The Reaction between 5-(*p*-Toluenesulfonamido)tetrazole and *p*-Toluenesulfonyl Chloride

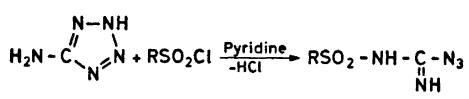
K. A. JENSEN and CARSTEN CHRISTOPHERSEN

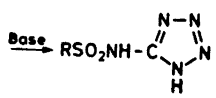
Department of General and Organic Chemistry, University of Copenhagen, The H. C. Ørsted Institute, DK-2100 Copenhagen, Denmark

5-(*p*-Toluenesulfonamido)tetrazole reacts with *p*-toluenesulfonyl chloride and pyridine at room temperature with spontaneous evolution of nitrogen and formation of the dipolar compound II. This reacts with nucleophiles with elimination of pyridine. During the reactions with ethanol or ammonia an infrared absorption band near 2200 cm^{-1} appears for a short time, indicating that a carbodiimide, $RSO_2N=C=N-NHSO_2R$, is formed as an intermediate. Compound II also eliminates pyridine on heating or in solution, probably forming dimers (or polymers) of the carbodiimide.

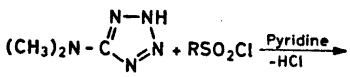
The primary product of the reaction between 5-aminotetrazole and *p*-toluenesulfonyl chloride in pyridine at temperatures below 70°C is known to be *p*-toluenesulfonylguanyl azide.[1] Under the influence of a base this is rearranged to the isomeric 5-(*p*-toluenesulfonamido)-tetrazole.

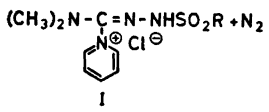
When, however, the temperature of the pyridine solution is raised above 90°C a violent reaction takes place with evolution of nitrogen.[2] Since we found [2] that 5-dimethylaminotetrazole reacted with *p*-toluenesulfonyl chloride in pyridine with evolution of nitrogen and formation of (1-*p*-toluenesulfonyl-4,4-dimethylcarbamohydrazonoyl)pyridinium chloride (I; semicarbazide numbering) it was anticipated





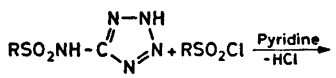
that a similar reaction had taken place between 5-(*p*-toluenesulfonamido)tetrazole and excess *p*-toluenesulfonyl chloride with the formation of compound II.

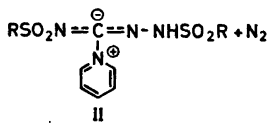




I

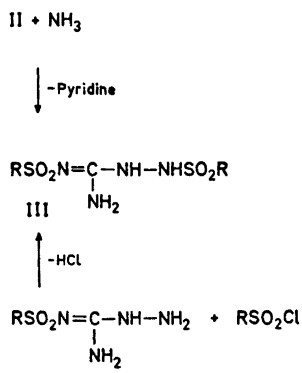
No compound corresponding to II could, however, be isolated from the solution. A possible reason for this negative result might be that the buffer solution pyridine/pyridinium chloride is too acid to induce a ring closure of the initially formed guanyl azide and that the nitrogen evolution originates from a thermal decomposition of the latter. However, the guanyl azide is not decomposed under the conditions of the experiment and it does not react with the sulfonyl chloride. It must therefore be concluded that some 5-(*p*-toluenesulfonamido)-tetrazole is actually formed and reacts with ex-





II

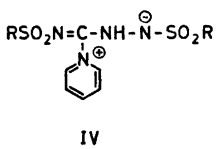
cess sulfonyl chloride under nitrogen evolution and formation of II, which, however, is unstable at the high temperatures used. We have now found that 5-(*p*-toluenesulfonamido)tetrazole in fact reacts with *p*-toluenesulfonyl chloride in pyridine solution with instantaneous release of nitrogen and the formation of a product which analytically corresponds to formula II. Chemical evidence in support of this structure is furnished by the reaction of II with ammonia. The product of this reaction was found to be in all respects identical with 1-(*p*-toluenesulfonamido-2-(*p*-toluenesulfonyl)guanidine (III), prepared from 2-(*p*-toluenesulfonyl)-1-aminoguanidine and *p*-toluenesulfonyl chloride.



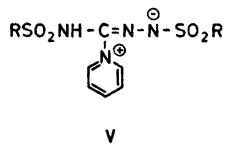
Analogously, the reaction of II with water gives rise to a product the elemental composition of which corresponds to that expected for 1,4-bis(*p*-toluenesulfonyl)semicarbazide. The corresponding thiosemicarbazide could not be obtained from the reaction of II with hydrogen sulfide (neither could it be prepared from *p*-toluenesulfonylhydrazine and *p*-toluenesulfonyl isothiocyanate).

The possibility that compound II should rather be represented by one of the tautomeric forms IV and V is rejected. These correspond to the conjugate base of I, which must be a very strong base since I is neutral. Compound II on the other hand is a very weak base (it does not form a hydrochloride). The structure depicted as II would also appear to be more plausible since it must be resonance-stabilized.

Compound I reacts with nucleophiles as a potential nitrilimine, $R_2N-C\equiv\overset{+}{N}-\overset{-}{N}-SO_2R'$, eliminating pyridinium chloride and forming a semicarbazide, a thiosemicarbazide, and an aminoguanidine with water, hydrogen sulfide, and ammonia, respectively.[2] Compound II, on the other hand, should be able to form a carbodiimide (VI) by elimination of pyridine. The product smells weakly of pyridine but could be recrystallized from acetone without change of composition, although with great loss. By evaporation of the filtrate, or by melting of compound II, a pyridine-free product was obtained the composition of which corresponds approximately to that of the carbodiimide. However, according to its infrared spectrum it cannot be a carbodiimide because there is no absorption near 2200 cm^{-1}. The spectrum exhibits an absorption band at 1725 cm^{-1}, which may originate from the grouping $RSO_2NHN=C$ since acetone *p*-toluenesulfonylhydrazone has a similar band. According to thin-layer chromatography the product contains at least ten compounds, which suggests the presence of four-membered rings since seven structurally isomeric diazetidines, each with several stereoisomers, could be formed by a dimerisation. Attempts at separation of the many compounds were not pursued further. However, the isolation of a small amount of crystalline *p*-tolyl *p*-toluenethiosulfonate, $CH_3C_6H_4SO_2-S-C_6H_4-CH_3$, from the melt shows that a possible dimerisation is accompanied by a more thorough decomposition. Incidentally, the molecular ion of this thiosulfonate and its fragmentation products account for most of the peaks in the mass spectrum of the melt. No ions corresponding to the carbodiimide or its polymers could be detected.

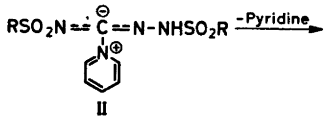


IV



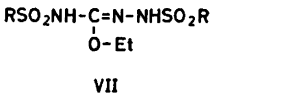
V

Evidence for the fleeting existence of the carbodiimide VI as an intermediate in the reactions of II with nucleophiles has been obtained from the reaction of II with ethanol. In this case products are obtained which initially show a strong infrared absorption in the range 2240–2260 cm^{-1}. This absorption disappears on drying, and the substance left is according to IR and NMR spectroscopic evidence *O*-ethyl 3-(*p*-toluenesulfonyl)-*p*-toluenesulfonimidocar-



II

VI



VII

bazate (VII). Accordingly the reaction of II with ethanol seems to proceed *via* the carbodiimide VI.

With *tert*-butyl alcohol II also gives a product with a strong infrared band at 2240 cm^{-1} which disappears on refluxing for a longer time. The reaction product is, however, not a carbazate but according to its infrared spectrum a similar mixture to that obtained by melting compound II.

During the reaction between compound II and ammonia in ethanol a transient absorption band is observed at 2180 cm^{-1}. The fact that this wavenumber differs somewhat from that observed during the reaction with ethanol may suggest that the carbodiimide forms a molecular complex with the nucleophile before reacting with it.

EXPERIMENTAL

^1H NMR spectra were recorded in $CDCl_3$ on a Varian A-60 instrument using TMS as internal standard. Chemical shifts are given in δ values (s = singlet; d = doublet; t = triplet; q = quartet; m = multiplet). IR spectra were recorded on a Perkin-Elmer Model 337 grating spectrophotometer. Elemental analyses were performed by the analytical laboratory of this department (Mr. Preben Hansen and his staff).

p-*Toluenesulfonylguanyl azide* [2,3] could conveniently be prepared directly by the reaction of the commercially available 5-aminotetrazole hydrate and two equivalents of *p*-toluenesulfonyl chloride in pyridine. The crude azide, which is obtained in almost quantitative yield by pouring the pyridine solution into ice-cold water, still contains traces of pyridine and is specially suited for the following base-catalyzed isomerization. The ring closure to *5-(*p*-toluenesulfonamido)-tetrazole* could thus be achieved merely by refluxing the azide in ethanolic solution for *ca.* 6 h. The tetrazole was obtained by concentrating the ethanolic solution *in vacuo*. The best solvent for recrystallization is water + 15 – 20 % ethanol. Yield *ca.* 25 g of the recrystallized product (m.p. 187 – 189°C) from 20.6 g of 5-aminotetrazole monohydrate (52 %).

Pyridinio-p-*toluenesulfonylhydrazono*-p-*toluenesulfonimidoformate* II. A solution of *p*-toluenesulfonyl chloride (1.6 g) in acetone (10 ml) was added dropwise to a stirred solution of 5-(*p*-toluenesulfonamido)-tetrazole (2 g) and pyridine (2 ml) in acetone (10 ml). The reaction proceeds with evolution of nitrogen; the temperature was kept at 5°C by cooling with ice until all had been added (20 min) and the stirring was continued without cooling. A crystalline precipitate separated eventually or on scratching. The stirring was continued for ½ – 1 h or until the evolution of nitrogen had stopped (usually not more than 80 % of the calculated amount is evolved). The yield is very variable. In one case a yield as high as 70 % was obtained by carrying out the reaction in pyridine solution and adding acetone afterwards but this experiment could not be reproduced. In most cases only 20 – 30 % was obtained. The compound is unstable in contact with the solution and was isolated immediately by centrifugation. After a few washings with acetone, in which the residue is somewhat soluble, the analytically pure substance was obtained as a light yellow solid. (Found: C 54.00; H 4.55; N 12.67; S 14.37. Calc. for $C_{20}H_{20}N_4O_4S_2$: C 54.05; H 4.54; N 12.61; S 14.40). M.p. 121 – 122°C (decomp.). In the infrared spectrum ν(C=N) is found as a strong doublet at 1620 – 1630 cm^{-1}. In the ^1H NMR spectrum the protons of the two methyl groups give rise to a broad singlet at δ 2.40 and the other protons to complicated series of multiplets extending from δ 7 to 9.

On melting it gives off pyridine. According to chromatography ($CHCl_3$, silica gel) the amorphous product formed is a complicated mixture, from which, however, a few percent of *S*-*p*-tolyl *p*-toluenethiosulfonate (m.p. 78 – 79°C, infrared spectrum identical with that of an authentic sample) could be obtained.

The substance is only slightly soluble in benzene or ether, somewhat more soluble in acetone or chloroform. It dissolves in aqueous NaOH with an orange-red colour which disappears on heating. On acidification of the solution 1,4-bis(*p*-toluenesulfonyl)semicarbazide was precipitated; this could, however, be prepared in a purer state without the use of NaOH (see below). When II is dissolved in boiling acetone only a few percent crystallize out again on cooling and when the filtrate is evaporated a pyridine-free substance is obtained with essentially the same spectral properties as the melt. The IR spectrum has characteristic absorptions at 1725 (m), 1600 (s) and 1570 (s) cm^{-1} (difference from II). NMR-spectrum: broadened singlet at δ 2.38, multiplet at δ 7 – 9.

When the acetone solution from the prepara-

tion of II was diluted with water and extracted with chloroform a mixture was obtained which by chromatography (benzene-ethanol, silica gel) was separated into several fractions. One of these was identified as acetone *p*-toluenesulfonylhydrazone by comparison with an authentic sample. M.p. 158°C IR spectra superimposable, NMR spectrum: δ 1.82 (d, 6H); 2.38 (s, 3H); 7.5 (m, 5H). The other fractions were amorphous and apparently polymeric substances with varying N:S ratio (1.5 – 3) but similar infrared spectra except in the 1500 – 1600 cm^{-1} region. No well-defined compounds could be isolated. However, on boiling with water one fraction yielded *p*-toluenesulfonamide and another yielded 1,4-bis(*p*-toluenesulfonyl)-semicarbazide, in addition to insoluble resinous material.

1,4-Bis(p-toluenesulfonyl)semicarbazide. When II (100 mg) was boiled with water (8 ml) most of it went into solution. On cooling of the filtered solution and addition of a drop of dilute hydrochloric acid a white solid separated (45 mg). It was purified by crystallization from water-ethanol (10:1). M.p. 197 – 198°C. (Found: C 46.95; H 4.40; N 11.19; S 16.76. Calc. for $C_{15}H_{17}N_3O_5S_2$: C 46.99; H 4.47; N 10.96; S 16.72). Its infrared spectrum exhibits a strong C=O band at 1710 cm^{-1}.

1-(p-Toluenesulfonamido)-2-(p-toluenesulfonyl)guanidine (III). (a) A suspension of 2-(*p*-toluenesulfonyl)-1-aminoguanidine [1] (0.58 g) in pyridine (1 ml) was treated with *p*-toluenesulfonyl chloride (0.48 g) for 30 min at room temperature followed by a few min at 100°C until all had dissolved. On addition of water to the solution a white solid separated, which was filtered off, washed with water and dried over H_2SO_4. Yield 0.80 g. M.p. 240°C after recrystallization from ethanol. (Found: C 47.01; H 4.81; N 14.53; S 16.78. Calc. for $C_{15}H_{18}N_4O_4S_2$: C 47.12; H 4.75; N 14.66; S 16.74). As expected the substance is soluble in aqueous NaOH (to give a colourless solution). It is also soluble in ethanol saturated with ammonia but separates unchanged from the boiling solution as the ammonia escapes.

The infrared spectrum (KBr) exhibits three strong and sharp N – H stretching bands at 3310, 3375 and 3475 cm^{-1} and two strong bands at 1640 and 1560 cm^{-1} (amide I and amide II bands). The presence of some rather pronounced bands in the 2700 – 2800 cm^{-1} range indicates that the compound may in part exist in a dipolar form with an $=NH_2^+$ group.

(b) Compound II (0.30 g) was dissolved in ethanolic ammonia (5 ml). The solution initially had a deep red colour, which faded in 10 – 15 sec. After 1 h at room temperature a quantitative amount of III was obtained on dilution of the solution with ether. According to its m.p. (240°C), analysis (Found: C 46.90; H 4.83; N 14.53; S 16.61), and infrared spectrum this product was identical with that prepared by procedure (a).

O-Ethyl 3-(p-toluenesulfonyl)-p-toluenesulfonimidocarbazate (VII). II (400 mg) was boiled with ethanol (20 ml) until all had been dissolved and the yellow colour had disappeared. The solution was evaporated *in vacuo* and dried over H_2SO_4. Before the latter drying the infrared spectrum of the residue dissolved in $CHCl_3$ exhibited an absorption band at 2260 cm^{-1}, the intensity of which decreased slowly. The substance which had been dried over H_2SO_4 did not exhibit this band but had a strong band at 1602 cm^{-1}, presumably due to ν(C=N). The NMR spectrum was consistent with the expected constitution. The yield was almost quantitative (400 mg) but the product was glassy. It could only be purified with great loss by dissolving it in ethanol-benzene (1:4) and filtering the solution through silica gel; on addition of petroleum ether colourless crystals with m.p. 119 – 120°C were obtained. (Found: C 49.31; H 5.14; N 10.03. Calc. for $C_{17}H_{21}N_3S_2O_5$: C 49.62; H 5.14; N 10.21). NMR spectrum: δ 0.93 (t, 3H); 2.40 (d, 6H); 3.90 (q, 2H); 7.50 (m, 10H).

Crystal Structures of Synthetic Analgetics. II. *l*-Methadone

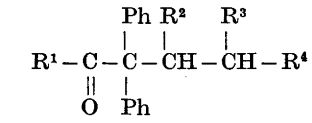
ERIK BYE

Department of Chemistry, University of Oslo, Oslo 3, Norway

The molecular and crystal structure of *l*-methadone has been determined by X-ray methods. The crystals are orthorhombic, space group $P2_12_12_1$ with unit cell dimensions $a = 9.637$ Å; $b = 11.385$ Å; $c = 16.866$ Å. The phase problem was solved by direct methods and the model refined to an R-value of 0.038 for 1687 observed reflections. Estimated standard deviations are 0.003 – 0.004 Å in interatomic distances and 0.2 – 0.3° in angles.

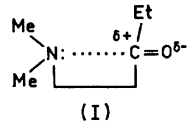
The dimethylamine group is (–)*syn clinal* relative to the quaternary carbon atom. There is a short intramolecular distance of 2.91 Å between the nitrogen atom and the carbonyl carbon atom and C3 is 0.06 Å out of the plane through C2, O and C4. The planes of the two phenyl rings make a dihedral angle of 80.6°.

The synthetic analgetic methadone may be characterized as the central compound among propylamines having morphine-like action. It belongs to a group of ketones with the general formula



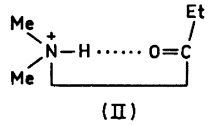
with $R^1 = Et$; $R^2 = H$; $R^3 = Me$; $R^4 = N(Me)_2$. The analgesic property of methadone and related compounds is believed to be dependent on a particular molecular conformation. Many investigations concerned with the preferred conformation of methadone have been reported.[1–4] Beckett *et al.*[1] and Beckett [2] proposed that the biologically important conformation of methadone resulted from an intramolecular interaction between the basic nitrogen atom and the carbonyl carbon atom (I).

This electrostatic attraction may bring the amine and the carbonyl group in close proximity.



(I)

Although an intramolecular hydrogen bond (II) is supposed to be present in solution,[1–4] no short distances were found between the nitrogen atom and the carbonyl group in the crystal structures of *d*-methadone hydrobromide [5] and dextropropoxyphene hydrochloride.[6]



(II)

The present structure determination was carried out to see if the particular conformation was preferred in the solid state of the free base.

EXPERIMENTAL

l-Methadone was prepared from commercially available *l*-methadone hydrochloride and single crystals were formed by recrystallization in diethyl ether by evaporation. The compound crystallizes as colourless, transparent parallelepipeds, and a crystal ground to a sphere ($r = 0.2$ mm) was used in the experiments.

Oscillation and Weissenberg photographs indicated orthorhombic symmetry. Systematically absent reflections were $h00$, $0k0$, $00l$ for odd indices; thus the space group is $P2_12_12_1$.

Unit cell dimensions were determined by least-squares methods from angular coordinates, measured on a Syntex P$\bar{1}$ diffractometer with graphite crystal monochromated Mo$K\alpha$-radiation. Three-dimensional intensity data were col-

Table 1. Observed and calculated structure factors. The columns are l, $10|F_o|$, and $10|F_c|$.

lected using the $2\theta-\theta$ autocollection program with variable scan rate and a cut-off for low intensities. The scan range was from 0.7° below $2\theta(\alpha_1)$ to 0.7° above $2\theta(\alpha_2)$, and the backgrounds were counted 0.7 times the intensity measuring time. The intensities of three standard reflections were measured periodically during the data collection. They showed no systematic variation. The e.s.d's in the intensities were taken as the square root of the total counts with a 2 % addition for instrumental instability.

A total of 1911 independent reflections were recorded within the limit of 0.66 for sin θ/λ, 1687 having a net count larger than 2 σ_I.

The data were corrected for Lorentz and polarization effects but not for absorption or secondary extinction.

All calculations were performed on a CDC 6600 computer using the programs described in Ref. 7, except for the phase determination which was done with the program MULTAN, written by Main *et al.*[8] Atomic form factors were those of Hanson *et al.*[9] for O, N, and C and of Stewart *et al.*[10] for H.

CRYSTAL DATA

(6:*R*)-6-Dimethylamino-4,4-diphenyl-3-heptanone, (*l*-methadone), $C_{21}H_{27}NO$, orthorhombic.

$a=9.637$ (1) Å, $b=11.385$ (2) Å, $c=16.866$ (2) Å.

$V=1850.4$ Å^3, M = 309.20, $Z=4$.

Melting point: 79 – 80°C.

$D_{obs}=1.10$ gcm^{-3} (flotation), $D_{calc}=1.11$ gcm^{-3}.

Systematic absences: $h00$, $0k0$, $00l$ for odd indices; space group $P2_12_12_1$.

STRUCTURE DETERMINATION

The structure was determined by direct methods. Preliminary scale and overall isotropic thermal vibration factor ($B=3.11$ Å^2) were derived by Wilson's statistical method and normalized structure factors were calculated. The phase determination was carried out by the program MULTAN, using the 344 highest E-values (≥ 1.25), and a total of 1400 relations of the $\sum_2$ formula.[11] The set of phases with the third highest figure of merit gave an E-map where 20 of the 23 non-hydrogen atoms could be located. Two successive Fourier refinement served to establish a trial structure of all the heavy atoms. Successive cycles of full matrix least-squares refinement, first with isotropic then with anisotropic thermal parameters gave an R-value of 0.09. Approximate positions of all the hydrogen atoms were calculated from stereochemical considerations. Giving these 27 atoms individual isotropic thermal parameters, the refinement converged at $R=0.038$ ($R_w=0.033$).

Inspection of the structure factor values of strong reflections, showed that nine probably were affected by secondary extinction. The differences $|F_o-F_c|$ for these reflections were less than 10 % of the F_c's, and the effect turned out to be negligible, both in the atomic parameters and the R-value.

Observed and calculated structure factors are listed in Table 1, and the atomic parameters in Tables 2 and 3. The anisotropic temperature factor is given by

$$\exp -(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)$$

The e.s.d.'s in bond lengths and angles were calculated to be 0.003 – 0.004 Å and 0.2 – 0.3°, respectively.

Table 2. Fractional atomic coordinates and thermal parameters with standard deviations (10^5) for non-hydrogen atoms.

DISCUSSION

Interatomic distances and bond angles are given in Tables 4 and 5, and shown in Fig. 1. The absolute configuration (6:*R*) of *l*-methadone has been chosen according to earlier reports.[5,12]

The analysis of the thermal parameters showed that the two aromatic rings could be regarded as rigid bodies, and the positional parameters of these atoms, including C4, were corrected for librational effects. The corrected bond lengths are also listed in Table 4.

The crystal structure as seen down the *b*-axis is illustrated in Fig. 2. There are no particularly short intermolecular distances in the structure.

The distance C1 – C2 (1.508 Å) is found to be shorter than normal, 1.537.[13] This is probably due to the thermal motion of the methyl carbon atom, also reported for dextropropoxyphene hydrochloride.[7]

The mean C – N bond length is 1.455 Å, in agreement with the mean value for amines (1.456 Å) reported by Falkenberg.[14]

The expected lengthening of C – C single bonds in a compound having a quaternary carbon atom is shown by the bond lengths 1.555 Å (C3 – C4), 1.559 Å (C4 – C5), 1.544 Å (C4 – C10), and 1.552 Å (C4 – C16). Owing to the four large groups attached to C4, there is considerable deviations from tetrahedral values in the bond angles involving this atom. Similar distortions are reported in *d*-methadone. HBr [5] and dextropropoxyphene.HCl.[6]

Each of the two phenyl rings A (C10,C15) and B (C16,C21) is found to be planar. C4 is coplanar with ring B, whereas it is 0.16 Å out of plane A. This latter deviation from planarity is probably caused by the strain around C4. The two planes form an angle of 80.6°. The dihedral angles C5 – C4 – C16 – C17 and C3 – C4 – C10 – C15 are as small as −4.9° and −29.8°, respectively, and

the opening of the trigonal angles O – C3 – C4 (122.5°), C4 – C10 – C15 (124.3°), and C4 – C16 – C17 (124.3°) decreases the repulsions between C5 and C17, and between O and C15, respectively.

An interesting short intramolecular distance is that between N and C3 which are separated by 2.912 Å, approximately 0.1 Å shorter than the sum of the van der Waals radii. This close proximity of N and C_{co} may be explained by an interaction between the lone pair of the nitrogen atom and the electropositive carbonyl carbon atom, as discussed in the introduction (I). The carbonyl carbon atom is elevated 0.06

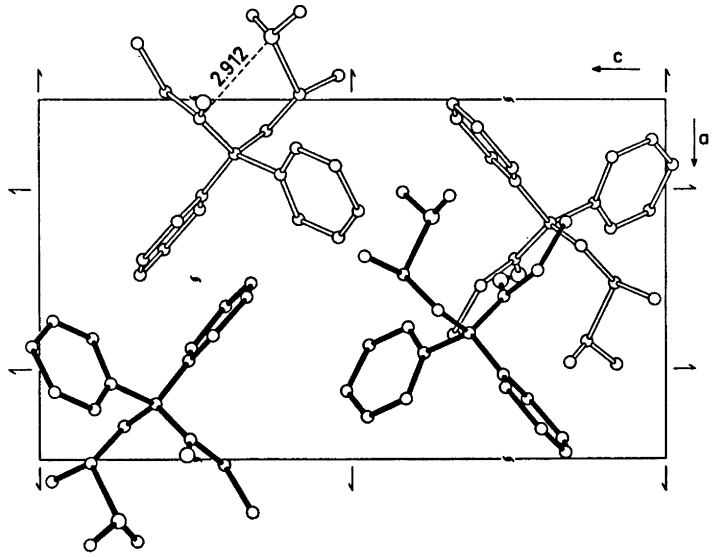

Fig. 2. The crystal structure of *l*-methadone as seen down the *b*-axis.

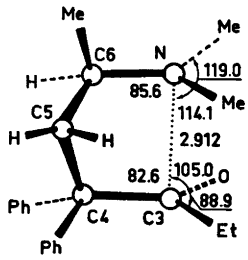

Fig. 3. Schematic drawing of the conformation of *l*-methadone.

Å out of the plane through the atoms to which it is bonded (towards the nitrogen atom.) The conformation of *l*-methadone, as seen perpendicular to a plane through C3,C4,C6 is shown in Fig. 3.

The conformation of methadone [1,2,4] proposed as necessary for analgesic activity is thus confirmed by this X-ray analysis. In the present structure the dimethylamine group is *gauche* relative to C4, the dihedral angle C4 – C5 – C6 – N being – 68.5°. It may be of great interest to see if other synthetic analgetics related to methadone are preferring a similar conformation in the solid state.

Note. The author has been made aware of the structure determination of the same compound carried out by H. B. Bürgi, E. Shefter and J. D. Dunitz, to be published in *Nature*. (The First European Crystallographic Meeting, Bordeaux, August 1973).

The Conformations of Some *gem*-Dimethyl Substituted Cyclic Anhydrides

GERD BORGEN

Kjemisk Institutt, Universitetet i Oslo, Oslo 3, Norway

Infrared spectroscopy shows that 3,3,6,6-tetramethyloctanedioic anhydride takes the same conformation in the crystal as in solution. Low-temperature ^{1}H NMR-spectroscopy of this 9-membered ring suggests C_2-symmetry, the two-fold axis passing through the ring oxygen in the anhydride group, and roughly D_3-symmetry for the ring skeleton. Two possible conformations are discussed for 3,3,7,7-tetramethylnonanedioic anhydride based on low-temperature NMR-spectroscopy, UV-absorptions, and dipole moment.

The acid anhydride group and two neighbouring carbon atoms should most likely tend to take the planar anti-anti form.[1] Also according to the determined crystal structure of monochloroacetic anhydride,[2a] electron diffraction of acetic anhydride [2b] and dipole moment investigations of benzoic and other anhydrides [3] the most stable conformation of the anhydride group seems to be the anti-anti form with varying deviations from planarity. In medium rings this conformation is not easily maintained and that is perhaps one of the reasons for the extreme instability of unsubstituted cyclic anhydrides.

We have earlier found that substitution with *gem*-dimethyl groups in certain positions facilitate the formation of 9- and 10-membered ring ketones.[4] Furthermore cyclic anhydrides of ring size 9 and 10, by substitution with *gem*-dimethyl groups were found to be easily formed and stable enough for conformational studies. In a previous paper [5] the syntheses of 3,3,6,6-tetramethyloctanedioic anhydride (a 9-membered ring), the corresponding dimer (an 18-membered ring), and 3,3,7,7-tetramethylnonanedioic anhydride (a 10-membered ring) have been described. A conformational analysis of these cyclic compounds is now reported.

In Table 1 the observed melting points, enthalpies and entropies of fusion and NMR coalescence temperatures at 100 MHz are listed. For comparison the anhydride of 3,3-dimethylpentanedioic acid (a 6-membered ring) has also been studied. (Pentane, octane, and nonanedioic anhydride = glutaric, suberic, and azelaic anhydride.)

In Table 2 the infrared absorption bands of the carbonyl groups, the ultraviolet absorp-

tions and the dipole moments are shown, together with the corresponding values for some 5- and 6-membered ring anhydrides and the anhydrides of acetic and propionic acid.

No correlation was found between the splitting of the IR carbonyl bands and the conformation of the anhydride groups. Similarly the differences in the IR absorption intensities of the two carbonyl bands were not large enough to allow conclusions to be drawn concerning the angle between the two C=O bonds, as indicated by Fayat *et al.*[6] In the 6-membered cyclic anhydride the band at lowest frequency is the strongest, in the 9-membered ring the two bands are of the same intensity, in the 10- and 18-membered cyclic anhydrides the highest frequency bands are the strongest.

The shift of the UV-absorption of the carbonyl group is dependent on the resonance and inductive effect of the neighbouring groups. A positive resonance effect and a negative inductive effect will both shift the spectrum ($n-\pi^*$) towards shorter wavelengths.[7] The group

$$-O-\overset{\overset{O}{\|}}{C}-R$$

has a +R and −I effect. In our cyclic anhydrides the inductive effect is more or less the same for all possible conformations. The resonance effect through the free electron pairs of the "ether" oxygen and the electrons of the carbonyl group is dependent on the dihedral angle but this conjugation is possible both in the *cis-cis* conformations of rings and in the *trans-trans* conformation of acetic anhydride. This explains why the values for the 5- and 6-membered rings are almost the same as for acetic anhydride (Table 2). Conclusions about the conformations of the cyclic anhydrides are therefore difficult to draw from the UV absorption values.

3,3,6,6-TETRAMETHYLOCTANEDIOIC ANHYDRIDE

Studies of the conformations and barriers to inversion in 9-membered rings with *gem*-dimethyl groups in 4 and 7 positions have been reported earlier.[8,9] The compounds were all found to have C_2 symmetry, D_3 for the carbon skeleton, with the functional group and the *gem*-dimethyl substituted carbons on the three quasi symmetry axes of the D_3 ring skeleton.

The NMR-spectra of 3,3,6,6-tetramethyl-octanedioic anhydride in $CDCl_3$ at 35°, 20°, and 0° are shown in Fig. 1. There were no further changes in the spectrum below 0°. The coalescence temperature (above 35°C) is higher than found earlier for a correspondingly tetramethyl substituted cyclononanone.[8]

In the low temperature spectrum there are two lines for the *gem*-dimethyl protons, one for the methylenes between the *gem*-dimethyl

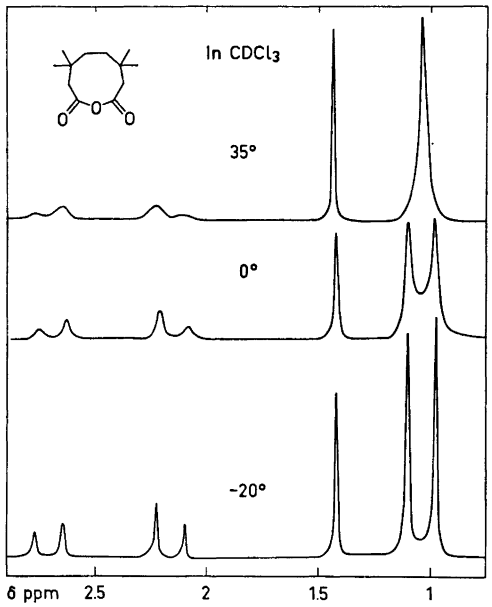

Fig. 1. The ^{1}H NMR-spectra of 3,3,6,6-tetramethyloctanedioic anhydride at different temperatures.

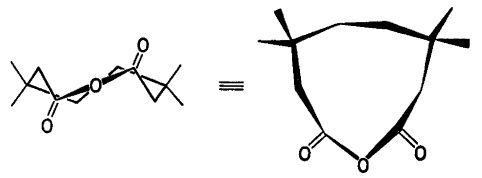

Fig. 2. Conformation of 3,3,6,6-tetramethyloctanedioic anhydride.

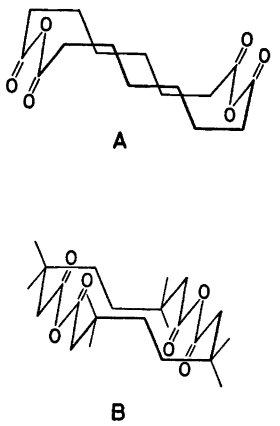

Fig. 3. A. Proposed ideal conformation for the unsubstituted dimer of octanedioic anhydride. B. Expected conformation for the dimer of 3,3,6,6-tetramethyloctanedioic anhydride.

groups and a quartet for the protons alpha to the anhydride groups. This means that there are only two types of methyl groups and two types of alpha protons. According to earlier considerations of possible conformations [8] this can only mean that the molecule has a C_2-symmetry, and probably D_3 symmetry for the ring skeleton, Fig. 2, as the earlier investigated tetramethyl substituted 9-membered rings.

The IR-spectra for the crystals and in CCl_4 solution were the same, indicating the same conformation in the crystals and in solution. The calorimetric values are in accordance with this observation.

DIMER OF 3,3,6,6-TETRAMETHYL-OCTANEDIOIC ANHYDRIDE

Hill and Carothers [10] found that the unsubstituted compound was stable up to the melting point 56 – 57°. Dale [1] has proposed that the ideal conformation for an unsubstituted cyclic dianhydride has the anhydride group and the two neighbouring carbon atoms coplanar to form the "bridges" as in Fig. 3 A; *gauche*-preferred bonds are in corner positions stabilizing the corners and the dipoles are anti-parallel.

In this conformation *gem*-dimethyl groups can, without serious interaction, only be placed in the corner positions, and not as they would in the tetramethyl substituted dimer, next to the corner positions.

Three other diamond lattice conformations are possible for the 18-membered cycloalkane.[11] Of these, the conformation, Fig. 3 B, would have planar anhydride groups, *gem*-dimethyl groups in the "corners", two-carbon bridges and dipoles opposed and would be the expected conformation for this compound, also because it most probably is the conformation for 1,1,4,4,10,10,-13,13-octamethylcyclo-octadecane.[12] However, the fact that the di-anhydride is a liquid and polymerizes by standing, may suggest that this conformation is not optimal, and makes it more probable that the dimeric anhydride exists as a mixture of conformations.

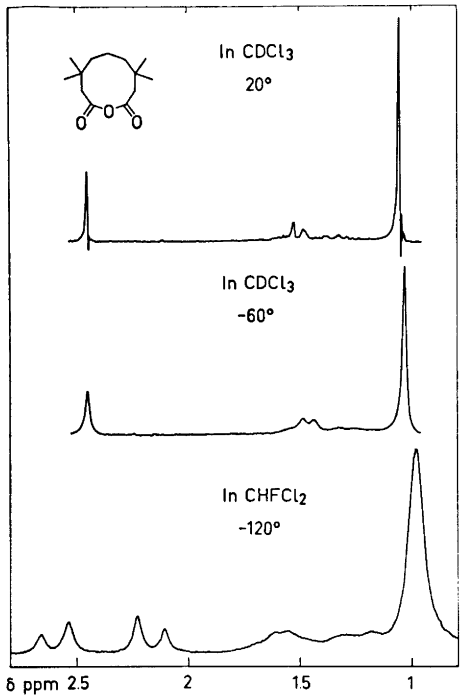

Fig. 4. The ^1H NMR-spectra of 3,3,7,7-tetramethylnonanedioic anhydride at different temperatures.

3,3,7,7-TETRAMETHYLNONANEDIOIC ANHYDRIDE

The NMR spectra of this 10-membered cyclic anhydride in $CDCl_3$ and $CHFCl_2$ at temperatures down to $-120°$ are shown in Fig. 4. The spectrum at the lowest temperature consists of a quartet for the alpha protons and the conclusion can be drawn that there are only two types of such protons and one type of α-CH_2 groups. The methyl signal has broadened but seems to require a lower temperature for full splitting. The spectrum at $-120°$ was the same in carbon disulphide. With only two types of alpha protons and the steric requirements of the two *gem*-dimethyl groups, the energetically possible conformations of this molecule are considerably reduced.

By semiquantitative calculations Dale [13] has found three probable conformations for 1,1,5,5-tetramethyl substituted cyclodecane. Two of these may be candidates for the conformation of the ring skeleton of 3,3,7,7-tetramethyl-

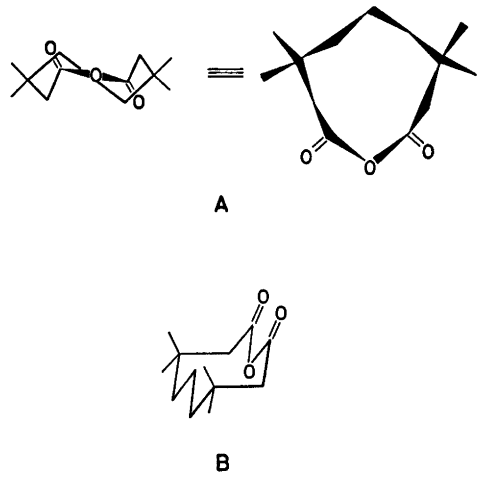

Fig. 5. Two possible conformations of 3,3,7,7-tetramethylnonanedioic anhydride.

nonanedioic anhydride. The third has no symmetry and is therefore not in accordance with the low temperature NMR-spectrum of the cyclic anhydride. The two actual conformations are shown in Fig. 5 A and B. Conformation A is the same as one of the two found by Dunitz in the crystal lattice of 4,4,8,8-tetramethylcyclodecane carboxylic acid.[14] Conformation B has already been proposed for cyclodecane-1,6-dione in solution.[15] The NMR-spectra, Fig. 4, shows a geminal coupling constant in the alpha protons of 12.5 cps. In conformation B one of the alpha protons is eclipsed with the C=O bond, in conformation A one alpha proton is almost eclipsed with the π-orbital in the C=O. In the first case the π-contribution to the coupling constant (dependent on the dihedral angle [16] should be below +0.5 cps, in the second case, −1.5 cps. As these contributions are small, and the observed coupling constant 12.5 cps is normal for such geminal protons (in the 9-membered ring anhydride, where the π-contribution should be zero, the corresponding J_{H-H}, was also 12.5) it is difficult to draw conclusions about the conformation from the geminal coupling constant of the alpha protons.

The similar degree of splitting of chemical shift of the two α-protons, as well as the similarity in the UV absorptions of the octane and nonane-dioic anhydrides indicates that the 10-membered cyclic anhydride may have the con-

formation A. The coplanarity in the anhydride group, preferred in open chain anhydrides may, however, be a reason for the molecule to chose conformation B. A surprising stability of this 10-membered cyclic anhydride, sligthly higher than the 9-membered ring anhydride is maybe explained by the coplanarity in conformation B and the stabilization of this conformation by the *gem*-dimethyl groups on the two "corners". As a cyclic anhydride the interactions are less and the deviations from the diamond lattice angles smaller than in the cycloalkane calculated by Dale and the conformation B therefore even more preferred.

The entropy and enthalpy of fusion of the tetramethylnonanedioic anhydride, Table 1, were on the same level as for the 9-membered ring anhydride. The IR-spectra were slightly different for the crystals in KBr and in CS_2 solution, however not sufficient to indicate different conformations in the two phases.

EXPERIMENTAL

Determination of dipole moments. Dielectric constants were measured at 20°C in a Weilheim Dipolmeter DM 01 in four different solutions of each compound. Refractive indices were measured on the same solutions in a Brice-Phoenix Differential Refractometer. Calculation of dipole moments was performed according to Hedestrand,[17] using no correction for atomic polarization.

Infrared spectra. These were recorded in a Perkin-Elmer Grating Infrared Spectrophotometer 457.

Ultraviolet spectra. The UV absorptions were determined in a Jasco Automatic Spectropolarimeter Model J-10.

Calorimetric measurements. A Perkin-Elmer Differential Scanning Calorimeter IB was used down to a temperature of −90°.

^1H NMR spectroscopy. The NMR spectra were recorded with a Varian HA 100 15 D instrument.

Tobacco Chemistry. 22. Structures and Syntheses of a Nor- and a Seco-terpenoid of the Drimane Series Isolated from Tobacco

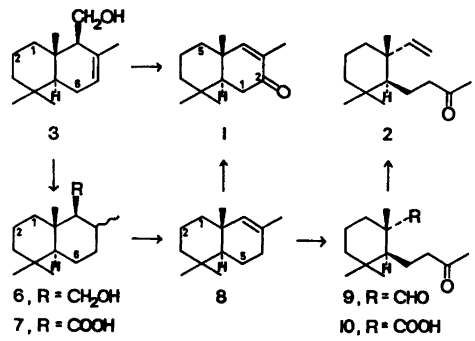
JOSEPH R. HLUBUCEK, ARNE J. AASEN, SVEN-OLOF ALMQVIST and CURT R. ENZELL*

Research Department, Swedish Tobacco Co., S-104 62 Stockholm 17, Sweden

The structures of two new tobacco compounds, (4a*R*,8a*S*)-4a,5,6,7,8,8a-hexahydro-3,4a,8,8-tetramethylnaphthalen-2(1H)-one (*1*) (isonordrimenone) and (1′*S*,6′*S*)-4-(2′,2′,6′-trimethyl-6′-vinylcyclohexyl)-2-butanone (*2*) were assigned on the basis of the spectral data and confirmed by synthesis. Both compounds are likely products of degradation of cyclic terpenoid precursors.

A neutral fraction of the volatile material from an extract of sun-cured Greek tobacco, *Nicotiana tabacum* L., yielded two minor components which were identified as the α,β-unsaturated ketone (*1*) and the vinyl ketone (*2*).[1] We now wish to report the structure elucidations, limited to a consideration of the spectral data because of the small quantities isolated, and the syntheses of these compounds from a common bicyclic intermediate (*8*) obtained by degradation of the sesquiterpene alcohol drimenol (*3*).

(4aR,8aS)-4a,5,6,7,8,8a-Hexahydro-3,4a,8,8-tetramethylnaphthalen-2(1H)-one (*1*). Accurate mass measurement of the molecular ion (*m/e* 206) in the mass spectrum of this tobacco compound gave the molecular formula $C_{14}H_{22}O$. The carbonyl absorption (ν_{max} 1673 cm^{-1}) and ultra-violet absorption (λ_{max} (EtOH) 237 nm, ε 6200) indicated a disubstituted α,β-unsaturated ketone. The NMR spectrum displayed singlets for three methyl groups (δ 0.88, 0.91 and 1.07) and a doublet for a methyl group on a double bond (δ 1.72, *J* 1 Hz). Irradiation at the frequency of the vinylic methyl group showed that the single olefinic proton (δ 6.37, q, *J* 1 Hz) was coupled to this methyl group. With no evidence for further unsaturation in



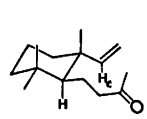
the molecule the molecular formula indicated a bicyclic compound, and the IR and UV spectral data supported a substituted α,β-unsaturated cyclohexanone structure. The downfield position of the quartet in the NMR spectrum for the olefinic proton indicated that it was β to the carbonyl group, and the collapse of the signal to a singlet in the above double irradiation experiment showed it to be coupled only to the methyl group and, hence, adjacent to a quaternary carbon atom. On addition of $Eu(fod)_3$-d_{27} a two proton multiplet at δ 2.12 – 2.62, assigned to the methylene group adjacent (α′) to the carbonyl function, was resolved into the strongly downfield-shifted AB part of an ABX system; the less strongly downfield-shifted X part was ascribed to a single proton, β′ to the carbonyl group, which lacked further spin-spin couplings and had to be adjacent to two fully substituted carbon atoms. These spectral data require the presence of a 2-methylcyclohex-2-en-1-one moiety and demonstrate how six of the remaining seven carbon atoms are linked to the ring. Since

three of these carbon atoms are present as tertiary methyl groups and another is quaternary it follows that the three remaining carbon atoms (C_3H_6) are present as methylene groups and the tobacco compound has structure *1*. The strong lanthanide induced shifts (LIS) observed in the NMR spectrum for C(3)CH_3 and C(1)H_2 and the less strongly induced shifts for the olefinic proton and C(8a)H are as expected. The relatively strong induced shift observed for C(4a)CH_3 and the weak induced shifts for C(8)(CH_3)$_2$ support the *trans*-fused structure *1*.

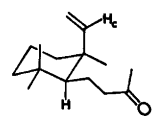
This tobacco compound (*1*) has not been isolated previously from a natural source but it has been reported as an oxidation product of the sesquiterpene alcohol drimenol (*3*).[2] Oxidation of the bicyclic olefin *8*, prepared from the sesquiterpene alcohol drimenol (*3*) as described below, with chromium trioxide in acetic acid solution provided an unambiguous synthesis of *1*. This product is identical in all respects to *1* isolated from tobacco. We have also confirmed that oxidation of drimenol (*3*) with chromium trioxide in pyridine gives isonordrimenone (*1*).[2]

(1'S,6'S)-4-(2',2',6'-Trimethyl-6'-vinylcyclohexyl)-2-butanone (2). The IR spectrum of this tobacco compound (*2*) with molecular formula $C_{15}H_{26}O$ (accurate mass measurement of molecular ion at *m/e* 222) showed absorptions characteristic of a carbonyl (1718 cm^{-1}) and a vinyl group (1637, 1008, 917 cm^{-1}). The three protons of the vinyl group appeared as an ABC system in the NMR spectrum (δ 4.89, H_A; 4.92, H_B; 5.64, H_C; $J_{AB} \sim 1$, J_{BC} 10, J_{AC} 18 Hz) and the absence of any coupling to other protons indicated that it was attached to a quaternary carbon atom. The presence of the $>CHCH_2CH_2COCH_3$ residue was established from the NMR spectrum (δ 2.06, CH_3CO) and the lanthanide induced shifts observed on the addition of Eu(fod)$_3$-d_{27}. The two proton multiplet at δ 2.15–2.5 for the methylene protons α to the carbonyl group was resolved into a strongly downfield-shifted triplet; spin-decoupling experiments confirmed the coupling of these protons to the two protons at C-4 which appeared as a less strongly downfield-shifted multiplet and, in turn, were coupled to the single proton γ to the carbonyl group which gave rise to a weakly downfield-shifted triplet. The absence of any further couplings to this last proton indicated that the $>CHCH_2CH_2COCH_3$ residue was attached to two fully substituted carbon atoms. The presence of the butanone sidechain was also supported by a prominent peak in the mass spectrum at *m/e* 164 ($M-C_3H_6O$) evidently arising from a McLafferty-type cleavage. With the vinyl group, the two quaternary carbon atoms carrying the 2-oxo-5-pentylidene moiety and the three methyl groups that appear as singlets in the NMR spectrum (δ 0.90, 0.92 and 1.02) there remains three methylene groups (C_3H_6) to construct the one ring required to satisfy the molecular formula. Since the two carbon atoms of the six-membered ring adjacent to the carbon atom bearing the butanone sidechain must be tetrasubstituted the structure *2* (stereochemistry undetermined) follows for this tobacco compound.

The relative stereochemistry may be deduced by distinguishing between the two configurations *4* and *5* possible when only chair conformations with the butanone sidechain in an equatorial position are considered. This was possible from an analysis of the LIS observed in the NMR spectrum on the addition of Eu(fod)$_3$-d_{27}. The preferred position of the europium complex about the carbonyl group



4



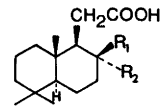
5

would be on the sterically less hindered side, α-side in *4* and *5*, and this is supported by the relatively strong LIS observed for C(1')H. The observed relative LIS for the three methyl groups and the vinyl proton H_c are in the order $Me \geq H_c \gg 2Me$ which is as expected for *4* but does not support the alternative configuration (*5*) for which the signals for the two α-methyl groups would be expected to display similar LIS which, in turn, would be greater than those for the β-methyl and the vinyl proton, H_c.

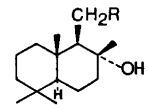
The structure *2* for this tobacco compound with stereochemistry as shown in *4* was confirmed by synthesis from the sesquiterpene alcohol drimenol (*3*) as outlined in the scheme.

The crude mixture of epimeric alcohols (*6*) obtained by the catalytic hydrogenation of drimenol (*3*)[3] was oxidised with chromium trioxide in 80 % acetic acid at room temperature in the presence of potassium hydrogen sulphate to give a 70 % yield of the epimeric acids *7*. Smooth decarboxylation of *7* was effected with lead tetraacetate in refluxing benzene in the presence of cupric acetate and pyridine[4] for an 80 % yield of the desired octahydronaphthalene intermediate *8*.

Ozonolysis of *8* at −78° in methylene chloride solution containing pyridine (1 equiv.) followed by a reductive work-up with zinc and acetic acid gave, in high yield, the unstable keto-aldehyde *9*. This essentially pure product was used in the next step without further purification. Only small amounts of the keto-aldehyde *9* were detected in the reaction product when ozonolysis of *8* in methanol suspension at −30° was followed by reduction of the hydroperoxides with dimethyl sulphide.[5] The main product of this reaction appeared to be the keto-acid (*10*). The attempted selective Wittig condensation of methylene triphenylphosphorane with the more reactive carbonyl group of *9* to give the desired vinyl ketone *2* gave a complex mixture of products. Eventually, inverse addition of a solution of methylenetriphenylphosphorane (1 equiv.) in dry dimethyl sulphoxide to a solution of the keto-aldehyde *9* in dry dimethyl sulphoxide at room temperature gave a low yield of the vinyl ketone *2*. The product was isolated by preparative gas-chromatography and displayed NMR, IR, and mass spectra identical to those of the tobacco compound *2*. The natural and synthetic products did not separate when co-injected on a capillary GC-column. The low specific rotation ($[\alpha]_D$ −0.5°) measured for the tobacco compound *2* in comparison to that for the synthetic material ($[\alpha]_D$ −10°) could not be used to establish the stereochemistry of the natural product. However, the very similar partial ORD curves of the natural and synthetic products obtained by measurement of the specific rotation at five different wavelengths (365 − 589 nm) confirmed that the synthetic product *2* and the tobacco compound *2* have identical absolute configurations. This is the first isolation of the C_{15} compound *2* from a natural source although it had been identified previously[6] as a cleavage product in the electrolytic decarboxylation of salts of the acids *11* and *12*.



11, $R_1 = CH_3$, $R_2 = OH$
12, $R_1 = OH$, $R_2 = CH_3$



13

The formation of isonordrimenone (*1*) and the vinyl ketone *2* by oxidation[2] of drimenol (*3*) and electrolysis of the salts of *11* and *12*, respectively, makes it attractive to suggest that bicyclic sesqui- or diterpenoids of the drimane (*e.g. 3*) or labdane type (relevant part of the labdane skeleton as in *13*) might act as precursors for the new nor- and seco-sesquiterpenoids *1* and *2*. Several natural products in the series *13* have recently been identified in Greek tobacco,[7] and related compounds such as 12-norambreinolide,[8] 8,13- and 8,13β-epoxylabd-14-en-12-one,[9] 12α-hydroxy-13-epimanoyl oxide,[10] and epimeric levantenolides,[11] are known tobacco leaf or smoke constituents.

EXPERIMENTAL

NMR, IR, UV, and mass spectra were recorded on Varian HA 100D and A60-A, Digilab FTS-14 and Perkin-Elmer 257, Beckmann DK-2A and LKB 9000 (70 eV) instruments, respectively. Optical rotations were measured on a Perkin-Elmer 141 instrument. Accurate mass measurements were carried out at the Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm. The mass spectra were obtained by gas liquid chromatography in combination with mass spectrometry (GLC-MS). A steel capillary column (0.5 mm × 50 m, Handy and Harman grade 316-S) coated with Emulphor by the dynamic packing method[12] was used for GLC-MS and analytical gas chromatography. A Varian 1700 gas chromatograph equipped with a glass column (3.2 mm × 3 m) packed with 5 % Carbowax 20M on Chromosorb G was used for preparative GLC.

Isolation. Compounds *1* and *2* were isolated from fraction B3 of an extract of sun-cured *Nicotiana tabacum* L. by a combination of liquid and preparative gas chromatography.[1]

(*4a*R,*8a*S)-*4a,5,6,7,8,8a-Hexahydro-3,4a,8-tetramethylnaphthalen-2-(1H)-one* (*1*) MS: *m/e* 206 (M^+, 42 %), 83 (100), 109 (48), 55 (34), 108 (33), 41 (33), 121 (27), 69 (26), 163 (24), 123 (23);

accurate mass measurement: $C_{14}H_{22}O$, found 206.1672, calc. 206.1671; λ_{max}(EtOH) 237 nm (ε 6200); λ_{max}(film) 1673 (s), 1640 (w), 1017 (m) cm^{-1}; δ ($CDCl_3$) 0.88 (3 H, s), 0.91 (3 H, s), 1.07 (3 H, s), 1.72 (3 H, d, J 1 Hz), 2.12–2.62 (2 H, m), 6.37 (1 H, q, J ~1 Hz). On addition of Eu(fod)$_3$-d_{27}: C(1)H_2 and C(8a)H appear as an ABX, r (relative induced shift) = 3.88 [C(5)H_2, 8 lines, J 4, 14, 18 Hz], 2.56 [C(3)CH_3, broad s], 1.9 [C(8a)H, dd, J 4, 14 Hz], 1.12 [C(4)H, broad s], 1.0 [C(4a)CH_3, s], 0.28 and 0.36 [C(8) (CH_3)$_2$, 2 s]. $[\alpha]_D^{20}$ +17.6 (c 0.21 in benzene).

(1'S,6'S)-4-(2',2',6'-Trimethyl-6'-vinylcyclohexyl)-2-butanone (*2*) MS: *m/e* 222 (M$^+$, 4.5 %), 43 (100), 41 (42), 109 (42), 81 (40), 82 (40), 95 (38), 67 (37), 55 (35), 69 (34), 123 (34); accurate mass measurement: $C_{15}H_{26}O$, found 222.1990, calc. 222.1984; $C_{12}H_{20}$, found 164.1558, calc. 164.1565; ν_{max}(film) 1718 (s), 1637 (w), 1162 (m), 1008 (w), 917 (m) cm^{-1}; δ ($CDCl_3$) 0.90 (3 H, s), 0.97 (3 H, s), 1.02 (3 H, s), 2.06 (3 H, s), 2.15–2.5 (2 H, m), $-CH=CH_2$ appears as an ABC: 4.89, H_A; 4.92, H_B; 5.64, H_C; J_{AB} 1, J_{BC} 10, J_{AC} 18 Hz. On addition of Eu(fod)$_3$-d_{27} r = 3.2 [C(3)H_2, t, J ~8 Hz], 3.2 [C(1)H_3, s], 2.4 [C(4)H_2, m], 1.0 [C(1')H, broad t, J ~5 Hz], 0.86 ($-CH=CH_2$,m), 0.5 and 0.58 ($-CH=CH_2$, 2 m), 0.66 (3 H, s), 0.44 (3 H, s), 0.34 (3 H, s). $[\alpha]^{20}$ −0.5° (589 nm), −12.7° (578), −15.2° (546), −33.3° (436), −74.2° (365) (c 0.2 in chloroform).

8ξ-Drimanol (*6*). Drimenol (*3*) (1 g) was hydrogenated in ethyl acetate solution (50 ml) with Adams catalyst (150 mg) at 20°/1 atm.[3] Filtration and removal of solvent afforded a colourless oil (1 g) that crystallised slowly on standing. No attempt was made to separate the minor product of hydrogenation, 8α-drimanol, from the major product, 8β-drimanol.

8ξ-Driman-11-oic acid (*7*). Oxidation of the crude product *6* from the hydrogenation of drimenol (*3*) by the method of Appel, Brooks and Overton [3] gave a poor yield of 8ξ-driman-11-oic acid *(7)*. The following procedure gave a 70 % yield of crystalline acid: A solution of chromium trioxide (345 mg) in 80 % acetic acid (12 ml) containing potassium hydrogen sulphate (340 mg), was added dropwise at room temperature to a stirred solution of the crude hydrogenation product *6* (1 g) in 10 % acetic acid (12 ml). After stirring at room temperature for a further 2 h the reaction mixture was diluted with water and extracted with ether. The combined ether extracts were washed with saturated sodium bicarbonate solution (to remove only 39 mg of acidic material that contained no *7* on acidification and extraction into ether) followed by 2 M sodium hydroxide solution. The combined alkaline extracts were acidified and extracted with ether, the ether fractions washed with water and the solvent evaporated to yield crystalline 8ξ-driman-11-oic acid (*7*) (0.55 g). The neutral residue (0.35 g) from this oxidation contained unreacted drimanol (6) and related aldehydes which, on further oxidation in 80 % acetic acid solution (5 ml) with chromium trioxide (230 mg) in 80 % acetic acid (5 ml) containing potassium hydrogen sulphate (230 mg) and work-up as described above, gave a further 0.2 g of crystalline 8ξ-driman-11-oic acid (*7*) ν_{max}(KBr) 2500–3600 (broad), 1700 cm^{-1} (s).

trans-1,2,3,4,4aα,5,6,8a-Octahydro-4α,4β,7,8aβ-tetramethylnaphthalene (8). A mixture of 8ξ-driman-11-oic acid (0.5 g), lead tetraacetate (2.5 g, freed of excess acetic acid under high vacuum), copper(II) acetate (0.4 g) and pyridine (0.25 ml) in dry benzene (60 ml) was heated under reflux for 2 h in a nitrogen atmosphere.[4] The insoluble lead salts were filtered off at room temperature and the filtrate was washed with water, dried (Na_2SO_4) and the benzene removed under reduced pressure. The crude product was filtered through silica (25 g) in 1 % ether/pentane to yield pure *8* (320 mg, 80 %). Accurate mass measurement: $C_{14}H_{24}$, found 192.1886, calc. 192.1878; δ ($CDCl_3$) 0.85 (3 H, s), 0.90 (3 H, s), 0.94 (3 H, s), 1.58 (3 H, broad s), 5.06 (1 H, q, J ~1.5 Hz); ν_{max}(film) 3000 (m), 1390 (m), 1379 (m), 1370 (m), 1030 (w), 848 (m) cm^{-1}; $[\alpha]_D^{20}$ +56.8° (c 0.95 in pentane).

Keto-aldehyde 9. Ozone was bubbled through a solution of *8* (320 mg) in methylene chloride solution (10 ml) containing pyridine (140 mg) at −78° until there was an excess of ozone at the outlet from the reaction vessel. Zinc (600 mg) and acetic acid (1.5 ml) were added and the reaction mixture was brought quickly to room temperature. After 2 h stirring at room temperature the reaction mixture was diluted with water and extracted with ether. The combined ether extracts were washed with water, saturated sodium chloride solution and dried (Na_2SO_4). Evaporation of the solvent under reduced pressure gave the keto-aldehyde *9* as a pale yellow liquid (368 mg). This unstable but essentially pure reaction product darkened quickly on standing and could not be purified successfully by chromatography on silica. It was reacted in the next step without further purification. MS: *m/e* 224 (M$^+$, 1 %), 43 (100), 69 (65), 41 (38), 95 (33), 81 (30), 109 (28), 123 (25), 55 (24); δ ($CDCl_3$) 0.92 (3 H, s), 0.95 (3 H, s), 1.10 (3 H, s), 2.07 (3 H, s), 2.2–2.45 (2 H, m), 9.28 (1 H, s). ν_{max} (film) 2690 (w), 1720 (s).

Vinyl ketone 2. A solution of methylene triphenylphosphorane (1 mM) in anhydrous dimethyl sulphoxide (10 ml), from the *in situ* reaction of methylsulphinyl carbanion (generated with 24 mg of sodium hydride) and methyl triphenylphosphonium bromide (360 mg),[14] was added under nitrogen pressure to a stirred solution of the crude keto-aldehyde *9* (224 mg, 1 mM) in anhydrous dimethyl sulphoxide (20 ml) over 1 h at room temperature. After a further hour at room temperature the reaction

mixture was diluted with water, acidified, and extracted with ether. The combined ether extracts were washed with water, saturated sodium chloride solution and dried (Na_2SO_4). Evaporation of the solvent gave a yellow oil (240 mg) which TLC showed to be a complex mixture of compounds. Pure vinyl ketone *2* was isolated in low yield by preparative gas chromatography. It displayed NMR and IR spectra indistinguishable from the spectra of *2* isolated from the tobacco. The synthetic and natural products did not separate when co-injected on a capillary GC column. $[\alpha]^{20}$ −10.0° (589 nm), −15.2 (578), −17.7 (546), −36.5 (436), −78.6 (365) (*c* 0.52 in chloroform).

Isonordrimenone (*1*). (i) The octahydronaphthalene *8* (20 mg) in acetic acid (2 ml) at 70° was treated dropwise (20 min) with a solution of chromium trioxide (20 mg) in acetic acid (1 ml). After a further 30 min at 70° the cooled reaction mixture was diluted with water and extracted with ether. The combined ether extracts were washed with saturated sodium bicarbonate solution, water and dried (Na_2SO_4). Chromatography on silica of the residue obtained on evaporation of the solvent gave pure isonordrimenone (*1*) (8 mg). It displayed NMR, IR, and mass spectra identical to those obtained for *1* isolated from the tobacco, and the synthetic and natural products did not separate when co-injected on a capillary GC column. $[\alpha]_D^{20}$ + 21.8° (*c* 0.22 in benzene).

(ii) Oxidation of drimenol (*3*) (30 mg) with chromium trioxide (75 mg) in dry pyridine (0.75 ml) as described by Appel, Brooks and Overton [3] gave a mixture of compounds from which isonordrimenone (*1*) (3 mg) was isolated by column chromatography on silica. This material was identical in all respects to *1* isolated from the tobacco and prepared by oxidation of *8* as described above.

Acknowledgements. We are indebted to Miss A.-M. Eklund for skilful technical assistance, to Professor H. H. Appel and Professor K. H. Overton for their generous gifts of drimenol, and to Professor K. Olsson, Agricultural College of Sweden, Uppsala, for placing their NMR spectrometer at our disposal.

Transformations of Steroids by Cell-free Preparations of *Penicillium lilacinum* NRRL 895. IV. Enzyme Catalyzed Acyl Transfer

KJELL CARLSTRÖM

Department of Pure and Applied Biochemistry, Royal Institute of Technology, and the Department of Obstetrics and Gynaecology, Sabbatsberg Hospital, Karolinska Institutet, S-11382 Stockholm,* Sweden

The cleavage of testosterone acetate by cell-free preparations from *P. lilacinum* was stimulated up to 2.3-fold by the addition of equimolar amounts of testosterone. Testosterone was found to be an acceptor of acyl groups derived from the acetyl esters of testosterone, epitestosterone, oestrone, epiandrosterone and desoxycorticosterone and from testosterone propionate. Epitestosterone inhibited the cleavage of testosterone acetate and did not act as an acyl acceptor to any significant degree. 4-Androstene-3,17-dione slightly stimulated the cleavage of testosterone acetate, probably acting as a modifier molecule.

Whereas the hydrolysis of steroid esters by microorganisms is well documented, reports on microbial esterification of hydroxysteroids seem to be less frequent.[1] Transformation of 4-androstene-3,17-dione into testosterone and testosterone acetate by *Saccaromyces fragilis* was demonstrated by McGuire *et al.*[2] Capek and co-workers showed that of 45 *Endomycetes* only the lactose fermenting species *S. fragilis*, *S. lactis*, *Candida pseudotropicalis*, and *Torulopsis sphaericus* were capable to acetylate testosterone. Steroids with 11α, 11β, 17α (sec), 20β, and 21-hydroxyls were not acetylated.[3] 3β-Hydroxy-C_{19}-steroids have been converted into the corresponding 3β-acetoxy compounds by *Penicillium oxalicum*.[17] 21-Acetylation of the acetonide of 9α-fluoro 16α-hydroxyhydrocortisone was demonstrated in *Trichoderma glaucum* by Holmlund *et al.*[4] Esterification of sterols with fatty acids and with succinic acid has been demonstrated in *Mycoplasma*, intestinal bacteria and *Mycobacteria*[5–8] *Aspergillus flavus* has been shown to convert oestrone into its sulphate.[9]

In the cases mentioned above, the acyl moiety was appearantly not derived from the steroid structure. The microbial formation of 17β acetates from 20-oxo-C_{21}-steroids is a result of a Baeyer-Villiger type of oxidation and must not be considered as an esterification.[1]

The steroid inducible esterase activity in cell-free preparations from *P. lilacinum* readily cleaves the ester bond of testosterone acetate.[10] When this reaction was studied, the product testosterone was found not to inhibit but instead to stimulate the reaction and to act as an acceptor of the acetyl group. The present communication describes transacylations carried out by esterase-active cell free preparations from *P. lilacinum* and the influence of some Δ^4-3-oxo-C_{19} steroids upon the esterase activity in such preparations.

MATERIALS AND METHODS

Abbreviations and trivial names. GLC: gas liquid chromatography; GC-MS: gas chromatography-mass spectrometry; TLC: thin layer chromatography; Desoxycorticosterone: 21-hydroxy-4-pregnene-3,20-dione; Epiandrosterone: 3β-hydroxy-5α-androstan-17-one; Epitestosterone: 17α-hydroxy-4-androsten-3-one; Oestrone: 3-hydroxy-1,3,5,(10)-oestratrien-17-one; Progesterone: 4-pregnene-3,20-dione; Testosterone: 17β-hydroxy-4-androsten-3-one.

Radioactive chemicals. [^{3}H]-Acetic anhydride (specific activity 0.050 Ci/mmol), [4-^{14}C]-4-

* Present address.

androstene-3,17-dione (specific activity 0.0588 Ci/mmol), [7-^{3}H]-testosterone (specific activity 25 Ci/mmol) and [1,2-^{3}H]-epitestosterone (specific activity 49 Ci/mmol) were obtained from New England Nuclear Corp., Boston, Mass. The steroids were purified by TLC before use. Acetates of radioactive steroids or with ^{3}H-labelled acetyl groups were prepared by acetylation with acetic anhydride in pyridine, followed by purification by TLC. In the enzyme experiments the solutions of radioactive steroids were diluted with unlabelled steroids to give a final radioactivity corresponding to approx. 300 cpm per 0.3 μmol steroid in 10 μl of ethanol for desoxycorticosterone-[^{3}H] acetate and 10 000 – 50 000 cpm for the other steroids.

Unlabelled steroids. 4-Androstene-3,17-dione, desoxycorticosterone acetate, epiandrosterone acetate, progesterone, testosterone and its acetate and propionate were obtained from Sigma Chemical Co., St Louis, Mo. Epitestosterone and its acetate were obtained from Steraloids Inc., Pawling, N.Y. and desoxycorticosterone from Ikapharm, Ramat-Gan, Israel. They were checked for purity by TLC and/or GLC.

Other chemicals. All other chemicals were of reagent grade and treated as described previously.[10]

Chromatographic systems. TLC was carried out on Silica gel GF_{254} (system 1)[11] and on Al_2O_3 GF_{254} (0.5 % ethanol in benzene as solvent). GLC on OV-17 and GC-MS were performed as previously described.[11]

Growth of organism and preparation of cell free extracts. P. lilacinum NRRL 895 was grown on Czapek-Dox medium, induced, washed and frozen as described previously.[11] Progesterone was used as induced (70 mg in 2 ml of dimethylformamide per 300 ml of culture). 0.06 M Tris-HCl pH 7.2 was used as buffer in the washing of the cells and in the preparation of cell free extracts.

Cell free extracts were prepared using high speed grinding with glass beads according to Hedenskog *et al.*[12] All procedures were carried out at +4°C. 7 – 9 g of frozen cells were thawed and suspended in buffer to a final volume of 21 ml. The suspension was ground for 30 min with an equal volume of glass beads (diameter 0.45 – 0.50 mm) in a 28 mm i.d. glass tube with a loop stirrer of 20 mm diameter, rotating at approx. 1500 – 2000 rpm. The supernatant was decanted and the beads were washed with two small portions of buffer which were combined with the first supernatant. Cell debris was removed by centrifugation at 6000 rpm for 15 min, yielding about 30 ml of crude supernatant. After centrifugation at 100 000 *g* for 60 min, the resulting supernatant was frozen in suitable aliquots at −22°C. After thawing at room temperature the extract was centrifuged at 6000 rpm for 15 min in order to remove inactive protein precipitated during the freezing and thawing procedure. The clear extract was diluted with 0.06 M Tris-HCl pH 7.2 (usually to a fourfold dilution) and used in the enzyme experiments.

Incubation of steroids with cell-free extracts. The procedures for incubation and for extraction of the reaction mixture were the same as those previously described.[13] Due to short reaction times (2 min) the incubations were carried out on a vortex mixer. Each steroid was added in 10 μl of ethanol and in each series the ethanol concentration was equalized. The enzyme solution was preincubated with the steroid additive, usually for 45 s (for technical reasons), and the steroid ester substrate was then added. All incubations were carried out in duplicates.

The esterase activity in these preparations is unstable at room temperature, loosing approx. 10 – 20 % of its original activity in 40 – 60 min.[10] Therefore reference incubations with enzyme and steroid ester were run at the beginning and at the end of the series. The decrease in esterase activity was assumed to be linear and was corrected for in the calculations.

Steroid analysis. The relative amount of steroid alcohol and steroid ester was determined by TLC and liquid scintillation counting as described previously.[13] It was checked that side reactions (*e.g.* alcohol dehydrogenation) did not take place to any detectable degree. The variation between individual samples in duplicate incubations was calculated as $S.D. = (\sum d^2/2N)^{\frac{1}{2}}$. In two series, one with a mean testosterone concentration of 31.6 mol % (4.2 – 49.3 %, N = 61) and another with a mean concentration of 80.3 mol % (51.9 – 95.8 %), N = 20) the S.D. was ± 1.5 mol %.

Identification of steroids. The fractions containing [7-^{3}H] testosterone acetate formed by acetyl transfer from unlabelled steroid acetates (with exception of epitestosterone acetate) were isolated individually by TLC on Silica gel GF_{254}, rechromatographed on Al_2O_3 GF_{254} and analyzed by GC-MS and GLC using OV-17 as stationary phase. Crystallization to constant specific activity was also carried out after addition of 30 mg of carrier testosterone acetate. The [7-^{3}H]testosterone acetate fractions obtained from the acetates of desoxycorticosterone, epiandrosterone and oestrone were pooled and crystallized. The [7-^{3}H]testosterone acetate obtained from [7-^{3}H]testosterone and unlabelled testosterone acetate was crystallized separately.

Due to difficulties in the separations of the 17-epimeric acetyl esters, the [7-^{3}H]testosterone acetate obtained by transacetylation from unlabelled epitestosterone acetate was only tentatively identified by its TLC R_F-value.

[7-^{3}H] testosterone propionate obtained by transacylation from non radioactive testosterone propionate was isolated by TLC on Silica gel GF_{254} and by rechromatography on Al_2O_3 GF_{254}. In the latter system the acetates and propionates of testosterone separated fairly

well (R_F-value for testosterone acetate 0.45, for testosterone propionate 0.53). The propionate was identified by crystallization to constant specific activity.

RESULTS

Acylation of testosterone. When [7-^{3}H]testosterone was incubated together with steroid acetates and with testosterone propionate, transfer of the acyl group from the ester substrate to testosterone could be demonstrated (Table 1). All the esters used are hydrolyzed by the esterase preparation.[10] TLC, GLC, and GC-MS properties for the testosterone acetate and propionate formed by transacylation were identical to those of authentic reference compounds. The results from the crystallizations to constant specific radioactivity are shown in Table 2.

When desoxycorticosterone-[^{3}H]acetate was incubated together with unlabelled testosterone, significant amounts of radioactivity could be recovered only in the testosterone acetate and desoxycorticosterone acetate fractions.

Ethyl acetate and sodium acetate did not serve as acetyl donors, even after prolonged incubation (20 min). Boiled extracts did not catalyze transacylations.

When [1,2-^{3}H]epitestosterone was incubated with enzyme preparation and testosterone acetate or epitestosterone acetate, significant amounts of [1,2-^{3}H]epitestosterone acetate could not be detected.

Effect of Δ^4-3-oxo-C_{19} steroids on the cleavage of [7-^{3}H]testosterone acetate and [1,2-^{3}H]epitestosterone acetate. The cleavage of testosterone acetate was clearly stimulated by testosterone and to a less degree also by 4-androstene-3, 17-dione (Tables 3–5). It was inhibited by epitestosterone (Tables 3 and 5). The hydrolysis of epitestosterone acetate was inhibited by epitestosterone and to a smaller degree also by testosterone. It was slightly stimulated by 4-androstene-3,17-dione (Table 3).

The increase in testosterone acetate cleavage depended on the amount of initially added free testosterone (Table 4). The figures clearly indicate that the effect was due to alcoholysis (transacylation) and thus the net amount of tritiated + unlabelled testosterone acetate in the mixture was not significantly affected. In

3 E	4-androstene-3,17--dione	115

[a] Initial concentration of [7-^{3}H]testosterone acetate (3T) or [1,2-^{3}H]epitestosterone acetate (3E) 3.04×10^{-4} M, incubation time 2.0 min, temp. 26°C. [b] Initial concentration 3.47×10^{-4} M. Preincubation time 45 s.

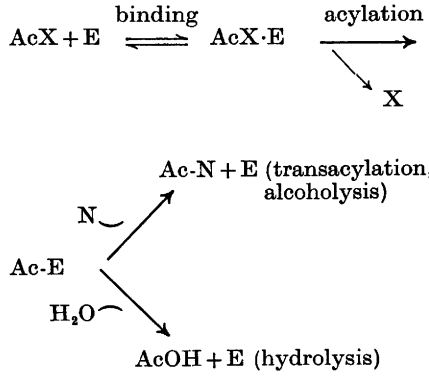
separate experiments the effect was found to be independent upon preincubation time (0 – 600 s).

Addition of equimolar amounts of 4-androstene-3,17-dione together with the 17-hydroxysteroids did not significantly influence the effects of testosterone (transacylation or stimulation of [7-^{3}H]testosterone acetate cleavage). The inhibitory effect of epitestosterone was slightly diminished by 4-androstene-3,17-dione (Table 5). When [4-^{14}C]4-androstene-3,17-dione was incubated with unlabelled testosterone acetate, no radioactivity could be detected in the testosterone acetate fraction. It was also found that the 17-oxo-group of [4-^{14}C]4-androstene-3,17-dione was not reduced in this system.

DISCUSSION

Acyl group transfer catalyzed by hydrolytic enzymes is well known.[14] However, transacylation between steroid esters and alcohols does not seem to have been reported to occur in microbial steroid metabolism.

The increase in testosterone acetate cleavage caused by testosterone is appearently due to "alcoholysis" since it corresponds to the amount of transacetylated steroid alcohol (Table 4). It is generally assumed that the enzyme catalyzed ester cleavage starts with a rapid binding step and proceeds *via* an acyl enzyme intermediate according to the following equation:[14]



where AcX is the ester, E the enzyme, AcX·E the enzyme substrate complex, X the alcohol, Ac – E the acyl-enzyme intermediate and N a nucleophile such as testosterone. If the acylations step is fast, the acyl-enzyme can be supplied as fast as it reacts further. Thus the rate of ester cleavage will be determined by the deacylation steps, *i.e.* hydrolysis or alcoholysis. The total rate of ester cleavage will increase linearly with increasing concentration of nucleophile.[15] The results presented in Table 4 clearly indicate that this is the case for the testosterone acetate cleavage.

The activation caused by 4-androstene-3,17-dione is probably analogous to the modifier action of acetone and other non hydroxylic compounds on esterases from pig and beef liver.[14,15] Greenzaid and Jencks found that nucleophiles such as methanol as well as modifier molecules (acetone, dioxane) increased the activity of pig liver esterase.[15] However, the modifiers were found to specificially suppress the degree of methanolysis. From this the authors postulated an alcohol binding site which might be occupied by the alcohol as well as by the modifier. The lack of effect of 4-androstene-3,17-dione on the transacylation

of testosterone does not necessarily speak against the existence of such an alcohol binding site in the preparation from *P. lilacinum*. It might be due to differences in affinity towards the 17 β-alcohol and the 17-ketone.

Epitestosterone was found to suppress the hydrolysis of testosterone acetate as well as of epitestosterone acetate. It was also not possible to demonstrate transacylation of epitestosterone. This latter finding can be easily explained by the steric differences between the epimeric 17-alcohols. Wynne and Shalitin have studied the influence of the structure of alcohols upon their action of beef liver esterase activity.[16] They assumed the alcohol binding site to be a narrow cleft "padded" with hydrophobic groups. This will fit well with the different behaviour of the two epimeric 17-hydroxysteroids: see Fig. 1. The less favourable configuration of the 17α-hydroxyl might also

explain its resistence towards enzymatic acetylation by yeasts as shown by Capek *et al.*[3]

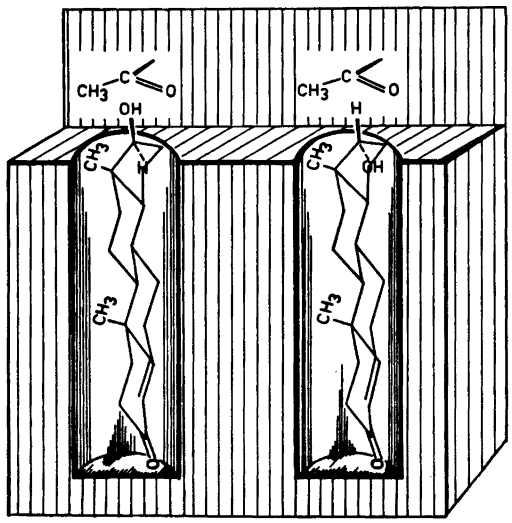

Fig. 1. Differences between testosterone and epitestosterone in reactivity: The 17β-hydroxyl group has a far more favourable position towards the acetyl group in the acetyl-enzyme complex.

