# The Crystal Structure of $Nb_{16}W_{18}O_{94}$ , a Member of a $(MeO)_xMeO_3$ Family of Compounds

### ARTHUR W. SLEIGHT\*

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The structure of a compound with the ideal formula  $\mathrm{Nb_{16}W_{18}O_{94}}$  has been determined from single crystal X-ray data. The actual composition of the crystal used is believed to be  $0.4\mathrm{NbO_{2.5}} \cdot 0.6\mathrm{WO_{3}}$ . The space group is  $P2_12_12$  with the unit-cell dimensions:

$$a = 12.251 \text{ Å}$$
  $b = 36.621 \text{ Å}$   $c = 3.94 \text{ Å}$ 

The structure is very similar to that of tetragonal potassium wolfram bronze,  $K_xWO_3$  and belongs to a family of the general formula  $(MeO)_xMeO_3$  where (MeO) has replaced the potassium in the pentagonal tunnels. Nonstoichiometry and results at other compositions in the  $Nb_2O_5-WO_3$  and  $Ta_2O_5-WO_3$  systems are discussed.

In a previous note <sup>1</sup> it was pointed out that a better understanding of the structural relationships between certain Nb—W and Ta—W oxides and the tetragonal potassium wolfram bronze (TKWB)<sup>2</sup> had been obtained. A more detailed account of these relationships, including the structure of Nb<sub>16</sub>W<sub>18</sub>O<sub>94</sub>, will be given here.

Banks and Noval³ first pointed out the existence of a composition in the Ta-W-O system (30 % Ta<sub>2</sub>O<sub>5</sub> · 70 % WO<sub>3</sub>) which gave an X-ray diffraction pattern very similar to TKWB. They were of the opinion that the phase actually existed over a range of compositions. The presence of this phase in the Ta<sub>2</sub>O<sub>5</sub>—WO<sub>3</sub> system has also been reported by Kovba and Trunov <sup>4</sup> who referred to it as having the formula Ta<sub>2</sub>O<sub>5</sub> · 3WO<sub>3</sub>.

The phase  $\mathrm{Nb_2O_5} \cdot 3\mathrm{WO_3}$  was first reported by Goldschmidt.<sup>5</sup> Kovba and Trunov <sup>4</sup> confirmed this, and Mohanty and Fiegel <sup>6,7</sup> demonstrated that the phase was structurally similar to TKWB. It was the opinion of Goldschmidt and of Mohanty and Fiegel that this phase also exists over a range of compositions.

A study of the Nb<sub>2</sub>O<sub>5</sub>—WO<sub>3</sub> and Ta<sub>2</sub>O<sub>5</sub>—WO<sub>3</sub> systems was undertaken to elucidate the structural principles involved. Since there are no alkali (or similar) cations present and since the oxygen-to-metal ratio is considerably

<sup>\*</sup> Present address: Central Research Department, E.I. du Pont de Nemours, Wilmington, Delaware, USA.

less than three, it was not apparent how these phases could be structurally related to TKWB. It was of further interest to determine if the phases were truly nonstoichiometric.

#### EXPERIMENTAL

Metal powders were used as starting materials. Niobium and tantalum were "Matthey Specpure" and wolfram was 99.9%. Two methods of preparation were used. In the first, intimate mixtures of the metals in correct proportions were oxidized in air at 500°C in alumina crucibles. Complete oxidation was confirmed by weight gain and sample appearance. The resulting mixture of oxides was pelleted and then sealed in a platinum tube with air (~l atm.) present. (Attempts to use evacuated tubes led to reduced products). The sealed platinum tubes were heated at temperatures from 1200° to 1400°C for one to three days. In general, the platinum tubes were heated in about one atmosphere of air, but in a few runs an external pressure of about 30 atm. of argon was used. The second preparative method was identical to the first except that the pure metals were oxidized and then intimately mixed in the correct proportions. No difference in the results for these two methods was detected.

The NbO<sub>2.5</sub>—WO<sub>3</sub> and TaO<sub>2.5</sub>—WO<sub>3</sub> systems were studied from 0.2NbO<sub>2.5</sub> (TaO<sub>2.5</sub>) · 0.8WO<sub>3</sub> up to 0.5NbO<sub>2.5</sub> (TaO<sub>2.5</sub>) · 0.5WO<sub>3</sub>, since this is roughly the region of occurrence for phases structurally related to TKWB. Products were pale yellow to white, and needles were generally present. In a few cases the products were grey or black due to reduction of the sample. Such products were not considered to be true members of the Ta<sub>2</sub>O<sub>5</sub>—WO<sub>3</sub> or Nb<sub>2</sub>O<sub>5</sub>—WO<sub>3</sub> systems. X-Ray powder patterns were obtained for all products using a Guinier camera with strictly monochromatic CuK $\alpha_1$  radiation and potassium chloride (a = 6.2919 Å at 20°) as an internal standard. True single crystals were rare at any composition. Needles between 0.3 and 0.4Nb or Ta were in fact always found to be polycrystalline, while needles between 0.4 and 0.5Nb or Ta were generally

incoherently twinned.

