

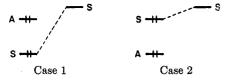

Figure 9. Some model arrangements of orbital lobes and intervening  $\sigma$  bonds. The symbols below each figure give the level ordering obtained for model compounds.

two nitrogen lone pairs. Clearly the symmetric position is more stabilized in case 2, the result of through-bond

coupling.

Consider also the likelihood of carrying out an oxidative cyclization of the type shown below. If one wants to form a bond between the two nitrogens one

clearly should seek out a situation with strong direct interaction. In that case the two electrons will be removed from an A orbital, decreasing N-N antibonding and correspondingly increasing bonding.

### Summary

This paper has been concerned with a necessary addendum to the chemist's view of a molecule. Localized orbitals or groups of orbitals may interact with each other directly, through space, or indirectly, through other bonds in the molecule. The latter interaction may operate over surprisingly long distances. The primary effects of such interaction and their most direct measure are through ionization potentials and electronic spectra. Stability and reactivity are affected as well. The analysis of these interactions is most conveniently made through the language of perturbation theory; here, as everywhere, the role of symmetry is paramount.<sup>20</sup>

It is a pleasure to acknowledge the aid of able coworkers, prime among them Akira Imamura and Rolf Gleiter, the congenial interaction with Edgar Heilbronner, the inspiration of the chemical literature, the pleasant environment of Cornell, and the generous sponsorship of the National Science Foundation, the National Institutes of Health, the Chevron Research Corporation, and the Sloan Foundation.

# Regiospecific and Stereospecific Introduction of Azide Functions into Organic Molecules

ALFRED HASSNER

Department of Chemistry, University of Colorado, Boulder, Colorado 80302

Received August 18, 1969

The synthetic chemist has at his disposal a variety of methods for the stereospecific introduction of oxygen functions into the carbon skeleton, e.g., via opening of epoxides, hydroboration of olefins, or reduction of ketones. Until recently the same has not been true for functional groups containing nitrogen.

Since halogens, X-X, usually add stereoselectively to multiple bonds, we envisaged a route in which X-N moieties would add across the carbon-carbon double bond. Indeed, when we explored iodine isocyanate (INCO) additions to alkenes, we found a useful route for the stereospecific synthesis of carbamates, aziridines, and oxazolidones, as well as cis or trans 2-amino alcohols.<sup>1</sup>

(1) (a) A. Hassner and C. H. Heathcock, Tetrahedron Lett., 393 (1963); (b) C. H. Heathcock and A. Hassner, Angew. Chem., 75, 344 1963); (c) A. Hassner and C. H. Heathcock, Tetrahedron, 20, 1037 (1964); (d) A. Hassner, M. E. Lorber, and C. H. Heathcock, J. Org. Chem., 32, 540 (1967).

Organic azides have been of recent interest in photochemistry,2 in cycloadditions,3 and as precursors to amine functions. Furthermore the ambident and amphoteric character of the azide function is indicated by its participation in electrophilic as well as in nucleophilic reactions. Since stereospecific methods for the introduction of an azide function were not well known, we decided to determine the feasibility of X-N<sub>3</sub> additions to olefins.

In studying the addition of an unsymmetrical reagent X-Y to an unsymmetrical olefin RCH=CHR', we were soon faced with the problem of establishing orientation as well as stereochemistry in the adduct. The Markovnikov rule is often inapplicable, and consequently we adopted the general term regioselectivity (latin, regio = direction) to describe directional selectivity in bond breaking or making, regardless of the mechanism involved.4 Thus, the exclusive formation of 2 in the IN<sub>3</sub> addition to tert-butylethylene (1) is described as I-tert-butyl regiospecific.

$$(CH_3)_3CCH=CH_2 + IN_3 \longrightarrow (CH_3)_3CCHCH_2N_3$$

$$\begin{matrix} & \downarrow & \downarrow \\ & \downarrow & \downarrow \\ & & \downarrow & \downarrow \\ & & \downarrow & 2 \end{matrix}$$