While the nucleophile testosterone does not affect the hydrolysis of testosterone acetone to any considerable degree but stimulates the total disappearance rate by alcoholysis, its action upon the cleavage epitestosterone acetate is quite different. Transacylation of testosterone from epitestosterone acetate occurs to only about one fifth of that observed in the testosterone-testosterone acetate system. The hydrolysis is partly inhibited and this results in a slight suppression of the total cleavage rate. Similar observations have been made previously by Greenzaid and Jencks, using highly purified preparations of pig liver esterase.[15] While the addition of methanol causes a slight suppression of the hydrolysis of phenyl acetate but an increase on total cleavage due to alcoholysis, the hydrolysis of smaller acetates such as methyl acetate was greatly suppressed which in some cases resulted in a decrease of the total cleavage rate. These findings together with differences in response to organophosphorus inhibitors led to the conclusion that at least two different types of active sites with differences in substrate specificity must exist. This might also be true for the esterase active preparations from *P. lilacinum*, especially when its adaptive nature is considered. It must also be kept in mind that this preparation is rather crude and might contain several esterase active proteins with different substrate specificity.

Acknowledgement. The GC-MS analysis was carried out at the Department of Chemistry 1, Karolinska Institutet, Stockholm, Sweden.

The Oxidation of Glycosides. XVII. Preparation of Some Methyl-hexodialdopyranoside-(1,5)-s

BIRGITTA PETTERSSON and OLOF THEANDER*

Chemistry Department, Swedish Forest Products Research Laboratory, Box 5604, S-114 86 Stockholm, Sweden

The 6-aldehydo derivatives of methyl 3-*O*-methyl-β-D-glucopyranoside and of the anomeric methyl glycopyranosides from L-glucose, L-mannose, D-galactose, and D-gulose have been prepared. During the oxidation of methyl 3-*O*-methyl-β-D-glucopyranoside small amounts of two keto-compounds were obtained: methyl 3-*O*-methyl-β-D-*arabino*-hexopyranosidulose and another one, which most likely is a diketo derivative of the parent glucoside.

The previously unreported methyl α- and β-D-*glycero*-D-*talo*-heptopyranosides were also prepared.

It was observed that 6-aldehydo derivatives of methyl β-D-glucopyranoside and its 4-*O*-methyl derivative were hydrolysed much faster than the unoxidised glucosides.[1] In order to study this effect in some detail, a number of 6-aldehydo-hexosides have been prepared, and their acid hydrolysis will be investigated. In the present paper we report the synthesis of methyl 3-*O*-methyl-β-D-gluco-hexodialdopyranoside-(1,5) (I), the 6-aldehydo derivatives of the anomeric methyl glycopyranosides of L-glucose (II, III), L-mannose (IV, V), D-galactose (VI, VII), and D-gulose (VIII, IX).

Methyl 3-*O*-methyl-β-D-gluco-hexodialdopyranoside-(1,5) (I) was prepared by a route similar to that followed for the corresponding 4-*O*-methyl derivative,[2] that is, by oxidation of methyl 3-*O*-methyl-β-D-glucopyranoside with chromium trioxide in acetone and subsequent fractionation of the products on carbon and cellulose columns. Compound I was obtained as an amorphous ($[\alpha]_D^{20}$ −13°) material and showed the chromatographic and electrophoretic properties of an aldehydo-glycoside.[3] The structure was demonstrated through the following reactions: Borohydride reduction gave only one product, methyl 3-*O*-methyl-β-D-glucopyranoside which, when hydrolysed, released only one sugar, 3-*O*-methyl-D-glucose. After acid hydrolysis of I to the free dialdose, partial reduction and demethylation with

boron trichloride,[4] glucose and gulose were the only monosaccharides detectable by paper chromatography and electrophoresis. Besides, supporting the structures of I, this result also indicated that no isomerisation of I or its hydrolysis product had occurred during the acid treatment.

Preparation of compound I was the primary object of this experiment, but two keto-compounds, formed in small amounts were also characterised. One of these compounds was amorphous ($[\alpha]_D^{20}$ −32°) and according to its chromatographic properties and migration in hydrogen sulphite electrophoresis [3,5] ($M_{vanillin}$ = 0.39, *cf.* 1.19 for compound I), appeared to be a mono-keto derivative. After borohydride reduction and demethylation this compound gave glucose and mannose as the only detectable monosaccharides, indicating that the compound is methyl 3-*O*-methyl-β-D-*arabino*-hexopyranosidulose (X).

The other compound was obtained crystalline (m.p. 141 – 142°; $[\alpha]_D^{20}$ −45.2°) and its chromatographic properties, migration in hydrogen sulphite electrophoresis ($M_{vanillin}$ = 1.37)[3,5] and elemental analysis indicated that it was a diketo compound, which make structure XI most likely. Borohydride reduction and demethylation yielded glucose, galactose, and small amounts of mannose as the main products in agreement with the proposed structure, XI.

D-Galactose oxidase has been widely used to oxidise the hydroxyl group at C-6 in D-galacto-pyranose residues to an aldehyde group.[6,7] The reaction is used when analysing such residues or when making tritium labelled compounds *via* reduction.[8] A discussion of previous work and substrate specificity of this oxidase has been published.[9] In the present work this method was used for the preparation of methyl β-D-*galacto*-hexodialdopyranoside-(1,5) from the corresponding galactoside. The reaction was not at all complete which is in accordance with the

Table 2. Preparation of methyl hexodialdopyranoside-(1,5)-s.

Substance	Yield %	$[\alpha]_D^{20}$ (H_2O)
Methyl 3-*O*-methyl β-D-*gluco*-hexodialdopyranoside-(1,5) (I)	10	−13°
Methyl α-L-*gluco*-hexodialdopyranoside-(1,5) (II)	44	−120°
Methyl β-L-*gluco*-hexodialdopyranoside-(1,5) (III)	70	+40°
Methyl α-L-*manno*-hexodialdopyranoside-(1,5) (IV)	60	−60°
Methyl β-L-*manno*-hexodialdopyranoside-(1,5) (V)	28	+69°
Methyl α-D-*galacto*-hexodialdopyranoside-(1,5) (VI)	34	+132°
Methyl β-D-*galacto*-hexodialdopyranoside-(1,5) (VII)	93[a] 8[b]	+8°
Methyl α-D-*gulo*-hexodialdopyranoside-(1,5) (VIII)	31	+116°
Methyl β-D-*gulo*-hexodialdopyranoside(-1,5) (IX)	47	−71°

[a] Prepared from the methyl heptoside with periodate oxidation. [b] Prepared from the methyl galactoside with enzymatic oxidation.

results obtained from oxidation of *o*-nitrophenyl-β-D-galactopyranoside.[8]

The aldehydo compound obtained from enzyme action was shown to be identical with a sample prepared by the route discussed below. Further verification of the structure was obtained by hydrolysis to *galacto*-hexodialdose and by conversion to galacturonic acid by bromine oxidation and hydrolysis.

Antia and Perry [10] prepared methyl β-D-gulopyranoside by oxidation of methyl β-D-*glycero*-D-*gulo*-heptopyranoside with 1 mol of periodate to the 6-aldehydo-glycoside, followed by borohydride reduction. We have used this synthetic route, but stopping at the 6-aldehydo stage, in the preparation of a series of methyl hexodialdopyranoside-(1,5)-s. The heptoses prepared from D-glucose by the cyanohydrin synthesis and from D-mannose and D-galactose by the nitromethane synthesis, were glycosidated with methanol-hydrogen chloride. The products after glycosidation were fractionated on a basic ion-exchange resin column.[11] Yields and properties of the pure anomeric methyl heptosides obtained are summarised in Table 1. Methyl α- and methyl β-D-*glycero*-D-*talo*-hepto-

Table 3. Electrophoretic mobilities of the aldehydo-glycosides and corresponding dialdoses.

Substance	Hydrogen sulphite pH 4,7 $M_{vanillin}$	Borate pH 10 $M_{glucose}$
Methyl β-D-*gluco*-hexodialdopyranoside-(1,5)	1.25	0.62
Methyl 4-*O*-methyl β-D-*gluco*-hexodialdopyranoside-(1,5)	1.22	0
Methyl 3-*O*-methyl β-D-*gluco*-hexodialdopyranoside-(1,5)	1.19	0.57
Methyl α-L-*gluco*-hexodialdopyranoside-(1,5)	1.07	0.47
Methyl β-L-*gluco*-hexodialdopyranoside-(1,5)	1.25	0.60
Methyl α-L-*manno*-hexodialdopyranoside-(1,5)	1.17	0.66
Methyl β-L-*manno*-hexodialdopyranoside-(1,5)	1.29	0.62

D-*gulo*-Hexodialdose	1.42	1.09

pyranosides have, to our knowledge, not been previously reported.

The heptosides (1 mol) were oxidised at low temperature with periodate (1.05 – 1.15 mol). The products were fractionated by cellulose column chromatography and amorphous, but, according to paper chromatography and electrophoresis, pure fractions of the 6-aldehydo-glycopyranosides II – IX were obtained. Yields, based on the heptosides used as starting materials, and optical properties of the pure top-fractions are given in Table 2. The corresponding derivatives of D-idose and D-talose were obtained in small yields only and were impure.

Characteristic for aldehydo-glycopyranosides as well as for dialdoses and osuloses is the appearance on the paper chromatograms of elongated spots, which are often multiple with tailing between, which indicates equilibria between various isomeric forms.[3] This, of course, complicates the chromatographic purification of the aldehydo-glycosides. On paper electrophoresis, either in hydrogen sulphite [5] or borate buffer, the aldehydo-glycosides show characteristic mobilities and give distinct spots (Table 3). Studies on the acid hydrolysis of the aldehydo-glycosides will be reported separately.

EXPERIMENTAL

Concentrations were carried out under reduced pressure below 40°. The following solvent systems were used for paper chromatography:

A. Butan-1-ol – ethanol – water (10:3:5).
B. Ethyl acetate – acetic acid – water (3:1:1).
C. Ethyl acetate – pyridine – water (8:2:1).

In paper electrophoresis the following buffers were used:
D. 0.1 M Sodium hydrogen sulphite,[5] pH 4,7 at 40°.
E. 0.1 M Borate, pH 10.
F. 0.4 M Boric acid, 1.0 M glycerol, pH 6.8 at 40°.[12]

Whatman No. 1 papers were used for the chromatographic separations. Visualization of the spots was through the following conventional carbohydrate spray reagents: *p*-anisidine hydrochloride, silver nitrate-sodium hydroxide and resorcinol-hydrochloric acid.

Preparation and characterisation of methyl 3-O-methyl-β-D-gluco-hexodialdopyranoside-(1,5) (I). Methyl 3-*O*-methyl-β-D-glucopyranoside was prepared as previously reported.[13,14] The glucoside was oxidised in a way similar to that described for the corresponding 4-*O*-methyl ether.[2]

Chromium trioxide (8.3 g) in small portions was added with agitation to cold, freshly distilled acetone (835 ml). A solution of the glucoside (12.5 g) in cold acetone (250 ml) was poured in a slow stream to the agitated chromium trioxide solution. The temperature was kept below +15°. The reaction mixture was then kept at room temperature for half an hour and after that refluxed for 1 h. After cooling, the precipitate was filtered off and heated under reflux with acetone (4 × 175 ml) with intermediate filtrations. The combined filtrates were concentrated to a small volume and diluted with water to a final volume of 200 ml. The aqueous solution was extracted with chloroform (4 × 100 ml) and then treated with cation exchanger (Dowex 50, H^+) and anion exchanger (Dowex 3, free base). After concentration the oxidation product was separated on a carbon-Celite column (6.5 × 70 cm) and eluted with aqueous ethanol 0 – 25 % (20 l) and, subsequently, with 75 % ethanol (4 l). The fraction (0.65 g) which contained the aldehydo-compound, also contained some starting material and probably some keto-compounds and was further fractionated on a silicic acid column (3.5 × 50 cm) with chloroform-ethanol (3:1) as eluent.

A chromatographically and electrophoretically pure top-fraction of methyl 3-*O*-methyl-β-D-*gluco*-hexodialdopyranoside-(1,5) I (0.16 g) was obtained (but the total amount of the aldehyde was considerably higher). The compound I was identified as follows. I (0.037 g) was reduced with excess potassium borohydride and after reaction the solution was treated with cation exchanger (Dowex 50, H^+) and evaporated. Remaining boric acid was removed by evaporation with methanol. The reduction product, according to paper chromatography (solvent A and B) and thin layer chromatography in chloroform-ethanol (3:1), was identical with authentic methyl 3-*O*-methyl-β-D-glucopyranoside. No further products were detected. The reduction product (0.022 g) was hydrolysed and the crystalline product obtained (m.p. 164.5 – 166.5°) was identified as 3-*O*-methyl-D-glucose by IR, mixed m.p., and its chromatographic properties compared to authentic material. No other sugars were detected in the mother liquor.

Part of compound I was treated with 0.5 M sulphuric acid at 80° for 4 h. After neutralisation with barium carbonate, the product was reduced with an amount of potassium borohydride sufficient to convert one aldehyde group only. After demethylation [4] with boron trichloride in methylene chloride at −80° the mixture of monosaccharides was investigated by paper chromatography (solvent A, B, and C) and electrophoresis (buffer E and F). These separations revealed the presence of the ex-

pected sugars glucose and gulose, but the absence of the other hexoses.

During the separation of the oxidation products, two other compounds, giving yellow colour with the anisidine spray, were collected (a: 0.010 g and b: 0.018 g).

Substance a was crystalline and after recrystallisation from ethanol exhibited a m.p. of 141 – 142°, $[\alpha]_D^{20} - 45.2°$ (*c* 0.6 water), and no mutarotation. Elemental analysis gave: C 47,1; H 6.44; O 47.0. Diketo compound $C_8H_{12}O_6$ requires: C 47.1; H 5.92; O 47.0; and monoketo compound $C_8H_{14}O_6$ requires: C 46.6; H 6.85; O 46.7. $M_{vanillin} = 1.37$ in buffer D and the elemental analysis indicated that the compound was a diketo compound. It was reduced with excess potassium borohydride and the reduction product was demethylated with boron trichloride in methylene chloride at −80°. Paper chromatography (solvents A, B, and C) and paper electrophoresis (buffer E and F) revealed the presence of glucose, galactose, and small amounts of mannose as the only sugars. This indicates that the positions of the keto groups are at C-2 and C-4 in methyl 3-*O*-methyl glucoside.

Mass spectrometry gave M^+ 204, which correspond to structure XI. No more material was available for further elucidation of the structure.

Compound b was a chromatographically pure, amorphous compound, $[\alpha]_D^{20} - 32°$ (*c* 0.3 water). After reduction and demethylation as above, glucose and mannose were the only sugars detected by paper chromatography and electrophoresis. This indicates that the compound has one keto group at C-2 and thus is *methyl 3-O-methyl-β-*D-arabino-*hexopyranosidulose* (*X*). The mobility in hydrogen sulphite electrophoresis ($M_v = 0.39$) is characteristic of a monoketo-glycoside.

*Preparation and characterisation of methyl β-*D-galacto-*hexodialdopyranoside-(1,5) (VI).* In small scale experiments the extent of oxidation of methyl β-D-galactopyranoside with D-galactose oxidase was estimated by paper chromatography. When amounts of enzyme reasonable for preparative scale work were used, the oxidation was far from complete.

In a typical larger scale experiment methyl β-D-galactopyranoside (3.30 g) in 0.01 M, pH 7.0, phosphate buffer (330 ml) containing catalase (0.16 g) and galactose oxidase (0.066 g); was shaken for 1.5 h at 37°. Both enzymes were obtained from Worthington Biochemical Company. Ethanol (80 ml), active carbon (10 g) and some Celite was added and the stirred mixture filtered and washed with 25 % ethanol. After standing in the cold one day some inorganic salts could be filtered off.

The filtrate was evaporated to a small volume, passed through ion exchange columns of Dowex 50 (H^+) and Dowex 3 (free base) and evaporated to dryness. Some methyl β-D-galactopyranoside (0.90 g) was removed after crystallisation and the mother liquor was fractionated on a cellulose column (Whatman CF 11 powder, 4.5 × 85 cm) using solvent A. A top-fraction of compound VI (0.27 g) was collected and was pure according to paper chromatography and electrophoresis.

Part of compound VI was hydrolysed with 0.5 M sulphuric acid at 100° for 4 h and the product obtained shown to be identical (by paper chromatography and electrophoresis) with a sample of *galacto*-hexodialdose prepared by a Rosenmund reduction of tetra-*O*-acetyl-galactaroyl dichloride.[19] Another part of VI was transformed to a product shown to be identical with galacturonic acid by bromine oxidation[20] and acid hydrolysis with 0.5 M sulphuric acid at 100° for 4 h.

Preparation and characterisation of the methyl hexodialdopyranoside-(1,5)-s (II – IX). The general route for the preparation of compounds II – IX was preparation of heptoses, glycosidation of the latter with methanol/hydrogen chloride and separation of the resulting anomeric methyl heptopyranosides. Controlled periodate oxidation of the pure heptosides and chromatographic purification of the corresponding methyl hexodialdopyranoside-(1,5)-s was then performed. Yields and physical properties of the methyl heptopyranosides and of the methyl hexodialdopyranoside(1,5)-s are given in Tables 1 and 2, respectively. Paper electrophoretic properties of the latter and the corresponding hexodialdoses are given in Table 3. The yields in Table 1 are based on the heptoses and in Table 2 on the methyl heptopyranosides.

D-*glycero*-D-*gulo*-Heptopyranose and D-*glycero*-D-*ido*-heptopyranose were prepared by cyanohydrin synthesis from D-glucose,[21] but the reductions of the intermediate heptono-1,4-lactones were made with sodium borohydride[22] instead of sodium amalgam.[21] D-*glycero*-D-*galacto*-Heptopyranose and D-*glycero*-D-*talo*-heptopyranose were prepared as previously reported by nitromethane condensation and the Nef reaction starting from D-mannose.[23–25] D-*glycero*-L-*manno*-Heptopyranose and D-*glycero*-L-*gluco*-heptopyranose were similarly prepared but starting from D-galactose[26] instead of the D-mannose.

The same conditions for the glycosidation were used for all heptoses and were essentially as previously described.[15] To a solution of the heptose in methanol, was added a methanol/hydrogen chloride mixture to give a final concentration of 10 % sugar and 1.5 % hydrogen chloride. After refluxing the solution for 6 h, most of the solvent was removed under reduced pressure at 30°. Water was then added and the solution neutralised with an anion exchange resin (Dowex 3, free base). The resulting mixture of methyl glycosides was fractionated on an anion exchange column (Dowex 1–X8, OH^-, 200 – 400 mesh).[11] Pyranosides were eluted faster than furanosides (the latter were not collected) and α-pyranosides

Table 4. Characterisation of the aldehydo-glycosides by (A) reduction and (B) hydrolysis and subsequent reduction.

Compound	Reaction products A	B[a]
Methyl α-L-*gluco*-hexodialdopyranoside-(1,5) (II)	Methyl α-L-glucopyranoside (identified by paper chromatography and electrophoresis)	Glucitol
Methyl β-L-*gluco*-hexodialdopyranoside-(1,5) (III)	Methyl β-L-glucopyranoside (identified as above)	Glucitol
Methyl α-L-*manno*-hexodialdopyranoside-(1,5) (IV)	Methyl α-L-mannopyranoside (identified as above)	Mannitol
Methyl β-L-*manno*-hexodialdopyranoside-(1,5) (V)	Methyl β-L-mannopyranoside (identified as above)	Mannitol
Methyl α-D-*galacto*-hexodialdopyranoside-(1,5) (VI)	Methyl α-D-galactopyranoside (identified as above)	Galacticol
Methyl β-D-*galacto*-hexodialdopyranoside-(1,5) (VII)	Methyl β-D-galactopyranoside (identified as above)	Galactitol
Methyl α-D-*gulo*-hexodialdopyranoside-(1,5) (VIII)	$[\alpha]_D^{20}$ +110° (H_2O) found $[\alpha]_D^{20}$ +109.4° (H_2O) lit. Me α-D-gulopyranoside	Glucitol
Methyl β-D-*gulo*-hexodialdopyranoside-(1,5) (IX)	$[\alpha]_D^{20}$ −80.5° (H_2O) found $[\alpha]_D^{20}$ −83° (H_2O) lit. Me β-D-gulopyranoside	Glucitol

[a] The retention times of the hexaacetates on GLC were: mannitol 0.78, galactitol 0.89, glucitol 1.00 and, as comparison, iditol 1.22.

well separated from β-pyranosides. The separations were followed polarimetrically and by paper-chromatography and pure fractions of anomeric methyl heptopyranosides were obtained. The physical data of the crystalline compounds were in good agreement with previously reported values (Table 1). To our knowledge the methyl α- and β-D-*glycero*-D-*talo*-heptopyranosides have not been previously reported. Elemental analysis: required for the methyl heptosides C 42.9; H 7.20; O 50.0. Obtained for methyl α-D-*glycero*-D-*talo*-heptoside, C 43.2; H 7.10; O 49.6. Obtained for methyl β-D-*glycero*-D-*talo*-heptoside, C 43.1; H 7.30; O 49.4.

The periodate oxidation of the various methyl heptopyranosides was made essentially as previously described for the oxidation of methyl β-D-*glycero*-D-*gulo*-heptopyranoside,[10] but with somewhat more than the theoretical amount of periodate. Based upon smallscale experiments the following excess was used in the preparations (otherwise made under similar conditions): 5 % and 15 % excess of sodium metaperiodate for the methyl α-D-*glycero*-D-*gulo*-heptoside and its β-anomer, respectively, and otherwise 10 % excess. The preparation procedure (10 % excess of oxidant) was as follows:

To a solution of the methyl heptoside (1.00 g in 50 ml water) at 0° was added with stirring 0.09 M sodium metaperiodate (55 ml) while maintaining the temperature below +3°. After one hour stirring at room temperature the solution was kept at +4° for 20 h. Barium carbonate equivalent to the original periodate was then added and the mixture again stirred. After filtering, ion exchange (Dowex 50, H^+ and Dowex 3, free base) and evaporation to a syrup, the product, obtained by extraction with warm 50 % ethanol, was (after evaporation) fractionated on a cellulose column (90 × 4 cm) using butan-1-ol saturated with water as eluent. Top-fractions (both fast- and slow-moving with similar equilibrium patterns) of pure methyl hexodialdopyranoside-(1,5)-s were collected (Table 2).

The aldehydo-glycosides were amorphous but behaved as pure components on paper chromatography and paper electrophoresis[3] (Table 3).

Each of them yielded essentially one component, the dialdose, on acid hydrolysis. Borohydride reduction of the aldehydo-glycosides and the dialdoses yielded the expected glycosides and alditols, respectively (Table 4).

The Use of Optically Active Half-esters of Methoxy-substituted Succinic Acids in the Stereospecific Synthesis of Long Chain Oxygenated Compounds

GÖRAN ODHAM,[a] BENTE PETTERSSON[a] and EINAR STENHAGEN[b]

[a]Lipid Chemistry Laboratory, University of Göteborg, Kråketorpsgatan 20, S-431 33 Mölndal, Sweden and [b]Institute of Medical Biochemistry, University of Göteborg, S-400 33 Göteborg 33, Sweden

The isomeric half-esters of (*S*)-methoxysuccinic acid have been prepared in the search for suitable intermediates for the synthesis of the β-glycol group of phthiocerol. The half-esters have very similar properties and differ mainly in the mass spectra and IR-spectra. Chain-lengthening of (*S*)-methyl 2-methoxy-3-carboxypropanoate by mixed electrolysis with dodecanoic acid in dimethylformamide gave a 21 % yield of (*S*)-methyl 2-methoxytetradecanoate.

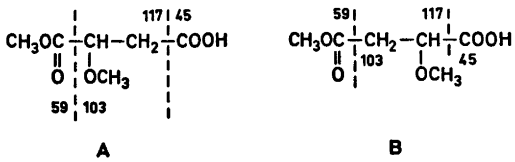
In the further search for routes for the stereospecific synthesis of phthiocerol and other optically active complex glycols we have investigated the possibilities of using the monoesters of methoxy succinic acids as suitable initial materials. These compounds were considered attractive as they are readily prepared from the commercially available D- and L-malic acids. The half-esters should be suitable for chain-lengthening by the use of the Kolbe reaction. There appears to be only one report in the literature concerning the synthesis of such a half-ester.[1] In this work the half-ester was prepared by boiling a solution of the anhydride of methylated L-malic acid in methanol. The optical rotation of the resulting product is reported as $[\alpha]_D^{20}$ −57.64° (*c*, 3.4874, acetone). No indication of the structure of this material is given.

Present work. It is well known that introduction of electron attracting groups (*e.g.* $-OCH_3$) next to the carbonyl carbon of the ester group markedly increases its positive character and hence will increase the velocity of base-catalyzed hydrolysis. Partial hydrolysis of dimethyl methoxysuccinate would thus predominantly result in the half-ester with the methoxyl substituent next to the free carboxyl group.

In contrast, formation of half-esters from unsymmetric anhydrides by reaction with hydroxyl compounds leads to predominance of ester on the more acidic carboxyl group. Accordingly, the material obtained by Purdie *et al.*[1] should have the structure (*S*)-methyl 2-methoxy-3-carboxypropanoate. We have repeated this work and obtained a product (A) with $[\alpha]_D^{22}$ −55.9° (*c*, 3.775, acetone), which is in good agreement with the value reported previously. An attempt by us to prepare the isomeric monoester (*S*)-methyl 3-methoxy-3-carboxypropanoate (B) *via* partial alkaline hydrolysis of the diester resulted in a compound with $[\alpha]_D^{24}$ −45.8° (*c*, 3.290, acetone).

The two monoesters (A and B) had practically identical gas chromatographic retention times on polar and non-polar stationary phases. This means unfortunately that it is at present impossible to state the isomeric purity of the two half-esters. The NMR spectra were also virtually identical whereas the infra-red spectra showed minor differences in the 1400 and 1050 cm^{-1} regions.

The mass spectra of the two esters show differences, however, which are consistent with the structures expected on theoretical grounds. None of the esters shows a peak due to the molecular ion (M = 162). The peaks of highest mass



number in both spectra are seen at $m/e = M - 18$ (loss of water). Significant peaks appear at the following mass numbers. Half ester A: 61(100), 103 (67), 61(27), 75(18), 132(16), 117(6), 114(5), 144(2); half ester B: 117(100), 59(64), 61(60), 103(60), 75(46), 71(30), 89(20), 99(20), 131(17), 144(5).

Attempts to lengthen the chain of the two half-esters by mixed anodic coupling with dodecanoic acid in dimethylformamide [2] gave a 21 % yield of (*S*)-methyl 2-methoxytetradecanoate when halfester (A) was used. Practically no cross-coupling was observed for half-ester (B). Similar experiments with (*S*)-methyl 2-acetoxy-3-carboxypropanoate as optically active unit as used by Horn and Pretorius [3] gave a yield of 14 % of the corresponding acetoxy-substituted compound.

We feel that optically active 2-methoxy-substituted esters prepared in the manner described are suitable as intermediates in the syntheses of more complex lipids containing methoxyl or hydroxyl groups. It has been shown previously [4] that the methoxyl compounds may be demethylated to the corresponding hydroxyl compounds without loss of optical activity. The methoxyl group can be retained as protecting group during chain lengthening operations to give for example polymethoxy or, after demethylation, polyhydroxy compounds.

EXPERIMENTAL

L-*Malic acid* (Fluka AG, Buchs, Switzerland) was used as initial material.

(S)-*Dimethyl 2-hydroxysuccinate* (dimethyl malate) was prepared from 50.0 g (0.373 mol) of L-malic acid by refluxing overnight with 500 ml of methanol containing 1 % of dry hydrogen chloride. After removal of the excess of methanol the crude ester was distilled. Yield 42.2 g (70.0 %) of b.p. 134–136°, 11 mm.

Dimethyl (S)-*2-methoxysuccinate*. To a mixture of 30.0 g (0.185 mol) of dimethyl malate and 105 g (0.740 mol) of methyl iodide was added during a period of 6 h 86 g (0.370 mol) of silver oxide (Fluka AG, Buchs, Switzerland). A spontaneous reaction occurred after initial heating. A further portion (25 g) of methyl iodide was added when about 2/3 of the silver oxide had been used. The reaction mixture was finally heated for 2 h and, after cooling, triturated with ether. After filtration and removal of volatile material the product was distilled yielding 24.1 g (74.0 %) of the methoxy ester. B.p. 116°, 11 mm. Purity 98.5 % as indicated by GC with HI-EFF 4 B as stationary phase. $[\alpha]_D^{25}$ −50.7° (acetone; *l*, 0.2; *c*, 3.24); $[\alpha]_D^{25}$ −42.2° (chloroform; *l*, 0.2; *c*, 1.60). Lardon and Reichstein [5] reported $[\alpha]_D^{16}$ −47.8° (*c*, 3.047 in acetone) and Fodor and Sóti [6] $[\alpha]_D^{28}$ −50.09° (*c*, 3.27 in acetone).

(S)-*2-Methoxysuccinic acid*. 17.3 g (0.0550 mol) of $Ba(OH)_2.8H_2O$ in 125 ml of distilled water was added to 8.7 g (0.0455 mol) of the above diester. The mixture was left for 1 h at room temperature and then for 2 h at 50°. After cooling the product was run through 70 g of Dowex 50 WX8 50/100 mesh ion exchange (H^+ form). Water was removed in a rotatory evaporator and the residue dried under vacuum over P_2O_5. The acid had m.p. 78.8–80.2°. Yield 5.6 g (77.0 %).

(S)-*Methyl 2-methoxy-3-carboxypropanoate (half-ester A)*. The free acid (5.5 g) was refluxed by heating in an oil bath at 60° for 4.5 h with 30 ml of acetyl chloride. The crude anhydride formed weighed 4.6 g after evaporation of volatile material. A mixture of 4.58 g (0.0353 mol) of the anhydride and 1.13 g (0.0353 mol) of methanol was heated at 50° for 4.5 h. 2.0 g of the reaction product which contained in addition to half-ester a small amount of diester (5 %) as indicated by GLC was chromatographed on silicic acid (50 g) (Mallinckrodt, 100–200 mesh, activated at 110° overnight) with ether:light petroleum (b.p. 40–60°) (35:65 v/v). After a small forerum (diester) 1.32 g of half-ester was eluted. It was a colorless viscous oil and had a purity of 98.5 % as indicated by GLC. $[\alpha]_D^{26}$ −55.9° (acetone; *l*, 0.2; *c*, 3.775). Purdie *et al.*[1] reported $[\alpha]_D^{20}$ −57.64° (*c*, 3.4874 in acetone).

(S)-*Methyl 3-methoxy-3-carboxypropanoate (half-ester B)*. A solution of 5.68 mmol of potassium hydroxide dissolved in 5 ml of methanol was added drop-wise at +4° to 1.00 g (5.68 mmol) of the diester dissolved in 5 ml of methanol. The reaction mixture was stirred overnight at room temperature and then evaporated to dryness. 2 ml of distilled water was added to the residue and the solution extracted twice with light petroleum (b.p. 40–60°). The aqueous phase was acidified with diluted hydrochloric acid (pH 1), saturated with sodium chloride and extracted five times with ethyl acetate. The combined organic extracts were dried ($MgSO_4$) and evaporated to dryness. The crude half-ester was purified by chromatography on silicic acid as described for (A). Yield 0.82 g of half-ester (B), being a colourless viscous oil. $[\alpha]_D^{24}$ −45.8° (acetone, *l*, 0.2; *c*, 3.290).

Chain-lengthening of half-ester (A). A mixture of (A) (1.083 g, 6.70 mmol) and 2.68 g (13.40 mmol) of dodecanoic acid in 35 ml of dimethylformamide containing 203 mg (2.01 mmol) of triethylamine was electrolyzed at 0.4 A (100 V) between platinum electrodes for 6 h. The methoxyester obtained was worked up by addition of light petroleum (b.p. 40 – 60°) and water to the reaction product. The aqueous phase was extracted once more with light petroleum and the combined organic phases washed with sodium carbonate, (5 % solution in water) and with water until neutral. Yield after drying ($MgSO_4$) and evaporation of solvent 1.40 g. The product was chromatographed on 30 g of the silicic acid described with ether:light petroleum (b.p. 40 – 60°) mixtures. 458 mg of docosane was eluted with 1:99 (v/v) and 389 mg (21.4 %) of (*S*)-methyl 2-methoxytetradecanoate with 1:1 (v/v). GLC indicated satisfactory purity (98 %) and the mass spectrum was consistent with the structure assumed. α_D^{30} −0.22° (*l*, 0.2; *c*, 4.20, chloroform), $[\alpha]_D^{30}$ −26.4° and $[M]_D^{30}$ −72. A similar experiment using half-ester (B) was made. GLC of the reaction product indicated only 2 % of methoxyester.

Chain-lengthening of (S)*-ethyl hydrogen 2-acetoxysuccinate.* A mixture of the acetoxy half-ester (4) 1.37 g (6.70 mmol) and 2.68 g (13.40 mmol) of dodecanoic acid was electrolyzed for 10 h in 40 ml of dimethylformamide containing 203 mg (2.09 mmol) of triethylamine (0.4 A, 120 V). The reaction product was worked up and purified as described. 303 mg (14 %) of (S)-ethyl 2-acetoxytetradecanoate was obtained.

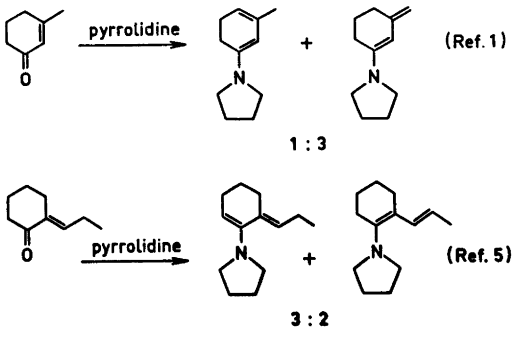
Formation of a Non-planar Dienamine from 1-(2-Indanylidene)-indan-2-one and Pyrrolidine

ULF EDLUND

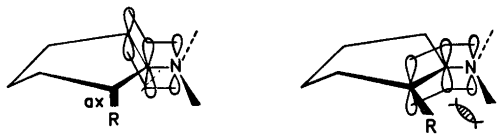
Department of Organic Chemistry, University of Umeå, S-901 87 Umeå, Sweden

1-(2-Indanylidene)indan-2-one (I) may be converted into a mixture of the linear dienamine, 3-(2-indenyl)-2-(*N*-pyrrolidyl)-indene (II), and isomeric enamine, 1-(2-indenyl)-2-(*N*-pyrrolidyl)indene (III). In the main product (II), isolated by recrystallization, the indenyl substituent is proposed to be more or less twisted out of conjugation as shown by protium-deuterium exchange and PMR data. Factors affecting the formation and the relative stability of the isomeric forms are briefly discussed.

Several investigations concerning the preparation and the structure of dienamines from cyclic and acyclic ketones have been published.[1-4] In the case of ketones with an endocyclic double bond the products generally appear as mixtures of dienamines among which linear forms seem to be predominant, or exclusive. A different behaviour has been reported for cisoid, unsaturated cyclohexanones where the cross-conjugated isomer is the major component in the dienamine mixture[5,6] (Scheme 1). In the case of enamines derived from 2-substituted ketones the isomeric distribution is controlled

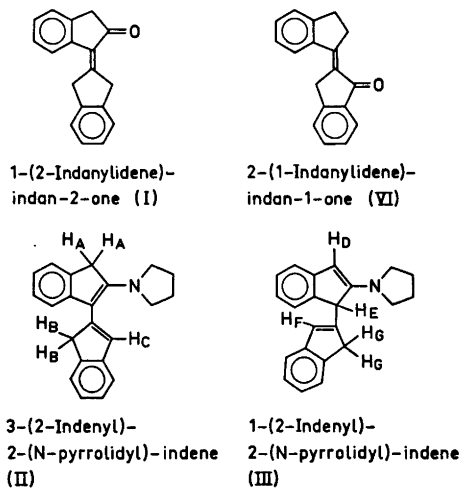


Scheme 1.



Scheme 2.

by various steric and electronic factors which affect the overlap between the nitrogen lone pair and the double bond of the enamine. Gurowitz and Joseph[7] have proposed that, within a given series, the greater the overlap the greater is the amount of the less substituted enamine (Scheme 2). In connection with the study of enamines from 1-methylindan-2-one we observed an isomeric ratio which deviated



Scheme 3.

from the general formulation mentioned above.[8] In the pyrrolidine enamine case, where overlap between the nitrogen lone pair and the double bond is strongest, the proportion of the most substituted enamine was greater than in the cases with other amine components. Since the controlling factors may or may not act in the same direction or will be differently weighted in our system, we have tried to obtain more information by studying the condensation between the reactive, secondary amine, pyrrolidine, and the planar, cisoid ketone 1-(2-indanylidene)indan-2-one (I)[9] (Scheme 3).

RESULTS AND DISCUSSION

Treatment of (I) with pyrrolidine in chloroform affords at room temperature two isomeric amines, (II) and (III), roughly in the ratio 9:1. Crystallization of the crude mixture from tetrachloroethylene gave only the pure isomer (II). The isomer (III) could not be obtained in a pure state. The ease of formation and the stability against hydrolysis are the same properties as ascribed to enamines of simpler 2-indanones.[8,10] In a comparative study, a similar compound, 2-(1-indanylidene)indan-1-one, ((VI),

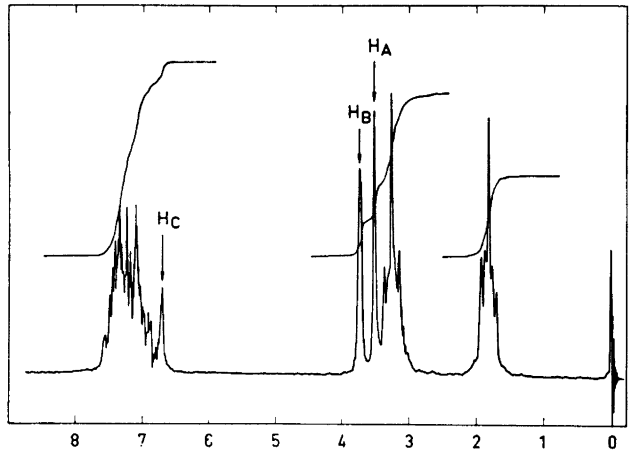


Fig. 1. PMR-spectrum of the pure isomer (II) (Concentration: 0.5 M) in chloroform-D. A small amount of 1,8-(*N*,*N*,*N'*,*N'*-tetramethyl)diaminonaphthalene is added to avoid equilibration due to acidic impurities in the solvent.

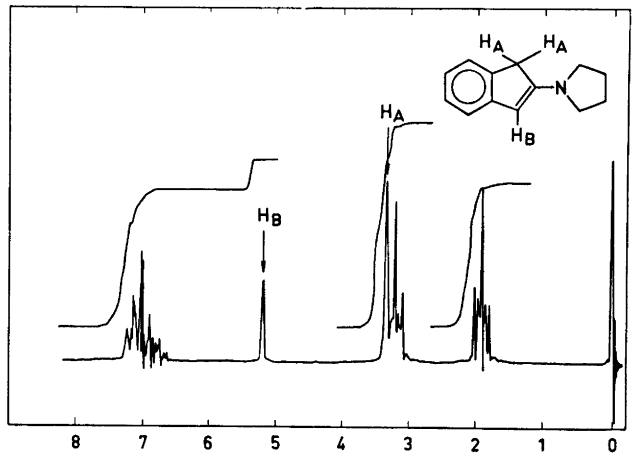

Fig. 2. PMR-spectrum of 2-(*N*-pyrrolidyl)indene (Concentration: 0.5 M) in chloroform-D.

Scheme 3) prepared according to Kipping,[11] was shown to be completely unreactive against condensation with pyrrolidine even after a prolonged reaction period. This demonstrates that the unusual reactivity observed for the simpler 2-indanones seems to be valid also in this unsaturated case (I). The PMR spectrum of the pure dienamine (II) is given in Fig. 1. This spectrum could be obtained only if the solvent chloroform-D had been carefully dried and with a trace of 1,8-(*N*,*N*,*N'*,*N'*-tetramethyl)diaminonaphthalene added in order to inhibit acid-catalyzed isomerization. The signals at $\delta \approx 1.6-2.0$ (ppm) and $\delta \approx 3.0-3.4$ (ppm) are ascribed to the protons of the pyrrolidine ring and the singlet at $\delta = 3.5$ (ppm) to the protons at the 1-position (H_A) in the enamine part. This assumption is based on the similarities with the spectrum of 2-(*N*-pyrrolidyl)indene shown in Fig. 2. The peaks from the protons at the 1- and 3-position in the indenyl part appear at $\delta = 6.7$ (ppm) (H_C) and $\delta = 3.7$ (ppm) (H_B), respectively, and the complex signals at $\delta \approx 6.7-7.7$ (ppm) are assigned to the eight aromatic protons. If the solution of (II) contains traces of acidic impurities, the PMR spectrum rapidly changes to that given in Fig. 3. In this spectrum the peaks at $\delta = 4.6$ and 5.3 (ppm) are interpreted as resulting from the protons H_E and H_D, respectively, in the isomeric form (III). The signals from the remaining protons in (III) are as expected overlapped by the signals from (II). As no changes in the spectrum (Fig. 3) was observed after addition of *p*-toluenesulphonic acid, the equilibrium ratio between (II) and (III), found to be 9:1, could be determined by integration. The area under the peak at $\delta = 3.7$ (ppm) due to H_B in (II) and H_G in (III) was compared with the area of the H_D and H_E peaks in (III) using the pyrrolidine proton signals at $\delta \approx 1.6-2.0$ (ppm) as internal standard. The equilibrium ratio is equal to that reported for pyrrolidyl enamines of 1-phenylindan-2-one.[12]

An interesting observation from this spectrum of (II) is the lowfield signal assigned to the terminal vinylic proton (H_C) with a shift value ($\delta = 6.7$ (ppm)) close to that ascribed to the olefinic proton in the 3-position of indenes ($\delta \approx 6.4-6.7$ (ppm)).[13,16,17] This fact cannot be in accordance with any significant increase in electron density at the carbon atom bearing the vinylic proton in our dienamine. This proposal is based on earlier reports [1,3] which clearly show that an increased conjugation caused a marked upfield shift of the signal from the terminal vinylic proton of the dienamine. Thus the PMR spectrum shows much greater likeness to a superposition of an enamine and an indene than a dienamine. This together with above-mentioned isomeric ratio and the non-coplanarity proposed for enamines of 1-phenylindan-2-one [12] suggests that the indene systems are twisted out of conjugation.

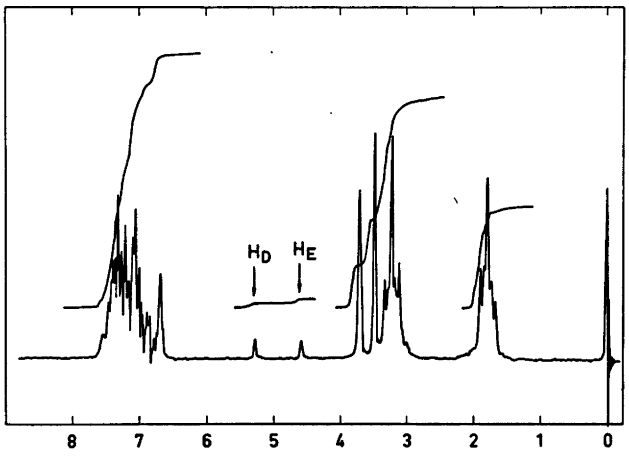

Fig. 3. PMR-spectrum of a mixture of (II) and (III) (9:1) (Concentration: 0.5 M) in chloroform-D. A catalytic amount of *p*-toluenesulphonic acid is added to confirm the equilibrium proportions (II/III = 9:1).

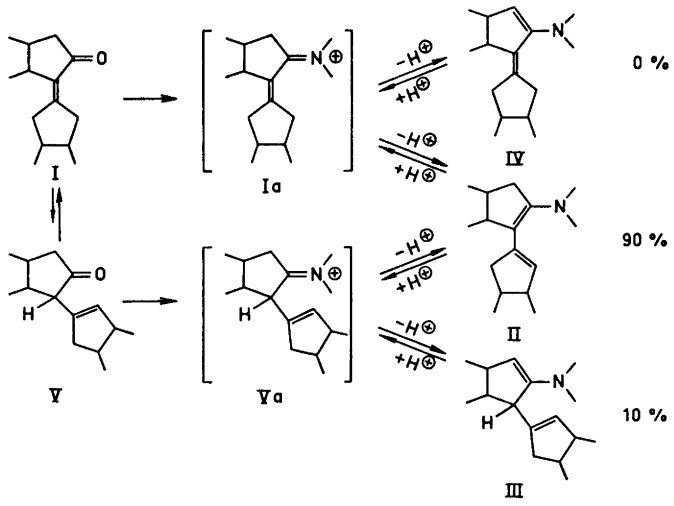

Scheme 4.

In order to confirm the assumption that the enamine part remains isolated from the indenyl substituent we have studied isotopic exchange between the equilibrium mixture (II + III) and methanol-OD, since deuterium incorporation rates have been shown to correlate well with estimated electron densities at different sites.[14] These results are summarized in Table 1, which shows that there is a fast exchange in the enamine part as compared to the indenyl part when chloroform was used as solvent. The decreased rate observed in pyridine could possibly be explained by hydrogen bonding between methanol-OD and pyridine. Even a small but significant deuterium content is observed in the indenyl substituent. This could be caused by involvement of an enimmonium structure like (I a, Scheme 4) but it can more likely be explained in terms of a simple base-catalyzed isotopic exchange as earlier reported.[15] To summarize, these results strongly indicate a decreased coplanarity and a decreased orbital interaction between the nitrogen lone pair and the indenyl substituent in agreement with our proposal.

Table 1. Protium-deuterium exchange between 3-(2-indenyl)-2-(*N*-pyrrolidyl)-indene (II) and 1-(2-indenyl)-2-(*N*-pyrrolidyl)indene (III) and methanol-OD at 27°C. Molar ratio: Amines: methanol-OD (1:4) Concentration of amines: 0.32 M.

Solvent	Time (h)	Percentage deuterium [a] in the enamine part (A,D,E)	Percentage deuterium [a] in the indenyl part (B,C,G,F)
Chloroform	0.5	18	0
	1.0	30	0
	2.0	50	0
	4.5	63	0
Pyridine	4.0	10	0
	27.0	33	5
	45.0	48	10
	64.0	50	13

[a] Estimated error ±4 %.

Consideration of the route of formation of the isomeric mixture (II + III) indicates that at least two different pathways are plausible (Scheme 4). One possibility is a direct formation of the highly sterically strained enimmonium structure (I a) followed by proton abstraction theoretically yielding two different structures (II + IV). The linear form (II) is thermodynamically much more stable than (IV). The observed equilibrium between (II) and (III) is then established through structure (V a) in accordance with the above-mentioned results from hydrogen-deuterium exchange. Another plausible pathway is a base-catalyzed inter-

conversion of the cisoid unsaturated ketone (I) to an indenyl-substituted 2-indanone (V). Subsequent reaction with pyrrolidine, in analogy with the preparation of alkyl-substituted enamines of 2-indanones, gives a less sterically restricted intermediate (V a) compared with (I a). Whether one or both of these mechanisms is operative cannot be clarified. No trace of formation of the isomer (IV) could be detected during the course of the reaction. This fact can be explained either by assuming that the mechanism proceeding *via* (I a) does not operate, or that (IV) possibly formed too rapidly isomerizes to structure (II) in order to be detected. Referring to the very high reactivity of 2-indanone and the alkylsubstituted 2-indanones it seems plausible to exclude the path *via* (I a).

The ratio between the obtained isomeric compounds (II + III) is quite different from that expected from earlier investigations of cisoid unsaturated ketones. In these studies the cross-conjugated isomer was, as mentioned, the predominating product. The factors, which affect the isomeric proportions in our case, seem to be the same as in the case of enamines of substituted 2-indanones. The unusually large proportion of the most substituted isomer, that was obtained when pyrrolidine was used as amine component, could possibly be caused by differently weighted steric effects in our enamine systems compared to the conditions in enamines of other substituted ketones. An extension of conjugation by the aromatic part and an increased difference in hyperconjugative stabilization between the 1-substituted and 3-substituted forms in our systems are factors that also could be responsible for this unexpected effect. However, these differences in isomeric proportions from those expected, on the basis of the now widely accepted rule of Gurowitz and Joseph,[7] correspond to very small differences in free energy of the different structures. This means, that any closer treatment of these factors is very difficult.

EXPERIMENTAL

A JEOL C-60 HL instrument was used to obtain the PMR spectra. The mass spectrum was recorded on a LKB 9000 mass spectrometer, and the IR spectrum was determined on a Perkin-Elmer 257 Spectrophotometer. Melting points are uncorrected.

1-(2-Indanylidene)indan-2-one (I) was prepared from 2-indanone according to a method published by Treibs and Schroth.[9] m.p. 176.5 – 178°C (lit.[9] 178°).

3-(2-Indenyl)-2-(N-pyrrolidyl)indene (II). A mixture of 2.0 g 1-(2-indanylidene)indan-2-one (0.007 mol) and 1.07 g pyrrolidine *p.a.* (0.015 mol) dissolved in 20 ml chloroform was allowed to stand for two days at room temperature over anhydrous calcium sulphate. Evaporation in vacuum affords a crude mixture mainly consisting of (II) and (III) approximately in a ratio 9:1. Recrystallization from tetrachloroethylene yields pure (II). The yield was 1.28 g. (52 %) m.p. 140 – 142°C. (Found: C 88.2; H 7.0; N 4.7. Calc. for $C_{22}H_{21}N$ (299): C 88.3; H 7.1; N 4.7.) $M^{+\cdot}$ (*m/e*): 299. $\nu_{C=C}$ (KBr): 1600, 1580 sh, 1550 (cm^{-1}).

PMR spectrum (Fig. 1, Fig. 3). Isomer (II): 1.6 – 2.0 (4 H complex), 3.0 – 3.4 (4 H complex), 3.5 (2 H_A singlet), 3.7 (2 H_B singlet), 5.7 (1 H_C singlet), 6.7 – 7.7 (8 H complex).

Isomer (III): 4.6 (1 H_E singlet), 5.3 (1 H_D singlet), (δ (ppm) in chloroform-D (TMS). Conc. 0.5 M).

Protium-deuterium exchange. Pyridine p.a. (Mallinckrodt) was freshly distilled and dried over calcium hydride. Chloroform *p.a.* was purified from alcohol. Methanol-OD (CIBA) was > 99 % D. The isotopic incorporation was followed by PMR-integration with sealed NMR tubes. Further data is given in Table 1.

The Binding of Quinacrine Mustard to Nucleic Acids

RITVA-KAJSA SELANDER

The Folkhälsan Institute of Genetics, P. O. Box 819, SF-00101 Helsinki 10, Finland

Quinacrine mustard forms complexes with nucleic acids in solution, as indicated by the yellow precipitation forming when native DNA and high concentrations of quinacrine mustard are mixed. This complex shows different biophysical properties as compared to the nucleic acid alone in solution. The viscosity is elevated, T_m is shifted towards higher temperatures, and the sedimentation constant is reduced. The polymer changes the fluorescence intensity of the dye: a net quench is obtained with all natural DNAs. The bonds between the dye and DNA depend on the pH and ionic strength in the solution. The binding between the dye and nucleic acids is also affected by the strandedness of the polymer. A greater quenching of the fluorescence intensity of quinacrine mustard is obtained with single stranded molecules than with double stranded ones. In a methyl green-DNA complex the methyl green is displaced by quinacrine mustard. This probably reflects competition between the two dyes.

The basic acridine dyes are able to bind nucleic acids in different ways. They are all capable of ionic binding to the phosphate groups in the nucleic acids with or without intercalation.[1-4]

The mode of interaction between acridine dyes and nucleic acid polymers has been studied by Dourlent and Hélène [5] with the dye proflavine. They found two bond species: a cooperative binding along the phosphate backbone and an interaction between the aromatic rings of the dye and nucleic acid bases, *i.e.* intercalation. These two processes are linked together. Further, the intercalation process is closely correlated to the secondary structure of the polymer. At low ionic strength and low concentration ratios of nucleic acid to proflavine the binding is an electrostatic interaction between the positively charged dye and the negatively charged phosphate groups. At high concentration ratios of nucleic acid to dye, a new complex is formed which suggests a van der Waals type of interaction between proflavine and the bases of the nucleic acid. Two models have been proposed for this second type of binding: the complete model of Lerman [6] and the partial intercalation model of Pritchard.[7] In the first model the dye is spaced between two bases in the opposite strands of the DNA helix. In the partial intercalation model the dye is spaced between two bases in the same strand of the nucleic acid. A complex formation between acridine dyes and single stranded nucleic acids provides evidence in support of the latter model.

Caspersson *et al.*[4] introduced the use of quinacrine and quinacrine mustard for staining cytological preparations. They chose quinacrine mustard because of the assumed guanine specificity of the dye. However, Ellison and Barr,[8] Weisblum and de Haseth,[9,10] Pachmann and Rigler,[11] and Michelson *et al.*[12] all showed that quinacrine and quinacrine mustard preferably stain chromosome regions rich in AT base pairs. Alternatively, proteins associated with (A+T) rich DNA might contribute to strong fluorescence, although this is hardly the case when purified DNAs or nucleotides in solution are tested.

The aim of the present investigation was to study the characteristics of the binding between quinacrine mustard and natural nucleic acids. Changes caused by the dye in some of the biophysical properties of DNA are reported. The results are discussed with reference to findings reported by other investigators using related dyes which also interact with nucleic acids.

EXPERIMENTAL

DNAs. DNA from mouse liver, calf thymus and *Saccharomyces cerevisiae* was isolated according to the method described by Marmur.[13]

The absorbance of 1 mg/ml of DNA from mouse liver and calf thymus was 21 at 257.5 nm in 0.1 × SSC * solution and of DNA isolated from *S. cerevisiae* 25.4 at 260.0 nm. This DNA was denatured, *i.e.* in single stranded form. The (G+C) content was 40 % for the DNA from mouse liver and calf thymus, and 43 % for the DNA isolated from *S. cerevisiae*. Phosphorus analysis gave 11.7 % phosphorus in mouse liver, 10.0 % in calf thymus, and 11.2 % in *S. cerevisiae* DNA. The absorbance of the sodium salt of highly polymerized calf thymus DNA (G+C, 45 %), purchased from the Sigma Chemical, U.S.A, was 21 at 260.0 nm, and the phosphorus content was 11.9 % (0.1 × SSC solution).

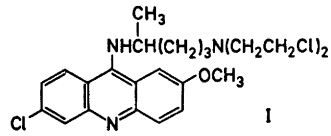
Deoxyribonucleic acid from *Escherichia coli*, (G+C, 50 %) and from *Clostridium perfringens* (G+C, 31 %) were purchased from the Sigma Chemical, U.S.A.

Denaturation was achieved by heating DNA (approx. 100 μg/ml in 0.1 × SSC solution) at 100°C for 10 min and then rapidly cooling it to 0°C. The change in absorption was measured spectrophotometrically and the temperature which produced 50 % of the total hyperchromicity resulting from the denaturation was taken to be T_m.

Native and denatured DNA (approx. 1 mg/ml) could be stored for at least 6 months at −70°C without degradation. The DNA concentration was determined either at the absorption peak at 260.0 nm or with the diphenylamine reaction.[14] The phosphorus analysis was as described by Tuan and Bonner.[15] The phosphorus content for the DNAs as well as the RNAs (see below) was rather high, indicating some contamination during the preparation of the nucleic acids. Deoxyribonuclease I from bovine pancreas was purchased from the Sigma Chemical, U.S.A.

RNAs. RNA from mouse liver and *S. cerevisiae* was isolated according to the method described by Kirby.[16] Stock solutions (approx. 1 mg/ml) were prepared in 0.1 × SSC solution and could be stored for 6 months at −25°C without degradation. The absorbance of mouse liver RNA at 260.0 nm was 20 and that of *S. cerevisiae* RNA 24.9. The (G+C) content of mouse liver RNA was 40 %. Phosphorus analysis gave 15.2 % phosphorus in mouse liver and 14.2 % in *S. cerevisiae* RNA. The RNA concentration was determined either at the absorption peak at 260.0 nm or with the orcinol reaction.[17]

Quinacrine mustard. Quinacrine mustard * (I) was a gift from the Sterling-Winthrop Research Institute, U.S.A. The fluorescence and absorption spectra and some other characteristics of the dye (anion and pH dependence) have been previously reported.[18] Stock solution of QM (2 mg/ml) in distilled water was stable for two weeks at 4°C in the dark. The solution remained clear the whole time without any changes in the absorption or fluorescence properties.



I

Fluorescence intensity. A fluorescence attachment ZFM4 to a Zeiss (PMQ II) spectrophotometer equipped with an excitation filter at 436 nm was used for determining the fluorescence intensity of the solution. The spectrophotometer was standardized with a fluorescence standard cuvette F 53 with excitation at 436 nm and with a fluorescence peak at 530 nm and a No. 10 slit arrangement.

The nucleic acids did not interfere with the QM fluorescence at 514 nm.[19] The theory and method of fluorimetric titration have been described by LePecq and Paoletti.[20] The binding parameters could be calculated by measuring the alteration of the fluorescence intensity of the dye under constant conditions of excitation, temperature, solvent composition and concentration. It was established that the fluorescence intensity alterations which occurred after mixing the polymer and the dye were complete within a few seconds and showed no further changes with time or additional mixing.

Absorption studies. Absorption spectra were recorded with a Zeiss (PMQ II) spectrophotometer. The absorption of the polymer did not disturb the determination of QM at 424.0 nm. The theory which was applied to the analysis of QM binding experiments has been described by Peacocke and Skerrett.[21] The association constants and the number of binding sites of the dye can be directly determined from the titration data with the Scatchard equation.[22] Although the curves obtained from the titration experiments with QM and polymers of unknown length deviate from the theoretical curves of Scatchard, his equation has been used in many investigations to determine the number of dye molecules bound to polymers.[5,23–26]

RESULTS

Effect of pH on QM. The effect of pH over the range 2 to 12 (in 0.015 M NaCl) on the ratio of the absorption at 424 nm and 365 nm of unbound QM is shown in Fig. 1. At pH ≥ 9.7 only the nitrogen atom of the diethylamine group of the side chain is protonated, but at pH ≤ 7 the dye is doubly protonated. The increase in the 424 nm to 365 nm ratio between the pH values 9.7 and 7 corresponds to a decrease in the fluorescence intensity of the dye.[18] The corre-

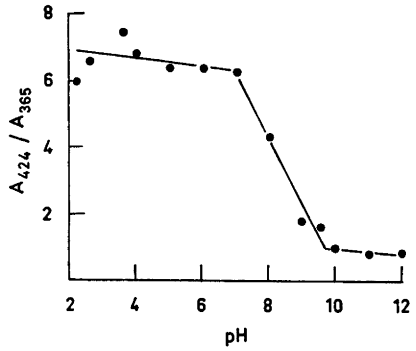

Fig. 1. Effect of pH on QM. Determinations were made in 0.015 M NaCl and the concentration of QM was 156 μM. pH was plotted against the changes in the ratio of absorption at 424 nm and 365 nm.

sponding pK_a values for quinacrine are 10.3 and 7.7, respectively.[27]

Interaction between QM and DNA. The reaction between QM and native DNA was indicated by the precipitation of yellow fibres brought about by the mixing of a solution containing a high concentration of the dye. At lower concentrations of the dye no precipitation occurred. In all the experiments reported below, concentration ranges of polymer and dye were chosen so that precipitation of the complex did not occur.

Effect of DNA on the fluorescence and absorption spectra of QM. In a QM-DNA mixture, quenching of the fluorescence intensity of the dye was noted at 514 nm, but no shift was found in the fluorescence spectrum of QM. However, DNA alters the absorption spectrum of QM as shown in Fig. 2. Increasing amounts of native mouse liver DNA were added to a solution with a constant amount of QM. The shift of the absorption maximum from 424 nm to higher wavelengths and the presence of an isosbestic point at 455 nm indicate the formation of specific complexes of the dye with DNA.[5] The ratio of the absorption at 424 nm and 365 nm decreases as the concentration of DNA increases. At very high concentration ratios of polymer to dye, there is a marked change in the absorption spectrum of QM (Fig. 2).

Fig. 3 depicts the difference spectra of QM in mixtures with native mouse liver DNA and with mouse liver RNA in 0.1 × SSC solution.

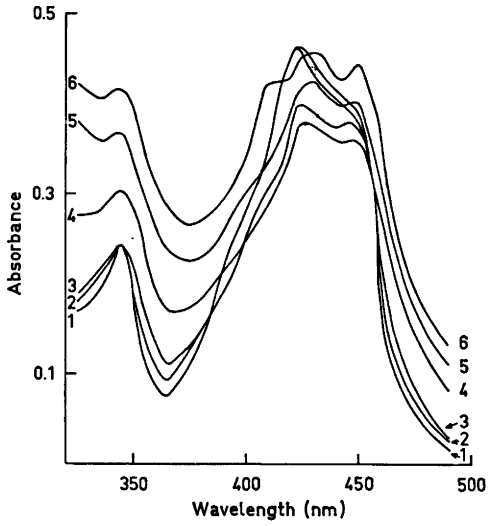

Fig. 2. Absorption spectra of QM partially and completely bound to native DNA. Determinations were made in McIlvaine's buffer, pH 7,[28] and the concentration of QM was (1) 50 μM. Concentrations of native mouse liver DNA phosphorus were: (2) 0.012 mM; (3) 0.129 mM; (4) 0.523 mM; (5) 0.928 mM and (6) 1.230 mM.

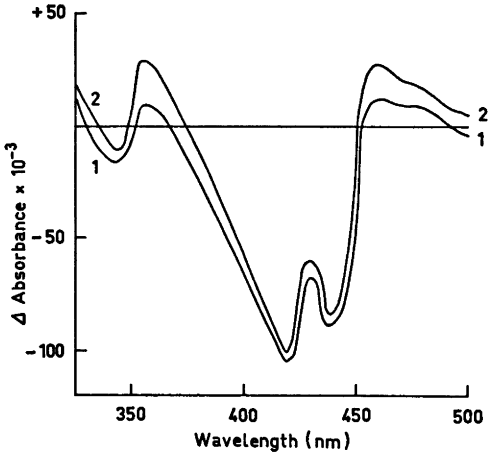

Fig. 3. Difference spectra of QM produced by nucleic acids. Determinations were made in 0.1 × SSC solution, pH 7, with 12.6 μM QM. (1) 0.535 mM RNA phosphorus, and (2) 0.464 mM double stranded DNA phosphorus. Both RNA and DNA were isolated from mouse liver (*cf.* Experimental).

Both nucleic acids depress the absorbance at 424 nm, although there were differences between double and single stranded nucleic acids.

Non-equilibrium dialysis. Since this was not an equilibrium dialysis, the possible dissociation of bound QM as the free QM concentration approached 0 would cause the fluorescence estimation at 514 nm to be too low. Mixtures of 0.5 mg/ml native calf thymus DNA with 0.05 mg/ml QM in 0.05 M Tris solution, pH 7.5, were dialyzed for 50 h at 0°C in viscose cellophane bags. The dialysis solution was changed frequently. After dialysis, the concentration of calf thymus DNA in the dialysis bag was 0.46 mg/ml and that of QM was 0.018 mg/ml which gave n 0.44. Native mouse liver DNA and QM, dialyzed in McIlvaine's buffer at pH 7.0, showed that 0.322 mg/ml DNA bound 0.014 mg/ml QM, *i.e.* n 0.45. The absorption of QM by the dialysis bag was slight as was the loss of nucleic acid to the external solution.

Effect of urea. Native mouse liver DNA (0.032 mg) was mixed with 0.02 mg QM in 0.1 × SSC solution with 3 M urea and 0.025 M sodium sulphate. In a solution without urea the quenching with excess DNA was $-22.8\ \Delta$ %, and with 3 M urea $-10.6\ \Delta$ %, *i.e.* a 50 % enhancement of the fluorescence intensity of QM in the presence of urea. [Δ % is the change of the fluorescence intensity of the mixture (in per cent) relative to the fluorescence intensity of QM alone.] The QM-DNA complex was unstable in urea, *i.e.* also some hydrogen bonds might be formed when QM reacts with DNA. The interaction between chloroquine as well as quinacrine and nucleic acids is stable in urea [29] while actinomycin D forms hydrogen bonds with DNA.[30]

Effect of pH on QM-DNA mixtures. The spectrum of bound QM varies considerably within the pH range examined (Fig. 4). Since the protonation of QM is largely unaffected at pH values below 7.0 (*cf.* Fig. 1) the pH-induced changes seen in acidic solutions must result from protonation in the nucleic acid. The ratio of the absorption at 424 nm and 365 nm of QM-calf thymus DNA (double stranded) shows a rapid decline at pH ≦ 3 and at pH ≧ 6 (Fig. 4). The single stranded molecules show a more irregular dependence on pH. The protonation of DNA begins at pH 3.5 – 4.[31] Adenine and cytosine protonate first (pK_a values between 5

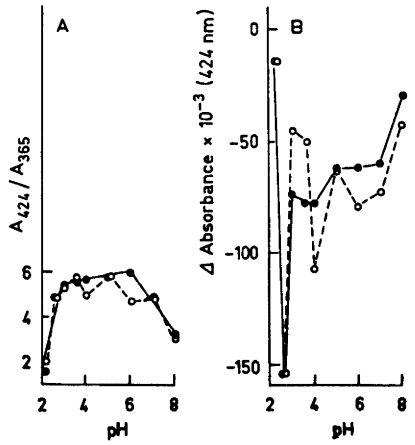

Fig. 4. Effect of pH on QM bound to nucleic acids. The determinations were made with 50 μM QM in McIlvaine's buffer. and 4) followed by guanine ($pK_a < 3$), which is almost fully protonated at pH ≦ 2.4. The decline in the 424 nm to 365 nm ratio at very acid pH is followed by an enhancement of the fluores-

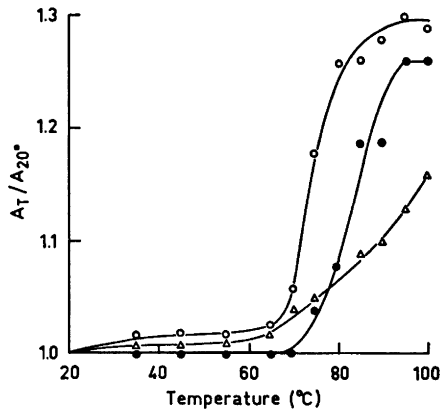

Fig. 5. Effect of QM on thermal denaturation of calf thymus DNA. Determinations were made in 0.05 M Tris solution, pH 7.5. Concentration of calf thymus NaDNA (Sigma) alone was, (○) 0.935 mM DNA phosphorus. (●) was dialyzed complex of 35 μM QM and 3.44 mM DNA phosphorus and, (△) was a mixture of 15 μM QM and 0.925 mM calf thymus DNA phosphorus.

cence at 514 nm and an enhancement of the absorption at 424 nm (Fig. 4). The absorption measurements at low pH were made within 10 min, so that possible depurination due to the acidic solution was negligible.[31] The denaturation of DNA at pH below 3 leads to a change in the binding of the dye through intercalation which leads to an increased binding of QM to the phosphate groups.[5] Since the spectrum of unbound QM varies within the pH range 7 to 8 (Fig. 1) it can be inferred that the changes found at pH above 6 for the bound ligand only depict the pH dependence of the unbound dye. Furthermore the denaturation of DNA at high pH occurs at pH above 11.[20]

Thermal denaturation of QM-DNA mixtures. The interaction between QM and native DNA is further demonstrated by the stabilizing effect of QM on DNA against denaturation by heat, as shown in Fig. 5. The T_m for (Sigma) calf thymus DNA was 73°C and the hyperchromicity 30 %. For a QM-DNA mixture (DNA-P/QM = 100) the T_m value was 83°C and the hyperchromicity 26 %, *i.e.* an increase in T_m of 10 degrees. When the proportion of QM in the mixture was raised (DNA-P/QM = 62), the T_m was increased to 90°C and the hyperchromicity reduced to 16 %. From these data it is evident that an increased stability of DNA was obtained with increased concentration ratios of QM to DNA. According to Cohen and Yielding[24] the T_m raises 9 degrees at a concentration ratio of chloroquine to DNA equal to 1:10. When the concentration ratios of the dye to DNA approaches 0, the T_m for the dye-DNA complex approaches the T_m for native DNA alone.

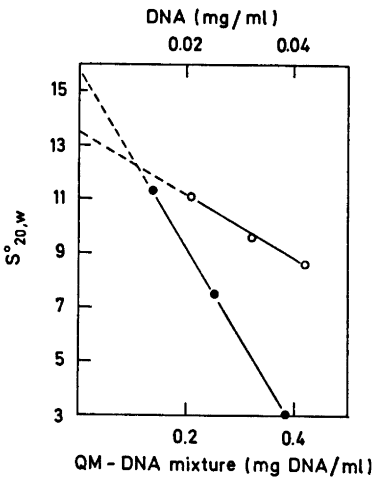

Fig. 6. Sedimentation constant of DNA and of QM-DNA mixtures. (●) DNA alone expressed in mg/ml, and (○) QM-DNA mixtures expressed in mg DNA/ml with 26 μM QM.

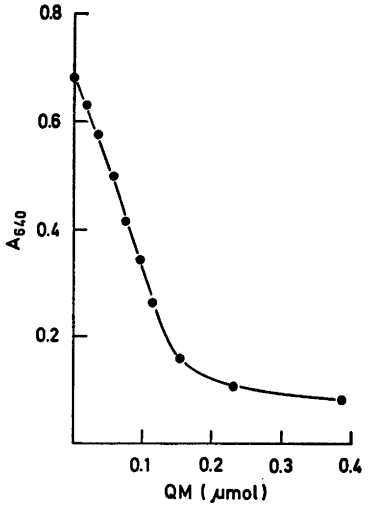

Fig. 7. Effect of QM on the methyl green-DNA complex. Increasing amounts of QM were added to 0.05 M Tris solution, pH 7.5, containing 33 mmol native mouse liver DNA phosphorus and 25 μmol methyl green. The mixtures were then allowed to stand for 18 h at room temperature (in the dark) before the absorption at 640 nm was estimated.

Analytical centrifugation. Analytical ultracentrifugation was performed in a Beckman Model E analytical ultracentrifuge equipped with an RTIC unit, a monochromator and a split beam photoelectric scanner as an accessory. The sedimentation of native mouse liver DNA was observed at 260 nm at 20°C and that of QM-DNA mixtures at 424 nm in 0.1 × SSC solution, pH 7. A 12 mm double sector cell with sapphire windows was used in the An-D-rotor at 42040 rpm. The sedimentation coefficients ($S_{20,w}^\circ$) were calculated from a plot of log *r versus* time and was corrected to the values in a solvent with the viscosity of water at 20°C. In Fig. 6 the sedimentation constant is plotted against the concentration of DNA. This extrapolates to a sedimentation constant of 13.5 S for the QM-DNA complex at zero concentration and to 15.7 S for native mouse liver DNA

alone, *i.e.* a decrease of approximately 14 % in the sedimentation constant. These results agree with those of Lerman [32] and Kurnick and Radcliffe [33] for the quinacrine-DNA complex. The sedimentation constants obtained were 12.4 S for DNA alone and 9.3 S for the quinacrine-DNA complex at zero concentration.[33] The decrease in the sedimentation constant suggests that the QM-DNA complex is more asymmetric than DNA alone.[32]

Displacement of methyl green. The effect of the addition of QM to the methyl green-DNA substrate [34] is presented in Fig. 7. At pH 7.5 free methyl green was converted to leukobase, with a resultant fall in the absorbance at absorption maximum of the methyl green-DNA complex (640 nm).[35] As the QM concentration was increased there was a progressive displacement of methyl green, although complete displacement did not occur. It is possible that the dye methyl green interferes with the approach of QM to the DNA molecule by preventing the intercalation of QM.

Inhibition of the DNase activity by QM. The methyl green-DNA substrate [34] could not be used in this study because of the progressive displacement of the dye from the complex when the concentration of QM was increased (cf. above) DNase assays were therefore performed by viscosimetry. Ostwald Fenske viscosity pipettes were used at 25°C. The pipettes were calibrated with water and gave an outflow time (with water) of 35 s at 25°C.

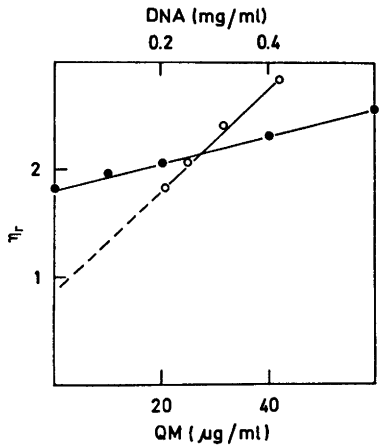

Fig. 8. Effect of QM on the viscosity of DNA. The results are presented as the relative viscosity (η_r), *i.e.* the outflow time of the solution divided by the outflow time of water. (O) increasing amounts of native mouse liver DNA (mg/ml), (●) 0.2 mg/ml native mouse liver DNA with increasing amounts of QM (μg/ml). The solution was 0.1 × SSC, pH 7, and each point represents the mean of three determinations.

In Fig. 8 the relative viscosities are plotted against the concentration of QM for the QM-DNA mixtures. The relative viscosities of DNA solutions are also shown in the figure. It was found that as the amount of QM was increased, the relative viscosity also increased up to 60 μg QM/ml, *i.e.* 0.3 mg dye per mg DNA. Kurnick and Radcliffe [33] reported a similar rise in the relative viscosity of a quinacrine-DNA mixture, with the maximum at 0.4 mg quinacrine per mg DNA.

In a series of assays with a DNase concentration of 20 μg/ml, 0.2 mg/ml native mouse liver DNA and varying amounts of QM in 0.1 × SSC solution, progressive reduction in the enzyme activity was observed as the relative concentration of QM increased. After a solution with 0.2 mg QM per mg DNA had been incubated at 37°C for 3 h the relative viscosity of DNA alone decreased by 17 %, while that of the QM-DNA mixture decreased by 12 %. The corresponding values for a solution with 0.1 mg QM per mg DNA was 40 % for DNA alone, and 37 % for the QM-DNA mixture (incubated for 6 h). The inhibition is obviously dependent on the concentration ratios of dye to DNA. A similar inhibition of DNase activity with quinacrine and a complete inhibition of the enzyme activity with chloroquine has been reported.[29,33]

Calculation of binding parameters. When increasing amounts of QM were added to a constant amount of polymer, the fluorescence intensity of the bound dye was quenched (Fig. 9). It is evident that those binding sites resulting in an increase of the quantum yield are occupied first, and that further additions of the dye result in reduction of the fluorescence enhancement. The reverse is illustrated in Fig. 10, where the effect of increasing amounts of native DNA and constant amounts of dye is shown. In Fig. 9 the greatest enhancement of the fluorescence intensity of the dye was obtained with native mouse liver DNA, while the curve of denatured (single stranded) DNA is about the same as

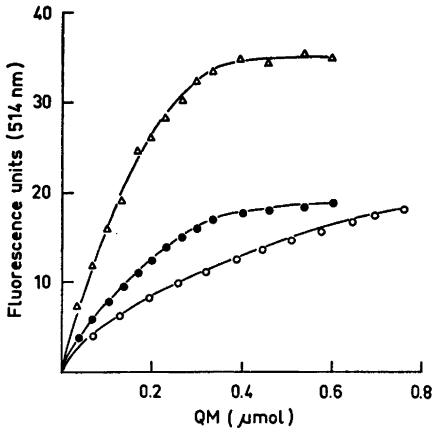

Fig. 9. Fluorescence enhancement of QM bound to nucleic acids. (△) to constant amount of native mouse liver DNA (3.77 mmol DNA phosphorus), (●) constant amount of denatured (single stranded) mouse liver DNA (3.77 mmol DNA phosphorus) and (○) constant amount of mouse liver RNA (4.91 mmol RNA phosphorus) was added increasing amounts of QM (μmol) in McIlvaine's buffer, pH 7.

that of mouse liver RNA. This quenching agrees with that of the DNAs of quinacrine and QM fluorescence intensity reported by others.[9-12]

The titration of DNAs by the fluorimetric method leads to anomalous binding curves which deviate from linearity in the Scatchard plot. Accordingly, the correct Scatchard plot is a line in which the slope of the first part of the

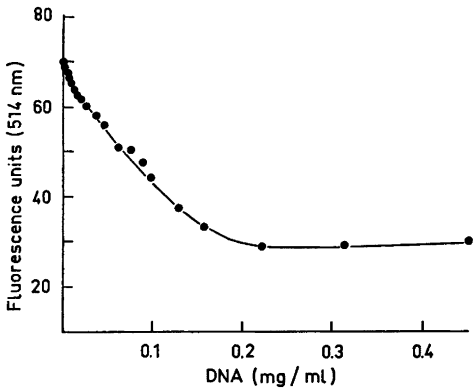

Fig. 10. Effect of DNA on the fluorescence intensity of QM. To a constant amount of QM (71.5 μmol) was added increasing amounts of native mouse liver DNA (mg/ml) in 0.1 × SSC solution, pH 7.

