
| 16 | GATE(H)2 | High side driver \#2. |
| 17 | GND2 | Return for \#2 drivers. |
| 18 | GATE(L)2 | Low side driver \#2. |
| 19 | $\mathrm{V}_{\text {CCL2 }}$ | Power for GATE(L)2. |
| 20 | SS | Soft Start capacitor pin. The Soft Start capacitor controls both Soft Start time and hiccup mode frequency. The COMP pin is clamped below Soft Start during start up and hiccup mode. |
| 21 | LGND | Return for internal control circuits and IC substrate connection. |
| 22 | $\mathrm{V}_{\mathrm{CCH} 1}$ | Power for GATE(H)1. UVLO Sense for High Side Driver supply connects to this pin. |
| 23 | GATE(H)1 | High side driver \#1. |
| 24 | GND1 | Return for \#1 drivers. |
| 25 | GATE(L) 1 | Low side driver \#1. |
| 26 | $\mathrm{V}_{\text {CCL1 }}$ | Power for GATE(L)1. |
| 27 | $\mathrm{V}_{\text {CCL }}$ | Power for internal control circuits. UVLO Sense for Logic connects to this pin. |
| 28 | Rosc | A resistor from this pin to ground sets operating frequency and $\mathrm{V}_{\mathrm{FB}}$ bias current. |

## APPLICATIONS INFORMATION

## FIXED FREQUENCY MULTI-PHASE CONTROL

In a multi-phase converter, multiple converters are connected in parallel and are switched on at different times. This reduces output current from the individual converters and increases the apparent ripple frequency. Because several converters are connected in parallel, output current can ramp up or down faster than a single converter (with the same value output inductor) and heat is spread among multiple components.

The CS5332 uses a two-phase, fixed frequency, Enhanced V ${ }^{2}$ architecture. Each phase is delayed $180^{\circ}$ from the previous phase. Normally GATE(H) transitions high at the beginning of each oscillator cycle. Inductor current ramps up until the combination of the current sense signal and the output ripple trip the PWM comparator and bring GATE(H) low. Once GATE $(\mathrm{H})$ goes low, it will remain low until the beginning of the next oscillator cycle. While GATE(H) is high, the Enhanced $\mathrm{V}^{2}$ loop will respond to line and load transients. Once GATE $(\mathrm{H})$ is low, the loop will not respond again until the beginning of the next cycle. Therefore, constant frequency Enhanced $\mathrm{V}^{2}$ will typically respond within the off-time of the converter.

The Enhanced $\mathrm{V}^{2}$ architecture measures and adjusts current in each phase. An additional input ( $\mathrm{C}_{\mathrm{X}}$ ) for inductor current information has been added to the $\mathrm{V}^{2}$ loop for each phase as shown in Figure 9.

Figure 9. Enhanced V ${ }^{2}$ Current Sense Scheme
The inductor current is measured across $\mathrm{R}_{\mathrm{S}}$, amplified by CSA and summed with the OFFSET and Output Voltage at the non-inverting input of the PWM comparator. The inductor current provides the PWM ramp and as inductor current increases the voltage on the positive pin of the PWM
comparator rises and terminates the PWM cycle. If the inductor starts the cycle with a higher current, the PWM cycle will terminate earlier providing negative feedback. The CS5332 provides a $\mathrm{C}_{\mathrm{X}}$ input for each phase, but the $\mathrm{CS}_{\mathrm{REF}}, \mathrm{V}_{\mathrm{FB}}$ and COMP inputs are common to all phases. Current sharing is accomplished by referencing all phases to the same $\mathrm{V}_{\mathrm{FB}}$ and COMP pins, so that a phase with a larger current signal will turn off earlier than phases with a smaller current signal.
Including both current and voltage information in the feedback signal allows the open loop output impedance of the power stage to be controlled. If the COMP pin is held steady and the inductor current changes, there must also be a change in the output voltage. Or, in a closed loop configuration when the output current changes, the COMP pin must move to keep the same output voltage. The required change in the output voltage or COMP pin depends on the scaling of the current feedback signal and is calculated as

$$
\Delta \mathrm{V}=\mathrm{RS} \times \mathrm{CSA} \text { Gain } \times \Delta \mathrm{I}
$$

The single-phase power stage output impedance is;
Single Stage Impedance $=\Delta \mathrm{V} / \Delta \mathrm{I}=\mathrm{RS} \times$ CSA Gain.
The multi-phase power stage output impedance is the single-phase output impedance divided by the number of phases. The output impedance of the power stage determines how the converter will respond during the first few $\mu$ s of a transient before the feedback loop has repositioned the COMP pin.
The peak output current of each phase can also be calculated from;

$$
\text { Ipkout }(\text { per phase })=\frac{V_{C O M P}-V_{F B}-V_{O F F S E T}}{R_{S} \times C S A}
$$

Figure 10 shows the step response of a single phase with the COMP pin at a fixed level. Before T1 the converter is in normal steady state operation. The inductor current provides the PWM ramp through the Current Sense Amplifier. The PWM cycle ends when the sum of the current signal, voltage signal and OFFSET exceed the level of the COMP pin. At T1 the output current increases and the output voltage sags. The next PWM cycle begins and the cycle continues longer than previously while the current signal increases enough to make up for the lower voltage at the $\mathrm{V}_{\mathrm{FB}}$ pin and the cycle ends at T2. After T2 the output voltage remains lower than at light load and the current signal level is raised so that the sum of the current and voltage signal is the same as with the original load. In a closed loop system the COMP pin would move higher to restore the output voltage to the original level.

Figure 10. Open Loop Operation

## Inductive Current Sensing

For lossless sensing current can be sensed across the inductor as shown in Figure 11. In the diagram, L is the output inductance and $\mathrm{R}_{\mathrm{L}}$ is the inherent inductor resistance. To compensate the current sense signal the values of R1 and C 1 are chosen so that $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} 1 \times \mathrm{C} 1$. If this criteria is met the current sense signal will be the same shape as the inductor current, the voltage signal at Cx will represent the instantaneous value of inductor current and the circuit can be analyzed as if a sense resistor of value $R_{L}$ was used as a sense resistor $\left(\mathrm{R}_{\mathrm{S}}\right)$.

Figure 11. Lossless Inductive Current Sensing with Enhanced $\mathbf{V}^{2}$
When choosing or designing inductors for use with inductive sensing, tolerances and temperature effects should be considered. Cores with a low permeability material or a large gap will usually have minimal inductance change with temperature and load. Copper magnet wire has a temperature coefficient of $0.39 \%$ per ${ }^{\circ} \mathrm{C}$. The increase in winding resistance at higher temperatures should be
considered when setting the $\mathrm{I}_{\text {LIM }}$ threshold. If a more accurate current sense is required than inductive sensing can provide, current can be sensed through a resistor as shown in Figure 9.

## Current Sharing Accuracy

PCB traces that carry inductor current can be used as part of the current sense resistance depending on where the current sense signal is picked off. For accurate current sharing, the current sense inputs should sense the current at the same point for each phase and the connection to the $\mathrm{CS}_{\text {REF }}$ should be made so that no phase is favored. (In some cases, especially with inductive sensing, resistance of the pcb can be useful for increasing the current sense resistance.) The total current sense resistance used for calculations must include any pcb trace between the CS inputs and the $\mathrm{CS}_{\text {REF }}$ input that carries inductor current.

Current Sense Amplifier Input Mismatch and the value of the current sense element will determine the accuracy of current sharing between phases. The worst case Current Sense Amplifier Input Mismatch is 5.0 mV and will typically be within 3.0 mV . The difference in peak currents between phases will be the CSA Input Mismatch divided by the current sense resistance. If all current sense elements are of equal resistance, a 3.0 mV mismatch with a $2.0 \mathrm{~m} \Omega$ sense resistance will produce a 1.5 A difference in current between phases.

## Operation at > 50\% Duty Cycle

For operation at duty cycles above $50 \%$ Enhanced V ${ }^{2}$ will exhibit subharmonic oscillation unless a compensation ramp is added to each phase. A circuit like the one on the left side of Figure 12 can be added to each current sense network to implement slope compensation. The value of R1 can be varied to adjust the ramp size.

Figure 12. External Slope Compensation Circuit

## Ramp Size and Current Sensing

Because the current ramp is used for both the PWM ramp and to sense current, the inductor and sense resistor values will be constrained. A small ramp will provide a quick transient response by minimizing the difference over which the COMP pin must travel between light and heavy loads, but a steady state ramp of $25 \mathrm{mV}_{\mathrm{P}-\mathrm{P}}$ or greater is typically required to prevent pulse skipping and minimize pulse width jitter. For resistive current sensing, the combination of the inductor and sense resistor values must be chosen to provide a large enough steady state ramp. For large inductor values the sense resistor value must also be increased.

For inductive current sensing the RC network must meet the requirement of $L / R_{L}=R \times C$ to accurately sense the $A C$ and DC components of the current the signal. Again the values for L and $\mathrm{R}_{\mathrm{L}}$ will be constrained in order to provide a large enough steady state ramp with a compensated current sense signal. A smaller $L$, or a larger $R_{L}$ than optimum might be required. But unlike resistive sensing, with inductive sensing small adjustments can be made easily with the values of R and C to increase the ramp size if needed.

If RC is chosen to be smaller (faster) than $\mathrm{L} / \mathrm{R}_{\mathrm{L}}$, the AC portion of the current sensing signal will be scaled larger than the DC portion. This will provide a larger steady state ramp, but circuit performance will be affected and must be evaluated carefully. The current signal will overshoot during transients and settle at the rate determined by $\mathrm{R} \times \mathrm{C}$. It will eventually settle to the correct DC level, but the error will decay with the time constant of $\mathrm{R} \times \mathrm{C}$. If this error is excessive it will effect transient response, adaptive positioning and current limit. During transients, the COMP pin will be required to overshoot along with the current signal in order to maintain the output voltage. The $\mathrm{V}_{\mathrm{DRP}}$ pin will also overshoot during transients and possibly slow the response. Single phase overcurrent will trip earlier than it would if compensated correctly and hiccup mode current limit will have a lower threshold for fast rise step loads than for slowly rising output currents.

The waveforms in Figure 13 show a simulation of the current sense signal and the actual inductor current during a positive step in load current with values of $\mathrm{L}=500 \mathrm{nH}$, $\mathrm{R}_{\mathrm{L}}=1.6 \mathrm{~m} \Omega, \mathrm{R} 1=20 \mathrm{k}$ and $\mathrm{C} 1=.01 \mu \mathrm{~F}$. For ideal current signal compensation the value of R1 should be $31 \mathrm{k} \Omega$. Due to the faster than ideal RC time constant there is an overshoot of $50 \%$ and the overshoot decays with a $200 \mu \mathrm{~s}$ time constant. With this compensation the $\mathrm{I}_{\text {LIM }}$ pin threshold must be set more than $50 \%$ above the full load current to avoid triggering hiccup mode during a large output load step.

