The MC33077 is a precision high quality, high frequency, low noise monolithic dual operational amplifier employing innovative bipolar design techniques. Precision matching coupled with a unique analog resistor trim technique is used to obtain low input offset voltages. Dual-doublet frequency compensation techniques are used to enhance the gain bandwidth product of the amplifier. In addition, the MC33077 offers low input noise voltage, low temperature coefficient of input offset voltage, high slew rate, high AC and DC open loop voltage gain and low supply current drain. The all NPN transistor output stage exhibits no deadband cross-over distortion, large output voltage swing, excellent phase and gain margins, low open loop output impedance and symmetrical source and sink AC frequency performance.

The MC33077 is tested over the automotive temperature range and is available in plastic DIP and SO-8 packages ( P and D suffixes).

- Low Voltage Noise: $4.4 \mathrm{nV} / \sqrt{\mathrm{Hz}}$ @ 1.0 kHz
- Low Input Offset Voltage: 0.2 mV
- Low TC of Input Offset Voltage: $2.0 \mu \mathrm{~V} /{ }^{\circ} \mathrm{C}$
- High Gain Bandwidth Product: 37 MHz @ 100 kHz
- High AC Voltage Gain: 370 @ 100 kHz

$$
1850 @ 20 \mathrm{kHz}
$$

- Unity Gain Stable: with Capacitance Loads to 500 pF
- High Slew Rate: $11 \mathrm{~V} / \mu \mathrm{s}$
- Low Total Harmonic Distortion: 0.007\%
- Large Output Voltage Swing: +14 V to -14.7 V
- High DC Open Loop Voltage Gain: 400 k (112 dB)
- High Common Mode Rejection: 107 dB
- Low Power Supply Drain Current: 3.5 mA
- Dual Supply Operation: $\pm 2.5 \mathrm{~V}$ to $\pm 18 \mathrm{~V}$

## APPLICATIONS INFORMATION

The MC33077 is designed primarily for its low noise, low offset voltage, high gain bandwidth product and large output swing characteristics. Its outstanding high frequency gain/phase performance make it a very attractive amplifier for high quality preamps, instrumentation amps, active filters and other applications requiring precision quality characteristics.

The MC33077 utilizes high frequency lateral PNP input transistors in a low noise bipolar differential stage driving a compensated Miller integration amplifier. Dual-doublet frequency compensation techniques are used to enhance the gain bandwidth product. The output stage uses an all NPN transistor design which provides greater output voltage swing and improved frequency performance over more conventional stages by using both PNP and NPN transistors (Class AB). This combination produces an amplifier with superior characteristics.

Through precision component matching and innovative current mirror design, a lower than normal temperature coefficient of input offset voltage ( $2.0 \mu \mathrm{~V} /{ }^{\circ} \mathrm{C}$ as opposed to 10 $\mu \mathrm{V} /{ }^{\circ} \mathrm{C}$ ), as well as low input offset voltage, is accomplished.

The minimum common mode input range is from 1.5 V below the positive rail $\left(\mathrm{V}_{\mathrm{CC}}\right)$ to 1.5 V above the negative rail $\left(\mathrm{V}_{\mathrm{EE}}\right)$. The inputs will typically common mode to within 1.0 V of both negative and positive rails though degradation in offset voltage and gain will be experienced as the common mode voltage nears either supply rail. In practice, though not recommended, the input voltage may exceed $\mathrm{V}_{\mathrm{CC}}$ by approximately 3.0 V and decrease below the $\mathrm{V}_{\mathrm{EE}}$ by approximately 0.6 V without causing permanent damage to the device. If the input voltage on either or both inputs is less than approximately 0.6 V , excessive current may flow, if not limited, causing permanent damage to the device.

The amplifier will not latch with input source currents up to 20 mA , though in practice, source currents should be limited to 5.0 mA to avoid any parametric damage to the device. If both inputs exceed $\mathrm{V}_{\mathrm{CC}}$, the output will be in the high state and phase reversal may occur. No phase reversal will occur if the voltage on one input is within the common mode range and the voltage on the other input exceeds $\mathrm{V}_{\mathrm{CC}}$. Phase reversal may occur if the input voltage on either or both inputs is less than 1.0 V above the negative rail. Phase reversal will be experienced if the voltage on either or both inputs is less than $\mathrm{V}_{\mathrm{EE}}$.

Through the use of dual-doublet frequency compensation techniques, the gain bandwidth product has been greatly enhanced over other amplifiers using the conventional single pole compensation. The phase and gain error of the amplifier remains low to higher frequencies for fixed amplifier gain configurations.

With the all NPN output stage, there is minimal swing loss to the supply rails, producing superior output swing, no crossover distortion and improved output phase symmetry with output voltage excursions (output phase symmetry being the amplifiers ability to maintain a constant phase
relation independent of its output voltage swing). Output phase symmetry degradation in the more conventional PNP and NPN transistor output stage was primarily due to the inherent cut-off frequency mismatch of the PNP and NPN transistors used (typically 10 MHz and 300 MHz , respectively), causing considerable phase change to occur as the output voltage changes. By eliminating the PNP in the output, such phase change has been avoided and a very significant improvement in output phase symmetry as well as output swing has been accomplished.
The output swing improvement is most noticeable when operation is with lower supply voltages (typically $30 \%$ with $\pm 5.0 \mathrm{~V}$ supplies). With a 10 k load, the output of the amplifier can typically swing to within 1.0 V of the positive rail $\left(\mathrm{V}_{\mathrm{CC}}\right)$, and to within 0.3 V of the negative rail $\left(\mathrm{V}_{\mathrm{EE}}\right)$, producing a $28.7 \mathrm{~V}_{\mathrm{pp}}$ signal from $\pm 15 \mathrm{~V}$ supplies. Output voltage swing can be further improved by using an output pull-up resistor referenced to the $\mathrm{V}_{\mathrm{CC}}$. Where output signals are referenced to the positive supply rail, the pull-up resistor will pull the output to $\mathrm{V}_{\mathrm{CC}}$ during the positive swing, and during the negative swing, the NPN output transistor collector will pull the output very near $\mathrm{V}_{\mathrm{EE}}$. This configuration will produce the maximum attainable output signal from given supply voltages. The value of load resistance used should be much less than any feedback resistance to avoid excess loading and allow easy pull-up of the output.
Output impedance of the amplifier is typically less than $50 \Omega$ at frequencies less than the unity gain crossover frequency (see Figure 19). The amplifier is unity gain stable with output capacitance loads up to 500 pF at full output swing over the $-55^{\circ}$ to $+125^{\circ} \mathrm{C}$ temperature range. Output phase symmetry is excellent with typically $4^{\circ} \mathrm{C}$ total phase change over a 20 V output excursion at $25^{\circ} \mathrm{C}$ with a $2.0 \mathrm{k} \Omega$ and 100 pF load. With a $2.0 \mathrm{k} \Omega$ resistive load and no capacitance loading, the total phase change is approximately one degree for the same 20 V output excursion. With a $2.0 \mathrm{k} \Omega$ and 500 pF load at $125^{\circ} \mathrm{C}$, the total phase change is typically only $10^{\circ} \mathrm{C}$ for a 20 V output excursion (see Figure 28).
As with all amplifiers, care should be exercised to insure that one does not create a pole at the input of the amplifier which is near the closed loop corner frequency. This becomes a greater concern when using high frequency amplifiers since it is very easy to create such a pole with relatively small values of resistance on the inputs. If this does occur, the amplifier's phase will degrade severely causing the amplifier to become unstable. Effective source resistances, acting in conjunction with the input capacitance of the amplifier, should be kept to a minimum to avoid creating such a pole at the input (see Figure 32). There is minimal effect on stability where the created input pole is much greater than the closed loop corner frequency. Where amplifier stability is affected as a result of a negative feedback resistor in conjunction with the
amplifier's input capacitance, creating a pole near the closed loop corner frequency, lead capacitor compensation techniques (lead capacitor in parallel with the feedback resistor) can be employed to improve stability. The feedback resistor and lead capacitor RC time constant should be larger than that of the uncompensated input pole frequency. Having a high resistance connected to the noninverting input of the amplifier can create a like instability problem. Compensation for this condition can be accomplished by adding a lead capacitor in parallel with the noninverting input resistor of such a value as to make the RC time constant larger than the RC time constant of the uncompensated input resistor acting in conjunction with the amplifiers input capacitance.

For optimum frequency performance and stability, careful component placement and printed circuit board layout should be exercised. For example, long unshielded input or output leads may result in unwanted input output coupling. In order to reduce the input capacitance, the body of resistors connected to the input pins should be physically close to the input pins. This not only minimizes the input pole creation for optimum frequency response, but also minimizes extraneous signal "pickup" at this node. Power supplies should be decoupled with adequate capacitance as close as possible to the device supply pin.

In addition to amplifier stability considerations, input source resistance values should be low to take full advantage
of the low noise characteristics of the amplifier. Thermal noise (Johnson Noise) of a resistor is generated by thermally-charged carriers randomly moving within the resistor creating a voltage. The rms thermal noise voltage in a resistor can be calculated from:

$$
\mathrm{E}_{\mathrm{nr}}=/ \overline{4 \mathrm{kTR} \times \mathrm{BW}}
$$

## where:

$\mathrm{k}=$ Boltzmann's Constant ( $1.38 \times 10^{-23}$ joules $/ \mathrm{k}$ )
$\mathrm{T}=$ Kelvin temperature
R = Resistance in ohms
BW = Upper and lower frequency limit in Hertz.
By way of reference, a $1.0 \mathrm{k} \Omega$ resistor at $25^{\circ} \mathrm{C}$ will produce a $4.0 \mathrm{nV} / \sqrt{\mathrm{Hz}}$ of rms noise voltage. If this resistor is connected to the input of the amplifier, the noise voltage will be gained-up in accordance to the amplifier's gain configuration. For this reason, the selection of input source resistance for low noise circuit applications warrants serious consideration. The total noise of the amplifier, as referred to its inputs, is typically only $4.4 \mathrm{nV} / \sqrt{\mathrm{Hz}}$ at 1.0 kHz .

The output of any one amplifier is current limited and thus protected from a direct short to ground, However, under such conditions, it is important not to allow the amplifier to exceed the maximum junction temperature rating. Typically for $\pm 15 \mathrm{~V}$ supplies, any one output can be shorted continuously to ground without exceeding the temperature rating.

Note: All capacitors are non-polarized.

## MC33078, MC33079

## Low Noise Dual/Quad Operational Amplifiers

The MC33078/9 series is a family of high quality monolithic amplifiers employing Bipolar technology with innovative high performance concepts for quality audio and data signal processing applications. This family incorporates the use of high frequency PNP input transistors to produce amplifiers exhibiting low input voltage noise with high gain bandwidth product and slew rate. The all NPN output stage exhibits no deadband crossover distortion, large output voltage swing, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source and sink AC frequency performance.

The MC33078/9 family offers both dual and quad amplifier versions, tested over the automotive temperature range and available in the plastic DIP and SOIC packages (P and D suffixes).

- Dual Supply Operation: $\pm 5.0 \mathrm{~V}$ to $\pm 18 \mathrm{~V}$
- Low Voltage Noise: $4.5 \mathrm{nV} / \sqrt{\mathrm{Hz}}$
- Low Input Offset Voltage: 0.15 mV
- Low T.C. of Input Offset Voltage: $2.0 \mu \mathrm{~V} /{ }^{\circ} \mathrm{C}$
- Low Total Harmonic Distortion: 0.002\%
- High Gain Bandwidth Product: 16 MHz
- High Slew Rate: 7.0 V/ $\mu \mathrm{s}$
- High Open Loop AC Gain: 800 @ 20 kHz
- Excellent Frequency Stability
- Large Output Voltage Swing: +14.1 V/ -14.6 V
- ESD Diodes Provided on the Inputs

## MC33272A, MC33274A

## Single Supply, <br> High Slew Rate, <br> Low Input Offset Voltage Operational Amplifiers

The MC33272/74 series of monolithic operational amplifiers are quality fabricated with innovative Bipolar design concepts. This dual and quad operational amplifier series incorporates Bipolar inputs along with a patented Zip-R-Trim element for input offset voltage reduction. The MC33272/74 series of operational amplifiers exhibits low input offset voltage and high gain bandwidth product. Dual-doublet frequency compensation is used to increase the slew rate while maintaining low input noise characteristics. Its all NPN output stage exhibits no deadband crossover distortion, large output voltage swing, and an excellent phase and gain margin. It also provides a low open loop high frequency output impedance with symmetrical source and sink AC frequency performance.

The MC33272/74 series is specified over $-40^{\circ}$ to $+85^{\circ} \mathrm{C}$ and are available in plastic DIP and SOIC surface mount packages.

- Input Offset Voltage Trimmed to $100 \mu \mathrm{~V}$ (Typ)
- Low Input Bias Current: 300 nA
- Low Input Offset Current: 3.0 nA
- High Input Resistance: $16 \mathrm{M} \Omega$
- Low Noise: $18 \mathrm{nV} / \sqrt{\mathrm{Hz}}$ @ 1.0 kHz
- High Gain Bandwidth Product: 24 MHz @ 100 kHz
- High Slew Rate: $10 \mathrm{~V} / \mu \mathrm{s}$
- Power Bandwidth: 160 kHz
- Excellent Frequency Stability
- Unity Gain Stable: w/Capacitance Loads to 500 pF
- Large Output Voltage Swing: +14.1 V/ -14.6 V
- Low Total Harmonic Distortion: 0.003\%
- Power Supply Drain Current: 2.15 mA per Amplifier
- Single or Split Supply Operation: +3.0 V to +36 V or $\pm 1.5 \mathrm{~V}$ to $\pm 18 \mathrm{~V}$
- ESD Diodes Provide Added Protection to the Inputs

## MC34071,2,4,A MC33071,2,4,A

## Single Supply 3.0 V to 44 V Operational Amplifiers

Quality bipolar fabrication with innovative design concepts are employed for the MC33071/72/74, MC34071/72/74 series of monolithic operational amplifiers. This series of operational amplifiers offer 4.5 MHz of gain bandwidth product, $13 \mathrm{~V} / \mu \mathrm{s}$ slew rate and fast settling time without the use of JFET device technology. Although this series can be operated from split supplies, it is particularly suited for single supply operation, since the common mode input voltage range includes ground potential $\left(\mathrm{V}_{\mathrm{EE}}\right)$. With a Darlington input stage, this series exhibits high input resistance, low input offset voltage and high gain. The all NPN output stage, characterized by no deadband crossover distortion and large output voltage swing, provides high capacitance drive capability, excellent phase and gain margins, low open loop high frequency output impedance and symmetrical source/sink AC frequency response.

The MC33071/72/74, MC34071/72/74 series of devices are available in standard or prime performance (A Suffix) grades and are specified over the commercial, industrial/vehicular or military temperature ranges. The complete series of single, dual and quad operational amplifiers are available in plastic DIP, SOIC and TSSOP surface mount packages.

- Wide Bandwidth: 4.5 MHz
- High Slew Rate: $13 \mathrm{~V} / \mu \mathrm{s}$
- Fast Settling Time: $1.1 \mu$ s to $0.1 \%$
- Wide Single Supply Operation: 3.0 V to 44 V
- Wide Input Common Mode Voltage Range: Includes Ground ( $\mathrm{V}_{\mathrm{EE}}$ )
- Low Input Offset Voltage: 3.0 mV Maximum (A Suffix)
- Large Output Voltage Swing: -14.7 V to +14 V (with $\pm 15 \mathrm{~V}$ Supplies)
- Large Capacitance Drive Capability: 0 pF to $10,000 \mathrm{pF}$
- Low Total Harmonic Distortion: 0.02\%
- Excellent Phase Margin: $60^{\circ}$
- Excellent Gain Margin: 12 dB
- Output Short Circuit Protection
- ESD Diodes/Clamps Provide Input Protection for Dual and Quad

## APPLICATIONS INFORMATION CIRCUIT DESCRIPTION/PERFORMANCE FEATURES

Although the bandwidth, slew rate, and settling time of the MC34071 amplifier series are similar to op amp products utilizing JFET input devices, these amplifiers offer other additional distinct advantages as a result of the PNP transistor differential input stage and an all NPN transistor output stage.

Since the input common mode voltage range of this input stage includes the $\mathrm{V}_{\mathrm{EE}}$ potential, single supply operation is feasible to as low as 3.0 V with the common mode input voltage at ground potential.

The input stage also allows differential input voltages up to $\pm 44 \mathrm{~V}$, provided the maximum input voltage range is not exceeded. Specifically, the input voltages must range between $\mathrm{V}_{\mathrm{EE}}$ and $\mathrm{V}_{\mathrm{CC}}$ supply voltages as shown by the maximum rating table. In practice, although not recommended, the input voltages can exceed the $\mathrm{V}_{\mathrm{CC}}$ voltage by approximately 3.0 V and decrease below the $\mathrm{V}_{\mathrm{EE}}$ voltage by 0.3 V without causing product damage, although output phase reversal may occur. It is also possible to source
up to approximately 5.0 mA of current from $\mathrm{V}_{\mathrm{EE}}$ through either inputs clamping diode without damage or latching, although phase reversal may again occur.

If one or both inputs exceed the upper common mode voltage limit, the amplifier output is readily predictable and may be in a low or high state depending on the existing input bias conditions.

Since the input capacitance associated with the small geometry input device is substantially lower ( 2.5 pF ) than the typical JFET input gate capacitance ( 5.0 pF ), better frequency response for a given input source resistance can be achieved using the MC34071 series of amplifiers. This performance feature becomes evident, for example, in fast settling D-to-A current to voltage conversion applications where the feedback resistance can form an input pole with the input capacitance of the op amp. This input pole creates a 2 nd order system with the single pole op amp and is therefore detrimental to its settling time. In this context, lower input capacitance is desirable especially for higher
values of feedback resistances (lower current DACs). This input pole can be compensated for by creating a feedback zero with a capacitance across the feedback resistance, if necessary, to reduce overshoot. For $2.0 \mathrm{k} \Omega$ of feedback resistance, the MC34071 series can settle to within $1 / 2$ LSB of 8 bits in $1.0 \mu \mathrm{~s}$, and within $1 / 2$ LSB of 12 -bits in $2.2 \mu \mathrm{~s}$ for a 10 V step. In a inverting unity gain fast settling configuration, the symmetrical slew rate is $\pm 13 \mathrm{~V} / \mu \mathrm{s}$. In the classic noninverting unity gain configuration, the output positive slew rate is $+10 \mathrm{~V} / \mu \mathrm{s}$, and the corresponding negative slew rate will exceed the positive slew rate as a function of the fall time of the input waveform.

Since the bipolar input device matching characteristics are superior to that of JFETs, a low untrimmed maximum offset voltage of 3.0 mV prime and 5.0 mV downgrade can be economically offered with high frequency performance characteristics. This combination is ideal for low cost precision, high speed quad op amp applications.

The all NPN output stage, shown in its basic form on the equivalent circuit schematic, offers unique advantages over the more conventional NPN/PNP transistor Class AB output stage. A $10 \mathrm{k} \Omega$ load resistance can swing within 1.0 V of the positive rail $\left(\mathrm{V}_{\mathrm{CC}}\right)$, and within 0.3 V of the negative rail ( $\mathrm{V}_{\mathrm{EE}}$ ), providing a $28.7 \mathrm{~V}_{\mathrm{pp}}$ swing from $\pm 15 \mathrm{~V}$ supplies. This large output swing becomes most noticeable at lower supply voltages.

The positive swing is limited by the saturation voltage of the current source transistor $\mathrm{Q}_{7}$, and $\mathrm{V}_{\mathrm{BE}}$ of the NPN pull up transistor $\mathrm{Q}_{17}$, and the voltage drop associated with the short circuit resistance, $\mathrm{R}_{7}$. The negative swing is limited by the saturation voltage of the pull-down transistor $\mathrm{Q}_{16}$, the voltage drop $I_{L} R_{6}$, and the voltage drop associated with resistance $\mathrm{R}_{7}$, where $\mathrm{I}_{\mathrm{L}}$ is the sink load current. For small valued sink currents, the above voltage drops are negligible, allowing the negative swing voltage to approach within millivolts of $\mathrm{V}_{\mathrm{EE}}$. For large valued sink currents ( $>5.0 \mathrm{~mA}$ ), diode D3 clamps the voltage across $\mathrm{R}_{6}$, thus limiting the negative swing to the saturation voltage of $\mathrm{Q}_{16}$, plus the forward diode drop of $\mathrm{D} 3\left(\approx \mathrm{~V}_{\mathrm{EE}}+1.0 \mathrm{~V}\right)$. Thus for a given supply voltage, unprecedented peak-to-peak output voltage swing is possible as indicated by the output swing specifications.

If the load resistance is referenced to $\mathrm{V}_{\mathrm{CC}}$ instead of ground for single supply applications, the maximum possible output swing can be achieved for a given supply voltage. For light load currents, the load resistance will pull the output to $\mathrm{V}_{\mathrm{CC}}$ during the positive swing and the output will pull the load resistance near ground during the negative swing. The load resistance value should be much less than that of the feedback resistance to maximize pull up capability.

Because the PNP output emitter-follower transistor has been eliminated, the MC34071 series offers a 20 mA
minimum current sink capability, typically to an output voltage of $\left(\mathrm{V}_{\mathrm{EE}}+1.8 \mathrm{~V}\right)$. In single supply applications the output can directly source or sink base current from a common emitter NPN transistor for fast high current switching applications.
In addition, the all NPN transistor output stage is inherently fast, contributing to the bipolar amplifier's high gain bandwidth product and fast settling capability. The associated high frequency low output impedance ( $30 \Omega$ typ @ 1.0 MHz ) allows capacitive drive capability from 0 pF to $10,000 \mathrm{pF}$ without oscillation in the unity closed loop gain configuration. The $60^{\circ}$ phase margin and 12 dB gain margin as well as the general gain and phase characteristics are virtually independent of the source/sink output swing conditions. This allows easier system phase compensation, since output swing will not be a phase consideration. The high frequency characteristics of the MC34071 series also allow excellent high frequency active filter capability, especially for low voltage single supply applications.

Although the single supply specifications is defined at 5.0 V , these amplifiers are functional to $3.0 \mathrm{~V} @ 25^{\circ} \mathrm{C}$ although slight changes in parametrics such as bandwidth, slew rate, and DC gain may occur.

If power to this integrated circuit is applied in reverse polarity or if the IC is installed backwards in a socket, large unlimited current surges will occur through the device that may result in device destruction.

Special static precautions are not necessary for these bipolar amplifiers since there are no MOS transistors on the die.

As with most high frequency amplifiers, proper lead dress, component placement, and PC board layout should be exercised for optimum frequency performance. For example, long unshielded input or output leads may result in unwanted input-output coupling. In order to preserve the relatively low input capacitance associated with these amplifiers, resistors connected to the inputs should be immediately adjacent to the input pin to minimize additional stray input capacitance. This not only minimizes the input pole for optimum frequency response, but also minimizes extraneous "pick up" at this node. Supply decoupling with adequate capacitance immediately adjacent to the supply pin is also important, particularly over temperature, since many types of decoupling capacitors exhibit great impedance changes over temperature.

The output of any one amplifier is current limited and thus protected from a direct short to ground. However, under such conditions, it is important not to allow the device to exceed the maximum junction temperature rating. Typically for $\pm 15 \mathrm{~V}$ supplies, any one output can be shorted continuously to ground without exceeding the maximum temperature rating.

## LM211, LM311

## Single Comparators

The ability to operate from a single power supply of 5.0 V to 30 V or $\pm 15 \mathrm{~V}$ split supplies, as commonly used with operational amplifiers, makes the LM211/LM311 a truly versatile comparator. Moreover, the inputs of the device can be isolated from system ground while the output can drive loads referenced either to ground, the $\mathrm{V}_{\mathrm{CC}}$ or the $\mathrm{V}_{\mathrm{EE}}$ supply. This flexibility makes it possible to drive DTL, RTL, TTL, or MOS logic. The output can also switch voltages to 50 V at currents to 50 mA . Thus the LM211/LM311 can be used to drive relays, lamps or solenoids.

*LM211: $\mathrm{T}_{\text {low }}=-25^{\circ} \mathrm{C}, \mathrm{T}_{\text {high }}=+85^{\circ} \mathrm{C}$
LM311: $\mathrm{T}_{\text {low }}=0^{\circ} \mathrm{C}, \mathrm{T}_{\text {high }}=+70^{\circ} \mathrm{C}$

1. Offset voltage, offset current and bias current specifications apply for a supply voltage range from a single 5.0 V supply up to $\pm 15 \mathrm{~V}$ supplies.
2. This rating applies for $\pm 15 \mathrm{~V}$ supplies. The positive input voltage limit is 30 V above the negative supply. The negative input voltage limit is equal to the negative supply voltage or 30 V below the positive supply, whichever is less.
3. The offset voltages and offset currents given are the maximum values required to drive the output within a volt of either supply with a 1.0 mA load. Thus, these parameters define an error band and take into account the "worst case" effects of voltage gain and input impedance.
4. The response time specified is for a 100 mV input step with 5.0 mV overdrive.
5. Do not short the strobe pin to ground; it should be current driven at 3.0 mA to 5.0 mA .

## APPLICATIONS INFORMATION

Figure 16. Improved Method of Adding Hysteresis Without Applying Positive Feedback to the Inputs

Figure 17. Conventional Technique for Adding Hysteresis

## TECHNIQUES FOR AVOIDING OSCILLATIONS IN COMPARATOR APPLICATIONS

When a high speed comparator such as the LM211 is used with high speed input signals and low source impedances, the output response will normally be fast and stable, providing the power supplies have been bypassed (with $0.1 \mu \mathrm{~F}$ disc capacitors), and that the output signal is routed well away from the inputs (Pins 2 and 3) and also away from Pins 5 and 6.

However, when the input signal is a voltage ramp or a slow sine wave, or if the signal source impedance is high ( $1.0 \mathrm{k} \Omega$ to $100 \mathrm{k} \Omega$ ), the comparator may burst into oscillation near the crossing-point. This is due to the high gain and wide bandwidth of comparators like the LM211 series. To avoid oscillation or instability in such a usage, several precautions are recommended, as shown in Figure 16.

The trim pins (Pins 5 and 6) act as unwanted auxiliary inputs. If these pins are not connected to a trim-pot, they should be shorted together. If they are connected to a trim-pot, a $0.01 \mu \mathrm{~F}$ capacitor ( C 1 ) between Pins 5 and 6 will minimize the susceptibility to AC coupling. A smaller capacitor is used if Pin 5 is used for positive feedback as in Figure 16. For the fastest response time, tie both balance pins to $\mathrm{V}_{\mathrm{CC}}$.

Certain sources will produce a cleaner comparator output waveform if a 100 pF to 1000 pF capacitor (C2) is connected directly across the input pins. When the signal source is applied through a resistive network, R1, it is usually advantageous to choose R2 of the same value, both for DC and for dynamic (AC) considerations. Carbon, tin-oxide, and metal-film resistors have all been used with good results in comparator input circuitry, but inductive wirewound resistors should be avoided.

When comparator circuits use input resistors (e.g., summing resistors), their value and placement are particularly important. In all cases the body of the resistor should be close to the device or socket. In other words, there should be a very short lead length or printed-circuit foil run between comparator and resistor to radiate or pick up signals. The same applies to capacitors, pots, etc. For example, if R1 = $10 \mathrm{k} \Omega$, as little as 5 inches of lead between the resistors and the input pins can result in oscillations that are very hard to dampen. Twisting these input leads tightly is the best alternative to placing resistors close to the comparator.

Since feedback to almost any pin of a comparator can result in oscillation, the printed-circuit layout should be engineered thoughtfully. Preferably there should be a groundplane under the LM211 circuitry (e.g., one side of a double layer printed circuit board). Ground, positive supply or negative supply foil should extend between the output and the inputs to act as a guard. The foil connections for the inputs should be as small and compact as possible, and should be essentially surrounded by ground foil on all sides to guard against capacitive coupling from any fast high-level signals (such as the output). If Pins 5 and 6 are not used, they should be shorted together. If they are connected to a trim-pot, the trim-pot should be located no more than a few inches away from the LM211, and a $0.01 \mu \mathrm{~F}$ capacitor should be installed across Pins 5 and 6 . If this capacitor cannot be used, a shielding printed-circuit foil may be advisable between Pins 6 and 7. The power supply bypass capacitors should be located within a couple inches of the LM211.
A standard procedure is to add hysteresis to a comparator to prevent oscillation, and to avoid excessive noise on the output. In the circuit of Figure 17, the feedback resistor of $510 \mathrm{k} \Omega$ from the output to the positive input will cause about 3.0 mV of hysteresis. However, if R2 is larger than $100 \Omega$ such as $50 \mathrm{k} \Omega$, it would not be practical to simply increase the value of the positive feedback resistor proportionally above $510 \mathrm{k} \Omega$ to maintain the same amount of hysteresis.
When both inputs of the LM211 are connected to active signals, or if a high-impedance signal is driving the positive input of the LM211 so that positive feedback would be disruptive, the circuit of Figure 16 is ideal. The positive feedback is applied to Pin 5 (one of the offset adjustment pins). This will be sufficient to cause 1.0 mV to 2.0 mV hysteresis and sharp transitions with input triangle waves from a few Hz to hundreds of kHz . The positive-feedback signal across the $82 \Omega$ resistor swings 240 mV below the positive supply. This signal is centered around the nominal voltage at Pin 5, so this feedback does not add to the offset voltage of the comparator. As much as 8.0 mV of offset voltage can be trimmed out, using the $5.0 \mathrm{k} \Omega$ pot and $3.0 \mathrm{k} \Omega$ resistor as shown.

## NCS2200 Series

## Advance Information <br> Low Voltage Comparators

The NCS2200 series is an industry first sub-one volt, low power comparator family. These devices consume only $10 \mu \mathrm{~A}$ of supply current. They are guaranteed to operate at a low voltage of 0.85 V which allows them to be used in systems that require less than 1.0 V and is fully operational up to 6.0 V which makes it convenient to be used in both 3.0 V and 5.0 V systems. Additional features include no output phase inversion when transitioning in/out of tri-state mode, internal hysteresis which allows for clean output switching, and rail-to-rail input performance. The NCS2200 series are available in the tiny SOT23-5 and SOT23-6 package and feature two industry standard pinouts.

The NCS22201/3 Series in the SOT23-6 package features an enable function which can be externally controlled. This lowers current consumption to $1.8 \mu \mathrm{~A}$ and allows for users to implement these devices in power sensitive applications such as portable electronics.

## Features

- Operating Voltage of 0.85 V to 6.0 V
- Rail-to-rail Input/Output Performance
- Low Supply Current of $10 \mu \mathrm{~A}$
- No Phase Inversion/Glitchless transitioning in or out of Tri-State Mode
- Complementary or Open Drain Output Configuration
- Available with the Enable Function
- Tiny SOT23-5 and SOT23-6 Package

## Typical Applications

- Single Cell NiCd/NiMH Battery Powered Applications
- Window Comparator
- Portable Electronics
- Voltage Detector
- Zero-Crossing Detectors
- Personal Digital Assistants

This device contains 93 active transistors.

## OPERATING DESCRIPTION

The NCS2200 Series is an industry first sub-one volt, low power comparators. These devices consume only $10 \mu \mathrm{~A}$ of supply current while achieving a typical propagation delay of $1.1 \mu \mathrm{~s}$ at 10 mV overdrive. They are guaranteed to operate at a low voltage of 0.85 V up to 6.0 V . This is accomplished by the use of a modified analog CMOS process which implements depletion MOSFET devices. The common-mode input voltage range extends 0.1 V above the upper and lower rail. They are available in SOT23-5 (compatible with the TSOP-5) and SOT23-6 packages. The SOT23-6 has the enable function which can be externally controlled. It allows for lower current consumption of 1.8 $\mu \mathrm{A}$. This makes the devices suitable for implementation in power sensitive applications such as portable electronics. When the enable pin is at a low level, the output will remain at a high or low level. The output will not respond to any changes at the input pins.

Figure 15. NCS230xSNxT1 Complementary Output Configuration

Figure 14. NCS2200 Series Disabled Supply Current

Conversely, when the enable pin is at a high level, the output will respond to change at the input pins. The enable pin should be connected to VCC when not in use. In addition, with the added feature of internal hysteresis, this allows for greater noise immunity and clean output switching.

## Output Stage

The NCS2200/1 has a complementary output which drives rail-to-rail output swing. The NCS2202/3 has an open drain N -channel output that can be pulled up to 6.0 V (max) with an external pull- up resistor. This allows for mixed-voltage system applications These devices can operate up to an 7.0 mA load. The output stage is designed so that shoot through current is minimized while switching. This enhancement eliminates the need for bypass capacitors. There is no output phase reversal when switching in or out of tri-state mode.

Figure 16. NCS230xSNxT1 Open Drain Output Configuration

The oscillation frequency can be programmed as follows:

$$
f=\frac{1}{T}=\frac{1}{2.2 R_{X} C_{X}}
$$

Figure 17. Schmitt Trigger Oscillator

The resistor divider $R_{1}$ and $R_{2}$ can be used to set the magnitude of the input pulse. The pulse width is set by adjusting $C_{1}$ and $R_{3}$.

## NCS2300 Series

## Advance Information <br> High Voltage Comparators

The NCS2300 Series are ultra-low power comparators. These devices consume only $11 \mu \mathrm{~A}$ of supply current. They operate at a wide voltage range of 1.7 V to 12 V . Additional features include no output phase inversion when transitioning in/out of tri-state mode, internal hysteresis which allows for clean output switching, and rail-to-rail input performance. The NCS2300 Series are available in the tiny SOT23-5 or SOT23-6 package with two industry standard pinouts.

The NCS2301/3 Series in the SOT23-6 package features an enable function which can be externally controlled. This lowers current consumption to $1.8 \mu \mathrm{~A}$ and allows for users to implement these devices in power sensitive applications such as portable electronics.

## Features

- Rail-to-Rail Input/Output Performance
- Low Supply Current of $11 \mu \mathrm{~A}$
- No Phase Inversion/Glitchless transitioning in or out of Tri-State Mode
- Complementary or Open Drain Output Configuration
- Available with the Enable Function
- Tiny SOT23-5 and SOT23-6 Package

## Typical Applications

- Portable Electronics
- Window Comparator
- Voltage Detector
- Zero-Crossing Detectors
- Personal Digital Assistants

This device contains 121 active transistors.

## Low Offset Voltage Dual Comparators

The LM393 series are dual independent precision voltage comparators capable of single or split supply operation. These devices are designed to permit a common mode range-to-ground level with single supply operation. Input offset voltage specifications as low as 2.0 mV make this device an excellent selection for many applications in consumer, automotive, and industrial electronics.

- Wide Single-Supply Range: 2.0 Vdc to 36 Vdc
- Split-Supply Range: $\pm 1.0$ Vdc to $\pm 18$ Vdc
- Very Low Current Drain Independent of Supply Voltage: 0.4 mA
- Low Input Bias Current: 25 nA
- Low Input Offset Current: 5.0 nA
- Low Input Offset Voltage: 5.0 mV (max) LM293/393
- Input Common Mode Range to Ground Level
- Differential Input Voltage Range Equal to Power Supply Voltage
- Output Voltage Compatible with DTL, ECL, TTL, MOS, and CMOS Logic Levels
- ESD Clamps on the Inputs Increase the Ruggedness of the Device without Affecting Performance

LM293 $\mathrm{T}_{\text {low }}=-25^{\circ} \mathrm{C}, \mathrm{T}_{\text {high }}=+85^{\circ} \mathrm{C}$
LM393 T $\mathrm{T}_{\text {low }}=0^{\circ} \mathrm{C}, \mathrm{T}_{\text {high }}=+70^{\circ} \mathrm{C}$
LM2903 $\mathrm{T}_{\text {low }}=-40^{\circ} \mathrm{C}, \mathrm{T}_{\text {high }}=+105^{\circ} \mathrm{C}$
$\mathrm{LM} 2903 \mathrm{~V} \mathrm{~T}_{\text {low }}=-40^{\circ} \mathrm{C}, \mathrm{T}_{\text {high }}=+125^{\circ} \mathrm{C}$
NCV2903 $\mathrm{T}_{\text {low }}=-40^{\circ} \mathrm{C}, \mathrm{T}_{\text {high }}=+125^{\circ} \mathrm{C}$. Guaranteed by design. NCV prefix is for automotive and other applications requiring site and change control.
2. The maximum output current may be as high as 20 mA , independent of the magnitude of $\mathrm{V}_{\mathrm{CC}}$, output short circuits to $\mathrm{V}_{\mathrm{CC}}$ can cause excessive heating and eventual destruction.
3. At output switch point, $\mathrm{V}_{\mathrm{O}} \simeq 1.4 \mathrm{Vdc}, \mathrm{R}_{\mathrm{S}}=0 \Omega$ with $\mathrm{V}_{\mathrm{Cc}}$ from 5.0 Vdc to 30 Vdc , and over the full input common mode range ( 0 V to $\mathrm{V}_{\mathrm{CC}}=-1.5 \mathrm{~V}$ ).
4. Due to the PNP transistor inputs, bias current will flow out of the inputs. This current is essentially constant, independent of the output state, therefore, no loading changes will exist on the input lines.
5. Input common mode of either input should not be permitted to go more than 0.3 V negative of ground or minus supply. The upper limit of common mode range is $\mathrm{V}_{\mathrm{CC}}-1.5 \mathrm{~V}$.
6. Response time is specified with a 100 mV step and 5.0 mV of overdrive. With larger magnitudes of overdrive faster response times are obtainable.
7. The comparator will exhibit proper output state if one of the inputs becomes greater than $\mathrm{V}_{\mathrm{CC}}$, the other input must remain within the common mode range. The low input state must not be less than -0.3 V of ground or minus supply.

## LM393, LM293, LM2903, LM2903V, NCV2903

## APPLICATIONS INFORMATION

These dual comparators feature high gain, wide bandwidth characteristics. This gives the device oscillation tendencies if the outputs are capacitively coupled to the inputs via stray capacitance. This oscillation manifests itself during output transitions $\left(\mathrm{V}_{\mathrm{OL}}\right.$ to $\left.\mathrm{V}_{\mathrm{OH}}\right)$. To alleviate this situation, input resistors $<10 \mathrm{k} \Omega$ should be used.

D1 prevents input from going negative by more than 0.6 V .

$$
\mathrm{R} 1+\mathrm{R} 2=\mathrm{R} 3
$$

$R 3 \leq \frac{R 5}{10}$ for small error in zero crossing.
Figure 8. Zero Crossing Detector (Single Supply)

Figure 10. Free-Running Square-Wave Oscillator

The addition of positive feedback $(<10 \mathrm{mV})$ is also recommended. It is good design practice to ground all unused pins.

Differential input voltages may be larger than supply voltage without damaging the comparator's inputs. Voltages more negative than -0.3 V should not be used.

## Single Supply Quad Comparators

These comparators are designed for use in level detection, low-level sensing and memory applications in consumer, automotive, and industrial electronic applications.

- Single or Split Supply Operation
- Low Input Bias Current: 25 nA (Typ)
- Low Input Offset Current: $\pm 5.0 \mathrm{nA}$ (Typ)
- Low Input Offset Voltage
- Input Common Mode Voltage Range to Gnd
- Low Output Saturation Voltage: 130 mV (Typ) @ 4.0 mA
- TTL and CMOS Compatible
- ESD Clamps on the Inputs Increase Reliability without Affecting Device Operation

## APPLICATIONS INFORMATION

These quad comparators feature high gain, wide bandwidth characteristics. This gives the device oscillation tendencies if the outputs are capacitively coupled to the inputs via stray capacitance. This oscillation manifests itself during output transitions $\left(\mathrm{V}_{\mathrm{OL}}\right.$ to $\left.\mathrm{V}_{\mathrm{OH}}\right)$. To alleviate this situation input resistors $<10 \mathrm{k} \Omega$ should be used. The

D1 prevents input from going negative by more than 0.6 V .

\mathrm{R} 1+\mathrm{R} 2=\mathrm{R} 3
$$

$R 3 \leq \frac{R 5}{10}$ for small error in zero crossing

Figure 9. Zero Crossing Detector (Single Supply)
addition of positive feedback ( $<10 \mathrm{mV}$ ) is also recommended. It is good design practice to ground all unused input pins.

Differential input voltages may be larger than supply voltages without damaging the comparator's inputs. Voltages more negative than -300 mV should not be used.
$\mathrm{V}_{\text {in(min) }} \approx 0.4 \mathrm{~V}$ peak for $1 \%$ phase distortion $(\Delta \Theta)$.

## Overvoltage Crowbar Sensing Circuit

This overvoltage protection circuit (OVP) protects sensitive electronic circuitry from overvoltage transients or regulator failures when used in conjunction with an external "crowbar" SCR. The device senses the overvoltage condition and quickly "crowbars" or short circuits the supply, forcing the supply into current limiting or opening the fuse or circuit breaker.

The protection voltage threshold is adjustable and the MC3423 can be programmed for minimum duration of overvoltage condition before tripping, thus supplying noise immunity.

The MC3423 is essentially a "two terminal" system, therefore it can be used with either positive or negative supplies.

Figure 5. Basic Configuration for Programmable Duration
of Overvoltage Condition Before Trip

## APPLICATION INFORMATION

## Basic Circuit Configuration

The basic circuit configuration of the MC3423 OVP is shown in Figure 3 for supply voltages from 4.5 V to 36 V , and in Figure 4 for trip voltages above 36 V . The threshold or trip voltage at which the MC3423 will trigger and supply gate drive to the crowbar SCR, Q1, is determined by the selection of R1 and R2. Their values can be determined by the equation given in Figures 3 and 4, or by the graph shown in Figure 8. The minimum value of the gate current limiting resistor, $\mathrm{R}_{\mathrm{G}}$, is given in Figure 9. Using this value of $\mathrm{R}_{\mathrm{G}}$, the SCR, Q1, will receive the greatest gate current possible without damaging the MC3423. If lower output currents are required, $\mathrm{R}_{\mathrm{G}}$ can be increased in value. The switch, S 1 , shown in Figure 3 may be used to reset the crowbar. Otherwise, the power supply, across which the SCR is connected, must be shut down to reset the crowbar. If a non current-limited supply is used, a fuse or circuit breaker, F1, should be used to protect the SCR and/or the load.

The circuit configurations shown in Figures 3 and 4 will have a typical propagating delay of $1.0 \mu \mathrm{~s}$. If faster operation is desired, Pin 3 may be connected to Pin 2 with Pin 4 left floating. This will result in decreasing the propagating delay to approximately $0.5 \mu \mathrm{~s}$ at the expense of a slightly increased TC for the trip voltage value.

## Configuration for Programmable Minimum Duration of Overvoltage Condition Before Tripping

In many instances, the MC3423 OVP will be used in a noise environment. To prevent false tripping of the OVP circuit by noise which would not normally harm the load, MC3423 has a programmable delay feature. To implement this feature, the circuit configuration of Figure 5 is used. In this configuration, a capacitor is connected from Pin 3 to $\mathrm{V}_{\mathrm{EE}}$. The value of this capacitor determines the minimum duration of the overvoltage condition which is necessary to trip the OVP. The value of C can be found from Figure 10. The circuit operates in the following manner: When $\mathrm{V}_{\mathrm{CC}}$ rises above the trip point set by R1 and R2, an internal current source (Pin 4) begins charging the capacitor, C, connected to Pin 3. If the overvoltage condition disappears before this occurs, the capacitor is discharged at a rate $\cong 10$ times faster than the charging rate, resetting the timing feature until the next overvoltage condition occurs.

Occasionally, it is desired that immediate crowbarring of the supply occur when a high overvoltage condition occurs, while retaining the false tripping immunity of Figure 5. In this case, the circuit of Figure 6 can be used. The circuit will operate as previously described for small overvoltages, but will immediately trip if the power supply voltage exceeds $\mathrm{V}_{\mathrm{Z} 1}+1.4 \mathrm{~V}$.

Figure 6. Configuration for Programmable Duration of Overvoltage Condition Before Trip/With Immediate Trip at High Overvoltages

## Additional Features

## 1. Activation Indication Output

An additional output for use as an indicator of OVP activation is provided by the MC3423. This output is an open collector transistor which saturates when the OVP is activated. In addition, it can be used to clock an edge triggered flip-flop whose output inhibits or shuts down the power supply when the OVP trips. This reduces or eliminates the heatsinking requirements for the crowbar SCR.

## 2. Remote Activation Input

Another feature of the MC3423 is its remote activation input, Pin 5. If the voltage on this CMOS/TTL compatible input is held below 0.8 V , the MC3423 operates normally. However, if it is raised to a voltage above 2.0 V , the OVP output is activated independent of whether or not an overvoltage condition is present. It should be noted that Pin 5 has an internal pull-up current source. This feature can be used to accomplish an orderly and sequenced shutdown of system power supplies during a system fault condition. In addition, the activation indication output of one MC3423 can be used to activate another MC3423 if a single transistor inverter is used to interface the former's indication output to the latter's remote activation input, as shown in Figure 7. In this circuit, the indication output (Pin 6) of the MC3423 on power supply 1 is used to activate the MC3423 associated with power supply 2. Q1 is any small PNP with adequate voltage rating.

Figure 7. Circuit Configuration for Activating One MC3423 from Another

Note that both supplies have their negative output leads tied together (i.e., both are positive supplies). If their positive leads are common (two negative supplies) the emitter of Q1 would be moved to the positive lead of supply 1 and R1 would therefore have to be resized to deliver the appropriate drive to Q1.

## Crowbar SCR Considerations

Referring to Figure 11, it can be seen that the crowbar SCR, when activated, is subject to a large current surge from the output capacitance, $\mathrm{C}_{\text {out }}$. This capacitance consists of the power supply output caps, the load's decoupling caps, and in the case of Figure 11A, the supply's input filter caps. This surge current is illustrated in Figure 12, and can cause SCR failure or degradation by any one of three mechanisms: di/dt, absolute peak surge, or $\mathrm{I}^{2} \mathrm{t}$. The interrelationship of these failure methods and the breadth of the applications make specification of the SCR by the semiconductor manufacturer difficult and expensive. Therefore, the designer must empirically determine the SCR and circuit elements which result in reliable and effective OVP operation. However, an understanding of the factors which influence the SCR's di/dt and surge capabilities simplifies this task.

## di/dt

As the gate region of the SCR is driven on, its area of conduction takes a finite amount of time to grow, starting as a very small region and gradually spreading. Since the anode current flows through this turned-on gate region, very high current densities can occur in the gate region if high anode currents appear quickly (di/dt). This can result in immediate destruction of the SCR or gradual degradation of its forward blocking voltage capabilities depending on the severity of the occasion.

Figure 8. R1 versus Trip Voltage

Figure 9. Minimum $\mathbf{R}_{\mathrm{G}}$ versus Supply Voltage

Figure 10. Capacitance versus Minimum Overvoltage Duration

Figure 11. Typical Crowbar OVP Circuit Configurations

Figure 12. Crowbar SCR Surge Current Waveform

Figure 13. Circuit Elements Affecting SCR Surge and di/dt

The usual design compromise then is to use a garden variety fuse (3AG or 3AB style) which cannot be relied on to blow before the thyristor does, and trust that if the SCR does fail, it will fail short circuit. In the majority of the designs, this will be the case, though this is difficult to guarantee. Of course, a sufficiently high surge will cause an open. These comments also apply to the fuse in Figure 11B.

The value of di/dt that an SCR can safely handle is influenced by its construction and the characteristics of the
gate drive signal. A center-gate-fire SCR has more di/dt capability than a corner-gate-fire type, and heavily overdriving ( 3 to 5 times $\mathrm{I}_{\mathrm{GT}}$ ) the SCR gate with a fast $<1.0 \mu$ s rise time signal will maximize its di/dt capability. A typical maximum number in phase control SCRs of less than $50 \mathrm{~A}(\mathrm{RMS})$ rating might be $200 \mathrm{~A} / \mu \mathrm{s}$, assuming a gate current of five times $\mathrm{I}_{\mathrm{GT}}$ and $<1.0 \mu$ s rise time. If having done this, a di/dt problem is seen to still exist, the designer can also decrease the di/dt of the current waveform by adding inductance in series with the SCR, as shown in Figure 13. Of course, this reduces the circuit's ability to rapidly reduce the DC bus voltage and a tradeoff must be made between speedy voltage reduction and di/dt.

## Surge Current

If the peak current and/or the duration of the surge is excessive, immediate destruction due to device overheating will result. The surge capability of the SCR is directly proportional to its die area. If the surge current cannot be reduced (by adding series resistance - see Figure 13) to a safe level which is consistent with the systems requirements for speedy bus voltage reduction, the designer must use a higher current SCR. This may result in the average current capability of the SCR exceeding the steady state current requirements imposed by the DC power supply.

## A WORD ABOUT FUSING

Before leaving the subject of the crowbar SCR, a few words about fuse protection are in order. Referring back to Figure 11 A , it will be seen that a fuse is necessary if the power supply to be protected is not output current limited. This fuse is not meant to prevent SCR failure but rather to prevent a fire!

In order to protect the SCR, the fuse would have to possess an $\mathrm{I}^{2} \mathrm{t}$ rating less than that of the SCR and yet have a high enough continuous current rating to survive normal supply output currents. In addition, it must be capable of successfully clearing the high short circuit currents from the supply. Such a fuse as this is quite expensive, and may not even be available.

## CROWBAR SCR SELECTION GUIDE

As an aid in selecting an SCR for crowbar use, the following selection guide is presented.

| Device | $\mathbf{I}_{\text {RMS }}$ | $\mathbf{I}_{\text {FSM }}$ | Package |

## NCP3712ASNT1

## Over Voltage Protected High Side Switch

This switch is primarily intended to protect loads from transients by isolating the load from the transient energy rather than absorbing it.

## Features

- Capable of Switching Loads of up to 200 mA without External Rboost
- Switch Shuts Off in Response to an Over Voltage Input Transient
- Features Active Turn Off for Fast Input Transient Protection
- Flexible Over Voltage Protection Threshold Set with External Zener
- Automatic Recovery after Transient Decays Below Threshold
- Withstands Input Transients up to 105 V Peak
- Guaranteed Off State with Enbl Input
- ESD Resistant in Accordance with the 2000 V Human Body Model
- Extremely Low Saturation Voltage

## Applications Include:

- High Voltage Transient Isolation
- Power Switching to Electronic Modules
- DC Power Distribution in Line Operated Equipment
- Buffering Sensitive Circuits from Poorly Regulated Power Supplies
- Pre-conditioning of Voltage Regulator Input Voltage

Figure 1. Typical Application Circuit

## INFORMATION FOR USING THE TSOP-6 SURFACE MOUNT PACKAGE MINIMUM RECOMMENDED FOOTPRINT FOR SURFACE MOUNTED APPLICATIONS

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to insure proper solder connection
interface between the board and the package. With the correct pad geometry, the packages will self align when subjected to a solder reflow process.

## TSOP-6 POWER DISSIPATION

The power dissipation of the TSOP-6 is a function of the drain pad size. This can vary from the minimum pad size for soldering to a pad size given for maximum power dissipation. Power dissipation for a surface mount device is determined by $\mathrm{T}_{\mathrm{J}(\max )}$, the maximum rated junction temperature of the die, $\mathrm{R}_{\theta \mathrm{JA}}$, the thermal resistance from the device junction to ambient, and the operating temperature, $\mathrm{T}_{\mathrm{A}}$. Using the values provided on the data sheet for the TSOP-6 package, $\mathrm{P}_{\mathrm{D}}$ can be calculated as follows:

$$
P_{D}=\frac{T_{J(\max )}-T_{A}}{R_{\theta J A}}
$$

The values for the equation are found in the maximum ratings table on the data sheet. Substituting these values into the equation for an ambient temperature $\mathrm{T}_{\mathrm{A}}$ of $25^{\circ} \mathrm{C}$, one can calculate the power dissipation of the device which in this case is 950 milliwatts.

$$
P_{D}=\frac{150^{\circ} \mathrm{C}-25^{\circ} \mathrm{C}}{132^{\circ} \mathrm{C} / \mathrm{W}}=950 \text { milliwatts }
$$

The $132^{\circ} \mathrm{C} / \mathrm{W}$ for the TSOP-6 package assumes the use of the recommended footprint on a glass epoxy printed circuit board to achieve a power dissipation of 950 milliwatts. There are other alternatives to achieving higher power dissipation from the TSOP-6 package. Another alternative would be to use a ceramic substrate or an aluminum core board such as Thermal Clad ${ }^{\mathrm{TM}}$. Using a board material such as Thermal Clad, an aluminum core board, the power dissipation can be doubled using the same footprint.

## SOLDERING PRECAUTIONS

The melting temperature of solder is higher than the rated temperature of the device. When the entire device is heated to a high temperature, failure to complete soldering within a short time could result in device failure. Therefore, the following items should always be observed in order to minimize the thermal stress to which the devices are subjected.

- Always preheat the device.
- The delta temperature between the preheat and soldering should be $100^{\circ} \mathrm{C}$ or less.*
- When preheating and soldering, the temperature of the leads and the case must not exceed the maximum temperature ratings as shown on the data sheet. When using infrared heating with the reflow soldering method, the difference shall be a maximum of $10^{\circ} \mathrm{C}$.
- The soldering temperature and time shall not exceed $260^{\circ} \mathrm{C}$ for more than 10 seconds.
- When shifting from preheating to soldering, the maximum temperature gradient shall be $5^{\circ} \mathrm{C}$ or less.
- After soldering has been completed, the device should be allowed to cool naturally for at least three minutes. Gradual cooling should be used as the use of forced cooling will increase the temperature gradient and result in latent failure due to mechanical stress.
- Mechanical stress or shock should not be applied during cooling.
*     * Soldering a device without preheating can cause excessive thermal shock and stress which can result in damage to the device.

## MC34161, MC33161

## Universal Voltage Monitors

The MC34161/MC33161 are universal voltage monitors intended for use in a wide variety of voltage sensing applications. These devices offer the circuit designer an economical solution for positive and negative voltage detection. The circuit consists of two comparator channels each with hysteresis, a unique Mode Select Input for channel programming, a pinned out 2.54 V reference, and two open collector outputs capable of sinking in excess of 10 mA . Each comparator channel can be configured as either inverting or noninverting by the Mode Select Input. This allows over, under, and window detection of positive and negative voltages. The minimum supply voltage needed for these devices to be fully functional is 2.0 V for positive voltage sensing and 4.0 V for negative voltage sensing.

Applications include direct monitoring of positive and negative voltages used in appliance, automotive, consumer, and industrial equipment.

- Unique Mode Select Input Allows Channel Programming
- Over, Under, and Window Voltage Detection
- Positive and Negative Voltage Detection
- Fully Functional at 2.0 V for Positive Voltage Sensing and 4.0 V for Negative Voltage Sensing
- Pinned Out 2.54 V Reference with Current Limit Protection
- Low Standby Current
- Open Collector Outputs for Enhanced Device Flexibility

This device contains 141 transistors.

## FUNCTIONAL DESCRIPTION

## Introduction

To be competitive in today's electronic equipment market, new circuits must be designed to increase system reliability with minimal incremental cost. The circuit designer can take a significant step toward attaining these goals by implementing economical circuitry that continuously monitors critical circuit voltages and provides a fault signal in the event of an out-of-tolerance condition. The MC34161, MC33161 series are universal voltage monitors intended for use in a wide variety of voltage sensing applications. The main objectives of this series was to configure a device that can be used in as many voltage sensing applications as possible while minimizing cost. The flexibility objective is achieved by the utilization of a unique Mode Select input that is used in conjunction with traditional circuit building blocks. The cost objective is achieved by processing the device on a standard Bipolar Analog flow, and by limiting the package to eight pins. The device consists of two comparator channels each with hysteresis, a mode select input for channel programming, a pinned out reference, and two open collector outputs. Each comparator channel can be configured as either inverting or noninverting by the Mode Select input. This allows a single device to perform over, under, and window detection of positive and negative voltages. A detailed description of each section of the device is given below with the representative block diagram shown in Figure 14.

## Input Comparators

The input comparators of each channel are identical, each having an upper threshold voltage of $1.27 \mathrm{~V} \pm 2.0 \%$ with 25 mV of hysteresis. The hysteresis is provided to enhance output switching by preventing oscillations as the comparator thresholds are crossed. The comparators have an input bias current of 60 nA at their threshold which approximates a $21.2 \mathrm{M} \Omega$ resistor to ground. This high impedance minimizes loading of the external voltage divider for well defined trip points. For all positive voltage sensing applications, both comparator channels are fully functional at a $\mathrm{V}_{\mathrm{CC}}$ of 2.0 V . In order to provide enhanced device ruggedness for hostile industrial environments, additional circuitry was designed into the inputs to prevent device latch-up as well as to suppress electrostatic discharges (ESD).

## Reference

The 2.54 V reference is pinned out to provide a means for the input comparators to sense negative voltages, as well as a means to program the Mode Select input for window detection applications. The reference is capable of sourcing in excess of 2.0 mA output current and has built-in short circuit protection. The output voltage has a guaranteed tolerance of $\pm 2.4 \%$ at room temperature.

The 2.54 V reference is derived by gaining up the internal 1.27 V reference by a factor of two. With a power supply voltage of 4.0 V , the 2.54 V reference is in full regulation, allowing the device to accurately sense negative voltages.

## Mode Select Circuit

The key feature that allows this device to be flexible is the Mode Select input. This input allows the user to program each of the channels for various types of voltage sensing applications. Figure 15 shows that the Mode Select input has three defined states. These states determine whether Channel 1 and/or Channel 2 operate in the inverting or noninverting mode. The Mode Select thresholds are shown in Figure 6. The input circuitry forms a tristate switch with thresholds at 0.63 V and $\mathrm{V}_{\text {ref }}+0.23 \mathrm{~V}$. The mode select input current is $10 \mu \mathrm{~A}$ when connected to the reference output, and $42 \mu \mathrm{~A}$ when connected to a $\mathrm{V}_{\mathrm{CC}}$ of 5.0 V , refer to Figure 7.

## Output Stage

The output stage uses a positive feedback base boost circuit for enhanced sink saturation, while maintaining a relatively low device standby current. Figure 11 shows that the sink saturation voltage is about 0.2 V at 8.0 mA over temperature. By combining the low output saturation characteristics with low voltage comparator operation, this device is capable of sensing positive voltages at a $\mathrm{V}_{\mathrm{CC}}$ of 1.0 V . These characteristics are important in undervoltage sensing applications where the output must stay in a low state as $\mathrm{V}_{\mathrm{CC}}$ approaches ground. Figure 5 shows the Output Voltage versus Supply Voltage in an undervoltage sensing application. Note that as $\mathrm{V}_{\mathrm{CC}}$ drops below the programmed 4.5 V trip point, the output stays in a well defined active low state until $\mathrm{V}_{\mathrm{CC}}$ drops below 1.0 V .

## APPLICATIONS

The following circuit figures illustrate the flexibility of this device. Included are voltage sensing applications for over, under, and window detectors, as well as three unique configurations. Many of the voltage detection circuits are shown with the open collector outputs of each channel connected together driving a light emitting diode (LED). This 'ORed' connection is shown for ease of explanation and it is only required for window detection applications.

Note that many of the voltage detection circuits are shown with a dashed line output connection. This connection gives the inverse function of the solid line connection. For example, the solid line output connection of Figure 16 has the LED 'ON' when input voltage $\mathrm{V}_{\mathrm{S}}$ is above trip voltage $\mathrm{V}_{2}$, for overvoltage detection. The dashed line output connection has the LED ' ON ' when $\mathrm{V}_{\mathrm{S}}$ is below trip voltage $\mathrm{V}_{2}$, for undervoltage detection.

The above figure shows the MC34161 configured as a dual positive overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when $\mathrm{V}_{\mathrm{S} 1}$ or $\mathrm{V}_{\mathrm{S} 2}$ exceeds $\mathrm{V}_{2}$. With the dashed line output connection, the circuit becomes a dual positive undervoltage detector. As the input voltage decreases from the peak towards ground, the LED will turn 'ON' when $\mathrm{V}_{\mathrm{S} 1}$ or $\mathrm{V}_{\mathrm{S} 2}$ falls below $\mathrm{V}_{1}$.

For known resistor values, the voltage trip points are:

$$
\mathrm{V}_{1}=\left(\mathrm{V}_{\mathrm{th}}-\mathrm{V}_{\mathrm{H}}\right)\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right) \quad \mathrm{V}_{2}=\mathrm{V}_{\mathrm{th}}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)
$$

For a specific trip voltage, the required resistor ratio is:

$$
\frac{R_{2}}{R_{1}}=\frac{V_{1}}{V_{t h}-V_{H}}-1 \quad \frac{R_{2}}{R_{1}}=\frac{V_{2}}{V_{t h}}-1
$$

Figure 16. Dual Positive Overvoltage Detector

The above figure shows the MC34161 configured as a dual positive undervoltage detector. As the input voltage decreases towards ground, the LED will turn 'ON' when $\mathrm{V}_{\mathrm{S} 1}$ or $\mathrm{V}_{\mathrm{S} 2}$ falls below $\mathrm{V}_{1}$. With the dashed line output connection, the circuit becomes a dual positive overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when $V_{S 1}$ or $V_{S 2}$ exceeds $V_{2}$.

For known resistor values, the voltage trip points are:

$$
\mathrm{V}_{1}=\left(\mathrm{V}_{\mathrm{th}}-\mathrm{V}_{\mathrm{H}}\right)\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right) \quad \mathrm{V}_{2}=\mathrm{V}_{\mathrm{th}}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)
$$

For a specific trip voltage, the required resistor ratio is:

$$
\frac{R_{2}}{R_{1}}=\frac{V_{1}}{V_{t h}-V_{H}}-1 \quad \frac{R_{2}}{R_{1}}=\frac{V_{2}}{V_{t h}}-1
$$

Figure 17. Dual Positive Undervoltage Detector

The above figure shows the MC34161 configured as a dual negative overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when $-\mathrm{V}_{\mathrm{S} 1}$ or $-\mathrm{V}_{\mathrm{S} 2}$ exceeds $\mathrm{V}_{2}$. With the dashed line output connection, the circuit becomes a dual negative undervoltage detector. As the input voltage decreases from the peak towards ground, the LED will turn 'ON' when $-\mathrm{V}_{\mathrm{S} 1}$ or $-\mathrm{V}_{\mathrm{S} 2}$ falls below $\mathrm{V}_{1}$.

For known resistor values, the voltage trip points are:

$$
\mathrm{V}_{1}=\frac{\mathrm{R}_{1}}{\mathrm{R}_{2}}\left(\mathrm{~V}_{\text {th }}-\mathrm{V}_{\text {ref }}\right)+\mathrm{V}_{\text {th }} \quad \mathrm{V}_{2}=\frac{\mathrm{R}_{1}}{\mathrm{R}_{2}}\left(\mathrm{~V}_{\text {th }}-\mathrm{V}_{\mathrm{H}}-\mathrm{V}_{\text {ref }}\right)+\mathrm{V}_{\text {th }}-\mathrm{V}_{\mathrm{H}}
$$

For a specific trip voltage, the required resistor ratio is:

$$
\frac{R_{1}}{R_{2}}=\frac{V_{1}-V_{\text {th }}}{V_{\text {th }}-V_{\text {ref }}} \quad \frac{R_{1}}{R_{2}}=\frac{V_{2}-V_{\text {th }}+V_{H}}{V_{\text {th }}-V_{H}-V_{\text {ref }}}
$$

Figure 18. Dual Negative Overvoltage Detector

The above figure shows the MC34161 configured as a dual negative undervoltage detector. As the input voltage decreases towards ground, the LED will turn 'ON' when $-V_{S 1}$ or $-V_{S 2}$ falls below $V_{1}$. With the dashed line output connection, the circuit becomes a dual negative overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when $-\mathrm{V}_{\mathrm{S} 1}$ or $-\mathrm{V}_{\mathrm{S} 2}$ exceeds $\mathrm{V}_{2}$.

For known resistor values, the voltage trip points are:

$$
\mathrm{V}_{1}=\frac{\mathrm{R}_{1}}{\mathrm{R}_{2}}\left(\mathrm{~V}_{\text {th }}-\mathrm{V}_{\mathrm{ref}}\right)+\mathrm{V}_{\text {th }} \quad \mathrm{V}_{2}=\frac{\mathrm{R}_{1}}{\mathrm{R}_{2}}\left(\mathrm{~V}_{\mathrm{th}}-\mathrm{V}_{\mathrm{H}}-\mathrm{V}_{\mathrm{ref}}\right)+\mathrm{V}_{\mathrm{th}}-\mathrm{V}_{\mathrm{H}}
$$

For a specific trip voltage, the required resistor ratio is:

$$
\frac{R_{1}}{R_{2}}=\frac{V_{1}-V_{\text {th }}}{V_{\text {th }}-V_{\text {ref }}} \quad \frac{R_{1}}{R_{2}}=\frac{V_{2}-V_{\text {th }}+V_{H}}{V_{\text {th }}-V_{H}-V_{\text {ref }}}
$$

Figure 19. Dual Negative Undervoltage Detector

The above figure shows the MC34161 configured as a positive voltage window detector. This is accomplished by connecting channel 1 as an undervoltage detector, and channel 2 as an overvoltage detector. When the input voltage $\mathrm{V}_{S}$ falls out of the window established by $\mathrm{V}_{1}$ and $\mathrm{V}_{4}$, the LED will turn 'ON'. As the input voltage falls within the window, $V_{S}$ increasing from ground and exceeding $V_{2}$, or $\mathrm{V}_{\mathrm{S}}$ decreasing from the peak towards ground and falling below $\mathrm{V}_{3}$, the LED will turn 'OFF'. With the dashed line output connection, the LED will turn 'ON' when the input voltage $\mathrm{V}_{\mathrm{S}}$ is within the window.

For known resistor values, the voltage trip points are:
For a specific trip voltage, the required resistor ratio is:

$$
\begin{array}{ll}
\mathrm{V}_{1}=\left(\mathrm{V}_{\mathrm{th} 1}-\mathrm{V}_{\mathrm{H} 1}\right)\left(\frac{\mathrm{R}_{3}}{\mathrm{R}_{1}+\mathrm{R}_{2}}+1\right) & \mathrm{V}_{3}=\left(\mathrm{V}_{\mathrm{th} 2}-\mathrm{V}_{\mathrm{H} 2}\right)\left(\frac{\mathrm{R}_{2}+\mathrm{R}_{3}}{\mathrm{R}_{1}}+1\right) \\
\mathrm{V}_{2}=\mathrm{V}_{\mathrm{th} 1}\left(\frac{\mathrm{R}_{3}}{\mathrm{R}_{1}+\mathrm{R}_{2}}+1\right) & \frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}=\frac{\mathrm{V}_{3}\left(\mathrm{~V}_{\mathrm{th} 2}-\mathrm{V}_{\mathrm{H} 2}\right)}{\mathrm{V}_{1}\left(\mathrm{~V}_{\mathrm{th} 1}-\mathrm{V}_{\mathrm{H} 1}\right)}-1
\end{array} \frac{\mathrm{R}_{3}}{\mathrm{R}_{1}}=\frac{\mathrm{V}_{3}\left(\mathrm{~V}_{1}-\mathrm{V}_{\mathrm{th} 1}+\mathrm{V}_{\mathrm{H} 1}\right)}{\mathrm{V}_{1}\left(\mathrm{~V}_{\mathrm{th} 2}-\mathrm{V}_{\mathrm{H} 2}\right)}
$$

Figure 20. Positive Voltage Window Detector

The above figure shows the MC34161 configured as a negative voltage window detector. When the input voltage $-\mathrm{V}_{\mathrm{S}}$ falls out of the window established by $\mathrm{V}_{1}$ and $\mathrm{V}_{4}$, the LED will turn 'ON'. As the input voltage falls within the window, $-\mathrm{V}_{\mathrm{S}}$ increasing from ground and exceeding $\mathrm{V}_{2}$, or $-\mathrm{V}_{\mathrm{S}}$ decreasing from the peak towards ground and falling below $\mathrm{V}_{3}$, the LED will turn 'OFF'. With the dashed line output connection, the LED will turn 'ON' when the input voltage $-\mathrm{V}_{\mathrm{S}}$ is within the window.

For known resistor values, the voltage trip points are:

$$
\begin{aligned}
& V_{1}=\frac{R_{1}\left(V_{\text {th2 }}-V_{\text {ref }}\right)}{R_{2}+R_{3}}+V_{\text {th2 }} \\
& V_{2}=\frac{R_{1}\left(V_{\text {th2 }}-V_{H 2}-V_{\text {ref }}\right)}{R_{2}+R_{3}}+V_{\text {th2 }}-V_{H 2} \\
& V_{3}=\frac{\left(R_{1}+R_{2}\right)\left(V_{\text {th }}-V_{\text {ref }}\right)}{R_{3}}+V_{\text {th1 }} \\
& V_{4}=\frac{\left(R_{1}+R_{2}\right)\left(V_{\text {th } 1}-V_{H 1}-V_{\text {ref }}\right)}{R_{3}}+V_{\text {th1 }}-V_{H 1}
\end{aligned}
$$

For a specific trip voltage, the required resistor ratio is:

$$
\begin{aligned}
& \frac{R_{1}}{R_{2}+R_{3}}=\frac{V_{1}-V_{\text {th2 }}}{V_{\text {th2 }}-V_{\text {ref }}} \\
& \frac{R_{1}}{R_{2}+R_{3}}=\frac{V_{2}-V_{\text {th2 }}+V_{H 2}}{V_{\text {th2 }}-V_{H 2}-V_{\text {ref }}} \\
& \frac{R_{3}}{R_{1}+R_{2}}=\frac{V_{\text {th1 }}-V_{\text {ref }}}{V_{3}-V_{\text {th1 }}} \\
& \frac{R_{3}}{R_{1}+R_{2}}=\frac{V_{\text {th1 }}-V_{H 1}-V_{\text {ref }}}{V_{4}+V_{H 1}-V_{\text {th } 1}}
\end{aligned}
$$

Figure 21. Negative Voltage Window Detector

The above figure shows the MC34161 configured as a positive and negative overvoltage detector. As the input voltage increases from ground, the LED will turn 'ON' when either $-\mathrm{V}_{\mathrm{S} 1}$ exceeds $\mathrm{V}_{2}$, or $\mathrm{V}_{\mathrm{S} 2}$ exceeds $\mathrm{V}_{4}$. With the dashed line output connection, the circuit becomes a positive and negative undervoltage detector. As the input voltage decreases from the peak towards ground, the LED will turn ' ON ' when either $\mathrm{V}_{\mathrm{S} 2}$ falls below $\mathrm{V}_{3}$, or $-\mathrm{V}_{\mathrm{S} 1}$ falls below $\mathrm{V}_{1}$.

For known resistor values, the voltage trip points are:

> For a specific trip voltage, the required resistor ratio is:

$$
\begin{array}{ll}
\mathrm{V}_{1}=\frac{\mathrm{R}_{3}}{\mathrm{R}_{4}}\left(\mathrm{~V}_{\mathrm{th} 1}-\mathrm{V}_{\mathrm{ref}}\right)+\mathrm{V}_{\mathrm{th} 1} & \mathrm{~V}_{3}=\left(\mathrm{V}_{\mathrm{th} 2}-\mathrm{V}_{\mathrm{H} 2}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)\right. \\
\mathrm{V}_{2}=\frac{\mathrm{R}_{3}}{\mathrm{R}_{4}}\left(\mathrm{~V}_{\mathrm{th} 1}-\mathrm{V}_{\mathrm{H} 1}-\mathrm{V}_{\mathrm{ref}}\right)+\mathrm{V}_{\mathrm{th} 1}-\mathrm{V}_{\mathrm{H} 1} & \mathrm{~V}_{4}=\mathrm{V}_{\mathrm{th} 2}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)
\end{array}
$$

$$
\begin{array}{ll}
\frac{R_{3}}{R_{4}}=\frac{\left(V_{1}-V_{\text {th1 }}\right)}{\left(V_{\text {th1 }}-V_{\text {ref }}\right)} & \frac{R_{2}}{R_{1}}=\frac{V_{4}}{V_{\text {th2 }}}-1 \\
\frac{R_{3}}{R_{4}}=\frac{\left(V_{2}-V_{\text {th1 }}+V_{H 1}\right)}{\left(V_{\text {th1 }}-V_{H 1}-V_{\text {ref }}\right)} & \frac{R_{2}}{R_{1}}=\frac{V_{3}}{V_{\text {th2 }}-V_{H 2}}-1
\end{array}
$$

Figure 22. Positive and Negative Overvoltage Detector

The above figure shows the MC34161 configured as a positive and negative undervoltage detector. As the input voltage decreases toward ground, the LED will turn ' ON' when either $\mathrm{V}_{\mathrm{S} 1}$ falls below $\mathrm{V}_{1}$, or $-\mathrm{V}_{\mathrm{S} 2}$ falls below $\mathrm{V}_{3}$. With the dashed line output connection, the circuit becomes a positive and negative overvoltage detector. As the input voltage increases from the ground, the LED will turn 'ON' when either $V_{S 1}$ exceeds $V_{2}$, or $-V_{S 1}$ exceeds $V_{1}$.

For known resistor values, the voltage trip points are:
For a specific trip voltage, the required resistor ratio is:

Figure 23. Positive and Negative Undervoltage Detector

$$
\begin{aligned}
& \mathrm{V}_{1}=\left(\mathrm{V}_{\mathrm{th} 1}-\mathrm{V}_{\mathrm{H} 1}\right)\left(\frac{\mathrm{R}_{4}}{\mathrm{R}_{3}}+1\right) \quad \mathrm{V}_{3}=\frac{\mathrm{R}_{1}}{\mathrm{R}_{2}}\left(\mathrm{~V}_{\mathrm{th}}-\mathrm{V}_{\mathrm{ref}}\right)+\mathrm{V}_{\mathrm{th} 2} \\
& \mathrm{~V}_{2}=\mathrm{V}_{\mathrm{th} 1}\left(\frac{\mathrm{R}_{4}}{\mathrm{R}_{3}}+1\right) \quad \mathrm{V}_{4}=\frac{\mathrm{R}_{1}}{\mathrm{R}_{2}}\left(\mathrm{~V}_{\mathrm{th}}-\mathrm{V}_{\mathrm{H} 2}-\mathrm{V}_{\mathrm{ref}}\right)+\mathrm{V}_{\mathrm{th} 2}-\mathrm{V}_{\mathrm{H} 2} \\
& \frac{R_{4}}{R_{3}}=\frac{V_{2}}{V_{t h 1}}-1 \\
& \frac{R_{1}}{R_{2}}=\frac{V_{4}+V_{H 2}-V_{\text {th2 }}}{V_{\text {th2 }}-V_{H 2}-V_{\text {ref }}} \\
& \frac{R_{4}}{R_{3}}=\frac{V_{1}}{V_{\text {th1 }}-V_{H 1}}-1 \quad \frac{R_{1}}{R_{2}}=\frac{V_{3}-V_{\text {th2 }}}{V_{\text {th2 }}-V_{\text {ref }}}
\end{aligned}
$$

The above figure shows the MC34161 configured as an overvoltage detector with an audio alarm. Channel 1 monitors input voltage $V_{S}$ while channel 2 is connected as a simple RC oscillator. As the input voltage increases from ground, the output of channel 1 allows the oscillator to turn 'ON' when $\mathrm{V}_{\mathrm{S}}$ exceeds $\mathrm{V}_{2}$.

For known resistor values, the voltage trip points are:

$$
\mathrm{V}_{1}=\left(\mathrm{V}_{\mathrm{th}}-\mathrm{V}_{\mathrm{H}}\right)\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right) \mathrm{V}_{2}=\mathrm{V}_{\mathrm{th}}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right)
$$

For a specific trip voltage, the required resistor ratio is:

$$
\frac{R_{2}}{R_{1}}=\frac{V_{1}}{V_{t h}-V_{H}}-1 \quad \frac{R_{2}}{R_{1}}=\frac{V_{2}}{V_{t h}}-1
$$

Figure 24. Overvoltage Detector with Audio Alarm

The above figure shows the MC34161 configured as a microprocessor reset with a time delay. Channel 2 monitors input voltage $\mathrm{V}_{\mathrm{S}}$ while channel 1 performs the time delay function. As the input voltage decreases towards ground, the output of channel 2 quickly discharges $\mathrm{C}_{\mathrm{DLY}}$ when $\mathrm{V}_{\mathrm{S}}$ falls below $\mathrm{V}_{1}$. As the input voltage increases from ground, the output of channel 2 allows $R_{D L Y}$ to charge $C_{D L Y}$ when $V_{S}$ exceeds $V_{2}$.

For known resistor values, the voltage trip points are: For a specific trip voltage, the required resistor ratio is:

$$
\mathrm{V}_{1}=\left(\mathrm{V}_{\mathrm{th}}-\mathrm{V}_{\mathrm{H}}\right)\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right) \quad \mathrm{V}_{2}=\mathrm{V}_{\mathrm{th}}\left(\frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}+1\right) \quad \frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}=\frac{\mathrm{V}_{1}}{\mathrm{~V}_{\mathrm{th}}-\mathrm{V}_{\mathrm{H}}}-1 \quad \frac{\mathrm{R}_{2}}{\mathrm{R}_{1}}=\frac{\mathrm{V}_{2}}{\mathrm{~V}_{\mathrm{th}}}-1
$$

For known $R_{D L Y} C_{D L Y}$ values, the reset time delay is:

$$
\mathrm{t}_{\mathrm{DLY}}=\mathrm{R}_{\mathrm{DLY}} C_{D L Y} \ln \quad\left(\frac{1}{1-\frac{\mathrm{V}_{\mathrm{th}}}{\mathrm{~V}_{\mathrm{CC}}}}\right)
$$

Figure 25. Microprocessor Reset with Time Delay

The above circuit shows the MC34161 configured as an automatic line voltage selector. The IC controls the triac, enabling the circuit to function as a fullwave voltage doubler or a fullwave bridge. Channel 1 senses the negative half cycles of the AC line voltage. If the line voltage is less than150 V, the circuit will switch from bridge mode to voltage doubling mode after a preset time delay. The delay is controlled by the $100 \mathrm{k} \Omega$ resistor and the $10 \mu \mathrm{~F}$ capacitor. If the line voltage is greater than 150 V , the circuit will immediately return to fullwave bridge mode.

Figure 26. Automatic AC Line Voltage Selector

## MC34161, MC33161

Figure 27. Step-Down Converter

| Test | Conditions | Results |
| :--- | :--- | :--- |
| Line Regulation | $\mathrm{V}_{\text {in }}=9.5 \mathrm{~V}$ to $24 \mathrm{~V}, \mathrm{I}_{\mathrm{O}}=250 \mathrm{~mA}$ | $40 \mathrm{mV}= \pm 0.1 \%$ |
| Load Regulation | $\mathrm{V}_{\mathrm{in}}=12 \mathrm{~V}, \mathrm{I}_{\mathrm{O}}=0.25 \mathrm{~mA}$ to 250 mA | $2.0 \mathrm{mV}= \pm 0.2 \%$ |
| Output Ripple | $\mathrm{V}_{\mathrm{in}}=12 \mathrm{~V}, \mathrm{I}_{\mathrm{O}}=250 \mathrm{~mA}$ | 50 mVpp |
| Efficiency | $\mathrm{V}_{\text {in }}=12 \mathrm{~V}, \mathrm{I}_{\mathrm{O}}=250 \mathrm{~mA}$ | $87.8 \%$ |

The above figure shows the MC34161 configured as a step-down converter. Channel 1 monitors the output voltage while Channel 2 performs the oscillator function. Upon initial power-up, the converters output voltage will be below nominal, and the output of Channel 1 will allow the oscillator to run. The external switch transistor will eventually pump-up the output capacitor until its voltage exceeds the input threshold of Channel 1. The output of Channel 1 will then switch low and disable the oscillator. The oscillator will commence operation when the output voltage falls below the lower threshold of Channel 1.

## NCP300, NCP301

## Voltage Detector Series

The NCP300 and NCP301 series are second generation ultra-low current voltage detectors. These devices are specifically designed for use as reset controllers in portable microprocessor based systems where extended battery life is paramount

Each series features a highly accurate under voltage detector with hysteresis which prevents erratic system reset operation as the comparator threshold is crossed.

The NCP300 series consists of complementary output devices that are available with either an active high or active low reset output. The NCP301 series has an open drain N -channel output with either an active high or active low reset output.

The NCP300 and NCP301 device series are available in the Thin SOT-23-5 package with seven standard under voltage thresholds. Additional thresholds that range from 0.9 V to 4.9 V in 100 mV steps can be manufactured.

## Features

- Quiescent Current of $0.5 \mu \mathrm{~A}$ Typical
- High Accuracy Under Voltage Threshold of $2.0 \%$
- Wide Operating Voltage Range of 0.8 V to 10 V
- Complementary or Open Drain Reset Output
- Active Low or Active High Reset Output

## Typical Applications

- Microprocessor Reset Controller
- Low Battery Detection
- Power Fail Indicator
- Battery Backup Detection

* The representative block diagrams depict active low reset output 'L' suffix devices. The comparator inputs are interchanged for the active high output ' H ' suffix devices.

This device contains 25 active transistors.

NCP300 and NCP301 series are measured with a 10 pF capacitive load. NCP301 has an additional 470 k pullup resistor connected from the reset output to +5.0 V . The reset output voltage waveforms are shown for the active low ' L ' devices. The upper detector threshold, $\mathrm{V}_{\mathrm{DET}}+$ is the sum of the lower detector threshold, $\mathrm{V}_{\mathrm{DET}}$ plus the input hysteresis, $\mathrm{V}_{\mathrm{HYS}}$.

## OPERATING DESCRIPTION

The NCP300 and NCP301 series devices are second generation ultra-low current voltage detectors. Figures 21 and 22 show a timing diagram and a typical application. Initially consider that input voltage $\mathrm{V}_{\text {in }}$ is at a nominal level and it is greater than the voltage detector upper threshold $\left(\mathrm{V}_{\mathrm{DET}+}\right)$, and the reset output (Pin 1) will be in the high state for active low devices, or in the low state for active high devices. If there is a power interruption and $V_{\text {in }}$ becomes significantly deficient, it will fall below the lower detector threshold ( $\mathrm{V}_{\text {DET- }}$ ). This sequence of events causes the Reset output to be in the low state for active low devices, or in the
high state for active high devices. After completion of the power interruption, $\mathrm{V}_{\text {in }}$ will again return to its nominal level and become greater than the $\mathrm{V}_{\mathrm{DET}+}$. The voltage detector has built-in hysteresis to prevent erratic reset operation as the comparator threshold is crossed.
Although these device series are specifically designed for use as reset controllers in portable microprocessor based systems, they offer a cost-effective solution in numerous applications where precise voltage monitoring is required. Figure 22 through Figure 29 shows various application examples.

Figure 23. Battery Charge Indicator

Figure 24. Window Voltage Detector

## APPLICATION CIRCUIT INFORMATION

Figure 25. Dual Power Supply Undervoltage Supervision

Figure 26. Microprocessor Reset Circuit with Additional Hysteresis

Comparator hysteresis can be increased with the addition of resistor $\mathrm{R}_{\mathrm{H}}$. The hysteresis equations have been simplified and do not account for the change of input current $l_{\text {in }}$ as $V_{\text {in }}$ crosses the comparator threshold. The internal resistance, $\mathrm{R}_{\mathrm{in}}$ is simply calculated using $\mathrm{l}_{\text {in }}=0.26 \mu \mathrm{~A}$ at 2.6 V .
$V_{\text {in }}$ Decreasing:

$$
\mathrm{V}_{\mathrm{th}}=\left(\frac{\mathrm{R}_{\mathrm{H}}}{\mathrm{R}_{\mathrm{in}}}+1\right)\left(\mathrm{V}_{\mathrm{DET}-}\right)
$$

$V_{\text {in }}$ Increasing:

$$
\mathrm{V}_{\mathrm{th}}=\left(\frac{\mathrm{R}_{\mathrm{H}}}{\mathrm{R}_{\mathrm{in}} \| \mathrm{R}_{\mathrm{L}}}+1\right)\left(\mathrm{V}_{\mathrm{DET}-}+\mathrm{V}_{\mathrm{HYS}}\right)
$$

$\mathrm{V}_{\text {HYS }}=\mathrm{V}_{\text {in }}$ Increasing $-\mathrm{V}_{\text {in }}$ Decreasing

Figure 27. Simple Clock Oscillator

This circuit monitors the current at the load. As current flows through the load, a voltage drop with respect to ground appears across $R_{\text {sense }}$ where $V_{\text {sense }}=I_{\text {load }}{ }^{*} R_{\text {sense. }}$. The following conditions apply:

If: Then:
$\mathrm{I}_{\text {Load }}<\mathrm{V}_{\text {DET- }} / \mathrm{R}_{\text {sense }}$ $\mathrm{L}_{\text {Load }} \geq\left(\mathrm{V}_{\text {DET-+ }} \mathrm{V}_{\text {HYS }}\right) / \mathrm{R}_{\text {sense }}$

Reset Output $=0 \mathrm{~V}$
Reset Output = $\mathrm{V}_{\mathrm{DD}}$

Figure 28. Microcontroller System Load Sensing

A simple voltage monitor can be constructed by connecting several voltage detectors as shown above. Each LED will sequentially turn on when the respective voltage detector threshold ( $\mathrm{V}_{\mathrm{DET}}+\mathrm{V}_{\mathrm{HYS}}$ ) is exceeded. Note that detector thresholds ( $\mathrm{V}_{\text {DET- }}$ ) that range from 0.9 V to 4.9 V in 100 mV steps can be manufactured.