Pure iodine azide (IN<sub>3</sub>) is explosive, and its reported<sup>5</sup> synthesis from the highly explosive AgN<sub>3</sub> and I<sub>2</sub> was not only undesirable but led to a mixture of products on reaction with olefins. This problem was solved by devising special methods for the preparation of IN<sub>3</sub>, BrN<sub>3</sub>, and ClN<sub>3</sub>. We succeeded in preparing iodine azide in solution in up to 0.25 M quantities by the reaction

$$ICl + NaN_3 \longrightarrow IN_3 + NaCl$$

in polar organic solvents.6 The other halogen azides were formed in a two-phase system (water-pentane) by the interaction of Br<sub>2</sub> or Cl<sub>2</sub> with NaN<sub>3</sub> in the presence of acid.7

#### **Iodine Azide Additions**

Stereochemical Aspects. When olefins were added at -10 to 25° to a solution of 1 equiv of IN<sub>3</sub> in acetonitrile, 1:1 adducts were formed in excellent yield. The addition appeared to be stereospecific, with cyclohexene (8) furnishing exclusively trans-2-azidocyclohexyl iodide (9), while cis- and trans-2-butene yielded the three and erythre adducts, respectively.6 This stereospecificity is noteworthy in view of Minisci's findings that the elements of ClN<sub>3</sub> add nonstereospecifically to cyclohexene.8

Although isomeric cis and trans olefins gave different

adducts, it was necessary to show whether syn or anti addition had taken place. To this end, and with the expectation of finding a route to vinyl azides which we hoped to use for photolytic studies, we attempted to eliminate HI from the β-iodoalkyl azides. Potassium tert-butoxide and 1,4-diazabicyclo [2.2.2] octane (DABCO) proved to be the reagents of choice, and as anticipated the elimination proceeded in an anti fashion. In open-chain systems the propensity for anti coplanar elimination of HI overcomes any unfavorable conformational effects; therefore elimination occurs from conformation 5 rather than from 4, giving rise to cis vinyl azides 6 from trans alkenes 3 and to trans vinyl azides starting with cis olefins.9a

In most open-chain systems the HI elimination is regiospecific, leading to vinyl azides rather than to allyl azides. This reflects a lower energy transition state, leading to the more substituted olefin. We took advantage of this fact to develop, by photolysis of these vinyl azides, a general synthesis of the 1-azirine ring system 7.9b

Consistent with the requirements for anti-coplanar HI elimination is the fact that trans iodo azide 9 leads to allyl azide 10 rather than to a vinyl azide, the formation of which would require a syn elimination of HI.

In eight-membered rings both syn and anti elimination becomes possible, leading to a trans or a cis olefin, respectively. When we treated the IN<sub>3</sub> adduct 12 from cis-cyclooctene (11) with base we obtained vinyl azide 13 which was stable at room temperature but converted to azirine 14 on photolysis. The thermal stability of 13 and its nmr spectrum (vinyl H at  $\tau$  4.7) render a trans-azidocyclooctene structure unlikely. In

(9) (a) A. Hassner and F. W. Fowler, J. Org. Chem., 33, 2686 (1968); (b) A. Hassner and F. W. Fowler, J. Amer. Chem. Soc., 90, 2869 (1968).

all vinyl azides, the proton trans to the azido group is significantly shielded in the nmr relative to the cis isomer (see Chart I).9a This is also true when the cis-R substituent is phenyl. The nmr spectrum of 13 fits a cis-dialkylvinyl azide structure; hence syn elimination of HI had taken place in the cyclooctane system. 10

Chart I Olefinic Proton Absorption in Vinyl Azides

Proof for anti addition of IN<sub>3</sub> is also provided by the LiAlH<sub>4</sub> reduction of the adducts. This reaction was studied in detail and found to be a highly stereospecific and useful method of aziridine synthesis. 11a Thus, erythro-2-azido-3-iodobutane (16a), the product of IN<sub>3</sub> addition to trans-2-butene, gives only trans-2,3dimethylaziridine (17a), whereas the threo isomer 16b (from cis-2-butene) furnished cis-dimethylaziridine (17b).