Table 1. Binding of QM to nucleic acids.[a]

Nucleic acid	Buffer system	Binding parameters n_1	n_2
DNA			
native mouse liver	0.1 × SSC, pH 7	0.17	1.11
denatured mouse liver	0.1 × SSC, pH 7	0.13	0.53
denatured *S. cerevisiae*	McIlvaine, pH 7	0.25	1.10
RNA			
mouse liver	0.1 × SSC, pH 7	0.09	0.19
mouse liver	McIlvaine, pH 7	0.31	0.50
S. cerevisiae	McIlvaine, pH 7	0.17	0.37

[a] Fluorimetric titration was used to estimate the parameter n, which was calculated according to the equation of Scatchard.[22] Each n value represents the mean of three determinations.

curve is negative. The line for titration of DNAs with QM does not conform with the hypothesis of independent binding sites because it is not a straight line. However, the intercept with the r axis (r is the molar ratio of bound dye to DNA phosphorus) can be determined, *i.e.* the value of n (the apparent number of binding sites). These values are given in Table 1. The value of n_1 for native DNA was 0.17 and that of n_2 was 1.11. The high value of n_2 might depend on the high phosphorus content in mouse liver DNA (*cf.* Experimental). For chloroquine-nucleic acid mixtures n values were between 0.15 and 0.75.[24] The n values for native DNA determined by fluorimetric titration agree well with those obtained by dialysis (*cf.* above) and by analytical ultracentrifugation (0.75).

Precipitation of QM-DNA complexes. When a QM-nucleic acid complex is precipitated from a mixture containing an excess of both QM and nucleic acid the value of n increases. After the precipitation, n for native calf thymus DNA was 0.81 and for denatured calf thymus DNA, 0.66. These high n values were partly caused by the high concentration of salt in the solution during precipitation of the yellow QM-nucleic acid complex with alcohol. This high salt concentration may cause aggregation of the dye molecules.[36]

Comparison of different nucleic acids. The

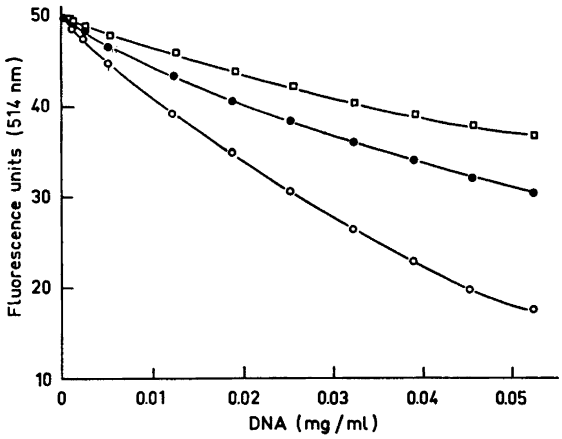

Fig. 11. Effect of different DNAs on the fluorescence intensity of QM. To a constant amount of QM (26 μmol) was added increasing amounts of native DNAs (mg/ml) in 0.1 × SSC solution, pH 7. DNAs: (□) *C. perfringens* (G+C, 31 %); (●) mouse liver (G+C, 40 %), and (○) *E. coli* (G+C, 50 %).

fluorimetric titration curves for different DNAs are shown in Fig. 11. The figure depicts the correlation between the (G+C) content of the DNA tested and the quenching effect on the fluorescence intensity of QM. It can be seen that the higher is the (G+C) content, the more readily the DNA quenches the fluorescence intensity of the dye. This finding is in line with the results reported by Weisblum and de Haseth [9,10] and Pachmann and Rigler [11] for the effect of DNAs on the fluorescence intensity of quinacrine. Polynucleotides behave in a similar way.[9,10,12,18]

The same relation between (G+C) content and quenching is also shown with denatured DNAs. The quenching of the fluorescence intensity of QM with excess denatured calf thymus or mouse liver DNA (G+C, 40 %) was approx. $-50\ \Delta$ % and for en equal amount of denatured *E. coli* DNA (G+C, 50 %), $-62\ \Delta$ %.

Interaction between QM and single stranded nucleic acids. Mixtures of either single stranded DNA or RNA with QM do not give rise to yellow precipitates at any of the concentration ranges of polymer and dye. However, there is an interaction between QM and RNA as is shown by changes in the absorption spectrum of QM when RNA is added to the solution (Fig. 3). This leads to quenching of the fluorescence intensity of QM. The fluorimetric titration with a constant amount of mouse liver RNA and increasing amounts of QM is shown in Fig. 9. The enhancement of the fluorescence intensity of the dye with RNA was about the same as with denatured DNA.

The n values for QM-RNA complexes are summarized in Table 1. They lie between 0.09 and 0.31 for n_1 and between 0.19 and 0.50 for n_2 depending on the ionic strength and pH of the solution. The different n values obtained for RNAs might also be due to the extremely high phosphorus content in the RNAs (*cf.* Experimental). Non-equilibrium dialysis of a mixture containing 0.5 mg/ml mouse liver RNA and 0.05 mg/ml QM in McIlvaine's buffer, gave n 0.27.

The effect of increasing amounts of the dye and a constant amount of denatured mouse liver DNA is also shown in Fig. 9. The enhancement of the fluorescence intensity of the dye was slighter with denatured DNA than with native DNA. A similar effect of the strandedness of the polymer on the binding of acridines has also been reported earlier.[6,24,33,37,38] Fluorimetric titration of denatured DNA (from mouse liver and from *S. cerevisiae*) with QM gave n_1 between 0.13 and 0.25, and n_2 between 0.53 and 1.10 (Table 1).

DISCUSSION

Binding mechanisms. Two different processes are involved in the interaction between dyes and polymers. The first binding (process I) is a weak ionic interaction between positively labelled dye molecules and negatively labelled groups of the polymer. Being an electrostatic interaction, the binding depends on the ionic strength in the solution, *i.e.* increased ionic strength leads to a decrease in process I. At high dye concentrations the absorption maximum of the dye is shifted to higher wavelengths. The isosbestic point suggests the existence of only one kind of binding (process I), *i.e.* the dye molecules are stacked along the phosphate backbone outside the double helix.[5]

The apparent number of binding sites (n) for interaction between QM and DNA in process I are higher than those reported for the interaction between chloroquine and DNA.[24] However, the QM-DNA interaction also shows a dependence on the ionic environment. Thus electrostatic factors are also important in the QM-DNA complex formation.

The second interaction (process II) is a strong binding, where the dye slips into the space between base residues in the helix of the polymer. According to Cohen and Yielding [24] this second type of binding comprises strongly reacting sites associated with bases, *i.e.* intercalation. Although the molecular structure of QM differs from that of chloroquine, the n values for process II were of the same order.[24] Pachmann and Rigler [11] found similar n values for the binding of proflavine and quinacrine with nucleic acids. Thus the side chain at C-9 of the dye does not influence the intercalation (process II) between the dye and the polymer.

Since the interaction between QM and native DNA was affected by urea as shown in this paper, some bindings between QM and DNA are hydrogen bonds. This idea is supported by the observations by Adkisson *et al.*[39] They showed that the bands which are brightly fluorescent after staining of *Drosophila* chromosomes with QM could be removed with acid.

Base-specificity. Several authors have reported base-specificity in the interaction between acridine dyes and nucleic acids.[9–12,40] However, acridines such as acridine orange [9] and 9-aminoacridine [10] show no base-specificity in the interaction with DNA in solution. The base-specificity can be demonstrated in solution with either mono- or polynucleotides containing the base guanine, or with DNAs that differ in the (G+C) content. In two previous papers I presented evidences for base-specificity of QM.[18,41] Quenching of the fluorescence intensity of QM was obtained with polyG, while polyA enhanced the fluorescence intensity of the dye. The relationship between the base content of the DNA and the degree of quenching of the fluorescence intensity of QM is further demonstrated in this paper. The higher the (G+C) content of the DNA the more the nucleic acid quenches the fluorescence intensity of QM in solution. A similar enhancement and quenching of fluorescence is obtained with acridines without a long side chain at C-9 (*e.g.* proflavine.)[9] Thus the side chain at C-9 of QM is not responsible for the base-specific reaction.

Conformational changes of the polymer. When a polymer is mixed with a dye in solution, the polymer undergoes molecular changes. These changes can be seen as altered hydrodynamic properties of the polymer. In the quinacrine-DNA complex, Kurnick and Radcliffe [33] reported an increased viscosity and a reduced sedimentation constant compared to those of native DNA alone. At low dye concentrations, *i.e.* at intercalation, the length of the helix is increased by the dye. At high concentration ratios of dye to polymer, the dye is lined up opposite the phosphate groups, thus increasing the diameter of the helix.

The stabilizing effect of QM on the polymer was shown by increased T_m and increased resistance to DNase depolymerization. The effect on T_m as well as on depolymerization by DNase depends on the concentration ratio of the dye to the polymer. An increased concentration ratio of the dye to polymer increases the protective effect of the dye on the polymer. The protective effect also depends on the salt concentration in the solution. When the salt concentration is increased the protective effect of the dye is reduced.

To stabilize a native nucleic acid against thermal strand separation it is not necessary for the acridine ring to have a side chain at C-9. Ramstein and Leng [40] reported a rise of the T_m for *Micrococcus lysodeikticus* DNA when mixed with proflavine, which does not have any side

chain at C-9. The agent can also be a simple aliphatic compound without any ring structure. Spermine, an aliphatic diaminopentane with two amino groups separated by four carbon atoms, is also active in raising the T_m of nucleic acids.[42] The two exocyclic amino groups in QM are separated by four carbon atoms, hence the dye can be considered a substituted 1,4-diaminopentane (see formula given above). Thus, it is not surprising that QM was as active as spermine in producing an effect on T_m.

Cytological implications. It is not easy to evaluate the relationship between results obtained with QM and nucleic acids in solution on the one hand and cytological fluorescence investigations on the other. There are several fundamental differences between the two systems. Firstly, metaphase chromosomes contain 50–80 % protein.[43] It is already known that proteins modify several of the fluorescent characteristics of QM in solution.[44] Secondly, the concentration of DNA in the interphase nucleus is greater than that normally used in solution.[10] This is apparent *e.g.* from the extremely rapid reassociation of denatured chromosomal DNA *in situ*.[45–47] Thirdly, the procedures used to obtain metaphase chromosome spreads certainly affect the structure and properties of both DNA and proteins.[48,49] Nevertheless, the base-specificity of the fluorescence intensity of QM with natural DNAs and nucleotides in solution is a striking phenomenon, which may well be related to the occurrence of differential brightness of fluorescence along metaphase chromosomes.

Acknowledgements. I should like to express my gratitude to Dr. Albert de la Chapelle for his support and advices. Generous gifts of quinacrine mustard from the Sterling Winthrop Research Institute are gratefully acknowledged. This investigation was supported by grants from the *Finnish National Research Council for Medical Sciences*, the *Sigrid Jusélius Foundation*, the *Waldemar von Frenckell Foundation*, the *Oscar Öflund Foundation* and the *Svenska Kulturfonden*.

Numerical Resolution of CCD-Curves

GÖRAN BLOMQUIST and SVANTE WOLD

Departments of Biochemistry and Organic Chemistry, University of Umeå, S-901 87 Umeå, Sweden

A Fortran program using correct statistical methods for resolution of counter-current distribution (CCD) curves is described. The program has been tested on CCD-curves of the isoenzymes of enolase and lactic dehydrogenase. The results show excellent reproducibility and that CCD on proteins can well be used for analytical purpose.

Partition in aqueous polymer two-phase systems is a method of great usefulness in the study of biological materials.[1] The partition behaviour depends mainly on such properties as charge and size. It is best expressed by the partition coefficient K defined as the concentration of the material in the upper phase/its concentration in the lower phase. If the K-values of two components in a sample differ sufficiently a couple of extractions are enough to achieve a satisfactory separation. However, for complex mixtures consisting of many components a multistage procedure (consisting of a large number of extractions) such as counter-current distribution (CCD) must be used.[1-3] CCD has been successfully used to study complex biological systems such as isoenzymes.[4] The resolution of the distribution curves obtained can be accomplished by calculation of the theoretical curves for the various components and by subsequently fitting a weighted sum of these theoretical curves to the observed data. The use of a computer will considerably simplify this tedious task and, in addition, allow the use of correct statistical methods. Moreover several different curves can be computed for the same case at the same time. By comparing the different theoretical curves with the experimental curve the most likely curve can easily be selected. In this paper we describe a Fortran computer program for resolution of CCD-curves and its application to some CCD-experiments with isoenzyme systems.

MATERIALS AND METHODS

The polymers used were Dextran T 500, batch No. 5996, Pharmacia Fine Chemicals, Uppsala, Sweden, and trimethyl aminopoly(ethylene glycol) (TMA PEG). The TMA PEG [5] was a generous gift from Dr. Göte Johansson. Dextran T 500 had a weight average molecular weight of 518 000 and the molecular weight of TMA PEG was about 6000. Enolase was prepared from baker's yeast by the method of Malmström [6] and was bought under the name Specialjäst from Jästbolaget, Sollentuna, Sweden. Lactic dehydrogenase (LDH) was prepared from pig liver. 500 g fresh pig liver was homogenized in 1 liter 10 mM potassium phosphate buffer, pH 7.3, in a Turmix mixer. The homogenate was centrifuged at 9000 g for 45 min and the supernatant was used as liver extract.

All chemicals used were of analytical grade. The water used was distilled twice in a quartz apparatus.

Enzyme assays. Enzyme activity was measured as change in absorbance at a suitable wavelength. All measurements were carried out at 20°C using a Unicam SP-800 spectrophotometer with tempered 1 cm quartz cuvettes.

Enolase was measured according to the method of Warburg and Christian,[7] and lactic dehydrogenase according to the method of Neilands.[8] No absolute activities were calculated.

Phase system. The phase system used contained 6.6 % dextran, 6.4 % TMA PEG and 5 mM potassium phosphate buffer, pH 6.5. In the experiments with lactate dehydrogenase 50 mM glycine–NaOH buffer pH 8.5 was used.

Counter-current distribution. The CCD experiments were carried out in the thin-layer counter-current distribution apparatus described by Albertsson.[1] Each chamber contained

0.7 ml upper phase and 0.7 ml lower phase. The enzyme mixture to be analysed was dissolved in 1.4 ml phase systems and loaded in chamber 0. Settling time used was 8 min and shaking time 30 s. 60 transfers were completed and the temperature was 22 ± 1°C.

After the CCD, 0.7 ml water was added to each chamber to obtain one phase and each chamber was analysed for enzyme activity.

COMPUTATION

1. Equations. The theoretical concentration in the i:th tube of a component with its maximum in the R:th tube is[2]

$$\eta_i = [60!/i!(60-i)!] \frac{K^i}{(K+1)^{60}} \varepsilon_R = T_{iR}\varepsilon_R \qquad (1)$$

with the partition coefficient K measured by

$$K = (R+0.5)/(60-R+0.5) \qquad (2)$$

Eqns. 1 and 2 are formulated for 60 transfers; in other cases the number 60 is changed appropriately. It must be noted that the model specified by eqns. 1 and 2 applies only to tubes 8 – 53.[2]

In order to completely specify the concentrations (η) of one component in the different tubes (60 in number), it is sufficient to specify the value of the parameter R (the tube number with maximal concentration of the component) and the relative concentration ε_R. Hence the resolution of a CCD curve involves (a) the selection of the number of peaks (N) and thereafter (b) estimation of the 2N parameters (ε_k, R_k, k = 1,2, . . . ,N) in the following eqn. (3) so that the curve fit is optimized.

$$y_i = \sum_{k=1}^{N} T_{iR_k}\varepsilon_k + e_i \qquad (3)$$

The residuals (e_i) describe the deviations between theoretical (η) and observed concentration (y) values. These residuals contain both errors of measurement and "model errors" due to simplifications inherent in the model (eqns. 1 and 2).

2. Criteria of goodness of fit. In the investigation of several CCD curves, it was found that the ordinary least squares criterion (eqn. 4 with all weights $w_i = 1$) was inadequate.

$$U = \sum_{i=1}^{60} e_i^2 w_i \qquad U = \min \qquad (4)$$

This inadequacy was interpreted as due to imperfections in the model for the peak shape (eqns. 1 and 2) in areas far from the peak maximum (R in eqn. 2). To compensate for this nonideal behaviour and, in addition, to decouple the peaks, we have instead used a weighted least squares criterion (eqn. 4) with the weights defined by

$$w_i = 0.1 + \sum_{k=1}^{N} e^{-0.5\Delta_{ki}} \qquad (5)$$

In eqn. 5 the summation is made over the N peaks (with index k) and Δ_{ki} denotes the distance between the i:th tube and the maximum of the k:th peak (R_k). Hence, the weight value for the i:th tube changes as different combinations of the peak maxima are tried in the iterative computational procedure. The weights have the values from 0.1 to *ca.* 1.5 at a peak maximum with two other maxima at the closest allowed distance (two points below and above, respectively).

In the computer program, however, options are provided also for the use of standard criteria, eqn. 4 with $w_i = y_i$ if the user feels that his data are behaving ideally.

3. Optimization strategy. The estimation of the parameters R_k and ε_k, $k = 1, 2, \ldots, N$; is a nonlinear problem corresponding to the minimization of the criterion U in eqn. 4. The problem can be linearized by the specification of the R_k parameters since this makes the weights in eqn. 5 defined as well as the T-values in eqn. 3. The strategy employed in the present computer program is based on this linearization and consists of a systematic variation of the set of R_k-parameters until the minimum of U in eqn. 4 is reached. For each new set U and the corresponding relative activity parameters (ε_k, $k = 1, 2, \ldots, N$) are computed by linear least squares. The following scheme of variation of the R_k-values has been used and found efficient.

1. Specify the number of peaks (N) and the starting values of the peak maxima (R_k, k = 1, 2, . . . , N). This is made at the input.

2. Compute U (eqn. 4) for this set of R_k values.

3. Set j = 1. This is an index which specifies the particular peak location which is currently sub-optimized.

4. Increase R_j with 1. Compute U.

5. Test if this new U is smaller than the last U (in step 2, 5, or 6). If "yes" save the new U-value and go to step 8.

6. Decrease R_j with 2, compute U.

7. Test if this new U is smaller than the last U (in step 2, 5, or 6). If "yes" save the new U-value and go to step 8. If "no" reset R_j to original value (add 1).

8. Increase j with 1. If j larger than N, go to step 9, otherwise to step 4.

9. If any change has been made, that is R_j+1 or R_j-1 has given better fit for at least one j, go back to step 3 and start a new cycle. (If the number of iterations already made is larger than a limit, usually 25, the procedure is terminated).

10. Output. (Number of iterations, parameter values, observed and calculated activity values for i=1 to 60, residuals and corresponding plot).

Some additional restrictions have been found practical. First, the peak maxima are not allowed to get closer than two tubes apart. Secondly, the peaks are not permitted to be closer than two tubes from the edges of the measured data.

The procedures has been programmed in Fortran for the CD3300 computer at the University of Umeå, Sweden. Program listings and a manual are available on request.

RESULTS AND DISCUSSIONS

As an example a comparison between experimental and theoretical curves of a CCD-experiment with enolase from baker's yeast is shown in Fig. 1. Fig. 1a shows the theoretical curve (○), and the experimental curve (□) when two components are assumed in the sample. In Fig. 1b three components are assumed. In Fig. 1a there is a gap between the sum of the two theoretical curves and the experimental curve around tube 32. However, when three components are assumed the two curves fit well except for tubes 49–55 which indicate a fourth component. It has previously been shown that enolase from baker's yeast can be separated into three components when subjected to CCD or electrophoresis.[5,6]

A more complex case to analyse is a CCD-experiment of the LDH isoenzyme system. As is well known LDH from different sources is composed of up to five isoenzymes which can be separated on gel electrophoresis. In a CCD-experiment with 60 transfers the different LDH isoenzymes overlap and make the numerical resolution of the experimental curve very time consuming. By use of the present computor program the calculation of the theoretical curves is simple and the comparison between theoretical curves and experimental curves (assuming different numbers of isoenzyme components) can easily be undertaken. In Fig. 2a a comparison of the experimental curve (□) and the theoretical curves (○) of a CCD-experiment assuming 4 components of LDH in the liver extract shows a good agreement. However, when 5 components of LDH are assumed (Fig. 2b) there is an excellent agreement between the experimental curve (□) and the sum of the theoretical curves (–).

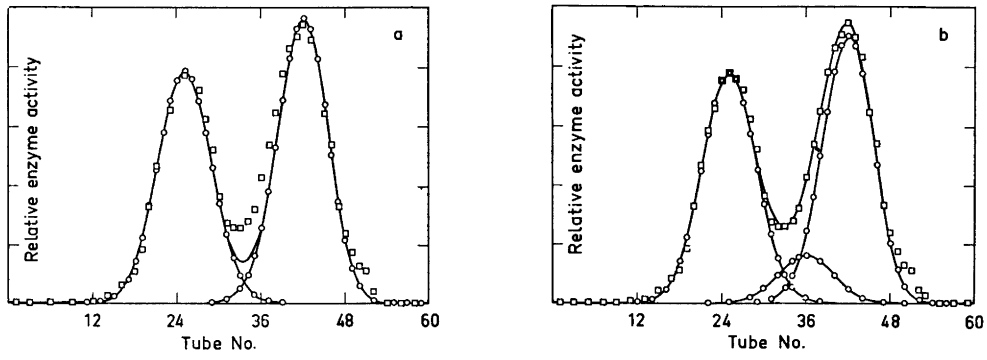

Fig. 1. Counter-current distribution of enolase from baker's yeast (□) represents experimental curve (○) represents theoretical curves and full line the sum of theoretical curves. In Fig. 1a two components are assumed while in Fig. 1b three components are assumed in the isoenzyme sample.

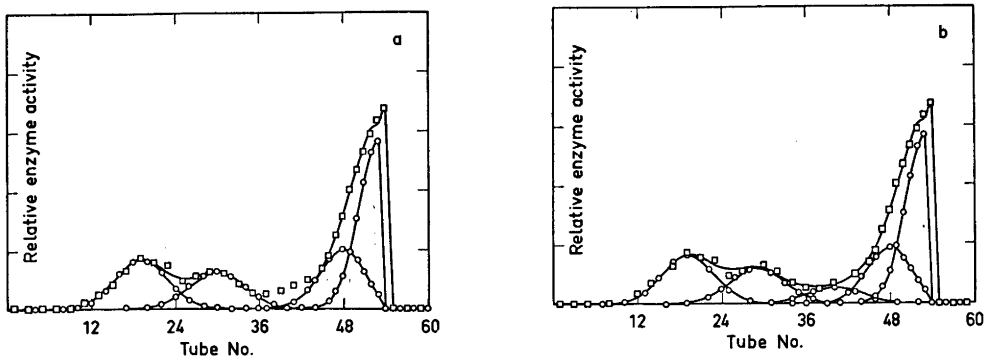

Fig. 2. Counter-current distribution of lactic dehydrogenase from pig liver. (□) represents experimental curve (○) represents theoretical curves and full line the sum of theoretical curves. In Fig. 2a 4 components are assumed while in Fig. 2b 5 components are assumed in the isoenzyme sample.

To study the reproducibility of CCD experiments and of the plotting of theoretical curves three CCD-experiments were performed at different times with the same enzyme preparation. The enzyme was stored at −25°C between the experiments which were carried out at 6 month intervals. Table 1 shows the position and amount of the different components of yeast enolase when subjected to CCD in the three experiments. The table indicates a very small variation in position of the three components from experiment to experiment. The variations are only ±1 tube which is within experimental error. The small

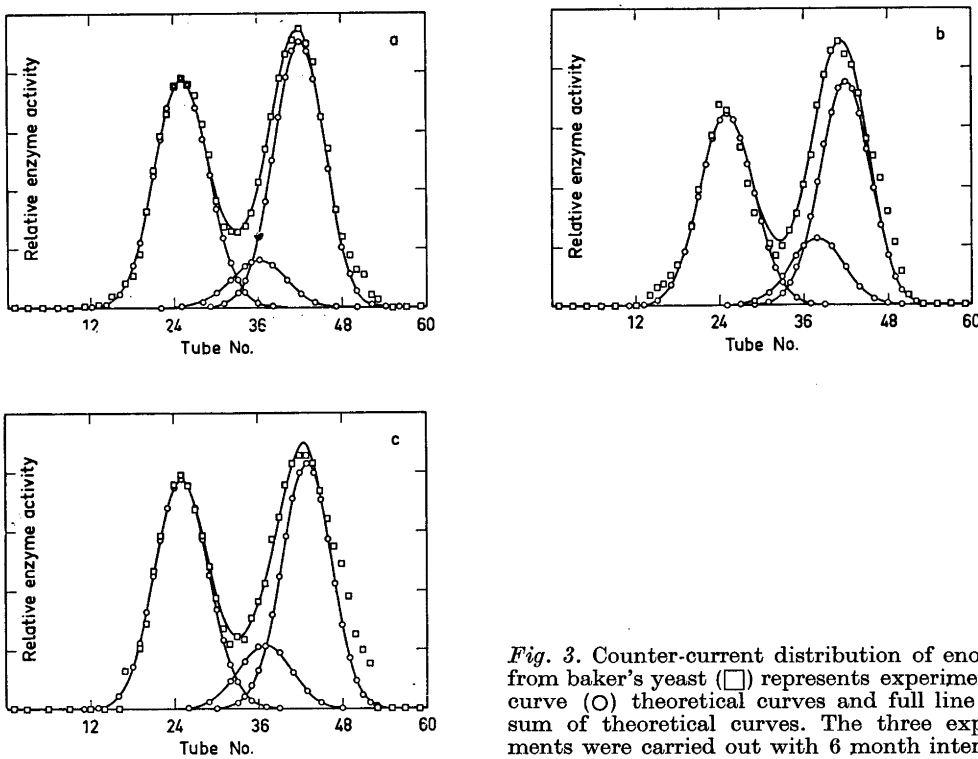

Fig. 3. Counter-current distribution of enolase from baker's yeast (□) represents experimental curve (○) theoretical curves and full line the sum of theoretical curves. The three experiments were carried out with 6 month interval.

Table 1.

		CCD-experiment 1	2	3
Position of peak No.	1	25	25	25
	2	36	38	37
	3	44	42	43
Percentage of total enzyme activity under peak No.	1	43	43	41
	2	9	12	14
	3	48	45	45

differences in the precentage of total enzyme activity under each peak in the three experiments may be explained by changes in the isoenzyme ratios due to storage.

In Fig. 3 (a, b and c) the three experiments are plotted. The reproducibility is very good and shows the value of the method for analytical purposes. Fig. 3 also shows that a fourth component may be to the right of the third peak. From gel electrophoresis enolase from baker's yeast is known to consist of three components.[9] It is never the less possible that a fourth component may be present in the enzyme preparation. To investigate this, further experiments with different enzyme preparations are necessary.

The computer program has been found to be excellent in the cases tested. It is not valid for calculations at the ends of the plot as can be seen in Fig. 2. To do further studies on the peak to the far right, one can change pH to make the K-value lower. The peak is then transferred to an area in which the computer program is valid and a theoretical resolution of the peak can be obtained.

Acknowledgement. We thank professor Per-Åke Albertsson for his interest and valuable criticism during the course of this work.

^{1}H- and ^{13}C-NMR Spectra of Phenyl-substituted Azole Derivatives. II. A Conformational Study

MIKAEL BEGTRUP

Department of Organic Chemistry, Technical University of Denmark, DK-2800 Lyngby, Denmark

^{13}C-NMR spectra of a number of phenyl-substituted pyrazolium bromides *1*, imidazolium bromides *2*, 1,2,3-triazolium bromides *4* and *5*, pyrazol-4-in-3-ones and -thiones *13* Z = O or S, imidazol-4-in-2-ones and -thiones *7* Z = O or S, 4-(1,2,3-triazolio)oxides and -sulfides *16*; Z = O or S, and 1,2,3-triazol-3-in-5-ones and -thiones *9*; Z = O or S have been recorded. Certain effects of substitution with methyl or chlorine have been measured. The magnitude of the chemical shifts of the benzene carbon atoms, particularly the *ortho*-carbon atoms, depends on the extent of interannular conjugation, and hence may provide information about the preferred conformation. Values for δ_{ortho}-C and the difference δ_{meta}-C − δ_{ortho}-C have been determined and their usefulness for assessing the extent of interannular conjugation in phenyl-substituted azoles with charged, zwitterionic, or partly aromatic heterocyclic rings has been demonstrated. ^{13}C-NMR data reveal that the heterocyclic ring of pyrazol-4-in-3-ones *13*; Z = O and triazol-3-in-5-ones *9*; Z = O, presumably takes up a twisted conformation, whereas the corresponding thiones are planar or nearly so. The ^{13}C-NMR-spectra render reliable information even in cases where ^{1}H-NMR-spectra fail to give correct results.

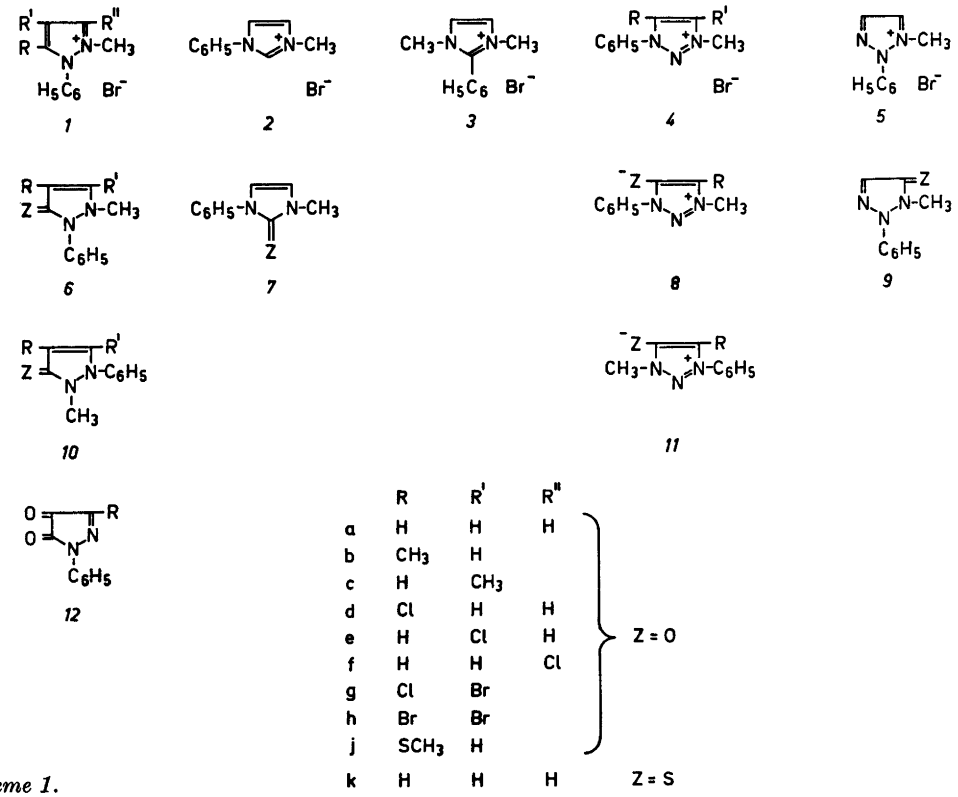
^{1}H- [1-6] and more recently ^{13}C-NMR-spectroscopy [7] has been employed for conformational studies of phenyl substituted heteroaromatic azoles. ^{1}H-NMR-spectra of unhindered compounds exhibit phenyl group multiplets, whereas phenyl substituted azoles with bulky substituents impeding interannular delocalization of the π-electrons give rise to phenyl group singlets or approximate singlets[1-3,5,6] When interannular conjugation in phenyl substituted azoles is extensive the electron density at C-2′ * increases leading to a high field shift of the C-2′ ^{13}C-NMR signal. Characteristic values for $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ were found when interannular conjugation was extensive or impeded, respectively.[7] The ^{13}C-NMR method was found to yield unambiguous results even in cases where the ^{1}H-NMR method fails.

So far, ^{1}H- or ^{13}C-NMR spectroscopy has not been applied systematically to conformational analysis of phenyl substituted azoles with charged, zwitterionic, or non-aromatic heterocyclic rings.

The marked deshielding of the *o*-phenyl protons in unhindered systems may be caused by several factors the relative significance of which is poorly understood.[1,2,4-6,9,10] Presumably, anisotropy effects induced by the heteroaromatic ring play a major role.[11,12] Since phenyl substituted azoles with non-aromatic heterocyclic rings are devoid of a heterocyclic ring current, ^{1}H-NMR would not be expected to be useful for conformational analysis in these systems. Even in conformational analysis of phenyl substituted azoles with charged or zwitterionic heterocyclic rings the values of ^{1}H-NMR-shifts should be interpreted with caution due to the uncertain origin of the shifts and to known exceptions from the rules.[7] In contrast, the ^{13}C-NMR method provides direct information about the extent of delocalization. Hence, reliable information about the conformation is expected in phenyl substituted azoles with charged, zwitterionic or non-aromatic rings.

Results of a ^{1}H- and ^{13}C-NMR investigation

* In the present paper the heterocyclic carbon atoms are numbered according to the IUPAC nomenclature.[8] The phenyl carbon atoms are denoted with a dash. Counting starts with the substituted atom (C-1′).



Scheme 1.

of such compounds are reported in the present paper. As representatives of charged azoles, phenyl substituted pyrazolium bromides *1*, imidazolium bromides *3*, and 1,2,3-triazolium bromides *4* and *5* have been studied. Zwitterionic azoles are represented by the phenyl substituted 4(1,2,3-triazolio)oxides and -sulfides *16*; Z = O and S. Finally, 1,2-disubstituted pyrazol-4-in-3-ones *13*; Z = O, -thiones *13*; Z = S, 1,3-disubstituted imidazol-4-in-2-ones *7*; Z = O, -thiones *7*; Z = S, 1,2-disubstituted 1,2,3-triazol-3-in-5-ones *9*; Z = O, and -thiones *9*; Z = S have been investigated as representatives of azole derivatives with reduced heteroaromaticity.*

* Undoubtedly, the azolinones and -thiones, like 2-pyridone and -thione,[13] are heteroaromatically stabilized to a certain extent through resonance structures such as *14* and *15*. Estimates of heteroaromatic stabilization are available only for pyrazolones *13*; Z = O, contradictory results being reported.[14–17]

RESULTS

Most of the pertinent ^{1}H-NMR-data have been published previously.[18–23] ^{13}C-Signals arising from the phenyl groups are summarized in the Tables 1, 2, and 3.

Proton noise-decoupled ^{13}C-NMR data for pyrazolium, imidazolium, and 1,2,3-triazolium bromides are presented in Tables 1 and 2.

In the non-decoupled spectrum of *1a* (Table 4), the two signals at lowest field and that at the next highest field exhibited the largest splittings. Hence these signals were assigned to the heterocyclic carbon atoms.[24a]

In the off-resonance proton-decoupled spectra of *1d*, *1e*, and *1f*, with irradiating upfield from the aromatic protons (see Experimental), the signals showing the largest residual coupling were ascribed to the proton-carrying C-3 and C-5 atoms. The (sharp) non-shifted singlets in *1d*, or *1e*, when compared to *1f*, were attributed

[a] The compounds were prepared as described in the experimental section. [b] Appearance of the phenyl group in the ^{1}H-NMR spectrum, bd (broad doublet), bs (broad singlet), m (multiplet), nm (narrow multiplet), s (singlet), 2+3 (a low field multiplet containing two protons plus a high field multiplet containing three protons).

to C-1′. In *1f*, the signal at lowest field, in *1d*, the signal at next lowest field, and in *1e*, the signal at next highest field appeared as (broad) singlets. Hence these signals were assigned to the chlorine-substituted carbon atoms C-5, C-3, and C-4, respectively. Consequently, the order $\delta_{C-5} > \delta_{C-3} > \delta_{C-4}$ was deduced for 1-methyl-2-phenyl-pyrazolium bromide *1a*.

Identification of the phenyl carbon atoms of *1a* through the fine structure of the undecoupled signals as described previously [7] proved unsuccessful since the spectra were indistinct and unresolvable and did no allow an unequivocal distinction between C-2′ and C-3′.* However, in all phenyl-substituted azole derivatives where a definite assignment, through undecoupled spectra, has been carried out (see Ref. 7 and below) the intensity of the signals decreases in the order C-3′ > C-2′ > C-4′. The same order of intensity was suggested by the identification of C-2′, C-3′, and C-4′ in *1a*, 1*d*, 1*e*, and

* The change in fine structure may be due to a change in the ratio between $^3J_{CCCH}$ and $^2J_{CCH}$ [7] or to the presence of a more strongly coupled spin system in the phenyl group of *1a* — and in other azolium salts as well — than in the azoles.

1f, as well as in the other azolium bromides *2*, *3*, *4*, and *5*.

The ^{13}C-NMR-signals of 1-methyl-3-phenyl-1,2,3-triazolium bromide *4a*, its 4- and 5-methyl derivatives *4b* and *4c*, as well as its 4- and 5-chloro derivatives *4d* and *4e* (Table 1), were identified similarly. The off-resonance spectra indicated that δ_{C-5} in *4b* and *4d* was larger than δ_{C-4} in *4c* and *4e*, respectively. Conversely, δ_{C-5} in *4c* and *4e* was larger than δ_{C-4} in *4b* and *4d*, respectively. Hence, δ_{C-5} was assumed to be larger than δ_{C-4} in 1-methyl-3-phenyl-1,2,3-triazolium bromide *4a*, a supposition confirmed by its undecoupled spectrum (Table 4) in which C-4 appeared with sharp doublet fine structure due to coupling to H-5. The fine structure of C-5 was a doublet with unresolved hyperfine structure. The doublet part is explained by coupling to H-4, the hyperfine structure by coupling to the methyl protons.

In the undecoupled spectrum of 1-methyl-3-phenyl-imidazolium bromide *2a* (Table 4) the fine structure of the three signals with large splittings, from low to high field, was a narrow, quartet-like pattern, an extended double doublet with broad peaks, and an extended double doublet with narrow peaks. The two high field signals were attributed to C-4 and C-5, the extended fine structure was attributed to large $^2J_{CCH}$ couplings. The signal with the broad peaks was attributed to C-5, the broadening arising from long range coupling to the methyl protons. The narrow, fine splitting of C-2 is the result of small $^3J_{CNCH}$ couplings. The strong deshielding of C-2 is caused by the two adjacent nitrogen atoms.

C-4 and C-5 in 1-methyl-2-phenyl-1,2,3-triazolium bromide *5a* could be distinguished, since the latter signal in the undecoupled spectrum (Table 4) appeared with unresolved hyperfine structure due to weak coupling to the methyl protons.

The ^{13}C-NMR signals of [1-methyl-3-phenyl-4-(1,2,3-triazolio)]-oxide *8a* and of [1-phenyl-3-methyl-4-(1,2,3-triazolio)]oxide *11a* (Table 3) were identified through the proton undecoupled spectra (Table 5). The signal exhibiting solely doublet fine structure was attributed to C-4. The doublet arises from coupling to H-5. C-4 of *8a* and *11a*, like common carbonyl carbon atoms,[24b] absorb at very low field. The signal with the largest splitting was attributed to C-5. C-5 of *8a* and *11a* resonate at higher field than the other aromatic carbon atoms. The signals of the

[a] The compounds were prepared as described in the references given. [b] Appearance of the phenyl group signal in the ^{1}H-NMR spectrum. See footnote *b*, Table 1. [c] The material was prepared analogous to the ethoxycarbonyl compound.[47] [d] The solution was saturated at room temperature. [e] The material was prepared analogous to *13m*.[51]

latter were identified through the undecoupled spectra as described previously.[7] The intensities of the proton noise decoupled signals of *8a* and *11a* decrease in the order C-3′ > C-2′ > C-4′ > C-5 > C-4 and C-1′. The order of intensities was used to identify the phenyl carbon signals of the 5-substituted 4(1,2,3-triazolio)oxides *8b*, *8h*, *11b*, *11h*, *11j*, and *16p* and those of the 4(1,2,3-triazolio)sulfides *8k* and *11k* (Table 3). The C-4 and C-5 signals of the 5-substituted 4(1,2,3-triazolio)oxides were assigned by their characteristic low field and high field positions, respectively. The 4(1,2,3-triazolio)sulfides *8k* and *11k* like the analogous oxygen compounds *8a* and *11a*, showed a low field and a high field ^{13}C-NMR signal (Table 3). Hence these signals were attributed to C-4 and C-5, respectively.

The ^{13}C-NMR signals (Table 3) of the pyrazol-4-in-3-ones *13*; Z = O, imidazol-4-in-2-ones *7*; Z = O, and 1,2,3-triazol-3-in-5-ones *9*; Z = O or S were identified analogously through undecoupled spectra (Table 5). Low field signals exhibiting only fine structure were ascribed to C = O carbon atoms and signals with large splittings to proton-carrying heterocyclic carbon atoms. Benzene carbon atoms were identified in the usual way.[7] C-5 of the pyrazol-4-in-3-one *6a* was identified as the heterocyclic carbon signal at the next lowest field since it appeared with quartet hyperfine structure due to a small long-range coupling to the methyl protons. In *10a* only broadening of the C-5 signal due to coupling to the methyl protons is observed.

C-3 and C-4 of the 4- and 5- substituted

Table 4. ^{13}C-^{1}H NMR coupling constants of phenyl substituted azolium bromides [a].

Compound		The carbon to which the coupling takes plane C-2	C-3	C-4	C-5	C-1′	C-2′	C-3′	C-4′	*N*-CH_3 / *C*-CH_3
				$^{1}J_{CH}$ / $^{2}J_{CCH}$ / $^{3}J_{CXCH}$ Hz						
				190			167	167	168	146
1-Methyl-2-phenyl-pyrazolium bromide	*1a*		7;7[b]	7;7					9

1-Methyl-2-phenyl-1,2,3-triazol-3-in-5-one *9*			201		10	165	163	163

[a] All coupling constants have been obtained by first order analysis. [b] The $^{3}J_{CXCH}$ coupling constants were distinguished from the $^{2}J_{CCH}$ coupling constants since the latter are of the same order of magnitude as $^{2}J_{CCH}$ in the triazole-derivatives *8a* and *11a*.

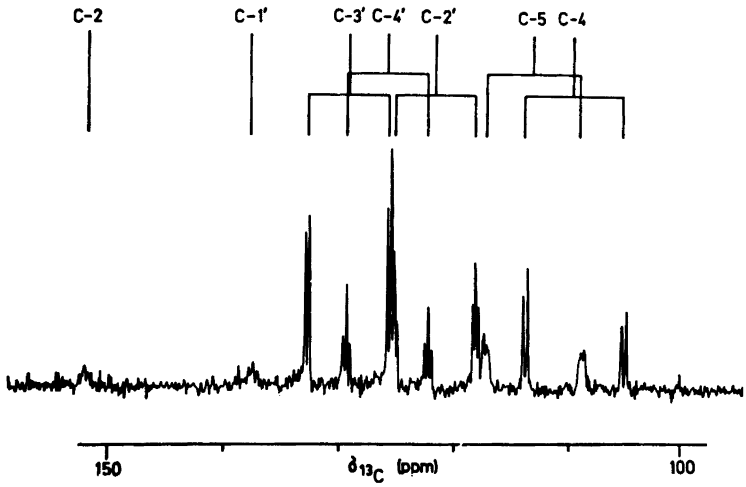

Fig. 1. Proton undecoupled ^{13}C-NMR spectrum of 1-methyl-3-phenyl-4-in-2-one *7a*.

pyrazol-4-in-3-ones *6c*, *6e*, *6g*, *6h*, *10c*, *10e*, *10g*, *10h*, *12b*, *13l*, *13m*, and *13o* were identified through their characteristic positions. C-4 in *12b* was identified as the second lowest field signal since its intensity, like that arising from C-3, was particularly low. Low intensity as the result of long relaxation time, T_1, is characteristic of carbonyl carbon atoms.[25a]

C-5 and the benzene ring carbon atoms of the substituted pyrazol-4-in-3-ones were identified, assuming the same order of intensities, C-3′ > C-2′ > C-4′ > C-4, C-5 > C-1′ > C-3, as observed in *6a* and *10a* and taking into account that substituent-carrying carbon atoms appear with strongly reduced intensity.[7]

The two sets of phenyl carbon signals of *13m* and *13n* were assigned by comparison with the phenyl carbon signals of *6a* and *10a*. For example, $\delta_{C-1'}$ of *10a* > $\delta_{C-1'}$ of *6a*. Hence, the low and high field C-1′ signals of *13m* were ascribed to the 1- and 2-phenyl groups, respectively. Similarly, the two sets of phenyl carbon signals of *13o* were identified by comparison with the phenyl carbon signals of *6c* and *10c*.

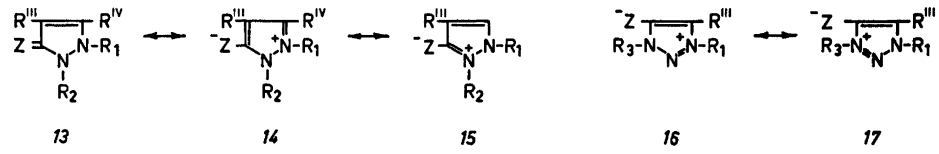
C-5 of 1-methyl-3-phenyl-imidazol-4-in-2-one *7a* was distinguished from C-4 as the signal which shows multiplet hyperfine structure due to coupling to the methyl protons (Fig. 1).

The ^{13}C-NMR signals of the thiones *6k* and *10k* were assigned comparing δ-values and relative intensity of signals with those of the corresponding oxygen analogues. The signals of the thiones *7k* and *9k* were identified through their undecoupled spectra as described for the corresponding oxygen analogues.

Superficially, δ^{13}_{C} of azolium ring carbon atoms is expected to increase when the number of ring nitrogen atoms, particularly in α-position or positively charged, increases. However, the observed ^{13}C chemical shifts are not in keeping with this assumption. (Thus δ_{C-5} of *1a* > δ_{C-5} of *5* > δ_{C-2} of *2a*). Nor are these shifts larger the faster the proton on the appropriate carbon atom is exchanged with deuterium in basic solution.[18,21,22]

According to calculations [26] and ^{13}C-NMR of the protonated azoles [27] or azines,[28] the electron density of α-carbon atoms increases when a heterocyclic ring nitrogen adopts a positive charge. This effect may account for the unexpected order in the present case.

In each of the methylphenylazolium bromides *1a*, *2a*, *4a*, and *5a* the chemical shift of a carbon atom adjacent to an *N*-methyl group is larger than that of a carbon atom adjacent to an *N*-phenyl group, indicating that the electron density is higher at the latter carbon atom. The protons at the appropriate carbon atoms absorb in the reverse order, which also corresponds to the relative acidity of the protons, as reflected by the rate of the base catalyzed deuterium exchange.[18,21] In *1a*, *2a*, *4a*, and *5a* $\delta^{13}_{CH_3N-1}$ is



13 14 15 16 17

p	CH_3	CH_3	C_6H_5	H	

Scheme 2.

larger the more electron attracting the ring is. (Thus δ_{CH_3N-1} of *4a* and *5a* > δ_{CH_3N-1} of *1a* > δ_{CH_3N-1} of *2a*).

Methyl carbon atoms at N-1 in 1,3-disubstituted 4(1,2,3-triazolio)oxides *16*; Z = O, absorb at 6.8 – 8.7 ppm lower field than methyl carbon atoms at N-3. This indicates that N-1 is more electron deficient than N-3, suggesting that the resonance structure *16*; Z = O (Scheme 2) is the major contributor to the 4(1,2,3-triazolio)oxide hybrid. The chemical shifts of C-4, C-5, and the N-1 methyl carbon atoms in the 4(1,2,3-triazolio)sulfides *8k* and *11k* are similar to those in the corresponding 4(1,2,3-triazolio)-oxides *8a* and *11a*, respectively. In contrast, δ_{CH_3N-3} is 4.1 ppm larger in the 4(1,2,3-triazolio)sulfide *11k* than δ_{CH_3N-3} in the corresponding 4(1,2,3-triazolio)oxide *11a*. δ_{CH_3N-1} in *8k* is larger than δ_{CH_3N-3} in *11k*, again indicating that *16*; Z = S, is the major contributor to the hybrid. This has recently been confirmed in the solid by X-ray studies of [1,3-dimethyl-4-(1,2,3-triazolio)] sulfide *16*; $R_1 = R_3 = CH_3$, Z = S.[29]

Methyl carbon atoms at N-1 in 1,2-disubstituted pyrazol-4-in-3-ones *13*; Z = O, absorb at 7.4 – 8.2 ppm lower field than N-2 methyl carbon atoms. This indicates that N-1 is more electron deficient than N-2, suggesting that the dipolar structure *14*; Z = O, contributes appreciably to the pyrazol-4-in-3-one hybrid. Arguments for [14] and against [15–17] the importance of zwitterionic structures have been presented, and some of the arguments have been critically analyzed.[30,31] It should be emphasized that the present data are only suggestive.

The ^{13}C-NMR chemical shifts of the heterocyclic ring- and the *N*-methyl carbon atoms of the thiones *6k*, *10k*, *7k*, and *9k* are quite different from those of the corresponding oxygen analogues.

A methyl group deshields the methyl carrying carbon atom 10.4 – 11.5 ppm in 1,3-disubstituted 1,2,3-triazolium salts *4*, 1,3-disubstituted 4(1,2,3-triazolio)oxides *16*; Z = O, and 1,2-disubstituted pyrazol-4-in-3-ones *13*; Z = O. Carbon atoms adjacent to the methyl-substituted carbons are shielded 1.5 – 2.1 ppm in 1,2,3-triazolium salts *4* and 4(1,2,3-triazolio)-oxides *16*; Z = O.

The effect of chlorine on the ^{13}C chemical shifts of azolium salts depends on the type of ring and the position of the substituent. Thus chlorine deshields the substituted carbon atom 0.9 – 1.3 ppm in the 1,2,3-triazolium bromides *4d* and *4e*. The adjacent carbon atom is shielded 2.0 – 2.2 ppm. Chlorine in the 4-position of the pyrazolium salt *1e* has a similar effect but chlorine in the 3- or 5-position of the pyrazolium salts *1d* and *1f* affects the ^{13}C chemical shift of the substituted and the adjacent carbon atom less than 0.4 ppm (Table 1). Chlorine in the 5-position of the pyrazolones *13*; Z = O, deshields the substituted and the adjacent carbon atom 1.5 – 1.9 and 1.2 – 1.3 ppm, respectively.

Bromine shields the substituted carbon atom *ca* 14.6 ppm in the 4(1,2,3-triazolio)oxides *16*; Z = O. The adjacent carbon atom is deshielded *ca* 3.0 ppm.

The effects of the substituents are similar to

Table 6. The ^{13}C chemical shift of C-2′ and the ^{13}C chemical shift difference between C-3′ and C-2′ for *C*- and *N*-phenyl substituted azole derivatives.

[a] See the footnote p. 71. The indications are typed in italics when the extent of hindrance has been estimated from the ^{13}C-NMR data and the substituents adjacent to the *N*-phenyl groups are stated in cases where a more exact specification is considered necessary. [b] When not otherwise stated the δ-values given are for deuteriochloroform solution with TMS as an internal standard. [c] The data have been published previously [7] but are shown for comparison. [d] The δ-values given are for deuterium oxide solution with *p*-dioxane as an internal standard. [e] Notice that the compound is *C*-phenyl substituted.

Table 7. $^1J^{13}_{CH_3N}$ coupling constants of *N*-methyl substituted azoles in deuteriochloroform.[a]

Compound	$^1J^{13}_{CH_3N}$ Hz
1-Methyl-pyrazole	140.0
1-Methyl-imidazole	140.9
1-Methyl-1,2,3-triazole	142.2
2-Methyl-1,2,3-triazole	142.0

[a] The values were determined by 60 MHz ^{1}H-NMR spectroscopy.

those observed in the phenyl substituted azoles.[7]

The $^1J^{13}_{CH}$ coupling constants of the heterocyclic carbon atoms in the azolium bromides *1*, *2*, *4*, and *5* are 12 – 20 Hz larger than the corresponding coupling constants of the parent 1-phenyl substituted azoles [7] (Table 4). The long range coupling constants are similar in *1*, *2*, *4*, and *5* and in the parent 1-phenyl-azoles. The $^1J^{13}_{CH_3N}$ coupling constants are 2 – 4 Hz larger in *1*, *2*, *4*, and *5* than in the parent 1-methyl substituted azoles (Table 7). The larger $^1J^{13}_{CH}$ coupling constants observed in the azolium salts, compared with the corresponding azoles, are explained by the increased electron deficiency of the azolium systems.

The $^1J^{13}_{CH}$ and $^2J^{13}_{CCH}$ coupling constants of the 1,2,3-triazol-3-in-5-one *9a*; the 4(1,2,3-triazolio)oxides *8a* and *11a*, imidazol-4-in-2-one *7a*, and the pyrazol-4-in-3-ones *6a* and *10a* (Table 5) are similar to the values found in the parent *N*-phenyl substituted compounds.[7] (Thus the $^1J^{13}_{CH}$ coupling constants decrease in the order $^1J_{CH-4}$ in *9a* and $^1J_{CH-5}$ in *8a* and *11a* > $^1J_{CH-4}$ in *7a* > $^1J_{CH-5}$ in *6a* and *10a* > $^1J_{CH-4}$ in *6a* and *10a*. Similarly, $^2J_{HCC-4}$ in *8a* and *11a* > $^2J_{HCC-4}$ in *7a* > $^2J_{HCC-3}$ and $^2J_{HCC-5}$ in *6a* and *10a* > $^2J_{HCC-4}$ in *6a* and *10a*).

DISCUSSION

The ^{13}C chemical shift of C-3′. In simple *N*-phenyl substituted azoles, $\delta_{C-3'} = 128.5 - 129.8$ ppm is the parameter least sensitive to ring type and substitution.[7] Similarly, C-3′ of the 4-(1,2,3-triazolio)oxides *16*; Z = O, 4-(1,2,3-triazolio)-sulfides *16*; Z = S, pyrazol-4-in-3-ones *13*; Z = O, pyrazol-4-in-3-thiones *13*; Z = S, 1,2,3-triazol-3-in-5-one *9a*, 1,2,3-triazol-3-in-5-thione *9k*, imidazol-4-in-2-one *7a*, and imidazol-4-in-2-thione *7k*, consistently resonate between 128.2 and 129.7 ppm (Table 3). The shifts of C-3′ of the azolium salts *1*, *2*, *4*, and *5* are slightly larger [129.8 – 130.5 ppm in deuteriochloroform solution (Table 2) and 130.8 – 133.4 ppm in deuterium oxide solution (Table 1)], presumably due to strong inductive electron attraction from the positively charged azolium ring.

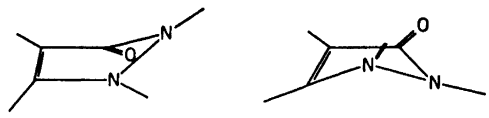
The ^{13}C chemical shift of C-2′. In simple *N*-phenyl substituted azoles, $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ are the parameters most susceptible to hindrance of interannular conjugation.[7] In Table 6, these parameters of simple phenyl substituted azoles are compared with those extracted from Tables 2 and 3 of the phenyl substituted derivatives with charged, zwitterionic, or partly aromatic heterocyclic rings. In the unhindered imidazolium salt *2* and triazolium salts *4a*, *4c*, and *4e*, $\delta_{C-2'}$ ($CDCl_3$) = 120.6 – 121.7 ppm and $\delta_{C-3'} - \delta_{C-2'}$ ($CDCl_3$) = 8.6 – 9.3 ppm. [In deuterium oxide solution $\delta_{C-2'} = 121.8 - 122.8$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 8.4 - 9.1$ ppm (Table 1)]. These values correspond to those of the unhindered azoles indicating that interannular conjugation is extensive in these salts. In the hindered * pyrazolium bromides *1a*, *1d*, *1e*, and *1f* and 1,2,3-triazolium bromides *4b*, *4d*, and *5a*, $\delta_{C-2'}$ ($CDCl_3$) = 125.7 – 129.1 ppm and $\delta_{C-3'} - \delta_{C-2'}$ ($CDCl_3$) = 1.3 – 4.2 ppm. [In deuterium oxide solution $\delta_{C-2'} = 125.9 - 131.1$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 2.1 - 4.9$ ppm (Table 1).] These values are similar to those of the hindered azoles. In the hindered *C*-phenyl substituted imidazolium salt *3*, $\delta_{C-2'} = 130.2$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 0.6$ ppm, *i. e.* values similar to those of the hindered *C*-phenyl substituted imidazoles.

In the unhindered [1-phenyl-3-methyl-4-(1,2,3-triazolio)]oxide *11a* and -sulfide *11k* the values of $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ correspond to those of the unhindered 1-phenyl substituted 1,2,3-triazoles indicating that interannular conjugation is extensive in *11a* and *11k*. Methyl, bromine, or methylthio in the 5-position of *11*; Z = O, impedes interannular conjugation as reflected by $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ which are

* In the following discussion it is assumed that the steric effects of substituents are similar to those in the azoles and that the steric effect of an *N*-methyl group and a *C*-methyl group are similar.

similar to those of the hindered 5-substituted 1,2,3-triazoles. In the [1-methyl-3-phenyl-4-(1,2,3-triazolio)]oxides *8*; Z=O, $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ deviate slightly from the values observed in the unhindered 1,2,3-triazoles indicating that the oxygen atom adjacent to the phenyl group impedes interannular conjugation insignificantly. In contrast, the sulfur atom of [1-methyl-3-phenyl-4-(1,2,3-triazolio)]sulfide *8k* impedes interannular conjugation as effectively as a methyl group, as evident from the similarity between $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ in *8k* (Table 3) and in 1-phenyl-5-methyl-1,2,3-triazole.[7] In the hindered *C*-phenyl substituted 4-(1,2,3-triazolio)-oxide *16p* $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ values correspond to those of the hindered *C*-phenyl substituted azoles.[7]

In 2-phenyl-5-methyl-pyrazol-5-in-3,4-dione *12b* and 2-phenyl-4-carbomethoxy-pyrazol-4-in-3-one *13l*, $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ values are similar to those of the unhindered 1-phenyl-pyrazoles indicating that the oxygen atom adjacent to the phenyl group does not impede interannular conjugation at all in *12b* and only slightly in *13l*. According to the ^{13}C-NMR data of 1-phenyl-5-methyl-pyrazole [7] and 1-methyl-2-phenyl-pyrazolium bromide *1a* (Table 2), the methyl group of 1-phenyl-2-methyl-pyrazol-4-in-3-one *10a* is expected to impede interannular conjugation. However, $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ values are roughly between those of the unhindered and hindered heteroaromatic pyrazoles. This implies that interannular conjugation in *6a* is impeded to a minor extent, due to the fact that the extent of interannular conjugation is a cos^2-function of the angle between the 2*p*-orbitals of the *N*-atom and the π-orbitals of the attached phenyl group.[32-34] Inspection of Dreiding models reveals that minor impediment of interannular conjugation is possible only if the pyrazole ring of *6a* is not planar but in isotropic phase takes up a conformation like that shown in Fig. 2. By replacement of oxygen in *6a* with sulfur, $\delta_{C-2'}$ increases to values similar to those of the hindered heteroaromatic pyrazoles. The sulfur atom cannot influence the phenyl group through space. Hence, the hindrance must be due to the *N*-2 methyl group. This seems possible only if the pyrazole ring is planar or almost so in the pyrazolthione *10k*. By introduction of methyl or bromine in the 5-position of the pyrazolone *10a*, $\delta_{C-2'}$ increases, and $\delta_{C-3'} - \delta_{C-2'}$ decreases to values similar to those of hindered 1-phenyl-pyrazoles. A similar effect of a 5-methyl group is observed in *13o*. The effect of a 5-methyl group is much larger than that of the *N*-2 methyl group (compare $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ values of *10a* and *10c*). This implies that the angle between the exocyclic bonds of *C*-5 and *N*-1 is smaller than that between the exocyclic bonds of *N*-1 and *N*-2. This in turn suggests that the 5-substituted 1-phenyl-2-methyl-pyrazol-4-in-3-ones *10b*, *10g*, and *10h* take up a skew conformation (Fig. 2). The strong impediment of 5-substituents indicates that the pyrazolones *6c*, *6e*, *6g*, *6h*, and *13o* in solution apparently do not adopt the conformation with a planar pyrazole ring and with the 5-substituent out of the plane, which has been observed by an X-ray study of 1,5-dimethyl-2-phenyl-4-bromo-pyrazol-4-in-3-one.[35]



18 *19*

Fig. 2. Possible nonplanear conformations of 1,2-disubstituted pyrazol-4-in-3-ones. *18* and *19* have been selected as the ideal envelope conformations with the least distorted conjugated carbonyl system. *18* seems more likely than *19* both for 1-methyl-2-phenyl-pyrazol-4-in-3-ones *6*; Z=O where the N-2 phenyl group is least hindered in the former, and for 1-phenyl-2-methyl-pyrazol-4-in-3-ones *10*; Z=O as discussed in the text.

In the 1-methyl-2-phenyl-pyrazol-4-in-3-ones *6a*, *6c*, *6g*, and *6h*, $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ values are not far from those of the hindered 1-phenyl-pyrazoles, indicating that interannular conjugation is impeded in the pyrazol-4-in-3-ones *6a*, *6c*, *6g*, and *6h*. In these, however, the combined effects of the *N*-1 methyl group and the *C*-3 oxygen atom are smaller than that of the single methyl group in 1-phenyl-5-methyl-pyrazole.[7] This again may be explained by assuming that the heterocyclic ring in the pyrazol-4-in-3-ones *6a*, *6c*, *6g*, and *6h* is not planar (see Fig. 2). A conformation like that observed for 1,5-dimethyl-2-phenyl-4-bromo-pyrazol-4-in-3-one in the crystal phase [35] seems more improbable. $\delta_{C-2'}$ in the pyrazol-4-in-3-thione *6k* is larger and $\delta_{C-3'} - \delta_{C-2'}$ is smaller than those of the

oxygen analog *6a* (Table 3). This indicates that replacement of an oxygen atom adjacent to the phenyl group with a sulfur atom increases the impediment of interannular conjugation. In *6k* the combined effects of the *N*-1 methyl group and the *C*-3 sulfur atom are similar to the combined effects of a methyl group and a sulfur atom in heteroaromatic compounds. (Thus the difference between $\delta_{C-2'}$ of *6k* and 1-phenylpyrazole [7] is 9.7 ppm and the difference between $\delta_{C-2'}$ of 1-phenyl-5-methyl-pyrazole [7] and 1-phenyl-pyrazole [7] plus the difference between $\delta_{C-2'}$ of *8k* and 1-phenyl-1,2,3-triazole [7] is 10.0 ppm. The corresponding difference for $\delta_{C-3'} - \delta_{C-2'} = -9.5$ and -11.6 ppm, respectively). This suggests that the heterocyclic ring of the pyrazol-thione *6k* is probably planar, or nearly so.

According to $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ values of *13m* and *13n*, an *N*-phenyl group impedes the interannular conjugation of an adjacent phenyl group to a smaller extent than an oxygen atom.

In 1-methyl-2-phenyl-1,2,3-triazol-3-in-5-one *9a*, $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ values fall between those of the hindered and unhindered 1-phenyl-1,2,3-triazoles or 1,2,3-triazolium bromides *4*, implying that interannular conjugation is impeded to a smaller extent in *9a* than in the hindered aromatic triazoles. This may be explained assuming that the heterocyclic ring of *9a* is not planar but takes up a skew conformation like the pyrazol-4-in-3-ones *13*; Z = O (see Fig. 2). Like in *13*, interannular conjugation vanishes in *9* by replacement of oxygen with sulfur as indicated by $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ of *9k*.

$\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ values of the imidazol-4-in-2-one *7a* correspond to those of 1-phenylimidazole indicating that interannular conjugation prevails in *7a*. When oxygen is replaced by the larger sulfur atom interannular conjugation vanishes as indicated by $\delta_{C-2'}$ and $\delta_{C-3'} - \delta_{C-2'}$ values of *7k*.

The ^{13}C chemical shift of C-4'. The chemical shift of C-4' varies much less than $\delta_{C-3'}$ with the extent of interannular conjugation. In the azolium bromides, the pyrazol-4-in-3-ones *13*; Z = O, and the pyrazol-4-in-3-thiones *13*; Z = S, C-4' is shifted to low field, and $\delta_{C-3'} - \delta_{C-4'}$ decreases when conjugation vanishes (Tables 1, 2, and 3). In the hindered and unhindered 4-(1,2,3-triazolio)oxides *16*; Z = O, only small variations in $\delta_{C-4'}$ and $\delta_{C-3'} - \delta_{C-4'}$ values are observed.

The ^{13}C chemical shift of C-1'. C-1' in *C*-phenyl substituted compounds is more shielded than C-1' of *N*-phenyl substituted compounds (compare $\delta_{C-1'}$ of *3* and *16p* with $\delta_{C-1'}$ of *2* and *11a*, respectively). $\delta_{C-1'}$ depends little on the extent of interannular conjugation. Generally, $\delta_{C-1'}$ and $\delta_{C-1'} - \delta_{C-3'}$ values decrease when conjugation vanishes. Conceivably, this high field shift of C-1' reflects increased electron density at the phenyl-substituted *N*-atom due to reduced delocalization of the *N*-lone pair in the hindered compounds. $\delta_{C-1'}$ and $\delta_{C-1'} - \delta_{C-3'}$ values of the unhindered 1,2,3-triazolium bromides *4a*, *4c*, and *4e* are slightly larger than those of the unhindered diazolium bromide *2*. Similarly, $\delta_{C-1'}$ and $\delta_{C-1'} - \delta_{C-3'}$ values of the hindered 1,2,3-triazolium bromides *4b*, *4d*, and *5* are slightly larger than those of the hindered diazolium bromides *1a*, *1d*, *1e*, and *1f* (Tables 1 and 2).

In the pyrazol-4-in-3-ones *13*; Z = O, $\delta_{C-1'}$, like $\delta^{15}_{CH_3N}$ (see above) depends primarily on the position of the phenyl group. Secondly, $\delta_{C-1'}$ depends on the extent of conjugation as described above.

Comparison between ^1H- and ^{13}C-NMR data. The phenyl groups of all of the hindered and unhindered *N*- and *C*-phenyl substituted azolium salts studied appear as singlets and multiplets, respectively, with two exceptions (Tables 1 and 2). The phenyl group of the hindered 1-methyl-2-phenyl-5-chloro-pyrazolium bromide *1d* appears as a multiplet both in deuteriochloroform and deuterium oxide solution. Secondly, the unhindered 1-methyl-3-phenyl-imidazolium bromide *2a* exhibits a phenyl group singlet in aqueous solution but a multiplet in deuteriochloroform solution. More inconsistencies between ^1H- and ^{13}C-NMR spectra are observed in the 4-(1,2,3-triazolio)oxides *16*; Z = O. Thus the unhindered [1-phenyl-3-methyl-4-(1,2,3-triazolio)]oxide *11a* and -sulfide *11k* exhibit phenyl group singlets or doublets, whereas the ^{13}C-NMR data indicate extensive interannular conjugation.

The hindered [1-methyl-3-phenyl-4-(1,2,3-triazolio)]sulfide *8k* exhibits a phenyl group multiplet, whereas the ^{13}C-NMR data imply that conjugation has vanished. In the 5-substituted [1-phenyl-3-methyl-4-(1,2,3-triazolio)]-oxides *11b*, *11h*, and *11i*, as well as in [1-methyl-3-phenyl-4-(1,2,3-triazolio)]oxide *8a*, the ^1H- and ^{13}C-NMR data are consistent. The observed

discrepancies between the ^{1}H- and ^{13}C-NMR data of 4-(1,2,3-triazolio)oxides and -sulfides may be explained by assuming that the major factor influencing the *o*-phenyl proton shifts is anisotropy by the *C*-oxygen or *C*-sulfur bonds. Hence, phenyl groups adjacent to these bonds appear as multiplets in the ^{1}H-NMR spectra, independent of the extent of conjugation. The appearance of the *C*-phenyl group of the hindered [1,3-dimethyl-5-phenyl-4-(1,2,3-triazolio)] oxide *16p* as a multiplet is in keeping with this assumption. In the [1-phenyl-3-methyl-4-(1,2,3-triazolio)]oxides (*11*; Z = O) or -sulfide *11k* the net anisotropy effect on the *o*-phenyl protons is zero, yielding phenyl group singlets in the ^{1}H-NMR spectra, independent of the extent of conjugation.

In compounds with reduced heteroaromaticity, ring current effects become of minor importance and other factors may determine the appearance of the phenyl group ^{1}H-NMR signal. The phenyl groups of the hindered 1-methyl-2-phenyl-pyrazol-4-in-3-ones *6c*, *6g*, and *6h* and -thione *6k* appear as singlets in the proton spectra. In contrast, the hindered 5-substituted 1-phenyl-2-methyl-pyrazol-4-in-3-ones *10c*, *10g*, and *10h* exhibit phenyl group multiplets in the ^{1}H-NMR spectra, while ^{13}C-NMR data reveal that conjugation has vanished. Like in the 4-(1,2,3-triazolio)oxide series, the position of the phenyl group and not the extent of interannular conjugation determines the appearance of the phenyl group in the ^{1}H-NMR spectra. A comparison of the ^{1}H-NMR spectra of *10a* and its 4,2′,4′,6′-tetradeuterio derivative (see Experimental) proved that it is the *o*-protons of *10a* which are deshielded relative to the *m*- and *p*-protons. Most likely, this is the case, too, in the 5-substituted derivatives *10*; Z = O, and the pyrazol-4-in-3-thione *10k*. The reason for the deshielding of the *o*-protons in *10*; Z = O, and *10k* is not clear.

The 1-methyl-2-phenyl-1,2,3-triazol-5-one *9a* and -thione *9k* behave like the analogous 1-phenyl-2-methyl-pyrazol-4-in-3-ones and -thione (*10*; Z = O or S), exhibiting a phenyl group multiplet in the ^{1}H-NMR spectra.

1-Methyl-3-phenyl-imidazol-4-in-2-one *7a* and -thione *7k* both exhibit a phenyl group multiplet in the ^{1}H-NMR spectra, whereas the ^{13}C-NMR data reveal that interannular conjugation is extensive in *7a* but vanishes in *7k*.

CONCLUSION

The results reveal that ^{13}C-NMR spectroscopy can be used for assessing the extent of interannular conjugation in *C*- and *N*-phenyl substituted azoles with charged, zwitterionic, or heterocyclic rings with reduced aromaticity. Comparison of the ^{1}H- and ^{13}C-NMR data demonstrates that ^{13}C-NMR spectroscopy apparently provides unambiguous information about the extent of interannular conjugation even in cases where ^{1}H-NMR spectroscopy leads to erroneous results or in azole derivatives with reduced heteroaromaticity where ^{1}H-NMR, as expected, provides no information about the extent of conjugation.

The ^{13}C-NMR data indicate that extensive interannular conjugation is present in unhindered *N*-phenyl substituted imidazolium salts *2*, 1,2,3-triazolium salts *4*, and 4-(1,2,3-triazolio)oxides *16*; Z = O, or sulfides *16*; Z = S. The data further imply that a given substituent in the partly heteroaromatic pyrazol-4-in-3-ones *13*; Z = O, or 1,2,3-triazol-5-ones *9*; Z = O, impedes interannular conjugation much less than in heteroaromatic systems. Therefore, the heterocyclic rings of *13*; Z = O and *9*; Z = O are believed to adopt a twisted conformation (Fig. 2).

An oxygen atom adjacent to a phenyl group impedes interannular conjugation only slightly, even in the heteroaromatic systems *8*; Z = O. In contrast, however, a sulfur atom adjacent to a phenyl group impedes interannular conjugation strongly. The ^{13}C-NMR data seem to indicate that the partly aromatic heterocyclic rings of the thiones *6k*, *10k*, *7k*, and *9k* are planar or nearly so, in contrast to the oxygen analogues.

The ^{13}C-NMR data for the unhindered and hindered charged or zwitterionic azoles, and species with reduced heteroaromaticity are summarized in Table 6. When these data are combined with those previously measured for phenyl-substituted azoles with aromatic uncharged heterocyclic rings, it may be concluded that in any *N*-phenyl substituted pyrazole derivatives of the types studied interannular conjugation is extensive if $\delta_{C-2'} = 118.5 - 118.8$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 10.5$ ppm but strongly impeded if $\delta_{C-2'} = 124.6 - 129.1$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 1.3 - 4.0$ ppm. Intermediate values signify a smaller hindrance to conjugation. Similarly, interannular conjugation is extensive in

imidazoles if $\delta_{C-2'} = 121.0 - 121.7$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 8.6 - 9.4$ ppm. In *N*-phenyl-1,2,3-triazole derivatives interannular conjugation is extensive if $\delta_{C-2'} = 118.3 - 120.9$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 8.9 - 10.6$ ppm but impeded if $\delta_{C-2'} = 124.1 - 125.7$ ppm* and $\delta_{C-2'} - \delta_{C-3'} = 3.7 - 5.2$ ppm. If these data are further combined it appears that in any *N*-phenyl substituted azole of the types studied, interannular conjugation is extensive if $\delta_{C-2'} = 118.3 - 121.7$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 8.6 - 10.6$ ppm but strongly impeded if $\delta_{C-2'} = 124.1 - 129.1$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 1.3 - 5.2$ ppm. In *C*-phenyl substituted azoles interannular conjugation is extensive if $\delta_{C-2'} = 124.7 - 126.4$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 2.1 - 3.8$ ppm but impeded if $\delta_{C-2'} = 127.8 - 128.1$ ppm ** and $\delta_{C-3'} - \delta_{C-2'} = 0 - 0.8$ ppm. Since the values in case of interannular conjugation do not overlap with values in case of strongly impeded conjugation the ^{13}C-NMR method is a powerful method for assessing the extent of interannular conjugation, and hence for conformational analysis, of phenyl substituted azole derivatives. In addition, the values presented in Table 6 may be useful for distinguishing between positional isomers. For example, 1-phenyl-3,4-disubstituted 1,2,3-triazolium salts *4c* may be distinguished from the 1-phenyl-3,5-disubstituted isomers *4b*. Furthermore, the size and possibly the orientation of a substituent adjacent to a phenyl group may be evaluated.

The compounds studied in the present and preceding papers may be taken as representative for a bulk of other compounds. Thus, the results become generally applicable to all *C*- and *N*-phenyl substituted azole derivatives. In the light of the results obtained, an investigation of the use of the ^{13}C-NMR method for conformational analysis of phenyl substituted azines with neutral, charged, zwitterionic, or with nonaromatic heterocyclic rings seems obvious.

* Extreme values ($\delta_{C-2'} = 131.1$ ppm and $\delta_{C-3'} - \delta_{C-2'} = 2.3$ ppm) have been observed for 1-methyl-2-phenyl-1,2,3-triazolium bromide *5* in aqueous solution.

** An extreme value ($\delta_{C-2'} = 130.2$ ppm) has been observed for 1,3-dimethyl-2-phenyl-imidazolium bromide *3* in aqueous solution.

EXPERIMENTAL

^{1}H-NMR spectra were obtained on a Varian A-60 instrument. Position of signals are given in ppm (δ-values) relative to tetramethylsilane (TMS) when deuteriochloroform was used as the solvent. When deuterium oxide was used as the solvent 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal standard.

^{13}C-NMR spectra were obtained using 0.695 mmole of compound dissolved in 1.20 ml of solvent (10 mm tube), when not otherwise stated. When deuteriochloroform was used as the solvent position of signals were measured relative to the center peak of the deuteriochloroform triplet (δ 76.9 ppm) [25b] and are given in ppm (δ-values) relative to TMS. When deuterium oxide was used as the solvent position of signals were measured relative to *p*-dioxane (δ 67.4 ppm) [25b] and are given in ppm (δ values) relative to TMS. The ^{13}C-NMR spectra were obtained on a Bruker WH-90 instrument using Fast Fourier Transform pulse technique. Unless otherwise stated, 1 000 scans were accumulated with 6000 Hz sweep using 8K computer memory. This corresponds to an accuracy of ± 0.07 ppm in the chemical shifts and of ± 3 Hz in the coupling contants. The repetition time was 3.0 sec. The decoupled spectra were obtained using proton-noise-decoupling. The undecoupled spectra were measured by the gated decoupling technique.[36] in order to maintain part of the Overhauser enhancement of the signals. Thus, the proton-noise decoupling was interrupted after 1.0 sec. After a delay of 0.4 sec, the pulse (4 μsec) was turned on again. This cycle was repeated every 3.0 sec, 6000 scans being accumulated. Off resonance decoupled spectra [24c,37-41] were measured irradiating with a low power (2 Watt) continuous wave radio frequency at 800 Hz to high field of the chloroform proton signal.

Preparation of azolium bromides

1-Methyl-2-phenyl-pyrazolium bromide 1a. 1-Methyl-2-phenyl-pyrazolium tosylate [42] (1.00 g) was dissolved in water and passed through Amberlite IRA 400 ion exchanger (65 ml) regenerated with aqueous hydrogen bromide. The eluate was filtered through activated carbon. The water was removed *in vacuo* and the residue was recrystallized from methanol-ether. This gave 0.70 g (98 %) of 1-methyl-2-phenyl-pyrazolium bromide *1a* as colourless crystals, m.p. 174°. The NMR-spectrum was identical with that of the corresponding pyrazolium tosylate, except that the tosylate ion signal had disappeared.

Similarly, the pyrazolium bromides *1d*, *1e*, and *1f* were prepared from the corresponding tosylates,[18] and the 1,2,3-triazolium bromides *4a*, *4b*, *4c*, *4d*, and *4e* from their tosylates.[21,43,44] The 1,2,3-triazolium bromide *5* was prepared in

an analogous manner from the corresponding fluorosulfonate.[22] Finally, the imidazolium bromides *2a* and *3* were prepared in the same way from the corresponding tosylates.[44] In all cases the yield was 95 – 100 %. The purity was controlled by ^{1}H-NMR spectroscopy. Further purification and combustion analysis of all azolium bromides was omitted since all of the corresponding tosylates (or fluorosulfonates) are well characterized compounds.

