

Exploiting Periodic First-Principles Calculations in NMR Spectroscopy of Disordered Solids

SHARON E. ASHBROOK* AND DANIEL M. DAWSON

School of Chemistry and EaStCHEM, University of St. Andrews, North Haugh, St. Andrews, KY16 9ST, United Kingdom

RECEIVED ON NOVEMBER 3, 2012

M uch of the information contained within solid-state nuclear magnetic resonance (NMR) spectra remains unexploited because of the challenges in obtaining high-resolution spectra and the difficulty in assigning those spectra. Recent advances that enable researchers to accurately and efficiently determine NMR parameters in periodic systems have revolutionized the application of density functional theory (DFT) calculations in solid-state NMR spectroscopy. These advances are particularly useful for experimentalists. The use of first-principles calculations aids in both the interpretation and assignment of the complex spectral line shapes observed for solids. Furthermore, calculations provide a method for evaluating potential structural models against experimental data for materials with poorly characterized structures.

Determining the structure of well-ordered, periodic crystalline solids can be straightforward using methods that exploit Bragg diffraction. However, the deviations from periodicity, such as compositional, positional, or temporal disorder, often produce the physical properties (such as ferroelectricity or ionic conductivity) that may be of commercial interest. With its sensitivity to the atomic-scale environment, NMR provides a potentially useful tool for studying disordered materials, and the combination of experiment with first-principles calculations offers a particularly attractive approach. In this Account, we discuss some of the issues associated with the practical implementation of first-principles calculations of NMR parameters in solids. We then use two key examples to illustrate the structural insights that researchers can obtain when applying such calculations to disordered inorganic materials.

First, we describe an investigation of cation disorder in $Y_2Ti_{2-x}Sn_xO_7$ pyrochlore ceramics using ⁸⁹Y and ¹¹⁹Sn NMR. Researchers have proposed that these materials could serve as host phases for the encapsulation of lanthanide- and actinidebearing radioactive waste. In a second example, we discuss how ¹⁷O NMR can be used to probe the dynamic disorder of H in hydroxyl-humite minerals ($nMg_2SiO_4 \cdot Mg(OH)_2$), and how ¹⁹F NMR can be used to understand F substitution in these systems.

The combination of first-principles calculations and multinuclear NMR spectroscopy facilitates the investigation of local structure, disorder, and dynamics in solids. We expect that applications will undoubtedly become more widespread with further advances in computational and experimental methods. Insight into the atomic-scale environment is a crucial first step in understanding the structure—property relationships in solids, and it enables the efficient design of future materials for a range of end uses.

Introduction

The wealth of potential information contained within solid-state NMR spectra often cannot be extracted easily or accurately, owing to the anisotropic nature of the interactions influencing the nuclear spins. For powdered solids, broad, featureless line shapes are typically seen, with limited resolution of distinct species. Despite technological advances providing increases in resolution and sensitivity, the interpretation and assignment of solid-state NMR spectra remains challenging. This is particularly true for inorganic solids, owing to the variety of nuclides studied, the diverse coordination environments, and the lack of extensive information (relative to ¹H and ¹³C NMR) in the literature. The recent introduction of the gauge-including projector augmented-wave (GIPAW)¹ approach (utilizing the framework of DFT²) enabled NMR parameters to be calculated easily and accurately for periodic solids. This method is of great interest to theoreticians and experimentalists alike, providing quantitative, theoretical support to relate experimental measurements and atomic-level structure in areas as diverse as biomaterials, minerals, porous frameworks, energy materials, and organic solids.³

There is a long tradition in the calculation of NMR parameters in quantum chemistry, but predominantly for molecular systems. In this approach, a periodic solid is approximated as a cluster, centered on the atom of interest, with the termination of bonds, usually by H. The accuracy of the calculation increases with cluster size, as does the computational cost and time. For extended structures, the termination can lead to significant structural perturbations and, therefore, inaccurate results. The use of a periodic approach, where the three-dimensional structure is recreated from a small-volume unit, enables accurate calculation for all atoms within a system simultaneously.⁴ The planewave pseudopotential approach¹ exploits the inherent translational symmetry of solids, enabling the straightforward calculation of NMR parameters including chemical shielding, quadrupolar interactions, scalar couplings, and paramagnetic interactions, and has significantly increased the application of such theoretical support among experimentalists.³ Calculations can be used to interpret and assign high-resolution spectra both for spin l = 1/2 and quadrupolar ($l \ge 1/2$) nuclei, and to provide information that is difficult to extract experimentally (i.e., the relative orientations of tensors), but can significantly influence the appearance of NMR spectra. Calculations can be utilized predictively, guiding experimental acquisition (e.g., the recently developed Optimization of Pulses Using Structure⁵ approach), particularly for challenging systems with poor sensitivity or unknown NMR parameters. For materials with poorly characterized structures, calculations provide a method for testing structural models against experimental measurements,³ as exemplified by the recent work by Charpentier and co-workers (combining NMR, DFT, and molecular dynamics) for the study of the structure of silicate glasses.⁶ The flexibility and ease with which theoretical structures can be altered provides fundamental insight into the dependence of NMR parameters upon the detailed local geometry.