Figure 29. LED Bar Graph Voltage Monitor

## NCP300, NCP301

## MINIMUM RECOMMENDED FOOTPRINT FOR SURFACE MOUNTED APPLICATIONS

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to insure proper solder connection
interface between the board and the package. With the correct pad geometry, the packages will self align when subjected to a solder reflow process.

THIN SOT-23-5

ORDERING INFORMATION

NOTE: The ordering information lists seven standard under voltage thresholds with active low outputs. Additional active low threshold devices, ranging from 0.9 V to 4.9 V in 100 mV increments and NCP300/NCP301 active high output devices, ranging from 0.9 V to 4.9 V in 100 mV increments can be manufactured. Contact your ON Semiconductor representative for availability. The electrical characteristics of these additional devices are shown in Tables 1 and 2.

## NCP304, NCP305

## Voltage Detector Series

The NCP304 and NCP305 series are second generation ultra-low current voltage detectors. These devices are specifically designed for use as reset controllers in portable microprocessor based systems where extended battery life is paramount.

Each series features a highly accurate under voltage detector with hysteresis which prevents erratic system reset operation as the comparator threshold is crossed.

The NCP304 series consists of complementary output devices that are available with either an active high or active low reset output. The NCP305 series has an open drain N-channel output with an active low reset output.

The NCP304 and NCP305 device series are available in the SC-82AB package with seven standard under voltage thresholds. Additional thresholds that range from 0.9 V to 4.9 V in 100 mV steps can be manufactured.

## Features

- Quiescent Current of $1.0 \mu \mathrm{~A}$ Typical
- High Accuracy Under Voltage Threshold of $2.0 \%$
- Wide Operating Voltage Range of 0.8 V to 10 V
- Complementary or Open Drain Reset Output
- Active Low or Active High Reset Output

## Typical Applications

- Microprocessor Reset Controller
- Low Battery Detection
- Power Fail Indicator
- Battery Backup Detection

## PIN CONNECTIONS AND <br> MARKING DIAGRAM

## ORDERING INFORMATION

See detailed ordering and shipping information in the ordering information section on page 2759 of this data sheet.

NCP305LSQxxT1
Open Drain Output Configuration

This device contains 38 active transistors.

6. In the case of CMOS Output Type: The time interval between the rising edge of $\mathrm{V}_{\mathrm{DD}}$ input pulse from 0.7 V to $\left(+\mathrm{V}_{\mathrm{DET}}\right)+2.0 \mathrm{~V}$ and output voltage level becoming to $\mathrm{V}_{\mathrm{DD}} / 2$. In the case of $\mathrm{N}_{\mathrm{CH}}$ Open Drain Output Type: Output pin is pulled up with a resistance of $470 \mathrm{k} \Omega$ to 5.0 V , the time interval between the rising edge of $\mathrm{V}_{\mathrm{DD}}$ input pulse from 0.7 V to $\left(+\mathrm{V}_{\mathrm{DET}}\right)+2.0 \mathrm{~V}$ and output voltage level becoming to 2.5.

NCP304 and NCP305 series are measured with a 10 pF capacitive load. NCP305 has an additional 470 k pullup resistor connected from the reset output to +5.0 V . The reset output voltage waveforms are shown for the active low ' L ' devices. The upper detector threshold, $\mathrm{V}_{\mathrm{DET}+}$ is the sum of the lower detector threshold, $\mathrm{V}_{\mathrm{DET}}$ plus the input hysteresis, $\mathrm{V}_{\mathrm{HYS}}$.

## OPERATING DESCRIPTION

The NCP304 and NCP305 series devices are second generation ultra-low current voltage detectors. Figures 25 and 26 show a timing diagram and a typical application. Initially consider that input voltage $\mathrm{V}_{\text {in }}$ is at a nominal level and it is greater than the voltage detector upper threshold $\left(\mathrm{V}_{\mathrm{DET}+}\right)$, and the reset output (Pin 1) will be in the high state for active low devices, or in the low state for active high devices. If there is a power interruption and $V_{\text {in }}$ becomes significantly deficient, it will fall below the lower detector threshold ( $\mathrm{V}_{\text {DET- }}$ ). This sequence of events causes the Reset output to be in the low state for active low devices, or in the
high state for active high devices. After completion of the power interruption, $\mathrm{V}_{\text {in }}$ will again return to its nominal level and become greater than the $\mathrm{V}_{\mathrm{DET}+}$. The voltage detector has built-in hysteresis to prevent erratic reset operation as the comparator threshold is crossed.
Although these device series are specifically designed for use as reset controllers in portable microprocessor based systems, they offer a cost-effective solution in numerous applications where precise voltage monitoring is required. Figure 26 through Figure 32 shows various application examples.

APPLICATION CIRCUIT INFORMATION

Figure 26. Microprocessor Reset Circuit

Figure 27. Battery Charge Indicator

Figure 28. Dual Power Supply Undervoltage Supervision

Figure 29. Microprocessor Reset Circuit with Additional Hysteresis

Comparator hysteresis can be increased with the addition of resistor $R_{H}$. The hysteresis equations have been simplified and do not account for the change of input current $l_{\text {in }}$ as $V_{\text {in }}$ crosses the comparator threshold. The internal resistance, $\mathrm{R}_{\mathrm{in}}$ is simply calculated using $\mathrm{I}_{\text {in }}=0.26 \mu \mathrm{~A}$ at 2.6 V .
$V_{\text {in }}$ Decreasing:

$$
\mathrm{V}_{\mathrm{th}}=\left(\frac{\mathrm{R}_{\mathrm{H}}}{\mathrm{R}_{\mathrm{in}}}+1\right)\left(\mathrm{V}_{\mathrm{DET}-}\right)
$$

$\mathrm{V}_{\text {in }}$ Increasing:

$$
\mathrm{V}_{\mathrm{th}}=\left(\frac{\mathrm{R}_{\mathrm{H}}}{\mathrm{R}_{\mathrm{in}} \| \mathrm{R}_{\mathrm{L}}}+1\right)\left(\mathrm{V}_{\mathrm{DET}-}+\mathrm{V}_{\mathrm{HYS}}\right)
$$

$\mathrm{V}_{\text {HYS }}=\mathrm{V}_{\text {in }}$ Increasing $-\mathrm{V}_{\text {in }}$ Decreasing

Figure 30. Simple Clock Oscillator

This circuit monitors the current at the load. As current flows through the load, a voltage drop with respect to ground appears across $R_{\text {sense }}$ where $V_{\text {sense }}=I_{\text {load }}{ }^{*} R_{\text {sense. }}$. The following conditions apply:
If:
$I_{\text {Load }}<\mathrm{V}_{\text {DET- }} / \mathrm{R}_{\text {sense }}$
$\mathrm{l}_{\text {Load }} \geq\left(\mathrm{V}_{\mathrm{DET}}+\mathrm{V}_{\text {HYS }}\right) / \mathrm{R}_{\text {sense }}$

Then:
Reset Output = 0 V
Reset Output $=V_{D D}$

Figure 31. Microcontroller Systems Load Sensing

A simple voltage monitor can be constructed by connecting several voltage detectors as shown above. Each LED will sequentially turn on when the respective voltage detector threshold ( $\mathrm{V}_{\mathrm{DET}-}+\mathrm{V}_{\mathrm{HYS}}$ ) is exceeded. Note that detector thresholds ( $\mathrm{V}_{\text {DET- }}$ ) that range from 0.9 V to 4.9 V in 100 mV steps can be manufactured.

Figure 32. LED Bar Graph

## INFORMATION FOR USING THE SC-82AB SURFACE MOUNT PACKAGE

## MINIMUM RECOMMENDED FOOTPRINT FOR SURFACE MOUNTED APPLICATIONS

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to insure proper solder connection
interface between the board and the package. With the correct pad geometry, the packages will self align when subjected to a solder reflow process.

NOTE: The ordering information lists seven standard under voltage thresholds with active low outputs. Additional active low threshold devices, ranging from 0.9 V to 4.9 V in 100 mV increments and NCP304 active high output devices, ranging from 0.9 V to 4.9 V in 100 mV increments can be manufactured. Contact your ON Semiconductor representative for availability. The electrical characteristics of these additional devices are shown in Tables 1 and 2.

## Undervoltage Sensing Circuit

The MC34064 is an undervoltage sensing circuit specifically designed for use as a reset controller in microprocessor-based systems. It offers the designer an economical solution for low voltage detection with a single external resistor. The MC34064 features a trimmed-in-package bandgap reference, and a comparator with precise thresholds and built-in hysteresis to prevent erratic reset operation. The open collector reset output is capable of sinking in excess of 10 mA , and operation is guaranteed down to 1.0 V input with low standby current. These devices are packaged in 3-pin TO-226AA, 8-pin SO-8 and Micro-8 surface mount packages.

Applications include direct monitoring of the 5.0 V MPU/logic power supply used in appliance, automotive, consumer and industrial equipment.

- Trimmed-In-Package Temperature Compensated Reference
- Comparator Threshold of 4.6 V at $25^{\circ} \mathrm{C}$
- Precise Comparator Thresholds Guaranteed Over Temperature
- Comparator Hysteresis Prevents Erratic Reset
- Reset Output Capable of Sinking in Excess of 10 mA
- Internal Clamp Diode for Discharging Delay Capacitor
- Guaranteed Reset Operation with 1.0 V Input
- Low Standby Current
- Economical TO-226AA, SO-8 and Micro-8 Surface Mount Packages

## MC34164, MC33164

## Micropower Undervoltage Sensing Circuits

The MC34164 series are undervoltage sensing circuits specifically designed for use as reset controllers in portable microprocessor based systems where extended battery life is required. These devices offer the designer an economical solution for low voltage detection with a single external resistor. The MC34164 series features a bandgap reference, a comparator with precise thresholds and built-in hysteresis to prevent erratic reset operation, an open collector reset output capable of sinking in excess of 6.0 mA , and guaranteed operation down to 1.0 V input with extremely low standby current. These devices are packaged in 3-pin TO-226AA, 8-pin SO-8 and Micro8 ${ }^{\text {TM }}$ surface mount packages.

Applications include direct monitoring of the 3.0 or 5.0 V MPU/logic power supply used in appliance, automotive, consumer, and industrial equipment.

- Temperature Compensated Reference
- Monitors 3.0 V (MC34164-3) or 5.0 V (MC34164-5) Power Supplies
- Precise Comparator Thresholds Guaranteed Over Temperature
- Comparator Hysteresis Prevents Erratic Reset
- Reset Output Capable of Sinking in Excess of 6.0 mA
- Internal Clamp Diode for Discharging Delay Capacitor
- Guaranteed Reset Operation With 1.0 V Input
- Extremely Low Standby Current: As Low as $9.0 \mu \mathrm{~A}$
- Economical TO-226AA, SO-8 and Micro8 Surface Mount Packages

Pin numbers adjacent to terminals are for the 3-pin TO-226AA package. Pin numbers in parenthesis are for the 8 -lead packages.

This device contains 28 active transistors.

Figure 11. Clamp Diode Forward Current versus Voltage

Figure 10. MC3X164-5 Reset Output
Saturation versus Sink Current

Figure 12. Reset Delay Time (MC3X164-5 Shown)

A time delayed reset can be accomplished with the addition of $C_{D L Y}$. For systems with extremely fast power supply rise times (<500 ns) it is recommended that the RCDLY time constant be greater than $5.0 \mu \mathrm{~s}$. $\mathrm{V}_{\text {th }}(\mathrm{MPU})$ is the microprocessor reset input threshold.

Figure 13. Low Voltage Microprocessor Reset

## MC34164, MC33164

Comparator hysteresis can be increased with the addition of resistor $\mathrm{R}_{H}$. The hysteresis equation has been simplified and does not account for the change of input current $\mathrm{I}_{\text {in }}$ as $\mathrm{V}_{\text {in }}$ crosses the comparator threshold (Figure 8). An increase of the lower threshold $\Delta \mathrm{V}_{\text {th(lower) }}$ will be observed due to $\mathrm{I}_{\text {in }}$ which is typically $10 \mu \mathrm{~A}$ at 4.3 V . The equations are accurate to $\pm 10 \%$ with $\mathrm{R}_{\mathrm{H}}$ less than $1.0 \mathrm{k} \Omega$ and $\mathrm{R}_{\mathrm{L}}$ between $4.3 \mathrm{k} \Omega$ and $43 \mathrm{k} \Omega$.

## Very Low Supply Current 3-Pin Microprocessor Reset Monitor

The NCP803 is a cost-effective system supervisor circuit designed to monitor $\mathrm{V}_{\mathrm{CC}}$ in digital systems and provide a reset signal to the host processor when necessary. No external components are required.

The reset output is driven active within $10 \mu \mathrm{sec}$ of $\mathrm{V}_{\mathrm{CC}}$ falling through the reset voltage threshold. Reset is maintained active for a minimum of 140 msec after $\mathrm{V}_{\mathrm{CC}}$ rises above the reset threshold. The NCP803 has an open drain active-low RESET output. The output of the NCP803 is guaranteed valid down to $\mathrm{V}_{\mathrm{CC}}=1.0 \mathrm{~V}$ and is available in a SOT-23 package.

The NCP803 is optimized to reject fast transient glitches on the $\mathrm{V}_{\mathrm{CC}}$ line. Low supply current of $1.0 \mu \mathrm{~A}\left(\mathrm{~V}_{\mathrm{CC}}=3.2 \mathrm{~V}\right)$ make this device suitable for battery powered applications.

## Features

- Precision $\mathrm{V}_{\mathrm{CC}}$ Monitor for $2.5 \mathrm{~V}, 3.0 \mathrm{~V}, 3.3 \mathrm{~V}$, and 5.0 V Supplies
- Precision Monitoring Voltages from 1.6 V to 4.9 V Available in 100 mV Steps
- 140 msec Guaranteed Minimum $\overline{\text { RESET Output Duration }}$
- $\overline{\text { RESET }}$ Output Guaranteed to $\mathrm{V}_{\mathrm{CC}}=1.0 \mathrm{~V}$
- Low $1.0 \mu \mathrm{~A}$ Supply Current
- $\mathrm{V}_{\mathrm{CC}}$ Transient Immunity
- Small SOT-23 Package
- No External Components
- Wide Operating Temperature: $-40^{\circ} \mathrm{C}$ to $105^{\circ} \mathrm{C}$

## Typical Applications

- Computers
- Embedded Systems
- Battery Powered Equipment
- Critical $\mu$ P Power Supply Monitoring

Figure 1. Typical Application Diagram

## PIN DESCRIPTION

| Pin No. | Symbol | Description |
| :---: | :---: | :--- |
| 1 | GND | Ground |
| 2 | RESET | RESET output remains low while $V_{C C}$ is below the reset voltage threshold, and for 240 msec (typ.) <br> after $V_{C C}$ rises above reset threshold. |
| 3 | $\mathrm{~V}_{\mathrm{CC}}$ | Supply Voltage: $\mathrm{C}=100 \mathrm{nF}$ is recommended as a bypass capacitor between $\mathrm{V}_{\mathrm{CC}}$ and GND. |

## APPLICATIONS INFORMATION

## $\mathrm{V}_{\mathrm{Cc}}$ Transient Rejection

The NCP803 provides accurate $\mathrm{V}_{\mathrm{CC}}$ monitoring and reset timing during power-up, power-down, and brownout/sag conditions, and rejects negative-going transients (glitches) on the power supply line. Figure 2 shows the maximum transient duration vs. maximum negative excursion (overdrive) for glitch rejection. Any combination of duration and overdrive which lies under the curve will not generate a reset signal. Combinations above the curve are detected as a brownout or power-down. Typically, transient that goes 100 mV below the reset threshold and lasts $5 \mu \mathrm{~s}$ or less will not cause a reset pulse. Transient immunity can be improved by adding a capacitor in close proximity to the $\mathrm{V}_{\mathrm{CC}}$ pin.

Figure 2. Maximum Transient Duration vs. Overdrive for Glitch Rejection at $25^{\circ} \mathrm{C}$

## Processors With Bidirectional I/O Pins

Some $\mu$ P's (such as Motorola 68HC11) have bi-directional reset pins which interface easily with the Open Drain RESET output of the NCP803. As shown in Figure 3, one can connect directly to the RESET output of the NCP803 to the $\overline{\text { RESET }}$ pin of the $\mu \mathrm{P}$. The pull-up resistor avoids an undetermined voltage of the $\overline{\text { RESET }}$ pin.

Figure 3. Interfacing to Bidirectional Reset I/O

## NCP803 RESET Output Allows Use With Two Power Supplies

In numerous applications the pull-up resistor placed on the $\overline{\mathrm{RESET}}$ output is connected to the supply voltage monitored by the IC. Nevertheless, a different supply voltage can also power this output and so level-shift from the monitored supply to reset the $\mu$ P. However, if the NCP803's supply goes below 1 V , the $\overline{\text { RESET }}$ output ability to sink current will decrease and the result is a high state on the pin even though the supply's IC is under the threshold level. This occurs at a $\mathrm{V}_{\mathrm{CC}}$ level that depends on the $\mathrm{R}_{\text {pull-up }}$ value and the voltage to which it is connected.

## MAX809 Series, MAX810 Series

## Very Low Supply Current 3-Pin Microprocessor Reset Monitors

The MAX809 and MAX810 are cost-effective system supervisor circuits designed to monitor $\mathrm{V}_{\mathrm{CC}}$ in digital systems and provide a reset signal to the host processor when necessary. No external components are required.

The reset output is driven active within $10 \mu \mathrm{sec}$ of $\mathrm{V}_{\mathrm{CC}}$ falling through the reset voltage threshold. Reset is maintained active for a minimum of 140 msec after $\mathrm{V}_{\mathrm{CC}}$ rises above the reset threshold. The MAX810 has an active-high RESET output while the MAX809 has an active-low $\overline{\text { RESET }}$ output. The output of the MAX809 is guaranteed valid down to $\mathrm{V}_{\mathrm{CC}}=1.0 \mathrm{~V}$. Both devices are available in a SOT-23 package.

The MAX809/810 are optimized to reject fast transient glitches on the $\mathrm{V}_{\mathrm{CC}}$ line. Low supply current of $1.0 \mu \mathrm{~A}\left(\mathrm{~V}_{\mathrm{CC}}=3.2 \mathrm{~V}\right)$ makes these devices suitable for battery powered applications.

## Features

- Precision $\mathrm{V}_{\mathrm{CC}}$ Monitor for $2.5 \mathrm{~V}, 3.0 \mathrm{~V}, 3.3 \mathrm{~V}$, and 5.0 V Supplies
- Precision Monitoring Voltages from 1.6 V to 4.9 V Available in 100 mV Steps
- 140 msec Guaranteed Minimum $\overline{\text { RESET Output Duration }}$
- $\overline{\text { RESET }}$ Output Guaranteed to $\mathrm{V}_{\mathrm{CC}}=1.0 \mathrm{~V}$
- Low Supply Current
- $\mathrm{V}_{\mathrm{CC}}$ Transient Immunity
- Small SOT-23 Package
- No External Components
- Wide Operating Temperature: $-40^{\circ} \mathrm{C}$ to $105^{\circ} \mathrm{C}$

## Typical Applications

- Computers
- Embedded Systems
- Battery Powered Equipment
- Critical $\mu$ P Power Supply Monitoring

Figure 1. Typical Application Diagram

## MAX809 Series, MAX810 Series

## APPLICATIONS INFORMATION

## $\mathrm{V}_{\mathrm{Cc}}$ Transient Rejection

The MAX809 provides accurate $\mathrm{V}_{\mathrm{CC}}$ monitoring and reset timing during power-up, power-down, and brownout/sag conditions, and rejects negative-going transients (glitches) on the power supply line. Figure 2 shows the maximum transient duration vs. maximum negative excursion (overdrive) for glitch rejection. Any combination of duration and overdrive which lies under the curve will not generate a reset signal. Combinations above the curve are detected as a brownout or power-down. Typically, transient that goes 100 mV below the reset threshold and lasts $5 \mu \mathrm{~s}$ or less will not cause a reset pulse. Transient immunity can be improved by adding a capacitor in close proximity to the $\mathrm{V}_{\mathrm{CC}}$ pin of the MAX809.

Figure 2. Maximum Transient Duration vs. Overdrive for Glitch Rejection at $25^{\circ} \mathrm{C}$

## RESET Signal Integrity During Power-Down

The MAX809 RESET output is valid to $\mathrm{V}_{\mathrm{CC}}=1.0 \mathrm{~V}$. Below this voltage the output becomes an "open circuit" and does not sink current. This means CMOS logic inputs to the $\mu \mathrm{P}$ will be floating at an undetermined voltage. Most digital systems are completely shutdown well above this voltage. However, in situations where $\overline{\mathrm{RESET}}$ must be maintained
valid to $\mathrm{V}_{\mathrm{CC}}=0 \mathrm{~V}$, a pull-down resistor must be connected from $\overline{\text { RESET }}$ to ground to discharge stray capacitances and hold the output low (Figure 3). This resistor value, though not critical, should be chosen such that it does not appreciably load $\overline{\text { RESET }}$ under normal operation ( $100 \mathrm{k} \Omega$ will be suitable for most applications).

Figure 3. Ensuring RESET Valid to $\mathrm{V}_{\mathrm{CC}}=0 \mathrm{~V}$

## Processors With Bidirectional I/O Pins

Some $\mu$ P's (such as Motorola 68HC11) have bi-directional reset pins. Depending on the current drive capability of the processor pin, an indeterminate logic level may result if there is a logic conflict. This can be avoided by adding a $4.7 \mathrm{k} \Omega$ resistor in series with the output of the MAX809 (Figure 4). If there are other components in the system which require a reset signal, they should be buffered so as not to load the reset line. If the other components are required to follow the reset I/O of the $\mu \mathrm{P}$, the buffer should be connected as shown with the solid line.

Figure 4. Interfacing to Bidirectional Reset I/O

## NCP302, NCP303

## Voltage Detector Series with Programmable Delay

The NCP302 and NCP303 series are second generation ultra-low current voltage detectors that contain a programmable time delay generator. These devices are specifically designed for use as reset controllers in portable microprocessor based systems where extended battery life is paramount.

Each series features a highly accurate under voltage detector with hysteresis and an externally programmable time delay generator. This combination of features prevents erratic system reset operation.

The NCP302 series consists of complementary output devices that are available with either an active high or active low reset. The NCP303 series has an open drain N -channel output with an active low reset output.

## Features

- Quiescent Current of $0.5 \mu \mathrm{~A}$ Typical
- High Accuracy Under Voltage Threshold of $2.0 \%$
- Externally Programmable Time Delay Generator
- Wide Operating Voltage Range of 0.8 V to 10 V
- Complementary or Open Drain Output
- Active Low or Active High Reset

## Typical Applications

- Microprocessor Reset Controller
- Low Battery Detection
- Power Fail Indicator
- Battery Backup Detection

## NCP302, NCP303

NCP302 and NCP303 series are measured with a 10 pF capacitive load. NCP303 has an additional 470 k pullup resistor connected from the reset output to +5.0 V . The reset output voltage waveforms are shown for the active low ' $L$ ' devices. Output time delay $t_{D 1}$ and $t_{D 2}$ are dependent upon the delay capacitance. Refer to Figures 12, 13, and 14. The upper detector threshold, $\mathrm{V}_{\mathrm{DET}}$ is the sum of the lower detector threshold, $\mathrm{V}_{\mathrm{DET}}$ plus the input hysteresis, $\mathrm{V}_{\mathrm{HYS}}$.

Figure 2. Measurement Conditions for $t_{D 1}$ and $t_{D 2}$

## NCP302, NCP303

## OPERATING DESCRIPTION

The NCP302 and NCP303 series devices consist of a precision voltage detector that drives a time delay generator. Figures 37 and 38 show a timing diagram and a typical application. Initially consider that input voltage $V_{i n}$ is at a nominal level and it is greater than the voltage detector upper threshold ( $\mathrm{V}_{\mathrm{DET}+}$ ). The voltage at Pin 5 and capacitor $\mathrm{C}_{\mathrm{D}}$ will be at the same level as $\mathrm{V}_{\mathrm{in}}$, and the reset output (Pin 1) will be in the high state for active low devices, or in the low state for active high devices. If there is a power interruption and $\mathrm{V}_{\text {in }}$ becomes significantly deficient, it will fall below the lower detector threshold ( $\mathrm{V}_{\mathrm{DET}}$ ) and the external time delay capacitor $C_{D}$ will be immediately discharged by an internal N-channel MOSFET that connects to Pin 5. This sequence of events causes the Reset output to be in the low state for active low devices, or in the high state for active high devices. After completion of the power interruption,
$\mathrm{V}_{\text {in }}$ will again return to its nominal level and become greater than the $\mathrm{V}_{\mathrm{DET}+\text {. }}$ The voltage detector will turn off the N -channel MOSFET and allow pullup resistor $\mathrm{R}_{\mathrm{D}}$ to charge external capacitor $\mathrm{C}_{\mathrm{D}}$, thus creating a programmable delay for releasing the reset signal. When the voltage at Pin 5 exceeds the inverter/buffer threshold, typically $0.675 \mathrm{~V}_{\mathrm{in}}$, the reset output will revert back to its original state. The reset output time delay versus capacitance is shown in Figures 12 through 14. The voltage detector and inverter/buffer have built-in hysteresis to prevent erratic reset operation.

Although these device series are specifically designed for use as reset controllers in portable microprocessor based systems, they offer a cost-effective solution in numerous applications where precise voltage monitoring and time delay are required. Figures 38 through 45 show various application examples.

## APPLICATION CIRCUIT INFORMATION

Figure 38. Microprocessor Reset Circuit

Figure 39. Battery Charge Indicator

Figure 40. Missing Pulse Detector or Frequency Detector

Figure 41. Microprocessor Reset Circuit with Additional Hysteresis

Comparator hysteresis can be increased with the addition of resistor $R_{H}$. The hysteresis equations have been simplified and do not account for the change of input current $l_{\text {in }}$ as $V_{\text {in }}$ crosses the comparator threshold. The internal resistance, $\mathrm{R}_{\mathrm{in}}$ is simply calculated using $\mathrm{I}_{\text {in }}=0.26 \mu \mathrm{~A}$ at 2.6 V .
$V_{\text {in }}$ Decreasing:

$$
\mathrm{V}_{\mathrm{th}}=\left(\frac{\mathrm{R}_{\mathrm{H}}}{\mathrm{R}_{\mathrm{in}}}+1\right)\left(\mathrm{V}_{\mathrm{DET}-}\right)
$$

$\mathrm{V}_{\text {in }}$ Increasing:

$$
\mathrm{V}_{\mathrm{th}}=\left(\frac{\mathrm{R}_{\mathrm{H}}}{\mathrm{R}_{\mathrm{in}} \| \mathrm{R}_{\mathrm{L}}}+1\right)\left(\mathrm{V}_{\mathrm{DET}-}+\mathrm{V}_{\mathrm{HYS}}\right)
$$

$\mathrm{V}_{\text {HYS }}=\mathrm{V}_{\text {in }}$ Increasing $-\mathrm{V}_{\text {in }}$ Decreasing

Figure 42. Simple Clock Oscillator

This circuit monitors the current at the load. As current flows through the load, a voltage drop with respect to ground appears across $R_{\text {sense }}$ where $V_{\text {sense }}=I_{\text {load }}{ }^{*} R_{\text {sense. }}$. The following conditions apply:

If:
$I_{\text {Load }}<\mathrm{V}_{\mathrm{DET}} / \mathrm{R}_{\text {sense }}$
$\mathrm{L}_{\text {Load }} \geq\left(\mathrm{V}_{\text {DET- }}+\mathrm{V}_{\text {HYS }}\right) / R_{\text {sense }}$

Then:
Reset Output = 0 V
Reset Output $=\mathrm{V}_{\mathrm{DD}}$

Figure 43. Microcontroller Systems Load Sensing

A simple voltage monitor can be constructed by connecting several voltage detectors as shown above. Each LED will sequentially turn on when the respective voltage detector threshold ( $\mathrm{V}_{\mathrm{DET}-}+\mathrm{V}_{\mathrm{HYS}}$ ) is exceeded. Note that detector thresholds ( $\mathrm{V}_{\text {DET- }}$ ) that range from 0.9 V to 4.9 V in 100 mV steps can be manufactured.

Figure 44. LED Bar Graph Voltage Monitor

For monitoring power supplies with a time delay reset, only a single NCP303 with delay capacitor is required.

Figure 45. Multiple Power Supply Undervoltage Supervision with Time Delay Reset

## MINIMUM RECOMMENDED FOOTPRINT FOR SURFACE MOUNTED APPLICATIONS

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to insure proper solder connection
interface between the board and the package. With the correct pad geometry, the packages will self align when subjected to a solder reflow process.

THIN SOT-23-5

ORDERING INFORMATION

NOTE: The ordering information lists seven standard under voltage thresholds with active low outputs. Additional active low threshold devices, ranging from 0.9 V to 4.9 V in 100 mV increments and NCP 302 active high output devices, ranging from 0.9 V to 4.9 V in 100 mV increments can be manufactured. Contact your ON Semiconductor representative for availability. The electrical characteristics of these additional devices are shown in Tables 1 and 2.

## MAX707, MAX708 $\mu$ P Supervisory Circuits

The MAX707/708 are cost-effective system supervisor circuits designed to monitor Vcc in digital systems and provide a reset signal to the host processor when necessary. No external components are required.

The reset output is driven active within $20 \mu \mathrm{sec}$ of Vcc falling through the reset voltage threshold. Reset is maintained with 200 mS of delay time after Vcc rise above the reset threshold. The MAX707/708 have a low quiescent current of $12 \mu \mathrm{~A}$ at $\mathrm{Vcc}=3.3 \mathrm{~V}$, an active-high RESET and active-low $\overline{\text { RESET }}$ with a push-pull output. The output is guaranteed valid down to $\mathrm{Vcc}=1.0 \mathrm{~V}$. The MAX707/708 have a Manual Reset $\overline{\mathrm{MR}}$ input and a +1.25 V threshold detector for power-fail input PFI. These devices are available in a Micro8 and SOIC-8 package.

## Features

- Precision Supply-Voltage Monitor MAX707: 4.63 V Reset Threshold Voltage MAX708: Standard Reset Threshold Voltages (Typical): $4.38 \mathrm{~V}, 3.08 \mathrm{~V}, 2.93 \mathrm{~V}, 2.63 \mathrm{~V}$
- Reset Threshold Available from 1.6 V to 4.9 V with 100 mV Increments (Factory Option)
- 200 mS (Typ) Reset Timeout Delay
- $12 \mu \mathrm{~A}(\mathrm{Vcc}=3.3 \mathrm{~V})$ Quiescent Current
- Active_High and Active_Low Reset Output
- Guaranteed RESET_L and RESET Output Valid to Vcc $=1.0 \mathrm{~V}$
- Voltage Monitor for Power-Fail or Low-Battery Warning
- 8 Pin SO or Micro8 Package

## Applications

- Computers
- Embedded System
- Battery Powered Equipment
- Critical $\mu$ P Power Supply Monitor

MAX707, MAX708

PIN DESCRIPTION (Pin No. with parentheses is for Micro8 package.)

| Pin No. | Symbol | Description |
| :---: | :---: | :--- |
| $1(3)$ | MR | Manual Reset Input. MR can be driven from TTL/CMOS logic or from a manual Reset switch. This input, <br> when floating, is internally pulled up to $\mathrm{V}_{\mathrm{CC}}$ with $50 \mathrm{~K} \Omega$ resistor. |
| $2(4)$ | $\mathrm{V}_{\mathrm{CC}}$ | Supply Voltage: $\mathrm{C}=100 \mathrm{nF}$ is recommended as a bypass capacitor between $\mathrm{V}_{\mathrm{CC}}$ and GND. |
| $3(5)$ | GND | Ground Reference |
| $4(6)$ | PFI | Power Fail Voltage Monitor Input. When PFI is less than 1.25 V, PFO goes low. Connect PFI to GND or <br> $\mathrm{V}_{\mathrm{CC}}$ when not used. |
| $5(7)$ | PFO | Power Fail Monitor Output. When PFI is less than 1.25 V , it goes low and sinks current. Otherwise, it <br> remains high. |
| $6(8)$ | NC | Non-connective Pin |
| $7(1)$ | RESET | Active Low RESET can be triggered by $\mathrm{V}_{\mathrm{CC}}$ below the threshold level or by a low signal on MR. It <br> remains low for 200 ms (typ.) after $\mathrm{V}_{\mathrm{CC}}$ rises above the reset threshold. |
| $8(2)$ | RESET | Active high RESET output the inverse of RESET one. |

## MAX707, MAX708

## APPLICATIONS INFORMATION

## Microprocessor Reset

To generate a processor reset, the manual Reset input allows different reset sources. A pushbutton switch can be
one of these. It is effectively debounced by the $1.0 \mu \mathrm{~s}$ minimum reset pulse width. As $\overline{\mathrm{MR}}$ is TTL/CMOS logic compatible, it can be driven by an external logic line.

Figure 12. RESET and MR Timing

## $\mathrm{V}_{\text {CC }}$ Transient Rejection

The MAX707/708 provides accurate $\mathrm{V}_{\mathrm{CC}}$ monitoring and reset timing during power-up, power-down, and brownout/sag conditions, and rejects negative glitches on the power supply line. Figure 13 shows the maximum transient duration vs. maximum negative excursion
(overdrive) for glitch rejection. For a given overdrive, the point of the curve is the maximum width of the glitch allowed before the device generates a reset signal. Transient immunity can be improved by adding a capacitor ( 100 nF for example) in close proximity to the $\mathrm{V}_{\mathrm{CC}}$ pin of the MAX707/708.

Figure 13. Maximum Transient Duration vs. Overdrive for Glitch Rejection at $25^{\circ} \mathrm{C}$

## RESET Signal Integrity During Power-Down

The MAX707/708 $\overline{\text { RESET }}$ output is valid until $\mathrm{V}_{\mathrm{CC}}$ falls below 1.0 V . Then, the output becomes an open circuit and no longer sinks current. This means CMOS logic inputs of the $\mu \mathrm{P}$ will be floating at an undetermined voltage. Most digital systems are completely shutdown well above this voltage. However, in the case RESET must be maintained valid to $\mathrm{V}_{\mathrm{CC}}=0 \mathrm{~V}$, a pull down resistor must be connected from $\overline{\text { RESET }}$ to ground to discharge stray capacitances and hold the output low (Figure 14). This resistor value, though not critical, should be chosen large enough not to load $\overline{\mathrm{RESET}}$ and small enough to pull it to ground. $\mathrm{R}=100 \mathrm{k} \Omega$ will be suitable for most applications.

Figure 14. Ensuring RESET Valid to $\mathrm{V}_{\mathrm{CC}}=0 \mathrm{~V}$

## Interfacing with $\mu \mathrm{Ps}$ with Bidirectional I/O Pins

Some $\mu$ Ps (such as Motorola 68HC11) have bidirectional reset pins. If, for example, the $\overline{\text { RESET output is driven high }}$ and the $\mu \mathrm{P}$ wants to put it low, indeterminate logic level may result. This can be avoided by adding a $4.7 \mathrm{k} \Omega$ resistor in series with the output of the MAX707/708 (Figure 15). If there are other components in the system that require a reset signal, they should be buffered so as not to load the reset line.

If the other components are required to follow the reset I/O of the $\mu \mathrm{P}$, the buffer should be connected as shown with the solid line.

Figure 15. Interfacing to Bidirectional Reset I/O

## Monitoring Additional Supply Levels

When connecting a voltage divider to PFI and adjusting it properly, you can monitor a voltage different than the unregulated DC one. As shown in Figure 16, to increase noise immunity, hysteresis may be added to the power-fail comparator just by a resistor between PFO and PFI. Not to unbalance the potential divider network, R3 should be 10 times the sum of the two resistors R1 and R2. If required, a capacitor between PFI and GND will reduce the sensitivity of the circuit to high-frequency noise on the line being monitored. The $\overline{\mathrm{PFO}}$ output may be connected to $\overline{\mathrm{MR}}$ input to generate a low level on the $\overline{\operatorname{RESET}}$ when Vcc_1 drops out of tolerance. Thus a $\overline{\text { RESET }}$ is generated when one of the two voltages is below its threshold level.

$$
\mathrm{VL}=1.25+\mathrm{R} 1 \times\left(\frac{1.25}{\mathrm{R} 2}+\frac{1.25-\mathrm{Vcc} \_2}{\mathrm{R} 3}\right)
$$

$$
\mathrm{VH}=1.25 \times\left(1+\mathrm{R} 1 \times\left(\frac{\mathrm{R} 2+\mathrm{R} 3}{\mathrm{R} 2 \times \mathrm{R} 3}\right)\right)
$$

$$
\mathrm{VHYS}=\mathrm{VH}-\mathrm{VL}=\frac{\mathrm{R} 1 \times \mathrm{Vcc} 2}{\mathrm{R} 3}
$$

## Integrated Relay/ Inductive Load Driver

- Provides a Robust Driver Interface between D.C. Relay Coil and Sensitive Logic Circuits
- Optimized to Switch Relays from a 3 V to 5 V Rail
- Capable of Driving Relay Coils Rated up to 2.5 W at 5 V
- Features Low Input Drive Current \& Good Back-to-Front Transient Isolation
- Internal Zener Eliminates Need for Free-Wheeling Diode
- Internal Zener Clamp Routes Induced Current to Ground for Quieter System Operation
- Guaranteed Off State with No Input Connection
- Supports Large Systems with Minimal Off-State Leakage
- ESD Resistant in Accordance with the 2000 V Human Body Model
- Low Sat Voltage Reduces System Current Drain by Allowing Use of Higher Resistance Relay Coils

## Applications Include:

- Telecom: Line Cards, Modems, Answering Machines, FAX Machines, Feature Phone Electronic Hook Switch
- Computer \& Office: Photocopiers, Printers, Desktop Computers
- Consumer: TVs \& VCRs, Stereo Receivers, CD Players, Cassette Recorders, TV Set Top Boxes
- Industrial: Small Appliances, White Goods, Security Systems, Automated Test Equipment, Garage Door Openers

## RELAY/INDUCTIVE LOAD DRIVER SILICON SMALLBLOCK ${ }^{\text {™ }}$ INTEGRATED CIRCUIT

- Automotive: 5.0 V Driven Relays, Motor Controls, Power Latches, Lamp Drivers
This device is intended to replace an array of three to six discrete components with an integrated SMT part. It is available in a SOT-23 package. It can be used to switch 3 to 6 Vdc inductive loads such as relays, solenoids, incandescent lamps, and small DC motors without the need of a free-wheeling diode.

Figure 12. Transient Thermal Response

## Using TTR Designing for Pulsed Operation

For a repetitive pulse operating condition, time averaging allows one to increase a device's peak power dissipation rating above the average rating by dividing by the duty cycle of the repetitive pulse train. Thus, a continuous rating of 200 mW of dissipation is increased to 1.0 W peak for a $20 \%$ duty cycle pulse train. However, this only holds true for pulse widths which are short compared to the thermal time constant of the semiconductor device to which they are applied.

For pulse widths which are significant compared to the thermal time constant of the device, the peak operating condition begins to look more like a continuous duty operating condition over the time duration of the pulse. In these cases, the peak power dissipation rating cannot be merely time averaged by dividing the continuous power rating by the duty cycle of the pulse train. Instead, the average power rating can only be scaled up a reduced amount in accordance with the device's transient thermal response, so that the device's max junction temperature is not exceeded.

Figure 12 of the MDC3105LT1 data sheet plots its transient thermal resistance, $\mathrm{r}(\mathrm{t})$ as a function of pulse width in ms for various pulse train duty cycles as well as for a single pulse and illustrates this effect. For short pulse widths near the left side of the chart, $\mathrm{r}(\mathrm{t})$, the factor, by which the continuous duty thermal resistance is multiplied to determine how much the peak power rating can be increased above the average power rating, approaches the duty cycle of the pulse train, which is the expected value. However, as the pulse width is increased, that factor eventually approaches 1.0 for all duty cycles indicating that the pulse width is sufficiently long to appear as a continuous duty condition to this device. For the MDC3105LT1, this pulse width is about 100 seconds. At this and larger pulse widths, the peak power dissipation capability is the same as the continuous duty power capability.

To use Figure 12 to determine the peak power rating for a specific application, enter the chart with the worst case pulse condition, that is the max pulse width and max duty cycle and determine the worst case $r(t)$ for your application. Then calculate the peak power dissipation allowed by using the equation,

$$
\begin{gathered}
\mathrm{Pd}(\mathrm{pk})=\left(\mathrm{T}_{\mathrm{Jmax}}-\mathrm{T}_{\text {Amax }}\right) \div\left(\mathrm{R}_{\theta \mathrm{JA}}{ }^{*} \mathrm{r}(\mathrm{t})\right) \\
\mathrm{Pd}(\mathrm{pk})=\left(150^{\circ} \mathrm{C}-\mathrm{T}_{\text {Amax }}\right) \div\left(556^{\circ} \mathrm{C} / \mathrm{W}^{*} \mathrm{r}(\mathrm{t})\right)
\end{gathered}
$$

Thus for a $20 \%$ duty cycle and a $\mathrm{PW}=40 \mathrm{~ms}$, Figure 12 yields $r(t)=0.3$ and when entered in the above equation, the max allowable $\mathrm{Pd}(\mathrm{pk})=390 \mathrm{~mW}$ for a max $\mathrm{T}_{\mathrm{A}}=85^{\circ} \mathrm{C}$.

Also note that these calculations assume a rectangular pulse shape for which the rise and fall times are insignificant compared to the pulse width. If this is not the case in a specific application, then the $\mathrm{V}_{\mathrm{O}}$ and $\mathrm{I}_{\mathrm{O}}$ waveforms should be multiplied together and the resulting power waveform integrated to find the total dissipation across the device. This then would be the number that has to be less than or equal to
the $\operatorname{Pd}(\mathrm{pk})$ calculated above. A circuit simulator having a waveform calculator may prove very useful for this purpose.

## Notes on SOA and Time Constant Limitations

Figure 10 is the Safe Operating Area (SOA) for the MDC3105LT1. Device instantaneous operation should never be pushed beyond these limits. It shows the SOA for the Transistor "ON" condition as well as the SOA for the zener during the turn-off transient. The max current is limited by the Izpk capability of the zener as well as the transistor in addition to the max input current through the resistor. It should not be exceeded at any temperature. The BJT power dissipation limits are shown for various pulse widths and duty cycles at an ambient temperature of $25^{\circ} \mathrm{C}$. The voltage limit is the max $\mathrm{V}_{\mathrm{CC}}$ that can be applied to the device. When the input to the device is switched off, the BJT "ON" current is instantaneously dumped into the zener diode where it begins its exponential decay. The zener clamp voltage is a function of that BJT current level as can be seen by the bowing of the $\mathrm{V}_{\mathrm{Z}}$ versus $\mathrm{I}_{\mathrm{Z}}$ curve at the higher currents. In addition to the zener's current limit impacting this device's 500 mA max rating, the clamping diode also has a peak energy limit as well. This energy limit was measured using a rectangular pulse and then translated to an exponential equivalent using the $2: 1$ relationship between the $\mathrm{L} / \mathrm{R}$ time constant of an exponential pulse and the pulse width of a rectangular pulse having equal energy content. These $\mathrm{L} / \mathrm{R}$ time constant limits in ms appear along the $\mathrm{V}_{\mathrm{Z}}$ versus $I_{Z}$ curve for the various values of $I_{Z}$ at which the Pd lines intersect the $\mathrm{V}_{\mathrm{CC}}$ limit. The $\mathrm{L} / \mathrm{R}$ time constant for a given load should not exceed these limits at their respective currents. Precise L/R limits on zener energy at intermediate current levels can be obtained from Figure 11.

## Designing with this Data Sheet

1. Determine the maximum inductive load current (at $\max \mathrm{V}_{\mathrm{CC}}$, min coil resistance \& usually minimum temperature) that the MDC3105 will have to drive and make sure it is less than the max rated current.
2. For pulsed operation, use the Transient Thermal Response of Figure 12 and the instructions with it to determine the maximum limit on transistor power dissipation for the desired duty cycle and temperature range.
3. Use Figures $10 \& 11$ with the SOA notes above to insure that instantaneous operation does not push the device beyond the limits of the SOA plot.
4. While keeping any $\mathrm{V}_{\mathrm{O} \text { (sat) }}$ requirements in mind, determine the max input current needed to achieve that output current from Figures $2 \& 6$.
5. For levels of input current below $100 \mu \mathrm{~A}$, use the input threshold curves of Figure 4 to verify that
there will be adequate input current available to turn on the MDC3105 at all temperatures.
6. For levels of input current above $100 \mu \mathrm{~A}$, enter Figure 3 using that max input current and determine the input voltage required to drive the MDC3105 from the solid $V_{\text {in }}$ versus $I_{i n}$ line. Select a suitable drive source family from those whose dotted lines cross the solid input characteristic line to the right of the $\mathrm{I}_{\mathrm{in}}, \mathrm{V}_{\text {in }}$ point.
7. Using the max output current calculated in step 1 , check Figure 7 to insure that the range of zener clamp voltage over temperature will satisfy all system \& EMI requirements.
8. Using Figures $8 \& 9$, insure that "OFF" state leakage over temperature and voltage extremes does not violate any system requirements.
9. Review circuit operation and insure none of the device max ratings are being exceeded.

## INFORMATION FOR USING THE SOT-23 SURFACE MOUNT PACKAGE MINIMUM RECOMMENDED FOOTPRINT FOR SURFACE MOUNTED APPLICATIONS

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to insure proper solder connection
interface between the board and the package. With the correct pad geometry, the packages will self align when subjected to a solder reflow process.

SOT-23

## SOT-23 POWER DISSIPATION

The power dissipation of the SOT-23 is a function of the pad size. This can vary from the minimum pad size for soldering to a pad size given for maximum power dissipation. Power dissipation for a surface mount device is determined by $\mathrm{T}_{\mathrm{J}(\max )}$, the maximum rated junction temperature of the die, $\mathrm{R}_{\theta \mathrm{JA}}$, the thermal resistance from the device junction to ambient, and the operating temperature, $\mathrm{T}_{\mathrm{A}}$. Using the values provided on the data sheet for the SOT-23 package, $\mathrm{P}_{\mathrm{D}}$ can be calculated as follows:

$$
P_{D}=\frac{T_{J(\max )}-T_{A}}{R_{\theta J A}}
$$

The values for the equation are found in the maximum ratings table on the data sheet. Substituting these values into the equation for an ambient temperature $\mathrm{T}_{\mathrm{A}}$ of $25^{\circ} \mathrm{C}$, one can
calculate the power dissipation of the device which in this case is 225 milliwatts.

$$
\mathrm{P}_{\mathrm{D}}=\frac{150^{\circ} \mathrm{C}-25^{\circ} \mathrm{C}}{556^{\circ} \mathrm{C} / \mathrm{W}}=225 \text { milliwatts }
$$

The $556^{\circ} \mathrm{C} / \mathrm{W}$ for the SOT-23 package assumes the use of the recommended footprint on a glass epoxy printed circuit board to achieve a power dissipation of 225 milliwatts. There are other alternatives to achieving higher power dissipation from the SOT-23 package. Another alternative would be to use a ceramic substrate or an aluminum core board such as Thermal Clad ${ }^{\text {TM }}$. Using a board material such as Thermal Clad, an aluminum core board, the power dissipation can be doubled using the same footprint.

## SOLDERING PRECAUTIONS

The melting temperature of solder is higher than the rated temperature of the device. When the entire device is heated to a high temperature, failure to complete soldering within a short time could result in device failure. Therefore, the following items should always be observed in order to minimize the thermal stress to which the devices are subjected.

- Always preheat the device.
- The delta temperature between the preheat and soldering should be $100^{\circ} \mathrm{C}$ or less.*
- When preheating and soldering, the temperature of the leads and the case must not exceed the maximum temperature ratings as shown on the data sheet. When using infrared heating with the reflow soldering method, the difference should be a maximum of $10^{\circ} \mathrm{C}$.
- The soldering temperature and time should not exceed $260^{\circ} \mathrm{C}$ for more than 10 seconds.
- When shifting from preheating to soldering, the maximum temperature gradient should be $5^{\circ} \mathrm{C}$ or less.
- After soldering has been completed, the device should be allowed to cool naturally for at least three minutes. Gradual cooling should be used as the use of forced cooling will increase the temperature gradient and result in latent failure due to mechanical stress.
- Mechanical stress or shock should not be applied during cooling
* Soldering a device without preheating can cause excessive thermal shock and stress which can result in damage to the device.

## Advance Information

## Integrated Relay/Solenoid

Driver
RELAY/SOLENOID DRIVER SILICON MONOLITHIC CIRCUIT BLOCK

- Optimized to Switch 3 V to 5 V Relays from a 5 V Rail
- Compatible with "TX" and "TQ" Series Telecom Relays Rated up to 625 mW at 3 V to 5 V
- Features Low Input Drive Current
- Internal Zener Clamp Routes Induced Current to Ground Rather Than Back to Supply
- Guaranteed Off State with No Input Connection
- Supports Large Systems with Minimal Off-State Leakage
- ESD Resistant in Accordance with the 2000 V Human Body Model
- Provides a Robust Driver Interface Between Relay Coil and Sensitive Logic Circuits

## Applications include

- Telecom Line Cards and Telephony
- Industrial Controls
- Security Systems
- Appliances and White Goods
- Automated Test Equipment
- Automotive Controls

This device is intended to replace an array of three to six discrete components with an integrated part. It can be used to switch other 3 to 5 Vdc Inductive Loads such as solenoids and small DC motors.

## MC1413, MC1413B, NCV1413B

## High Voltage, High Current Darlington Transistor Arrays

The seven NPN Darlington connected transistors in these arrays are well suited for driving lamps, relays, or printer hammers in a variety of industrial and consumer applications. Their high breakdown voltage and internal suppression diodes insure freedom from problems associated with inductive loads. Peak inrush currents to 500 mA permit them to drive incandescent lamps.

The MC1413, B with a $2.7 \mathrm{k} \Omega$ series input resistor is well suited for systems utilizing a 5.0 V TTL or CMOS Logic.

## MC34271

## Liquid Crystal Display and Backlight Integrated Controller

The MC34271 is a low power dual switching voltage regulator, specifically designed for handheld and laptop applications, to provide several regulated output voltages using a minimum of external parts. Two uncommitted switching regulators feature a very low standby bias current of $5.0 \mu \mathrm{~A}$, and an operating current of 7.0 mA capable of supplying output currents in excess of 200 mA .

Both devices have three additional features. The first is an ELD Output that can be used to drive a backlight or a liquid crystal display. The ELD output frequency is the clock divided by 256 . The second feature allows four additional output bias voltages, in specific proportions to $\mathrm{V}_{\mathrm{B}}$, one of the switching regulated output voltages. It allows use of mixed logic circuitry and provides a voltage bias for N -Channel load control MOSFETs ${ }^{\mathrm{TM}}$. The third feature is an Enable input that allows a logic level signal to turn-"off" or turn-"on" both switching regulators.

Due to the low bias current specifications, this device is ideally suited for battery powered computer, consumer, and industrial equipment where an extension of useful battery life is desirable.

## MC34271 Features:

- Low Standby Bias Current of $5.0 \mu \mathrm{~A}$
- Uncommitted Switching Regulators Allow Both Positive and Negative Supply Voltages
- Logic Enable Allows Microprocessor Control of All Outputs
- Synchronizable to External Clock
- Mode Commandable for ELD and LCD Interface
- Frequency Synchronizable
- Auxiliary Output Bias Voltages Enable Load Control via N-Channel FETs

## OPERATING DESCRIPTION

The MC34271 is a monolithic, fixed frequency power switching regulator specifically designed for dc to dc converter and battery powered applications. This device operates as a fixed frequency, voltage mode regulator containing all the active functions required to directly implement step-up, step-down and voltage inverting converters with a minimum number of external components. Potential markets include battery powered, handheld, automotive, computer, industrial and cost sensitive consumer products. A description of each section is given below with the representative block diagram shown in Figure 11

## Oscillator

The oscillator frequency is programmed by resistor $\mathrm{R}_{\mathrm{T}}$. The charge to discharge ratio is controlled to yield a $95 \%$ maximum duty cycle at the switch outputs. During the fall time of the internal sawtooth waveform, the oscillator generates an internal blanking pulse that holds the inverting input of the AND gates high, disabling the output switching MOSFETs. The internal sawtooth waveform has a nominal peak voltage of 3.3 V and a valley voltage of 1.7 V .

## Pulse Width Modulators

Both pulse width modulators consist of a comparator with the oscillator ramp voltage applied to the noninverting input, while the error amplifier output is applied to the inverting input. A third input to the comparator has a 0.5 mA typical current source that can be used to implement soft start. Output switch conduction is initiated when the ramp waveform is discharged to the valley voltage. As the ramp voltage increases to a voltage that exceeds the error amplifier output, the latch resets, terminating output MOSFET conduction for the duration of the oscillator ramp. This PWM/latch combination prevents multiple output pulses during a given oscillator cycle.

Each PWM circuit is enabled by a logic input. When disabled, the entire block is turned off, drawing only leakage current from the power source. Shared circuits, like the
reference and oscillator, can be activated by either $\mathrm{EN}_{1}$ or $\mathrm{EN}_{2}$.

Circuit \#1 has an ELD output which may be used to drive an LCD or backlight. Its output frequency is the oscillator frequency divided by 1024.

## Error Amplifiers and Reference

Each error amplifier is provided with access to both inverting and noninverting inputs, and the output. The Error Amplifiers' Common Mode Input Range is 0 to 2.5 V . The amplifiers have a minimum dc voltage gain of 60 dB . The 1.25 V reference has an accuracy of $\pm 4.0 \%$ at room temperature.

External loop compensation is required for converter stability. A simple low-pass filter is formed by connecting a resistive divider from the output to the error amplifier inverting input, and a series resistor-capacitor from the error amplifier output also to the to the inverting input. The step down converter is easiest to compensate for stability. The step-up and voltage inverting configurations, when operated as continuous conduction boost or flyback converters, are more difficult to compensate, and may require a lower loop design bandwidth.

## MOSFET Switch Outputs

The output MOSFETs are designed to switch a maximum of 60 V , with a peak drain current capability of 500 mA . In circuit \#1 an additional $\mathrm{DRV}_{1}$ output is provided for interfacing with an external MOSFET.The gates of the MOSFETs are held low when the circuit is disabled.

## Auxiliary Output Voltages

Output voltages $\mathrm{V}_{0}$ through $\mathrm{V}_{4}$ are provided for use as references or bias voltages. $\mathrm{V}_{0}$ is the circuit \#2 output voltage, when an internal FET switch is activated. The other auxiliary output voltages are proportional to $\mathrm{V}_{\mathrm{B}}$. The amplifiers for $V_{1}$ and $V_{2}$ are powered from $V_{0}$, while the amplifiers for $V_{3}$ and $V_{4}$ are powered from $V_{D D}$.

Figure 12. Auxiliary Supply Configuration

Figure 13. EL PANEL Drive Circuit

## MC33441

## Electroluminescent Lamp Driver IC

The MC33441 is a DC-AC inverter integrated circuit for driving EL lamps. It can boost the supply voltage to the level required by EL lamps and also provide high voltage AC lamp excitation. It consists of an oscillator, a frequency divider, a coil driving circuit and a switched H -bridge network. The input supply voltage range is from 1.8 V to 3.5 V and is capable to supply a typical 140 Vpp AC output voltage. The standby current of the device is typically 10nA which is ideal for low power portable products. Externally, one inductor and one resistor are needed to generate the desirable voltage charge and to fine tune the oscillator's frequency. This device is offered in 8-Pin TSSOP miniature package. The operating temperature is $-20^{\circ} \mathrm{C}$ to $70^{\circ} \mathrm{C}$.

## Features:

- Battery Operation $1.8 \mathrm{~V}-3.5 \mathrm{~V}$
- Typical Voltage Output 140Vpp
- Typical Standby Current 10nA
- Internal Oscillator with External Tuning Resistor
- Enable Control Pin with a 300K Internal Pull-Down Resistor
- $8-$ Pin TSSOP Package $($ Thickness $=1.05 \mathrm{~mm}$, Width $=4.5 \mathrm{~mm}$,

Length $=3.1 \mathrm{~mm} \&$ Lead Pitch $=0.65 \mathrm{~mm})$
Types of Applications:

- Pagers, Cellular Phones, Portable CD Players/Minidisks
- Databanks, Calculators

## OPERATING DESCRIPTION

## General

The MC33441 is a DC-AC inverter integrated circuit for driving EL lamps. It can boost the supply voltage to the level required by EL lamps and also provide high voltage AC lamp excitation. It consists of an oscillator, a frequency divider, a coil driving circuit and a switched H -bridge network. The input supply voltage range is from 1.8 V to 3.5 V and is capable to supply a typical 140 Vpp AC output voltage. The standby current of the device is typically 10 nA which is ideal for low power portable products. Externally, one inductor and one resistor are needed to generate the desirable voltage charge and to fine tune the oscillator's frequency. This device is offered in 8 -Pin TSSOP packages. The operating temperature is $-20^{\circ} \mathrm{C}$ to $70^{\circ} \mathrm{C}$.

## Oscillator and Frequency Divider

Two circuits are put together to form the oscillator. They are Vref and Ibias. The functionality of Vref block is to generate a zero temperature coefficient (TC) voltage reference which is about 1.27 V . This 1.27 V will then be used in Ibias circuit to provide current biasing to all of the internal circuits with the value equal to Vref divided by an internal resistor. Besides of that, an external resistor is also connected to this circuit block for setting the oscillator's frequency. The temperature coefficient is dominated by the value of that resistor. Therefore, if a low TC resistor is used, the oscillator frequency's TC can be kept low.

The current mirrors with the induced current equal to the Vref divided by an external resistor are used to charge and discharge an internal capacitor to provide a $50 \%$ duty cycle clock signal. This original clock pulse will then be fed into the frequency divider which will generate two additional clock signals with different frequency and duty cycle to the coil-driver and the H -bridge circuits. The oscillator frequency is governed by the following equation:
$\mathrm{F}_{\mathrm{OSC}}=\left(\frac{1}{6 \times \mathrm{R}_{\mathrm{EXT}} \times \mathrm{C}_{\mathrm{INT}}} \mathrm{Hz}\right)=\frac{1.667 \times 10^{10}}{R_{\mathrm{EXT}}} \mathrm{Hz}$
$\mathrm{F}_{\mathrm{COIL}}=\mathrm{F}_{\mathrm{OSC}} \div 4$
$\mathrm{F}_{\mathrm{EL}}=\mathrm{F}_{\mathrm{OSC}} \div 384$
where $\mathrm{C}_{\text {INT }}$ is about 10 pF .

## Coil Driver

The coil driver is basically a simplified boost converter. It takes a higher frequency clock signal from the frequency divider to turn on/off the main switch alternatively. When the main switch is on, current will flow through the coil to ground. Once the switch is being turned off, the energy stored in the coil will be released to the external capacitor (EL lamp) through an internal diode. According to the frequency of the clock signals between the coil driver and the H -bridge, the external capacitor (EL lamp) will be charging to the desirable level.

Current limit circuit (typical 70mA \& max. 150mA) is implemented in this device. Since the current through the coil will increase corresponding to the input voltage, if the input voltage is high and the inductance of the coil is small, the coil can be saturated. The current limit feature is used to avoid this happen. The main switch is parallel to a much smaller switch which has their collector and their base connected together. However, the emitter of the smaller switch is tied to a sensing resistor while the emitter of the main switch is connected to ground. The coil current will split into two according to the sizing ratio between the main and the smaller switch. The current through the smaller switch will also flow through the sensing resistor and generates a voltage. If the voltage across this sensing resistor is above the pre-set value, then both switches
will be turned off and the energy will release to the EL lamp. And, those switches will remain off until the next clock cycle.

## H-Bridge Network

To achieve the 140 V peak-to-peak voltage, H-bridge network is used to charge and discharge the EL lamp. The switching frequency of the bridge network is controlled by a clock signal from the divider with its frequency much lower than the one to the coil-driver. Moreover, to reduce the current consumption, the biasing current to the two low-side switches of the H -bridge is not activated until the coil-driver circuit needed to release the energy to the EL lamp. Then, the biasing circuit will be on and be ready before the main switch in the coil-driver really starts to turn off.

## External Components

System designer will base on the application to decide the size and the type of the EL lamp to be used. The external resistance ( $\mathrm{R}_{\mathrm{EXT}}$ ) at RT1 pin determines the excitation frequency ( $\mathrm{F}_{\mathrm{EL}}$ ) for the lamp. The relationship between $\mathrm{R}_{\mathrm{EXT}}$ and the frequency is:
$\mathrm{F}_{\mathrm{EL}}=\mathrm{F}_{\mathrm{OSC}} \div 384$
By substitute the equation of FOSC from Oscillator \& Frequency Divider.

$$
\mathrm{F}_{\mathrm{EL}}=\frac{4.341 \times 10^{7}}{R_{\mathrm{EXT}}} \mathrm{~Hz}
$$

so
$R_{E X T}=\frac{4.341 \times 10^{7}}{F_{E L}} \Omega$

Moreover, if a low TC resistor is used, the oscillator frequency's TC can be kept low. The filter capacitor is to provide a smooth and more stable output waveform for the EL lamp. The value of this capacitor depends on the input voltage and the coil's inductance value. Equations below can be used to estimate filter capacitor's value at different input voltage.

## Best Case Approximation for the Filter Capacitor: <br> $\mathrm{C}_{\text {FILTER }}=0.026 \times\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\text {SW }}\right)^{2} /\left(\mathrm{L} \times \mathrm{F}_{\mathrm{OSC}}{ }^{2}\right)$

## Worst Case Approximation for the Filter Capacitor:

$\mathrm{C}_{\text {FILTER }}=0.085 \times\left(\mathrm{V}_{\text {in }}-\mathrm{V}_{\mathrm{SW}}\right)^{2} /\left(\mathrm{L} \times \mathrm{F}_{\mathrm{OSC}^{2}}{ }^{2}\right)$
where $\mathrm{V}_{\text {IN }}$ is the input voltage, $\mathrm{V}_{\text {SW }}$ is voltage across the switch when it is on, L is the coil's value and $\mathrm{F}_{\text {OSC }}$ is the clock frequency.
Measurement below is recorded with the condition: coil $=1 \mathrm{mH}$, EL lamp $=2.2 \mathrm{nF}$ and at room temperature.

Table 1: Reference for C $_{\text {FILTER }}$

| VDD | $\mathbf{R}_{\text {EXT }}$ | C $_{\text {FILTER }}$ |
| :---: | :---: | :---: |
| 1.8 V | $100 \mathrm{~K}-130 \mathrm{~K} \Omega$ | $5 \mathrm{n}-10 \mathrm{nF}$ |
| 2.0 V | $100 \mathrm{~K}-130 \mathrm{~K} \Omega$ | $10 \mathrm{n}-22 \mathrm{nF}$ |
| 2.5 V | $100 \mathrm{~K}-130 \mathrm{~K} \Omega$ | $10 \mathrm{n}-22 \mathrm{nF}$ |
| 3.0 V | $100 \mathrm{~K}-130 \mathrm{~K} \Omega$ | $22 \mathrm{nF}-33 \mathrm{nF}$ |

## APPLICATION INFORMATION

## EL Lamp Selection

EL lamps are a laminate which exhibit a capacitance on the order of 2.5 nF to 3.5 nF per square inch. The light will emit as the high voltage is applied across the electrodes of this capacitance. The color of the emitted light is determined by the type of chemical used and the frequency of the excitation voltage. On the other hand, the lamp brightness increases approximately the square of the applied voltage and nearly linear to the excitation frequency. Once a lamp has been selected, the operating frequency and the essential voltage for the optimum performance is determined. Then, the driver circuit can begin to design.

## Inductor Selection (L1)

Use a $1 \mathrm{mH} / 0.15 \mathrm{~A}$ inductor for MC33441. Higher inductor values can be used to reduce the peak transient coil current from the battery supply. As the value of the inductor (L1), increases, the resistor (R1) value may need to increase correspondingly to provide optimum performance. While a lower inductor values lead to smaller physical size, it will generate a higher peak coil current. A lower resistor (R1) value should be used when a lower inductance coil is being used.

The inductor must have a saturation current rating equal to or bigger than the peak coil current which is 150 mA .

## Filter Capacitor Selection (C2)

See Table 1 for the estimated value of the filter capacitors based on the input voltage supply. Since the maximum voltage of the filter capacitor can reach 70 V or even 80 V , capacitor with high voltage rating will be required.

## Resistor Selection (R1)

Since the fundamental frequency of the oscillator is set by the external resistor (R1), the temperature coefficient of the frequency is dominated by the value of this resistor. A low temperature coefficient (TC) resistor is suggested to use for keeping the variation of oscillator's frequency low against the operation temperature range. (See Page 4, Fig. 3 \& Fig. 4)
$R 1=R_{E X T}=\frac{4.341 \times 10^{7}}{\mathrm{~F}_{\mathrm{EL}}} \Omega$

## Layout

The MC33441 is high output voltage operation make PC board layout critical to minimize ground bounce and noise. Locate input bypass capacitor, filter capacitor and oscillator's resistor as close to the device pins as possible.

## CS1087

## Vacuum Fluorescent Display Tube Driver

The VFD Driver is a microprocessor interface IC that drives a multiplexed VF (Vacuum Fluorescent) display tube. It consists of a 32-bit shift register, a 32-bit transparent data latch, a metal mask ROM, six 20 mA anode output drivers, twenty-three 2 mA anode output drivers, and three 50 mA grid drivers with output enables.

## Features

- Power On Reset
- Display Dimming Possible
- Three, 50 mA Grid Drivers
- Anode Options - DIP-40 and PCLL-44:
- 6 @ 20 mA
- 23 @ 2 mA
- Anode Options - SO-28L:
- 3 @ 20 mA
- 15 @ 2 mA

Figure 2. Block Diagram

## OPERATION DESCRIPTION

Upon the initial application of power, the power on reset function will cause all of the anode and grid driver outputs to be off and all shift register outputs to be set low. Data is fed into the shift register through the $\mathrm{D}_{\text {IN }}$ pin at the rising edge of the CLK input. Thirty two bits of data are capable of being stored by the shift register. Once the desired pattern is stored in the shift register, it can be transferred to the latch by setting the STB input high. The output of each latch drives its corresponding output stage. A logic high input to the shift register/latch will cause the corresponding output to turn on. A logic low input to the shift register/latch will cause the corresponding output to turn off. Please note that if the STB is held high, the outputs of the latch reflect the outputs of the corresponding shift register bits and will change if data is shifted in.

The three GRID outputs are gated by the GREN input. When GREN is low, the GRID outputs are forced low regardless of the state of the corresponding latch output. When GREN is high, the GRID outputs correspond to the state of their respective latch outputs. The anode outputs, AN1 to AN29 are always enabled.

The Dout pin is the output of the last stage of the shift register to allow serial cascading of this IC with other devices. Data from the last stage of the shift register is supplied to the $D_{\text {OUT }}$ pin delayed by $1 / 2$ CLK cycle. Data on the $\mathrm{D}_{\text {OUT }}$ output changes with the falling edges of the CLK to prevent logic race conditions between the CLK and the $\mathrm{D}_{\text {IN }}$ of the next IC in the serial chain.

* Selected grid goes high only if input bit pattern from shift register to grid is high.

Figure 3. Typical Operation

Unused grid and anode drivers should have their respective bits set to logic low in the data stream.

Multiple grid or anode drivers may be connected together, but must be programmed to the same logic state for proper device operation. Maximum package power must be observed and care must be taken to maintian junction temperature below $+150^{\circ} \mathrm{C}$.

Care must be taken when interfacing this part to a microprocessor. The $\mathrm{D}_{\mathrm{OUT}}$ output $\mathrm{V}_{\mathrm{OH}}$ is specified at 3.9 V
to 5.1 V at an $\mathrm{I}_{\mathrm{OUT}}$ of -1.0 mA . Lower current loads will result in a higher output voltage. $\mathrm{V}_{\mathrm{OH}}=5.2 \mathrm{~V}(\mathrm{typ})$ with no load. $\mathrm{V}_{\mathrm{OH}}=5.7 \mathrm{~V}$ (max) with no load. Protection or workarounds for the device may be needed at the application level. No protection is needed when interfacing with other parts in this family (CS1087, CS1088, or CS1089).

Figure 2. Block Diagram

## OPERATION DESCRIPTION

Upon the initial application of power, the power on reset function will cause all of the anode and grid driver outputs to be off and all shift register outputs to be set low. Data is fed into the shift register through the $\mathrm{D}_{\text {IN }}$ pin at the rising edge of the CLK input. Thirty four bits of data are capable of being stored by the shift register. Once the desired pattern is stored in the shift register, it can be transferred to the latch by setting the STB input high. The output of each latch drives its corresponding output stage. A logic high input to the shift register/latch will cause the corresponding output to turn on. A logic low input to the shift register/latch will
cause the corresponding output to turn off. Please note that if the STB is held high, the outputs of the latch reflect the outputs of the corresponding shift register bits and will change if data is shifted in.
The three GRID outputs are gated by the GREN input. When GREN is low, the GRID outputs are forced low regardless of the state of the corresponding latch output. When GREN is high, the GRID outputs correspond to the state of their respective latch outputs. The anode outputs, AN1 to AN31 are always enabled.

Figure 2. Block Diagram

## OPERATION DESCRIPTION

Upon the initial application of power, the power on reset function will cause all of the anode and grid driver outputs to be off and all shift register outputs to be set low. Data is fed into the shift register through the $\mathrm{D}_{\text {IN }}$ pin at the rising edge of the CLK input. Thirty two bits of data are capable of being stored by the shift register. Once the desired pattern is stored in the shift register, it can be transferred to the latch by setting the STB input high. The output of each latch drives its corresponding output stage. A logic high input to the shift register/latch will cause the corresponding output to turn on. A logic low input to the shift register/latch will cause the corresponding output to turn off. Please note that if the STB is held high, the outputs of the latch reflect the outputs of the corresponding shift register bits and will change if data is shifted in.

The three GRID outputs are gated by the GREN input. When GREN is low, the GRID outputs are forced low regardless of the state of the corresponding latch output. When GREN is high, the GRID outputs correspond to the state of their respective latch outputs. The anode outputs, AN1 to AN29 are always enabled.

The $D_{\text {OUT }}$ pin is the output of the last stage of the shift register to allow serial cascading of this IC with other devices. Data from the last stage of the shift register is supplied to the $D_{\text {OUT }}$ pin delayed by $1 / 2$ CLK cycle. Data on the $\mathrm{D}_{\text {OUT }}$ output changes with the falling edges of the CLK to prevent logic race conditions between the CLK and the $\mathrm{D}_{\text {IN }}$ of the next IC in the serial chain.

* Selected grid goes high only if input bit pattern from shift register to grid is high.

Figure 3. Typical Operation

Unused grid and anode drivers should have their respective bits set to logic low in the data stream.

Multiple grid or anode drivers may be connected together, but must be programmed to the same logic state for proper device operation. Maximum package power must be observed and care must be taken to maintian junction temperature below $+150^{\circ} \mathrm{C}$.

Care must be taken when interfacing this part to a microprocessor. The $\mathrm{D}_{\mathrm{OUT}}$ output $\mathrm{V}_{\mathrm{OH}}$ is specified at 3.9 V
to 5.1 V at an $\mathrm{I}_{\mathrm{OUT}}$ of -1.0 mA . Lower current loads will result in a higher output voltage. $\mathrm{V}_{\mathrm{OH}}=5.2 \mathrm{~V}$ (typ) with no load. $\mathrm{V}_{\mathrm{OH}}=5.7 \mathrm{~V}$ (max) with no load. Protection or workarounds for the device may be needed at the application level. No protection is needed when interfacing with other parts in this family (CS1087, CS1088, or CS1089).

## CS8312

## IGBT Ignition Predriver with Dynamic Current Regulation

The CS8312 is a bipolar microprocessor interface IC designed to drive an IGBT (or logic level MOSFETs) powering large inductive loads in harsh operating environments. The IC's dynamic current limit function lets the microprocessor adjust the current limit threshold to the real time needs of the system.

CLI, the current limit input, sets the current limit for the IGBT high or low as directed by the system microprocessor. CLI also raises and lowers the threshold on the diagnostic FLAG output signal. The FLAG output signals the microprocessor when the current level approaches current limit on the IGBT. The CTRL input enables the FLAG function.

## Features

- $\mu \mathrm{P}$ Compatible Inputs
- Adjustable Current Limit Thresholds
- External Sense Resistor
- Flag Signal to Indicate Output Status

## PACKAGE PIN DESCRIPTION

| PACKAGE PIN \# |  | FIN SYMBOL |  |
| :---: | :---: | :---: | :--- |
| DIP-8 | SO-8 |  | Indicates whether current through the IGBT has reached a pre- <br> set level. |
| 1 | 1 | SENSE + | Positive input to current comparator. |
| 2 | 2 | SENSE- | Ground (SENSE-) for current sense resistor. |
| 3 | 3 | GND | Ground connection. |
| 4 | 4 | OUT | Output voltage to IGBT (MOSFET) gate. |
| 5 | 5 | CLI | Current limit input increase. |
| 6 | 6 | CTRL | Control input. |
| 7 | 7 | VCC |  |
| 8 | 8 | Supply voltage. |  |

## CIRCUIT DESCRIPTION

## Flag Function (See Figure 2)

The flag indicates when the voltage across the two sense pins is approaching a current limit level that has been determined by the value of the external sense resistor ( $\mathrm{R}_{\text {SENSE }}$ ) and the state of the CTRL and CLI pins. If the voltage across the sense pins (SENSE+, SENSE-) is less than the flag turn-on voltage, then the FLAG is off. When the voltage between the sense pins equals the FLAG turn on voltage, the FLAG will latch on until the CTRL pin goes low. FLAG is disabled whenever CTRL is low. Changing the CLI pin from low to high will increase nominal FLAG turn on voltage by approximately $45 \%$.

Table 1. FLAG Timing Sequence

| State | CONTROL | SENSE $_{+}$ | FLAG |
| :---: | :---: | :---: | :---: |
| 0 | Low | $X$ | OFF |
| 1 | High | Below Threshold | OFF |
| 2 | High | Above Threshold | ON |
| 3 | High | $X$ | ON |
| 0 | Low | $X$ | OFF |

## Output Stage

The CS8312 output (OUT) saturates and supplies voltage to the IGBT (or MOSFET) gate once the CTRL switches from low to high. As current through the IGBT (MOSFET) increases and the voltage across the sense resistor passes the flag turn on voltage, the FLAG will turn on. If the current through the sense resistor continues to rise and the sense resistor voltage reaches the regulation sense voltage, then the gate voltage will fall to a level that regulates the driver and maintains the regulation sense voltage at the sense resistor.

## Current Limit Function

Changing the CLI pin from a logic low to a logic high increases the FLAG turn on voltage by approximately 45\% and the regulation sense voltage by approximately $39 \%$ respectively.

## CS7054

## Low Side PWM FET Controller

The CS7054 is a monolithic integrated circuit designed primarily to control the rotor speed of permanent magnet, direct current (DC) brush motors. It drives the gate of an N channel power MOSFET or IGBT with a user-adjustable, fixed frequency, variable duty cycle, pulse width modulated (PWM) signal. The CS7054 can also be used to control other loads such as incandescent bulbs and solenoids. Inductive current from the motor or solenoid is recirculated through an external diode.

The CS7054 accepts a DC level input signal of 0 to 5.0 V to control the pulse width of the output signal. This signal can be generated by a potentiometer referenced to the on-chip 5.0 V linear regulator, or a filtered $0 \%$ to $100 \%$ PWM signal also referenced to the 5.0 V regulator.

The IC is placed in a sleep state by pulling the CTL lead below 0.5 V . In this mode everything on the chip is shut down except for the on-chip regulator and the overall current draw is less than $275 \mu \mathrm{~A}$. There are a number of on-chip diagnostics that look for potential failure modes and can disable the external power MOSFET.

## Features

- 200 mA Peak PWM Gate Drive Output
- Patented Voltage Compensation Circuit
- $100 \%$ Duty Cycle Capability
- $5.0 \mathrm{~V}, \pm 3.0 \%$ Linear Regulator
- Low Current Sleep Mode
- Overvoltage Protection
- Overcurrent Protection of External MOSFET/IGBT
- Output Inhibit

Figure 7. OUTPUT Voltage (Sinking Current) vs Temperature

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## Oscillator

The IC sets up a constant frequency triangle wave at the Cosc lead whose frequency is determined by the external components $\mathrm{R}_{\mathrm{OSC}}$ and $\mathrm{C}_{\mathrm{OSC}}$ by the following equation:

$$
\text { Frequency }=\frac{0.83}{\text { ROSC } \times \operatorname{COSC}}
$$

The peak and valley of the triangle wave are proportional to $\mathrm{V}_{\mathrm{CC}}$ by the following:

$$
\begin{aligned}
& \text { VALLEY }=0.2 \times V_{C C} \\
& V_{\text {PEAK }}=0.8 \times V_{C C}
\end{aligned}
$$

This is required to make the voltage compensation function properly. In order to keep the frequency of the oscillator constant the current that charges CosC must also vary with supply. $\mathrm{R}_{\mathrm{OSC}}$ sets up the current which charges COSC. The voltage across $\mathrm{R}_{\mathrm{OSC}}$ is $50 \%$ of $\mathrm{V}_{\mathrm{CC}}$ and therefore:

$$
\mathrm{I} \mathrm{ROSC}=0.5 \times \frac{\mathrm{VCC}}{\mathrm{ROSC}}
$$

$\mathrm{I}_{\text {ROSC }}$ is multiplied by two (2) internally and transferred to the C OSC lead. Therefore:

$$
\mathrm{I} \operatorname{cosc}= \pm \frac{\mathrm{V}_{\mathrm{CC}}}{\mathrm{ROSC}_{\mathrm{OSC}}}
$$

The period of the oscillator is:

$$
\mathrm{T}=2 \mathrm{COSC} \times \frac{\mathrm{VPEAK}-\mathrm{VVALLEY}}{\mathrm{I} \operatorname{COSC}}
$$

The $\mathrm{R}_{\text {OSC }}$ and COSC components can be varied to create frequencies over the range of 15 Hz to 25 kHz . With the suggested values of $105 \mathrm{k} \Omega$ and 390 pF for $\mathrm{R}_{\mathrm{OSC}}$ and $\mathrm{C}_{\mathrm{OSC}}$ respectively, the nominal frequency will be approximately 20 kHz . $\mathrm{I}_{\mathrm{ROSC}}$, at $\mathrm{V}_{\mathrm{CC}}=14 \mathrm{~V}$, will be $66.7 \mu \mathrm{~A}$. $\mathrm{I}_{\mathrm{ROSC}}$ should not change over a more than $2: 1$ ratio and therefore C OSC should be changed to adjust the oscillator frequency.

## Voltage Duty Cycle Conversion

The IC translates an input voltage at the CTL lead into a duty cycle at the OUTPUT lead. The transfer function incorporates ON Semiconductor's patented Voltage Compensation method to keep the average voltage and current across the load constant regardless of fluctuations in the supply voltage. The duty cycle is varied based upon the input voltage and supply voltage by the following equation:

$$
\text { Duty Cycle }=100 \% \times \frac{2.8 \times \mathrm{V}_{\mathrm{CTL}}}{\mathrm{~V}_{\mathrm{CC}}}
$$

An internal DC voltage equal to:

$$
V_{D C}=\left(1.683 \times V_{C T L}\right)+V_{V A L L E Y}
$$

is compared to the oscillator voltage to produce the compensated duty cycle. The transfer is set up so that at $\mathrm{V}_{\mathrm{CC}}$ $=14 \mathrm{~V}$ the duty will equal $\mathrm{V}_{\mathrm{CTL}}$ divided by $\mathrm{V}_{\text {REG }}$. For
example at $\mathrm{V}_{\mathrm{CC}}=14 \mathrm{~V}, \mathrm{~V}_{\mathrm{REG}}=5.0 \mathrm{~V}$ and $\mathrm{V}_{\mathrm{CTL}}=2.5 \mathrm{~V}$, the duty cycle would be $50 \%$ at the output. This would place a 7.0 V average voltage across the load. If $\mathrm{V}_{\mathrm{CC}}$ then drops to 10 V , the IC would change the duty cycle to $70 \%$ and hence keep the average load voltage at 7.0 V .

Figure 8. Voltage Compensation

### 5.0 V Linear Regulator

There is a $5.0 \mathrm{~V}, 5.0 \mathrm{~mA}$ linear regulator available at the $\mathrm{V}_{\mathrm{REG}}$ lead for external use. This voltage acts as a reference for many internal and external functions. It has a drop out of approximately 1.5 V at room temperature and does not require an external capacitor for stability.

## Current Sense and Timer

The IC differentially monitors the load current on a cycle by cycle basis at the $I_{\text {SENSE }+}$ and $\mathrm{I}_{\text {SENSE- }}$ leads. The differential voltage across these two leads is amplified internally and compared to the voltage at the $\mathrm{I}_{\mathrm{ADJ}}$ lead. The gain, $\mathrm{A}_{\mathrm{V}}$, is set internally and externally by the following equation:

$$
A V=\frac{V_{I(A D J)}}{\text { ISENSE }+-I_{\text {SENSE }-}}=\frac{37000}{1000+\mathrm{R}_{\mathrm{CS}}}
$$

The current limit ( $\mathrm{I}_{\mathrm{LIM}}$ ) is set by the external current sense resistor ( $\mathrm{R}_{\text {SENSE }}$ ) placed across the $\mathrm{I}_{\text {SENSE }}$ and $\mathrm{I}_{\text {SENSE- }}$ terminals and the voltage at the $\mathrm{I}_{\mathrm{ADJ}}$ lead.

$$
\operatorname{ILIM}=\frac{1000+\mathrm{R}_{\mathrm{CS}}}{37000} \times \frac{\mathrm{V}_{\mathrm{I}}(\mathrm{ADJ})}{\mathrm{RSENSE}^{2}}
$$

The $\mathrm{R}_{\mathrm{CS}}$ resistors and $\mathrm{C}_{\mathrm{CS}}$ components form a differential low pass filter which filters out high frequency noise generated by the switching of the external MOSFET and the associated lead noise. $\mathrm{R}_{\mathrm{CS}}$ also forms an error term in the gain of the $\mathrm{I}_{\text {LIM }}$ equation because the $\mathrm{I}_{\text {SENSE }}$ and $\mathrm{I}_{\text {SENSE- }}$ leads are low impedance inputs thereby creating a good current sensing amplifier. Both leads source $50 \mu \mathrm{~A}$ while the chip is in run mode. $\mathrm{R}_{\mathrm{CS}}$ should be much less than $1000 \Omega$ to minimize error in the $\mathrm{I}_{\mathrm{LIM}}$ equation. $\mathrm{I}_{\mathrm{ADJ}}$ should be biased between 1.0 V and 4.0 V .