4,2′,4′,6′-Tetradeuterio-1-phenyl-2-methyl-pyrazol-4-in-3-one. 1-Phenyl-2-methyl-pyrazol-4-in-3-one *10a*[18] (142 mg) and conc. dideuterio sulfuric acid (99 % enriched) (0.44 ml) were heated with stirring to 140° for 3 h. Deuterium oxide (4.4 ml) was then added and the solution was neutralized with potassium carbonate, freshly dried at 140° for 24 h. The solvent was then removed *in vacuo* and the residue was extracted with boiling chloroform (5 × 10 ml). After removal of the chloroform the treatment with dideuterio sulfuric acid was repeated. After the chloroform extraction and removal of the chloroform the residue was extracted with boiling ethyl acetate (5 × 10 ml). The solution was filtered through activated carbon and the ethyl acetate was removed affording 69 mg (47 %) of crude 4,2′,4′,6′-tetradeuterio-1-phenyl-2-methyl-pyrazol-4-in-3-one, m.p. 93 – 96°. Recrystallizations from ethyl acetate-hexane raised the melting point to 109 – 112°. A comparison of the ^{13}C-NMR spectra of the starting material *10a* and the tetradeuterio derivative showed that the latter compound was devoid of absorptions due to C-4 and C-4′. The signal due to C-2′ was strongly reduced. In contrast, the signals due to C-3, C-5, and C-3′ showed no loss in intensity. Replacement of hydrogen with deuterium at a carbon atom gives rise to a prolongation of the relaxation time, T_1, and hence to loss in intensity of the ^{13}C-signal.[45] Consequently, the ^{13}C-NMR data indicate that H-4, H-2′, H-4′, and H-6′ have been replaced with deuterium. The ^{1}H-NMR spectrum of the starting material *10a* exhibits a phenyl group multiplet at 7.2 – 7.6 ppm. In contrast, the ^{1}H-NMR spectrum of the tetradeuterio derivative exhibits two broad singlets at 7.58 and 7.55 ppm corresponding to H-5 and the two *m*-protons, respectively.

Correlations between Pantothenate Uptake, Phospholipid Synthesis and Pantothenate-binding Protein Formation in *Pseudomonas fluorescens* P-2

P. MÄNTSÄLÄ

Department of Biochemistry, University of Turku, SF-20500 Turku 50, Finland

Correlations were investigated between increased pantothenate uptake and the formation of pantothenate-binding protein and phospholipids in *Pseudomonas fluorescens* P-2. Ethanolamine, choline, sarcosine, glyoxylate, and serine increased pantothenate uptake in whole cells, even in the presence of chloramphenicol. On the other hand, pantothenate, glycerol, and glucose were the most effective of the compounds investigated in synthesizing phospholipids both in whole cells and in membrane vesicles prepared from *Pseudomonas fluorescens* P-2. Although growth on ethanolamine, choline, and sarcosine was negligible over several hours, incorporation of ^{32}P continued linearly from the very beginning. The concentration of total phospholipids and phosphatidyl ethanolamine followed cell growth quite closely.

Pantothenate-binding protein was formed only in the presence of pantothenate and pantoate.

Correlation was observed between pantothenate uptake and formation of pantothenate-binding protein when the cells were cultured on pantothenate and pantoate, whereas phospholipid synthesis was rapid on any of several good energy sources.

Active transport systems of several B-group vitamins and related compounds and their regulation in micro-organisms have been reported.[1–7] It is sometimes difficult to determine the type of regulation operating in the accumulation of compounds, because regulation of intracellular concentrations of the vitamins as well as other metabolites involves control not only of their biosynthesis but also of entry and exit of the compounds. It has long been recognized that this process is rarely one of passive diffusion: it involves specific carrier- or binding-proteins having affinities for their substrates.[8] Furthermore, suggestions have been made that a lactose transport system might require the synthesis of membrane lipids.[9,10]

In previous studies we have found pantothenate transport activities in *Pseudomonas fluorescens* P-2 to increase during growth on glyoxylate, glycolate, and glycine, even when growth was inhibited with chloramphenicol.[7] The present work investigates whether there are correlations between pantothenate transport activities in the whole cells, phospholipid synthesis and the formation of pantothenate-binding protein during the growth of *Pseudomonas fluorescens* P-2.

METHODS

Organism and growth conditions. Pseudomonas fluorescens P-2 was cultured aerobically at 30°C in media containing, per litre, 1.35 g of KH_2PO_4, 0.26 g of $MgSO_4.7H_2O$, 3 mg of $FeSO_4.7H_2O$, 2.1 mg Na_2MoO_4, 1.5 mg of $MnSO_4$ and 10 mmol of a carbon source.[11] 0.66 g of $(NH_4)_2SO_4$ was added as a source of nitrogen when carbon compounds containing no nitrogen groups were used as energy sources. The media were adjusted to pH 7.0 and applied immediately.

The strain was maintained on slopes of a pantothenate agar medium. Turbidity measurements were made with a Klett-Summerson colorimeter employing filter 62.

Preparation of protoplasts and membrane vesicles. Protoplasts and membrane vesicles were prepared by the lysozyme-EDTA method of Kaback.[12] Cells, taken from different growth

phases (20 mg of dry weight), were centrifuged at 10 000 *g* for 30 min and washed twice with 10 mM Tris-HCl (pH 8.0). The washed cells were suspended in 30 mM Tris-HCl buffer containing sucrose (20 %), dipotassium magnesium EDTA (15 mM), and lysozyme (0.5 mg/ml, Sigma Chemical Company, St. Louis, Mo., U.S.A.) and incubated for 20 min at 25°C. Protoplasts were collected by centrifugation for 15 min at 16 000 *g*. Lysis of protoplasts was produced by osmotic treatment in the presence of DNase II (Sigma Chemical Company, St. Louis, Mo., U.S.A.). Incubations were carried out at 30°C and centrifugations at 27 000 *g*. The purity of membrane vesicles was established by electron and phase contrast microscopy methods.

Measurement of pantothenate uptake into whole cells. An assay method for [1-^{14}C]-labelled pantothenate uptake into whole cells was described earlier by Mäntsälä.[13] The initial velocities of pantothenate uptake were determined by incubation of the cells (250 μg of dry weight), [1-^{14}C]-pantothenate (75 000 cpm, specific activity 4.75 mCi/mmol, The New England Nuclear Corporation, Boston, Mass., U.S.A.), potassium pantothenate (0.05 μmol) and $MgSO_4.7H_2O$ (0.5 μmol) in 0.2 ml of the reaction mixture at 30°C for various reaction times.

Measurement of pantothenate uptake into membrane vesicles. In total volume of 0.2 ml, the reaction mixtures contained 4 μmol of $MgSO_4.7H_2O$, 10 μmol of potassium phosphate buffer (pH 6.6), 75000 cpm of [1-^{14}C]-pantothenate, 0.01, μmol of potassium pantothenate, of 4 μmol ascorbate, 0.02 μmol of phenazine methosulfate, and 0.16 mg of membrane protein. Reactions were terminated by addition of 2 ml of 0.2 M NaCl, and membrane vesicles were washed immediately with 8 ml of 0.2 M NaCl on Millipore membrane filters (0.3 μm pore-size). The filters were dried and activities were measured in a scintillation spectrometer.

Phospholipid extraction and estimations. Samples (1 mg of dry weight) were taken at intervals during growth and centrifuged at 5000 *g*. The cell pellets were washed with phosphate-free medium and recentrifuged. The samples of whole cells and membrane vesicles (as prepared above) were inoculated into 20 ml of media containing about 2 μCi of [^{32}P]-labelled phosphate/ml, (The Radiochemical Centre, Amersham, U. K.), 10 μmol of potassium phosphate and other compounds, as described in the "Organism and growth conditions section". After incubation at 30°C, the samples were precipitated with 2 ml of cold 50 % TCA, filtered and washed twice with 3 ml of 5 % TCA and 3 ml of distilled water on a Millipore filter (0.3 μm pore-size). The filters were then dried and placed in extraction vessels from which phospholipids were eluted with 5 ml of a methanol-chloroform solution (1:2, by vol). The extraction was repeated twice at room temperature overnight. The solutions were poured into scintillation vials, the solvent removed *in vacuo* and activities counted in toluene-based scintillation fluid.

Chromatography was carried out on glass plates with a layer of silicic acid. Two-dimensional separations were made. The first solvent used was chloroform-methanol-water (70:30:5 by vol) and the second chloroform-methanol-7 M NH_4OH (60:35:5 by vol). After development the plates were sprayed with 0.2 % ninhydrin and then with molybdenum reagent.[14] The standard phospholipids were purchased from Koch-Light Laboratories Ltd., Colnbrook, Buckinghamshire, U.K. For quantitative determination of phosphatidyl ethanolamine and phosphatidyl glycerol, the spots were scraped from the plates and the phospholipids were eluted with 5 ml of scintillation fluid.

Protein was determined by the method of Lowry *et al.*[15]

Preparation of crude extract and shock fluid. Crude cell extracts were prepared by freezing and thawing as described by Mäntsälä and Nurmikko,[16] and shock fluid by the procedure of Neu and Heppel.[17] Samples (80 mg of dry weight) were taken from the cultures at different phases of growth. The shock fluid was concentrated by lyophilization.

Assay of pantothenate-binding activity. Binding activity towards crude extracts and shock fluids were assayed as described earlier[13] and by equilibrium dialysis. The dialysis sacs containing binding material (2 mg of protein) were shaken for 24 h at 4°C in tubes containing 600 000 cpm of [1-^{14}C]-pantothenate in 0.1 ml. After dialysis the samples were pipetted onto Millipore filters, dried and counted in a scintillation spectrometer.

RESULTS

Pantothenate transport into whole cells and membrane vesicles of Pseudomonas fluorescens *P-2.* In a previous study the uptake of pantothenate into whole cells of *Pseudomonas fluorescens* P-2 was found to increase in the presence of glyoxylate, glycolate, and glycine, even when growth was inhibited with chloramphenicol, but not in the absence of nitrogen.[7] Ethanolamine, choline, sarcosine, and serine without added pantothenate have now also been found to increase pantothenate transport activities (Fig. 1). As can be seen, while the most effective compounds in the early phases of growth are glyoxylate and ethanolamine, after several hours pantothenate and pantoate become the most effective. Activities begin to decrease on glyoxylate, ethanolamine, choline,

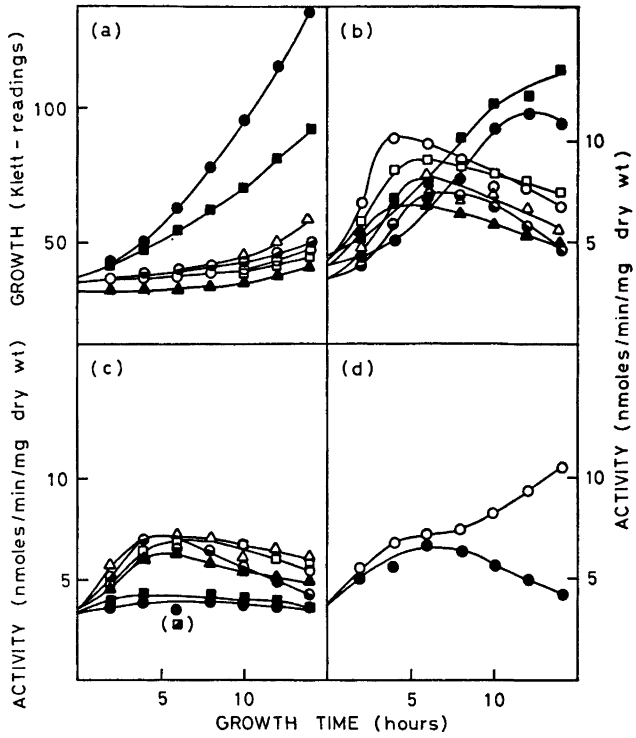

Fig. 1. Effect of pantothenate, pantoate, glyoxylate, ethanolamine, choline, serine, and sarcosine on pantothenate transport activity in *Pseudomonas fluorescens* P-2. Pre-cultivations were carried out on pantothenate. The reaction mixture contained [1-^{14}C]-pantothenate (75 000 cpm, specific activity 4.75 mCi/mmol), potassium pantothenate (0.05 μmol), $MgSO_4.7H_2O$ (0.5 μmol) and about 250 μg dry wt cell suspension in 0.2 ml. The reaction mixture was incubated at 30° and reactions were terminated at intervals of one minute by washing the cells on Millipore filters with 10 ml of 0.2 M NaCl solution.

sarcosine, and serine during the exponential phase of growth. In these cases moreover, the rise in transport activities was not prevented by added carbon compounds.

Membrane vesicles prepared from cells taken from the lag, acceleration, exponential, and stationary phases of growth on ethanolamine, choline, sarcosine, and serine accumulated [1-^{14}C]-pantothenate almost equally and without dependence on the growth phase (Fig. 2). Accumulation of pantothenate, negligible without an added electron donor system, is increased about 5 – 10 times when an artificial electron donor system, ascorbate-phenazine methosulfate, is used.

Incorporation of ^{32}P into phospholipid fractions of whole cells, protoplasts and membrane vesicles. Although ethanolamine, choline, sarcosine, and serine are the most effective compounds on pantothenate uptake into whole cells (Fig. 1), incorporation of ^{32}P is most rapid into cells grown on pantothenate, glycerol, and glucose and, in general, on compounds that allow rapid growth (Fig. 3). However, although growth

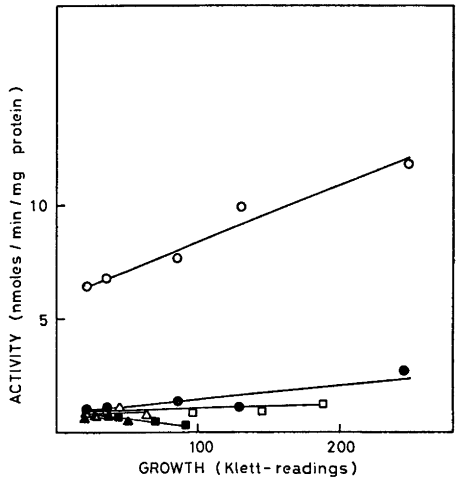

Fig. 2. Accumulation of [1-^{14}C]-pantothenate in membrane vesicles from *Pseudomonas fluorescens* P-2 grown on ethanolamine, choline, sarcosine, and serine. The reaction mixtures contained in a total volume of 0.2 ml, 4 μmol of $MgSO_4.7H_2O$, 10 μmol of potassium phosphate buffer (pH 6.6), 75 000 cpm of [1-^{14}C]-pantothenate, 0.01 μmol of potassium pantothenate and about 0.16 mg of membrane protein. Ascorbate-phenazine methosulfate was used as an artificial electron donor. Other experimental conditions were the same as in the legend to Fig. 1.

is almost negligible for several hours on ethanolamine, choline, sarcosine, and serine, incorporation of ^{32}P into phospholipids increases from the very beginning. When the growth reaches the acceleration phase, ^{32}P incorporation into phospholipid fractions also increases.

The results given in Table 1 are in good agreement with those presented in Fig. 3. Protoplasts and membrane vesicles prepared from the cells grown on pantothenate, glycerol, and glucose incorporate [^{32}P]-labelled phosphate more rapidly than the protoplasts and membrane vesicles prepared from the cells grown on ethanolamine, choline, sarcosine, and serine.

Because no correlation between total phospholipid synthesis and pantothenate uptake was observed when bacteria were cultured on glyoxylate, ethanolamine, choline, sarcosine, and serine, the synthesis of individual phospholipids during growth was investigated. It can be seen that concentrations of phosphatidyl ethanolamine are high throughout all growth phases in whole cells and parallel total incorporation of ^{32}P very closely (Fig. 4). In contrast, the synthesis of phosphatidyl glycerol, another common phospholipid in *Pseudomonas fluorescens* P-2, ceases very rapidly when the cells are transferred from pantothenate or

Table 1. Incorporation of [^{32}P]-labelled phosphate into phospholipids of protoplasts and membrane vesicles from *Pseudomonas fluorescens* P-2. Protoplasts and membrane vesicles were prepared by the method of Kaback (1971) [12] as described in the "Preparation of protoplasts and membrane vesicles" section. Activities were determined as described in the legend to Fig. 3.

glycerol media into ethanolamine, choline, sarcosine, or serine media. Phosphatidyl glycerol synthesis accelerates again when growth continues. At the end of the exponential phase of growth, phosphatidyl glycerol synthesis ceases and some degradation of the phospholipid is observed.

Table 2 shows the results of ^{32}P incorporation into phosphatidyl ethanolamine and phosphatidyl glycerol in protoplasts and membrane vesicles. The results resemble those obtained for whole cells (Fig. 4).

Formation of pantothenate-binding activity during growth on pantothenate, pantoate, ethanolamine and choline. Pantothenate-binding activity follows growth only in pantothenate and pantoate media (Fig. 5). In the course of two generations, the cells grown on pantothenate and pantoate lose their binding activity on ethanolamine and choline both in the shock fluids and the crude extracts. These results suggest the inducible nature of the pantothenate-binding protein and that there is a correlation between pantothenate transport activities in whole cells and pantothenate-binding activity on pantothenate and pantoate but not on ethanolamine and choline.

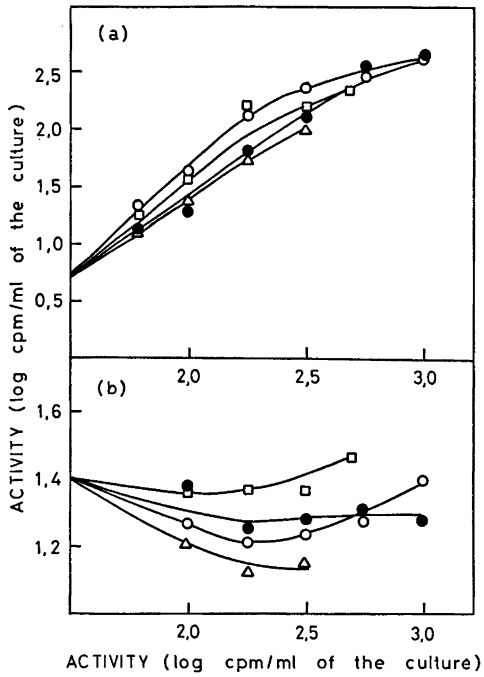

Fig. 4. Relative amounts of phosphatidyl ethanolamine and phosphatidyl glycerol in *Pseudomonas fluorescens* P-2 cells. Phosphatidyl ethanolamine and phosphatidyl glycerol were separated and quantitatively determined by thin-layer chromatography, radioactivity of the spots being measured in a scintillation spectrometer.

DISCUSSION

Although the data presented in this paper demonstrate that there are no correlations between pantothenate transport activities in whole cells and phospholipid synthesis, they do reveal some general properties of the transport process and phospholipid synthesis in *Pseudomonas fluorescens* P-2. It has been found that pantothenate transport is an inducible process requiring cell multiplication.[7] The results concerning phospholipid synthesis in *Ps. fluorescens* P-2 are in good agreement with those of Ballesta and Schaechter[18] for *E. coli*. They found that the total phospholipid synthesis as well as the synthesis of phosphatidyl ethanolamine, the main phospholipid component, is related to growth and cell division. This may be due to the fact that phosphatidyl ethanolamine is normally rather stable compared, for instance, with phosphatidyl glycerol.[18–20] The linear incorporation of ^{32}P into phospholipids at the beginning of growth on the compounds mentioned in Fig. 3 probably reflects a turnover of phospholipids rather than a net synthesis because the transfer of the cells from a richer to a poorer medium causes strong inhibition of phospholipid metabolism. Concentrations of phosphatidyl glycerol decrease about 40 % during 4 – 6 h growth on ethanolamine, choline, sarcosine, and serine. These results and those of Ballesta and Schaechter[18] suggest that the metabolism of phosphatidyl glycerol is related not to growth and cell

division but to other cell processes. Cronan [21] reported that the phospholipid composition of the cells was altered when cultures of *E. coli* progressed from exponential growth to the stationary phase. Bertsch *et al.*[22] reported similar findings for *Bacillus magaterium* cells. When cells of *Pseudomonas fluorescens* are transferred from a rich medium to a poor one some phospholipids may be altered, thus preventing phospholipid degradation in the new growth conditions.

Several reports suggest a close relationship between the transport system and binding-protein.[8,23–26] Correlations were observed between pantothenate transport and formation of binding-protein in this work as well.

The finding that pantothenate uptake in *Pseudomonas fluorescens* P-2 is an inducible process [7] implies the possibility that growth on ethanolamine, choline, sarcosine, and serine stimulates the synthesis of pantothenate-binding protein. Nevertheless, binding activities remain low, at least on ethanolamine and choline. Unpublished results in our laboratory suggest that pantothenate uptake into membrane vesicles from *Pseudomonas fluorescens* P-2 is stimulated (except in the presence of the artificial electron donor system, ascorbate-phenazine methosulfate) in the presence of ethanolamine, choline, and sarcosine too. On the other hand, it is not clear whether the above-mentioned compounds can serve as direct electron donors in whole cells as well. Further results concerning pantothenate transport into membrane vesicles from *Pseudomonas fluorescens* P-2 will be published later.

The author thanks Professor V. Nurmikko for his help during this work and Mr. T. Huttunen for technical assistance.

A Novel Iridoid Glucoside Isolated from *Lamium album* L.

P. EIGTVED, S. ROSENDAL JENSEN and B. JUHL NIELSEN*

Department of Organic Chemistry, Technical University of Denmark, DK-2800 Lyngby, Denmark

Whole plants of white dead-nettle (*Lamium album* L., Labiatae) contain, as the major glucoside, a novel iridoid. Its structure *1* is assigned mainly on the basis of PMR-data for the glucoside itself, its acetates, and bis-benzylidene derivatives. The aglucone, set free by hydrolysis with emulsin, is characterized as a triacetate. Proton coupling constants are utilized for estimating the most favoured conformations of the individual compounds. The results are in accord with those expected from considerations of steric interactions.

The genus *Lamium* is rich in iridoid glucosides.[1,2] In the white dead-nettle, *L. album* L. we have found the major glucoside to be a novel iridoid for which we propose the name lamiridoside** (for data, see Tables 1 and 3).

The PMR-spectrum of lamiridoside (*1*, see Table 1) exhibits absorptions typical for iridoid glucosides possessing a C-4 methoxycarbonyl grouping. Signals at 7.53, 5.68, and 3.82 ppm can be ascribed to H-3, H-1, and $COOCH_3$, respectively.[2] The doublet character ($J = 0.8$ Hz) of the signal at 7.53 ppm signifies the presence of a proton at C-5, a novelty in so far as all formerly known iridoids from *Lamium* species carry a hydroxy group at C-5.[1] Irradiation at 7.53 and 5.68 ppm ($J = 1.5$ Hz) revealed absorptions attributable to the H-5 and H-9 protons at 2.97 ppm and 2.89 ppm, respectively. A signal at 4.10 ppm was assigned to H-6 since double resonance experiments showed it to couple with both H-5 ($J = 3$ Hz) and another proton absorbing at 3.72 ppm ($J = 4.5$ Hz), *viz.* H-7. The last signal arising from the non-sugar moiety, a three-proton singlet at 1.27 ppm, could be assigned to a methyl group positioned at a tertiary carbon carrying an

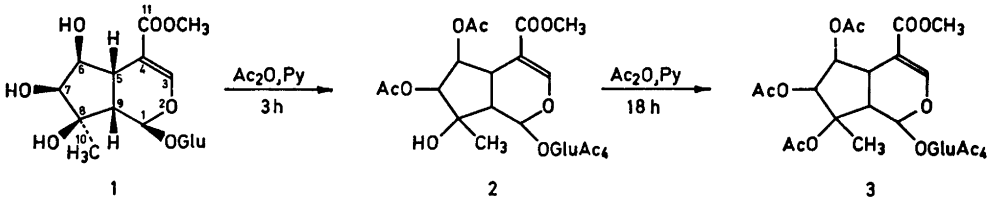
[a] The spectra were recorded on a Varian HA-100 instrument in $CDCl_3$, with TMS as an internal reference, except for *1*, recorded in D_2O, with DSS as a reference. [b] ± 0.02 ppm. [c] ± 0.5 Hz.



1 2 3

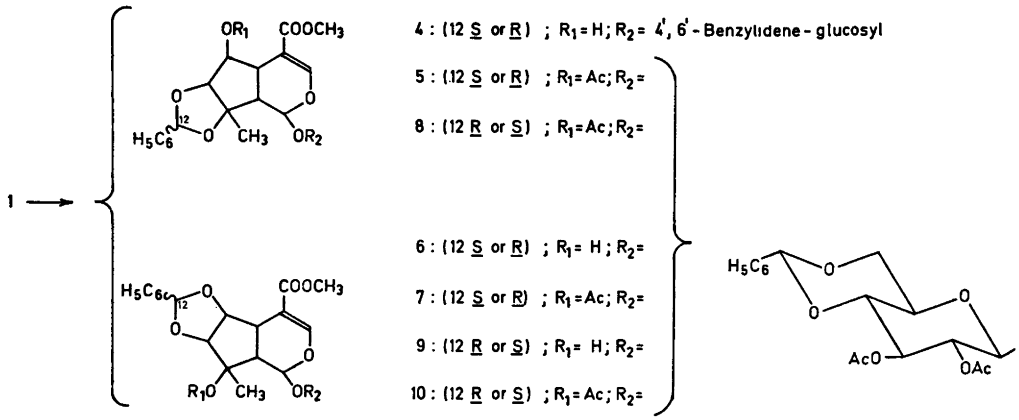
oxygen atom. Taken together, these data support the gross structure *1* (disregarding stereochemistry) for lamiridoside. In keeping herewith, acetylation afforded a hexaacetate *2* or a heptaacetate *3*, depending on conditions. The PMR-spectra of the acetates (Table 1) provided additional evidence for the proposed structure. Thus, acetylation of the tertiary hydroxyl group caused low field shifts of the absorptions of the neighbouring protons, the signals arising from H-7, H-9, and CH_3-10 being shifted 0.54, 0.33, and 0.25 ppm, respectively.

Assuming configurational similarity of lamiridoside with other iridoids,[2] H-1, H-5, and H-9 can be placed in α-, β-, and β-positions, respectively (*vide infra*), leaving the configurations at the three carbinol centers in the five-membered ring undecided. The coupling constants $J_{5,6}$ and $J_{6,7}$ of *1*, *2*, and *3* are of little help here, since they all fall within the range of 3 – 5 Hz, and hence are compatible with a *cis*- as well as a *trans*-junction.[4,5]

Other means were therefore sought to settle the stereochemistry. Treatment of *1* with benzaldehyde and zinc chloride yielded a mixture of bis-benzylidene derivatives. The PMR-spectrum of this mixture showed, within the region of the benzylic protons (5.5 – 6.5 ppm), a broad singlet attributable to the 4′,6′-benzylidene-glucosyl moiety and four different signals of varying intensity at lower field, signifying the presence of at least four isomers in the reaction mixture. From this mixture all four isomers were isolated either as such, or in acetylated forms.

Chromatography of the mixture afforded the amorphous compound *4*, converted upon acetylation under mild conditions into the crystalline triacetate *5*. A pronounced shift to low field (1.42 ppm) of the H-6 signal on passing from *4* to *5*, when compared to those of H-7 and CH_3-10 (0.11 and 0.03 ppm, respectively), securely positions the second benzylidene group at C-7 and C-8 in these compounds.

Acetylation under mild conditions of the remaining mixture afforded, after chromatography, a crystalline diacetate *6*. Acetylation of *6* under forcing conditions produced the triacetate *7*. On comparing the PMR-spectra of *6* and *7*, it appears that the low field shifts of H-7, H-9, and CH_3-10 (0.73, 0.37, and 0.26 ppm, respectively) are similar to those found by going from *2* to *3*. Consequently, *6* and *7* can be formulated as 6,7-benzylidene derivatives.



Additional to *6*, another crystalline compound could be isolated from the remaining mixture, namely the triacetate *8*, formulated as a 7,8-benzylidene compound mainly because of the low field position of H-6 (5.05 ppm), suggesting the presence of an acetoxy group at C-6.

The mother liquor from the crystallization of *8* was rich in the diacetate *9*, which was not obtained in the pure state (only a PMR-spectrum was recorded of this derivative). Acetylation of the latter, under forcing conditions, yielded the triacetate *10*. Comparison of the PMR-spectra of *9* and *10* revealed that H-7, H-9, and CH_3-10 were shifted 0.79, 0.34, and 0.28 ppm, respectively, towards lower field, shifts similar to those observed on going from *2* to *3*, and from *6* to *7*. Consequently, *9* and *10* must be 6,7-benzylidene compounds and hence epimers of *6* and *7*, respectively.

Since both 6,7- and 7,8-benzylidene compounds are formed in the reaction with benzaldehyde, it follows that all the hydroxy groups of the iridoid moiety in lamiridoside are positioned on the same face of the molecule.[3] The remaining problem, *viz.* on which side, is resolved by consideration of the coupling constants $J_{5,6}$ for the compounds *6*, *7*, *9* and *10*. The consistently low value of $J_{5,6}(\leq 1$ Hz) demands a dihedral angle close to 90° between H-5 and H-6, necessitating a *trans* relationship of these protons.[4,5] Consequently, the hydroxy groups at C-6, C-7, and C-8 in lamiridoside are all occupying β-positions.

Hydrolytic cleavage of *1* with emulsin afforded glucose, identified by paper chromatography with authentic glucose as a reference, and, in addition, the amorphous aglucone *11*, which was converted, under mild conditions, into a triacetate (*12*). By comparison of the PMR-spectra of *2* and *12*, the stereochemistry at C-1 in *12* appears to be identical with that of lamiridoside and its derivatives. The small value of $J_{1,9}$ (1.9 Hz) in *12* clearly places H-1 in an equatorial position, an arrangement prevailing also in the other derivatives, except in *4*, *5*, and *8*. In the latter, the overall conformation of the dihydropyrane ring is obviously altered, with H-1 assuming more or less an axial position, resulting in an increased value of the coupling constant $J_{1,9}$. This change in conformation is accompanied by low field shifts of H-5 and CH_3-10, and shifts to higher field of H-9. Assuming an α-situated acetoxy group at C-1 in *12*, an equatorial H-1 would require a conformation similar to that prevailing in *4*, *5*, and *8*; this is definitely not in accord with the observed PMR-data.

Turning to the glucose moiety of lamiridoside, the PMR-spectra of *1* and its derivatives clearly show the presence of a pyranose ring, attached to the aglucone through a β-glucosidic linkage, as evidenced by the large coupling constant $J_{1'2'}$ (7.5 Hz) observable in *1* and *4*.

In the above conclusions, the presence of a *cis*-fused ring system was assumed. Inspection of a Dreiding model shows the alternative *trans*-fused system to be far more strained, permitting only a single conformer for each of the two *trans*-fused forms. In both of these, the cyclopentane ring will adopt a twist form, namely $^5T_9$ for the 5β,9α- and $^9T_5$ for the 5α,9β-fusion.[6] These conformations demand dihedral angles between H-5 and H-6 of 170° or 20°, respectively, incompatible with the observed coupling constants ranging from 0.5 to 8 Hz. Moreover, the ring strain should be reflected in a shift of the UV-maximum when compared with that of the known *cis*-fused compounds, all absorbing within the 230 – 240 nm range.[2] Again, the compounds *1*, *2*, *3*, and *12* all exhibit UV-absorptions within the range 232 – 238 nm, in accord with the presence of *cis*-fused rings.

PMR has recently been shown to be of value in assessing the most favoured conformations of five-ring systems like furanosides.[6,7] Applying the treatment given by Hall *et al.*[6] for furanosides to the cyclopentane ring in the iridoid skeleton, we arrive at reasonable conclusions for lamiridoside and its derivatives. In the "cycle of pseudorotation" (*Cyclops*) of interchanging envelope (*V*) and twist (*T*) forms for this system,[6] we have substituted C-8, C-7, C-6, C-5, and C-9 with the corresponding atoms in the furanoses, *viz.* O, C-1, C-2, C-3, and C-4, respectively, and adopted the angle values measured by Hall *et al.* The error introduced by this approximation is considered to be negligible in the present approach.

The coupling constants listed in Table 1 can be used to divide the compounds into four groups as specified in Table 2 (*10* cannot be classified since $J_{5,9}$ is unknown because H-5 and H-9 have closely similar chemical shifts).

Table 2. Favoured conformers and data for estimation of these.

Group (compounds)	$J_{measured}$	Calculated dihedral angle ± 10°	Favoured conformers	Dihedral angle in favoured conformers

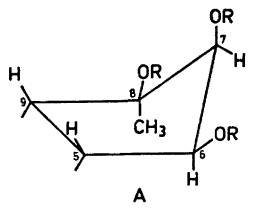
[a] In $CHCl_3$. [b] After additional drying.

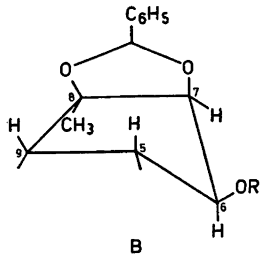
Using Karplus relationship * for calculating the dihedral angles and arbitrarily adding and subtracting 10° to the values found, a conservative estimate of the angles is obtained (se Table 2). Comparing the values with those derived from the *Cyclops* sequence and eliminating conformers which do not fit, first for $\angle H_6H_7$, then for $\angle H_5H_6$ and $\angle H_5H_9$, only a small number of conformers are left for each group of compounds (see Table 2).

* We have used the curve as given by Williams and Fleming.[8]

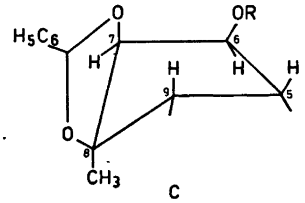
Thus, group A, comprising the compounds *1*, *2*, *3*, and *12*, is found preferentially to adopt the ^7V and $^7T_8$ conformations. Inspection of models of these conformers leaves only one possibility for the conformation of the dihydropyrane ring, namely a distorted half chair (HC_9^1) with an axial orientation of the glucose moiety and $\angle H_1H_9$ close to 70°. In the ^7V conformation (depicted as *A*) the interactions between the bulky groups are minimal, the oxygen substituents on C-6 and C-8 being pseudo-equatorial and that on C-7 together with the methyl group on C-8 pseudo-axial.



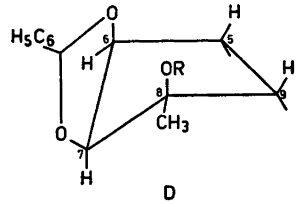
A



B



C



D

Group B, consisting of the 7,8-benzylidene compounds *4* and *8*, is found to favour the V_6 and ${}^7T_6$ conformers, of which V_6 is depicted as *B*. Again, this conformation introduces only minimal steric interactions of the bulky groups on the five-membered ring. The dihydropyrane ring in this case, however, is in an almost planar conformation, save for C-1 pointing downwards and giving rise to an equatorial position of the sugar moiety.

In group C, solely made up of *5* (the triacetate of *4*) the conformation of the molecule is less obvious. The above treatment leads to two sets of possible five-ring conformers, *viz.* ${}^8V$ and $V_8-{}^7T_8$. Models indicate, however, that the former requires an $\angle H_1H_9$ of either 180° (HC_9^1) or 90° ($Boat_{0,5}$), the latter agreeing with that calculated for *5*, namely 120 – 140°. Consequently, the ${}^8V$ conformation can be disregarded. The change observed in going from *4* to *5* is not easily explained, as a larger steric interaction prevails in $V_8-{}^7T_8$ (V_8 depicted as *C*). However, the effects of the benzylidene groups, with their unknown stereochemistry, are obscure.

Considering the last group of compounds, D, comprising the 6,7-benzylidene compounds *6*, *7*, and *9*, we find only one set of preferred conformers V_7 and ${}^6T_7$ for the cyclopentane ring (V_7 is depicted as *D*). The dihydropyrane ring in this case, as in group B, is almost planar except for C-1, here pointing upwards and giving rise to an axial position of the glucose moiety.

Obviously, the number of low-energy conformers of the five-ring is restricted through fusion with the dihydropyrane ring, which, on the other hand, is conformationally influenced by the presence of the five-membered ring. The present results indicate that in the mutual interactions between the two rings, the nature of the substituents in the five-ring play a dominant role.

However well the conformations arrived at by consideration of sterical interactions and analysis of coupling constants coincide, it is important to stress the element of speculation involved in the latter analyses, both in the present and previous work.[6,7] It is hoped, however, that considerations such as those described above may help in acquiring a more detailed picture of the actual state of iridoid molecules in solution.

EXPERIMENTAL

Melting points are uncorrected and were determined in capillary tubes in a heated bath. Preparative TLC was performed on 20 × 40 cm plates coated with 1 mm layers of silica gel PF_{254} (Merck); bands were detected by UV-light. Analyses were performed at Dr. A. Bernhardt, Mikroanalytisches Laboratorium, Elbach über Engelskirchen, Germany.

Isolation of lamiridoside (*1*). Fresh plant material * (850 g, collected close to the labora-

* A voucher has been deposited in the Botanical Museum of the University of Copenhagen under the file No. IOK 152/72.

tory) was homogenized in EtOH and worked up as previously described.[9] The resulting Me_2CO eluate (*ca.* 8 g) was chromatographed twice on SiO_2 (300 g), with $CHCl_3$-MeOH (3:1) as the eluent. On standing, the main fraction (3.2 g) deposited crystalline KNO_3 (400 mg, identified by the IR-spectrum).[10] Purification was achieved by adsorption on activated carbon (10 g), washing with H_2O, and elution of the glucoside fraction with MeOH. A colourless, amorphous product was obtained by evaporating the solvent (2.0 g; 0.24 %). λ_{max}(EtOH) 238 nm (ε 10 200). PMR: 4.83 ppm (*d*, $J_{1'2'} = 7.5$ Hz; H-1'), 3.35 – 3.95 ppm (absorptions corresponding to the sugar-protons in glucosides); further data in the tables.

Lamiridoside hexaacetate (2). Acetylation of *1* (490 mg), in pyridine (5 ml) and Ac_2O (3 ml) for 3 h at room temperature, gave, after chromatography on SiO_2 (Et_2O – EtOAc; 9:1), *2* (484 mg). Recrystallization from MeOH gave an analytical specimen, m.p. 126.5 – 128°. λ_{max}(EtOH) 234 nm (ε 10 650). Further data in the tables.

Lamiridoside heptaacetate (3) was obtained analogously, by prolonging the acetylation time to 18 h; m.p. 189 – 190°. λ_{max} (EtOH) 232 nm (ε 10 100). Further data in the tables.

Preparation of benzylidene derivatives. 1 (710 mg) was stirred with freshly distilled C_6H_5CHO (23 ml) and anhydrous $ZnCl_2$ (1.2 g) for 3 h at room temperature. The homogeneous, slightly yellow reaction mixture was poured into saturated $NaHCO_3$ solution (100 ml) and extracted with pentane (3 × 100 ml) which was then discarded. The aqueous solution was extracted with EtOAc (3 × 150 ml) which, after drying, was concentrated *in vacuo*. The residue (944 mg) was subjected to preparative TLC to give two bands by elution with $CHCl_3$ – EtOAc (1:1); a faster running band (*fract. A*, 490 mg) and a slower running band (*fract. B*, 165 mg). The latter was rechromatographed to give a homogeneous (PMR, TLC), amorphous product: *7,8 – 4',6'-dibenzylidene lamiridoside (4)*. (Elemental analyses showed this preparation to retain about 1 mol of H_2O, which could not be removed even by rechromatography followed by rigorous drying in high vacuum). PMR-spectrum: 7.30 – 7.60 ppm (*m*; 11 H, 10 arom. H and H-3); 6.20 and 5.44 ppm (*s*'s; 2 benzylidene H); 4.28 ppm (*d*; $J = 7.5$ Hz, H-1'). Further data in the tables.

Acetylation of *4* (Py/Ac_2O; 5 h, 25°) provided *6,2',3'-triacetyl 7,8 – 4',6'-dibenzylidene lamiridoside (5)*, which was crystallized from MeOH to give a colourless solid, m.p. 136 – 137°. PMR-spectrum: 7.30 – 7.60 ppm (*m*, 11 H, 10 arom. H and H-3); 6.03 and 5.52 ppm (*s*'s; 2 benzylidene H); *ca.* 5.4 ppm (*m*; H-3'); 5.02 ppm (*m*, H-1' and H-2'); 2.14, 2.05 and 1.95 ppm (3 × OAc). Further data in the tables.

Fraction A (see above) was acetylated (Py/Ac_2O; 5 h, 25°) and gave, after work up, a mixture (630 mg), which was separated into two bands (*fract. C* and *D*) by preparative TLC (C_6H_6 – Et_2O; 3:1). The slower running fraction *C* (126 mg) was recrystallized from MeOH to give *2',3'-diacetyl 6,7 – 4',6'-dibenzylidene lamiridoside (6)* as colourless crystals, m.p. 221 – 223° (softening and resolidifying at 141 – 145°). PMR-spectrum: 7.30 – 7.60 ppm (*m*; 10 arom. H and H-3); 5.79 and 5.49 ppm (*s*'s; 2 benzylidene H); 5.32 ppm (*m*; H-3'); 4.99 ppm (*m*; 2H, H-1' and H-2'); 4.37 ppm (*dd*; $J = 4$Hz and 10 Hz, H-4'); 2.02 and 1.90 ppm (2 × OAc). Further data in the tables.

Acetylation of *6* overnight at 80 – 90°, followed by preparative TLC (C_6H_6 – Et_2O; 1:1) gave the amorphous *8,2',3'-triacetyl 6,7 – 4',6'-dibenzylidene lamiridoside (7)*. PMR-spectrum: 7.30 – 7.60 ppm (*m*; 10 arom. H and H-3); 5.77 and 5.51 ppm (*s*'s; 2 benzylidene H); 5.33 ppm (*m*; H-3'); 5.01 ppm (*m*; H-1' and H-2'); 2.03, 2.01, and 1.91 ppm (3 × OAc). Further data in the tables.

From *fraction D* (465 mg) above a compound separated on crystallization from EtOH. Recrystallization gave *6,2',3'-triacetyl 12*-epi-*7,8 – 4',6'-dibenzylidene lamiridoside (8)* as colourless crystals (285 mg) m.p. 204°. PMR-spectrum: 7.30 – 7.60 ppm (*m*; 10 arom. H and H-3); 5.95 and 5.49 ppm (*s*'s; 2 benzylidene H); *ca.* 5.4 ppm (*m*; H-3'); 5.05 ppm (*m*; H-1' and H-2'); 4.40 ppm (*m*; H-4'); 2.03, 1.96 and 1.91 ppm (3 × OAc). Further data in the tables.

The mother liquors from the crystallization of *8* contained, according to PMR, *8* and another compound in the proportion 1:4. Repeated chromatography (Et_2O – EtOAc-pentane; 1:1:1) resulted in an improvement of the ratio to 1:10. This inhomogeneous preparation, mainly consisting of *2',3'-diacetyl 12*-epi-*6,7 – 4',6'-dibenzylidene lamiridoside (9)*, was not subjected to further purification; only a PMR-spectrum was recorded: 7.30 – 7.60 ppm (*m*; 10 arom. H and H-3); 6.25 and 5.51 ppm (*s*'s; 2 benzylidene H); 5.35 ppm (*m*; H-3'); 5.01 ppm (*m*; H-1' and H-2'); 4.42 ppm (*m*; H-4'); 2.04 and 1.92 ppm (2 × OAc). Further PMR-data in Table 1.

Acetylation of the preparation above (130 mg) for 3 days at 80° gave, after work-up and chromatographic separation (C_6H_6 – Et_2O; 1:1), *8,2',3'-triacetyl 12*-epi-*6,7-4',6'-dibenzylidene lamiridoside (10)* as a colourless foam. PMR-spectrum: 7.30 – 7.60 ppm (*m*; 10 arom. H and H-3); 6.14 and 5.56 ppm (*s*'s; 2 benzylidene H); 5.38 ppm; (*m*; H-3'); 5.04 ppm (*m*; H-1' and H-2'); 4.46 ppm (*dd*; $J = 4$ and 9.5 Hz, H-4'); 2.09, 2.07, and 1.95 Hz (3 × OAc). Further data in the tables.

Enzymic hydrolysis of lamiridoside. (1) (500 mg) was dissolved in H_2O (15 ml) and emulsin (200 mg) was added. After stirring for 3 h, *1* had disappeared (TLC), and the mixture was filtered through activated carbon (5 g) and celite (4 g). The filter cake was washed with H_2O (100 ml), and glucose was identified

in the filtrate by co-chromatography with authentic glucose on paper (solvent: BuOH-EtOH-H_2O; 4:1:4). Elution of the filter cake with MeOH (100 ml), and evaporation of the solvent gave an apparently stable, sirupy residue (196 mg), which could not be induced to crystallize. Its PMR-spectrum was in accordance with that expected for the aglucone. Without further purification, the aglucone was acetylated (Py/Ac_2O; 2 h, room temp.). Preparative TLC with $C_6H_6-Et_2O$ (2:1) as the eluent and extraction of the main band gave the *aglucone triacetate (11*, 70 mg). Crystallization from $EtOAc-Et_2O$ afforded the pure compound, m.p. 153–155°. λ_{max} (EtOH) 232 nm (ε 10 450). Further data in the tables.

Note added in proof. After the present paper was submitted, Brieskorn and Ahlborn[11] reported the isolation of the same glucoside, named 'lamalbid', from '*Flores lamii albi*'. We accept the latter name and hence consider the designation 'lamiridoside' as redundant.

Acknowledgements. The authors are grateful to Dr. K. Rahn, the Botanical Museum, Copenhagen, for botanical identification of the plant material, and to Professor A. Kjær of this Institute for kind assistance with the manuscript.

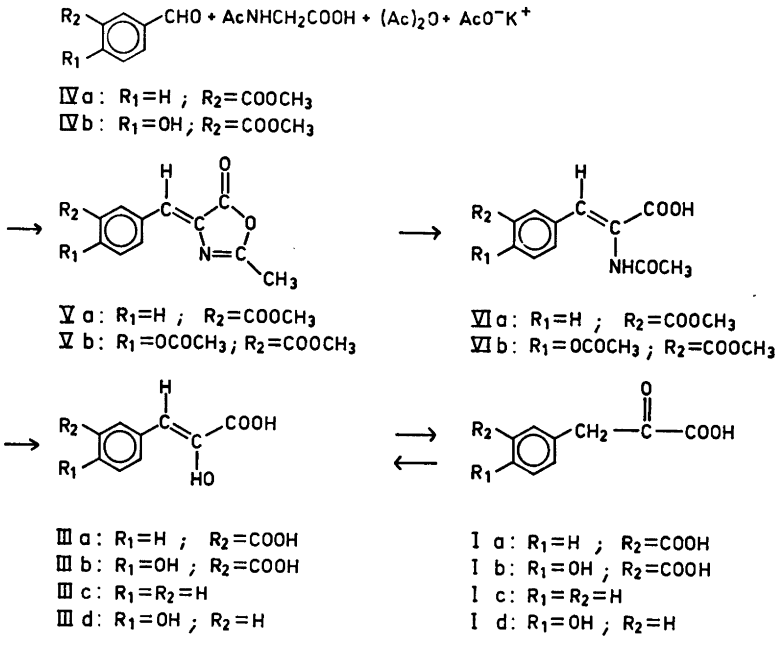
Synthesis and Properties of 3-(3-Carboxyphenyl)pyruvic Acid and 3-(3-Carboxy-4-hydroxyphenyl)pyruvic Acid

PEDER OLESEN LARSEN and ELZBIETA WIECZORKOWSKA

Department of Organic Chemistry, Royal Veterinary and Agricultural University, DK-1871 Copenhagen, Denmark

3-(3-Carboxyphenyl)pyruvic acid and 3-(3-carboxy-4-hydroxyphenyl)pyruvic acid have been synthesized from the corresponding benzaldehydes *via* azlactones and α-acetaminocinnamic acids. The equilibrium and equilibration rate between the two keto acids above, phenylpyruvic acid, and *p*-hydroxyphenylpyruvic acid and the corresponding enolic acids have been studied by PMR and UV spectroscopy. The configuration of the enolic acids and of the azlactones and α-acetamino acids have been determined.

3-(3-Carboxyphenyl)pyruvic acid (Ia) and 3-(3-carboxy-4-hydroxyphenyl)pyruvic acid (Ib) are the keto acids corresponding to 3-(3-carboxyphenyl)alanine (IIa) and 3-(3-carboxy-4-hydroxyphenyl)alanine (IIb). IIa and IIb occur free in various higher plants.[1–4] Biosynthesis of IIa and IIb has been proposed to proceed from chorismic acid *via* isochorismic acid [2-(3-carboxy-1,2-dihydro-2-hydroxyphenoxy)acrylic acid], isoprephenic



acid [3-(3-carboxy-4-hydroxycyclohexa-2,5-dienyl)pyruvic acid] and Ia and Ib on basis of incorporation studies with stereospecifically tritium-labeled shikimic acids.[5] Ia has been identified on spectroscopic evidence as a result of chemical rearrangement of isochorismic acid,[6] whereas Ib was unknown. For these reasons the synthesis and characterization of Ia and Ib were undertaken. The equilibrium of the keto forms Ia and Ib with the corresponding enol forms IIIa and IIIb was studied by PMR and UV spectroscopy and the results were compared with those obtained for the keto forms (Ic and Id) and the corresponding enol forms (IIIc and IIId) of phenylpyruvic acid and *p*-hydroxyphenylpyruvic acid.

The syntheses were accomplished by use of the classical Erlenmeyer method,[7] starting from isophthalaldehydic acid methyl ester (IVa)[8] or 5-formylsalicylic acid methyl ester (IVb)[9] and proceeding *via* 4-(3-carbomethoxybenzylidene)-2-methyl-2-oxazolin-5-one (the azlactone of α-acetamino-3-carbomethoxycinnamic acid) (Va) or 4-(3-carbomethoxy-4-acetyloxybenzylidene)-2-methyl-2-oxazolin-5-one (the azlactone of α-acetamino-3-carbomethoxy-4-acetyloxycinnamic acid) (Vb) and α-acetamino-3-carbomethoxycinnamic acid (VIa) or α-acetamino-3-carbomethoxy-4-acetoxycinnamic acid (VIb), respectively. Isolation of the intermediates VIa and VIb was not necessary. V and VI are tentatively assigned *Z*-configuration since the δ-values (see Experimental) for the olefinic protons in these compounds are similar to those reported (in $CDCl_3$) for *Z*-4-benzylidene-2-phenyl-2-oxazolin-5-one and *Z*-α-benzaminocinnamic acid methyl ester and differ from those of the corresponding *E*-isomers.[10–12] A reported δ-value (in D_2O) of 7.28 ppm for the vinylic proton in *Z*-α-(methylaminoacetyl)aminocinnamic acid[13] also supports this assignment. The syntheses were performed under acidic conditions to avoid base induced degradation. Phenylpyruvic acid and derivatives thereof substituted in the *o*- or *p*-position with substituents with negative mesomeric effects are decomposed by base to the corresponding substituted toluene and oxalate.[14] *p*-Hydroxyphenylpyruvic acid and other phenylpyruvic acids substituted in the *o*- or *p*-position with substituents with a positive mesomeric effect are decomposed by base to the corresponding substituted benzaldehydes.[14–16] Phenylpyruvic acids can also be synthesized in high yields from aromatic aldehydes and hydantoin.[14,16] The azlactone method was chosen in the present case, however, since a method was sought which subsequently could be adopted for synthesis of ^{14}C-labeled material, and since ^{14}C-glycine is easily available.

Phenylpyruvic acid and *p*-hydroxyphenylpyruvic acid exist in the crystalline state solely as the enols IIIc and IIId, whereas the salts exist mainly as ketones, as established by chemical studies and ultraviolet spectroscopy.[17] As expected, therefore, the PMR spectra in DMSO of the freshly dissolved free acids only show the presence of singlets for the olefinic protons in IIIa (δ 6.50 ppm), IIIb (δ 6.41 ppm), IIIc (δ 6.41 ppm), and IIId (δ 6.31 ppm) besides the protons in the aromatic nuclei. The δ-values found are in close agreement with those previously reported for IIIa, IIIc, and IIId.[6] III is tentatively assigned the *Z*-configuration partly on the basis of the δ-values for the olefinic protons and partly on the basis of the UV-spectra (see below). The δ-values for the proton at C_3 with *E*- or *Z*-configuration can be calculated as 5.88 ppm and 6.40 ppm, respectively, assuming additivity of substituent effects on chemical shifts of olefinic protons[18] and using the same values for the effect of the hydroxy group as those reported[18] for alkoxy groups. The spectra of the lithium salts of the four acids in D_2O exhibited beside signals for the aromatic protons only benzylic protons as singlets, indicating that in the salts the anions corresponding to I are present. The signals for the benzylic protons slowly disappear as a result of exchange with D_2O.

In aqueous acid an equilibrium is established between I and III, as previously established for Ic – IIIc and Id – IIId.[17] The tautomerization of IIId follows reversible first-order kinetics, increasing in speed with increase in pH.[17] This was confirmed by UV measurements for all four acids as demonstrated in Table 1. Half times and rate constants for establishing the equilibrium at 25° both in 1 M HCl and in phosphate buffer at pH 6.35 are given. Determination of the amount of enol present at equilibrium in 1 M HCl permitted the calculation of the individual rate constants for the keto-enol tautomerization.

Table 1. Keto-enol tautomerization of phenylpyruvic acids at 25°. For designation of compounds see formula chart.

Compound	1 M HCl					Phosphate buffer pH 6.35	
	$t_{½}$[a] (min)	k[a] (min^{-1})	% enol at equilibrium	$k_{I→III}$ (min^{-1})	$k_{III→I}$ (min^{-1})	$t_{½}$[a] (min)	k[a] (min^{-1})
Ia – IIIa	10	6.9×10^{-2}	7	6.4×10^{-3}	6.3×10^{-2}	5	1.3×10^{-1}
Ib – IIIb	29	2.4×10^{-2}	12	2.9×10^{-3}	2.1×10^{-2}	16.5	4.2×10^{-2}
Ic – IIIc	16	4.4×10^{-2}	10	4.5×10^{-3}	4.0×10^{-2}	3.5	2.0×10^{-1}
Id – IIId	51	1.4×10^{-2}	17	2.4×10^{-3}	1.1×10^{-2}	11.5	6.0×10^{-2}

[a] For equilibration.

The values found in 1 M HCl for Id – IIId are in good agreement with those reported for this compound at pH 1.[17] For Ia – IIIa it has been stated that keto to enol conversion in strong acid does not occur readily,[6] but this is contradicted by the present results.

Presumably the conversion of keto to enol takes place without acid catalysis [19] and the rate is determined by the kinetic acidity of the protons on C_3. The order of the rate constants for I→III is that expected from the inductive and mesomeric effects of the substituents in the aromatic ring in I. The changed order of half-times and corresponding rate constants at pH 6.35 supposedly reflects the change of sign of the inductive effect of the aromatic carboxyl group by ionization.

In these considerations no regard is made to the hydration of I. It can, however, be expected that the degree of hydration is nearly the same for all four compounds and the effect on the order of the rate constants would be opposite to the effect described above.[20]

UV-data for the enols in 1 M HCl and for the anions of the enols at pH 6.35 are recorded in Table 2. The amount of enol at equilibrium at pH 6.35 supposedly is negligible. Therefore the UV-absorption recorded at equilibrium pre-

Table 2. UV-data for enol and keto forms of phenylpyruvic acids at 25°. For designation of compounds see formula chart.

sumably represents the anions of the ketones as given in Table 2. The high ε-values for the high wavelength absorption band for the enols support the *Z*-configuration for these compounds since ε_{max} for the corresponding band for the similar configuration of cinnamic acid (*E*-cinnamic acid) is 20 000 whereas ε_{max} for the opposite configuration (*Z*-cinnamic acid) is only 9000.[21] The intensity and location of these bands are only changed very little in the corresponding anions of the cinnamic acids.[21] The spectral data for IIIa, IIIc, and IIId are in agreement with those reported in the literature.[6,16,22,23] In the spectrum of the anion of Ib the salicylic acid grouping is clearly visible.

EXPERIMENTAL

PMR spectra were measured on a JEOL-C-60 HL instrument. Chemical shifts are given in ppm downfield from TMS in deuterio-DMSO and from sodium 2,2,3,3,-tetradeuterio-3-(trimethylsilyl)propionate in D_2O. UV-spectra were measured on a Zeiss DMR-21 instrument at 25°. Transformations of enol to keto forms in 1 M HCl and in 0.06 M phosphate buffer pH 6.35 were observed at λ_{max} for the highest positioned absorption band of the enol form (see Table 1) in freshly prepared solutions and half-times for equilibration were determined as described in the literature.[17] Transformations of keto to enol forms in 1 M HCl were observed by acidification of neutral solutions. Extrapolations to $t=0$ permitted the determination of ε-values in acid for both keto and enol forms and the combined data permitted calculation of the equilibrium composition. Melting points are uncorrected. Microanalyses were performed by Mr. G. Cornali and his staff.

4-(3-Carbomethoxybenzylidene)-2-methyl-2-oxazolin-5-one (Va). A mixture of isophthalaldehydic acid methyl ester (IVa)[8] (5.01 g), acetylglycine (3.16 g), and potassium acetate (2.5 g) in acetic anhydride (5.5 ml) was kept with stirring at 100° for 3 h. After cooling overnight crystals of Va were collected by filtration and washed with methylene chloride. Yield 2.93 g (45 %), m.p. 185–187°. Recrystallization from benzene-benzine (80–110°) produced an analytical sample of yellow needles, m.p. 195–197°. (Found: C 59.64; H 4.33; N 5.33. Calc. for $C_{13}H_{11}O_5N$: C 59.77; H 4.24; N 5.36). PMR-spectrum in deuterio-DMSO: δ 2.41 (3 H) singlet, methyl; δ 3.95 (3 H) singlet, methoxyl; δ 7.36 (1 H) singlet, olefinic; δ 7.75–8.87 (4 H) multiplet, aromatic.

4-(3-Carbomethoxy-4-acetyloxybenzylidene)-2-methyl-2-oxazolin-5-one (Vb). A mixture of 5-formylsalicylic acid methyl ester sodium salt (IVb)[9] (406 mg), acetylglycine (234 mg), and potassium acetate (200 mg) in acetic anhydride (2 ml) was kept with stirring under nitrogen at 100–110° for 2 h. After cooling overnight crystals of Vb were collected by filtration and washed with ethanol. Yield 366 mg (60 %), m.p. 140–141°. Recrystallization from benzene produced an analytical sample of yellow needles, m.p. 140–141°. (Found: C 59.47; H 4.46; N 4.42. Calc. for $C_{15}H_{13}O_6N$: C 59.40; H 4.36; N 4.62.) PMR-spectrum in deuterio-DMSO: δ 2.34 (3 H) singlet, acetoxy; δ 2.42 (3 H) singlet, methyl; δ 3.87 (3 H) singlet, methoxyl; δ 7.33 (1 H) singlet, olefinic; δ 7.41–8.82 (3 H) multiplet, aromatic.

α-Acetamino-3-carbomethoxycinnamic acid (VIa). A suspension of Va (123 mg) in water (5 ml) and ethanol (5 ml) was refluxed for 2 h. After removal of part of the solvents by evaporation and cooling overnight crystals of VIa were collected by filtration. Yield 68 mg (52 %), m.p. 217–219° (decomp.). Recrystallization from methanol produced an analytical sample, m.p. 222° (decomp.). (Found: C 59.15; H 5.15; N 5.32. Calc. for $C_{13}H_{13}O_5N$: C 59.31; H 4.97; N 5.32.) PMR-spectrum in deuterio-DMSO: δ 2.05 (3 H) singlet, acetyl; δ 3.91 (3 H), singlet, methoxyl; δ 7.36 (1 H) singlet, olefinic; δ 7.42–8.3 (4 H) multiplet, aromatic.

α-Acetamino-3-carbomethoxy-4-acetyloxycinnamic acid (VIb). Vb (121 mg) in water (10 ml) and methanol (5 ml) was refluxed for 4 h. After removal of part of the solvent, filtration and cooling crystals of VIb were collected by filtration. Yield 94 mg (73 %). Recrystallization from ethyl acetate produced an analytical sample. m.p. 180°. (Found: C 55.69; H 4.83; N 4.28. Calc. for $C_{15}H_{15}NO_7$: C 56.08; H 4.70; N 4.35.) PMR-spectrum in deuterio-DMSO: δ 2.05 (3 H) singlet, acetyl; δ 2.34 (3 H) singlet, acetoxy; δ 3.87 (3 H) singlet, methoxyl; δ 7.34 (1 H) singlet, olefinic; δ 7.47–8.28 (3 H) multiplet, aromatic.

3-(3-Carboxyphenyl)pyruvic acid in enol form (IIIa). A solution of Va (980 mg) in ethanol (20 ml) and 2 M HCl (40 ml) was refluxed under nitrogen for 2.5 h. The solution was decolourised with charcoal and after cooling overnight colourless crystals of IIIa were collected, m.p. 222–224° (decomp.). Yield 670 mg (80 %). Two recrystallizations from 2 M HCl produced an analytical sample, m.p. 219–222° (decomp.). (Found: C 57.46; H 4.04. Calc. for $C_{10}H_8O_5$: C 57.69; H 3.87.) PMR-spectrum in deuterio-DMSO: δ 6.50 (1 H) singlet, olefinic; δ 7.34–8.48 (4 H) multiplet, aromatic. PMR-spectrum of lithium salt in D_2O: δ 4.18 (2 H) singlet, benzyl; δ 7.28–7.82 (4 H) multiplet, aromatic. For PMR-data, *cf.* Ref. 6.

3-(3-Carboxy-4-hydroxyphenyl)pyruvic acid in enol form (IIIb). A solution of Vb (366 mg) in ethanol (10 ml) and 4 M HCl (35 ml) was refluxed under nitrogen for 14 h. After cooling overnight and filtration the solution was left in the refrigerator for three days. Crystals of IIIb were collected by filtration. Yield 169

mg (68 %), m.p. 230 – 235° (decomp.). Recrystallization from 2 M HCl produced an analytical sample, m.p. 234 – 237° (decomp.). (Found: C 53.64; H 3.77. Calc. for $C_{10}H_8O_6$: C 53.58; H 3.59.) PMR-spectrum in deuterio-DMSO: δ 6.41 (1 H) singlet, olefinic; δ 6.9 – 8.45 (3 H) multiplet, aromatic. PMR-spectrum of lithium salt in D_2O: δ 4.08 (2 H), singlet, benzyl; δ 6.8 – 7.8 (3 H) multiplet, aromatic.

Ib – IIIb is rapidly decomposed at pH > 8 at room temperature. The corresponding aldehyde has been identified in the decomposition mixture by UV-spectroscopy.

Mass Spectra of Substituted 1,2,3,4-Thiatriazoles

KAI ARNE JENSEN, SVEND TREPPENDAHL,* CARSTEN CHRISTOPHERSEN and GUSTAV SCHROLL

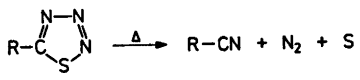
Department of General and Organic Chemistry, University of Copenhagen, The H. C. Ørsted Institute, DK-2100 Copenhagen, Denmark

The mass spectra of 14 1,2,3,4-thiatriazoles have been recorded and interpreted with the aid of high resolution mass measurements and by the application of the metastable defocusing technique. The observed electron impact induced fragmentations are compared with the known thermal decompositions of these compounds.

The electron impact induced decompositions of heterocyclic compounds have received appreciable attention during the last decade, and mass spectrometry has as a result of these investigations become an important tool in the structure elucidation of this type of compounds.[1-3]

Although several classes of heterocyclic compounds thus have been investigated no detailed studies dealing with the mass spectra of thiatriazoles ** have been published. In connection with the study of the fragmentations of 1,2,3-thiadiazoles the mass spectrum of 5-phenylthiatriazole has been scrutinized.[4]

Thiatriazoles are known to be rather unstable compounds,[5] decomposing upon heating by the loss of N_2 and S according to the scheme:



The purpose of this investigation is twofold, partly to examine whether mass spectrometry can be used for the identification of this type of heterocyclic compounds, partly to compare the electron impact induced fragmentations with the known thermal decompositions of thiatriazoles.

Comparisons of thermally and electron impact induced processes are often complicated by the possibility of pyrolysis of the sample in the inlet system of the mass spectrometer. In order to prevent such decompositions prior to ionization the thiatriazoles were introduced through the direct inlet at a temperature below 100°C. Applying this technique it was possible to obtain a mass spectrum (Fig. 4) of 5-mercaptothiatriazole (XI) (known to explode at 50–60°C at atmospheric pressure) with a molecular ion peak of *ca.* 40 % relative abundance. The presence of an abundant molecular ion peak indicates that some of the sample has evaporized unchanged into the ion source, but it does not exclude that pyrolysis has also taken place. As the pyrolysis of the thiatriazoles leads to the formation of sulfur, the presence of peaks in the mass spectra at *m/e* n·32 corresponding to $S^{+\cdot}$ (n = 2, 3,...8) can be taken as evidence for a thermal destruction of the sample. Thus in the case of 5-mercaptothiatriazole (XI) the mass spectrum (Fig. 4) contains peaks at *m/e* 128 and 64, indicating that some of the sample decomposes during the evaporation.

This investigation deals with the mass spectra (Figs. 1–4) of 14 thiatriazoles (I–XIV). Depending on the substituent in the 5-position the compounds can be divided into three groups:

A: 5-Arylthiatriazoles (I–II)

B: 5-Aminothiatriazoles (III–X)

C: 5-Thiothiatriazoles (XI–XIV)

* Present address: Institute for Chemistry, Faculty of Medicine, University of Copenhagen, Rådmandsgade 71, DK-2200 Copenhagen, Denmark.

** The positional numerals are for the sake of brevity omitted.

A:

I. R=-C_6H_5

II. R=-C_6H_4-p-CH_3

B:

III. R=-NH_2

IV. R=-$NHCH_3$

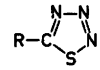
XI. R=-SH

XII. R=-SCH_3

XIII. R=-SCH_2CH_3

XIV. R=-SC_6H_5



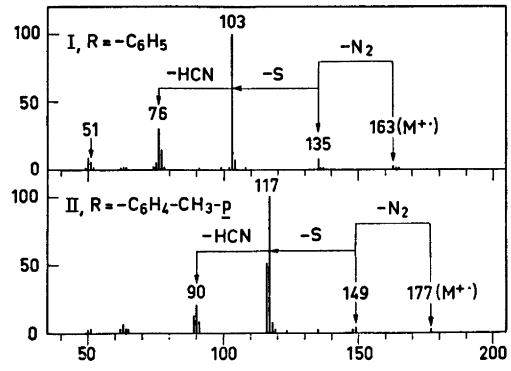


Fig. 1.

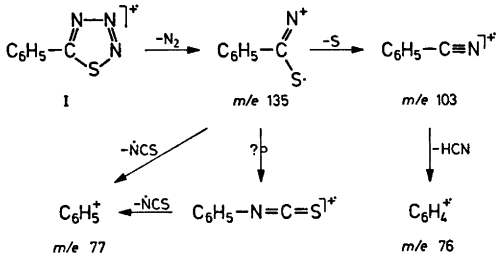
DISCUSSION

A. 5-Arylthiatriazoles

The base peak (*m/e* 103) in the mass spectrum (Fig. 1) of 5-phenylthiatriazole (I) is due to ionized benzonitrile and the peaks at *m/e* 76 and 75 correspond to the known decomposition products of $C_6H_5CN^{+\cdot}$ [6] (I) is known to decompose into benzonitrile upon heating,[5] and in order to ascertain whether 103^+ was the result of a pyrolysis prior to ionization or due to an electron impact induced process metastable defocusing technique (MDT) was applied. It was found that 103^+ is formed by the decomposition of 135^+ (by the loss of S) as suggested by Zeller *et al.*[4]

The peak at *m/e* 135 is due to ions formed by the loss of N_2 from the molecular ion. A similar thermal process is not known for this compound. The composition of the $M-N_2$ ion corresponds to that of phenylisothiocyanate and phenylthiocyanate. From the mass spectra of C_6H_5NCS [7] and C_6H_5SCN [8] we are most inclined to assign the $M-N_2$ ion to ionized phenylisothiocyanate. The formation of this ion requires a phenyl migration from C(5) to N(4).

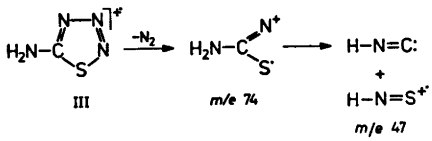


If the phenyl group is substituted by *p*-tolyl, the decomposition pattern observed for (I) is expanded by the loss of a hydrogen atom from $M-N_2$ as well as from $M-N_2S$, probably leading to the formation of isothiocyano- and cyanotropylium ions, respectively.[6]

B. 5-Aminothiatriazoles

The mass spectrum (Fig. 2) of 5-aminothiatriazole (III) displays rather abundant peaks at *m/e* 102, 74, 47, and 42, corresponding to $M^{+\cdot}$, $M-N_2$, $HNS^{+\cdot}$, and $H_2N-CN^{+\cdot}$, respectively. The molecular ion has an abundance of *ca.* 16 % Σ_{40}; in the mass spectrum of the methylamino analogue (IV) the abundance of $M^{+\cdot}$ is 18.5 % Σ_{40}, whereas the remaining compounds (V–X) from this group display molecular ion peaks with abundances less than 5 % Σ_{40}. The decrease of molecular ion intensity with increasing size of the alkyl substituent is a well known phenomenon, but the situation is normally reversed when the alkyl group is replaced by an aromatic moiety such as phenyl. In the mass spectrum (Fig. 3) of 5-phenylaminothiatriazole (VIII), however, the abundance of the molecular ion is only 0.8 % Σ_{40}.

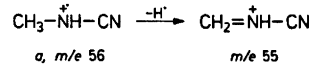
The decrease in molecular ion abundance with increasing size of the alkyl is normally due to the possibility for new reactions when the side chain is enlarged, and this is also the case here, as seen from below.



The $M-N_2$ ion from 5-aminothiatriazole (III) has the composition CH_2N_2S and this fragment decomposes into the ion $HNS^{+\cdot}$ and neutral HCN. In the mass spectra of the two 5-arylthiatriazoles (I–II) the $M-N_2$ ions corresponded to ionized arylisothiocyanates, but an analogous skeletal rearrangement (leading to $H_2N-N=C=S^{+\cdot}$) is neither reasonable from a mass spectrometric point of view, nor in agreement with the further loss of HCN and formation of $HNS^{+\cdot}$. The genesis of $HNS^{+\cdot}$ requires the formation of a S–N bond.

Although the mass spectrum of 5-methylaminothiatriazole (IV) displays an abundant peak at *m/e* 88, corresponding to $M-N_2$, the peaks due to the subsequent decomposition by loss of HCN (*m/e* 61) or formation of $HNS^{+\cdot}$ (*m/e* 47) are not as significant as in the case of III. Further, the $M-N_2$ ion from IV is found to decompose by the loss of ·H (*m/e* 87) and $\cdot CH_3$ (*m/e* 73 = CHN_2S, H. R.) as indicated by the presence of the appropriate metastable peaks. These differences between the decompositions of the $M-N_2$ ions from III and IV makes the assignment of a general structure to the $M-N_2$ ions impossible.

As in the mass spectrum of III that of IV displays an abundant peak corresponding to $M-N_2S$. This ion is assigned to the structure *a*. The peak at *m/e* 55 is due to $M-HN_2S$, formed by α-cleavage in *a*:



The dominating features in the mass spectra (Figs. 2–3) of the higher homologues are formation of *N*-alkyl cyanamides, which decompose further by α-cleavage, and formation of alkyl ions. Finally, these mass spectra display minor peaks corresponding to ionized alkylisothiocyanates ($M-HN_3$) and to the known fragments of these ions.[7]

The mass spectrum (Fig. 3) of 5-phenylamino-

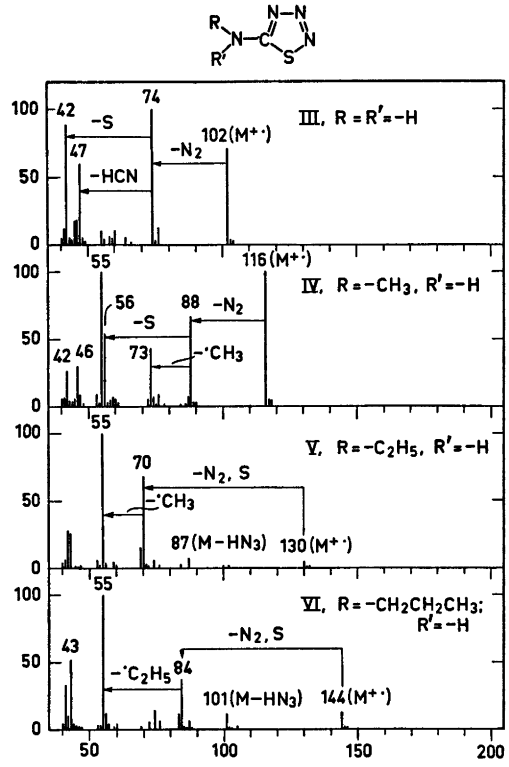


Fig. 2.

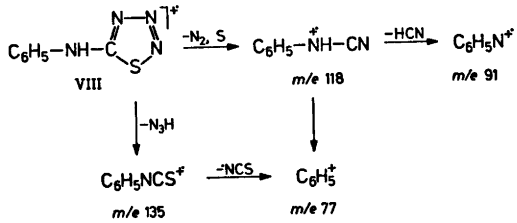
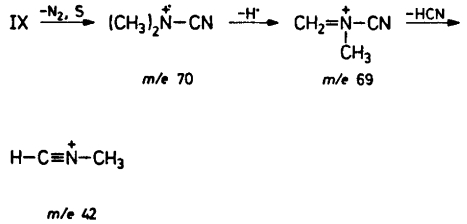
thiatriazole (VIII) reveals that the formation of phenylisothiocyanate (*m/e* 135) and phenylcyanamide (*m/e* 118) are important processes. Peaks corresponding to the decomposition products of the two compounds are found in agreement with the mass spectra of C_6H_5NCS [7] and C_6H_5NHCN. [9]

The mass spectra (Fig. 6) of dimethylamino (IX) and dipropylaminothiatriazole (X) display peaks corresponding to a fragmentation pattern very similar to that of the monoalkyl analogues (IV – VII), *i.e.* formation and decomposition of

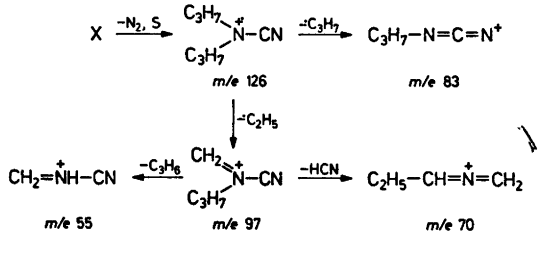


ionized cyanamides. In the case of IX the following sequence is observed:



The $M-N_2$ peak in the mass spectrum of IX is due to an ion undergoing subsequent decomposition through the expulsion of a methyl radical. A similar process was observed for the monomethyl analogue (IV).

The loss of N_2S from the molecular ion of dipropylaminothiatriazole (X) leads to the formation of ionized dipropylcyanamide (*m/e* 126), undergoing α-cleavage by loss of $\cdot C_2H_5$ (*m/e* 97) followed by the elimination of C_3H_6 (*m/e* 55). Minor peaks in the mass spectrum of X are due to loss of a propyl radical from the ionized cyanamide (*m/e* 83) and to the elimination of HCN from the α-cleavage product (*m/e* 70), as depicted in the Scheme:



C. 5-Thiothiatriazoles

The mass spectrum (Fig. 4) of 5-mercaptothiatriazole (XI) contains peaks corresponding to various $S_n^{+\cdot}$ ions. This finding is a strong indication of an initial pyrolysis of the sample in the ion source prior to ionization, whereas the

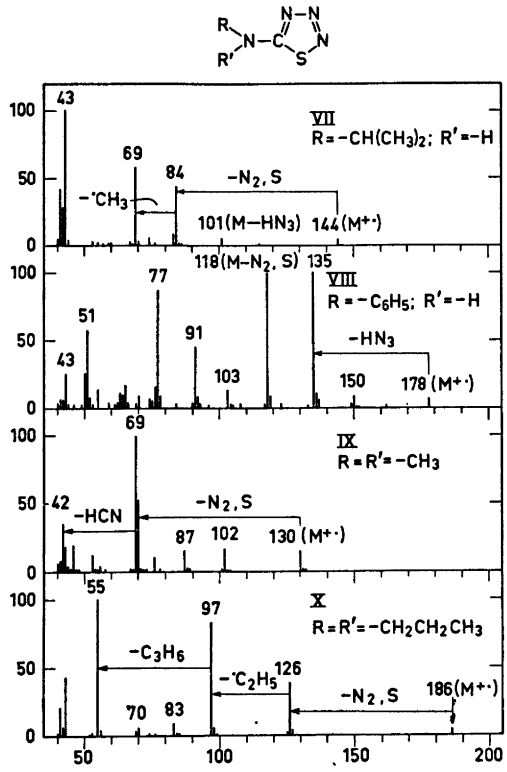


Fig. 3.

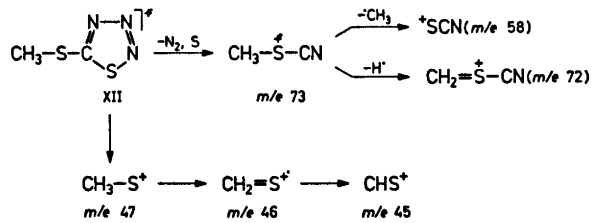
presence of a fairly abundant molecular ion peak clearly depicts that a large portion of the sample evaporizes unchanged from the probe tip. The peaks at *m/e* 76 and 59 are due to $CS_2^{+\cdot}$ and $HSCN^{+\cdot}$, respectively. These ions might be thermal in their origin.

