MDT-2A Teflon Pulsed Plasma Thruster

Shih-Ming An* and Han-Ji Wu*

Space Science and Technology Center, Academia Sinica, Beijing, China

Abstract

A PULSED plasma microthruster system (MDT-2A) was designed, built, and laboratory tested for space test. The impulse bit amplitude of the thruster is $13 \mu\text{lb-s}$. Five watts of bus power are required. An ignition subsystem of low voltage is used. The thruster has passed a series of performance and environmental tests. The microthruster system is ready for space test.

Contents

Pulsed plasma thrusters using solid Teflon as propellant have been researched and used in many countries because of their advantages, such as simplicity, reliability, ease of control, fast action, and ability to produce small, precise, reproducible impulse bits. The MDT-2A Teflon pulsed plasma thruster, shown in Fig. 1, is a flight test model. It consists of three subsystems: 1) a thruster subsystem, 2) a power conditioner and telemetry signal converter subsystem, and 3) an ignition subsystem. All of the subsystems are enclosed in a metallic package.

The thruster subsystem has two nozzles in a side-by-side arrangement and works alternately. The two nozzles have a common main energy storage capacitor and ignition capacitor. In addition, each nozzle has its own propellant, feed system, and discharge channel formed by a pair of electrodes and a pair of insulation sides. The electrode material is stainless steel and insulation sides are made of 95-98% aluminum oxide. The operation process of the thruster subsystem is similar to the LES-6 thruster.¹

The power conditioner accepts a low dc voltage (24-28 V) and converts it to a 2 kV and 150 V dc needed by the thruster. At the same time the power conditioner also provides a controlling pulse for the ignition subsystem so that the two nozzles of the thruster work alternately. By using a constant-rate-of-energy transfer technique, using the proportional exciting mode of the power switch transistor and decreasing the "hold time" at peak voltage on the main energy storage capacitor, a total power conditioner efficiency of not less than 80% has been attained.

Two telemetry signals control the MDT-2A thruster. One is for the main discharge current and the other for the charge voltage of the main energy storage capacitor. Based on these two signals, the operation situation of the thruster in space can be determined. The block diagram of the power conditioner and telemetry signal converter is shown in Fig. 2.

A feature of the MDT-2A thruster is that it uses a low voltage discharge initiating circuit and coaxial solid state igniter plug with an interior electrode of large diameter. This circuit is shown in Fig. 3. The silicon controlled rectifier (SCR) is an important component in the circuit. It controls the

ignition capacitor C_1 discharge into transformer T . At the beginning of the experiment, the capacitance of the ignition capacitor was $0.5-1 \mu\text{F}$ and its charge voltage was selected at 500 V. It was similar to other circuits which work at 450-650 V.¹⁻³ But experiments indicated the SCR failed to control the discharge under vacuum conditions because the seal of the SCR was not good. This permitted air that was trapped inside

Dimension, cm^3	$31.6 \times 12.6 \times 16.5$

the SCR during manufacture to slowly leak out. When the pressure within the SCR was reduced to a critical value, Paschen breakdown occurred within the SCR. In order to solve this problem it was necessary to select the SCR very carefully. Unfortunately, the number of SCRs satisfying the demands of sealing are very few.

As it is well known, however, the lowest value of Paschen breakdown voltage is not less than 200 V, independent of pressure, electrode separation, and gas composition. Thus, if the charge voltage of the ignition capacitor is less than 200 V, even if the SCR is situated in a vacuum, it should not be affected. In fact, the charge voltage for the MDT-2A thruster is only 150 V. Many experiments for various types of SCRs have proved that such a low voltage is appropriate. An ordinary commercial SCR can be used without any trouble.⁴ The final voltage applied to the igniter plug via the transformer is several thousand volts, which is quite enough to energize the igniter plug.

The MDT-2A thruster uses a coaxial solid state plug with an interior electrode of large diameter. This kind of plug causes the arc formed by the discharge of the main energy storage capacitor to move over a larger area. It means that the arc column has a wider contact with the ablated profile of the propellant rod and thus causes the horizontal curvature of the ablated profile to decrease.⁵ In addition, the life of the plug is increased. There are some records of 10^7 discharges for such plugs.

The general performance of the MDT-2A thruster is summarized in Table 1. This thruster has already passed the environmental tests, including vibration, shock, and thermal-vacuum tests. It is ready for space test.

Conclusions

In the past few years the MDT-2A solid Teflon pulsed plasma thruster was built and tested. Subsequently it also passed a series of environmental tests. The low voltage (150-V) ignition system can greatly lower the performance demands of the SCR. Now the MDT-2A thruster is ready for space test.

SPACECRAFT CHARGING BY MAGNETOSPHERIC PLASMAS—v. 47

Edited by Alan Rosen, TRW, Inc.

Spacecraft charging by magnetospheric plasma is a recently identified space hazard that can virtually destroy a spacecraft in Earth orbit or a space probe in extra terrestrial flight by leading to sudden high-current electrical discharges during flight. The most prominent physical consequences of such pulse discharges are electromagnetic induction currents in various on-board circuit elements and resulting malfunctions of some of them; other consequences include actual material degradation of components, reducing their effectiveness or making them inoperative.

The problem of eliminating this type of hazard has prompted the development of a specialized field of research into the possible interactions between a spacecraft and the charged planetary and interplanetary mediums through which its path takes it. Involved are the physics of the ionized space medium, the processes that lead to potential build-up on the spacecraft, the various mechanisms of charge leakage that work to reduce the build-up, and some complex electronic mechanisms in conductors and insulators, and particularly at surfaces exposed to vacuum and to radiation.

As a result, the research that started several years ago with the immediate engineering goal of eliminating arcing caused by flight through the charged plasma around Earth has led to a much deeper study of the physics of the planetary plasma, the nature of electromagnetic interaction, and the electronic processes in currents flowing through various solid media. The results of this research have a bearing, therefore, on diverse fields of physics and astrophysics, as well as on the engineering design of spacecraft.