When the current through the external MOSFET exceeds $\mathrm{I}_{\text {LIM, }}$, an internal latch is set and the output pulls the gate of the MOSFET low for the remainder of the oscillator cycle (fault mode). At the start of the next cycle, the latch is reset and the IC reverts back to run mode until another fault occurs. If a number of faults occur in a given period of time, the IC "times out" and disables the MOSFET for a long period of time to let it cool off. This is accomplished by charging the C CLT capacitor each time an over current condition occurs. If a cycle goes by with no overcurrent fault occurring, an even smaller amount of charge will be removed from $\mathrm{C}_{\mathrm{FLT}}$. If enough faults occur together, eventually $\mathrm{C}_{\mathrm{FLT}}$ will charge up to 2.4 V and the fault latch will be set. The fault latch will not be reset until the $\mathrm{C}_{\mathrm{FLT}}$ discharges to 0.6 V . This action will continue indefinitely if the fault persists.

The off time and on time are set by the following:

$$
\begin{aligned}
& \text { Off Time }=C_{F L T} \times \frac{2.4 \mathrm{~V}-0.6 \mathrm{~V}}{4.5 \mu \mathrm{~A}} \\
& \text { On Time }=\mathrm{C}_{\mathrm{FLT}} \times \frac{2.4 \mathrm{~V}-0.6 \mathrm{~V}}{\mathrm{I}_{\mathrm{AVG}}}
\end{aligned}
$$

where:

$$
\begin{gathered}
\mathrm{I} \mathrm{AVG}=(295.5 \mu \mathrm{~A} \times \mathrm{DC})-[4.5 \mu \mathrm{~A} \times(1-\mathrm{DC})] \\
\mathrm{I} \mathrm{AVG}=(300 \mu \mathrm{~A} \times \mathrm{DC})-4.5 \mu \mathrm{~A} \\
\mathrm{DC}=\mathrm{PWM} \text { Duty Cycle }
\end{gathered}
$$

## Sleep State

This device will enter into a low current mode ( $<275 \mu \mathrm{~A}$ ) when CTL lead is brought to less than 0.5 V . All functions are disabled in this mode, except for the regulator.

## Inhibit

When the inhibit voltage is greater than 2.5 V the internal latch is set and the external MOSFET will be turned off for the remainder of the oscillator cycle. The latch is then reset at the start of the next cycle.

## Overvoltage Shutdown

The IC will disable the output during an overvoltage event. This is a real time fault event and does not set the
internal latch and therefore is independent of the oscillator timing (i.e. asynchronous). There is no undervoltage lockout. The device will shutdown gracefully once it runs out of headroom. This happens at the point when VREG falls out of regulation.

## Reverse Battery

The CS7054 will not survive a reverse battery condition. Therefore, a series diode is required between the battery and the $\mathrm{V}_{\mathrm{CC}}$ lead.

## Load Dump

$\mathrm{V}_{\mathrm{CC}}$ is internally clamped to 30 V . It is recommended that a $51 \Omega$ resistor, ( $\mathrm{R}_{\mathrm{S}}$ ) is placed in series with $\mathrm{V}_{\mathrm{CC}}$ to limit the current flow into the IC in the event of a 40 V peak transient condition.

## Using the CS7054 as a Frequency Converter

Figure 9 shows the CS7054 configured for use as a frequency converter. In the setup shown, a 150 Hz square wave from a microprocessor is converted to a 10 kHz square wave. The duty cycle of each waveform is identical. The amplitude of the input waveform is 5.0 V , but does not need to be. The input amplitude requirement just needs to be high enough to switch the external bipolar transistor. The 10 kHz oscillator frequency is setup per the oscillator section of this data sheet.

The external resistor divider composed of the 3.6 k and 6.2 k resistors supplies 5.0 V to the CTL pin when the input duty cycle is at $100 \%$. This also makes the output waveform 100\%.

The RC filter ( $1.0 \mathrm{M} \Omega$ and $0.1 \mu \mathrm{~F}$ ) sets up a pole at 1.6 Hz :

$$
\begin{aligned}
f & =\frac{1}{2 \pi R C}=\frac{1}{2 \pi\left[1 \mathrm{M} \Omega+\left(\frac{(6.2 \mathrm{k})(3.6 \mathrm{k})}{6.2 \mathrm{k}+3.6 \mathrm{k}}\right)\right](0.1 \mu \mathrm{~F})} \\
& =1.6 \mathrm{~Hz}
\end{aligned}
$$

In this case, the pole is 2 orders of magnitude below the input waveform. Care must be taken to provide the appropriate DC level on the control pin in addition to providing the required response time.
*Note the current limit feature of the CS7054 has been defeated by grounding the ISENSE+ and the $\mathrm{I}_{\text {SENSE- }}$ pins and connecting the $\mathrm{I}_{\mathrm{ADJ}}$ lead to $\mathrm{V}_{\text {REG }}$.

## CS4124

## High Side PWM FET Controller

The CS4124 is a monolithic integrated circuit designed primarily to control the rotor speed of permanent magnet, direct current (DC) brush motors. It drives the gate of an N channel power MOSFET or IGBT with a user-adjustable, fixed frequency, variable duty cycle, pulse width modulated (PWM) signal. The CS4124 can also be used to control other loads such as incandescent bulbs and solenoids. Inductive current from the motor or solenoid is recirculated through an external diode.

The CS4124 accepts a DC level input signal of 0 to 5.0 V to control the pulse width of the output signal. This signal can be generated by a potentiometer referenced to the on-chip 5.0 V linear regulator, or a filtered $0 \%$ to $100 \%$ PWM signal also referenced to the 5.0 V regulator.

The IC is placed in a sleep state by pulling the CTL lead below 0.5 V . In this mode everything on the chip is shutdown except for the on-chip regulator and the overall current draw is less than $275 \mu \mathrm{~A}$. There are a number of on-chip diagnostics that look for potential failure modes and can disable the external power MOSFET.

## Features

- 150 mA Peak PWM Gate Drive Output
- Patented Voltage Compensation Circuit
- $100 \%$ Duty Cycle Capability
- $5.0 \mathrm{~V}, \pm 3.0 \%$ Linear Regulator
- Low Current Sleep Mode
- Overvoltage Protection
- Boost Mode Power Supply
- Output Inhibit

## APPLICATIONS INFORMATION

## THEORY OF OPERATION

## Oscillator

The IC sets up a constant frequency triangle wave at the Cosc lead whose frequency is related to the external components $\mathrm{R}_{\mathrm{OSC}}$ and $\mathrm{C}_{\mathrm{OSC}}$, by the following equation:

$$
\text { Frequency }=\frac{0.83}{\text { ROSC } \times \text { COSC }}
$$

The peak and valley of the triangle wave are proportional to $\mathrm{V}_{\mathrm{CC}}$ by the following:

$$
\begin{aligned}
& \text { VVALLEY }=0.1 \times V_{C C} \\
& V_{\text {PEAK }}=0.7 \times V_{C C}
\end{aligned}
$$

This is required to make the voltage compensation function properly. In order to keep the frequency of the oscillator constant the current that charges Cosc must also vary with supply. $\mathrm{R}_{\mathrm{OSC}}$ sets up the current which charges COSC. The voltage across $\mathrm{R}_{\mathrm{OSC}}$ is $50 \%$ of $\mathrm{V}_{\mathrm{CC}}$ and therefore:

$$
\mathrm{I} \mathrm{ROSC}=0.5 \times \frac{\mathrm{VCC}}{\mathrm{ROSC}}
$$

$\mathrm{I}_{\text {ROSC }}$ is multiplied by (2) internally and transferred to the Cosc lead. Therefore:

$$
\mathrm{I} \operatorname{cosc}= \pm \frac{\mathrm{VCC}_{\mathrm{CC}}}{\mathrm{ROSC}_{\mathrm{OS}}}
$$

The period of the oscillator is:

$$
\mathrm{T}=2 \mathrm{COSC} \times \frac{\mathrm{VPEAK}-\mathrm{V}_{\mathrm{VALLEY}}}{\mathrm{I} \operatorname{COSC}}
$$

The $\mathrm{R}_{\text {OSC }}$ and COSC components can be varied to create frequencies over the range of 15 Hz to 25 kHz . With the suggested values of $93.1 \mathrm{k} \Omega$ and 470 pF for $\mathrm{R}_{\mathrm{OSC}}$ and $\mathrm{C}_{\mathrm{OSC}}$, the nominal frequency will be approximately 20 kHz . $\mathrm{I}_{\text {ROSC }}$, at $\mathrm{V}_{\mathrm{CC}}=14 \mathrm{~V}$, will be $66.7 \mu \mathrm{~A}$. $\mathrm{I}_{\text {ROSC }}$ should not change over a more than $2: 1$ ratio and therefore $\mathrm{C}_{\text {OSC }}$ should be changed to adjust the oscillator frequency.

## Voltage Duty Cycle Conversion

The IC translates an input voltage at the CTL lead into a duty cycle at the OUTPUT lead. The transfer function incorporates ON Semiconductor's patented Voltage Compensation method to keep the average voltage and current across the load constant regardless of fluctuations in the supply voltage. The duty cycle is varied based upon the input voltage and supply voltage by the following equation:

$$
\text { Duty Cycle }=100 \% \times \frac{2.8 \times \mathrm{V}_{\mathrm{CTL}}}{\mathrm{~V}_{\mathrm{CC}}}
$$

An internal DC voltage equal to:

$$
V_{D C}=\left(1.683 \times V_{C T L}\right)+V_{V A L L E Y}
$$

is compared to the oscillator voltage to produce the compensated duty cycle. The transfer is set up so that when $\mathrm{V}_{\mathrm{CC}}=14 \mathrm{~V}$ the duty cycle will equal $\mathrm{V}_{\mathrm{CTL}}$ divided by $\mathrm{V}_{\mathrm{REG}}$. For example at $\mathrm{V}_{\mathrm{CC}}=14 \mathrm{~V}, \mathrm{~V}_{\text {REG }}=5.0 \mathrm{~V}$ and $\mathrm{V}_{\mathrm{CTL}}=2.5 \mathrm{~V}$,
the duty cycle would be $50 \%$ at the output. This would place a 7.0 V average voltage across the load. If $\mathrm{V}_{\mathrm{CC}}$ then drops to 10 V , the IC would change the duty cycle to $70 \%$ and hence keep the average load voltage at 7.0 V .

Figure 7. Voltage Compensation

### 5.0 V Linear Regulator

There is a $5.0 \mathrm{~V}, 5.0 \mathrm{~mA}$ linear regulator available at the $\mathrm{V}_{\mathrm{REG}}$ lead for external use. This voltage acts as a reference for many internal and external functions. It has a drop out of approximately 1.5 V at room temperature.

## Current Sense and Timer

The IC differentially monitors the load current on a cycle by cycle basis at the ISENSE+ and ISENSE- leads. The differential voltage across these two leads is amplified internally and compared to the voltage at the $\mathrm{I}_{\text {ADJ }}$ lead. The gain, $A_{V}$ is set internally and externally by the following equation:

$$
A V=\frac{\left.V_{I(A D J}\right)}{\text { ISENSE }+- \text { ISENSE }-}=\frac{37000}{1000+R_{C S}}
$$

The current limit ( $\mathrm{I}_{\mathrm{LIM}}$ ) is set by the external current sense resistor ( $\mathrm{R}_{\text {SENSE }}$ ) placed across the $\mathrm{I}_{\text {SENSE }}$ and $\mathrm{I}_{\text {SENSE- }}$ terminals and the voltage at the $\mathrm{I}_{\mathrm{ADJ}}$ lead.

$$
\mathrm{I} \mathrm{LIM}=\frac{1000+\mathrm{R}_{\mathrm{CS}}}{37000} \times \frac{\mathrm{V}_{\mathrm{I}}(\mathrm{ADJ})}{\mathrm{R}_{\text {SENSE }}}
$$

The $\mathrm{R}_{\mathrm{CS}}$ resistors and $\mathrm{C}_{\mathrm{CS}}$ components form a differential low pass filter which filters out high frequency noise generated by the switching of the external MOSFET and the associated lead noise. $\mathrm{R}_{\mathrm{CS}}$ also forms an error term in the gain of the $\mathrm{I}_{\text {LIM }}$ equation because the $\mathrm{I}_{\text {SENSE+ }}$ and $\mathrm{I}_{\text {SENSE- }}$ leads are low impedance inputs thereby creating a good current sensing amplifier. Both leads source $50 \mu \mathrm{~A}$ while the chip is in run mode. $\mathrm{I}_{\mathrm{ADJ}}$ should be biased between 1.0 V and 4.0 V. When the current through the external MOSFET exceeds $\mathrm{I}_{\mathrm{LIM}}$, an internal latch is set and the output pulls the gate of the MOSFET low for the remainder of the oscillator
cycle (fault mode). At the start of the next cycle, the latch is reset and the IC reverts back to run mode until another fault occurs. If a number of faults occur in a given period of time, the IC "times out" and disables the MOSFET for a long period of time to let it cool off. This is accomplished by charging the $\mathrm{C}_{\mathrm{FLT}}$ capacitor each time an over current condition occurs. If a cycle goes by with no overcurrent fault occurring, an even smaller amount of charge will be removed from $\mathrm{C}_{\text {FLT }}$. If enough faults occur together, eventually $\mathrm{C}_{\mathrm{FLT}}$ will charge up to 2.4 V and the fault latch will be set. The fault latch will not be reset until C $\mathrm{C}_{\text {FT }}$ discharges to 0.6 V . This action will continue indefinitely if the fault persists.

The off time and on time are set by the following:

$$
\begin{aligned}
& \text { Off Time }=\text { CFLT } \times \frac{2.4 \mathrm{~V}-0.6 \mathrm{~V}}{4.5 \mathrm{~A}} \\
& \text { On Time }=\text { CFLT } \times \frac{2.4 \mathrm{~V}-0.6 \mathrm{~V}}{\mathrm{I}_{\mathrm{AVG}}}
\end{aligned}
$$

where:

$$
\begin{gathered}
\mathrm{I} \mathrm{AVG}=(295.5 \mu \mathrm{~A} \times \mathrm{DC})-[4.5 \mu \mathrm{~A} \times(1-\mathrm{DC})] \\
\mathrm{I} \mathrm{AVG}=(300 \mu \mathrm{~A} \times \mathrm{DC})-4.5 \mu \mathrm{~A} \\
\mathrm{DC}=\text { PWM Duty Cycle }
\end{gathered}
$$

## Boost Switch Mode Power Supply

The CS4124 has an integrated boost mode power supply which charges the gate of the external high-side MOSFET to greater than 5.0 V above $\mathrm{V}_{\mathrm{CC}}$. Three leads are used for voltage boost. They are Boost, PMP and SNI. The PMP lead is the collector of a darlington tied NPN power transistor. This device charges the inductor during its on time. The boost lead is the input to chip from the external reservoir capacitor. The SNI lead is the emitter of the power NPN and is connected externally to the $\mathrm{R}_{\mathrm{SNI}}$ resistor.

The power supply is controlled by the oscillator. At the start of a cycle an R-S flip flop is set the internal power NPN transistor is turned on and energy begins to build up in the
inductor. The $\mathrm{R}_{\mathrm{SNI}}$ resistor sets the peak current of the inductor by tripping a comparator when the voltage across the resistor is 450 mV . The flip flop is reset and the inductor delivers its stored energy to the load. The ripple voltage ( $\mathrm{V}_{\text {RIPPLE }}$ ) at the Boost lead is controlled by CBoost. A snubber circuit, made up of a series resistor and capacitor, is required to dampen the ringing of the inductor. A value of $4.0 \Omega$ is recommended for $\mathrm{R}_{\mathrm{SNI}}$.

A zener diode is needed between the boost output voltage and the battery. This will clamp the boost lead to a specified value above the battery to prevent damage to the IC. A 9.0 volt zener diode is recommended.

## Sleep State

This device will enter into a low current mode ( $<275 \mu \mathrm{~A}$ ) when CTL lead is brought to less than 0.5 V . All functions are disabled in this mode, except for the regulator.

## Inhibit

When the inhibit is greater than 2.5 V the internal latch is set and the external MOSFET will be turned off for the remainder of the oscillator cycle. The latch is then reset at the start of the next cycle.

## Overvoltage Shutdown

The IC will disable the output during an overvoltage event. This is a real time fault event and does not set the internal latch and therefore is independent of the oscillator timing (i.e. asynchronous). There is 325 mV (typical) of hysteresis on the overvoltage function. There is no undervoltage lockout. The device will shutdown gracefully once it runs out of headroom.

## Reverse Battery

The CS4124 will not survive a reverse battery condition. A series diode is required between the battery and the $\mathrm{V}_{\mathrm{CC}}$ lead for reverse battery.

## Load Dump

A $10 \Omega$ resistor, (RS) is placed in series with $\mathrm{V}_{\mathrm{CC}}$ to limit the current into the IC during 40 V peak transient conditions.

## High Speed Dual MOSFET Drivers

The MC34152/MC33152 are dual noninverting high speed drivers specifically designed for applications that require low current digital signals to drive large capacitive loads with high slew rates. These devices feature low input current making them CMOS/LSTTL logic compatible, input hysteresis for fast output switching that is independent of input transition time, and two high current totem pole outputs ideally suited for driving power MOSFETs. Also included is an undervoltage lockout with hysteresis to prevent system erratic operation at low supply voltages.

Typical applications include switching power supplies, dc-to-dc converters, capacitor charge pump voltage doublers/inverters, and motor controllers.

This device is available in dual-in-line and surface mount packages.

- Two Independent Channels with 1.5 A Totem Pole Outputs
- Output Rise and Fall Times of 15 ns with 1000 pF Load
- CMOS/LSTTL Compatible Inputs with Hysteresis
- Undervoltage Lockout with Hysteresis
- Low Standby Current
- Efficient High Frequency Operation
- Enhanced System Performance with Common Switching Regulator Control ICs

## APPLICATIONS INFORMATION

## Description

The MC34152 is a dual noninverting high speed driver specifically designed to interface low current digital circuitry with power MOSFETs. This device is constructed with Schottky clamped Bipolar Analog technology which offers a high degree of performance and ruggedness in hostile industrial environments.

## Input Stage

The Logic Inputs have 170 mV of hysteresis with the input threshold centered at 1.67 V . The input thresholds are insensitive to $\mathrm{V}_{\mathrm{CC}}$ making this device directly compatible with CMOS and LSTTL logic families over its entire operating voltage range. Input hysteresis provides fast output switching that is independent of the input signal transition time, preventing output oscillations as the input thresholds are crossed. The inputs are designed to accept a signal amplitude ranging from ground to $\mathrm{V}_{\mathrm{CC}}$. This allows the output of one channel to directly drive the input of a second channel for master-slave operation. Each input has a $30 \mathrm{k} \Omega$ pull-down resistor so that an unconnected open input will cause the associated Drive Output to be in a known low state.

## Output Stage

Each totem pole Drive Output is capable of sourcing and sinking up to 1.5 A with a typical 'on' resistance of $2.4 \Omega$ at 1.0 A . The low 'on' resistance allows high output currents to be attained at a lower $\mathrm{V}_{\mathrm{CC}}$ than with comparative CMOS drivers. Each output has a $100 \mathrm{k} \Omega$ pull-down resistor to keep the MOSFET gate low when $\mathrm{V}_{\mathrm{CC}}$ is less than 1.4 V . No over current or thermal protection has been designed into the device, so output shorting to $\mathrm{V}_{\mathrm{CC}}$ or ground must be avoided.
Parasitic inductance in series with the load will cause the driver outputs to ring above $\mathrm{V}_{\mathrm{CC}}$ during the turn-on transition, and below ground during the turn-off transition. With CMOS drivers, this mode of operation can cause a destructive output latch-up condition. The MC34152 is immune to output latch-up. The Drive Outputs contain an internal diode to $\mathrm{V}_{\mathrm{CC}}$ for clamping positive voltage transients. When operating with $\mathrm{V}_{\mathrm{CC}}$ at 18 V , proper power supply bypassing must be observed to prevent the output ringing from exceeding the maximum 20 V device rating. Negative output transients are clamped by the internal NPN pull-up transistor. Since full supply voltage is applied
across the NPN pull-up during the negative output transient, power dissipation at high frequencies can become excessive. Figures 20, 21, and 22 show a method of using external Schottky diode clamps to reduce driver power dissipation.

## Undervoltage Lockout

An undervoltage lockout with hysteresis prevents erratic system operation at low supply voltages. The UVLO forces the Drive Outputs into a low state as $\mathrm{V}_{\mathrm{CC}}$ rises from 1.4 V to the 5.8 V upper threshold. The lower UVLO threshold is 5.3 V , yielding about 500 mV of hysteresis.

## Power Dissipation

Circuit performance and long term reliability are enhanced with reduced die temperature. Die temperature increase is directly related to the power that the integrated circuit must dissipate and the total thermal resistance from the junction to ambient. The formula for calculating the junction temperature with the package in free air is:

$$
T_{J}=T_{A}+P_{D}\left(R_{\theta J A}\right)
$$

where: $\quad T_{J}=$ Junction Temperature
$\mathrm{T}_{\mathrm{A}}=$ Ambient Temperature
$P_{D}=$ Power Dissipation
$R_{\theta J A}=$ Thermal Resistance Junction to Ambient
There are three basic components that make up total power to be dissipated when driving a capacitive load with respect to ground. They are:

$$
P_{D}=P_{Q}+P_{C+P} T
$$

where: $\quad P_{Q}=$ Quiescent Power Dissipation
$P_{C}=$ Capacitive Load Power Dissipation
$\mathrm{P}_{\mathrm{T}}=$ Transition Power Dissipation
The quiescent power supply current depends on the supply voltage and duty cycle as shown in Figure 17. The device's quiescent power dissipation is:

$$
\mathrm{P}_{\mathrm{Q}}=\mathrm{V}_{\mathrm{CC}}\left(\mathrm{I}_{\mathrm{CCL}}[1-\mathrm{D}]+\mathrm{I}_{\mathrm{CCH}}[\mathrm{D}]\right)
$$

$$
\text { where: } \quad \begin{aligned}
& \mathrm{I}_{\mathrm{CCL}}=\text { Supply Current with Low State Drive } \\
& \text { Outputs } \\
& \mathrm{I}_{\mathrm{CCH}}=\text { Supply Current with High State Drive } \\
& \text { Outputs } \\
& \mathrm{D}=\text { Output Duty Cycle }
\end{aligned}
$$

The capacitive load power dissipation is directly related to the load capacitance value, frequency, and Drive Output voltage swing. The capacitive load power dissipation per driver is:

$$
\text { where: } \begin{aligned}
\mathrm{P}_{\mathrm{C}} & =\mathrm{V}_{\mathrm{CC}}\left(\mathrm{~V}_{\mathrm{OH}}-\mathrm{V}_{\mathrm{OL}}\right) \mathrm{C}_{\mathrm{L}} \mathrm{f} \\
\mathrm{~V}_{\mathrm{OH}} & =\text { High State Drive Output Voltage } \\
\mathrm{V}_{\mathrm{OL}} & =\text { Low State Drive Output Voltage } \\
\mathrm{C}_{\mathrm{L}} & =\text { Load Capacitance } \\
\mathrm{f} & =\text { Frequency }
\end{aligned}
$$

When driving a MOSFET, the calculation of capacitive load power $\mathrm{P}_{\mathrm{C}}$ is somewhat complicated by the changing
gate to source capacitance $\mathrm{C}_{\mathrm{GS}}$ as the device switches. To aid in this calculation, power MOSFET manufacturers provide gate charge information on their data sheets. Figure 18 shows a curve of gate voltage versus gate charge for the ON Semiconductor MTM15N50. Note that there are three distinct slopes to the curve representing different input capacitance values. To completely switch the MOSFET 'on,' the gate must be brought to 10 V with respect to the source. The graph shows that a gate charge $\mathrm{Q}_{\mathrm{g}}$ of 110 nC is required when operating the MOSFET with a drain to source voltage $\mathrm{V}_{\mathrm{DS}}$ of 400 V .

Figure 18. Gate-to-Source Voltage versus Gate charge
The capacitive load power dissipation is directly related to the required gate charge, and operating frequency. The capacitive load power dissipation per driver is:

$$
P_{C(M O S F E T)}=V_{C C} Q_{g} f
$$

The flat region from 10 nC to 55 nC is caused by the drain-to-gate Miller capacitance, occurring while the MOSFET is in the linear region dissipating substantial amounts of power. The high output current capability of the MC34152 is able to quickly deliver the required gate charge for fast power efficient MOSFET switching. By operating the MC34152 at a higher $\mathrm{V}_{\mathrm{CC}}$, additional charge can be provided to bring the gate above 10 V . This will reduce the 'on' resistance of the MOSFET at the expense of higher driver dissipation at a given operating frequency.
The transition power dissipation is due to extremely short simultaneous conduction of internal circuit nodes when the Drive Outputs change state. The transition power dissipation per driver is approximately:

$$
\begin{aligned}
& \mathrm{P}_{\mathrm{T}} \approx \mathrm{~V}_{\mathrm{CC}}\left(1.08 \mathrm{~V}_{\mathrm{CC}} \mathrm{C}_{\mathrm{L}} \mathrm{f}-8 \times 10^{-4}\right) \\
& \mathrm{P}_{\mathrm{T}} \text { must be greater than zero. }
\end{aligned}
$$

Switching time characterization of the MC34152 is performed with fixed capacitive loads. Figure 14 shows that for small capacitance loads, the switching speed is limited by transistor turn-on/off time and the slew rate of the internal nodes. For large capacitance loads, the switching speed is limited by the maximum output current capability of the integrated circuit.

## LAYOUT CONSIDERATIONS

High frequency printed circuit layout techniques are imperative to prevent excessive output ringing and overshoot. Do not attempt to construct the driver circuit on wire-wrap or plug-in prototype boards. When driving large capacitive loads, the printed circuit board must contain a low inductance ground plane to minimize the voltage spikes induced by the high ground ripple currents. All high current loops should be kept as short as possible using heavy copper runs to provide a low impedance high frequency path. For optimum drive
performance, it is recommended that the initial circuit design contains dual power supply bypass capacitors connected with short leads as close to the $\mathrm{V}_{\mathrm{CC}}$ pin and ground as the layout will permit. Suggested capacitors are a low inductance $0.1 \mu \mathrm{~F}$ ceramic in parallel with a $4.7 \mu \mathrm{~F}$ tantalum. Additional bypass capacitors may be required depending upon Drive Output loading and circuit layout.

Proper printed circuit board layout is extremely critical and cannot be over emphasized.

Series gate resistor $\mathrm{R}_{\mathrm{g}}$ may be needed to damp high frequency parasitic oscillations caused by the MOSFET input capacitance and any series wiring inductance in the gate-source circuit. $R_{g}$ will decrease the MOSFET switching speed. Schottky diode $\mathrm{D}_{1}$ can reduce the driver's power dissipation due to excessive ringing, by preventing the output pin from being driven below ground.

Figure 20. MOSFET Parasitic Oscillations

Figure 22. Isolated MOSFET Drive

In noise sensitive applications, both conducted and radiated EMI can be reduced significantly by controlling the MOSFET's turn-on and turn-off times.

Figure 23. Controlled MOSFET Drive

The totem-pole outputs can furnish negative base current for enhanced transistor turn-off, with the addition of capacitor $\mathrm{C}_{1}$.

## APPLICATIONS INFORMATION

## Description

The MC34151 is a dual inverting high speed driver specifically designed to interface low current digital circuitry with power MOSFETs. This device is constructed with Schottky clamped Bipolar Analog technology which offers a high degree of performance and ruggedness in hostile industrial environments.

## Input Stage

The Logic Inputs have 170 mV of hysteresis with the input threshold centered at 1.67 V . The input thresholds are insensitive to $\mathrm{V}_{\mathrm{CC}}$ making this device directly compatible with CMOS and LSTTL logic families over its entire operating voltage range. Input hysteresis provides fast output switching that is independent of the input signal transition time, preventing output oscillations as the input thresholds are crossed. The inputs are designed to accept a signal amplitude ranging from ground to $\mathrm{V}_{\mathrm{CC}}$. This allows the output of one channel to directly drive the input of a second channel for master-slave operation. Each input has a $30 \mathrm{k} \Omega$ pull-down resistor so that an unconnected open input will cause the associated Drive Output to be in a known high state.

## Output Stage

Each totem pole Drive Output is capable of sourcing and sinking up to 1.5 A with a typical 'on' resistance of $2.4 \Omega$ at 1.0 A. The low 'on' resistance allows high output currents to be attained at a lower $\mathrm{V}_{\mathrm{CC}}$ than with comparative CMOS drivers. Each output has a $100 \mathrm{k} \Omega$ pull-down resistor to keep the MOSFET gate low when $\mathrm{V}_{\mathrm{CC}}$ is less than 1.4 V . No over current or thermal protection has been designed into the device, so output shorting to $\mathrm{V}_{\mathrm{CC}}$ or ground must be avoided.

Parasitic inductance in series with the load will cause the driver outputs to ring above $\mathrm{V}_{\mathrm{CC}}$ during the turn-on transition, and below ground during the turn-off transition. With CMOS drivers, this mode of operation can cause a destructive output latch-up condition. The MC34151 is immune to output latch-up. The Drive Outputs contain an internal diode to $\mathrm{V}_{\mathrm{CC}}$ for clamping positive voltage transients. When operating with $\mathrm{V}_{\mathrm{CC}}$ at 18 V , proper power supply bypassing must be observed to prevent the output ringing from exceeding the maximum 20 V device rating. Negative output transients are clamped by the internal NPN pull-up transistor. Since full supply voltage is applied across
the NPN pull-up during the negative output transient, power dissipation at high frequencies can become excessive. Figures 20, 21, and 22 show a method of using external Schottky diode clamps to reduce driver power dissipation.

## Undervoltage Lockout

An undervoltage lockout with hysteresis prevents erratic system operation at low supply voltages. The UVLO forces the Drive Outputs into a low state as $\mathrm{V}_{\mathrm{CC}}$ rises from 1.4 V to the 5.8 V upper threshold. The lower UVLO threshold is 5.3 V , yielding about 500 mV of hysteresis.

## Power Dissipation

Circuit performance and long term reliability are enhanced with reduced die temperature. Die temperature increase is directly related to the power that the integrated circuit must dissipate and the total thermal resistance from the junction to ambient. The formula for calculating the junction temperature with the package in free air is:
where:

$$
\begin{aligned}
\mathrm{T}_{\mathrm{J}} & =\mathrm{T}_{\mathrm{A}}+\mathrm{P}_{\mathrm{D}}\left(\mathrm{R}_{\theta \mathrm{JA}}\right) \\
\mathrm{T}_{\mathrm{J}} & =\text { Junction Temperature } \\
\mathrm{T}_{\mathrm{A}} & =\text { Ambient Temperature } \\
\mathrm{P}_{\mathrm{D}} & =\text { Power Dissipation } \\
\mathrm{R}_{\theta \mathrm{JA}} & =\text { Thermal Resistance Junction to Ambient }
\end{aligned}
$$

There are three basic components that make up total power to be dissipated when driving a capacitive load with respect to ground. They are:

$$
\text { where: } \quad \begin{aligned}
& \mathrm{P}_{\mathrm{D}}=\mathrm{P}_{\mathrm{Q}}+\mathrm{P}_{\mathrm{C}}+\mathrm{P}_{\mathrm{T}} \\
& \mathrm{P}_{\mathrm{Q}}=\mathrm{Quiescent} \text { Power Dissipation } \\
& \mathrm{P}_{\mathrm{C}}=\text { Capacitive Load Power Dissipation } \\
& \mathrm{P}_{\mathrm{T}}=\text { Transition Power Dissipation }
\end{aligned}
$$

The quiescent power supply current depends on the supply voltage and duty cycle as shown in Figure 17. The device's quiescent power dissipation is:

$$
\mathrm{P}_{\mathrm{Q}}=\mathrm{V}_{\mathrm{CC}}\left(\mathrm{I}_{\mathrm{CCL}}(1-\mathrm{D})+\mathrm{I}_{\mathrm{CCH}}(\mathrm{D})\right)
$$

where: $\quad \mathrm{I}_{\mathrm{CCL}}=$ Supply Current with Low State Drive Outputs
$\mathrm{I}_{\mathrm{CCH}}=$ Supply Current with High State Drive Outputs
D = Output Duty Cycle
The capacitive load power dissipation is directly related to the load capacitance value, frequency, and Drive Output voltage swing. The capacitive load power dissipation per driver is:

$$
\text { where: } \quad \begin{aligned}
\mathrm{P}_{\mathrm{C}} & =\mathrm{V}_{\mathrm{CC}}\left(\mathrm{~V}_{\mathrm{OH}}-\mathrm{V}_{\mathrm{OL}}\right) \mathrm{C}_{\mathrm{L}} \mathrm{f} \\
\mathrm{~V}_{\mathrm{OH}} & =\text { High State Drive Output Voltage } \\
\mathrm{V}_{\mathrm{OL}} & =\text { Low State Drive Output Voltage } \\
\mathrm{C}_{\mathrm{L}} & =\text { Load Capacitance } \\
\mathrm{f} & =\text { frequency }
\end{aligned}
$$

When driving a MOSFET, the calculation of capacitive load power $\mathrm{P}_{\mathrm{C}}$ is somewhat complicated by the changing gate to source capacitance $\mathrm{C}_{\mathrm{GS}}$ as the device switches. To aid in this calculation, power MOSFET manufacturers provide
gate charge information on their data sheets. Figure 18 shows a curve of gate voltage versus gate charge for the ON Semiconductor MTM15N50. Note that there are three distinct slopes to the curve representing different input capacitance values. To completely switch the MOSFET 'on', the gate must be brought to 10 V with respect to the source. The graph shows that a gate charge $\mathrm{Q}_{\mathrm{g}}$ of 110 nC is required when operating the MOSFET with a drain to source voltage $\mathrm{V}_{\mathrm{DS}}$ of 400 V .

Figure 18. Gate-To-Source Voltage versus Gate Charge

The capacitive load power dissipation is directly related to the required gate charge, and operating frequency. The capacitive load power dissipation per driver is:

$$
P_{C}(M O S F E T)=V_{C} Q_{g} f
$$

The flat region from 10 nC to 55 nC is caused by the drain-to-gate Miller capacitance, occurring while the MOSFET is in the linear region dissipating substantial amounts of power. The high output current capability of the MC34151 is able to quickly deliver the required gate charge for fast power efficient MOSFET switching. By operating the MC34151 at a higher $\mathrm{V}_{\mathrm{CC}}$, additional charge can be provided to bring the gate above 10 V . This will reduce the 'on' resistance of the MOSFET at the expense of higher driver dissipation at a given operating frequency.

The transition power dissipation is due to extremely short simultaneous conduction of internal circuit nodes when the Drive Outputs change state. The transition power dissipation per driver is approximately:

$$
\begin{aligned}
& P_{\mathrm{T}}=V_{C C}\left(1.08 \mathrm{~V}_{\mathrm{CC}} C_{\mathrm{L}} f-8 \text { y } 10^{-4}\right) \\
& \mathrm{P}_{\mathrm{T}} \text { must be greater than zero. }
\end{aligned}
$$

Switching time characterization of the MC34151 is performed with fixed capacitive loads. Figure 14 shows that for small capacitance loads, the switching speed is limited by transistor turn-on/off time and the slew rate of the internal nodes. For large capacitance loads, the switching speed is limited by the maximum output current capability of the integrated circuit.

## LAYOUT CONSIDERATIONS

High frequency printed circuit layout techniques are imperative to prevent excessive output ringing and overshoot. Do not attempt to construct the driver circuit on wire-wrap or plug-in prototype boards. When driving large capacitive loads, the printed circuit board must contain a low inductance ground plane to minimize the voltage spikes induced by the high ground ripple currents. All high current loops should be kept as short as possible using heavy copper runs to provide a low impedance high frequency path. For

The MC34151 greatly enhances the drive capabilities of common switching regulators and CMOS/TTL logic devices.

Figure 19. Enhanced System Performance with Common Switching Regulators

Output Schottky diodes are recommended when driving inductive loads at high frequencies. The diodes reduce the driver's power dissipation by preventing the output pins from being driven above $\mathrm{V}_{\mathrm{CC}}$ and below ground.

Figure 21. Direct Transformer Drive
optimum drive performance, it is recommended that the initial circuit design contains dual power supply bypass capacitors connected with short leads as close to the $\mathrm{V}_{\mathrm{CC}}$ pin and ground as the layout will permit. Suggested capacitors are a low inductance $0.1 \mu \mathrm{~F}$ ceramic in parallel with a $4.7 \mu \mathrm{~F}$ tantalum. Additional bypass capacitors may be required depending upon Drive Output loading and circuit layout.

Proper printed circuit board layout is extremely critical and cannot be over emphasized.

#### Abstract

Series gate resistor $\mathrm{R}_{\mathrm{g}}$ may be needed to damp high frequency parasitic oscillations caused by the MOSFET input capacitance and any series wiring inductance in the gate-source circuit. $\mathrm{R}_{\mathrm{g}}$ will decrease the MOSFET switching speed. Schottky diode $D_{1}$ can reduce the driver's power dissipation due to excessive ringing, by preventing the output pin from being driven below ground.

## Single IGBT Gate Driver

The MC33153 is specifically designed as an IGBT driver for high power applications that include ac induction motor control, brushless dc motor control and uninterruptable power supplies. Although designed for driving discrete and module IGBTs, this device offers a cost effective solution for driving power MOSFETs and Bipolar Transistors. Device protection features include the choice of desaturation or overcurrent sensing and undervoltage detection. These devices are available in dual-in-line and surface mount packages and include the following features:

- High Current Output Stage: 1.0 A Source/2.0 A Sink
- Protection Circuits for Both Conventional and Sense IGBTs
- Programmable Fault Blanking Time
- Protection against Overcurrent and Short Circuit
- Undervoltage Lockout Optimized for IGBT's
- Negative Gate Drive Capability
- Cost Effectively Drives Power MOSFETs and Bipolar Transistors

This device contains 133 active transistors.

## OPERATING DESCRIPTION

## GATE DRIVE

## Controlling Switching Times

The most important design aspect of an IGBT gate drive is optimization of the switching characteristics. The switching characteristics are especially important in motor control applications in which PWM transistors are used in a bridge configuration. In these applications, the gate drive circuit components should be selected to optimize turn-on, turn-off and off-state impedance. A single resistor may be used to control both turn-on and turn-off as shown in Figure 30. However, the resistor value selected must be a compromise in turn-on abruptness and turn-off losses. Using a single resistor is normally suitable only for very low frequency PWM. An optimized gate drive output stage is shown in Figure 31. This circuit allows turn-on and turn-off to be optimized separately. The turn-on resistor, $\mathrm{R}_{\mathrm{on}}$, provides control over the IGBT turn-on speed. In motor control circuits, the resistor sets the turn-on di/dt that controls how fast the free-wheel diode is cleared. The interaction of the IGBT and free-wheeling diode determines
the turn-on dv/dt. Excessive turn-on dv/dt is a common problem in half-bridge circuits. The turn-off resistor, $\mathrm{R}_{\text {off }}$, controls the turn-off speed and ensures that the IGBT remains off under commutation stresses. Turn-off is critical to obtain low switching losses. While IGBTs exhibit a fixed minimum loss due to minority carrier recombination, a slow gate drive will dominate the turn-off losses. This is particularly true for fast IGBTs. It is also possible to turn-off an IGBT too fast. Excessive turn-off speed will result in large overshoot voltages. Normally, the turn-off resistor is a small fraction of the turn-on resistor.

The MC33153 contains a bipolar totem pole output stage that is capable of sourcing 1.0 amp and sinking 2.0 amps peak. This output also contains a pull down resistor to ensure that the IGBT is off whenever there is insufficient $\mathrm{V}_{\mathrm{CC}}$ to the MC33153.

In a PWM inverter, IGBTs are used in a half-bridge configuration. Thus, at least one device is always off. While
the IGBT is in the off-state, it will be subjected to changes in voltage caused by the other devices. This is particularly a problem when the opposite transistor turns on.

When the lower device is turned on, clearing the upper diode, the turn-on dv/dt of the lower device appears across the collector emitter of the upper device. To eliminate shoot-through currents, it is necessary to provide a low sink impedance to the device that is in the off-state. In most applications the turn-off resistor can be made small enough to hold off the device that is under commutation without causing excessively fast turn-off speeds.

Figure 30. Using a Single Gate Resistor

Figure 31. Using Separate Resistors for Turn-On and Turn-Off

A negative bias voltage can be used to drive the IGBT into the off-state. This is a practice carried over from bipolar Darlington drives and is generally not required for IGBTs. However, a negative bias will reduce the possibility of shoot-through. The MC33153 has separate pins for $\mathrm{V}_{\mathrm{EE}}$ and Kelvin Ground. This permits operation using a $+15 /-5.0 \mathrm{~V}$ supply.

## INTERFACING WITH OPTOISOLATORS

## Isolated Input

The MC33153 may be used with an optically isolated input. The optoisolator can be used to provide level shifting, and if desired, isolation from ac line voltages. An optoisolator with a very high dv/dt capability should be used, such as the Hewlett Packard HCPL4053. The IGBT gate turn-on resistor should be set large enough to ensure
that the opto's dv/dt capability is not exceeded. Like most optoisolators, the HCPL4053 has an active low open-collector output. Thus, when the LED is on, the output will be low. The MC33153 has an inverting input pin to interface directly with an optoisolator using a pull up resistor. The input may also be interfaced directly to 5.0 V CMOS logic or a microcontroller.

## Optoisolator Output Fault

The MC33153 has an active high fault output. The fault output may be easily interfaced to an optoisolator. While it is important that all faults are properly reported, it is equally important that no false signals are propagated. Again, a high dv/dt optoisolator should be used.

The LED drive provides a resistor programmable current of 10 to 20 mA when on, and provides a low impedance path when off. An active high output, resistor, and small signal diode provide an excellent LED driver. This circuit is shown in Figure 32.

Figure 32. Output Fault Optoisolator

## UNDERVOLTAGE LOCKOUT

It is desirable to protect an IGBT from insufficient gate voltage. IGBTs require 15 V on the gate to achieve the rated on-voltage. At gate voltages below 13 V , the on-voltage increases dramatically, especially at higher currents. At very low gate voltages, below 10 V , the IGBT may operate in the linear region and quickly overheat. Many PWM motor drives use a bootstrap supply for the upper gate drive. The UVLO provides protection for the IGBT in case the bootstrap capacitor discharges.

The MC33153 will typically start up at about 12 V . The UVLO circuit has about 1.0 V of hysteresis and will disable the output if the supply voltage falls below about 11 V .

## PROTECTION CIRCUITRY

## Desaturation Protection

Bipolar Power circuits have commonly used what is known as "Desaturation Detection". This involves monitoring the collector voltage and turning off the device if this voltage rises above a certain limit. A bipolar transistor will only conduct a certain amount of current for a given base drive. When the base is overdriven, the device is in
saturation. When the collector current rises above the knee, the device pulls out of saturation. The maximum current the device will conduct in the linear region is a function of the base current and the dc current gain $\left(\mathrm{h}_{\mathrm{FE}}\right)$ of the transistor.

The output characteristics of an IGBT are similar to a Bipolar device. However, the output current is a function of gate voltage instead of current. The maximum current depends on the gate voltage and the device type. IGBTs tend to have a very high transconductance and a much higher current density under a short circuit than a bipolar device. Motor control IGBTs are designed for a lower current density under shorted conditions and a longer short circuit survival time.

The best method for detecting desaturation is the use of a high voltage clamp diode and a comparator. The MC33153 has a Fault Blanking/Desaturation Comparator which senses the collector voltage and provides an output indicating when the device is not fully saturated. Diode D1 is an external high voltage diode with a rated voltage comparable to the power device. When the IGBT is "on" and saturated, D1 will pull down the voltage on the Fault Blanking/Desaturation Input. When the IGBT pulls out of saturation or is "off", the current source will pull up the input and trip the comparator. The comparator threshold is 6.5 V , allowing a maximum on-voltage of about 5.8 V .

A fault exists when the gate input is high and $\mathrm{V}_{\mathrm{CE}}$ is greater than the maximum allowable $\mathrm{V}_{\mathrm{CE}(\mathrm{sat)}}$. The output of the Desaturation Comparator is ANDed with the gate input signal and fed into the Short Circuit and Overcurrent Latches. The Overcurrent Latch will turn-off the IGBT for the remainder of the cycle when a fault is detected. When input goes high, both latches are reset. The reference voltage is tied to the Kelvin Ground instead of the $\mathrm{V}_{\mathrm{EE}}$ to make the threshold independent of negative gate bias. Note that for proper operation of the Desaturation Comparator and the Fault Output, the Current Sense Input must be biased above the Overcurrent and Short Circuit Comparator thresholds. This can be accomplished by connecting Pin 1 to $\mathrm{V}_{\mathrm{CC}}$.

Figure 33. Desaturation Detection

The MC33153 also features a programmable fault blanking time. During turn-on, the IGBT must clear the opposing free-wheeling diode. The collector voltage will remain high until the diode is cleared. Once the diode has
been cleared, the voltage will come down quickly to the $\mathrm{V}_{\mathrm{CE}(\mathrm{sat})}$ of the device. Following turn-on, there is normally considerable ringing on the collector due to the COSS capacitance of the IGBTs and the parasitic wiring inductance. The fault signal from the Desaturation Comparator must be blanked sufficiently to allow the diode to be cleared and the ringing to settle out.

The blanking function uses an NPN transistor to clamp the comparator input when the gate input is low. When the input is switched high, the clamp transistor will turn "off", allowing the internal current source to charge the blanking capacitor. The time required for the blanking capacitor to charge up from the on-voltage of the internal NPN transistor to the trip voltage of the comparator is the blanking time.

If a short circuit occurs after the IGBT is turned on and saturated, the delay time will be the time required for the current source to charge up the blanking capacitor from the $\mathrm{V}_{\mathrm{CE}(\mathrm{sat})}$ level of the IGBT to the trip voltage of the comparator. Fault blanking can be disabled by leaving Pin 8 unconnected.

## Sense IGBT Protection

Another approach to protecting the IGBTs is to sense the emitter current using a current shunt or Sense IGBTs. This method has the advantage of being able to use high gain IGBTs which do not have any inherent short circuit capability. Current sense IGBTs work as well as current sense MOSFETs in most circumstances. However, the basic problem of working with very low sense voltages still exists. Sense IGBTs sense current through the channel and are therefore linear with respect to the collector current. Because IGBTs have a very low incremental on-resistance, sense IGBTs behave much like low-on resistance current sense MOSFETs. The output voltage of a properly terminated sense IGBT is very low, normally less than 100 mV .
The sense IGBT approach requires fault blanking to prevent false tripping during turn-on. The sense IGBT also requires that the sense signal is ignored while the gate is low. This is because the mirror output normally produces large transient voltages during both turn-on and turn-off due to the collector to mirror capacitance. With non-sensing types of IGBTs, a low resistance current shunt ( 5.0 to $50 \mathrm{~m} \Omega$ ) can be used to sense the emitter current. When the output is an actual short circuit, the inductance will be very low. Since the blanking circuit provides a fixed minimum on-time, the peak current under a short circuit can be very high. A short circuit discern function is implemented by the second comparator which has a higher trip voltage. The short circuit signal is latched and appears at the Fault Output. When a short circuit is detected, the IGBT should be turned-off for several milliseconds allowing it to cool down before it is turned back on. The sense circuit is very similar to the desaturation circuit. It is possible to build a combination circuit that provides protection for both Short Circuit capable IGBTs and Sense IGBTs.

## APPLICATION INFORMATION

Figure 34 shows a basic IGBT driver application. When driven from an optoisolator, an input pull up resistor is required. This resistor value should be set to bias the output transistor at the desired current. A decoupling capacitor should be placed close to the IC to minimize switching noise.

A bootstrap diode may be used for a floating supply. If the protection features are not required, then both the Fault Blanking/Desaturation and Current Sense Inputs should both be connected to the Kelvin Ground (Pin 2). When used with a single supply, the Kelvin Ground and $\mathrm{V}_{\mathrm{EE}}$ pins should be connected together. Separate gate resistors are recommended to optimize the turn-on and turn-off drive.

Figure 34. Basic Application

Figure 35. Dual Supply Application

When used in a dual supply application as in Figure 35, the Kelvin Ground should be connected to the emitter of the IGBT. If the protection features are not used, then both the Fault Blanking/Desaturation and the Current Sense Inputs should be connected to Ground. The input optoisolator should always be referenced to $\mathrm{V}_{\mathrm{EE}}$ -

If desaturation protection is desired, a high voltage diode is connected to the Fault Blanking/Desaturation pin. The
blanking capacitor should be connected from the Desaturation pin to the $V_{E E}$ pin. If a dual supply is used, the blanking capacitor should be connected to the Kelvin Ground. The Current Sense Input should be tied high because the two comparator outputs are ANDed together. Although the reverse voltage on collector of the IGBT is clamped to the emitter by the free-wheeling diode, there is normally considerable inductance within the package itself. A small resistor in series with the diode can be used to protect the IC from reverse voltage transients.

Figure 36. Desaturation Application
When using sense IGBTs or a sense resistor, the sense voltage is applied to the Current Sense Input. The sense trip voltages are referenced to the Kelvin Ground pin. The sense voltage is very small, typically about 65 mV , and sensitive to noise. Therefore, the sense and ground return conductors should be routed as a differential pair. An RC filter is useful in filtering any high frequency noise. A blanking capacitor is connected from the blanking pin to $\mathrm{V}_{\mathrm{EE}}$. The stray capacitance on the blanking pin provides a very small level of blanking if left open. The blanking pin should not be grounded when using current sensing, that would disable the sense. The blanking pin should never be tied high, that would short out the clamp transistor.

Figure 37. Sense IGBT Application

## CS1112

## Quad Power Output Driver

The CS1112 is a Power Output Driver. The IC incorporates four protected DMOS low-side drivers designed to drive inductive and resistive loads in an automotive environment. The outputs are controlled by an 8-bit serial peripheral interface (SPI) or its associated parallel input. Each output contains overcurrent protection, open load detection, and inductive flyback clamps. The device is overvoltage protected. Overcurrent and open load faults are reported over the SPI port, and at the STATUS lead.

## I/O Control

SPI communication is initiated by asserting CSB low. Data at the SI lead is transferred on the rising edge of SCLK. The MSB is transferred first. The outputs become active at the rising edge of CSB. Diagnostic status bits are transferred out the SO lead at the falling edge of SCLK. The SO lead is high impedance while CSB is high. An open drain output, (STATUS) reports a fault (short to $\mathrm{V}_{\mathrm{PWR}}$, GND, or open load) has occurred at one or more of the outputs.

## Protection

Each output independently detects shorts to $V_{\text {PWR }}$ while the output is "on" and open load/short to ground while the output is "off". The fault register will be set if a fault occurs at the output. The fault register will be reset if the fault condition is removed from the output. The fault data is latched when CSB is asserted low.

If an overcurrent condition or short circuit to $V_{\text {BATT }}$ occurs, the output goes into a low duty cycle mode for the duration of the fault. The outputs are disabled during an overvoltage or undervoltage condition.

## Features

- 4.0 MHz Serial Input Bus
- Parallel Input Control
- $1.0 \Omega$ DMOS Drivers (typ)
- Power On Reset
- Internal Flyback Clamps
- Status Output
- Fault Protection
- 46 V Peak Transient
- Power Limiting
- Undervoltage
- Overvoltage
- Fault Reporting
- Open Load
- Short Circuit
- 8 Internally Fused Leads

| 23 | STATUS | Open drain output, which is asserted when an open load or <br> overcurrent condition occurs at any of the outputs. |
| 24 | ROSC | $82 \mathrm{k} \Omega$ resistor tied to ground to set up accurate internal cur- <br> rent sources. |

## CIRCUIT DESCRIPTION

## Typical Operation

Control of the CS1112 can be done using the Serial Peripheral Interface (SPI) port using the Data Input information in Table 1, or the outputs can be controlled via the parallel inputs (IN0, IN1, IN2, IN3). IN0 controls OUT0, IN1 controls OUT1, IN2 controls OUT2, and IN3 controls

OUT3. Turning the output drivers on is an OR function with the SPI input and the parallel inputs.

Note: To prevent damage to the IC or the output load, $\mathrm{V}_{\mathrm{DD}}$ must be above the Power on Reset threshold ( 3.5 V ) before IN0, IN1, IN2, or IN3 are asserted high ( $<70 \% \mathrm{~V}_{\mathrm{DD}}$ ).

## BLOCK DIAGRAM

## APPLICATION INFORMATION

## CIRCUIT DESCRIPTION

The CS1112 was developed for use in very noisy and very harsh environments such as seen in an automobile system. The device has four low-side switches all controlled through an 8-bit Serial Peripheral Interface (SPI) port. Control of the outputs is also OR'd with parallel inputs. This is a critical feature enhancement over similar devices because of the ease in which the parallel inputs can be used to control the outputs in a Pulse Width Modulation (PWM) mode. Creating a PWM mode using just the serial port input is not a practical application.

This part uses ON Semiconductor's POWERSENSE ${ }^{\text {TM }}$ process technology. POWERSENSE combines the robustness of Bipolar with the dense logic capability of CMOS, and the power capabilities of DMOS.

Power consumption is kept to a minimum using POWERSENSE in comparison to a bipolar technology. A bipolar process requires DC bias currents to power-up the integrated circuit. This is needed in many applications requiring analog circuitry, but is not needed here. Digital POWERSENSE logic dissipates power only when switching because that is when transient gate charging current flows. POWERSENSE logic requires little space, and is a good economical solution. The DMOS side of the process provides a robust user interface to the outside world on each of the outputs. Peak transient capability of each output is rated at a maximum of 46 V (typical of an automotive load dump transient).

The CS1112 uses quasi-vertical DMOS transistors resulting in an output resistance $\left(\mathrm{R}_{\mathrm{DS}(\mathrm{ON})}\right)$ at each output of less than $1.0 \Omega @ 13 \mathrm{~V}$ and $500 \mathrm{~mA} @ 25^{\circ} \mathrm{C}$.

The part can be put in a sleep mode where the part draws less than $2.0 \mu \mathrm{~A}$ of bias current from $\mathrm{V}_{\text {PWR. }}$. The part enters this sleep mode when $\mathrm{V}_{\mathrm{DD}} \leq 0.5 \mathrm{~V}$. Maximum quiescent current for the device is 5.0 mA maximum for any combination of output drivers enabled.

Fault reporting is controlled by the CS1112. Overcurrent and short to $\mathrm{V}_{\text {BATT }}$ are detected when the output is on. Open load and short to ground are detected when the output is off. Faults are reported out of the serial output (SO) pin as a new 8 -bit word is being fed into the serial input (SI) pin.

Figure 3 highlights the SPI interface between the microprocessor and the CS1112. The SPI control inputs and all other logic inputs are compatible with 5.0 V CMOS logic levels.

Figure 3.
The four communication lines which define the SPI interface are the SI, SO, CSB, and SCLK. The parallel inputs, which control the outputs can also connect to the same microprocessor, a separate microprocessor, or any other sensor or electrical device which meets the voltage requirements of the $\operatorname{CS} 1112\left(\mathrm{~V}_{\mathrm{IN}(\max )}=\mathrm{V}_{\mathrm{DD}}+0.3 \mathrm{~V}\right)$.

SPI communication is as follows (2 scenarios):

## 1. 8-Bit Normal Operation

CSB pin is brought low activating the SPI port. Faults detected since the last CSB low to high transition are latched into the serial register when CSB goes low. 8 command bits are clocked into the SI pin. The four fault bits are clocked out of the SO pin. CSB pin is brought high translating the final 4 bits to the outputs turning them on or off. Faults are then detected and saved in the fault register when CSB goes low.
2. 16-Bit Operation For Command Verify

CSB pin is brought low activating the SPI port. 16 bits are clocked into the SI pin (the last 4 are the 4 control pins for the four outputs). CSB pin is brought high translating the last 4 bits to the outputs turning them on or off.
CSB pin is brought low activating the SPI port. 16 new bits are clocked into the SI pin. As the new bits are being clocked in, the first 8 bits being clocked out of the SO pin are the fault bits, followed by the first 8 bits which were clocked in (the verification bits). The verification bits should replicate the command bits.
Serial clock frequencies up to 4.0 MHz can be used by the CS1112.

Internal pull-up circuitry is provided on the Chip Select Bar (CSB) pin. Internal active pulldowns are provided on the parallel input pins (IN0, IN1, IN2, IN3, and SI pin).

A product highlight of this part is its ability to be daisy-chained with other parts which follow the SPI protocol as defined in Figure 1. Figure 4 displays this aspect. The serial output of each device is fed into the serial input of the next device. All data bits are clocked into their respective registers, while the CSB pin is low. The drivers are switched to the resulting command when the CSB pin is brought back high.

Figure 4.
Multiple SPI port devices can also be connected in a parallel fashion (Figure 5) instead of the daisy-chained connection previously shown. The microprocessor controls the CS1112 in a multiplex fashion allowing the serial data input to be input to the device when the device is activated through the CSB pin. This creates a system whose number of outputs is a multiple of 4 . Figure 5 displays a 12 output setup.

Figure 5.
Figure 6 displays the device controlling 4 outputs with the use of its SPI port. Figure 7 displays the device controlling 1 output with the SPI port, and 3 outputs being controlled
with the parallel inputs allowing them to run in a PWM mode.

Figure 6.

Figure 7.
The CS1112 provides a very efficient way of controlling 4 output drivers by minimizing the number of I/O pins through use of the SPI port, and still provides the flexibility of pulse width modulating the output drivers where needed. The use of the SPI also allows the integrated circuit to communicate directly with the microprocessor.

While designed for an automotive environment, the CS1112 can be used in other applications in the computer market, industrial market, telecommunications market, or any other instance where numerous drivers are needed. All parts are $100 \%$ tested and guaranteed to meet all parameters specified in the electrical characteristics. These specifications cover the entire voltage range for $\mathrm{V}_{\mathrm{PWR}}$ (9.0 V to 17 V ), and $\mathrm{V}_{\mathrm{DD}}(4.5 \mathrm{~V}$ to 5.5 V$)$.

## FAULT MODE OPERATION

The CS1112 provides protection for a multitude of system faults and conditions. These include Overvoltage, Current Limit, Open Circuit, Output Short to Power, Output Short to Ground, and Flyback Clamp.

## Overvoltage

The IC is constantly monitoring the voltage on the VPWR pin. If the voltage on this pin exceeds the Overvoltage Shutdown Threshold (typically 35 V ), all outputs immediately turn off. The programmed outputs (via serial or parallel input) turn back on once the voltage is brought back down below this level.

## Current Limit/Short to $\mathrm{V}_{\text {BATT }}$

When the output current exceeds the Overcurrent (4.5 A typical) for the Short Circuit/Overcurrent Sense Time (typically $62.5 \mu \mathrm{~s}$ ) as it would do during an output short to $\mathrm{V}_{\text {BATT }}$, its fault status bit will be latched to a logic one. The fault status bit remains latched until the rising edge of CSB. The output will go into a low duty cycle mode (typically $1.56 \%$ ) as long as the overcurrent condition exists, and the channel is on. This protects the integrated circuit from damaging itself due to its thermal limits.

## Open Circuit/Short to Ground

Open circuit conditions are detected while the outputs are off. A fault bit is set when the Open Load "Off" Detection Voltage (typically $0.5 \times \mathrm{V}_{\mathrm{DD}}$ ) is present for the Open Load "Off" Sense Time (typically $62.5 \mu \mathrm{~s}$ ) as it would do during an output short to ground.

## Flyback Clamp

While the flyback clamp is not a fault mode, it is a protection feature of the CS1112. When driving inductive loads, it is normal to observe high voltage spikes on the output pin due to the stored energy in the windings when the device is turned off. On-chip clamps on the outputs limit the voltage amplitude on the pin to prevent damage to the device. Each output has an Output Clamp which limits the output voltage to 52 V (typical when measured at 20 mA for $100 \mu \mathrm{~s}$ ).

## PIN FUNCTION DESCRIPTION

## SI

The SI (Serial Input) receives serial 8-bit or 16-bit words sent most significant bit first. Data is clocked in on the rising edge of SCLK. An internal active pull-down is connected to this input. CMOS logic levels are required on this pin.

## SO

The SO (Serial Output) can be connected to the serial data input pin of the microprocessor, or it can be daisy-chained to the serial input (SI) of another SPI compatible device. This pin is tri-stated unless a low CSB pin selects the device.

The signal on this pin is clocked from the falling edge of the SCLK pin. The serial output data provides fault information for each output and returns most significant bit (bit 7) first. Bits 0 through 3 are output fault bits for outputs 0 through 3 , respectively. In 8 -bit SPI mode, bits $0-3$, under normal conditions return all zeros representing no faults. A 1 indicates a fault. The output from this pin conforms to CMOS logic levels.

## Rosc

An $82 \mathrm{k} \Omega$ resistor tied to ground sets up an accurate internal current source.

## CSB

The CSB (Chip Select Bar) is the select pin when the microprocessor wants to communicate with the CS1112. A low on this pin enables the SPI communication with the device and enables the SO pin. After the digital word is clocked into the IC, a transition from low to high on the CSB pin translates the last 4 bits of information turning the outputs on or off. An internal active pull-up is connected to this input. CMOS logic levels are required on this pin.

## SCLK

The SCLK (Serial Clock) clocks the internal shift registers. This pin controls the data being shifted into the SI pin, and data being shifted out of the SO pin. CMOS logic levels are required on this pin.

## INO, IN1, IN2, IN3

These pins control their corresponding numbered output. These are the parallel input pins which may be used to PWM the outputs. They have 230 mV of hysteresis. These inputs are OR'd with their corresponding input bit in the serial control byte. An internal active pull-down is connected to these pins. CMOS logic levels are required on these pins.

## OUTO, OUT1, OUT2, OUT3

These pins are the output low-side driver pins. They all have typically $1.0 \Omega \mathrm{R}_{\mathrm{DS}(\mathrm{ON})}$ at $\mathrm{V}_{\mathrm{PWR}}=13 \mathrm{~V}$. Current limit on these pins has a minimum specification of 3.0 A . A low duty cycle mode ( $1.5 \%$ typ.) will initiate at a minimum of 1 A and before the current limit.

## $V_{\text {PWR }}$

14 V Battery voltage input. $5.0 \mathrm{~mA}(\max )$ is needed.
$V_{D D}$
5.0 V Supply input. 5.0 mA (max) is needed.

## STATUS

Open drain output. This pin goes low when an open load or overcurrent condition occurs on any of the outputs. This provides immediate notification to the controller that a fault is present. The controller can subsequently query the device (serially) to determine its origin.

## CS1107

## CIRCUIT DESCRIPTION

The CS1107 relay driver IC provides up to 350 mA of drive current in a low-side configuration. The Output driver pin is controlled through the TTL compatible Control input pin. A high condition on the Control pin turns the output pin on.

The Fault pin reports short circuit, open circuit, and overtemperature conditions on the IC. If a fault is present, the open collector output $\overline{\text { Fault }}$ pin will be low. Typical numbers for faults are: exceeding 500 mA of drive current will report a short circuit. Less than 40 mA (typical) will report an open circuit. A temperature fault will be reported when the die temperature exceeds $180^{\circ} \mathrm{C}$ (typical). Faults
are only reported when the Control pin is high, due to the low quiescent current when the Control pin is low and the output device is turned off.
Overcurrent protection is provided by duty cycle control. When the Output current exceeds the current limit threshold, the output enters duty cycle mode to reduce power dissipation of the IC to a safe level. The higher the threshold is exceeded the lower the duty cycle becomes.
A 33 V on-chip zener diode on the Output pin protects the device from flyback pulses when a relay is turned off. The saturation voltage of this pin will not exceed 1.5 V at 350 mA .

## CIRCUIT DESCRIPTION

The CS1108 lamp driver IC provides up to 350 mA of drive current in a low-side configuration. The Output driver pin is controlled through the TTL compatible Control input pin. A high condition on the Control pin turns the output pin on.

The Fault pin reports short circuit, open circuit, and overtemperature conditions on the IC. If a fault is present, the open collector output $\overline{\text { Fault }}$ pin will be low. Typical numbers for faults are: exceeding 500 mA of drive current will report a short circuit. Less than 40 mA (typical) will report an open circuit. A temperature fault will be reported when the die temperature exceeds $180^{\circ} \mathrm{C}$ (typical). Faults are only reported when the Control pin is high, due to the low quiescent current when the Control pin is low and the output device is turned off.

The CS1108 is designed to provide overcurrent protection by duty cycle control. When the lamp current exceeds the internally programmed current limit threshold (typically 500 mA ), the output enters duty cycle mode to reduce power dissipation of the IC to a safe level.

Typical lamps have a low resistance when off and the current will exceed the current limit threshold during the initial inrush period. During this inrush time, the IC will be operating in the duty cycle mode. Due to characteristics of lamps in this mode, they may appear dimly lit. This condition will persist for a breif time until the lamp resistance has increased enough to reduce it's current below the threshold. Once this occurs the lamp will appear at full brightness. During the inrush period the Fault pin will be forced low indicating that duty cycle mode is in operation.

Thermal protection has been designed into this IC. Should duty cycle mode operate for an extended amount of time and the power limitations of the IC are exceeded the IC die temperature will rise. Once the die temperature reaches the thermal temperature limit, the internal cicuitry will shutoff the output and the lamp will turn off. Once the die temperature lowers below the thermal threshold, the output will be allowed to turn back on.

## CS8240

## 500 mA High Side (PNP) Driver with On-Chip Flyback Diode

The CS8240 is a fast, PNP high side driver capable of delivering up to 500 mA into a resistive or inductive load in harsh automotive or industrial environments. An internal flyback diode clamp is incorporated for inductive loads. The input ( $\mathrm{V}_{\mathrm{IN}}$ ) is TTL and CMOS compatible and has hysteresis to minimize the effects of noise. When the input is high, the output is on. When the input is low, the output is off and the supply voltage quiescent current is very low ( $<1.0 \mu \mathrm{~A}$, typ). For device protection, the CS8240 incorporates thermal shutdown, short circuit current limiting, overvoltage shutdown, and reverse battery protection. The CS8240 can withstand supply voltage transients of $60 \mathrm{~V}(\mathrm{~min})$ and -50 V .

The CS8240 is available in an overmolded 5 lead TO-220 package and is a competitive replacement for the LM-1921, LM-1951, LM-1952, MC-3399, and L-9350.

## Features

## CIRCUIT DESCRIPTION

## Input Stage

The input stage is a self biased band gap based circuit with a positive going trip point of 1.45 V (typ) and a negative going trip point of 1.20 V (typ) ( 250 mV of hysteresis). When the input voltage is below the positive trip point, the quiescent current of the supply voltage line is less than $1.0 \mu \mathrm{~A}$, (typ). When the input voltage exceeds the positive trip point ( 1.45 V , typ), the input stage "wakes up" the rest of the CS8240 circuitry and turns on the output stage.

## Output Stage

The output stage is built around a high current PNP output transistor. A control amplifier monitors the saturation voltage of the output PNP and maintains a balance of low saturation voltage and minimum base drive to the PNP for
the given output current. The base drive of the PNP is the dominant component of the quiescent current of the CS8240 and is dependent on the level of output current.

Short circuit protection ( 1.1 A, typ) is also incorporated in the output stage.

## Protection Circuitry

In addition to the short circuit protection mentioned above, the CS8240 also incorporates a thermal shutdown circuit ( $165^{\circ} \mathrm{C}$, typ) and a high voltage shutdown circuit ( 33 V , typ), both of which cut off the drive to the PNP output transistor when excessive current is drawn. Inherent in the design of the CS8240 is transient protection to +60 V and -50 V on the supply line. The CS8240 is ESD protected in excess of 2.0 kV (Human Body Model).

## NCV7601

## Quad Driver

This automotive grade product provides a versatile interface between control logic and many types of loads. The inputs accept a wide range of control signal levels while the open-collector outputs feature independent thermal and current limiting. Integral transient suppression diodes are provided at all inputs and outputs.

## DETAILED OPERATING DESCRIPTION

The NCV7601 Quad Driver consists of four identical driver sections with output clamp diodes and a common bias generator.

Each driver input (Figure 2) is buffered by a PNP emitter follower for reduced input bias current and features a nominal 18 V Zener input clamp for transient protection. Each input is compared to a separate temperature-compensated reference, which provides a nominal 1.35 V comparison threshold. With the addition of an external series resistor, the inputs can be interfaced directly to +14 V automotive system voltages. Floating inputs are interpreted as high.

Each driver output NPN is supplied with a substantially fixed base current from the $+5.0 \mathrm{~V} \mathrm{~V}_{\mathrm{CC}}$ pin by a pre-driver.

Each pre-driver multiplies a temperature-compensated reference current when its control input and the common enable input is high. Current limit and thermal limit circuits act independently within the pre-driver to reduce base drive to the output NPN. The independent limit operation allows the driver to handle inrush current from lamp loads while protecting the driver from fault conditions that exist long enough to raise the temperature at that driver to its thermal limit threshold. Each driver has its own temperature-sensing device located in close proximity to the output NPN. The separate sensing devices are strategically placed at the corners of the die to reduce interaction between them.

## APPLICATIONS INFORMATION

The NCV7601 Quad Driver interfaces high power loads to low power control signals. The four open-collector NAND drivers with common ENABLE are TTL, DTL and CMOS compatible. Any number of drivers may be parallel connected to drive loads greater than each driver's nominal capability. Power for the Quad's control logic and output pre-drive is supplied from the $+5.0 \mathrm{~V} \mathrm{~V}_{\mathrm{CC}}$ pin, and is proportional to the number of active inputs. Minimum standby power is consumed when the ENABLE input is low. Each driver is individually protected with current limit and thermal limit circuitry. Drivers with fault loads are protected while drivers with normal loads continue to operate, provided that sufficient heat sinking maintains a good thermal gradient between all drivers.

Clamp diodes at each driver output provide a means for managing inductive load transients. The common cathode pin for each driver pair can be connected to the load supply voltage for suppression of minor transients resulting from
wiring harness inductances. The use of an external Zener diode or TVS (Transient Voltage Suppressor) device such as the ON Semiconductor 1.5 SMCXXXAT3 series is strongly recommended when driving large inductive loads or when load supply transients can be expected to exceed the Quad Driver's VCE (SUS) rating. The use of a TVS device provides an additional benefit by reducing the decay time of inductive loads. More information on safeguarding the Quad's output NPN's and about transient suppression methods and device selection is available in ON Semiconductor application notes "Understanding Power Transistors Breakdown Parameters", document number AN1628/D, "A Review of Transients and their Means Of Suppression", document number AN843/D and "Transient Power Capability of Zener Diodes", document number AN784/D. All application notes are available through the Literature Distribution Center or via our website at http://www.onsemi.com.

## CS2082

## Dual Airbag <br> Deployment ASIC

The CS2082 controls and monitors two airbag firing loops. The independent firing loops are low- and high-side controlled. Device communication is through a Serial Peripheral Interface (SPI) port, and includes frame error detection circuitry for data reliability.

Diagnostics include squib resistance measurement and continuous monitoring for shorts to ground, shorts to battery, and for open loops. The high- and low-side drivers can be individually activated to guarantee function and to identify shorts between firing loops. Additional features include power on reset, overtemperature protection, a charge pump, high-side safing sensor closure detection, an analog multiplexer, a monitor to ensure battery potential, and a programmable monitor to ensure firing potential.

## Features

- Serial Input Bus
- Two Squib Outputs
- Low- and High-Side Control
- Monitors
- Squib Resistance
- Short to Ground or Battery
- Battery Potential
- Firing Potential
- Safing Sensor Detection
- 60 V Peak Transient Voltage

| 18 | $\mathrm{D}_{\mathrm{IN}}$ | Function |
| 19 | $\mathrm{~V}_{\mathrm{CC}}$ | 5.0 V Regulated Supply. |
| 20 | GND | Signal Ground. |

## FUNCTIONAL DESCRIPTION

The CS2082 is an automotive air bag deployment and diagnostic system for up to two independent firing loops. Communication with the ASIC is through a synchronous serial port using Serial Peripheral Interface (SPI) protocol, at CLK rates up to 2.0 MHz .

Data is simultaneously sent from the DOUT pin and received at the $\mathrm{D}_{\text {IN }}$ pin under the control of the CS and CLK pins. Error detection logic is included in the SPI to guard against glitches on either the CS or CLK logic signal inputs. A valid CS frame must contain exactly 8 CLK cycles for each CS low-high-low transition. Detection of a frame error will cause input data for that frame to be ignored and an error code ( $\$ \mathrm{FE}$ ) to be sent during the next valid CS frame.

The data at $\mathrm{D}_{\text {OUT }}$ is sent MSB first and is guaranteed valid before the rising edge of CLK. The 8 bits sent from $\mathrm{D}_{\text {OUT }}$ after CS goes high will be the previous data received, data from either the status register or the fault register, or the CS frame error code (\$FE).

The data at $\mathrm{D}_{\text {IN }}$ is received MSB first and must be valid before the rising edge of CLK. The 8 bits received at $\mathrm{D}_{\mathrm{IN}}$ before CS goes low will be the current command. Table 1 defines the legal 8-bit SPI commands, where $\mathrm{d}=$ four data bits and $\mathrm{x}=$ don't care. All other inputs will be ignored

Table 1. Valid CS2082 SPI Commands

| COMMAND | FUNCTION |
| :---: | :--- |
| $\$ 1 \mathrm{x}$ | Read Staus Register |
| $\$ 2 \mathrm{x}$ | Read Fault Register |
| $\$ 3 \mathrm{~d}$ | Squib Resistance Measurements |
| $\$ 4 \mathrm{~d}$ | Analog MUX Select |
| $\$ 5 \mathrm{~d}$ | Low Side Switch Control |
| $\$ 6 \mathrm{~d}$ | Auxiliary Control Register |
| $\$$ Ad | High Side Switch Control |

## Read Status Register - \$1x

The $\$ 1 x$ command causes the data contained in the status register to be sent from $\mathrm{D}_{\text {OUT }}$ during the next valid CS frame. The status register reports the condition of the firing paths, closure detection of an external safing switch between
the $\mathrm{V}_{\text {RES }}$ and VR1 pins, the state of the internal charge pump, and the state of external $\mathrm{V}_{\text {BAT }}$ and $\mathrm{V}_{\text {RES }}$ power supplies. The status register is an 8 -bit active-high register with bit definition as shown in Table 2.

Table 2. Status Register Bit Definition

| BIT | VALUE | DESCRIPTION |
| :---: | :---: | :--- |
| D7 | 0 | Always Logic zero |
| D6 | 0 | Always Logic zero |
| D5 | F1 | SH1 and SL1 switches active |
| D4 | F2 | SH2 and SL2 switches active |
| D3 | SSC | Safing Sensor is closed |
| D2 | RL | V REs voltage is below trip $^{\text {D1 }}$ |
| BL | V $_{\text {BAT }}$ voltage is below trip |  |
| D0 | CL | CHRG voltage is below trip |

## Read Fault Register - \$2x

The $\$ 2 x$ command causes the data contained in the fault register to be sent from $\mathrm{D}_{\text {OUT }}$ during the next valid CS frame. The register reports fire path faults by continuously comparing each path to a portion of the voltage at the $\mathrm{V}_{\text {BAT }}$ pin. The fault register is an 8-bit active-high register with bit definition as shown in Table 3.

Table 3. Fault Register Bit Definition

| BIT | VALUE | DESCRIPTION |
| :---: | :---: | :--- |
| D7 | 0 | Always Logic zero |
| D6 | 0 | Always Logic zero |
| D5 | 0 | Always Logic zero |
| D4 | 0 | Always Logic zero |
| D3 | SB2 | High Side of Sqib 2 above <br> $75 \% ~ V_{\text {BAT }}$ trip threshold |
| D2 | SB1 | High Side of Sqib 1 above <br> $75 \% V_{\text {BAT trip threshold }}$ |
| D1 | SG2 | Low Side of Sqib 2 below <br> $25 \% ~ V_{\text {BAT }}$ trip threshold |
| D0 | SG1 | Low Side of Sqib 1 below <br> $25 \% ~ V_{\text {BAT }}$ trip threshold |

Each SHx pin is pulled up to $\mathrm{V}_{\text {BAT }}$ while each SLx pin is pulled down to GND through separate nominal $10 \mathrm{k} \Omega$ resistors, thus biasing each normal fire path to about $1 / 2$ $\mathrm{V}_{\text {BAT }}$. An open fire path has been detected if both the SBx and SGx bits are set for that path. To detect faults between fire paths and to test driver function, each driver should be activated individually. The activated driver should cause its respective fault bit to be set. If an activated driver does not set its respective fault bit, a driver fault has been detected. If an activated driver causes the fault bit of an inactivated driver to be set, a fault between fire paths has been detected. Table 4 defines the implied ranges over which the various types of faults can be detected.

Table 4. Implied Resistive Fault Detection Ranges

| Fault | Min | Nom | Max | Unit |
| :--- | :---: | :---: | :---: | :---: |
| Short to Ground | 1 | 5 | 10 | $\mathrm{k} \Omega$ |
| Short to Battery | 1 | 5 | 10 | $\mathrm{k} \Omega$ |
| Open | 5 | 20 | 40 | $\mathrm{k} \Omega$ |
| Driver Open | 1 | 5 | 10 | $\mathrm{k} \Omega$ |
| Driver Shorted | 1 | 5 | 10 | $\mathrm{k} \Omega$ |
| Squib to Squib | 1 | 5 | 10 | $\mathrm{k} \Omega$ |

## Squib Resistance Measurement - \$3d

The \$3d command activates squib resistance measurement for the selected firing path. The respective active-high bit definitions are shown in Table 5. At power-up, the default path is 'None.'

Table 5. Squib Resistance Path Select

| D3 | D2 | D1 | D0 | Path |
| :---: | :---: | :---: | :---: | :--- |
| $x$ | $x$ | 0 | 0 | NONE |
| $x$ | $x$ | 0 | 1 | SQUIB 1 |
| $x$ | $x$ | 1 | 0 | SQUIB 2 |
| $x$ | $x$ | 1 | 1 | NONE |

Squib resistance is measured by forcing 50 mV nominal (proportional to $\mathrm{V}_{\mathrm{CC}}$ ) across the squib. The resulting squib current is passed to an external load resistor at the MR pin, converting the current back into a voltage. This voltage may be read directly at the MR pin, or passed through the analog multiplexer to be read at the AOUT pin. The known values of the squib differential voltage ( $\mathrm{V}_{\text {DIFF }}$ ) and the MR resistance $\left(\mathrm{R}_{\mathrm{MR}}\right)$, and the measured MR voltage $\left(\mathrm{V}_{\mathrm{MR}}\right)$ indicate squib resistance such that:

$$
\text { RSQUIB }=\frac{\mathrm{R}_{\mathrm{MR}} \times \mathrm{V}_{\text {DIFF }}}{\mathrm{V}_{\mathrm{MR}}}
$$

Typical MR voltage response for $\mathrm{R}_{\mathrm{MR}}=50 \Omega$ over a squib resistance range of $0.6 \Omega$ to $6.0 \Omega$ is illustrated in Figure 2.

Figure 2. Typical MR Voltage Response
Measurement accuracy of the CS2082 with combined tolerances and with and external $1 \%$ load resistor at the MR pin can be defined by the equation:

$$
\begin{aligned}
& =\operatorname{RSQ}(\mathrm{A})+12.5 \% /-15.94 \%
\end{aligned}
$$

where $\mathrm{V}_{\text {DIFF(IDEAL) }}$ and $\mathrm{R}_{\mathrm{MR} \text { (IDEAL) }}$ are the assumed values for the squib resistance solution algorithm, $\mathrm{R}_{\mathrm{SQ}(\mathrm{A})}$ is the actual squib resistance, and $\mathrm{R}_{\mathrm{SQ}(\mathrm{E})}$ is the result of the solution algorithm. An additional error may be added if the MR voltage is measured through the analog multiplexer.

In operation, current is sourced from $\mathrm{V}_{\mathrm{BAT}}$ to the SHx pin, through the squib to the SLx pin, and returned to ground through the MR load resistor. Current clamps are provided for both the SHx and SLx pins and a voltage clamp is provided for the MR pin. These clamps along with the resolution of the ADC are the constraining factors for the minimum and maximum measurable squib resistance values.
The minimum measurable squib resistance can be defined as:

$$
\frac{V_{\operatorname{DIFF}(\mathrm{MIN})}}{\operatorname{IIIM}(\mathrm{MAX})} \leq \mathrm{R}_{\text {SQUIB }(\mathrm{MIN})} \leq \frac{\mathrm{V}_{\mathrm{DIFF}}(\mathrm{MIN}) \times \mathrm{R}_{\mathrm{MR}(\mathrm{MIN})}}{\mathrm{V}_{\mathrm{CLAMP}}(\mathrm{MAX})}
$$

The maximum measurable squib resistance can be defined as:
$R_{\text {SQUIB }}(\mathrm{MAX})=\frac{\mathrm{V}_{\text {DIFF }}(\mathrm{MAX}) \times \mathrm{R}_{\text {MR(MAX }} \times\left(2^{\mathrm{n}}-1\right)}{\mathrm{V}_{\mathrm{CC}}(\mathrm{MIN})}$
In the above equations, $V_{\text {DIFF }}$ is the $\mathrm{SHx}-\mathrm{SLx}$ forced differential voltage, $\mathrm{I}_{\text {LIM }}$ is the SHx resistive measure current limit, $\mathrm{V}_{\text {CLAMP }}$ is the MR clamp voltage, $\mathrm{R}_{\mathrm{MR}}$ is the toleranced MR load resistor value and $n$ is the number of bits of resolution of the ADC.

It should be noted that during resistive measurements, faults to GND or BAT (dependent on $\mathrm{V}_{\text {BAT }}$ voltage and
squib resistance) may be reported by the fault register and should be ignored.

Power Dissipation during resistive measurement can be calculated as:

$$
P=I_{\text {SQUIB }}\left(V_{\text {BAT }}-V_{\text {DIFF }}\right)-\left(I_{\text {SQUIB }} \times R_{M R}\right)
$$

where $\mathrm{V}_{\text {BAT }}$ is the voltage at the CS2082 $\mathrm{V}_{\text {BAT }}$ pin and $\mathrm{I}_{\text {SQUIB }}$ is the measurement current through the squib. A typical value for P is 300 mW when $\mathrm{V}_{\mathrm{BAT}}=13.5$,
$\mathrm{V}_{\mathrm{DIFF}}=50 \mathrm{mV}, \mathrm{R}_{\text {SQUIB }}=2.0 \Omega$ and $\mathrm{R}_{\mathrm{MR}}=49.9 \Omega$
The resultant increase in power dissipation will cause a corresponding increase in die temperature which will cause a corresponding decrease in time to thermal shutdown of the CS2082. To minimize the impact of squib resistive measurements on time to thermal shutdown a 5\% duty cycle is recommended.

## Analog MUX - \$4d

The $\$ 4 \mathrm{~d}$ command selects one of five states at the AOUT pin. The states are: High-Z; MR voltage; A $\mathrm{A}_{\text {IN }}$ voltage; proportion of $\mathrm{V}_{\mathrm{BAT}}$; proportion of $\mathrm{V}_{\text {RES }}$. The active-high Analog Mux select register bit definitions are shown in Table 6. All other states will be interpreted as High-Z. At power-up, the default state is 'High-Z.'

Table 6. Analog MUX Output Select

| D3 | D2 | D1 | D0 | State |
| :---: | :---: | :---: | :---: | :--- |
| 0 | 0 | 0 | 0 | High-Z |
| 0 | 0 | 0 | 1 | MR |
| 0 | 0 | 1 | 0 | AIN |
| 0 | 1 | 0 | 0 | BAT |
| 1 | 0 | 0 | 0 | RES |

## Low Side Switch Control - \$5d

The \$5d command activates the low side switches. When a data bit is low that switch is turned on. More than one switch can be activated at a time. Bit assignment is shown in Table 7. At power-up, no switches are active.

Table 7. Low Side Switch Select

| D3 | D2 | D1 | D0 | Active |
| :---: | :---: | :---: | :---: | :--- |
| $x$ | $x$ | 0 | 0 | BOTH |
| $x$ | $x$ | 0 | 1 | SL2 |
| $x$ | $x$ | 1 | 0 | SL1 |
| $x$ | $x$ | 1 | 1 | NONE |

## Auxiliary Control Register - \$6d

The $\$ 6 \mathrm{~d}$ command selects the $\mathrm{V}_{\text {RES }}$ Monitoring trip threshold. The threshold determines when the \$1x Status Register reports $\mathrm{V}_{\text {RES }}=1$. Bit assignment is shown in Table 8. At power-up, default trip is 17 V .