Figure 13. Inductive Sensing waveform during a Load Step with Fast RC Time Constant ( $50 \mu \mathrm{~s} / \mathrm{div}$ )

## Current Limit

Two levels of overcurrent protection are provided. Any time the voltage on a Current Sense pin exceeds CS REF by more than the Single Phase Pulse by Pulse Current Limit, the PWM comparator for that phase is turned off. This provides fast peak current protection for individual phases. The outputs of all the currents are also summed and filtered to compare an averaged current signal to the voltage on the $\mathrm{I}_{\text {LIM }}$ pin. If this voltage is exceeded, the fault latch trips and the Soft Start capacitor is discharged by a $7.5 \mu \mathrm{~A}$ source until the COMP pin reaches 0.2 V . Then Soft-Start begins. The converter will continue to operate in this mode until the fault condition is corrected.

## Overvoltage Protection

Overvoltage protection (OVP) is provided as a result of the normal operation of the Enhanced $V^{2}$ control topology with synchronous rectifiers. The control loop responds to an overvoltage condition within 400 ns , causing the top MOSFET's to shut off, and the synchronous MOSFET's to turn on. This results in a "crowbar" action to clamp the output voltage and prevent damage to the load. The regulator will remain in this state until the overvoltage condition ceases or the input voltage is pulled low.

## Transient Response and Adaptive Positioning

For applications with fast transient currents the output filter is frequently sized larger than ripple currents require in
order to reduce voltage excursions during transients. Adaptive voltage positioning can reduce peak-peak output voltage deviations during load transients and allow for a smaller output filter. The output voltage can be set higher than nominal at light loads to reduce output voltage sag when the load current is stepped up and set lower than nominal during heavy loads to reduce overshoot when the load current is stepped up. For low current applications a droop resistor can provide fast accurate adaptive positioning. However at high currents, the loss in a droop resistor becomes excessive. For example, in a 50 A converter a $1.0 \mathrm{~m} \Omega$ resistor to provide a 50 mV change in output voltage between no load and full load would dissipate 2.5 Watts.

Lossless adaptive positioning is an alternative to using a droop resistor, but must respond quickly to changes in load current. Figure 14 shows how adaptive positioning works. The waveform labeled normal shows a converter without adaptive positioning. On the left, the output voltage sags when the output current is stepped down and later overshoots when current is stepped back down. With fast (ideal) adaptive positioning the peak to peak excursions are cut in half. In the slow adaptive positioning waveform the output voltage is not repositioned quickly enough after current is stepped up and the upper limit is exceeded.

Figure 14. Adaptive Positioning
The CS5332 can be configured to adjust the output voltage based on the output current of the converter. (Refer to Figure 1.)

To set the no-load positioning, a resistor is placed between the output voltage and $\mathrm{V}_{\mathrm{FB}}$ pin. The $\mathrm{V}_{\mathrm{FB}}$ bias current will develop a voltage across the resistor to decrease the output voltage. The $\mathrm{V}_{\mathrm{FB}}$ bias current is dependent on the value of $\mathrm{R}_{\mathrm{OSC}}$. See Figure 4 on the datasheet.

During no load conditions the $\mathrm{V}_{\mathrm{DRP}}$ pin is at the same voltage as the $\mathrm{V}_{\mathrm{FB}}$ pin, so none of the $\mathrm{V}_{\mathrm{FB}}$ bias current flows through the $\mathrm{V}_{\text {DRP }}$ resistor. When output current increases the $\mathrm{V}_{\mathrm{DRP}}$ pin increases proportionally and the $\mathrm{V}_{\mathrm{DRP}}$ pin current offsets the $\mathrm{V}_{\mathrm{FB}}$ bias current and causes the output voltage to decrease.

The $\mathrm{V}_{\mathrm{FB}}$ and $\mathrm{V}_{\mathrm{DRP}}$ pins take care of the slower and DC voltage positioning. The first few $\mu$ s are controlled primarily by the ESR and ESL of the output filter. The transition between fast and slow positioning is controlled by the ramp size and the error amp compensation. If the ramp size is too large or the error amp too slow there will be a long transition
to the final voltage after a transient. This will be most apparent with lower capacitance output filters.

Note: Large levels of adaptive positioning can cause pulse width jitter.

## Error Amp Compensation

The transconductance error amplifier requires a capacitor between the COMP pin and GND. Use of values less than 1.0 nF may result in error amp oscillation of several MHz .

The capacitor between the COMP pin and the inverting error amplifier input and the parallel resistance of the $\mathrm{V}_{\mathrm{FB}}$ resistor and the $\mathrm{V}_{\mathrm{DRP}}$ resistor are used to roll off the error amp gain. The gain is rolled off at a high enough frequency to give a quick transient response, but low enough to cross zero dB well below the switching frequency to minimize ripple and noise on the COMP pin.

## UVLO

The CS5332 has undervoltage lockout functions connected to two pins. One, intended for the logic and low-side drivers, with a 4.4 V turn-on threshold is connected to the $\mathrm{V}_{\text {CCL }}$ pin. A second, for the high side drivers, has a 2.0 V threshold and is connected to the $\mathrm{V}_{\mathrm{CCH} 1}$ pin.

The UVLO threshold for the high side drivers was chosen at a low value to allow for flexibility in the part and an input voltage as low as 3.3 V . In many applications this will be disabled or will only check that the applicable supply is on - not that it is at a high enough voltage to run the converter.

For the $12 \mathrm{~V}_{\text {IN }}$ converter in Figure 1. the UVLO pin for the high side driver is pulled up by the 5.0 V supply (through two diode drops) and the function is not used. The diode between the Soft Start pin and the 12 V supply holds the Soft Start pin near GND and prevents start-up while the 12 V supply is off. In an application where a higher UVLO threshold is necessary a circuit like the one in Figure 15 will lock out the converter until the 12 V supply exceeds 9.0 V .

Figure 15. External UVLO Circuit

## Remote Sense

In some applications that require remote output voltage sensing, there are conditions when the path of the feedback signal can be broken. In a voltage regulator module (VRM) the remote voltage feedback sense point is typically off the
module. If the module is powered apart from the intended application, the feedback will be left open. On a motherboard, the feedback path might be broken when the processor socket is left open. Without the feedback connection the output voltage is likely to exceed the intended voltage. To protect the circuit from overvoltage conditions, a resistor can be connected between the local output voltage and the remote sense line as shown in Figure 16.

Figure 16. Remote Sense Connection

## Soft Start Enable, and Hiccup Mode

A capacitor between the Soft Start pin and GND controls Soft Start and hiccup mode slopes. A $0.1 \mu \mathrm{~F}$ capacitor with $30 \mu \mathrm{~A}$ charge current will allow the output to ramp up at 0.3 $\mathrm{V} / \mathrm{ms}$ or 1.5 V in 5.0 ms at start-up.

When a fault is detected due to overcurrent or UVLO the converter will enter a low duty cycle hiccup mode. During hiccup mode the converter will not switch from the time a fault is detected until the Soft Start capacitor has discharged below the Soft Start Discharge Threshold and then charged back up above the Channel Start Up Offset.

The Soft Start pin will disable the converter when pulled below 0.3 V .

## Layout Guidelines

With the fast rise, high output currents of microprocessor applications, parasitic inductance and resistance should be
considered when laying out the power, filter and feedback signal sections of the board. Typically, a multi-layer board with at least one ground plane is recommended. If the layout is such that high currents can exist in the ground plane underneath the controller or control circuitry, the ground plane can be slotted to reroute the currents away from the controller. The slots should typically not be placed between the controller and the output voltage or in the return path of the gate drive. Additional power and ground planes or islands can be added as required for a particular layout.

Gate drives experience high di/dt during switching and the inductance of gate drive traces should be minimized. Gate drive traces should be kept as short and wide as practical and should have a return path directly below the gate trace.

Output filter components should be placed on wide planes connected directly to the load to minimize resistive drops during heavy loads and inductive drops and ringing during transients. If required, the planes for the output voltage and return can be interleaved to minimize inductance between the filter and load.

Voltage feedback should be taken from a point of the output or the output filter that doesn't favor any one phase. If the feedback connection is closer to one inductor than the others the ripple associated with that phase may appear larger than the ripple associated with the other phases and poor current sharing can result.

The current sense signal is typically tens of milli-volts. Noise pick-up should be avoided wherever possible. Current feedback traces should be routed away from noisy areas such as switch nodes and gate drive signals. The paths should be matched as well as possible. It is especially important that all current sense signals be picked off at similar points for accurate current sharing. If the current signal is taken from a place other than directly at the inductor any additional resistance between the pick-off point and the inductor appears as part of the inherent inductor resistance and should be considered in design calculations. Capacitors for the current feedback networks should be placed as close to the current sense pins as practical.

## DESIGN PROCEDURE

## Current Sensing, Power Stage and Output Filter Components

1. Choose the output filter components to meet peak transient requirements. The formula below can be used to provide an approximate starting point for capacitor choice, but will be inadequate to calculate actual values.

$$
\Delta \mathrm{V}_{\mathrm{PEAK}}=(\Delta \mathrm{I} / \Delta \mathrm{T}) \times \mathrm{ESL}+\Delta \mathrm{I} \times \mathrm{ESR}
$$

Ideally the output filter should be simulated with models including ESR, ESL, circuit board parasitics and delays due to switching frequency and converter response. Typically both bulk capacitance (electrolytic, Oscon, etc,) and low impedance capacitance (ceramic chip) will be required. The bulk capacitance provides "hold up" during the converter response. The low impedance capacitance reduces steady state ripple and bypasses the bulk capacitance during slewing of output current.
2. For inductive current sensing (only) choose the current sense network RC to provide a 25 mV minimum ramp during steady state operation.

$$
R=\left(V_{\text {IN }}-V_{\text {OUT }}\right) \times \frac{V_{\text {OUT }} / V_{\text {IN }}}{F \times C \times 25 \mathrm{mV}}
$$

Then choose the inductor value and inherent resistance to satisfy $\mathrm{L} / \mathrm{R}_{\mathrm{L}}=\mathrm{R} \times \mathrm{C}$.
For ideal current sense compensation the ratio of $L$ and $R_{L}$ is fixed, so the values of $L$ and $R_{L}$ will be a compromise typically with the maximum value $\mathrm{R}_{\mathrm{L}}$ limited by conduction losses or inductor temperature rise and the minimum value of L limited by ripple current.
3. For resistive current sensing choose L and $\mathrm{R}_{\mathrm{S}}$ to provide a steady state ramp greater than 25 mV .

$$
\mathrm{L} / \mathrm{RS}_{\mathrm{S}}=\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times \mathrm{TON} / 25 \mathrm{mV}
$$

Again the ratio of $L$ and $R_{L}$ is fixed and the values of L and $\mathrm{R}_{\mathrm{S}}$ will be a compromise.
4. Calculate the high frequency output impedance (ConverterZ) of the converter during transients. This is the impedance of the Output filter ESR in parallel with the power stage output impedance (PwrstgZ) and will indicate how far from the original level ( $\Delta \mathrm{VR}$ ) the output voltage will typically recover to within one switching cycle. For a good transient response $\Delta \mathrm{VR}$ should be less than the peak output voltage overshoot or undershoot.

$$
\begin{array}{r}
\Delta \mathrm{VR}=\text { ConverterZ } \times \mathrm{ESR} \\
\text { ConverterZ }=\frac{\text { PwrstgZ } \times \mathrm{ESR}}{\text { PwrstgZ }+\mathrm{ESR}}
\end{array}
$$

where:

$$
\text { PwrstgZ }=R_{S} \times \text { CSA Gain/2.0 }
$$

Multiply the converterZ by the output current step size to calculate where the output voltage should recover to within the first switching cycle after a transient. If the ConverterZ is higher than the value required to recover to where the adaptive positioning is set, the remainder of the recovery will be controlled by the error amp compensation and will typically recover in $10-20 \mu \mathrm{~s}$.

$$
\Delta \mathrm{VR}=\Delta \mathrm{I} \text { OUT } \times \text { ConverterZ }
$$

Make sure that $\Delta \mathrm{VR}$ is less than the expected peak transient for a good transient response.
5. Adjust L and $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ as required to meet the best combination of transient response, steady state output voltage ripple and pulse width jitter.