This Account aims to demonstrate how the application of GIPAW calculations has aided the investigation of the atomic-scale environment in disordered inorganic solids using NMR spectroscopy. Structure determination for wellordered crystalline solids is usually straightforward using Bragg diffraction. However, it is often the deviations in periodicity, for example, compositional, positional, or temporal disorder, that produce the physical properties of commercial interest. The sensitivity of NMR to the atomic-scale environment, and the simultaneous use of DFT calculations to interpret spectra, offers an exciting approach for investigating disordered solids. After a brief discussion of some aspects of the practical implementation of GIPAW DFT calculations, the new insight into disorder and dynamics that the combination of calculation and experiment can provide will be illustrated through examples from recent work.

Practical Aspects of GIPAW Calculations

In DFT, the total energy is expressed as a function of the electron density, ρ , enabling a cost-efficient calculation of the ground state electronic structure (and its dependent properties).² While most energetic contributions can be computed exactly, the form of the "exchange-correlation" energy, describing interelectron interactions, is unknown. Several approximations attempt to account for this, including the local density approximation (LDA),² which assumes constant ρ over a small region of space. It is possible to improve accuracy by also considering the gradient of ρ , that is, gradient generalized approximations (GGA).^{2,4} In recent applications of GIPAW calculations to solids, the PBE⁷ implementation of GGA has proved a robust, accurate, and, consequently, popular approach.

Typically, before DFT calculations of NMR parameters can be used interpretively, it is necessary to evaluate their accuracy (and understand their limitations) for a particular nuclide. This is especially true for inorganic solids that contain a wide range of NMR-active species, about which relatively little (in comparison to ¹H and ¹³C) may be known in the literature. This evaluation is conventionally achieved by a comparison of calculated and measured NMR parameters for a series of crystalline solids with well-characterized structures. Several such investigations have been undertaken recently, including, for example, ²⁵Mg, ³⁹K, and ⁷¹Ga.³

The accuracy of the planewave pseudopotential calculations considered here depends upon two variable parameters that are chosen in each calculation: (i) the number of planewaves used, described by a cutoff energy, E_{cut} , and (ii) the number of regularly spaced points (*k*-points) in the Brillouin zone (i.e., the primitive unit cell in reciprocal space) sampled.⁴ Ideally, these should be infinitely large; however, the choices are constrained by the hardware and computing time available. It is sufficient to ensure calculations are "converged"; that is, the calculated results do not improve significantly if more

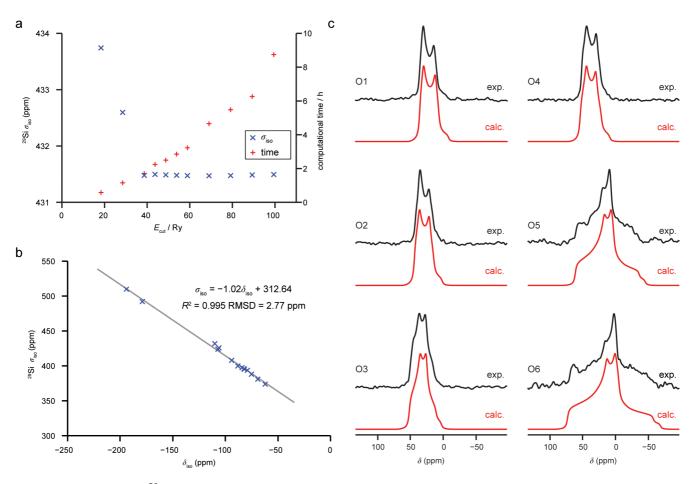

FIGURE 1. (a) Plot showing the ²⁹Si calculated isotropic shielding of SiO₂ coesite as a function of the planewave cutoff energy, E_{cut} . The computational time is also shown. (b) Comparison of ²⁹Si calculated isotropic shielding and experimental isotropic shifts for a series of silicates. planewaves/*k*-points are used.⁴ One advantage of such calculations is that it is possible to vary systematically the values of both parameters and observe the effect upon the calculation. An example is shown in Figure 1a, where the calculated ²⁹Si chemical shielding of SiO₂ (coesite) is plotted as a function of $E_{\rm cut}$ with a fixed number of *k*-points. There are significant changes in chemical shielding as $E_{\rm cut}$ is increased initially, but these become smaller for higher values. However, the time (and cost) of the calculation (also plotted in Figure 1a) continues to increase with $E_{\rm cut}$. The choice of $E_{\rm cut}$ should, therefore, balance accuracy and cost, with 45 Ry appearing optimal here.