Table 8. VRES Monitor Trip Select

| D3 | D2 | D1 | D0 | Trip |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $x$ | $x$ | $x$ | 0 | 17 V |  |
| $x$ | x | x | 1 | 23 V |  |

## High Side Switch Control - \$Ad

The \$Ad command activates the high side switches. When a data bit is high, that switch is turned on. More than one switch can be activated at a time. Bit assignment is shown in Table 9. Note that the $\$ 5 \mathrm{~d}$ and $\$$ Ad commands are binary complements, i.e., by sending 1010xx11, both high side switches are activated, and by sending the complement 0101xx00, both low side switches are activated. At power-up, no switches are active.

Table 9. High Side Switch Select

| D3 | D2 | D1 | D0 | Active |
| :---: | :---: | :---: | :---: | :--- |
| $x$ | $x$ | 0 | 0 | NONE |

## APPLICATIONS INFORMATION

## General Information

The Electronic Industries Association (EIA) has released the EIA-232D specification detailing the requirements for the interface between data processing equipment and data communications equipment. This standard specifies not only the number and type of interface leads, but also the voltage levels to be used. The MC1488 quad driver and its companion circuit, the MC1489 quad receiver, provide a complete interface system between DTL or TTL logic levels and the EIA-232D defined levels. The EIA-232D requirements as applied to receivers are discussed herein.

The required input impedance is defined as between $3000 \Omega$ and $7000 \Omega$ for input voltages between 3.0 and 25 V in magnitude; and any voltage on the receiver input in an open circuit condition must be less than 2.0 V in magnitude. The MC1489 circuits meet these requirements with a maximum open circuit voltage of one $\mathrm{V}_{\mathrm{BE}}$.

The receiver shall detect a voltage between - 3.0 and -25 V as a Logic " 1 " and inputs between 3.0 and 25 V as a Logic " 0 ." On some interchange leads, an open circuit of power "OFF" condition ( $300 \Omega$ or more to ground) shall be decoded as an "OFF" condition or Logic "1." For this reason, the input hysteresis thresholds of the MC1489 circuits are all above ground. Thus an open or grounded input will cause the same output as a negative or Logic " 1 " input.

## Device Characteristics

The MC1489 interface receivers have internal feedback from the second stage to the input stage providing input hysteresis for noise rejection. The MC1489 input has typical
turn-on voltage of 1.25 V and turn-off of 1.0 V for a typical hysteresis of 250 mV . The MC1489A has typical turn-on of 1.95 V and turn-off of 0.8 V for typically 1.15 V of hysteresis.

Each receiver section has an external response control node in addition to the input and output pins, thereby allowing the designer to vary the input threshold voltage levels. A resistor can be connected between this node and an external power supply. Figures 4, 6 and 7 illustrate the input threshold voltage shift possible through this technique.

This response node can also be used for the filtering of high frequency, high energy noise pulses. Figures 10 and 11 show typical noise pulse rejection for external capacitors of various sizes.

These two operations on the response node can be combined or used individually for many combinations of interfacing applications. The MC1489 circuits are particularly useful for interfacing between MOS circuits and MDTL/MTTL logic systems. In this application, the input threshold voltages are adjusted (with the appropriate supply and resistor values) to fall in the center of the MOS voltage logic levels (see Figure 12).

The response node may also be used as the receiver input as long as the designer realizes that he may not drive this node with a low impedance source to a voltage greater than one diode above ground or less than one diode below ground. This feature is demonstrated in Figure 13 where two receivers are slaved to the same line that must still meet the EIA-232D impedance requirement.

## Quad Line EIA-232D Driver

The MC1488 is a monolithic quad line driver designed to interface data terminal equipment with data communications equipment in conformance with the specifications of EIA Standard No. EIA-232D.

## Features:

- Current Limited Output
$\pm 10 \mathrm{~mA}$ typical
- Power-Off Source Impedance
$300 \Omega$ minimum
- Simple Slew Rate Control with External Capacitor
- Flexible Operating Supply Range
- Compatible with All ON Semiconductor MDTL and MTTL Logic Families

## APPLICATIONS INFORMATION

The Electronic Industries Association EIA-232D specification details the requirements for the interface between data processing equipment and data communications equipment. This standard specifies not only the number and type of interface leads, but also the voltage levels to be used. The MC1488 quad driver and its companion circuit, the MC1489 quad receiver, provide a complete interface system between DTL or TTL logic levels and the EIA-232D defined levels. The EIA-232D requirements as applied to drivers are discussed herein.

The required driver voltages are defined as between 5.0 and 15 V in magnitude and are positive for a Logic " 0 " and negative for a Logic " 1 ." These voltages are so defined when the drivers are terminated with a 3000 to $7000 \Omega$ resistor. The MC1488 meets this voltage requirement by converting a DTL/TTL logic level into EIA-232D levels with one stage of inversion.

The EIA-232D specification further requires that during transitions, the driver output slew rate must not exceed 30 V per microsecond. The inherent slew rate of the MC1488 is much too fast for this requirement. The current limited output of the device can be used to control this slew rate by connecting a capacitor to each driver output. The required capacitor can be easily determined by using the relationship $\mathrm{C}=\mathrm{I}_{\mathrm{OS}} \times \Delta \mathrm{T} / \Delta \mathrm{V}$ from which Figure 12 is derived. Accordingly, a 330 pF capacitor on each output will guarantee a worst case slew rate of 30 V per microsecond.

Figure 12. Slew Rate versus Capacitance for $\mathrm{I}_{\mathrm{SC}}=10 \mathrm{~mA}$

The interface driver is also required to withstand an accidental short to any other conductor in an interconnecting cable. The worst possible signal on any conductor would be another driver using a plus or minus $15 \mathrm{~V}, 500 \mathrm{~mA}$ source. The MC1488 is designed to indefinitely withstand such a short to all four outputs in a package as long as the power supply voltages are greater than 9.0 V (i.e., $\mathrm{V}_{\mathrm{CC}} \geqslant 9.0 \mathrm{~V}$; $\mathrm{V}_{\mathrm{EE}} \leqslant-9.0 \mathrm{~V}$ ). In some
power supply designs, a loss of system power causes a low impedance on the power supply outputs. When this occurs, a low impedance to ground would exist at the power inputs to the MC1488 effectively shorting the $300 \Omega$ output resistors to ground. If all four outputs were then shorted to plus or minus 15 V , the power dissipation in these resistors would be excessive. Therefore, if the system is designed to permit low impedances to ground at the power supplies of the drivers, a diode should be placed in each power supply lead to prevent overheating in this fault condition. These two diodes, as shown in Figure 13, could be used to decouple all the driver packages in a system. (These same diodes will allow the MC1488 to withstand momentary shorts to the $\pm 25$ V limits specified in the earlier Standard EIA-232B.) The addition of the diodes also permits the MC1488 to withstand faults with power supplies of less than the 9.0 V stated above.

Figure 13. Power Supply Protection to Meet Power Off Fault Conditions

The maximum short circuit current allowable under fault conditions is more than guaranteed by the previously mentioned 10 mA output current limiting.

## Other Applications

The MC1488 is an extremely versatile line driver with a myriad of possible applications. Several features of the drivers enhance this versatility:

1. Output Current Limiting - this enables the circuit designer to define the output voltage levels independent of power supplies and can be accomplished by diode clamping of the output pins. Figure 14 shows the MC1488 used as a DTL to MOS translator where the high level voltage output is clamped one diode above ground. The resistor divider shown is used to reduce the output voltage below the 300 mV above ground MOS input level limit.
2. Power Supply Range - as can be seen from the schematic drawing of the drivers, the positive and negative driving elements of the device are essentially independent and do not require matching power supplies. In fact, the positive supply can vary from a minimum 7.0 V (required for driving the negative pulldown section) to the maximum specified 15 V . The negative supply can vary from approximately -2.5 V to the minimum specified -15 V . The

Figure 14. MDTL/MTTL-to-MOS Translator

MC1488 will drive the output to within 2.0 V of the positive or negative supplies as long as the current output limits are not exceeded. The combination of the current limiting and supply voltage features allow a wide combination of possible outputs within the same quad package. Thus if only a portion of the four drivers are used for driving EIA-232D lines, the remainder could be used for DTL to MOS or even DTL to DTL translation. Figure 15 shows one such combination.

Figure 15. Logic Translator Applications

## Dual EIA-423/EIA-232D Line Driver

The MC3488A dual is single-ended line driver has been designed to satisfy the requirements of EIA standards EIA-423 and EIA-232D, as well as CCITT X.26, X. 28 and Federal Standard FIDS1030. It is suitable for use where signal wave shaping is desired and the output load resistance is greater than 450 ohms. Output slew rates are adjustable from $1.0 \mu$ s to $100 \mu$ s by a single external resistor. Output level and slew rate are insensitive to power supply variations. Input undershoot diodes limit transients below ground and output current limiting is provided in both output states.

The MC3488A has a standard 1.5 V input logic threshold for TTL or NMOS compatibility.

- PNP Buffered Inputs to Minimize Input Loading
- Short Circuit Protection
- Adjustable Slew Rate Limiting
- MC3488A Equivalent to 9636A
- Output Levels and Slew Rates are Insensitive to Power Supply Voltages
- No External Blocking Diode Required for $V_{E E}$ Supply
- Second Source $\mu$ A9636A

## MC26LS30

## Dual Differential

## (EIA-422-A)/ <br> Quad Single-Ended

 (EIA-423-A) Line DriversThe MC26LS30 is a low power Schottky set of line drivers which can be configured as two differential drivers which comply with EIA-422-A standards, or as four single-ended drivers which comply with EIA-423-A standards. A mode select pin and appropriate choice of power supplies determine the mode. Each driver can source and sink currents in excess of 50 mA .

In the differential mode (EIA-422-A), the drivers can be used up to 10 Mbaud. A disable pin for each driver permits setting the outputs into a high impedance mode within $\mathrm{a}+10 \mathrm{~V}$ common mode range.

In the single-ended mode (EIA-423-A), each driver has a slew rate control pin which permits setting the slew rate of the output signal so as to comply with EIA-423-A and FCC requirements and to reduce crosstalk. When operated from symmetrical supplies (+5.0 V), the outputs exhibit zero imbalance

The MC26LS30 is available in a $16-$ pin surface mount package. Operating temperature range is $-40^{\circ}$ to $+85^{\circ} \mathrm{C}$.

- Operates as Two Differential EIA-422-A Drivers, or Four Single-Ended EIA-423-A Drivers
- High Impedance Outputs in Differential Mode
- Short Circuit Current Limit In Both Source and Sink Modes
- $\pm 10$ V Common Mode Range on High Impedance Outputs
- $\pm 15$ V Range on Inputs
- Low Current PNP Inputs Compatible with TTL, CMOS, and MOS Outputs
- Individual Output Slew Rate Control in Single-Ended Mode
- Replacement for the AMD AM26LS30 and National Semiconductor DS3691

## APPLICATIONS INFORMATION

(Pin numbers refer to SO-16 package only.)

## Description

The MC26LS30 is a dual function line driver - it can be configured as two differential output drivers which comply with EIA-422-A Standard, or as four single-ended drivers which comply with EIA-423-A Standard. The mode of operation is selected with the Mode pin (Pin 4) and appropriate power supplies (see Table 1). Each of the four outputs is capable of sourcing and sinking 60 to 70 mA while providing sufficient voltage to ensure proper data transmission.

As differential drivers, data rates to 10 Mbaud can be transmitted over a twisted pair for a distance determined by the cable characteristics. EIA-422-A Standard provides guidelines for cable length versus data rate. The advantage of a differential (balanced) system over a single-ended system is greater noise immunity, common mode rejection, and higher data rates.

Where extraneous noise sources are not a problem, the MC26LS30 may be configured as four single-ended drivers transmitting data rates to 100 Kbaud . Crosstalk among wires within a cable is controlled by the use of the slew rate control pins on the MC26LS30.

## Mode Selection (Differential Mode)

In this mode (Pins 4 and 8 at ground), only a +5.0 V supply $\pm 5 \%$ is required at $\mathrm{V}_{\mathrm{CC}}$. Pins 2 and 7 are the driver inputs, while Pins $10,11,14$ and 15 are the outputs (see Block Diagram on page 1). The two outputs of a driver are always complementary and the differential voltage available at each pair of outputs is shown in Figure 6 for $\mathrm{V}_{\mathrm{CC}}=5.0 \mathrm{~V}$. The differential output voltage will vary directly with $\mathrm{V}_{\mathrm{CC}}$. A "high" output can only source current, while a "low" output can only sink current (except for short circuit current - see Figure 8).

The two outputs will be in a high impedance mode when the respective Enable input (Pin 3 or 6) is high, or if $\mathrm{V}_{\mathrm{CC}} \leqslant$ 1.1 V . Output leakage current over a common mode range of $\pm 10 \mathrm{~V}$ is typically less than $1.0 \mu \mathrm{~A}$.

The outputs have short circuit current limiting, typically, less than 100 mA over a voltage range of 0 to +6.0 V (see Figure 8). Short circuits should not be allowed to last indefinitely as the IC may be damaged.

Pins $9,12,13$ and 16 are not normally used when in this mode, and should be left open.

## (Single-Ended Mode)

In this mode (Pin $4 \geq 2.0 \mathrm{~V}$ ) $\mathrm{V}_{\mathrm{CC}}$ requires +5.0 V , and $\mathrm{V}_{\mathrm{EE}}$ requires -5.0 V , both $\pm 5.0 \%$. Pins $2,3,6$, and 7 are inputs for the four drivers, and Pins 15, 14, 11, and 10 (respectively) are the outputs. The four drivers are independent of each other, and each output will be at a positive or a negative voltage depending on its input state, the load current, and the supply voltage. Figures $10 \& 11$ indicate the high and low output voltages for $\mathrm{V}_{\mathrm{CC}}=5.0 \mathrm{~V}$, and $\mathrm{V}_{\mathrm{EE}}=-5.0 \mathrm{~V}$. The graph
of Figure 10 will vary directly with $\mathrm{V}_{\mathrm{CC}}$, and the graph of Figure 11 will vary directly with $\mathrm{V}_{\mathrm{EE}}$. A "high" output can only source current, while a "low" output can only sink current (except short circuit current - see Figure 14).
The outputs will be in a high impedance mode only if $\mathrm{V}_{\mathrm{CC}} \leqslant 1.1 \mathrm{~V}$. Changing $\mathrm{V}_{\mathrm{EE}}$ to 0 V does not set the outputs to a high impedance mode. Leakage current over a common mode range of $\pm 10 \mathrm{~V}$ is typically less than $1.0 \mu \mathrm{~A}$.
The outputs have short circuit current limiting, typically less than 100 mA over a voltage range of $\pm 6.0 \mathrm{~V}$ (see Figure 14). Short circuits should not be allowed to last indefinitely as the IC may be damaged.
Capacitors connected between Pins 9, 12, 13, and 16 and their respective outputs will provide slew rate limiting of the output transition. Figure 16 indicates the required capacitor value to obtain a desired rise or fall time (measured between the $10 \%$ and $90 \%$ points). The positive and negative transition times will be within $\approx \pm 5 \%$ of each other. Each output may be set to a different slew rate if desired.

## Inputs

The five inputs determine the state of the outputs in accordance with Table 1. All inputs (regardless of the operating mode) have a nominal threshold of +1.3 V , and their voltage must be kept within a range of 0 V to +15 V for proper operation. If an input is taken more than 0.3 V below ground, excessive currents will flow, and the proper operation of the drivers will be affected. An open pin is equivalent to a logic high, but good design practices dictate that inputs should never be left open. Unused inputs should be connected to ground. The characteristics of the inputs are shown in Figure 9.

## Power Supplies

$\mathrm{V}_{\mathrm{CC}}$ requires $+5.0 \mathrm{~V}, \pm 5 \%$, regardless of the mode of operation. The supply current is determined by the IC's internal bias requirements and the total load current. The internally required current is a function of the load current and is shown in Figure 7 for the differential mode.
In the single-ended mode, $\mathrm{V}_{\text {EE }}$ must be $-5.0 \mathrm{~V}, \pm 5 \%$ in order to comply with EIA-423-A standards. Figures 12 and 13 indicate the internally required bias currents as a function of total load current (the sum of the four output loads). The discontinuity at 0 load current exists due to a change in bias current when the inputs are switched. The supply currents vary $\approx \pm 2.0 \mathrm{~mA}$ as $\mathrm{V}_{\mathrm{CC}}$ and $\mathrm{V}_{\mathrm{EE}}$ are varied from $4.75 \mathrm{~V} \mid$ to $|5.25 \mathrm{~V}|$.
Sequencing of the supplies during power-up/ power-down is not required.
Bypass capacitors ( $0.1 \mu \mathrm{~F}$ minimum on each supply pin) are recommended to ensure proper operation. Capacitors reduce noise induced onto the supply lines by the switching action of the drivers, particularly where long P.C. board tracks are involved. Additionally, the capacitors help absorb
transients induced onto the drivers' outputs from the external cable (from ESD, motor noise, nearby computers, etc.).

## Operating Temperature Range

The maximum ambient operating temperature, listed as $+85^{\circ} \mathrm{C}$, is actually a function of the system use (i.e., specifically how many drivers within a package are used) and at what current levels they are operating. The maximum power which may be dissipated within the package is determined by:

$$
P_{D \max }=\frac{T_{J \max }-T_{A}}{R_{\theta J A}}
$$

where $\mathrm{R}_{\theta \mathrm{JA}}=$ package thermal resistance which is typically:
$120^{\circ} \mathrm{C} / \mathrm{W}$ for the SOIC (D) package,
$\mathrm{T}_{\text {Jmax }}=$ max. allowable junction temperature $\left(150^{\circ} \mathrm{C}\right)$
$\mathrm{T}_{\mathrm{A}}=$ ambient air temperature near the IC package.

1) Differential Mode Power Dissipation

For the differential mode, the power dissipated within the package is calculated from:

$$
\mathrm{P}_{\mathrm{D}}=\left[\left(\mathrm{V}_{\mathrm{CC}}-\mathrm{V}_{\mathrm{OD}}\right) \times \mathrm{IO}_{\mathrm{O}}\right](\text { each driver })+\left(\mathrm{V}_{\mathrm{CC}} \times \mathrm{I}_{\mathrm{B}}\right)
$$

where: $\quad \mathrm{V}_{\mathrm{CC}}=$ the supply voltage

$$
\begin{aligned}
\mathrm{V}_{\mathrm{OD}}= & \text { is taken from Figure } 6 \text { for the known } \\
& \text { value of } \mathrm{I}_{\mathrm{O}}
\end{aligned}
$$

As indicated in the equation, the first term (in brackets) must be calculated and summed for each of the two drivers, while the last term is common to the entire package. Note that the term $\left(\mathrm{V}_{\mathrm{CC}}-\mathrm{V}_{\mathrm{OD}}\right)$ is constant for a given value of $\mathrm{I}_{\mathrm{O}}$ and does not vary with $\mathrm{V}_{\mathrm{CC}}$. For an application involving the following conditions:
$\mathrm{T}_{\mathrm{A}}=+85^{\circ} \mathrm{C}, \mathrm{I}_{\mathrm{O}}=-60 \mathrm{~mA}$ (each driver), $\mathrm{V}_{\mathrm{CC}}=5.25 \mathrm{~V}$, the suitability of the package types is calculated as follows.

The power dissipated is:

$$
\begin{aligned}
& \mathrm{PD}=[3.0 \mathrm{~V} \times 60 \mathrm{~mA} \times 2]+(5.25 \mathrm{~V} \times 18 \mathrm{~mA}) \\
& \mathrm{PD}=454 \mathrm{~mW}
\end{aligned}
$$

The junction temperature calculates to:

$$
\begin{aligned}
\mathrm{T} \mathrm{~J}= & 85^{\circ} \mathrm{C}+\left(0.454 \mathrm{~W} \times 120^{\circ} \mathrm{C} / \mathrm{W}\right)=139^{\circ} \mathrm{C} \text { for the } \\
& \text { SOIC package. }
\end{aligned}
$$

Since the maximum allowable junction temperature is not exceeded in any of the above cases, either package can be used in this application.
2) Single-Ended Mode Power Dissipation

For the single-ended mode, the power dissipated within the package is calculated from:

$$
\begin{aligned}
& \mathrm{PD}_{\mathrm{D}}=\left(\mathrm{I}_{\mathrm{B}}+\times \mathrm{V}_{\mathrm{CC}}\right)+\left(\mathrm{I}_{\mathrm{B}}-\times \mathrm{V}_{\mathrm{EE}}\right)+ \\
& {\left[\left(\mathrm{I}_{\mathrm{O}} \times\left(\mathrm{V}_{\mathrm{CC}}-\mathrm{V}_{\mathrm{OH}}\right)\right](\text { each driver })\right.}
\end{aligned}
$$

The above equation assumes $I_{O}$ has the same magnitude for both output states, and makes use of the fact that the absolute value of the graphs of Figures 10 and 11 are nearly identical. $\mathrm{I}_{\mathrm{B}}+$ and $\mathrm{I}_{\mathrm{B}}-$ are obtained from the right half of Figures 12 and 13 , and $\left(\mathrm{V}_{\mathrm{CC}}-\mathrm{V}_{\mathrm{OH}}\right)$ can be obtained from Figure 10. Note that the term $\left(\mathrm{V}_{\mathrm{CC}}-\mathrm{V}_{\mathrm{OH}}\right)$ is constant for a given value of $\mathrm{I}_{\mathrm{O}}$ and does not vary with $\mathrm{V}_{\mathrm{CC}}$. For an application involving the following conditions:
$\mathrm{T}_{\mathrm{A}}=+85^{\circ} \mathrm{C}, \mathrm{I}_{\mathrm{O}}=-60 \mathrm{~mA}$ (each driver), $\mathrm{V}_{\mathrm{CC}}=5.25 \mathrm{~V}$, $\mathrm{V}_{\mathrm{EE}}=-5.25 \mathrm{~V}$, the suitability of the package types is calculated as follows.

The power dissipated is:

$$
\begin{aligned}
\mathrm{PD}= & (24 \mathrm{~mA} \times 5.25 \mathrm{~V})+(-3.0 \mathrm{~mA} \times-5.25 \mathrm{~V})+ \\
& {[60 \mathrm{~mA} \times 1.45 \mathrm{~V} \times 4.0] } \\
\mathrm{PD}= & 490 \mathrm{~mW}
\end{aligned}
$$

The junction temperature calculates to:

$$
\begin{aligned}
\mathrm{TJ}= & 85^{\circ} \mathrm{C}+\left(0.490 \mathrm{~W} \times 120^{\circ} \mathrm{C} / \mathrm{W}\right)=144^{\circ} \mathrm{C} \text { for the } \\
& \text { SOIC package. }
\end{aligned}
$$

Since the maximum allowable junction temperature is not exceeded in any of the above cases, either package can be used in this application.

## SYSTEM EXAMPLES

(Pin numbers refer to SO-16 package only.)

## Differential System

An example of a typical EIA-422-A system is shown in Figure 17. Although EIA-422-A does not specifically address multiple driver situations, the MC26LS30 can be used in this manner since the outputs can be put into a high impedance mode. It is, however, the system designer's responsibility to ensure the Enable pins are properly controlled so as to prevent two drivers on the same cable from being "on" at the same time.

The limit on the number of receivers and drivers which may be connected on one system is determined by the input current of each receiver, the maximum leakage current of each "off" driver, and the DC current through each terminating resistor. The sum of these currents must not exceed the capability of the "on" driver ( $\approx 60 \mathrm{~mA}$ ). If the cable is of any significant length, with receivers at various points along its length, the common mode voltage may vary along its length, and this parameter must be considered when calculating the maximum driver current.

The cable requirements are defined not only by the AC characteristics and the data rate, but also by the DC resistance. The maximum resistance must be such that the minimum voltage across any receiver inputs is never less than 200 mV .

The ground terminals of each driver and receiver in Figure 17 must be connected together by a dedicated wire (or the shield) in the cable to provide a common reference. Chassis grounds or power line grounds should not be relied on for this common connection as they may generate significant common mode differences. Additionally, they usually do not provide a sufficiently low impedance at the frequencies of interest.

## Single-Ended System

An example of a typical EIA-423-A system is shown in Figure 18. Multiple drivers on a single data line are not possible since the drivers cannot be put into a high impedance mode. Although each driver is shown connected to a single receiver, multiple receivers can be driven from a single driver as long as the total load current of the receivers and the terminating resistor does not exceed the capability of the driver $(\approx 60 \mathrm{~mA})$. If the cable is of any significant length, with receivers at various points along its length, the common mode voltage may vary along its length, and this parameter must be considered when calculating the maximum driver current.

The cable requirements are defined not only by the AC characteristics and the data rate, but also by the DC resistance. The maximum resistance must be such that the
minimum voltage across any receiver inputs is never less than 200 mV .
The ground terminals of each driver and receiver in Figure 18 must be connected together by a dedicated wire (or the shield) in the cable so as to provide a common reference. Chassis grounds or power line grounds should not be relied on for this common connection as they may generate significant common mode differences. Additionally, they usually do not provide a sufficiently low impedance at the frequencies of interest.

## Additional Modes of Operation

If compliance with EIA-422-A or EIA-423-A Standard is not required in a particular application, the MC26LS30 can be operated in two other modes.

1) The device may be operated in the differential mode ( Pin $4=0$ ) with $\mathrm{V}_{\text {EE }}$ connected to any voltage between ground and -5.25 V . Outputs in the low state will be referenced to $\mathrm{V}_{\mathrm{EE}}$, resulting in a differential output voltage greater than that shown in Figure 6. The Enable pins will operate the same as previously described.
2) The device may be operated in the single-ended mode (Pin $4=1$ ) with $\mathrm{V}_{\mathrm{EE}}$ connected to any voltage between ground and -5.25 V . Outputs in the high state will be at a voltage as shown in Figure 10, while outputs in a low state will be referenced to $\mathrm{V}_{\mathrm{EE}}$.

## Termination Resistors

Transmission line theory states that, in order to preserve the shape and integrity of a waveform traveling along a cable, the cable must be terminated in an impedance equal to its characteristic impedance. In a system such as that depicted in Figure 17, in which data can travel in both directions, both physical ends of the cable must be terminated. Stubs leading to each receiver and driver should be as short as possible.
In a system such as that depicted in Figure 18, in which data normally travels in one direction only, a terminator is theoretically required only at the receiving end of the cable. However, if the cable is in a location where noise spikes of several volts can be induced onto it, then a terminator (preferably a series resistor) should be placed at the driver end to prevent damage to the driver.

Leaving off the terminations will generally result in reflections which can have amplitudes of several volts above $\mathrm{V}_{\mathrm{CC}}$ or several volts below ground or $\mathrm{V}_{\mathrm{EE}}$. These overshoots/undershoots can disrupt the driver and/or receiver, create false data, and in some cases, damage components on the bus.

## MC26LS30

1. Terminating resistors $\mathrm{R}_{\mathrm{T}}$ should be located at the physical ends of the cable.
2. Stubs should be as short as possible.
3. Receivers = AM26LS32, MC3486, SN75173 or SN75175.
4. Circuit grounds must be connected together through a dedicated wire.

Figure 18. EIA-423-A Example

## Quad EIA-485 Line Drivers with Three-State Outputs

The ON Semiconductor MC75172B/174B Quad Line drivers are differential high speed drivers designed to comply with the EIA-485 Standard. Features include three-state outputs, thermal shutdown, and output current limiting in both directions. These devices also comply with EIA-422-A, and CCITT Recommendations V. 11 and X. 27 .

The MC75172B/174B are optimized for balanced multipoint bus transmission at rates in excess of 10 MBPS . The outputs feature wide common mode voltage range, making them suitable for party line applications in noisy environments. The current limit and thermal shutdown features protect the devices from line fault conditions. These devices offer optimum performance when used with the MC75173 and MC75175 line receivers.

Both devices are available in 16-pin plastic DIP and 20-pin wide body surface mount packages.

- Meets EIA-485 Standard for Party Line Operation
- Meets EIA-422-A and CCITT Recommendations V. 11 and X. 27
- Operating Ambient Temperature: $-40^{\circ} \mathrm{C}$ to $+85^{\circ} \mathrm{C}$
- High Impedance Outputs
- Common Mode Output Voltage Range: -7 to 12 V
- Positive and Negative Current Limiting
- Transmission Rates in Excess of 10 MBPS
- Thermal Shutdown at $150^{\circ} \mathrm{C}$ Junction Temperature, $\left( \pm 20^{\circ} \mathrm{C}\right)$
- Single 5.0 V Supply
- Pin Compatible with TI SN75172/4 and NS $\mu$ A96172/4
- Interchangeable with MC3487 and AM26LS31 for EIA-422-A Applications

## APPLICATIONS INFORMATION

## Description

The MC75172B and MC75174B are differential line drivers designed to comply with EIA-485 Standard (April 1983) for use in balanced digital multipoint systems containing multiple drivers. The drivers also comply with EIA-422-A and CCITT Recommendations V. 11 and X.27. The drivers meet the EIA-485 requirement for protection from damage in the event that two or more drivers attempt to transmit data simultaneously on the same cable. Data rates in excess of 10 MBPS are possible, depending on the cable length and cable characteristics. A single power supply, $5.0 \mathrm{~V}, \pm 5 \%$, is required at a nominal current of 60 mA , plus load currents.

## Outputs

Each output (when active) will be a low or a high voltage, which depends on the input state and the load current (see Table 1, 2 and Figures 7 to 10). The graphs apply to each driver, regardless of how many other drivers within the package are supplying load current.

Table 1. MC75172B Truth Table

|  | Enables |  | Outputs |  |
| :---: | :---: | :---: | :---: | :---: |
| Data Input | EN | EN | Y | Z |
| H | H | X | H | L |
| L | H | X | L | H |
| H | X | L | H | L |
| L | X | L | L | H |
| X | L | H | Z | Z |

Table 2. MC75174B Truth Table

|  |  | Outputs |  |
| :---: | :---: | :---: | :---: |
| Data Input | Enable | Y | Z |
| H | H | H | L |
| L | H | L | H |
| X | L | Z | Z |

$\mathrm{H}=$ Logic high, $\mathrm{L}=$ Logic low, $\mathrm{X}=$ Irrelevant, $\mathrm{Z}=$ High impedance
The two outputs of a driver are always complementary. A "high" output can only source current out, while a "low" output can only sink current (except for short circuit current - see Figure 16).

The outputs will be in the high impedance mode when:
a) the Enable inputs are set according to Table 1 or 2;
b) $\mathrm{V}_{\mathrm{CC}}$ is less than 1.5 V ;
c) the junction temperature exceeds the trip point of the thermal shutdown circuit (see below). When in this condition, the output's source and sink capability are shut off, and only leakage currents will flow (see Figures 13, 14). Disabled outputs may be taken to any voltage between -7.0 V and 12 V without damage.

The drivers are protected from short circuits by two methods:
a) Current limiting is provided at each output, in both the source and sink direction, for shorts to any voltage within the range of 12 V to -7.0 V , with respect to circuit ground (see Figure 16). The short circuit current will flow until the fault is removed, or until the thermal shutdown circuit activates (see below). The current limiting circuit has a negative temperature coefficient and requires no resetting upon removal of the fault condition.
b) A thermal shutdown circuit disables the outputs when the junction temperature reaches $150^{\circ} \mathrm{C}$, $\pm 20^{\circ} \mathrm{C}$. The thermal shutdown circuit has a hysteresis of $\approx 12^{\circ} \mathrm{C}$ to prevent oscillations. When this circuit activates, the output stage of each driver is put into the high impedance mode, thereby shutting off the output currents. The remainder of the internal circuitry remains biased. The outputs will become active once again as the IC cools down.

## Driver Inputs

The driver inputs determine the state of the outputs in accordance with Tables 1 and 2. The driver inputs have a nominal threshold of 1.2 V , and their voltage must be kept within the range of 0 V to $\mathrm{V}_{\mathrm{CC}}$ for proper operation. If the voltage is taken more than 0.5 V below ground, excessive currents will flow, and proper operation of the drivers will be affected. An open pin is equivalent to a logic high, but good design practices dictate that inputs should never be left open. The characteristics of the driver inputs are shown in Figure 15. This graph is not affected by the state of the Enable pins.

## Enable Logic

Each driver's outputs are active when the Enable inputs (Pins 4 and 12) are true according to Tables 1 and 2.

The Enable inputs have a nominal threshold of 1.2 V and their voltage must be kept within the range of 0 V to $\mathrm{V}_{\mathrm{CC}}$ for proper operation. If the voltage is taken more than 0.5 V below ground, excessive currents will flow, and proper operation of the drivers will be affected. An open pin is equivalent to a logic high, but good design practices dictate that inputs should never be left open. The Enable input characteristics are shown in Figure 15.

## Operating Temperature Range

The minimum ambient operating temperature is listed as $-40^{\circ} \mathrm{C}$ to meet EIA- 485 specifications, and $0^{\circ} \mathrm{C}$ to meet EIA-422-A specifications. The higher $\mathrm{V}_{\mathrm{OD}}$ required by EIA-422-A is the reason for the narrower temperature range.

The maximum ambient operating temperature (applicable to both EIA-485 and EIA-422-A) is listed as $85^{\circ} \mathrm{C}$. However, a lower ambient may be required depending on system use (i.e. specifically how many drivers within a package are used) and at what current levels they are operating. The maximum power which may be dissipated within the package is determined by:

$$
P D_{\max }=\frac{\mathrm{T}_{\mathrm{Jmax}}{ }^{-\mathrm{T}_{\mathrm{A}}}}{\mathrm{R}_{\theta J A}}
$$

where: $\quad \mathrm{R}_{\theta J \mathrm{~A}}=$ package thermal resistance (typical $70^{\circ} \mathrm{C} / \mathrm{W}$ for the DIP package, $85^{\circ} \mathrm{C} / \mathrm{W}$ for SOIC package);
$\mathrm{T}_{\mathrm{Jmax}}=$ max. operating junction
temperature, and
$\mathrm{T}_{\mathrm{A}}=$ ambient temperature.
Since the thermal shutdown feature has a trip point of $150^{\circ} \mathrm{C}, \pm 20^{\circ} \mathrm{C}, \mathrm{T}_{\text {Jmax }}$ is selected to be $130^{\circ} \mathrm{C}$. The power dissipated within the package is calculated from:
PD

$$
\left.=\left\{\left[\left(\mathrm{V}_{\mathrm{CC}}-\mathrm{V}_{\mathrm{OH}}\right) \bullet \mathrm{I}_{\mathrm{OH}}\right]+\mathrm{V}_{\mathrm{OL}} \bullet \mathrm{I}_{\mathrm{OL}}\right)\right\} \text { each }
$$

$$
\text { driver }+\left(\mathrm{V}_{\mathrm{CC}} \bullet \mathrm{I}_{\mathrm{CC}}\right)
$$

where: $\quad \mathrm{V}_{\mathrm{CC}}=$ the supply voltage;
$\mathrm{V}_{\mathrm{OH}}, \mathrm{V}_{\mathrm{OL}}$ are measured or estimated from
Figures 7 to 10;
$\mathrm{I}_{\mathrm{CC}}=$ the quiescent power supply current (typical 60 mA ).
As indicated in the equation, the first term (in brackets) must be calculated and summed for each of the four drivers, while the last term is common to the entire package.

Example 1: $\mathrm{T}_{\mathrm{A}}=25^{\circ} \mathrm{C}, \mathrm{I}_{\mathrm{OL}}=\mathrm{I}_{\mathrm{OH}}=55 \mathrm{~mA}$ for each driver, $\mathrm{V}_{\mathrm{CC}}=5.0 \mathrm{~V}$, DIP package. How many drivers per package can be used?

Maximum allowable power dissipation is:

$$
\mathrm{PD}_{\max }=\frac{130^{\circ} \mathrm{C}-25^{\circ} \mathrm{C}}{70^{\circ} \mathrm{C} / \mathrm{W}}=1.5 \mathrm{~W}
$$

Since the power supply current of 60 mA dissipates 300 mW , that leaves $1.2 \mathrm{~W}(1.5 \mathrm{~W}-0.3 \mathrm{~W})$ for the drivers. From Figures 7 and $9, \mathrm{~V}_{\mathrm{OL}} \approx 1.75 \mathrm{~V}$, and $\mathrm{V}_{\mathrm{OH}} \approx 3.85 \mathrm{~V}$. The power dissipated in each driver is:
$\{(5.0-3.85) \bullet 0.055\}+(1.75 \bullet 0.055)=160 \mathrm{~mW}$.
Since each driver dissipates 160 mW , the four drivers per package could be used in this application.

Example 2: $\mathrm{T}_{\mathrm{A}}=85^{\circ} \mathrm{C}, \mathrm{I}_{\mathrm{OL}}=27.8 \mathrm{~mA}, \mathrm{I}_{\mathrm{OH}}=20 \mathrm{~mA}$ for each driver, $\mathrm{V}_{\mathrm{CC}}=5.0 \mathrm{~V}$, SOIC package. How many drivers per package can be used?

Maximum allowable power dissipation is:

$$
\mathrm{PD}_{\max }=\frac{130^{\circ} \mathrm{C}-85^{\circ} \mathrm{C}}{85^{\circ} \mathrm{C} / \mathrm{W}}=0.53 \mathrm{~W}
$$

Since the power supply current of 60 mA dissipates 300 mW , that leaves $230 \mathrm{~mW}(530 \mathrm{~mW}-300 \mathrm{~mW})$ for the
drivers. From Figures 8 and 10 (adjusted for $\mathrm{V}_{\mathrm{CC}}=5.0 \mathrm{~V}$ ), $\mathrm{V}_{\mathrm{OL}} \approx 1.38 \mathrm{~V}$, and $\mathrm{V}_{\mathrm{OH}} \approx 4.27 \mathrm{~V}$. The power dissipated in each driver is:

$$
\{(5.0-4.27) \bullet 0.020\}+(1.38 \bullet 0.0278)=53 \mathrm{~mW}
$$

Since each driver dissipates 53 mW , the use of all four drivers in a package would be marginal. Options include reducing the load current, reducing the ambient temperature, and/or providing a heat sink.

## System Requirements

EIA-485 requires each driver to be capable of transmitting data differentially to at least 32 unit loads, plus an equivalent DC termination resistance of $60 \Omega$, over a common mode voltage of -7.0 to 12 V . A unit load (U.L.), as defined by EIA-485, is shown in Figure 17.

Reprinted from EIA-485, Electronic Industries Association, Washington,DC.

Figure 17. Unit Load Definition

A load current within the shaded regions represents an impedance of less than one U.L., while a load current of a magnitude outside the shaded area is greater than one U.L. A system's total load is the sum of the unit load equivalents of each receiver's input current, and each disabled driver's output leakage current. The $60 \Omega$ termination resistance mentioned above allows for two $120 \Omega$ terminating resistors.
Using the EIA-485 requirements (worst case limits), and the graphs of Figures 7 and 9, it can be determined that the maximum current an MC75172B or MC75174B driver will source or sink is $\approx 65 \mathrm{~mA}$.

## System Example

An example of a typical EIA-485 system is shown in Figure 18. In this example, it is assumed each receiver's input characteristics correspond to 1.0 U.L. as defined in Figure 17. Each "off" driver, with a maximum leakage of $\pm 50 \mu \mathrm{~A}$ over the common mode range, presents a load of $\approx 0.06$ U.L. The total load for the active driver is therefore 8.3 unit loads, plus the parallel combination of the two terminating resistors ( $60 \Omega$ ). It is up to the system software to control the driver Enable pins to ensure that only one driver is active at any time.

## MC75172B MC75174B

## Termination Resistors

Transmission line theory states that, in order to preserve the shape and integrity of a waveform traveling along a cable, the cable must be terminated in an impedance equal to its characteristic impedance. In a system such as that depicted in Figure 18, in which data can travel in both directions, both physical ends of the cable must be terminated. Stubs, leading to each receiver and driver, should be as short as possible.

Leaving off the terminations will generally result in reflections which can have amplitudes of several volts above $\mathrm{V}_{\mathrm{CC}}$ or below ground. These overshoots and undershoots can disrupt the driver and/or receiver operation, create false data, and in some cases damage components on the bus.

NOTES: 1. Compliance with V. 11 and X. 27 (Blue book) output impedance requires external resistors in series with the outputs of the MC75172B and MC75174B. 2. $\mathrm{T}_{\mathrm{B}}=$ Bit time.

## Additional Information

Copies of the EIA Recommendations (EIA-485 and EIA-422-A) can be obtained from the Electronics Industries Association, Washington, D.C. (202-457-4966). Copies of the CCITT Recommendations (V. 11 and X.27) can be obtained from the United States Department of Commerce, Springfield, VA (703-487-4600).

## Timers

The MC1455 monolithic timing circuit is a highly stable controller capable of producing accurate time delays or oscillation. Additional terminals are provided for triggering or resetting if desired. In the time delay mode, time is precisely controlled by one external resistor and capacitor. For astable operation as an oscillator, the free-running frequency and the duty cycle are both accurately controlled with two external resistors and one capacitor. The circuit may be triggered and reset on falling waveforms, and the output structure can source or sink up to 200 mA or drive MTTL circuits.

- Direct Replacement for NE555 Timers
- Timing from Microseconds through Hours
- Operates in Both Astable and Monostable Modes
- Adjustable Duty Cycle
- High Current Output Can Source or Sink 200 mA
- Output Can Drive MTTL
- Temperature Stability of $0.005 \%$ per ${ }^{\circ} \mathrm{C}$
- Normally ON or Normally OFF Output
 changing $R$ and $C$ (see Figure 16).

## GENERAL OPERATION

The MC1455 is a monolithic timing circuit which uses an external resistor - capacitor network as its timing element. It can be used in both the monostable (one-shot) and astable modes with frequency and duty cycle controlled by the capacitor and resistor values. While the timing is dependent upon the external passive components, the monolithic circuit provides the starting circuit, voltage comparison and other functions needed for a complete timing circuit. Internal to the integrated circuit are two comparators, one for the input signal and the other for capacitor voltage; also a flip-flop and digital output are included. The comparator reference voltages are always a fixed ratio of the supply voltage thus providing output timing independent of supply voltage.

## Monostable Mode

In the monostable mode, a capacitor and a single resistor are used for the timing network. Both the threshold terminal and the discharge transistor terminal are connected together in this mode (refer to circuit in Figure 14). When the input voltage to the trigger comparator falls below $1 / 3 \mathrm{~V}_{\mathrm{CC}}$, the comparator output triggers the flip-flop so that its output sets low. This turns the capacitor discharge transistor "off" and drives the digital output to the high state. This condition allows the capacitor to charge at an exponential rate which is set by the RC time constant. When the capacitor voltage reaches $2 / 3 \mathrm{~V}_{\mathrm{CC}}$, the threshold comparator resets the flip-flop. This action discharges the timing capacitor and returns the digital output to the low state. Once the flip-flop
has been triggered by an input signal, it cannot be retriggered until the present timing period has been completed. The time that the output is high is given by the equation $t=1.1 \mathrm{R}_{\mathrm{A}} \mathrm{C}$. Various combinations of R and C and their associated times are shown in Figure 16. The trigger pulse width must be less than the timing period.

A reset pin is provided to discharge the capacitor, thus interrupting the timing cycle. As long as the reset pin is low, the capacitor discharge transistor is turned "on" and prevents the capacitor from charging. While the reset voltage is applied the digital output will remain the same. The reset pin should be tied to the supply voltage when not in use.

Figure 17. Astable Circuit

## Astable Mode

In the astable mode the timer is connected so that it will retrigger itself and cause the capacitor voltage to oscillate between $1 / 3 V_{C C}$ and $2 / 3 V_{C C}$. See Figure 17.

The external capacitor changes to $2 / 3 \mathrm{~V}_{\mathrm{CC}}$ through $\mathrm{R}_{\mathrm{A}}$ and $R_{B}$ and discharges to $1 / 3 V_{C C}$ through $R_{B}$. By varying the ratio of these resistors the duty cycle can be varied. The charge and discharge times are independent of the supply voltage.
The charge time (output high) is given by:

$$
t_{1}=0.695\left(R_{A}+R_{B}\right) C
$$

The discharge time (output low) is given by:

$$
t_{2}=0.695\left(R_{B}\right) C
$$

Thus the total period is given by:

$$
T=t_{1}+t_{2}=0.695\left(R_{A}+2 R_{B}\right) C
$$

The frequency of oscillation is then: $f=\frac{1}{T}=\frac{1.44}{\left(R_{A}+2 R_{B}\right) C}$ and may be easily found as shown in Figure 19.
The duty cycle is given by: $D C=\frac{R_{B}}{R_{A}+2 R_{B}}$
To obtain the maximum duty cycle $\mathrm{R}_{\mathrm{A}}$ must be as small as possible; but it must also be large enough to limit the

## APPLICATIONS INFORMATION

## Linear Voltage Ramp

In the monostable mode, the resistor can be replaced by a constant current source to provide a linear ramp voltage. The capacitor still charges from $0 \mathrm{~V}_{\mathrm{CC}}$ to $2 / 3 \mathrm{~V}_{\mathrm{CC}}$. The linear ramp time is given by:

$$
t=\frac{2}{3} \frac{V_{C C}}{1} \text {, where } I=\frac{V_{C C}-V_{B}-V_{B E}}{R_{E}}
$$

If $V_{B}$ is much larger than $V_{B E}$, then $t$ can be made independent of $\mathrm{V}_{\mathrm{CC}}$.

Figure 22. Linear Voltage Ramp Waveforms

## Missing Pulse Detector

The timer can be used to produce an output when an input pulse fails to occur within the delay of the timer. To accomplish this, set the time delay to be slightly longer than the time between successive input pulses. The timing cycle is then continuously reset by the input pulse train until a change in frequency or a missing pulse allows completion of the timing cycle, causing a change in the output level.

Figure 21. Missing Pulse Detector

Figure 23. Missing Pulse Detector Waveforms

## Pulse Width Modulation

If the timer is triggered with a continuous pulse train in the monstable mode of operation, the charge time of the capacitor can be varied by changing the control voltage at Pin 5. In this manner, the output pulse width can be modulated by applying a modulating signal that controls the threshold voltage.

Figure 24. Pulse Width Modulator

Figure 25. Pulse Width Modulation Waveforms

## Test Sequences

Several timers can be connected to drive each other for sequential timing. An example is shown in Figure 26 where the sequence is started by triggering the first timer which runs for 10 ms . The output then switches low momentarily and starts the second timer which runs for 50 ms and so forth.

## GENERAL OPERATING INFORMATION

## Carrier Feedthrough

Carrier feedthrough is defined as the output voltage at carrier frequency with only the carrier applied (signal voltage $=0$ ).

Carrier null is achieved by balancing the currents in the differential amplifier by means of a bias trim potentiometer (R1 of Figure 5).

## Carrier Suppression

Carrier suppression is defined as the ratio of each sideband output to carrier output for the carrier and signal voltage levels specified.

Carrier suppression is very dependent on carrier input level, as shown in Figure 22. A low value of the carrier does not fully switch the upper switching devices, and results in lower signal gain, hence lower carrier suppression. A higher than optimum carrier level results in unnecessary device and circuit carrier feedthrough, which again degenerates the suppression figure. The MC1496 has been characterized with a 60 mVrms sinewave carrier input signal. This level provides optimum carrier suppression at carrier frequencies in the vicinity of 500 kHz , and is generally recommended for balanced modulator applications.

Carrier feedthrough is independent of signal level, $\mathrm{V}_{\mathrm{S}}$. Thus carrier suppression can be maximized by operating with large signal levels. However, a linear operating mode must be maintained in the signal-input transistor pair - or harmonics of the modulating signal will be generated and appear in the device output as spurious sidebands of the suppressed carrier. This requirement places an upper limit on input-signal amplitude (see Figure 20). Note also that an optimum carrier level is recommended in Figure 22 for good carrier suppression and minimum spurious sideband generation.

At higher frequencies circuit layout is very important in order to minimize carrier feedthrough. Shielding may be necessary in order to prevent capacitive coupling between the carrier input leads and the output leads.

## Signal Gain and Maximum Input Level

Signal gain (single-ended) at low frequencies is defined as the voltage gain,

$$
A_{V S}=\frac{V_{0}}{V_{S}}=\frac{R_{L}}{R_{e}+2 r_{e}} \text { where } r_{e}=\frac{26 \mathrm{mV}}{15(\mathrm{~mA})}
$$

A constant dc potential is applied to the carrier input terminals to fully switch two of the upper transistors "on" and two transistors "off" ( $\left.\mathrm{V}_{\mathrm{C}}=0.5 \mathrm{Vdc}\right)$. This in effect forms a cascode differential amplifier.

Linear operation requires that the signal input be below a critical value determined by $\mathrm{R}_{\mathrm{E}}$ and the bias current I5.

$$
V_{S} \leqslant 15 R_{E}(\text { Volts peak })
$$

Note that in the test circuit of Figure $10, \mathrm{~V}_{\mathrm{S}}$ corresponds to a maximum value of 1.0 V peak.

## Common Mode Swing

The common-mode swing is the voltage which may be applied to both bases of the signal differential amplifier, without saturating the current sources or without saturating the differential amplifier itself by swinging it into the upper switching devices. This swing is variable depending on the particular circuit and biasing conditions chosen.

## Power Dissipation

Power dissipation, $\mathrm{P}_{\mathrm{D}}$, within the integrated circuit package should be calculated as the summation of the voltage-current products at each port, i.e. assuming $\mathrm{V} 12=\mathrm{V} 6, \mathrm{I} 5=\mathrm{I} 6=\mathrm{I} 12$ and ignoring base current, $\left.\mathrm{P}_{\mathrm{D}}=2 \mathrm{I} 5(\mathrm{~V} 6-\mathrm{V} 14)+\mathrm{I} 5\right) \mathrm{V} 5-\mathrm{V} 14$ where subscripts refer to pin numbers.

## Design Equations

The following is a partial list of design equations needed to operate the circuit with other supply voltages and input conditions.

## A. Operating Current

The internal bias currents are set by the conditions at Pin 5. Assume:

$$
\begin{aligned}
& \mathrm{I} 5=\mathrm{I} 6=\mathrm{I} 12, \\
& \mathrm{I}_{\mathrm{B}} \ll \mathrm{I}_{\mathrm{C}} \text { for all transistors }
\end{aligned}
$$

then :

$$
R 5=\frac{V--\phi}{I 5}-500 \Omega \begin{aligned}
& \text { where: } \begin{array}{l}
\text { R5 is the resistor between } \\
\text { Pin } 5 \text { and ground } \\
\phi=0.75 \text { at } T_{A}=+25^{\circ} \mathrm{C}
\end{array}
\end{aligned}
$$

The MC1496 has been characterized for the condition $\mathrm{I}_{5}=1.0 \mathrm{~mA}$ and is the generally recommended value.
B. Common-Mode Quiescent Output Voltage

$$
\mathrm{V} 6=\mathrm{V} 12=\mathrm{V}+-\mathrm{I} 5 \mathrm{R}_{\mathrm{L}}
$$

## Biasing

The MC1496 requires three dc bias voltage levels which must be set externally. Guidelines for setting up these three levels include maintaining at least 2.0 V collector-base bias on all transistors while not exceeding the voltages given in the absolute maximum rating table;

$$
\begin{aligned}
& 30 \mathrm{Vdc} \geq[(\mathrm{V} 6, \mathrm{~V} 12)-(\mathrm{V} 8, \mathrm{~V} 10)] \geq 2 \mathrm{Vdc} \\
& 30 \mathrm{Vdc} \geq[(\mathrm{V} 8, \mathrm{~V} 10)-(\mathrm{V} 1, \mathrm{~V} 4)] \geq 2.7 \mathrm{Vdc} \\
& 30 \mathrm{Vdc} \geq[(\mathrm{V} 1, \mathrm{~V} 4)-(\mathrm{V} 5)] \geq 2.7 \mathrm{Vdc}
\end{aligned}
$$

The foregoing conditions are based on the following approximations:

$$
\mathrm{V} 6=\mathrm{V} 12, \mathrm{~V} 8=\mathrm{V} 10, \mathrm{~V} 1=\mathrm{V} 4
$$

## MC1496, MC1496B

Bias currents flowing into Pins $1,4,8$ and 10 are transistor base currents and can normally be neglected if external bias dividers are designed to carry 1.0 mA or more.

## Transadmittance Bandwidth

Carrier transadmittance bandwidth is the 3.0 dB bandwidth of the device forward transadmittance as defined by:

$$
\left.\gamma 21 \mathrm{C}=\frac{\mathrm{i}_{\mathrm{O}}(\text { each sideband })}{\mathrm{v}_{\mathrm{S}}(\text { signal })} \right\rvert\, \mathrm{V}_{\mathrm{O}}=0
$$

Signal transadmittance bandwidth is the 3.0 dB bandwidth of the device forward transadmittance as defined by:

$$
\left.\gamma 21 \mathrm{~S}=\frac{\mathrm{i}_{\mathrm{O}}(\text { signal })}{\mathrm{v}_{\mathrm{S}}(\text { signal })} \right\rvert\, \mathrm{V}_{\mathrm{c}}=0.5 \mathrm{Vdc}, \mathrm{~V}_{\mathrm{O}}=0
$$

## Coupling and Bypass Capacitors

Capacitors C1 and C2 (Figure 5) should be selected for a reactance of less than $5.0 \Omega$ at the carrier frequency.

## Output Signal

The output signal is taken from Pins 6 and 12 either balanced or single-ended. Figure 11 shows the output levels of each of the two output sidebands resulting from variations
in both the carrier and modulating signal inputs with a single-ended output connection.

## Negative Supply

$\mathrm{V}_{\mathrm{EE}}$ should be dc only. The insertion of an RF choke in series with $\mathrm{V}_{\mathrm{EE}}$ can enhance the stability of the internal current sources.

## Signal Port Stability

Under certain values of driving source impedance, oscillation may occur. In this event, an RC suppression network should be connected directly to each input using short leads. This will reduce the Q of the source-tuned circuits that cause the oscillation.

An alternate method for low-frequency applications is to insert a $1.0 \mathrm{k} \Omega$ resistor in series with the input (Pins 1, 4). In this case input current drift may cause serious degradation of carrier suppression.

## OPERATIONS INFORMATION

The MC1496, a monolithic balanced modulator circuit, is shown in Figure 23.

This circuit consists of an upper quad differential amplifier driven by a standard differential amplifier with dual current sources. The output collectors are cross-coupled so that full-wave balanced multiplication of the two input voltages occurs. That is, the output signal is a constant times the product of the two input signals.

Mathematical analysis of linear ac signal multiplication indicates that the output spectrum will consist of only the sum and difference of the two input frequencies. Thus, the device may be used as a balanced modulator, doubly balanced mixer, product detector, frequency doubler, and other applications requiring these particular output signal characteristics.

The lower differential amplifier has its emitters connected to the package pins so that an external emitter resistance may be used. Also, external load resistors are employed at the device output.

## Signal Levels

The upper quad differential amplifier may be operated either in a linear or a saturated mode. The lower differential amplifier is operated in a linear mode for most applications.

For low-level operation at both input ports, the output signal will contain sum and difference frequency
components and have an amplitude which is a function of the product of the input signal amplitudes.

For high-level operation at the carrier input port and linear operation at the modulating signal port, the output signal will contain sum and difference frequency components of the modulating signal frequency and the fundamental and odd harmonics of the carrier frequency. The output amplitude will be a constant times the modulating signal amplitude. Any amplitude variations in the carrier signal will not appear in the output.

The linear signal handling capabilities of a differential amplifier are well defined. With no emitter degeneration, the maximum input voltage for linear operation is approximately 25 mV peak. Since the upper differential amplifier has its emitters internally connected, this voltage applies to the carrier input port for all conditions.

Since the lower differential amplifier has provisions for an external emitter resistance, its linear signal handling range may be adjusted by the user. The maximum input voltage for linear operation may be approximated from the following expression:

$$
\mathrm{V}=(\mathrm{I} 5)\left(\mathrm{R}_{\mathrm{E}}\right) \text { volts peak. }
$$

This expression may be used to compute the minimum value of $\mathrm{R}_{\mathrm{E}}$ for a given input voltage amplitude.

Figure 24. Typical Modulator Circuit

| Carrier Input Signal ( $\mathrm{V}_{\mathrm{C}}$ ) | Approximate Voltage Gain | Output Signal Frequency(s) |
| :---: | :---: | :---: |
| Low-level dc | $\frac{R_{L} V_{C}}{2\left(R_{E}+2 r_{e}\right)\left(\frac{K T}{q}\right)}$ | $f_{M}$ |
| High-level dc | $\frac{R_{L}}{R_{E}+2 r_{e}}$ | $f_{M}$ |
| Low-level ac | $\frac{R_{L} V_{C}(r m s)}{2 \sqrt{2}\left(\frac{K T}{q}\right)\left(R_{E}+2 r_{e}\right)}$ | $f_{C} \pm f_{M}$ |
| High-level ac | $\frac{0.637 R_{L}}{R_{E}+2 r_{e}}$ | $f_{C} \pm f_{M}, 3 f_{C} \pm f_{M}, 5 f_{C} \pm f_{M}, \ldots$ |

2. Low-level Modulating Signal, $\mathrm{V}_{\mathrm{M}}$, assumed in all cases. $\mathrm{V}_{\mathrm{C}}$ is Carrier Input Voltage.
3. When the output signal contains multiple frequencies, the gain expression given is for the output amplitude ofeach of the two desired outputs, $f_{C}+f_{M}$ and $f_{C}-f_{M}$.
4. All gain expressions are for a single-ended output. For a differential output connection, multiply each expression by two.
5. $R_{L}=$ Load resistance.
6. $\mathrm{R}_{\mathrm{E}}=$ Emitter resistance between Pins 2 and 3 .
7. $r_{e}=$ Transistor dynamic emitter resistance, at $25^{\circ} \mathrm{C}$;

$$
\mathrm{re} \approx \frac{26 \mathrm{mV}}{15(\mathrm{~mA})}
$$

8. $\mathrm{K}=$ Boltzmann's Constant, $\mathrm{T}=$ temperature in degrees Kelvin, $\mathrm{q}=$ the charge on an electron.
$\frac{K T}{q} \approx 26 \mathrm{mV}$ at room temperature
Figure 25. Voltage Gain and Output Frequencies

The gain from the modulating signal input port to the output is the MC1496 gain parameter which is most often of interest to the designer. This gain has significance only when the lower differential amplifier is operated in a linear mode, but this includes most applications of the device.

As previously mentioned, the upper quad differential amplifier may be operated either in a linear or a saturated mode. Approximate gain expressions have been developed for the MC1496 for a low-level modulating signal input and the following carrier input conditions:

1) Low-level dc
2) High-level dc
3) Low-level ac
4) High-level ac

These gains are summarized in Figure NO TAG, along with the frequency components contained in the output signal.

## APPLICATIONS INFORMATION

Double sideband suppressed carrier modulation is the basic application of the MC1496. The suggested circuit for this application is shown on the front page of this data sheet.

In some applications, it may be necessary to operate the MC1496 with a single dc supply voltage instead of dual supplies. Figure 26 shows a balanced modulator designed for operation with a single 12 Vdc supply. Performance of this circuit is similar to that of the dual supply modulator.

## AM Modulator

The circuit shown in Figure 27 may be used as an amplitude modulator with a minor modification.

All that is required to shift from suppressed carrier to AM operation is to adjust the carrier null potentiometer for the proper amount of carrier insertion in the output signal.
However, the suppressed carrier null circuitry as shown in Figure 27 does not have sufficient adjustment range. Therefore, the modulator may be modified for AM operation by changing two resistor values in the null circuit as shown in Figure 28.

## Product Detector

The MC1496 makes an excellent SSB product detector (see Figure 29).

This product detector has a sensitivity of 3.0 microvolts and a dynamic range of 90 dB when operating at an intermediate frequency of 9.0 MHz .

The detector is broadband for the entire high frequency range. For operation at very low intermediate frequencies down to 50 kHz the $0.1 \mu \mathrm{~F}$ capacitors on Pins 8 and 10 should be increased to $1.0 \mu \mathrm{~F}$. Also, the output filter at Pin 12 can be tailored to a specific intermediate frequency and audio amplifier input impedance.

As in all applications of the MC1496, the emitter resistance between Pins 2 and 3 may be increased or decreased to adjust circuit gain, sensitivity, and dynamic range.

This circuit may also be used as an AM detector by introducing carrier signal at the carrier input and an AM signal at the SSB input.
The carrier signal may be derived from the intermediate frequency signal or generated locally. The carrier signal may be introduced with or without modulation, provided its level

## MC1496, MC1496B

is sufficiently high to saturate the upper quad differential amplifier. If the carrier signal is modulated, a 300 mVrms input level is recommended.

## Doubly Balanced Mixer

The MC1496 may be used as a doubly balanced mixer with either broadband or tuned narrow band input and output networks.

The local oscillator signal is introduced at the carrier input port with a recommended amplitude of 100 mVrms .

Figure 30 shows a mixer with a broadband input and a tuned output.

## Frequency Doubler

The MC1496 will operate as a frequency doubler by introducing the same frequency at both input ports.

Figures 31 and 32 show a broadband frequency doubler and a tuned output very high frequency (VHF) doubler, respectively.

## Phase Detection and FM Detection

The MC1496 will function as a phase detector. High-level input signals are introduced at both inputs. When both inputs are at the same frequency the MC1496 will deliver an output which is a function of the phase difference between the two input signals.
An FM detector may be constructed by using the phase detector principle. A tuned circuit is added at one of the inputs to cause the two input signals to vary in phase as a function of frequency. The MC1496 will then provide an output which is a function of the input signal frequency.

## Brushless DC Motor Controller

The MC33033 is a high performance second generation, limited feature, monolithic brushless dc motor controller which has evolved from ON Semiconductor's full featured MC33034 and MC33035 controllers. It contains all of the active functions required for the implementation of open loop, three or four phase motor control. The device consists of a rotor position decoder for proper commutation sequencing, temperature compensated reference capable of supplying sensor power, frequency programmable sawtooth oscillator, fully accessible error amplifier, pulse width modulator comparator, three open collector top drivers, and three high current totem pole bottom drivers ideally suited for driving power MOSFETs. Unlike its predecessors, it does not feature separate drive circuit supply and ground pins, brake input, or fault output signal.

Included in the MC33033 are protective features consisting of undervoltage lockout, cycle-by-cycle current limiting with a selectable time delayed latched shutdown mode, and internal thermal shutdown.

Typical motor control functions include open loop speed, forward or reverse direction, and run enable. The MC33033 is designed to operate brushless motors with electrical sensor phasings of $60^{\circ} / 300^{\circ}$ or $120^{\circ} / 240^{\circ}$, and can also efficiently control brush dc motors.

- 10 to 30 V Operation
- Undervoltage Lockout
- 6.25 V Reference Capable of Supplying Sensor Power
- Fully Accessible Error Amplifier for Closed Loop Servo Applications
- High Current Drivers Can Control External 3-Phase MOSFET Bridge
- Cycle-By-Cycle Current Limiting
- Internal Thermal Shutdown
- Selectable $60^{\circ} / 300^{\circ}$ or $120^{\circ} / 240^{\circ}$ Sensor Phasings
- Also Efficiently Control Brush DC Motors with External MOSFET H-Bridge

## INTRODUCTION

The MC33033 is one of a series of high performance monolithic dc brushless motor controllers produced by ON Semiconductor. It contains all of the functions required to implement a limited-feature, open loop, three or four phase motor control system. Constructed with Bipolar Analog technology, it offers a high degree of performance and ruggedness in hostile industrial environments. The MC33033 contains a rotor position decoder for proper commutation sequencing, a temperature compensated reference capable of supplying sensor power, a frequency programmable sawtooth oscillator, a fully accessible error amplifier, a pulse width modulator comparator, three open collector top drive outputs, and three high current totem pole bottom driver outputs ideally suited for driving power MOSFETs.

Included in the MC33033 are protective features consisting of undervoltage lockout, cycle-by-cycle current limiting with a latched shutdown mode, and internal thermal shutdown.

Typical motor control functions include open loop speed control, forward or reverse rotation, and run enable. In addition, the MC33033 has a $60^{\circ} / \overline{120^{\circ}}$ select pin which configures the rotor position decoder for either $60^{\circ}$ or $120^{\circ}$ sensor electrical phasing inputs.

## FUNCTIONAL DESCRIPTION

A representative internal block diagram is shown in Figure 18, with various applications shown in Figures 34, $36,37,41,43$, and 44 . A discussion of the features and function of each of the internal blocks given below and referenced to Figures 18 and 36.

## Rotor Position Decoder

An internal rotor position decoder monitors the three sensor inputs (Pins $4,5,6$ ) to provide the proper sequencing of the top and bottom drive outputs. The Sensor Inputs are designed to interface directly with open collector type Hall Effect switches or opto slotted couplers. Internal pull-up resistors are included to minimize the required number of external components. The inputs are TTL compatible, with their thresholds typically at 2.2 V . The MC33033 series is designed to control three phase motors and operate with four of the most common conventions of sensor phasing. A $60^{\circ} / 120^{\circ}$ Select (Pin 18) is conveniently provided which affords the MC33033 to configure itself to control motors having either $60^{\circ}, 120^{\circ}, 240^{\circ}$ or $300^{\circ}$ electrical sensor phasing. With three Sensor Inputs there are eight possible input code combinations, six of which are valid rotor positions. The remaining two codes are invalid and are usually caused by an open or shorted sensor line. With six valid input codes, the decoder can resolve the motor rotor position to within a window of 60 electrical degrees.

The Forward/Reverse input ( $\operatorname{Pin} 3$ ) is used to change the direction of motor rotation by reversing the voltage across the stator winding. When the input changes state, from high to low with a given sensor input code (for example 100), the enabled top and bottom drive outputs with the same alpha designation are exchanged ( $A_{T}$ to $A_{B}, B_{T}$ to $B_{B}, C_{T}$ to $C_{B}$ ). In effect the commutation sequence is reversed and the motor changes directional rotation.

Motor on/off control is accomplished by the Output Enable (Pin19). When left disconnected, an internal pull-up resistor to a positive source enables sequencing of the top and bottom drive outputs. When grounded, the Top Drive Outputs turn off and the bottom drives are forced low, causing the motor to coast.
The commutation logic truth table is shown in Figure 19. In half wave motor drive applications, the Top Drive Outputs are not required and are typically left disconnected.

## Error Amplifier

A high performance, fully compensated Error Amplifier with access to both inputs and output (Pins 9, 10, 11) is provided to facilitate the implementation of closed loop motor speed control. The amplifier features a typical dc voltage gain of $80 \mathrm{~dB}, 0.6 \mathrm{MHz}$ gain bandwidth, and a wide input common mode voltage range that extends from ground to $\mathrm{V}_{\text {ref. }}$. In most open loop speed control applications, the amplifier is configured as a unity gain voltage follower with the Noninverting Input connected to the speed set voltage source. Additional configurations are shown in Figures 29 through 33.

## Oscillator

The frequency of the internal ramp oscillator is programmed by the values selected for timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged from the Reference Output (Pin 7) through resistor $\mathrm{R}_{\mathrm{T}}$ and discharged by an internal discharge transistor. The ramp peak and valley voltages are typically 4.1 V and 1.5 V respectively. To provide a good compromise between audible noise and output switching efficiency, an oscillator frequency in the range of 20 to 30 kHz is recommended. Refer to Figure 1 for component selection.

## Pulse Width Modulator

The use of pulse width modulation provides an energy efficient method of controlling the motor speed by varying the average voltage applied to each stator winding during the commutation sequence. As $\mathrm{C}_{\mathrm{T}}$ discharges, the oscillator sets both latches, allowing conduction of the Top and Bottom Drive Outputs. The PWM comparator resets the upper latch, terminating the Bottom Drive Output conduction when the positive-going ramp of $\mathrm{C}_{\mathrm{T}}$ becomes greater than the Error Amplifier output. The pulse width modulator timing diagram is shown in Figure 20. Pulse width modulation for speed control appears only at the Bottom Drive Outputs.

NOTES: 1. $V=$ Any one of six valid sensor or drive combinations.
$X=$ Don't care.
2. The digital inputs (Pins $3,4,5,6,18,19$ ) are all TTL compatible. The current sense input (Pin 12) has a 100 mV threshold with respect to Pin 13. A logic 0 for this input is defined as $<85 \mathrm{mV}$, and a logic 1 is $>115 \mathrm{mV}$.
3. The top drive outputs are open collector design and active in the low ( 0 ) state.
4. With $60^{\circ} / 120^{\circ}$ (Pin 18) in the high (1) state, configuration is for $60^{\circ}$ sensor electrical phasing inputs. With Pin 18 in the low (0) state, configuration is for $120^{\circ}$ sensor electrical phasing inputs.
5. Valid $60^{\circ}$ or $120^{\circ}$ sensor combinations for corresponding valid top and bottom drive outputs.
6. Invalid sensor inputs; All top and bottom drives are off.
7. Valid sensor inputs with enable $=0$; All top and bottom drives are off.
8. Valid sensor inputs with enable and current sense $=1$; All top and bottom drives are off.

Figure 19. Three Phase, Six Step Commutation Truth Table (Note 1)

## Current Limit

Continuous operation of a motor that is severely over-loaded results in overheating and eventual failure. This destructive condition can best be prevented with the use of cycle-by-cycle current limiting. That is, each on-cycle is treated as a separate event. Cycle-by-cycle current limiting is accomplished by monitoring the stator current build-up each time an output switch conducts, and upon sensing an over current condition, immediately turning off the switch and holding it off for the remaining duration of oscillator ramp-up period. The stator current is converted to a voltage by inserting a ground-referenced sense resistor $\mathrm{R}_{\mathrm{S}}$ (Figure 34) in series with the three bottom switch transistors $\left(\mathrm{Q}_{4}, \mathrm{Q}_{5}, \mathrm{Q}_{6}\right)$. The voltage developed across the sense resistor is monitored by the current sense input (Pin 12), and compared to the internal 100 mV reference. If the current sense threshold is exceeded, the comparator resets the lower latch and terminates output switch conduction. The value for the sense resistor is:

$$
R_{S}=\frac{0.1}{I_{\text {stator(max) }}}
$$

The dual-latch PWM configuration ensures that only one single output conduction pulse occurs during any given oscillator cycle, whether terminated by the output of the Error Amplifier or the current limit comparator.

## Reference

The on-chip 6.25 V regulator (Pin 7) provides charging current for the oscillator timing capacitor, a reference for the Error Amplifier, and can supply 20 mA of current suitable for directly powering sensors in low voltage applications. In higher voltage applications it may become necessary to transfer the power dissipated by the regulator off the IC. This is easily accomplished with the addition of an external pass transistor as shown in Figure 21. A 6.25 V reference level was chosen to allow implementation of the simpler NPN circuit, where $V_{\text {ref }}-V_{\text {BE }}$ exceeds the minimum voltage required by Hall Effect sensors over temperature. With proper transistor selection, and adequate heatsinking, up to one amp of load current can be obtained.

## Undervoltage Lockout

A dual Undervoltage Lockout has been incorporated to prevent damage to the IC and the external power switch transistors. Under low power supply conditions, it guarantees that the IC and sensors are fully functional, and that there is sufficient Bottom Drive Output voltage. The positive power supply to the IC $\left(\mathrm{V}_{\mathrm{CC}}\right)$ is monitored to a threshold of 8.9 V . This level ensures sufficient gate drive necessary to attain low $\mathrm{R}_{\mathrm{DS}(\mathrm{on})}$ when interfacing with standard power MOSFET devices. When directly powering the Hall sensors from the reference, improper sensor
operation can result if the reference output voltage should fall below 4.5 V . If one or both of the comparators detects an undervoltage condition, the top drives are turned off and the

Figure 20. PWM Timing Diagram

Transistor $Q_{1}$ is a common base stage used to level shift from $V_{C C}$ to the high motor voltage, $\mathrm{V}_{\mathrm{M}}$. The collector diode is required if $\mathrm{V}_{\mathrm{CC}}$ is present while $\mathrm{V}_{\mathrm{M}}$ is low.

Figure 22. High Voltage Interface with NPN Power Transistors

Bottom Drive Outputs are held in a low state. Each of the comparators contain hysteresis to prevent oscillations when crossing their respective thresholds.

The NPN circuit is recommended for powering Hall or opto sensors, where the output voltage temperature coefficient is not critical. The PNP circuit is slightly more complex, but also more accurate. Neither circuit has current limiting.

Figure 21. Reference Output Buffers

Figure 23. High Voltage Interface with N-Channel Power MOSFETs

The addition of the RC filter will eliminate current-limit instability caused by the leading edge spike on the current waveform. Resistor $\mathrm{R}_{\mathrm{S}}$ should be a low inductance type.

Figure 24. Current Waveform Spike Suppression

Series gate resistor $R_{g}$ will damp any high frequency oscillations caused by the MOSFET input capacitance and any series wiring induction in the gate-source circuit. Diode D is required if the negative current into the Bottom Drive Outputs exceeds 50 mA .

Figure 25. MOSFET Drive Precautions

The totem pole output can furnish negative base current for enhanced transistor turn-off, with the addition of capacitor C .

Figure 26. Bipolar Transistor Drive

Figure 28. High Voltage Boost Supply

Virtually lossless current sensing can be achieved with the implementation of SENSEFET power switches.

Figure 27. Current Sensing Power MOSFETs

Figure 29. Differential Input Speed Controller

Resistor $R_{1}$ with capacitor $C$ sets the acceleration time constant while $R_{2}$ controls the deceleration. The values of $R_{1}$ and $R_{2}$ should be at least ten times greater than the speed set potentiometer to minimize time constant variations with different speed settings.

Figure 30. Controlled Acceleration/Deceleration

The rotor position sensors can be used as a tachometer. By differentiating the positive-going edges and then integrating them over time, a voltage proportional to speed can be generated. The error amp compares this voltage to that of the speed set to control the PWM.

Figure 32. Closed Loop Speed Control

## Drive Outputs

The three Top Drive Outputs (Pins 1, 2, 20) are open collector NPN transistors capable of sinking 50 mA with a minimum breakdown of 30 V . Interfacing into higher voltage applications is easily accomplished with the circuits shown in Figures 22 and 23.

The three totem pole Bottom Drive Outputs (Pins 15, 16, 17) are particularly suited for direct drive of N -Channel MOSFETs or NPN bipolar transistors (Figures 24, 25, 26, and 27). Each output is capable of sourcing and sinking up to 100 mA .

## Thermal Shutdown

Internal thermal shutdown circuity is provided to protect the IC in the event the maximum junction temperature is exceeded. When activated, typically at $170^{\circ} \mathrm{C}$, the IC acts as though the regulator was disabled, in turn shutting down the IC.

The SN74LS145 is an open collector BCD to One of Ten decoder. When connected as shown, input codes 0000 through 1001 steps the PWM in increments of approximately $10 \%$ from 0 to $90 \%$ on-time. Input codes 1010 through 1111 will produce $100 \%$ on-time or full motor speed.

Figure 31. Digital Speed Controller

This circuit can control the speed of a cooling fan proportional to the difference between the sensor and set temperatures. The control loop is closed as the forced air cools the NTC thermistor. For controlled heating applications, exchange the positions of $R_{1}$ and $R_{2}$.

Figure 33. Closed Loop Temperature Control

## SYSTEM APPLICATIONS

## Three Phase Motor Commutation

The three phase application shown in Figure 34 is an open loop motor controller with full wave, six step drive. The upper power switch transistors are Darlington PNPs while the lower switches are N-Channel power MOSFETs. Each of these devices contains an internal parasitic catch diode that is used to return the stator inductive energy back to the power supply. The outputs are capable of driving a delta or wye connected stator, and a grounded neutral wye if split supplies are used. At any given rotor position, only one top and one bottom power switch (of different totem poles) is enabled. This configuration switches both ends of the stator winding from supply to ground which causes the current flow to be bidirectional or full wave. A leading edge spike is usually present on the current waveform and can cause a current-limit error. The spike can be eliminated by adding
an RC filter in series with the Current Sense Input. Using a low inductance type resistor for $\mathrm{R}_{\mathrm{S}}$ will also aid in spike reduction. Figure 35 shows the commutation waveforms over two electrical cycles. The first cycle ( $0^{\circ}$ to $360^{\circ}$ ) depicts motor operation at full speed while the second cycle ( $360^{\circ}$
to $720^{\circ}$ ) shows a reduced speed with about $50 \%$ pulse width modulation. The current waveforms reflect a constant torque load and are shown synchronous to the commutation frequency for clarity.

Figure 34. Three Phase, Six Step, Full Wave Motor Controller

Rotor Electrical Position (Degrees)

Figure 35. Three Phase, Six Step, Full Wave Commutation Waveforms

## MC33033

Figure 36 shows a three phase, three step, half wave motor controller. This configuration is ideally suited for automobile and other low voltage applications since there is only one power switch voltage drop in series with a given
stator winding. Current flow is unidirectional or half wave because only one end of each winding is switched. The stator flyback voltage is clamped by a single zener and three diodes.

Figure 36. Three Phase, Three Step, Half Wave Motor Controller

## Three Phase Closed Loop Controller

The MC33033, by itself, is capable of open loop motor speed control. For closed loop speed control, the MC33033 requires an input voltage proportional to the motor speed. Traditionally this has been accomplished by means of a tachometer to generate the motor speed feedback voltage. Figure 37 shows an application whereby an MC33039, powered from the 6.25 V reference (Pin 7) of the MC33033, is used to generate the required feedback voltage without the need of a costly tachometer. The same Hall sensor signals used by the MC33033 for rotor position decoding are utilized by the MC33039. Every positive or negative going transition of the Hall sensor signals on any of the sensor lines causes the MC33039 to produce an output pulse of defined amplitude and time duration, as determined by the external resistor $R_{1}$ and capacitor $C_{1}$. The resulting output train of
pulses present at Pin 5 of the MC33039 are integrated by the Error Amplifier of the MC33033 configured as an integrator, to produce a dc voltage level which is proportional to the motor speed. This speed proportional voltage establishes the PWM reference level at Pin 11 of the MC33033 motor controller and completes or closes the feedback loop. The MC33033 outputs drive a TMOS power MOSFET 3-phase bridge. High current can be expected during conditions of start-up and when changing direction of the motor.

The system shown in Figure 37 is designed for a motor having 120/240 degrees Hall sensor electrical phasing. The system can easily be modified to accommodate $60 / 300$ degree Hall sensor electrical phasing by removing the jumper $\left(\mathrm{J}_{1}\right)$ at Pin 18 of the MC33033.

Figure 37. Closed Loop Brushless DC Motor Control With the MC33033 Using the MC33039

## Sensor Phasing Comparison

There are four conventions used to establish the relative phasing of the sensor signals in three phase motors. With six step drive, an input signal change must occur every 60 electrical degrees, however, the relative signal phasing is dependent upon the mechanical sensor placement. A comparison of the conventions in electrical degrees is shown in Figure 38. From the sensor phasing table (Figure 39), note that the order of input codes for $60^{\circ}$ phasing is the reverse of $300^{\circ}$. This means the MC33033, when the $60^{\circ} / \overline{120^{\circ}}$ select (Pin 18) and the FWD/REV (Pin 3) both in the high state (open), is configured to operate a $60^{\circ}$ sensor phasing motor in the forward direction. Under the same conditions a $300^{\circ}$ sensor phasing motor would operate equally well but in the reverse direction. One would simply have to reverse the FWD/REV switch (FWD/REV closed) in order to cause the $300^{\circ}$ motor to also operate in the same direction. The same difference exists between the $120^{\circ}$ and $240^{\circ}$ conventions.

Figure 38. Sensor Phasing Comparison

| Sensor Electrical Phasing (Degrees) |  |  |  |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $60^{\circ}$ |  |  | $120^{\circ}$ |  |  | $240^{\circ}$ |  |  | $300^{\circ}$ |  |  |
| $\mathrm{S}_{\text {A }}$ | $\mathrm{S}_{\mathrm{B}}$ | $\mathrm{S}_{\mathrm{C}}$ | $\mathrm{S}_{\text {A }}$ | $\mathrm{S}_{\mathrm{B}}$ | $\mathrm{S}_{\mathrm{C}}$ | $\mathrm{S}_{\mathrm{A}}$ | $\mathrm{S}_{B}$ | $\mathrm{S}_{\mathrm{C}}$ | $\mathrm{S}_{\mathrm{A}}$ | $\mathrm{S}_{\mathrm{B}}$ | $\mathrm{S}_{\mathrm{C}}$ |
| 1 | 0 | 0 | 1 | 0 | 1 | 1 | 1 | 0 | 1 | 1 | 1 |
| 1 | 1 | 0 | 1 | 0 | 0 | 1 | 0 | 0 | 1 | 1 | 0 |
| 1 | $17$ | 1 | 1 | 1 | 0 | 1 | 0 | 1 | 1 | 0 | 0 |
| 0 | 1 | 1 | 0 | 1 | 0 | 0 | 0 | 1 | 0 | 0 | 0 |
| 0 | 0 | 1 | 0 | 1 | 1 | 0 | 1 | 1 | 0 | 0 | 1 |
| 0 | 0 | 0 | 0 | 0 | 1 | 0 | 1 | 0 | 0 | 1 | 1 |

In this data sheet, the rotor position has always been given in electrical degrees since the mechanical position is a function of the number of rotating magnetic poles. The relationship between the electrical and mechanical position is:
Electrical Degrees $=$ Mechanical Degrees $\left(\frac{\text { \#Rotor Poles }}{2}\right)$
An increase in the number of magnetic poles causes more electrical revolutions for a given mechanical revolution. General purpose three phase motors typically contain a four pole rotor which yields two electrical revolutions for one mechanical.

## Two and Four Phase Motor Commutation

The MC33033 configured for $60^{\circ}$ sensor inputs is capable of providing a four step output that can be used to drive two or four phase motors. The truth table in Figure 40 shows that by connecting sensor inputs $\mathrm{S}_{\mathrm{B}}$ and $\mathrm{S}_{\mathrm{C}}$ together, it is possible to truncate the number of drive output states from six to four. The output power switches are connected to $\mathrm{B}_{\mathrm{T}}, \mathrm{C}_{\mathrm{T}}, \mathrm{B}_{\mathrm{B}}$, and $\mathrm{C}_{\mathrm{B}}$. Figure 41 shows a four phase, four step, full wave motor control application. Power switch transistors $\mathrm{Q}_{1}$ through $\mathrm{Q}_{8}$ are Darlington type, each with an internal parasitic catch diode. With four step drive, only two rotor position sensors spaced at 90 electrical degrees are required. The commutation waveforms are shown in Figure 42.
Figure 43 shows a four phase, four step, half wave motor controller. It has the same features as the circuit in Figure 36, except for the deletion of speed adjust.

## Brush Motor Control

Though the MC33033 was designed to control brushless dc motors, it may also be used to control dc brush-type motors. Figure 44 shows an application of the MC33033 driving a H-bridge affording minimal parts count to operate a brush-type motor. Key to the operation is the input sensor code [100] which produces a top-left $\left(\mathrm{Q}_{1}\right)$ and a bottom-right $\left(\mathrm{Q}_{3}\right)$ drive when the controller's Forward/Reverse pin is at logic [1]; top-right $\left(\mathrm{Q}_{4}\right)$, bottom-left $\left(\mathrm{Q}_{2}\right)$ drive is realized when the Forward/Reverse pin is at logic [0]. This code supports the requirements necessary for H -bridge drive accomplishing both direction and speed control.

The controller functions in a normal manner with a pulse width modulated frequency of approximately 25 kHz . Motor speed is controlled by adjusting the voltage presented to the noninverting input of the Error Amplifier establishing the PWM's slice or reference level. Cycle-by-cycle current limiting of the motor current is accomplished by sensing the voltage ( 100 mV threshold) across the $\mathrm{R}_{\mathrm{S}}$ resistor to ground of the H -bridge motor current. The over current sense circuit makes it possible to reverse the direction of the motor, on the
fly, using the normal Forward/Reverse switch, and not have to completely stop before reversing.