## Current Limit

When the sum of the Current Sense amplifiers ( $\mathrm{V}_{\text {ITOTAL }}$ ) exceeds the voltage on the $\mathrm{I}_{\text {LIM }}$ pin the part will enter hiccup mode. For inductive sensing the $\mathrm{I}_{\text {LIM }}$ pin voltage should be set based on the inductor resistance (or current sense resistor) at max temperature and max current. To set the level of the $\mathrm{I}_{\text {LIM }}$ pin:
6. $\mathrm{V}_{\mathrm{I}(\mathrm{LIM})}=\mathrm{R} \times \operatorname{IOUT}(\mathrm{LIM}) \times \mathrm{CS}$ to ILIM Gain
where:
R is $\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$;
$\mathrm{I}_{\mathrm{OUT}(\mathrm{LIM})}$ is the current limit threshold.
For the overcurrent to work properly the inductor time constant (L/R) should be $\leq$ the Current sense RC. If the RC is too fast, during step loads the current waveform will appear larger than it is (typically for a few hundred $\mu \mathrm{s}$ ) and may trip the current limit at a level lower than the DC limit.

## Adaptive Positioning

7. To set the amount of voltage positioning below the DAC setting at no load, connect a resistor $\left(\mathrm{R}_{\mathrm{V}}(\mathrm{FB})\right)$ between the output voltage and the $\mathrm{V}_{\mathrm{FB}}$ pin. Choose $\mathrm{R}_{\mathrm{V}}(\mathrm{FB})$ as;

$$
R V(F B)=N L \text { Position } / V_{F B} \text { Bias Current }
$$

See Figure 4 for $V_{\text {FB }}$ Bias Current.
8. To set the difference in output voltage between no load and full load, connect a resistor $\left(\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}\right)$ between the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pins. $\mathrm{R}_{\mathrm{V} \text { (DRP) }}$ can be calculated in two steps. First calculate the difference between the $\mathrm{V}_{\mathrm{DRP}}$ and $\mathrm{V}_{\mathrm{FB}}$ pin at full load. (The $\mathrm{V}_{\mathrm{FB}}$ voltage should be the same as the DAC voltage during closed loop operation.) Then choose the $\mathrm{R}_{\mathrm{V}(\mathrm{DRP})}$ to source enough current across $\mathrm{R}_{\mathrm{V}}(\mathrm{FB})$ for the desired change in output voltage.

$$
\Delta \mathrm{V}_{\mathrm{V}(\mathrm{DRP})}=\mathrm{IOUTFL} \times \mathrm{R} \times \mathrm{CS} \text { to } \mathrm{V}_{\mathrm{DRP}} \text { Gain }
$$

where:
$\mathrm{R}=\mathrm{R}_{\mathrm{L}}$ or $\mathrm{R}_{\mathrm{S}}$ for one phase;
IOUTFL is the full load output current.

$$
\mathrm{RV}(\mathrm{DRP})=\Delta \mathrm{V}_{\mathrm{DRP}} \times \operatorname{RV}(\mathrm{FB}) / \Delta \mathrm{V}_{\mathrm{OUT}}
$$

## Calculate Input Filter Capacitor Current Ripple

The procedure below assumes that phases do not overlap and output inductor ripple current $(\mathrm{P}-\mathrm{P})$ is less than the average output current of one phase.
9. Calculate Input Current
$\mathrm{IIN}_{\mathrm{N}}=\frac{\mathrm{V}_{\text {OUT }} \times \mathrm{IOUT}}{\left(\text { Efficiency } \times \mathrm{V}_{\text {IN }}\right)}$
10. Calculate Duty Cycle (per phase).

## Duty Cycle $=\frac{\mathrm{V}_{\text {OUT }}}{\left(\text { Efficiency } \times \mathrm{V}_{\text {IN }}\right)}$

11. Calculate Apparent Duty Cycle.

Apparent Duty Cycle $=$ Duty Cycle $\times \#$ of Phases
12. Calculate Input Filter Capacitor Ripple Current. Use the chart in Figure 17 to calculate the normalized ripple current ( $\mathrm{K}_{\mathrm{RMS}}$ ) based on the reciprocal of Apparent Duty Cycle. Then multiply the input current by $\mathrm{K}_{\mathrm{RMS}}$ to obtain the Input Filter Capacitor Ripple Current.

Figure 17. Normalized Input Filter Capacitor Ripple Current

## DESIGN EXAMPLE

Choose the component values for a $240 \mathrm{kHz}, 12 \mathrm{~V}$ to 1.525 V, 41 A converter with lossless current sensing, adaptive positioning and a 50 A current limit. The adaptive positioning is chosen 50 mV below the DAC setting at no load and 50 mV below the no-load position with 41 A out. The peak output voltage transient is 70 mV max during a 41 A step current.

## Current Sensing, Power Stage and Output Filter Components

1.Assume $1.5 \mathrm{~m} \Omega$ of output filter ESR.

$$
\begin{aligned}
& \text { 2.R } \begin{aligned}
& =\left(\mathrm{V}_{\mathrm{IN}}-\mathrm{V}_{\mathrm{OUT}}\right) \times\left(\mathrm{V}_{\mathrm{OUT}} / \mathrm{V} \mathrm{IN}\right) /(\mathrm{F} \times \mathrm{C} \times 25 \mathrm{mV}) \\
& =(12-1.55) \times(1.55 / 12) /(240 \mathrm{k} \times .01 \mu \mathrm{~F} \times 25 \mathrm{mV}) \\
& =22.5 \mathrm{k}
\end{aligned} \\
& \mathrm{~L} / \mathrm{R}_{\mathrm{L}}=.01 \mu \mathrm{~F} \times 22.5 \mathrm{k} \Omega=225 \mu \mathrm{~s} \\
& \begin{aligned}
\text { Choose } R \mathrm{~L} & =2.0 \mathrm{~m} \Omega
\end{aligned} \\
& \begin{aligned}
& \mathrm{L}=2.0 \mathrm{~m} \Omega \times 225 \mu \mathrm{~s}=450 \mathrm{nH} \\
& \text { 3. } \mathrm{n} / \mathrm{a}
\end{aligned} \\
& \begin{aligned}
\text { 4. } \text { PwrstgZ } & =R_{\mathrm{L}} \times \mathrm{CSA} \text { Gain } / 2.0 \\
& =2.0 \mathrm{~m} \Omega \times 3.15 / 2=3.1 \mathrm{~m} \Omega
\end{aligned}
\end{aligned}
$$

$$
\text { ConverterZ }=\frac{\text { PwrstgZ } \times \text { ESR }}{\text { PwrstgZ }+ \text { ESR }}
$$

$$
=\frac{3.1 \mathrm{~m} \Omega \times 1.5 \mathrm{~m} \Omega}{3.1 \mathrm{~m} \Omega+1.5 \mathrm{~m} \Omega} \cong 1.0 \mathrm{~m} \Omega
$$

$$
\Delta \mathrm{VR}=1.0 \mathrm{~m} \Omega \times 41 \mathrm{~A}=41 \mathrm{mV}
$$

5. n/a

## Current Limit

$$
\text { 6. } \begin{aligned}
\mathrm{V}_{\mathrm{I}(\mathrm{LIM})} & =\mathrm{R}_{\mathrm{L}} \times \operatorname{IOUT}(\mathrm{LIM}) \times \mathrm{CS} \text { to ILIM Gain } \\
& =2.0 \mathrm{~m} \Omega \times 50 \mathrm{~A} \times 6.25=625 \mathrm{mV}
\end{aligned}
$$

## Adaptive Positioning

$$
\text { 7. } \begin{aligned}
& \mathrm{RV}(\mathrm{FB})=\mathrm{NL} \text { Position } / \mathrm{V} \text { FB Bias Current } \\
&=50 \mathrm{mV} / 18 \mu \mathrm{~A}=2.78 \mathrm{k} \Omega \\
& \text { 8. } \begin{aligned}
\Delta \mathrm{V} R \mathrm{DP} & =\mathrm{R}_{\mathrm{L}} \times \mathrm{IOUT} \times \mathrm{Current} \text { Sense to } \mathrm{V} \text { DRP Gain } \\
& =2.0 \mathrm{~m} \Omega \times 41 \mathrm{~A} \times 3.1=254 \mathrm{mV} \\
\mathrm{RV}(\mathrm{DRP}) & =\Delta \mathrm{V} \mathrm{DRP} \times \mathrm{RV}(\mathrm{FB}) / \Delta \mathrm{V}_{\mathrm{OUT}} \\
& =254 \mathrm{mV} \times 2.78 \mathrm{k} \Omega / 50 \mathrm{mV}=25.4 \mathrm{k} \Omega
\end{aligned}
\end{aligned}
$$

9. $\mathrm{I}_{\mathrm{I}} \mathrm{N}=\frac{1.52 \mathrm{~V} \times 41 \mathrm{~A}}{\left(0.85 \times 12 \mathrm{~V}_{\mathrm{IN}}\right)}=6.1 \mathrm{~A}$
10. Duty Cycle $=\frac{1.52 \mathrm{~V}}{(0.85 \times 12 \mathrm{~V} \text { IN })}=0.15$
11. Apparent Duty Cycle $=0.15 \times 2.0=0.3$
12. RMS ripple is $6.1 \mathrm{~A} \times 1.5=9.2 \mathrm{~A}$

## MC33501, MC33503

### 1.0 V, Rail-to-Rail, Single Operational Amplifiers

The MC33501/503 operational amplifier provides rail-to-rail operation on both the input and output. The output can swing within 50 mV of each rail. This rail-to-rail operation enables the user to make full use of the entire supply voltage range available. It is designed to work at very low supply voltages ( 1.0 V and ground), yet can operate with a supply of up to 7.0 V and ground. Output current boosting techniques provide high output current capability while keeping the drain current of the amplifier to a minimum.