The absence of any peaks, corresponding to $S_n^{+\cdot}$ in the mass spectra of the remaining compounds belonging to this class can be taken as evidence for the absence of thermal processes. The mass spectrum of methylthiothiatriazole (XII) displays peaks due to the processes listed below:



Processes of minor contribution to the total ion current include the loss of $\cdot CH_3$ (*m/e* 118), loss of N_2 (*m/e* 105), and a combined expulsion of N_2 and $\cdot CH_3$ leading to S_2CN^+ (*m/e* 90). As in the case of the mercaptothiatriazole (XI) $CS_2^{+\cdot}$ gives rise to a fairly abundant peak (*m/e* 76). The assignment of the $M-N_2S$ ion to the structure of ethylthiocyanate is supported by the decomposition pattern of this compound.[10]

The base peak (*m/e* 135) in the mass spectrum of phenylthiothiatriazole (XIV) is due to ionized phenylthiocyanate, the decomposition of which is known.[8] Minor peaks are due to $M-N_2$ and $CS_2^{+\cdot}$.

CONCLUSIONS

As it will be evident from the discussion above the electron impact induced decompositions of the thiatriazoles resemble the pyrolytic loss of N_2S. In all cases the $M-N_2S$ ion together with the fragmentation products from the $M-N_2S$ ion are responsible for the major part of the total ion current.

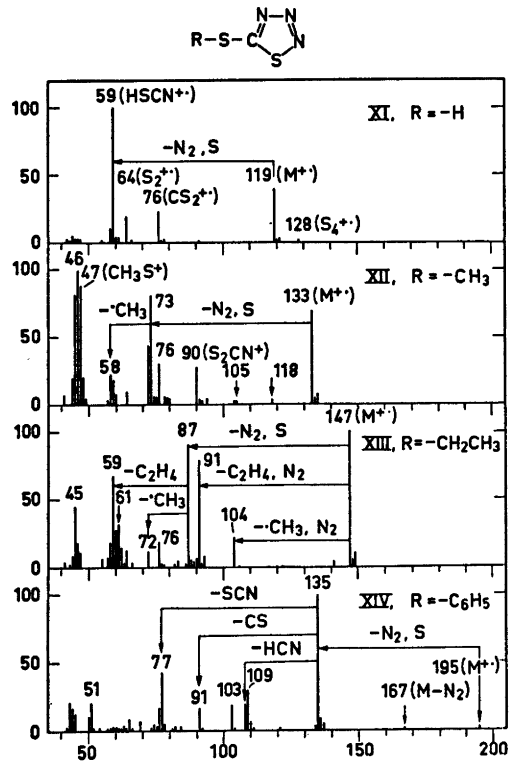


Fig. 4.

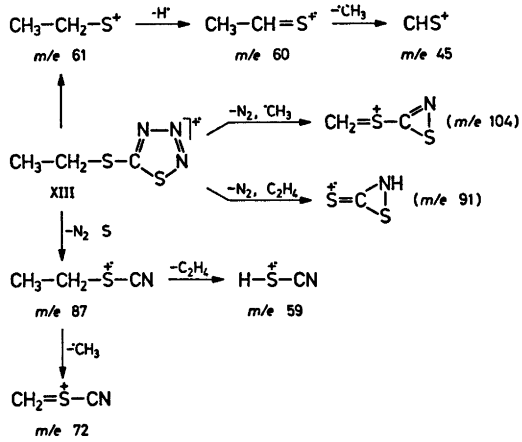

Rearrangement processes not observed upon pyrolysis include the formation of $M-N_2$ ions (observed in most spectra) and elimination of HN_3 (observed for some of the aminothiatriazoles).

EXPERIMENTAL

The mass spectra were recorded at an AEI MS902 mass spectrometer. The samples were introduced through the direct inlet at a temperature below 100°C. All thiatriazoles were prepared in accordance with previously published procedures.[5]

Covalent Binding of Proteins to Polysaccharides by Cyanogen Bromide and Organic Cyanates. III. Structural Studies on the Linkage Region

KENNETH BROSTRÖM, STIG EKMAN, LENNART KÅGEDAL and STIG ÅKERSTRÖM *

Department of Organic Chemistry, Pharmacia AB, Box 604, S-751 25 Uppsala 1 and Chemical Institute, University of Uppsala, Box 531, S-751 21 Uppsala 1, Sweden

The reaction between cyanogen bromide activated methyl 4,6-*O*-benzylidene-α-D-glucopyranoside, Sephadex, or dextran and amino acids or peptides has been investigated. The coupling between the activated carbohydrate and the amino compound involves formation of isourea groups. The simultaneous release of ammonia is independent of the coupling reaction. Part of the ammonia is derived from hydrolysis of carbamate groups but most of it is derived from other groups in the activated carbohydrate.

Proteins can be covalently linked to polysaccharides if the latter are first treated with cyanogen bromide [1] or organic cyanates.[2] Previous proposals [3,4] concerning the nature of the linkage region in such complexes are not unambiguous. We have previously discussed the nature of the activated complex.[5–8] In the present communication, the bonds between the carbohydrates and the fixed amino compounds are re-examined.

EXPERIMENTAL

Apparatus and methods. IR-spectra in KBr were recorded with a Unicam 200 instrument. The amino acid analyses were made according to Spackman *et al.*[9] For the amino acid directly linked to the modified carbohydrate, this analysis gave low values. Corrections were therefore made assuming that the analysis of the second amino acid in a dipeptide linked to the carbohydrate was correct. The ammonia was determined by the Kjeldahl method. The molecular weights were determined by gel chromatography.[10] The melting points were determined in a pre-heated melting point apparatus. As the compounds investigated were amorphous, and further melted under decomposition, these values are not very accurate. Concentrations and dryings were performed under reduced pressure.

Materials. Sephadex® G-25 Superfine and Dextran T10 ($\overline{M}_w$9300, $\overline{M}_n$5700) from Pharmacia Fine Chemicals, Uppsala, were used. The cyanogen bromide (BrCN) was purchased from Fluka AG. Pre-coated TLC-plates Silicia Gel F_{254} and solvent system $CHCl_3/CH_3OH$ 1:1 were used. Cyanogen bromide activated Sephadex (SxOH*) was prepared as previously described.[2] Cyanogen bromide activated methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (MBGP*) was prepared as described previously except that $CHCl_3$ was exchanged for CH_2Cl_2 as extraction solvent.[6] In the experiments performed, the nitrogen content of MBGP* varied from 2.0 to 4.5 %. Sephadex-carbonate was prepared as described for cellulose-carbonate.[11] IR 1750 cm^{-1}(>C=O, acyclic), 1800 cm^{-1} (>C=O, cyclic).

1. *Coupling of glycine to MBGP** (*Ia*). To MBGP* (2.0 g, N 2,4 %) in acetone (40 ml) was added an aqueous solution (40 ml) of glycine (4.0 g) and triethylamine (2 ml). The mixture was stirred for 0.5 h at room temperature, evaporated to dryness and dried for 1 h at 80°. The residue was pulverized, dried again to ensure that all triethylamine had been removed, and thereafter stirred in water (50 ml) at room temperature for 20 min. The solid product was filtered off, washed with boiling acetone (10 ml), dried and precipitated from water (50 ml). After 20 h in a refrigerator (4°) the precipitate was filtered, dried at 110° for 0.5 h giving an amorphous product (0.2 g) that was hygroscopic. M.p. 176–177°d. (Found: C 52.2; H 6.0, N 6.9; glycine 2.25 mmol/g. Calc. for $C_{17}H_{22}O_8N_2$:

* To whom correspondence should be addressed.

C 53.5; H 5.7; N 7.25; glycine 2.40 mmol/g). The product was homogeneous on TLC. The glycine value is low, due to incomplete hydrolysis, and is not corrected. An IR spectrum showed a double peak at 1680, 1700 cm^{-1} (C=N, stretching).

2. *Coupling of glycylglycine to MBGP* (Ib).* To MBGP* (2.0 g, N 2.7 %) in acetone (30 ml) was added an aqueous solution (30 ml) of glycylglycine (2.0 g) and triethylamine (2.0 ml). The mixture was stirred for 20 min at 20° and evaporated at 50° for 3 h, whereupon the product was washed on a filter with acetone (3 × 20 ml) and finally dried for 1 h at 80°. Two precipitations from hot water (50 ml) and drying at 80° for 2 h afforded an amorphous product (0.4 g) which was homogeneous on TLC. M.p. 187°d. (Found: C 51.4; H 5.7; N 9.0; O 32.5; glycine 4.25 mmol/g. Calc. for $C_{19}H_{25}O_9N_3$: C 51.9; H 5.7; N 9.6; O 32.8; glycine 4.55 mmol/g). The glycine value is low for the same reason as above, and is not corrected. An IR spectrum showed a double peak at 1665, 1690 cm^{-1} (C=N, stretching).

3. *Sephadex-carbamate* was prepared by treating Sephadex-carbonate (0.5 g) with liq. NH_3 (2 ml) for 15 min. After evaporating excess NH_3, the product was washed with water (15 ml), dioxane, (20 ml), ether (20 ml) and finally dried at 50°. 0.53 g. IR 1715 cm^{-1} ($-CONH_2$). N 4.5 %.

4. *Hydrolysis of Sephadex-carbamate.* Sephadex-carbamate (0.250 g, from exp. 3) was stirred in 0.5 M aqueous $NaHCO_3$ (10 ml) at 23°. After various intervals, the reaction mixture was centrifuged, and the supernatant removed, the residue washed with water (10 ml), centrifuged, and the supernatant removed. The washing procedure was repeated twice. The NH_3 present in the combined supernatants was determined. After 1, 2, 4, 22, 28, and 51 h; 2.8, 5.6, 9.2, 26.8, 29.6, and 42.8 μmol NH_3 per g Sephadex-carbamate, respectively, were releazed.

5. *Hydrolysis of Sephadex-carbamate in the presence of different amino compounds.* The Sephadex-carbamate (3.0 g, from exp. 3) was reacted with methanol (5 ml) in 0.5 M aqueous $NaHCO_3$ (10 ml) for 18 h at room temperature to remove remaining carbonate groups. The reaction was followed by IR. The product was filtered and washed with water, water-methanol 1:1, methanol, ether and finally dried at 40° for 20 min. This product (0.250 g) in 0.5 M aqueous $NaHCO_3$ (10 ml) was stirred with glycine (0.075 g), glycylglycine (0.132 g) or glycyl-L-leucine (0.188 g), respectively, for 25 h at 20°. The pH of the solutions was adjusted to 8.4 by adding solid Na_2CO_3. The working up and the determination of NH_3 was carried out as in Exp. 4. After corrections for small amounts of impurities in the amino compounds used the NH_3 liberated was found to be 16 – 28 μmol per g Sephadex-carbamate.

6. *Hydrolysis of SxOH*.* SxOH* (N 1.9 %, 0.250 g) was treated as in Exp. 4. After 0.5, 1, 2, 6, and 21 h, 54, 72, 84, 120, and 132 μmol NH_3 per g SxOH*, respectively, were released.

7. *The reaction of amino compounds with SxOH*.* A. To glycine, glycine ethylester, and glycyl-L-leucine (1.00 g), respectively, in 0.5 M aqueous $NaHCO_3$ (2 ml) was added SxOH* (0.4 g) and the mixtures were stirred for 20 h at room temperature. After filtration, the products were washed with 0.5 M $NaHCO_3$, 0.01 M HCl, 1 M NaCl solution, water, water-acetone (3:1, 1:1, 1:3), acetone, and dried for 2 h at 40°. A blank, containing SxOH* but no amino compound was run parallel with the other samples. The results are given in Table 1.

B. To glycine, glycine ethylester and glycine-L-leucine (0.40 g), respectively, in 0.5 M aqueous $NaHCO_3$ (2.5 ml) was added SxOH* (0.40 g). The mixtures were stirred for 15 h at room temperature and worked up as above. A blank was run as above. The results are given in Table 2.

Table 1. Binding of amino compounds to SxOH*.

C. Solutions of glycine, glycine ethylester and glycine-L-leucine (0.25 g), respectively, in 1 M aqueous $NaHCO_3$ (10 ml) were adjusted to pH 8.4 by addition of solid Na_2CO_3. SxOH* (0.250 g) was added and stirring was continued for 18 h at room temperature. The reaction mixtures were centrifuged, the supernatants removed, and the residues washed with water, centrifuged, and the supernatants removed. The washing procedure was repeated twice. The NH_3 content of the combined supernatants was determined. The products were washed and dried as above. The results are given in Table 3.

D. The reactions between SxOH* (N 5.65 %, 0.250 g) and glycine, glycine ethylester, alanine, glycylglycine, glycyl-L-leucine, glycyltyrosine (1 mmol) and aqueous ammonia (68 μmol), respectively, in 0.5 M aqueous $NaHCO_3$ (10 ml) at 25° were allowed to proceed for 24 h. Excees CO_2 was removed at 50° during 5 min. The pH of the buffer solutions was 8.2 – 8.3. The working up procedure was as described in Exp. C. The results are given in Table 4.

8. *Dextran cross-linked by BrCN (dextran*).* A. Dextran 10 (45 g) was dissolved in water (300 ml) in a 500 ml three-necked flask provided with a stirrer and a pH-electrode. BrCN (7.9 g) was added in portions over 90 min. The pH was maintained at 10.5 by adding 5 M NaOH. After neutralization with 5 M HCl, the solution was dialyzed against tap water for 3 days and thereafter in distilled water for 2 days. The solution was then concentrated to 200 ml at 65°, the cross-linked dextran precipitated, using 2.5 l ethanol, and dried for 2 h at 40°. $\overline{M}_w$ 229 000, $\overline{M}_n$ 17 000. N 1.40 %.

B. Conditions and working up procedure as above. BrCN (8.9 g) was added in portions over 90 min. $\overline{M}_w$ 1 080 000, $\overline{M}_n$ 23 000.

9. *Reaction of glycine and glycylglycine with dextran*.* A. Glycine (1 mmol) and dextran* (from exp. 8B, 0.5 g) were dissolved in 1 M aqueous $NaHCO_3$ (10 ml). After 15 h at 20°, the reaction mixture was dialysed for 5 days and freeze-dried. $\overline{M}_w$ 111 000, $\overline{M}_n$ 13 000, glycine 37.5 μmol/g. A parallel experiment using the same reaction conditions, was performed with dextran * (from exp. 8B, 0.5 g). $\overline{M}_w$ 148 000, $\overline{M}_n$ 17 000.

B. Glycylglycine (1 mmol) and dextran* (from exp. 8A, 0.5 g) were dissolved in 0.5 M aqueous $NaHCO_3$ (10 ml). After 23 h at 25°, the reaction mixture was dialysed for 5 days

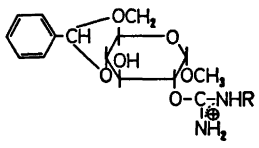
and freeze-dried. $\overline{M}_w$ 57 000, $\overline{M}_n$ 11 000, glycine 51 μmol/g. A parallel experiment, using the same reaction conditions, was performed with dextran* (from exp. 8A, 0.5 g). $\overline{M}_w$ 71 000, $\overline{M}_n$ 15 000.

RESULTS

1. *Studies with model compounds.* When MBGP* was reacted with glycine or glycylglycine in water-acetone, using triethylamine as catalyst, only one type of addition products could be isolated. These are isourea derivatives (I) according to evidence given below.



R: $-CH_2COO^{\ominus}$ $-CH_2CONHCH_2COO^{\ominus}$

Ia Ib

The products obtained contained impurities from the activation of MBGP and were purified by various washing procedures and repeated precipitations from hot aqueous solution. The purified products are amorphous and are only soluble in hot water and methanol, indicating a dipolar structure. The elemental analyses ruled out a carbamate or imidocarbonate structure but were in accordance with the proposed isourea formula (I). This was also confirmed by the characteristic double peak at 1660 – 1700 cm^{-1} in the IR-spectrum.[12] No attempts to separate the 2- and 3-isomers were performed.

II. *The reactions of amino compounds with SxOH* and dextran**. The products obtained by reacting SxOH* with amino compounds in dilute alkaline solution have been given structures represented schematically in II – IV.[3,13,14]

SxOCNHR (O) II SxOCNHR (NH) III $(SxO)_2C=NR$ IV

If products of type III or IV are formed at least one molecule of ammonia per molecule amino compound incorporated into the Sephadex matrix would be liberated. As shown in Table 4, the amount of ammonia liberated during the coupling procedure is 280 – 320 μmol/g SxOH* and the amount of amino compound incorporated 309 – 701 μmol/g SxOH*. Under the same conditions but with no amino compound, SxOH* releases 268 μmol/g SxOH* due to partial hydrolysis of carbamate and other groups in the SxOH* matrix. Thus, only a few percent of the released ammonia may come from reactions leading to *N*-substituted carbamates (III) and *N*-substituted imidocarbonates (IV), which shows that the main component is the isourea derivative (II).

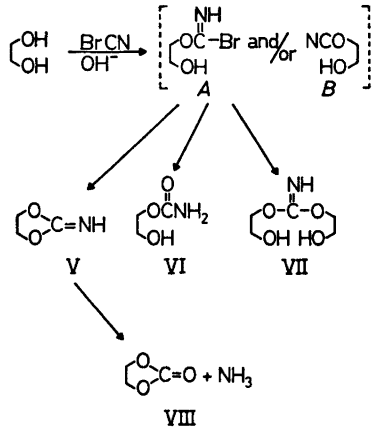
The carbamate groups in SxOH* are only slowly hydrolyzed under the weak alkaline conditions used, as was shown from studies with Sephadex-carbamate, prepared by reacting Sephadex-carbonate with liquid ammonia. The Sephadex-carbamate was hydrolyzed and the ammonia released determined. Only 15 – 30 μmol of ammonia per g Sephadex-carbamate was obtained (Exp. 4 – 5), thus demonstrating that only a small part (5 – 10 %) of the ammonia liberated could then arise from hydrolysis of carbamate groups in SxOH*. The main part of the ammonia liberated during the coupling procedure must originate from the hydrolysis of other groups in the SxOH* matrix. Thus, SxOH* was hydrolysed in 0.5 M aqueous $NaHCO_3$, and the ammonia determined as a function of time. Most of the ammonia was liberated within the first 6 h, giving after 21 h totally 132 μmol of ammonia per g SxOH* (Exp. 6). It may be noted that this SxOH* only contained 1.9 % N, while, in most experiments performed, the nitrogen content was 5.6 – 6.0 %.

Dextran * was obtained by reacting concentrated low molecular weight dextran solutions with BrCN in alkaline media. The product was kept in water for several days to make sure that the unstable five-membered *trans*-cyclic imidocarbonate groups,[5] which also are formed, were completely hydrolysed. The dextran* was then reacted with some amino compounds and the molecular weights and the amino acid contents of the products determined (Exp. 9A and B).

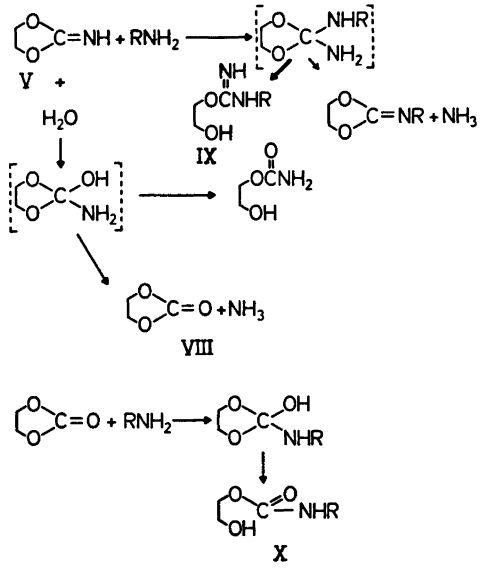
DISCUSSION

The reaction of BrCN in dilute alkaline solution with vicinal *trans*-hydroxyl groups as in Sephadex or dextran is represented schematically in Scheme 1. The structures A[15] and B are proposed as intermediated leading to end-products with the structures V – VIII.

Proof of the existence of the reactive groups V, the carbamate groups VI, and the carbonate groups VIII was presented in studies on a model compound, MBGP.[6] The acyclic imidocarbonate structures VII are formed mainly by cross-linking two glucose units in different dextran chains. This is indicated by the reduced swelling capacity of the SxOH* and by the increase in molecular weight when low molecular weight dextrans are treated with excess of BrCN [2] (Exp. 8A and B). The amount of VIII in SxOH* is low since its characteristic IR-absorption at 1800 – 1830 cm^{-1} is very weak. Under favourable activation conditions, it has been found that about 50 % of the nitrogen incorporated in the activated products is due



Scheme 1.



Scheme 2.

to imidocarbonate groups (V).[5] Thus, it can be concluded that the reactive groups V and the carbamate groups (VI) are the main structures present in BrCN activated carbohydrates, containing vicinal *trans*-hydroxyl groups and that V and VI both have IR-absorption at 1715 cm^{-1}.

The reaction of V with an amino compound in $NaHCO_3$ solution and the side reaction the alkaline hydrolysis of V, is shown in Scheme 2. The first step is presumably a nucleophilic addition of the amino compound to V, giving a five-membered unstable intermediate which subsequently rearranges to the stable isourea derivative IX. Investigations with a model compound (MBGP) have resulted in the isolation and characterization of only one type of addition product, the isourea derivative. Only a few percent of the total amount of ammonia anticipated, if *N*-substituted imidocarbonates are the only reaction products, has been found. It may also be pointed out that the amount of NH_3 released is rather constant and thus independent of the amount of amino compound incorporated in the Sephadex matrix (Tables 3 and 4). Furthermore, as shown in Tables 1 – 2, particularly where the amount of amino compound in the products is high, the calculated nitrogen content for the isourea structure agrees fairly well with the value found.

The hydrolysis of V under the coupling conditions used may compete with the addition of the amino compound to SxOH*. Thus, V may by addition of water be transformed into a reactive intermediate (Scheme 2), giving either the carbamate or the carbonate, the latter formed with concomitant release of ammonia.

Several products obtained by reacting SxOH* with amino compounds have been examined by IR-spectroscopy. No absorption at 1800 – 1830 cm^{-1}, characteristic of the carbonate group, has been found. If, however, some carbonate groups are formed, they may react with the amino compound, giving as end-products *N*-substituted carbamates (X), which as discussed above can only be present in a few percent.

When dextran*, in which the reactive *trans*-cyclic imidocarbonate groups have been removed, is treated with amino compounds under mild basic conditions, the molecular weight decreases more than when the dextran* is treated similarly but in the absence of the amino compounds. This indicates that the acyclic structures VII, which are likely to be the remaining reactive groups, react at least to some extent with the amino compounds giving structures IX and X. Stable, low molecular weight acyclic imidocarbonates, analogous to XI, are known,[16] and the formation of such structures cannot be excluded. The main part of the decrease in molecular weight arises from the hydrolytic cleavage of the acyclic imidocarbonates (VII) with the formation of carbamates (VI). Small amounts of the acyclic carbonates (XII) may also be formed. These may then react with amino compounds to give the *N*-substituted carbamates (X).

It has been shown that some of the ammonia released during the coupling procedure may arise from hydrolysis of carbamates and from the formation of imidocarbonates or carbonates. However, the main part was demonstrated to originate from hydrolysis of other groups in the SxOH*. At present we can only speculate as to which groups are responsible and suggest that during the activation procedure part of the imidocarbonate groups (V) may have reacted with BrCN to give cyanamide groups. During the mild alkaline conditions of the coupling reaction, nitrogen compounds may be released from these groups and give ammonia during the strong alkaline conditions of the Kjeldahl analysis.

The ammonia released from SxOH* may react with imidocarbonate groups in the SxOH*, yielding isourea groups. However, from the experiments with added ammonia (Table 4), it is evident that this reaction is of little importance.

Two Dibenzofurans Obtained on Oxidative Degradation of the Moss *Polytrichum commune* Hedw.

MAGNUS ERICKSON[a] and GERHARD E. MIKSCHE[b]

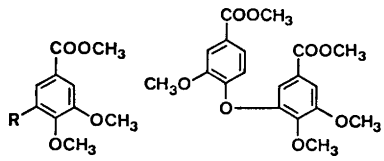
[a]Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden and [b]Organic Chemistry 2, Chemical Center, Box 740, S-220 07 Lund 7, Sweden

Stalks of the moss *Polytrichum commune* Hedw. were finely ground and the resulting meal was extracted and heated at 170° with aqueous NaOH-Na_2S for 3 h. The dissolved material was methylated with dimethyl sulfate, oxidized with $KMnO_4$-$NaIO_4$ in aqueous sodium hydroxide and with H_2O_2 in aqueous sodium carbonate. The crude mixture of products was treated with diazomethane. In addition to methyl veratrate and dimethyl isohemipate, two new esters were isolated and identified as methyl 4,7,9-trimethoxy-2-dibenzofurancarboxylate and methyl 3-(4,7,9-trimethoxy-2-dibenzofuranyl)-propanoate. Neither dimethyl 2′,5,6-trimethoxydiphenylether-3,4′-dicarboxylate nor dimethyl 5,5′-dehydrodiveratrate, two oxidation products characteristic of guaiacyl and guaiacyl-syringyl lignins, could be detected. This finding indicates that *Polytrichum commune* does not contain lignin.

A method for the structural characterization of lignins has recently been described.[1] This method (in this paper referred to as "oxidative degradation") comprises the solubilization of the lignin of the preextracted, finely ground plant material by heating with aqueous NaOH-Na_2S for 3 h at 170°, followed by methylation with dimethyl sulfate, and oxidation with permanganate-periodate in aqueous sodium hydroxide and with H_2O_2 in aqueous sodium carbonate. The resulting mixture of aryl carboxylic acids is treated with diazomethane in methanol-ether, and the major esters thus formed are measured by quantitative gas-liquid chromatography (GLC). Their relative amounts are indicative of the type of lignin originally present.

As the presence of lignin in non-vascular plants, notably the taxon Bryophyta, is still a matter of dispute (for a recent survey, see Ref. 2), we decided to investigate some mosses (Musci) and liverworts (Hepaticae) by this method. The present paper is restricted to the presentation of the results from the oxidative degradation of stalks of the moss *Polytrichum commune* Hedw.

Gas-liquid chromatography of the methyl esters obtained on oxidative degradation of preextracted *Polytrichum commune* meal (200 mg) indicated the presence of methyl veratrate (*1*) and dimethyl isohemipate (*2*), later confirmed by mass spectrometry (MS). Esters *1* and *2* have also been found to be the dominant members of the mononuclear ester fractions resulting from the oxidative degradation of a number of conifers [1,3] and ferns.[3]



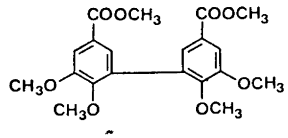
1 R = H
2 R = $COOCH_3$

3

The composition of the binuclear ester fraction, as roughly defined by the volatility properties of its members in GLC analysis, was completely different from the composition of corresponding fractions obtained from guaiacyl

* Part XIII of the series "Gas Chromatographic Analysis of Lignin Oxidation Products". Part XII, see Ref. 13.

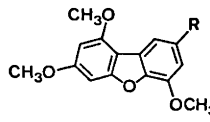
lignins (the lignins of most gymnosperms and Pteridophyta). Dimethyl 2′,5,6-trimethoxydiphenylether-3,4′-dicarboxylate (*3*) and dimethyl 5,5′-dehydrodiveratrate (*4*), the two major binuclear esters obtained from guaiacyl lignins, could not be detected among the degradation products of *Polytrichum commune* Hedw.



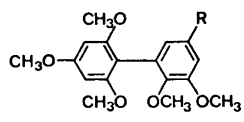
4

Instead, two unknown compounds, termed *A* and *B*, dominated the binuclear ester fraction from the moss. The mass spectra of *A* (molecular ion at $m/e = 316$, base peak) and of *B* (molecular ion at $m/e = 344$, base peak) were rather uninformative concerning the basic skeleton of these compounds. High resolution mass spectrometry indicated an elemental composition of $C_{17}H_{16}O_6$ for *A* and $C_{19}H_{20}O_6$ for *B*.

In order to obtain *A* and *B* in milligram quantities for NMR analysis, a total of 7 g of moss meal was oxidatively degraded. Separation of the products by preparative thin layer chromatography (TLC) yielded 15 mg of *A*, colourless crystals of m.p. 196 – 198°, and 19 mg of *B*, colourless crystals of m.p. 84.5 – 85.5°. The NMR spectrum of *A* revealed the presence of four methoxyl groups and four deshielded protons, coupled in pairs with coupling constants corresponding to *m*-positioned aromatic protons. The shift of the strongly deshielded proton at δ 8.27 ppm was indicative of in-plane deshielding by a neighbouring ring (*cf.* Ref. 4). On the basis of this spectroscopic evidence, structure *5*, methyl 4,7,9-trimethoxy-2-dibenzofurancarboxylate, was assigned to *A*. This assignment was confirmed by synthesis of *5 via* the biphenyls *8*, *9*, *10*, and *11*, and the dibenzofuran *7*.



5 R = $COOCH_3$
6 R = $CH_2CH_2COOCH_3$
7 R = CH_3



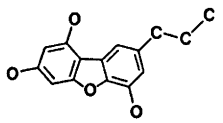
8 R = $COOH$
9 R = $COOCH_3$
10 R = CH_2OH
11 R = CH_3

The NMR spectrum of *B* indicated the same ring system as in *A*, but with the methoxycarbonyl substituent replaced by a 2-methoxycarbonylethyl side chain. This was supported by the prominent M – 73 fragment (CH_2-$COOCH_3$) in the mass spectrum of *B*. Furthermore, *B* was found to yield *A* on oxidative degradation. It thus could be concluded that *B* is represented by structure *6*, methyl 3-(4,7,9-trimethoxy-2-dibenzofuranyl)-propanoate. It seems very likely that, on oxidation of *Polytrichum commune* meal, *A* is formed *via B* or from a parent structure common to *A* and *B*.

It should be noted that this method for oxidative degradation originally had been optimized for the characterization of lignins in vascular plants. The reason why *B* is not completely oxidized to *A* in the experiments with moss meal must be due to an insufficiency of oxidant. This insufficiency may be caused by the comparatively large amounts of organic material dissolved by the NaOH-Na_2S pretreatment of the moss meal.

Since in the method used, methylation of phenolic hydroxyl groups precedes the oxidative degradation, nothing could be ascertained about the number of methylated phenolic hydroxyl groups originally present in the parent structures of type *12*. In a degradation experiment with *Polytrichum commune* meal, an answer to this question was found by using hexadeuterio-dimethyl sulfate in the methylation step. Mass spectra of deuterated components corresponding to *5* and *6* demonstrated the incorporation of three trideuterio-methyl groups (M + 9) per molecule. Thus all the methoxyl groups of *A* and *B* are derived from non-methylated phenolic hydroxyl groups originally present in parent structures of type *12*. By the same technique, it was furthermore demonstrated that the esters *1* and *2* are derived from non-methylated 4-alkyl and 3,5-dialkyl pyrocatechol units, respectively, rather than from the corresponding units of guaiacyl type as in guaiacyl and guaiacyl-syringyl lignins. The demethylation of methoxyl groups by the pretreatment with NaOH-Na_2S at 170° is comparatively slow and can be neglected.[5]

When *Polytrichum commune* meal was heated with NaOH-Na_2S, methylated with dimethyl



12

sulfate, and treated with diazomethane, omitting the oxidation steps, compound *B* (*6*) could be detected while *A* (*5*) was absent. On the other hand, neither of them was found to be formed on mild alkaline hydrolysis of the plant material with aqueous KOH at 25°, or by boiling with 0.2 M HCl in dioxane-water (9:1, "acidolysis" [6]). To rule out the possibility of the precursor of *B* being an artefact formed from phloroglucinol and 4-alkylpyrocatechol structures eventually present, 4-methylcatechol and phloroglucinol were heated with aqueous NaOH-Na_2S at 170° and the reaction product methylated. No formation of *7* could be observed, however.

The biogenesis of the dibenzofuran structures yielding *A* and *B* remains to be properly explained. Obviously, one part of structure *6* is a phenylpropane, probably formed *via* a shikimic acid pathway. The substitution pattern of the other moiety is that of phloroglucinol and indicates formation by head–to-tail condensation of acetate units followed by cyclisation.

From the experiments described above it can thus be concluded that the moss *Polytrichum commune* Hedw. contains 3-(2-dibenzofuranyl)-propyl structures with oxygen functions in the 4-, 7-, and 9- positions (*12*). These entities are not connected with the bulk cell wall material by ester linkages. *Polytrichum commune* does not contain lignin, although structures partially derived from C_6C_3-units are present. This finding invalidates the postulation [7] that *Polytrichum commune* has a lignin of the *p*-hydroxyphenyl type.

EXPERIMENTAL

Plant material. Upper parts of stalks of *Polytrichum commune* Hedw., as long as covered with green leaves, were collected in Halland (southern Sweden). After removal of the leaves and fixation in ethanol, the stalks were ground and the resulting meal extracted and dried as described.[1]

Treatment of the moss meal with NaOH-Na_2S, methylation and oxidation. See Ref. 1.

GLC. See Ref. 1. *Retention times* (SE 30, relative to *4*, $t=240°$): *5*, 0.92; *6*, 1.43; *7*, 0.40; *9*, 0.60; *11*, 0.24.

MS. Identification: AEI MS 20. *High resolution:* AEI MS 902. *Electron energy:* 70 eV. *Source:* 200°. *Intensity relative to base peak (rel. int.):* ≥ 5 %. *Lower mass limit:* $m/e=100$.

NMR. 60 MHz, in $CDCl_3$, tetramethylsilane as internal standard, δ-values (ppm).

TLC. Silica gel HF 254, Merck. R_F*-values* (acetone-hexane 1:2): *1*, 0.29; *A*, 0.35; *B*, 0.25.

Isolation of compounds A *and* B. For this purpose, 7 g of preextracted moss meal was used. The permanganate oxidation was carried out in 7 batches. Appreciable amounts of MnO_2 precipitated during this reaction. The combined products were treated with H_2O_2 and then with diazomethane as described.[1] The resulting viscous oil (0.5 g) was chromatographed on preparative TLC plates (acetone-hexane 1:2). A major fraction contained compounds *1*, *A* and *B*. These components were separated by repeated TLC on analytical plates (toluene, acetone-hexane 1:2).

Compound *A*, *methyl 4,7,9-trimethoxy-2-dibenzofurancarboxylate* (5), colourless crystals (15 mg), m.p. 196–198° (ethyl acetate-hexane). (Found: C 64.67; H 5.16. Calc. for $C_{17}H_{16}O_6$ (316.32): C 64.55; H 5.10). A mixed m.p. with synthetic compound *5* showed no depression. *A* and synthetic *5* gave identical mass and NMR spectra. *NMR* (3 %): δ 3.86 (3) s, OCH_3; 3.96 (3) s, OCH_3; 4.00 (3) s, OCH_3; 4.07 (3) s, OCH_3; 6.42 (1) d, H_8; 6.71 (1) d, H_6; 7.56 (1) d, H_3; 8.27 (1) d, H_1. $J_{1,3}=1.5$ Hz. $J_{6,8}=1.9$ Hz. *MS. m/e, rel. int.*: 316, 100; 301, 11; 285, 22; 273, 19; 258, 11; 257, 9; 228, 5; 227, 8; 212, 10; 199, 5; 158, 11; 143, 10; 142.5, 24; 106, 11. *Exact mass of the molecular ion.* Found: 316.0936. Calc. for $C_{17}H_{16}O_6$: 316.0947.

Compound *B*, *methyl 3-(4,7,9-trimethoxy-2-dibenzofuranyl)-propanoate* (6), 19 mg, colourless needles, m.p. 84.5–85.5° (ethyl acetate). (Found: C 66.12; H 5.88. Calc. for $C_{19}H_{20}O_6$ (344.37): C 66.27; H 5.85). *NMR* (5 %): δ *ca.* 2.87 (4) m, CH_2CH_2; 3.68 (3) s, OCH_3; 3.85 (3) s, OCH_3; 3.98 (3) s, OCH_3; 4.01 (3) s, OCH_3; 6.35 (1) d, H_8; 6.69 (2) m, H_6 and H_3; 7.41 (1) broad d, H_1. $J_{6,8}=1.9$ Hz. *MS. m/e, rel. int.*: 344, 100; 316, 6; 313, 8; 301, 5; 285, 41; 284, 13; 271, 85; 270, 7; 256, 10; 241, 9; 227, 10; 226, 7; 213, 14; 167, 15; 149, 45; 142.5, 11. *Exact mass of the molecular ion.* Found: 344.1260. Calc. for $C_{19}H_{20}O_6$: 344.1260.

In addition to *A* and *B*, 37 mg of *methyl veratrate* (1), m.p. 56–57° (ether-hexane, Ref. 12, m.p. 58°) was isolated.

Oxidation of B. Dimethyl isohemipate (*2*, as internal standard) and *B* (4 mg) were oxidized with permanganate-periodate, the H_2O_2 step being omitted. After methylation of the products with diazomethane, analysis by GLC dem-

onstrated the formation of *A* in about 60 % yield and the presence of traces of *B* (identification by MS).

Acidolysis of moss meal. 200 mg of preextracted moss meal was acidolyzed.[6] The reaction product was methylated with diazomethane and analyzed by GLC. No *B* could be detected. Trimethylsilylation [Bis(trimethylsilyl)trifluoroacetamide, Pierce, in pyridine], followed by GLC, did not reveal the presence of binuclear degradation products.

Mild alkaline hydrolysis of moss meal. Moss meal (preextracted, 200 mg) was suspended in 25 ml of 2 M KOH under nitrogen for 26 h. After methylation with dimethyl sulfate, the solids were filtered off, the filtrate was neutralized, evaporated to dryness, and oxidized as usual. No *A* or *B* could be detected by GLC.

Treatment of moss meal with NaOH-Na_2S at 170°. The methylated (dimethyl sulfate) products were dissolved in methanol and methylated with ethereal diazomethane. GLC demonstrated the presence of minor amounts of *B*.

Treatment of phloroglucinol and 4-methylpyrocatechol with NaOH-Na_2S at 170°. A solution of 33 mg of 4-methylcatechol and 33 mg of phloroglucinol in 10 ml of aqueous NaOH-Na_2S was heated to 170° for 3 h. The solution was acidified, extracted with acetone-$CHCl_3$ (1:1), and the evaporation residue was methylated with dimethyl sulfate. *7* could not be detected by GLC.

Syntheses

2′,4′,5,6,6′-Pentamethoxybiphenyl-3-carboxylic acid (8). A mixture of bromophloroglucinol trimethyl ether[8] (3.8 g), methyl 5-bromoveratrate[9] (4.0 g), and copper bronze (10 g) was heated under nitrogen at 240° for 4 h. The ethyl acetate extract of the products was distilled *in vacuo* at 0.01 Torr. The fraction collected between 160 and 215° was saponified with KOH in MeOH-H_2O. From the alkaline solution, 1.1 g of *2,2′,4,4′,6,6′-hexamethoxybiphenyl*, m.p. 156° (Ref. 10, m.p. 156°), was isolated by extraction with ether. Neutralization afforded a mixture of 5,5′-dehydrodiveratric acid and *8*, from which *8* could be separated by soaking with acetone. Recrystallization from acetone yielded 480 mg of *8*, m.p. 238–239°. (Found: C 61.89; H 5.79. Calc. for $C_{18}H_{20}O_7$ (348.36): C 62.06; H 5.79).

Diazomethane and *8* (450 mg) gave *9* (440 mg), m.p. 145.5–146.5° (ethyl acetate-hexane). (Found: C 62.85; H 6.17. Calc. for $C_{19}H_{22}O_7$ (362.39): C 62.97; H 6.12). *NMR* (10 %): δ 3.65 (3) s, OCH_3; 3.68 (6) s, 2 OCH_3; 3.84 (6) s, 2 OCH_3; 3.92 (3) s, OCH_3; 6.19 (2) s, $H_{3'}$ and $H_{5'}$; 7.48 (1) d, H_4; 7.55 (1) broadened d, H_2. $J_{2,4}$ = 2.0 Hz.

2,2′,3,4′,6′-Pentamethoxy-5-hydroxymethylbiphenyl (10). Reduction of *9* (390 mg) with $LiAlH_4$ (180 mg) in tetrahydrofuran (40 ml) gave *10* as a colourless oil. *NMR* (10 %): δ *ca.* 2.3 (1) broad s, OH; 3.57 (3) s, OCH_3; 3.66 (6) s, 2 OCH_3; 3.83 (6) s, 2 OCH_3; 4.57 (2) s, $ArCH_2$; 6.18 (2) s, $H_{3'}$ and $H_{5'}$; 6.67 (1) d, H_6; 6.98 (1) d, H_4. $J_{4,6}$ = 2.0 Hz.

2,2′,3,4′,6′-Pentamethoxy-5-methylbiphenyl (11). Hydrogenolysis of *10* (Pd, 10 % on charcoal, in ethanol, 1 atm H_2) gave 243 mg of *11*, m.p. 122–123.5° (methanol). (Found: C 67.71; H 7.00. Calc. for $C_{18}H_{22}O_5$ (318.38): C 67.91; H 6.97). *NMR* (10 %): δ 2.30 (3) s, $ArCH_3$; 3.55 (3) s, OCH_3; 3.68 (6) s, 2 OCH_3; 3.82 (6) s, 2 OCH_3; 6.18 (2) s, $H_{3'}$ and $H_{5'}$; 6.52 (1) m, H_6; 6.67 (1) broad d, H_4. $J_{4,6}$ = 1.8 Hz.

1,3,6-Trimethoxy-8-methyl-dibenzofuran (7). For the method, see Ref. 11. The solution of 145 mg *11* in 10 ml HBr (48 %) and 10 ml glacial acetic acid in a thick walled, evacuated glass ampoule was heated to 110° for 24 h. The contents were neutralized with 40 % KOH and the solution extracted with ether (4 × 40 ml), then washed with dithionite and dried. The methylated (diazomethane) product was purified by TLC (acetone-hexane 1:2). Crystallization from methanol yielded 61 mg of *7*, m.p. 108.5–110.5. (Found: C 70.44; H 5.98. Calc. for $C_{16}H_{16}O_4$ (272.31): C 70.57; H 5.92). *NMR* (10 %): δ 2.46 (3) s, $ArCH_3$; 3.83 (3) s, OCH_3; 3.97 (3) s, OCH_3; 4.02 (3) s, OCH_3; 6.35 (1) d, H_2; 6.68 (1) m, H_7; 6.71 (1) d, H_4; 7.40 (1) m, H_9. $J_{2,4}$ = 1.9 Hz.

Methyl 4,7,9-trimethoxy-2-dibenzofurancarboxylate (5). 40 mg of *7* was oxidized, with omission of the H_2O_2 step. After methylation with CH_2N_2, 14 mg of *5*, m.p. 195–197°, were obtained (ethyl acetate). (Found: C 64.09; H 5.13. Calc. for $C_{17}H_{16}O_6$ (316.32): C 64.55; H 5.10).

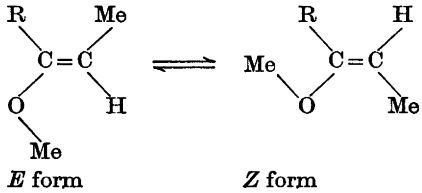
Thermodynamics of Vinyl Ethers. IV. Rotational Isomerism and the Relative Stabilities of the Geometric Isomers of Alkyl 1-Propenyl Ethers

ESKO TASKINEN and PIRJO LIUKAS

Department of Chemistry, University of Turku, SF-20500 Turku 50, Finland

Equilibrium concentrations of the *E* and *Z* forms of some alkyl 1-propenyl ethers have been determined in the neat liquid at various temperatures. The values of $\Delta H°$ and $\Delta S°$ of these reactions suggest the presence of planar s-*cis* and s-*trans* (but not the nonplanar *gauche*) rotamers in the *E* forms of the compounds studied. An exception is *t*-butyl 1-propenyl ether which probably adopts only the s-*trans* configuration in each of the geometric isomers. The enthalpy of the s-*trans* rotamer of the *E* isomer of methyl 1-propenyl ether is about 4.0 kJ mol^{-1} higher than that of the s-*cis* rotamer. The relatively high enthalpy and entropy values of compounds of the type (*Z*)-MeOC(R_1)=CHR_2, where R_1 and R_2 are alkyl groups, are explained to be due to steric interactions between the methoxy group and R_1 in the planar s-*trans* rotamer.

In previous papers,[1-3] the relative stabilities of various α,β-unsaturated (vinyl) ethers differing in either the degree of double bond substitution by alkyl groups or geometric isomerism about the double bond have been studied. A considerable increase of enthalpy (as well as entropy) has been observed to result from the introduction of an alkyl group at the β carbon of the vinyl group in a *cis* position with respect to the methoxy group as in the reaction



E form ⇌ *Z* form (1)

for which, in case R=Me, $\Delta H°$ (g, 298.15 K)= 9.85±0.41 kJ mol^{-1} and $\Delta S°$ (g, 298.15 K)= 13.4±0.9 J K^{-1} mol^{-1}.[3] In the compounds studied previously in this series, the group R has always been larger than hydrogen and therefore it was felt necessary to obtain thermodynamic data for reaction (1) in the case R=H. Compounds of this kind have been the subject of several investigations[4-7] among which the most extensive work is that of Okuyama *et al.*[6] These authors reported the values of the thermodynamic functions of isomerization for reaction (1) (R=H) but, unfortunately, the values of $\Delta H°$, $\Delta S°$, T, and the equilibrium constant K given are in mutual disagreement. In order to check the results of the above authors, the relative stabilities of a number of alkyl 1-propenyl ethers were determined over a relatively wide range of temperature (more than 100 K). In the experimental performance of the measurements, the procedure proposed by Okuyama *et al.*[6] was used with slight modifications.

EXPERIMENTAL

Materials. Methyl 1-propenyl ether (I). 1-Chloropropyl methyl ether was prepared from methanol, propionaldehyde, and hydrogen chloride by the procedure described by Swallen and Boord.[8] The crude chloro ether was dropped in boiling pyridine after which I could be isolated from the reaction mixture by fractional distillation. After redistillation from metallic sodium, the yield of I boiling at 318.9–320.6 K/101.0 kPa was about 60 % (lit.,[5] I*Z* b.p. 316.7–317.2 K/101.9 kPa, I*E* 321.2–321.7

K/102.8 kPa). The product consisted of *ca.* equimolar amounts of the geometric isomers, and it was fractionated further to give the isomer mixtures used in the equilibrations.

Ethyl 1-propenyl ether (II). A 50 % yield of propionaldehyde diethyl acetal (b.p. 396.2–397.2 K/101.3 kPa) was obtained from propionaldehyde (0.5 mol), ethanol (1.75 mol) and concentrated hydrochloric acid (1 cm^3).[9] The acetal was heated with a small amount of sodium hydrogen sulfate in a distillation apparatus and the mixture of ethanol and II which was collected at 338–348 K was washed four times with water and the organic layer was dried over calcium chloride. The yield of II (b.p. 339–347 K/101.6 kPa, lit.,[10] II*Z* 342.2 K/100.6 kPa, II*E* 348.2 K/101.0 kPa) was about 23 %.

Isopropyl 1-propenyl ether (III). Propionaldehyde di-isopropyl acetal (b.p. 316.2 K/1.6 kPa) was prepared as described by Kulesza *et al.*[11] The yield was 34 %. The product was cleaved to a mixture of isopropyl alcohol and III by means of a catalytic amount of sulfanilic acid in the manner described above for II. The yield of III (b.p. 356.0–358.0 K/100.9 kPa, lit.,[10] III*Z* 356.2 K/100.0 kPa, III*E* 363.7 K/100.0 kPa) was 55 %.

s-*Butyl 1-propenyl ether* (IV). This product was prepared as described above for III. The di-*s*-butyl acetal of propionaldehyde (b.p. 340.2 K/1.3 kPa), which was obtained in 22 % yield, was cleaved to *s*-butyl alcohol and IV by distillation from sulfanilic acid. The yield of IV (b.p. 378.0–383.0 K/101.6 kPa) was about 20 %.

t-*Butyl 1-propenyl ether* (V). *t*-Butyl allyl ether was prepared from *t*-butyl alcohol, allyl alcohol and sulfuric acid.[12] The product (b.p. 373.2 K/101.3 kPa) was obtained in *ca.* 6 % yield. It was isomerized to *t*-butyl 1-propenyl ether by means of potassium *t*-butoxide in 1,2-dimethoxyethane.[4] After redistillation from sodium, the yield of V (pure *Z* isomer) was 25 %. The product boiled at 370.2–371.2 K/98.7 kPa.

Phenyl 1-propenyl ether (VI). Allyl phenyl ether was obtained from allyl bromide, phenol and potassium carbonate in acetone.[13] The product (b.p. 349.2–350.2 K/1.6 kPa) was isolated in 80 % yield. It was isomerized to VI (pure *Z* isomer) as described above for V. The yield of the product (b.p. 336.2 K/1.2 kPa, lit.,[14] 344 K/2.0 kPa) was 50 %.

Mercuric acetate (E. Merck AG, *pro analysi*) was used as received.

NMR spectra. The NMR spectra of the vinyl ethers studied were recorded on a 60 MHz Perkin Elmer Model R 10 spectrometer at 307 K. Carbon tetrachloride was used as solvent and tetramethylsilane as internal standard. The concentrations of the vinyl ethers were *ca.* 20 % (v/v). In general, mixtures of isomers were used for recording the spectra and because of the relatively low concentrations of the *E* isomers in the mixtures, accurate peak positions and coupling constants for the *E* forms could not be measured. An exception is I. The NMR spectra are shown in Table 1.

Procedure. The purities of the vinyl ethers used as substrates in the equilibrations were higher than 98 %. This was found by gas chromatography and NMR spectra. The impurity was mainly the corresponding acetal, the peak of which was easily separated from those of the vinyl ethers in the gas chromatographic analysis.

Table 1. NMR spectra of some alkyl 1-propenyl ethers in carbon tetrachloride at 307 K. Peak positions are given in τ values.

[a] The signal of the g proton was not detected.

During the equilibrations, the only detectable side reaction was a slight increase of the amount of the acetal. The isomerization experiments were conducted in the neat liquid with mercuric acetate as catalyst. The amount of the catalyst in the substrate varied from 5 to 10 mass %. The substrate-catalyst combinations were enclosed in small ampoules which were then kept at the appropriate temperatures. For the tracking of the progress of isomerization, ampoules were quickly transferred to an ice-water bath to "stop" the isomerization (this procedure was necessary only for equilibrations carried out considerably above room temperature; at lower temperatures, the slowness of the isomerization reaction made this step superfluous) after which the ampoules were broken and a small volume (*ca.* 20 % of the original sample size) of a suitable organic base (diethyl amine, triethyl amine) was added into the substrate-catalyst mixture to prevent isomerization during the analysis. Okuyama *et al.*[6] did not use any base in their experiments but it is our experience that the reproducibility of the subsequent gas chromatographic analysis was essentially better if the samples of the equilibrium mixture injected into the gas chromatograph contained sufficient amounts of some organic base. After the isomer ratios in successive samples were found to be unchanged, the state of equilibrium was considered having been attained and the following samples were analyzed over sufficiently extended periods of time (usually about three to five times the time necessary for the isomer ratio to become constant) to ascertain that the isomer ratio really remained unchanged. Moreover, in many cases the position of equilibrium was approached from both sides and the results of such experiments were in nice agreement. Peak areas, which were considered to be proportional to the molar concentrations of the isomers,[1] were determined by the cut-and-weigh method. The column used in the analyses contained 10 % Carbowax 1500 on Chromosorb G. The order of elution through this column was *Z*, *E* in each case.

Determination of normal boiling points. The normal boiling points of the compounds studied were determined by the gas chromatographic method described previously.[2] The following compounds were used for the preparation of the reference curve (compound, relative retention time, normal boiling point): ethyl vinyl ether, 0.166, 309.7 K; isobutyl vinyl ether, 0.299, 356.2 K; isobutylidene ethyl ether, 0.366, 366.7 K; 1-methoxycyclopentene, 0.622, 387.0 K; 1-ethoxycyclopentene, 1.000, 409.0 K. The following boiling points were obtained for the compounds I–V (compound, relative retention time, boiling point at 101.3 kPa): I*Z*, 0.181, 316.2 K; I*E*, 0.195, 321.4 K; II*Z*, 0.238, 337.2 K; II*E*, 0.263, 345.4 K; III*Z*, 0.299, 356.2 K; III*E*, 0.329, 363.0 K; IV*Z*, 0.487, 377.9 K; IV*E*, 0.564, 383.2 K; V*Z*, 0.409, 371.5 K; V*E*, 0.473, 376.8 K. For the determination of the boiling points of VI*Z* and VI*E*, the reference curve was made by means of the following data: 1-ethoxycyclopentene, 0.460, 409.0 K; 1-methoxycyclohexene, 0.540, 417.0 K; 1-ethoxycyclohexene, 0.697, 435.0 K; 1-propoxycyclohexene, 1.000, 455.9 K. The relative retention times of VI*Z* and VI*E* were 0.904 and 1.000 corresponding to normal boiling points of 450.9 and 455.9 K, respectively.

RESULTS

The primary results of the equilibration experiments are shown in Table 2. From the values of the equilibrium constant at various temperatures, the values of $\Delta G°$, $\Delta H°$, and $\Delta S°$ at 298.15 K for each $E \rightleftharpoons Z$ isomerization were calculated as described earlier [1] and the results are collected in Table 3. In each case, a strictly linear relation between $\Delta G°$ and temperature was observed. By means of eqns (2) and (10) given in Ref. 2 the values of $\Delta H°$ and $\Delta S°$ in the liquid state were converted to those in the ideal gas state at 298.15 K (Table 4).

DISCUSSION

In general, our results (Table 3) are in qualitative agreement with those of Okuyama *et al.*[6] in the sense that the entropy change in each $E \rightleftharpoons Z$ isomerization is positive and that the enthalpy of isomerization decreases as the size of the alkyl group R increases. Quantitatively, the agreement between our results and those of Okuyama *et al.* is, however, poor. For example, in the reaction V*E*⇌V*Z* (R = *t*-Bu) the entropy change is about 0.4 J K^{-1} mol^{-1} according to Okuyama *et al.* but 6.3 J K^{-1} mol^{-1} according to our results. Similarly, in II*E*⇌II*Z* (R = Et), the values of $\Delta H°$ and $\Delta S°$ are *ca.* 1.6 kJ mol^{-1} and 7.9 J K^{-1} mol^{-1}, respectively, in the paper of Okuyama *et al.* but about −0.65 kJ mol^{-1} and 1.1 J K^{-1} mol^{-1} according to our results.

It seems that the simplest case in the $E \rightleftharpoons Z$ reactions studied is the reaction V*E*⇌V*Z* (R = *t*-Bu). This can be inferred from the bulky size of the *t*-Bu group, which makes the s-*cis* configuration (see below) highly unfavored even in the *E* isomer. In the *Z* isomer the s-*cis* configuration is completely out of question. Therefore, as the orientation of the *t*-BuO group apparently remains unchanged in the reaction, the values of $\Delta H°$ and $\Delta S°$ may be considered

Table 2. Values of the mean equilibrium constant K and its standard error for the $E=Z$ isomerization reactions of some alkyl 1-propenyl ethers in the neat liquid. Mercuric acetate was used as catalyst. c denotes catalyst concentration, t the time from the start of the equilibration when the first accepted sample was analyzed and n the number of independent determinations. Initial contents of the Z isomers in the equilibration mixtures (mol %): a 77.0; b 40.0; c 76.5; d 81.4; e 49.0; f 83.5; g 100.0.

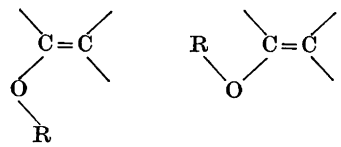
reflecting only the enthalpy and entropy changes due to the altered position of the methyl group attached to the double bond. In the gas phase at 298.15 K, $\Delta H° = -2.94$ kJ mol^{-1}, which shows that there is a kind of attraction between the oxygen atom and the methyl group of the *Z* isomer. A similar situation prevails in 1-chloropropenes in which the enthalpy of the *Z* isomer is reported to be *ca.* 3.8 kJ mol^{-1} lower than that of the *E* isomer.[15] For a compilation of other similar examples, see Ref. 16.

Next let us consider the isomerization of I*E* to I*Z* (R=Me). It is generally accepted that methyl vinyl ether (MVE) exists as a mixture of at least two rotamers the most stable of which is the planar s-*cis* rotamer (see, for example, Ref. 17 and the references cited therein). Thus it seems justified to assume that I*E* also exists mainly in the s-*cis* configuration:



s-*cis* s-*trans*

On the other hand, this configuration is impossible for I*Z* because of steric hindrance. Hence a change in the spatial orientation of the methoxy group is a necessity in the reaction I*E*⇌I*Z*. Apparently, the orientation of the methoxy group in I*Z* is the same as in the less stable rotamer of MVE. Owen and Seip [18] and Aroney *et al.*[19] have suggested that the second rotamer of MVE has a nonplanar heavy atom skeleton which results from the rotation of the methoxy group about the O−C= bond. This view has been critisized by Katritzky *et al.*[20] and Cadioli and Pincelli.[17] The latter authors studied the electronic structure of MVE through SCF calculations. The second rotamer of MVE was predicted to be s-*trans* with an enthalpy about 8.4 kJ mol^{-1} higher than that of s-*cis*. The enthalpy of the nonplanar *gauche* rotamer (suggested by Owen and Seip [18] and Aroney *et al.*[19]) was calculated to be about 24 to 28 kJ mol^{-1} higher than that of the s-*cis* rotamer. The experimental difference in the enthalpies of the two most stable rotamers of MVE, 4.8 ± 1.0 kJ mol^{-1} in the gas phase at 298.15 K,[21] does not essentially differ from the value calculated by Cadioli and Pincelli.

The enthalpy change in I*E*⇌I*Z* is about 3.37 kJ mol^{-1} more positive than in V*E*⇌V*Z* (Table 4), which apparently is to be ascribed to the rotation of the methoxy group from the s-*cis* configuration (in I*E*) to the other configuration, *gauche* or s-*trans* (in I*Z*). It seems, however, that I*E* exists as a mixture of two rotamers (*cf.* MVE) and hence the enthalpy of the mixture of rotamers is higher than that of the pure s-*cis* rotamer, which has the lower enthalpy. The difference between the enthalpies of the rotamers may be estimated as follows. Assuming that the entropy difference between the rotamers is negligible, the mol fraction of the less stable rotamer may be estimated to be about 0.15 (at 298.15 K) if it is further assumed (as a first approximation) that the enthalpy difference does not essentially differ from that between the rotamers of MVE (4.8 kJ mol^{-1}). If the enthalpies of the rotamers of I*E* are denoted by H_t and H_c where H_t is the enthalpy of the less stable rotamer and equal to $(H_c + 4.8)$ kJ mol^{-1} (as a first approximation), the following equation can be written:

$$H_t - [0.85H_c + 0.15(H_c + 4.8)] = 3.37 \qquad (2)$$

Hence $H_t - H_c$ is *ca.* 4.1 kJ mol^{-1}. If this enthalpy difference is used to estimate the mol fractions of the rotamers of I*E* (assuming $\Delta S = 0$), the mol fractions are obtained as 0.84 (s-*cis*) and 0.16 (s-*trans* or *gauche*). Eqn. (2) may now be replaced by

$$H_t - [0.84H_c + 0.16(H_c + 4.1)] = 3.37 \qquad (3)$$

from which $H_t - H_c$ about 4.0 kJ mol^{-1}. The result achieved seems very reasonable.

The entropy change in the I*E*⇌I*Z* isomerization reaction, 2.85 J K^{-1} mol^{-1} in the gas phase at 298.15 K, is considerably less positive than

the entropy change in V*E*⇌V*Z*, 5.26 J K^{-1} mol^{-1}. This is probably due to the presence of two rotamers in I*E*, which, through the entropy of mixing, increases the entropy of I*E* by as much as 3.66 J K^{-1} mol^{-1}, if the mol fractions of the rotamers are taken as 0.84 and 0.16 (see above). Therefore, the entropy of isomerization of the pure s-*cis* rotamer of I*E* to I*Z* (which apparently exists as the pure s-*trans* rotamer, see later) should be about $3.66+2.85\cong6.5$ J K^{-1} mol^{-1}. The contribution of the entropy of mixing on the total entropy is, however, very sensitive to the values of the mol fractions of the rotamers and if the mol fractions are taken as 0.90 and 0.10, the "corrected" entropy change in I*E*⇌I*Z* is obtained as 5.5 J K^{-1} mol^{-1}. Hence the entropy change in this reaction is practically equal to that in V*E*⇌V*Z*, if the presence of rotational isomers in I*E* is taken into account.

It seems that the value of $\Delta S°$ in the reaction I*E*⇌I*Z* is reasonable only if it is accepted that the configuration of the methoxy group of I*Z* is s-*trans*, which may be deduced as follows. If I*Z* existed in the nonplanar *gauche* configuration, this would imply the presence of two enantiomeric isomers in which the C atom of the methoxy group lies either below or above the plane formed by the group of the other heavy atoms (O−C=C−C). In this case the value of the entropy change in the above reaction should be about 5.8 J K^{-1} mol^{-1} ($=R$ ln 2) more positive than can be explained by the reasoning given above. However, as shown above, the "corrected" entropy change is very close to the entropy change in V*E*⇌V*Z* in which no change in the configuration of the *t*-BuO group is expected. Hence only one rotamer is present in I*Z* and this rotamer must be s-*trans*. Thus it seems justified to assume that the configuration of the less stable rotamer of MVE is also s-*trans*, not *gauche*, in accordance with the predictions of Cadioli and Pincelli [17] and Katritzky *et al.*[20]

It is of interest to compare the values of $\Delta H°$ and $\Delta S°$ of the following reactions (gas phase, 298.15 K):

$$\underset{I\!E}{(E)\text{-MeOCH}=\text{CHMe}} \rightleftharpoons \underset{I\!Z}{(Z)\text{-MeOCH}=\text{CHMe}} \quad (4)$$

$\Delta H°=0.43$ kJ mol^{-1}, $\Delta S°=2.85$ J K^{-1} mol^{-1}

$$\underset{VII\!E}{(E)\text{-MeOC(Me)}=\text{CHMe}} \rightleftharpoons \underset{VII\!Z}{(Z)\text{-MeOC(Me)}=\text{CHMe}} \quad (5)$$

$\Delta H°=9.85$ kJ mol^{-1}, $\Delta S°=13.4$ J K^{-1} mol^{-1} (Ref. 3)

A similar change of structure is seen to lead to very different values of $\Delta H°$ and $\Delta S°$ and, curiously enough, the enthalpy change is more positive in the latter reaction despite the *cis* methyl-methyl interaction in VII*E*. As a possible explanation, it might be thought that the planar s-*trans* configuration is strongly unfavoured in VII*Z* because of the close approach of the hydrogen atoms of the methoxy group and those of the α methyl group in this rotamer. As also the planar s-*cis* configuration is impossible in VII*Z*, the methoxy group is forced to adopt a nonplanar configuration in which conjugation between the lone pair electrons of the oxygen atom and the π electrons of the double bond is essentially decreased, which leads to decreased stability. Thus it appears that VII*Z* might exist as a mixture of several rotamers. On the contrary, VII*E* probably exists only in the s-*cis* configuration because of the high enthalpy of the s-*trans* rotamer. The entropy of VII*Z* is increased by the presence of several rotamers and therefore the entropy change in VII*E*⇌VII*Z* is exceptionally positive.

As to the values of $\Delta H°$ in the other isomerization reactions studied, a continuous decrease in $\Delta H°$ is observed as the size of the alkyl group increases. This probably reflects an increase of s-*trans* rotamers in the *E* isomers, due to the increase of strain in the s-*cis* configuration as the alkyl group becomes bulkier. It seems, however, that also the entropy term might favor s-*trans* rotamers because of restricted rotation of the alkyl group in the s-*cis* configuration. This should be apparent from the high entropy change, 37.5 ± 8.3 J K^{-1} mol^{-1}, in the s-*cis* to s-*trans* reorientation of the *t*-BuO group in *t*-butyl formate.[22] The values of $\Delta S°$ in the above reactions are also qualitatively interpretable in terms of increased concentrations of the s-*trans* rotamers in the *E* isomers. A quantitative explanation of the enthalpy and entropy changes in these reactions is hardly possible.

Acknowledgement. The authors thank Mr. Jouko Sohlman for the synthesis of methyl 1-propenyl ether.

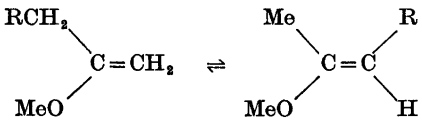
Thermodynamics of Vinyl Ethers. VI. The Stabilizing Effect of Methoxymethyl and (Methoxycarbonyl)methyl Groups on the Ethylenic Linkage of Vinyl Ethers

ESKO TASKINEN and ANTTI MÄKINEN

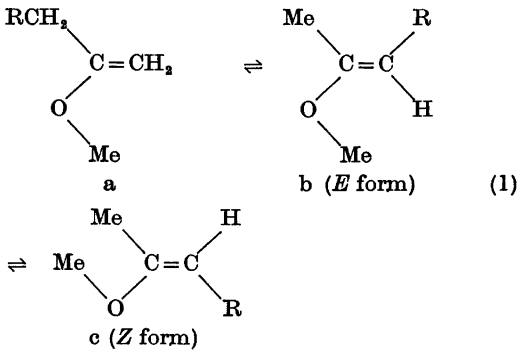
Department of Chemistry, University of Turku, SF-20500 Turku 50, Finland

Thermodynamics of the following isomerization reaction have been studied by means of chemical equilibration:



The values of $\Delta H°$ (g, 298.15 K) (0.53 ± 0.47 kJ mol^{-1} for R = CH_3OCH_2 and 0.77 ± 0.39 kJ mol^{-1} for R = CH_3OCOCH_2) show that the stabilizing effect of a methoxymethyl or (methoxycarbonyl)methyl group on the double bond of a vinyl ether is equal within experimental error to that of an unsubstituted alkyl group, such as Me, Et, or i-Pr.

In part III of this series,[1] thermodynamics of the following isomerization reaction were studied:



(R = Me, Et, i-Pr)

The values of $\Delta H°$ for the a⇌b isomerization were found to be practically independent of the alkyl group R, $\Delta H°$ (g, 298.15 K) = 0.45 ± 0.38, 0.78 ± 0.39, and 0.60 ± 0.37 kJ mol^{-1} for the Me, Et and i-Pr derivatives, respectively, which shows that the stabilizing effect of the alkyl group on the double bond of the b isomer was practically independent of R. Excluding destabilizing steric interactions, the stabilizing energy of the alkyl group was evaluated as *ca.* 4.3 kJ mol^{-1}, which is considerably less than the stabilization, *ca.* 11 kJ mol^{-1}, brought about by R on the double bond of a corresponding olefinic hydrocarbon. This was assumed to be due to electron delocalization in vinyl ethers, which leads to a shift of negative charge to the β carbon of the double bond. Electropositive alkyl groups, when attached to the β carbon, were assumed to oppose this electron delocalization by their inductive effect, and thus their stabilizing effect on vinyl ethers is considerably weaker than on olefins.

However, it might be expected that if the alkyl group R were essentially less electropositive than Me, Et or i-Pr, electron delocalization in b would be restored and thus the group R should stabilize the double bond more effectively. To test the validity of this assumption, thermodynamics of reaction (1) were studied in cases R = CH_3OCH_2 and R = CH_3OCOCH_2. Both of these groups are noticeably more electronegative than Me, Et, or i-Pr.

EXPERIMENTAL

Materials. 2,4-Dimethoxy-1-butene (Ia) and isomers (Ib, Ic). 2-Methoxyethyl methyl ketone was prepared from methyl vinyl ketone and

methanol in the presence of mercuric oxide and boron trifluoride etherate.[2] The yield of the product boiling at 410 – 411 K/101.8 kPa was 60 %. It was converted to its dimethyl acetal by means of trimethyl orthoformate in methanol.[3] The yield of the acetal, b.p. 335 – 336 K/2.7 kPa, was 62 %. The acetal was distilled slowly from Al_2O_3 to give a mixture of methanol and the desired vinyl ethers.[4] The product was washed with water and dried over $CaCl_2$. After redistillation from metallic sodium the yield of the mixture of the isomeric vinyl ethers (b.p. *ca.* 401 K/101.6 kPa) was about 20 %.

Methyl 4-methoxy-4-pentenoate (IIa) and isomers (IIb, IIc). Levulinic acid (0.86 mol), methanol (2.7 mol), benzene (250 cm³), and concentrated sulfuric acid (24 cm³) were refluxed for 24 h, after which the mixture was poured into water and the organic layer was washed with sat. $NaHCO_3$ solution and water. After drying over $CaSO_4$, the product was distilled to give a 22 % yield of the methyl ester of levulinic acid, b.p. 362 – 364 K/2.1 kPa. The ester was converted to its dimethyl acetal, as described above for I. However, the acetal was not isolated but the crude acetal was distilled slowly from a small amount of *p*-toluenesulfonic acid. After a forerun of methanol, a 72 % yield of the isomeric vinyl ethers could be collected at 350 – 359 K/2.3 kPa.

NMR spectra. The NMR spectra were recorded in CCl_4 solutions (*ca.* 20 vol %) at 307 K with TMS as internal standard. NMR spectra could not be obtained for the *Z* isomers because of their low concentration in the synthesis products. For the spectra of Ia and Ib, the isomers were separated by preparative GLC; the spectra of IIa and IIb were recorded on a mixture containing equimolar amounts of IIa and IIb. Peak positions and some coupling constants:

Ia $CH_3OCH_2CH_2C(OCH_3)=CH_2$
a b c d ef
τ 6.72 (a), 6.56 (b), 7.71 (c), 6.48 (d), 6.14 (ef); $J_{bc}=6.9$ Hz.

Ib $(E)-CH_3-C(OCH_3)=CH-CH_2OCH_3$
a b c d e
τ 8.21 (a), 6.50 (b), 5.47 (c), 6.16 (d), 6.80 (e); $J_{bd}=7.5$ Hz.

IIa $CH_3OCOCH_2CH_2C(OCH_3)=CH_2$
a b c d ef
τ 6.39 (a), 7.62 (bc), 6.50 (d), 6.18 (ef); $J_{bc}=0.0$ Hz.

IIb $(E)-CH_3-C(OCH_3)=CH-CH_2COOCH_3$
a b c d e
τ 8.25 (a), 6.50 (b), 5.54 (c), 7.08 (d), 6.39 (e); $J_{cd}=7.4$ Hz.

Procedure. The details of the equilibration procedure have been described previously.[1,5,6] The equilibrations were carried out in cyclohexane solutions with iodine as catalyst. The column used in the gas chromatographic analyses was a 4 m column containing 10 % Carbowax 1500 on Chromosorb G. The isomers were eluted in alphabetical order. Of the geometric isomers b and c, the one with the higher thermodynamic stability (b) was taken as the *E* isomer.[1,6] Because of the relatively poor resolution of the peaks of IIb and IIc, the amount of the latter in the equilibrium mixtures could not be determined with sufficient accuracy. Hence isomerization data involving this compound have not been included in this work. However, the error in the area of the peak of IIb, caused by the poor resolution of the peaks of the geometric isomers, was negligible because of the low concentration of IIc. Peak areas, which were considered to be proportional to the molar concentrations of the isomers,[5] were determined by the cut-and-weigh method.

In the case $R=CH_3OCOCH_2$, the position of equilibrium could be approached from both sides. However, in the case $R=CH_3OCH_2$, only Ia was used for the equilibrations, for sufficient amounts of IIb could not be separated owing to the low yield of the synthesis. In the latter case, the progress of isomerization was followed by GLC and after the isomer composition ceased to change, the position of equilibrium was considered having been attained. To be sure that true equilibrium had been reached, the following samples of the equilibration mixture were analyzed over sufficiently extended periods of time to detect possible changes in the isomer ratios.

Determination of normal boiling points.[6] *Ia, Ib, and Ic:* Reference curve (compound, b.p. at 101.3 kPa, relative retention time): isobutyl vinyl ether, 356.2 K, 0.228; isobutylidene ethyl ether, 366.7 K, 0.279; 1-methoxycyclopentene, 387.0 K, 0.485; 1-ethoxycyclopentene, 409.0 K, 0.780; 1-methoxycyclohexene, 417.1 K, 1.000. The relative retention times of Ia, Ib, and Ic were 0.543, 0.745, and 0.745 leading to normal b.p.'s of 392.7 K, 406.2 K, and 406.2 K, respectively. *IIa, IIb, and IIc:* Reference curve: 1-methoxycyclopentene, 387.0 K, 0.294; 1-ethoxycyclopentene, 409.0 K, 0.391; 1-methoxycyclohexene, 417.1 K, 0.473; 1-ethoxycyclohexene, 435.0 K, 0.648; 1-propoxycyclohexene, 455.9 K, 1.000. The relative retention times of IIa, IIb, and IIc were 0.668, 0.793, and 0.812 leading to normal b.p.'s of 436.8 K, 444.9 K, and 446.1 K, respectively.

RESULTS

Table 1 shows the mean values of the equilibrium constant *K* and its standard error at different temperatures. Table 2 gives the values of $\Delta G°$, $\Delta H°$, and $\Delta S°$ of isomerization at 298.15 K, which were calculated from the variation of the mean equilibrium constant with

temperature, as described previously.[5] The values of $\Delta H°$ and $\Delta S°$ in the ideal gas state at 298.15 K were evaluated as shown in part II of this series.[6]

DISCUSSION

According to Table 2, the values of $\Delta H°$ (g, 298.15 K) for the reaction a⇌b, in cases R = CH_3OCH_2 and R = CH_3OCOCH_2, are very similar and moreover, comparable to those for the same reaction in cases R = Me, Et, or i-Pr, as is seen from Table 3.

As it is apparent that steric repulsions between the two *cis* alkyl groups in the b isomer are very similar in each case, the results of this work reveal the rather unexpected fact that the stabilizing effect of a methoxymethyl or (methoxycarbonyl)methyl group on the double bond of a vinyl ether does not noticeably differ from that of an unsubstituted alkyl group. Thus one might be tempted to draw the conclusion

Table 3.

R	σ^* (Ref. 7)	$\Delta H°$(g, 298.15 K)/kJ mol^{-1}	Ref.
CH_3OCH_2	0.52	0.53 ± 0.47	This work
CH_3OCOCH_2	0.73 [a]	0.77 ± 0.39	This work
CH_3	0.00	0.45 ± 0.38	1
CH_3CH_2	−0.10	0.78 ± 0.39	1
$(CH_3)_2CH$	−0.19	0.60 ± 0.37	1

[a] Obtained by dividing the σ^*-value of the methoxycarbonyl group by 2.8, the factor that approximately corresponds to the attenuation of the inductive effect by one methylene group.

that the inductive effect of the group R has no effect on its stabilizing power. However, the similar stabilization energies may be due to a fortuitous compensation of two opposing effects. Damico [8] has found that in methyl octenoates, equilibrium distribution of the double bond disfavors the 3-octenoate with respect to the 4-, 5-, or 6-octenoates, the equilibrium ratio of the 3-isomer to any of the other isomers mentioned being about 0.3 (at 398 K). Similarly, in methyl pentenyl ethers, the ratio of the 2-pentenyl isomer to the 3-pentenyl isomer was about 0.6 (at 293 K). Thus methoxymethyl and (methoxycarbonyl)methyl groups do not stabilize the double bond of an ordinary olefin so effectively as unsubstituted alkyl groups. As the σ^*-values of the methoxymethyl and (methoxycarbonyl)methyl groups do not significantly differ from that of a hydrogen atom (0.49),[7] it might be thought that these groups restore the electron delocalization that is present in vinyl ethers with no substituents on the β carbon of the vinyl group, but because of their weaker "intrinsic" ability to stabilize olefinic double bonds, the net stabilization on vinyl ethers is comparable to that caused by an unsubstituted alkyl group. However, it seems amazing that the two opposite effects should completely compensate each other in both cases.

The Conformations of Cyclotetradeca-1,8-diyne

ELSE AUGDAHL, GERD BORGEN, JOHANNES DALE and JOSTEIN KRANE

Kjemisk Institutt, Universitetet i Oslo, Oslo 3, Norway

A conformational change takes place in the solid at 30° for cyclotetradeca-1,8-diyne. The high-temperature solid phase conformation is indistinguishable by IR- and Raman-spectroscopy from the solution conformation, which is identified by dynamic ^1H and ^{13}C NMR-spectroscopy. Conformational interconversion mechanisms are discussed.

When cyclotetradeca-1,8-diyne was first synthesized,[1] its high melting point and ease of formation were rationalized on the basis of a single strain-free chair-like conformation (A, Fig. 1) although the closely related boat-like conformation B could not be excluded. There are also other possible ways of constructing a ring conformation with staggered pentamethylene chains (C and D), but these contain a larger number of *gauche* bonds and were therefore disregarded. Nevertheless, the crystal conformation, as determined by King [2] using X-ray methods, turned out to be C and not A or B. This result remained unexplained, and conformation C had to be assumed also for the solution, since very similar IR-spectra were observed for the solid, the melt and the solutions (Fig. 2 c,b,a).

We have now found by calorimetry that there is a solid-solid transition point at 30° with relatively small enthalpy and entropy changes ($\Delta H_{tr} = 1.06$ kcal/mol; $\Delta S_{tr} = 3.5$ e.u.) compared with the changes at the melting point (98°; $\Delta H_m = 5.07$ kcal/mol; $\Delta S_m = 13.7$ e.u.). Since there is a considerable heating of the sample by the beam during the IR-measurement, it is clear that our earlier solid spectrum (Fig. 2c) referred to the high-temperature crystal phase, whereas the crystal structure was determined on the low-temperature phase. In fact, the IR-spectrum of a cooled sample (Fig. 2d) is markedly different, and it may be significant that the bands are more numerous and each individual band is no sharper than in the high-temperature solid. It therefore seemed possible that the upper crystal phase and the solution might after all contain the conformation A, and that by cooling the solid there is a change to the more compact conformation C (see Fig. 1). The latter has a lower symmetry in

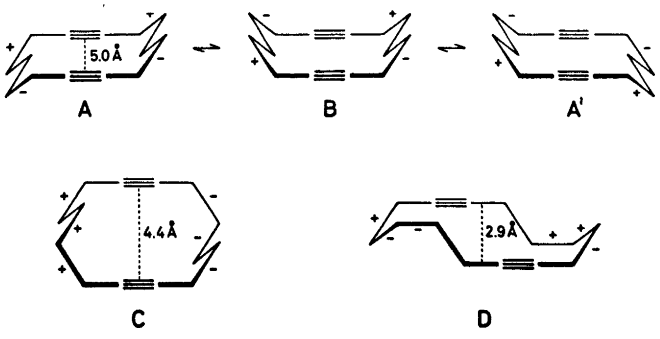

Fig. 1. Possible conformations of cyclotetradeca-1,8-diyne having staggered CH_2-CH_2 bonds. Right- and left-handed *gauche* bonds are indicated by + and − signs.