## LAYOUT CONSIDERATIONS

Do not attempt to construct any of the motor control circuits on wire-wrap or plug-in prototype boards. High frequency printed circuit layout techniques are imperative to prevent pulse jitter. This is usually caused by excessive noise pick-up imposed on the current sense or error amp inputs. The printed circuit layout should contain a ground plane with low current signal and high drive and output buffer grounds returning on separate paths back to the power supply input filter capacitor $\mathrm{V}_{\mathrm{M}}$. Ceramic bypass capacitors $(0.01 \mu \mathrm{~F})$ connected close to the integrated circuit at $\mathrm{V}_{\mathrm{CC}}$, $\mathrm{V}_{\text {ref }}$ and error amplifier noninverting input may be required depending upon circuit layout. This provides a low impedance path for filtering any high frequency noise. All high current loops should be kept as short as possible using heavy copper runs to minimize radiated EMI.

Figure 44. H-Bridge Brush-Type Controller

## Brushless DC Motor Controller

The MC33035 is a high performance second generation monolithic brushless DC motor controller containing all of the active functions required to implement a full featured open loop, three or four phase motor control system. This device consists of a rotor position decoder for proper commutation sequencing, temperature compensated reference capable of supplying sensor power, frequency programmable sawtooth oscillator, three open collector top drivers, and three high current totem pole bottom drivers ideally suited for driving power MOSFETs.

Also included are protective features consisting of undervoltage lockout, cycle-by-cycle current limiting with a selectable time delayed latched shutdown mode, internal thermal shutdown, and a unique fault output that can be interfaced into microprocessor controlled systems.

Typical motor control functions include open loop speed, forward or reverse direction, run enable, and dynamic braking. The MC33035 is designed to operate with electrical sensor phasings of $60^{\circ} / 300^{\circ}$ or $120^{\circ} / 240^{\circ}$, and can also efficiently control brush DC motors.

- 10 to 30 V Operation
- Undervoltage Lockout
- 6.25 V Reference Capable of Supplying Sensor Power
- Fully Accessible Error Amplifier for Closed Loop Servo Applications
- High Current Drivers Can Control External 3-Phase MOSFET Bridge
- Cycle-By-Cycle Current Limiting
- Pinned-Out Current Sense Reference
- Internal Thermal Shutdown
- Selectable $60^{\circ} / 300^{\circ}$ or $120^{\circ} / 240^{\circ}$ Sensor Phasings
- Can Efficiently Control Brush DC Motors with External MOSFET H-Bridge

## PIN FUNCTION DESCRIPTION

| Pin | Symbol | Description |
| :---: | :---: | :---: |
| 1, 2, 24 | $\mathrm{B}_{\mathrm{T}}, \mathrm{A}_{\mathrm{T}}, \mathrm{C}_{T}$ | These three open collector Top Drive outputs are designed to drive the external upper power switch transistors. |
| 3 | Fwd/Rev | The Forward/Reverse Input is used to change the direction of motor rotation. |
| 4, 5, 6 | $\mathrm{S}_{\mathrm{A}}, \mathrm{S}_{\mathrm{B}}, \mathrm{S}_{\mathrm{C}}$ | These three Sensor Inputs control the commutation sequence. |
| 7 | Output Enable | A logic high at this input causes the motor to run, while a low causes it to coast. |
| 8 | Reference Output | This output provides charging current for the oscillator timing capacitor $\mathrm{C}_{\boldsymbol{T}}$ and a reference for the error amplifier. It may also serve to furnish sensor power. |
| 9 | Current Sense Noninverting Input | A 100 mV signal, with respect to Pin 15, at this input terminates output switch conduction during a given oscillator cycle. This pin normally connects to the top side of the current sense resistor. |
| 10 | Oscillator | The Oscillator frequency is programmed by the values selected for the timing components, $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. |
| 11 | Error Amp Noninverting Input | This input is normally connected to the speed set potentiometer. |
| 12 | Error Amp Inverting Input | This input is normally connected to the Error Amp Output in open loop applications. |
| 13 | Error Amp Out/PWM Input | This pin is available for compensation in closed loop applications. |
| 14 | Fault Output | This open collector output is active low during one or more of the following conditions: Invalid Sensor Input code, Enable Input at logic 0, Current Sense Input greater than 100 mV (Pin 9 with respect to Pin 15), Undervoltage Lockout activation, and Thermal Shutdown. |
| 15 | Current Sense Inverting Input | Reference pin for internal 100 mV threshold. This pin is normally connected to the bottom side of the current sense resistor. |
| 16 | Gnd | This pin supplies a ground for the control circuit and should be referenced back to the power source ground. |
| 17 | $\mathrm{V}_{\text {CC }}$ | This pin is the positive supply of the control IC. The controller is functional over a minimum $\mathrm{V}_{\mathrm{CC}}$ range of 10 to 30 V . |
| 18 | $\mathrm{V}_{\mathrm{C}}$ | The high state $\left(\mathrm{V}_{\mathrm{OH}}\right)$ of the Bottom Drive Outputs is set by the voltage applied to this pin. The controller is operational over a minimum $\mathrm{V}_{\mathrm{C}}$ range of 10 to 30 V . |
| 19, 20, 21 | $\mathrm{C}_{\mathrm{B}}, \mathrm{B}_{\mathrm{B}}, \mathrm{A}_{\mathrm{B}}$ | These three totem pole Bottom Drive Outputs are designed for direct drive of the external bottom power switch transistors. |
| 22 | $60 \% 120^{\circ}$ Select | The electrical state of this pin configures the control circuit operation for either $60^{\circ}$ (high state) or $120^{\circ}$ (low state) sensor electrical phasing inputs. |
| 23 | Brake | A logic low state at this input allows the motor to run, while a high state does not allow motor operation and if operating causes rapid deceleration. |

## INTRODUCTION

The MC33035 is one of a series of high performance monolithic DC brushless motor controllers produced by Motorola. It contains all of the functions required to implement a full-featured, open loop, three or four phase motor control system. In addition, the controller can be made to operate DC brush motors. Constructed with Bipolar Analog technology, it offers a high degree of performance and ruggedness in hostile industrial environments. The MC33035 contains a rotor position decoder for proper commutation sequencing, a temperature compensated reference capable of supplying a sensor power, a frequency programmable sawtooth oscillator, a fully accessible error amplifier, a pulse width modulator comparator, three open collector top drive outputs, and three high current totem pole bottom driver outputs ideally suited for driving power MOSFETs.

Included in the MC33035 are protective features consisting of undervoltage lockout, cycle-by-cycle current limiting with a selectable time delayed latched shutdown mode, internal thermal shutdown, and a unique fault output that can easily be interfaced to a microprocessor controller.

Typical motor control functions include open loop speed control, forward or reverse rotation, run enable, and dynamic braking. In addition, the MC33035 has a $60^{\circ} / \overline{120^{\circ}}$ select pin which configures the rotor position decoder for either $60^{\circ}$ or $120^{\circ}$ sensor electrical phasing inputs.

## FUNCTIONAL DESCRIPTION

A representative internal block diagram is shown in Figure 19 with various applications shown in Figures 36, 38, $39,43,45$, and 46 . A discussion of the features and function of each of the internal blocks given below is referenced to Figures 19 and 36.

## Rotor Position Decoder

An internal rotor position decoder monitors the three sensor inputs (Pins 4, 5, 6) to provide the proper sequencing of the top and bottom drive outputs. The sensor inputs are designed to interface directly with open collector type Hall Effect switches or opto slotted couplers. Internal pull-up resistors are included to minimize the required number of external components. The inputs are TTL compatible, with their thresholds typically at 2.2 V . The MC33035 series is designed to control three phase motors and operate with four of the most common conventions of sensor phasing. A $60^{\circ} \overline{120}^{\circ}$ Select (Pin 22) is conveniently provided and affords the MC33035 to configure itself to control motors having either $60^{\circ}, 120^{\circ}, 240^{\circ}$ or $300^{\circ}$ electrical sensor phasing. With three sensor inputs there are eight possible input code combinations, six of which are valid rotor positions. The remaining two codes are invalid and are usually caused by an open or shorted sensor line. With six valid input codes, the decoder can resolve the motor rotor position to within a window of 60 electrical degrees.

The Forward/Reverse input ( $\operatorname{Pin} 3$ ) is used to change the direction of motor rotation by reversing the voltage across
the stator winding. When the input changes state, from high to low with a given sensor input code (for example 100), the enabled top and bottom drive outputs with the same alpha designation are exchanged $\left(\mathrm{A}_{\mathrm{T}}\right.$ to $\mathrm{A}_{\mathrm{B}}, \mathrm{B}_{\mathrm{T}}$ to $\mathrm{B}_{\mathrm{B}}, \mathrm{C}_{\mathrm{T}}$ to $\left.\mathrm{C}_{\mathrm{B}}\right)$. In effect, the commutation sequence is reversed and the motor changes directional rotation.
Motor on/off control is accomplished by the Output Enable (Pin 7). When left disconnected, an internal $25 \mu \mathrm{~A}$ current source enables sequencing of the top and bottom drive outputs. When grounded, the top drive outputs turn off and the bottom drives are forced low, causing the motor to coast and the $\overline{\text { Fault }}$ output to activate.

Dynamic motor braking allows an additional margin of safety to be designed into the final product. Braking is accomplished by placing the Brake Input (Pin 23) in a high state. This causes the top drive outputs to turn off and the bottom drives to turn on, shorting the motor-generated back EMF. The brake input has unconditional priority over all other inputs. The internal $40 \mathrm{k} \Omega$ pull-up resistor simplifies interfacing with the system safety-switch by insuring brake activation if opened or disconnected. The commutation logic truth table is shown in Figure 20. A four input NOR gate is used to monitor the brake input and the inputs to the three top drive output transistors. Its purpose is to disable braking until the top drive outputs attain a high state. This helps to prevent simultaneous conduction of the the top and bottom power switches. In half wave motor drive applications, the top drive outputs are not required and are normally left disconnected. Under these conditions braking will still be accomplished since the NOR gate senses the base voltage to the top drive output transistors.

## Error Amplifier

A high performance, fully compensated error amplifier with access to both inputs and output (Pins 11, 12, 13) is provided to facilitate the implementation of closed loop motor speed control. The amplifier features a typical DC voltage gain of $80 \mathrm{~dB}, 0.6 \mathrm{MHz}$ gain bandwidth, and a wide input common mode voltage range that extends from ground to $\mathrm{V}_{\text {ref }}$. In most open loop speed control applications, the amplifier is configured as a unity gain voltage follower with the noninverting input connected to the speed set voltage source. Additional configurations are shown in Figures 31 through 35.

## Oscillator

The frequency of the internal ramp oscillator is programmed by the values selected for timing components $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$. Capacitor $\mathrm{C}_{\mathrm{T}}$ is charged from the Reference Output (Pin 8) through resistor $\mathrm{R}_{\mathrm{T}}$ and discharged by an internal discharge transistor. The ramp peak and valley voltages are typically 4.1 V and 1.5 V respectively. To provide a good compromise between audible noise and output switching efficiency, an oscillator frequency in the range of 20 to 30 kHz is recommended. Refer to Figure 1 for component selection.

NOTES: 1. $V=$ Any one of six valid sensor or drive combinations $\quad X=$ Don't care.
2. The digital inputs (Pins $3,4,5,6,7,22,23$ ) are all TTL compatible. The current sense input (Pin 9 ) has a 100 mV threshold with respect to Pin 15. A logic 0 for this input is defined as $<85 \mathrm{mV}$, and a logic 1 is $>115 \mathrm{mV}$.
3. The fault and top drive outputs are open collector design and active in the low (0) state.
4. With $60^{\circ} / 120^{\circ}$ select (Pin 22) in the high (1) state, configuration is for $60^{\circ}$ sensor electrical phasing inputs. With Pin 22 in low (0) state, configuration is for $120^{\circ}$ sensor electrical phasing inputs.
5. Valid $60^{\circ}$ or $120^{\circ}$ sensor combinations for corresponding valid top and bottom drive outputs.
6. Invalid sensor inputs with brake $=0$; All top and bottom drives off, Fault low.
7. Invalid sensor inputs with brake $=1$; All top drives off, all bottom drives on, Fault low.
8. Valid $60^{\circ}$ or $120^{\circ}$ sensor inputs with brake $=1$; All top drives off, all bottom drives on, Fault high.
9. Valid sensor inputs with brake $=1$ and enable $=0$; All top drives off, all bottom drives on, Fault low.
10. Valid sensor inputs with brake $=0$ and enable $=0$; All top and bottom drives off, Fault low.
11. All bottom drives off, Fault low.

Figure 20. Three Phase, Six Step Commutation Truth Table (Note 1)

## Pulse Width Modulator

The use of pulse width modulation provides an energy efficient method of controlling the motor speed by varying the average voltage applied to each stator winding during the commutation sequence. As $\mathrm{C}_{\mathrm{T}}$ discharges, the oscillator sets both latches, allowing conduction of the top and bottom drive outputs. The PWM comparator resets the upper latch, terminating the bottom drive output conduction when the positive-going ramp of $\mathrm{C}_{\mathrm{T}}$ becomes greater than the error amplifier output. The pulse width modulator timing diagram is shown in Figure 21. Pulse width modulation for speed control appears only at the bottom drive outputs.

## Current Limit

Continuous operation of a motor that is severely over-loaded results in overheating and eventual failure. This destructive condition can best be prevented with the use of cycle-by-cycle current limiting. That is, each on-cycle is treated as a separate event. Cycle-by-cycle current limiting is accomplished by monitoring the stator current build-up each time an output switch conducts, and upon
sensing an over current condition, immediately turning off the switch and holding it off for the remaining duration of oscillator ramp-up period. The stator current is converted to a voltage by inserting a ground-referenced sense resistor $\mathrm{R}_{\mathrm{S}}$ (Figure 36) in series with the three bottom switch transistors $\left(\mathrm{Q}_{4}, \mathrm{Q}_{5}, \mathrm{Q}_{6}\right)$. The voltage developed across the sense resistor is monitored by the Current Sense Input (Pins 9 and 15), and compared to the internal 100 mV reference. The current sense comparator inputs have an input common mode range of approximately 3.0 V . If the 100 mV current sense threshold is exceeded, the comparator resets the lower sense latch and terminates output switch conduction. The value for the current sense resistor is:

$$
R_{S}=\frac{0.1}{I_{\text {stator(max) }}}
$$

The $\overline{\text { Fault }}$ output activates during an over current condition. The dual-latch PWM configuration ensures that only one single output conduction pulse occurs during any given oscillator cycle, whether terminated by the output of the error amp or the current limit comparator.

Figure 21. Pulse Width Modulator Timing Diagram Reference

The on-chip 6.25 V regulator (Pin 8) provides charging current for the oscillator timing capacitor, a reference for the error amplifier, and can supply 20 mA of current suitable for directly powering sensors in low voltage applications. In higher voltage applications, it may become necessary to transfer the power dissipated by the regulator off the IC. This is easily accomplished with the addition of an external pass transistor as shown in Figure 22. A 6.25 V reference level was chosen to allow implementation of the simpler NPN circuit, where $\mathrm{V}_{\text {ref }}-\mathrm{V}_{\mathrm{BE}}$ exceeds the minimum voltage required by Hall Effect sensors over temperature. With proper transistor selection and adequate heatsinking, up to one amp of load current can be obtained.

The NPN circuit is recommended for powering Hall or opto sensors, where the output voltage temperature coefficient is not critical. The PNP circuit is slightly more complex, but is also more accurate over temperature. Neither circuit has current limiting.

## Undervoltage Lockout

A triple Undervoltage Lockout has been incorporated to prevent damage to the IC and the external power switch transistors. Under low power supply conditions, it guarantees that the IC and sensors are fully functional, and that there is sufficient bottom drive output voltage. The positive power supplies to the IC $\left(\mathrm{V}_{\mathrm{CC}}\right)$ and the bottom drives $\left(\mathrm{V}_{\mathrm{C}}\right)$ are each monitored by separate comparators that have their thresholds at 9.1 V . This level ensures sufficient gate drive necessary to attain low $\mathrm{R}_{\mathrm{DS}(\mathrm{on})}$ when driving standard power MOSFET devices. When directly powering the Hall sensors from the reference, improper sensor operation can result if the reference output voltage falls below 4.5 V . A third comparator is used to detect this condition. If one or more of the comparators detects an undervoltage condition, the Fault Output is activated, the top drives are turned off and the bottom drive outputs are held in a low state. Each of the comparators contain hysteresis to prevent oscillations when crossing their respective thresholds.

## Fault Output

The open collector Fault Output (Pin 14) was designed to provide diagnostic information in the event of a system malfunction. It has a sink current capability of 16 mA and can directly drive a light emitting diode for visual indication. Additionally, it is easily interfaced with TTL/CMOS logic for use in a microprocessor controlled system. The Fault Output is active low when one or more of the following conditions occur:

1) Invalid Sensor Input code
2) Output Enable at logic [0]
3) Current Sense Input greater than 100 mV
4) Undervoltage Lockout, activation of one or more of the comparators
5) Thermal Shutdown, maximum junction temperature being exceeded
This unique output can also be used to distinguish between motor start-up or sustained operation in an overloaded condition. With the addition of an RC network between the Fault Output and the enable input, it is possible to create a time-delayed latched shutdown for overcurrent. The added circuitry shown in Figure 23 makes easy starting of motor systems which have high inertial loads by providing additional starting torque, while still preserving overcurrent protection. This task is accomplished by setting the current limit to a higher than nominal value for a predetermined time. During an excessively long overcurrent condition, capacitor $\mathrm{C}_{\text {DLY }}$ will charge, causing the enable input to cross its threshold to a low state. A latch is then formed by the positive feedback loop from the Fault Output to the Output Enable. Once set, by the Current Sense Input, it can only be reset by shorting CDLY or cycling the power supplies.

Figure 22. Reference Output Buffers

## Drive Outputs

The three top drive outputs (Pins 1, 2, 24) are open collector NPN transistors capable of sinking 50 mA with a minimum breakdown of 30 V . Interfacing into higher voltage applications is easily accomplished with the circuits shown in Figures 24 and 25.

The three totem pole bottom drive outputs (Pins 19, 20, 21) are particularly suited for direct drive of $\mathrm{N}-$ Channel MOSFETs or NPN bipolar transistors (Figures 26, 27, 28 and 29). Each output is capable of sourcing and sinking up to 100 mA . Power for the bottom drives is supplied from $\mathrm{V}_{\mathrm{C}}$ (Pin 18). This separate supply input allows the designer added flexibility in tailoring the drive voltage, independent
of $\mathrm{V}_{\mathrm{CC}}$. A zener clamp should be connected to this input when driving power MOSFETs in systems where $\mathrm{V}_{\mathrm{CC}}$ is greater than 20 V so as to prevent rupture of the MOSFET gates.

The control circuitry ground (Pin 16) and current sense inverting input (Pin 15) must return on separate paths to the central input source ground.

## Thermal Shutdown

Internal thermal shutdown circuitry is provided to protect the IC in the event the maximum junction temperature is exceeded. When activated, typically at $170^{\circ} \mathrm{C}$, the IC acts as though the Output Enable was grounded.

Figure 23. Timed Delayed Latched Over Current Shutdown

Transistor $Q_{1}$ is a common base stage used to level shift from $V_{C c}$ to the high motor voltage, $\mathrm{V}_{\mathrm{M}}$. The collector diode is required if $\mathrm{V}_{\mathrm{CC}}$ is present while $\mathrm{V}_{\mathrm{M}}$ is low.

Figure 24. High Voltage Interface with NPN Power Transistors

Figure 25. High Voltage Interface with N-Channel Power MOSFETs

Series gate resistor $R_{g}$ will dampen any high frequency oscillations caused by the MOSFET input capacitance and any series wiring induction in the gate-source circuit. Diode D is required if the negative current into the Bottom Drive Outputs exceeds 50 mA .

Figure 27. MOSFET Drive Precautions

The addition of the RC filter will eliminate current-limit instability caused by the leading edge spike on the current waveform. Resistor $R_{S}$ should be a low inductance type.

Figure 26. Current Waveform Spike Suppression

The totem-pole output can furnish negative base current for enhanced transistor turn-off, with the addition of capacitor C .

Figure 28. Bipolar Transistor Drive

Control Circuitry Ground (Pin 16) and Current Sense Inverting Input (Pin 15) must return on separate paths to the Central Input Source Ground.

Virtually lossless current sensing can be achieved with the implementation of SENSEFET power switches

Figure 29. Current Sensing Power MOSFETs

Figure 31. Differential Input Speed Controller

This circuit generates $\mathrm{V}_{\text {Boost }}$ for Figure 25.
Figure 30. High Voltage Boost Supply

Resistor $R_{1}$ with capacitor $C$ sets the acceleration time constant while $R_{2}$ controls the deceleration. The values of $R_{1}$ and $R_{2}$ should be at least ten times greater than the speed set potentiometer to minimize time constant variations with different speed settings.

Figure 32. Controlled Acceleration/Deceleration

The SN74LS145 is an open collector BCD to One of Ten decoder. When connected as shown, input codes 0000 through 1001 steps the PWM in increments of approximately $10 \%$ from 0 to $90 \%$ on-time. Input codes 1010 through 1111 will produce $100 \%$ on-time or full motor speed.

The rotor position sensors can be used as a tachometer. By differentiating the positive-going edges and then integrating them over time, a voltage proportional to speed can be generated. The error amp compares this voltage to that of the speed set to control the PWM.

Figure 34. Closed Loop Speed Control

This circuit can control the speed of a cooling fan proportional to the difference between the sensor and set temperatures. The control loop is closed as the forced air cools the NTC thermistor. For controlled heating applications, exchange the positions of $\mathrm{R}_{1}$ and $\mathrm{R}_{2}$.

Figure 35. Closed Loop Temperature Control

## SYSTEM APPLICATIONS

## Three Phase Motor Commutation

The three phase application shown in Figure 36 is a full-featured open loop motor controller with full wave, six step drive. The upper power switch transistors are Darlingtons while the lower devices are power MOSFETs. Each of these devices contains an internal parasitic catch diode that is used to return the stator inductive energy back to the power supply. The outputs are capable of driving a delta or wye connected stator, and a grounded neutral wye if split supplies are used. At any given rotor position, only one top and one bottom power switch (of different totem poles) is enabled. This configuration switches both ends of the stator winding from supply to ground which causes the current flow to be bidirectional or full wave. A leading edge spike is usually present on the current waveform and can cause a current-limit instability. The spike can be eliminated by adding an RC filter in series with the Current Sense Input. Using a low inductance type resistor for $\mathrm{R}_{\mathrm{S}}$ will also aid in
spike reduction. Care must be taken in the selection of the bottom power switch transistors so that the current during braking does not exceed the device rating. During braking, the peak current generated is limited only by the series resistance of the conducting bottom switch and winding.

$$
I_{\text {peak }}=\frac{V_{M}+E M F}{R_{\text {switch }}+R_{\text {winding }}}
$$

If the motor is running at maximum speed with no load, the generated back EMF can be as high as the supply voltage, and at the onset of braking, the peak current may approach twice the motor stall current. Figure 37 shows the commutation waveforms over two electrical cycles. The first cycle ( $0^{\circ}$ to $360^{\circ}$ ) depicts motor operation at full speed while the second cycle $\left(360^{\circ}\right.$ to $\left.720^{\circ}\right)$ shows a reduced speed with about $50 \%$ pulse width modulation. The current waveforms reflect a constant torque load and are shown synchronous to the commutation frequency for clarity.

Figure 36. Three Phase, Six Step, Full Wave Motor Controller

Figure 37. Three Phase, Six Step, Full Wave Commutation Waveforms

Figure 38 shows a three phase, three step, half wave motor controller. This configuration is ideally suited for automotive and other low voltage applications since there is only one power switch voltage drop in series with a given stator winding. Current flow is unidirectional or half wave because only one end of each winding is switched. Continuous braking with the typical half wave arrangement presents a motor overheating problem since stator current is limited only by the winding resistance. This is due to the lack of upper power switch transistors, as in the full wave circuit, used to disconnect the windings from the supply voltage
$\mathrm{V}_{\mathrm{M}}$. A unique solution is to provide braking until the motor stops and then turn off the bottom drives. This can be accomplished by using the Fault Output in conjunction with the Output Enable as an over current timer. Components $R_{\text {DLY }}$ and $C_{\text {DLY }}$ are selected to give the motor sufficient time to stop before latching the Output Enable and the top drive AND gates low. When enabling the motor, the brake switch is closed and the PNP transistor (along with resistors $\mathrm{R}_{1}$ and $\mathrm{R}_{\mathrm{DLY}}$ ) are used to reset the latch by discharging $\mathrm{C}_{\text {DLY }}$. The stator flyback voltage is clamped by a single zener and three diodes.

Figure 38. Three Phase, Three Step, Half Wave Motor Controller

## Three Phase Closed Loop Controller

The MC33035, by itself, is only capable of open loop motor speed control. For closed loop motor speed control, the MC33035 requires an input voltage proportional to the motor speed. Traditionally, this has been accomplished by means of a tachometer to generate the motor speed feedback voltage. Figure 39 shows an application whereby an MC33039, powered from the 6.25 V reference (Pin 8) of the MC33035, is used to generate the required feedback voltage without the need of a costly tachometer. The same Hall sensor signals used by the MC33035 for rotor position decoding are utilized by the MC33039. Every positive or negative going transition of the Hall sensor signals on any of the sensor lines causes the MC33039 to produce an output pulse of defined amplitude and time duration, as determined by the external resistor $\mathrm{R}_{1}$ and capacitor $\mathrm{C}_{1}$. The output train
of pulses at Pin 5 of the MC33039 are integrated by the error amplifier of the MC33035 configured as an integrator to produce a DC voltage level which is proportional to the motor speed. This speed proportional voltage establishes the PWM reference level at Pin 13 of the MC33035 motor controller and closes the feedback loop. The MC33035 outputs drive a TMOS power MOSFET 3-phase bridge. High currents can be expected during conditions of start-up, breaking, and change of direction of the motor.

The system shown in Figure 39 is designed for a motor having 120/240 degrees Hall sensor electrical phasing. The system can easily be modified to accommodate $60 / 300$ degree Hall sensor electrical phasing by removing the jumper $\left(\mathrm{J}_{2}\right)$ at Pin 22 of the MC33035.

Figure 39. Closed Loop Brushless DC Motor Control Using The MC33035 and MC33039

## Sensor Phasing Comparison

There are four conventions used to establish the relative phasing of the sensor signals in three phase motors. With six step drive, an input signal change must occur every 60 electrical degrees; however, the relative signal phasing is dependent upon the mechanical sensor placement. A comparison of the conventions in electrical degrees is shown in Figure 40. From the sensor phasing table in Figure 41, note that the order of input codes for $60^{\circ}$ phasing is the reverse of $300^{\circ}$. This means the MC33035, when configured for $60^{\circ}$ sensor electrical phasing, will operate a motor with either $60^{\circ}$ or $300^{\circ}$ sensor electrical phasing, but resulting in opposite directions of rotation. The same is true for the part when it is configured for $120^{\circ}$ sensor electrical phasing; the motor will operate equally, but will result in opposite directions of rotation for $120^{\circ}$ for $240^{\circ}$ conventions.

Figure 40. Sensor Phasing Comparison

| Sensor Electrical Phasing (Degrees) |  |  |  |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| 0 | 0 | 0 | 0 | 0 | 1 | 0 | 1 | 0 | 0 | 1 | 1 |

Figure 41. Sensor Phasing Table

In this data sheet, the rotor position is always given in electrical degrees since the mechanical position is a function of the number of rotating magnetic poles. The relationship between the electrical and mechanical position is:

$$
\text { Electrical Degrees }=\text { Mechanical Degrees }\left(\frac{\# \text { Rotor Poles }}{2}\right)
$$

An increase in the number of magnetic poles causes more electrical revolutions for a given mechanical revolution. General purpose three phase motors typically contain a four pole rotor which yields two electrical revolutions for one mechanical.

## Two and Four Phase Motor Commutation

The MC33035 is also capable of providing a four step output that can be used to drive two or four phase motors. The truth table in Figure 42 shows that by connecting sensor inputs $S_{B}$ and $S_{C}$ together, it is possible to truncate the number of drive output states from six to four. The output power switches are connected to $\mathrm{B}_{\mathrm{T}}, \mathrm{C}_{\mathrm{T}}, \mathrm{B}_{\mathrm{B}}$, and $\mathrm{C}_{\mathrm{B}}$. Figure 43 shows a four phase, four step, full wave motor control application. Power switch transistors $\mathrm{Q}_{1}$ through $\mathrm{Q}_{8}$ are Darlington type, each with an internal parasitic catch diode. With four step drive, only two rotor position sensors spaced at 90 electrical degrees are required. The commutation waveforms are shown in Figure 44.
Figure 45 shows a four phase, four step, half wave motor controller. It has the same features as the circuit in Figure 38, except for the deletion of speed control and braking.

## MC33035

Rotor Electrical Position (Degrees)

Figure 44. Four Phase, Four Step, Full Wave Motor Controller

## Brush Motor Control

Though the MC33035 was designed to control brushless DC motors, it may also be used to control DC brush type motors. Figure 46 shows an application of the MC33035 driving a MOSFET H-bridge affording minimal parts count to operate a brush-type motor. Key to the operation is the input sensor code [100] which produces a top-left $\left(\mathrm{Q}_{1}\right)$ and a bottom-right $\left(\mathrm{Q}_{3}\right)$ drive when the controller's forward/reverse pin is at logic [1]; top-right $\left(\mathrm{Q}_{4}\right)$, bottom-left $\left(\mathrm{Q}_{2}\right)$ drive is realized when the Forward/Reverse pin is at logic [0]. This code supports the requirements necessary for H -bridge drive accomplishing both direction and speed control.

The controller functions in a normal manner with a pulse width modulated frequency of approximately 25 kHz . Motor speed is controlled by adjusting the voltage presented to the noninverting input of the error amplifier establishing the PWM's slice or reference level. Cycle-by-cycle current limiting of the motor current is accomplished by sensing the voltage ( 100 mV ) across the $\mathrm{R}_{\mathrm{S}}$ resistor to ground of the H -bridge motor current. The over current sense circuit
makes it possible to reverse the direction of the motor, using the normal forward/reverse switch, on the fly and not have to completely stop before reversing.

## LAYOUT CONSIDERATIONS

Do not attempt to construct any of the brushless motor control circuits on wire-wrap or plug-in prototype boards. High frequency printed circuit layout techniques are imperative to prevent pulse jitter. This is usually caused by excessive noise pick-up imposed on the current sense or error amp inputs. The printed circuit layout should contain a ground plane with low current signal and high drive and output buffer grounds returning on separate paths back to the power supply input filter capacitor $\mathrm{V}_{\mathrm{M}}$. Ceramic bypass capacitors $(0.1 \mu \mathrm{~F})$ connected close to the integrated circuit at $\mathrm{V}_{\mathrm{CC}}, \mathrm{V}_{\mathrm{C}}, \mathrm{V}_{\text {ref }}$ and the error amp noninverting input may be required depending upon circuit layout. This provides a low impedance path for filtering any high frequency noise. All high current loops should be kept as short as possible using heavy copper runs to minimize radiated EMI.

Figure 46. H-Bridge Brush-Type Controller

## Closed Loop Brushless Motor Adapter

The MC33039 is a high performance closed-loop speed control adapter specifically designed for use in brushless DC motor control systems. Implementation will allow precise speed regulation without the need for a magnetic or optical tachometer. This device contains three input buffers each with hysteresis for noise immunity, three digital edge detectors, a programmable monostable, and an internal shunt regulator. Also included is an inverter output for use in systems that require conversion of sensor phasing. Although this device is primarily intended for use with the MC33035 brushless motor controller, it can be used cost effectively in many other closed-loop speed control applications.

- Digital Detection of Each Input Transition for Improved Low Speed Motor Operation
- TTL Compatible Inputs With Hysteresis
- Operation Down to 5.5 V for Direct Powering from MC33035 Reference
- Internal Shunt Regulator Allows Operation from a Non-Regulated Voltage Source
- Inverter Output for Easy Conversion between $60^{\circ} / 300^{\circ}$ and $120^{\circ} / 240^{\circ}$ Sensor Phasing Conventions

Figure 1. Typical Three Phase, Six Step Motor Application

## OPERATING DESCRIPTION

The MC33039 provides an economical method of implementing closed-loop speed control of brushless DC motors by eliminating the need for a magnetic or optical tachometer. Shown in the timing diagram of Figure 1, the three inputs (Pins 1, 2, 3) monitor the brushless motor rotor position sensors. Each sensor signal transition is digitally detected, OR'ed at the Latch 'Set' Input, and causes $\mathrm{C}_{\mathrm{T}}$ to discharge. A corresponding output pulse is generated at $f_{\text {out }}$ (Pin 5) of a defined amplitude, and programmable width determined by the values selected for $\mathrm{R}_{\mathrm{T}}$ and $\mathrm{C}_{\mathrm{T}}$ (Pin 6). The average voltage of the output pulse train increases with motor speed. When fed through a low pass filter or integrator, a DC voltage proportional to speed is generated. Figure 2 shows the proper connections for a typical closed
loop application using the MC33035 brushless motor controller. Constant speed operation down to 100 RPM is possible with economical three phase four pole motors.

The $\phi_{\mathrm{A}}$ inverter output (Pin 4) is used in systems where the controller and motor sensor phasing conventions are not compatible. A method of converting from either convention to the other is shown in Figure 3. For a more detailed explanation of this subject, refer to the text above Figure 39 on the MC33035 data sheet.

The output pulse amplitude $\mathrm{V}_{\mathrm{OH}}$ is constant with temperature and controlled by the supply voltage on $\mathrm{V}_{\mathrm{CC}}$ (Pin 8). Operation down to 5.5 V is guaranteed over temperature. For systems without a regulated power supply, an internal 8.25 V shunt regulator is provided.

## MC33030

## DC Servo Motor Controller/Driver

The MC33030 is a monolithic DC servo motor controller providing all active functions necessary for a complete closed loop system. This device consists of an on-chip op amp and window comparator with wide input common-mode range, drive and brake logic with direction memory, Power $\mathrm{H}-$ Switch driver capable of 1.0 A , independently programmable over-current monitor and shutdown delay, and over-voltage monitor. This part is ideally suited for almost any servo positioning application that requires sensing of temperature, pressure, light, magnetic flux, or any other means that can be converted to a voltage.

Although this device is primarily intended for servo applications, it can be used as a switchmode motor controller.

- On-Chip Error Amp for Feedback Monitoring
- Window Detector with Deadband and Self Centering

Reference Input

- Drive/Brake Logic with Direction Memory
- 1.0 A Power H-Switch
- Programmable Over-Current Detector
- Programmable Over-Current Shutdown Delay
- Over-Voltage Shutdown

This device contains 119 active transistors.

## OPERATING DESCRIPTION

The MC33030 was designed to drive fractional horsepower DC motors and sense actuator position by voltage feedback. A typical servo application and representative internal block diagram are shown in Figure 17. The system operates by setting a voltage on the reference input of the Window Detector (Pin 1) which appears on (Pin 2). A DC motor then drives a position sensor, usually a potentiometer driven by a gear box, in a corrective fashion so that a voltage proportional to position is present at Pin 3. The servo motor will continue to run until the voltage at Pin 3 falls within the dead zone, which is centered about the reference voltage.

The Window Detector is composed of two comparators, A and B, each containing hysteresis. The reference input, common to both comparators, is pre-biased at $1 / 2 \mathrm{~V}_{\mathrm{CC}}$ for simple two position servo systems and can easily be overridden by an external voltage divider. The feedback voltage present at Pin 3 is connected to the center of two resistors that are driven by an equal magnitude current source and sink. This generates an offset voltage at the input of each comparator which is centered about Pin 3 that can float virtually from $\mathrm{V}_{\mathrm{CC}}$ to ground. The sum of the upper and lower offset voltages is defined as the window detector input dead zone range.

To increase system flexibility, an on-chip Error Amp is provided. It can be used to buffer and/or gain-up the actuator position voltage which has the effect of narrowing the dead zone range. A PNP differential input stage is provided so that the input common-mode voltage range will include ground. The main design goal of the error amp output stage was to be able to drive the window detector input. It typically can source 1.8 mA and sink $250 \mu \mathrm{~A}$. Special design considerations must be made if it is to be used for other applications.

The Power H-Switch provides a direct means for motor drive and braking with a maximum source, sink, and brake current of 1.0 A continuous. Maximum package power dissipation limits must be observed. Refer to Figure 15 for thermal information. For greater drive current requirements, a method for buffering that maintains all the system features is shown in Figure 30.

The Over-Current Monitor is designed to distinguish between motor start-up or locked rotor conditions that can occur when the actuator has reached its travel limit. A fraction of the Power H-Switch source current is internally fed into one of the two inverting inputs of the current comparator, while the non-inverting input is driven by a programmable current reference. This reference level is controlled by the resistance value selected for $\mathrm{R}_{\mathrm{OC}}$, and must be greater than the required motor run-current with its
mechanical load over temperature; refer to Figure 8. During an over-current condition, the comparator will turn off and allow the current source to charge the delay capacitor, $\mathrm{C}_{\text {DLY }}$. When C DLY charges to a level of 7.5 V , the set input of the over-current latch will go high, disabling the drive and brake functions of the Power H -Switch. The programmable time delay is determined by the capacitance value-selected for C CLY .

This system allows the Power H-Switch to supply motor start-up current for a predetermined amount of time. If the rotor is locked, the system will time-out and shut-down. This feature eliminates the need for servo end-of-travel or limit switches. Care must be taken so as not to select too large of a capacitance value for $C_{D L Y}$. An over-current condition for an excessively long time-out period can cause the integrated circuit to overheat and eventually fail. Again, the maximum package power dissipation limits must be observed. The over-current latch is reset upon power-up or by readjusting $\mathrm{V}_{\text {Pin } 2}$ as to cause $\mathrm{V}_{\text {Pin }} 3$ to enter or pass through the dead zone. This can be achieved by requesting the motor to reverse direction.

An Over-Voltage Monitor circuit provides protection for the integrated circuit and motor by disabling the Power H -Switch functions if $\mathrm{V}_{\mathrm{CC}}$ should exceed 18 V . Resumption of normal operation will commence when $\mathrm{V}_{\mathrm{CC}}$ falls below 17.4 V .

A timing diagram that depicts the operation of the Drive/Brake Logic section is shown in Figure 18. The waveforms grouped in [1] show a reference voltage that was preset, appearing on Pin 2, which corresponds to the desired actuator position. The true actuator position is represented by the voltage on Pin 3. The points $\mathrm{V}_{1}$ through $\mathrm{V}_{4}$ represent the input voltage thresholds of comparators A and B that cause a change in their respective output state. They are defined as follows:
$\mathrm{V}_{1}=$ Comparator B turn-off threshold
$\mathrm{V}_{2}=$ Comparator A turn-on threshold
$\mathrm{V}_{3}=$ Comparator A turn-off threshold
$\mathrm{V}_{4}=$ Comparator B turn-on threshold
$\mathrm{V}_{1}-\mathrm{V}_{4}=$ Comparator B input hysteresis voltage
$\mathrm{V}_{2}-\mathrm{V}_{3}=$ Comparator A input hysteresis voltage
$\mathrm{V}_{2}-\mathrm{V}_{4}=$ Window detector input dead zone range
$\left|\left(\mathrm{V}_{2}-\mathrm{V}_{\text {Pin2 }}\right)-\left(\mathrm{V}_{\text {Pin2 }}-\mathrm{V}_{4}\right)\right|=$ Window detector input voltage

It must be remembered that points $\mathrm{V}_{1}$ through $\mathrm{V}_{4}$ always try to follow and center about the reference voltage setting if it is within the input common-mode voltage range of Pin 3 ; Figures 4 and 5 . Initially consider that the feedback input voltage level is somewhere on the dashed line between $\mathrm{V}_{2}$ and $\mathrm{V}_{4}$ in [1]. This is within the dead zone range as defined above and the motor will be off. Now if the reference voltage is raised so that $V_{\text {Pin } 3}$ is less than $V_{4}$, comparator $B$ will turn-on [3] enabling $\bar{Q}$ Drive, causing Drive Output A to sink and B to source motor current [8]. The actuator will move in Direction $B$ until $V_{\text {Pin }} 3$ becomes greater than $V_{1}$. Comparator B will turn-off, activating the brake enable [4]
and $\bar{Q}$ Brake [6] causing Drive Output A to go high and B to go into a high impedance state. The inertia of the mechanical system will drive the motor as a generator creating a positive voltage on Pin 10 with respect to Pin 14 . The servo system can be stopped quickly, so as not to over-shoot through the dead zone range, by braking. This is accomplished by shorting the motor/generator terminals together. Brake current will flow into the diode at Drive Output B, through the internal $\mathrm{V}_{\mathrm{CC}}$ rail, and out the emitter of the sourcing transistor at Drive Output A. The end of the solid line and beginning of the dashed for $\mathrm{V}_{\operatorname{Pin} 3}$ [1] indicates the possible resting position of the actuator after braking.

Figure 17. Representative Block Diagram and Typical Servo Application

If $\mathrm{V}_{\text {Pin } 3}$ should continue to rise and become greater than $\mathrm{V}_{2}$, the actuator will have over shot the dead zone range and cause the motor to run in Direction A until $\mathrm{V}_{\text {Pin } 3}$ is equal to $\mathrm{V}_{3}$. The Drive/Brake behavior for Direction A is identical to that of B . Overshooting the dead zone range in both directions can cause the servo system to continuously hunt or oscillate. Notice that the last motor run-direction is stored in the direction latch. This information is needed to determine whether Q or $\overline{\mathrm{Q}}$ Brake is to be enabled when $\mathrm{V}_{\text {Pin }}$ 3 enters the dead zone range. The dashed lines in [8,9] indicate the resulting waveforms of an over-current condition that has exceeded the programmed time delay. Notice that both Drive Outputs go into a high impedance state until $\mathrm{V}_{\text {Pin } 2}$ is readjusted so that $\mathrm{V}_{\text {Pin } 3}$ enters or crosses through the dead zone [7, 4].

The inputs of the Error Amp and Window Detector can be susceptible to the noise created by the brushes of the DC motor and cause the servo to hunt. Therefore, each of these inputs are provided with an internal series resistor and are pinned out for an external bypass capacitor. It has been found that placing a capacitor with short leads directly across the brushes will significantly reduce noise problems. Good quality RF bypass capacitors in the range of 0.001 to $0.1 \mu \mathrm{~F}$ may be required. Many of the more economical motors will generate significant levels of RF energy over a spectrum that extends from DC to beyond 200 MHz . The capacitance value and method of noise filtering must be determined on a system by system basis.

Thus far, the operating description has been limited to servo systems in which the motor mechanically drives a potentiometer for position sensing. Figures 19, 20, 27, and 31 show examples that use light, magnetic flux, temperature, and pressure as a means to drive the feedback element. Figures 21, 22 and 23 are examples of two position, open loop servo systems. In these systems, the motor runs the actuator to each end of its travel limit where the Over-Current Monitor detects a locked rotor condition and shuts down the drive. Figures 32 and 33 show two possible methods of using the MC33030 as a switching motor controller. In each example a fixed reference voltage is applied to Pin 2. This causes $\mathrm{V}_{\text {pin }} 3$ to be less than $\mathrm{V}_{4}$ and Drive Output A, Pin 14, to be in a low state saturating the TIP42 transistor. In Figure 32, the motor drives a tachometer that generates an ac voltage proportional to RPM. This voltage is rectified, filtered, divided down by the speed set potentiometer, and applied to Pin. 8. The motor will accelerate until $\mathrm{V}_{\text {Pin } 3}$ is equal to $\mathrm{V}_{1}$ at which time Pin 14 will go to a high state and terminate the motor drive. The motor will now coast until $\mathrm{V}_{\text {Pin }} 3$ is less than $\mathrm{V}_{4}$ where upon drive is then reapplied. The system operation of Figure 31 is identical to that of 32 except the signal at Pin 3 is an amplified average of the motors drive and back EMF voltages. Both systems exhibit excellent control of RPM with variations of $\mathrm{V}_{\mathrm{CC}}$; however, Figure 32 has somewhat better torque characteristics at low RPM.

## Stepper Motor Driver

The MC3479 is designed to drive a two-phase stepper motor in the bipolar mode. The circuit consists of four input sections, a logic decoding/sequencing section, two driver-stages for the motor coils, and an output to indicate the $\overline{\text { Phase A }}$ drive state.

- Single Supply Operation: 7.2 to 16.5 V
- $350 \mathrm{~mA} /$ Coil Drive Capability
- Clamp Diodes Provided for Back-EMF Suppression
- Selectable $\overline{\mathrm{CW}} / \mathrm{CCW}$ and $\overline{\text { Full }} /$ Half Step Operation
- Selectable High/Low Output Impedance (Half Step Mode)
- TTL/CMOS Compatible Inputs
- Input Hysteresis: 400 mV Minimum
- Phase Logic Can Be Initialized to $\overline{\text { Phase A }}$
- Phase A Output Drive State Indication (Open-Collector)

Figure 3. Bias/Set Timing (Refer to Figure 2)

| Pin No. |  | Function | Symbol | Description |
| :---: | :---: | :---: | :---: | :---: |
| 20-Pin | 16-Pin |  |  |  |
| 20 | 16 | Power Supply | $\mathrm{V}_{\mathrm{M}}$ | Power supply pin for both the logic circuit and the motor coil current. Voltage range is +7.2 to +16.5 volts. |
| $\begin{gathered} \hline 4,5,6,7 \\ 14,15,16 \\ 17 \end{gathered}$ | $\begin{gathered} 4,5, \\ 12.13 \end{gathered}$ | Ground | Gnd | Ground pins for the logic circuit and the motor coil current. The physical configuration of the pins aids in dissipating heat from within the IC package. |
| 1 | 1 | Clamp Diode Voltage | $\mathrm{V}_{\mathrm{D}}$ | This pin is used to protect the outputs where large voltage spikes may occur as the motor coils are switched. Typically a diode is connected between this pin and Pin 16. See Figure 11. |
| $\begin{gathered} 2,3, \\ 18,19 \end{gathered}$ | $\begin{gathered} 2,3, \\ 14,15 \end{gathered}$ | Driver Outputs | $\begin{aligned} & \mathrm{L} 1, \mathrm{~L} 2 \\ & \mathrm{~L} 3, \mathrm{~L} 4 \end{aligned}$ | High current outputs for the motor coils. L1 and L2 are connected to one coil, and L3 and L4 to the other coil. |
| 8 | 6 | Bias/Set | $\overline{\mathrm{B}} / \mathrm{S}$ | This pin is typically 0.7 volts below $\mathrm{V}_{\mathrm{M}}$. The current out of this pin (through a resistor to ground) determines the maximum output sink current. If the pin is opened ( $l_{\mathrm{BS}}<5.0 \mu \mathrm{~A}$ ) the outputs assume a high impedance condition, while the internal logic presets to a Phase A condition. |
| 9 | 7 | Clock | Clk | The positive edge of the clock input switches the outputs to the next position. This input has no effect if Pin 6 is open. |
| 11 | 9 | Full/Half Step | F/HS | When low (Logic "0"), each clock input pulse will cause the motor to rotate one full step. When high, each clock pulse will cause the motor to rotate one-half step. See Figure 7 for sequence. |
| 12 | 10 | Clockwise/ Counterclockwise | CW/CCW | This input allows reversing the rotation of the motor. See Figure 7 for sequence. |
| 10 | 8 | Output Impedance Control | OIC | This input is relevant only in the half step mode (Pin $9>2.0 \mathrm{~V}$ ). When low (Logic "0"), the two driver outputs of the non-energized coil will be in a high impedance condition. When high the same driver outputs will be at a low impedance referenced to $\mathrm{V}_{\mathrm{M}}$. See Figure 7. |
| 13 | 11 | Phase A | Ph A | This open-collector output indicates (when low) that the driver outputs are in the Phase A condition ( $\mathrm{L} 1=\mathrm{L} 3=\mathrm{V}_{\mathrm{OHD}}, \mathrm{L} 2=\mathrm{L} 4=\mathrm{V}_{\mathrm{OLD}}$ ). |

## APPLICATION INFORMATION

## General

The MC3479 integrated circuit is designed to drive a stepper positioning motor in applications such as disk drives and robotics. The outputs can provide up to 350 mA to each of two coils of a two-phase motor. The outputs change state with each low-to-high transition of the clock input, with the new output state depending on the previous state, as well as the input conditions at the logic controls.

## Outputs

The outputs (L1-L4) are high current outputs (see Figure 5), which when connected to a two-phase motor, provide two full-bridge configurations (L3 and L4 are not shown in Figure 5). The polarities applied to the motor coils depend on which transistor $\left(\mathrm{Q}_{\mathrm{H}}\right.$ or $\left.\mathrm{Q}_{\mathrm{L}}\right)$ of each output is on, which in turn depends on the inputs and the decoding circuitry.

Figure 4. Clock Timing (Refer to Figure 2)

Figure 5. Output Stages

The maximum sink current available at the outputs is a function of the resistor connected between Pin 6 and ground (see section on $\overline{\mathrm{Bias}} /$ Set operation). Whenever the outputs are to be in a high impedance state, both transistors $\left(\mathrm{Q}_{\mathrm{H}}\right.$ and $\mathrm{Q}_{\mathrm{L}}$ of Figure 5) of each output are off.

## $V_{D}$

This pin allows for provision of a current path for the motor coil current during switching, in order to suppress back-EMF voltage spikes. $\mathrm{V}_{\mathrm{D}}$ is normally connected to $\mathrm{V}_{\mathrm{M}}$ (Pin 16) through a diode (zener or regular), a resistor, or directly. The peaks instantaneous voltage at the outputs must not exceed $\mathrm{V}_{\mathrm{M}}$ by more than 6.0 V . The voltage drop across the internal clamping diodes must be included in this portion of the design (see Figure 6). Note the parasitic diodes (Figure 5) across each $\mathrm{Q}_{\mathrm{L}}$ of each output provide for a complete circuit path for the switched current.

Figure 6. Clamp Diode Characteristics

## Full/Half Step

When this input is at a Logic " 0 " ( $<0.8 \mathrm{~V}$ ), the outputs change a full step with each clock cycle, with the sequence direction depending on the $\overline{\mathrm{CW}} / \mathrm{CCW}$ input. There are four steps ( $\overline{\text { Phase } \mathrm{A}}, \overline{\mathrm{B}}, \overline{\mathrm{C}}, \overline{\mathrm{D}}$ ) for each complete cycle of the sequencing logic. Current flows through both motor coils during each step, as shown in Figure 7.

When taken to a Logic " 1 " (>2.0 V), the outputs change a half step with each clock cycle, with the sequence direction depending on the $\overline{\mathrm{CW}} / \mathrm{CCW}$ input. Eight steps ( $\overline{\text { Phase A }}$ to $\overline{\mathrm{H}})$ result for each complete cycle of the sequencing logic. $\overline{\text { Phase } A}, \overline{\mathrm{C}}, \overline{\mathrm{E}}$ and $\overline{\mathrm{G}}$ correspond (in polarity) to $\overline{\text { Phase } \mathrm{A}}, \overline{\mathrm{B}}$, $\overline{\mathrm{C}}$, and $\overline{\mathrm{D}}$, respectively, of the full step sequence. $\overline{\text { Phase } \mathrm{B}}, \overline{\mathrm{D}}$, $\overline{\mathrm{F}}$ and $\overline{\mathrm{H}}$ provide current to one motor coil, while de-energizing the other coil. The condition of the outputs of the de-energized coil depends on the OIC input, see Figure 7 timing diagram.

## OIC

The output impedance control input determines the output impedance to the de-energized coil when operating in the half-step mode. When the outputs are in $\overline{\text { Phase } B}, \overline{\mathrm{D}}, \overline{\mathrm{F}}$ or $\overline{\mathrm{H}}$
(Figure 7) and this input is at a Logic " 0 " ( $<0.8 \mathrm{~V}$ ), the two outputs to the de-energized coil are in a high impedance condition - $\mathrm{Q}_{\mathrm{L}}$ and $\mathrm{Q}_{\mathrm{H}}$ of both outputs (Figure 5) are off. When this input is at a Logic " 1 " (>2.0 V), a low impedance output is provided to the de-energized coil as both outputs have $\mathrm{Q}_{\mathrm{H}}$ on $\left(\mathrm{Q}_{\mathrm{L}}\right.$ off $)$. To complete the low impedance path requires connecting $\mathrm{V}_{\mathrm{D}}$ to $\mathrm{V}_{\mathrm{M}}$ as described elsewhere in this data sheet.

## $\overline{B i a s} /$ Set

This pin can be used for three functions: a) determining the maximum output sink current; b) setting the internal logic to a known state; and c) reducing power consumption.
a) The maximum output sink current is determined by the base drive current supplied to the lower transistors $\left(\mathrm{Q}_{\mathrm{LS}}\right.$ of Figure 5) of each output, which in turn, is a function of $\mathrm{I}_{\mathrm{BS}}$. The appropriate value of $\mathrm{I}_{\mathrm{BS}}$ is determined by:

$$
I_{B S}=I_{O D} \times 0.86
$$

where $\mathrm{I}_{\mathrm{BS}}$ is in microamps, and $\mathrm{I}_{\mathrm{OD}}$ is the motor current/coil in milliamps.

Figure 7. Output Sequence

The value of $R_{B}$ (between this pin and ground) is then determined by:

$$
R_{B}=\frac{V_{M}-0.7 V}{I_{B S}}
$$

b) When this pin is opened (raised to $V_{M}$ ) such that $I_{B S}$ is $<5.0 \mu \mathrm{~A}$, the internal logic is set to the Phase A condition, and the four driver outputs are put into a high impedance state. The $\overline{\text { Phase A }}$ output (Pin 11) goes active (low), and input signals at the controls are ignored during this time. Upon re-establishing $\mathrm{I}_{\mathrm{BS}}$, the driver outputs become active, and will be in the Phase $\overline{\mathrm{A}}$ position $\left(\mathrm{L} 1=\mathrm{L} 3=\mathrm{V}_{\mathrm{OHD}}, \mathrm{L} 2=\mathrm{L} 4=\mathrm{V}_{\mathrm{OLD}}\right)$. The circuit will then respond to the inputs at the controls.

The Set function (opening this pin) can be used as a power-up reset while supply voltages are settling. A CMOS logic gate (powered by $\mathrm{V}_{\mathrm{M}}$ ) can be used to control this pin as shown in Figure 11.
c) Whenever the motor is not being stepped, power dissipation in the IC and in the motor may be lowered by reducing $\mathrm{I}_{\mathrm{BS}}$, so as to reduce the output (motor) current. Setting $\mathrm{I}_{\mathrm{BS}}$ to $75 \mu \mathrm{~A}$ will reduce the motor current, but will not reset the internal logic as described above. See Figure 12 for a suggested circuit.

## Power Dissipation

The power dissipated by the MC3479 must be such that the junction temperature $\left(\mathrm{T}_{\mathrm{J}}\right)$ does not exceed $150^{\circ} \mathrm{C}$. The power dissipated can be expressed as:

$$
\mathrm{P}=\left(\mathrm{V}_{\mathrm{M}} \times \mathrm{I}_{\mathrm{M}}\right)+\left(2 \times \mathrm{I}_{\mathrm{OD}}\right)\left[\left(\mathrm{V}_{\mathrm{M}}-\mathrm{V}_{\mathrm{OHD}}\right)+\mathrm{V}_{\mathrm{OLD}}\right]
$$

where $\quad V_{M}=$ Supply voltage;
$\mathrm{I}_{\mathrm{M}}=$ Supply current other than $\mathrm{I}_{\mathrm{OD}}$;
$\mathrm{I}_{\mathrm{OD}}=$ Output current to each motor coil;
$\mathrm{V}_{\mathrm{OHD}}=$ Driver output high voltage;
$\mathrm{V}_{\text {OLD }}=$ Driver output low voltage .
The power supply current $\left(\mathrm{I}_{\mathrm{M}}\right)$ is obtained from Figure 8. After the power dissipation is calculated, the junction temperature can be calculated using:

$$
T_{J}=\left(P \times R_{\theta J A}\right)+T_{A}
$$

where $\mathrm{R}_{\theta \mathrm{JA}}=$ Junction-to-ambient thermal resistance ( $52^{\circ} \mathrm{C} / \mathrm{W}$ for the DIP, $72^{\circ} \mathrm{C} / \mathrm{W}$ for the FN Package);

$$
\mathrm{T}_{\mathrm{A}}=\text { Ambient Temperature }
$$

Figure 8. Power Supply Current

For example, assume an application where $\mathrm{V}_{\mathrm{M}}=12 \mathrm{~V}$, the motor requires $200 \mathrm{~mA} /$ coil, operating at room temperature with no heatsink on the IC. $\mathrm{I}_{\mathrm{BS}}$ is calculated:

$$
\begin{aligned}
& \mathrm{I}_{\mathrm{BS}}=200 \times 0.86 \\
& \mathrm{I}_{\mathrm{BS}}=172 \mu \mathrm{~A}
\end{aligned}
$$

$\mathrm{R}_{\mathrm{B}}$ is calculated:

$$
\begin{aligned}
& \mathrm{R}_{\mathrm{B}}=(12-0.7) \mathrm{V} / 172 \mu \mathrm{~A} \\
& \mathrm{R}_{\mathrm{B}}=65.7 \mathrm{k} \Omega
\end{aligned}
$$

From Figure $8, \mathrm{I}_{\mathrm{M}}$ (max) is determined to be 40 mA . From Figure $9, \mathrm{~V}_{\mathrm{OLD}}$ is 0.46 volts, and from Figure $10,\left(\mathrm{~V}_{\mathrm{M}}-\right.$ $\left.\mathrm{V}_{\mathrm{OHD}}\right)$ is 1.4 volts.

$$
\begin{aligned}
& \mathrm{P}=(12 \times 0.040)+(2 \times 0.2)(1.4+0.46) \\
& \mathrm{P}=1.22 \mathrm{~W} \\
& \mathrm{~T}_{\mathrm{J}}=\left(1.22 \mathrm{~W} \times 52^{\circ} \mathrm{C} / \mathrm{W}\right)+25^{\circ} \mathrm{C} \\
& \mathrm{~T}_{\mathrm{J}}=88^{\circ} \mathrm{C}
\end{aligned}
$$

This temperature is well below the maximum limit. If the calculated $\mathrm{T}_{\mathrm{J}}$ had been higher than $150^{\circ} \mathrm{C}$, a heatsink such as the Staver Co. V-7 Series, Aavid \#5802, or Thermalloy \#6012 could be used to reduce $\mathrm{R}_{\theta \mathrm{JJA}}$. In extreme cases, forced air cooling should be considered.

The above calculation, and $\mathrm{R}_{\theta \mathrm{JA}}$, assumes that a ground plane is provided under the MC3479 (either or both sides of the PC board) to aid in the heat dissipation. Single nominal width traces leading from the four ground pins should be avoided as this will increase $\mathrm{T}_{\mathrm{J}}$, as well as provide potentially disruptive ground noise and $\mathrm{I}_{\mathrm{R}}$ drops when switching the motor current.

Figure 9. Maximum Saturation Voltage Driver Output Low

Figure 10. Maximum Saturation Voltage Driver Output High

Figure 11. Typical Applications Circuit

- Suggested value for $\mathrm{R}_{\mathrm{B} 1}\left(\mathrm{~V}_{\mathrm{M}}=12 \mathrm{~V}\right)$ is $150 \mathrm{k} \Omega$.
- $\mathrm{R}_{\mathrm{B}}$ calculation (see text) must take into account
the current through $\mathrm{R}_{\mathrm{B} 1}$.

Figure 12. Power Reduction

## CS8441

## Stepper Motor Driver with Divide by Select

The CS8441 is a Stepper Motor Driver that implements an H -Bridge design in order to drive two coils in an eight step sequence per revolution in the divide by 1 mode; 16 step sequence in the divide by 2 mode. The H -Bridge is capable of delivering 85 mA to the load.

The sequencer insures that the odometer is monotonic. This sequencer is configured such that simultaneous conduction does not occur. Before each successive output sequence the part is taken through a state where both outputs are turned off individually. This tends to minimize the inductive kick back energy that the part must absorb. On-chip clamp diodes are across each output to protect the part from the kick back energy that it must absorb.

Additional part protection is provided by two functions. The first being "short circuit protection." This function will protect the part in the case of a shorted or partially shorted load. The second protection function is the "overvoltage function." This function monitors the level of the supply voltage. In transient conditions such as load dump, the part will shut down, protecting itself.

## Features

- No Cross-Conduction in Either H-Bridge
- Divide by 1 and Divide by 2 Modes
- Guaranteed Monotonic
- On-Chip Flyback Diodes
- Fault Protection
- Overvoltage
- Load Dump Protection to 60 V

## CIRCUIT OPERATION

## SPEED SENSOR INPUT

SENSOR is a PNP comparator input which accepts a sine wave or a square wave input. This input is protected from excursions above $\mathrm{V}_{\mathrm{CC}}$ as well as any below ground, as long as the current is limited to 1.5 mA . It has an active clamp set to zero volts to prevent negative input voltages from disrupting normal operation. The sensor input can withstand $150 \mathrm{~V}_{\mathrm{DC}}$ as long as the input current is limited to 1.5 mA max. using a series resistor of $100 \mathrm{k} \Omega$.

## COIL DRIVER OUTPUTS

Simultaneously energizing the source and sink on either leg is not permitted, i.e. Q1 \& Q2 or Q3 \& Q4 cannot be energized simultaneously.

Circuit function is not affected by inductive transients due to coil loads as specified in the Transition States section.

The transition states occur as indicated in Table 1 without any intermediate states permitted.

Table 1. Transition States

| State | Coil A | Coil B |
| :---: | :---: | :---: |
| 0 | + | + |
| 1 | OFF | + |
| 2 | - | + |
| 3 | - | OFF |
| 4 | - | - |
| 5 | OFF | - |
| 6 | + | - |
| 7 | + | OFF |

The polarity definition for the coil driver outputs is as follows:

| Polarity | Connect Coil + | Connect Coil - |
| :---: | :---: | :---: |
| Positive (+) | V $_{\text {CC }}$ | GND |
| Negative ( - ) | GND | $\mathrm{V}_{\mathrm{CC}}$ |

## DIVIDER SELECT INPUT

The speed sensor input frequency is divided by one or divided by two by connecting the divider select input, (Pin 5) as follows:

Logic $0=$ divide by 2 .
Logic $1=$ divide by 1 .

Figure 2. Coil Driver Output

## CS4161

## 85 mA Dual H-Bridge Odometer Driver with Divide by Select and UVLO

The CS4161 is a Stepper Motor Driver that implements an H -Bridge design in order to drive two coils in an eight step sequence per revolution in the divide by 1 mode; 16 step sequence in the divide by 2 mode. The H -Bridge is capable of delivering 85 mA to the load.

The sequencer insures that the odometer is monotonic. This sequencer is configured such that simultaneous conduction does not occur. Before each successive output sequence the part is taken through a state where both outputs are turned off individually. This tends to minimize the inductive kick back energy that the part must absorb. On chip clamp diodes are across each output to protect the part from the kick back energy that it must absorb.

The CS4161 includes overvoltage and short circuit protection circuitry. It is lead for lead compatible with the CS8441. The CS4161 includes an additional undervoltage lockout (UVLO) function which disables the output stage until the supply voltage rises above 5.6 V , typically. The UVLO has hysteresis to prevent any power up glitching.

## Features

- Undervoltage Lockout
- Cross-Conduction Prevention Logic
- Divide by 1 and Divide by 2 Modes
- Guaranteed Monotonic
- On-Chip Flyback Diodes
- Fault Protection
- Overvoltage
- Load Dump Protection to 60 V

## CIRCUIT OPERATION

## SPEED SENSOR INPUT

SENSOR is a PNP comparator input which accepts either a sine wave or a square wave input. This input is protected from excursions above $\mathrm{V}_{\mathrm{CC}}$ as well as any below ground as long as the current is limited to 1.5 mA . It has an active clamp set to zero volts to prevent negative input voltages from disrupting normal operation. The sensor input can withstand $150 \mathrm{~V}_{\mathrm{DC}}$ as long as the input current is limited to 1.5 mA max. using a series resistor of $100 \mathrm{k} \Omega$.

## COIL DRIVER OUTPUTS

Simultaneously energizing the source and sink on either leg is not permitted, i.e. Q1 \& Q2 or Q3 \& Q4 cannot be energized simultaneously.

Circuit function is not affected by inductive transients due to coil loads as specified in the Transition States section.

The transition states occur as indicated in Table 1 without any intermediate states permitted.

Table 1. Transition States

| State | Coil A | Coil B |
| :---: | :---: | :---: |
| 0 | + | + |
| 1 | OFF | + |
| 2 | - | + |
| 3 | - | OFF |
| 4 | - | - |
| 5 | OFF | - |
| 6 | + | - |
| 7 | + | OFF |

The polarity definition for the coil driver outputs is as follows:

| Polarity | Connect Coil + | Connect Coil - |
| :---: | :---: | :---: |
| Positive (+) | $\mathrm{V}_{\mathrm{CC}}$ | GND |
| Negative (-) | GND | $\mathrm{V}_{\mathrm{CC}}$ |

## DIVIDER SELECT INPUT

The speed sensor input frequency is either divided by one or divided by two depending on the state of the SELECT input as follows:

Logic $0=$ divide by 2 .
Logic $1=$ divide by 1 .

## Universal Motor Speed Controller

The TDA1085C is a phase angle triac controller having all the necessary functions for universal motor speed control in washing machines. It operates in closed loop configuration and provides two ramp possibilities.

- On-Chip Frequency to Voltage Converter
- On-Chip Ramps Generator
- Soft-Start
- Load Current Limitation
- Tachogenerator Circuit Sensing
- Direct Supply from AC Line
- Security Functions Performed by Monitor

## GENERAL DESCRIPTION

The TDA 1085C triggers a triac accordingly to the speed regulation requirements. Motor speed is digitally sensed by a tachogenerator and then converted into an analog voltage.

The speed set is externally fixed and is applied to the internal linear regulation input after having been submitted to programmable acceleration ramps. The overall result
consists in a full motor speed range with two acceleration ramps which allow efficient washing machine control (Distribute function).
Additionally, the TDA 1085C protects the whole system against AC line stop or variations, overcurrent in the motor and tachogenerator failure.

## INPUT/OUTPUT FUNCTIONS

(Refer to Figures 1 and 8)

Voltage Regulator - (Pins 9 and 10) This is a parallel type regulator able to sink a large amount of current and offering good characteristics. Current flow is provided from AC line by external dropping resistors R1, R2, and rectifier: This half wave current is used to feed a smothering capacitor, the voltage of which is checked by the IC.

When $\mathrm{V}_{\mathrm{CC}}$ is reached, the excess of current is derived by another dropping resistor R10 and by Pin 10 . These three resistors must be determined in order:

- To let 1.0 mA flow through Pin 10 when AC line is minimum and $\mathrm{V}_{\mathrm{CC}}$ consumption is maximum (fast ramps and pulses present).
- To let $\mathrm{V}_{10}$ reach 3.0 V when AC line provides maximum current and $\mathrm{V}_{\mathrm{CC}}$ consumption is minimum (no ramps and no pulses).
- All along the main line cycle, the Pin 10 dynamic range must not be exceeded unless loss of regulation.
An AC line supply failure would cause shut down.
The double capacitive filter built with R1 and R2 gives an efficient $\mathrm{V}_{\mathrm{CC}}$ smoothing and helps to remove noise from set speeds.

Speed Sensing - (Pins 4, 11, 12) The IC is compatible with an external analog speed sensing: its output must be applied to Pin 4, and Pin 12 connected to Pin 8.

In most of the applications it is more convenient to use a digital speed sensing with an inexpensive tachogenerator which doesn't need any tuning. During every positive cycle at Pin 12, the capacitor $C_{P i n} 11$ is charged to almost $\mathrm{V}_{\mathrm{CC}}$ and during this time, Pin 4 delivers a current which is 10 times the one charging $\mathrm{C}_{\text {Pin }}$ 11. The current source gain is called $G$ and is tightly specified, but nevertheless requires an adjustment on $\mathrm{R}_{\mathrm{Pin} 4}$. The current into this resistor is proportional to $\mathrm{C}_{\text {Pin }} 11$ and to the motor speed; being filtered by a capacitor, $V_{\text {Pin } 4}$ becomes smothered and represents the "true actual motor speed".

To maintain linearity into the high speed range, it is important to verify that $\mathrm{C}_{\mathrm{Pin} 11}$ is fully charged: the internal source on Pin 11 has $100 \mathrm{~K} \Omega$ impedance. Nevertheless $\mathrm{C}_{\text {Pin } 11}$ has to be as high as possible as it has a large influence on FV/C temperature factor. A $470 \mathrm{~K} \Omega$ resistor between Pins 11 and 9 reduces leakage currents and temperature factor as well, down to neglectable effects.

Pin 12 also has a monitoring function: when its voltage is above 5.0 V , the trigger pulses are inhibited and the IC is
reset. It also senses the tachogenerator continuity, and in case of any circuit aperture, it inhibits pulse, avoiding the motor to run out of control. In the TDA 1085C, Pin 12 is negatively clamped by an internal diode which removes the necessity of the external one used in the former circuit.
Ramp Generator - (Pins 5, 6, 7) The true Set Speed value taken in consideration by the regulation is the output of the ramp generator ( $\operatorname{Pin} 7$ ). With a given value of speed set input (Pin 5), the ramp generator charges an external capacitor $C_{\text {Pin } 7}$ up to the moment $V_{\text {Pin } 5}$ (set speed) equals $\mathrm{V}_{\text {Pin }} 4$ (true speed), see Figure 2. The IC has an internal charging current source of 1.2 mA and delivers it from 0 to 12 V at Pin 7. It is the high acceleration ramp ( 5.0 s typical) which allows rapid motor speed changes without excessive strains on the mechanics. In addition, the TDA 1085C offers the possibility to break this high acceleration with the introduction of a low acceleration ramp (called Distribution) by reducing the Pin 7 source current down to $5.0 \mu \mathrm{~A}$ under Pin 6 full control, as shown by following conditions:

- Presence of high acceleration ramp $V_{\text {Pin } 5}>V_{\text {Pin } 4}$
- Distribution occurs in the $V_{\text {Pin }} 4$ range (true motor speed) defined by $\mathrm{V}_{\text {Pin } 6} \leqq \mathrm{~V}_{\text {Pin } 4} \leqq 2.0 \mathrm{~V}_{\text {Pin } 6}$
For two fixed values of $V_{\text {Pin }} 5$ and $V_{\text {Pin 6 }}$, the motor speed will have high acceleration, excluding the time for $\mathrm{V}_{\text {Pin } 4}$ to go from $\mathrm{V}_{\text {Pin }} 6$ to two times this value, high acceleration again, up to the moment the motor has reached the set speed value, at which it will stay, see Figure 3.
Should a reset happen (whatever the cause would be), the above mentioned successive ramps will be fully reprocessed from 0 to the maximum speed. If $\mathrm{V}_{\operatorname{Pin} 6}=0$, only the high acceleration ramp occurs.
To get a real zero speed position, Pin 5 has been designed in such a way that its voltage from 0 to 80 mV is interpreted as a true zero. As a consequence, when changing the speed set position, the designer must be sure that any transient zero would not occur: if any, the entire circuit will be reset.
As the voltages applied by Pins 5 and 6 are derived from the internal voltage regulator supply and Pin 4 voltage is also derived from the same source, motor speed (which is determined by the ratios between above mentioned voltages) is totally independent from $\mathrm{V}_{\mathrm{CC}}$ variations and temperature factor.

Control Amplifier - (Pin 16) It amplifies the difference between true speed (Pin 4) and set speed (Pin 5), through the
ramp generator. Its output available at Pin 16 is a double sense current source with a maximum capability of $\pm 100 \mu \mathrm{~A}$ and a specified transconductance ( $340 \mu \mathrm{~A} / \mathrm{V}$ typical). Pin 16 drives directly the trigger pulse generator, and must be loaded by an electrical network which compensates the mechanical characteristics of the motor and its load, in order to provide stability in any condition and shortest transient response; see Figure 4.

This network must be adjusted experimentally.
In case of a periodic torque variations, Pin 16 directly provides the phase angle oscillations.

Trigger Pulse Generator - (Pins 1, 2, 5, 13, 14, 15) This circuit performs four functions:

- The conversion of the control amplifier DC output level to a proportional firing angle at every main line half cycle.
- The calibration of pulse duration.
- The repetition of the pulse if the triac fails to latch on if the current has been interrupted by brush bounce.
- The delay of firing pulse until the current crosses zero at wide firing angles and inductive loads.
$R_{\text {Pin }} 15$ programs the Pin 14 discharging current. Saw tooth signal is then fully determined by R15 and C14 (usually 47 nF ). Firing pulse duration and repetition period are in inverse ratio to the saw tooth slope.

Pin 13 is the pulse output and an external limiting resistor is mandatory. Maximum current capability is 200 mA .
Current Limiter - (Pin 3) Safe operation of the motor and triac under all conditions is ensured by limiting the peak current. The motor current develops an alternative voltage in the shunt resistor ( $0.05 \Omega$ in Figure 4). The negative half waves are transferred to Pin 3 which is positively preset at a voltage determined by resistors R3 and R4. As motor current increases, the dynamical voltage range of Pin 3 increases and when Pin 3 becomes slightly negative in respect to Pin 8, a current starts to circulate in it. This current, amplified typically 180 times, is then used to discharge Pin 7 capacitor and, as a result, reduces firing angle down to a value where an equilibrium is reached. The choice of resistors R3, R4 and shunt determines the magnitude of the discharge current signals on $C_{\text {Pin }} 7$.

Notice that the current limiter acts only on peak triac current.

## APPLICATION NOTES

## (Refer to Figure 4)

## Printed Circuit Layout Rules

In the common applications, where TDA 1085C is used, there is on the same board, presence of high voltage, high currents as well as low voltage signals where millivolts count. It is of first magnitude importance to separate them from each other and to respect the following rules:

- Capacitor decoupling pins, which are the inputs of the same comparator, must be physically close to the IC, close to each other and grounded in the same point.
- Ground connection for tachogenerator must be directly connected to Pin 8 and should ground only the tacho. In effect, the latter is a first magnitude noise generator due to its proximity to the motor which induces high $\mathrm{d} \phi / \mathrm{dt}$ signals.
- The ground pattern must be in the "star style" in order to fully eliminate power currents flowing in the ground network devoted to capacitors decoupling sensitive Pins: 4, 5, 7, 11, 12, 14, 16.
As an example, Figure 5 presents a PC board pattern which concerns the group of sensitive Pins and their associated capacitors into which the a.m. rules have been implemented. Notice the full separation of "Signal World" from "Power", one by line AB and their communication by a unique strip.

These rules will lead to much satisfactory volume production in the sense that speed adjustment will stay valid in the entire speed range.

## Power Supply

As dropping resistor dissipates noticeable power, it is necessary to reduce the $\mathrm{I}_{\mathrm{CC}}$ needs down to a minimum.

Triggering pulses, if a certain number of repetitions are kept in reserve to cope with motor brush wearing at the end of its life, are the largest $\mathrm{I}_{\mathrm{CC}}$ user. Classical worst case configuration has to be considered to select dropping resistor. In addition, the parallel regulator must be always into its dynamic range, i.e., $\mathrm{I}_{\text {Pin } 10}$ over 1.0 mA and $\mathrm{V}_{\text {Pin }} 10$ over 3.0 V in any extreme configuration. The double filtering cell is mandatory.

## Tachogenerator Circuit

The tacho signal voltage is proportional to the motor speed. Stability considerations, in addition, require an RC filter, the pole of which must be looked at. The combination of both elements yield a constant amplitude signal on Pin 12 in most of the speed range. It is recommended to verify this maximum amplitude to be within 1.0 V peak in order to have the largest signal/noise ratio without resetting the integrated circuit (which occurs if $\mathrm{V}_{\text {Pin }} 12$ reaches 5.5 V ). It must be also verified that the Pin 12 signal is approximately balanced between "high" (over 300 mV ) and "low". An 8-poles tacho is a minimum for low speed stability and a 16 -poles is even better.

The RC pole of the tacho circuit should be chosen within 30 Hz in order to be as far as possible from the 150 Hz which corresponds to the AC line 3rd harmonic generated by the motor during starting procedure. In addition, a high value resistor coming from $\mathrm{V}_{\mathrm{CC}}$ introduces a positive offset at Pin 12, removes noise to be interpreted as a tacho signal. This offset should be designed in order to let Pin 12 reach at least - 200 mV (negative voltage) at the lowest motor speed. We remember the necessity of an individual tacho ground connection.

## Frequency to Voltage Converter - F V/C

$\mathrm{C}_{\text {Pin }} 11$ has a recommended value of 820 pF for 8-poles tachos and maximum motor rpm of 15000 , and $\mathrm{R}_{\text {Pin }} 11$ must be always 470 K .
$\mathrm{R}_{\text {Pin } 4}$ should be choosen to deliver within 12 V at maximum motor speed in order to maximize signal/noise ratio. As the $\mathrm{FV} / \mathrm{C}$ ratio as well as the $\mathrm{C}_{\text {Pin } 11}$ value are dispersed, $R_{\text {Pin } 4}$ must be adjustable and should be made of a fixed resistor in service with a trimmer representing 25\% of the total. Adjustment would become easier.

Once adjusted, for instance at maximum motor speed, the FV/C presents a residual non linearity; the conversion factor ( mV per RPM) increases by within $7.7 \%$ as speed draws to zero. The guaranteed dispersion of the latter being very narrow, a maximum $1 \%$ speed error is guaranteed if during Pin 5 network design the small set values are modified, once forever, according this increase.

The following formulas give $V_{\text {Pin } 4 \text { : }}$

$$
\begin{aligned}
& V_{\text {Pin } 4}=G .0 \cdot\left(V_{C C}-V_{a}\right) \cdot C_{\text {Pin } 11} \cdot R_{4} \cdot f \cdot{ }_{\left(1+\frac{120 k}{} \frac{1}{R_{\text {Pin } 11}}\right)}{ }^{\text {In volts. }} \\
& G .0 \cdot\left(V_{C C}-V_{a}\right) \simeq 140 \\
& V_{a}=2 . V_{B E} \\
& 120 \mathrm{k}=R_{\text {int }}, \text { on Pin } 11
\end{aligned}
$$

Speed Set - (Pin 5) Upon designer choice, a set of external resistors apply a series of various voltages corresponding to the various motor speeds. When switching external resistors, verify that no voltage below 80 mV is ever applied to Pin 5. If so, a full circuit reset will occur.

Ramps Generator - (Pin 6) If only a high acceleration ramp is needed, connect Pin 6 to ground.

When a Distribute ramp should occur, preset a voltage on Pin 6 which corresponds to the motor speed starting ramp point. Distribution (or low ramp) will continue up to the moment the motor speed would have reached twice the starting value.

The ratio of two is imposed by the IC. Nevertheless, it could be externally changed downwards (Figure 6) or upwards (Figure 7).

The distribution ramp can be shortened by an external resistor from $\mathrm{V}_{\mathrm{CC}}$ charging $\mathrm{C}_{\text {Pin 7 }}$, adding its current to the internal $5.0 \mu \mathrm{~A}$ generator.

Figure 2. Acceleration Ramp

## Power Circuits

Triac Triggering pulse amplitude must be determined by Pin 13 resistor according to the needs in Quadrant IV. Trigger pulse duration can be disturbed by noise signals generated by the triac itself, which interfere within Pins 14 and 16 , precisely those which determine it. While easily visible, this effect is harmless.

The triac must be protected from high AC line $\mathrm{dV} / \mathrm{dt}$ during external disturbances by $100 \mathrm{nF} \times 100 \Omega$ network.

Shunt resistor must be as non-inductive as possible. It can be made locally by using constantan alloy wire.

When the load is a DC fed universal motor through a rectifier bridge, the triac must be protected from commutating dV/dt by a 1.0 to 2.0 mH coil in series with $\mathrm{MT}_{2}$.

Synchronization functions are performed by resistors sensing AC line and triac conduction. 820 k values are normal but could be reduced down to 330 k in order to detect the "zeros" with accuracy and to reduce the residual DC line component below 20 mA .

## Current Limitation

The current limiter starts to discharge Pin 7 capacitor (reference speed) as the motor current reaches the designed threshold level. The loop gain is determined by the resistor connecting Pin 3 to the series shunt. Experience has shown that its optimal value for a 10 Arms limitation is within $2.0 \mathrm{k} \Omega$ Pin 3 input has a sensitivity in current which is limited to reasonable values and should not react to spikes.
If not used, Pin 3 must be connected to a maximum positive voltage of 5.0 V rather than be left open.

## Loop Stability

The Pin 16 network is predominant and must be adjusted experimentally during module development. The values indicated in Figure 4 are typical for washing machine applications but accept large modifications from one model to another. R16 (the sole restriction) should not go below 33 k , otherwise slew rate limitation will cause large transient errors for load steps.

## CS4121

## Low Voltage Precision Air-Core Tach/Speedo Driver

The CS4121 is specifically designed for use with air-core meter movements. The IC provides all the functions necessary for an analog tachometer or speedometer. The CS4121 takes a speed sensor input and generates sine and cosine related output signals to differentially drive an air-core meter.

Many enhancements have been added over industry standard tachometer drivers such as the CS289 or LM1819. The output utilizes differential drivers which eliminates the need for a zener reference and offers more torque. The device withstands 60 V transients which decreases the protection circuitry required. The device is also more precise than existing devices allowing for fewer trims and for use in a speedometer.

The CS4121 is compatible with the CS8190, and provides higher accuracy at a lower supply voltage ( 8.0 V min. as opposed to 8.5 V ). It is functionally operational to 6.5 V .

## Features

- Direct Sensor Input
- High Torque Output
- Low Pointer Flutter
- High Input Impedance
- Overvoltage Protection
- Accurate to 8.0 V Functional to 6.5 V (typ)
- Internally Fused Leads in SO-20 Package and DIP-16

## CIRCUIT DESCRIPTION and APPLICATION NOTES

The CS4121 is specifically designed for use with air-core meter movements. It includes an input comparator for sensing an input signal from an ignition pulse or speed sensor, a charge pump for frequency to voltage conversion, a bandgap voltage regulator for stable operation, and a function generator with sine and cosine amplifiers to differentially drive the meter coils.

From the partial schematic of Figure 7, the input signal is applied to the $\mathrm{FREQ}_{\text {IN }}$ lead, this is the input to a high impedance comparator with a typical positive input threshold of 2.0 V and typical hysteresis of 0.5 V . The output of the comparator, SQout, is applied to the charge pump input $\mathrm{CP}+$ through an external capacitor $\mathrm{C}_{\mathrm{CP}}$. When the input signal changes state, $\mathrm{C}_{\mathrm{CP}}$ is charged or discharged through R3 and R4. The charge accumulated on $\mathrm{C}_{\mathrm{CP}}$ is mirrored to C4 by the Norton Amplifier circuit comprising of Q1, Q2 and Q3. The charge pump output voltage, F/V ${ }_{\text {OUT }}$, ranges from 2.0 V to 6.3 V depending on the input signal frequency and the gain of the charge pump according to the formula:

```
\(\mathrm{F} / \mathrm{V}_{\text {OUT }}=2.0 \mathrm{~V}+2.0 \times \mathrm{FREQ} \times \mathrm{C}_{\mathrm{CP}} \times \mathrm{R}_{\mathrm{T}} \times\left(\mathrm{V}_{\mathrm{REG}}-0.7 \mathrm{~V}\right)\)
```

$\mathrm{R}_{\mathrm{T}}$ is a potentiometer used to adjust the gain of the $\mathrm{F} / \mathrm{V}$ output stage and give the correct meter deflection. The F/V output voltage is applied to the function generator which generates the sine and cosine output voltages. The output voltage of the sine and cosine amplifiers are derived from the on-chip amplifier and function generator circuitry. The various trip points for the circuit (i.e., $0^{\circ}, 90^{\circ}, 180^{\circ}, 270^{\circ}$ ) are determined by an internal resistor divider and the bandgap voltage reference. The coils are differentially driven, allowing bidirectional current flow in the outputs, thus providing up to $305^{\circ}$ range of meter deflection. Driving the coils differentially offers faster response time, higher current capability, higher output voltage swings, and reduced external component count. The key advantage is a higher torque output for the pointer.