Figure 1b shows a comparison of the ²⁹Si calculated isotropic shielding and the corresponding experimental isotropic chemical shielding for a series of simple silicates.^{8,9} Good agreement is observed, with linear regression showing that the line of best fit has a gradient close to the ideal value of -1. Such agreement demonstrates that this approach is suitable for the calculation of ²⁹Si chemical shifts, and gives some indication of the accuracy of the results that

1966 = ACCOUNTS OF CHEMICAL RESEARCH = 1964-1974 = 2013 = Vol. 46, No. 9

can be expected (i.e., an average error of $\sim 1\%$ in Figure 1b). For nuclei with I = 1/2, such as ²⁹Si, the most commonly calculated parameter is the isotropic shielding, σ_{iso} . Although the anisotropy of the shielding tensor (i.e., its magnitude or "span", $\Omega (= \delta_{11} - \delta_{33})$, and shape or "skew", $\kappa (= 3(\delta_{22} - \delta_{iso})/\Omega))$ is also calculated, this is often more difficult to measure experimentally when spectra contain multiple distinct resonances (as it is removed by the rapid magic-angle spinning (MAS) used to improve resolution and sensitivity), and only more recently have experiment and calculation been compared.³ However, for quadrupolar nuclei, the magnitude and asymmetry of the quadrupolar interaction, Co and η_{Q} , respectively, are also excellent probes of local structure and affect the NMR spectra obtained. This is shown in Figure 1c, where ¹⁷O line shapes, extracted for the six distinct sites resolved in a high-resolution MQMAS¹⁰ spectrum of MgSiO₃ (orthoenstatite), are compared with line shapes simulated using parameters calculated using GIPAW.⁹ The excellent agreement enables a full assignment of the

FIGURE 2. (b) Plot of AI–O and P–O bond distances for calcined AIPO-14 prior to and post structural optimization.

spectrum, which contradicts a previous literature assignment based on empirical relationships between NMR parameters and the local structure, demonstrating both the success of DFT for calculating NMR parameters in periodic solids and the need to treat earlier results with some caution.

In contrast to experiment, where chemical shifts are quoted relative to a reference value, calculations provide the absolute shielding. The two are related by

$$\delta_{\rm iso}^{\rm calc} = (\sigma_{\rm ref} - \sigma_{\rm iso}^{\rm calc}) \tag{1}$$

where σ_{ref} is the reference shielding. This can be determined by a comparison of calculated shielding and experimental shift for a series of materials, as in Figure 1b, where the *y* intercept of the line of best fit gives σ_{ref} (here, 312.64 ppm).

One crucial consideration when calculating NMR parameters is the availability and accuracy (or otherwise) of a crystal structure or structural model. Structures are often obtained from diffraction experiments, or can be generated computationally. In some cases, for example, for singlecrystal diffraction data, structures may sometimes be used without modification. However, for powder diffraction data, or if lighter atoms have not been located directly but added manually, it may be necessary to "optimize" the geometry before calculation of NMR parameters. In this procedure, the coordinates of some or all of the atoms are varied, in order to minimize the forces upon them. For traditional DFT methods, this often results in an expansion of the unit cell owing, at least partly, to the underestimation of dispersion interactions in the exchange-correlation functional.^{2,3} One option is to constrain the unit cell parameters during geometry optimization to those determined by diffraction. While suitable for molecular and ordered solids, this approach is inapplicable to disordered materials where and optimization is vital for obtaining the minimum energy structure.^{3,6} The recent introduction of semiempirical dispersion correction schemes^{2,3,11} has provided an alternative option.

Figure 2a shows ²⁷Al and ³¹P MAS NMR spectra of the calcined aluminophosphate, AIPO-14.¹² The four P species are resolved by ³¹P MAS NMR, but quadrupolar broadening results in overlapping line shapes for ²⁷Al (although MQMAS experiments resolve four sites). Spectra simulated using NMR parameters calculated for the crystal structure obtained from powder diffraction are shown in Figure 2a. Poor agreement is observed for both nuclei, with the broader ²⁷Al line shapes reflecting high $C_{\rm Q}$ values (5.5–10.1 MHz), in contrast to those observed experimentally (2.5–4.9 MHz). However, the calculated forces upon the atoms are high, indicating that geometry optimization is required. Figure 2a

also shows spectra simulated using NMR parameters calculated after optimization (using the TS¹¹ dispersion correction scheme). The agreement with experiment is significantly improved, particularly for the calculated ²⁷Al C_Q values. Furthermore, the changes in the ³¹P chemical shifts upon optimization change the spectral assignment. Figure 2b shows the alteration of the local structure (Al–O and P–O bond lengths) upon optimization. The typical change in the Al–O distance is ~0.03 Å, although larger changes (0.07–0.1 Å) are observed. The range of Al–O distances is considerably smaller for the optimized structure and similar changes are observed for the P–O distances. The initial and optimized structures would be hard to distinguish by diffraction,¹² but the changes in local structure significantly affect the calculated NMR parameters.