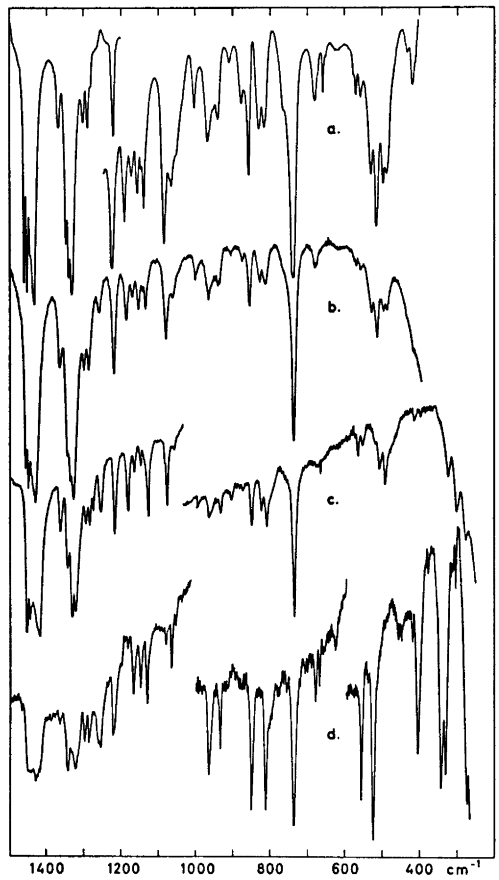

Fig. 2. Infrared spectra of cyclotetradeca-1,8-diyne (a) in solution in CCl_4 (left curve) and in CS_2 (right curve); (b) in liquid film at 110°; (c) in solid film at 40°; and (d) in solid film at −70°.

the pentamethylene chain and must give rise to a greater number of infrared active vibrations.

NMR-SPECTROSCOPY

The 251 MHz ^1H and 63.1 MHz ^{13}C NMR-spectra strongly suggest that A (or B) is in fact the solution conformation. In the compressed ^1H spectrum (Fig. 3) the three bands due to the α-, β-, and γ-protons on cooling broaden at −150° and each then splits up into two bands at −165° ($T_c \sim -160°$ (α-protons)); $\Delta G^{\ddagger} = 5.0 \pm 0.2$ kcal/mol. Only one process is observed. The ^{13}C spectrum on the other hand remains

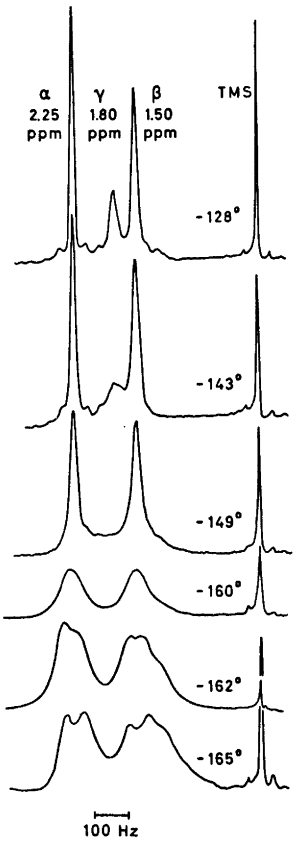

Fig. 3. 251 MHz ^1H spectra at various temperatures of a 1 % solution of cyclotetradeca-1,8-diyne in $CHCl_2F/CHClF_2$ (4:1).

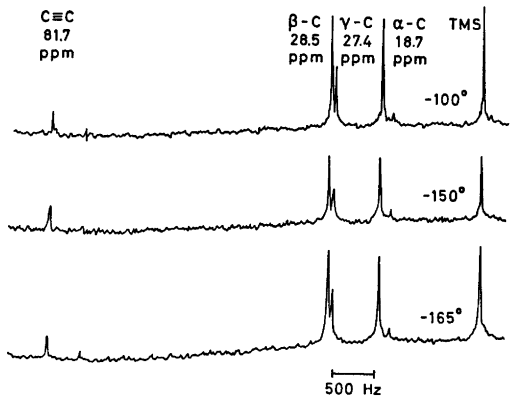

Fig. 4. Proton-decoupled 63.1 MHz ^{13}C Fourier transform spectra (500 transients) at various temperatures of a 4 % solution of cyclotetradeca-1,8-diyne in $CHCl_2F/CHClF_2$ (4:1).

unchanged on cooling through this temperature range (Fig. 4), so that there can be only one type each of all four constitutionally different carbon atoms. The most simple and immediate interpretation is of course that the solution contains the chair-like conformation, and that the geminally non-equivalent hydrogen atoms of each CH_2 become equivalent by direct flipping to the boat-like conformation B and further on to the inverted "chair" A′ (Fig. 1). However, this is an energetically expensive mechanism, since each step must involve a more or less concerted *syn*-eclipsing of two CC-bonds. Also, one cannot *a priori* exclude that the low-temperature spectrum only reflects the apparent symmetry of a rapidly exchanging species of still lower symmetry, such as C or D. We have therefore analysed the situation on the basis of a multistep conformational interconversion scheme constructed on the same principles as earlier [3] for cycloalkanes (Fig. 5).

CONFORMATIONAL INTERCONVERSION PATHS

Assuming that A is the lowest-energy conformation of cyclotetradeca-1,8-diyne, it can be converted over a series of barriers, each involving the full eclipsing of only one CC-bond, to the inverted conformation A′, and this can occur along two different paths (Fig. 5). One path goes through three intermediate conformational minima to B and then through three equivalent minima in the reversed order to A′. The other path goes through nine minima among which are both C and D and their equivalents D′ and C′. Each path, as well as a mixture of both paths in equal or unequal amounts, would satisfy the observed spectra revealing a single process, but it is difficult to estimate which of the several barriers on each is highest and therefore decisive kinetically, and it is equally difficult to guess which of the two paths is actually preferred.

An analogous scheme can be constructed on the assumption that B is the lowest-energy conformation; conformation A then plays the role of an intermediate on one path, and C and D are replaced by similar conformations on the other path. The NMR-spectra can make no distinction between A and B, and it is even possible that the chemical shifts are too close to

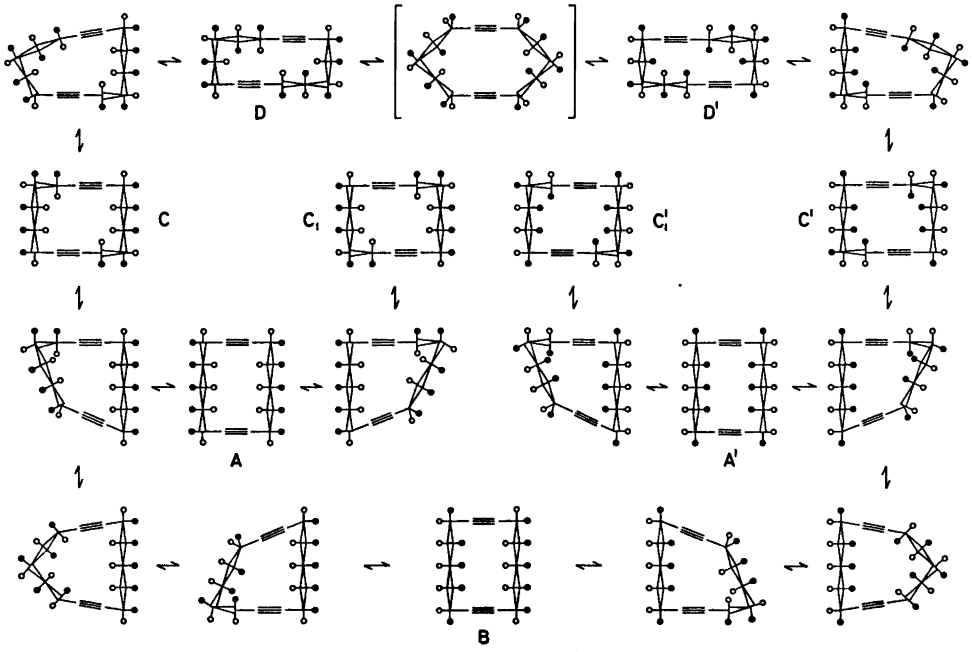

Fig. 5. Conformational interconversion paths for cyclotetradeca-1,8-diyne.

allow detection of a mixture of the two. Also the gas-phase electron-diffraction data, which have been discussed [4] on the basis of the chair-like conformation A of large vibrational amplitudes, would hardly allow a distinction to be made between A and B.

If one of the less symmetric conformations, C or D, had been of lowest energy, two separate processes should have been observed in dynamic NMR-spectroscopy. Thus, the interconversion scheme in Fig. 5 shows that C can either be converted to C′ along the path CDD′C′, whereby unequal α- and β-carbon atoms are fully exchanged, but not their geminally different hydrogen atoms, or it can be converted to C_1 along the path CAC_1, whereby again the carbon atoms but not the hydrogen atoms are exchanged. Only when both processes can occur, will complete exchange of all geminal hydrogen atoms take place, for example by going from C to C_1′ *via* DD′C′A′ or from C′ to C_1 *via* D′DCA. Since the decisive barrier on path CDD′C′ is different from that on path CAC_1, one should expect to observe the high-temperature process only by ^1H spectroscopy and the low-temperature process both by ^1H and ^{13}C spectroscopy. The possibility that the latter has such a low barrier that the coalescence temperature is below −165° seems unlikely. The observed value of 5 kcal/mol is already quite low, considering that full eclipsing of a CC-bond is involved in the barrier and that the conformational minima have completely staggered polymethylene chains and so must be very low in energy.

Thus, also the observation of one, and not two, dynamic processes in NMR-spectroscopy suggests that A (or B) is the solution conformer of cyclotetradeca-1,8-diyne.

CHAIR OR BOAT?

The chair conformation (A) and the boat conformation (B) are expected to have similar energies for the isolated molecule and in solution, since the two pentamethylene chains are too far apart to interact directly, and since there is hardly any rotational barrier for the methyl groups in dimethylacetylene and similar compounds.[5] On the other hand, the crystal lattice may well favour the centro-symmetric chair, as observed for the related molecules 1,6-dioxacyclodeca-3,8-diyne [6] and cyclotetradeca-1,3,8,10-tetryne.[7]

Not only the NMR-spectra are unsuited for settling this question. Also, the IR-spectra are expected to be very similar for the two conformations. The mechanical coupling between the pentamethylene chains being very weak, the hydrogen vibrations, which dominate the IR-spectrum, must obey the local symmetry, which is the same in both conformations. It is therefore dangerous to draw any conclusion from the observation (Fig. 2) that the IR-spectra of the upper solid phase, the melt and the solutions are very nearly identical. On the other hand, the Raman spectra should be dominated by the more strongly coupled skeletal vibrations, and by the C≡C stretching. Thus, if the upper solid contains conformation A, only the symmetric C≡C stretching mode should appear strongly in the Raman spectrum, while a mixture of A and B should show two additional bands due to both C≡C stretching modes of B.

The recorded Raman-spectra (Table 1), however, only confirmed what the IR-spectra had already shown, that the lower solid phase is different from the upper solid phase. Only very marginal differences exist between solution and upper solid phase spectra even at the lowest frequencies. The strongest band in all three phases is at 2230 cm^{-1} and there is no indication of its splitting in solution. The additional band at 2280 cm^{-1} is too far away compared with the very modest splitting expected for so weakly coupled triple bonds, and is probably due to an overtone in Fermi resonance, as observed for other acetylenes.[5] Thus, it can only be concluded that the solution and the upper solid phase contains either of the conformations A or B or an identical mixture of the two.

The possibility that the upper solid phase contains a mixture of A and B is rendered unlikely by the normal magnitude of the entropy of melting. Only expanded crystal lattices displaying a very low entropy of melting, are generally capable of accepting different molecules. Hence, also the solution contains only one conformation.

It remains to make a choice between the chair and the boat, of which only the former has a center of symmetry. This is of course in principle possible by a comparison of IR and Raman spectra, but in such large molecules numerous

accidental coincidences must occur. It seems most likely, however, that the high-temperature solid contains the chair, and we have then to conclude that the chair is also alone in solution and in the melt. Such a conformational preference can only be attributed to a preference for staggering across the triple bond, as observed for simple acetylenes,[5] but the effect seems surprisingly strong in view of the very low barriers to methyl rotation in simple acetylenes.[5]

EXPERIMENTAL

Calorimetric data. A Perkin-Elmer Differential Scanning Calorimeter 1 B was used down to a temperature of −90°.

Infrared spectra. These were recorded with a Perkin-Elmer model 225 spectrometer. Saturated solutions in CS_2 and CCl_4 were measured using 0.5 mm KBr cells. The low temperature spectrum was obtained with a VLT-2 cell from RIIC, cooled with dry ice. The sample was contained between two pressed KBr discs. A heated cell from Perkin-Elmer equipped with KBr optics was used for studying the melt.

Raman spectra. These were measured with a Cary model 81 spectrometer equipped with a CRL 52G argon ion laser (5145 Å). Concentrated solutions in CS_2 and CCl_4 and the upper solid phase were studied using the 180° illumination technique and capillary cells. The low temperature spectrum was obtained under 90° illumination employing a cryostat with a copper tip cooled with liquid nitrogen.

NMR spectra. The spectra of $CHCl_2F/CHClF_2$ solutions were obtained on Prof. Anet's superconducting solenoid NMR spectrometer operating at 251 MHz for protons and at 63.1 MHz for ^{13}C. Acquisition and Fourier transform of free induction spectra were carried out with a Data General Nova computer.

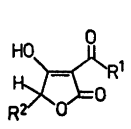
Short Communications

Naturally Occurring Lactones and Lactames. IV. Friedel-Crafts Acylation of the Tetronic Acid Nucleus and Synthesis of (*S*)-Carolic Acid

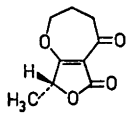
FINN HEDE ANDRESEN,[a] AXEL SVENDSEN[b] and PER M. BOLL[b]

[a] Chemical Laboratory II, University of Copenhagen, The H. C. Ørsted Institute, DK-2100 Copenhagen Ø, Denmark and [b]Department of Chemistry, Odense University, DK-5000 Odense, Denmark

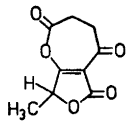
This note is concerned with the Friedel-Crafts acylation of the tetronic acid nucleus as part of our attempt to develop general methods for the synthesis of the more complex mold tetronic acids. The application of this reaction has previously been reported by Haynes and Jamieson,[1] who found that only 3,3-substituted tetronic acids and 3-phenyltetronic acid (in 20 % yield) could be acylated, whereas 5-methyltetronic acid, which is naturally occurring and a possible precursor to some mold tetronic acids, underwent no acylation. Recently Bloomer and Kappler [2] reported the acylation of 5-methyltetronic acid to 3-butyryl-5-methyltetronic acid and to (*RS*)-carolic acid, just as they have synthesized (*R*)-carolic acid by acylating (*R*)-5-methyltetronic acid obtained by degradation of naturally occurring (*R*)-carolic acid.[3]



(1)



(2)



(3)

By modifying the acylation procedure of Haynes and Jamieson [1] we were able to acylate the tetronic acids (*1*) listed in Table 1. Furthermore, acylating (*S*)-5-methyltetronic acid, synthesized from ethyl (*S*)-lactate,[4] with 4-chlorobutyryl chloride, we obtained (*S*)-carolic acid identical in all respects with authentic carolic acid (*3*) isolated from *Penicillium charlesii* except for the specific rotation, which was of opposite sign.

It should be mentioned that in accordance with Haynes and Jamieson [1] cyclohexane-spiro-5-tetronic acid appeared not to undergo acylation.

Attempts to synthesize (*R,S*)-carolinic acid (*3*) from 5-methyltetronic acid by acylating with β-carbomethoxypropionyl chloride was not met with success. On working up the reaction mixture only succinic anhydride could be isolated.

Experimental. Standard acylation procedure. To 2.0 mmol tetronic acid and 2.2 mmol of the appropriate acid chloride was added 3 mmol of tin (IV) chloride. The solution was kept at room temperature for about 2 min to allow the

formation of an enol ester and was then heated to 110° and maintained at this temperature for 3 h. After cooling, the mixture was poured into ice-cold 4 N hydrochloric acid and extracted repeatedly with chloroform, and the extract was shaken with concentrated aqueous sodium hydrogen carbonate. The aqueous layer was acidified with conc. hydrochloric acid and extracted with chloroform. The dried chloroform extract gave on evaporation the pure 3-acylated tetronic acid. Only 3-acetyl- and 3-propionyl-tetronic acid had to be recrystallized from petrol ether.

(R,S)-*Carolic acid.* 5-Methyltetronic acid (4.38 mmol) was acetylated with 500 mmol of 4-chlorobutyryl chloride to give 0.47 g of dark red oil, which solidified when treated with ether. Four recrystallizations from ethyl acetate-light petrol gave 50 mg (5 %) of amber coloured crystals, m.p. 112.5–115.2°. Sublimation rised the m.p. to 116–118°. ^{1}H NMR in $CDCl_3$: 1.46 d (CH_3), 4.64 q (H), 3.45 t ($COCH_2$), 2.28 m ($CH_2CH_2CH_3$), 4.80 t (CH_2O). M_{MS} = 182.05843; M_{calc} = 182.0579 (Lit. [5] m.p. 117°).

(S)-*Carolic acid.* Acylation of 2 mmol of synthetic (*S*)-5-methyltetronic acid [4] resulted in the isolation of 70 mg (14 %) colourless crystals m.p. 130–132° (Lit.[6] 132°). $[\alpha]_{546}^{25}$ −70.8° (c = 0.49, H_2O) (Lit. val. for the enantiomeric form +84°) ^{1}H NMR as above.

Attempted synthesis of (R,S)-*carolinic acid (3).* 5-Methyltetronic acid (4.38 mmol), 5.0 mmol of β-carbethoxypropionyl chloride and 6.50 mmol of tin(IV) chloride reacted very slowly and did not become homogeneous. On working up about 100 mg of a yellow syrupy reaction product was obtained. On acid hydrolysis and extraction with a small amount of chloroform, the chloroform extract contained only succinic anhydride.

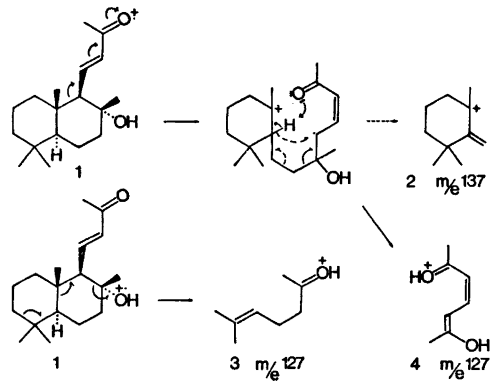
Tobacco Chemistry. 26. Synthesis of 14,15-Bisnor-8-hydroxylabd-11*E*-en-13-one, A New Tobacco Constituent

JOSEPH R. HLUBUCEK, ARNE J. AASEN, SVEN-OLOF ALMQVIST and CURT R. ENZELL*

Research Department, Swedish Tobacco Co., Box 17 007, S-104 62 Stockholm, Sweden

Current research in this laboratory has revealed that tobacco flavour comprises a large number of norisoprenoid constituents.[1,2] The present report deals with the identification and synthesis of a probable diterpenoid degradation product isolated from a medium-volatile, neutral fraction [3] of an extract [4] of sun-cured Greek *Nicotiana tabacum* L.

The elemental composition of this new tobacco compound, $C_{18}H_{30}O_2$, was established by high resolution mass spectrometry. The two oxygen atoms were accomodated by a *3E*-penten-2-oxo-1-ylidene moiety, >CH−CH=CH−CO−CH_3, [978 and 1661 cm^{-1}, 230 nm, δ 2.24 (3H, s), δ 6.16 (1 H, d, J 16 Hz), δ 6.82 (1 H, dd, J 10 and 16 Hz)], and a tertiary hydroxyl group (3450 cm^{-1}) attached to a methyl substituted [δ 1.26, (3 H, s)] carbon atom, >C(OH)−CH_3, respectively. Based on this evidence, the presence of three quaternary methyl groups (singlets at δ 0.83, 0.89, 0.99), its electron-impact induced fragmentation pattern being characteristic of labdane-type diterpenoids devoid of oxygen-substituents on ring A (*cf.* Scheme 1),[5] and no indication of further double bonds, 14,15-bisnor-8-hydroxy-labd-11*E*-en-13-one (*1*)** appeared likely as the structure for this new tobacco compound. This structure, including the stereochemistry inferred in *1*, was confirmed by total synthesis using drimenol [6] (*5*) as starting material.



Scheme 1.

**Nomenclature according to J. W. Rowe, Oct., 1968; personal communication.

formation of an enol ester and was then heated to 110° and maintained at this temperature for 3 h. After cooling, the mixture was poured into ice-cold 4 N hydrochloric acid and extracted repeatedly with chloroform, and the extract was shaken with concentrated aqueous sodium hydrogen carbonate. The aqueous layer was acidified with conc. hydrochloric acid and extracted with chloroform. The dried chloroform extract gave on evaporation the pure 3-acylated tetronic acid. Only 3-acetyl- and 3-propionyl-tetronic acid had to be recrystallized from petrol ether.

(R,S)-*Carolic acid.* 5-Methyltetronic acid (4.38 mmol) was acetylated with 500 mmol of 4-chlorobutyryl chloride to give 0.47 g of dark red oil, which solidified when treated with ether. Four recrystallizations from ethyl acetate-light petrol gave 50 mg (5 %) of amber coloured crystals, m.p. 112.5–115.2°. Sublimation rised the m.p. to 116–118°. ^{1}H NMR in $CDCl_3$: 1.46 d (CH_3), 4.64 q (H), 3.45 t ($COCH_2$), 2.28 m ($CH_2CH_2CH_3$), 4.80 t (CH_2O). M_{MS} = 182.05843; M_{calc} = 182.0579 (Lit. [5] m.p. 117°).

(S)-*Carolic acid.* Acylation of 2 mmol of synthetic (*S*)-5-methyltetronic acid [4] resulted in the isolation of 70 mg (14 %) colourless crystals m.p. 130–132° (Lit.[6] 132°). $[\alpha]_{546}^{25}$ −70.8° (c = 0.49, H_2O) (Lit. val. for the enantiomeric form +84°) ^{1}H NMR as above.

Attempted synthesis of (R,S)-*carolinic acid (3).* 5-Methyltetronic acid (4.38 mmol), 5.0 mmol of β-carbethoxypropionyl chloride and 6.50 mmol of tin(IV) chloride reacted very slowly and did not become homogeneous. On working up about 100 mg of a yellow syrupy reaction product was obtained. On acid hydrolysis and extraction with a small amount of chloroform, the chloroform extract contained only succinic anhydride.

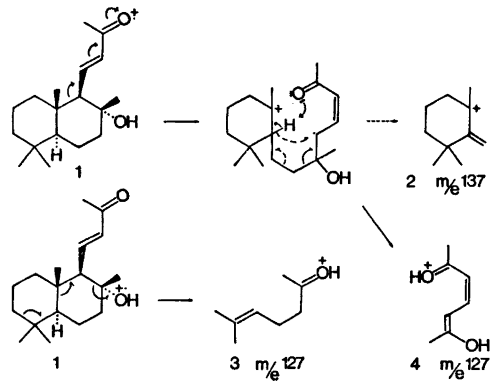
Tobacco Chemistry. 26. Synthesis of 14,15-Bisnor-8-hydroxylabd-11*E*-en-13-one, A New Tobacco Constituent

JOSEPH R. HLUBUCEK, ARNE J. AASEN, SVEN-OLOF ALMQVIST and CURT R. ENZELL*

Research Department, Swedish Tobacco Co., Box 17 007, S-104 62 Stockholm, Sweden

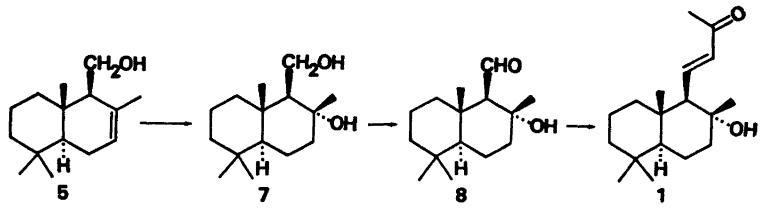
Current research in this laboratory has revealed that tobacco flavour comprises a large number of norisoprenoid constituents.[1,2] The present report deals with the identification and synthesis of a probable diterpenoid degradation product isolated from a medium-volatile, neutral fraction [3] of an extract [4] of sun-cured Greek *Nicotiana tabacum* L.

The elemental composition of this new tobacco compound, $C_{18}H_{30}O_2$, was established by high resolution mass spectrometry. The two oxygen atoms were accomodated by a *3E*-penten-2-oxo-1-ylidene moiety, >CH−CH=CH−CO−CH_3, [978 and 1661 cm^{-1}, 230 nm, δ 2.24 (3H, s), δ 6.16 (1 H, d, J 16 Hz), δ 6.82 (1 H, dd, J 10 and 16 Hz)], and a tertiary hydroxyl group (3450 cm^{-1}) attached to a methyl substituted [δ 1.26, (3 H, s)] carbon atom, >C(OH)−CH_3, respectively. Based on this evidence, the presence of three quaternary methyl groups (singlets at δ 0.83, 0.89, 0.99), its electron-impact induced fragmentation pattern being characteristic of labdane-type diterpenoids devoid of oxygen-substituents on ring A (*cf.* Scheme 1),[5] and no indication of further double bonds, 14,15-bisnor-8-hydroxy-labd-11*E*-en-13-one (*1*)** appeared likely as the structure for this new tobacco compound. This structure, including the stereochemistry inferred in *1*, was confirmed by total synthesis using drimenol [6] (*5*) as starting material.



Scheme 1.

**Nomenclature according to J. W. Rowe, Oct., 1968; personal communication.



Scheme 2.

Drimenol (*5*) was converted to the diol *7* *via* the epoxide *6* as described elsewhere.[7] The diol *7* was oxidised employing Collins' reagent,[8] to the hydroxyaldehyde *8* which in turn was subjected to base-catalysed aldol condensation with acetone followed by *in situ* dehydration furnishing 14,15-bisnor-8-hydroxylabd-11*E*-en-13-one (*1*, Scheme 2), identical in all respects to the natural product. Very recently it has been reported that *1* could be obtained by oxidative degradation of the diterpenoid abienol.[9] 14,15-Bisnor-8-hydroxylabd-11*E*-13-one (*1*) has been isolated previously from the resin of *Abies sibirica* and the published [10] data are in agreement with ours except that *1* isolated by the Russian workers was reported to be optically inactive.

Experimental. NMR, IR, UV, and mass spectra were recorded on Varian XL-100, Digilab FTS-14, Beckmann DB-2A, and LKB 9000 (70 eV) instruments, respectively. Rotations were measured on a Perkin-Elmer 141 instrument, and accurate mass determinations were carried out at the Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm.

*14, 15-Bisnor-8-hydroxylabd-11*E*-en-13-one* (*1*, 40 mg) was isolated from a medium-volatile, neutral fraction [3] of an extract [4] of sun-cured Greek *Nicotiana tabacum*. L. leaves, employing liquid chromatography on silica gel. The fractionation of this medium-volatile material will be described elsewhere.[3] M.p. 126–127° (lit.[10] 126°); MS: *m/e* 278 (M^+, 7), 43 (100), 109 (56), 260 (33), 41 (32), 95 (27), 81 (26), 69 (26), 137 (25), 245 (25); accurate mass determination: $C_{18}H_{30}O_2$, found 278.2250, calc. 278.2246; $C_7H_{11}O_3$, found 127.0764, calc. 127.0759; $C_8H_{15}O$, found 127.1123, calc. 127.1123; δ ($CDCl_3$): 0.83 (3 H, s), 0.89 (3 H, s), 0.99 (3 H, s), 1.26 (3 H, s), 2.24 (3 H, s), 6.16 (1 H, d, *J* 16 Hz), 6.82 (1 H, dd, *J* 10 and 16 Hz); ν_{max}(KBr): 3450 (broad), 3026 (w), 1661 (s), 1633 (shoulder), 1268 (m), 1123 (m), 1084 (m), 986 (m), 978 (m), 970 (shoulder); λ_{max} (EtOH): 230 nm (ε 9300); $[\alpha]_D^{20}$ 15.8° (*c* 0.43, $CHCl_3$).

8-Hydroxydriman-11-al (*8*). 8,11-Dihydroxydrimane (*7*, 17 mg) [7] was added to a suspension of anhydrous CrO_3-pyridine complex (Collins' reagent,[8] 100 mg) in methylene chloride (2 ml). The dark mixture was stirred for 75 min at room temperature, diluted with ether and filtered through celite. The concentrated filtrate was applied in chloroform solution to a silica gel column (2 g) packed in 10 % ether/pentane. Elution with 50 % ether/pentane gave crystalline hydroxyaldehyde *8* (12 mg). δ ($CDCl_3$) 0.85 (3 H, s), 0.91 (3 H, s), 1.14 (3 H, s), 1.40 (3 H, s), 3.3 (1 H, broad s), 10.02 (1 H, d, *J* 2 Hz); ν_{max} (KBr): 3400 (broad), 2740 (w), 1710 (s); $[\alpha]_D^{20}$ 66.2° (*c* 0.58, $CHCl_3$).

*Synthetic 14,15-bisnor-8-hydroxylabd-11*E*-en-13-one* (*1*). 10 % aqueous KOH solution (0.5 ml) was added to a solution of the hydroxyaldehyde *8* (7 mg) in acetone (3 ml) and the mixture heated under reflux for 7 h. The cooled reaction mixture was concentrated *in vacuo*, diluted with ether, washed well with water and dried (Na_2SO_4). The residue obtained after evaporation of the solvent was chromatographed on silica gel (2 g) to yield crystalline *1* (4 mg), indistinguishable from *1* isolated from tobacco.

The Structure of Methyl α-D-Galacturonic Acid Methyl Ester

JOHAN HJORTÅS,[a] BJØRN LARSEN,[b] FRODE MO[a] and SRINUAN THANOMKUL[a]*

[a] Institutt for røntgenteknikk, Universitetet i Trondheim-NTH and [b] Institutt for marin biokjemi, Universitetet i Trondheim-NTH, N-7034 Trondheim-NTH, Norway

Uronic acids are constituents of a number of biologically important macromolecules. The physical and biological properties of these polymers are greatly influenced by the identity of the uronic acid, or acids, present and by conformational parameters for the uronic acid molecules. In contrast to other sugars such information is extremely scarce for the uronic acids. We have therefore initiated a program for the study of uronic acid conformation by X-ray crystallographic methods.

Methyl α-D-galacturonic acid methyl ester was synthesized according to the method of Jones and Stacey.[1] The yield was 20 % and the recrystallized product had a melting point of 148° C and $[\alpha]_D^{20} = 127°$ ($c = 1.0$, water.) Single crystals of suitable size were obtained by crystallization from a mixture of equal volumes of methanol and acetone at elevated temperatures.

Crystal data are: $C_6H_{14}O_7.H_2O$, orthorhombic space group $P2_12_12_1$, cell dimensions (with estimated standard deviations in parentheses) $a = 6.489(3)$ Å, $b = 8.004(3)$ Å, $c = 20.869(12)$ Å, calculated density 1.471 g cm^{-3} (measured 1.473 g cm^{-3}), number of molecules in the unit cell: $Z = 4$.

2386 observed reflexions were collected by an automatic Picker FACS-1 diffractometer using Mo$K\alpha$ radiation and the $\omega/2\theta$ scanning mode with max. $2\theta = 70°$. The structure was solved by a multisolution tangent refinement procedure using the program TANNY.[2] Refinement was performed by means of Fourier and least-squares techniques using programs from the XRAY system.[3] Refinement with isotropic temperature factors for all heavy atoms yielded the conventional R-factor of 0.060.

The pyranose ring has the expected $^4C_1$ chair conformation as shown in Fig. 1. The carbon atom C(8) of the glycosidic methyl group is *gauche* to the ring oxygen atom $O(5)$ and *trans* to C(2). The C(5) methyl ester group is nearly planar and equatorial to the ring, with $O(6)$ *cis* to O(5) and O(7) *trans* to O(5). The carboxyl C(6) – O(6) double bond is 1.190 Å, C(6) – O(7) is 1.326 Å and O(7) – C(7) is 1.443 Å. Other bond lengths and angles are similar to those of methyl α-D-galactopyranoside monohydrate[4] and other hexoses.[5]

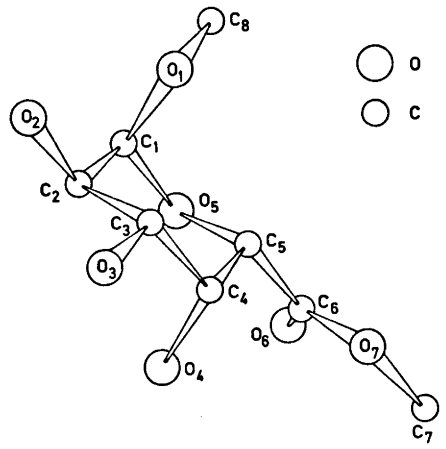

Fig. 1. Projection of the molecule, only with heavy atoms, on 100 plane.

Further refinement and a more detailed account of the structure will be published elsewhere. Additional work is in progress with the aim of obtaining information on the binding of cations to the uronic acids and their polymers. The results will also be valuable as basis for investigations of ionic bonds in solutions by other physical methods, *e.g.* NMR spectroscopy.

This work is part of S.T.'s thesis for a degree of Licentiatus Technicae (Lic. techn.) at The University in Trondheim-NTH sponsored by the Norwegian Agency for International Development (NORAD) which is gratefully acknowledged.

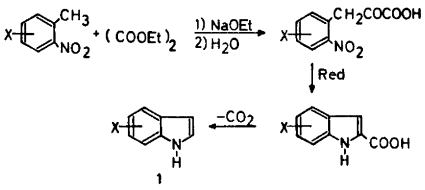
New Syntheses of Substituted Indoles

JAN BAKKE

AB Bofors, Nobelkrut, Bofors, Sweden*

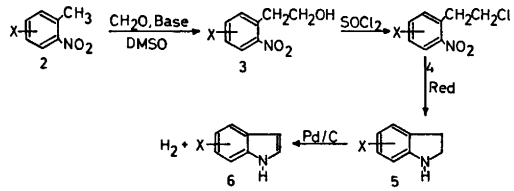
A number of syntheses of indoles are recorded.[1] Few of these, however, are suitable for the synthesis of indoles substituted in the benzene ring and unsubstituted in the pyrrole ring (*e.g. 1*). The Reissert synthesis [2] is one of the more used methods for the preparation of this type of indole, and has been applied in the case of number of substituted indoles:[3,4]



Although the yields are high for the first two steps, the decarboxylation in the last step gives highly varying yields.[3] A new synthesis for indoles of the type *1* could therefore be useful.

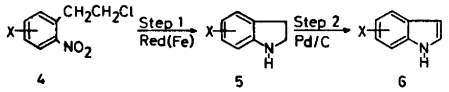
Some time ago, the addition of substituted and unsubstituted *o*- and *p*-nitrotoluenes to various aldehydes was reported.[5] The products (*3*) from the addition of *o*-nitrotoluenes (*2*) to formaldehyde were considered as potential starting materials for the synthesis of indoles as they contained a chain of two carbon atoms in the *ortho* position to a nitrogen atom. One possible way to the indoles would be *via* the 2,3-dihydroindoles (*5*). Ferber [6] obtained dihydroindole itself (*5*, X=H) by reduction and cyclization of 2-*o*-(nitrophenyl)ethyl chloride (*4*, X=H) prepared by nitration of 2-phenylethyl chloride.

Chlorination with thionyl chloride of 2-(*o*-nitrophenyl)ethanol obtained from *o*-nitrotoluene and formaldehyde gave 2-(*o*-nitrophenyl)ethyl chloride (*4*, X=H) in 80 % yield. Reduction of this compound by iron turnings activated by hydrochloric acid in aqueous suspension gave 2,3-dihydroindole (*5*, X=H) which was isolated by steam distillation (yield 85 %). The dehydrogenation of dihydroindole to indole was performed with palladium on carbon in refluxing toluene (yield 93 %). Volumetric experiments showed that 1 mol of hydrogen gas was evolved in the course of this reaction.



After success in the synthesis of indole itself, the reaction sequence was tried for some substituted indoles. The results are given in Table 1. The conditions are not optimalized and the results might be improved by using bromination instead of chlorination of the alcohol *3*. In some cases, catalytic hydrogenation may be of advantage instead of the reduction by iron turnings.

Table 1. Synthesis of substituted indoles from *o*-nitrotoluenes.



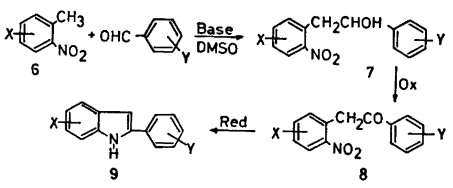
X (pos. in *4*)	Yield, Step 1, %	Yield, Step 2[a], %
H	85	93
4-Cl	55	52 [b]
6-Cl	71	73 (m.p. 84–86°)[c]
4-NO_2	59	64 (m.p. 105–107°)[d]

[a] Products were identified by comparison of IR, GLC, and m.p. (for crystalline compounds) with authentic samples. Products containing halogens gave satisfactory halogen analyses. [b] GLC showed the product to be 96 % pure and to contain 3 % indole. [c] M.p. lit.[3] 86–87°. [d] The products were 4-aminodihydroindole and 4-aminoindole, m.p. 4-aminoindole lit.[4] 108°.

This convenient preparation of dihydroindole itself also facilitates the synthesis of indoles substituted in the 5- or 7-positions. Terentév *et al.*[7] have synthesized such indoles by substitution of dihydroindole followed by dehydrogenation. The limitation of our procedure with respect to the preparation of 5- or 7-substituted indoles lies in the fact that the intermediate nitrotoluenes substituted at position 3 or 5 are not readily available.

When *o*-nitrotoluenes are added to arylaldehydes, 2-arylindoles (*9*) may be synthesized by oxidation of the alcohols *7* followed by reduction of the ketones *8*:

* Present address: University of Trondheim, Department of Chemistry, Norges lærerhøgskole, N-7000 Trondheim, Norway.



o-Nitrotoluene and benzaldehyde gave 1-phenyl-2-(*o*-nitrophenyl)ethanol (*7*, X = Y = H) which was oxidized by concentrated nitric acid in the presence of chloroform. *o*-Nitrobenzyl phenyl ketone (*8*, X = Y = H) was obtained in 98 % yield (m.p. 75 – 77°, IR (KBr): 3100, 2910, 1690, 1620, 1600, 1580, 1520, 1450, 1410, 1360, 1290, 1210, 1005, 995, 790, 730, 700, 690, 675 cm^{-1}).

Catalytic reduction of *8* gave 2-phenylindole in 85 % yield (m.p. 187 – 188°, lit.[8] 186°).

Our results thus show two useful routes to substituted indoles; one to indoles substituted in the benzene ring and unsubstituted in the pyrrol ring, and one to indoles with an aryl group in the 2-position.

The Conformation of a *gem*-Dimethyl-substituted Cycloheptene

GERD BORGEN

Kjemisk Institutt, Universitetet i Oslo, Oslo 3, Norway

In a previous paper[1] the synthesis of a cycloheptene derivative, 2-carboxy-3,3,6,6-tetramethyl-cycloheptene is described. Variable-temperature NMR-spectra are now obtained of this compound, with a coalescence temperature as high as −40° in 100 MHz NMR.

In Fig. 1 the ^1H NMR-spectra of 2-carboxy-3,3,6,6-tetramethyl-cycloheptene in $CDCl_3$ at 35°, −41°, and −66° and in $CHFCl_2$ at −85° are shown.

The absorption for the *gem*-dimethyl protons at lowest field changes gradually into two sharp lines at low temperature, the other methyl signal is broad, but is not resolved at −85°C. The difference in chemical shift between the two methylene protons alpha to the double bond is *ca.* 50 Hz, their geminal coupling constant 14 Hz. The vicinal coupling, to the olefinic proton, of the methylene proton at lowest field is 7 Hz, the other is uncertain because of overlapping of lines from the other methylenes in the ring.

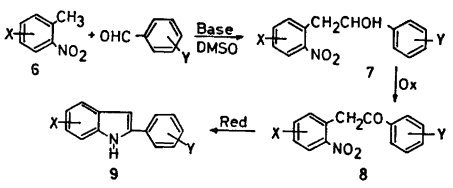
The triplet of the olefinic proton is not fully resolved at −66°, at −85° the signal is hidden by the signals of the proton in the solvent.

The free energy of activation for the exchange process was calculated[2] resulting in $\Delta G^{\ddagger} = 12.2$ kcal/mol.

The infrared spectra were taken of the crystalline solid in KBr and in CS_2 solution. IR-absorption bands at 1730 and 3510 cm^{-1} showed that the solution contained some monomeric acid together with the hydrogen-bonded dimer. Otherwise, the spectra of the two phases were alike which indicate that the cycloheptene skeleton takes the same conformation in solution as in the crystal, and that there is only one conformer in the solution.

The compound melted at 130° and no solid-solid transition was observed by differential calorimetry. The entropy and enthalpy of fusion were $\Delta S = 23.9$ cal/mol deg. and $\Delta H = 9.7$ kcal/mol.

As a result of independent calculations Favini *et al.*[3] found the chair and Allinger *et al.*[4] the boat to be the lowest energy form of cycloheptene. From NMR-data most investigators find the chair conformation in cycloheptene derivatives.[5,6] In 20 different benzocycloheptene derivatives, described by Kabuss *et al.*[7] including one with substituents in 3 and 6 positions analogous to our compound, only one conformer occurred in the low temperature NMR-spectra, presumably that of the chair form. Grunwald and Price[8] found two conformers by low temperature NMR of 3,3,6,6-



o-Nitrotoluene and benzaldehyde gave 1-phenyl-2-(*o*-nitrophenyl)ethanol (*7*, X = Y = H) which was oxidized by concentrated nitric acid in the presence of chloroform. *o*-Nitrobenzyl phenyl ketone (*8*, X = Y = H) was obtained in 98 % yield (m.p. 75 – 77°, IR (KBr): 3100, 2910, 1690, 1620, 1600, 1580, 1520, 1450, 1410, 1360, 1290, 1210, 1005, 995, 790, 730, 700, 690, 675 cm^{-1}).

Catalytic reduction of *8* gave 2-phenylindole in 85 % yield (m.p. 187 – 188°, lit.[8] 186°).

Our results thus show two useful routes to substituted indoles; one to indoles substituted in the benzene ring and unsubstituted in the pyrrol ring, and one to indoles with an aryl group in the 2-position.

The Conformation of a *gem*-Dimethyl-substituted Cycloheptene

GERD BORGEN

Kjemisk Institutt, Universitetet i Oslo, Oslo 3, Norway

In a previous paper[1] the synthesis of a cycloheptene derivative, 2-carboxy-3,3,6,6-tetramethyl-cycloheptene is described. Variable-temperature NMR-spectra are now obtained of this compound, with a coalescence temperature as high as −40° in 100 MHz NMR.

In Fig. 1 the ^1H NMR-spectra of 2-carboxy-3,3,6,6-tetramethyl-cycloheptene in $CDCl_3$ at 35°, −41°, and −66° and in $CHFCl_2$ at −85° are shown.

The absorption for the *gem*-dimethyl protons at lowest field changes gradually into two sharp lines at low temperature, the other methyl signal is broad, but is not resolved at −85°C. The difference in chemical shift between the two methylene protons alpha to the double bond is *ca.* 50 Hz, their geminal coupling constant 14 Hz. The vicinal coupling, to the olefinic proton, of the methylene proton at lowest field is 7 Hz, the other is uncertain because of overlapping of lines from the other methylenes in the ring.

The triplet of the olefinic proton is not fully resolved at −66°, at −85° the signal is hidden by the signals of the proton in the solvent.

The free energy of activation for the exchange process was calculated[2] resulting in $\Delta G^{\ddagger} = 12.2$ kcal/mol.

The infrared spectra were taken of the crystalline solid in KBr and in CS_2 solution. IR-absorption bands at 1730 and 3510 cm^{-1} showed that the solution contained some monomeric acid together with the hydrogen-bonded dimer. Otherwise, the spectra of the two phases were alike which indicate that the cycloheptene skeleton takes the same conformation in solution as in the crystal, and that there is only one conformer in the solution.

The compound melted at 130° and no solid-solid transition was observed by differential calorimetry. The entropy and enthalpy of fusion were $\Delta S = 23.9$ cal/mol deg. and $\Delta H = 9.7$ kcal/mol.

As a result of independent calculations Favini *et al.*[3] found the chair and Allinger *et al.*[4] the boat to be the lowest energy form of cycloheptene. From NMR-data most investigators find the chair conformation in cycloheptene derivatives.[5,6] In 20 different benzocycloheptene derivatives, described by Kabuss *et al.*[7] including one with substituents in 3 and 6 positions analogous to our compound, only one conformer occurred in the low temperature NMR-spectra, presumably that of the chair form. Grunwald and Price[8] found two conformers by low temperature NMR of 3,3,6,6-

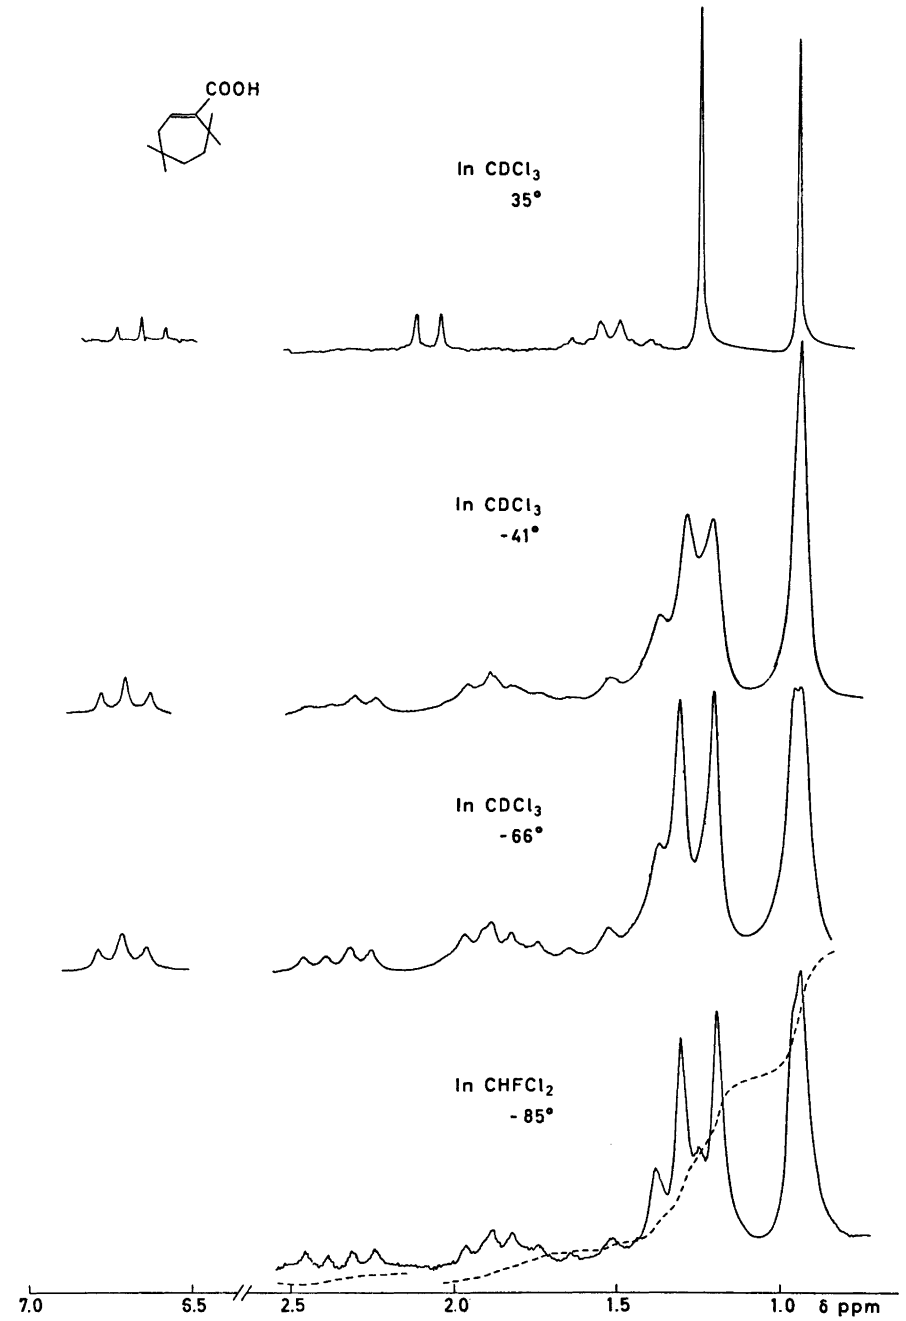

Fig. 1. Changes in the ^1H NMR-spectra of 2-carboxy-3,3,6,6-tetramethylcycloheptene at low temperatures.

tetramethylbenzocycloheptene, a conclusion based on new peaks arising in the methyl region by lowering the temperature. Our cycloheptene derivative has the *gem*-dimethyl groups in the same positions and new peaks arise in the low temperature spectra in lower part of the methyl region. This may be due to a second conformer but could also be explained by overlapping caused by the chemical shifts and the coupling of the methylenes in positions 4 and 5, which in the low temperature spectrum is extended over a region of at least 60 Hz. The fact that the infrared spectra show only one conformer in solution makes the last explanation the most probable and our assumption is that only one conformer is present.

From models it can be seen that the energetically possible forms of 2-carboxy-3,3,6,6-tetramethylcycloheptene are the two inverted chair forms and the two boat forms, however, only one of the two inverted twist boat forms. In the other the methyl-methyl interaction is too severe.

According to Favini *et al.*[3] the dihedral angle, ω_7, is the same in the chair and the boat forms of cycloheptene and = $-72.2°$. The π-contribution to the geminal coupling constant of the 7-protons in these two conformations should then be almost zero.[9] Our observed value $J_7^{gem} = 14$ Hz is as expected for this size ring, (cyclohexane = 13 Hz) and the same as the value found for the 7-protons in benzo-cycloheptene = 14.1 Hz,[6] which is found to take the chair conformation. The conclusion that may be drawn from the π-contribution to the coupling constant of the 7-protons is therefore that our cycloheptene derivative takes either the chair or the boat conformation.

The observed vicinal coupling constant $J_{17} = 7$ Hz is likewise in accordance with the dihedral angles of the chair and boat conformations and the corresponding theoretical values for allylic proton-proton coupling.[10]

The result of the analysis of the low-temperature NMR-spectra of 2-carboxy-3,3,6,6-tetramethylcycloheptene is therefore that the conformation is either the chair or the boat.

The inversion barrier in cycloheptene itself is calculated from NMR-data[11] at $-160°$ to be 5.0 kcal/mol. The *gem*-dimethyl groups make it more difficult to find low-energy interconversion paths between the different forms, and this explains the considerably higher coalescence temperature, $-40°$C, and the corresponding higher barrier, 12.2 kcal/mol, in 2-carboxy-3,3,6,6-tetramethylcycloheptene.

The NMR-spectra were recorded with a Varian HA 100 15 D instrument. For the calorimetric measurements a Perkin-Elmer Differential Scanning Calorimeter IB was used.

Isomerization of ε-Carotene to β-Carotene and of Lutein to Zeaxanthin

A. G. ANDREWES

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway

More than 25 years ago Karrer and Jucker[1] reported the base catalyzed isomerization of α-carotene (*1*, β,ε-carotene by new nomenclature,[2] stereochemistry subsequently assigned[3]) by prolonged treatment with NaOEt/EtOH in benzene at elevated temperature. Extensive decolorization of the carotene occurred and from 30 mg of α-carotene (*1*) a small amount of β-carotene (*2*, β,β-carotene[2]) was isolated. The same authors reported the sodium ethoxide catalyzed isomerization of lutein (*3*, β,ε-carotene-3,3′-diol[2]) to zeaxanthin (*4*, β,β-carotene-3,3′-diol,[2] Scheme 1). More recently, Kargl and Quackenbush[4] reported the isomerization of δ-carotene (*5*, ε,ψ-carotene,[2] stereochemistry later assigned[5]) to γ-carotene (*6*, β,ψ-carotene[2]) by the procedure described by Karrer and Jucker.[1]

tetramethylbenzocycloheptene, a conclusion based on new peaks arising in the methyl region by lowering the temperature. Our cycloheptene derivative has the *gem*-dimethyl groups in the same positions and new peaks arise in the low temperature spectra in lower part of the methyl region. Isomerization of ε-Carotene to β-Carotene and of Lutein to Zeaxanthin

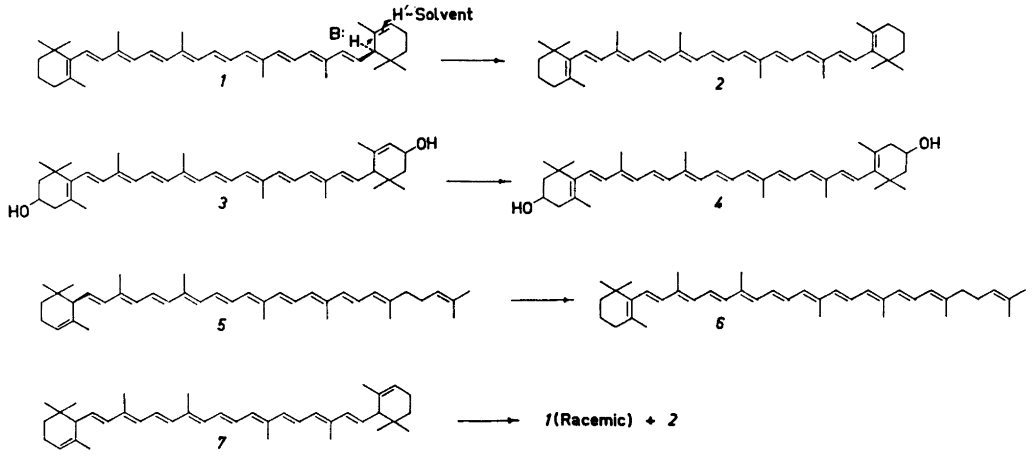
A. G. ANDREWES

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway

More than 25 years ago Karrer and Jucker[1] reported the base catalyzed isomerization of α-carotene (*1*, β,ε-carotene by new nomenclature,[2] stereochemistry subsequently assigned[3]) by prolonged treatment with NaOEt/EtOH in benzene at elevated temperature. Extensive decolorization of the carotene occurred and from 30 mg of α-carotene (*1*) a small amount of β-carotene (*2*, β,β-carotene[2]) was isolated. The same authors reported the sodium ethoxide catalyzed isomerization of lutein (*3*, β,ε-carotene-3,3′-diol[2]) to zeaxanthin (*4*, β,β-carotene-3,3′-diol,[2] Scheme 1). More recently, Kargl and Quackenbush[4] reported the isomerization of δ-carotene (*5*, ε,ψ-carotene,[2] stereochemistry later assigned[5]) to γ-carotene (*6*, β,ψ-carotene[2]) by the procedure described by Karrer and Jucker.[1]



Scheme 1.

Attempts to utilize this procedure for the small scale (0.2 – 1.0 mg) isomerization of α-carotene (*1*) to β-carotene (*2*) or ε-carotene (*7*, ε,ε-carotene [2]) to α-carotene (*1*) and β-carotene (*2*) failed. Buchecker *et al.*[6] reported similar difficulties during attempts to isomerize lutein (*3*) to zeaxanthin (*4*). A modified base catalyzed isomerization was developed to allow small scale conversions of α-type (ε by new nomenclature [2]) end groups to β-type end groups.

Treatment of synthetic, racemic ε-carotene (*7*, 0.125 mg) with KOH/MeOH (20 %, 0.5 ml), benzene (0.5 ml) and anhydrous dimethyl sulfoxide (DMSO, 2 ml) in a sealed tube under an atmosphere of nitrogen at 118°C for 15 – 30 min gave, after the usual extractive isolation and chromatography, α-carotene (*1*, racemic, 16 – 28 %) and β-carotene (*2*, 16 – 21 %). Total pigment recovery including unreacted ε-carotene (*7*) was 51 – 68 %. The composition and total pigment recovery depended on reaction time. Shorter reaction times yielded higher pigment recovery, higher conversion to α-carotene (*1*) and lower conversion to β-carotene (*2*). Increased reaction times resulted in higher conversion to β-carotene but lower total pigment recovery. When NaOEt, KOEt, or *t*-BuOK were used as base the carotene was completely degraded in 10 min.

Attempted isomerization of lutein (*3*) to zeaxanthin (*4*) using the above optimum conditions failed. However, when a solution of lutein (*3*, 1.0 mg), KOMe/MeOH (5 %, 0.5 ml) and DMSO (2 ml) in a sealed tube under N_2 was heated at 118°C for 20 min, zeaxanthin was formed in 10 – 15 % yield. Stereochemical aspects of this reaction are treated separately.[7]

Instruments used were those commonly employed in this laboratory.[8] Identity of all products of the isomerization study was established by electronic absorption spectroscopy, mass spectrometry and chromatography including co-chromatography with authentic specimens. α-Carotene (*1*), β-carotene (*2*), and ε-carotene (*3*) were separated on Al_2O_3 plates developed with petroleum ether, ethyl ether (95 + 5). Lutein (*3*) and zeaxanthin (*4*) were separated on plates prepared from MgO, $Ca(OH)_2$, kieselgel G, $CaSO_4$ and H_2O (9 + 12 + 30 + 3 + 93) activated for 1 h at 100°C; developed with acetone-petroleum ether-isopropanol (20 + 77 + 3).

Carotenoids of Higher Plants. 7.* On the Absolute Configuration of Lutein

A. G. ANDREWES,[a] G. BORCH [b] and S. LIAAEN-JENSEN[a]

[a]Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway and [b]Chemistry Laboratory A, Technical University of Denmark, DK-2800 Lyngby, Denmark

Lutein (*1*) possesses three chiral centers at C-3, C-3′, and C-6′. The absolute configurations at C-3 and C-6′ are generally agreed to be *R*.[1-3] However, the chirality at C-3′ of lutein has been assigned both the *R* and *S* configuration by different investigators. De Ville *et al.*[4] favoured the *S* configuration (*1a*) on the basis of biogenetic correlation of lutein (*1*) with (*R*)-β-cryptoxanthin. Later, Buchecker *et al.*[2,3] presented strong evidence for the *R* configuration at C-3′ of lutein (*1b*) on the basis of PMR analysis of (+)-3-methoxy-α-ionone, chemically derived from lutein (*1b*), and by chemical correlation with synthetic 3-methoxy-α-ionones of established stereochemistry.

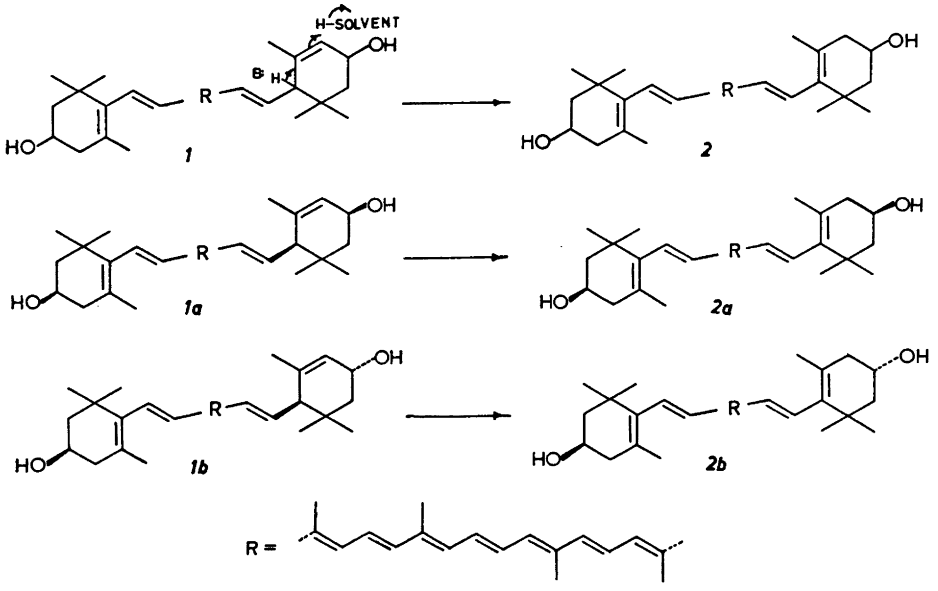
Recently, Andrewes[5] has reported an improved isomerization of lutein (*1*) to zeaxanthin (*2*, Scheme *1*). Provided extensive racemization of the asymmetric centers at 3,3′ of *1* and *2* was avoided, the isomerization of lutein (*1*) to zeaxanthin (*2*) would represent an independent check of the chirality at C-3′ of lutein (*1*). This logical inference has already been pointed out by Buchecker *et al.*[3]

In the absence of racemization, isomerization of (3*R*,3′*S*,6′*R*)-lutein (*1a*) would provide (3*R*,3′*R*)-zeaxanthin (*2a*, identical to natural zeaxanthin, stereochemistry known[6]). On the other hand, isomerization of (3*R*,3′*R*,6′*R*)-lutein (*1b*) would give (3*R*,3′*S*)-zeaxanthin (*2b*, Scheme *1*). From the well tested additivity hypothesis,[6] the former should be optically active while the latter is an optically inactive *meso* compound. CD measurement of zeaxanthin obtained from lutein should then reveal the chirality of lutein at C-3′.

A plausible mechanism for the isomerization of lutein to zeaxanthin is given in Scheme 1. Various mechanisms may be considered to account for possible racemization at C-3,3′ of *1* and *2* via a ketone/enolate type intermediate in alkaline DMSO. To check the extent of racemization to be expected, natural zeaxanthin (*2*, 1.0 mg) was treated with KOMe/MeOH in DMSO as previously described for the isomerization of lutein[5] (no methyl ethers were formed).

The CD spectrum of recovered *trans* zeaxanthin showed the following $\Delta\varepsilon$-values in EPA solution at 285 nm in two separate experiments: $\Delta\varepsilon = -11.7 \pm 10\ \%$ (0.093 mg sample, spectrophotometrically determined using E (1 %, 1 cm) = 2280 at 452 nm in

* No. 6 *Acta Chem. Scand.* *26* (1972) 4121.



Scheme 1.

acetone) and $\Delta\varepsilon = -11.2 \pm 10$ % (0.158 mg sample), compared with $\Delta\varepsilon = -14.8 \pm 10$ % (0.360 mg sample) obtained in a parallel measurement for natural, untreated *trans* zeaxanthin *ex* alfalfa.

The latter value for natural zeaxanthin in EPA solution is in satisfactory agreement with values reported at 285 nm (dioxane) by Buchecker [7] ($\Delta\varepsilon = -16.2$) and by Bartlett *et al.*[6] ($\Delta\varepsilon = -11.8$). The value ($\Delta\varepsilon = -29$) in EPA solution reported by us [8] for zeaxanthin *ex* Flexithrix is now considered erroneously high by a factor of two.

The quantitative CD data for alkali-treated and untreated natural zeaxanthin thus show that 76 – 79 % (± 10 %) retention of optical activity (corresponding to *ca.* 11 % inversion or 22 % racemization) was obtained after alkali treatment of natural zeaxanthin.

Natural lutein (*1*, 5 mg) yielded after isomerization under identical conditions *trans*-zeaxanthin (0.521 mg). The CD-spectrum of zeaxanthin thus prepared showed no optical activity, which supports structure *1b* for lutein.

It might be argued that the allylic 3′-position in the ε-ring of lutein (*1*) may be more susceptible to racemization than the non-allylic 3-position in the β-ring. If this were the case, then zeaxanthin obtained from the isomerization of lutein should still show optical activity due to the residual asymmetry at C-3.

The *R*-chirality of lutein, previously assigned by Buchecker *et al.*,[2,3] is thus considered confirmed.

Lutein and zeaxanthin were separated and identified as described earlier.[5] Instrumentation was as commonly used in our laboratories.[9]

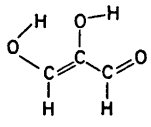
The Crystal Structure of Triose Reductone

DAG SEMMINGSEN

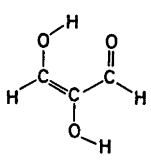
Department of Chemistry, University of Oslo, Oslo 2, Norway

The crystal and molecular structure of triose reductone (2-propen-2,3-diol-1-one) has been determined from three-dimensional X-ray diffraction data measured by counter methods. The space group is $Pna2_1$; $a = 10.601(2)$ Å, $b = 3.647(1)$ Å, $c = 10.008(3)$ Å. The structure has been refined to $R_w = 0.04$ for 811 independent observed reflections. The estimated standard deviations in bond lengths involving non-hydrogen atoms are 0.002 Å. The compound crystallizes in a *trans*-enol form. Both hydrogen bonds are *inter*molecular and form a three-dimensional network.

Triose reductone ($C_3H_4O_3$) is a labile decomposition product which is formed when monosaccharides are heated with alkali in aqueous solutions at elevated temperatures.[1] It is known that the compound carries an aci-reductone group ($-CO-COH=COH-$); however, the molecule may exist in two enol forms:



I



II

In contrast to the acyclic β-diketones the *trans*-enol(I) may also be stabilized through *intra*-molecular hydrogen bonds. A previous X-ray investigation [2] of the rubidium salt of triose reductone has shown that the anion has a *trans* structure corresponding to I. Recent work based upon NMR studies has established the existence of the *cis*-isomer (II) in acetone solutions.[3] However, spectroscopic investigations (infrared, Raman) seem to indicate that in the crystalline state the molecule prefers the *trans*-enol form (I) with the two available hydrogen atoms engaged in *intra*-molecular hydrogen bonds forming two five-membered rings.[4]

The present X-ray diffraction study was undertaken in order to establish the structure in the crystalline state and to examine the hydrogen bonding properties of this compound. A comparative study of the cyclic homologue, reductic acid (2-cyclopentene-2,3-diol-1-one) is now being carried out in this laboratory.

EXPERIMENTAL

The compound was synthesized by the method described by von Euler and Eistert,[1] and purified by slow sublimation (55°C, 0.01 mmHg). Single crystals were obtained by recrystallization from a mixture of ether and hydrochloric acid. Preliminary photographic investigations implied the space group to be either $Pnma$ or $Pna2_1$, thus confirming the results of Aurivillius and Lundgren.[5] The space group $Pna2_1$ was tentatively assumed and proved correct by the successful outcome of the analysis. Unit cell dimensions were determined from measurements of 18 reflections using a manual Picker four-circle diffractometer (CuK radiation). For intensity measurements a crystal with approximate dimensions $0.39 \times 0.27 \times 0.43$ mm^3 was used. Due to instability in air and moisture, the crystal was mounted in a sealed glass capillary. Intensity measurements were made on a SYNTEX P$\bar{1}$ automatic four-circle diffractometer with graphite monochromated Mo$K\alpha$ radiation. The crystal was mounted with the b-axis near the goniometer head spindle axis. Intensities were measured within one octant for $2\theta < 75°$ with the $\omega - 2\theta$ scanning mode and a scan range in 2θ from 1.0° below 2θ (α_1) to 1.0° above 2θ (α_2). The scan speed for each reflection was calculated from a preliminary stationary-crystal stationary-counter measurement of the intensity and varied between 1.0 and 8.0°/min so as to main-

tain satisfactory counting statistics even for reflections of moderate intensity. Above $2\theta = 45°$ a rejection level was specified to avoid measurement of reflections with intensities less than the threshold value. A total of 957 independent intensities were recorded of which 811 had intensities greater than twice their standard deviations estimated from counting statistics. The intensities of three standard reflections measured for every 50 reflections showed no significant change in intensity. Lorentz and polarization corrections were applied. Atomic

Table 1. Observed and calculated structure factors. (The five columns list values of h, k, l, $10F_o$, and $10F_c$.)

Table 2. Fractional atomic coordinates and thermal parameters with estimated standard deviations ($\times 10^5$). The anisotropic temperature factor is given by $\exp -(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)$.

CRYSTAL DATA

Triose reductone $C_3H_4O_3$, orthorhombic; $a=10.601(2)$ Å, $b=3.647(1)$ Å, $c=10.008(3)$ Å, $\varrho_{obs}=1.50$ g/cm³ (flotation). $\varrho_{calc}=1.49$ g/cm³, $Z=4$.

STRUCTURE DETERMINATION

The orientation of the molecule was found from a three-dimensional Patterson synthesis. The model was then translated stepwise through the unit cell and R over 50 low order reflections was determined for each step. The coordinates corresponding to the R-minimum were refined further by the "minimum residual method".[9] Least squares refinements assuming isotropic thermal parameters converged with $R_w=0.22$ and $R=0.17$. Introduction of anisotropic thermal parameters yielded $R_w=0.052$ and $R=0.047$. The hydrogen atoms were located from a difference Fourier map. Refinement of individual isotropic temperature factors for these atoms gave reasonable values, and refinements terminated with $R_w=0.043$ and $R=0.035$. The weight analysis based on the standard deviations from counting statistics showed only small intensity variations except for the smallest F-values. No secondary extinction effects were observed. A final difference Fourier map contained no larger density fluctuations than ± 0.35 e Å^{-3}. Observed and calculated structure factors are listed in Table 1 and atomic parameters in Table 2. Magnitudes and directions of the principal axes of the ellipsoids of vibration are given in Table 4. The r.m.s. discrepancy between the atomic vibration tensor components obtained in the structure analysis and those calculated from the rigid-body parameters found by analysis of the librational, translational, and screw motion of the molecule [10] is 0.0009, indicating that the molecule may be regarded as a rigid body. However, the ratio of "observed" to calculated parameters is small (1.8). The eigen values of **T** are 0.21, 0.17, and 0.16 Å while the r.m.s. libration amplitudes are 7.9, 4.1, and 2.1°. The two larger axes of libration lie approximately in the molecular plane (see below), the largest being nearly

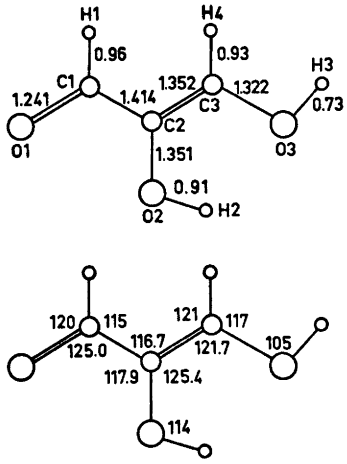

Fig. 1. Schematical drawing of the molecule showing bond distances and angles (uncorrected values).

parallel with the axis of minimum inertia. The translational vibration is largest in the direction perpendicular to the molecular plane. Corrections in bond lengths for librational motion range from 0.003 Å to 0.009 Å (Table 4).

DISCUSSION

Bond lengths and angles are listed in Table 4 and Fig. 1. The compound is found to have the *trans* structure (I). However, both hydrogen bonds are *inter*-molecular.

The molecular dimensions of triose reductone agree fairly well with those found in dialuric acid,[11,12] and thus there is also considerable conjugation in the alternating bond system of triose reductone. In both ascorbic [13] and dialuric acids [11,12] a large difference between the C–O bond lengths of the central and terminal hydroxyl groups is found. A similar difference is also observed in triose reductone (0.03 Å). It therefore appears likely that the terminal hydroxyl group carries the acidic proton, as it does in ascorbic acid.[14]

The molecule is nearly planar (Table 5). Deviations from planarity are mostly due to a slight rotation around the C1–C2 single bond, the dihedral angle O1–C1–C2–O2 being 3.3°. The enediol group (–COH=COH–), however, is exactly planar and the atoms H3 and H4 also lie in this plane, while H2 deviates significantly.

Table 5. Deviations from least squares planes (Å). Plane No. **1** is through all heavy atoms, plane no. **2** is through all heavy atoms except O1. Deviations of atoms not defining the planes in parentheses.

Atom	1	2
O1	0.019	(0.050)
O2	−0.006	−0.001
O3	0.011	−0.000
C1	−0.024	−0.001
C2	−0.006	0.003
C3	−0.002	−0.001
H1	(−0.050)	(−0.025)
H2	(0.380)	(0.377)
H3	(0.020)	(0.006)
H4	(0.003)	(0.007)

The two hydroxylic protons are both involved in *inter*-molecular hydrogen bonds to the carbonyl oxygen atom at distances 2.635(2) Å, and 2.744(2) Å. The shorter bond is that involving the terminal hydroxyl group. This bond lies approximately in the plane of the molecule, while the other bond is significantly out of this plane. A similar situation is also found in dialuric [11,12] and ascorbic acid.[13]

There are two short *intra*-molecular O···O contacts (O1···O2 2.76 Å, O2···O3 2.83 Å) which may be regarded as possible hydrogen bond contacts. There were, however, no maxima in the difference Fourier map that could be interpreted in terms of hydrogen bonding between these atoms. There is therefore no evidence of a disordered or bifurcated hydrogen bond system. The distance O3···H2 is 2.56 Å and must therefore be regarded as a normal van der Waals contact. The facile sublimation of triose reductone has been attributed to the existence of a double five-membered chelate ring structure.[15] Attempts to verify this kind of structure in the vapour phase by electron diffraction and microwave spectroscopy at this institute have so far been unsuccessful, due to the low stability and the low volatility of this compound.

As illustrated in Fig. 2 the molecules are hydrogen bonded to each other to form a three-dimensional network. The stronger hydrogen

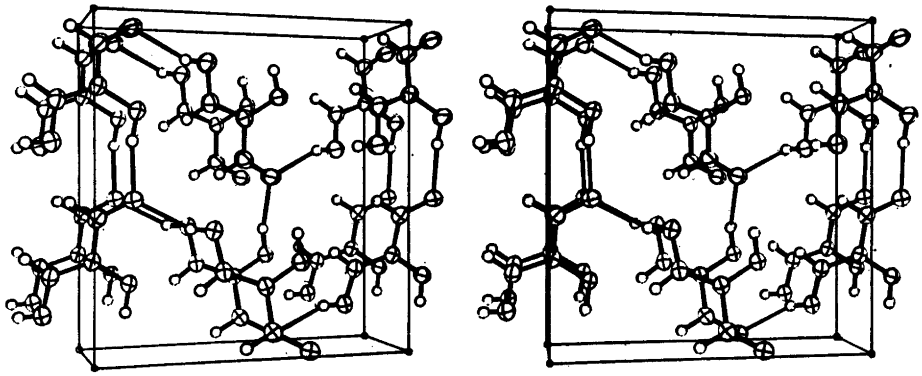

Fig. 2. Stereoscopic illustration of the structure of triose reductone. Thermal ellipsoids are scaled to include 50 % probability. Covalent bonds are filled, hydrogen bonds are open. (Johnson, C.K. (1965) *ORTEP*. ORNL-3794, Oak Ridge National Laboratory, Tennessee).

bonds between the terminal oxygen atoms form alternating zig-zag chains running parallel with the (011) and (0$\bar{1}$1) planes, respectively. These chains are cross-linked by the weaker hydrogen bonds along [100].

Electrochemical Cleavage of Some Cyclic Sulphones

BO LAMM [a] and JACQUES SIMONET [b]

[a] Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden and [b] Laboratoire d'Electrochimie Organique, Université de Clermont-Ferrand, Les Cezeaux, BP 45, F-63 170 Aubière, France

A series of compounds having a sulphonyl group in a saturated ring annealed to a benzene ring has been synthesized and subjected to polarography, coulometry and preparative electrolysis at a mercury cathode. The compounds are found to be cleaved in a two-electron process to yield sulphinate ions, the structures of which indicate the cleavage mode. In the compounds having a four-, five-, six-, or seven-membered ring with the sulphonyl group bound to the aromatic ring, the cleavage takes place preferentially across this bond, in contrast to the behaviour of analogous open-chain alkyl aryl sulphones. The cleavage modes are discussed in terms of the different conformation and, in consequence, *d* orbital participation, of the sulphonyl group in the cyclic and open-chain sulphones. Also, the five-ring isomer in which the sulphonyl group is in a benzylic position, *o*-xylylene sulphone, has been found to undergo C—S cleavage.

In an earlier communication,[1] the cleavage mode of the three cyclic sulphones *2*—*4* (see Fig. 1) was described. The bond between the sulphonyl group and the aromatic ring was found to be broken, contrasting the behaviour of simple alkyl aryl sulphones. The latter type of compounds are cathodically cleaved between the sulphonyl group and the alkyl group.[2,3] Only in alkyl aryl sulphones carrying a strongly electron-attracting substituent, *e.g.*, *p*-cyano, is cleavage between the aromatic ring and the sulphonyl group observed.[4]

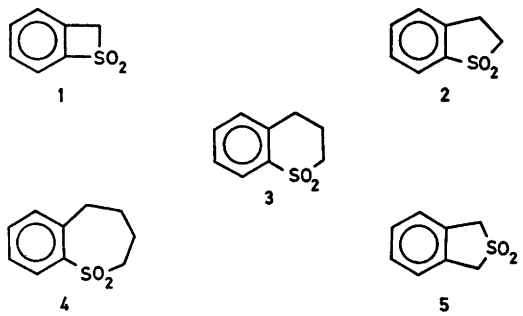

Fig. 1. Cyclic sulphones studied in the present work.

The present paper gives a full account of the electrochemical behaviour of the above-mentioned cyclic sulphones at a mercury cathode. In addition, the compound with a four-membered ring, *1*, has been included and also, the five-membered sulphone *5*. The four-membered ring compound was readily cleaved to give a mixture of the two possible isomeric sulphinate ions in the approximate ratio 4:1. The main product was α-toluenesulphinate ion, indicating that *1* follows the behaviour of *2*—*4*. The compound *5* was included since it is a cyclic sulphone in which the sulphur atom is not bound to an aromatic carbon atom. It was cleaved in wet *N*,*N*-dimethylformamide (DMF), with a tetraalkylammonium halide as the supporting electrolyte, at a potential close to the cathodic limit.