The output angle, $\Theta$, is equal to the $\mathrm{F} / \mathrm{V}$ gain multiplied by the function generator gain:

$$
\Theta=A_{F} / V \times A_{F G}
$$

where:

$$
\mathrm{AFG}=77^{\circ} / \mathrm{V}(\mathrm{typ})
$$

The relationship between input frequency and output angle is:

$$
\begin{aligned}
& \Theta=A_{F G} \times 2.0 \times \mathrm{FREQ} \times \mathrm{CCP} \times \mathrm{RT} \times\left(\mathrm{V}_{\mathrm{REG}}-0.7 \mathrm{~V}\right) \\
& \Theta=970 \times \mathrm{FREQ} \times \mathrm{C}_{\mathrm{CP}} \times \mathrm{RT}
\end{aligned}
$$

The ripple voltage at the F/V converter's output is determined by the ratio of $\mathrm{C}_{\mathrm{CP}}$ and C 4 in the formula:

$$
\Delta \mathrm{V}=\frac{\mathrm{C}_{\mathrm{CP}}\left(\mathrm{~V}_{\mathrm{REG}}-0.7 \mathrm{~V}\right)}{\mathrm{C} 4}
$$

Ripple voltage on the F/V output causes pointer or needle flutter especially at low input frequencies.

The response time of the F/V is determined by the time constant formed by $\mathrm{R}_{\mathrm{T}}$ and C 4 . Increasing the value of C 4 will reduce the ripple on the $\mathrm{F} / \mathrm{V}$ output but will also increase the response time. An increase in response time causes a very slow meter movement and may be unacceptable for many applications.

## Design Example

Maximum meter Deflection $=270^{\circ}$
Maximum Input Frequency $=350 \mathrm{~Hz}$
10. Select $R_{T}$ and $C_{C P}$

$$
\Theta=970 \times \mathrm{FREQ} \times \mathrm{C}_{\mathrm{CP}} \times \mathrm{RT}=270^{\circ}
$$

Let $\mathrm{C}_{\mathrm{T}}=0.0033 \mu \mathrm{~F}$, find $\mathrm{R}_{\mathrm{T}}$

$$
\begin{gathered}
\mathrm{RT}=\frac{270^{\circ}}{970 \times 350 \mathrm{~Hz} \times 0.0033 \mu \mathrm{~F}} \\
\mathrm{RT}=243 \mathrm{k} \Omega
\end{gathered}
$$

$\mathrm{R}_{\mathrm{T}}$ should be a $250 \mathrm{k} \Omega$ potentiometer to trim out any inaccuracies due to IC tolerances or meter movement pointer placement.

## 11. Select R3 and R4

Resistor R3 sets the output current from the voltage regulator. The maximum output current from the voltage regulator is 10 mA . R3 must ensure that the current does not exceed this limit.

Choose R3 $=3.3 \mathrm{k} \Omega$
The charge current for $\mathrm{C}_{\mathrm{CP}}$ is

$$
\frac{\mathrm{V}_{\mathrm{REG}}-0.7 \mathrm{~V}}{3.3 \mathrm{k} \Omega}=1.90 \mathrm{~mA}
$$

$\mathrm{C}_{\mathrm{CP}}$ must charge and discharge fully during each cycle of the input signal. Time for one cycle at maximum frequency is 2.85 ms . To ensure that $\mathrm{C}_{\mathrm{CP}}$ is charged, assume that the $(\mathrm{R} 3+\mathrm{R} 4) \mathrm{C}_{\mathrm{CP}}$ time constant is less than $10 \%$ of the minimum input period.

$$
\mathrm{T}=10 \% \times \frac{1}{350 \mathrm{~Hz}}=285 \mu \mathrm{~s}
$$

$$
\begin{aligned}
& \text { Choose } 4=1.0 \mathrm{k} \Omega \\
& \text { Discharge time: } \begin{aligned}
\mathrm{t}_{\mathrm{DCHG}} & =\mathrm{R} 3 \times \mathrm{C}_{\mathrm{CP}}=3.3 \mathrm{k} \Omega \times 0.0033 \mu \mathrm{~F} \\
& =10.9 \mu \mathrm{~s}
\end{aligned} \\
& \begin{aligned}
\text { Charge time: } \mathrm{t}_{\mathrm{CHG}} & =(\mathrm{R} 3+\mathrm{R} 4) \mathrm{C}_{\mathrm{CP}}=4.3 \mathrm{k} \Omega \times 0.0033 \mu \mathrm{~F} \\
& =14.2 \mu \mathrm{~s}
\end{aligned}
\end{aligned}
$$

## 12. Determine C4

C 4 is selected to satisfy both the maximum allowable ripple voltage and response time of the meter movement.

$$
\mathrm{C} 4=\frac{\mathrm{C}_{\mathrm{CP}}\left(\mathrm{~V}_{\mathrm{REG}}-0.7 \mathrm{~V}\right)}{\Delta \mathrm{V}_{\mathrm{MAX}}}
$$

With $\mathrm{C} 4=0.47 \mu \mathrm{~F}$, the $\mathrm{F} / \mathrm{V}$ ripple voltage is 44 mV .

Figure 7. Partial Schematic of Input and Charge Pump

Figure 8. Timing Diagram of RREQ $_{\text {IN }}$ and $I_{C P}$

Notes:

1. For $58 \%$ Speed Input $\mathrm{T}_{\text {MAX }} \leq 5.0 / \mathrm{f}_{\mathrm{MAX}}$ where $\mathrm{T}_{\mathrm{MAX}}=\mathrm{C}_{\mathrm{CP}}(\mathrm{R} 3+\mathrm{R} 4)$ $f_{M A X}=$ maximum speed input frequency
2. The product of C 4 and $\mathrm{R}_{\mathrm{T}}$ have a direct effect on gain and therefore directly affect temperature compensation.
3. $\mathrm{C}_{\mathrm{CP}}$ Range; 20 pF to $0.2 \mu \mathrm{~F}$.
4. $\mathrm{R}_{\mathrm{T}}$ Range; $100 \mathrm{k} \Omega$ to $500 \mathrm{k} \Omega$.
5. The Ic must be protected from transients above 60 V and reverse battery conditions.
6. Additional filtering on $\mathrm{FREQ}_{I N}$ lead may be required.
7. Gauge coil connections to the IC must be kept as short as possible ( $\leq 3.0$ inch) for best pointer stability.

Figure 9. Speedometer or Tachometer Application

Notes:

1. The product of $C 4$ and $R_{T}$ have a direct effect on gain and therefore directly affect temperature compensation.
2. $\mathrm{C}_{\mathrm{CP}}$ Range; 20 pF to $0.2 \mu \mathrm{~F}$.
3. $R_{T}$ Range; $100 \mathrm{k} \Omega$ to $500 \mathrm{k} \Omega$.
4. The Ic must be protected from transients above 60 V and reverse battery conditions.
5. Additional filtering on $F_{R E Q}{ }_{I N}$ lead may be required.
6. Gauge coil connections to the IC must be kept as short as possible ( $\leq 3.0$ inch) for best pointer stability.

## CS4122

## Triple Air-Core Gauge Driver with Serial Input Bus

The CS4122 converts digital data from a microprocessor to complementary DC outputs and drives air-core meter movements for vehicle instrument panels. It is optimized for one $360^{\circ}$ gauge and two $112^{\circ}$ gauges. The digital data controls the voltage applied to the quadrature coils of the meters with a $0.35^{\circ}$ resolution for the major $\left(360^{\circ}\right)$ gauge and $0.44^{\circ}$ resolution for the minor $\left(112^{\circ}\right)$ gauges. The accuracy is $\pm 0.75^{\circ}$ for the major and $\pm 1.00^{\circ}$ for the minors. The interface from the microcontroller is by a SPI compatible serial connection using up to a 2.0 MHz shift clock rate.

The digital code is shifted into the appropriate DAC and multiplexer. These two blocks provide a tangential conversion function to change the digital data into the appropriate DC coil voltage. The major gauge driver can position a pointer anywhere within a $360^{\circ}$ circle while the minor gauge drivers are limited to an arc of $112.2^{\circ}$.

The output buffers are capable of supplying up to 70 mA per coil and are protected against output short circuit conditions. A thermal protection circuit limits the junction temperature to approximately $160^{\circ} \mathrm{C}$.

A fault output lead goes low when any of the outputs are shorted or the device is in a thermal shutdown state. This ASIC is designed on POWERSENSE ${ }^{\text {TM }} 3.0$.

## Features

- Serial Input Bus
- 2.0 MHz Operating Frequency
- Independently Addressable Gauges
- Tangential Drive Algorithm
- 70 mA Drive Circuits
- $0.75^{\circ}$ Major Accuracy
- Power-On-Reset
- Protection Features
- Short Circuit
- Overtemperature
- Internally Fused Leads in SO-24L Package

## APPLICATIONS INFORMATION

THEORY OF OPERATION
The CS4122 is for interfacing between a microcontroller or microprocessor and air-core meters commonly used in automotive vehicles for speedometers, tachometers and auxiliary gauges. These meters are built using 2 coils placed at $90^{\circ}$ orientation to each other. A magnetized disc floats in the middle of the coils and responds to the magnetic field generated by each coil. The disc has a shaft attached to it that protrudes out of the assembly. A pointer indicator is attached to this shaft and in conjunction with a separate printed scale displays the vehicle's speed, engine's speed or other information such as fuel quantity or battery voltage.

The disc (and pointer) respond to the vector sum of the voltages applied to the coils. Ideally, this relationship follows a sine/cosine equation. Since this is a transcendental and non-linear function, devices of this type use an approximation for this relationship. The CS4122 uses a tangential algorithm as shown in Figure 2 for the major $\left(360^{\circ}\right)$ gauge. Only one output varies in any $45^{\circ}$ range.

Note: The actual slopes are segmented but are shown here as straight lines for simplicity.

Figure 2. Major Gauge Outputs

## Quadrant I

$$
\theta=\operatorname{Tan}^{-1}\left[\frac{\left(\mathrm{~V}_{\mathrm{SIN}+}\right)-\left(\mathrm{V}_{\mathrm{SIN}-}\right)}{\left(\mathrm{V}_{\mathrm{COS}}+\right)-\left(\mathrm{V}_{\mathrm{COS}}-\right)}\right]
$$

For $\theta=0.176^{\circ}$ to $44.824^{\circ}$ :

$$
\mathrm{V}_{\mathrm{SIN}}=\operatorname{Tan} \theta \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

$$
V_{\mathrm{COS}}=0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

For $\theta=45.176^{\circ}$ to $89.824^{\circ}$ :
$\mathrm{V}_{\mathrm{SIN}}=0.748 \times \mathrm{V}_{\mathrm{BB}}$
$\mathrm{V}_{\mathrm{COS}}=\operatorname{Tan}\left(90^{\circ}-\theta\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}$

## Quadrant II

$$
\begin{aligned}
& \theta=180^{\circ}-\operatorname{Tan}^{-1}\left[\frac{\left(\mathrm{~V}_{\mathrm{SIN}+}\right)-\left(\mathrm{V}_{\mathrm{SIN}-}\right)}{\left(\mathrm{V}_{\mathrm{COS}+}\right)-\left(\mathrm{V}_{\mathrm{COS}}-\right)}\right] \\
& \text { For } \theta=90.176^{\circ} \text { to } 134.824^{\circ}: \\
& \quad \mathrm{V}_{\mathrm{SIN}}=0.748 \times \mathrm{V}_{\mathrm{BB}} \\
& \quad \mathrm{~V}_{\mathrm{COS}}=-\operatorname{Tan}\left(\theta-90^{\circ}\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
\end{aligned}
$$

For $\theta=135.176^{\circ}$ to $179.824^{\circ}$ :

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{SIN}}=\operatorname{Tan}\left(180^{\circ}-\theta\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}} \\
& \mathrm{~V}_{\mathrm{COS}}=-0.748 \times \mathrm{V}_{\mathrm{BB}}
\end{aligned}
$$

## Quadrant III

$$
\theta=180^{\circ}+\operatorname{Tan}^{-1}\left[\frac{(\mathrm{~V} \mathrm{SIN}+)-\left(\mathrm{V}_{\mathrm{SIN}-}\right)}{\left(\mathrm{V}_{\mathrm{COS}}+\right)-\left(\mathrm{V}_{\mathrm{COS}}-\right)}\right]
$$

For $\theta=180.176^{\circ}$ to $224.824^{\circ}$ :

$$
\mathrm{V}_{\mathrm{SIN}}=-\operatorname{Tan}\left(\theta-180^{\circ}\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

$$
V_{\mathrm{COS}}=-0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

For $\theta=225.176^{\circ}$ to $269.824^{\circ}$ :

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{SIN}}=-0.748 \times \mathrm{V}_{\mathrm{BB}} \\
& \mathrm{~V}_{\mathrm{COS}}=-\operatorname{Tan}\left(270^{\circ}-\theta\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
\end{aligned}
$$

## Quadrant IV

$$
\theta=360^{\circ}-\operatorname{Tan}^{-1}\left[\frac{(\mathrm{~V} \mathrm{SIN}+)-\left(\mathrm{V}_{\mathrm{SIN}-}\right)}{\left(\mathrm{V}_{\mathrm{COS}+}\right)-\left(\mathrm{V}_{\mathrm{COS}}-\right)}\right]
$$

For $\theta=270.176^{\circ}$ to $314.824^{\circ}$ :

$$
\mathrm{V}_{\mathrm{SIN}}=-0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

$$
V_{\mathrm{COS}}=\operatorname{Tan}\left(\theta-270^{\circ}\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

For $\theta=315.176^{\circ}-359.824^{\circ}$ :

$$
\mathrm{V}_{\mathrm{SIN}}=-\operatorname{Tan}\left(360^{\circ}-\theta\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

$$
V_{\mathrm{COS}}=0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

Figure 3. Major Gauge Response

The minor gauge coil outputs differ in that only one of the coils in each movement is driven by the IC. The other is driven directly by the analog supply voltage, specifically one-half of this voltage. The common output assures that this is true. By varying the voltage across the other coil to a greater voltage, the pointer can be deflected more than $45^{\circ}$ to each side of the externally driven coil. This relationship is shown in Figure 4.

Note: There are actually 8 segments, but only 3 are shown here for simplicity.

Figure 4. Minor Gauge Outputs

## Quadrant I, II

$$
\begin{aligned}
& \theta=56.1^{\circ}-\operatorname{Tan}^{-1}\left[\frac{\left(\mathrm{~V}_{\mathrm{C}+}\right)-\left(\mathrm{V}_{\mathrm{C}-}\right)}{\mathrm{V}_{\mathrm{BB}}-\mathrm{V}_{(\mathrm{VBB} / 2)}}\right] \\
& \mathrm{V}_{\mathrm{COIL}}=\mathrm{V}_{(\mathrm{VBB} / 2)} \times \operatorname{Tan}\left(56.1^{\circ}-\theta\right)
\end{aligned}
$$

Figure 5. Minor Gauge Outputs
To drive a gauge's pointer to a particular angle, the microcontroller sends a 12 bit digital word to the CS4122. These 12 bits are divided as shown in Figure 6. However, from a software programmer's viewpoint, a $360^{\circ}$ circle is divided into 1024 equal parts of $.35^{\circ}$ each and a $112.2^{\circ}$ arc is divided into 256 parts of $.44^{\circ}$ each. Table 1 shows the data associated with the $45^{\circ}$ divisions of the $360^{\circ}$ driver. Table 2 shows the data for the center and end points of the $112.2^{\circ}$ drivers. Setting the address to " 11 " disables all outputs.

The 12 bits are shifted into the device's shift register MSB first using a SPI compatible scheme. This method is shown in Figures 6 and 7. The first 2 bits select the output driver for which the data is intended. The CS must be high and remain high for SCLK to be enabled. Data on SI is shifted in on the
rising edge of the synchronous clock signal. Data in the shift register is shifted to SO on the falling edge of SCLK. This arrangement allows the cascading of devices. SO is always enabled. Data shifts through without affecting the outputs until CS is brought low. At this time, the internal DAC is updated and the outputs change accordingly.

Figure 7. Serial Data Timing Diagram
The DAC for the major gauge driver outputs 128 discrete levels selected by bits D6 - D0. These bits are XOR'd with D7 to invert them when choosing the 2nd half of each quadrant (each odd octant). This reduces the number of
resistors and switches required. The MUX chooses which signals to send to the output amplifiers based upon D9 - D7. There are three choices for each amplifier: high, low or the DAC output.

The DAC's for the minor gauge drivers similarly output 128 discrete levels selected by bits D6 - D0. These bits are also XOR'd with D7 to invert them when choosing the 2nd half of the output range. The MUX chooses which signals to send to the output amplifiers based upon D7. There are two choices for each amplifier; high or the DAC output. Bits D8 and D9 are not used, but should be set to " 00 " to ensure that the minor gauge outputs are enabled.

The output buffers are unity gain amplifiers. Each of the 8 outputs is designed to swing close to the supply rails to maximize the voltage across the coils to produce maximum torque. Additionally, this lowers the power dissipation. The current for each output is also monitored. If any of the major gauge outputs exceed the maximum value, all of the major outputs are disabled. If any of the minor gauge outputs exceed the maximum value, all of the minor outputs are disabled. The falling edge of the CS re-enables the outputs with the fault condition but they remain on only if the overcurrent situation has been eliminated.

## CS8190

## Precision Air-Core <br> Tach/Speedo Driver with Return to Zero

The CS8190 is specifically designed for use with air-core meter movements. The IC provides all the functions necessary for an analog tachometer or speedometer. The CS8190 takes a speed sensor input and generates sine and cosine related output signals to differentially drive an air-core meter.

Many enhancements have been added over industry standard tachometer drivers such as the CS289 or LM1819. The output utilizes differential drivers which eliminates the need for a zener reference and offers more torque. The device withstands 60 V transients which decreases the protection circuitry required. The device is also more precise than existing devices allowing for fewer trims and for use in a speedometer.

## Features

- Direct Sensor Input
- High Output Torque
- Low Pointer Flutter
- High Input Impedance
- Overvoltage Protection
- Return to Zero
- Internally Fused Leads in DIP-16 and SO-20L Packages

## CIRCUIT DESCRIPTION and APPLICATION NOTES

The CS8190 is specifically designed for use with air-core meter movements. It includes an input comparator for sensing an input signal from an ignition pulse or speed sensor, a charge pump for frequency to voltage conversion, a bandgap voltage regulator for stable operation, and a function generator with sine and cosine amplifiers to differentially drive the meter coils.

From the partial schematic of Figure 7, the input signal is applied to the $\mathrm{FREQ}_{\text {IN }}$ lead, this is the input to a high impedance comparator with a typical positive input threshold of 2.0 V and typical hysteresis of 0.5 V . The output of the comparator, SQout, is applied to the charge pump input CP+ through an external capacitor $\mathrm{C}_{\mathrm{CP}}$. When the input signal changes state, $\mathrm{C}_{\mathrm{CP}}$ is charged or discharged through R3 and R4. The charge accumulated on $\mathrm{C}_{\mathrm{CP}}$ is mirrored to C4 by the Norton Amplifier circuit comprising of Q1, Q2 and Q3. The charge pump output voltage, F/V OUT, ranges from 2.0 V to 6.3 V depending on the input signal frequency and the gain of the charge pump according to the formula:

$$
\mathrm{F} / \mathrm{VOUT}_{\mathrm{O}}=2.0 \mathrm{~V}+2.0 \times \mathrm{FREQ} \times \mathrm{C} C P \times \mathrm{RT} \times(\mathrm{VREG}-0.7 \mathrm{~V})
$$

$\mathrm{R}_{\mathrm{T}}$ is a potentiometer used to adjust the gain of the $\mathrm{F} / \mathrm{V}$ output stage and give the correct meter deflection. The F/V output voltage is applied to the function generator which generates the sine and cosine output voltages. The output voltage of the sine and cosine amplifiers are derived from the
on-chip amplifier and function generator circuitry. The various trip points for the circuit (i.e., $0^{\circ}, 90^{\circ}, 180^{\circ}, 270^{\circ}$ ) are determined by an internal resistor divider and the bandgap voltage reference. The coils are differentially driven, allowing bidirectional current flow in the outputs, thus providing up to $305^{\circ}$ range of meter deflection. Driving the coils differentially offers faster response time, higher current capability, higher output voltage swings, and reduced external component count. The key advantage is a higher torque output for the pointer.

The output angle, $\Theta$, is equal to the $\mathrm{F} / \mathrm{V}$ gain multiplied by the function generator gain:

$$
\Theta=A_{F} / V \times A_{F G}
$$

where:

$$
\mathrm{AFG}=77^{\circ} / \mathrm{V}(\mathrm{typ})
$$

The relationship between input frequency and output angle is:

$$
\begin{aligned}
& \Theta=A_{F G} \times 2.0 \times \mathrm{FREQ} \times \mathrm{C}_{\mathrm{CP}} \times \mathrm{RT} \times\left(\mathrm{V}_{\mathrm{REG}}-0.7 \mathrm{~V}\right) \\
& \quad \text { or, } \\
& \Theta=970 \times \mathrm{FREQ} \times \mathrm{C}_{\mathrm{CP}} \times \mathrm{RT}
\end{aligned}
$$

The ripple voltage at the $\mathrm{F} / \mathrm{V}$ converter's output is determined by the ratio of $\mathrm{C}_{\mathrm{CP}}$ and C 4 in the formula:

$$
\Delta \mathrm{V}=\frac{\mathrm{C} \mathrm{CP}\left(\mathrm{~V}_{\mathrm{REG}}-0.7 \mathrm{~V}\right)}{\mathrm{C} 4}
$$

Figure 7. Partial Schematic of Input and Charge Pump

Figure 8. Timing Diagram of FREQ $_{\text {IN }}$ and $\mathrm{I}_{\mathrm{CP}}$

Ripple voltage on the F/V output causes pointer or needle flutter especially at low input frequencies.

The response time of the F/V is determined by the time constant formed by RT and C4. Increasing the value of C4 will reduce the ripple on the $\mathrm{F} / \mathrm{V}$ output but will also increase the response time. An increase in response time causes a very slow meter movement and may be unacceptable for many applications.

The CS8190 has an undervoltage detect circuit that disables the input comparator when $\mathrm{V}_{\mathrm{CC}}$ falls below 8.0 V (typical). With no input signal the F/V output voltage decreases and the needle moves towards zero. A second undervoltage detect circuit at 6.0 V (typical) causes the function generator to
generate a differential SIN drive voltage of zero volts and the differential COS drive voltage to go as high as possible. This combination of voltages (Figure 2) across the meter coil moves the needle to the $0^{\circ}$ position. Connecting a large capacitor(> $2000 \mu \mathrm{~F}$ ) to the $\mathrm{V}_{\mathrm{CC}}$ lead ( C 2 in Figure 9) increases the time between these undervoltage points since the capacitor discharges slowly and ensures that the needle moves towards $0^{\circ}$ as opposed to $360^{\circ}$. The exact value of the capacitor depends on the response time of the system, the maximum meter deflection and the current consumption of the circuit. It should be selected by breadboarding the design in the lab.

Figure 9. Speedometer or Tachometer Application

## Design Example

Maximum meter Deflection $=270^{\circ}$
Maximum Input Frequency $=350 \mathrm{~Hz}$

1. Select $\mathbf{R}_{\mathbf{T}}$ and $\mathbf{C}_{\mathbf{C P}}$

$$
\Theta=970 \times \mathrm{FREQ} \times \mathrm{C}_{\mathrm{CP}} \times \mathrm{R}_{\mathrm{T}}=270^{\circ}
$$

Let $\mathrm{C}_{\mathrm{CP}}=0.0033 \mu \mathrm{~F}$, find $\mathrm{R}_{\mathrm{T}}$

$$
\begin{gathered}
\mathrm{R} \mathrm{~T}=\frac{270^{\circ}}{970 \times 350 \mathrm{~Hz} \times 0.0033 \mu \mathrm{~F}} \\
\mathrm{RT}=243 \mathrm{k} \Omega
\end{gathered}
$$

RT should be a $250 \mathrm{k} \Omega$ potentiometer to trim out any inaccuracies due to IC tolerances or meter movement pointer placement.

## 2. Select R3 and R4

Resistor R3 sets the output current from the voltage regulator. The maximum output current from the voltage regulator is 10 mA . R3 must ensure that the current does not exceed this limit.

Choose R3 $=3.3 \mathrm{k} \Omega$
The charge current for $\mathrm{C}_{\mathrm{CP}}$ is

$$
\frac{\mathrm{V}_{\mathrm{REG}}-0.7 \mathrm{~V}}{3.3 \mathrm{k} \Omega}=1.90 \mathrm{~mA}
$$

$\mathrm{C}_{\mathrm{CP}}$ must charge and discharge fully during each cycle of the input signal. Time for one cycle at maximum frequency is 2.85 ms . To ensure that $\mathrm{C}_{\mathrm{CP}}$ is charged, assume that the
$(\mathrm{R} 3+\mathrm{R} 4) \mathrm{C}_{\mathrm{CP}}$ time constant is less than $10 \%$ of the minimum input period.

$$
\mathrm{T}=10 \% \times \frac{1}{350 \mathrm{~Hz}}=285 \mu \mathrm{~s}
$$

Choose R4 $=1.0 \mathrm{k} \Omega$.
Discharge time: ${ }_{\mathrm{DCHG}}=\mathrm{R} 3 \times \mathrm{C}_{\mathrm{CP}}=3.3 \mathrm{k} \Omega \times 0.0033 \mu \mathrm{~F}$

$$
=10.9 \mu \mathrm{~s}
$$

Charge time: $\mathrm{t}_{\mathrm{CHG}}=(\mathrm{R} 3+\mathrm{R} 4) \mathrm{C}_{\mathrm{CP}}=4.3 \mathrm{k} \Omega \times 0.0033 \mu \mathrm{~F}$

$$
=14.2 \mu \mathrm{~s}
$$

## 3. Determine C4

C 4 is selected to satisfy both the maximum allowable ripple voltage and response time of the meter movement.

$$
\mathrm{C} 4=\frac{\mathrm{C}_{\mathrm{CP}}(\mathrm{VREG}-0.7 \mathrm{~V})}{\Delta \mathrm{V}_{\mathrm{MAX}}}
$$

With $\mathrm{C} 4=0.47 \mu \mathrm{~F}$, the $\mathrm{F} / \mathrm{V}$ ripple voltage is 44 mV .
The last component to be selected is the return to zero capacitor C 2 . This is selected by increasing the input signal frequency to its maximum so the pointer is at its maximum deflection, then removing the power from the circuit. C2 should be large enough to ensure that the pointer always returns to the $0^{\circ}$ position rather than $360^{\circ}$ under all operating conditions.

Figure 10 shows how the CS8190 and the CS8441 are used to produce a Speedometer and Odometer circuit.

Notes:

1. $\mathrm{C} 2=10 \mu \mathrm{~F}$ with CS8441 application.
2. The product of C 4 and $\mathrm{R}_{\mathrm{T}}$ have a direct effect on gain and therefore directly affect temperature compensation.
3. C 4 Range; 20 pF to $0.2 \mu \mathrm{~F}$.
4. R4 Range; $100 \mathrm{k} \Omega$ to $500 \mathrm{k} \Omega$.
5. The IC must be protected from transients above 60 V and reverse battery conditions.
6. Additional filtering on the $\mathrm{FREQ}_{I \mathrm{~N}}$ lead may be required.
7. Gauge coil connections to the IC must be kept as short as possible ( $\leq 3.0$ inch) for best pointer stability.

Figure 10. Speedometer With Odometer or Tachometer Application

In some cases a designer may wish to use the CS8190 only as a driver for an air-core meter having performed the F/V conversion elsewhere in the circuit.

Figure 11 shows how to drive the CS8190 with a DC voltage ranging from 2.0 V to 6.0 V . This is accomplished by forcing a voltage on the $\mathrm{F} / \mathrm{V}_{\text {OUT }}$ lead. The alternative scheme shown in Figure 12 uses an external op amp as a buffer and operates over an input voltage range of 0 V to 4.0 V .

Figures 11 and 12 are not temperature compensated.

## CS8191

## Precision Air-Core <br> Tach/Speedo Driver with Short Circuit Protection

The CS8191 is specifically designed for use with 4 quadrant air-core meter movements. The IC includes an input comparator for sensing input frequency such as vehicle speed or engine RPM, a charge pump for frequency to voltage conversion, a bandgap reference for stable operation and a function generator with sine and cosine amplifiers that differentially drive the meter coils.

The CS8191 has a higher torque output and better output signal symmetry than other competitive parts (CS289, and LM1819). It is protected against short circuit and overvoltage ( 60 V ) fault conditions. Enhanced circuitry permits functional operation down to 8.0 V .

## Features

- Direct Sensor Input
- High Output Torque
- Wide Output Voltage Range
- High Impedance Inputs
- Accurate Down to $10 \mathrm{~V}_{\mathrm{CC}}$
- Fault Protection
- Overvoltage
- Short Circuit
- Low Voltage Operation
- Internally Fused Leads in DIP-16 and SO-20L Packages

## CIRCUIT DESCRIPTION and APPLICATION NOTES

The CS8191 is specifically designed for use with air-core meter movements. It includes an input comparator for sensing an input signal from an ignition pulse or speed sensor, a charge pump for frequency to voltage conversion, a bandgap voltage regulator for stable operation, and a function generator with sine and cosine amplifiers to differentially drive the meter coils.

From the partial schematic of Figure 7, the input signal is applied to the $\mathrm{FREQ}_{\text {IN }}$ lead, this is the input to a high impedance comparator with a typical positive input threshold of 2.7 V and typical hysteresis of 0.4 V . The output of the comparator, SQout, is applied to the charge pump input $\mathrm{CP}+$ through an external capacitor $\mathrm{C}_{\mathrm{CP}}$. When the input signal changes state, $\mathrm{C}_{\mathrm{CP}}$ is charged or discharged through R3 and R4. The charge accumulated on $\mathrm{C}_{\mathrm{CP}}$ is mirrored to C4 by the Norton Amplifier circuit comprising of Q1, Q2 and Q3. The charge pump output voltage, F/V ranges from 2.0 V to 6.3 V depending on the input signal frequency and the gain of the charge pump according to the formula:
$\mathrm{F} / \mathrm{V}_{\text {OUT }}=2.0 \mathrm{~V}+2.0 \times \mathrm{FREQ} \times \mathrm{C} \mathbf{C P} \times \mathrm{RT} \times(\mathrm{VREG}-0.7 \mathrm{~V})$
$\mathrm{R}_{\mathrm{T}}$ is a potentiometer used to adjust the gain of the F/V output stage and give the correct meter deflection. The F/V output voltage is applied to the function generator which generates the sine and cosine output voltages. The output voltage of the sine and cosine amplifiers are derived from the
on-chip amplifier and function generator circuitry. The various trip points for the circuit (i.e., $0^{\circ}, 90^{\circ}, 180^{\circ}, 270^{\circ}$ ) are determined by an internal resistor divider and the bandgap voltage reference. The coils are differentially driven, allowing bidirectional current flow in the outputs, thus providing up to $305^{\circ}$ range of meter deflection. Driving the coils differentially offers faster response time, higher current capability, higher output voltage swings, and reduced external component count. The key advantage is a higher torque output for the pointer.
The output angle, $\Theta$, is equal to the $\mathrm{F} / \mathrm{V}$ gain multiplied by the function generator gain:

$$
\Theta=A_{F} / V \times A_{F G},
$$

where:

$$
\mathrm{AFG}=77^{\circ} / \mathrm{V}(\mathrm{typ})
$$

The relationship between input frequency and output angle is:

or,
$\Theta=970 \times \mathrm{FREQ} \times \mathrm{C}_{\mathrm{CP}} \times \mathrm{RT}$
The ripple voltage at the F/V converter's output is determined by the ratio of $\mathrm{C}_{\mathrm{CP}}$ and C 4 in the formula:

$$
\Delta \mathrm{V}=\frac{\mathrm{CCP}\left(\mathrm{~V}_{\mathrm{REG}}-0.7 \mathrm{~V}\right)}{\mathrm{C} 4}
$$

Ripple voltage on the F/V output causes pointer or needle flutter especially at low input frequencies.

The response time of the $\mathrm{F} / \mathrm{V}$ is determined by the time constant formed by $\mathrm{R}_{\mathrm{T}}$ and C 4 . Increasing the value of C 4
will reduce the ripple on the F/V output but will also increase the response time. An increase in response time causes a very slow meter movement and may be unacceptable for many applications.

Figure 7. Partial Schematic of Input and Charge Pump

Figure 8. Timing Diagram of FREQ $_{\text {IN }}$ and $\mathrm{I}_{\mathbf{C P}}$

Notes:

1. The product of $C 4$ and $R_{T}$ have a direct effect on gain and therefore directly affect temperature compensation.
2. C 4 Range; 20 pF to $0.2 \mu \mathrm{~F}$.
3. R4 Range; $100 \mathrm{k} \Omega$ to $500 \mathrm{k} \Omega$.
4. The IC must be protected from transients above 60 V and reverse battery conditions.
5. Additional filtering on the $\mathrm{FREQ}_{\mathrm{IN}}$ lead may be required.
6. Gauge coil connections to the IC must be kept as short as possible ( $\leq 3.0$ inch) for best pointer stability.

Figure 9. Speedometer or Tachometer Application

## Design Example

Maximum meter Deflection $=270^{\circ}$
Maximum Input Frequency $=350 \mathrm{~Hz}$

1. Select $\mathbf{R}_{\mathbf{T}}$ and $\mathbf{C}_{\mathbf{C P}}$

$$
\Theta=970 \times \mathrm{FREQ} \times \mathrm{C} C P \times \mathrm{R}_{\mathrm{T}}
$$

Let $\mathrm{C}_{\mathrm{CP}}=0.0033 \mu \mathrm{~F}$, find $\mathrm{R}_{\mathrm{T}}$

$$
\begin{gathered}
\mathrm{RT}=\frac{270^{\circ}}{970 \times 350 \mathrm{~Hz} \times 0.0033 \mu \mathrm{~F}} \\
\mathrm{RT}=243 \mathrm{k} \Omega
\end{gathered}
$$

RT should be a $250 \mathrm{k} \Omega$ potentiometer to trim out any inaccuracies due to IC tolerances or meter movement pointer placement.

## 2. Select R3 and R4

Resistor R3 sets the output current from the voltage regulator. The maximum output current from the voltage regulator is 10 mA . R3 must ensure that the current does not exceed this limit.

Choose R3 $=3.3 \mathrm{k} \Omega$
The charge current for $\mathrm{C}_{\mathrm{CP}}$ is

$$
\frac{\mathrm{V}_{\mathrm{REG}}-0.7 \mathrm{~V}}{3.3 \mathrm{k} \Omega}=1.90 \mathrm{~mA}
$$

$\mathrm{C}_{\mathrm{CP}}$ must charge and discharge fully during each cycle of the input signal. Time for one cycle at maximum frequency is 2.85 ms . To ensure that $\mathrm{C}_{\mathrm{CP}}$ is charged, assume that the $(\mathrm{R} 3+\mathrm{R} 4) \mathrm{C}_{\mathrm{CP}}$ time constant is less than $10 \%$ of the minimum input period.

$$
\mathrm{T}=10 \% \times \frac{1}{350 \mathrm{~Hz}}=285 \mu \mathrm{~s}
$$

Choose R4 $=1.0 \mathrm{k} \Omega$.
Discharge time: $\mathrm{t}_{\mathrm{DCHG}}=\mathrm{R} 3 \times \mathrm{C}_{\mathrm{CP}}=3.3 \mathrm{k} \Omega \times 0.0033 \mu \mathrm{~F}$

$$
=10.9 \mu \mathrm{~s}
$$

Charge time: $\mathrm{t}_{\mathrm{CHG}}=(\mathrm{R} 3+\mathrm{R} 4) \mathrm{C}_{\mathrm{CP}}=4.3 \mathrm{k} \Omega \times 0.0033 \mu \mathrm{~F}$

$$
=14.2 \mu \mathrm{~s}
$$

## 3. Determine C4

C 4 is selected to satisfy both the maximum allowable ripple voltage and response time of the meter movement.

$$
\mathrm{C} 4=\frac{\mathrm{C}_{\mathrm{CP}}\left(\mathrm{~V}_{\mathrm{REG}}-0.7 \mathrm{~V}\right)}{\Delta \mathrm{V}_{\mathrm{MAX}}}
$$

With $\mathrm{C} 4=0.47 \mu \mathrm{~F}$, the $\mathrm{F} / \mathrm{V}$ ripple voltage is 44 mV .
Figure 10 shows how the CS8191 and the CS8441 are used to produce a Speedometer and Odometer circuit.

Figure 10. Speedometer With Odometer or Tachometer Application

In some cases a designer may wish to use the CS8191 only as a driver for an air-core meter having performed the F/V conversion elsewhere in the circuit.

Figure 11 shows how to drive the CS8191 with a DC voltage ranging from 2.0 V to 6.0 V . This is accomplished by forcing a voltage on the $\mathrm{F} / \mathrm{V}_{\text {OUT }}$ lead. The alternative scheme shown in Figure 12 uses an external op amp as a buffer and operates over an input voltage range of 0 V to 4.0 V .

Figures 11 and 12 are not temperature compensated.

Figure 12. Driving the CS8191 from an External DC Voltage Using an Op Amp Buffer

Figure 11. Driving the CS8191 from an External DC Voltage

| $\mathrm{R}_{\text {©JA }}$ | Typical | 50 | 55 | ${ }^{\circ} \mathrm{C} / \mathrm{W}$ |

## CS4192

## Single Air-Core Gauge Driver

The CS4192 is a monolithic BiCMOS integrated circuit used to translate a digital 10-bit word from a microprocessor/microcontroller to complementary DC outputs. The DC outputs drive an air-core meter commonly used in vehicle instrument panels. The 10 bits of data are used to linearly control the quadrature coils of the meter directly with a $0.35^{\circ}$ resolution and $\pm 1.2^{\circ}$ accuracy over the full $360^{\circ}$ range of the gauge. The interface from the microcontroller is by a Serial Peripheral Interface (SPI) compatible serial connection using up to a 2.0 MHz shift clock rate.

The digital code, which is directly proportional to the desired gauge pointer deflection, is shifted into a DAC and multiplexer. These two blocks provide a tangential conversion function to change the digital data into the appropriate DC coil voltage for the angle demanded. The tangential algorithm creates approximately $40 \%$ more torque in the meter movement than does a sin-cos algorithm at $45^{\circ}, 135^{\circ}, 225^{\circ}$, and $315^{\circ}$ angles. This increased torque reduces the error due to pointer droop at these critical angles.

Each output buffer is capable of supplying up to 70 mA per coil and the buffers are controlled by a common OE enable pin. The output buffers are turned off when OE is brought low, while the logic portion of the chip remains powered and continues to operate normally. OE must be high before the falling edge of CS to enable the output buffers. The status pin (ST) reflects the state of the outputs and is low whenever the outputs are disabled.

The Serial Gauge Driver is self-protected against fault conditions. Each driver is protected for 125 mA (typ.) overcurrent while a global thermal protection circuit limits junction temperature to $170^{\circ} \mathrm{C}$ (typ.). The output drivers are disabled anytime the IC protection circuitry detects an overcurrent or overtemperature fault. The drivers remain disabled until a falling edge is presented on CS. If the fault is still present, the output drivers automatically disable themselves again.

## Features

- Serial Input Bus
- 2.0 MHz Operating Frequency
- Tangential Drive Algorithm
- 70 mA Drive Circuits
- $0.5^{\circ}$ Accuracy (Typ.)
- Power-On-Reset
- Protection Features
- Output Short Circuit
- Overtemperature
- Internally Fused Leads in SO-16L Package

2. Designed to meet these characteristics over the stated voltage and temperature ranges, though may not be $100 \%$ parametrically tested in production.
3. OE must be high at falling edge of CS. This condition ensures valid output for any given input.

PIN FUNCTION DESCRIPTION

| PACKAGE PIN \# | PIN SYMBOL | FUNCTION |
| :---: | :---: | :---: |
| 16 Lead SO Wide |  |  |
| 1 | SIN- | Negative output for SINE coil. |
| 2 | SIN+ | Positive output SINE coil. |
| 3 | $\mathrm{V}_{\mathrm{BB}}$ | Analog supply. Nominally 13.5 V . |
| 4, 5, 12, 13 | GND | Ground. |
| 6 | SI | Serial data input. Data present at the rising edge of the clock signal is shifted into the internal shift register. |
| 7 | $\mathrm{V}_{\mathrm{CC}}$ | 5.0 V logic supply. The internal registers and latches are reset by a POR generated by the rising edge of the voltage on this pin. |
| 8 | OE | Controls the state of the output buffers. A logic low on this pin turns them off. |
| 9 | SCLK | Serial clock for shifting in/out of data. Rising edge shifts data on SI into the shift register and the falling edge changes the data on SO. |
| 10 | CS | When high allows data at SI to be shifted into part with the rising edges of SCLK. The falling edge transfers the shift register contents into the DAC and multiplexer to update the output buffers. The falling edge also reenables the output drivers if they have been disabled by a fault. |
| 11 | ST | STATUS reflects the state of the outputs and is low anytime the outputs are disabled, either by OE or the internal protection circuitry. Requires external pull-up resistor. |
| 14 | SO | Serial data output. Existing 10-bit data is shifted out when new data is shifted in. Allows cascading of multiple devices on common serial port. |
| 15 | COS- | Negative output for COSINE coil. |
| 16 | COS+ | Positive output for COSINE coil. |

## APPLICATIONS INFORMATION

THEORY OF OPERATION
The SACD is for interfacing between a microcontroller or microprocessor and air-core meter movements commonly used in automotive vehicles for speedometers and tachometers. These movements are built using two coils placed at a $90^{\circ}$ orientation to each other. A magnetized disc floats in the middle of the coils and responds to the magnetic field generated by each coil. The disc has a shaft attached to it that protrudes out of the assembly. A pointer indicator is attached to this shaft and in conjunction with a separate printed scale displays the vehicle's speed or the engine's speed.

The disc (and pointer) respond to the vector sum of the voltages applied to the coils. Ideally, this relationship follows a sine/cosine equation. Since this is a transcendental and non-linear function, devices of this type use an approximation for this relationship. The SACD uses a tangential algorithm as shown in Figure 2. Only one output varies in any 45 degree range.

Figure 2. SIN, COS Outputs

## Quadrant I

$$
\theta=\operatorname{Tan}^{-1}\left[\frac{\mathrm{~V}_{\mathrm{SIN}+}-\mathrm{V}_{\mathrm{SIN}-}}{\mathrm{V}_{\mathrm{COS}+}-\mathrm{V}_{\mathrm{COS}}-}\right]
$$

For $\theta=0.176^{\circ}$ to $44.824^{\circ}$ :

$$
\mathrm{V}_{\mathrm{SIN}}=\operatorname{Tan} \theta \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

$$
V_{\mathrm{COS}}=0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

For $\theta=45.176^{\circ}$ to $89.824^{\circ}$ :

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{SIN}}=0.748 \times \mathrm{V}_{\mathrm{BB}} \\
& \mathrm{~V}_{\mathrm{COS}}=\operatorname{Tan}\left(90^{\circ}-\theta\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
\end{aligned}
$$

## Quadrant II

$$
\theta=180^{\circ}-\operatorname{Tan}^{-1}\left[\frac{\mathrm{~V}_{\mathrm{SIN}+}-\mathrm{V}_{\mathrm{SIN}-}}{\mathrm{V}_{\mathrm{COS}+}-\mathrm{V}_{\mathrm{COS}}-}\right]
$$

For $\theta=90.176^{\circ}$ to $134.824^{\circ}$ :

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{SIN}}=0.748 \times \mathrm{V}_{\mathrm{BB}} \\
& \mathrm{~V}_{\mathrm{COS}}=-\operatorname{Tan}\left(\theta-90^{\circ}\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
\end{aligned}
$$

$$
\begin{aligned}
& \text { For } \theta=135.176^{\circ} \text { to } 179.824^{\circ}: \\
& \quad V_{\mathrm{SIN}}=\operatorname{Tan}\left(180^{\circ}-\theta\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}} \\
& \mathrm{~V}_{\mathrm{COS}}=-0.748 \times \mathrm{V}_{\mathrm{BB}}
\end{aligned}
$$

## Quadrant III

$$
\theta=180^{\circ}+\operatorname{Tan}^{-1}\left[\frac{\mathrm{~V}_{\mathrm{SIN}}+-\mathrm{V}_{\mathrm{SIN}-}}{\mathrm{V}_{\mathrm{COS}+}-\mathrm{V}_{\mathrm{COS}}-}\right]
$$

For $\theta=180.176^{\circ}$ to $224.824^{\circ}$ :

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{SIN}}=-\operatorname{Tan}\left(\theta-180^{\circ}\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}} \\
& \mathrm{~V}_{\mathrm{COS}}=-0.748 \times \mathrm{V}_{\mathrm{BB}}
\end{aligned}
$$

For $\theta=225.176^{\circ}$ to $269.824^{\circ}$ :

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{SIN}}=-0.748 \times \mathrm{V}_{\mathrm{BB}} \\
& \mathrm{~V}_{\mathrm{COS}}=-\operatorname{Tan}\left(270^{\circ}-\theta\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
\end{aligned}
$$

## Quadrant IV

$$
\theta=360^{\circ}-\operatorname{Tan}^{-1}\left[\frac{\mathrm{~V}_{\mathrm{SIN}+}-\mathrm{V}_{\mathrm{SIN}-}}{\mathrm{V}_{\mathrm{COS}+}-\mathrm{V}_{\mathrm{COS}}-}\right]
$$

For $\theta=270.176^{\circ}$ to $314.824^{\circ}$ :

$$
\mathrm{V}_{\mathrm{SIN}}=-0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

$$
\mathrm{V}_{\mathrm{COS}}=\operatorname{Tan}\left(\theta-270^{\circ}\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}
$$

For $\theta=315.176^{\circ}-359.824^{\circ}$ :
$\mathrm{V}_{\mathrm{SIN}}=-\operatorname{Tan}\left(360^{\circ}-\theta\right) \times 0.748 \times \mathrm{V}_{\mathrm{BB}}$
$\mathrm{V}_{\mathrm{COS}}=0.748 \times \mathrm{V}_{\mathrm{BB}}$

Figure 3. Gauge Response
To drive the gauge's pointer to a particular angle, the microcontroller sends a 10 -bit digital word into the serial port. These 10 bits are divided as shown in Figure 4.

Figure 4. Definition of Serial Word

However, from a software programmers viewpoint, a $360^{\circ}$ circle is divided into 1024 equal parts of $0.35^{\circ}$ each. Table 1 shows the data associated with the $45^{\circ}$ divisions of the $360^{\circ}$ driver.

Table1. Nominal Output ( $\mathrm{V}_{\mathrm{BB}}=14 \mathrm{~V}$ )

| Input Code <br> (Decimal) | Ideal <br> Degrees | Nominal <br> Degrees | $\mathbf{V}_{\text {SIN }}$ <br> $(\mathrm{V})$ | $\mathbf{V}_{\text {Cos }}$ <br> $(\mathrm{V})$ |
| :---: | :---: | :---: | :---: | :---: |
| 0 | 0 | 0.176 | 0.032 | 10.476 |
| 128 | 45 | 45.176 | 10.476 | 10.412 |
| 256 | 90 | 90.176 | 10.476 | -0.032 |
| 384 | 135 | 135.176 | 10.412 | -10.476 |
| 512 | 180 | 180.176 | -0.032 | -10.476 |
| 640 | 225 | 225.176 | -10.476 | -10.412 |
| 768 | 270 | 270.176 | -10.476 | 0.032 |
| 896 | 315 | 315.176 | -10.476 | 10.476 |
| 1023 | 359.65 | 359.826 | -0.032 | 10.476 |

The 10 bits are shifted into the device's shift register MSB first using an SPI compatible scheme. This method is shown in Figure 5. The CS must be high and remain high for SCLK to be enabled. Data on SI is shifted in on the rising edge of the synchronous clock signal. Data in the shift register changes at SO on the falling edge of SCLK. This arrangement allows the cascading of devices. SO is always enabled. Data shifts through without affecting the outputs until CS is brought low. At this time the internal DAC is updated and the outputs change accordingly.

Figure 5. Serial Data Timing Diagram
Figure 6 shows the power-up sequence for the CS4192. Note the IC requires a pulse on the Chip Select (CS) pin to clear the Status Fault (ST) after power up. OE must be high before the falling edge of CS to enable the output buffers.

Figure 6. Power Up Sequence

CS4192

Figure 7. Application Diagram

## Zero Voltage Switch Power Controller

The UAA2016 is designed to drive triacs with the Zero Voltage technique which allows RFI-free power regulation of resistive loads. Operating directly on the AC power line, its main application is the precision regulation of electrical heating systems such as panel heaters or irons.

A built-in digital sawtooth waveform permits proportional temperature regulation action over $\mathrm{a} \pm 1^{\circ} \mathrm{C}$ band around the set point. For energy savings there is a programmable temperature reduction function, and for security a sensor failsafe inhibits output pulses when the sensor connection is broken. Preset temperature (i.e. defrost) application is also possible. In applications where high hysteresis is needed, its value can be adjusted up to $5^{\circ} \mathrm{C}$ around the set point. All these features are implemented with a very low external component count.

- Zero Voltage Switch for Triacs, up to 2.0 kW (MAC212A8)
- Direct AC Line Operation
- Proportional Regulation of Temperature over a $1^{\circ} \mathrm{C}$ Band
- Programmable Temperature Reduction
- Preset Temperature (i.e. Defrost)
- Sensor Failsafe
- Adjustable Hysteresis
- Low External Component Count

NOTES: 1. Output pulses are centered with respect to zero crossing point. Pulse width is adjusted by the value of $R_{\text {sync }}$. Refer to application curves.
2. The actual sawtooth period depends on the AC power line frequency. It is exactly 2048 times the corresponding period. For the 50 Hz case it is 40.96 sec . For the 60 Hz case it is 34.13 sec . This is to comply with the European standard, namely that 2.0 kW loads cannot be connected or removed from the line more than once every 30 sec .
3.350 mV corresponds to $5^{\circ} \mathrm{C}$ temperature reduction. This is tested at probe using internal test pad. Smaller temperature reduction can be obtained by adding an external resistor between Pin 4 and $\mathrm{V}_{\mathrm{CC}}$. Refer to application curves.
4.350 mV corresponds to a hysteresis of $5^{\circ} \mathrm{C}$. This is tested at probe using internal test pad. Smaller additional hysteresis can be obtained by adding an external resistor between Pin 2 and $\mathrm{V}_{\mathrm{cc}}$. Refer to application curves
5. Parameter guaranteed but not tested. Worst case 10 mV corresponds to $0.15^{\circ} \mathrm{C}$ shift on set point.
6. Measured at probe by internal test pad. 70 mV corresponds to $1^{\circ} \mathrm{C}$. Note that the proportional band is independent of the NTC value.
7. At very low temperature the NTC resistor increases quickly. This can cause the sensor input voltage to reach the failsafe threshold, thus inhibiting output pulses; refer to application schematics. The corresponding temperature is the limit at which the circuit works in the typical application. By setting this threshold at $0.05 \mathrm{~V}_{\text {ref }}$, the NTC value can increase up to 20 times its nominal value, thus the application works below $-20^{\circ} \mathrm{C}$.

Figure 1. Application Schematic

## APPLICATION INFORMATION

(For simplicity, the LED in series with $R_{\text {out }}$ is omitted in the following calculations.)

## Triac Choice and $\mathbf{R}_{\text {out }}$ Determination

Depending on the power in the load, choose the triac that has the lowest peak gate trigger current. This will limit the output current of the UAA2016 and thus its power consumption. Use Figure 4 to determine $\mathrm{R}_{\text {out }}$ according to the triac maximum gate current $\left(\mathrm{I}_{\mathrm{GT}}\right)$ and the application low temperature limit. For a 2.0 kW load at 220 Vrms , a good triac choice is the ON Semiconductor MAC212A8. Its maximum peak gate trigger current at $25^{\circ} \mathrm{C}$ is 50 mA .

For an application to work down to $-20^{\circ} \mathrm{C}, \mathrm{R}_{\text {out }}$ should be $60 \Omega$. It is assumed that: $\mathrm{I}_{\mathrm{GT}}(\mathrm{T})=\mathrm{I}_{\mathrm{GT}}\left(25^{\circ} \mathrm{C}\right) \times \exp (-\mathrm{T} / 125)$ with T in ${ }^{\circ} \mathrm{C}$, which applies to the MAC212A8.

## Output Pulse Width, $\mathbf{R}_{\text {sync }}$

The pulse with $\mathrm{T}_{\mathrm{P}}$ is determined by the triac's $\mathrm{I}_{\text {Hold }}, \mathrm{I}_{\text {Latch }}$ together with the load value and working conditions (frequency and voltage):

Given the RMS AC voltage and the load power, the load value is:

$$
\mathrm{R}_{\mathrm{L}}=\mathrm{V}^{2} \mathrm{rms} / \mathrm{POWER}
$$

The load current is then:

$$
\mathrm{I}_{\text {Load }}=\left(\mathrm{Vrms} \times \sqrt{2} \times \sin (2 \pi \mathrm{ft})-\mathrm{V}_{\mathrm{TM}}\right) / \mathrm{R}_{\mathrm{L}}
$$

where $\mathrm{V}_{\mathrm{TM}}$ is the maximum on state voltage of the triac, f is the line frequency.

$$
\text { Set } I_{\text {Load }}=I_{\text {Latch }} \text { for } t=T_{P} / 2 \text { to calculate } T_{P} \text {. }
$$

Figures 6 and 7 give the value of $T_{P}$ which corresponds to the higher of the values of $\mathrm{I}_{\text {Hold }}$ and $\mathrm{I}_{\text {Latch }}$, assuming that $\mathrm{V}_{\mathrm{TM}}=1.6 \mathrm{~V}$. Figure 8 gives the $\mathrm{R}_{\text {sync }}$ that produces the corresponding $\mathrm{T}_{\mathrm{P}}$.

## $\mathbf{R}_{\text {Supply }}$ and Filter Capacitor

With the output current and the pulse width determined as above, use Figures 9 and 10 to determine R $_{\text {Supply }}$, assuming that the sinking current at $\mathrm{V}_{\text {ref }}$ pin (including NTC bridge current) is less than 0.5 mA . Then use Figure 11 and 12 to determine the filter capacitor $\left(\mathrm{C}_{\mathrm{F}}\right)$ according to the ripple desired on supply voltage. The maximum ripple allowed is 1.0 V .

Figure 3. Zero Voltage Technique

## CIRCUIT FUNCTIONAL DESCRIPTION

## Power Supply (Pin 5 and Pin 7)

The application uses a current source supplied by a single high voltage rectifier in series with a power dropping resistor. An integrated shunt regulator delivers a $\mathrm{V}_{\mathrm{EE}}$ voltage of -8.6 V with respect to $\operatorname{Pin} 7$. The current used by the total regulating system can be shared in four functional blocks: IC supply, sensing bridge, triac gate firing pulses and zener current. The integrated zener, as in any shunt regulator, absorbs the excess supply current. The 50 Hz pulsed supply current is smoothed by the large value capacitor connected between Pins 5 and 7.

## Temperature Sensing (Pin 3)

The actual temperature is sensed by a negative temperature coefficient element connected in a resistor divider fashion. This two element network is connected between the ground terminal Pin 5 and the reference voltage -5.5 V available on Pin 1. The resulting voltage, a function of the measured temperature, is applied to Pin 3 and internally compared to a control voltage whose value depends on several elements: Sawtooth, Temperature Reduction and Hysteresis Adjust. (Refer to Application Information.)

## Temperature Reduction

For energy saving, a remotely programmable temperature reduction is available on Pin 4. The choice of resistor $\mathrm{R}_{1}$ connected between Pin 4 and $\mathrm{V}_{\mathrm{CC}}$ sets the temperature reduction level.

## Comparator

When the positive input ( $\operatorname{Pin} 3$ ) receives a voltage greater than the internal reference value, the comparator allows the triggering logic to deliver pulses to the triac gate. To improve the noise immunity, the comparator has an adjustable hysteresis. The external resistor $\mathrm{R}_{3}$ connected to Pin 2 sets the hysteresis level. Setting Pin 2 open makes a 10 mV hysteresis level, corresponding to $0.15^{\circ} \mathrm{C}$. Maximum

Figure 4. Output Resistor versus Triac Gate Current
hysteresis is obtained by connecting Pin 2 to $\mathrm{V}_{\mathrm{CC}}$. In that case the level is set at $5^{\circ} \mathrm{C}$. This configuration can be useful for low temperature inertia systems.

## Sawtooth Generator

In order to comply with European norms, the ON/OFF period on the load must exceed 30 seconds. This is achieved by an internal digital sawtooth which performs the proportional regulation without any additional component. The sawtooth signal is added to the reference applied to the comparator negative input. Figure 2 shows the regulation improvement using the proportional band action.

## Noise Immunity

The noisy environment requires good immunity. Both the voltage reference and the comparator hysteresis minimize the noise effect on the comparator input. In addition the effective triac triggering is enabled every $1 / 3 \mathrm{sec}$.

## Failsafe

Output pulses are inhibited by the "failsafe" circuit if the comparator input voltage exceeds the specified threshold voltage. This would occur if the temperature sensor circuit is open.

## Sampling Full Wave Logic

Two consecutive zero-crossing trigger pulses are generated at every positive mains half-cycle. This ensures that the number of delivered pulses is even in every case. The pulse length is selectable by $\mathrm{R}_{\text {sync }}$ connected on Pin 8 . The pulse is centered on the zero-crossing mains waveform.

## Pulse Amplifier

The pulse amplifier circuit sinks current pulses from Pin 6 to $\mathrm{V}_{\mathrm{EE}}$. The minimum amplitude is 70 mA . The triac is then triggered in quadrants II and III. The effective output current amplitude is given by the external resistor $\mathrm{R}_{\text {out }}$. Eventually, an LED can be inserted in series with the Triac gate (see Figure 1).

## CS3341, CS3351, CS387

## Alternator Voltage Regulator Darlington Driver

The CS3341/3351/387 integral alternator regulator integrated circuit provides the voltage regulation for automotive, 3-phase alternators.

It drives an external power Darlington for control of the alternator field current. In the event of a charge fault, a lamp output pin is provided to drive an external darlington transistor capable of switching on a fault indicator lamp. An overvoltage or no STATOR signal condition activates the lamp output.

The CS3341 and CS3351 are available in SO-14 packages. The CS387 is available as a Flip Chip.

## Features

- Drives NPN Darlington
- Short Circuit Protection
- 80 V Load Dump
- Temperature Compensated Regulation Voltage
- Shorted Field Protection Duty Cycle, Self Clearing

## APPLICATIONS INFORMATION

The CS3341 and CS3351 IC's are designed for use in an alternator charging system. The circuit is also available in flip-chip form as the CS387.

In a standard alternator design (Figure 3), the rotor carries the field winding. An alternator rotor usually has several N and $S$ poles. The magnetic field for the rotor is produced by forcing current through a field or rotor winding. The Stator windings are formed into a number of coils spaced around a cylindrical core. The number of coils equals the number of pairs of N and S poles on the rotor. The alternating current in the Stator windings is rectified by the diodes and applied to the regulator. By controlling the amount of field current, the magnetic field strength is controlled and hence the output voltage of the alternator.

Referring to Figure 4, a typical application diagram, the oscillator frequency is set by an external capacitor connected between OSC and ground. The sawtooth waveform ramps between 1.0 V and 3.0 V and provides the timing for the system. For the circuit shown the oscillator frequency is approximately 140 Hz . The alternator voltage is sensed at Terminal A via the resistor divider network R1/R2 on the Sense pin of the IC. The voltage at the sense pin determines the duty cycle for the regulator. The voltage is adjusted by potentiometer R2. A relatively low voltage on the sense pin causes a long duty cycle that increases the Field current. A high voltage results in a short duty cycle.

The ignition Terminal (I) switches power to the IC through the $\mathrm{V}_{\mathrm{CC}}$ pin. In the CS3351 the Stator pin senses the voltage from the stator. This will keep the device powered while the voltage is high, and it also senses a stopped engine condition and drives the Lamp pin high after the stator
timeout expires. The Lamp pin also goes high when an overvoltage condition is detected on the sense pin. This causes the darlington lamp drive transistor to switch on and pull current through the lamp. If the system voltage continues to increase, the field and lamp output turn off as in an overvoltage or load dump condition.

The SC or Short Circuit pin monitors the field voltage. If the drive output and the SC voltage are simultaneously high for a predetermined period, a short circuit condition is assumed and the output is disabled. The regulator is forced to a minimum short circuit duty cycle.

## CS1124

## Dual Variable-Reluctance Sensor Interface IC

The CS1124 is a monolithic integrated circuit designed primarily to condition signals used to monitor rotating parts.

The CS1124 is a dual channel device. Each channel interfaces to a Variable Reluctance Sensor, and monitors the signal produced when a metal object is moved past that sensor. An output is generated that is a comparison of the input voltage and the voltage produced at the $\mathrm{IN}_{\text {Adj }}$ lead. The resulting square-wave is available at the OUT pin.

When the DIAG pin is high, the reference voltage at $\mathrm{IN}_{\text {Adj }}$ is increased. This then requires a larger signal at the input to trip the comparator, and provides for a procedure to test for an open sensor.

## Features

- Dual Channel Capability
- Built-In Test Mode
- On-Chip Input Voltage Clamping
- Works from 5.0 V Supply
- Accurate Built-In Hysteresis

Figure 2. Application Diagram

## THEORY OF OPERATION

## NORMAL OPERATION

Figure 2 shows one channel of the CS1124 along with the necessary external components. Both channels share the $\mathrm{IN}_{\text {Adj }}$ pin as the negative input to a comparator. A brief description of the components is as follows:
$\mathbf{V}_{\mathbf{R S}}$ - Ideal sinusoidal, ground referenced, sensor output - amplitude usually increases with frequency, depending on loading.
$\mathbf{R}_{\mathbf{R S}}$ - Source impedance of sensor.
$\mathbf{R 1} / \mathbf{R}_{\text {Adj }}$ - External resistors for current limiting and biasing.

INP1/IN $\mathbf{N d j}$ - Internal current sources that determine trip points via R1/R ${ }_{\text {Adj }}$.

COMP1 - Internal comparator with built-in hysteresis set at 160 mV .
OUT1 - Output $0 \mathrm{~V}-5.0 \mathrm{~V}$ square wave with the same frequency as $\mathrm{V}_{\mathrm{RS}}$.
By inspection, the voltage at the ( + ) and (-) terminals of COMP1 with $\mathrm{V}_{\mathrm{RS}}=0 \mathrm{~V}$ are:

$$
\begin{equation*}
\mathrm{V}^{+}=\operatorname{INP} 1(\mathrm{R} 1+\mathrm{RRS}) \tag{1}
\end{equation*}
$$

$$
\begin{equation*}
\mathrm{V}^{-}=\mathrm{IN}_{\mathrm{Adj}} \times \mathrm{R}_{\mathrm{Adj}} \tag{2}
\end{equation*}
$$

As $V_{R S}$ begins to rise and fall, it will be superimposed on the DC biased voltage at $\mathrm{V}^{+}$.

$$
\begin{equation*}
\mathrm{V}+=\operatorname{INP} 1\left(\mathrm{R} 1+\mathrm{R}_{\mathrm{RS}}\right)+\mathrm{V}_{\mathrm{RS}} \tag{3}
\end{equation*}
$$

To get comparator COMP1 to trip, the following condition is needed when crossing in the positive direction,

$$
\begin{equation*}
\mathrm{V}+>\mathrm{V}^{-}+\mathrm{V}_{\mathrm{HYS}} \tag{4}
\end{equation*}
$$

( $\mathrm{V}_{\text {HYS }}$ is the built-in hysteresis set to 160 mV ), or when crossing in the negative direction,

$$
\begin{equation*}
\mathrm{V}+<\mathrm{V}^{-}-\mathrm{V}_{\mathrm{HYS}} \tag{5}
\end{equation*}
$$

Combining equations 2,3 , and 4 , we get:

$$
\begin{equation*}
\operatorname{INP} 1\left(R 1+R_{R S}\right)+V_{R S}>I_{A d j} \times R_{A d j}+V_{H Y S} \tag{6}
\end{equation*}
$$

therefore,

$$
\begin{equation*}
V_{R S}(+T R P)<\operatorname{IN}_{\text {Adj }} \times R_{\text {Adj }}-\operatorname{INP} 1\left(R 1+R_{R S}\right)+V_{H Y S} \tag{7}
\end{equation*}
$$

It should be evident that tripping on the negative side is:

$$
\begin{equation*}
V_{R S}(-T R P)<I_{A d j} \times R_{A d j}-\operatorname{INP} 1\left(R 1+R_{R S}\right)-V_{H Y S} \tag{8}
\end{equation*}
$$

In normal mode,

$$
\begin{equation*}
\mathrm{INP} 1=\mathrm{IN}_{\mathrm{Adj}} \tag{9}
\end{equation*}
$$

We can now re-write equation (7) as:

$$
\begin{equation*}
\mathrm{V}_{\mathrm{RS}(+\mathrm{TR})}>\operatorname{INP1}\left(\mathrm{R}_{\mathrm{Adj}}-\mathrm{R} 1-\mathrm{R}_{\mathrm{RS}}\right)+\mathrm{V}_{\mathrm{HYS}} \tag{10}
\end{equation*}
$$

By making

$$
\begin{equation*}
R_{\text {Adj }}=R 1+R_{R S} \tag{11}
\end{equation*}
$$

you can detect signals with as little amplitude as $\mathrm{V}_{\text {HYS }}$.
A design example is given in the applications section.

## OPEN SENSOR PROTECTION

The CS1124 has a DIAG pin that when pulled high (5.0 V), will increase the $\mathrm{IN}_{\text {Adj }}$ current source by roughly $50 \%$.

Equation (7) shows that a larger $\mathrm{V}_{\mathrm{RS}(+\mathrm{TRP})}$ voltage will be needed to trip comparator COMP1. However, if no $\mathrm{V}_{\mathrm{RS}}$ signal is present, then we can use equations 1,2 , and 4 (equation 5 does not apply in this mode) to get:

$$
\begin{equation*}
\text { INP1 } \left.\mathrm{R} 1+\mathrm{R}_{\mathrm{RS}}\right)>\operatorname{INP} 1 \times \mathrm{K}_{\mathrm{I}} \times \mathrm{R}_{\text {Adj }}+\mathrm{V}_{\mathrm{HYS}} \tag{12}
\end{equation*}
$$

Since $R_{R S}$ is the only unknown variable we can solve for $\mathrm{R}_{\mathrm{RS}}$,

$$
\begin{equation*}
\mathrm{R}_{\mathrm{RS}}=\frac{\mathrm{INP} 1 \times \mathrm{K}_{\mathrm{I}} \times \mathrm{R}_{\mathrm{Adj}}+\mathrm{V}_{\mathrm{HYS}}}{\mathrm{INP} 1}-\mathrm{R} 1 \tag{13}
\end{equation*}
$$

Equation (13) shows that if the output switches states when entering the diag mode with $\mathrm{V}_{\mathrm{RS}}=0$, the sensor impedance must be greater than the above calculated value. This can be very useful in diagnosing intermittent sensor.

## INPUT PROTECTION

As shown in Figure 2, an active clamp is provided on each input to limit the voltage on the input pin and prevent substrate current injection. The clamp is specified to handle $\pm 12 \mathrm{~mA}$. This puts an upper limit on the amplitude of the sensor output. For example, if R1 $=20 \mathrm{k}$, then

$$
\mathrm{V}_{\mathrm{RS}(\mathrm{MAX})}=20 \mathrm{k} \times 12 \mathrm{~mA}=240 \mathrm{~V}
$$

Therefore, the $\mathrm{V}_{\mathrm{RS}(\mathrm{pk}-\mathrm{pk})}$ voltage can be as high as 480 V . The CS1124 will typically run at a frequency up to 1.8 MHz if the input signal does not activate the positive or negative input clamps. Frequency performance will be lower when the positive or negative clamps are active. Typical performance will be up to a frequency of 680 kHz with the clamps active.

## CIRCUIT DESCRIPTION

Figure 3 shows the part operating near the minimum input thresholds. As the sin wave input threshold is increased, the low side clamps become active (Figure 4). Increasing the amplitude further (Figure 5), the high-side clamp becomes active. These internal clamps allow for voltages up to -250 V and 250 V on the sensor side of the setup (with $\mathrm{R} 1=\mathrm{R} 2=$ 22 k ) (reference the diagram page 3183).

Figure 6 shows the effect using the diagnostic (DIAG) function has on the circuit. The input threshold (negative) is switched from a threshold of -160 mV to +160 mV when DIAG goes from a low to a high. There is no hysteresis when DIAG is high.

Figure 3. Minimum Threshold Operation

Figure 5. Low- and High-Side Clamps

Figure 6. Diagnostic Operation

## CS1124

## APPLICATION INFORMATION

Referring to Figure 2, the following will be a design example given these system requirements:

$$
\begin{gathered}
\mathrm{R}_{\mathrm{RS}}=1.5 \mathrm{k} \Omega(>12 \mathrm{k} \Omega \text { is considered open }) \\
\mathrm{V}_{\mathrm{RS}}(\mathrm{MAX})=120 \mathrm{~V}_{\mathrm{pk}} \\
\mathrm{~V}_{\mathrm{RS}}(\mathrm{MIN})=250 \mathrm{mV}_{\mathrm{pk}} \\
\mathrm{FVRS}_{\mathrm{V}}=10 \mathrm{kHz} @ \mathrm{~V}_{\mathrm{RS}}(\mathrm{MIN})=40 \mathrm{~V}_{\mathrm{pk}-\mathrm{pk}}
\end{gathered}
$$

## 1. Determine tradeoff between R1 value and power

 rating. (use $1 / 2$ watt package)$$
\mathrm{PD}=\frac{\left(\frac{120}{\sqrt{2}}\right)^{2}}{\mathrm{R} 1}<1 / 2 \mathrm{~W}
$$

Set R1 $=15 \mathrm{k}$. (The clamp current will then be $120 / 15 \mathrm{k}$ $=8.0 \mathrm{~mA}$, which is less than the 12 mA limit.)

## 2. Determine $\mathbf{R}_{\text {Adj }}$

Set $R_{\text {Adj }}$ as close to $\mathrm{R} 1+\mathrm{R}_{\mathrm{RS}}$ as possible.
Therefore, $\mathrm{R}_{\mathrm{Adj}}=17 \mathrm{k}$.

## 3. Determine $\mathrm{V}_{\mathrm{RS}(+\mathrm{TRP})}$ using equation (7).

$$
\begin{aligned}
V_{R S}(+T R P)= & 11 \mu \mathrm{~A} \times 17 \mathrm{k}-11 \mu \mathrm{~A}(15 \mathrm{k}+1.5 \mathrm{k})+160 \mathrm{mV} \\
& V_{R S}(+ \text { TRP })=166 \mathrm{mV} \text { typical } \\
& \text { (easily meets } 250 \mathrm{mV} \text { minimum })
\end{aligned}
$$

## 4. Calculate worst case $\mathrm{V}_{\mathrm{RS}(+ \text { TRP) }}$

Examination of equation (7) and the spec reveals the worst case trip voltage will occur when:

$$
\begin{aligned}
& \mathrm{V}_{\mathrm{HYS}}=180 \mathrm{mV} \\
& \mathrm{IN}_{\text {Adj }}=16 \mu \mathrm{~A} \\
& \text { INP1 }=15 \mu \mathrm{~A} \\
& \text { R1 }=14.25 \mathrm{k} \text { (5\% low) } \\
& \mathrm{R}_{\text {Adj }}=17.85 \mathrm{k}(5 \% \text { High }) \\
& \mathrm{V}_{\mathrm{RS}(+) \mathrm{MAX}}=16 \mu \mathrm{~A}(17.85 \mathrm{k}) \\
& -15 \mu \mathrm{~A}(14.25 \mathrm{k}+1.5 \mathrm{k})+180 \mathrm{mV} \\
& =229 \mathrm{mV}
\end{aligned}
$$

which is still less than the 250 mV minimum amplitude of the input.
5. Calculate $\mathbf{C 1}$ for low pass filtering

Since the sensor guarantees $40 \mathrm{~V}_{\mathrm{pk}-\mathrm{pk}} @ 10 \mathrm{kHz}$, a low pass filter using R1 and C1 can be used to eliminate high frequency noise without affecting system performance.

$$
\text { Gain Reduction }=\frac{0.29 \mathrm{~V}}{20 \mathrm{~V}}=0.0145=-36.7 \mathrm{~dB}
$$

Therefore, a cut-off frequency, $\mathrm{f}_{\mathrm{C}}$, of 145 Hz could be used.

$$
\mathrm{C} 1 \leq \frac{1}{2 \pi f \mathrm{CR} 1} \leq 0.07 \mu \mathrm{~F}
$$

Set $\mathrm{C} 1=0.047 \mu \mathrm{~F}$.
6. Calculate the minimum $R_{\text {RS }}$ that will be indicated as an open circuit. (DIAG = 5.0 V)

Rearranging equation (7) gives

$$
\mathrm{R}_{\mathrm{RS}}=\frac{\left[\begin{array}{l}
\mathrm{V}_{\mathrm{HYS}}+\left[\mathrm{INP} 1 \times \mathrm{K}_{\mathrm{I}} \times \mathrm{R}_{\text {Adj }}\right] \\
-\mathrm{V}_{\mathrm{RS}}(+\mathrm{TRP})
\end{array}\right]}{\mathrm{INP} 1}-\mathrm{R} 1
$$

But, $\mathrm{V}_{\mathrm{RS}}=0$ during this test, so it drops out.
Using the following as worst case Low and High:

|  | Worst Case Low ( $\mathbf{R}_{\text {RS }}$ ) | Worst Case High ( $\mathbf{R}_{\mathbf{R S}}$ ) |
| :---: | :---: | :---: |
| $\mathrm{IN}_{\text {Adj }}$ | $23.6 \mu \mathrm{~A}=15 \mu \mathrm{~A} \times 1.57$ | $10.7 \mu \mathrm{~A}=7.0 \mu \mathrm{~A} \times 1.53$ |
| $\mathrm{R}_{\text {Adj }}$ | 16.15 k | 17.85 k |
| $\mathrm{V}_{\mathrm{HYS}}$ | 135 mV | 185 mV |
| INP1 | $16 \mu \mathrm{~A}$ | $6.0 \mu \mathrm{~A}$ |
| R1 | 15.75 k | 14.25 k |
| K | 1.57 | 1.53 |

$$
\begin{aligned}
\mathrm{R}_{\mathrm{RS}} & =\frac{135 \mathrm{mV}+23.6 \mu \mathrm{~A} \times 16.15 \mathrm{k}}{16 \mu \mathrm{~A}}-15.75 \mathrm{k} \\
& =16.5 \mathrm{k}
\end{aligned}
$$

Therefore,

$$
\operatorname{RRS}(\mathrm{MIN})=16.5 \mathrm{k} \text { (meets } 12 \mathrm{k} \text { system spec) }
$$

and,

$$
\begin{aligned}
\operatorname{RRS}(\mathrm{MAX}) & =\frac{185 \mathrm{mV}+10.7 \mu \mathrm{~A} \times 17.85 \mathrm{k}}{6.0 \mu \mathrm{~A}}-14.25 \mathrm{k} \\
& =48.4 \mathrm{k}
\end{aligned}
$$

## NCP5351

## Product Preview

## Synchronous Power MOSFET Driver

The NCP5351 is a dual MOSFET gate driver optimized to drive the gates of both high and low side Power MOSFETs in a Synchronous Buck converter. The NCP5351 is an excellent companion to multiphase controllers that do not have integrated gate drivers, such as ON Semiconductor's CS5323, CS5305 or CS5307. This architecture provides a power supply designer great flexibility by being able to locate the gate drivers close to the MOSFETs.

4 Amp drive capability makes the NCP5351 ideal for minimizing switching losses in MOSFETs with large input capacitance. Optimized internal, adaptive non-overlap circuitry further reduces switching losses by preventing simultaneous conduction of both MOSFETs.

The floating top driver design can accommodate MOSFET drain voltages as high as 25 V . Both gate outputs can be driven low, and supply current reduced to less than $10 \mu \mathrm{~A}$, by applying a low logic level to the Enable (EN) pin. An Undervoltage Lockout function ensures that both driver outputs are low when the supply voltage is low, and a Thermal Shutdown function provides the IC with overtemperature protection.

The NCP5351 is pin-to-pin compatible with the SC1205 and is available in a standard SO-8 package.

## Features

- 4 A Peak Drive Current
- Rise and Fall Times Typically < 15 ns
- Propagation Delay from Inputs to Outputs < 20 ns Maximum
- Adaptive Non-Overlap Time Optimized for Power MOSFETs Switching > 20 A/Phase
- Floating Top Driver Accommodates Applications Up to 25 V
- Undervoltage Lockout to Prevent Switching When the Power Supply Is Unreliable
- Thermal Shutdown Protection Against Overtemperature
- <1 mA Quiescent Current - Enable (EN) Asserted (No Switching)
- <10 $\mu \mathrm{A}$ Quiescent Current - Enable (EN) Deasserted (Disables Switching)

Figure 2. Timing Diagram

## PACKAGE PIN DESCRIPTION

| Pin Number | Pin Symbol | Description |
| :---: | :---: | :---: |
| 1 | DRN | The switching node common to the high and low-side FETs. The high-side (TG) driver and supply (BST) are referenced to this pin. |
| 2 | TG | Driver output to the high-side MOSFET gate. |
| 3 | BST | Bootstrap supply voltage input. In conjunction with a Schottky diode to $\mathrm{V}_{\mathrm{S}}$, a $0.1 \mu \mathrm{~F}$ to $1.0 \mu \mathrm{~F}$ ceramic capacitor connected between BST and DRN develops supply voltage for the high-side driver (TG). |
| 4 | CO | Logic level control input produces complementary output states - no inversion at TG; inversion at BG. |
| 5 | EN | Logic level enable input forces TG and BG low, and supply current to less than $10 \mu \mathrm{~A}$ when EN is low. |
| 6 | $\mathrm{V}_{\text {S }}$ | Power supply input. A $0.1 \mu \mathrm{~F}$ to $1.0 \mu \mathrm{~F}$ ceramic capacitor should be connected from this pin to PGND. |
| 7 | BG | Driver output to the low-side (synchronous rectifier) MOSFET gate. |
| 8 | PGND | Ground. |

Figure 3. Application Diagram

## CS3361

## Alternator Voltage Regulator FET Driver

The CS3361 integral alternator regulator integrated circuit provides the voltage regulation for automotive, 3-phase alternators.

It drives an external logic level N channel enhancement power FET for control of the alternator field current. In the event of a charge fault, a lamp output pin is provided to drive an external darlington transistor capable of switching on a fault indicator lamp. An overvoltage or no Stator signal condition activates the lamp output.

A STATOR Power Up feature is incorporated for systems which require power up activation by sensing the crank cycle of the starter at the stator. This eliminates unnecessary current drain when the ignition is turned on, but the car is not running. The CS3361 is available in an SO-14 package.

## Features

- Drives Logic Level Power NFET
- 80 V Load Dump
- Temperature Compensated Regulation Voltage
- Shorted Field Protection Duty Cycle, Self Clearing
- STATOR Power Up

## APPLICATIONS INFORMATION

The CS3361 is designed for use in an alternator charging system.

In a standard alternator design (Figure 3), the rotor carries the field winding. An alternator rotor usually has several N and $S$ poles. The magnetic field for the rotor is produced by forcing current through a field or rotor winding. The Stator windings are formed into a number of coils spaced around a cylindrical core. The number of coils equals the number of pairs of N and S poles on the rotor. The alternating current in the Stator windings is rectified by the diodes and applied to the regulator. By controlling the amount of field current, the magnetic field strength is controlled and hence the output voltage of the alternator.

Referring to Figure 4, a typical application diagram, the oscillator frequency is set by an external capacitor connected between OSC and ground. The sawtooth waveform ramps between 1.0 V and 3.0 V and provides the timing for the system. For the circuit shown the oscillator frequency is approximately 140 Hz . The alternator voltage is sensed at Terminal A via the resistor divider network R1/R2 on the Sense pin of the IC. The voltage at the sense pin determines the duty cycle for the regulator. The voltage is adjusted by potentiometer R2. A relatively low voltage on the sense pin causes a long duty cycle that increases the Field current. A high voltage results in a short duty cycle.

The ignition Terminal (I) switches power to the IC through the $\mathrm{V}_{\mathrm{CC}}$ pin. The Stator pin monitors the voltage from the stator and senses a stopped engine condition. It drives the Lamp pin high after the stator timeout expires. The Lamp pin also goes high when an overvoltage condition
is detected on the sense pin. This causes the darlington lamp drive transistor to switch on and pull current through the lamp. If the system voltage continues to increase, the field and lamp output turn off as in an overvoltage or load dump condition.
The SC or Short Circuit pin monitors the field voltage. If the drive output and the SC voltage are simultaneously high for a predetermined period, a short circuit condition is assumed and the output is disabled. The regulator is forced to a minimum short circuit duty cycle.

## MC34280

## Power Supply \&

Management IC for Handheld Electronic Products

The MC34280 is a power supply integrated circuit which provides two boost regulated outputs and some power management supervisory functions. Both regulators apply Pulse-Frequency-Modulation (PFM). The main step-up regulator output can be externally adjusted from 2.7 V to 5 V . An internal synchronous rectifier is used to ensure high efficiency (achieve 87\%). The auxiliary regulator with a built-in power transistor can be configured to produce a wide range of positive voltage (can be used for LCD contrast voltage). This voltage can be adjusted from +5 V to +25 V by an external potentiometer; or by a microprocessor, digitally through a 6 -bit internal DAC.

The MC34280 has been designed for battery powered hand-held products. With the low start-up voltage from 1 V and the low quiescent current (typical $35 \mu \mathrm{~A}$ ); the MC34280 is best suited to operate from 1 to 2 AA/ AAA cell. Moreover, supervisory functions such as low battery detection, CPU power-on reset, and back-up battery control, are also included in the chip. It makes the MC34280 the best one-chip power management solution for applications such as electronic organizers and PDAs.

## FEATURES:

- Low Input Voltage, 1V up
- Low Quiescent Current in Standby Mode: $35 \mu$ A typical
- PFM and Synchronous Rectification to ensure high efficiency ( $87 \%$ @ 200 mA Load)
- Adjustable Main Output: nominal 3.3V @ 200mA max, with 1.8 V input
- Auxiliary Output Voltage can be digitally controlled by microprocessor
- Auxiliary Output Voltage: $+5 \mathrm{~V} @ 25 \mathrm{~mA}$ max, with 1.8 V input +25 V @ 15 mA max, with 1.8 V input
- Current Limit Protection
- Power-ON Reset Signal with Programmable Delay
- Battery Low Detection
- Lithium Battery Back-up
- 32-Pin LQFP Package

## APPLICATIONS:

- Digital Organizer and Dictionary
- Personal Digital Assistance (PDA)
- Dual Output Power Supply (For MPU, Logic, Memory, LCD)
- Handheld Battery Powered Device (1-2 AA/AAA cell)

## DETAILED OPERATING DESCRIPTION

## General

The MC34280 is a power supply integrated circuit which provides two boost regulated outputs and some power management supervisory functions. Both regulators apply Pulse-Frequency-Modulation (PFM). The main boost regulator output can be externally adjusted from 2.7 V to 5 V . An internal synchronous rectifier is used to ensure high efficiency (achieve $87 \%$ ). The auxiliary regulator with a built-in power transistor can be configured to produce a wide range of positive voltage (can be used to supply a LCD contrast voltage). This voltage can be adjusted from +5 V to +25 V by an external potentiometer; or by a microprocessor, digitally through a 6-bit internal DAC.

The MC34280 has been designed for battery powered hand-held products. With the low start-up voltage from 1V and the low quiescent current (typical $35 \mu \mathrm{~A}$ ); the MC34280 is best suited to operate from 1 to $2 \mathrm{AA} / \mathrm{AAA}$ cell. Moreover, supervisory functions such as low battery detection, CPU power-on reset, and back-up battery control, are also included in the chip. It makes the MC34280 the best one-chip power management solution for applications such as electronic organizers and PDAs.