The crystal used for single crystal analysis was picked from a sample of the composition 0.4Nb which had been heated at  $1400^{\circ}$ C for one day. The crystal was a parallelepiped with a length of 0.078 mm and sides of 0.015 and 0.021 mm. Weissenberg photographs were taken around the needle axis (c axis) using  $CuK\alpha$  radiation. All the layer lines thus obtainable were registered using multiple film techniques. Precession photographs were taken for 0kl and k0l data using  $MoK\alpha$  radiation. The relative intensities of the reflections were visually estimated by comparison with an intensity scale prepared by registering accurately defined exposures with a suitable reflection from the crystal. The crystal was twinned but most of the reflections were resolved. The intensity ratio for equivalent reflections from the two individuals of the twin ranged from five to ten. The data were corrected for absorption using a program by Werner. Due to the twinning of the crystal these corrections were not very accurate; however, the shape of the crystals provides an absorption correction which is nearly constant for the reflections used.

The W<sup>3+</sup> and Nb<sup>3+</sup> scattering curves used were taken from Thomas and Umeda.<sup>9</sup> The O<sup>-</sup> scattering curve was taken from Hartree.<sup>10</sup> Corrections for dispersion were made. Most of the calculations involved in the crystal structure determination were facilitated

by the use of the electronic computers BESK and FACIT.

### DERIVATION OF THE STRUCTURE

The single crystal photographs showed orthorhombic symmetry. The cell constants are given in Table 1. The only systematic absences were h odd for h00 reflections and k odd for 0k0 reflections; thus, the space group was uniquely determined as  $P2_12_12$ . Since upper level photographs were very similar to the zero level, it is likely that all atoms lie very close to the (001) and (002) planes. However, the increasing differences between the various layer lines most likely indicates a puckering of the network. In view of this and the size

	a, $A$	b, Å	$c$ , $ ilde{\mathbf{A}}$	$\mathbf{T}^{\circ}\mathbf{C}$

Table 1. Cell dimensions with reaction temperatures.\*

of the cell, the structure was solved in projection using hk0 data only. The close agreement of the intensity data with those given by crystals in the  $TaO_{2.5}$ —WO<sub>3</sub> system indicated that there was no appreciable ordering among the niobium and wolfram atoms. Therefore, Nb and W were assumed to be randomly distributed at the metal sites. It was further obvious from the data that this structure could be viewed as a superstructure of TKWB.

The structure of TKWB (Fig. 1b) can be regarded as a complex network of WO<sub>3</sub> octahedra sharing corners. The resulting pentagonal tunnels and perovskite-like cages are partially filled with K atoms. Although the potassium content may vary, the ratio of oxygen to wolfram in the network remains at three. In the Nb<sub>2</sub>O<sub>5</sub>—WO<sub>3</sub> and Ta<sub>2</sub>O<sub>5</sub>—WO<sub>3</sub> systems the ratio of oxygen-tometal is less than three. The high density of the 0.4Nb composition, 5.95, indicated that, rather than oxygen deficiency, the tunnels were being filled in some manner.

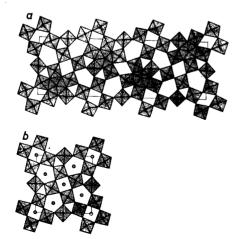

Fig. 1. The crystal structure of (a) Nb<sub>16</sub>W<sub>18</sub>O<sub>94</sub> and (b) tetragonal potassium wolfram bronze according to Magnéli.<sup>2</sup>

<sup>\*</sup> Oxygen pressure was about one atmosphere except where otherwise indicated.

The metals present seemed too small to occupy the K positions. (The coordination of K is 15 in the pentagonal tunnels and 12 in the perovskite-like cages). However, by placing oxygens in K positions, more suitable sites for the metal atoms could be provided. Placing oxygen in the perovskite cages produces octahedra, but these are electrostatically unfavorable since they would share edges with four others. Placing oxygen in the pentagonal tunnels produces pentagonal bipyramids. These also share edges, but are more favorable because the metal-to-metal distances are greater.