All of the compounds *1*—*5* are described in the literature, and the published syntheses were largely followed. Only with *1* were difficulties met with. The synthesis has been described by Dittmer and Davis [5] and involves several steps, the last of which gives only 3 % yield. In this work, the yield in the final step was increased to 15 %. An alternative route to *1*, reaction of *o*-chlorophenyl methyl sulphone with potassium amide in liquid ammonia, turned out to yield not *1*, but instead, *o*-aminophenyl methyl sulphone. The latter method, which involves a

benzyne intermediate, has been successfully employed for the synthesis of a benzocyclobutane derivative.[6]

The compounds *1*–*5* were polarographed in DMF with tetrabutylammonium iodide as the supporting salt. Coulometric experiments at a large-surface mercury cathode were also performed, and finally, preparative electrolyses on a gram scale. Identification of the sulphinate ions formed upon electrolysis was carried out by PMR after conversion to sulphones.

EXPERIMENTAL

General. Melting points have been determined on a Kofler Heizbank. Pressures are given in SI units. 1 Pa = 7.5×10^{-3} mmHg, 1 MPa = 145 psi.

Syntheses. 2H-*Benzo*[b]*thiete-1,1-dioxide* (*1*) was prepared essentially according to Dittmer and Davis.[5] However, silver oxide in boiling xylene was used in the last step instead of triethylamine in benzene to bring about a double dehydrobromination.[7] The yield in this step was 15 %. The compound had the same m.p. (126–128°) and PMR spectrum (in $CDCl_3$, 2 H singlet at δ 5.1 and 4 H singlet at δ 7.55) as previously found.[5]

Benzo[b]*thiophene-1,1-dioxide.* 1-Benzothiophene (Columbia Organic Chemicals Co.) was oxidized on a 0.2 mol scale to the corresponding sulphone with hydrogen peroxide in acetic acid solution.[8] After recrystallization from ethanol, a 69 % yield was secured, m.p. 142°, lit.[8] 142–143°.

2,3-Dihydrobenzo[b]*thiophene-1,1-dioxide* (*2*). The preceding compound was hydrogenated on a 50 mmol scale in tetrahydrofuran solution in a Parr apparatus,[9] using 10 % palladium on carbon as the catalyst. At an initial pressure of 0.31 MPa, the reaction required 15 min. After recrystallization from ethanol, the yield was 80 %, m.p. 92°, lit.[9] 91–92°.

3-Phenylmercaptopropionic acid. This compound was synthesized on a 0.5 mol scale from thiophenol and 3-bromopropionic acid.[10] The yield was 87 %, m.p. 54–56°, lit.[10] 59°.

Thiochroman-4-one-1,1-dioxide. Cyclization of the preceding compound was performed on a 0.1 mol scale in conc. sulphuric acid.[10] The crude thiochroman-4-one thus obtained was directly oxidized to the sulphone by a mixture of 20 ml 30 % hydrogen peroxide and 40 ml glacial acetic acid.[11] The crude product was recrystallized from ethanol. Needles were obtained, overall yield 49 %, m.p. 133°, lit.[11] 131–132°.

Thiochromane-1,1-dioxide (*3*). Of the preceding compound, 4.9 g (25 mmol) was dissolved in 100 ml glacial acetic acid. One drop of conc. hydrochloric acid and 0.1 g 10 % palladium on carbon were added, and the mixture was hydrogenated at room temperature in a Parr apparatus, using an initial pressure of 0.28 MPa. After 1 h, the expected amount of hydrogen (50 mmol) had been consumed, and the solution was filtered and vacuum evaporated to dryness. After recrystallization from ethanol, 3.45 g of product were obtained, yield 76 %, m.p. 88–89°, lit.[12] 87.5–88°.

5-Oxo-2,3,4,5-tetrahydrobenzo[b]*thiepin.* First, 4-phenylmercaptobutyric acid was prepared on a 1 mol scale from thiophenol and γ-butyrolactone according to Reppe.[13] The yield was almost quantitative. Of the crude product, 0.33 mol was cyclized in polyphosphoric anhydride according to Traynelis and Love.[14] Distillation yielded 39.7 g (67 %) of product, b.p. 98° at 53 Pa, lit.[14] 119–120° at 200 Pa.

5-Oxo-2,3,4,5-tetrahydrobenzo[b]*thiepin-1,1-dioxide.* Of the preceding compound, 24 g was oxidized with 30 % hydrogen peroxide and glacial acetic acid.[14] After recrystallization from ethanol, 20.2 g (71 %) of colourless plates were obtained, m.p. 153–155°, lit.[14] 155–156°.

2,3,4,5-Tetrahydrobenzo[b]*thiepin-1,1-dioxide* (*4*). Hydrogenation of the preceding compound was performed at about 40° starting with 10.5 g (0.05 mol) in 200 ml glacial acetic acid, 3 drops of conc. hydrochloric acid and 0.2 g 10 % palladium on carbon. The initial pressure was 0.33 MPa. After 14 h, 0.1 mol of hydrogen had been consumed. Filtration, vacuum evaporation and recrystallization from hexane yielded 8.7 g (89 %) of product, m.p. 78°, lit.[12,14] 77–78°.

1,3-Dihydrobenzo[c]*thiophene-2,2-dioxide* (*5*). α,α'-Dibromo-*o*-xylene, 100 g (0.38 mol), was allowed to react with sodium sulphide, following the directions of von Braun,[15] to yield 20.6 g (40 %) of the corresponding cyclic sulphide. Without undue delay, the sulphide was oxidized with peracetic acid according to Cava and Deana[16] to give, after recrystallization from ethanol containing 5 % tetrahydrofuran, 14.7 g (58 %) of the sulphone, m.p. 150°, lit.[16] 150–151°.

Benzyl o-tolyl sulphone, which was needed for identification, was synthesized from *o*-thiocresol and benzyl chloride in aqueous sodium hydroxide solution, the intermediate sulphide being oxidized to the sulphone by 10 % peracetic acid. In *Beilstein's Handbuch*, this compound is erroneously described as a yellow oil, but in fact forms colourless crystals. After recrystallization from ethanol, m.p. 94–94.5°, PMR $CDCl_3$: 3 H singlet at δ 2.53, 2 H singlet at δ 4.33, 9 H multiplet at δ 7.0–7.9.

Methyl phenyl sulphone and other sulphones needed for comparison purposes were either available from previous work or prepared by straightforward methods. Their melting points agree with literature values, and the structures were verified by PMR.

Polarography. The *N,N*-dimethylformamide (DMF) used for electroanalytical work was dried over anhydrous sodium sulphate and distilled through a 50 cm glass-helix column. After a 5–10 % forerun, a constant boiling

centre cut was taken at 94°/18.6. kPa. The solvent was stored in the dark and used within a week after distillation. Tetrabutylammonium iodide was from Fluka AG, polarography grade. A Tacussel Tipol 3-electrode polarograph was used. The sweep rate was 2.5 mV/s. The substrate concentration was 10^{-3} M, and that of supporting salt, 0.1 M.

Coulometry. A 0.25 M solution of tetrabutylammonium bromide in DMF was used as supporting electrolyte. The mercury cathode, about 10 cm^2, was agitated by a magnetic stirring bar, and the anode compartment was separated by a glass frit. A Tacussel type RM 04 vessel was used. The potentiostat and coulometer were Tacussel type ASA 4SHT and IG4 10A, respectively. The coulometric runs were performed on 20 – 30 mg amounts of substrate. In some runs, a tenfold excess of phenol was added after the initial current had decayed and the electrolysis resumed.

Macroelectrolyses. The procedure for compounds *2 – 4* has been published earlier.[1] For practical reasons (ease of workup, since extremely little material was available), compound *1* had to be electrolyzed in 1 M tetramethylammonium chloride in methanol. Compound *2* was electrolyzed in methanol as well, and gave the some product as previously obtained in DMF. Galvanostatic conditions were used for *1 – 4*. In contrast, *5* was electrolyzed at −2.2 V *vs.* Ag,AgI/0.25 M I^- using a Tage Juul type G-30 potentiostat. In this case, the supporting electrolyte was 0.25 M methyltributylammonium iodide in DMF containing 5 % water. Dry DMF was found to cause pumping of electrolyte into the cathode compartment, a greyish sludge (probably organomercury compounds) being also formed. This is thought to be caused by decomposition of the supporting electrolyte.

After the electrolyses, the catholyte was separated and allowed to react with benzyl chloride (*1 – 4*) or methyl iodide (*5*) by warming to 60 – 80° for 3 h and leaving overnight. The sulphinate ions were thus converted into sulphones, which were isolated by evaporation, dilution with water and extraction with methylene chloride or ether. For compounds *1* and *2*, the sulphones were compared with authentic material (m.p. and PMR spectra). For compound *5*, the reaction with methyl iodide yielded a sulphone which, after recrystallization twice from ether, had the m.p. 73 – 74° and PMR data in $CDCl_3$: 3 H singlet at δ 2.43, 3 H singlet at δ 2.80, 2 H singlet at δ 4.32, and 4 H singlet at δ 7.27. Elemental analysis (Microanalytical service of C.N.R.S., France): Found C 58.71; H 6.44; O 17.08; S 17.26. Calc. for $C_9H_{12}O_2S$: C 58.67; H 6.56; O 17.37; S 17.40. Based on these data, the compound was identified as methyl (*o*-methyl)benzyl sulphone. This compound has not been found in the literature. The PMR spectrum of the crude product revealed no other identifiable compounds, but only trace impurities.

RESULTS AND DISCUSSION

Electroanalytical work. The polarographic and coulometric results are given in Table 1. It has been shown earlier[3] that methyl phenyl sulphone gives rise to a two-electron, irreversible polarographic wave in DMF. Since the diffusion coefficients should be rather similar for the compounds studied in this work, it can be concluded from inspection of the $i/\sqrt{h}$-values in Table 1 that the cyclic sulphones give two-electron waves as well. As already observed for methyl phenyl sulphone, addition of a ten- to twentyfold excess of phenol as a proton donor increased the wave height by less than 15 % except for compound *2*, for which the height was increased by up to 40 %. The coulometric runs in absence of phenol give values indicating a two-electron process.

Addition of a ten- to twentyfold excess of phenol in the coulometric runs after the first

[a] *Versus* Ag,AgI/0.1 M Bu_4NI, DMF. [b] *Versus* SCE in water, determined for methyl phenyl sulphone and calculated for the other sulphones. [c] No proton donor added. [d] Electrolysis continued after addition of excess phenol. [e] Taken from Ref. 3.

current had decayed to its background value caused the current to increase, and the experiments were continued until the current had again attained its background value. The last column in Table 1 thus represents the sum of the first and the second current-time integrals. For compound *1*, no phenol was added since the catholyte was saved for an attempted transformation to derivatives, and for compound *5*, which requires a much more negative potential than the others, phenol addition caused hydrogen ion discharge.

In an earlier study,[3] it was shown that no second wave is observed with methyl phenyl sulphone upon addition of phenol, the interpretation being that the benzenesulphinate ion initially formed is too weakly basic to be protonated by phenol. However, by titration with sulphuric acid, the free benzenesulphinic acid could be liberated, which then gave a polarographic wave.[18] With the cyclic sulphones in the present study, the preparative experiments show that araliphatic sulphinates are formed. A probable interpretation of our data is that the araliphatic sulphinic acids are weaker than benzenesulphinic acid, so that in the acid-base equilibrium

$$\text{Phenol} + \text{sulphinate} \rightleftharpoons \text{phenolate} + \text{sulphinic acid}$$

a sufficient sulphinic acid concentration prevails so as to permit a significant current.

Since the polarographic half-wave potentials for all compounds were found to be unaffected by phenol addition (*i.e.*, by the acidity of the medium), the potential-determining transition state in the irreversible reaction cannot contain a proton from the medium. The mechanism for cleavage of methyl phenyl sulphone has been already discussed,[3] and it appears probable that the same mechanism applies to the cyclic sulphones.

It is interesting to note the dependence of the half-wave potentials on the ring size. The four-membered ring is more easily cleaved than is methyl phenyl sulphone, whereas the five-, six-, and seven-membered rings are more difficult to cleave. Compound *5* is considerably more difficult to cleave than any of the others, since it is a benzylic sulphone. In fact, *5* does not give a polarographic wave in methanol, and an attempted preparative run in this medium, which has been so successfully used by Horner and Neumann [2] for other benzyl sulphones, failed completely, hydrogen evolution being the only reaction.

Preparative results. As is seen in Table 2, compounds *1*–*4* all give sulphinate ions resulting from cleavage between the sulphonyl group and the aromatic ring, though *1* is also cleaved to a minor extent between the sulphonyl group and the benzylic carbon atom. It was mentioned in Ref. 1 that impurity peaks in the PMR spectra of the products obtained from compounds *2*–*4* suggest 10–20 % cleavage to give *o*-alkylsulphinate ions. Reexamination by GLC indicates that none of this is formed for *2* and *3*, whereas for the seven-ring compound *4*, 15 % *S*-alkyl cleavage might have taken place. Comparison with authentic benzyl *o*-butylphenyl sulphone has not been carried out, though. The result for *5* is straightforward; carbon-sulphur rather than carbon-carbon cleavage takes place, the former alternative being *a priori* expected.

The main reason for including *1* in the present study was that Horner had suggested [2] that in

Table 2. Derivatives obtained upon alkylation of sulphinate ions in catholyte.

the cleavage of a mixed sulphone, the relative stability of the different possible radicals formed after transfer of one electron should determine the cleavage mode. At first sight, one might therefore expect *1* to give *o*-toluenesulphinate ion as the main product. However, our experimental results do not invalidate Horner's argument, because even if bond-breaking is significant in the critical transition state, the incipient benzyl radical is formed in the very conformation least suitable for mesomeric interaction with the benzene ring, the odd electron orbital being orthogonal to the aromatic π system.

Since the behaviour of *1* follows that of *2 – 4*, the arguments below apply to the whole series *1 – 4*. In a preliminary communication,[1] it was suggested that the vibrational pattern of the cyclic compounds might influence the cleavage mode, or that "the detailed mechanism of electron transfer" might be different. It was believed that tetramethylammonium amalgam is the reducing agent at the rather negative cleavage potentials for *2 – 4*. The results for *1* force us to dismiss the second possibility altogether, since the half-wave potential is *less* negative than that of methyl phenyl sulphone, which is directly reduced by the cathode.[3]

We feel that the most fruitful approach is to consider the resonance interaction between the sulphonyl group and the aromatic π system as a function of the orientation of the sulphonyl group. Gerdil and Lucken [19] have made an electron spin resonance and polarographic study of the sulphone group in diphenyl sulphone, dibenzothiophene-*S*,*S*-dioxide and thianthrene-*S*,*S*,*S'*,*S'*-tetroxide. The orientation of the sulphonyl group with respect to the aromatic rings is different in all these compounds. In the terminology originally introduced by Koch and Moffitt [20] the dibenzothiophene-*S*,*S*-dioxide is an example of Case I conjugation, whereas diphenyl sulphone represents Case II. The thianthrene tetroxide is intermediate between these two.

When one makes MO calculations of the interaction between the sulphur 3*d* orbitals and the aromatic π system, the symmetry properties of the *d* orbitals must be considered. Gerdil and Lucken [19] argued that since different *d* orbitals combine with the π system in Case I and II, respectively, the energy levels of the MO's are also different in the two cases, and in particular, the energy of the LVMO is lowered upon going from Case I to Case II conjugation.

The cyclic compounds in the present study all represent Case I conjugation, whereas methyl phenyl sulphone, the geometry of which is known *via* dipole moment measurements [21] and X-ray cristallography of a halogenated derivative,[22] is an example of Case II. The two cases are illustrated in Fig. 2.

If the energy of the LVMO (to which the initial electron transfer takes place in cathodic reactions) is higher in the Case I compounds *2 – 4* than in the Case II compound methyl

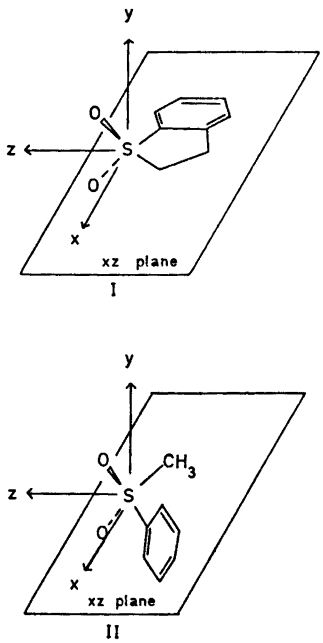

Fig. 2. Orientation of the sulphonyl group in 2,3-dihydrobenzo[*b*]thiophene-1,1-dioxide and methyl phenyl sulphone. The O–S–O bonds are in the *yz* plane. In the upper compound, all carbon atoms are in the *xz* plane. In the lower compound, the benzene ring is perpendicular to the *xz* plane.

phenyl sulphone, which is reasonable in view of Gerdil and Lucken's analysis,[10] we have a rationale for the observed bond-breaking as well as for the more negative half-wave potentials for the cyclic compounds. The four-membered compound *1* represents a special case, in which ring strain must be taken into account.

Acknowledgements. We cordially thank Dr. G. Jeminet for drawing our attention to the quantum-chemical treatment referred to above and for fruitful discussions. Experimental assistance has been provided by Mrs. A. Lamm and by Misses A. Järborg, C. Nyberg and G. Suvén. Their help is much appreciated. Financial support, including a travel grant to B. L. from the *Swedish Natural Science Research Council* is gratefully acknowledged.

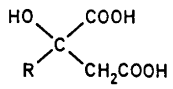
Absolute Configurations of 2-Alkylmalic Acids

SVANTE BRANDÄNGE, STAFFAN JOSEPHSON and STAFFAN VALLÉN

Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm 50, Sweden

The absolute configurations of some naturally occurring 2-alkylmalic acids (V, VII–X) have all been shown to be *R* by asymmetric syntheses of (*S*)-III, -VI and -VIII (Fig. 1) and CD measurements on molybdate complexes of the synthetic and the natural acids. The key compound in the syntheses is the epoxide (*R*)-XII, obtained in 14 % enantiomeric excess by asymmetric synthesis.

Several 2-alkylmalic acids (I), as well as 2-benzylmalic acid (VIII), occur naturally. Thus, 2-methylmalic acid (citramalic acid, II) is produced by microorganisms and has been detected in or isolated from many fruits. Both (+)- and (−)-citramalic acid have been found. 2-Ethylmalic acid (III) and 2-propylmalic acid (IV) are also synthesised by microorganisms. 2-Isopropylmalic acid (V) is an intermediate in the leucine biosynthesis; its (−)-form has been isolated from different sources, *e.g.* a culture broth of a mutant of *Saccharomyces cerevisiae*.[1]



I:	R= alkyl	VI:	R= $CH_2CH_2CH_2CH_3$
II:	R= CH_3	VII:	R= $CH_2CH(CH_3)_2$
III:	R= CH_2CH_3	VIII:	R= $CH_2C_6H_5$
IV:	R= $CH_2CH_2CH_3$	IX:	R= $CH_2CH_2CH(CH_3)_2$
V:	R= $CH(CH_3)_2$	X:	R= $CH_2CH_2CH_2C(CH_3)_2OH$

2-Isobutylmalic acid [2] (VII) and 2-benzylmalic acid [3] (VIII) are components of two Orchidaceae alkaloids, and 2-(3-methylbutyl)malic acid [4] (IX) and 2-(4-hydroxy-4-methyl-pentyl)malic acid [4] (X) are components of alkaloids from *Cephalotaxus harringtonia*. The absolute configuration has been determined only for citramalic acid. By correlation with (*S*)-(+)-mevalolactone, (+)-citramalic acid has been shown to possess the *S*-configuration.[5,6] The fermentation product 2-hydroxymethylmalic acid (itatartaric acid) has been correlated with citramalic acid.[7] Strong evidence for the *R*-configuration of the natural forms of VII and VIII has recently been obtained from asymmetric synthesis coupled with CD studies.[8]

CD spectra of α-hydroxy acids as molybdate complexes give information on their absolute configurations at the α carbon atoms.[9] It was, however, uncertain whether the Cotton effects of (*S*)-2-methylmalic acid and the (*S*)-2-substituted malic acids with larger substituents would be strictly comparable. For that reason syntheses of the latter acids were performed.

Ethyl chloropyruvate was condensed with the lithium enolate [10] obtained from (−)-menthyl acetate and lithium diisopropylamide, and the resulting mixed ester was transformed into the partially racemic diethyl ester XI. Treatment of XI with lithium hydride in hexamethylphosphortriamide gave the epoxide XII. Opening of the epoxide ring by catalytic hydrogenation afforded, as predominant enantiomer, (*S*)-(+)-diethyl citramalate [10] the specific rotation of which showed that the epoxide (*R*)-XII was present in 14 % enantiomeric excess. The asymmetric syntheses using ethyl pyruvate [10] and ethyl chloropyruvate thus both yielded 2-substituted malic acids in which the *S*-forms predominated. The (*S*)-diethyl esters XIII, XIV, and XV (Fig. 1) were prepared by cleavage of the epoxide ring in (*R*)-XII with the ap-

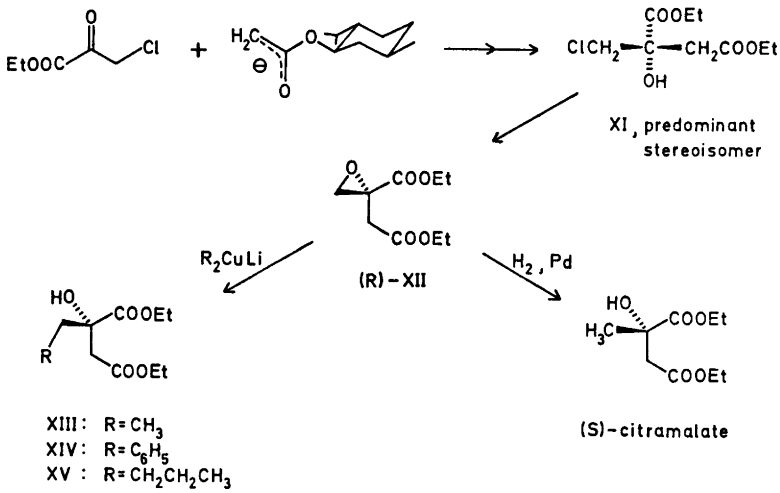


Fig. 1. Reaction scheme for the asymmetric syntheses of (*S*)-XIII, -XIV, and -XV (esters of (*S*)-III, -VIII, and -VI).

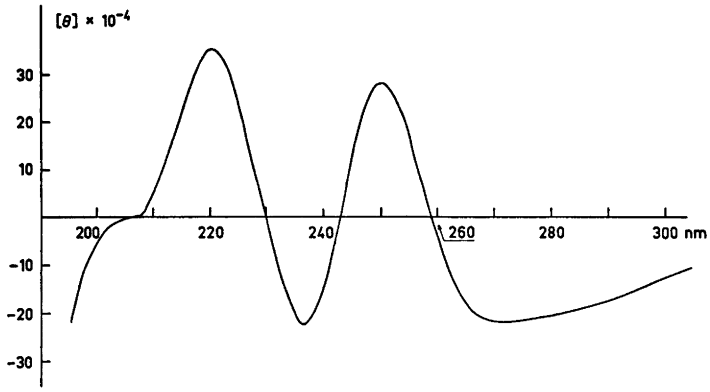

Fig. 2. CD spectrum of (*R*)-(−)-V molybdate complex, 2 mM solution in water, pH 3.3, cell 0.5 mm.

propriate cuprate reagents. Epoxide ring opening reactions with lithium dimethylcuprate and lithium diphenylcuprate have been described by Johnson *et al.*,[11] and the reactions between XII and these copper reagents gave the esters XIII and XIV (Fig. 1) in good yields. The diethyl ester of (*S*)-2-butylmalic acid (XV) was synthesised analogously. It seems reasonable to assume that the molybdate complexes of this acid and (*S*)-VII should give similar CD curves.

Molybdate complexes of the synthetic (*S*)-2-alkylmalic acids were prepared and investigated by CD. All these complexes and those of (*S*)-malic acid [9] and (*S*)-citramalic acid [8] show similar Cotton effects. A sample of (−)-2-isopropylmalic acid [(−)-V], isolated by Sai,[1] shows the opposite Cotton effects (Fig. 2) and consequently has the *R*-configuration. The natural forms of VII and VIII also show the opposite Cotton effects,[8] as do the natural forms of IX and X, and all these acids consequently also have the *R*-configuration.

EXPERIMENTAL

General methods were the same as previously described.[8] The diethyl 2-alkylmalates, purified by preparative GLC, were hydrolysed with 4 M hydrochloric acid (reflux 3 days). The solutions were concentrated (40°, 15 mm) and the acids were dried in a vacuum. Molybdate solu-

tions having pH values between 3.3 and 3.5 (2.0 mol of sodium molybdate per mol hydroxy acid) were prepared from these crude acids and CD spectra were recorded as previously described.[8]

Ethyl chloropyruvate was prepared according to Stekol,[13] starting with 144 g of ethyl pyruvate and 135 ml of sulphuryl chloride. In the distillation (55–58°, 7–8 mm) two fractions were taken. The first fraction (96 g) consisted of (NMR) 75 % ethyl chloropyruvate, 10 % ethyl pyruvate and 15 % ethyl dichloropyruvate. The second fraction (28 g) consisted of (NMR) 90 % ethyl chloropyruvate, 3 % ethyl pyruvate and 7 % ethyl dichloropyruvate.

Diethyl 2-(chloromethyl)malate (XI). A mixture of diisopropylamine (28.5 g, 0.28 mol) in tetrahydrofuran (150 ml) and butyllithium in ether (270 ml, 1.0 M) was stirred under nitrogen at −10° for 40 min. The resulting solution of lithium diisopropylamide was cooled to −78°, a solution of (−)-menthyl acetate (46.6 g, 0.25 mol) in tetrahydrofuran (250 ml) was added during 45 min, and the mixture stirred at the same temperature for 30 min. Ethyl chloropyruvate (42.8 g, 0.29 mol) was then added during 30 min, the temperature being kept at −78°, and the mixture was stirred for another 15 min before the temperature was allowed to rise to 0°. The mixture was poured into dilute hydrochloric acid-ice, the aqueous layer (pH 4–5) was extracted with chloroform, and the chloroform phase was dried (Na_2SO_4) and concentrated. NMR of the product showed comparable amounts of ethyl (−)-menthyl 2-(chloromethyl)malate and (−)-menthyl acetate. The crude product was treated with ethanol (1 l) and conc. sulphuric acid (30 ml) under reflux for 5 days. Part of the ethanol was evaporated. Partition between water and chloroform gave a product which on distillation (90–92°, 0.5 mm) yielded 16.1 g of an 80/20 mixture of XI and (−)-menthol. Redistillation yielded pure (GLC) XI, $[\alpha]_{578}^{24}$ −1.1° (*c* 6.6, chloroform). MS (*m/e*, relative intensity): M^+ = 238 (not observed), 189 (8), 167 (28), 165 (86), 121 (32), 119 (100), 79 (8), 77 (26), 29 (71). NMR (CCl_4): τ 5.70 (q, 2 H), τ 5.81 (q, 2 H), τ 6.00 (s, 1 H), τ 6.30 (s, 2 H), τ 7.12 and 7.28 (AB spectrum, 2 H, J = 16 Hz), τ 8.67 (t, 3 H), τ 8.73 (t, 3 H).

The *epoxide XII* was prepared by treatment of XI (7.2 g, 0.030 mol) with lithium hydride (0.48 g, 0.060 mol) in hexamethylphosphortriamide (HMPA, 15 ml, 65°, 1.5 h). The reaction mixture was poured into dilute hydrochloric acid-ice, extracted three times with ether, and the extract dried (Na_2SO_4) and concentrated. GLC indicated a 50 % conversion to XII (higher yields were obtained in some pilot experiments). As the distilled (60–62°, 2 mm) sample of XII contained approximately 10 % of XI, XII was purified by preparative GLC. The substance thus obtained was indistinguishable (GLC, MS) from a sample of XII obtained by epoxidation of diethyl itaconate.[7] MS: M^+ = 202 (not observed), 157 (27), 129 (40), 128 (29), 101 (95), 29 (100).

Hydrogenation of XII. The epoxide XII (100 mg) in ethanol (4 ml) was hydrogenated in the presence of palladium on charcoal (60 mg) and anhydrous potassium carbonate (50 mg). Diethyl citramalate, indistinguishable (GLC, MS) from an authentical sample was isolated by preparative GLC, $[\alpha]_{578}^{24}$ +2.9° (*c* 4.6, chloroform). MS: M^+ = 204 (not observed), 159 (3), 131 (87), 103 (17), 85 (73), 43 (100), 29 (35). Pure (+)-diethyl citramalate shows $[\alpha]_{578}^{24}$ +20.1°.[10]

2-Ethylmalic acid. A solution of lithium dimethylcuprate (2 mmol) in ether (10 ml) was prepared at 0°.[12] The epoxide XII (0.15 g, 0.75 mmol) in ether (2 ml) was added, and after 10 min at 0° the reaction mixture was poured into dilute hydrochloric acid. Separation of the ether layer and drying (Na_2SO_4) followed by preparative GLC (indicating 100 % ring opening) afforded diethyl 2-ethylmalate, $[\alpha]_{578}^{24}$ +1.3° (*c* 2.4, chloroform). MS: M^+ = 218 (not observed), 189 (2), 145 (63), 99 (50), 57 (100), 29 (50).

2-Butylmalic acid. Propyllithium in ether (2 ml, 0.75 M) was added to a stirred suspension of copper(I) iodide (150 mg, 0.80 mmol) in ether (10 ml), kept at −20° under nitrogen. After 1 min a solution of XII (72 mg, 0.36 mmol) in ether (5 ml) was added dropwise. The mixture was kept between −10° and −20° for 40 min and worked up as above. Preparative GLC, indicating 95 % purity of the product, gave diethyl 2-butylmalate, $[\alpha]_{578}^{24}$ +2.2° (*c* 0.7, chloroform). MS: M^+ = 246 (not observed), 189 (2), 173 (40), 127 (18), 85 (100), 57 (42), 29 (53).

2-Benzylmalic acid. Triethyl phosphite (830 mg, 5 mmol) in 5 ml of ether was added to a stirred suspension of copper(I) iodide (475 mg, 2.5 mmol) in 5 ml ether, and the mixture was stirred under nitrogen at room temperature for 15 min, a clear solution being produced.[14] The temperature was lowered to −60°, a solution of phenyllithium (6.7 ml, 0.75 M, 5.0 mmol) in ether was added, and after 10 min at −60°, a solution of XII (75 mg, 0.38 mmol) in ether was added. The temperature was then allowed to rise to −10°, and the reaction product isolated as above. The alkaloid phalaenopsine,[3] subjected to ethanolysis, afforded a sample of diethyl 2-benzylmalate which was indistinguishable (GLC, MS) from the sample obtained from XII. The latter showed $[\alpha]_{578}^{24}$ +1.8° (*c* 0.9, chloroform). MS: M^+ = 280 (not observed), 262 (13), 207 (25), 189 (20), 161 (16), 119 (27), 115 (44), 91 (100).

Acknowledgements. We thank Dr. Björn Lüning for his interest in this work and Mr. R. G. Powell, Northern Regional Research Laboratory, Peoria, Illinois and Dr. T. Sai, Asahi Breweries Ltd, Tokyo, who kindly supplied the *Cephalotaxus* acids and (−)-2-isopropylmalic acid, respectively. Mr. Jan Glans

and Dr. Rolf Håkansson, Kemicentrum, Lund, kindly measured the CD spectra and Dr. Lennart Kenne and Dr. Jörgen Lönngren the mass spectra. This work was supported by the *Swedish Natural Science Research Council.*

Base- and Acid-catalyzed Prototropic Rearrangements of 1-Methyl-2-(*N*-piperidyl)indene

ULF EDLUND [a] and GÖRAN BERGSON [b]

[a] Department of Organic Chemistry, University of Umeå, S-901 87 Umeå and [b]Department of Organic Chemistry, University of Uppsala, Box 531, S-751 21 Uppsala 1, Sweden

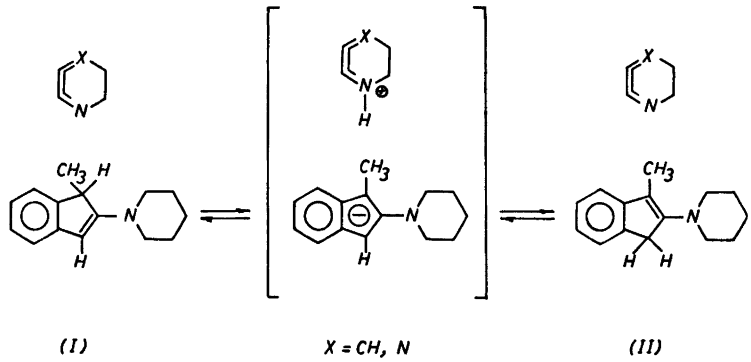
The 1,3-tautomerization of an amino-substituted indene I has been investigated by using basic or acidic catalysts in pyridine solution. Compared to 1,2-dialkylsubstituted indenes the isomerization rate found for I is considerably decreased when basic catalysts (DABCO or quinuclidine) are used. This retarding effect, caused by the 2-nitrogen, is in agreement with acidity differences obtained by simple Hückel calculation. Alkylsubstituted indenes do not undergo acid-catalyzed 1,3-isomerization. However, I rearranges rapidly in the presence of small amounts of strong acid due to the enamine character. Rate constants are given for the base- and acid-catalyzed isomerizations.

The alkylsubstituted indenes have, by kinetic and stereochemical studies, been found to undergo base-catalyzed rearrangements, which proceed in a suprafacial mode under certain conditions.[1,2] An alkyl substituent was found to decrease the rate constant for this reaction but the magnitude of this effect also depends on the nature of the catalyst.[1g] In connection with these studies of the 1,3-proton transfer reactions we wanted to investigate the influence on the rate of a nitrogen atom directly bonded to the carbon atom in the 2-position of the indene ring. Under similar conditions as those used in the indene studies, we have earlier reported that none or a very slow rearrangement could be observed using aliphatic amines as catalysts, like triethylamine.[1n] Base-catalyzed 1,3-proton shifts in enamines have not been studied earlier but a carbanion mechanism has been proposed to account for the *cis-trans* isomerizations of aliphatic enamines in basic media.[3] Furthermore, these compounds would be expected to undergo acid-catalyzed rearrangement owing to their enamine structure. This behaviour of enamines is a well-documented fact,[4] but no detailed investigation has yet been published. A few years ago Johnson mentioned that the presence of one thousandth percent of acid caused equilibration of substituted enamines in 5 min at room temperature.[5] Apparently, the observed thermodynamic equilibrium must be established through an immonium structure possibly preceded by an *N*-protonated salt.[4a]

RESULTS AND DISCUSSION

The present paper is limited to a study of the base-catalyzed and the acid-catalyzed tautomerizations of 1-methyl-2-(*N*-piperidyl)indene (I), (Scheme 1,3). Concerning the 1,2-dialkyl-substituted indenes the thermodynamic equilibrium favours almost completely the 2,3-substituted isomer since an alkyl substituent at the double bond afforded a more stable form.[1g] In the case of isomeric enamines the thermodynamic ratio is determined by a balance between steric and electronic effects which affect the overlap between the nitrogen lone pair and the double bond.[6] Thus we have found that the equilibrium constant between II and I (Scheme 1) is 0.41 ± 0.01 in pyridine solution.

We have studied the base-catalyzed proton transfer in pyridine, a protophilic solvent of moderate polarity, using effective catalysts like 1,4-diaza-bicyclo[2.2.2]octane (DABCO) and quinuclidine. These bases have been shown to be superior to aliphatic amines in prototropic



Scheme 1.

indene rearrangements owing to their rigidity and consequent lower activation entropy.[1j] The reaction was found to follow the kinetics of a pseudo-first order reversible reaction, the observed rate constant being proportional to the base concentration within the limits of experimental error. No significant isomerization could be noticed in the absence of base in a parallel experiment showing that pyridine is too weak a base to be responsible for any catalytic effect. The phenomenological rate constant k_1 for the forward reaction I $\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}}$ II was found at unit base concentration to be about 0.49×10^{-2} l mol^{-1} min^{-1} and 0.12×10^{-2} l mol^{-1} min^{-1} for quinuclidine and DABCO, respectively, at 35°C (*cf.* Table 1). Including the statistical factor this shows that quinuclidine is about eight times more effective than DABCO, a ratio close to that found for the rearrangement of 1-methylindene.[1j] Substitution of the hydrogen in the 2-position by the *N*-piperidyl moiety causes a very large decrease in the isomerization rate. A slower rate is also observed for 1,2-dimethylindene (Table 2) as well as for other 1,2-dialkylsubstituted indenes, but the difference between 1,2-dimethyl- and 1-methyl-2-ethylindene is small.[1g] Thus we conclude that in determining the exceptionally low rate for I the conjugation between the nitrogen lone pair and the indene π-system plays a major role. A Hückel π-electron energy

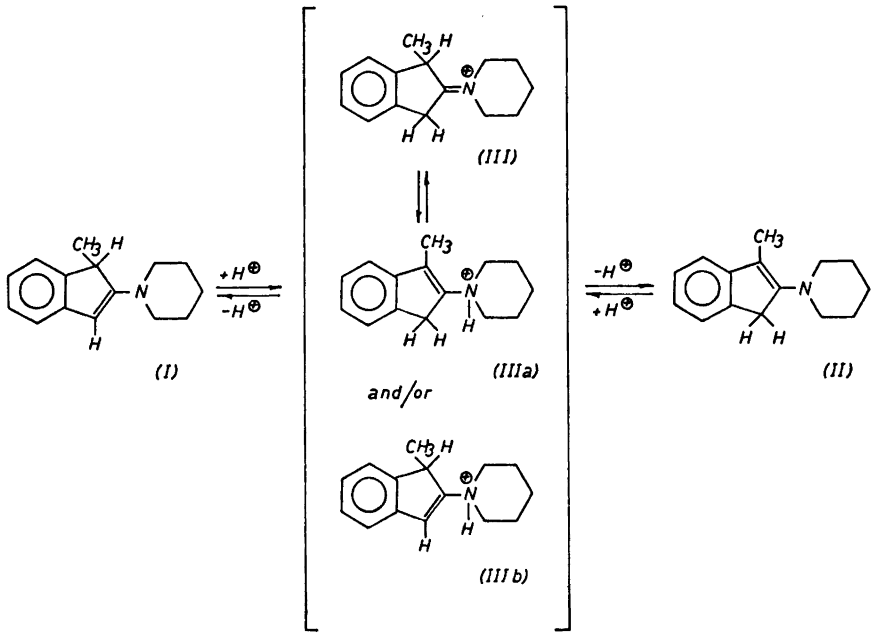
calculation (Scheme 2) predicts that 2-aminoindenes should be less acidic than indene by about 2 pK_A units. A lower acidity should, of course, result in a decreased isomerization rate due to correlation between the kinetic and thermodynamic acidity.[7a] The acidity of 2-aminoindene was estimated using the correlation given by Streitwieser [7b] between pK_A and the difference in Hückel total π-energy between the carbon acid and the corresponding anion. We used the same parameters in our calculation as recommended earlier [8] *i.e.* $h_N = 1.5$ and $k_{CN} = 0.8$. This implies, of course, that we have assumed maximum overlap of the nitrogen lone pair and the π-system in the indene ring. Thus our calculation gives an upper limit for the effect of the nitrogen atom in the π-electron system. Scheme 2 also shows the net charges and the bond orders in our systems. In Scheme 1 we have proposed that the rearrangement between I and II proceeds *via* an ion pair in analogy with the mechanisms put forward for the other 1,3-prototropic reactions.[1,2] An interesting question in this connection is whether there exists a discrete ion pair in which the substituted ammonium ion is situated above the nitrogen atom in the piperidine ring and whether an internal rotation within such an ion pair can be affected by rotation around the C_2-N bond. These questions cannot be answered since we have not as yet been able to prepare optically active substrates.

The acid-catalyzed isomerization between I and II is represented in Scheme 3. The reac-



Scheme 3.

tion was initiated by addition of a small amount (*ca.* 10^{-3} M) of the perchlorate salt III. Thus the intermediate III in the reaction also serves as the catalyst. As can be seen from Table 1, the reaction is strictly pseudo-first order within the limits of experimental error. The rate is remarkably rapid k_1 being about 200×10^{-2} l mol^{-1} min^{-1} at unit catalyst concentration. Thus very low catalyst concentrations must be used, but in pyridine the reaction is slow enough to permit a usual kinetic study probably due to the fact that pyridine interacts through hydrogen bonding to the catalyst. A preliminary experiment using acid-free chloroform as a solvent, where such bonding cannot occur, gives a rearrangement rate about fifty times as great as in pyridine solution. The *N*-protonated enamines IIIa and/or IIIb are possibly involved in the reaction since *N*-protonation is presumably favoured kinetically compared to *C*-protonation in our system.[11] However, the *C*-protonated form III is thermodynamically more stable than (IIIa)/(IIIb).

EXPERIMENTAL

All PMR-work was performed on a JEOL C-60 HL instrument. The mass spectrum was obtained with an LKB 9000 mass spectrometer. The GC-analyses were made on a PYE M64 with a flame ionization detector and nitrogen as the carrier gas.

1-Methyl-2-(N-piperidyl)indene (I). The contaminated 1-methyl-2-(*N*-piperidyl)indene (4 % of II) was prepared as earlier described.[11] To a solution of 3.99 g of this enamine (0.0187 mol) in 30 ml methanol a small amount of triethylamine was added to avoid fast isomerization. Crystallization at 0°C overnight yielded 1.22 g pure I (0.0057 mol, 19 % from 1-methylindan-2-one) as colourless large prisms, m.p. 33.0–33.5°C. PMR spectrum in tetrachloroethylene was free from any traces of isomeric impurities (Fig. 1).

The perchlorate salt (III). The perchlorate salt was synthesized in analogy with a method reported by Blomquist and Moriconi.[9] To an ethereal solution of 2.0 g of 1-methyl-2-(*N*-piperidyl)indene (0.0094 mol) a mixture of 25 ml 70 % perchloric acid and 25 ml absolute ethanol was added to the blue colour of Congo red paper (pH < 3). The immonium salt precipitates immediately. One recrystallization from acetone gave colourless needles of III. Yield: 1.8 g (61 % 0.0057 mol) m.p. 156–158°C.

Solvent, substrate and catalysts. Pyridine (Mallinckrodt analytical reagent) was kept over potassium hydroxide for two weeks before being fractionally distilled[10] and then, finally, stored over calcium hydride under nitrogen

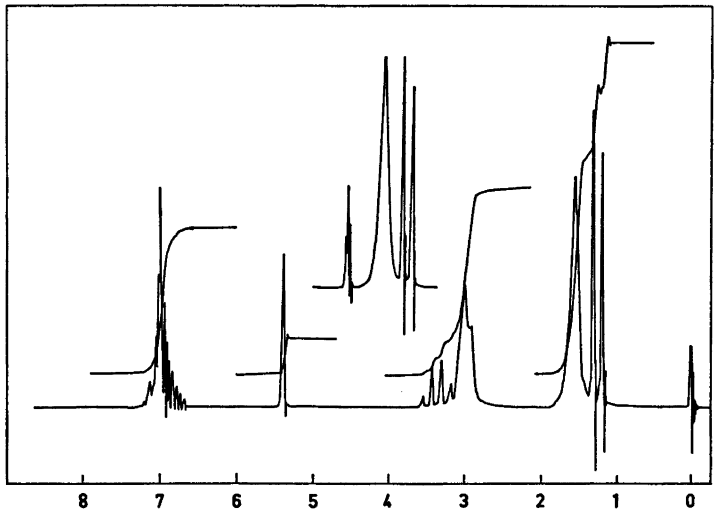


Fig. 1. PMR spectrum of pure 1-methyl-2-(*N*-piperidyl)-indene (I) in tetrachloroethylene with TMS as internal reference. Concentration: 2 M. Temperature: 27°C. (Compare the inset part of the spectrum from the thermodynamic mixture.)

atmosphere. GLC-analysis of the pure isomer I (1 % Apiezon L on Chromosorb W: 300 cm × 6 mm: Det. 180° C/col. 150° C/inj. 210°C. 1 % SE 30: 180 cm × 6 mm: Det. 180°C/col. 150°C/inj. 180°C. 1 % XE 60: 180 cm × 6 mm: Det. 140°C/col. 120°C/inj. 180°C) shows at least 99.5 % purity except for isomeric contamination, since attempts to resolve the two isomers have been unsuccessful. DABCO (Kebo *purum*) was recrystallized from hexane. Quinuclidine was generated from its hydrochloride (Fluka) and purified by sublimation.

Kinetics. All glassware including NMR-tubes, was dried at 150°C for at least 16 h. Pure I and the desired amount of the catalyst were weighed in a 5 ml volumetric flask and were then diluted with pyridine. Concerning the base-catalyzed runs, the rearrangement was performed at a constant temperature (35.0 ± 0.1°C) in a thermostat (Colora Ultra-Thermostat Type MB). From the reaction solution 0.5 ml aliquots were drawn and the appropriate PMR-signal measured.

In the acid-catalyzed runs a desired volume was drawn from a 100 ml 0.01 M solution of III in pyridine and injected to a given solution volume of I. From this mixture a 1 ml sample was withdrawn and filled into an NMR-tube under nitrogen. After careful sealing of the tube, the isomerization was performed at 27.0°C in the PMR-probe. The estimated errors in temperature measurements were ±0.3°C. The inaccuracies in weighing (±0.0001 g) and pipetting are considered to be small compared to those involved in the kinetic parameters and are therefore neglected in Table 1.

The rearrangement was followed by PMR-technique by measuring the increase in intensity of the 3-methyl proton peak at approximately 2 ppm. No significant rearrangement could be observed without any added catalyst. The equilibrium constant was determined by integration over the vinylic proton signal from the least substituted isomer and over the 3-methyl peak from the most substituted one. No change in the equilibrium proportions could be observed in the different runs. A least squares program PROGAEXP [11] has been used to evaluate the rate parameters. The residuals were randomly generated. The accuracy of the estimated values was set to two times the standard deviation ($\pm 2\sigma$).

Mass Spectra of α-Allenic Alcohols and Some Isomeric Acetylenic Analogues*

CONNY BOGENTOFT, LARS-INGE OLSSON and ALF CLAESSON

Department of Organic Chemistry, Faculty of Pharmacy, University of Uppsala, Box 574, S-751 23 Uppsala, Sweden

The mass spectra of eleven α-allenic alcohols have been recorded. Deuterium labelling in some of the compounds studied made possible a structural interpretation of the principal fragments. The main fragmentation route consists of α-cleavage with loss of the allenyl group. A comparison has also been made between some isomeric tertiary allenic, α-acetylenic (propargylic), and β-acetylenic alcohols in order to investigate the possibility of using mass spectrometry to differentiate between isomeric allenes and acetylenes. In spite of the similarities of the spectra of the allenic and the β-acetylenic compounds it can be concluded that mass spectrometry is useful for such purposes.

Only scant attention has been paid to the mass spectra of allenes.[1-4] As part of an investigation currently in progress on the chemistry of allenes [5] it was necessary to use GLC and MS as major tools of identification. In the present paper we summarize our experience on the mass spectral behaviour of eleven α-allenic alcohols, I–XI.

Allene-acetylene isomerization is a well known problem encountered in most work with these types of compounds. Few attempts [6] have been made to use mass spectrometry to differentiate between isomeric allenes and acetylenes. Thus we found it of importance to include also this approach in the present investigation. We have compared two allenic tertiary alcohols (VII and XI) with their isomeric acetylenic compounds XII, XIII and XIV, XV respectively. Deuterium labelling in some of these compounds (*cf.* Table 1 and Fig. 1) made possible structural assignments to the principal fragments. The fragmentation discussed is supported by appropriate shift(s) in the deuteriated analogues. The mass spectra of compound I–XV are given in Table 2.

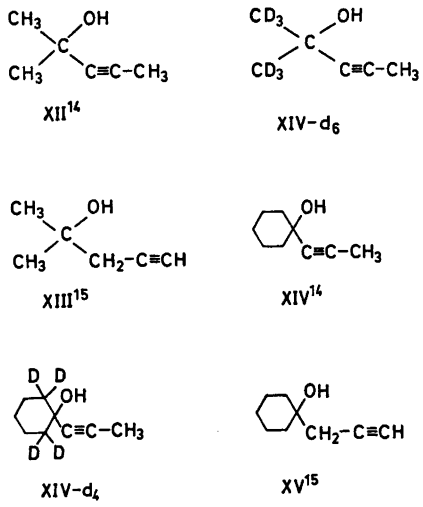

Fig. 1. Tertiary acetylenic alcohols and some deuteriated analogues.

α-Allenic alcohols. In general, the molecular peaks of the allenic alcohols studied are small (0.01 – 0.7 %, *cf.* Table 2). As expected, only the primary alcohols I and II exhibit a prominent $M^+ - H_2O$ peak while the secondary derivatives have smaller peaks of this kind (5 – 10 %). The molecular ions of the tertiary alcohols show no tendency to lose water on electron impact. However, this type of fission

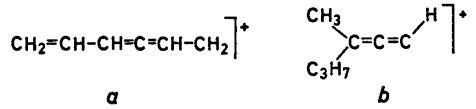
occurs as a secondary process in the fragmentation of compounds V, VI, and VIII.

Two primary alcohols (I and II) were examined, their mode of fragmentation being quite similar. Compound II is the methyl analogue of I which facilitates the interpretation of the spectra because of the possibility to exploit the shift technique. The spectra are complex and many peaks correspond to fragments formed after loss of alkyl moieties, *e.g.* *m/e* 97 ($M^+ - 15$), 84 ($M^+ - 28$), 83 ($M^+ - 29$), and 69 ($M^+ - 43$) in the spectra of I. This type of cleavage is sometimes combined with consecutive or preceding losses of water. Two common routes of importance are noticed: (*i*). The molecular ions lose H_2O and the species formed then expel a methyl radical as shown by a metastable peak. This decomposition pathway leads to the base peak at *m/e* 79 (*a*) in the spectrum of compound I while the analogous peak *m/e* 93 in the spectrum of II amounts to 40 %.



a *b*

(*ii*). A major mode of fission of I and II corresponds to $M^+ - CH_2OH$ and gives rise to the base peak *m/e* 95 (*b*) in the spectrum of II. This indicates that the positive charge of the

molecular ion can reside on the allenic function and trigger the ejection of the hydroxymethyl group. However, the secondary and tertiary alcohols exhibit this fragmentation to a less extent.

The decomposition of the secondary alcohols III and IV occurs mainly through cleavage α to the hydroxyl group. The base peak *m/e* 69 in the spectrum of III corresponds to loss of the butyl group, while the molecular ion splits off the allenyl group less easily. In the present investigation compound IV is the only alcohol containing an aromatic group. As expected, this group governs the decomposition, *e.g.* the α-fission occurs exclusively with loss of the allenyl group to form *m/e* 107 (base peak). The presence of the aromatic group is also reflected in the intensity of the molecular ion (9 %).

The tertiary alcohols V, VI, and VII all have a terminal allenyl group. In principle, three different types of groups, methyl, vinyl, and allenyl can be lost in an α-cleavage of compound V. However, the loss of the latter group dominates and the $M^+ - 39$ peak is the base peak in the spectrum. The α-cleavage of compound VI occurs to an equal extent with loss of the propyl (*m/e* 83) and the allenyl group (*m/e* 87).

A peak at *m/e* 67, which is shifted to *m/e* 68 in the deuteriated analogue V-d_1, is represented by species *c*. This fragment is also formed in the decomposition of compounds VI, X, and XI which likewise have a terminal allenyl group.

$CH_2=C=CH-C\equiv O^+$

c

The spectrum of compound V exhibits an abundant peak at *m/e* 43 (93 %) corresponding to an acetyl moiety. This species is associated with the methyl group located on the α-carbon to the hydroxyl group. A prominent acetyl fragment is also found in the breakdown pattern of compounds VI, VII, and VIII. The corresponding peak sometimes constitutes the base peak, *e.g.* in the spectrum of VI. A comparable ion having structure *d* is formed in the fragmentation of compound IX.

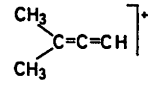
$CH_3-CH_2-C\equiv O^+$

d

The spectrum of compound VII shows a small peak at $M^+ - CH_3$ (*m/e* 83). In the spectrum of the hexadeuteriated analogue VII-d_6, which has an isotopic purity of at least 99 %, this peak is split into four peaks corresponding to $M^+ - CH_3$, $M^+ - CDH_2$, $M^+ - CD_2H$, $M^+ - CD_3$ of almost equal intensity. The reason for this behaviour may be an incomplete hydrogen scrambling, since the calculated values for a random loss of the above methyl groups from the molecular ion of VII-d_6 are 1:9:15:5, respectively.

Compounds VIII and IX do not have a terminal allenyl group. The main fragmentation pathway of these compounds is α-cleavage with loss of the allenic group. This behaviour is analogous to that of the other tertiary alcohols studied. Thus the $M^+ - 67$ peak corresponding to the loss of the allenic group is the base peak in the spectrum of compound IX. The formed moiety then expels H_2O, *e.g.* to rise to *m/e* 81 in the spectrum of VIII.

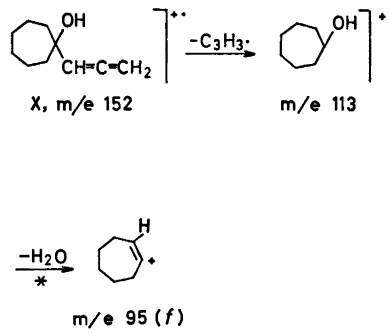
The allenic group is not a preferred site for the charge localization in the ionizing process of the secondary and tertiary alcohols studied. There is an abundant peak at *m/e* 39 in the spectra of the compounds having a terminal allenyl group (III, IV, V, VI, VII, X, and XI) but on the other hand, the analogous fragment *e* corresponding to *m/e* 67 in the spectra of VIII and IX is of minor importance.



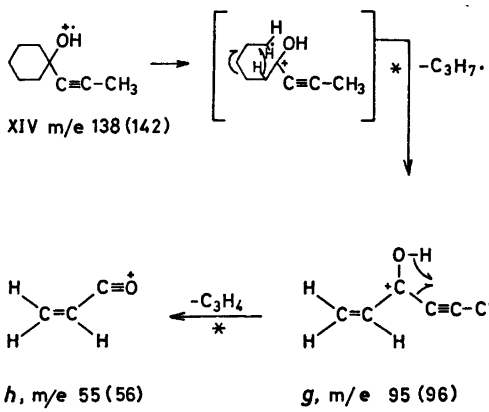
e

The breakdown pattern of compounds X and XI is dominated by peaks corresponding to ions derived from the cycloalkyl rings. The major mode of fragmentation is loss of the allenyl group and subsequent expulsion of H_2O from the formed ion to give a stable fragment, corresponding to *m/e* 95 (*f*) and *m/e* 81 in the fragmentation of X and XI, respectively (*cf.* Scheme 1).

Compounds XI and XIV are exposed to a dissociation route involving complex fissions of the ring as outlined in Scheme 2. It is substantiated by metastable ions, high resolution measurements, and by shifts in the spectra of the deuteriated analogues XI-d_1, XI-d_4, and



Scheme 1.



Scheme 2.

XIV-d_4, respectively, *e.g.* species *g* and *h* are shifted only one mass unit.

Acetylenic tertiary alcohols. Compounds XII and XIV exhibit modes of fragmentation which differ from those of their allenic counterparts VII and XI and their β-acetylenic isomers XIII and XV. The important difference is that no $M^+ - 39$ peak is present in the spectra, *i.e.* no fission occurs in the acetylenic chain. The acetylenic group behaves similarly to a vinyl group in this respect and analogous results have been noticed for acetylenic amines.[7,8] Instead, the major fragmentation route for XII implies loss of a methyl radical. The fragmentation of compound XIV occurs mainly in the cyclohexyl ring, *e.g.* the formation of $M^+ - 29$ and $M^+ - 43$. Deuterium labelling reveals that the $M^+ - 15$ ion is formed through loss of a methyl group from the acetylenic chain. The most important route of fragmentation is outlined in Scheme 2 and involves a site-specific hydrogen transfer to the expelled radical.

The β-acetylenic alcohols XIII and XV afford essentially the same breakdown pattern as their allenic isomers VII and XI (*cf.* Table 2). However, there are differences in the relative intensities of various peaks, which make it possible to differentiate between the isomers. Compared to compound XI, the fragmentation mode of XV seems to involve to a less extent the cyclohexyl ring, *m/e* 95 is only 3 %. To obtain an accurate identification of these two types of compounds only based on mass spectral data, a comparison with reference compounds is needed.

In conclusion, the allenic alcohols studied mainly fragment through α-cleavage. In this type of fission, the allenyl group can be anticipated to behave similarly to a vinyl or to a propargyl group. Judging from the similarity of the spectra of the β-acetylenic and allenic alcohols, the latter case seems to be relevant. α-Cleavage with loss of the allenyl group is the main fragmentation route of the tertiary alcohols. However, in some compounds, *e.g.* III, an alkyl group of similar size is lost to an equal extent.

The study of the isomeric allenic, α-acetylenic, and β-acetylenic tertiary alcohols shows that the α-acetylenic derivatives behave quite differently due to the fact that fission does not occur preferentially next to an acetylenic bond.

In spite of the similarities of the spectra of the allenic and β-acetylenic compounds it can be concluded that mass spectrometry is a useful method for distinguishing between isomeric allenic and acetylenic alcohols.

EXPERIMENTAL

Infrared and NMR spectra of all compounds are in full agreement with the proposed structures.

All reactions with $LiAlH_4$ or Grignard reagents were performed under a nitrogen atmosphere.

Elemental analyses were performed in the laboratories of Dr. A. Bernhardt, Mülheim, West Germany.

The mass spectra were recorded on an AEI MS-30 mass spectrometer, connected to a Pye 104 gas chromatograph. The ionizing energy was maintained at 70 eV, the accelerating voltage

at 4 kV and the temperature of the source at 200°. High resolution spectra were obtained on an Atlas MS 1 mass spectrometer in the laboratory of Dr. R. Ryhage.

High resolution measurements of 1-(1-propynyl)cyclohexanol (XIV).

Measured mass	Theoretical	Formula
55.0532	55.0547	C_4H_7

3-Methyl-6-(tetrahydro-2-pyranyloxy)-1-hexen-4-yn-3-ol (XVI) was prepared as described for similar compounds[13] from 3-(tetrahydro-2-pyranyloxy)propyne (40.7 g; 0.29 mol) and methyl vinyl ketone (18.0 g; 0.26 mol). Yield 23 %. B.p. 108°/0.15 mmHg. (Found: C 68.3; H 8.83. Calc. for $C_{12}H_{18}O_3$: C 68.5; H 8.63).

1-Phenyl-4-(tetrahydro-2-pyranyloxy)-2-butyn-1-ol (XVII). Prepared as above from 3-(tetrahydro-2-pyranyloxy)propyne (77.1 g; 0.55 mol) and benzaldehyde (53.0 g; 0.50 mol). Yield 95 %. B.p. 130°/0.1 mmHg.

2,4,7-Trimethyl-7-(tetrahydro-2-pyranyloxy)-2-octen-5-yn-4-ol (XVIII). Prepared as above from 3-methyl-3-(tetrahydro-2-pyranyloxy)butyne[16] (67.0 g; 0.40 mol) and mesityl oxide (36.2 g; 0.37 mol). Yield 69 %. B.p. 100°/0.1 mmHg. (Found: C 72.4; H 9.61. Calc. for $C_{16}H_{26}O_3$: C 72.1; H 9.88).

2-(Methyl-d_3)-5-(tetrahydro-2-pyranyloxy)-3-pentyn-2-ol-1,1,1-d_3 (XIX) was prepared as above using acetone-d_6. B.p. 95°/0.15 mmHg. Yield 77 %.

1[3-(Tetrahedro-2-pyranyloxy)-1-propynyl]-cyclohexanol-2,2,6,6-d_4 (XX) was prepared as above using cyclohexanone-2,2,6,6-d_4. B.p. 128°/0.1 mmHg. Yield 40 %.

2-(Methyl-d_3)-3-pentyn-2-ol-1,1,1-d_3 (XII-d_6) was synthesized as described for the undeuteriated compound[14] using acetone-d_6. B.p. 140°/760 mmHg. Yield 69 %.

1-(1-Propynyl)cyclohexanol-2,2,6,6-d_4 (XIV-d_4) was prepared as described for the undeuteriated compound[14] using cyclohexanone-2,2,6,6-d_4. B.p. 115°/20 mmHg. Yield 86 %.

α-Allenic alcohols IV, V, VII-d_6, VIII and XI-d_4. Prepared according to Landor[9] from $LiAlH_4$ and the tetrahydropyranol derivatives XVI–XX.

Synthesis of the mono-deuteriated allenic alcohols III-d_1, V-d_1, IX-d_1 and XI-d_1. From $LiAlD_4$ (0.315 g; 7.5 mmol) and the appropriate tetrahydropyranyl derivative (6.0 mmol) (*cf.* the preparation of the undeuteriated alcohols). Micro distillation was applied for the isolation. The yields were between 30 and 50 %.

The Crystal and Molecular Structure of Dimedone

DAG SEMMINGSEN

Department of Chemistry, University of Oslo, Oslo 3, Norway

The crystal and molecular structure of dimedone, 5,5-dimethyl-1,3-cyclohexanedione, has been determined from three-dimensional single crystal X-ray diffraction data. The space group is $P2_1/c$, with cell dimensions $a = 10.040(1)$, $b = 6.823(1)$, $c = 12.984(2)$ Å, $\beta = 116.20(1)°$. There are four molecules in the unit cell. The structure has been refined by full matrix least-squares methods to a weighted R-factor of 0.046 for the 1428 independent reflections. The estimated standard deviations in bond lengths involving non-hydrogen atoms are 0.002 Å. The molecules crystallize in the enol form and are hydrogen bonded to each other forming infinite helices parallel to the b axis. The hydrogen bond length is 2.593 Å.

Dimedone (5,5-dimethyl-1,3-cyclohexanedione) is a white crystalline solid of melting point 148 – 149°C. It is commonly used as a reagent for separation and identification of aldehydes.[1] Unlike acyclic β-dicarbonyl compounds, enolization of dimedone gives a *trans*-enol where *intra*-molecular hydrogen bonding is impossible.[2,3] Nevertheless, dimedone is believed to exist largely in the enol form both in solution [5] and in the solid state.[4] In solvents incapable of forming hydrogen bonds the comparatively high enol content has been explained by assuming a hydrogen bonded dimeric enol form.[2,3] Several X-ray investigations of acyclic β-diketones have been carried out,[6–8] but there is a paucity of structural data for the cyclic analogs. An X-ray investigation of dimedone has therefore been undertaken.

EXPERIMENTAL

A commercial sample of dimedone was purified and crystallized from methanol. The observed extinctions, $h0l$ for $l = 2n + 1$ and $0k0$ for $k = 2n + 1$ uniquely determined the space group as $P2_1/c$. The cell dimensions were determined at room temperature on a manual four circle diffractometer using CuK radiation. The crystal used for the collection of intensity data was of nearly spherical form with diameter 0.35 mm. Data were collected on a SYNTEX P$\bar{1}$ diffractometer by the $\omega/2\theta$ scan technique using a graphite monochromator and Mo$K\alpha$ radiation ($= 0.71069$ Å) at 18°C. Each reflection was scanned from $2\theta_{\alpha 1} - 0.85°$ to $2\theta_{\alpha 2} + 0.85°$, at a variable scan rate ranging from 1°/min to 12°/min depending on intensity. Stationary-counter-stationary-crystal background counts were made at the upper and lower extremities of the 2θ scan range for each reflection. A rejection level was also specified to avoid measurement of reflections with intensities less than the threshold value. The intensities of three standard reflections, measured every 50′ reflections, showed no change during the data collection. A total of 1548 independent intensities were recorded, out to $2\theta < 70°$. Of these, 1428 reflections had intensities greater than twice their standard deviations. The intensities and their standard deviations were corrected for Lorentz and polarization effects and a 2 % uncertainty in diffractometer stability was included in the standard deviations. No corrections were made for absorption since intensity errors from this source are less than 1.5 % ($\mu = 0.09$ mm^{-1}). All programs applied are written or revised for CDC 3300 by Dahl *et al.*[11]

CRYSTAL DATA

Dimedone, $C_8H_{12}O_2$, F.W. 140.2, monoclinic; $a = 10.040$ (1), $b = 6.823$ (1), $c = 12.984$ (2) Å, $\beta = 116.20$ (1)°, $V = 798.3$ Å^3, F (000) = 444, $Z = 4$, $\varrho_{obs} = 1.15$ g cm^{-3}, $\varrho_{calc} = 1.15$ g cm^{-3}. Space group $P2_1/c$.

SOLUTION AND REFINEMENT

The phase problem was solved three-dimensionally by a computer program based on

symbolic addition methods. By permuting the signs of two structure invariant reflections with large unitary structure amplitudes, four sets of 350 signs were determined. From one of the resulting Fourier maps, peaks corresponding to all the heavy atoms were located. The trial structure was refined by full-matrix least-squares technique. A difference Fourier synthesis led to the location of the hydrogen atoms with the exception of those of the methyl groups. The coordinates for these atoms were calculated assuming staggered positions of the methyl groups relative to C5. Refinement of all positional and thermal parameters including a common isotropic thermal parameter for the methyl hydrogen atoms terminated at $R_w = 0.046$ and $R = 0.040$. Unobserved reflections were excluded throughout the refinement. Weight analysis showed that weighting based on standard deviations from counter statistics was satisfactory. No correction for secondary extinction was necessary. Atomic form factors were those of Hanson *et al.*[9] except for hydrogen.[10] A final difference Fourier map contained no larger density fluctuations than ± 0.3 e/Å^3. The parameters obtained in the last cycle of refinement are given in Table 1 together with their estimated standard deviations. Table 2 contains the observed and calculated structure factors.

Rigid-body analysis of translational, liberational, and screw motion [11] of the molecule gave a r.m.s. value of 0.0033 Å^2 when all the non-hydrogen atoms were included. When the two methyl carbon atoms were excluded, the r.m.s. value dropped to 0.0022 Å.^{2} The cyclohexene ring and the two oxygen atoms may therefore be regarded as a rigid body. Corrections in bond lengths generally exceed the standard devia-

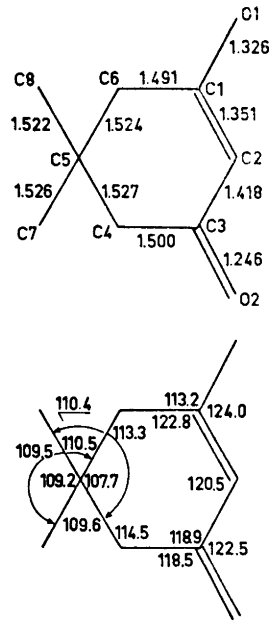

Fig. 1. Schematic drawing of the molecule showing bond distances and angles. (Bond distances uncorrected for librational motion).

Table 1. Fractional atomic coordinates and thermal parameters with estimated standard deviations ($\times 10^5$), isotropic temperature factor and positional parameters ($\times 10^4$) for the hydrogen atoms. The anisotropic temperature factor is given by $\exp -(B_{11}h^2 + B_{22}k^2 + B_{22}l^2 + B_{12}hk + B_{13}hl + B_{23}kl)$.

tions as shown in Table 3. The r.m.s. translational amplitudes corresponding to the discrepancy of 0.0022 Å are 0.22, 0.20, and 0.18 Å and the r.m.s. liberational amplitudes are 5.5, 3.9, and 2.9°.

DISCUSSION

Bond lengths and angles are given in Table 3 and Fig. 1. The molecular arrangement in the unit cell is shown in Fig. 2. The compound crystallizes in the *trans*-enol form as expected from spectroscopic investigations,[2,4] and there is an *inter*-molecular hydrogen bond (2.593 Å) between the hydrogen atom of the enol hydroxyl and the oxygen atom of the carbonyl group. These bonds tie the molecules in helices along the two-fold screw axes. The molecules thus form polymers rather than dimers as has been found in solution. However, formation of a dimer with two hydrogen bridges as suggested,[2,3] seems to be incompatible with normal hydrogen bonds if reasonable van der Waals distances are assumed. The O···O distance is significantly larger than corresponding distances found in analoguous *cis*-enolized β-diketones (2.43 – 2.50 Å).[6-8] In the open *trans* arrangement in dimedone, *inter*-molecular nonbonded repulsions may preferably give an expansion of the O···O distance, whereas in the *cis*-enolized β-diketones investigated,[6-8] there are varying amounts of *intra*-molecular nonbonded repulsions giving the opposite effect. The hydrogen atom (H6) is unambiguously located in an asymmetric position near O1 (O1 – H6 = 0.87 Å), and is situated very close to the least-squares plane through the conjugated enol system. The angle O1 – H6···O2 is 177°.

The distances in the enol system reveal a considerable degree of conjugation, although not as much as in the *cis*-analogues.[6-8] Similar conjugation effects have also been found in ascorbic,[13] dialuric,[14] and α-methyltetronic acids.[15] Changes in bond lengths due to hydrogen bond formation in the conjugated system in barbiturates have been discussed by Craven *et al.*[16] It is also reasonable to assume that formation of hydrogen bonds is partly responsible for the relatively large amount of conjugation in the above mentioned systems.

The conformation of the molecule might be described as an envelope. The carbon atom C5 is displaced by 0.61 Å from a least-squares plane through the other carbon atoms in the ring and the oxygen atoms (Table 4). The deviations from the plane are probably significant. The oxygen atoms and C4, and the other carbon atoms are displaced on opposite sides of the plane. The deviations thus give the cyclohexene ring a slightly curved boat-shaped form. The small deviation of O1 from a plane through C2, C1, and C6 is possibly associated with the formation of the hydrogen bond. The other deviations may be due to non-bonded interactions, expecially between O2 and C1′ across the two-fold screw axis in $x = 0$ and O2 and H1 across the centre of symmetry in $x = 0$. Very

C6	−0.007
C5	(−0.61)
H1	(−0.063)
H6	(0.087)

similar deviations are found in the conformation of related six-membered rings.[17]

The sp^2-sp^3 and sp^3-sp^3 bonds have fairly normal values.[18] The angles inside the ring progressively decrease from values close to 120° near the double bond to a tetrahedral value at C5. The arrangements around C5, C7, and C8 are very regular, none of the angles departing much from tetrahedral values, and the hydrogen atoms at C4 and C6 are in staggered positions relative to the methyl groups at C7 and C8.

Nuclear Magnetic Resonance of Aromatic Heterocyclics. VIII. A Comparative Study of ^{1}H and ^{13}C Spectra of Some 2-Substituted Furans, Thiophenes, Selenophenes and Tellurophenes

F. FRINGUELLI,[a] S. GRONOWITZ,[b]* A.-B. HÖRNFELDT,[b] I. JOHNSON[b] and A. TATICCHI[a]

[a] Instituto di Chimica Organica, Università di Perugia, Perugia, Italia and [b] Division of Organic Chemistry 1, Chemical Center, University of Lund, P.O. Box 740, S-220 07 Lund 7, Sweden

A systematic investigation of the influence of the heteroatom on ^{1}H- and ^{13}C-NMR parameters in 2-substituted furans, thiophenes, selenophenes and tellurophenes has been carried out. In addition to the parent compounds, the formyl, acetyl, carboxyl, carbomethoxy, methylthio and hydroxymethyl derivatives were studied.

Linear correlations between the electronegativity of the heteroatoms and several of the NMR parameters were observed, as well as between the shifts of the corresponding protons and carbons in the four heterocyclic series. These can be used for predicting shifts of unknown selenophene and tellurophene derivatives, when those of thiophene are known.

$^{125}Te-H$ couplings were determined for the tellurophenes and compared with $^{77}Se-H$ couplings.

Extensive work on the effect of substituents on the proton NMR parameters of thiophenes,[1,2] furans,[3] and selenophenes [4] have previously been carried out by Gronowitz and coworkers. As early as 1962 a linear correlation between the 3-proton shifts in 2-substituted thiophenes and the corresponding shifts in 2-substituted furans was observed. The same was also found for the 5-proton shifts. We were therefore interested in extending this investigation to the selenophene and tellurophene series, as well as in extending our study to ^{13}C NMR. Only a few ^{13}C NMR investigations of these heterocyclic systems have been carried out,[5-9] from which basic information about chemical shift regions and most $^{13}C-H$ couplings may be obtained. Takahashi and coworkers,[9] who studied six 2- and six 3-substituted thiophenes, observed a linear correlation between the C_2 shift of 3-substituted derivatives and the C_3 shift in 2-substituted compounds, and also a linear correlation between C_5 shifts and H_5 shifts of 2-substituted thiophenes.

A systematic study of the influence of the heteroatom of these four related aromatic systems on the transmittance of substituent effects to different positions of the rings would perhaps provide some information related to the aromaticity of these rings and could contribute to an understanding of the chemical differences between these systems. Both experimental results and theoretical calculations have indicated that correlations exist between ^{13}C chemical shifts and charge densities.

In the present paper, due to synthetic difficulties in preparing 2-substituted tellurophenes, the series of derivatives studied had to be limited to the 2-formyl, 2-acetyl, 2-carboxyl, 2-carbomethoxy, 2-hydroxymethyl, and 2-methylthio derivatives of furan, thiophene, selenophene, and tellurophene, besides the parent compounds. This number and types of substituents are of course not representative enough for a test of the applicability of the Swain and Lupton two-parameter equation, which hitherto has been successfully applied by us to the chemical shifts of 5- and 4-substituted 2-fluorothiophenes and 5-substituted 3-fluorothiophenes,[10,11] as well as to proton chemical shifts of thiophenes [1,2] and selenophenes.[4]

In the furan, thiophene, and selenophene series, we have recently finished an extensive study of representative 2- and 3-substituted derivatives, and have found that certain ^{13}C shifts can be excellently correlated with the reactivity constants $\mathscr{F}$ and $\mathscr{R}$ of Swain and Lupton.[12]

^{1}H NMR SPECTRA

The ^{1}H NMR spectra of tellurophene, 2-acetyltellurophene, and 2-tellurophene carboxylic acid in deuteriochloroform solution have been described earlier.[13] Assignments of chemical shifts in tellurophene were based on analogy with thiophene and selenophene and on shift effects caused by substituents. In order to obtain comparable ^{1}H NMR data for the six derivatives of the four heterocycles discussed in this paper, the spectra were recorded in deuterioacetone solutions.

In those cases when the substituent was electron-attracting the absorptions of the aromatic hydrogens were well separated, while the 2-hydroxymethyl and 2-methylthio compounds showed more strongly coupled spectra for the β-hydrogens. The refined δ and J values were obtained iteratively using an extended version of the QCPE program UEAITR (No. 188). The original version of UEAITR is given in Ref. 14. After a preliminary estimate of the parameters the calculations were performed until the best least squares fit was ob-

[a] Determined from ^{77}Se spectra.

tained (RMS 0.02) The procedure resulted in calculated proton spectra with average deviations from the observed frequencies of 0.01 Hz or less.

The shifts and coupling constants are given in Table 1.

The ^{1}H NMR tellurophene spectrum showed satellite spectra due to ^{13}C as well as ^{125}Te. A representative spectrum showing tellurophene satellites are given in Fig. 1. Thus, the magnitude of the coupling between the heteroatom and the three ring-hydrogens could be observed, as previously done for selenophene.[15] The measurement conditions for the two heteroatoms are comparable, they are of the same natural abundance and the sensitivity of selenium is about half that of tellurium. The absolute values of the tellurium-hydrogen couplings of the tellurophene derivatives are given in Table 2. The same relative order $|J_{X-H_5}| \gg |J_{X-H_4}| \sim |J_{X-H_3}|$ was found for some selenophene derivatives.[15] For each compound the magnitude of J_{X-H_4} is, however, larger than that of J_{X-H_3}.

The intervals for the largest heteroatom-hydrogen coupling, $|J_{X-H_5}|$, are 91.7 – 100.4 Hz and 44.8 – 48.5 Hz for the tellurophene and selenophene derivatives, respectively. There is a simple relation between coupling constants involving various isotopic nuclear species,

and the J value for a pair of nuclei.[16] The magnitudes of coupling constants between different nuclei are often compared by means of their reduced coupling constants, K,[17] defined as

$$K = (4\pi^2/h\gamma_A\gamma_B)J_{AB}$$

The products of the magnetogyric ratios $\gamma_{Se}\gamma_H$ and $\gamma_{Te}\gamma_H$ are of opposite signs. By introducing the visual α-coupling constants for unsubstituted tellurophene and selenophene, 100.4 Hz and 47.5 Hz, respectively, the reduced coupling constants were calculated to be $K_{Se-H} = |2.07|$ and $K_{Te-H} = |2.64|$. As the magnitudes are of the same order the same type of coupling mechanism seems to operate in both cases. The small difference might be due to the deviation in geometry for the two five-membered rings.

From Table 2 it is obvious that there is no systematic variation in the coupling constants due to the substituents.

From the ^{13}C satellite spectrum in the ^1H NMR spectrum of tellurophene, the $^{13}C-H_\alpha$ and $^{13}C-H_\beta$ cuplings were determined to be 183 Hz and 159 Hz, respectively. This is in agreement with the data for the other three heterocycles, where $^{13}C-H_\alpha$ is also found to be larger than $^{13}C-H_\beta$.[6]

^{13}C NMR SPECTRA

The ^{13}C NMR spectra were also recorded in deuterioacetone solution and the shifts were determined from the proton-decoupled spectra. The assignment of the α- and β-carbons in unsubstituted tellurophene was established from the undecoupled spectrum and based on the magnitude of the direct couplings. The smaller splitting was recognized in the low field ^{13}C absorption in the tellurophene spectrum. Thus the relative order of the carbon chemical shifts is opposite that of the hydrogens.