The reductive ring closure of 9 or 12 to fused aziridines (e.g., 15) in essentially quantitative yield is a further indication of the trans stereochemistry in these IN<sub>3</sub> adducts.

Based on these facts, we suggested that the IN<sub>3</sub> addition involved electrophilic attack on the olefin with formation of a three-membered-ring iodonium ion, e.g., 19. It may be of interest to comment here on the reason for the common preponderance of anti addition over syn addition of halogens or halogenoids to olefins,

(10) This is consistent with recent findings by J. Sicher, Collect.

Czech. Chem. Commun., 32, 2104, 2122 (1967).
(11) (a) A. Hassner, G. J. Matthews, and F. W. Fowler, J. Amer. Chem. Soc., 91, 5046 (1969); (b) R. B. Woodward and R. Hoffmann, Angew. Chem., Intern. Ed. Engl., 8, 781 (1969).

especially since a concerted collapse of type

$$\begin{smallmatrix} C & X \\ \parallel & \downarrow \\ C & Y \end{smallmatrix} \longrightarrow \begin{smallmatrix} C - X \\ \mid & \downarrow \\ C - Y \end{smallmatrix}$$

appears most reasonable. However, orbital symmetry considerations<sup>11b</sup> suggest that concerted nonphotochemical syn addition  $(2_s + 2_s)$  of X-Y to olefins is forbidden. whereas anti addition (2<sub>s</sub> + 2<sub>a</sub>) is allowed. From a simpler point of view it becomes clear that concerted syn addition of X-Y to a double bond should be most favorable when X-Y is not easily polarized and its bond length approximates the C=C bond length. For instance, syn hydroboration of olefins can be explained by approach of the empty p orbital of boron to the  $\pi$  electrons of the double bond (probably complex formation), necessitating a parallel alignment of H in a manner similar to that indicated below. Since the B-H bond length corresponds within 0.2 Å to the C=C bond length, syn collapse can occur. This is not

9026 
$$H-B < C-C$$

possible for IN<sub>3</sub> additions due to the large radius of iodine. If polarization of X-Y is facile, an ionic addition will be initiated by the approach of the electrophilic terminus of the reagent to the  $\pi$  cloud of the olefin. The most effective solvation of the transition state takes place when the positive end of the X-Y dipole approaches the  $\pi$ -electron cloud at right angles to the plane of the olefin, so that the negative portion of the X-Y dipole can be stabilized by solvation (see 18).

Once a three-membered-ring intermediate (19) is formed it follows that, unless equilibration to a free carbonium ion takes place, opening will preferentially occur from the back side resulting in anti addition of X-Y. It is possible that, unlike in bromination of olefins, the rate-determining step in IN<sub>3</sub> additions involves opening of the cyclic ion 19 which is formed in a fast equilibrium step.

In conformity with the intermediacy of 21 is the IN<sub>3</sub> addition to 2-cholestene (20) which afforded the trans-diaxial adduct  $22.^6$  This can be explained by ionic IN<sub>3</sub> attack on the  $\pi$  cloud of the olefin from the less hindered  $\alpha$  side of the steroid. Stereoelectronic control favors diazial opening of the iodonium ion in a chair conformation. Prior to these studies the major evidence for three-membered-ring iodonium ions had come from solvolysis reactions. Recently Olah and coworkers also provided spectral evidence for the presence of halonium ions in solution.