For ordered solids, a periodic approach, recreating the three-dimensional structure from a single unit cell, is efficient and intuitive. However, for disordered materials, where this periodicity is not rigidly retained, periodic boundary conditions limit the possible environments that can be considered in a calculation. In such cases, the aperiodic structure is commonly approximated as a crystal composed of periodically repeating "supercells".⁴ The supercell chosen must be sufficiently large to minimize the effect of the structural variation on the neighboring cells. This approach can be applied to isolated molecules, defects in solids, surfaces, and even solutions, in addition to disordered materials.³

Finally, it should be noted that whereas NMR experiments are carried out at finite temperature, most DFT calculations are performed at 0 K, that is, on static structures with no temperature directly included. It is well-known that there are many dynamic processes present in solids, which may ultimately limit the accuracy of calculations. However, as NMR is sensitive to dynamics, the differences between calculated and experimental NMR parameters offer insight into the presence and nature of motional processes present.^{3,4}

Application to Disordered Solids

Although the comparison of experimental and calculated NMR parameters for simple solids is prerequisite, the real power of first-principles calculations is their ability to provide insight where structural characterization is more difficult. The vast majority of the information available from solidstate NMR spectra remains unexploited owing to the challenge of obtaining high-resolution spectra, and the difficulty of interpretation and assignment, particularly for disordered materials. First-principles calculations can unlock this untapped potential and provide new information on the atomic-scale environment, as highlighted by the following examples.

Cation Disorder in Pyrochlore Ceramics. The chemical flexibility of oxides with the pyrochlore (A₂B₂O₇) structure has generated interest in their utility as hosts for the immobilization of lanthanide- and actinide-bearing nuclear waste.¹³ While titanate-based pyrochlores are chemically durable, the incorporation of Sn or Zr increases their tolerance to radiation damage. A detailed insight into local structure and disorder in these materials is vital for understanding their physical and chemical properties, and ultimately for the design of improved wasteforms. The sensitivity of NMR to the atomic-scale environment ensures it is ideally suited for this purpose.

Figure 3a shows ⁸⁹Y and ¹¹⁹Sn MAS NMR spectra^{14,15} of $Y_2Ti_{2-x}Sn_xO_7$, a model solid solution that remains pyrochlore throughout its compositional range, where Y^{3+} (similar charge and size to lanthanides/actinides) provides a direct, non-radioactive probe of the local environment. Although both ⁸⁹Y and ¹¹⁹Sn have I = 1/2 (natural abundances of 100% and 8.6%, respectively), the low gyromagnetic ratio of 89 Y and long T₁ relaxation times (often 100– 1000 s) limit sensitivity and make experimental acquisition considerably more challenging than for 119 Sn. In Y₂Ti_{2-x}Sn_xO₇, Y occupies the eight-coordinate A site, with Sn/Ti occupying the six-coordinate B site. In both cases, the next-nearest neighbor (NNN) environment is similar, with each surrounded by six B sites. The ⁸⁹Y NMR spectra display numerous spectral resonances, presumably associated with different numbers and/or arrangements of Sn/Ti occupying the surrounding B sites.¹⁵ However, despite the similar NNN environment, the ¹¹⁹Sn MAS NMR spectra exhibit far fewer resonances, particularly at higher Ti content.¹⁵

Interpretation of the experimental spectra is facilitated by first-principles calculations, where the effect upon the NMR parameters of a change in the local environment can be investigated easily. When considering B-site substitution, it is impractical to perform calculations on truly disordered solids (as an unfeasibly large number of atoms would be involved), and a simplified approach is required.¹⁶ The local environment of one Y (or Sn) cation within the unit cell is systematically varied to include all possible combinations of Sn/Ti on the six surrounding B sites, as shown in Figure 3b.¹⁶ Structures are optimized and NMR parameters calculated for all Y (or Sn) within the cell. Calculated (⁸⁹Y and ¹¹⁹Sn) chemical shifts^{15,16} are shown in Figure 3c, with the number and spatial arrangement of Sn NNN (*n*) indicated. For ⁸⁹Y, there is a systematic increase of ~20 ppm in the average chemical