- Low Voltage, Single Supply Operation (1.0 V and Ground to 7.0 V and Ground)
- High Input Impedance: Typically 40 fA Input Bias Current
- Typical Unity Gain Bandwidth @ 5.0 V = 4.0 MHz, @ $1.0 \mathrm{~V}=3.0 \mathrm{MHz}$
- High Output Current ( $\mathrm{I}_{\mathrm{SC}}=40 \mathrm{~mA} @ 5.0 \mathrm{~V}, 13 \mathrm{~mA} @ 1.0 \mathrm{~V}$ )
- Output Voltage Swings within 50 mV of Both Rails @ 1.0 V
- Input Voltage Range Includes Both Supply Rails
- High Voltage Gain: 100 dB Typical @ 1.0 V
- No Phase Reversal on the Output for Over-Driven Input Signals
- Input Offset Trimmed to 0.5 mV Typical
- Low Supply Current ( $\mathrm{I}_{\mathrm{D}}=1.2 \mathrm{~mA} /$ per Amplifier, Typical)
- $600 \Omega$ Drive Capability
- Extended Operating Temperature Range ( -40 to $105^{\circ} \mathrm{C}$ )

## Applications

- Single Cell NiCd/Ni MH Powered Systems
- Interface to DSP
- Portable Communication Devices
- Low Voltage Active Filters
- Telephone Circuits
- Instrumentation Amplifiers
- Audio Applications
- Power Supply Monitor and Control
- Transistor Count: 98

Figure 2. Representative Block Diagram

## General Information

The MC33501/503 dual operational amplifier is unique in its ability to provide 1.0 V rail-to-rail performance on both the input and output by using a SMARTMOS ${ }^{T M}$ process. The amplifier output swings within 50 mV of both rails and is able to provide 50 mA of output drive current with a 5.0 V supply, and 10 mA with a 1.0 V supply. A 5.0 MHz bandwidth and a slew rate of $3.0 \mathrm{~V} / \mu \mathrm{s}$ is achieved with high speed depletion mode NMOS (DNMOS) and vertical PNP transistors. This device is characterized over a temperature range of $-40^{\circ} \mathrm{C}$ to $105^{\circ} \mathrm{C}$.

## Circuit Information

## Input Stage

One volt rail-to-rail performance is achieved in the MC33501/503 at the input by using a single pair of depletion mode NMOS devices (DNMOS) to form a differential amplifier with a very low input current of 40 fA . The normal input common mode range of a DNMOS device, with an ion implanted negative threshold, includes ground and relies on the body effect to dynamically shift the threshold to a positive value as the gates are moved from ground towards the positive supply. Because the device is manufactured in a p-well process, the body effect coefficient is sufficiently large to ensure that the input stage will remain substantially saturated when the inputs are at the positive rail. This also applies at very low supply voltages. The 1.0 V rail-to-rail input stage consists of a DNMOS differential amplifier, a folded cascode, and a low voltage balanced mirror. The low voltage cascoded balanced mirror provides high 1st stage gain and base current cancellation without sacrificing signal integrity. Also, the input offset voltage is trimmed to less than 1.0 mV because of the limited available supply voltage. The body voltage of the input DNMOS differential pair is internally trimmed to minimize the input offset voltage. A common mode feedback path is also employed to enable the offset voltage to track over the input common mode voltage. The total operational amplifier quiescent current drop is $1.3 \mathrm{~mA} / \mathrm{amp}$.

## Output Stage

An additional feature of this device is an "on demand" base current cancellation amplifier. This feature provides base drive to the output power devices by making use of a buffer amplifier to perform a voltage-to-current conversion. This is done in direct proportion to the load conditions. This "on demand" feature allows these amplifiers to consume only a few micro-amps of current when the output stage is in its quiescent mode. Yet it provides high output current when required by the load. The rail-to-rail output stage current boost circuit provides 50 mA of output current with a 5.0 V supply (For a 1.0 V supply output stage will do 10 mA ) enabling the operational amplifier to drive a $600 \Omega$ load. A buffer is necessary to isolate the load current effects in the output stage from the input stage. Because of the low voltage conditions, a DNMOS follower is used to provide an essentially zero voltage level shift. This buffer isolates any load current changes on the output stage from loading the input stage. A high speed vertical PNP transistor provides excellent frequency performance while sourcing current. The operational amplifier is also internally compensated to provide a phase margin of 60 degrees. It has a unity gain of 5.0 MHz with a 5.0 V supply and 4.0 MHz with a 1.0 V supply.

## Low Voltage Operation

The MC33501/503 will operate at supply voltages from 0.9 to 7.0 V and ground. When using the MC33501/503 at supply voltages of less than 1.2 V , input offset voltage may increase slightly as the input signal swings within approximately 50 mV of the positive supply rail. This effect occurs only for supply voltages below 1.2 V , due to the input depletion mode MOSFETs starting to transition between the saturated to linear region, and should be considered when designing high side dc sensing applications operating at the positive supply rail. Since the device is rail-to-rail on both input and output, high dynamic range single battery cell applications are now possible.

## MC33502

### 1.0 V, Rail-to-Rail, Dual Operational Amplifier

The MC33502 operational amplifier provides rail-to-rail operation on both the input and output. The output can swing within 50 mV of each rail. This rail-to-rail operation enables the user to make full use of the entire supply voltage range available. It is designed to work at very low supply voltages ( 1.0 V and ground), yet can operate with a supply of up to 7.0 V and ground. Output current boosting techniques provide high output current capability while keeping the drain current of the amplifier to a minimum.

- Low Voltage, Single Supply Operation (1.0 V and Ground to 7.0 V and Ground)
- High Input Impedance: Typically 40 fA Input Current
- Typical Unity Gain Bandwidth @ 5.0 V = 5.0 MHz, @ $1.0 \mathrm{~V}=4.0 \mathrm{MHz}$
- High Output Current ( $\mathrm{I}_{\mathrm{SC}}=40 \mathrm{~mA} @ 5.0 \mathrm{~V}, 13 \mathrm{~mA} @ 1.0 \mathrm{~V}$ )
- Output Voltage Swings within 50 mV of Both Rails @ 1.0 V
- Input Voltage Range Includes Both Supply Rails
- High Voltage Gain: 100 dB Typical @ 1.0 V
- No Phase Reversal on the Output for Over-Driven Input Signals
- Input Offset Trimmed to 0.5 mV Typical
- Low Supply Current ( $\mathrm{I}_{\mathrm{D}}=1.2 \mathrm{~mA} /$ per Amplifier, Typical)
- $600 \Omega$ Drive Capability
- Extended Operating Temperature Range ( -40 to $105^{\circ} \mathrm{C}$ )

## Applications

- Single Cell NiCd/Ni MH Powered Systems
- Interface to DSP
- Portable Communication Devices
- Low Voltage Active Filters
- Telephone Circuits
- Instrumentation Amplifiers
- Audio Applications
- Power Supply Monitor and Control
- Compatible with VCX Logic

## General Information

The MC33502 dual operational amplifier is unique in its ability to provide 1.0 V rail-to-rail performance on both the input and output by using a SMARTMOS ${ }^{T M}$ process. The amplifier output swings within 50 mV of both rails and is able to provide 50 mA of output drive current with a 5.0 V supply, and 10 mA with a 1.0 V supply. A 5.0 MHz bandwidth and a slew rate of $3.0 \mathrm{~V} / \mu$ s is achieved with high speed depletion mode NMOS (DNMOS) and vertical PNP transistors. This device is characterized over a temperature range of $-40^{\circ} \mathrm{C}$ to $105^{\circ} \mathrm{C}$.

## Circuit Information

## Input Stage

One volt rail-to-rail performance is achieved in the MC33502 at the input by using a single pair of depletion mode NMOS devices (DNMOS) to form a differential amplifier with a very low input current of 40 fA . The normal input common mode range of a DNMOS device, with an ion implanted negative threshold, includes ground and relies on the body effect to dynamically shift the threshold to a positive value as the gates are moved from ground towards the positive supply. Because the device is manufactured in a p-well process, the body effect coefficient is sufficiently large to ensure that the input stage will remain substantially saturated when the inputs are at the positive rail. This also applies at very low supply voltages. The 1.0 V rail-to-rail input stage consists of a DNMOS differential amplifier, a folded cascode, and a low voltage balanced mirror. The low voltage cascoded balanced mirror provides high 1st stage gain and base current cancellation without sacrificing signal integrity. Also, the input offset voltage is trimmed to less than 1.0 mV because of the limited available supply voltage. The body voltage of the input DNMOS differential pair is internally trimmed to minimize the input offset voltage. A common mode feedback path is also employed to enable the offset voltage to track over the input common mode voltage. The total operational amplifier quiescent current drop is $1.3 \mathrm{~mA} / \mathrm{amp}$.

## Output Stage

An additional feature of this device is an "on demand" base current cancellation amplifier. This feature provides base drive to the output power devices by making use of a buffer amplifier to perform a voltage-to-current conversion. This is done in direct proportion to the load conditions. This "on demand" feature allows these amplifiers to consume only a few micro-amps of current when the output stage is in its quiescent mode. Yet it provides high output current when required by the load. The rail-to-rail output stage current boost circuit provides 50 mA of output current with a 5.0 V supply (For a 1.0 V supply output stage will do 10 mA ) enabling the operational amplifier to drive a $600 \Omega$ load. A buffer is necessary to isolate the load current effects in the output stage from the input stage. Because of the low voltage conditions, a DNMOS follower is used to provide an essentially zero voltage level shift. This buffer isolates any load current changes on the output stage from loading the input stage. A high speed vertical PNP transistor provides excellent frequency performance while sourcing current. The operational amplifier is also internally compensated to provide a phase margin of 60 degrees. It has a unity gain of 5.0 MHz with a 5.0 V supply and 4.0 MHz with a 1.0 V supply.

## Low Voltage Operation

The MC33502 will operate at supply voltages from 0.9 to 7.0 V and ground. When using the MC33502 at supply voltages of less than 1.2 V , input offset voltage may increase slightly as the input signal swings within approximately 50 mV of the positive supply rail. This effect occurs only for supply voltages below 1.2 V , due to the input depletion mode MOSFETs starting to transition between the saturated to linear region, and should be considered when designing high side dc sensing applications operating at the positive supply rail. Since the device is rail-to-rail on both input and output, high dynamic range single battery cell applications are now possible.

## Low Voltage, Rail-to-Rail Operational Amplifiers

The MC33201/2/4 family of operational amplifiers provide rail-to-rail operation on both the input and output. The inputs can be driven as high as 200 mV beyond the supply rails without phase reversal on the outputs, and the output can swing within 50 mV of each rail. This rail-to-rail operation enables the user to make full use of the supply voltage range available. It is designed to work at very low supply voltages ( $\pm 0.9 \mathrm{~V}$ ) yet can operate with a supply of up to +12 V and ground. Output current boosting techniques provide a high output current capability while keeping the drain current of the amplifier to a minimum. Also, the combination of low noise and distortion with a high slew rate and drive capability make this an ideal amplifier for audio applications.