The unit cell contains 12 pentagonal tunnels which are divided into 3 four-fold sites by symmetry. From the composition it was thought that only one of these sites was being used. (At 0.47Nb one fourfold site would be exactly filled). The site thought most probable is shown in Fig. 1a. Refinement of this model by the least squares and Fourier methods proved it to be correct.

As previously stated the Nb and W atoms were assumed to be statistically distributed at the metal sites. A difference map, after refinement of the parameters to an R value of 8.0 %, indicated that the distribution was not strictly statistical. Refinement of the Nb to W ratio at each site led to an R-factor of 6.9 %. A difference map then showed mainly satellite peaks of the metal atoms. The largest of these was less than 25 % of an oxygen. These peaks were thought to arise from at least three sources: disorder, anisotropic temperature factors for the metal atoms, and super-position errors due to the assumption that an oxygen in projection with a metal atom has the same x and y coordinates. Cruickshank's weighting scheme 11 was used in the final least squares refinement.

The observed and calculated structure factors are given in Table 2. The observed structure factors with asterisks were not used in the final least squares refinement. The R-factor including these reflections is 8.0 %. The final parameters are given in Table 3. The standard deviations for the metal positions amount to about 0.004 Å while those for oxygens 1-15 amount to about 0.05 Å. Oxygens 16-23 were assumed to have the same x and y coordinates as metal atoms 1-8. The standard deviations of a, the atom fraction of W on a site, are about 0.05. Correlations of about 0.60 were found between the temperature factor at a metal site and the atom fraction of W at that site. It should be noted that it was assumed that the  $Me_1$  site was completely filled with a mixture of Nb and W. (Also 0.6 moles of  $O_2$  per unit cell was left unaccounted for). However, if this pentagonal tunnel is not completely filled, as discussed in the next section, the value of a for  $Me_1$  given in Table 3 would be low.

Some interatomic distances and angles are given in Table 4. The standard deviations average at 0.05 Å for the metal-oxygen distances and 0.07 Å for the oxygen-oxygen distances. The standard deviations for the angles average at 0.2°. It should be noted that the filled tunnel is much more regular and smaller than the empty tunnels.

## NONSTOICHIOMETRY AND RESULTS AT OTHER COMPOSITIONS

Crystals examined from the compositions 0.4Ta (1400°C and  $\sim$ 1 atm. O<sub>2</sub>), 0.5Nb and 0.5Ta showed the same superstructure as that of 0.4Nb (1400°C

and  $\sim 1$  atm.  $O_2$ ). All crystals exhibited a strong tendency to twin, but the tendency was definitely greater in the Ta system. The individuals of the twin had their c axes in common and were joined in such a way as to create the fourfold axis of the derivative structure (TKWB). The unit cell thus had the superficial appearance of being tetragonal with a=36 Å.

Compositions somewhat richer in W gave powder diffraction patterns also very similar to TKWB but with no superstructure as indicated in Table 1. It should be pointed out that the compositions 0.4Nb and 0.4Ta can exist with or without the superstructure depending on the conditions. The upper limit of WO<sub>3</sub> in these phases was about 0.65W in the niobium system but at least 0.8W in the tantalum system. The diffraction lines for 0.2Ta were, however, very broad.

The formula for all these TKWB-like phases could be written as  $W_{30-3x}\text{Nb}_{4x}\text{O}_{90+x}$  (or  $W_{30-3x}\text{Ta}_{4x}\text{O}_{90+x}$ ) assuming that the metal to oxygen ratio in the tunnels is always one. When x is four (or very close to four) an ordering of the filled tunnels occurs. For values of x less than four the

filled tunnels are apparently randomly distributed. This could easily be a metastable condition. In fact Roth  $^{12}$  has suggested that ordering does occur at x=3 under the proper conditions.

The ideal composition for the structure in Fig. 1 is  $0.47 Me^{v} O_{2.5} \cdot 0.53 W O_{3}$  (Nb<sub>16</sub>W<sub>18</sub>O<sub>94</sub> or Ta<sub>16</sub>W<sub>18</sub>O<sub>94</sub>), but a small range of nonstoichiometry may exist due to disorder at the tunnels. That is, a few of the "unfilled tunnels" might be filled at compositions somewhat poorer in W than 0.53W, and a few of the "filled tunnels" might be vacant at compositions richer in W than 0.53W.