With 1-hexene (23a) or styrene (23b) the addition proceeded regiospecifically to yield the secondary azide 24a or 24b, respectively. This indicated to us that the reaction path involved either the free carbonium

ion 27 or a three-membered-ring iodonium ion that is opened regiospecifically. A choice between these two intermediates might be possible on the basis of stereochemical observations in the IN<sub>3</sub> addition to  $\beta$ -substituted styrenes. These additions proceed stereospecifically anti, suggesting the involvement of 26. However, these findings do not exclude the intermediacy of a benzylic cation in which there was a barrier to rotation (i.e., from 27 to 28 or corresponding trigonal ions). To minimize nonbonded interactions during the rotation of 27 to 28 and to test whether conversion of 26 to a benzylic cation occurs before opening of the three-membered ring by  $N_3$ , we chose as a stereochemical substrate an olefin with the smallest  $\beta$  substituent, e.g.,  $cis-\beta$ -deuteriostyrene (25, R = H, R' = D). When  $IN_3$  was added to this olefin, 29a was obtained which, on anti elimination of HI, gave exclusively  $\alpha$ -azido-trans- $\beta$ -

Regiochemical Aspects. A good probe for the mechanism is often the regiochemistry of a reaction. The data discussed so far for the IN<sub>3</sub> addition to terminal olefins are consistent with the intermediacy of a three-membered ring ion, 31, opening of which proceeds via the lower energy transition state (32 rather than 34 when R can stabilize an incipient positive charge).

$$\begin{array}{c} N_3 \\ \downarrow \\ RCH - CH_2 \end{array} \leftarrow \begin{array}{c} \delta_+ \\ RCH - CH_2 \end{array} \leftarrow \begin{array}{c} RCH - CH_2 \\ \downarrow \\ 1 \end{array} \rightarrow \begin{array}{c} RCH - CH_2 \end{array} \rightarrow \begin{array}{c} RCH - CH_2 \\ \downarrow \\ 1 \end{array} \rightarrow \begin{array}{c} N_3 \\ \uparrow \\ RCH - CH_2 \end{array} \rightarrow \begin{array}{c} N_3 \\ \downarrow \\ 1 \end{array} \rightarrow \begin{array}{c} N_3 \\ \downarrow$$

If the above considerations are valid, then an electron-withdrawing R group in 31 should destabilize transition state 32 relative to 34. Indeed, we were able to show that ester 36a leads to a 20:80 mixture of 35:33 ( $R = CO_2C_2H_5$ ) and 36b gave exclusively the I-carbonyl regiospecific  $1N_3$  adduct 35.6 In the case of unsaturated ketones, a mixture of regioisomers was formed when  $R = CH_3$  (37a) but only one isomer resulted from chalcone (37b). These results indicate that there is a delicate balance involved in opening of iodonium ion intermediates adjacent to a carbonyl

group (31, R = R'C=0). In addition to the electronic factors mentioned above, one must consider the high propensity for nucleophilic displacements at the  $\alpha$ carbon (more so for ketones than for esters).

A further test is provided by the behavior of methylenecycloalkanes. In both 38 and 39, electronic control (stabilization of a transition state of type 32 by the electron-donating ring residues) prevails with exclusive formation of 40 and 41, respectively.6 At this point, attension is called to the remarkable regioselectivity of the IN<sub>3</sub> reagent. By contrast, INCO addition to

$$\begin{array}{cccc}
C = CH_2 & & & & & & \\
C + CH_2 & & & & & & \\
(CH_2)_n & & & & & & \\
38, n = 3 & & & & & & \\
39, n = 5 & & & & & & \\
\end{array}$$

methylenecyclohexane (39) or to 1-hexene (23a) gives a mixture of regioisomers, 17 and opening of the aziridium ion 42 also leads to regioisomeric halo amines depending on the nature of R.18

We predicted one exception among the methylenecycloalkanes with respect to the regiochemistry of IN<sub>3</sub> addition, namely, 43, because transition state 44 (cyclopropylcarbinyl cation) is expected to be stabilized with respect to 46 (cyclopropyl cation). Indeed, we found that methylenecyclopropane (43) gave the IN<sub>3</sub> adduct 45 characterized by its mass spectrum ( $C_3H_4I^+$  at m/e 167) and by HI elimination to a vinyl azide. 19 No elimination occurred on base treatment of 40 or 41.