- Low Voltage, Single Supply Operation
(+1.8 V and Ground to +12 V and Ground)
- Input Voltage Range Includes both Supply Rails
- Output Voltage Swings within 50 mV of both Rails
- No Phase Reversal on the Output for Over-driven Input Signals
- High Output Current ( $\mathrm{I}_{\mathrm{SC}}=80 \mathrm{~mA}$, Typ)
- Low Supply Current ( $\mathrm{I}_{\mathrm{D}}=0.9 \mathrm{~mA}$, Typ)
- $600 \Omega$ Output Drive Capability
- Extended Operating Temperature Ranges
$\left(-40^{\circ}\right.$ to $+105^{\circ} \mathrm{C}$ and $-55^{\circ}$ to $\left.+125^{\circ} \mathrm{C}\right)$
- Typical Gain Bandwidth Product $=2.2 \mathrm{MHz}$

1. The differential input voltage of each amplifier is limited by two internal parallel back-to-back diodes. For additional differential input voltage range, use current limiting resistors in series with the input pins.
2. The input common mode voltage range is limited by internal diodes connected from the inputs to both supply rails. Therefore, the voltage on either input must not exceed either supply rail by more than 500 mV .
3. Power dissipation must be considered to ensure maximum junction temperature ( $\mathrm{T}_{\mathrm{J}}$ ) is not exceeded. (See Figure 2)

## DETAILED OPERATING DESCRIPTION

## General Information

The MC33201/2/4 family of operational amplifiers are unique in their ability to swing rail-to-rail on both the input and the output with a completely bipolar design. This offers low noise, high output current capability and a wide common mode input voltage range even with low supply voltages. Operation is guaranteed over an extended temperature range and at supply voltages of $2.0 \mathrm{~V}, 3.3 \mathrm{~V}$ and 5.0 V and ground.

Since the common mode input voltage range extends from $\mathrm{V}_{\mathrm{CC}}$ to $\mathrm{V}_{\mathrm{EE}}$, it can be operated with either single or split voltage supplies. The MC33201/2/4 are guaranteed not to latch or phase reverse over the entire common mode range, however, the inputs should not be allowed to exceed maximum ratings.

## Circuit Information

Rail-to-rail performance is achieved at the input of the amplifiers by using parallel NPN-PNP differential input stages. When the inputs are within 800 mV of the negative rail, the PNP stage is on. When the inputs are more than 800 mV greater than $\mathrm{V}_{\mathrm{EE}}$, the NPN stage is on. This switching of input pairs will cause a reversal of input bias currents (see Figure 6). Also, slight differences in offset voltage may be noted between the NPN and PNP pairs. Cross-coupling techniques have been used to keep this change to a minimum.
In addition to its rail-to-rail performance, the output stage is current boosted to provide 80 mA of output current, enabling the op amp to drive $600 \Omega$ loads. Because of this high output current capability, care should be taken not to exceed the $150^{\circ} \mathrm{C}$ maximum junction temperature.

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to ensure proper solder connection interface
between the board and the package. With the correct pad geometry, the packages will self-align when subjected to a solder reflow process.

## NCS2001

### 0.9 V, Rail-to-Rail, Single Operational Amplifier

The NCS2001 is an industry first sub-one volt operational amplifier that features a rail-to-rail common mode input voltage range, along with rail-to-rail output drive capability. This amplifier is guaranteed to be fully operational down to 0.9 V , providing an ideal solution for powering applications from a single cell Nickel Cadmium (NiCd) or Nickel Metal Hydride (NiMH) battery. Additional features include no output phase reversal with overdriven inputs, trimmed input offset voltage of 0.5 mV , extremely low input bias current of 40 pA , and a unity gain bandwidth of 1.4 MHz at 5.0 V . The tiny NCS2001 is the ideal solution for small portable electronic applications and is available in the space saving SOT23-5 and SC70-5 packages with two industry standard pinouts.

## Features

- 0.9 V Guaranteed Operation
- Rail-to-Rail Common Mode Input Voltage Range
- Rail-to-Rail Output Drive Capability
- No Output Phase Reversal for Over-Driven Input Signals
- 0.5 mV Trimmed Input Offset
- 10 pA Input Bias Current
- 1.4 MHz Unity Gain Bandwidth at $\pm 2.5 \mathrm{~V}, 1.1 \mathrm{MHz}$ at $\pm 0.5 \mathrm{~V}$
- Tiny SC70-5 and SOT23-5 Packages

## Typical Applications

- Single Cell NiCd/NiMH Battery Powered Applications
- Cellular Telephones
- Pagers
- Personal Digital Assistants
- Electronic Games
- Digital Cameras
- Camcorders
- Hand Held Instruments

This device contains 63 active transistors.

## APPLICATION INFORMATION AND OPERATING DESCRIPTION

## GENERAL INFORMATION

The NCS2001 is an industry first rail-to-rail input, rail-to-rail output amplifier that features guaranteed sub one volt operation. This unique feature set is achieved with the use of a modified analog CMOS process that allows the implementation of depletion MOSFET devices. The amplifier has a 1.0 MHz gain bandwidth product, $2.2 \mathrm{~V} / \mu \mathrm{s}$ slew rate and is operational over a power supply range less than 0.9 V to as high as 7.0 V .

## Inputs

The input topology chosen for this device series is unconventional when compared to most low voltage operational amplifiers. It consists of an N -channel depletion mode differential transistor pair that drives a folded cascade stage and current mirror. This configuration extends the input common mode voltage range to encompass the $\mathrm{V}_{\mathrm{EE}}$ and $\mathrm{V}_{\mathrm{CC}}$ power supply rails, even when powered from a combined total of less than 0.9 volts. Figure 27 and 28 show the input common mode voltage range versus power supply voltage.

The differential input stage is laser trimmed in order to minimize offset voltage. The N -channel depletion mode MOSFET input stage exhibits an extremely low input bias current of less than 10 pA . The input bias current versus temperature is shown in Figure 4. Either one or both inputs can be biased as low as $\mathrm{V}_{\mathrm{EE}}$ minus 300 mV to as high as 7.0 V without causing damage to the device. If the input common mode voltage range is exceeded, the output will not display a phase reversal. If the maximum input positive or negative voltage ratings are to be exceeded, a series resistor must be used to limit the input current to less than 2.0 mA .

The ultra low input bias current of the NCS2001 allows the use of extremely high value source and feedback resistor without reducing the amplifier's gain accuracy. These high value resistors, in conjunction with the device input and printed circuit board parasitic capacitances $\mathrm{C}_{\mathrm{i}}$, will add an additional pole to the single pole amplifier in Figure 30. If low enough in frequency, this additional pole can reduce the phase margin and significantly increase the output settling time. The effects of $\mathrm{C}_{\mathrm{in}}$, can be canceled by placing a zero into the feedback loop. This is accomplished with the addition of capacitor $\mathrm{C}_{\mathrm{fb}}$. An approximate value for $\mathrm{C}_{\mathrm{fb}}$ can be calculated by:

$$
\mathrm{C}_{\mathrm{fb}}=\frac{\mathrm{R}_{\mathrm{in}} \times \mathrm{C}_{\mathrm{in}}}{\mathrm{R}_{\mathrm{fb}}}
$$

$$
\mathrm{C}_{\mathrm{in}}=\text { Input and printed circuit board capacitance }
$$

Figure 30. Input Capacitance Pole Cancellation

## Output

The output stage consists of complimentary P and N channel devices connected to provide rail-to-rail output drive. With a 2.0 k load, the output can swing within 50 mV of either rail. It is also capable of supplying over 75 mA when powered from 5.0 V and 1.0 mA when powered from 0.9 V .

When connected as a unity gain follower, the NCS2001 can directly drive capacitive loads in excess of 820 pF at room temperature without oscillating but with significantly reduced phase margin. The unity gain follower configuration exhibits the highest bandwidth and is most prone to oscillations when driving a high value capacitive load. The capacitive load in combination with the amplifier's output impedance, creates a phase lag that can result in an under-damped pulse response or a continuous oscillation. Figure 32 shows the effect of driving a large capacitive load in a voltage follower type of setup. When driving capacitive loads exceeding 820 pF , it is recommended to place a low value isolation resistor between the output of the op amp and the load, as shown in figure 31. The series resistor isolates the capacitive load from the output and enhances the phase margin. Refer to figure 33. Larger values of R will result in a cleaner output waveform but excessively large values will degrade the large signal rise and fall time and reduce the output amplitude. Depending upon the capacitor characteristics, the isolation resistor value will typically be between 50 to 500 ohms. The output drive capability for resistive and capacitive loads is shown in Figures 2, 3, and 23.

Isolation resistor $\mathrm{R}=50$ to 500
Figure 31. Capacitance Load Isolation

Note that the lowest phase margin is observed at cold temperature and low supply voltage.

Figure 32. Small Signal Transient Response with Large Capacitive Load

Figure 33. Small Signal Transient Response with Large Capacitive Load and Isolation Resistor.

The non-inverting input threshold levels are set so that the capacitor voltage oscillates between $1 / 3$ and $2 / 3$ of $\mathrm{V}_{\mathrm{CC}}$. This requires the resistors $\mathrm{R}_{1 \mathrm{a}}, \mathrm{R}_{1 \mathrm{~b}}$ and $\mathrm{R}_{2}$ to be of equal value. The following formula can be used to approximate the output frequency.

$$
\mathrm{f}_{\mathrm{O}}=\frac{1}{1.39 \mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}}
$$

Figure 34. 0.9 V Square Wave Oscillator

The timing capacitor $C_{T}$ will charge through diode $D_{2}$ and discharge through diode $D_{1}$, allowing a variable duty cycle. The pulse width of the signal can be programmed by adjusting the value of the trimpot. The capacitor voltage will oscillate between $1 / 3$ and $2 / 3$ of $V_{C C}$, since all the resistors at the non-inverting input are of equal value.

## MINIMUM RECOMMENDED FOOTPRINT FOR SURFACE MOUNTED APPLICATIONS

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to insure proper solder connection
interface between the board and the package. With the correct pad geometry, the packages will self align when subjected to a solder reflow process.

## NCS7101

### 1.8 Volt Rail-to-Rail Operational Amplifier

The NCS7101 operational amplifier provides rail-to-rail operation on both the input and output. The output can swing within 50 mV of each rail. This rail-to-rail operation enables the user to make full use of the entire supply voltage range available. It is designed to work at very low supply voltages ( 1.8 V and ground), yet can operate with a supply of up to 10 V and ground. The NCS7101 is available in the space saving SOT23-5 package with two industry standard pinouts.

## Features

- Low Voltage, Single Supply Operation (1.8 V and Ground to 10 V and Ground)
- 1.0 pA Input Bias Current
- Unity Gain Bandwidth of 1.0 MHz at 5.0 V , 0.9 MHz at 1.8 V
- Output Voltage Swings Within 50 mV of Both Rails @ 1.8 V
- No Phase Reversal on the Output for Over-Driven Input Signals
- Input Offset Trimmed to 1.0 mV
- Low Supply Current ( $\mathrm{I}_{\mathrm{D}}=1.0 \mathrm{~mA}$ )
- Works Down to Two Discharged NiCd Battery Cells
- ESD Protected Inputs Up to 2.0 kV

## Typical Applications

- Dual NiCd/NiMH Cell Powered Systems
- Portable Communication Devices
- Low Voltage Active Filters
- Power Supply Monitor and Control
- Interface to DSP

This device contains 68 active transistors.

## APPLICATION INFORMATION AND OPERATING DESCRIPTION

## GENERAL INFORMATION

The NCS7101 is a rail-to-rail input, rail-to-rail output operational amplifier that features guaranteed 1.8 volt operation. This feature is achieved with the use of a modified analog CMOS process that allows the implementation of depletion MOSFET devices. The amplifier has a 1.0 MHz gain bandwidth product, $1.2 \mathrm{~V} / \mu \mathrm{s}$ slew rate and is operational over a power supply range less than 1.8 V to as high as 10 V .