However, there is another mechanism whereby this structure could extend to compositions richer in WO<sub>3</sub>. A powder diffraction pattern for  ${\rm Ta_8W_{26}O_{94}}$  (prepared from  ${\rm Ta_2O_5}$ , WO<sub>3</sub>, and W) was identical to that of  ${\rm Ta_{16}W_{18}O_{94}}$  except for a considerable decrease in the d-spacings. This indicates that a certain amount of reduced W may replace Ta or Nb. It is well known that WO<sub>3</sub> tends to lose oxygen at high temperatures. Thus, it seems likely that compositions in the systems  ${\rm Nb_2O_5-WO_3}$  and  ${\rm Ta_2O_5-WO_3}$  may lose oxygen at high temperatures. This oxygen might well be reabsorbed on cooling if it is available.

Therefore, it is suggested that when the compositions 0.4Nb or 0.4Ta were heated to  $1400^{\circ}$ C under low oxygen pressure ( $\sim$ 1 atm.) some oxygen left the sample, and the formula  $Me_{34}O_{94}$  was obtained. The color of the products indicated, however, that the W was fully oxidized. The necessary oxygen may have entered some of the empty tunnels. The accuracy of the data for the crystal of composition 0.4Nb is not sufficient to prove this suggestion. However, an observation which further indicates this mechanism is that a superstructure was not found at 0.4Nb or 0.4Ta at 1400°C under higher oxygen pressure ( $\sim$ 60 atm.) or in any case at 1300°C.

The contents of the unit cell at 0.4Nb according to this latter model would be  $Me_{34}O_{95,2}$  leading to a density of 6.14. If instead some "filled tunnels" were vacant, *i.e.*,  $Me_{33.3}O_{93.3}$ , a density of 6.01 would be obtained. Unfortunately, the experimentally determined density of 5.95 is not sufficiently accurate

to distinguish between these two models.

### DISCUSSION

There are actually a large number of compounds which have structures that can be viewed as two-dimensional networks of corner-sharing octahedra. In the third dimension these networks are stacked one directly upon the other and fused again by corner-sharing octahedra. These networks form 3, 4, 5, or 6 membered rings which become tunnels in three dimensions.  $^{14-17}$  The tunnels may be empty as in  $\mathrm{ReO_3}$ ,  $\mathrm{MoW_{11}O_{36}}$ , and  $\mathrm{MoW_{14}O_{45}}$ . They may also be (partially) filled with alkali or similar cations as in the various wolfram bronzes of the type  $A_x\mathrm{WO_3}$ .  $^{16}$ 

The pentagonal tunnels may also be filled with metal and oxygen forming a string of pentagonal bipyramids which share apices. This is the case for  $\mathrm{Nb_{16}W_{18}O_{94}}$  and  $\mathrm{Ta_{16}W_{18}O_{94}}$  and suggests a family of structures with the general formula  $(Me\mathrm{O})_{2}Me\mathrm{O}_{3}$ . A previously known structure which would fall into this family is  $\mathrm{Mo_{10}O_{28}}$  or  $(\mathrm{MoO})\mathrm{Mo_{9}O_{27}}$ . The structures of  $\mathrm{W_{18}O_{49}}$  and  $\mathrm{Mo_{17}O_{47}}$  are very closely related to those of this family, but they involve

some edge-sharing octahedra as well.

The next step would be a family of the type  $A_x(MeO)_yMeO_3$ . Recent structure determinations for  $NaNb_6O_{15}F^{22}$  and  $LiNb_6O_{15}F^{23}$  performed at this Institute have established that indeed such a family does exist. Furthermore, in many other systems:  $BaO-Nb_2O_5$ , <sup>24</sup> PbO- $Nb_2O_5$ , <sup>25</sup>  $Na_2O-Nb_2O_5$ , <sup>26</sup>  $K_2O-Nb_2O_5$ , <sup>27</sup>  $Na_2O-Ta_2O_5$ , <sup>27</sup> and  $K_2O-Ta_2O_5$ , <sup>27</sup> phases have been reported to give diffraction patterns very similar to that of TKWB. Most of these phases will fit the general formula  $A_x(MeO)_yMeO_3$ . For example,  $BaO \cdot 2Nb_2O_5$  could be rewritten as  $Ba_2(NbO)Nb_7O_{21}$  or x=2/7 and y=1/7.

Acknowledgements. I would like to express my sincere gratitude to the head of this Institute, Professor A. Magnéli, who suggested this work and made it possible. Thanks are also due to many others at this Institute. In particular, I wish to thank Drs. L. Kihlborg and S. Åsbrink, Mr. L. J. Norrby and Mrs. S. Nord. Further thanks are due to the Computer Division of the National Swedish Rationalization Agency for the use of the computers BESK and FACIT EDB. This investigation was made possible through financial support of the Swedish Natural Science Research Council and the Royal Swedish Academy of Science (the Kemiska prisgruppens särskilda fond). I would also like to acknowledge helpful discussions with Dr. C. Prewitt.