Next we tested neopentyl system 1 to determine whether the iodonium ion 31 ( $R = tert-C_4H_9$ ) is opened with methyl rearrangement. We found that no methyl migration had occurred and that the IN<sub>3</sub> addition product 2 was of opposite regiochemistry from 33 (derived of 1-hexene).9 It is obvious that the large tert-butyl group exerts a strong steric effect in the opening of the three-membered-ring iodonium ion 31. Similar effects have been observed in the opening of three-membered-ring episulfonium ions.<sup>20</sup>

(19) A. Hassner, G. J. Matthews, and A. B. Levy, University of Colorado, unpublished results.

Even an isopropyl group can cause considerable hindrance in the opening of iodonium ions, and a particularly high degree of regioselectivity is noticed when the electronic effects of the substituents are balanced, i.e., 47 gave a mixture of IN3 adducts 49 and 50 whereas 48 gave solely the I-isopropyl regiospecific adduct (51).9a

$$(CH_3)_2CHCH = CHR$$

$$47, R = H$$

$$48, R = CH_3$$

$$I \qquad N_3$$

$$47 \longrightarrow (CH_3)_2CHCH - CH_2N_3 + (CH_3)_2CHCH - CH_2I$$

$$49 \qquad 50$$

$$I \qquad N_3$$

$$48 \longrightarrow (CH_3)_2CHCH - CHCH_3$$

On the other hand, any steric effects appear compensated by electronic factors in the formation of 53 from 2,6-dimethylstyrene (52).19

Rearrangements. The data presented so far do not necessarily imply that a three-membered iodonium ion intermediate persists until attacked by a nucleophile and is never opened by neighboring group participation. In some systems the propensity for rearrangement is so large (lower transition state energies) that these processes do indeed take place. Examples are provided by methylenenorbornene (54) and benzonorbornadiene (56) which lead to rearranged products 55 and 57, respectively, in almost quantitative yield.21

Unlike tert-butylethylene (1) in which no rearrangement was observed, tritylethylene (58) reacts with IN<sub>3</sub> to form exclusively 59, the product of phenyl migration.21 This is due to release of steric crowding as well as to the superior ability of the phenyl group to participate in the stabilization of a neighboring charge.

Dehydrohalogenation of **59** by means of *tert*-BuO<sup>-</sup>K<sup>+</sup> in DMSO led to formation of 60. We were able to show that azide 62 was the precurser of 60. The reaction

sequence involves an allyl azide rearrangement from 61 to 62, which is presumably intramolecular.<sup>22</sup> One equivalent of  $N_2$  was evolved during the conversion.

3,3-Diphenyl propene also adds  $\mathrm{IN}_3$  with complete rearrangement.

Additions to Triple Bonds. We considered it interesting to ascertain whether unsaturated three-membered iodonium ions (e.g., 66) are capable of existence. To this end we investigated the addition of IN<sub>3</sub> to acetylenes<sup>23</sup> and soon discovered that 1-phenylpropyne (63) reacted with IN<sub>3</sub> in the opposite regiochemical sense than on acid-catalyzed hydration (compare 65 to 67).<sup>24</sup> Structure proof for 67 was furnished by its mass spectrum and by zinc reduction in aqueous acetic acid leading to phenylacetone exclusively and in high yield. It was shown on model systems that such reductions provide a marker for the position of the azide function in vinyl azides.

A rational explanation is that hydration involves protonation to a vinyl, benzylic cation, 64, whereas IN<sub>3</sub> addition proceeds *via* the cyclic ion 66. The opening of 66 by azide ions to yield 67 first appears regiochemically unusual. On closer inspection it becomes apparent that two cyclic ions 66 can exist, one in which the  $\pi$  orbitals of the double bond are parallel and overlapping with those of the benzene ring (see 68) and one in which

there is orbital overlap between the positively charged three-membered ring and the benzene ring (and hence the  $\pi$  orbitals of the aromatic ring are perpendicular to those of the olefinic double bond).