## Inputs

The input topology of this device series is unconventional when compared to most low voltage operational amplifiers. It consists of an N -channel depletion mode differential transistor pair that drives a folded cascode stage and current mirror. This configuration extends the input common mode voltage range to encompass the $\mathrm{V}_{\mathrm{EE}}$ and $\mathrm{V}_{\mathrm{CC}}$ power supply rails, even when powered from a combined total of less than 1.8 volts. Figures 27 and 28 show the input common mode voltage range versus power supply voltage.

The differential input stage is laser trimmed in order to minimize offset voltage. The N-channel depletion mode MOSFET input stage exhibits an extremely low input bias current of less than 40 pA . The input bias current versus temperature is shown in Figure 4. Either one or both inputs can be biased as low as $\mathrm{V}_{\text {EE }}$ minus 300 mV to as high as 10 V without causing damage to the device. If the input common mode voltage range is exceeded, the output will not display a phase reversal but it may latch in the appropriate high or low state. The device can then be reset by removing and reapplying power. If the maximum input positive or negative voltage ratings are to be exceeded, a series resistor must be used to limit the input current to less than 2.0 mA .
The ultra low input bias current of the NCS7101 allows the use of extremely high value source and feedback resistor without reducing the amplifier's gain accuracy. These high value resistors, in conjunction with the device input and printed circuit board parasitic capacitances $\mathrm{C}_{\mathrm{in}}$, will add an additional pole to the single pole amplifier shown in Figure 30. If low enough in frequency, this additional pole can reduce the phase margin and significantly increase the output settling time. The effects of $\mathrm{C}_{\mathrm{in}}$, can be canceled by placing a zero into the feedback loop. This is accomplished with the addition of capacitor $\mathrm{C}_{\mathrm{fb}}$. An approximate value for $\mathrm{C}_{\mathrm{fb}}$ can be calculated by:

$$
\mathrm{C}_{\mathrm{fb}}=\frac{\mathrm{R}_{\mathrm{in}} \times \mathrm{C}_{\mathrm{in}}}{\mathrm{R}_{\mathrm{fb}}}
$$

$$
\mathrm{C}_{\text {in }}=\text { Input and printed circuit board capacitance }
$$

Figure 30. Input Capacitance Pole Cancellation

## Output

The output stage consists of complimentary P and N channel devices connected to provide rail-to-rail output drive. With a 2.0 k load, the output can swing within 100 mV of either rail. It is also capable of supplying over 95 mA when powered from 10 V and 3.0 mA when powered from 1.8 V .

When connected as a unity gain follower, the NCS7101 can directly drive capacitive loads in excess of 390 pF at room temperature without oscillating but with significantly reduced phase margin. The unity gain follower configuration exhibits the highest bandwidth and is most prone to oscillations when driving a high value capacitive load. The capacitive load in combination with the amplifier's output impedance, creates a phase lag that can result in an under-damped pulse response or a continuous oscillation. Figure 32 shows the effect of driving a large capacitive load in a voltage follower type of setup. When driving capacitive loads exceeding 390 pF , it is recommended to place a low value isolation resistor between the output of the op amp and the load, as shown in Figure 31. The series resistor isolates the capacitive load from the output and enhances the phase margin. Refer to Figure 33. Larger values of R will result in a cleaner output waveform but excessively large values will degrade the large signal rise and fall time and reduce the output's amplitude. Depending upon the capacitor characteristics, the isolation resistor value will typically be between 50 to 500 ohms. The output drive capability for resistive and capacitive loads is shown in Figures 2, 3, and 23.

Isolation resistor $\mathrm{R}=50$ to 500
Figure 31. Capacitance Load Isolation
Note that the lowest phase margin is observed at cold temperature and low supply voltage.

Figure 32. Small Signal Transient Response with Large Capacitive Load

Figure 33. Small Signal Transient Response with Large Capacitive Load and Isolation Resistor.

Output Voltage

Timing Capacitor
Voltage

The non-inverting input threshold levels are set so that the capacitor voltage oscillates between $1 / 3$ and $2 / 3$ of $V_{C C}$. This requires the resistors $R_{1 \mathrm{a}}, R_{1 b}$ and $R_{2}$ to be of equal value. The following formula can be used to approximate the output frequency.

$$
\mathrm{f}_{\mathrm{O}}=\frac{1}{1.39 \mathrm{R}_{\mathrm{T}} \mathrm{C}_{\mathrm{T}}}
$$

Figure 34. Square Wave Oscillator

The timing capacitor $C_{T}$ will charge through diode $D_{2}$ and discharge through diode $\mathrm{D}_{1}$, allowing a variable duty cycle. The pulse width of the signal can be programmed by adjusting the value of the trimpot. The capacitor voltage will oscillate between $1 / 3$ and $2 / 3$ of $\mathrm{V}_{\mathrm{CC}}$, since all the resistors at the non-inverting input are of equal value.

## MC33171, MC33172, MC33174

## Single Supply 3.0 V to 44 V, Low Power Operational Amplifiers

Quality bipolar fabrication with innovative design concepts are employed for the MC33171/72/74 series of monolithic operational amplifiers. These devices operate at $180 \mu \mathrm{~A}$ per amplifier and offer 1.8 MHz of gain bandwidth product and $2.1 \mathrm{~V} / \mu \mathrm{s}$ slew rate without the use of JFET device technology. Although this series can be operated from split supplies, it is particularly suited for single supply operation, since the common mode input voltage includes ground potential ( $\mathrm{V}_{\mathrm{EE}}$ ). With a Darlington input stage, these devices exhibit high input resistance, low input offset voltage and high gain. The all NPN output stage, characterized by no deadband crossover distortion and large output voltage swing, provides high capacitance drive capability, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source/sink AC frequency response.

The MC33171/72/74 are specified over the industrial/ automotive temperature ranges. The complete series of single, dual and quad operational amplifiers are available in plastic as well as the surface mount packages.

- Low Supply Current: $180 \mu \mathrm{~A}$ (Per Amplifier)
- Wide Supply Operating Range: 3.0 V to 44 V or $\pm 1.5 \mathrm{~V}$ to $\pm 22 \mathrm{~V}$
- Wide Input Common Mode Range, Including Ground ( $\mathrm{V}_{\mathrm{EE}}$ )
- Wide Bandwidth: 1.8 MHz
- High Slew Rate: 2.1 V/ $\mu \mathrm{s}$
- Low Input Offset Voltage: 2.0 mV
- Large Output Voltage Swing: -14.2 V to +14.2 V (with $\pm 15 \mathrm{~V}$ Supplies)
- Large Capacitance Drive Capability: 0 pF to 500 pF
- Low Total Harmonic Distortion: 0.03\%
- Excellent Phase Margin: $60^{\circ}$
- Excellent Gain Margin: 15 dB
- Output Short Circuit Protection
- ESD Diodes Provide Input Protection for Dual and Quad

## APPLICATIONS INFORMATION - CIRCUIT DESCRIPTION/PERFORMANCE FEATURES

Although the bandwidth, slew rate, and settling time of the MC33171/72/74 amplifier family is similar to low power op amp products utilizing JFET input devices, these amplifiers offer additional advantages as a result of the PNP transistor differential inputs and an all NPN transistor output stage.

Because the input common mode voltage range of this input stage includes the $\mathrm{V}_{\mathrm{EE}}$ potential, single supply operation is feasible to as low as 3.0 V with the common mode input voltage at ground potential.

The input stage also allows differential input voltages up to $\pm 44 \mathrm{~V}$, provided the maximum input voltage range is not exceeded. Specifically, the input voltages must range between $\mathrm{V}_{\mathrm{CC}}$ and $\mathrm{V}_{\text {EE }}$ supply voltages as shown by the maximum rating table. In practice, although not recommended, the input voltages can exceed the $\mathrm{V}_{\mathrm{CC}}$ voltage by approximately 3.0 V and decrease below the $\mathrm{V}_{\mathrm{EE}}$ voltage by 0.3 V without causing product damage, although output phase reversal may occur. It is also possible to source up to 5.0 mA of current from $\mathrm{V}_{\mathrm{EE}}$ through either inputs' clamping diode without damage or latching, but phase reversal may again occur. If at least one input is within the common mode input voltage range and the other input is within the maximum input voltage range, no phase reversal will occur. If both inputs exceed the upper common mode input voltage limit, the output will be forced to its lowest voltage state.

Since the input capacitance associated with the small geometry input device is substantially lower ( 0.8 pF ) than that of a typical JFET ( 3.0 pF ), the frequency response for a given input source resistance is greatly enhanced. This becomes evident in D-to-A current to voltage conversion applications where the feedback resistance can form a pole with the input capacitance of the op amp. This input pole creates a 2nd Order system with the single pole op amp and is therefore detrimental to its settling time. In this context, lower input capacitance is desirable especially for higher values of feedback resistances (lower current DACs). This input pole can be compensated for by creating a feedback zero with a capacitance across the feedback resistance, if necessary, to reduce overshoot. For $10 \mathrm{k} \Omega$ of feedback resistance, the MC33171/72/74 family can typically settle to within $1 / 2 \mathrm{LSB}$ of 8 bits in $4.2 \mu \mathrm{~s}$, and within $1 / 2 \mathrm{LSB}$ of 12 bits in $4.8 \mu \mathrm{~s}$ for a 10 V step. In a standard inverting unity gain fast settling configuration, the symmetrical slew rate is typically $\pm 2.1 \mathrm{~V} / \mu \mathrm{s}$. In the classic noninverting unity gain configuration the typical output positive slew rate is also $2.1 \mathrm{~V} / \mu \mathrm{s}$, and the corresponding negative slew rate will usually exceed the positive slew rate as a function of the fall time of the input waveform.