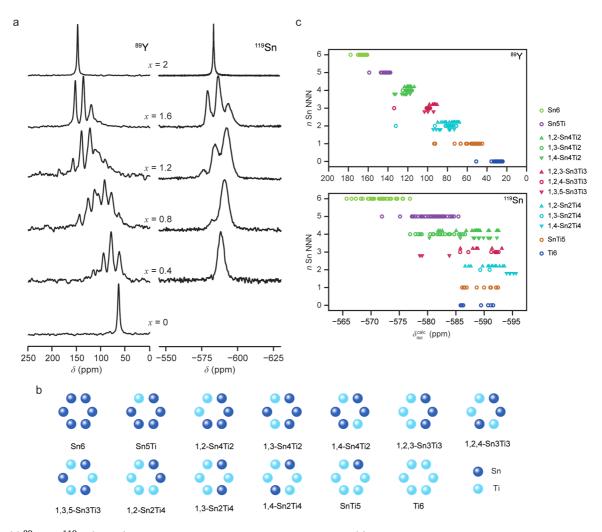

FIGURE 3. (a) ⁸⁹Y and ¹¹⁹Sn (14.1 T) MAS NMR spectra of $Y_2Ti_{2-x}Sn_xO_7$ pyrochlores. (b) Possible arrangements of Sn/Ti on the six NNN B sites that surround both A and B cation sites. (c) Plots showing the calculated ⁸⁹Y and ¹¹⁹Sn isotropic chemical shifts as a function of the number of Sn NNN. Reprinted with permission from ref 16. Copyright 2009 American Chemical Society. shift as Sn is substituted onto the NNN B sites, a change of similar magnitude to the spacing of the spectral resonances. For any *n* Sn NNN, however, a similar range of chemical shifts is predicted for the different spatial arrangements of Sn/Ti. This suggests that the different ⁸⁹Y resonances resolved experimentally result from different n Sn NNN, and that the broadening, splittings and shoulders present reflect the different spatial arrangements of these neighbors and longer-range structural changes. In contrast, a small change in the average ¹¹⁹Sn chemical shift is observed with the introduction of Ti into Sn-rich NNN environments;¹⁵ however, this change reduces as the Ti content of the surrounding B sites increases, resulting in overlap of the calculated chemical shifts. This agrees with the experimental NMR spectra in Figure 3a, where broad, overlapped resonances are observed. Further DFT calculations reveal two opposing contributions to the ¹¹⁹Sn chemical shift; an upfield shift produced by the substitution of Ti into the NNN environment, and a concomitant downfield shift arising from the change in unit cell size upon substitution of the smaller cation.¹⁵ Although these contributions are also present for ⁸⁹Y, the former is considerably larger than the latter, resulting in well-resolved spectral resonances.¹⁶

Although DFT provides a general understanding of the spectral appearance (and a tentative assignment for ⁸⁹Y), there remains some need for caution. Owing to the range of calculated shifts for each environment, some resonances with similar shifts are assigned to differing NNN environments, and others with very different shifts are attributed to the same NNN environment. Confidence in the assignment can be improved by considering an additional probe of the local environment, for example, the span of the shielding

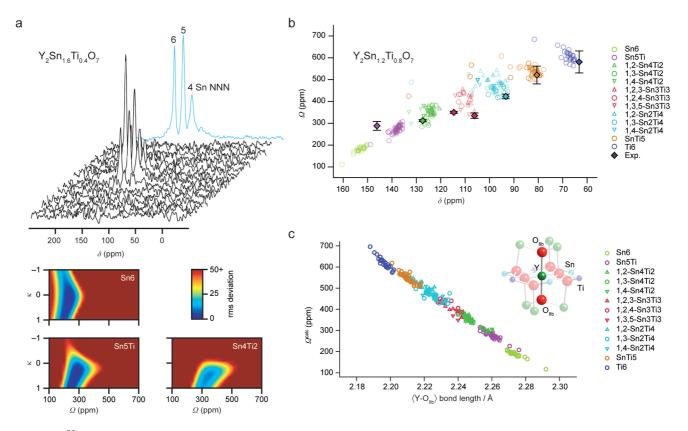

FIGURE 4. (a) ⁸⁹Y (14.1 T) CSA-amplified PASS spectrum of $Y_2Ti_{0.4}Sn_{1.6}O_7$, acquired in a total experiment time of ~12.5 days, with contour plots showing the rms deviation from analytical fitting of each sideband manifold for varying Ω and κ . (b) Plot showing the calculated ⁸⁹Y shielding parameters (isotropic shift and span) for disordered pyrochlore model structures. anisotropy (Ω). Although a sensitive probe of structure, the shielding anisotropy is removed under the rapid MAS used to improve spectral resolution and sensitivity. Information can be obtained from slow MAS spectra, but for systems containing multiple environments, overlapping sideband manifolds can lead to difficulties in extracting accurate information. A number of two-dimensional methods have been proposed to overcome this, where fast MAS affords high resolution, but the anisotropic interaction is "recoupled" in a second dimension, producing a sideband manifold that can be analyzed. "Amplification" of the interaction, enabling the accurate measurement of smaller anisotropies (e.g., the CSA-amplified PASS experiment), is also possible.^{17,18} These approaches, originally implemented for ¹³C and ³¹P, have recently been extended to ⁸⁹Y, with appropriate modification of the experimental pulse sequence and the fitting procedures employed.19