In the latter case as well as in the case of the open carbonium ion **64**, the positive charge at the  $\alpha$  carbon is stabilized by delocalization into the benzene ring and the nucleophile attacks at this position. In **68**, on the other hand, the aromatic ring cannot contribute by resonance to stabilization of the iodonium ion and, since  $CH_3$  can stabilize an incipient positive charge better by an inductive effect than  $C_6H_5$ , opening by the nucleophile occurs preferentially at the carbon  $\alpha$  to methyl.

IN<sub>3</sub> obviously reacts by heterolytic cleavage during attack on the multiple bond. This is particularly noticeable in its behavior with isocyanides in which the carbon is known to be nucleophilic. Thus phenyl isocyanide (69) leads to 5-iodotetrazole 70 in high yield, undoubtedly by the reaction sequence shown below.<sup>6</sup>

### Bromine Azide. Ionic vs. Free-Radical Additions

Since the electronegativity of Br and Cl is higher than that of I and probably also higher than that of the  $N_3$  radical, we expected  $BrN_3$  and/or  $ClN_3$  to be capable of free-radical behavior toward olefins. It was gratifying to see these predictions come true. Thus in

the reaction of styrene with BrN<sub>3</sub> the regiochemistry of the products depended dramatically upon the polarity of the solvent.<sup>7</sup> In nitromethane the adduct was 72,

resulting from ionic electrophilic attack of BrN<sub>3</sub> on the olefin, whereas in pentane even in the absence of free-radical initiators the reaction proceeded through attack of N<sub>3</sub> on the double bond to give exclusively the opposite regioisomer 75. The structure of the ionic and free radical BrN<sub>3</sub> adducts was obvious from dehydrobromination to 73 and 76, respectively.

Using solvents of intermediate polarity such as methylene chloride or acetonitrile variable mixtures of the regioisomers 72 and 75 were obtained. The freeradical mechanism of addition was substantiated by the fact that the proportion of the ionic adduct 72 was increased in the dark or in the presence of oxygen (a free-radical inhibitor), whereas the proportion of 75 was increased in the presence of light or peroxides.

We found the free-radical addition to BrN<sub>3</sub> to be nonstereospecific; for instance, cyclohexene gave a mixture of cis and trans adducts. Similarly, 2-cholestene (77) reacted with BrN<sub>3</sub> under free-radical conditions to give two stereoisomers 78 and 79. By contrast the ionic addition led solely to the diaxial adduct 80 ( $W_{1/2}$ ) at C-2 and C-3 = 6 and 8 Hz), due to stereoelectronic influences in the opening of the three-membered-ring bromonium ion in the chair conformation of the cyclohexane ring.<sup>7</sup> The structures of isomers **78–80** were deduced in part from the chemical shift values of the C-19 methyl group and the half-width of the protons at C-2 and C<sub>3</sub> ( $W_{1/2}$  < 12 Hz for equatorial H's and >15 Hz for axial H's).25

 $C_8$ 

The ionic addition of BrN<sub>3</sub> occurs stereospecifically trans with alkyl-substituted olefins such as cis- and trans-2-butene. With cis- $\beta$ -deuteriostyrene, however, we found a mixture of adducts as evidenced by the formation of a mixture of  $\alpha$ -azido- $\beta$ -deuteriostyrenes (81) and 82) on HBr elimination. 15 These results indicated that a three-membered-ring bromonium ion, 83, is stable when flanked by alkyl groups, but that even one

phenyl substituent is sufficient to cause equilibration of 84 to a benzyl cation 85. As was shown above the corresponding phenyl-substituted iodonium ion 86 is

opened by azide ions before it can equilibrate to the carbonium ion 87.

Further evidence that a three-membered-ring bromonium ion (e.g., 83 or 84) is slightly less stable, and consequently less discriminating in its reactions than the corresponding iodonium ion, is obtained from the reaction of BrN<sub>3</sub> with terminal olefins 23a and 1. The product ratios (88/89 and 90/91) were determined by gc and by nmr integration of the corresponding vinyl azide formed by potassium tert-butoxide induced elimination of HBr.