## Pulse Frequency Modulation (PFM)

Both regulators apply PFM. With this switching scheme, every cycle is started as the feedback voltage is lower than the internal reference. This is normally performed by internal comparator. As cycle starts, Low-Side switch (i.e. M1 in Figure 1) is turned ON for a fixed ON time duration (namely, $\mathrm{T}_{\mathrm{on}}$ ) unless current limit comparator senses coil current reaches its preset limit. In the latter case, M1 is OFF instantly. So $\mathrm{T}_{\mathrm{on}}$ is defined as the maximum ON time of M1. When M1 is ON, coil current ramps up so energy is being stored inside the coil. At the moment just after M1 is OFF, the Synchronous Rectifier (i.e. M2 in Figure 1) or any rectification device (such as Schottky Diode of Auxiliary Regulator) is turned ON to direct coil current to charge up the output bulk capacitor. Provided that coil current is not reached, every switching cycle delivers fixed amount of energy to the bulk capacitor. So for higher loading, larger amount of energy (Charge) is withdrawn from the bulk capacitor, and as output voltage is needed to regulated, larger amount of Charge is needed to be supplied to the bulk capacitor, that means switching frequency is needed to be increased; and vice-versa.

## Main Regulator

Figure 20 shows the simplified block diagram of Main Regulator. Notice that precise bias current Iref is generated by a VI converter and external resistor RIref, where

$$
\text { Iref }=\frac{0.5}{\text { RIref }}(\mathrm{A})
$$

This bias current is used for all internal current bias as well as setting VMAIN value. For the latter application, Iref is doubled and fed as current sink at Pin 1. With external resistor RMAINb tied from Pin1 to Pin32, a constant level shift is generated in between the two pins. In close-loop operation, voltage at Pin 1 (i.e. Output feedback voltage) is needed to be regulated at the internal reference voltage level, 1.22 V . Therefore, the delta voltage across Pin 1 and Pin 32 which can be adjusted by RMAINb determines the Main Output voltage. If the feedback voltage drops below 1.22 V , internal comparator sets switching cycle to start. So, VMAIN can be calculated as follows.

From the above equation, although VMAIN can be adjusted by RMAINb and RIref ratio, for setting VMAIN, it is suggested, by changing RMAINb value with RIref kept at 480K. Since changing RIref will alter internal bias current which will affect timing functions of Max ON time ( $T_{O N 1}$ ) and Min OFF time ( $T_{O F F 1}$ ). Their relationships are as follows;

$$
\begin{aligned}
& T_{O N 1}=1.7 \times 10^{-11} \times \text { RIref }(\mathrm{S}) \\
& T_{O F F 1}=6.4 \times 10^{-12} \times \text { RIref }(\mathrm{S})
\end{aligned}
$$

## Continuous Conduction Mode and Discontinuous Conduction Mode

In Figure 21, regulator is operating at Continuous Conduction Mode. A switching cycle is started as the output feedback voltage drops below internal voltage reference VREF. At that instant, the coil current does not drop to zero yet, and it starts to ramp up for the next cycle. As the coil current ramps up, loading makes the output voltage to decrease as the energy supply path to the output bulk capacitor is disconnected. And after Ton elapsed, M1 is OFF, M2 becomes ON, energy is dumped to the bulk capacitor. Output voltage is increased as excessive charge is pumped in, then it is decreased after the coil current drops below the loading. Notice the abrupt spike of output voltage is due to ESR of the bulk capacitor. Feedback voltage can be resistor-divided down or level-shift down from the output voltage. As this feedback voltage drops below VREF, next switching cycle starts.

## DETAILED OPERATING DESCRIPTION (Cont'd)

Figure 20. Simplified Block Diagram of Main Regulator

In Figure 22, regulator is operating at Discontinuous Conduction Mode, waveforms are similar to those of Figure 21. However, coil current drops to zero before next switching cycle starts.

To estimate conduction mode, below equation can be used.

$$
\text { Iroom }=\frac{\eta \times T_{O N} \times V_{i n}{ }^{2}}{2 \times L \times V o u t}-I_{\text {LOAD }}
$$

where, $\eta$ is efficiency, refer to Figure 6
if $I_{\text {room }}>0$, the regulator is at Discontinuous Conduction mode
if $I_{\text {room }}=0$, the regulator is at Critical Conduction mode where coil current just drops to zero and next cycle starts.
if $I_{\text {room }}<0$, the regulator is at Continuous Conduction mode

$$
\begin{align*}
& T_{S W}=\frac{T_{O N}}{1-\eta\left(\frac{\text { Vin }}{\text { Vout }}\right)}(\mathrm{S}) ; \\
& { }^{I_{p k}}=\frac{I_{L O A D}}{1-\left(\frac{T_{O N}}{T_{S W}}\right)}+\frac{\operatorname{Vin} \times T_{O N}}{2 \times L} \tag{A}
\end{align*}
$$

For Discontinuous Conduction mode, provided that current limit is not reached,

$$
\begin{aligned}
T_{S W} & =\frac{V i n \cdot T_{O N}^{2}}{2 \cdot L \cdot I_{L O A D} \cdot\left(\frac{\text { Vout }}{\eta \cdot V i n}-1\right)} \\
I_{p k} & =\frac{V i n}{L} \cdot T_{O N} \quad \text { (A) }
\end{aligned}
$$

For Continuous Conduction mode, provided that current limit is not reached,

Figure 21. Waveforms of Continuous Conduction Mode

Figure 22. Waveforms of Discontinuous Conduction Mode

## DETAILED OPERATING DESCRIPTION (Cont'd)

## Synchronous Rectification

A Synchronous Rectifier is used in the main regulator to enhance efficiency. Synchronous rectifier is normally realized by powerFET with gate control circuitry which, however, involved relative complicated timing concerns. In Figure 20, as main switch M1 is being turned OFF, if the synchronous switch M2 is just turned ON with M1 not being completed turned OFF, current will be shunt from the output bulk capacitor through M2 and M1 to ground. This power loss lowers overall efficiency. So a certain amount of dead time is introduced to make sure M1 is completely OFF before M 2 is being turned ON , this timing is indicated as $\mathrm{t}_{\mathrm{dh}}$ in Figure 21.

When the main regulator is operating in continuous mode, as M2 is being turned OFF, and M1 is just turned ON with M2 not being completed OFF, the above mentioned situation will occur. So dead time is introduced to make sure M2 is completed OFF before M1 is being turned ON, this is indicated as $\mathrm{t}_{\mathrm{dl}}$ in Figure 21.

When the main regulator is operating in discontinuous mode, as coil current is dropped to zero, M2 is supposed to be OFF. Fail to do so, reverse current will flow from the output bulk capacitor through M2 and then the inductor to the battery input. It causes damage to the battery. So M2-voltage-drop sensing comparator (COMP3 of Figure 20) comes with fixed offset voltage to switch M2 OFF before any reverse current builds up. However, if M2 is
switch OFF too early, large residue coil current flows through the body diode of M2 and increases conduction loss. Therefore, determination on the offset voltage is essential for optimum performance.

## Auxiliary Regulator

The Auxiliary Regulator is a boost regulator, applies PFM scheme to enhance high efficiency and reduce quiescent current. An internal voltage comparator (COMP1 of Figure 23) detects when the voltage of Pin VAUXFBN drops below that of Pin VAUXFBP. The internal power BJT is then switched ON for a fixed-ON-time (or until the internal current limit is reached), and coil current is allowed to build up. As the BJT is switched OFF, coil current will flow through the external Schottky diode to charge up the bulk capacitor. After a fixed-mimimum-OFF time elapses, next switching cycle will start if the output of the voltage comparator is HIGH. Refer to Figure 23, the VAUX regulation level is determined by the equation as follows,

$$
V_{A U X}=V A U X F B P \cdot\left(1+\frac{R_{A U X b}}{R_{A U X a}}\right)(\mathrm{V})
$$

Where Max ON Time, TON2, and Min OFF Time, TOFF2 can be determined by the following equations.

$$
\begin{aligned}
& T_{O N 2}=1.7 \times 10^{-11} \times \text { RIref }(\mathrm{S}) \\
& T_{\text {OFF2 }}=2.1 \times 10^{-12} \times \text { RIref }(\mathrm{S})
\end{aligned}
$$

Figure 23. Simplified Block Diagram of Auxiliary Regulator

## DETAILED OPERATING DESCRIPTION (Cont'd)

## Auxiliary Regulator (Cont'd)

As the Auxiliary Regulator control scheme is the same as the Main Regulator, equations for conduction mode, Tsw and Ipk can also be applied, However, $\eta$ to be used for caculation is refered to Figure 8, 10, or 12.

If external potentiometer is used for voltage level adjustment, internal 1.22 V reference voltage can be used as shown in the application diagram of Figure 24.

## Current Limit for Both regulators

From Figure 20 and Figure 23, sense devices (senseFET or senseBJT) are applied to sample coil current as the low-side switch is ON. With that sample current flowing through a sense resistor, sense-voltage is developed. Threshold detector (COMP2 in both figures) detects whether the sense-voltage is higher than preset level. If it happens, detector output reset the flip-flop to switch OFF low-side switch, and the switch can only be ON as next cycle starts.

Figure 24. Application Diagram with External Potentiometer for VAUX Adjustment

## DETAILED OPERATING DESCRIPTION (Cont'd)

## Auxiliary voltage adjustment

The VAUX voltage can be adjusted by the microprocessor control signals, namely, VAUXCON and VAUXADJ. The control signal pattern is shown in Figure 4. The input truth table is shown in Figure 25.

When VAUXEN is LOW, the Auxiliary Regulator is shut down, only the counter content is retained. The initial counter content is mid-range of 6 -bit.

At the rising edge of VAUXCON, if VAUXADJ is LOW (/ HIGH), each following VAUXADJ pulse enclosed by the VAUXCON pulse packet increments (/ decrements) the 6-bit counter. At the falling edge of VAUXCON, the counter content is then latched to a 6-bit DAC and is converted to a voltage level of VAUXREF between 1.1 V and 2.2 V .

At the falling edge of VAUXCON, if VAUXADJ is HIGH, the counter content will be reset to mid-range (1.65V). This is also the default setting just after power-ON reset is removed.

The 6-bit DAC converts the counter content to voltage level ranging from 1.1 to 2.2 V , so there are altogether 64 levels, and each voltage step is 17 mV . When the counter content reaches its maximum or minimum, further pulse of VAUXADJ will be disregarded, until counting direction is changed.

## Power-ON Reset

The Power-ON Reset block accepts external active HIGH ENABLE signal to activate the IC after battery is plugged in. During the startup period (see Figure 2), the internal startup circuitry is enabled to pump up VMAIN to a certain voltage level, which is the user-defined VMAIN output level minus an offset of 0.15 V . The internal power-on reset signal is then disabled to activate the main regulator and conditionally the
auxiliary regulator. Meanwhile, the startup circuitry will be shut down. The Power-ON Reset block also starts to charge up the external capacitor tied from Pin PDELAY to ground with precise constant current. As the Pin PDELAY's voltage reaches an internal set threshold, Pin PORB will go HIGH to awake the microprocessor. And,

$$
T_{P O R}=\left(\frac{1.22}{0.5}\right) \times C_{p o r} \times R / r e f(S)
$$

From Figure 3, if, by any chance, VMAIN is dropped below the user-defined VMAIN output level minus 0.5 V , PORB will go LOW to indicate the OUTPUT LOW situation. And, the IC will continue to function until the VMAIN is dropped below 2 V .

## Low-Battery-Detect

The Low-Battery-Detect block is actually a voltage comparator. Pin LOWBAT is LOW, if the voltage of external Pin LOWBATSEN is lower than 0.85 V internal reference. The IC will neglect this warning signal. Pin LOWBAT will become HIGH, if the voltage of external Pin LOWBATSEN is recovered to more than 1.1V. From Figure 1, with external resistors RLBa and RLBb, thresholds of Low-Battery-Detect can be adjusted based on the equations below.

$$
\begin{aligned}
& v_{\text {LOBAThigh }}=1.1 \times\left(1+\frac{R_{\text {LBa }}}{R_{\text {LBb }}}\right)(\mathrm{V}) \\
& v_{\text {LOBATIOW }}=0.85 \times\left(1+\frac{R_{L B a}}{R_{\text {LBb }}}\right)(\mathrm{V})
\end{aligned}
$$

| VAUXEN | VAUXCON | VAUXADJ | RESULT |
| :---: | :---: | :---: | :--- |
| 0 | X | X | Hold the counter content |
| 1 | 0 | X | Hold the counter content |
| 1 | - | 0 | Set "countup" flag HIGH |
| 1 | - | 1 | Set "countup" flag LOW |
| 1 | - | 0 | Increment (/ Decrement) the counter if "countup" flag is HIGH (/ LOW) |
| 1 |  | 1 | DAC the counter content to VAUXREF voltage level (1.1 - 2.2 V) <br> Reset the counter to mid-range, then convert the counter content to <br> VAUXREF voltage level (1.65V) |
| 1 |  |  |  |

Figure 25. Auxiliary Voltage Control Input Truth Table

## DETAILED OPERATING DESCRIPTION (Cont'd)

## Lithium-Battery backup

The backup conduction path which is provided by an internal power switch (typ. 13 Ohm ) can be controlled by internal logic or microprocessor.

If LIBATCL is LOW, the switch, which is then controlled by internal logic, is ON when the battery is removed and VMAIN is dropped below LIBATIN by more than 100 mV , and returns OFF when the battery is plugged back in.

If LIBATCL is HIGH, the switch is controlled by microprocessor through LIBATON. The truth table is shown in Figure 26.

## Efficiency and Output Ripple

For both regulators, when large values are used for feedback resistors (>50kOhm), stray capacitance of pin 1 (VMAINFB) and pin 20 (VAUXFBN) can add "lag" to the
feedback response, destabilizing the regulator and creating a larger ripple at the output. From Figure 1, ripple of Main and AUX regulator can be reduced by CMAINb, CAUXa and CAUXb ranging from 100 pF to 100 nF respectively. Reducing the ripple is also with improving efficiency, system designers are recommended to do experiments on capacitance values based on the PCB design.

## Bypass Capacitors

If the metal leads from battery to coils are long, its stray resistance can put additional power loss to the system as AC current is being conducted. In that case, bypass capacitors (CMAINbp and CAUXbp of Figure 1) are recommended to remove AC components of coil currents to minimize that power loss to optimize efficiency.

| LIBATCL | LIBATON | Action |
| :---: | :---: | :--- |
| 0 | $X$ | The switch is ON when the battery is removed and VMAIN is dropped below LIBATIN <br> by more than 100 mV ; The switch is OFF when the battery is plugged in. |

## MC33680

## Dual DC-DC Regulator for Electronic Organizer

The MC33680 is a dual DC-DC regulator designed for electronic organizer applications. Both regulators apply Pulse-Frequency-Modulation (PFM). The main step-up regulator output can be externally adjusted from 2.7 V to 5 V . An internal synchronous rectifier is used to ensure high efficiency (achieve 87\%). The auxiliary regulator with a built-in power transistor can be configured to produce a wide range of positive voltage (can be used for LCD contrast voltage). This voltage can be adjusted from +5 V to +25 V by an external potentiometer.

The MC33680 has been designed for battery powered hand-held products. With the low start-up voltage from 1 V and the low quiescent current (typical $35 \mu \mathrm{~A}$ ); the MC33680 is best suited to operate from 1 to 2 AA/ AAA cell. Moreover, supervisory functions such as low battery detection, CPU Power-Good signal, and back-up battery control, for lithium battery or supercap are also included in the chip.

## FEATURES:

- Low Input Voltage, 1V up
- Low Quiescent Current in Standby Mode: $35 \mu$ A typical
- PFM and Synchronous Rectification to ensure high efficiency ( $87 \%$ @ 60mA Load)
- Adjustable Main Output: +2.7 V to +5 V nominal 3.3V @ 100mA max, with 1.8 V input
- Auxiliary Output Voltage: +5 V to +25 V
$+5 \mathrm{~V} @ 25 \mathrm{~mA}$ max, with 1.8 V input $+25 \mathrm{~V} @ 15 \mathrm{~mA}$ max, with 1.8 V input
- Current Limit Protection
- Power-Good Signal with Programmable Delay
- Battery Low Detection
- Lithium Battery or Supercap Back-up
- 32-Pin LQFP Package

## APPLICATIONS:

- Digital Organizer and Dictionary
- Dual Output Power Supply (For MPU, Logic, Memory, LCD)
- Handheld Battery Powered Device (1-2 AA/AAA cell)

## DETAILED OPERATING DESCRIPTION General

The MC33680 is a dual DC-DC regulator designed for electronic organizer applications. Both regulators apply Pulse-Frequency-Modulation (PFM). The main boost regulator output can be externally adjusted from 2.7 V to 5 V . An internal synchronous rectifier is used to ensure high efficiency (achieve $87 \%$ ). The auxiliary regulator with a built-in power transistor can be configured to produce a wide range of positive voltage (can be used for LCD contrast voltage). This voltage can be adjusted from +5 V to +25 V by an external potentiometer.
The MC33680 has been designed for battery powered hand-held products. With the low start-up voltage from 1V and the low quiescent current (typical $35 \mu \mathrm{~A}$ ), the MC33680 is best suited to operate from 1 to $2 \mathrm{AA} / \mathrm{AAA}$ cell. Moreover, supervisory functions such as low battery detection, CPU Power-Good signal, and back-up battery control, are also included in the chip. It makes the MC33680 the best one-chip power management solution for applications such as electronic organizers and PDAs.

## Pulse Frequency Modulation (PFM)

Both regulators apply PFM. With this switching scheme, every cycle is started as the feedback voltage is lower than the internal reference. This is normally performed by internal comparator. As cycle starts, Low-Side switch (i.e. M1 in Figure 1) is turned ON for a fixed ON time duration (namely, $\mathrm{T}_{\text {on }}$ ) unless current limit comparator senses coil current has reached its preset limit. In the latter case, M1 is OFF instantly. So $\mathrm{T}_{\text {on }}$ is defined as the maximum ON time of M1. When M1 is ON, coil current ramps up, so energy is being stored inside the coil. At the moment just after M1 is OFF, the Synchronous Rectifier (i.e. M2 in Figure 1) or any rectification device (such as Schottky Diode of Auxiliary Regulator) is turned ON to direct coil current to charge up the output bulk capacitor. Provided that coil current limit is not reached, every switching cycle delivers fixed amount of energy to the bulk capacitor. For higher loading, a larger amount of energy (Charge) is withdrawn from the bulk capacitor, and a larger amount of Charge is then supplied to the bulk capacitor to regulate output voltage. This implies switching frequency is increased; and vice-versa.

## Main Regulator

Figure 18 shows the simplified block diagram of Main Regulator. Notice that precise bias current Iref is generated by a VI converter and external resistor RIref, where

$$
\text { Iref }=\frac{0.5}{\text { RIref }}(\mathrm{A})
$$

This bias current is used for all internal current bias as well as setting VMAIN value. For the latter application, Iref is doubled and fed as current sink at Pin 1. With external resistor RMAINb tied from Pin1 to Pin32, a constant voltage level shift is generated in between the two pins. In close-loop operation, voltage at Pin 1 (i.e. Output feedback voltage) is needed to be regulated at the internal reference voltage level, 1.22 V . Therefore, the delta voltage across Pin 1 and Pin 32 which can be adjusted by RMAINb determines the Main Output voltage. If the feedback voltage drops below 1.22 V , internal comparator sets switching cycle to start. So, VMAIN can be calculated as follows.

$$
V M A I N=1.22+\frac{R M A I N b}{R / r e f}(\mathrm{~V})
$$

From the above equation, although VMAIN can be adjusted by RMAINb and RIref ratio, for setting VMAIN, it is suggested, by changing RMAINb value with RIref kept at 480K. Since changing RIref will alter internal bias current which will affect timing functions of Max ON time ( $T_{O N 1}$ ) and Min OFF time ( $T_{\text {OFFl }}$ ). Their relationships are as follows;

$$
\begin{aligned}
& T_{O N 1}=1.7 \times 10^{-11} \times \text { RIref }(\mathrm{S}) \\
& T_{O F F 1}=6.4 \times 10^{-12} \times \text { RIref }(\mathrm{S}) \\
& \text { Continuous Conduction Mode and Discontinuous } \\
& \text { Conduction Mode }
\end{aligned}
$$

In Figure 19, regulator is operating at Continuous Conduction Mode. A switching cycle is started as the output feedback voltage drops below internal voltage reference VREF. At that instant, the coil current is not yet zero, and it starts to ramp up for the next cycle. As the coil current ramps up, loading makes the output voltage to decrease as the energy supply path to the output bulk capacitor is disconnected. After Ton elapses, M1 is OFF, M2 is ON, energy is pumped to the bulk capacitor. Output voltage is increased as excessive charge is pumped in, then it is decreased after the coil current drops below the loading. Notice the abrupt spike of output voltage is due to ESR of the bulk capacitor. Feedback voltage can be resistor-divided down or level-shift down from the output voltage. As this feedback voltage drops below VREF, next switching cycle starts.

## MC33680

## DETAILED OPERATING DESCRIPTION (Cont'd)

Figure 18. Simplified Block Diagram of Main Regulator

In Figure 20, regulator is operating at Discontinuous Conduction Mode, waveforms are similar to those of Figure 19. However, coil current drops to zero before next switching cycle starts.

To estimate conduction mode, below equation can be used.

$$
\text { Iroom }=\frac{\eta \times T_{\text {ON }} \times \text { Vin }^{2}}{2 \times L \times \text { Vout }}-I_{L O A D}
$$

where, $\eta$ is efficiency, refer to Figure 4
if $I_{\text {room }}>0$, the regulator is at Discontinuous Conduction mode
if $I_{\text {room }}=0$, the regulator is at Critical Conduction mode where coil current just drops to zero and next cycle starts.
if $I_{\text {room }}<0$, the regulator is at Continuous Conduction mode

For Continuous Conduction mode, provided that current limit is not reached,

$$
\begin{aligned}
& T_{S W}=\frac{T_{O N}}{1-\eta\left(\frac{\text { Vin }}{\text { Vout }}\right)}(\mathrm{S}) ; \\
& I_{p k}=\frac{I_{L O A D}}{1-\left(\frac{T_{O N}}{T_{S W}}\right)}+\frac{\operatorname{Vin} \times T_{O N}}{2 \times L}(\mathrm{~A})
\end{aligned}
$$

For Discontinuous Conduction mode, provided that current limit is not reached,

$$
\begin{align*}
T_{S W} & =\frac{V i n \cdot T_{O N}^{2}}{2 \cdot L \cdot I_{L O A D} \cdot\left(\frac{\text { Vout }}{\eta \cdot \text { Vin }}-1\right)}  \tag{S}\\
I_{p k} & =\frac{V i n}{L} \cdot T_{O N} \quad(\mathrm{~A})
\end{align*}
$$

Figure 20. Waveforms of Discontinuous Conduction Mode

## DETAILED OPERATING DESCRIPTION (Cont'd) Synchronous Rectification

A Synchronous Rectifier is used in the main regulator to enhance efficiency. Synchronous rectifier is normally realized by powerFET with gate control circuitry which, however, involved relative complicated timing concerns. In Figure 19, as main switch M1 is being turned OFF, if the synchronous switch M2 is just turned ON with M1 not being completely turned OFF, current will be shunted from the output bulk capacitor through M2 and M1 to ground. This power loss lowers overall efficiency. So a certain amount of dead time is introduced to make sure M1 is completely OFF before M2 is being turned ON , this timing is indicated as $\mathrm{t}_{\mathrm{dh}}$ in Figure 20.

When the main regulator is operating in continuous mode, as M2 is being turned OFF, and M1 is just turned ON with M2 not being completed OFF, the above mentioned situation will occur. So dead time is introduced to make sure M2 is completed OFF before M1 is being turned ON, this is indicated as $\mathrm{t}_{\mathrm{dl}}$ in Figure 20.

When the main regulator is operating in discontinuous mode, as coil current is dropped to zero, M2 is supposed to be OFF. Fail to do so, reverse current will flow from the output bulk capacitor through M2 and then the inductor to the battery input. It causes damage to the battery. So M2-voltage-drop sensing comparator (COMP3 of Figure 18) comes with fixed offset voltage to switch M2 OFF before any reverse current builds up. However, if M2 is switch OFF too early, large residue coil current flows through the body diode of M2 and increases conduction loss.

Therefore, determination on the offset voltage is essential for optimum performance.

## Auxiliary Regulator

The Auxiliary Regulator is a boost regulator, applies PFM scheme to enhance high efficiency and reduce quiescent current. An internal voltage comparator (COMP1 of Figure 21) detects when the voltage of Pin VAUXFBN drops below that of Pin VAUXFBP. The internal power BJT is then switched ON for a fixed-ON-time (or until the internal current limit is reached), and coil current is allowed to build up. As the BJT is switched OFF, coil current will flow through the external Schottky diode to charge up the bulk capacitor. After a fixed-mimimum-OFF time elapses, next switching cycle will start if the output of the voltage comparator is HIGH. Refer to Figure 21, the VAUX regulation level is determined by the equation as follows,

$$
\begin{equation*}
V_{A U X}=V A U X F B P \cdot\left(1+\frac{R_{A U X b}}{R_{A U X a}}\right) \tag{V}
\end{equation*}
$$

Where Max ON Time, TON2, and Min OFF Time, TOFF2 can be determined by the following equations.

$$
\begin{aligned}
& T_{O N 2}=1.7 \times 10^{-11} \times \text { RIref }(\mathrm{S}) \\
& T_{O F F 2}=2.1 \times 10^{-12} \times \text { RIref }(\mathrm{S})
\end{aligned}
$$

As the Auxiliary Regulator control scheme is the same as the Main Regulator, equations for conduction mode, Tsw and Ipk can also be applied, However, $\eta$ to be used for calculation is referred to Figures 6, 8, or 10.

Figure 21. Simplified Block Diagram of Auxiliary Regulator

## DETAILED OPERATING DESCRIPTION (Cont'd) Current Limit for Both regulators

From Figure 18 and Figure 21, sense devices (senseFET or senseBJT) are applied to sample coil current as the low-side switch is ON. With that sample current flowing through a sense resistor, sense-voltage is developed. Threshold detector (COMP2 in both Figures) detects whether the sense-voltage is higher than preset level. If it happens, detector output reset the flip-flop to switch OFF low-side switch, and the switch can only be ON as next cycle starts.

## Power-Good Signal

During the startup period (see Figure 2), the internal startup circuitry is enabled to pump up VMAIN to a certain voltage level, which is the user-defined VMAIN output level minus an offset of 0.15 V . The internal Power-Good signal is then enabled to activate the main regulator and conditionally the auxiliary regulator. Meanwhile, the startup circuitry will be shut down. The Power-Good signal block also starts to charge up the external capacitor tied from Pin PDELAY to ground with precise constant current. As the Pin PDELAY's voltage reaches an internal set threshold, Pin PORB will go HIGH to awake the microprocessor. This delay is stated as follows;

$$
T_{P O R}=\left(\frac{1.22}{0.5}\right) \times C_{p o r} \times R / r e f(\mathrm{~S})
$$

From Figure 3, if, by any chance, VMAIN is dropped below the user-defined VMAIN output level minus 0.5 V , PORB will go LOW to indicate the OUTPUT LOW situation. And, the IC will continue to function until the VMAIN is dropped below 2 V .

## Low-Battery-Detect

The Low-Battery-Detect block is actually a voltage comparator. Pin LOWBAT is LOW, if the voltage of external Pin LOWBATSEN is lower than 0.85 V . The IC will neglect this warning signal. Pin LOWBAT will become HIGH, if the voltage of external Pin LOWBATSEN is recovered to more than 1.1V. From Figure 1, with external resistors RLBa and RLBb, thresholds of Low-Battery-Detect can be adjusted based on the equations below.

$$
\begin{aligned}
& v_{\text {LOBAThigh }}=1.1 \times\left(1+\frac{R_{\text {LBa }}}{R_{\text {LBb }}}\right)(\mathrm{V}) \\
& v_{\text {LOBATIow }}=0.85 \times\left(1+\frac{R_{\text {LBa }}}{R_{\text {LBb }}}\right)(\mathrm{V})
\end{aligned}
$$

## Lithium-Battery backup

The backup conduction path which is provided by an internal power switch (typ. 13 Ohm ) can be controlled by internal logic or microprocessor.
If LIBATCL is LOW, the switch, which is then controlled by internal logic, is ON when the battery is removed and VMAIN is dropped below LIBATIN by more than 100 mV , and returns OFF when the battery is plugged back in.
If LIBATCL is HIGH, the switch is controlled by microprocessor through LIBATON. The truth table is shown in Figure 22.

## Efficiency and Output Ripple

For both regulators, when large values are used for feedback resistors (>50kOhm), stray capacitance of pin 1 (VMAINFB) and pin 20 (VAUXFBN) can add "lag" to the feedback response, destabilizing the regulator and creating a larger ripple at the output. From Figure 1, ripple of Main and AUX regulator can be reduced by capacitors in parallel with RMAINb, RAUXa and RAUXb ranging from 100 pF to 100 nF respectively. Reducing the ripple is also with improving efficiency, system designers are recommended to do experiments on capacitance values based on the PCB design.

## Bypass Capacitors

If the metal lead from battery to coils are long, its stray resistance can put additional power loss to the system as AC current is being conducted. In that case, bypass capacitors should be placed closely to the coil, and connected from $\mathrm{V}_{\text {BAT }}$ to ground. This reduces AC component of coil current passing through the long metal lead, thus minimizing that portion of power loss.

| LIBATCL | LIBATON | Action |
| :---: | :---: | :--- |
| 0 | X | The switch is ON when the battery is removed and VMAIN is dropped below LIBATIN by <br> more than $100 \mathrm{mV} ;$ <br> The switch is OFF when the battery is plugged in. |
| 1 | 0 | The switch is OFF |
| 1 | 1 | The switch is ON |

## MC33560

## Power Management and Interface IC for Smartcard Readers and Couplers

The MC33560 is an interface IC for smartcard reader/writer applications. It enables the management of any type of smart or memory card through a simple and flexible microcontroller interface. Moreover, several couplers can be coupled in parallel, thanks to the chip select input pin (pin \#5). The MC33560 is particularly suited to low power and portable applications because of its power saving features and the minimum of external parts required. Battery life is extended by the wide operating range and the low quiescent current in stand by mode. A highly sophisticated protection system guarantees timely and controlled shutdown upon error conditions.

- $100 \%$ Compatible with ISO 7816-3 Standard
- Wide Battery Supply Voltage Range: $1.8 \mathrm{~V}<\mathrm{V}_{\mathrm{BAT}}<6.6 \mathrm{~V}$
- Programmable $\mathrm{V}_{\mathrm{CC}}$ Supply for 3.0 V or 5.0 V Card Operation
- Power Management for Very Low Quiescent Current in Stand By Mode ( $30 \mu \mathrm{~A}$ max)
- Microprocessor Wake-up Signal Generated Upon Card Insertion
- Self Contained DC/DC Converter to Generate $\mathrm{V}_{\mathrm{CC}}$ using a Minimum of Passive Components
- Controlled Power Up/Down Sequence for High Signal Integrity on the Card I/O and Signal Lines
- Programmable Card Clock Generator
- Chip Select Capability for Parallel Coupler Operation
- High ESD Protection on Card Pins (4.0 kV, Human Body Model)
- Fault Monitoring $\mathrm{V}_{\text {BATlow }}, \mathrm{V}_{\mathrm{CClow}}$ and $\mathrm{I}_{\mathrm{CClim}}$
- All Card Outputs Current Limited and Short Circuit Protected
- Tested Operating Temperature Range: $-25^{\circ} \mathrm{C}$ to $+85^{\circ} \mathrm{C}$

1. Maximum electrical ratings are those values beyond which damage to the device may occur. $\mathrm{T}_{\mathrm{A}}=25^{\circ} \mathrm{C}$.
2. Human body model, $\mathrm{R}=1500 \Omega, \mathrm{C}=100 \mathrm{pF}$.
3. Maximum thermal rating beyond which damage to the device may occur.
4. See Figures 2 and 3.

This device contains protection circuitry to guard against damage due to high static voltages or electric fields. However precautions must be taken to avoid applications of any voltage higher than maximum rated voltages to this high impedance circuit. For proper operation, input and output voltages should be constrained to the ranges indicated in the recommended operating conditions.

Table 1. PIN FUNCTION DESCRIPTION

| Pin | Symbol | Type | Name/Function |
| :--- | :---: | :---: | :---: |

## CONTROLLER INTERFACE

| 2 | PWRON | INPUT pull down | This pin is used to start operation of the internal DC/DC converter. In programming mode, this pin is used to set the "Output Voltage" switch. (See Table 2). |
| :---: | :---: | :---: | :---: |
| 3 | INT | OUTPUT pull up | This open collector pin indicates a change in the card presence circuit status. When a card is inserted or extracted, the pin goes to logic level " 0 ". The signal is reset to logic level " 1 " upon the rising edge of $\overline{C S}$ or upon the rising edge of PWRON. In the case of a multislot application, two or more INT outputs are connected together and the microcontroller has to poll all the MC33560s to identify which slot was detected. |
| 4 | RDYMOD | I/O \& pull up | This bidirectional pin has tri-state output and schmitt trigger input. <br> * When RDYMOD is forced to 0 , the MC33560 can be set to programming mode by a negative transition on $\overline{C S}$. <br> * When RDYMOD is connected to a high impedance, the MC33560 is in normal operating mode, and RDYMOD is in output mode (See Tables 2 and 4): <br> - With $\overline{C S}=L$ and PWRON=H, RDYMOD indicates the status of the DC/DC converter. <br> - With $\overline{C S}=L$ and PWRON $=L$, RDYMOD indicates the status of the card detector. |
| 5 | $\overline{\text { CS }}$ | INPUT pull up | This is the MC33560 chip select signal. Pins 2, 6, 7, 10, 20, 21 are disabled when $\overline{C S}=H$. When RDYMOD=L, the MC33560 enters programming mode upon the falling edge of CS. <br> (See Figure 20) |
| 6 | RESET | INPUT pull down | The signal present at this input pin is translated to pin 14 (the card reset signal) when $\overline{\mathrm{CS}}=\mathrm{L}$. The signal on this pin is latched when $\overline{\mathrm{CS}}=\mathrm{H}$. This pin is also used in programming mode. (See Table 2) |
| 7 | 10 | I/O | This pin connects to the Serial I/O port of a microcontroller. A bi-directional level translator adapts the serial I/O signal between the smartcard and the microcontroller. The level translator is enabled when $\overline{C S}=\mathrm{L}$. The signal on thispin is latched when $\overline{C S}=\mathrm{H}$. This pin is also used in programming mode. (See Table 2) |
| 8 | INVOUT | CLK OUTPUT | The ASYCLKIN (pin 9) signal is buffered and inverted to generate the output signal INVOUT. This output is used for multislot applications, where the ASYCLKIN inputs and INVOUT outputs are daisy-chained. (See the multislot application example in Figure 31) |
| 9 | ASYCLKIN | CLK INPUT high impedance | This pin can be connected to the microcontroller master clock or any clock signal for asynchronous cards. The signal is fed to the internal clock selector circuit, and is translated to CRDCLK at the same frequency, or divided by 2 or 4 , depending on programming. (See Table 3) |
| 10 | SYNCLK | CLK INPUT pull down | This function is used for communication with synchronous cards, and the pin is generally connected to the controller serial interface clock signal. The signal is fed to the internal clock selector circuit, and is translated to CRDCLK upon appropriate programming of the MC33560 (See Table 3). When selected at programming, the signal on this pin is latched when $\overline{C S}=\mathrm{H}$. |
| 20 | C8 | I/O | General purpose input/output. It has the same behavior as I/O, except for programming. It can be connected to a bidirectional port of the microcontroller. The level translator is enabled when CS=L, and the signal is latched whenCS=H. (Compare with pin 19) |
| 21 | C4 | I/O | General purpose input/output. It has the same behaviour as I/O, except for programming. It can be connected to a bidirectional port of the microcontroller. The level translator is enabled when $\overline{C S}=L$, and the signal is latched when $\overline{C S}=H$. (Compare with pin 16) |

CARD INTERFACE

| 11 | CRDIO | I/O | This pin connects to the serial I/O pin of the card connector. A bidirectional level translator <br> adapts the serial I/O signal between the card and the microcontroller. (Compare with pin 7) |
| :---: | :--- | :--- | :--- |
| 14 | CRDRST | OUTPUT | This pin connects to the RESET pin of the card connector. A level translator adapts the <br> RESET signal driven by the microcontroller. (Compare with pin 6 ) |
| 15 | CRDCLK | OUTPUT | This pin connects to the CLK pin of the card connector. The CRDCLK signal is the output of <br> the clock selector circuit. The clock selection is programmed using pins 2,6 and 7 with <br> RDYMOD forced to "0". |
| 16 | CRDC4 | I/O | General purpose input/output. It has the same behavior as CRDIO. It can be connected to the <br> C4 pin of the card connector. |
| 17 | CRDDET | INPUT high <br> impedance | This pin connects to the card detection switch of the card connector. Card detection phase is <br> determined with pin 18. This pin needs an external pull-up or pull-down resistor to operate <br> properly. |

| Pin | Symbol | Type | Name/Function |
| :---: | :--- | :--- | :--- |
| CARD INTERFACE |  |  |  |
| 18 | CRDCON | INPUT high <br> impedance | This pin connects to PGND or VBAT, or possibly to an output port of the microcontroller. With <br> this pin set to a logic "0", the presence of a card is signalled with a logic "1" on pin 17. With <br> this pin set to a logic "1", the presence of a card is signalled with a logic "0" on pin 17. |
| 19 | CRDC8 | I/O | General purpose input/output. It has the same behavior as CRDIO. It can be connected to the <br> C8 pin of the card connector. |

CURRENT LIMIT AND THERMAL PROTECTION

| 1 | PGND | POWER | This pin is the return path for the current flowing into pin 22 (L1). It must be connected to <br> CRDGND using appropriate grounding techniques. |
| :---: | :--- | :--- | :--- |
| 12 | CRDGND | POWER | This pin is the signal ground. It must be connected to the ground pin of the card connector. It <br> is the reference level for all analog and digital signals. |
| 13 | CRDVCC | POWER | This pin connects to the $V_{C C}$ pin of the card connector. It is the reference level for a logic "1" <br> of pins 11, 14, 15, 16 and 19. |
| 22 | L1 | POWER | This pin connects to an external inductance for the DC/DC converter. Please refer to the <br> description of the DC/DC converter functional block. |
| 23 | VBAT | POWER | This pin is connected to the supply voltage. Logic level "1" of pins 2 to 10, 17, 18, 20 and 21 is <br> referenced to $V_{\text {BAT. Operation of the MC33560 is inhibited when V } V_{\text {BAT }} \text { is lower than the }}$ <br> minimum value. |
| 24 | ILIM | POWER | This pin can be connected to the PGND pin, or to a resistor connected to PGND, or left open, <br> depending on the peak coil current needed to supply the card. |

## PROGRAMMING AND STATUS FUNCTIONS

The MC33560 features a programming interface and a status interface. Figure 20 shows how to enter and exit programming mode; Table 2 shows which pins are used to access the various functions.

Figure 20. MC33560 Programming Sequence

Table 2. PIN USE FOR PROGRAMMING AND STATUS FUNCTIONS

## MC33560

## CARD VCC AND CARD CLOCK PROGRAMMING

The CRDV $_{\text {CC }}$ and ASYCLK programming options allow the system clock frequency to be matched to the card clock frequency and to select 3.0 V or $5.0 \mathrm{~V} \mathrm{CRDV}_{\mathrm{CC}}$ supply. Table 3 shows the values of PWRON, RESET and IO for the possible options. The default power reset condition is state 4 (synchronous clock and $\mathrm{CRDV}_{\mathrm{CC}}=5.0 \mathrm{~V}$ ). All states are latched for each output variable in programming mode at the positive transition of $\overline{\mathbf{C S}}$ (see Figure 20).

Table 3. CARD VCC AND CARD CLOCK TRUTH TABLE

| STATE\# | PWRON | RESET | IO | CRDVCc | CRDCLK |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 0 | L | L | L | 3 V | SYNCLK |
| 1 | L | L | H | 3 V | ASYCLKIN/4 |
| 2 | L | H | H | 3 V | ASYCLKIN/2 |
| 3 | L | H | L | 3 V | ASYCLKIN |
| 4 | H | L | L | 5 V | SYNCLK |
| 5 | H | L | H | 5 V | ASYCLKIN/4 |
| 6 | H | H | H | 5 V | ASYCLKIN/2 |
| 7 | H | H | L | 5 V | ASYCLKIN |

Note: Card clock integrity is maintained during all frequency commutations (no spikes).
State 4 is the default state at power on.

## DC/DC CONVERTER AND CARD DETECTOR STATUS

The MC33560 status can be polled when $\overline{\mathbf{C S}}=\mathbf{L}$. Please consult Table 2 for a description of input and output signals. The significance of the status message is described in Table 4.

Table 4. RDYMOD STATUS MESSAGES

| PWRON <br> (input) | RDYMOD <br> (output) | Message |
| :--- | :--- | :---: |
| LOW | LOW | No card |
| LOW | HIGH | Card present |
| HIGH | LOW | DC/DC converter overload |
| HIGH | HIGH | DC/DC converter OK |

## DETAILED OPERATING DESCRIPTION

## INTRODUCTION

The MC33560 smartcard interface IC has been designed to provide all necessary functions for safe data transfers between a microcontroller and a smartcard or memory card.

A card detector scans for the presence of a card and generates a debounced wake-up signal to the microcontroller.

Communication and control signal levels are translated between the digital interface and the card interface by the voltage level translator, and the card clock is matched to the system clock frequency by the programmable card clock
generator. The power management unit enables the DC/DC converter for card power supply, supervises the power up/down sequence of the card's I/O and signal lines, and keeps the power consumption very low in stand by mode.

All card interface pins have adequate ESD protection, and fault monitoring ( $\mathrm{V}_{\text {BATlow, }}, \mathrm{V}_{\mathrm{CClow}}, \mathrm{I}_{\mathrm{CClim}}$ ) guarantees hazard-free card reader operation.

Several MC33560s can be operated in parallel, using the same control and data bus, through the use of the chip select signal CS.

Figure 21. MC33560 Operating Modes

## OPERATING MODES

The MC33560 has five operating modes:

- stand by
- programming
- active
- transaction
- idle

The transitions between these different states are shown in Figure 21 above.

## STAND BY MODE

Stand by mode allows the MC33560 to detect card insertion and monitor the power supply while keeping the power consumption at a minimum. It is obtained with $\overline{\mathbf{C S}}=\mathbf{H}$ and $\mathbf{P W R O N}=\mathbf{L}$.

When the MC33560 detects a card, $\overline{\mathbf{I N T}}$ is asserted low to wake up the Microcontroller.

## PROGRAMMING MODE

The programming mode allows the user to configure the card $\mathrm{V}_{\mathrm{cc}}$ and the card clock signal for his specific application. The card supply, $\mathrm{CRDV}_{\mathrm{cc}}$, can be programmed to 3 V or 5 V , and the card clock signal can be defined to be either synchronous, or asynchronous divided by 1,2 or 4.

Programming mode is obtained with RDYMOD=L followed by a negative transition on $\overline{\mathbf{C S}}$. The programming options are shown in Table 3. Programmed values are latched on a positive transition of $\overline{\mathbf{C S}}$ with RDYMOD=L.

## ACTIVE MODE

In active mode, the MC33560 is selected, the RDYMOD pin becomes an output, and the MC33560 status can be polled. Power is not applied to the card.

The microcontroller polls the MC33560 by asserting $\overline{\mathbf{C S}}=\mathbf{L}$ and reading the RDYMOD pin.

If a card is present, the microcontroller starts the DC/DC converter by asserting $\mathbf{P W R O N}=\mathbf{H}$. This starts the automatic power on sequence: when $\mathrm{CRDV}_{\mathrm{cc}}$ reaches the undervoltage level $\left(\mathrm{V}_{\mathrm{T} 5 \mathrm{H}}\right.$ or $\mathrm{V}_{\mathrm{T} 3 \mathrm{H}}$, depending on programming), the card sequencer validates CRDIO, CRDRST, CRDCLK, CRDC4, CRDC8 pins according to the ISO7816-3 sequence (see Figure 26). The MC33560 is now in transaction mode, and the system is ready for data exchange via the three I/O lines and the RESET line.

## TRANSACTION MODE

In transaction mode, the MC33560 maintains power and the selected clock signal applied to the card, and the levels of the IO, RESET, C4 and C8 signals between the microcontroller and the card are translated depending on the supply voltages $\mathrm{V}_{\mathrm{BAT}}$ and $\mathrm{V}_{\mathrm{CC}}$.

The DC/DC converter status can be monitored on the RDYMOD pin.

## IDLE MODE

Idle mode is used when maintaining a card powered up without communicating with it. When an asynchronous clock is used, the selected clock signal is applied to the card.

## POWER DOWN OPERATION

Power-down can be initiated by the controlling microprocessor, by stopping the DC/DC converter with $\mathbf{P W R O N}=\mathbf{L}$ while $\overline{\mathbf{C S}}=\mathbf{L}$, or by the MC33560 itself when an error condition has been detected $\left(\mathrm{CRDV}_{\mathrm{cc}}\right.$ undervoltage, overcurrent longer than 160 ms typ., overtemperature, "hot"
card extraction). The communication session is terminated in a given sequence defined in ISO7816-3.

The MC33560 then goes into active mode, in which its status can be polled.

Stand by mode is reached by deselecting the MC33560 ( $\overline{\mathrm{CS}}=\mathbf{H}$ ).

## FUNCTIONAL BLOCKS

## CARD DETECTOR

This block monitors the card contact CRDDET (during insertion and extraction), filters the incoming waveform and generates an interrupt signal $\overline{\mathbf{I N T}}$ after each change. In order to identify which coupler activated the $\overline{\text { INT }}$ line (multicoupler application) the microcontroller scans both circuits via $\overline{\mathbf{C S}}$ and reads the RDYMOD pin.

The programming input CRDCON tells the level detector which type of mechanical contact is implemented (normally open or normally closed). Special care is taken to hold the current consumption very low on this part of the circuit which is continuously powered by the VBAT supply.

The CRDDET pin has high impedance input, and an external resistor must be connected to pull-up or pull- down, depending on CRDCON. This resistor is chosen according to the maximum leakage current of the card connector and the PCB.

The card detector has an internal $50 \mu$ s debouncing delay. The micro controller has to insert an additional delay (in the ms range) to allow the card contacts to stabilize in the card connector before setting $\mathbf{P W R O N}=\mathbf{H}$.

When the card detector circuit detects a card extraction, it activates the power-down sequence and stops the converter, regardless of the PWRON signal. The $50 \mu$ s delay of the debouncer is enough to ensure that all card signals have reached a safe value before communication with the card takes place.

## CARD STATUS

The controlling microprocessor is informed of the MC33560 status by interrupt and by polling. When a card is extracted or inserted, the $\overline{\mathbf{I N T}}$ line is asserted low. The interrupt is cleared upon the rising edge of $\overline{\mathbf{C S}}$ or upon the rising edge of PWRON $(\overline{\mathbf{I N T}}$ line set to high state).

The microprocessor can poll the status at any time by reading the RDYMOD pin with proper PWRON setting (see Tables 2 and 4).

Since $\overline{\text { INT }}$ and RDYMOD have a high value pull-up resistor ( $240 \mathrm{k} \Omega$ typ.), their rise time can be as long as $10 \mu \mathrm{~s}$ if parasitic capacitance is high and no other pull-up circuitry is connected.

## POWER MANAGER

The task of the power manager is to activate only those circuit functions which are needed for a determined operating mode in order to minimize power consumption (see Figure 19).

In stand by mode ( $\mathbf{P W R O N}=\mathbf{L}$ ) the power manager keeps only the "card present" detector alive. All card interface pins are forced to ground potential.

In the event of a power-up request from the microcontroller (PWRON L to $\mathbf{H}$ transition, $\overline{\mathbf{C S}}=\mathbf{L}$ ) the power manager starts the DC/DC converter. As soon as the CRDVCC supply reaches the operating voltage range, the circuit activates the card signals in the following sequence:

CRDVCC, CRDIO, CRDCLK, CRDC4/C8, CRDRST
At the end of the transaction (PWRON reset to $\mathbf{L}, \overline{\mathbf{C S}}=\mathbf{L}$ ) or forced card extraction, the CRDVCC supply powers down and the card signal deactivation sequence takes place:

CRDRST, CRDC4/C8, CRDCLK, CRDIO, CRDVCC
When $\overline{\mathbf{C S}}=\mathbf{L}$, the bi-directional signal lines (IO, C4 and C8) are put into high impedance state to avoid signal collision with the microcontroller in transmission mode.

## BATTERY UNDERVOLTAGE DETECTOR

The task of this block is to monitor the supply voltage, and to allow operation of the DC/DC converter only with valid voltage (typically 1.5 V ). The comparator has been designed to have stability better than 20 mV in the temperature range.

## DC/DC CONVERTER

Upon request from the power manager, the DC/DC converter generates the CRDVCC supply for the smartcard. The output voltage is programmable for 3.0 V or 5.0 V (see Table 3) to guarantee full cross compatibility of the reader for 5.0 V and 3.0 V smartcards. The wide voltage supply range, $1.8 \mathrm{~V}<\mathrm{V}_{\mathrm{BAT}}<6.6 \mathrm{~V}$, accommodates a broad range of coupler applications with different battery configurations (single cell or multiple cells, serial or parallel connections).

The CRDVCC is current-limited and short-circuit-proof. To avoid excessive battery loading during a card short-circuit, a current integration function forces the power-down sequence (see Figure 28). To retry the session, the microprocessor works through the power on sequence as defined in the power manager section.

## DC/DC Converter operating principles

The DC/DC converter architecture used in the MC33560 allows step-up and step-down voltage conversion to be done. The unique regulation architecture permits an automatic transition from step-up to step-down, and from zero to full load, without affecting the output characteristics.

DC/DC Converter Description: The converter architecture is very similar to the boost architecture, with an active rectifier in place of the diode. The switching transistor is connected to ground through a resistor network in order to adjust the maximum peak current (see Figure 22). A transistor connected to the converter output (CRDVCC) forces this pin to a low voltage when the converter is not operating. This prevents erratic voltage supply to the smartcard when not in use.

The MC33560 has a built in oscillator; the DC/DC converter requires only one inductor and the output filtering capacitor to operate.

Step-Up Operation: When the card supply voltage is lower than the battery voltage, the converter operates like a boost converter; the active rectifier behavior is similar to that of a diode.

Step-Down Operation: When the card supply voltage is higher than the battery voltage, the rectifier control circuit puts the power rectifying transistor in conduction when the $\mathrm{L}_{1}$ voltage reaches $\mathrm{V}_{\mathrm{BAT}}+\mathrm{V}_{\text {FSAT22 }}$. The voltage across the rectifying transistor is higher than in step-up operation. The efficiency is lower, and similar to a linear regulator.

Fault Detection: The DC/DC converter has several features that help to avoid electrical overstress of the MC33560 and of the smartcard, and help to ensure that data transmission with the smartcard occurs only when its supply voltage is within predetermined limits. These functions are:

- overtemperature detection,
- current limitation, and
- card supply undervoltage detection.

The level at which current will be limited is defined by the maximum card supply current programmed with the external components L1 and RLIM.
The undervoltage detection levels for 3.0 V and 5.0 V card supply are preset internally to the MC33560.

Figure 22. DC/DC Converter Functional Block

The overcurrent and undervoltage protection features are complementary, and will shut the circuit off either if the overcurrent is high enough to bring the CRDVCC output below the preset threshold, either after 160 ms (typ.)

In addition, the DC/DC converter will be allowed to start only if the battery supply voltage is high enough to allow normal operation (1.8 V).

The undervoltage comparator has a hysteresis and a delay of typically 20 ms to ensure stable operation. The current detector is a comparator associated with two resistors: one $2.0 \Omega$ attached to PGND and usually connected to analog ground, and a $0.5 \Omega$ attached to ILIM, usually connected to ground through an external resistor to adjust the maximum peak current. The voltage developed across this resistor network is then compared to a 120 mV (typical) reference voltage, and the comparator output performs a cycle-by-cycle peak current limitation by switching off the low side transistor when the voltage exceeds 120 mV .

The internal ILIMCOMP signal is monitored to stop the converter if current limitation is continuously detected
during 160 ms (typical). This allows normal operation with high filtering capacitance and low peak current, even at converter start-up. As a result, a short circuit to ground on the card connector or a continuous overcurrent is reported by RDYMOD 160 ms (typical) after power up.

Unexpected card extraction: The MC33560 detects card extraction and runs a power down sequence if card power is still on when extraction occurs. An active pull-down switch clamps CRDVCC to GND within $150 \mu \mathrm{~s}$ (max) after extraction is detected. The external capacitors will then be discharged. With typical capacitor values of $10 \mu \mathrm{~F}$ and 47 nF as indicated in the application schematic, the time needed to discharge CRDVCC to a voltage below 0.4 V can be estimated to less than $750 \mu \mathrm{~s}$. The total time aftercard extraction detection until CRDVCC reaches 0.4 V is then estimated to $900 \mu \mathrm{~s}$ (max). All smartcard connector contacts will be deactivated before CRDVCC deactivation. This ensures that no electrical damage will be caused to the smartcard under abnormal extraction conditions.
3.0 V/5.0 V programming: It is possible to set the card supply voltage to 3.0 V or 5.0 V at any time, before DC/DC converter start, or during converter operation. When switching from 3.0 V to 5.0 V , a 160 ms (typical) delay blanks the undervoltage fault detection to allow filter capacitor charging.

PWM: The free-running integrated oscillator has two working modes:

- variable on-state and fixed frequency (typically 120 KHz ) for average to heavy loads.
- variable on-state and variable frequency for light loads.

The frequency can be as low as a few kHz if no load is connected to CRDVCC.

The charging current of the timing capacitor is related to the $\mathrm{V}_{\text {BAT }}$ supply voltage, to allow better line regulation, and to increase stability.

Filtering Capacitor: A high value allows efficient filtering of card current spikes. Low values allow low start-up charging current. Care must be taken not to combine low capacitor value with high current limiting, as this can generate high ripple. Usual values range from $4.7 \mu \mathrm{~F}$ to $47 \mu \mathrm{~F}$, depending on current limiting.

Selecting the external components L1 and RLIM: The choice of inductor L1 and resistor R4 is made by using Figure 8 ( 5.0 V card) and/or Figure $9(3.0 \mathrm{~V}$ card) on page 8:

First, determine the maximum current that the application requires to supply to the card (ICCmax, on the y-axis)

Then, select one curve that crosses the selected ICCmax level. The curve is associated with an inductance value $(22 \mu \mathrm{H}, 47 \mu \mathrm{H}$, or $100 \mu \mathrm{H})$.

Finally, use the intersection of the curve and the ICCmax level to find the Rlim value on the x -axis.

Good starting values are : $\mathrm{L} 1=47 \mu \mathrm{H} ; \mathrm{R}_{\mathrm{lim}}=0.5 \Omega$
Note also that, for a high inductance value $(100 \mu \mathrm{H})$, the filtering capacitor is generally charged before inductance current reaches current limitation, while for alow inductance value, the current limitation is activated after a few converter cycles.

Battery requirements: Having determined the $L_{1}$ and $\mathrm{R}_{\mathrm{lim}}$ values, the maximum current drawn from the battery supply is shown by the curves in Figures 6 and 7 .

When the application is powered by a single 3.0 V battery, special care has to be taken to extend its lifetime. When lithium batteries approach the end-of-life, their internal resistance increases, while voltage decreases. This phenomenon can prevent the start-up of the DC/DC converter if the current limiting is set too high, because of the filtering capacitor charging current.

## CLOCK GENERATOR

The primary purpose of the clock generator module is to match the smartcard operating frequency to the system frequency. The source frequency can be provided to ASYCLKIN by the microcontroller itself or from an external oscillator circuit.

In programming mode (RDYMOD=L and $\overline{\mathbf{C S}}$ asserted low) the three input variables PWRON, IO and RESET are used to configure the two output variables CRDVCC and CRDCLK as described in Table 3. This circuit setup is latched during the positive transition of $\overline{\mathbf{C S}}$.

Furthermore, in asynchronous mode the system clock frequency ASYCLKIN can be divided by a factor of 1,2 or 4. The circuit controls the frequency commutation to guarantee that the card clock signal remains free from spikes and glitches. In addition, this circuit ensures that CRDCLK signal pulses will not be shorter than the shortest and/or longer than the longest of the clock signals present before and after programming changes.

The INVOUT output is provided to drive other circuits without additional load to the microprocessor quartz oscillator. It can also be used to build a local RC oscillator. This driver has been optimized for low consumption; it has no hysteresis, and input levels are not symmetrical. If the ASYCLKIN pin is connected to a sine wave, the duty cycle will not always be $50 \%$ at INVOUT.

## Clock generator operating principles

Synchronous Clock: This clock is used mainly for memory cards. It can also be used for asynchronous (microprocessor) cards, allowing the use of two different clock sources. The status of SYNCLK is latched at CRDCLK when $\overline{\mathbf{C S}}$ goes high, so that data (the $\mathbf{I O}$ pin) and clock are always consistent at the card connector, whatever the $\overline{\mathbf{C S}}$ status is. When using the synchronous clock, the clock output becomes active only when the MC33560 is selected with $\overline{\mathbf{C S}}$.

Asynchronous Clock: This clock is used mainly for microprocessor cards. When applied, the clock output remains active even when the MC33560 is not selected with $\overline{\mathbf{C S}}$, in order to keep the microprocessor running and avoid an unwanted reset. The ASYCLKINsignal is buffered at the INVOUT pin, so that several MC33560 systems can use the same clock with one load only.

Depending on programming, the frequency is fed directly, or divided by 2 or by 4 to the CRDCLK pin. If the duty cycle of the applied clock signal is not exactly symmetrical, it is recommended that the clock signal be divided by two or four to guarantee $50 \%$ duty cycle.

Clock Signal Synchronization and Consistency (see Figure 29). The clock divider includes synchronization logic that controls the switch from synchronous clock to asynchronous (and vice-versa), from any division ratio to any other ratio, during $\overline{\mathbf{C S}}$ changes and at power up. The synchronization logic guarantees that each clock cycle on the CRDCLK pin is finished before changing clock selection (and has always the adequate duration), regardless of the moment the programming is changed.

At power-up, when ASYCLKIN is selected, the clock signal at the CRDCLK pin has an entire length, according to the selected divide ratio, whatever the ASYCLKIN signal is versus the internal sequencer timing.

Figure 23. Clock Generator Functional Block

## BIDIRECTIONAL LEVEL TRANSLATOR

This module (used on IO/CRDIO, C4/CRDC4, C8/CRDC8, see Figure 24) adapts the signal voltage levels of the I/O and control lines between the micro controller (supplied by $\mathrm{V}_{\mathrm{BAT}}$ ) and the smartcard (supplied by $\mathrm{CRDV}_{\mathrm{CC}}$ )

When $\overline{\mathbf{C S}}$ is low, with CRDVCC on, and start sequencing completed, this module is transparent for the data, and acts as if the card was directly connected to the reader microcontroller. The core of the level shifter circuit defined for the bidirectional CRDIO, CRDC4 and CRDC8 lines consists of a NMOS switch which can be driven to the logic low state from either side (microcontroller or card). If both sides work in transmission mode with opposite phase, then signal collision on the line is not avoidable. In this case, the peak current is limited to a safe value for the integrated circuit and the smartcard.

During high-to-low transitions, the NMOS transistor impedance ( $\mathrm{T} 1=250 \Omega$ max.) is low enough to charge parasitic capacitance, and have a high enough dv/dt. On low to high transition, the NMOS transistor is not active above a certain voltage, and an acceleration circuit is activated to ensure a high dv/dt.

When the chip is disabled $(\overline{\mathbf{C S}}=\mathbf{H})$ with the voltage supply CRDVCC still active, the IO, C4 and $\mathbf{C 8}$ lines keep their last logic state.

When the converter is off, a transistor forces the CRDIO, CRDC4 and CRDC8 lines to a low state, thus preventing any unwanted voltage level to be applied to the data lines when the card is not in use.

Figure 24. Bidirectional Translator Functional Block

## SECURITY FEATURES

The MC33560 has a number of unique security functions to guarantee that no electrical damage will be caused to the smartcard:

- Battery supply minimum voltage threshold
- Card supply undervoltage and overcurrent detection with automatic shutdown
- Card pin overvoltage clamp to CRDVCC
- Card presence detector for "clean" and fast shut-down
- Consistent card signal sequencing at start-up and power-down, according to ISO7816, even on error conditions
- Consistent clock signal, even when division ratio or synchronization clock signal are changed "on the fly" during a card session (see Figure 29)

Active pull-down on all card pins, including CRDVCC, when not in normal operating mode.

A current limiting function and an overtemperature detector are limiting power dissipation.

## ESD PROTECTION

Due to the nature of smartcards, the card interface pins must absorb high ESD (Electro Static Discharge) energy during card insertion. In addition, the control circuits attached to these pins must safely withstand short circuits and voltage transients during forced card extraction.

Therefore, the MC33560 features enhanced ESD protection, current limitation and short circuit protection on all smartcard interface pins, including C4 and C8.

## PARALLEL OPERATION

For applications where two or more MC33560 are used, the digital control and data bus lines are common to all MC33560. Only the chip select signal, $\overline{\mathbf{C S}}$, requires a separate line for each interface.
While deselected, all communication pins except CRDCLK will keep their logical state on the card side, and will go to high impedance mode on the microprocessor side.
Figure 31 shows a typical application of a dual card reader. This arrangement was chosen only to illustrate the parallel operation of two card interfaces in the same module. The discrete capacitor components are necessary to provide low
impedance on the supply lines VBAT and CRDVCC and to suppress the high frequency noise due to the $\mathrm{DC} / \mathrm{DC}$ converter. The load resistors are external in order to adapt the sense current of the "cardpresent" switches.

## MINIMUM POWER CONSUMPTION CONSIDERATIONS

All analog blocks except the $\mathrm{V}_{\text {BAT }}$ comparator and the card presence detector are disabled in stand by mode ( $\overline{\mathbf{C S}}=\mathbf{H}: \mathrm{DC} / \mathrm{DC}$ converter stopped).

In order to maintain stand by current at a minimum value, all pins with pull-up resistance ( $\overline{\mathbf{C S}}, \overline{\overline{I N T}}, \mathbf{R D Y M O D}$ ) have to be kept in the high state or left open, and pins with pull-down resistance (RESET, SYNCLK, PWRON) have to be kept in the low state or left open. ASYCLKIN should not be connected to an active clock signal during stand by to avoid dynamic currents. This is valid also for SYNCLK, except that it can be left open.

## NCN6000

## Compact Smart Card Interface IC

The NCN6000 is an integrated circuit dedicated to the smart card interface applications. The device handles any type of smart card through a simple and flexible microcontroller interface. On top of that, thanks to the built-in chip select pin, several couplers can be connected in parallel. The device is particularly suited for low cost, low power applications, with high extended battery life coming from extremely low quiescent current.

## Features

- 100\% Compatible with ISO7816-3 and EMV Standard
- Wide Battery Supply Voltage Range: $2.7 \leq$ Vbat $\leq 6.0 \mathrm{~V}$
- Programmable CRD_VCC Supply to Cope with either 3.0 V or 5.0 V Card Operation
- Built-in DC/DC Converter Generates the CRD_VCC Supply with a Single External Low Cost Inductor only, providing a High Efficiency Power Conversion
- Full Control of the Power Up/Down Sequence Yields High Signal Integrity on both the Card I/O and the Signal Lines
- Programmable Card Clock Generator
- Built-in Chip Select Logic allows Parallel Coupling Operation
- ESD Protection on Card Pins ( 8.0 kV, Human Body Model)
- Fault Monitoring includes $\mathrm{Vbat}_{\text {low }}$ and $\mathrm{Vcc}_{\text {low, }}$, providing Logic Feedback to External CPU
- Card Detection Programmable to Handle Positive or Negative Going Input
- Built-in Programmable CRD_CLK Stop Function Handles both High or Low State

Typical Application

- E-Commerce Interface
- ATM Smart Card
- Pay TV System

Figure 4. Programming and Normal Operation Basic Timing

The programming can be achieved with the card powered ON or OFF. The identification of the interrupt is carried out by polling the STATUS pin, the Vbat voltage and the DC/DC results being provided on the same pin as depicted by the
table in Figure 4. During the programming mode, the $\overline{\text { PGM }}$ pin can be released to High since the mode is internally latched by the Negative going transition presents on the Chip Select pin.

Figure 5. Interrupt Servicing and Card Polling

When a card is either inserted or extracted, the CRD_DET pin signal is debounced internally prior to pull the INT pin to Low. The built-in logic circuit automatically accommodates positive or negative input signal slope, on both insertion and extraction state, depending upon the polarity defined during the initialization sequence. The default condition is Normally Open switch, negative going card detection. The external CPU shall acknowledge the request by forcing $\overline{\mathrm{CS}}=\mathrm{L}$ which, in turn, releases the $\overline{\mathrm{INT}}$ pin to High upon positive going of Chip Select (Table 4). Polling the STATUS pin as depicted in Table 3 identifies the active card. If a card is present, the STATUS returns High,
otherwise a Low is presented pin 5 . The $50 \mu$ s digital filter is activated during both Insertion and Extraction of the card. The MPU shall clear the INT line when the card has been extracted, making the interrupt function available for other purposes. However, neither the NCN6000 operation nor the smart card I/O line or commands are affected by the state of the $\overline{\mathrm{INT}} \mathrm{pin}$.

On the other hand, clearing the $\overline{\mathrm{INT}}$ and reading the STATUS register can be performed by a single read by the MPU: states S1 and S2 can be combined in a single instruction, the same for S3 and S4.

PIN FUNCTIONS AND DESCRIPTION

| Pin | Name | Type | Description |
| :---: | :---: | :---: | :---: |
| 1 | A0 | INPUT | This pin is combined with A1, PGM, RESET and I/O to program the chip mode of operation and to read the data provided by STATUS. <br> (Figures 4 and 5 and Tables 2 and 3) |
| 2 | A1 | INPUT | This pin is combined with A0, PGM, RESET and I/O to program the chip mode of operation and to read the data provided by STATUS. <br> (Figures 4 and 5 and Tables 2 and 3) |
| 3 | PGM | INPUT | This pin is combined with A0, A1, RESET and I/O to program the chip mode of operation and to read the data provided by STATUS. <br> (Figures 4 and 5 and Tables 2 and 3) |
| 4 | PWR_ON | INPUT Pull Down | This pin validates the operation of the internal DC/DC converter: <br> $\overline{C S}=L+P W R \_O N=$ Negative going: $D C / D C$ is OFF <br> $\overline{C S}=L+$ PWR_ON = Positive going: $D C / D C$ is ON <br> Note: The PWR_ON bit must be combined with a Low state $\overline{C S}$ signal to activate the function. (Table 2) |
| 5 | STATUS | OUTPUT | This pin provides logic state related to the card and NCN6000 status. According to the A0, A1 and PGM logic state, this pin carries either the Card present status or the Vbat or the DC/DC operation state. When PGM $=\mathrm{L}$, STATUS is not affected, see Table 2. |
| 6 | CS | INPUT Pull Up | This pin provides the NCN6000 chip select function. The PWR_ON, RESET, I/O, A0, <br>  device jumps to the programming mode (Figure 4 and Tables 1, 2 and 3). The Chip Select pin must be a unique physical address when more than one card are controlled by a single MPU. The data presented by the MPU are latched upon positive going edge of the Chip Select pin. |

| internal functions (Figure 5 and Tables 2 and 3). |  |  |  |

## NCN6000

PIN FUNCTIONS AND DESCRIPTION (continued)

| Pin | Name | Type | Description |
| :---: | :---: | :---: | :--- |
| 16 | GROUND | SIGNAL | The logic and low level analog signals shall be connected to this ground pin. This pin <br> must be externally connected to the PWR_GND pin 17. The designer must make <br> sure no high current transients are shared with the low signal currents flowing into <br> this pin. |
| 17 | PWR_GND | POWER | This pin is the Power Ground associated with the built-in DC/DC converter and must <br> be connected to the system ground together with GROUND pin 11. Using good <br> quality ground plane is recommended to avoid spikes on the logic signal lines. |
| 18 | Lout_L | POWER | The High Side of the external inductor is connected between this pin and Lout_H to <br> provide the DC/DC function. The built-in MOS devices provide the switching function <br> together with the CRD_VCC voltage rectification. |
| 19 | Lout_H | POWER | The High Side of the external inductor is connected between this pin and Lout_L to <br> provide the DC/DC function. The current flowing into this inductor is limited by a <br> sense resistor internally connected from Vbat/pin 20 and pin 19. Typically, Lout $=$ <br> 22 $\mu \mathrm{H}$, with ESR < 2.0 $\Omega$, for a nominal 55 mA output load. |
| 20 | Vbat | POWER | This pin is connected to the supply voltage and monitored by the NCN6000. The <br> operation is inhibited when Vbat is below the minimum 2.70 V value, followed by a <br> PWR_DOWN sequence and a Low STATUS state. |

5. Ceramic X7R, SMD types capacitors are mandatory to achieve the CRD_VCC specifications. When electrolytic capacitor is used, the external filter must include a 100 nF , max $50 \mathrm{~m} \Omega$ ESR capacitor in parallel, to reduce both the high frequency noise and ripple to a minimum. Depending upon the PCB layout, it might be necessary is to use two $6.8 \mu \mathrm{~F} / 10 \mathrm{~V} /$ ceramic/X7R//SMD1206 in parallel, yielding an improved CRD_VCC ripple over the temperature range.
6. According to ISO7816-3, paragraph 4.3.2.

## Card VCC, Card CLOCK and Card Detection Polarity Programming

The CRD_VCC and CLOCK_IN programming options allows matching the system frequency with the card clock frequency, and to select 3.0 V or 5.0 V CRD_VCC supply. The CRD_DET programming option allows the usage of either Normally Open or Normally Close detection switch. Table 3 highlights the A0, A1, $\overline{\mathrm{PGM}}$ and I/O logic states for the possible options. The default power up reset condition
is state 1: asynchronous clock, ratio $1 / 1$, CRD_CLK active, CRD_DET = Normally Open, CRD_VCC = 3.0 V. All states are latched for each output variable in programming mode at the positive going slope of Chip Select $[\overline{\mathrm{CS}}]$ signal. It is the system designer's responsibility to set up the options needed to match the chip with the peripherals. In particular, when using Normally Close switch, the CRD_DET polarity must be defined during the first cycles of the initialization.

Table 3. Card VCC, Card Clock and Card Detection Polarity Truth Table

9. The programmed conditions are latched upon the Chip Select (CS, pin 6) positive going transient.
10. Card clock integrity is guaranteed no spikes whatever be the frequency switching.
11. The STATUS register is not affected when the NCN6000 operates in any of the programming functions.
12. The CRD_VCC and CRD_CLK are not affected when the NCN6000 operates outside their respective decoded logic address.
13. The High Level on STATUS in registors $\$ 00$ to $\$ 0 F$, inclusive, having being implemented to reduce current comsumption but have no other meanings.
14. At turn on, the NCN6000 is initialized with CRD_VCC $=3.0 \mathrm{~V}, \mathrm{CLOCK} \_$IN Ratio $=1 / 1$, CRD_CLK $=$ START, CRD_DET $=$ Normally Open.

## DC/DC Converter and Card Detector Status

The NCN6000 status can be polled when $\overline{\mathrm{CS}}=\mathrm{L}$. Please consult Figures 4 and 5 for a description of input and output signals. The status message is described in Table 4.

Note: in order to cope with a start up under low battery condition, the Vbat OK message uses a negative logic as depicted here below.

Table 4. Card and DC/DC Status Output

| PGM | A1 | A0 | STATUS | Message |
| :---: | :---: | :---: | :--- | :--- |
| HIGH | L | L | LOW | No Card |
| HIGH | L | L | HIGH | Card Present |
| HIGH | L | H | LOW | DC/DC Converter <br> Overloaded |
| HIGH | L | H | HIGH | DC/DC Converter OK |
| HIGH | H | L | LOW | Vbat OK |
| HIGH | H | L | HIGH | Vbat Undervoltage |
| HIGH | H | H | HIGH | CRD_VCC OK |
| HIGH | H | H | LOW | CRD_VCC Undervoltage |

The STATUS pin provides a feedback related to the detection of the card, the state of the DC/DC converter, the Vbat undervoltage and CRD_VCC undervoltage situations. When $\overline{\mathrm{PGM}}=\mathrm{H}$, the STATUS pin returns a High if a card is detected present, a Low being asserted if there is no card inserted. In any case, the external card is not automatically powered up. When the external MPU asserts $\mathrm{PWR} \_\mathrm{ON}=\mathrm{H}$, together with $\overline{\mathrm{CS}}=\mathrm{L}$, the CRD_VCC supply is provided to the card and the state of the DC/DC converter, the Vbat and the CRD_VCC can be polled through the STATUS pin.

## Card Power Supply Timing

At power up, the CRD_VCC power supply rise time depends upon the current capability of the DC/DC converter associated with the external inductor L1 and the reservoir capacitor connected across CRD_VCC and GROUND.

On the other hand, at turn off, the CRD_VCC fall time depends upon the external reservoir capacitor and the peak current absorbed by the internal CMOS transistor built across CRD_VCC and GROUND. These behaviors are depicted in Figure 6. Since these parameters have finite values, depending upon the external constraints, the designer must take care of these limits if the $t_{\mathrm{ON}}$ or the $\mathrm{t}_{\mathrm{OFF}}$ provided by the data sheets does not meet his requirements.

Figure 6. Card Power Supply Turn ON and OFF Timing

## Basic Operating Modes Flow Chart

The NCN6000 brings all the functions necessary to handle data communication between a host computer and the smart card. The built-in Chip Select pin provides a simple way to share the same MPU bus with several card interface. On top of that, the logic control are derived from specific pins, avoiding the risk of mixing up the operation when the interface is controlled by a low end microcontroller.

During the transaction operation, the external MPU takes care of whatever is necessary to he data on the single
bidirectional I/O line. Leaving aside the DC-DC control and associated failures, the NCN6000 does not take any further responsibility in the data transaction.
When the chip operates in the programming mode, the NCN6000 provide a flexible access to set up the CRD_VCC voltage, the CRD_CLK and the CRD_DET smart card signals.
The external micro controller takes care of the smart card transaction and shall handle the interface accordingly.

Figure 7. Operating Modes Flow Chart

## Standby Mode

The Standby Mode allows the NCN6000 to detect a card insertion, keeping the power consumption at a minimum. The power supply CRD_VCC is not applied to the card, until the external controllers set PWR_ON $=\mathrm{H}$ with $\overline{\mathrm{CS}}=\mathrm{L}$.

| Standby Mode <br> Logic Conditions: |  | Card Output: |
| :--- | :--- | :--- |
| $\overline{\text { CS }}$ | $=H$ | CRD_VCC $=0 \mathrm{~V}$ |
| PWR_ON | $=H$ | CRD_CLK $=$ L |
| A0 | $=Z$ | CRD_RST $=$ L |
| A1 | $=Z$ | CRD_IO $=$ L |
| PGM | $=Z$ |  |
| I/O | $=Z$ |  |
| RESET | $=Z$ |  |

When a card is inserted, the internal logic filters the signal present pin 11, then asserts the $\overline{\mathrm{INT}}$ pin to Low if the pulse applied to CRD_DET is longer than $150 \mu \mathrm{~s}$. The external MPU shall run whatever is necessary to handle the card.

The $\overline{\mathrm{INT}}$ is cleared (return to High) when a positive going transition is asserted to either the $\overline{\mathrm{CS}}$ or to the PWR_ON signal logically combined with Chip Select = Low.

## Programming Mode

The programming mode allows the configuration of the card power supply, card clock and Card Detection input logic polarity. These signals (CRD_VCC, CRD_CLK and CRD_DET) are described in the pin description paragraph associated with Tables 1 and 3 and Figures 4 and 8.

| Programming Mode <br> Logic Conditions: |  | Card Output: |
| :---: | :---: | :---: |
| CS | $=\mathrm{L}$ | CRD_VCC $=0 \mathrm{~V}$ |
| PWR_ON | $=\mathrm{L}$ | CRD_CLK $=$ L |
| A0 | = H/L | CRD_RST $=\mathrm{L}$ |
| A1 | = H/L | CRD_IO $=\mathrm{H} / \mathrm{L}$ depending upon |
| PGM | $=\mathrm{L}$ | the previous I/O pin |
| I/O | = L/ H | logic state |
| RESET | $=\mathrm{L} / \mathrm{H}$ |  |

The I/O and $\overline{\text { RESET }}$ pins are not connected to the smart card and become logic inputs to control the NCN6000 programming sequence. The programmed values are latched upon transition of $\overline{\mathrm{CS}}$ from Low to High, $\overline{\mathrm{PGM}}$ being Low during the transition.
When a programming mode is validated by a Chip Select negative going transient, the mode is latched and $\overline{\text { PGM }}$ can be released to High. This latch is automatically reset when $\overline{\mathrm{CS}}$ returns to High.

The logic input signals can be set simultaneously, or one bit a time (using either a STAA or a BSET function), the key point being the minimum delay between the shorter bit and the Chip Select pulse. The programmed value is latched into the NCN6000 register on the $\overline{\mathrm{CS}}$ positive going edge.

Figure 8. Minimum Programming Timings

## Active Mode

In the active mode, the NCN6000 is selected by the external MPU and the STATUS pin can be polled to get the status of either the DC/DC converter or the presence of the card (inserted or not valid). The power is not connected to the card: CRD_VCC $=0 \mathrm{~V}$.

| Active Mode |  |  |  |
| :---: | :---: | :---: | :---: |
| Logic Conditions: |  | Card Output: |  |
| CS | $=\mathrm{L}$ | CRD_VCC | $=0 \mathrm{~V}$ |
| PWR_ON | $=\mathrm{L}$ | CRD_CLK | $=\mathrm{L}$ |
| A0 | $=\mathrm{L}$ | CRD_RS | $=\mathrm{L}$ |
| A1 | $=\mathrm{L}$ | CRD_IO | $=\mathrm{H} / \mathrm{L}$ depending upon |
| PGM | $=\mathrm{H}$ |  | the previous I/O pin |
| I/O | = Z |  | logic state |
| RESET | = Z |  |  |
| STATUS | $=\underset{\text { Insert }}{ }$ |  |  |

The Chip Select pulse [ $\overline{\mathrm{CS}}$ ] will automatically clear the previously asserted $\overline{\mathrm{INT}}$ signal upon the positive going transition.
If a card is present, the MPU shall activate the DC/DC converter by asserting PWR_ON = H. The NCN6000 will automatically run a power up sequence when the CRD_VCC reaches the undervoltage level (either $\mathrm{V}_{\mathrm{C} 5 \mathrm{H}}$ or $\mathrm{V}_{\mathrm{C} 3 \mathrm{H}}$, depending upon the CRD_VCC voltage supply programmed). The CRD_IO, CRD_RST and CRD_CLK pins are validated, according to the ISO7816-3 sequence. The interface is now in transaction mode and the system is ready for data exchange through the I/O and $\overline{\text { RESET lines. }}$ At any time, the micro controller can change the CRD_CLK frequency and mode, or the CRD_VCC value as determined by the card being in use.

## Transaction Mode

During the transaction mode, the NCN6000 maintains power supply and clock signal to the card. All the signal levels related with the card are translated as necessary to cope with the MPU and the card.

The DC/DC converter status and the Vbat state can be monitored on the STATUS by using the A0 and A1 logic inputs as depicted Tables 3 and 4.

```
Transaction Mode
Logic Conditions: Card Output:
\begin{tabular}{lll}
\(\overline{\text { CS }}\) & \(=\) L & CRD_VCC \(=3.0\) or 5.0 V \\
PWR_ON & \(=\) H & CRD_CLK \(=\) CLOCK \\
A0 & \(=\) H & CRD_RST \(=\) H/L \\
A1 & \(=\) H & CRD_IO \(=\) DATA \\
\(\overline{\text { PGM }}\) & \(=\) H & \\
I/O & \(=\) DATA & \\
& TRANSFER & \\
\(\overline{\text { RESET }}\) & \(=\) H/L & \\
STATUS & \(=\) L/H DC/DC & \\
& & status: Fail/Pass?
\end{tabular}
```

To make sure the data are not polluted by power losses, it is recommended to check the state of CRD_VCC before launching a new data transaction. Since $\overline{\mathrm{CS}}=\mathrm{L}$, this is achieved by forcing bits A0 and A1 according to Table 4, and reading the STATUS pin 5.

## Idle Mode

The idle mode is used when a card is powered up ( CRD _VCC $=\mathrm{Vcc}$ ), without communication on going.

| Idle Mode |  |  |
| :---: | :---: | :---: |
| Logic Conditions: |  | Card Output: |
| $\overline{\mathrm{CS}}$ | $=\mathrm{L}$ | CRD_VCC $=3.0$ or 5.0 V |
| PWR_ON | $=\mathrm{H}$ | CRD_CLK = CLOCK active or |
| A0 | $=\mathrm{H}$ | L or H |
| A1 | $=\mathrm{H}$ | CRD_RST = H |
| PGM | $=\mathrm{H}$ | CRD_IO = Z |
| I/O | = Z |  |
| RESET | $=\mathrm{H}$ |  |
| STATUS | = L/H according to the internal register results |  |

## Logic Conditions: Card Output:

In addition, the CRD_CLK signal can be stopped, as depicted in Tables 3 and 4, to minimize the current consumption of the external smart card, leaving CRD_VCC active.

## Power Down Operation

The power down mode can be initiated by either the external MPU (pulling PWR_ON = L) or by one of the internal error condition (CRD_VCC overload or Vbat Low). The communication session is terminated immediately, according to the ISO7816-3 sequence. On the other hand, the MPU can run the Standby mode by forced $\overline{\mathrm{CS}}=\mathrm{H}$.

When the card is extracted, the interface shall detect the operation and run the Power Shut Off of the card as described by the ISO/CEI 7816-3 sequence depicted here after:

ISO7816-3 sequence:
$\Rightarrow$ Force RST to Low
$\Rightarrow$ Force CLK to Low, unless it is already in this state $\Rightarrow$ Force CRD_IO to Low
$\Rightarrow$ Shut Off the CRD_VCC supply
Since the internal digital filter is activated for any card insertion or extraction, the physical power sequence will be activated $150 \mu$ s maximum after the card has been extracted. Of course, such a delay does not exist when the MPU launch the power down intentionally.

The time delay between each negative going signal is 500 ns typical (Figure 10).

Figure 9. Typical Power Down Sequence in the NCN6000 Interface

Figure 10. Power Down Sequence Details

## Card Detection

The card detector circuit provides a $500 \mathrm{k} \Omega$ pull up resistor to bias the CRD_DET pin, yielding a logic High when the pin is left open (assuming a NO switch). The internal logic associated with pin 11 provides an automatic selection of the slope card detection, depending upon the polarity set by the external MPU. At start up, the CRD_DET is preset to cope with Normally Open switch. When a Normally Close switch is used in the card socket, it is mandatory to program the NCN6000 chip during the initialization sequence, otherwise the system will not start if a card was previously inserted. Table 3 gives the programming code for such a function. The next lines provide a typical assembler source to handle this CRD_DET Normally Close polarity:

```
Smart EQU $20 ; NCN6000 Physical CS Address
    LDX #$1000 ; Offset
    LDAA #$09 ; I/O = H, A0 = A1 = L, RESET = H
    STAA smart, X ; Set CRD_DET = Normally Closed
        Switch
```

The CRD_DET polarity can be updated at any time, during the Program Mode sequence ( $\overline{\mathrm{PGM}}=\mathrm{L}$ ), but, generally speaking, is useless since the switch does not change during the usage of the considered module. On the other hand, the card detection switch shall be connected across pin 11 and ground, for any polarity selected.

The transition presents pin 11, whatever be the polarity, is filtered out by the internal digital filter circuit, avoiding false interrupt. In addition to the minimum internal $50 \mu \mathrm{~s}$ timing, the MPU shall provide an additional delay to cope with the mechanical stabilization of the card interface (typically 3 ms ), prior to valid the CRD_VCC supply.
When a card is inserted, the detector circuit asserts $\mathrm{INT}=$ Low as depicted before. When the NCN6000 detects a card extraction, the power down sequence is activated, regardless of the PWR_ON state, and the $\overline{\mathrm{INT}}$ pin is asserted Low. It is up to the external MPU to clear this interrupt by forcing a chip select pulse as depicted in Figure 5.

The $75 \mu$ s delay represent the digital filter built-in the NCN6000 chip being used for the characterization. Any pulse shorter than this delay does not generate an interrupt. However, to guarantee an interrupt will be generated, the CRD_DET signal must be longer than $150 \mu$ s as defined by the specification.