Figure 4a shows an ⁸⁹Y CSA-amplified PASS spectrum of $Y_2Ti_{0.4}Sn_{1.6}O_7$,¹⁹ acquired in a total experimental time of ~12.5 days (highlighting the challenges of ⁸⁹Y NMR for disordered materials). For each resonance, values of Ω ,

contour plots, also in Figure 4a show the root-mean-square (rms) error associated with fits for varying values of Ω (and κ), and provide information on the "best fit" and associated confidence limits. The experimentally measured values of Ω can be compared to those calculated as described above.¹⁹ Figure 4b summarizes the variation in both the calculated isotropic and anisotropic shielding with the NNN environment, with a significant change in Ω (of ~80 ppm) observed as Sn/Ti is substituted onto the surrounding B sites. Figure 4b also plots experimental measurements (in this case for $Y_2Ti_{0.8}Sn_{1.2}O_7$), demonstrating that spectral assignment is considerably eased by considering two parameters simultaneously. With the assignment complete, insight into the distribution of Sn/Ti is gained by comparing the relative spectral intensities to the probability of finding a particular number of Sn/Ti NNN.^{15,19} The best match indicates randomly distributed Sn/Ti, with no evidence for clustering or ordering of the B-site cations. Furthermore, it is possible to correlate changes in Ω directly to the detailed local structure, as shown in Figure 4c, where the dependence upon the

(and κ) can be measured from the sideband manifold. The

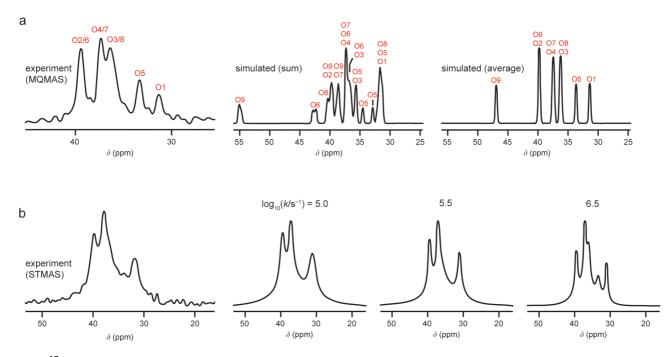

FIGURE 5. ¹⁷O (9.4 T) isotropic (a) MQMAS and (b) STMAS spectra of clinohumite (4Mg₂SiO₄.Mg(OH)₂). Also shown in panel (a) are spectra resulting from the summation and averaging of simulated ¹⁷O isotropic spectra calculated for different possible arrangements of the hydroxyl groups. In panel (b), STMAS spectra are simulated using the calculated NMR parameters for the different structural models, and an additional line broadening determined using a simple model for motional broadening. (average) $Y-O_{8b}$ bond distance is plotted. A strong, almost linear, correlation (of ca. -109 ppm/0.02 Å) is observed, enabling the estimation of such distances for the differing environments in disordered $Y_2Ti_{2-x}Sn_xO_7$ pyrochlores.¹⁹

The combination of high-resolution NMR and GIPAW DFT calculations enables detailed information to be obtained about the nature of the B-site cation disorder in pyrochlores and provides detailed insight into the local geometry, information that is difficult to obtain from diffraction-based methods. Such an approach offers great potential for future application in this area, particularly for understanding the more complex ceramic phases of interest in waste encapsulation.

Disorder in Hydrous Silicates. The Earth's mantle contains an estimated 200–500 ppm hydrogen (often termed "water"),²⁰ although little is known about its exact mechanism of incorporation into the structures of the nominally anhydrous inner-Earth minerals. As the structural chemistry of low levels of hydrogen is difficult to determine by diffraction, NMR spectroscopy offers a useful alternative approach. The dominant mineral in the Earth's upper mantle is olivine (α -Mg_{1.8}Fe_{0.2}SiO₄). The minerals in the hydroxyl-humite group, *n*Mg₂SiO₄·Mg(OH)₂, have been proposed as models of the defect sites that occur when water is incorporated into olivine, as their structures can be viewed as consisting of *n* layers of forsterite (the Mg end-member of the α -Mg_{2-x}Fe_xSiO₄ solid solution) alternating with layers of $Mg(OH)_2$.²¹ Diffraction studies of clinohumite (n = 4) have revealed two distinct H sites (H1 and H2) for each hydroxyl group, each with 50% occupancy, indicating the disordered nature of the minerals.²¹