That HBr elimination occurs stereospecifically anti from bromine azide adducts, in the same way as HI elimination takes place from iodine azide adducts, is shown by the fact that the mixture of cis and trans adducts 93 and 94 obtained from dihydropyran 92 yields a mixture of unreacted 94 and vinyl azide 95.19

## **Chlorine Azide Additions**

Recently Poutsma was able to show that chlorination of olefins proceeds by competing radical and ionic processes. The ability of  $BrN_3$  to react with olefins via two pathways prompted us to examine the behavior of chlorine azide under analogous conditions. As expected,  $ClN_3$  added to olefins primarily as a free-radical reagent providing a source of  $N_3$  radicals. Thus in pentane or  $CH_2Cl_2$ , even in the presence of air, styrene furnished 96 as the sole product. In nitromethane in the presence of oxygen 96 was still formed in 17% yield, together with 48% of 97 and 23% of  $\beta$ -chlorostyrene. Under forcing conditions in the presence of fuming sulfuric acid a 92% yield of the ionic adduct 97 was obtained.

$$\begin{array}{c} C_{6}H_{5}CH-CH_{2}N_{3} \\ \hline \\ C_{1} \\ \hline \\ 96 \\ \\ C_{6}H_{5}CH=CH_{2}+ClN_{3} \\ \hline \\ 23b \\ \hline \\ CH_{7}NO_{2} \\ \hline \\ H_{2}SO_{4}-SO_{3} \\ \hline \\ C_{6}H_{5}CH-CH_{2}Cl \\ \hline \\ N_{3} \\ \hline \\ 97 \\ \end{array}$$

Even IN<sub>3</sub>, which in acetonitrile reacts exclusively as an I<sup>+</sup> reagent, can be induced to react by an N<sub>3</sub> radical mechanism. For instance, in pentane and with N<sub>2</sub> purging, styrene (23b) gave the free radical adduct 98 in yields of up to 40%.<sup>7</sup>

#### Conclusion

The addition of halogen azides to olefins provides a useful method for the stereospecific and regiospecific introduction of an azide function into organic moleculs. The resulting  $\beta$ -haloalkyl azides serve as starting materials for vinyl azides, amines, amino ketones, azirines, aziridines, and other N-heterocycles. From the mechanistic point of view these reactions shed light on the behavior of three-membered-ring halonium ion intermediates and the electronic, steric, and conformational factors governing ionic as well as free-radical additions to olefins and acetylenes.

It is obvious that the addition of IN<sub>3</sub> to multiple bonds generally proceeds by an ionic mechanism, while ClN<sub>3</sub> adds predominantly by a free-radical pathway.

(26) M. L. Poutsma, J. Amer. Chem. Soc., 87, 2161, 2172 (1965).

BrN<sub>3</sub> is easily induced to react either by a free-radical or by an ionic pathway and even IN<sub>3</sub> or ClN<sub>3</sub> can add to olefins choosing a dual mechanism under forcing conditions. These results suggest that the mechanism of addition of bromine and of other halogens to unsaturated compounds may also be strongly affected by the polarity of the solvents and the reaction conditions employed, but that this is often not recognized. The halogen azides have the advantage that the reaction mechanism can usually be inferred from the observed regiochemistry, while in halogen additions this is not the case. An example is furnished below.

It has recently been reported<sup>27</sup> that 3,3,3-triphenyl-propene (58) is brominated to yield a mixture of 102 and 103 and both products were presumed to arise from an ionic process. Our experience with this olefin indicated that ionic addition of IN<sub>3</sub> or BrN<sub>3</sub> leads exclusively to rearrangement (see 59 and 99), whereas free-radical addition of BrN<sub>3</sub> led largely to an unrearranged adduct, 101, indicating that the intermediate radical 100, unlike the corresponding carbonium ion, is trapped efficiently by BrN<sub>3</sub> before it can rearrange.<sup>21</sup> Closer scrutiny of the bromination of 58 in the presence of free-radical inhibitors revealed that bromide 102 resulted from ionic bromination whereas dibromo adduct 103 was in fact a free-radical addition product.<sup>21</sup>