The all NPN output stage, shown in its basic form on the equivalent circuit schematic, offers unique advantages over the more conventional NPN/PNP transistor Class AB output stage. A $10 \mathrm{k} \Omega$ load resistance can typically swing within
0.8 V of the positive rail $\left(\mathrm{V}_{\mathrm{CC}}\right)$ and negative rail $\left(\mathrm{V}_{\mathrm{EE}}\right)$, providing a 28.4 Vpp swing from $\pm 15 \mathrm{~V}$ supplies. This large output swing becomes most noticeable at lower supply voltages.
The positive swing is limited by the saturation voltage of the current source transistor Q7, the VBE of the NPN pull-up transistor Q17, and the voltage drop associated with the short circuit resistance, R5. For sink currents less than 0.4 mA , the negative swing is limited by the saturation voltage of the pull-down transistor Q15, and the voltage drop across R4 and R5. For small valued sink currents, the above voltage drops are negligible, allowing the negative swing voltage to approach within millivolts of $\mathrm{V}_{\mathrm{EE}}$. For sink currents ( $>0.4 \mathrm{~mA}$ ), diode D3 clamps the voltage across R4. Thus the negative swing is limited by the saturation voltage of Q 15 , plus the forward diode drop of $\mathrm{D} 3\left(\approx \mathrm{~V}_{\mathrm{EE}}+1.0 \mathrm{~V}\right)$. Therefore an unprecedented peak-to-peak output voltage swing is possible for a given supply voltage as indicated by the output swing specifications.
If the load resistance is referenced to $\mathrm{V}_{\mathrm{CC}}$ instead of ground for single supply applications, the maximum possible output swing can be achieved for a given supply voltage. For light load currents, the load resistance will pull the output to $\mathrm{V}_{\mathrm{CC}}$ during the positive swing and the output will pull the load resistance near ground during the negative swing. The load resistance value should be much less than that of the feedback resistance to maximize pull-up capability.
Because the PNP output emitter-follower transistor has been eliminated, the MC33171/72/74 family offers a 15 mA minimum current sink capability, typically to an output voltage of $\left(\mathrm{V}_{\mathrm{EE}}+1.8 \mathrm{~V}\right)$. In single supply applications the output can directly source or sink base current from a common emitter NPN transistor for current switching applications.
In addition, the all NPN transistor output stage is inherently faster than PNP types, contributing to the bipolar amplifier's improved gain bandwidth product. The associated high frequency low output impedance ( $200 \Omega$ typ @ 1.0 MHz ) allows capacitive drive capability from 0 pF to 400 pF without oscillation in the noninverting unity gain configuration. The $60^{\circ}$ phase margin and 15 dB gain margin, as well as the general gain and phase characteristics, are virtually independent of the source/sink output swing conditions. This allows easier system phase compensation, since output swing will not be a phase consideration. The AC characteristics of the MC33171/72/74 family also allow excellent active filter capability, especially for low voltage single supply applications.

Although the single supply specification is defined at 5.0 V , these amplifiers are functional to at least 3.0 V @ $25^{\circ} \mathrm{C}$. However slight changes in parametrics such as bandwidth, slew rate, and DC gain may occur.

If power to this integrated circuit is applied in reverse polarity, or if the IC is installed backwards in a socket, large unlimited current surges will occur through the device that may result in device destruction.

As usual with most high frequency amplifiers, proper lead dress, component placement and PC board layout should be exercised for optimum frequency performance. For example, long unshielded input or output leads may result in unwanted input/output coupling. In order to preserve the relatively low input capacitance associated with these amplifiers, resistors connected to the inputs should be immediately adjacent to the input pin to minimize additional stray input capacitance. This not only minimizes the input
pole for optimum frequency response, but also minimizes extraneous "pick up" at this node. Supply decoupling with adequate capacitance immediately adjacent to the supply pin is also important, particularly over temperature, since many types of decoupling capacitors exhibit great impedance changes over temperature.
The output of any one amplifier is current limited and thus protected from a direct short to ground. However, under such conditions, it is important not to allow the device to exceed the maximum junction temperature rating. Typically for $\pm 15 \mathrm{~V}$ supplies, any one output can be shorted continuously to ground without exceeding the maximum temperature rating.

## MC33178, MC33179

## Low Power, Low Noise Operational Amplifiers

The MC33178/9 series is a family of high quality monolithic amplifiers employing Bipolar technology with innovative high performance concepts for quality audio and data signal processing applications. This device family incorporates the use of high frequency PNP input transistors to produce amplifiers exhibiting low input offset voltage, noise and distortion. In addition, the amplifier provides high output current drive capability while consuming only $420 \mu \mathrm{~A}$ of drain current per amplifier. The NPN output stage used, exhibits no deadband crossover distortion, large output voltage swing, excellent phase and gain margins, low open-loop high frequency output impedance, symmetrical source and sink AC frequency performance.

The MC33178/9 family offers both dual and quad amplifier versions, tested over the vehicular temperature range, and are available in DIP and SOIC packages.

- $600 \Omega$ Output Drive Capability
- Large Output Voltage Swing
- Low Offset Voltage: 0.15 mV (Mean)
- Low T.C. of Input Offset Voltage: $2.0 \mu \mathrm{~V} /{ }^{\circ} \mathrm{C}$
- Low Total Harmonic Distortion: 0.0024\%
(@ 1.0 kHz w/600 $\Omega$ Load)
- High Gain Bandwidth: 5.0 MHz
- High Slew Rate: 2.0 V/ $\mu \mathrm{s}$
- Dual Supply Operation: $\pm 2.0 \mathrm{~V}$ to $\pm 18 \mathrm{~V}$
- ESD Clamps on the Inputs Increase Ruggedness without Affecting Device Performance

## APPLICATION INFORMATION

This unique device uses a boosted output stage to combine a high output current with a drain current lower than similar bipolar input op amps. Its $60^{\circ}$ phase margin and 15 dB gain margin ensure stability with up to 1000 pF of load capacitance (see Figure 24). The ability to drive a minimum $600 \Omega$ load makes it particularly suitable for telecom applications. Note that in the sample circuit in Figure 34 both A2 and A3 are driving equivalent loads of approximately $600 \Omega$.

The low input offset voltage and moderately high slew rate and gain bandwidth product make it attractive for a variety of other applications. For example, although it is not single supply (the common mode input range does not include ground), it is specified at +5.0 V with a typical common mode rejection of 110 dB . This makes it an excellent choice for use with digital circuits. The high common mode rejection, which is stable over temperature, coupled with a low noise figure and low distortion, is an ideal op amp for audio circuits.

The output stage of the op amp is current limited and therefore has a certain amount of protection in the event of a short circuit. However, because of its high current output, it is especially important not to allow the device to exceed the maximum junction temperature, particularly with the

MC33179 (quad op amp). Shorting more than one amplifier could easily exceed the junction temperature to the extent of causing permanent damage.

## Stability

As usual with most high frequency amplifiers, proper lead dress, component placement, and PC board layout should be exercised for optimum frequency performance. For example, long unshielded input or output leads may result in unwanted input/output coupling. In order to preserve the relatively low input capacitance associated with these amplifiers, resistors connected to the inputs should be immediately adjacent to the input pin to minimize additional stray input capacitance. This not only minimizes the input pole frequency for optimum frequency response, but also minimizes extraneous "pick up" at this node. Supplying decoupling with adequate capacitance immediately adjacent to the supply pin is also important, particularly over temperature, since many types of decoupling capacitors exhibit great impedance changes over temperature.

Additional stability problems can be caused by high load capacitances and/or a high source resistance. Simple compensation schemes can be used to alleviate these effects.

If a high source of resistance is used ( $\mathrm{R} 1>1.0 \mathrm{k} \Omega$ ), a compensation capacitor equal to or greater than the input capacitance of the op amp ( 10 pF ) placed across the feedback resistor (see Figure 35) can be used to neutralize that pole and prevent outer loop oscillation. Since the closed loop transient response will be a function of that capacitance, it is important to choose the optimum value for that capacitor. This can be determined by the following Equation:

$$
\begin{equation*}
\mathrm{C}_{\mathrm{C}}=(1+[\mathrm{R} 1 / \mathrm{R} 2])^{2} \times \mathrm{C}_{\mathrm{L}}\left(\mathrm{Z}_{\mathrm{O}} / \mathrm{R}_{2}\right) \tag{1}
\end{equation*}
$$

where: $Z_{O}$ is the output impedance of the op amp.

For moderately high capacitive loads ( $500 \mathrm{pF}<\mathrm{C}_{\mathrm{L}}$ $<1500 \mathrm{pF}$ ) the addition of a compensation resistor on the order of $20 \Omega$ between the output and the feedback loop will help to decrease miller loop oscillation (see Figure 36). For high capacitive loads ( $\mathrm{C}_{\mathrm{L}}>1500 \mathrm{pF}$ ), a combined compensation scheme should be used (see Figure 37). Both the compensation resistor and the compensation capacitor affect the transient response and can be calculated for optimum performance. The value of $\mathrm{C}_{\mathrm{C}}$ can be calculated using Equation (1). The Equation to calculate $\mathrm{R}_{\mathrm{C}}$ is as follows:

$$
\begin{equation*}
\mathrm{R}_{\mathrm{C}}=\mathrm{ZO} \times \mathrm{R} 1 / \mathrm{R} 2 \tag{2}
\end{equation*}
$$

Figure 37. Compensation Circuit for High Capacitive Loads

## LM324, LM324A, LM224, LM2902, LM2902V, NCV2902

## Quad Differential Input, Low Power Operational Amplifiers

The LM324 series are low-cost, quad operational amplifiers with true differential inputs. They have several distinct advantages over standard operational amplifier types in single supply applications. The quad amplifier can operate at supply voltages as low as 3.0 V or as high as 32 V with quiescent currents about one-fifth of those associated with the MC1741 (on a per amplifier basis). The common mode input range includes the negative supply, thereby eliminating the necessity for external biasing components in many applications. The output voltage range also includes the negative power supply voltage.

- Short Circuited Protected Outputs
- True Differential Input Stage
- Single Supply Operation: 3.0 V to 32 V (LM224, LM324, LM324A)
- Low Input Bias Currents: 100 nA Maximum (LM324A)
- Four Amplifiers Per Package
- Internally Compensated
- Common Mode Range Extends to Negative Supply
- Industry Standard Pinouts
- ESD Clamps on the Inputs Increase Ruggedness without Affecting Device Operation

Figure 1. Representative Circuit Diagram (One-Fourth of Circuit Shown)

## CIRCUIT DESCRIPTION

The LM324 series is made using four internally compensated, two-stage operational amplifiers. The first stage of each consists of differential input devices Q20 and Q18 with input buffer transistors Q21 and Q17 and the differential to single ended converter Q3 and Q4. The first stage performs not only the first stage gain function but also performs the level shifting and transconductance reduction functions. By reducing the transconductance, a smaller compensation capacitor (only 5.0 pF ) can be employed, thus saving chip area. The transconductance reduction is accomplished by splitting the collectors of Q20 and Q18. Another feature of this input stage is that the input common mode range can include the negative supply or ground, in single supply operation, without saturating either the input devices or the differential to single-ended converter. The second stage consists of a standard current source load amplifier stage.

Single Supply

Figure 2. Large Signal Voltage Follower Response
Each amplifier is biased from an internal-voltage regulator which has a low temperature coefficient thus giving each amplifier good temperature characteristics as well as excellent power supply rejection.

Split Supplies

## LM324, LM324A, LM224, LM2902, LM2902V, NCV2902

Figure 15. Function Generator

Figure 16. Multiple Feedback Bandpass Filter

Given: $f_{0}=$ center frequency
$A\left(f_{0}\right)=$ gain at center frequency
Choose value $\mathrm{f}_{0}, \mathrm{C}$
Then: $\quad R 3=\frac{Q}{\pi f_{0} C}$

$$
\mathrm{R} 1=\frac{\mathrm{R} 3}{2 \mathrm{~A}\left(\mathrm{f}_{0}\right)}
$$

$$
R 2=\frac{R 1 R 3}{4 Q^{2} R 1-R 3}
$$

For less than 10\% error from operational amplifier, $\frac{Q_{0} f_{0}}{B W}<0.1$
where $\mathrm{f}_{0}$ and BW are expressed in Hz .
If source impedance varies, filter may be preceded with voltage follower buffer to stabilize filter parameters.

## LM358, LM258, LM2904, LM2904A, LM2904V, NCV2904

## Single Supply Dual Operational Amplifiers

Utilizing the circuit designs perfected for Quad Operational Amplifiers, these dual operational amplifiers feature low power drain, a common mode input voltage range extending to ground $/ \mathrm{V}_{\mathrm{EE}}$, and single supply or split supply operation. The LM358 series is equivalent to one-half of an LM324.