A high-resolution isotropic ¹⁷O (9.4 T) NMR spectrum of clinohumite, obtained from a MQMAS experiment, is shown in Figure 5a.²² Five resonances are resolved, although their relative intensities (2:2:2:1:1) suggest that all eight silicate oxygens are observed. (Note the hydroxyl oxygen (O9) is not observed at this magnetic field strength and MAS rate, owing to its large C_0). A tentative assignment of the spectrum can be made by comparison to spectra of chondrodite and forsterite (not shown).²² Figure 5a also shows an ¹⁷O isotropic spectrum, simulated using NMR parameters from GIPAW DFT calculations.²³ These were carried out for a series of model structures, with differing positions of the hydroxyl groups within the unit cell, and the results from each calculation summed together, to model the disordered mineral. There is poor agreement between calculation and experiment, with many more resonances observed in the calculated spectra, indicating that the NMR parameters are sensitive to the exact hydroxyl positions. However, if the calculated NMR parameters of each oxygen species in each of the structural models are averaged, the simulated spectrum (also shown in Figure 5a) agrees much better with experiment,²³ suggesting that there is dynamic, rather than

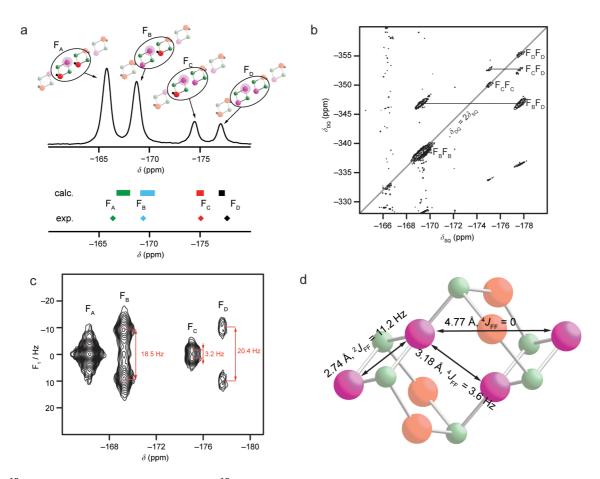

FIGURE 6. ¹⁹F (a) MAS, (b) through-space DQMAS, and (c) ¹⁹F *J*-resolved NMR spectra of (54%) fluorinated clinohumite ($4Mg_2SiO_4 \cdot Mg(OH,F)_2$). In panel (a), calculated chemical for model structures with varying amounts and positions of F substitution are shown. (d) An expanded view of the structure of fully fluorinated clinohumite, showing distances between adjacent fluorine sites and calculated *J* couplings. Reprinted with permission from ref 29. Copyright 2010 American Chemical Society.

static, disorder of the hydroxyl groups, resulting in a full averaging of the NMR parameters. The simulated spectrum also shows that the previous assignment of O7 and O3 must be reversed.

The presence of dynamics in clinohumite is supported by the isotopic spectrum obtained from STMAS²⁴ (an alternative to MQMAS for removing quadrupolar broadening), where a significant broadening of some of the resonances is observed (Figure 5b).²³ STMAS spectra are sensitive to microsecond time scale dynamics,²⁵ owing to the use of satellite transitions within the experiment. The broadening observed depends upon the change in the quadrupolar interaction during the motional process and the time scale of this change. As the first of these can be determined using the calculations described above (if the magnitude, asymmetry, and relative orientation of the quadrupole tensor for each oxygen species in all possible model structures are known), the latter can, therefore, also be established (using a simple model for motional broadening²⁶). Figure 5b also shows ¹⁷O STMAS isotropic spectra simulated using the calculated NMR parameters for different motional rates.²³ Despite the simplicity of the models used, good agreement between experiment and calculation is obtained when $\log_{10} k = 5.5$ (i.e., $k \approx 3.2 \times 10^5 \text{ s}^{-1}$). This measurement is supported by ²H MAS NMR (not shown) of deuterated dinohumite, where the temperature-dependent line width allows an activation energy of 40 ± 4 kJ mol⁻¹ for H1/H2 exchange to be determined.²⁷

Many natural humite minerals exist with significant levels of fluorine substitution. Diffraction studies of fluorine-rich clinohumite show a single hydrogen site arising from the formation of OH···F hydrogen bonds, which inhibits H1/H2 exchange. Although this indicates some degree of local order, the positions of F⁻ and OH⁻ are not distinguished by diffraction.²⁸ However, a ¹⁹F MAS NMR spectrum of (54%) fluorinated clinohumite, shown in Figure 6a, reveals four distinct F environments, indicating a more disordered material than previously thought.²⁹ GIPAW DFT calculations (using supercells with differing levels and positions of F substitution) reveal four ranges of chemical shifts, in agreement with the experimental resonance positions, as shown in Figure 6a.²⁹ The calculations reveal that the ¹⁹F chemical shift is sensitive to the nature of the nearby anions (i.e., F^- or OH^-); the two closest are at 2.7 and 3.2 Å. The assignment of the spectral resonances can be confirmed using two-dimensional correlation spectra, for example, as shown in Figure 6b, where pairs of peaks either side of the diagonal indicate two F in close spatial proximity (as transfer is through the dipolar coupling).²⁹