The Chip Select pulse is generated by the external micro controller, the minimum pulse width being $2 \mu \mathrm{~s}$ to make sure the card is detected.

The oscillogram, Figure 11, depicts the behavior for a Normally Open switch, the delay existing between the interrupt negative going state and the $\overline{\mathrm{CS}}$ being Low comes from the particular software latency existing in this particular MPU.

Figure 11. Card Insertion Detection and Interrupt Signals

Figure 12. Card Extraction Detection and Interrupt Signals

When the card is extracted, the CRD_DET signal generates an interrupt, assuming the positive pulse width is longer than the digital filter. The oscillogram, Figure 12, depicts the behavior for a Normally Open switch.

Note: since the internal pull up resistor is relatively high ( $500 \mathrm{k} \Omega$ typical), one must use a $10 \mathrm{M} \Omega$ input impedance probe to read this signal.

Figure 13. Interrupt Acknowledgement During a Card Insertion Detection Sequence

The interrupt signal, provided pin 9, is cleared by a positive going Chip Select signal as depicted by the oscillogram, Figure 13. The $\overline{\mathrm{CS}}$ pulse width is irrelevant, as long as it is larger than $2.0 \mu \mathrm{~s}$, to activate a different sequence. Leaving the interrupt signal Low has no influence
on the internal behavior of the NCN6000, but will be automatically cleared when the DC/DC will be activated by the MPU ( $\overline{\mathrm{CS}}=\mathrm{L}, \mathrm{PWR} \_\mathrm{ON}=$ Positive High transition)

## Power Management

The purpose of the power management is to activate the circuit functions needed to run a given mode of operation, yielding a minimum current consumption on the Vbat supply. In the Standby mode ( $\mathrm{PWR} \_\mathrm{ON}=\mathrm{L}$ ), the power management provides energy to the card detection circuit only. All the card interface pins are forced to ground potential.

In the event of a power up request coming from the external MPU (PWR_ON $=\mathrm{H}, \overline{\mathrm{CS}}=\mathrm{L}$ ), the power manager starts the DC/DC converter.

When the CRD_VCC voltage reaches the programmed value ( 3.0 V or 5.0 V ), the circuit activates the card signals according to the following sequence:

$$
\begin{aligned}
& \text { CRD_VCC } \\
& \Rightarrow \text { CRD_IO } \\
& \quad \Rightarrow C R D \_C L K \\
& \quad \Rightarrow C R D \_R S T
\end{aligned}
$$

The logic level of the data lines are asserted High or Low, depending upon the state forced by the external MPU, when the start up sequence is completed. Under no situation the NCN6000 shall launch automatically a smart card ATR sequence. Assuming PWR_ON $=\mathrm{H}$, the CRD_VCC voltage
is maintained whatever be the logic level presents on Chip Select, pin 6.

At the end of the transaction, asserted by the MPU (PWR_ON $=\mathrm{L}, \overline{\mathrm{CS}}=\mathrm{L}$ ), or under a card extraction, the ISO7816-3 power down sequence takes place:

$$
\begin{aligned}
& \text { CRD_RST } \\
& \Rightarrow \text { CRD_CLK } \\
& \Rightarrow \text { CRD_IO } \\
& \quad \Rightarrow \text { CRD_VCC }
\end{aligned}
$$

When $\overline{\mathrm{CS}}=\mathrm{H}$, the bi-directional I/O line (pins 8 and 15) is forced into the High impedance mode to avoid signal collision with any data coming from the external MPU.

The CRD_VCC voltage is controlled by means of $\overline{\mathrm{CS}}$ and PWR_ON logic signal as depicted Figure 14. The PWR_ON logic level define the CRD_VCC voltage status, the amplitude being the one pre programmed into the chip.
In order to avoid uncontrolled command applied to the smart card, the NCN6000 internal logic circuit, together with the Vbat monitoring, clamps the card outputs until the CRD_VCC voltage reaches the minimum value. During the CRD_VCC slope, all the card outputs are kept Low and no spikes can be write to the smart card. The oscillogram on the right hand side is a magnification of the curves given on the opposite side.

Figure 14. Card Power Supply Control

Figure 15. Smart Card Signals Sequence at Power On

## Vbat Supply Voltage Monitoring

The built-in comparator, associated with the band gap reference, continuously monitors the + Vbat input. During the start up, all the NCN6000 functions are deactivated and no data transfer can take place. When the +Vbat voltage rises above 2.35 V (typical), the chip is activated and all the functions becomes available. The typical behavior is provided here after Figure 16. At this point, the internal Power On Reset signal is activated (not accessible externally) and all the logic signals are forced into the states as defined by Table 3 .

If the + Vbat voltage drops below 2.25 V (typical) during the operation, the NCN6000 generate a Power Down sequence and is forced in a no operation mode. The built-in 100 mV (typical) hysteresis avoids unstable operation when the battery voltage slowly varies around the 2.30 V .

On the other hand, the micro controller can read the STATUS signal, pin 5, to control the state of the battery prior to launch either a NCN6000 programming or an ATR sequence (Table 4).

Note: Drawing is not to scale and voltages are typical. See specifications data for details.
Figure 16. Typical Vbat Monitoring

## DC/DC Converter Operation

The built-in DC/DC converter is based on a modified boost structure to cover the full battery and card operating voltage range. The built-in battery voltage monitor provides an automatic system to accommodate the mode of operation whatever be the Vbat and CRD_VCC voltages. Comparator U3/Figure 17 tracks the two voltages and set up the operating mode accordingly.

Figure 17. Basic DC/DC Structure

When the input voltage Vbat is lower than the programmed CRD_VCC, the system operates under the boost mode, providing the voltage regulation and current limit to the smart card. In this mode, the external inductor, typically $22 \mu \mathrm{H}$, stores the energy to drive the +5.0 V card supply from the external low voltage battery. The
oscillogram, Figure 18, depicts the DC/DC behavior under these two modes of operation.

Beside the DC/DC converter, NMOS Q4 provides a low impedance to ground during the Power Down sequence, yielding the $250 \mu \mathrm{~s}$ maximum switch time depicted in the data sheet.

Figure 18. DC/DC Operating Modes

When the input voltage Vbat is higher than the programmed CRD_VCC, the system operates under a step down mode, yielding the voltage regulation and current limit identical to the boost mode. In this case, the built-in structure turns Off Q1 and inverts the Q2 substrate bias to control the current flowing to the load.These operations are fully automatic and transparent for the end user.

The High and Low limits of the current flowing into the external inductor L1 are sensed by the operational amplifier U1 associated with the internal shunt R1. Since this shunt resistor is located on the hot side of the inductor, the device reads both the charge and discharge of the inductor, providing a clean operation of the converter.

In order to optimize the DC/DC power conversion efficiency, it is recommended to use external inductor with $\mathrm{R}<2.0 \Omega$.

The output capacitor C 1 stores the energy coming from the converter and smooths the CRD_VCC voltage applied to the external card. At this point, care must be observed, beside the micro farad value, to select the right type of capacitor. According to the capacitor's manufacturers, the internal ESR can range from a low $10 \mathrm{~m} \Omega$ to more than $3.0 \Omega$, thus yielding high losses during the $\mathrm{DC} / \mathrm{DC}$ operation, depending upon the technology used to build the capacitor.

Figure 19. Typical DC Operating Current
The standard electrolytic capacitors have the low cost advantage for a relative high micro farad value, but have poor tolerance, high leakage current and high ESR.

The tantalum type brings much lower leakage current together with high capacity value per volume, but cost can be an issue and ESR is rarely better than $500 \mathrm{~m} \Omega$.
The new ceramic type have a very low leakage together with ESR in the $50 \mathrm{~m} \Omega$ range, but value above $10 \mu \mathrm{~F}$ are relatively rare. Moreover, depending upon the low cost ceramic material used to build these capacitors, the thermal coefficient can be very bad, as depicted in Figure 20. The X7R type is highly recommended to achieve low voltage ripple.

Figure 20. Typical Y7R Ceramic Type Value as a Function of the Temperature.

## NCN6000

Based on the experiments carried out during the NCN6000 characterization, the best comprise, at time of printing this document, is to use two $6.8 \mu \mathrm{~F} / 10 \mathrm{~V} /$ Ceramic/X7R capacitor in parallel to achieve the CRD_VCC filtering. The ESR will not extend $50 \mathrm{~m} \Omega$ over the temperature range and the combination of standard parts provide an acceptable $-20 \%$ to $+20 \%$ tolerance,
together with a low cost. Obviously, the capacitor must be SMD type to achieve the extremely low ESR and ESL necessary for this application. Figure 21 illustrates the CRD_VCC ripple observed in the NCN6000 demo board depending upon the type of capacitor used to filter the output voltage.

Table 5. Ceramic/Electrolytic Capacitors Comparison

| Manufacturers | Type/Series | Format | Max Value | Tolerance | Typ. Z @ 500 kHz |
| :---: | :---: | :---: | :---: | :---: | :---: |
| MURATA | CERAMIC/GRM225 | 0805 | $10 \mu \mathrm{~F} / 6.3 \mathrm{~V}$ | $+80 \% /-20 \%$ | $30 \mathrm{~m} \Omega$ |
| VISHAY | Tantalum/594C/593C |  | $10 \mu \mathrm{~F} / 16 \mathrm{~V}$ |  | $450 \mathrm{~m} \Omega$ |
| VISHAY | Electrolytic/94SV |  | $10 \mu \mathrm{~F} / 10 \mathrm{~V}$ | $-20 \% /+20 \%$ | $400 \mathrm{~m} \Omega$ |
|  | Electrolytic Low Cost |  | $10 \mu \mathrm{~F} / 10 \mathrm{~V}$ | $-35 \% /+50 \%$ | $2.0 \Omega$ |

Top Trace $=$ Electrolytic or Tantalum $10 \mu \mathrm{~F}$ Bottom Trace $=$ X7R $10 \mu \mathrm{~F}$ ceramic
The high ripple pulse across CRD_VCC is the consequence of the large ESR of the electrolytic capacitor.

Figure 21. CRD_VCC Ripple as a Function of the Capacitor Technology

Figure 22. External Capacitor Current Charge and CRD_VCC Voltage Ripple.

Figure 23. CRD_VCC Voltage Ripple

## Clock Divider

The main purpose of the built-in clock generator is threefold:

1. Adapts the voltage level shifter to cope with the different voltages that might exist between the MPU and the Smart Card.
2. Provides a frequency division to adapt the Smart Card operating frequency from the external clock source.
3. Controls the clock state according to the smart card specification.
In addition, the NCN6000 adjusts the signal coming from the microprocessor to get the Duty Cycle window as defined by the ISO7816-3 specification.

The logic input pins A0, A1, $\overline{\mathrm{PGM}}, \mathrm{I} / \mathrm{O}$ and $\overline{\mathrm{RESET}}$ fulfill the programming functions when both $\overline{\mathrm{PGM}}$ and $\overline{\mathrm{CS}}$ are

Low. The clock input stage (CLOCK_IN) can handle a 40 MHz frequency maximum, the divider being capable to provide a $1: 8$ ratio. Of course, the ratio must be defined by the engineer to cope with the Smart Card considered in a given application and, in any case, the output clock [CRD_CLK] shall be limited to 20 MHz maximum signal. In order to maximize the CLOCK_IN bandwidth, this pin has no Schmitt trigger input. The simple associated CMOS has a $\mathrm{Vbat} / 2$ threshold level. In order to minimize the $\mathrm{dI} / \mathrm{dt}$ and $\mathrm{dV} / \mathrm{dV}$ developed in the CRD_CLK line, the peak current as been internally limited to 30 mA peak (typical @ $C R D \_V C C=5.0 \mathrm{~V}$ ), hence limited the rise and fall time to 10 ns typical. Consequently, the NCN6000 fulfills the ISO7816 specification up to 10 MHz maximum, but can be used up to 20 MHz when the final application operates in a limited ambient temperature range.

Figure 24. Simplified Frequency Divider and Programming Functions

In order to avoid any duty cycle out of the frequency smart card ISO7816-3 specification, the divider is synchronized by the last flip flop, thus yielding a constant $50 \%$ duty cycle, whatever be the divider ratio. Consequently, the output

CRD_CLK frequency division can be delayed by eight CLOCK_IN pulses and the microcontroller software must take this delay into account prior to launch a new data transaction.

The example given by the oscillogram here above highlights the delay coming from the internal clock duty cycle resynchronization. In this example, the clock is internally divided by 2 prior to be applied to the CRD_CLK pin. Since the clock signal is asynchronous, it is up to the programmer to make sure the next card transaction is not
activated before the CRD_CLK signal has been updated. Generally speaking, such a delay can be derived from the maximum clock frequency provided to the interface, keeping in mind the maximum delay is eight incoming clock pulses.

Figure 25. Clock Programming Examples

The clock can be re-programmed without halting the rest of the circuit, whatever be the new clock divider ratio. In
particular, the CRD_VCC can be applied to the card while the clock is re-programmed.

Figure 26. Command Stop Clock HIGH

The CRD_CLK signal is halted in the High logic state, following the Chip Select positive going transition. Logic Input conditions:
$\begin{array}{ll}\overline{\text { PGM }} & =\text { Low } \\ \overline{\text { RESET }} & \text { Low } \\ \text { I/O } & \text { Low }\end{array}$

A0 = Low
A1 = Low
$\overline{\mathrm{CS}}=$ Low pulsed

Figure 27. Command Stop Clock LOW

The CRD_CLK signal is halted in the Low logic state, following the Chip Select positive going transition. Logic Input conditions:
$\overline{\text { PGM }}=$ Low
A0 = Low
$\overline{\text { RESET }}=$ Low
I/O = High

A1 = Low
$\overline{\mathrm{CS}}=$ Low, pulsed

Figure 28. Command Resume Clock Normal Operation

The CRD_CLK signal is resumed in the normal operation, following the Chip Select positive going transition. The previous halted state is irrelevant and the clock signal is synchronized with the internal clock divider to avoid non CRD_CLK 50\% duty cycle.
$\overline{\text { PGM }}=$ Low
A0 $=$ Low
$\overline{\text { RESET }}=$ High
A1 = Low
I/O = Low
$\overline{\mathrm{CS}}=$ Low, pulsed

回是 1.00 V

Figure 29. Card Clock Rise and Fall Time

Since the CRD_CLK signal can generate very fast transient (i.e. $\mathrm{tr}=2.5 \mathrm{~ns} @ \mathrm{Cp}=10 \mathrm{pF}$ ), adapting the design to cope with the EMV noise specification might be necessary at final check out. Using an external RC network is a way to reduce the dv/dt, hence the EMI noise.

Typically, the external series resistor is $10 \Omega$, the total capacitance being 30 pF to 50 pF

## Bidirectional Level Shifter

The NCN6000 carries out the voltage difference between the MPU and the Smart Card I/O signals. When the start sequence is completed, and if no failures have been detected, the device becomes essentially transparent for the data transferred on the I/O line. To fulfill the ISO7816-3 specification, both sides of the I/O line have built in pulsed circuitry to accelerate the signal rise transient. The I/O line is connected on both side of the interface by a NMOS switch which provide the level shifter and, thanks to its relative high internal impedance, protects the Smart Card in the event of data collision. Such a situation could occurs if either the MPU of the smart card forces a signal in the opposite logic level direction.

When the $\overline{\mathrm{CS}}$ signal goes High, or if the MPU is running any of the programming functions, the built in register holds the previous state presents on the input I/O pin. This

Figure 30. Basic Internal I/O Level Shifter
mechanism is useful to force the CRD_IO card pin in either a High or a Low pre-defined logic state. It is the responsibility of the programmer to set up the I/O line according to the system's activity
Device Q4 provides a low impedance to ground when the CRD_IO line is deactivated. This mechanism avoids noise presence on this line during any of the power operation.
When either side of this level shifter is forced to Low, the externally connected device will be forward biased by the DC current flowing through the pull up resistors as depicted in Figure 30. Since these two resistors will carry $350 \mu \mathrm{~A}$ max each under the worst case conditions, care must be observed to make sure the external device will be capable to handle this level of current. Note: the typical series impedance of the internal MOS device (Q3, Figure 30) is $400 \Omega$.

The oscillograms Figure 31 give the worst case operation when the stray capacitance is 15 pF .

Note: The I/O data depends solely upon the smart card ATR content, the NCN6000 being not involved in these data.

Figure 32. Typical I/O and RST Signals During an ATR Sequence.

## Input Schmitt Triggers

All the Logic Input pins have built-in Schmitt trigger circuits to prevent the NCN6000 against uncontrolled operation. The typical dynamic characteristics of the related pins are depicted in Figure 33.

The output signal is guaranteed to go High when the input voltage is above $0.70 * \mathrm{Vbat}$, and will go Low when the input voltage is below $0.30^{*}$ Vbat.

The CLOCK_IN pin has been design to provide a 40 MHz bandwidth clock receiver input, capable to drive the internal clock divider. This front end circuit yields a constant Duty Cycle signal, according to the ISO specification, to the external smart card, even when the NCN6000 division ratio is $1: 1$.

Figure 33. Typical Schmitt Trigger Characteristic

## Interrupt Function

The NCN6000 flags the external microprocessor by pulling down the $\overline{\mathrm{INT}}$ signal provided in pin 9. This signal is activated by one of the here below referenced operations.

Table 6. Interrupt Functions

|  | Pin Related | Clear Function | STATUS Pin 5 |
| :--- | :---: | :--- | :--- |
| Card Insertion and <br> Extraction | 11 | Positive Going Chip Select, or logical <br> combination of Chip Select Low and <br> PWR_ON Positive Going | High = Card Presents <br> Low $=$ No Card Inserted |
| DC/DC Converter <br> Overloaded | 15 | Positive Going Chip Select, or logical <br> combination of Chip Select Low and <br> PWR_ON Positive Going | High = DC/DC Operates Normally <br> Low $=$ Output CRD_VCC Overloaded |

Leaving the $\overline{\mathrm{INT}}$ pin Low has no influence on the NCN6000 internal behavior. It is up to the engineering to decide when and how the interrupt will be cleared from this pin. As described before, this can be achieved by either
providing a Chip Select positive transient, or by starting the DC/DC converter with the standard command PWR_ON = H and $\overline{\mathrm{CS}}=\mathrm{L}$.

## Security Features

In order to protect both the interface and the external smart card, the NCN6000 provides security features to prevent catastrophic failures as depicted here after.

Pin Current Limitation: In the case of a short circuit to ground, the current forced by the device is limited to 15 mA for any pins, except CRD_CLK pin. No feedback is provided to the external MPU.

DC/DC Operation: The internal circuit continuously senses the CRD_VCC voltage and, in the case of either over or undervoltage situation, update the STATUS register accordingly. This register can be read out by the MPU.

Battery Voltage: Both the Over and Undervoltage are detected by the NCN6000, a POWER_DOWN sequence and the STATUS register being updated accordingly. The external MPU can read the STATUS pin to take whatever is appropriate to cope with the situation.

## ESD Protection

The NCN6000 includes silicon devices to protect the pins against the ESD spikes voltages. To cope with the different ESD voltages developed across these pins, the built-in structures have been designed to handle either 2.0 kV , when related to the microcontroller side, or 8.0 kV when connected with the external contacts. Practically, the CRD_RST, CRD_CLK, CRD_IO and CRD_DET pins can sustain 8 kV , the digital pins being capable to sustain 2 kV . The CRD_VCC pin has the same 8 kV ESD protection, but can source up to 55 mA continuously, the absolute maximum current being 100 mA .

To save as much battery current as possible when no card is inserted, one should use a Normally Open Card Detection switch connected pin 11. Since the internal card detection circuit source $10 \mu \mathrm{~A}$ (typical) to bias the switch, using a Normally Open avoid this direct sink to ground from the battery.

## Parallel Operation

When two or more NCN6000 operate in parallel on a common digital bus, the Chip Select pin allows the selection of one chip from the bank of the paralleled devices. Of course, the external MPU shall provide one unique $\overline{\mathrm{CS}}$ line for each of the NCN6000 considered interfaces. When a given interface is selected by $\overline{\mathrm{CS}}=\mathrm{L}$, all the logic inputs becomes active, the chip can be programmed or/and the external card can be accessed. When $\overline{\mathrm{CS}}=\mathrm{H}$, all the input logic pins are in the high impedance state, thus leaving the bus available for other purpose. On the other hand, when $\overline{\mathrm{CS}}=\mathrm{H}$, the CRD_IO and CRD_RST hold the previous I/O and $\overline{\text { RESET }}$ logic state, the CRD_CLK being either active or stopped, according to the programmed state forced by the MPU.

Since there is one single I/O line to communicate with the external microcontroller, one should provide a software routine to save the code when data exchanged are performed between the two cards. Generally speaking, the internal microcontroller RAM can be used to support such a transaction.

The CRD_VCC voltage and CRD_CLK signal of each NCN6000 can be operated simultaneously, these two pins being activated even when the related chip select is High. As depicted Figure 14, the DC/DC converter is not deactivated when PWR_ON goes to Low when $\overline{\mathrm{CS}}=$ High.

## Minimum Power Consumption

To achieve a minimum current consumption, the interface shall be programmed as follow:

1. Turn off the DCDC converter : this will disconnect the smart card if still inserted in the socket), reducing the power supply to the minimum needed to control the interface.
2. Force the input signals to a logic High to avoid current flowing through the pull up resistors. This applies to the here below table:

| $\overline{\mathbb{I N T}}$ | Pin 9 |
| :--- | :---: |
| $\overline{\text { CS }}$ | Pin 6 |
| STATUS | Pin 5 |
| I/O | Pin 8 |
| CRD_IO | Pin 14 |

To save as much battery current as possible when no card is inserted, one should use a Normally Open Card Detection switch connected pin 11 to ground. Since the internal card detection circuit source is $10 \mu \mathrm{~A}$ (typical), using such a NO switch saves the direct sink to ground current from the battery to ground.

During this mode of operation, the only active sub functions are the card detection and the battery monitoring. The activity resume immediately after either a card insertion, or a $\overline{\mathrm{CS}}=$ Low signal applied to pin 6 .

## Printed Circuit Board Layout

Since the NCN6000 carries high speed currents together with high frequency clock, the printed circuit board must be carefully designed to avoid the risk of uncontrolled operation of the interface.

A typical single-sided PCB layout is provided in Figure 34 highlighting the ground technique.

The card socket uses a low cost ISO only version, all the parts being located on the Component side. Connector J3 makes reference to the microcontroller used by the final application. Of course, the connector is not necessary and standard copper tracks might be used to connect the MPU to the NCN6000 interface chip.

Figure 34. Typical Single Sided Printed Circuit Board Layout

## Application Note

A partial schematic diagram of the demo board designed to support the NCN6000 applications is depicted Figure 35. This schematic diagram highlights the interface between the micro controller and the Smart Card, leaving aside the peripherals used to control the MPU.

## Conclusion

From a practical stand point, the CRD_VCC output capacitor has been split into two $6.8 \mu \mathrm{~F} / 10 \mathrm{~V} / \mathrm{X} 7 \mathrm{R}$, one being located as close as possible across pins 13 and 17 of the NCN6000, the second one being located close by the smart card physical connector. On the other hand, cares have
been observed to minimize the cross coupling between the clock signals (both Input and CRD_CLK) and the other signals presents on the board.
The micro controller holds the software necessary to program the NCN6000, together with the code handling the T0 operation. Provisions are made to provide a communication link with an external computer by using the RS232 standard port.
Thanks to the Chip Select signal, several NCN6000 can share a common data bus as depicted Figure 36. In this example, two interfaces are connected to a single MPU, the $\overline{\mathrm{CS}}$ pins being controlled by two different signals.

## NCN6010

## SIM Card Supply and Level Shifter

The NCN6010 is a level shifter analog circuit designed to translate the voltages between a SIM Card and an external microcontroller. A built-in DC/DC converter makes the NCN6010 useable to drive any type of SIM card. The device fulfills the GSM 11.11 specification. The external MPU has an access to a dedicated input STOP pin, providing a way to switch off the power applied to the SIM card in case of failure or when the card is removed.

## Features

- Supports 3.0 V or 5.0 V Operating SIM Card
- Built-in Pull Up Resistor for I/O Pin in Both Directions
- All Pins are Fully ESD Protected, According to GSM Specification
- Supports 10 MHz Clock
- 6.0 kV ESD Proof on SIM Card Pins

## Typical Applications

- Cellular Phone SIM Interface
- Identification Module

## ON Semiconductor ${ }^{\text {w }}$

PIN DESCRIPTIONS

| Pin | Name | Type | Description |
| :---: | :---: | :---: | :---: |
| 1 | $V_{D D}$ | POWER | This pin is connected to the system controller power supply suitable to operate from a 3.6 V typical battery. A low ESR ceramic capacitor ( $4.7 \mu \mathrm{~F}$ typical) shall be used to bypass the power supply voltage. |
| 2 | STOP | INPUT | A Low level on this pin resets the SIM interface, switching off the SIM_VCC, according to the ISO7816-3 Power Down procedure (See Table 1 and Figure 3). |
| 3 | MOD_V ${ }_{\text {cc }}$ | INPUT | The signal present on this pin programs the SIM_VCC value (See Table 1): $\begin{aligned} & \text { MOD_VCC }=\mathrm{L} \rightarrow \text { SIM_VCC }=5.0 \mathrm{~V} \\ & \text { MOD_VCC }=\mathrm{H} \rightarrow \text { SIM_VCC }=3.0 \mathrm{~V} \end{aligned}$ |
| 4 | PWR_ON | INPUT | The signal present on this pin controls the SIM_VCC state (See Table 1): PWR_ON $=\mathrm{L} \rightarrow$ SIM_VCC $=$ Open, no supply connected to the SIM card. PWR_ON $=\mathrm{H} \rightarrow$ SIM_VCC = Active, the card is powered. |
| 5 | I/O | INPUT | This pin is connected to an external microcontroller or GSM management unit. A bi-directional level translator adapts the serial I/O signal between the smart card and the external controller. A built-in constant $20 \mathrm{k} \Omega$ (typical) resistor provides a high impedance state when not activated. |
| 6 | CLOCK | INPUT | The clock signal, coming from the external controller, must have a Duty Cycle within the Min/Max values defined by the specification (typically $50 \%$ ). The built-in level shifter translates the input signal to the external SIM card CLK input. |
| 7 | RESET | INPUT | The RESET signal present at this pin is connected to the SIM card. The internal level shifter translates the level according to the voltages present at pin 1 and the SIM_VCC programmed value. |
| 8 | SIM_RST | OUTPUT | This pin is connected to the RESET pin of the card connector. A level translator adapts the external RESET signal to the SIM card. A built-in active pull down connects this pin to ground when the device is in a nonoperating mode. |
| 9 | SIM_CLK | OUTPUT | This pin is connected to the CLK pin of the card connector. The CLOCK signal comes from the external clock generator, the internal level shifter being used to adapt the voltage defined for the SIM_VCC. A built-in active pull down connects this pin to ground when the device is in a nonoperating mode. |
| 10 | GND | GROUND | This pin is the GROUND reference for the integrated circuit and associated signals. Cares must be observed to avoid voltage spikes when the device operates in a normal operation. |
| 11 | SIM_I/O |  | This pin handles the connection to the serial I/O of the card connector. A bi-directional level translator adapts the serial I/O signal between the card and the microcontroller. A $20 \mathrm{k} \Omega$ (typical) pull up resistor provides a High impedance state for the SIM card I/O link. |
| 12 | Cta | POWER | This pin is connected to the external capacitor used by the internal Charge Pump converter. Using Low ESR ceramic type is recommended (X5R or X7R). |
| 13 | Ctb | POWER | This pin is connected to the external capacitor used by the internal Charge Pump converter. Using Low ESR ceramic type is recommended (X5R or X7R). |
| 14 | SIM_VCC | POWER | This pin is connected to the SIM card power supply pin. An internal Charge Pump converter is programmable by the external MPU to supply either 3.0 V or 5.0 V output voltage. An external $1.0 \mu \mathrm{~F}$ minimum ceramic capacitor (ESR $<100 \mathrm{~m} \Omega$, X5R or X7R recommended) must be connected across SIM_VCC and GND. <br> During a normal operation, the SIM_VCC voltage can be set to 3.0 V followed by a 5.0 V value, or can start directly to any of these two values. When the voltage is adjusted downward (from 5.0 V to 3.0 V ) cares must be observed as reverse peak current can flow from the external capacitors to the battery during a short amount of time (in the $1.0 \mu \mathrm{~s}$ range). When such a voltage adjustment is necessary, it is recommended to force SIM_VCC to zero, wait $350 \mu$ s minimum, then reprogram the chip to get SIM_VCC $=3.0 \mathrm{~V}$. |

5. Internal NMOS device, biased to $V_{D D}$, provides low impedance when SIM_V $V_{C C}$ is disconnected to sustain GSM 11.11-200 $\mu \mathrm{A}$ input current test.
6. The SIM_CLK clock can operate up to 10 MHz , but the rise and fall time are not guaranteed to be fully within the ISO7816 specification over the temperature range. Typically, tr and tf are 12 ns @ CRD_CLK $=10 \mathrm{MHz}$.
7. Digital inputs undershoot $<-0.30 \mathrm{~V}$, Digital inputs overshoot $<0.30 \mathrm{~V}$.

## Card Supply Charge Pump Converter

The NCN6010 device provides three pins to control the operation of the interface as depicted in Table 1. The built-in charge pump converter circuit provides either a 3.0 V or a 5.0 V output voltage as defined by the programming mode. The external capacitor connected across pins 12 and 13 is used to generate the step up voltage. Since the device operates at 800 kHz typically, one must use high quality, Low ESR type, ceramic capacitor ( 220 nF recommended). The second external capacitor, connected across pin 14 and GND, smooths the output voltage coming from the Charge Pump. A high quality, Low ESR capacitor is necessary to achieve the SIM_VCC ripple voltage ( $1.0 \mu \mathrm{~F}$ Ceramic type is recommended).

The setting of the SIM_VCC voltage, using MOD_VCC $=0$ or 1 , can only be made when PWR_ON is Low. Consequently, a new supply voltage adjustment is performed by first deactivating the SIM card, followed by reactivating it with the new supply voltage. The SIM_VCC voltage can be reprogrammed straightforward when the output voltage increases from 3.0 V to 5.0 V . On the other
hand, although it is possible to change the SIM_VCC voltage from 5.0 V to 3.0 V , it is recommended to switch off the Charge Pump prior to reprogram the SIM_VCC voltage from the high 5.0 V to a low 3.0 V .
The DC/DC converter operates under two modes as defined by the logic level present at MOD_VCC/pin 3:
MOD_VCC $=0$ SIM_CC $=5.0 \mathrm{~V}, \pm 10 \%$. This is the default condition at start up.

MOD_VCC = 1 The Charge Pump is not activated and the SIM_VCC voltage is equal to the $\mathrm{V}_{\mathrm{DD}}$ supply minus the internal maximum 50 mV drop.

The NCN6010 provides a POWER DOWN sequence, according to the ISO7816-3 specification.

Since a built-in active pull down MOS pull the SIM_VCC pin to ground when the smart card is deactivated, a $350 \mu \mathrm{~s}$ minimum delay must be observed prior to reactivate the power supply. This timing assumes a $1.0 \mu \mathrm{~F}$ external reservoir capacitor connected across SIM_VCC and Ground.

Table 1. Programming Functions

| STOP | MOD_VCC | PWR_ON | Operation Mode |
| :---: | :---: | :---: | :--- |
| 0 | X | X | The SIM card supply is disabled, the SIM_VCC pin is Open, SIM_RST $=$ L, <br> SIM_I/O $=\mathrm{L}$, SIM_CLK $=\mathrm{L}$ |
| 1 | 0 | 0 | The NCN6010 is in the power down mode. The SIM card supply is disabled, <br> SIM_VCC = Open, SIM_RST $=$ L, SIM_CLK $=$ L, SIM_IO $=$ L. <br> The SIM_VCC voltage is programmed to 5.0 V. |
| 1 | 1 | 0 | The NCN6010 is in the power down mode. The SIM card supply is disabled, <br> SIM_VCC = Open, SIM_RST $=$ L, SIM_CLK $=$ L, SIM_IO $=$ L. <br> The SIM_VCC voltage is programmed to 3.0 V. |
| 1 | X | 1 | The NCN6010 is in normal operating mode. The SIM card supply is enabled, SIM_VCC <br> voltage is the one previously programmed, all the SIM interface pins are active. |

## Table 1: Programming Mode

When the card is removed, the STOP pin shall be asserted Low to disable the NCN6010. A mechanical switch, or equivalent, can be either sensed by the MPU, or directly connected to pin 2 , to handle the procedure.

## Power Up Sequence

When the charge pump is activated, MOD_VCC = Low, the SIM card related level shifter pins are biased to the 5.0 V
voltage. When the output voltage starts from zero, as depicted in Figure 3, a $50 \mu$ s stabilization delay (typical) is necessary to make sure all the output signals are biased at the nominal 5.0 V voltage. To avoid a card transaction error, the user must take this delay into account and program the chip accordingly.

Figure 3. Power On Sequence

## Power Down Operation

The power down mode can be initiated by either the PWR_ON or by the STOP pin condition. In both cases, the communication I/O session is terminated immediately, according to the ISO7816-3 sequence as depicted in Figure 4. When the PWR_ON signal is set Low, the NCN6010 goes to the power down mode. According to the ISO7816-3 procedure defined to deactivate the SIM contacts, the input pins I/O, CLOCK and RESET must be Low before the PWR_ON is taken Low. When the

PWR_ON is Low, the SIM_IO, SIM_CLK and SIM_RST pins are forced to Low and the SIM_VCC pin is left floating.
When the STOP signal is Low, the SIM_IO, SIM_CLK and SIM_RST are forced Low, the SIM_VCC being left floating, until the STOP pin is taken High again.

When the card is extracted, the external MPU shall detect the operation and run the Power Down of the card by forcing PWR_ON input to Low. The NCN6010 fulfills the power sequence as defined by the ISO/CEI 7816-3 norm (see oscillogram given in Figure 5).

Force SIM RST to Low
Force SIM_CLK to Low, unless it is already in this state
Force SIM IO to Low
Shut Off the SIM_V ${ }_{C C}$ supply

Figure 4. ISO7816-3 Power Down Sequence

Figure 5. Power Down Sequence Oscillogram

## Level Shifters

When the SIM card voltage is either higher or lower than the MPU $V_{D D}$ supply, the level shifters can be reprogrammed to cope with the expected output voltage. When the MPU and the SIM card operate under the same supply voltage, the DC/DC converter is not activated (SIM_VCC $=\mathrm{V}_{\mathrm{DD}}-50 \mathrm{mV}$ ) and the signals go directly through the level shifters.

The bi-directional I/O line provides a way to automatically adapt the voltage difference between the $\mu \mathrm{CU}$ and the SIM card. In addition with the pull up resistor, an active pull up circuit (Figure 6 Q1 and Q2) provides a fast charge of the stray capacitance, yielding a rise time fully within the ISO/EMV specifications.

Figure 6. Basic I/O Line Interface

The typical waveform provided in Figure 7 shows how the accelerator operates. During the first 200 ns (typical), the slope of the rise time is solely a function of the pull up resistor associated with the stray capacitance. During this period, the PMOS devices are not activated since the input voltage is below their Vgs threshold. When the input slope
crosses the Vgsth, the opposite one shot is activated, providing a low impedance to charge the capacitance, thus increasing the rise time as depicted in Figure 7. The same mechanism applies for the opposite side of the line to make sure the system is optimum.

Figure 7. SIM_IO Rise and Fall Time Oscillogram

## Input Schmitt Triggers

All the Logic Input pins have built-in Schmitt trigger circuits to prevent the NCN6010 against uncontrolled operation. The typical dynamic characteristics of the related pins are depicted in Figure 8.

The output signal is guaranteed to go High when the input voltage is above $0.70^{*} \mathrm{Vbat}$, and will go Low when the input voltage is below $0.30 *$ Vbat.

Figure 8. Typical Schmitt Trigger Characteristic

## Charge Pump Converter

The converter uses a switched capacitor technique to increase the SIM_VCC voltage up to 5.0 V from a 3.3 V typical battery. The concept, depicted in Figure 9, charges the transfer capacitor C1 up to the Vcc value, then connects this capacitor is series with the input voltage-output
reservoir network. The voltage developed across the load is, theoretically, twice the battery voltage, but the system must takes into account the losses associated with the power switches and the internal ohmic drops.

Figure 9. Basic Charge Pump Converter

When the output voltage is programmed to 3.0 V , the clocks are inactive and the load is directly connected to the battery by means of switch S5. The SIM_VCC voltage follows the input value, minus the drop coming from the internal resistance. The current is limited by the Ron of the power device S 5 and t he output voltage will decrease as the load current increases above 20 mA (typical). Figure 10 illustrates the theoretical waveforms.

Figure 10. Basic Charge Pump Operating Timings

When the NCN6010 is programmed in the 5.0 V output voltage, the clocks are activated, switch S5 is disconnected and the output voltage is the result of the C 1 charge transfer into the output load. The current is limited by three mains parameters:

- the Ron of the switching MOS (S1 through S4)
- the operating frequency
- the C1/C2 ratio and their ESR

The first parameters are depending upon the internal structure and size of the NMOS/PMOS devices used to
design the chip. The third parameter is adjustable by the user and, beside the micro farad values, the type of capacitors plays a significant role. As a matter of fact, using a low cost electrolytic model will ruin the efficiency due to the high ESR of such a capacitor. It is highly recommended to use ceramic types, preferably from the X5R or X7R series, to achieve the efficiency and the SIM_VCC output voltage ripple. Table 2 summarizes the characteristics of the most common type of capacitors.

Table 2. Comparison of Capacitor Types

| Manufacturers | Type/Serie | Format | Max Value | Tolerance | Typ. Z @ 500 kHz |
| :---: | :---: | :---: | :---: | :---: | :---: |
| MURATA | CERAMIC/GRM225 | 0805 | $10 \mu \mathrm{~F} / 6.3 \mathrm{~V}$ | $+80 \% /-20 \%$ | $30 \mathrm{~m} \Omega$ |
| VISHAY | Tantalum/594C/593C | 1206 | $10 \mu \mathrm{~F} / 16 \mathrm{~V}$ | - | $450 \mathrm{~m} \Omega$ |
| VISHAY | Electrolytic/94SV | 1206 | $10 \mu \mathrm{~F} / 10 \mathrm{~V}$ | $-20 \% /+20 \%$ | $400 \mathrm{~m} \Omega$ |

It is clear that, with nearly half an ohm of resistance is series with the pure capacitor, the tantalum or the electrolytic type will generate high voltage spikes and poor regulation in the high frequency operating charge pump built into the NCN6010. Moreover, with ESR in the 3.0 Ohm range, low cost capacitors are not suitable for this application.

Figure 11 provides the schematic diagram of the simulated charge pump circuit. Although this schematic does not
represent the accurate internal structure of the NCN6010, it can be used for engineering purpose. The ABM devices S 1 , S2, S4 and S5 have been defined in the PSPICE model to represent the NMOS and PMOS used in the silicon. The ESR value of C2 and C3 can be adjusted, at PSPICE level, to cope with any type of external capacitors and are useful to double check the behavior of the system as a function of the external passives components.

Figure 11. Charge Pump Simulation Schematic Diagram

## NCN6010

The operating waveforms are given in Figure 12 to illustrate the high peak current flowing in the transfer
capacitor. The real ripple voltage, coming from the engineering board, is given in Figure 13.

Figure 12. Simulated Charge Pump Typical Waveforms

Figure 13. SIM_VCC Output Voltage Ripple @ lout = 10 mA

Figure 14. Engineering Test Board

The layout of the PCB is a key parameter to avoid the voltage spikes that could pollute the rest of the system. Figure 16 represents a typical printed circuit lay out, based on the schematic diagram given in Figure 14, highlighting the large ground plane used in this engineering tool.

Obviously, a GSM application will use much less area, but cares must be observed to locate the capacitors as close as possible to the integrated circuit associated pins.

Capacitors C1, C2, C3, C4 and C5 are ceramic, X7R, 10 V, surface mount.

Figure 15. Engineering Test Board Silk Layer

## NCN6011

## Low Power Level Shifter

The NCN6011 is a level shifter analog circuit designed to translate the voltages between a SIM Card and an external microcontroller. The device handles all the signals needed to control the data transaction between the external Card and the MPU.

## Features

- 2.7 to 6.0 V Input and/or Output Voltage Range
- 500 nA Quiescent Supply Current
- All Pins are Fully ESD Protected
- Supports 10 MHz Clock
- Provides a Logic I/O Enable Function
- Rx/Tx Communication Capability

Typical Applications

- SIM/GSM/SMARTCARD Interface

Figure 1. Typical Interface Application

PIN DESCRIPTIONS (Pin numbers in parenthesis are related to the TSSOP-14 package) (Pin numbers in bold are related to the MIcro-10 package)

| Pin | Name | Type | Description |
| :---: | :---: | :---: | :---: |
| (1) | - | NA | No Connection. (TSSOP-14 Only) |
| $\begin{gathered} 1 \\ (2) \end{gathered}$ | I/O | INPUT | This pin is connected to an external microcontroller. A bidirectional level translator adapts the serial I/O signal between the smart card and the external controller. A built-in constant $20 \mathrm{k} \Omega$ typical resistor provides a high impedance state when not activated. |
| $\begin{gathered} \mathbf{2} \\ (3) \end{gathered}$ | $V_{D D}$ | POWER | This pin is connected to the system controller power supply and the input voltage can range from 2.7 to 6.0 V . |
| $\begin{gathered} \hline 3 \\ (4) \end{gathered}$ | CLOCK | INPUT | The clock signal, coming from the external controller, must have a Duty Cycle within the Min/Max limits defined by the specification (typically $50 \%$ ). The built-in level shifter translates the input signal to the external SIM card voltage supply. |
| $\begin{gathered} \hline \mathbf{4} \\ (5) \end{gathered}$ | RESET | INPUT | The RESET signal present at this pin is provided by the MPU. The internal level shifter translates the level according to the voltages applied to pin 3 and pin 12. |
| $\begin{gathered} \mathbf{5} \\ (6) \end{gathered}$ | IO_ENABLE | INPUT | This logic input pin forces SIM_IO pin to Low when IO_ENABLE = Low, leaving this signal High when IO_ENABLE = High. The signal is not latched and the SIM_IO pin is released to a logic High when IO_ENABLE = High. When this condition is met, the SIM_IO logic status depends upon the signal presence pin I/O. When the MPU uses two different channels to exchange data with the SIM card, the IO_ENABLE pin can be used to as a Write line to the external card, the I/O pin being used to Read data from the SIM card. |
| (7) | - | NA | No Connection. (TSSOP-14 Only) |
| (8) | - | NA | No Connection. (TSSOP-14 Only) |
| $\begin{gathered} \hline \mathbf{6} \\ (9) \end{gathered}$ | GND | GROUND | This pin is the GROUND reference for the integrated circuit and associated signals. High frequency layout techniques are requested to connect the GND pin to the external functions. |
| $\begin{gathered} 7 \\ (10) \end{gathered}$ | SIM_RST | OUTPUT | This pin is connected to the RST pin of the card connector. A voltage level translator adapts the external RESET signal (coming from the MPU) to the smart card. |
| $\begin{gathered} \hline 8 \\ (11) \end{gathered}$ | SIM_CLK | OUTPUT | This pin is connected to the CLK pin of the card connector. The CLOCK signal comes from the external clock generator. The internal voltage level shifter adapts the clock signal flowing through this link. Care must be observed to prevent AC coupling with adjacent lines and signals PCB tracks. |
| $\begin{gathered} 9 \\ (12) \end{gathered}$ | SIM_VCC | POWER | This pin is connected to the smart card VCC power supply pin. The voltage, provided by an external power supply, can range from 2.7 V to 6.0 V. The NCN6011 does not regulate or protect the voltage supply applied to the external card. |
| $\begin{gathered} 10 \\ (13) \end{gathered}$ | SIM_I/O | OUTPUT | This pin handles the connection to the serial I/O of the card connector. A bidirectional voltage level translator adapts the serial I/O signal between the card and the microcontroller. A $20 \mathrm{k} \Omega$ typical pull up resistor provides a High impedance state for the SIM card I/O link. |
| (14) | - | NA | No Connection. (TSSOP-14 Only) |

## Level Shifters

The built-in level shifters accommodate the differential voltage between the external MPU and the SIM card. Neither the logic nor the functions of the SIM signals are affected by the interface.

The NCN6011 does not regulate the SIM_VCC, nor does it detect the overload current.

## Bidirectional Level Shifter

The NCN6011 carries out the voltage difference between the MPU and the Smart Card I/O signals. When the start sequence is completed, and if no failures have been detected, the device becomes essentially transparent for the data transferred on the I/O line. To fulfill the ISO7816-3 specification, both sides of the I/O line have built-in pulsed circuitry to accelerate the signal rise transient. The I/O line is connected on both sides of the interface by a NMOS switch which provide the level shifter and, thanks to its relative high internal impedance, protects the Smart Card in the event of data collision. Such a situation could occur if either the MPU of the smart card forces a signal in the opposite logic level direction.

Figure 8. Typical I/O and SIM_IO Waveform, $\mathrm{V}_{\mathrm{DD}}=\mathrm{V}_{\mathrm{CC}}=5.0 \mathrm{~V}$, ENABLE $=$ LOw

Figure 7. Basic Internal I/O Level Shifter

Figure 9. Typical SIM_IO Activated by ENABLE Pin, I/O = High (open drain)

## Input Schmitt Triggers

All the Logic Input pins have built-in Schmitt trigger circuits to prevent the NCN6011 against uncontrolled operation. The typical dynamic characteristics of the related pins are depicted in Figure 10.

The output signal is guaranteed to go High when the input voltage is above $0.70^{*} \mathrm{Vb}$ bat, and will go Low when the input voltage is below $0.30^{*} \mathrm{Vbat}$.

Figure 10. Typical Schmitt Trigger Characteristic

## ESD Protection

The NCN6011 includes silicon devices to protect the pins against the ESD spikes voltages. To cope with the different ESD voltages developed across these pins, the built-in structures have been designed to handle either 2.0 kV , when related to the microcontroller side, or 4.0 kV when connected with the external contacts. Practically, the SIM_RST, SIMD_CLK and SIM_IO pins can sustain 4.0 kV .

## Printed Circuit Board Layout

Since the NCN6011 carries high speed currents together with high frequency clock, the printed circuit board must be carefully designed to avoid the risk of uncontrolled operation of the interface.
Care must be observed to avoid common copper track sharing small signal and high power with a relative high impedance. On top of that, the clock signal (both input and output) shall be properly shielding to minimize the high frequency cross talk between this line and the rest of the circuit. In particular, the SIM_RST signal shall be protected from interference generated by the SIM_CLK line. Such protection can be achieved by surrounding the SIM_CLK track by a copper track connected to ground. Generally speaking, the ground plane shall be as large as possible for a given printed circuit board area.

## MC33170

## RF Amplifier Companion Chip for Dual-Band Cellular Subscriber Terminal

The MC33170 is a complete solution for drain modulated dual-band GSM 900MHz and DCS-1800MHz Power Amplifiers. Thanks to its internal decoder, the MC33170 drastically simplifies the interface between the PAs and the baseband logic section, providing an immediate gain in part count but also in occupied copper area. The device is also ready for 1 V platforms since it accepts logic high control signals down to $900 \mathrm{mV} @ 25^{\circ} \mathrm{C}$.

A priority management system ensures the negative is present before authorizing the power modulation, giving the necessary ruggedness to the final design. This function can easily be disabled for PAs not requiring a negative bias.

The device is able to directly drive an external P or N -channel with the possibility to linearize the overall response via the internal high-performance control amplifier and easily implement system gain.

Finally, an LDO delivers a stable voltage, usable for external biasing purposes.

- 1 V platform compatible: ON voltage $=900 \mathrm{mV}$, OFF voltage $=$ 300 mV max
- Priority management system prevents power modulation before negative bias establishes
- High performance 4.5 MHz gain-bandwidth product operational amplifier
- Drives N or P -channel MOSFET
- 2.5 V low-noise LDO
- Idle mode input for very low power consumption (standby mode)

PIN DESCRIPTION

| Pin No. | Pin Name | Function | Description |
| :---: | :---: | :---: | :---: |
| 1 | Band Selection | Selects the transmit band | A level high on this input selects the DCS chain. A zero selects the GSM chain. |
| 2 | Tx Enable | Starts the power | A level high on this pin enables the DCS/GSM chain and establishes a low-resistance link between pin 5 and 7 |
| 3 | GSM-900 | Biases the 900MHz section | When pin 1 is at zero and pin 2 goes high, the LDO voltage appears on this pin (pin 14 is high) |
| 4 | DCS-1800 | Biases the 1.8 GHz section | When pin 1 is at one and pin 2 goes high, the LDO voltage appears on this pin (pin 14 is high) |
| 5 | PA Start-up | Enables the PA power section | When pin 2 goes high, the battery voltage appears on this pin with a 700 mA peak current capability (pin 14 is high) |
| 6 | Gnd | The IC ground | The IC ground |
| 7 | Vbat | The IC power supply | This pin is wired to the battery terminal. A 100 nF decoupling capacitor is recommended, depending on the supply impedance |
| 8 | LDO | Low DropOut regulator | This output requires a 100 nF decoupling and is able to deliver up to 10 mA continuous |
| 9 | NINV | Positive OPAMP input | The non-inverting OPAMP input |
| 10 | INV | Negative OPAMP input | The inverting OPAMP input |
| 11 | Vboost | Boost voltage from the PA | This pin connects to a boost voltage delivered by the RF PA. This boost is necessary when driving an N -channel |
| 12 | Out | The OPAMP output | The output of the OPAMP/MOSFET driver pin |
| 13 | Negative Reg. | The PA negative clip | This pin clips the PA negative bias to - 5 V and prevents/authorizes the modulation depending on its typical level : $\begin{aligned} & <5.5 \mathrm{~V}-2.5 \mathrm{~V}>\mathrm{OK} \\ & <1.3 \mathrm{~V}--3.5 \mathrm{~V}>\mathrm{NOTOK} \\ & <-4.2 \mathrm{~V}--5 \mathrm{~V}>\mathrm{OK} \end{aligned}$ <br> Max. clipping current is 5 mA |
| 14 | Common Enable | Enables the whole IC | When high, this pin puts the IC in on-mode |

## Lack of negative circuitry behavior:

The MC33170 hosts a circuitry that prevents the power modulation startup if the negative bias is not established. However, to accommodate with PAs that do make use of a
negative bias, it is possible to connect pin 13 to pin 7 and thus invalidate the protection circuitry. The below sketch details the available levels to fulfil this function

MC33170 operating truth table, pin levels:

| TxEN | Band Selection | Common Enable | GSM-900 | DCS-1800 | PA startup |
| :---: | :---: | :---: | :---: | :---: | :---: |
| X | X | 0 | High-impedance | High-impedance | High-impedance |
| 0 | X | 1 | High-impedance | High-impedance | High-impedance |
| 1 | 0 | 1 | $\mathrm{V}_{\text {LDO }}$-Io.RDS ${ }_{(0 \mathrm{ON})}$ | High-impedance |  |
| 1 | 1 | 1 | High-impedance | $\mathrm{V}_{\text {LDO-Io. }} \mathrm{RDS}_{(\mathrm{ON})}$ | $\mathrm{V}_{\mathrm{BAT}}$-Io.RDS ${ }_{(\mathrm{ON})}$ |

Io is the current delivered by the considered pin, $\operatorname{RDS}(\mathrm{ON})$ is the switch series resistance as defined in the section Steering Switches

## MC33170 application hints

The MC33170 represents a major leap toward miniaturization and compactness of Power Amplifiers (PAs) systems. Prior to talk about the 33170 application circuits, let us review how a classical dual-band transmission chain is implemented. At the beginning of the chain, the power ramping signal is delivered by the Baseband's Digital to

Analog Converter (DAC). Because of the digitization, a natural discontinuity appears between the various steps the signal is made of. As a matter of fact, this sharp transitions create undesirable effects and need to be smoothed by an external circuitry (figure 13).

Figure 13. DAC's signal can be smoothed by an appropriate circuitry

The filtering action can be implemented in a various way, but usually a 3rd order Bessel filter represents a good choice. Actual solutions require the use of an external operational amplifier (OPAMP) dedicated to this function.

For drain-controlled PAs, the power is directly dependent upon the supply delivered to the device. Several methods exist but the preferred one stays the N or P channel modulation. In this application, the N -channel is wired in a source-follower configuration and therefore needs an external voltage to ensure its adequate enhancement. This upper voltage can be obtained from a step-up converter or directly from ON Semiconductor PAs, as with the MRFIC0919 or MRFIC1819. To quickly charge/discharge the MOSFET Ciss capacitor, a dedicated driver is needed, with a voltage swing high enough to bias the N -channel toward its specified RDSON.

Radio-Frequency PAs need stable bias levels to keep their operating point at the right place, despite supply variations. A Low DropOut (LDO) regulator is the obvious choice for
this purpose. Unfortunately, to keep the quiescent power at its minimum during the GSM/DCS time-frame pauses (e.g. no power delivered), it is important to quickly remove the bias from the PAs. Conversely, the LDO shall be fast enough to bias the PAs at anytime, without hampering the overall response time. Such a task is difficult for an off-the-shelf regulator: a specific component has to be found.
Thanks to their innovative designs, ON Semiconductor PAs, such as the aforementioned ones, do not require any external negative sources. However, some synchronization signals are needed to activate the internal circuitry and provide them with a stable operating point. This is usually done by using external low/high power switches.
Finally, a safety system needs to be implemented to prevent the modulation start in case the negative bias is not established.
Gathering all these information onto a final drawing gives birth to figure 14.

Figure 14. Actual solution to drive a two-PA configuration

## MC33170 as a Bessel filter

Thanks to its package, the MC33170 simplifies the implementation of any filtering/driving configuration, e.g. with either an N or P -channel MOSFET. Figure 15a details
the way to wire a 100 kHz filter while driving an N -channel MOSFET. In this application, a third order filter is achieved by combining a first pole passive RC-filter, followed by a second-order Sallen-Key complex pole-pair section.

Figure 15a. Using the MC33170's OPAMP to filter out the DAC discontinuities

As one can see, it is easy to select the desired gain value via the 100k feedback resistors and accordingly tailor it to the DAC output level. Figure 15a performs the filtering function but also delivers the adequate sink/source current to drive the MOSFET transistor. The two-component section of figure 2 is reduced into a single one, saving cost and PCB area. It also important to point out that the OPAMP section can be totally disabled by the Common Enable pin.

## Benefits of the closed loop configuration

One of the MC33170's key applications is to make the modulation section operating in a closed-loop configuration. That is to say, the power chain is closed
through the feedback resistor (the $100 \mathrm{k} \Omega$ network in figure 3) and forces the output to follow the input ramp. With N -channels, it brings several benefits:

1. The input ramp does no longer deals with the MOSFET threshold voltage which can introduce a certain amount of delay in the response time.
2. At low powers, the distributions between the $\mathrm{RDS}_{(\mathrm{ON})}$ is automatically compensated.

With P-channels, the application does not need an elevated voltage to ensure the channel enhancement but maximizes the presence of the OPAMP to ensure a fully linear chain.

Figure 15b. Going down with the 100 kHz filter

## The need of a fast regulator

Since the internal LDO controls the PA's bias points, it is important to quickly drive the regulator in order to ensure the minimum consumption during the non-modulation phases. A standard LDO has difficulties to react in less than $30 \mu \mathrm{~s}$.

Figure 15c. Going up with the 100 kHz filter
This delay would be unacceptable in a system operating with fast frames. The MC33170 internal LDO has be designed to react within less than $10 \mu \mathrm{~s}$, ensuring a prompt bias establishment. Figure 16 shows the way the bias voltage takes place, without any overshoot.

Figure 16. A fast LDO ensures an immediate bias availability

The LDO requires a standard 100 nF decoupling capacitor to keep its output stable. The typical output noise stays within $100 \mu \mathrm{~V}$ from 100 Hz to 100 kHz .

## High and low current switches

The MC33170 hosts two types of steering switch. The first one only deals with low currents since it delivers the
operating bias voltage to the PAs. With two distinct switches, the MC33170 low-current switches control the RF PA GSM 900 MHz or DCS 1.8 GHz . Once again, the reaction time of these elements is optimized to ensure a fast operation. Figure 17a depicts the typical signal variations. Please note that the Tx pin is controlled via a logic 01 of 1 V ensuring the compatibility with 1V platforms.

Figure 17a. Typical GSM/DCS pins response time

Figure 17b. Peak current capability of the power switch

## Complete dual-band application

Figure 18 shows how implementing the MC33170 in a complete dual-band application where a 100 kHz filter is combined with the MOSFET driver.

Figure 18. A complete dual-band application with the MC33170

## Application

The MC33170 has been designed to fulfill the requirements of the new ON Semiconductor dual-band RF amplifier, the MRFIC1859. For demonstration purposes, the
device was driven by the MC33170 in a simple gain two configuration. The below picture shows how the power signal drives the PA's drain.

Figure 19. The driving signal delivered by the MC33170 allows fully linear power modulation

## GSM specifications

In order to meet the GSM specifications, the modulation edges must be smoothed to fit into the spectral template. This can be accomplished by implementing figure 18 's

Bessel filter and adjusting the cutoff frequency. Once the edges are smoothed, the complete systems nicely fits into the GSM template, as depicted by figure 20.

Figure 20. Thanks to its flexibility, the MC33170 helps reaching the GSM specs

## NCS5000

## Integrated RF Schottky Detector

The NCS5000 is an integrated schottky detector intended for use as a level detector in RF measurement/power control applications such as those found in GSM handsets. The detector converts the peak RF voltage applied to a DC level. The circuit consists of an RF schottky detector, a reference schottky diode, as well as biasing and control circuitry. There is an enable input that allows the part to be placed in a low power state when not in use.

The detector is designed for operation up to 2.0 GHz and can operate with input power levels up to +25 dBm . There is a fixed offset of 10 mV (nominal) between the Reference Detector and the RF Detector under no applied RF. The two detectors are monolithically integrated so that they closely track over temperature, voltage and process.

The NCS5000 is housed in a very small TSOP-6 package ideal for portable applications. The TSOP-6 package is a lower profile, footprint compatible package to the SOT23-6.

## Features

- Wide Operating Frequency Range to 2.0 GHz
- 2.7-5.5 V Operating Voltage
- Very Low Operating Current of $300 \mu \mathrm{~A}$
- Enable Control to Place the Part in a Low Current Standby Mode
- Typical Standby Current of $<1.0 \mu \mathrm{~A}$
- -40 to $85^{\circ} \mathrm{C}$ Operating Temperature Range
- Very Small TSOP-6 Package

## Typical Applications

- Cellular Handsets (GSM and DCS1800/PCS1900)
- Wireless Data Modems
- Transmitter Power Measurement and Control
- Test Equipment

## APPLICATION INFORMATION

The NCS5000 is an integrated RF schottky detector designed for use in level detector and power amplifier control circuits. The device is optimized for large signal applications (Pin $>-20 \mathrm{dBm}$ ) such as those found in GSM handsets and data modems. This device has been designed for applications that require operation from a single $\mathrm{Li}-\mathrm{Ion}$ or multi- $\mathrm{Ni}-\mathrm{MH}$ battery pack. The operating range is $2.7-5.5 \mathrm{~V}$ so the device can be powered directly from the battery or a low drop out regulator. To support power sequencing, an Enable circuitry is included which allows the
device to be placed into a very low power state $(<3.0 \mu \mathrm{~W})$ when not in use.

In addition to the RF detector, a reference detector is included so the NCS5000 can be used to implement a differential detector. Since the RF and reference detectors are integrated on the same silicon, they track each other tightly over temperature, bias voltage, and process. Each detector is biased with approximately $45 \mu \mathrm{~A}$ of current and there is a built-in offset of 10 mV (nom) between the RF and the Reference Detector.

## INFORMATION FOR USING THE TSOP-6 SURFACE MOUNT PACKAGE

## MINIMUM RECOMMENDED FOOTPRINT FOR SURFACE MOUNTED APPLICATIONS

Surface mount board layout is a critical portion of the total design. The footprint for the semiconductor packages must be the correct size to insure proper solder connection
interface between the board and the package. With the correct pad geometry, the packages will self align when subjected to a solder reflow process.

The power dissipation of the TSOP-6 is a function of the pad size. This can vary from the minimum pad size for soldering to a pad size given for maximum power dissipation. Power dissipation for a surface mount device is determined by $\mathrm{T}_{\mathrm{J}(\max )}$, the maximum rated junction temperature of the die, $\mathrm{R}_{\theta \mathrm{JA}}$, the thermal resistance from the device junction to ambient, and the operating temperature, $\mathrm{T}_{\mathrm{A}}$. Using the values provided on the data sheet for the TSOP-6 package, $\mathrm{P}_{\mathrm{D}}$ can be calculated as follows:

$$
P_{D}=\frac{T_{J(\text { max })}-T_{A}}{R_{\theta J A}}
$$

The values for the equation are found in the maximum ratings table on the data sheet. Substituting these values into the equation for an ambient temperature $\mathrm{T}_{\mathrm{A}}$ of $25^{\circ} \mathrm{C}$, one can calculate the power dissipation of the device which in this case is 400 milliwatts.

$$
\mathrm{P}_{\mathrm{D}}=\frac{150^{\circ} \mathrm{C}-25^{\circ} \mathrm{C}}{300^{\circ} \mathrm{C} / \mathrm{W}}=417 \text { milliwatts }
$$

The $300^{\circ} \mathrm{C} / \mathrm{W}$ for the TSOP-6 package assumes the use of the recommended footprint on a glass epoxy printed circuit board to achieve a power dissipation of 417 milliwatts.

## SOLDERING PRECAUTIONS

The melting temperature of solder is higher than the rated temperature of the device. When the entire device is heated to a high temperature, failure to complete soldering within a short time could result in device failure. Therefore, the following items should always be observed in order to minimize the thermal stress to which the devices are subjected.

- Always preheat the device.
- The delta temperature between the preheat and soldering should be $100^{\circ} \mathrm{C}$ or less.*
- When preheating and soldering, the temperature of the leads and the case must not exceed the maximum temperature ratings as shown on the data sheet. When using infrared heating with the reflow soldering method, the difference should be a maximum of $10^{\circ} \mathrm{C}$.
- The soldering temperature and time should not exceed $260^{\circ} \mathrm{C}$ for more than 10 seconds.
- When shifting from preheating to soldering, the maximum temperature gradient should be $5^{\circ} \mathrm{C}$ or less.
- After soldering has been completed, the device should be allowed to cool naturally for at least three minutes. Gradual cooling should be used as the use of forced cooling will increase the temperature gradient and result in latent failure due to mechanical stress.
- Mechanical stress or shock should not be applied during cooling.
*Soldering a device without preheating can cause excessive thermal shock and stress which can result in damage to the device.

## Advance Information

## Antenna Switch Controller

The MDC5100 is designed to control GaAs RF switches which require positive and negative going control voltages to select the switch path. All input control signals are 3 V CMOS-logic compatible to allow for direct interface to a microcontroller. The device also has an accessory detect pin for use in applications where there is a portable handset to mobile adapter. The device is designed to interface directly with Double Pull-Double Throw (DPDT) switches such as the M/A-Com SW 363.

This device in combination with a GaAs RF switch can be used to achieve duplex isolation in many Time Division Duplex Radios like DECT or in Frequency Division Duplex Radios employing time division multiple access with staggered Transit/Receive time slots such as GSM. It can also be used to control an RF switch in dual band radio applications. The device is housed in a miniature Micro-8 for minimum space utilization.

## Features

- Micro-miniature Low Profile Micro 8 Package
- 3 V CMOS Logic Control Inputs
- Ultra-low Quiescent Current of $400 \mu \mathrm{~A}$ Typical
- Wide Operating Temperature Range of -40 to $85^{\circ} \mathrm{C}$

## Applications

- GSM and PCS Portable Phones
- Mobile to Portable Accessories
- Wireless LAN Modems
- Specialized TDD and TDMA Radios
- Dual Band Phones

## Antenna Switch Control

The MDC5101 inputs TxE and RxE Logic Signals with an accessory input termination option and, allows positive and negative control voltages in accordance with the enclosed truth table. This device is primarily intended to control GaAs RF switches. It is also designed to interface with most HCMOS MCUs such as the ON Semiconductor MC68338.

The MDC5101 is intended to replace a circuit of up to 18 discrete components and is available in a Micro- 8 package. This device, in combination with a compatible RF switch, can be used to achieve duplex isolation in any Time Division Duplex Radio like GSM and DCS1800 with staggered Transmit Receive Time Slots. It can also be used to control an RF switch in dual band radio applications.

This integrated solution in a Micro-8 package compared with a discrete solution will add a great value in performance with less board space consumption.

## Features

- Miniature Micro-8 Surface Mount Package Saves Board Space
- Logic Level Control
- Designed to Interface with Microcontrollers

## 5101

## ORDERING INFORMATION

MDC5101R2 13 inch Reel, 4000 units

## ESD Rating

ESD protection on each pin to $\pm 2500 \mathrm{~V}$ per MIL-STD6883 method 3015 , using human body model of $100 \mathrm{pF}, 1500$ Ohms and using the machine model to $\pm 200 \mathrm{~V}$ at 100 pF and 0 Ohms. Parts must meet electrical requirement after testing.

ELECTRICAL CHARACTERISTICS $\left(\mathrm{V}_{\mathrm{CC}}=2.75 \mathrm{~V}, \mathrm{~V}_{\mathrm{EE}}=-5.0 \mathrm{~V}, \mathrm{~T}_{\mathrm{A}}=\mathrm{T}_{\text {low }}\right.$ to $\mathrm{T}_{\text {high }}$ unless otherwise noted)

## Low Voltage Bias Stabilizer with Enable

- Maintains Stable Bias Current in N-Type Discrete Bipolar Junction and Field Effect Transistors
- Provides Stable Bias Using a Single Component Without Use of Emitter Ballast and Bypass Components
- Operates Over a Wide Range of Supply Voltages Down to 1.8 Vdc
- Reduces Bias Current Variation Due to Temperature and Unit-to-Unit Parametric Changes
- Consumes $<0.5 \mathrm{~mW}$ at $\mathrm{V}_{\mathrm{CC}}=2.75 \mathrm{~V}$
- Active High Enable is CMOS Compatible

This device provides a reference voltage and acts as a DC feedback element around an external discrete, NPN BJT or N-Channel FET. It allows the external transistor to have its emitter/source directly grounded and still operate with a stable collector/drain DC current. It is primarily intended to stabilize the bias of discrete RF stages operating from a low voltage regulated supply, but can also be used to stabilize the bias current of any linear stage in order to eliminate emitter/source bypassing and achieve tighter bias regulation over temperature and unit variations. The "ENABLE" polarity nulls internal current, Enable current, and RF transistor current in "STANDBY." This device is intended to replace a circuit of three to six discrete components.

The combination of low supply voltage, low quiescent current drain, and small package make the MDC5001T1 ideal for portable communications applications such as:

- Cellular Telephones
- Pagers
- PCN/PCS Portables
- GPS Receivers
- PCMCIA RF Modems
- Cordless Phones
- Broadband and Multiband Transceivers and Other Portable Wireless Products

## MDC5001T1

NOTE 1: $\mathrm{V}_{\mathrm{BE} 3}$ is used to simulate actual operating conditions that reduce $\mathrm{V}_{\mathrm{CE} 2}$ \& $\mathrm{H}_{\mathrm{FE} 2}$, and increase $\mathrm{I}_{\mathrm{B} 2}$ \& $\mathrm{V}_{\text {ref }}$.

## CLOSED LOOP TEST CIRCUITS

Figure 17. RF Stage $\mathrm{I}_{\mathrm{C} 3}$ versus $\mathrm{T}_{\mathrm{A}}$ Test Circuit

## MDC5001T1

## APPLICATION CIRCUITS

Step 1: Choose $\mathrm{V}_{\mathrm{CC}}$ (1.8 V Min to 10 V Max)
Step 2: Insure that Min $\mathrm{V}_{\mathrm{ENBL}}$ is $\geq$ minimum indicated in Figures 5 and 6.
Step 3: Choose bias current, $\mathrm{I}_{\mathrm{C} 3}$, and calculate needed $\mathrm{I}_{\text {out }}$ from typ $\mathrm{H}_{\text {FE3 }}$
Step 4: From Figure 1, read $\mathrm{V}_{\text {ref }}$ for $\mathrm{V}_{\mathrm{CC}}$ and $\mathrm{I}_{\text {out }}$ calculated.
Step 5: Calculate Nominal $\mathrm{R} 5=\left(\mathrm{V}_{\mathrm{CC}}-\mathrm{V}_{\text {ref }}\right) \div\left(\mathrm{I}_{\mathrm{C} 3}+\mathrm{I}_{\mathrm{out}}\right)$. Tweak as desired.
Figure 18. Class A Biasing of a Typical 900 MHz BJT Amplifier Application

## MDC5001T1

Step 1: Choose $V_{C C}$ (1.8 V Min to 10 V Max)
Step 2: Insure that Min $V_{\text {ENBL }}$ is $\geq$ minimum indicated in Figures 5 and 6.
Step 3: Choose bias current, $\mathrm{I}_{\mathrm{D}}$, and determine needed gate-source voltage, $\mathrm{V}_{\mathrm{GS}}$.
Step 4: Choose $I_{\text {out }}$ keeping in mind that too large an $I_{\text {out }}$ can impair MDC5000 $\Delta \mathrm{V}_{\text {ref }} / \Delta T_{J}$ performance (Figure 2) but too large an R6 can cause $l_{\text {DGO }} \& I_{G S O}$ to bias on the FET.
Step 5: Calculate $\mathrm{R} 6=\left(\mathrm{V}_{\mathrm{GS}}+\mathrm{E}_{\mathrm{GS}}\right) \div \mathrm{I}_{\text {out }}$
Step 6: From Figure 1, read $V_{\text {ref }}$ for $V_{C C} \& I_{\text {out }}$ chosen
Step 7: Calculate Nominal $R 5=\left(V_{C C}-V_{\text {ref }}\right) \div\left(I_{D}+I_{\text {out }}\right.$. Tweak as desired.

## CASE OUTLINES AND PACKAGE DIMENSIONS

TSSOP-24
CASE 948K-01
ISSUE O

NOTES:

1. Dimensioning and tolerancing per ansi Y14.5M, 1982.
2. CONTROLLING DIMENSION: MILLIMETER.
3. DIMENSION A DOES NOT INCLUDE MOLD FLASH, PROTRUSIONS OR GATE BURRS. MOLD FLASH OR GATE BURRS SHALL NOT EXCEED 0.15 (0.006) PER SIDE.
4. DIMENSION B DOES NOT INCLUDE INTERLEAD FLASH OR PROTRUSION. INTERLEAD FLASH OR protrusion shal not exceed 0.25 (0.010) PER SIDE
5. DIMENSION K DOES NOT INCLUDE DAMBAR DIMENSION KDOESNOA INCLUDE DA
PROTRUSION. ALIOWABLE DAMBAR PROTRUSION SHALL BE 0.08 (0.003) TOTALIN EXCESS OF THE KDIMENSION AT MAXIMUM MATERIAL CONDITIN.
6. TERMINAL NUMBERS ARE SHOWN FOR REFERENCE ONLY.
7. DIMENSION A AND B ARE TO BE DETERMINED at datum PLANE -W-.

CASE 965-01
ISSUE O

DETAIL P

NOTES: Y DIMENSIONIN
2. CONTROLING DIMENSION: ML HMETER
2. CIMENSIONS D AND EDO NOT INCLUDE
3. DIMENSIONS D AND E DO NOT INCLUDE MOLD FLASH OR PROTRUSIONS AND ARE MEASURED AT THE PARTING LINE. MOLD FLASH OR PROTRUSIONS SHALL NOT EXCEED 0.15 (0.006) PER SIDE.
4. TERMINAL NUMBERS ARE SHOWN FOR REFERENCE ONLY.
5. THE LEAD WIDTH DIMENSION (b) DOES NOT INCLUDE DAMBAR PROTRUSION. ALLOWABLE DAMBAR PROTRUSION SHALL BE 0.08 (0.003) TOTAL IN EXCESS OF THE LEAD WIDTH DIMENSION AT MAXIMUM MATERIAL CONDITION. DAMBAR CANNOT BE LOCATED ON THE LOWER RADIUS OR THE FOOT. MINIMUM SPACE RADIUS OR THE FOOT. MINIMUM SPACE
BETWEEN PROTRUSIONS AND ADJACENT LEAD BETWEEN PROTRUS
TO BE 0.46 ( 0.018 ).

## ON SEMICONDUCTOR STANDARD DOCUMENT TYPE DEFINITIONS

## DATA SHEET CLASSIFICATIONS

A Data Sheet is the fundamental publication for each individual product/device, or series of products/devices, containing detailed parametric information and any other key information needed in using, designing-in or purchasing of the product(s)/device(s) it describes. Below are the three classifications of Data Sheet: Product Preview; Advance Information; and Fully Released Technical Data

## PRODUCT PREVIEW

A Product Preview is a summary document for a product/device under consideration or in the early stages of development. The Product Preview exists only until an "Advance Information" document is published that replaces it. The Product Preview is often used as the first section or chapter in a corresponding reference manual. The Product Preview displays the following disclaimer at the bottom of the first page: "This document contains information on a product under development. ON Semiconductor reserves the right to change or discontinue this product without notice."

## ADVANCE INFORMATION

The Advance Information document is for a device that is NOT fully qualified, but is in the final stages of the release process, and for which production is eminent. While the commitment has been made to produce the device, final characterization and qualification may not be complete. The Advance Information document is replaced with the "Fully Released Technical Data" document once the device/part becomes fully qualified. The Advance Information document displays the following disclaimer at the bottom of the first page: "This document contains information on a new product. Specifications and information herein are subject to change without notice."

## FULLY RELEASED TECHNICAL DATA

The Fully Released Technical Data document is for a product/device that is in full production (i.e., fully released). It replaces the Advance Information document and represents a part that is fully qualified. The Fully Released Technical Data document is virtually the same document as the Product Preview and the Advance Information document with the exception that it provides information that is unavailable for a product in the early phases of development, such as complete parametric characterization data. The Fully Released Technical Data document is also a more comprehensive document than either of its earlier incarnations. This document displays no disclaimer, and while it may be informally referred to as a "data sheet," it is not labeled as such.

## DATA BOOK

A Data Book is a publication that contains primarily a collection of Data Sheets, general family and/or parametric information, Application Notes and any other information needed as reference or support material for the Data Sheets. It may also contain cross reference or selector guide information, detailed quality and reliability information, packaging and case outline information, etc.

## APPLICATION NOTE

An Application Note is a document that contains real-world application information about how a specific ON Semiconductor device/product is used, or information that is pertinent to its use. It is designed to address a particular technical issue. Parts and/or software must already exist and be available.

## SELECTOR GUIDE

A Selector Guide is a document published, generally at set intervals, that contains key line-item, device-specific information for particular products or families. The Selector Guide is designed to be a quick reference tool that will assist a customer in determining the availability of a particular device, along with its key parameters and available packaging options. In essence, it allows a customer to quickly "select" a device. For detailed design and parametric information, the customer would then refer to the device's Data Sheet. The Master Components Selector Guide (SG388/D) is a listing of ALL currently available ON Semiconductor devices.

## REFERENCE MANUAL

A Reference Manual is a publication that contains a comprehensive system or device-specific descriptions of the structure and function (operation) of a particular part/system; used overwhelmingly to describe the functionality or application of a device, series of devices or device category. Procedural information in a Reference Manual is limited to less than 40 percent (usually much less).

## HANDBOOK

A Handbook is a publication that contains a collection of information on almost any give subject which does not fall into the Reference Manual definition. The subject matter can consist of information ranging from a device specific design information, to system design, to quality and reliability information.

## ADDENDUM

A documentation Addendum is a supplemental publication that contains missing information or replaces preliminary information in the primary publication it supports. Individual addendum items are published cumulatively. The Addendum is destroyed upon the next revision of the primary document.

#### Abstract

ON Semiconductor and are trademarks of Semiconductor Components Industries, LLC (SCILLC). SCILLC reserves the right to make changes without further notice to any products herein. SCILLC makes no warranty, representation or guarantee regarding the suitability of its products for any particular purpose, nor does SCILLC assume any liability arising out of the application or use of any product or circuit, and specifically disclaims any and all liability, including vithout limitation special, consequential or incidental damages. "Typical" parameters which may be provided in SCILLC data sheets and/ or specifications can and do vary in different applications and actual performance may vary over time. All operating parameters, including "Typicals" must be validated for each customer application by customer's technical experts. SCILLC does not convey any license under its patent rights nor the rights of others. SCILLC products are not designed, intended, or authorized for use as components in systems intended for surgical implant into the body, or other applications intended to support or sustain life, or for any other application in which the failure of the SCILLC product could create a situation where personal injury or death may occur. Should Buyer purchase or use SCILLC products for any such unintended or unauthorized application, Buyer shall indemnify and hold SCILLC and its officers, employees, subsidiaries, affiliates, and distributors harmless against all claims, costs, damages, and expenses, and reasonable attorney fees arising out of, directly or indirectly, any claim of personal injury or death associated with such unintended or unauthorized use, even if such claim alleges that SCILLC was negligent regarding the design or manufacture of the part. SCILLC is an Equal Opportunity/ Affirmative Action Employer.

[^2]:    10. Output voltages from 2.0 V to 6.0 V , in 0.1 V increments, are available on request.
    *Q2, 2001
[^3]:    ${ }^{*} \mathrm{C}_{\text {in }}$ is required if regulator is located an appreciable distance from power supply filter.
    ${ }^{* *} C_{O}$ is not needed for stability; however, it does improve transient response.

[^4]:    $z z=05,08,09,12,15,18$ or 24
    A = Assembly Location
    L = Wafer Lot
    Y = Year
    WW = Work Week

[^5]:    ${ }^{*} \mathrm{C}_{\text {in }}$ is required if regulator is located an appreciable distance from power supply filter. (See Applications Informationfor details.)
    ${ }^{* *} \mathrm{C}_{o}$ is not needed for stability; however, it does improve transient response.

[^6]:    xx = Nominal Voltage
    A = Assembly Location
    WL = Wafer Lot
    Y = Year
    WW = Work Week

[^7]:    *Contact your ON Semiconductor sales representative for other output voltage values.

[^8]:    *Pin 6 GND is not directly shorted to the fused paddle GND. The fused paddle GND (pins 4, 5, 12, 13) is connected through the substrate. Pin 6 must be electrically connected to at least one of the fused paddle GND's on the PC board.

[^9]:    1. $\mathrm{I}_{\text {out }}$ (Output Current) is the measured current when the output voltage drops below 0.3 V with respect to $\mathrm{V}_{\text {out }}$ at $\mathrm{I}_{\text {out }}=30 \mathrm{~mA}$.
[^10]:    ${ }^{*} \mathrm{C}_{1}$ is required if the regulator is far from the power source filter.
    ${ }^{* *} \mathrm{C}_{2}$ is required for stability.

[^11]:    1. 10 second maximum.
[^12]:    This document contains information on a product under development. ON Semiconductor reserves the right to change or discontinue this product without notice.

[^13]:    *Additional ordering information can be found on page 727 of this data sheet.
    $\dagger$ TO-220 is 3 -pin, straight leaded. $D^{2}$ PAK are all 3 -pin.

[^14]:    ${ }^{*} \mathrm{C}_{1}$ is required if the regulator is far from the power source filter.
    ${ }^{* *} \mathrm{C}_{2}$ is required for stability.

[^15]:    ${ }^{*} \mathrm{C}_{1}$ required if regulator is located far from power supply filter.
    ${ }^{* *} \mathrm{C}_{2}$ and $\mathrm{C}_{3}$ required for stability. Capacitor must operate at minimum temperature expected during system operations.

[^16]:    ${ }^{*} \mathrm{C}_{1}$ required if regulator is located far from power supply filter.
    ${ }^{* *} \mathrm{C}_{2}$ and $\mathrm{C}_{3}$ required for stability. Capacitor must operate at minimum temperature expected during system operations.

[^17]:    ${ }^{*} \mathrm{C}_{1}$ required if regulator is located far from power supply filter.
    ${ }^{* *} \mathrm{C}_{2}$ and $\mathrm{C}_{3}$ required for stability. Capacitor must operate at minimum temperature expected during system operations.

[^19]:    2. For $\mathrm{V}_{\mathrm{IN}} \leq 4.5 \mathrm{~V}$, a RESET = Low may occur with the output in regulation.
[^20]:    This document contains information on a new product. Specifications and information
    herein are subject to change without notice.

[^21]:    2. For $\mathrm{VIN} \leq 4.5 \mathrm{~V}$, a RESET = Low may occur with the output in regulation.
[^22]:    This document contains information on a new product. Specifications and information

[^23]:    * Add Q1, C13, and R7-R10, and Change R4 to 2.0 k $\Omega$ for Charger Output

[^24]:    *Measurements performed using Voltech PM1200 ac power analysis.

[^25]:    Control Logic Inputs from Microcontroller Output Ports

[^26]:    NOTE: 2 Refer to "Voltage Sensing" text of Operating Description. Guaranteed by Design Only; NOT TESTED.

[^27]:    This document contains information on a new product. Specifications and information herein are subject to change without notice.

[^28]:    $x x x=3.3,5.0,12,15$, or ADJ
    A = Assembly Location
    WL = Wafer Lot
    Y = Year
    WW = Work Week

[^29]:    Vout $=15 \mathrm{~V}$
    A: Output Pin Voltage, 10 V/DIV
    B: Inductor Current, 2.0 A/DIV
    C: Inductor Current, 2.0 A/DIV, AC-Coupled
    D: Output Ripple Voltage, $50 \mathrm{mV} / \mathrm{dDIV}$, AC-Coupled
    Horizontal Time Base: $5.0 \mu \mathrm{~s} / \mathrm{DIV}$

[^30]:    2. Guaranteed by design, not $100 \%$ tested in productions.
[^31]:    6. Low duty cycle pulse techniques are used during test to maintain junction temperature as close to ambient temperature as possible.
[^32]:    3. Guaranteed by design, not $100 \%$ tested in production.
[^33]:    2. Not tested in production. Specification is guaranteed by design.
[^34]:    * Consult your local sales representative for other package options.

[^35]:    Trace 1- Regulator Output Voltage ( $100 \mathrm{mV} / \mathrm{div}$.)
    Trace 2- Regulator Output Voltage (10 A/div.)

[^36]:    Trace 1- Regulator Output Voltage (1.0 V/div.)
    Trace 2- Regulator Output Voltage (20 V/div.)

[^37]:    1. Split Power Supplies.
[^38]:    This document contains information on a new product. Specifications and information

[^39]:    2. Low duty cycle pulse techniques are used during test to maintain junction temperature as close to ambient as possible.
    3. $\mathrm{T}_{\text {low }}=0^{\circ} \mathrm{C}$ for MC34064
    $-40^{\circ} \mathrm{C}$ for MC33064
    $\mathrm{T}_{\text {high }}=+70^{\circ} \mathrm{C}$ for MC34064
    $+85^{\circ} \mathrm{C}$ for MC33064
[^40]:    2. Low duty cycle pulse techniques are used during test to maintain the junction temperature as close to ambient as possible.
    $\mathrm{T}_{\text {low }}=-40^{\circ} \mathrm{C}$ for MC33153 $\quad \mathrm{T}_{\text {high }}=+105^{\circ} \mathrm{C}$ for MC33153
[^41]:    X = Don't Care; MSB is Transferred first.

[^42]:    * $\mathrm{V}_{\mathrm{CC}}=6.0 \mathrm{~V}$ TO 26 V

[^43]:    ${ }^{*} \mathrm{~V}_{\text {in }}$ switched from 0.8 to 2.0 V .
    Typical values determined at $25^{\circ} \mathrm{C}$ ambient and 5.0 V supply.

[^44]:    1. $\mathrm{T}_{\text {low }}=0^{\circ} \mathrm{C}$ for MC1496
    $=-40^{\circ} \mathrm{C}$ for MC1496B
    $\mathrm{T}_{\text {high }}=+70^{\circ} \mathrm{C}$ for MC1496

    $$
    =+125^{\circ} \mathrm{C} \text { for MC1496B }
    $$