These amplifiers have several distinct advantages over standard operational amplifier types in single supply applications. They can operate at supply voltages as low as 3.0 V or as high as 32 V , with quiescent currents about one-fifth of those associated with the MC1741 (on a per amplifier basis). The common mode input range includes the negative supply, thereby eliminating the necessity for external biasing components in many applications. The output voltage range also includes the negative power supply voltage.

- Short Circuit Protected Outputs
- True Differential Input Stage
- Single Supply Operation: 3.0 V to 32 V (LM258/LM358)

$$
3.0 \mathrm{~V} \text { to } 26 \mathrm{~V}(\mathrm{LM} 2904, \mathrm{~A}, \mathrm{~V})
$$

- Low Input Bias Currents
- Internally Compensated
- Common Mode Range Extends to Negative Supply
- Single and Split Supply Operation
- ESD Clamps on the Inputs Increase Ruggedness of the Device without Affecting Operation

10. Short circuits from the output to $\mathrm{V}_{\mathrm{CC}}$ can cause excessive heating and eventual destruction. Destructive dissipation can result from simultaneous shorts on all amplifiers.

## CIRCUIT DESCRIPTION

The LM358 series is made using two internally compensated, two-stage operational amplifiers. The first stage of each consists of differential input devices Q20 and Q18 with input buffer transistors Q21 and Q17 and the differential to single ended converter Q3 and Q4. The first stage performs not only the first stage gain function but also performs the level shifting and transconductance reduction functions. By reducing the transconductance, a smaller compensation capacitor (only 5.0 pF ) can be employed, thus saving chip area. The transconductance reduction is accomplished by splitting the collectors of Q20 and Q18. Another feature of this input stage is that the input common mode range can include the negative supply or ground, in single supply operation, without saturating either the input devices or the differential to single-ended converter. The second stage consists of a standard current source load amplifier stage.

Each amplifier is biased from an internal-voltage regulator which has a low temperature coefficient thus giving each amplifier good temperature characteristics as well as excellent power supply rejection.

Figure 15. Function Generator

Given: $\quad f_{0}=$ center frequency
$A\left(f_{0}\right)=$ gain at center frequency
Choose value $f_{0}, C$

Then: $\quad R 3=\frac{Q}{\pi f_{0} C}$
$\mathrm{R} 1=\frac{\mathrm{R} 3}{2 \mathrm{~A}\left(\mathrm{f}_{0}\right)}$

$$
\mathrm{R} 2=\frac{\mathrm{R} 1 \mathrm{R} 3}{4 \mathrm{Q}^{2} \mathrm{R} 1-\mathrm{R} 3}
$$

For less than $10 \%$ error from operational amplifier. $\frac{Q_{0} f_{0}}{B W}<0.1$ Where $\mathrm{f}_{0}$ and BW are expressed in Hz .

If source impedance varies, filter may be preceded with voltage follower buffer to stabilize filter parameters.

## MC3403, MC3303

## Single Supply Quad Operational Amplifiers

The MC3403 is a low cost, quad operational amplifier with true differential inputs. The device has electrical characteristics similar to the popular MC1741C. However, the MC3403 has several distinct advantages over standard operational amplifier types in single supply applications. The quad amplifier can operate at supply voltages as low as 3.0 V or as high as 36 V with quiescent currents about one third of those associated with the MC1741C (on a per amplifier basis). The common mode input range includes the negative supply, thereby eliminating the necessity for external biasing components in many applications. The output voltage range also includes the negative power supply voltage.

- Short Circuit Protected Outputs
- Class AB Output Stage for Minimal Crossover Distortion
- True Differential Input Stage
- Single Supply Operation: 3.0 V to 36 V
- Split Supply Operation: $\pm 1.5 \mathrm{~V}$ to $\pm 18 \mathrm{~V}$
- Low Input Bias Currents: 500 nA Max
- Four Amplifiers Per Package
- Internally Compensated
- Similar Performance to Popular MC1741C
- Industry Standard Pinouts
- ESD Diodes Added for Increased Ruggedness

MAXIMUM RATINGS

| Rating | Symbol | Value | Unit |
| :--- | :---: | :---: | :---: |
| Power Supply Voltages <br> Single Supply <br> Split Supplies | $\mathrm{V}_{\mathrm{CC}}$ <br> $\mathrm{V}_{\mathrm{CC}}, \mathrm{V}_{\mathrm{EE}}$ | 36 <br> $\pm 18$ | Vdc |

## CIRCUIT DESCRIPTION

$20 \mu s / D I V$
Figure 2. Inverter Pulse Response

The MC3403/3303 is made using four internally compensated, two-stage operational amplifiers. The first stage of each consists of differential input device Q24 and Q22 with input buffer transistors Q25 and Q21 and the differential to single ended converter Q3 and Q4. The first
stage performs not only the first stage gain function but also performs the level shifting and transconductance reduction functions. By reducing the transconductance, a smaller compensation capacitor (only 5.0 pF ) can be employed, thus saving chip area. The transconductance reduction is accomplished by splitting the collectors of Q24 and Q22. Another feature of this input stage is that the input common mode range can include the negative supply or ground, in single supply operation, without saturating either the input devices or the differential to single-ended converter. The second stage consists of a standard current source load amplifier stage.

The output stage is unique because it allows the output to swing to ground in single supply operation and yet does not exhibit any crossover distortion in split supply operation. This is possible because Class AB operation is utilized.

Each amplifier is biased from an internal voltage regulator which has a low temperature coefficient, thus giving each amplifier good temperature characteristics as well as excellent power supply rejection.

$$

Figure 14. Function Generator

Choose value $f_{0}, C$

$$
\text { Then: } \quad R 3=\frac{Q}{\pi f_{0} C} \quad R 1=\frac{R 3}{2 A\left(f_{0}\right)} \quad R 2=\frac{R 1 R 5}{4 Q^{2} R 1-R 5}
$$

For less than $10 \%$ error from operational amplifier $\frac{\mathrm{O}_{0} f_{0}}{B W}<0.1$
where $f_{0}$ and $B W$ are expressed in Hz .

If source impedance varies, filter may be preceded with voltage follower buffer to stabilize filter parameters.

Figure 15. Multiple Feedback Bandpass Filter

## LM301A, LM201A

## Non Compensated Single Operational Amplifiers

A general purpose operational amplifier that allows the user to choose the compensation capacitor best suited to his needs. With proper compensation, summing amplifier slew rates to $10 \mathrm{~V} / \mu \mathrm{s}$ can be obtained.

- Low Input Offset Current: 20 nA Maximum Over Temperature Range
- External Frequency Compensation for Flexibility
- Class AB Output Provides Excellent Linearity
- Output Short Circuit Protection
- Guaranteed Drift Characteristics

## TCA0372, TCA0372B

### 1.0 A Output Current, Dual Power Operational Amplifiers

The TCA0372 is a monolithic circuit intended for use as a power operational amplifier in a wide range of applications, including servo amplifiers and power supplies. No deadband crossover distortion provides better performance for driving coils.

- Output Current to 1.0 A
- Slew Rate of $1.3 \mathrm{~V} / \mu \mathrm{s}$
- Wide Bandwidth of 1.1 MHz
- Internal Thermal Shutdown
- Single or Split Supply Operation
- Excellent Gain and Phase Margins
- Common Mode Input Includes Ground
- Zero Deadband Crossover Distortion

Figure 9. Bidirectional DC Motor Control with Microprocessor-Compatible Inputs

For circuit stability, ensure that $R_{x}>\frac{2 R 3 \cdot R 1}{R_{M}}$ where, $R_{M}=$ internal resistance of motor.
The voltage available at the terminals of the motor is: $V_{M}=2\left(V_{1}-\frac{V_{S}}{2}\right)+\left|R_{0}\right| \cdot I_{M}$
where, $\left|R_{0}\right|=\frac{2 R 3 \cdot R 1}{R_{X}}$ and $I_{M}$ is the motor current.

## LM833

## Low Noise, Audio Dual Operational Amplifier

The LM833 is a standard low-cost monolithic dual general-purpose operational amplifier employing Bipolar technology with innovative high-performance concepts for audio systems applications. With high frequency PNP transistors, the LM833 offers low voltage noise ( $4.5 \mathrm{nV} / \sqrt{\mathrm{Hz}}$ ), 15 MHz gain bandwidth product, $7.0 \mathrm{~V} / \mu \mathrm{s}$ slew rate, 0.3 mV input offset voltage with $2.0 \mu \mathrm{~V} /{ }^{\circ} \mathrm{C}$ temperature coefficient of input offset voltage. The LM833 output stage exhibits no deadband crossover distortion, large output voltage swing, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source/sink AC frequency response.

For an improved performance dual/quad version, see the MC33079 family.

- Low Voltage Noise: $4.5 \mathrm{nV} / \sqrt{\mathrm{Hz}}$
- High Gain Bandwidth Product: 15 MHz
- High Slew Rate: 7.0 V/ $\mu \mathrm{s}$
- Low Input Offset Voltage: 0.3 mV
- Low T.C. of Input Offset Voltage: $2.0 \mu \mathrm{~V} /{ }^{\circ} \mathrm{C}$
- Low Distortion: 0.002\%
- Excellent Frequency Stability
- Dual Supply Operation

## MAXIMUM RATINGS

| Rating | Symbol | Value | Unit |
| :--- | :---: | :---: | :---: |
| Supply Voltage (VCC to $\mathrm{V}_{\mathrm{EE}}$ ) | $\mathrm{V}_{\mathrm{S}}$ | +36 | V |
| Input Differential Voltage Range <br> (Note 1) | $\mathrm{V}_{\mathrm{IDR}}$ | 30 | V |
| Input Voltage Range (Note 1) | $\mathrm{V}_{\mathrm{IR}}$ | $\pm 15$ | V |
| Output Short Circuit Duration (Note 2) | $\mathrm{tsC}_{\mathrm{tc}}$ | Indefinite |  |
| Operating Ambient Temperature <br> Range | $\mathrm{T}_{\mathrm{A}}$ | -40 to +85 | ${ }^{\circ} \mathrm{C}$ |
| Operating Junction Temperature | $\mathrm{T}_{\mathrm{J}}$ | +150 | ${ }^{\circ} \mathrm{C}$ |
| Storage Temperature | $\mathrm{T}_{\mathrm{stg}}$ | -60 to +150 | ${ }^{\circ} \mathrm{C}$ |
| Maximum Power Dissipation <br> (Notes 2 and 3) | $\mathrm{P}_{\mathrm{D}}$ | 500 | mW |

1. Either or both input voltages must not exceed the magnitude of $\mathrm{V}_{\mathrm{CC}}$ or $\mathrm{V}_{\mathrm{EE}}$.
2. Power dissipation must be considered to ensure maximum junction temperature ( $\mathrm{T}_{\mathrm{J}}$ ) is not exceeded (see power dissipation performance characteristic).
3. Maximum value at $\mathrm{T}_{\mathrm{A}} \leq 85^{\circ} \mathrm{C}$.