Similar two-dimensional spectra, using transfer via the J coupling, can also be obtained. The magnitude of these J couplings can be determined from the line shapes in the J-resolved spectrum, as shown in Figure 6c.²⁹ No couplings are observed for F_A (surrounded by OH^- groups), while couplings of \sim 3–4 and \sim 18–19 Hz are observed for F_B and F_C, respectively. For F_D, both small and larger couplings are apparent. There are two possible "through-bond" pathways between adjacent F species (F-Mg-F' and F-Mg-O-Mg-F'), perhaps accounting for two different couplings; however, the F-Mg interaction is expected to be mostly ionic in character. Previously "through-space" J couplings between F atoms in close spatial proximity but not formally chemically bonded have been observed previously in organofluorine compounds.³⁰ This interaction is thought to be via direct overlap of fluorine lone pairs. The distance between adjacent fluorines in clinohumite is similar to the sum of the ionic radii suggesting that there may be a significant through-space component to the J coupling. Some insight can be obtained from calculations carried out for a $3 \times 1 \times 1$ supercell of fully fluorinated clinohumite, where couplings between adjacent $^{19}\mathrm{F}\,\mathrm{of}\,{\sim}3.5$ and 12 Hz are found, as shown in Figure 6d.²⁹Although perfect agreement between experiment and calculation is impossible owing to the simplified nature of the model, the calculated values agree qualitatively with experiment. It is also noticeable that, as shown in Figure 6d, there are two possible interactions between F with similar "through-bond" (i.e., ⁴J_{FF}) pathways but differing distances (3.18 and 4.77 Å, respectively). However, significant J couplings are only calculated between the two closest F species, confirming the through-space character of the interaction.

Once assigned, the relative intensities of the ¹⁹F resonances provide insight into the anion disorder in fluorinated humites. The NMR spectra reveal that although the formation of $OH \cdots F$ hydrogen bonds appears favorable, these minerals are significantly disordered, with F-rich and OH-rich regions present. Only the H1 site is occupied when hydrogen

bonds are formed, whereas H1 and H2 are both occupied (and in dynamic exchange) in the OH-rich regions.²⁹

Summary

Recent advances enabling accurate and efficient determination of NMR parameters in periodic systems have revolutionized the application of DFT calculations in solid-state NMR spectroscopy. Calculations can be used to assign high-resolution spectra and, for more complex materials, such as those discussed here, aid spectral interpretation and provide insight into the atomic-scale structure and disorder. The increasing availability of large computing facilities is enabling the study of larger, more complicated systems, while developments in processor technology continue to increase calculation efficiency. These improvements will ease the investigation of disordered materials in the future. Anticipated software developments, for example, the more widespread incorporation of dispersion forces, relativistic effects and paramagnetic interactions into available codes, will improve the scope and accuracy of calculations. In general, NMR spectroscopy, with its sensitivity to local structure, offers a complementary tool to diffraction for obtaining a complete picture of solid-state structures. DFT calculations connect these techniques, enabling confirmation, adaption or refinement of structural models, and providing more detailed local information. This combined approach is becoming more widespread and rapid progress is anticipated in the coming years, with the ultimate goal of understanding structure-property relationships in solids, enabling materials to be "designed" for specific applications.

BIOGRAPHICAL INFORMATION

Sharon E. Ashbrook (b. 1975) graduated with an MChem from Hertford College, Oxford, in 1997, before studying for her DPhil (2001) in Oxford in the group of Professor Stephen Wimperis. In 2003, she was awarded a Royal Society Dorothy Hodgkin Fellowship, which she held at the Department of Earth Sciences, Cambridge and, subsequently, in St. Andrews. She also held the Charles and Katherine Darwin Research Fellowship at Darwin College, Cambridge. From 2005, she was appointed as an RCUK Academic Fellow in the School of Chemistry at the University of St. Andrews, and was promoted to Reader in 2009. Her research focuses on the application of multinuclear solid-state NMR techniques, and their combination with first-principles DFT calculations, to investigate structure, disorder and dynamics in inorganic solids, and she has published ~ 100 papers in this area. She was awarded the RSC Harrison Prize in 2004, the RSC Marlow Award for Physical Chemistry in 2011, and the RSE Makdougall Brisbane Medal for Physical Science in 2012.

Daniel M. Dawson (b. 1987) obtained an MChem from the University of Liverpool in 2009 and is currently studying for a Ph.D. in the group of Sharon Ashbrook. His work is focused on understanding microporous materials through a combination of solid-state NMR spectroscopy and DFT calculations.