In the 2-substituted derivatives, the quaternary 2-carbon is directly identified by its lower intensity and the absence of the direct coupling, and the 5-carbon by the largest direct

coupling. The assignments of the 3- and 4-carbons are based on the expected substituent shift effects, as compared with those obtained for benzene,[18] thiophene,[12] and selenophene derivatives.[12] The assignments thus obtained for the 3- and 4-carbons are also supported by considerations of the long-range couplings. By other ^{13}C measurements it has namely been demonstrated that the long-range coupling over three bonds (^3J) is generally larger than ^2J.[8] This is also the case for 2-substituted thiophenes and selenophenes,[12] where it was proven by a study of deuterated derivatives. On the other hand, furans seem to be an exception to this rule.[12]

The undecoupled spectra of the tellurophene derivatives studied in this paper were of first order. In addition to the large splitting, J_{C-H}, each of the unsubstituted carbons appears as two quartets as a result of long-range couplings. These quartets overlap only in one case, namely that of methyl 2-tellurophenecarboxylate. Still all coupling could be obtained as shown in Fig. 2. The ^{13}C parameters are given in Table 3.

DISCUSSION

The difference in the proton chemical shifts of the α- and β-hydrogens in these five-membered heterocyclics has been suggested as a criterion of aromaticity. In the pure liquids the following differences were found: thiophene (0.132), selenophene (0.569), tellurophene (0.957), and furan (1.061).[19] This order is in agreement with that of decreasing aromaticity based on several criteria.[19]

The same general trend is observed in 20 % deuterioacetone solutions, except for an inversion between furan and tellurophene (*cf.* Table 4). However, a closer analysis of the shifts indicates that the β-hydrogen shifts vary systematically with the +M effect of the heteroatom O > S > Se > Te, and give a good correlation with the Pauling electronegativity data for the heteroatoms (O = 3.5, S = 2.5, Se = 2.4, Te = 2.1; $r = 0.99$). The α-hydrogen shifts, on the other hand, vary irregularly, and this is probably due to the fact that in addition to electronic effects, the anisotropy of the heteroatom also plays an important role in determining the α-shifts. In all four systems, however, the α-hydrogen resonances occur at lower field than the corresponding β-hydrogen resonances.

Table 4. α- and β-Hydrogen shifts (ppm) for furan, thiophene, selenophene, and tellurophene in deuterioacetone solution using TMS as internal standard.

Heteroatom	δ_α	δ_β
O ($E = 3.5$)	7.46	6.36
S ($E = 2.5$)	7.40	7.10
Se ($E = 2.4$)	8.10	7.33
Te ($E = 2.1$)	8.97	7.79
Correlation coefficient	0.81	0.999

The shift differences are even more pronounced in the ^{13}C spectra, but it is only the magnitudes of the differences between the α- and β-carbon shifts that follow the expected aromaticity order: thiophene |1.7|, selenophene |1.7| tellurophene |11.0|, and furan |33.2|. (*Cf.* Table 5, where the ^{13}C parameters for benzene also are given.) The real differences of the ^{13}C shifts, however, show no relation to aromaticity. The resonances of the α-carbons of furan and selenophene occur at lower field than those of the β-hydrogens, while the opposite is true for thiophene and tellurophene.

Table 5. α- and β-^{13}C NMR parameters for furan, thiophene, selenophene, and tellurophene in deuterioacetone solution using TMS as internal standard.

Heteroatom	C_α	C_β	$^1J_{C-H\alpha}$	$^1J_{C-H\beta}$
O	143.6	110.4	201	175
S	125.6	127.3	185	168
Se	131.0	128.8	189	166
Te	127.3	138.0	183	159
Benzene	128.7		159	

Table 6. Chemical shifts (ppm) of the ring protons of some furans, thiophenes, selenophenes, and tellurophenes relative to the α- and β-hydrogens in the parent compounds in deuterioacetone solution.

Furthermore, the α-carbon shifts vary irregularly and are quite similar for thiophene, selenophene, and tellurophene. The β-carbon shifts, on the other hand, are systematically shifted upfield with increasing +M effect of the heteroatom, and are again linearly correlated with the electronegativity of the heteroatoms ($r = 0.998$: $C_\beta = -18.9\ E_x$).

Good correlations were also obtained between the electronegativity of the heteroatoms and the magnitude of the couplings $^1J_{C-H\alpha}$ ($r = 0.96$) and $^1J_{C-H\beta}$($r = 0.94$). It is generally accepted that the direct $^{13}C-H$ couplings are related to the amount of *s*-character on the carbon nucleus and to the electronegativity of the substituents, the coupling constant increasing with electronegativity. This is for instance evident for the *trans* J_{CH} coupling in vinyl derivatives,[20] and has also been observed in acetylenic systems.[21]

Good linear correlations are also observed between shifts and coupling constants. Both C_α *versus* $^1J_{C-H\alpha}$ and C_β *versus* $^1J_{C-H\beta}$ give $r = 0.98$. For the proton shifts, an acceptable correlation was only obtained for C_β *versus* $^1J_{C-H\beta}$.

The absence of a linear correlation between the α-proton shift ($\delta_{H\alpha}$) and $^1J_{C-H\alpha}$ could be expected. Goldstein and Reddy [22] have used deviations from linear correlations between proton chemical shifts and $^{13}C-H$ coupling constants to estimate diamagnetic anisotropy effects. They assumed that in the absence of diamagnetic anisotropy effects and medium effects a linear correlation would be obtained. This was also the case for vinyl derivatives, while benzene and thiophene showed deviations of 78 Hz and 40 Hz, respectively (at 40 MHz). Goldstein and Reddy ascribed these deviations to anisotropy effects of the ring-current type. A preliminary study of the other five-membered heterocycles showed that the deviation form the "vinyl" line was even greater for selenophene, and for tellurophene especially great. This fact and the different behaviour of α- and β-hydrogens indicate strongly that other contributions to anisotropy than ring-current effects are responsible for the deviations. The good linear correlation between ^{13}C shifts and direct $C-H$ couplings again illustrates the fact [23-25] that carbon shifts are much less influenced by diamagnetic anisotropy effects

than the proton shifts.

Galasso [26] has recently carried out CNDO/2 calculations on the four chalcogen heterocyclics. The total charge densities at the α- and β-carbons obtained by him gave the following good linear correlations against the ^{13}C shifts: $C_\alpha = 74.3q + 129.3$ ($r = 0.974$); $C_\beta = 532.8q + 161.7$ ($r = 0.998$).

The proton-proton coupling constants J_{45} and J_{35} are very sensitive to a change of the heteroatom, and excellent linear correlations are obtained for all six derivatives (*cf.* Table 1). Similar observations have previously been made in vinylic systems [27] and 2-substituted thiophenes.[28] Also the coupling J_{34} increases with decreasing electronegativity. However, the correlations are not as good as for J_{45} and J_{35} and the sensitivity to changes in electronegativity is not as great.

The proton shifts relative to those of the α- and β-hydrogens of the parent compounds are given in Table 6, and the corresponding ^{13}C shifts in Table 7. The ^{13}C values for the furans, thiophenes, and selenophenes are taken from Ref. 12.

Even if the data unfortunately are limited, interesting differences between the four ring systems can be observed. The ease of transmission of the substitution resonance effects to the 5-hydrogen and 5-carbon increased in the series furan < thiophene < selenophene < tellurophene. As good correlations were obtained for the 5-proton shifts against the 5-carbon shifts in all four systems ($r > 0.97$), the same transmission mechanism seems to be operating both for carbon and proton. This sensitivity of the 5-position to substituent effects from the 2-position indicates that the heavier chalcogens transmit the substituent effects more efficiently, which may be due to the fact that the *d*-orbitals are easily polarisable. Obviously more material is needed in order to place this hypothesis on a firmer basis. However, the efficient transmission of the heavier heteroatoms to the 5-position can hardly be related to the aromaticity in these systems (*cf.* Ref. 3).

The resonance of the 2-carbon was shifted as a function of both the substituent inductive effect and the +M effect of the heteroatom, giving good correlations (*cf.* Table 7). The shifts of the 3- and 4-carbons caused by the substituents decreased steadily on going from furan to tellurophene. For each type of substituent we carried out linear correlations between the ^{13}C shifts and the electronegativity of the heteroatom. Very good correlations were observed for all ring carbons in compounds containing −I−M substituents, except for C_4 in the 2-acetyl series. For electron-donating substituents, correlations with electronegativity were only observed for the C_2 and C_4 resonances (*cf.* Table 7). Our data are of course too limited to decide if these deviations are due to different transmittance mechanisms for electron-attracting and electron-donating groups. It has been suggested that such differences exist.[2]

A comparison of Tables 6 and 7 shows that the 3- and 4-proton did not vary in the same systematic way as the corresponding carbons with the electronegativity of the heteroatom. This observation reflects the difference between ^1H and ^{13}C with regard to the ring current effect, anisotropy contribution and shift range.

Good correlations between the carbonyl ^{13}C shifts with electronegativity of the heteroatom have been obtained. This was also the case when the methyl of the methylthio and carbomethoxy group and the hydroxymethyl group were correlated with electronegativity. Only the methyl of the acetyl group fails to give such correlation (*cf.* Table 7).

Attempts were made to correlate the various ^1H and ^{13}C shifts with each other. The linear correlations obtained when the relative shifts of the furans, selenophenes, and tellurophenes reported in Tables 6 and 7 were plotted *versus* the relative shifts of the thiophenes are given in eqns. 1−9 for protons and 10−21 for carbons.

^{13}C

$\Delta C_O^2 = 0.81\Delta C_S^2 - 5.05$; $r = 0.99$ (eqn. 10)
$\Delta C_{Se}^2 = 1.11\Delta C_S^2 - 0.62$; $r = 0.99$ (eqn. 11)
$\Delta C_{Te}^2 = 1.40\Delta C_S^2 - 1.76$; $r = 0.99$ (eqn. 12)
$\Delta C_O^3 = 1.22\Delta C_S^3 - 0.11$; $r = 0.99$ (eqn. 13)
$\Delta C_{Se}^3 = 1.17\Delta C_S^3 - 1.57$; $r = 0.99$ (eqn. 14)
$\Delta C_{Te}^3 = 1.37\Delta C_S^3 - 3.84$; $r = 0.95$ (eqn. 15)
$\Delta C_O^4 = 1.28\Delta C_S^4 - 0.75$; $r = 0.99$ (eqn. 16)
$\Delta C_{Se}^4 = 1.18\Delta C_S^4 - 0.43$; $r = 0.99$ (eqn. 17)
$\Delta C_{Te}^4 = 1.13\Delta C_S^4 - 0.71$; $r = 0.89$ (eqn. 18)
$\Delta C_O^5 = 0.58\Delta C_S^5 + 0.28$; $r = 0.98$ (eqn. 19)
$\Delta C_{Se}^5 = 1.14\Delta C_S^5 - 0.50$; $r = 0.99$ (eqn. 20)
$\Delta C_{Te}^5 = 1.56\Delta C_S^5 - 3.05$; $r = 0.97$ (eqn. 21)

In most cases both the proton and ^{13}C shifts give good correlations ($r > 0.97$), the exceptions were observed for the tellurophenes. It is, however, difficult to understand why some of these lines do not pass through the origin. These relations can anyhow be used for predicting shifts of unknown selenophene and tellurophene derivatives, when those of thiophene are known. It is thus obvious that the NMR parameters of the four heterocycles show certain systematic regularities, which should be verified by an investigation of a larger and more representative number of substituted derivatives.

EXPERIMENTAL

All NMR spectra were recorded with a Varian XL-100-15 NMR spectrometer, equipped with frequency sweep, proton wide band decoupler, Fourier transform operation, and frequency counter. The transmitter frequency for ^{13}C was 25.142 MHz and for ^{1}H 100.01 MHz. The shifts were determined with an accuracy of ± 0.1 ppm and ± 0.005 ppm relative to TMS. The ^{13}C shifts were measured on proton decoupled spectra on 20 % solutions in CD_3COCD_3. The coupling constants were obtained with an accuracy of ± 0.02 Hz from proton spectra and ± 0.25 Hz from the ^{13}C spectra.

Studies on the Bacteriolytic Activity of *Streptomyces albus* Culture Filtrates. 1. The Effect of Variations in Cultivation Conditions and the Screening of Various Enzyme Specificities

L. AKSNES and A. GROV

The University of Bergen, School of Medicine, The Gade Institute, Department of Microbiology, N-5000 Bergen, Norway

Optimal conditions for production of bacteriolytic enzymes of *Streptomyces albus* G have been studied, and found to depend on stimulation and selection of strain, composition of medium, inoculum, and incubation. The culture filtrates lysed whole cells and mucopeptide/cell wall of *Staphylococcus aureus*, *Planococcus*, *Micrococcus luteus*, *M. conglomeratus*, *M. lysodeikticus*, *Sarcina lutea*, and *Bacillus megaterium*. Results are presented to show that the lytic activity of the cultures is composed of an endo-*N*-acetylmuramidase, an *N*-acetylmuramyl-L-alanine amidase, several endopeptidases with specific activity on mucopeptide linkages, and caseinolytic activity. The specificities likely to be present are discussed in relation to apparently broken mucopeptide bonds.

Bacteriolytic enzymes have been isolated from a variety of sources including plants, animal tissues, and various microorganisms and, specially in the latter source, a great spectrum of specific lytic enzymes has been demonstrated.[1] Such enzymes, which are capable of solubilizing mucopeptide networks, the basic structure of all bacterial cell walls, belong to three classes: (1) Glycosidases or hexosaminidases which hydrolyse the polysaccharide (glycan) chains, (2) endo-peptidases, splitting the bonds within the peptides and their cross-links, and (3) acetylmuramyl-L-alanine amidases which cleave the junction between polysaccharides and peptides.[1-3] Proteolytic activity of soil microorganisms was discovered a long time ago,[4,5] but the first systematic study was carried out by Welsch [6] working with *Streptomyces albus* strain G. Subsequent works,[7-9] using fractional precipitation, ion exchange resin, and various test bacteria revealed that *Streptomyces* strains produce a complex system of lytic enzymes. This was confirmed by Ghuysen and collaborators (*cf.* Ref. 1) in their extensive work on the enzymes from *Streptomyces albus* G.

Bacteriolytic enzymes are of considerable interest in various fields; as potentially useful chemotherapeutics, in biochemical and genetical studies, and in the study of mucopeptide chemistry.[1]

Streptomyces strains are reported to vary on cultivation in both growth and pigmentation [10] as well as in the ability to produce lytic enzymes.[7,11] Therefore, the aim of the present study was to examine the growth conditions and to select strains with high capability for synthesis of lytic enzymes.

MATERIALS AND METHODS

Chemicals. Bacto beef extract (B 126), bactopeptone (B 118), special agar Noble, and trypsin were purchased from Difco Laboratories, Detroit, Mich., U.S.A.; hen egg-white lysozyme (3× crystalline) from Calbiochem. Inc., Los Angeles, Calif., U.S.A.; proteose peptone (code L46) and peptone bacteriological (L37) from Oxoid Ltd., London, England, and trypticase-soy from Baltimore Biological Laboratories, Baltimore, Md., U.S.A. Standard amino acids were obtained from Eastman Organic Chemicals Department, Rochester, N.Y., U.S.A.; dinitrophenyl(DNP)-amino acids from Nutritional Biochemicals Co., Cleveland,

Ohio, U.S.A.; casein, muramic acid, and glucosamine from Koch-Light Laboratories Ltd., Colnbrook, Bucks., England; penta-glycine and ethylene-oxide from Fluka, CH-9470 Buchs, Switzerland, and Amberlite IRC-50 ion-exchange resin from the British Drug Houses Ltd., Poole, Dorset, England. Dialyzer tubing was purchased from A. H. Thomas Co., Philadelphia, Pa., U.S.A. Thin-layer plates (polygram Cel 300 and polygram sil N-HR) were from Machery, Nagel & Co., 516 Düren, BRD; Tabsorb (ethylene glycol adipate coated on chromosorb W), used as column material on gas chromatography, from Regis Chemical Co., Chicago, Ill, U.S.A., and trifluoroacetic acid anhydride from Pierce Chemical Co., Morton Grove, Ill, U.S.A. Trichloroacetic acid, 1-fluoro-2,4-dinitrobenzene (FDNB), diethylether, *p*-dimethylaminobenzaldehyde, acetic acid, chloroform, benzylalcohol, butanol, pyridine, ninhydrin, and all inorganic chemicals (reagent grade) were obtained from E. Merck, Darmstadt, BRD.

Organisms. *Streptomyces albus* G, *Staphylococcus aureus* Copenhagen (Sa), *Streptococcus pyogenes* A (Sp), *Planococcus* 2389 (Pc), *Micrococcus luteus* 144 (M-144), *Micrococcus conglomeratus* 84 (M-84), *Micrococcus lysodeikticus* NCTC 2665 (Ml), and *Sarcina lutea* (Sl) were from the laboratory stock of organisms at the Institute. *Bacillus megaterium* KM (Bm) was kindly provided by Dr. J.-M. Ghuysen, Service de Bactériologie, Université de Liège, Belgium.

Media. The following media were made up to 1 l in deionized water: nutrient broth, pH 7.2, containing 3 g bacto-beef extract, 10 g bacto-peptone and 5 g NaCl. For cultivation of the halofilic *Planococcus* 60 g NaCl were added. Mucopeptide medium contained 2.5 g mucopeptide from Sa, 1 g K_2HPO_4 and 1 g $MgSO_4.7H_2O$. Agar-mucopeptide medium contained in addition 10 g special agar Noble. The peptone media contained 10 g peptone, 1 g K_2HPO_4, 1 g $MgSO_4.7H_2O$, 0.5 g KCl, and 2 g $NaNO_3$.

Growth and harvesting of the test-bacteria. The test-bacteria were grown aerobically on nutrient broth; 4 h inoculum (100 ml) was transferred to 900 ml fresh medium and incubated on a shaking machine at 37°C. The growth was followed spectrophotometrically at 600 nm on a Unicam SP 800 and the bacteria were harvested at the end of the exponential growth-phase, using a Sorvall RC-2 centrifuge (10 000 *g*). After washing in buffer of 0.15 M NaCl, 0.01 M phosphate, pH 7.2, the bacteria were stored at −25°C.

Heat-killed bacteria. Portions of test-bacteria were suspended in distilled water and placed in a boiling water bath for 15 min to denature autolytic enzymes,[12] then washed three times in water and freeze-dried.

Preparation of mucopeptide. Mucopeptides were prepared and analyzed as described earlier.[13] To remove possible *O*-acetyl groups at the 6-position of muramic acid, the mucopeptide preparations were further extracted for 20 min with 9 N NH_4OH at 20°C.[14] After thorough washing with distilled water the mucopeptides were freeze-dried and examined by thin-layer and gas chromatography.

Preparation of cell wall. Isolation of mucopeptide from Bm was difficult since the bacteria clotted on suspension in trichloroacetic acid. Therefore, cell wall material was prepared from Bm according to the method used previously.[15] As for mucopeptides, the cell wall was further trypsinated and extracted with 9 N NH_4OH, to remove *O*-acetyl groups [14] and ester-linked D-alanine from teichoic acid,[16] then washed thoroughly, freeze-dried and examined chromatographically.[15]

Ethylene-oxide treatment of mucopeptides/cell wall. To mask free amino groups of mucopeptide/cell wall preparations, a hydroxyethylation procedure described by Ghuysen *et al.*[2] was employed.

Analytical procedures

Thin-layer chromatography in one and two dimensions was performed on cellulose and silica plates in the following solvent systems: (A) Chloroform:benzyl alcohol:HAc (70:30:3, by vol.),[17] (B) benzyl alcohol:chloroform:methanol:H_2O:NH_3 (25 %) (30:30:30:6:2, by vol.),[2] (C) butanol:HAc:H_2O (4:1:1, by vol.),[2] and (D) pyridine:H_2O (4:1, v/v).[2] Ninhydrin [18] and silver nitrate [18] were used as colour reagents.

Gas chromatography of trifluoroacetylated amino acid butyl esters [19] was carried out on a Perkin-Elmer 900 chromatograph fitted with flame ionization detector and a disc integrator. Tabsorb (80 − 100 mesh), in columns of 200 cm length and 2 mm inner diameter, was used as supporting material. The temperature was increased linearly (4°C/min) from 100°C to 200°C and was then held for 10 min at 210°C, the carrier gas (N_2) having a flow rate of 33 ml/min.

Tests for free groups. Estimation of the increase in free amino groups of enzymatically degraded mucopeptides/cell wall and the identification of *N*-terminal amino acids were carried out by the use of 1-fluoro-2,4-dinitrobenzene (FDNB) according to the description of Ghuysen *et al.*[2] Soluble *N*-acetyl amino sugars were detected by the Morgan − Elson reaction [2] and the increase in reducing groups was measured by the method of Park and Johnson with modifications.[2,20]

Reducing end-group determination. Samples of digested mucopeptide/cell wall, isolated oligosaccharides from preparative thin-layer chromatography and standard amino sugars (glucosamine and muramic acid) were reduced with $NaBH_4$.[21] Reduced and hydrolyzed (3 N HCl for 4 h at 95°C in sealed tubes) preparations were desalted by extraction with pyridine and analyzed by thin-layer chromatography.

Selection of lytic strain and its cultivation. *Streptomyces albus* G was plated on agar-

mucopeptide medium and incubated at 28°C, separate colonies being then inspected. The diameter of the clearing zone around the colony, read after 4 days, was taken as a measure of the lytic activity. Colonies showing high lytic activity were replated on agar-mucopeptide medium every fourth day and incubated at 28°C. For production of enzymes the selected strain (a colony with high lytic activity) was replated once more on agar-mucopeptide medium, grown for 2 days and then transferred to 20 ml of the mucopeptide medium. After 30 h at 28°C on a shaker (Microid Flask Shaker, Griffin & Tatlock Ltd., London, England) operating at a rate of 50 – 60 rotations/min the inoculum was transferred to 1 l of proteose peptone medium and further incubated with shaking for 50 – 60 h.

Concentration and purification of enzymes by the use of Amberlite.[14,22] After removal of mycelia by filtering through glass wool, the culture filtrate was mixed with one half its volume of distilled water and then 0.5 % (by weight) of Amberlite IRC-50 (H^+) was added. After 1 h with stirring at 4°C, the pH of the suspension was adjusted to 5.0 with concentrated acetic acid and the stirring continued for 10 h. The ion-exchange resin was then isolated by centrifugation, washed in distilled water, resuspended in 10 % K_2HPO_4 (approx. 10 ml/g of dry resin) and, while stirring, 25 % NH_4OH was added until the pH was stable at 8.0. The suspension was further stirred for 5 h, centrifuged to remove the resin, and finally dialyzed against 0.01 M Tris-HCl pH 8.0. The dialyzed supernatant is further referred to as crude enzyme preparation (CEP).

Quantitative determination of mycelia. Duplicates of culture (20 ml each) were centrifuged at 3000 *g*. The mycelia were thoroughly washed in distilled water, dried at 90°C and weighed.

Test for bacteriolytic activity. Bacteriolytic activity was expressed as reduction in turbidity of suspensions of bacteria or mucopeptide/cell wall compared to equal suspensions without enzyme. Heat-killed bacteria were washed twice in 0.01 M Tris-HCl buffer pH 8.0, and suspensions (0.5 ml) of bacteria and mucopeptide/cell wall in this buffer were adjusted to give a turbidity of 1.0 at 600 nm with 1.0 cm cell thickness after the addition of enzyme (0.25 ml). This corresponds to a cell concentration of about 5×10^8 cells/ml or a concentration of mucopeptides/cell wall of approximately 1 mg/ml. The suspensions were incubated at 37°C, the lytic activity, followed on a Unicam SP 800, being expressed as reduction in turbidity after 60 min (ΔT_{60}) when $\Delta T_{60} = (\Delta T_t/t) \times 60$. All measurements of activity were carried out before 50 % reduction in turbidity was reached.

Definition of bacteriolytic units. One lytic unit is defined as the activity, at the conditions described above, that gives a $\Delta T_{60} = 1.0$ in a suspension of Sa. Lytic units/ml is then referred to as $\Delta T_{60} \times 4$.

Test for caseinolytic activity. This was performed according to the method described by Petit *et al.*[14] and expressed as reduction in turbidity after 60 min (ΔT_{60}) as for bacteriolytic activity.

EXPERIMENTS AND RESULTS

Substrates for lytic enzymes. The results of gas chromatographic examination of mucopeptides/cell wall with respect to amino acids are given in Table 1, showing a dominance of the amino acids characteristic of mucopeptides. The molar ratio of these amino acids (Table 2) and the absence of teichoic acids in the mucopeptide preparations, as found serologically by double diffusion in agar and chromatographically by

search for glycerol and ribitol,[18,15] indicate that the preparations are satisfactorily pure.

Selection of lytic populations of Streptomyces albus *G.* Colonies with various lytic zones (0–0.5 cm diameter) appeared on agar-mucopeptide medium, each colony giving rise to new ones with variable lytic ability. However, upon further selection the extension of the highest lytic zones reached after 4 months a diameter of approximately 2.5 cm. There was no observable change in the maximal lytic activity of these colonies after 4 months, when the necessary replating and selections had been performed.

Influence of type of peptone on growth and enzyme production. Two litre flasks containing 0.5 ml of peptone medium made from various types of peptone were inoculated with 20 ml of *Streptomyces albus* G cultures and incubated with shaking at 28°C for 60 h. Five cultivations, a total of 5 × 4 flasks, were prepared for each peptone type, and the amount of mycelia and maximum lytic activity, measured on heat-killed cells of Sa and Bm, was determined. Considerable variations in lytic activity were observed within each peptone type and even in the flasks of the same cultivation. The variation in the amount of mycelia was small. Culture filtrates with low lytic activity appeared yellow-brownish in colour, whereas those with high activity were dark brown. The mean values of mycelia and lytic activity are listed in Table 3, indicating that the type of peptone apparently is of importance as far as lytic activity is concerned, proteose peptone being superior in this respect.

Effect of variation in the volume of inoculum. Three series of proteose peptone medium, each consisting of 0.25, 0.50, 0.75 and 1.0 l, were prepared in 2 l flasks, then inoculated with 20, 40 and 60 ml of culture and cultivated at 28°C with shaking for 60 h. The lytic activity in the different series, measured on heat-killed cells of Sa and Bm, showed rather small variations.

Table 3. The amount of mycelia and bacteriolytic activity in cultures of *Streptomyces albus* G using various types of peptone.

Type of peptone	Mycelia g/l	ΔT_{60} on Sa	ΔT_{60} on Bm
Bacto peptone	3.0	0.2	0.3
Proteose peptone	2.9	1.2	1.6
Peptone bacteriological	2.7	0.4	0.5
Trypticase Soy	2.6	0.2	0.3

Table 4. Bacteriolytic activity in cultures of *Streptomyces albus* G after direct inoculation and after preculture.

Inoculum	ΔT_{60} on Sa	ΔT_{60} on Bm
150 ml preculture	0.2	0.3
250 ml preculture	0.2	0.3
20 ml direct inoculum	1.2	1.6

Effect of precultures on peptone medium. Precultures were prepared by transferring 20 ml inoculum to 150 and 250 ml of proteose peptone medium. After 15 h of incubation the precultures were used to inoculate 1 l portions (2 l flasks) of proteose peptone medium. The resultant lytic activities, taken as the mean values of two cultivations each of 4 flasks, are listed in Table 4, showing a remarkably lower activity after use of precultures than after a direct inoculum.

Growth and lytic spectrum. In accordance with the results obtained in the varied culture conditions, all further cultures were prepared using

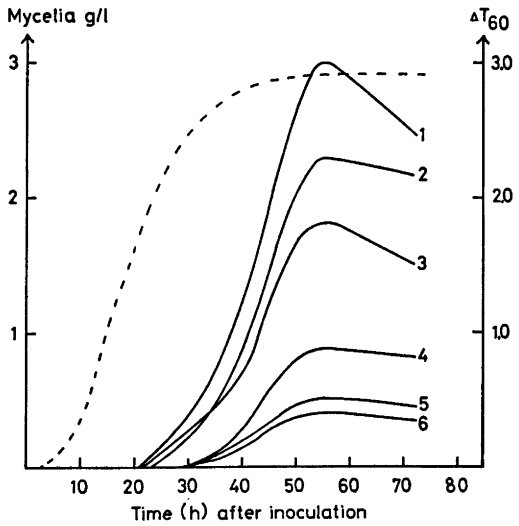

Fig. 1. The amount of mycelia (- - -), bacteriolytic activity tested on Bm(1), Sa (3), Ml and Sl (4), M-144 and M-84 (5) and Sp (6), and caseinolytic activity (2) of a culture of *Streptomyces albus* G at various time intervals. Samples for testing were taken every fifth hour.

20 ml 30 h inoculum to 1 l proteose peptone medium in 2 l flasks, which were then incubated with shaking (50 – 60 rotations/min) at 28°C for 55 h.

Fig. 1 illustrates the growth (expressed as the amount of mycelia) and lytic activity (tested on all test-bacteria as well as casein) of a representative culture. Samples for testing were taken every fifth hour. Extracellular lytic activity was detected in the culture at the end of the exponential growth-phase and reached a maximum in the stationary phase of growth. Lytic activity was demonstrated by all test-bacteria, and the bacteriolytic as well as caseinolytic activities reached maximum at the same time interval. Although the total lytic activity varied from one culture to another, the ratios between the degree of lysis of different test-bacteria were found to be nearly constant. Solubilization of mucopeptides/cell wall with culture filtrates (taken at the time of maximum lytic activity) revealed smaller differences in the lytic spectrum compared to that tested on whole cells (Table 5). Mucopeptides were, however, rather variable as substrate for testing of lytic activities, probably due to heterogeneity with regard to molecular size. Incubation of

Table 5. Bacteriolytic activity of culture filtrate (at maximum) as measured on heat-killed bacteria and on mucopeptides/cell wall.

Bacteria	ΔT_{60} on heat-killed cells	ΔT_{60} on mucopeptide	ΔT_{60} on cell wall
Sa	1.8	1.2	–
M-144	0.5	0.7	–
M-84	0.5	0.9	–
Ml	0.9	0.6	–
Bm	3.0	–	1.7

ethylene-oxide-treated mucopeptides of Sa, M-144, M-84, Ml, and Pc and cell wall of Bm with the culture filtrate increased the amount of free amino groups and reducing groups in all samples, indicating the presence of both peptidases and hexosaminidases.

Lytic activities adsorbed to and eluted from Amberlite. Dialyzed eluate from the resin (CEP) lysed heat-killed bacteria and casein similar to the culture filtrate, indicating that all activities observed were adsorbed to and eluted from the resin. However, only about 50 % of the total bacteriolytic activity and 25 % of the caseinolytic activity were recovered. The remaining activity of the culture filtrate was not adsorbed by the addition of new resin. In spite of low recovery, a rapid concentration and marked purification of the enzymes were obtained. Thus, the absorbance at 280 nm of the culture filtrate (10 × diluted) and CEP was 0.5 and 0.31, respectively. The ratios between degree of lysis on the various test-bacteria seemed similar for culture filtrate, for culture filtrate absorbed with Amberlite, and for CEP.

Samples of ethylene-oxide treated mucopeptides/cell wall (2 parts of 2 mg/ml) were digested with CEP (1 part) and egg-white lysozyme (1 part of 50 μg/ml), the free amino groups were traced with DNP and the mixtures then hydrolyzed. Chromatography of ether extracts in solvent system A and of water-saturated butanol extracts in system B revealed the amino acid derivatives listed in Table 6, which indicates that several types of linkages have been split on digestion with CEP.

Determination of hexosaminidase specificity. Bm cell wall (2 mg/ml in 0.01 M Tris-HCl, pH 8.0) was incubated with CEP at 37°C for 12 h.

Table 6. Dinitrophenyl-amino acids detected chromatographically after treatment of mucopeptides/cell wall with crude enzyme preparation (CEP) and egg-white lysozyme (E.L.).

	Mucopeptide [a]										Cell wall [a]	
	M-84		M-144		Ml		Sa		Pc		Bm	
	CEP	E.L.	CEP	E.L.	CEP	E.L.	CEP	E.L.	CEP	E.L.	CEP	E.L.

DNP-DAP	−	−	−	−	−	−	−	−	−	−	++	++

[a] + to +++: weak to strong colour reaction.

Samples of digested cell wall were reduced with $NaBH_4$, and both reduced and non-reduced samples were hydrolyzed and chromatographed in two dimensions using solvent systems C and D. A spot in the chromatogram of non-reduced samples corresponding to muramic acid was strongly reduced after treatment with $NaBH_4$, while a spot corresponding to muraminitol appeared on the chromatograms. The intensity of the spot corresponding to glucosamine remained unchanged and glucosaminitol was not detected in the reduced samples. This indicates that the only hexosaminidase present is an *N*-acetyl-muramidase.

Test on amidase activity. Mucopeptide of Sa (4 mg) was suspended in and digested with 2 ml (2 lytic units) of *N*-acetylglucosaminidase isolated from lysostaphin,[23] for 12 h at 37°C, pH 8.0. Undissolved material was removed by centrifugation and the supernatant further digested with CEP. Thin-layer chromatography in system C gave a ninhydrin and silver nitrate positive spot with an R_F of 0.25. Preparative chromatography in system C, elution of the material at $R_F = 0.25$, and chromatography of a 3 N HCl hydrolysate (4 h at 95°C) showed two spots corresponding to standard glucosamine and muramic acid. Neither in thin-layer nor gas chromatography could any amino acid be observed in 6 N HCl hydrolysate (18 h at 105°C) of a corresponding eluate. The presence of an oligosaccharide, free of amino acids, thus suggests that the CEP contains amidase activity in accordance with the observed free *N*-terminal alanine in digests of all mucopeptides/cell wall (Table 6).

Test on glycyl-glycine splitting. Treatment of penta-glycine (0.15 mg/ml) with CEP (enzyme/substrate = 1/1 by vol., pH 8.0, 37°C for 12 h) was without effect as judged by free amino group determination and chromatography in system C.[14]

DISCUSSION

The selection of *Streptomyces albus* G gave colonies with increasing ability to produce bacteriolytic enzymes. However, the lytic activity of separate colonies varied after a number of successive selections. Without a continuous selection, the lytic activity of organisms from a colony with high activity diminished with time. This is in accordance with earlier observations on *Streptomyces albus* strains grown on nutrient broth.[7,11] Consequently, continuous selection was found necessary to keep a stable lytic population, although this includes a risk of variation in the strain during the study. The experiment with precultures on peptone medium showed that a selected population rapidly loses its bacteriolytic activity on peptone medium. A direct inoculation from mucopeptide medium therefore seems necessary to obtain maximal lytic activity of the culture. The production of lytic enzymes apparently varied with type of peptone, this phenomenon not being explicable on the basis of the peptone composition.

The strain selections were performed on medium with mucopeptide from *S. aureus* Copenhagen, but the resultant CEP (Crude enzyme preparation) also lysed all the other test-bacteria. The lytic activity, however, varied considerably from one type of bacteria to another. This may be due to differences in mucopeptide structures, chemistry and/or thickness, and secondary effects of other com-

ponents present.[2,8,24] Variations in the lytic spectrum of various cultures were not observed. Although the total activity varied, the ratios between activities on the different bacteria seemed nearly constant. This indicates that the production of lytic enzymes directed against different bacteria is intimately correlated. Of the characterized Streptomyces strains, only *Streptomyces albus* G [6,11] is found to lyse all the test bacteria used in this study. In contrast to earlier observations on *Streptomyces albus* G [25] and *Streptomyces* S-35,[26] that lytic activity of the culture supernatant parallelled the amount of mycelia, the lytic activity in the present experiments appeared at the end of the exponential growth-phase. This may indicate that the lytic activity is due to endoenzymes released by autolysis.

The mucopeptide exhibits the mechanical strength of cell wall structures, and enzymatic hydrolysis of either the glycan chain or the peptide subunits (*cf.* Ref. 1) will usually cause lysis of the cell. The prepared mucopeptides/cell wall seemed pure and apparently suitable as substrates for enzymes as far as component composition and molar proportions are concerned (Tables 1 and 2). Except for a high content of alanine and small amounts of glycine in the *M. lysodeikticus* mucopeptide, the results of analyses of the other preparations agree fairly well with earlier reports. However, insoluble materials like these must be heterogeneous with respect to aggregation, content of natural free groups and groups set free during preparation and treatment.[2] Solubilization by enzymes [12] may reveal free groups not susceptible for reaction with reagents before digestion. The complex and macromolecular structure makes a complete masking of groups impossible.[14] In spite of existent uncertainty, however, some suggestions as to the enzyme specificities of *Streptomyces albus* G culture may be made.

N-Acetylhexosaminidase, amidase, and endopeptidase activities have clearly been demonstrated, the latter activity most probably being composed of several enzymes. Since only muramic acid was found to be reduced by $NaBH_4$, the presence of only one hexosaminidase is likely, *i.e.* *N*-acetyl-muramidase. *M. conglomeratus* 84 has a high content of alanine [13] and is comparable with *M. roseus* Thr− [27,14] having an alanine tripeptide bridge between the terminal D-alanine of one tetrapeptide chain and ε-lysine of an adjacent tetrapeptide. According to the results of digestion with CEP, followed by DNP-tracing, two linkages, D-alanyl-L-alanine and L-alanyl-L-alanine, may have been hydrolyzed. This corresponds to the activities of the earlier observed SA and MR endopeptidases.[14,22] Also *Streptococcus pyogenes*, found to have an alanine dipeptide bridge,[28] is lysed by the same endo-peptidases as *M. roseus*.[1]

The lack of activity of CEP on a pentaglycine preparation and the absence of detectable ε-DNP-lysine on examination of *S. aureus* mucopeptide digest indicate that, in the lysis of *S. aureus*, peptidase activity is mostly located to D-alanyl-glycine linkages.[14,24] The tetrapeptides of *B. megaterium* KM mucopeptide contain diaminopimelic acid (DAP) instead of lysine and a direct linkage between D-alanine in one peptide to DAP in another is proposed.[29,30] This linkage is apparently broken on digestion with CEP (Table 6), indicating the presence of the KM-endopeptidase activity,[22,31] which has also been demonstrated in the culture filtrate of *Streptomyces* L_3.[32]

In *Planococcus* 2389 mucopeptide the linkage between tetrapeptides is shown to be effected through D-glutamic acid (D-alanyl-γ-D-glutamyl-ε-lysine).[33] Results of DNP-tracing indicate that the D-alanyl-γ-D-glutamyl linkage is broken by digestion with CEP. This linkage has been found to be split by the KM-endopeptidase of *Streptomyces albus* G.[31]

Mucopeptides of both *M. lysodeikticus* NCTC 2665 [14,34] and *Sarcina lutea* [35] are found to contain D-alanyl-ε-lysine linkages. Increase of DNP-ε-lysine after treatment with CEP therefore, indicates splitting of the D-alanyl-ε-lysine bridge and an activity corresponding to the ML endopeptidase.[14,22] The structure of mucopeptide of *M. luteus* 144 has not been revealed, but analyses indicate a structure similar to that of *M. lysodeikticus*. However, mucopeptide from *M. luteus* ATCC 398 has been found to contain the amino acids alanine, glutamic acid, glycine, and lysine at a ratio of 2:2:1:1 and a cross-bridge of γ-L-glutamyl-glycine [36] is proposed. Accordingly the result of DNP-tracing may indicate that the CEP splits the glycyl-ε-lysine bond of this

bridge, an activity which to our knowledge has not previously been observed in *Streptomyces* cultures.

An attempt to separate the observed endopeptidase, *N*-acetylmuramidase, *N*-acetylmuramyl-L-alanine amidase, and caseinolytic activities will be reported in a subsequent paper.

Studies on the Bacteriolytic Activity of *Streptomyces albus* Culture Filtrates. 2. Fractionation on Ion-exchange Chromatography and Gel Filtration

L. AKSNES and A. GROV

The University of Bergen, School of Medicine, The Gade Institute, Department of Microbiology, N-5000 Bergen, Norway

Experiments in fractionation of the various lytic activities of *Streptomyces albus* cultures have been carried out using Amberlite IRC-50 and Carboxy methyl cellulose cation-exchangers, electrophoresis in agarose and polyacrylamide gel, and gel filtration on Sephadex. Apparently pure *N*-acetylmuramyl-L-alanine amidase and endo-*N*-acetylmuramidase were isolated on carboxy methyl cellulose columns, whereas all endo-peptidase activities, and one caseinolytic activity were eluted together. Neither on electrophoresis nor gel filtration were the latter activities separated. These results, in addition to optimal pH and salt concentration, indicate that apparently different enzyme specificities had very similar molecular properties.

In a preceding paper [1] the study of strain selection, optimal conditions for enzyme production, and a screening of the enzyme specificities in the culture filtrates of *Streptomyces albus* G were described. Degradation of mucopeptide/cell wall releasing oligosaccharides with the C-1 position of muramic acid free, without detectable free reducing endgroup of glucosamine, showed the presence in the culture filtrates of an endo-*N*-acetylmuramidase. Amidase activity, *i.e.* *N*-acetylmuramyl-L-alanine amidase, was demonstrated by the release of oligosaccharides free of amino acids, and dinitrophenyl tracing of *N*-terminal amino acids of digests of mucopeptide/cell wall of various bacteria indicated the presence of several endopeptidases. In addition caseinolytic activity was demonstrated.

The present paper comprises the results of the attempts to separate highly purified, specific enzymes from the culture filtrate.

MATERIALS AND METHODS

Chemicals. Amberlite IRC-50 (H^+), analytical grade, and *N,N'*-methylene-bisacrylamide were obtained from British Drug Houses Ltd., Poole, Dorset, England; Carboxy methyl cellulose (CMC) cation exchanger (lot no. 39B-04701, medium mesh, 0.66 mequiv./g), cytochrome C and β-alanine from Sigma Chemical Co., Mo., U.S.A., and acrylamide from Eastman Organic Chemicals Department, Rochester, N.Y., U.S.A. Acrylic acid, polyethylene glycol (20 000) and 2,4-lutidine were purchased from Fluka AG, CH-9470 Buchs, Switzerland; agarose from Behringwerke AG, Marburg a.d. Lahn, BRD, Sephadex G-75 and blue dextran 2000 from Pharmacia, Uppsala, Sweden, and dialyzer tubing from A. H. Thomas Co., Philadelphia, Pa., U.S.A. Coomassie brilliant blue was obtained from Serva, D-6900 Heidelberg, BRD; *N,N,N',N'*-tetramethylethylene diamine, riboflavin, and ammonium persulphate for disc electrophoresis from Canalco, Rockville, Md., U.S.A., and Freund's complete adjuvant from Difco Laboratories, Detroit, Mich., U.S.A. Hen egg-white lysozyme (3× crystalline) was from Calbiochem. Inc., Los Angeles, Calif., U.S.A.; myoglobin from Koch-Light Laboratories Ltd., Colnbrook, Bucks., England, and chymotrypsinogen from Boehringer, Mannheim, BRD. The other chemicals used were as described previously.[1]

The *organisms*, *Staphylococcus aureus* Copenhagen (Sa), *Streptococcus pyogenes* A (Sp), *Planococcus* 2389 (Pc), *Micrococcus luteus* 144 (M-144), *M. conglomeratus* 84 (M-84), *M. lysodeikticus* NCTC 2665 (Ml), *Sarcina lutea* (Sl) and

Bacillus megaterium KM (Bm), *media, growth* and *harvesting, mucopeptides/cell wall, thin-layer chromatography, tests for free groups, tests for bacteriolytic and caseinolytic activities* were as described or referred to in Ref. 1.

Absorption to and elution from Amberlite IRC-50.[1-3] A detailed description of the procedure has been given earlier,[1] and the dialyzed eluate (0.01 M Tris-HCl pH 8.0) is referred to as crude enzyme preparation (CEP). Experiments were also carried out in which washed, enzyme-loaded resin was transferred to columns and eluted with a salt-gradient (0 – 1 M NaCl) or stepwise with buffers of increasing pH (4.5 – 9.0). Concentration of enzyme solutions was obtained using polyethylene glycol in dialyzer tubing.

Fractionation on carboxymethyl cellulose.[2-5] CMC was pretreated with 0.2 M NaOH and 0.2 M HCl, washed in 0.05 M Tris-HCl, pH 8.0 to constant pH, equilibrated against 0.01 M Tris-HCl, pH 8.0, evacuated to remove air-bubbles, and then applied to a column (3.6 cm diam. × 3.0 cm) which was given a hydrostatic pressure of 20 cm. Enzyme solutions were applied to the column at a rate of 10 ml/h, then washed with 500 ml of 0.01 M Tris-HCl pH 8.0, the same buffer being used for elution arranged to give an NaCl-gradient from 0 to 0.2 M in 1 l elution buffer. The elution rate was 20 ml/h and 10 ml fractions were collected.

Gel filtration on Sephadex G-75. Sephadex G-75 in 0.01 M Tris-HCl, pH 8.0, containing 0.02 % Na-azide, was applied to a column (1.8 × 95 cm) and the void volume determined using blue dextran. After application of 2 ml of material, elution was performed with 0.01 M Tris-HCl pH 8.0 at a rate of 20 ml/h using a peristaltic pump (LKB Produkter, Stockholm, Sweden). Fractions of 5 ml were collected.

Apparent molecular weight was determined by the method of Andrews [6] using the Sephadex G-75 column described above and cytochrome C, egg-white lysozyme, myoglobin, and chymotrypsinogen as references.

Electrophoresis in agarose was performed according to the method of Scheidegger [7] using an LKB 6800 A immunoelectrophoretic apparatus (LKB Produkter).

Detection of bacteriolytic activity was attained by sandwiching approx. 0.5 mm of 1 % special agar Noble in 0.01 M Tris-HCl pH 8.0 containing 5 mg/ml of heat-killed bacteria, over the electrophoretic slides followed by incubation at 37°C.

Caseinolytic activity was similarly detected using 0.3 % casein in 1 % agar. After incubation the slides were placed in 5 % trichloroacetic acid to visualize undigested casein.

Polyacrylamide gel (disc) electrophoresis was carried out essentially according to the method of Ornstein [8] using two running systems: I as described by Broom [9] and II as described by Joice and Klemperer,[10] both previously used for separation of basic proteins. Ten µl of enzyme solutions dialyzed against the electrodic buffer (diluted 1/4) [11] and made up to 50 % in glycerol, were applied to the top of the gels. The equipment used was a Shandon disc electrophoresis apparatus (Shandon Scientific Company Ltd., London, England). The staining procedure was as described by Maurer.[12] Detection of bacteriolytic and caseinolytic activities in the gels were principally carried out as described above. The buffer used for gels run in system II was 0.05 M Tris-HCl pH 8.5. The gels were divided along the long axis and placed on agar containing heat-killd bacteria/casein.

Antisera. Rabbits were injected intramuscularly with enzyme solutions, 80 units/ml [1] dialyzed against 0.07 M sodium phosphate, pH 7.2, containing 0.15 M NaCl, mixed with an equal volume of Freund's complete adjuvant. Two injections (1 ml of enzyme solution/dose) were given 3 weeks apart and the animals were bled 2 weeks after the last injection. Sera were heated at 56°C for 30 min to inactivate complement, 1 % merthiolate was added as preservative (one drop/10 ml serum) and the sera were then stored at −25°C.

Serological techniques. Examinations for precipitating antibodies were performed by ring test [13] and double diffusion in agar.[14] Immunoelectrophoresis was carried out with an LKB apparatus as described by the manufacturer, and inhibition of bacteriolytic activity by serum was tested after incubation at 37°C for 2 h of 1/1 mixtures of serum, diluted in the phosphate-buffered saline, and enzyme in 0.01 M Tris-HCl pH 8.0.

RESULTS

Amberlite. The CEP (dialyzed eluate from the resin) was as previously [1] found to contain the same lytic spectrum as that of the culture filtrates. In spite of a low yield (approximately 50 % of the total bacteriolytic activity of the culture filtrate) the enzymes of large volumes were rapidly isolated in relatively small volumes. At the same time a 100 fold purification was obtained [1] in relation to the absorbance at 280 nm. The fractionation experiments using salt-gradient or stepwise elution with increasing pH were both unsuccessful. The lytic material was in both cases released in a large elution volume without detectable separation of different activities. All further fractionation experiments were carried out on CEP.

CM-cellulose. Some caseinolytic but no bacteriolytic activity was observed in the washings. Every second fraction of the eluate

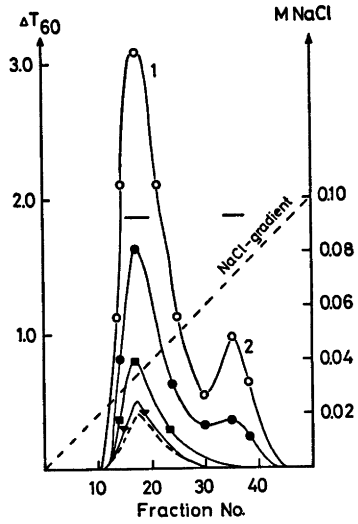

Fig. 1. Lytic activity in fractions from the CMC-column, eluted with NaCl-gradient, as tested on heat-killed cells of Bm (○), Sa (●), Ml and Sl (■), M-84 and M-144 (▼), and on Sp (- - -). ΔT_{60} (reduction in turbidity after 60 min) = $(\Delta T_t/t) \times 60$.

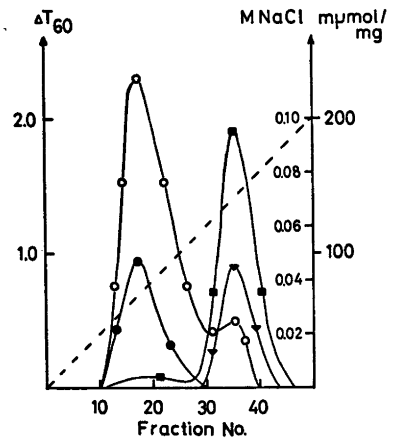

Fig. 2. Fractions from the CMC-column, eluted with NaCl-gradient (- - -), showing caseinolytic activity (●), increase in free amino groups (○) tested on Sa mucopeptide, and increase in reducing groups (■) and *N*-acetylamino sugars (▼) tested on Bm cell wall. ΔT_{60}: See legend Fig. 1.

was tested for bacteriolytic activity on heat-killed bacteria, caseinolytic activity and increase of free groups after digestion of Sa-mucopeptide and Bm-cell wall (Figs. 1 and 2). Two peaks with lytic activity were revealed; one (1) with lytic activity on all the test bacteria, the other (2) only for Sa and Bm when incubation time was 90 min. Longer incubation time showed trace of lysis on the other bacteria as well. Fractions were bulked as indicated by the horizontal lines in Fig. 1. The caseinolytic activity was eluted in one peak (Fig. 2) which overlapped peak 1. Tests on ethylene-oxide treated Sa-mucopeptide and Bm-cell wall showed the same elution profile. Fractions increasing the amount of free amino groups corresponded to peak 1, whereas fractions increasing the amount of reducing groups and of free *N*-acetylamino sugars corresponded to peak 2. The fractions showed no absorbance at 280 nm.

The occurrence and degree of activity of peak 2 varied considerably from one culture to another. When peak 2 did not appear, digestion of mucopeptide/cell wall with culture filtrate showed no increase in reducing groups or *N*-acetylamino sugars. The yield of bacteriolytic and caseinolytic activities was 75–

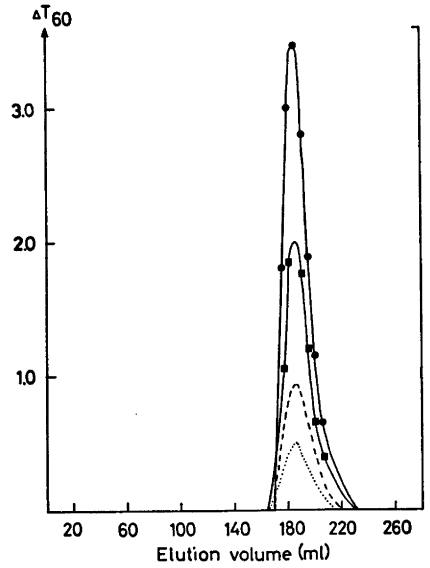

Fig. 3. Lytic activity in eluate from Sephadex G-75 on heat-killed cells of Bm (●), Sa (■), Ml and Sl (- - -), M-84, M-144 and Sp (···). Each fraction was 5 ml. ΔT_{60}: See legend Fig. 1.

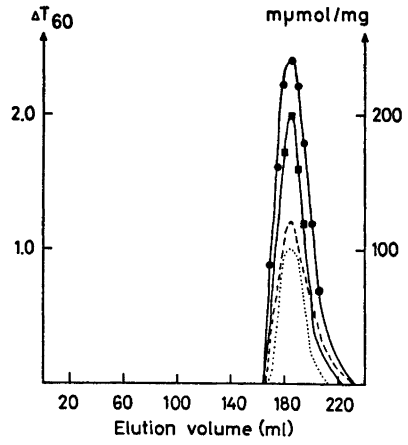

Fig. 4. Fractions (5 ml) from Sephadex G-75 column showing caseinolytic activity (- - -), increase in free amino groups (●) tested on Sa mucopeptide, and increase in reducing groups (■) and *N*-acetylamino sugars (···) as tested on Bm cell wall. ΔT_{60}: See legend Fig. 1.

80 % and about 30 %, respectively. Other dimensions of column or changes in the buffer system and salt gradient did not give better separation of different activities or the two peaks.

Sephadex G-75. Figs. 3 and 4 show the result of filtration on Sephadex G-75 of 10 ml CEP which had been concentrated to 2 ml following dialysis against 0.01 M Tris-HCl pH 8.0. All bacteriolytic and caseinolytic activity was eluted in one peak, the fractions of which also increased the amount of free amino groups, reducing groups and *N*-acetylamino sugars upon digestion of ethylene-oxide treated Sa-mucopeptide and Bm-cell wall. No absorbance was detected at 280 nm. Apparent molecular weight of the material in the peak was calculated to be 16 000.

Maximal release of free groups by various enzyme fractions. The increase in the amount of free amino groups, reducing groups, and *N*-acetylamino sugars of ethylene-oxide treated mucopeptide/cell wall after digestion with CEP, CMC-peak 1 and CMC-peak 2, is given in Table 1. All enzyme solutions were concentrated to about 30 units/ml and dialyzed before incubation with substrate until constant values were observed. All the three enzyme solutions gave a 100 % reduction in turbidity of all mucopeptide/cell wall preparations. In comparison egg-white lysozyme gave about 80 % reduction in turbidity under the conditions employed. It appears from Table 1 that there is a general increase in free amino groups in all digests, but that the effect of the CEP is markedly higher than that of the two other enzyme solutions. The CEP and CMC-peak 2 showed a significant increase in the amount of reducing groups and *N*-acetylamino sugars, whereas only a very small increase was observed in these after treatment with CMC-peak 1.

Specific activities. Dinitrophenyl-tracing of ethylene-oxide treated mucopeptide/cell wall digested with CMC-peak 1 revealed a significant increase of DNP-alanine only in M-84 (Table 2). The digests of M-144 and Ml mucopeptides contained DNP-ε-lysine, Sa mucopeptide DNP-glycine, Pc mucopeptide DNP-glutamic acid and Bm cell wall contained DNP-diaminopimelic acid. This indicates the presence of the same peptidase activities as demonstrated in culture filtrates,[1] whereas the amidase seems to be absent. Reduction with $NaBH_4$, hydrolysis

Table 1. Maximal increase (mμmol/mg) of free amino groups (DNP), reducing groups (P-J) and *N*-acetylamino sugars (M-E) after digestion of mucopeptide/cell wall with crude enzyme preparation (CEP), CMC-peak 1 and CMC-peak 2.

Substrate	CEP			CMC-peak 1			CMC-peak 2		
	DNP	P-J	M-E	DNP	P-J	M-E	DNP	P-J	M-E
M-84 mucopeptide	400	200	85	240	20	0	150	200	80
M-144 »	120	90	40	80	0	0	70	80	30

DNP-ε-Lys	−	+++	+++	−	−	−
DNP-DAP	−	−	−	−	−	++

[a] (+) to +++: weak to strong colour reaction.

and chromatography of mucopeptide digested with CMC-peak 2 revealed appearance of muraminitol and disappearance of muramic acid, contrary to the findings with non-reduced digest. This shows that the muramidase, previously demonstrated in the culture filtrate,[1] is separated from the major portion of peptidases on CMC and located to peak 2. Search for the amidase activity observed in the culture filtrate [1] showed that, under the conditions described, the amidase was not bound to the CMC-column and could be obtained from the effluent.

Electrophoresis in agarose. Samples of culture filtrate, CEP, and CMC-peak 1, all concentrated to approximately 40 units/ml, were subjected to electrophoresis in agarose at pH 8.6 and 250 V for 120 min. Lytic activity was tested on all test bacteria and casein, a representative picture being shown in Fig. 5. The bacteriolytic activity seemed electrophoretically homogeneous, showing activity on all test bacteria in the same spot, and identical mobility of this activity of both culture filtrate, CEP, and CMC-peak 1. Several spots with caseinolytic activity were revealed in CEP (Fig. 5A) and culture filtrate, whereas only one caseinolytic spot, having identical mobility with that of bacteriolytic activity, was demonstrated with CMC-peak 1.

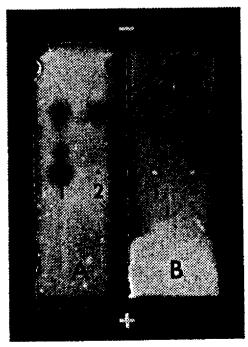

Fig. 5. Electrophoresis in agarose, pH 8.6, 250 V, 120 min, of CEP (1) and CMC-peak 1 (2) tested for caseinolytic (A) and bacteriolytic activity (B).

Disc electrophoresis. Samples of CEP, CMC-peak 1, and a 1/1 mixture of CMC-peaks 1 and 2, all concentrated to approximately 40 units/ml and dialyzed, were run at pH 8.3 and pH 4.3. For all enzyme solutions only one active area, having lytic activity on all test bacteria and casein, was observed. Fig. 6 shows the position of caseinolytic activity (A), bacteriolytic activity (B) and stained lysozyme (C) after electrophoresis in systems I and II.

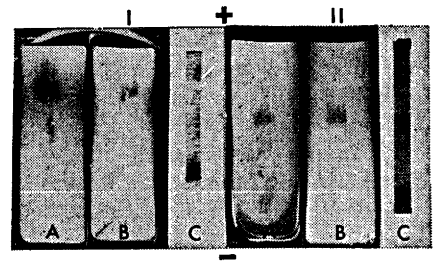

Fig. 6. Mobility of caseinolytic (A) and bacteriolytic (B) activity on (I) disc electrophoresis in system I (1 ma/tube for 10 min + 3 ma/tube for 50 min) and (II) system II (50 V for 10 min + 150 V for 50 min). Egg-white lysozyme (C) was included for comparison and visualized by staining. In system I, lysozyme was first run for 10 min with 1 ma/tube then for 25 min with 3 ma/tube.

Immunology. In contrast to the preimmune sera, rabbit antisera prepared against CEP and

CMC-peak 1 contained precipitating antibodies against the enzyme solutions. Double diffusion in agar using undiluted sera and enzyme solutions concentrated to about 40 units/ml, showed reaction of identity between CEP and CMC-peak 1 with only one detectable precipitin line. A comparison between bacteriolytic activity (Fig. 7A) and serological activity (Fig. 7B) after immunoelectrophoresis (250 V, 120 min) of CEP and CMC-peak 1 (40 units/ml), showed that the electrophoretic movement of the antigen responsible for the precipitin line was less than that of lytic activity. Experiments in inhibition of lytic activity by sera showed that both immune sera and preimmune sera gave complete inhibition, the immune sera being most effective, *i.e.* inhibiting at the highest dilution.

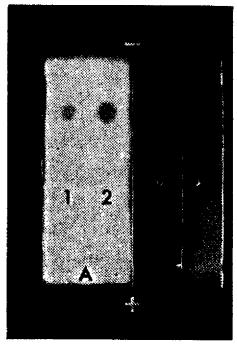

Fig. 7. Immunoelectrophoresis (250 V for 120 min) of CEP (1) and CMC-peak 1 (2) following tests for bacteriolytic (A) and serological (B) activities.

Kinetics. Measurements of the decrease in turbidity at 600 nm of suspensions of heat-killed bacteria and enzyme solutions as a function of time showed a linearity for all enzyme preparations and all test bacteria until approximately 65 % reduction. Thereafter the curves became flatter.

Serial dilutions (in 0.01 M Tris-HCl pH 8.0) of the enzyme preparations all showed the same relative reduction in activity on all test bacteria. Fig. 8 illustrates the results of CEP tested on heat-killed Sa and Bm cells.

The influence of variation in pH on the lytic activity of CEP and CMC-peak 1 was tested between pH 3.5 and 9.5 using Na-acetate (pH 3.5 – 5.5), Na-phosphate (pH 5.5 – 7.5) and Tris-HCl (pH 7.5 – 9.5) buffers. Heat-killed bacteria (1 mg/ml of water), buffer (0.04 M) and enzyme solution (dialyzed against 5 mM Tris-HCl pH 7.5) were mixed at a ratio of 2:3:1. All enzyme solutions showed maximal activity on all test bacteria at a pH of approximately 8.5.

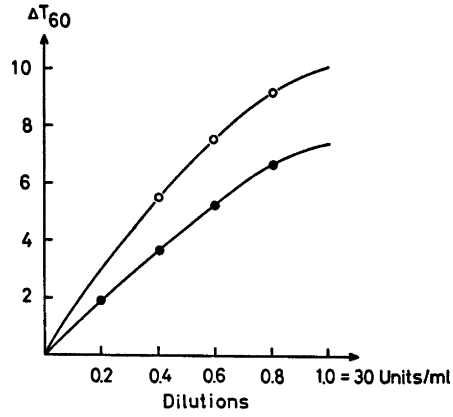

Fig. 8. Lytic activity of dilutions of CEP on heat-killed Bm (O) and Sa (●) bacteria. ΔT_{60}: See legend Fig. 1.

Lytic activity on heat-killed bacteria of both CEP and CMC-peak 1 in 0.01 M Tris-HCl pH 8.0, showed maximum at a NaCl concentration of approximately 0.01 M. Higher concentrations of NaCl inhibited the lytic activity, which was nearly zero at 0.16 M NaCl. The same conditions, pH 8.5 and 0.01 M NaCl, were also found to be optimal for digestion of mucopeptides.

The bacteriolytic activity of CEP or CMC-peak 1, tested on all bacteria in 0.01 M Tris-HCl pH 8.0, was not influenced by the presence of casein (0.5 mg/ml).

Stability. Enzyme solutions stored at 4°C in 0.01 M Tris-HCl pH 8.0, 0.02 % Na-azide, showed a high degree of stability. After one month about 5 % loss in lytic activity was observed. The enzymatic activities were also stable at −25°C.

DISCUSSION

The crude enzyme preparation (CEP) used in the present fractionation experiments corre-

sponds to the materials in other studies of *Streptomyces albus* G.[2-5] The bacteriolytic activity observed was completely bound to CM-cellulose, and fractionation on columns usually gave two peaks with lytic activity (Fig. 1). The material of peak 1, starting elution at 0.02 M NaCl and thus being weakly bound, contained practically all the endopeptidase activities. Digestion of mucopeptides/cell wall increased the amount of free amino groups, and the ratio between the degree of activity on the different test bacteria was approximately the same as that of CEP. Removal of the activity in CMC-peak 2 thus seemed to have little influence on the total lytic activity. Under the conditions imposed, peak 2 lysed mainly *B. megaterium* and *S. aureus*, and varied quantitatively from one culture to another. The material (peak 2) lysed mucopeptides/cell wall and increased the amount of free reducing groups and *N*-acetyl-amino sugars, whereas the increase of free amino groups was very small, the accessibility of these groups for reaction with FDNB probably being due to solubilization. This indicates that the activity of peak 2 is mostly dominated by an endo-*N*-acetylhexosaminidase which is shown to be an endo-*N*-acetylmuramidase. The properties of this agree well with those of the F_1-endo-*N*-acetylmuramidase [4] which also showed a somewhat stronger adsorption to CM-cellulose than the endopeptidases.

Optimal pH of the F_1-enzyme for lysis of different bacteria has been found to vary considerably (pH 3.5 – 8.0).[4] This may explain the difference in lytic activity and in the release of reducing groups on testing different bacteria with fractions of CMC-peak 2 and other solutions supposed to contain muramidase activity.

Mixtures of certain lytic activities from *Streptomyces albus* G have been found to act synergistically,[15,16] and the activity peaks of eluates from CMC-columns may therefore be due to favourable mixtures of enzymes and not to real quantities. Due to the low protein content indicated spectrophotometrically (280 nm), this was difficult to determine.

The *N*-acetylmuramyl-L-alanine amidase demonstrated in the CEP [1] was not adsorbed to CM-cellulose under the conditions imposed. This was also found in earlier studies.[2,3] The non-adsorbed material, containing the amidase, showed no lytic activity, thus suggesting, in agreement with an earlier supposition,[17] that the amidase is non-lytic on whole bacteria.

Electrophoresis in agarose and polyacrylamide and also gel filtration on Sephadex showed only one zone of bacteriolytic activity, indicating that the molecular properties of the apparent different enzyme specificities are very similar. Separation of several activities of *Streptomyces* culture filtrates on CMC-columns has been reported.[2-5] However, although all endo-peptidases reported, including MR, SA, ML, and KM, also seemed to be present in the CEP,[1] no separation was obtained.

Several caseinolytic enzymes were present in the CEP and could be separated on electrophoresis in agarose and by adsorption to CMC. The caseinolytic activity bound to CMC was eluted together with bacteriolytic activity in peak 1, these activities being also associated after electrophoresis and gel filtration. This suggests the possibility that the same enzyme might have bacteriolytic and caseinolytic activity, but casein in the test-solution did not seem to influence the degree of bacteriolysis. Caseinolytic activity has previously been found in association with the MR endo-peptidase,[2,3]

Most bacteriolytic enzymes isolated have been found to be basic proteins with a high isoelectric point.[2,3,18] The results of electrophoresis in gel in the present experiments also indicated basic proteins with pI-values above 8.6. According to the apparent molecular weight (16 000) it is reasonable to expect that the observed difference between the lytic enzymes and egg-white lysozyme (pI 11.0, Mw 14 000) [19] in electrophoretic mobility on polyacrylamide gel (Fig. 6) is due to difference in charge. On the other hand, due to the basic character of the enzymes, a possible retardation on Sephadex which influences the molecular weight determination,[20] cannot be excluded.

With a few exceptions,[4,21] all lytic enzymes previously isolated from *Streptomyces albus* G have been shown to have pH optima in the same range as found in this study,[15,16,22] and the low optimal salt-concentration is also in accordance with earlier findings.

The immunoelectrophoretic experiment showed that the material responsible for precipitation with antiserum in agar was different from that with lytic activities. However, this antigenic material does not need to be present

in high amounts since the ability of proteins to evoke immunological response may vary considerably.[23] Although the sera showed high activity of non-specific inhibitors,[24,25] the inhibition studies may suggest that the antisera contained specific inhibiting antibodies.

The reported results of fractionation studies on the lytic activities of *Streptomyces* cultures show great diversity, to some degree probably due to treatment and selection of the strain for enzyme production. In the present experiments fractionation on CMC-columns separated the CEP into three portions: (1) the material not adsorbed, containing non-lytic *N*-acetylmuramyl-L-alanine amidase, (2) CMC-peak 1 containing endo-peptidases, free of detectable amidase and hexosaminidase activities, and (3) CMC-peak 2, consisting mainly of endo-*N*-acetylmuramidase.

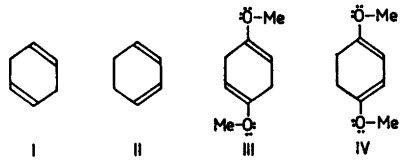
Thermodynamics of Vinyl Ethers. VII.* The Relative Stabilities of 1,4-Dimethoxy-1,4-cyclohexadiene and 1,4-Dimethoxy-1,3-cyclohexadiene

ESKO TASKINEN

Department of Chemistry, University of Turku, SF-20500 Turku 50, Finland

The relative stabilities of 1,4-dimethoxy-1,4-cyclohexadiene and 1,4-dimethoxy-1,3-cyclohexadiene have been determined at various temperatures between 273.2 and 422.2 K by means of chemical equilibration. In cyclohexane solution at 298.15 K, the following values were obtained for the changes of the thermodynamic functions on going from the former to the latter: $\Delta G^\circ = -2.061 \pm 0.014$ kJ mol^{-1}, $\Delta H^\circ = -0.17 \pm 0.18$ kJ mol^{-1}, $\Delta S^\circ = 6.4 \pm 0.6$ J K^{-1} mol^{-1} and $\Delta C_p^\circ = -9.2 \pm 4.2$ J K^{-1} mol^{-1}. In the ideal gas state at 298.15 K, the values of ΔH° and ΔS° were calculated to be -1.14 ± 0.35 kJ mol^{-1} and 5.5 ± 0.8 J K^{-1} mol^{-1}, respectively.

From the thermodynamic point of view, the relative stabilities of the isomeric carbocyclic dienes, 1,4-cyclohexadiene (I) and 1,3-cyclohexadiene (II), form an interesting subject of



I II III IV

investigation. The latter is a conjugated diene and thus it might be expected *a priori* that it should exhibit at least some of the enhanced thermodynamic stability characteristic of open-chain conjugated dienes, such as 1,3-butadiene. Against this background it seems surprising that in the liquid phase at 368 K, the equilibrium mixture of I and II contains only 68.9 % of the conjugated diene (II).[1] Thus, at equilibrium, II is favored over I by a factor of only 2.22, and moreover, if the effect of statistical factors on the equilibrium in question is considered, it is observed that the preponderance of II is mainly due to the fact that II is statistically favored over I by a factor of 2. Hence the equilibrium constant for the reaction I⇌II should be written as 1.11 if the effect of statistical factors on the position of equilibrium is eliminated. Accordingly, the Gibbs free energy difference between the isomers I and II is practically zero. As to the enthalpy difference, the enthalpy of hydrogenation (acetic acid, 298.15 K) of I to cyclohexane is reported [2,3] to be *ca.* 1.3 kJ mol^{-1} more negative than that of II, which shows that the enthalpy of the conjugated diene is only 1.3 kJ mol^{-1} lower than that of the unconjugated diene (assuming, of course, that I and II are solvated to the same extent in acetic acid). Thus it appears that either conjugation is weak in 1,3-cyclohexadiene or it is much more strained than I. As a continuation of this author's investigations on the effect of structural factors on the stability of vinyl ethers it was of interest to find out the effect of substitution of methoxy groups for the 1,4-hydrogen atoms of I and II on the relative stabilities of the conjugated and nonconjugated diene. Hence the isomeric vinyl ethers 1,4-dimethoxy-1,4-cyclohexadiene (III) and 1,4-dimethoxy-1,3-cyclohexadiene (IV) were prepared and thermodynamics of their interconversion were studied.

* Part VI: Taskinen, E. and Mäkinen, A. *Acta Chem. Scand. B 28* (1974) 121.

EXPERIMENTAL

Materials. A 76 % yield of a mixture of III and IV was obtained when 0.089 mol of 1,4-cyclohexanedione was treated with 0.196 mol of trimethyl orthoformate in methanol.[4] The cleavage of the tetramethyl acetal of 1,4-cyclohexanedione to methanol and the isomeric vinyl ethers was effected by fractionation from a small amount of *p*-toluenesulfonic acid. The boiling temperature of the product containing 79 mol % of IV was 474–475 K/101.8 kPa.

NMR spectra (*ca.* 20 % solutions in CCl_4 at 306 K). III: τ 5.49 (C=C–H), 6.50 (O–CH_3), 7.25 (–CH_2–); IV: τ 5.26 (C=C–H), 6.50 (O–CH_3), 7.70 (–CH_2–).

Determination of normal boiling points.[5] Reference curve (compound, normal boiling point, relative retention time): 1-methoxycyclopentene, 387.0 K, 0.245; 1-ethoxycyclopentene, 409.0 K, 0.298; 1-methoxycyclohexene, 417.1 K, 0.347; 1-ethoxycyclohexene, 435.0 K, 0.433; 1-propoxycyclohexene, 455.9 K, 0.608; 1-cyclopentoxycyclopentene, 479.7 K, 1.000. The relative retention times of III and IV were 0.878 and 0.773 leading to normal boiling points of 475.2 and 469.2 K, respectively.

Procedure. The performance of the equilibrations has been described previously.[5] Cyclohexane was used as solvent and iodine as catalyst. At each temperature, the position of equilibrium was approached from both directions. One of the initial mixtures of III and IV consisted of 79 mol % of IV (the crude synthetic product) and the other 55 mol % of IV (obtained by fractionation of the crude synthetic product). As the equilibrium mixtures contained *ca.* 67 to 70 mol % of IV, the position of equilibrium could thus be approached from both directions. The column used in the GLC analyses was a 4 m column containing 10 % Carbowax 1500 on Chromosorb G. The compounds were eluted in the order IV, III. The areas of the peaks were integrated by means of a Hewlett-Packard 3370 B integrator.

RESULTS

The values of the mean equilibrium constant K and its standard error at various temperatures are shown in Table 1. As it turned out that the values of $\Delta H°$ and $\Delta S°$ of the reaction in question do not remain constant over the range of temperature covered by the measurements, the following equation [6] was fitted to the values of K:

$$\ln K = A + B/T + C \ln T \qquad (1)$$

This equation requires that $\Delta H°$ varies linearly as T ($\Delta C_p° = \text{constant}$). The fitting was performed on an IBM 1130 computer. The following results were obtained for the isomerization of III to IV in cyclohexane at 298.15 K:

Table 1. Values of the mean equilibrium constant K and its standard error for the iodine-catalyzed reaction 1,4-dimethoxy-1,4-cyclohexadiene ⇌ 1,4-dimethoxy-1,3-cyclohexadiene in cyclohexane solution at various temperatures. Substrate concentration 0.2 mol dm^{-3}, catalyst concentration 0.008 mol dm^{-3}.

T/K	K
273.2	2.281 ± 0.012
283.2	2.317 ± 0.017
294.5	2.317 ± 0.011
308.2	2.295 ± 0.002
323.7	2.267 ± 0.008
345.2	2.252 ± 0.004
355.2	2.215 ± 0.007
373.2	2.218 ± 0.011
400.2	2.161 ± 0.009
422.2	2.123 ± 0.013

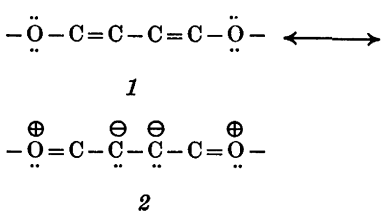
$\Delta G° = -2.061 \pm 0.014$ kJ mol^{-1}
$\Delta H° = -0.17 \pm 0.18$ kJ mol^{-1}
$\Delta S° = 6.4 \pm 0.6$ J K^{-1} mol^{-1}
$\Delta C_p° = -9.2 \pm 4.2$ J K^{-1} mol^{-1}

(the errors are twice the standard errors). The values of $\Delta H°$ and $\Delta S°$ in the ideal gas state at 298.15 K were calculated to be -1.14 ± 0.35 kJ mol^{-1} and 5.5 ± 0.8 J K^{-1} mol^{-1}, respectively, by means of the equations for the standard enthalpy and standard entropy of vaporization at 298.15 K derived in Ref. 5.

DISCUSSION

The enthalpy of 1,3-cyclohexadiene (II) is reported to be *ca.* 1.3 kJ mol^{-1} lower than that of 1,4-cyclohexadiene (I) in acetic acid at 298.15 K, and if the boiling points of I and II are taken as 358.8 and 353.7 K, respectively,[7] the enthalpy of isomerization of I to II is calculated [5] to be about -2.1 kJ mol^{-1} in the ideal gas state at 298.15 K. As the enthalpy change for III→IV is about -1.14 kJ mol^{-1} under the same external conditions, the values of $\Delta H°$ for I→II and III→IV are equal within experimental error. Thus the substitution of methoxy groups for the 1,4-hydrogen atoms of I and II has no observable effect on the enthalpy difference

between the conjugated and nonconjugated diene. This shows that although there is, in principle, a long conjugated system in IV (−O−C=C−C=C−O−), the stabilization brought about by this system is no greater than the stabilization due to the two ordinary vinyl ether functions (O−C=C) in III together. This is understandable, since the resonance structure *2* of the conjugated system in IV shows that an enhanced resonance would lead to a transfer of negative charge at adjacent carbon atoms, which causes structure *2* to be of relatively high energy.



1

2

On the other hand, it was shown in a previous part of this series [8] that electropositive (electron-donating) alkyl groups when attached to the β-carbon of the ethylenic linkage of a vinyl ether tend to oppose the resonance between the lone-pair electrons of the oxygen atom and the π-electrons of the double bond, owing to their inductive effect. In III, there is an alkyl group formed by the ring carbon atoms attached to the β-carbon of each double bond, and thus the extent of resonance stabilization in III is not so pronounced as in vinyl ethers with no β-alkyl substituents. Hence, as the experimental results show, the methoxy groups of III and IV cause a similar stabilization in each compound.

The entropy difference between I and II may be estimated as follows. Assuming that the enthalpy of isomerization of I to II is −1.3 kJ mol^{-1} in the liquid phase at 368 K at which temperature the equilibrium constant for I→II is reported to be 2.22 (see introduction), the entropy change is *ca.* 3.1 J K^{-1} mol^{-1} in the liquid phase. If the value of $\Delta S°$ is assumed to be independent of temperature and if it is corrected to correspond to the ideal gas state,[5] the entropy change in I→II is obtained as about 2.0 J K^{-1} mol^{-1} at 298.15 K. However, II is statistically favored over I by a factor of 2 and thus a term $R \ln 2 = 5.8$ J K^{-1} mol^{-1} should be subtracted from the observed entropy change to eliminate the effect of statistical factors on $\Delta S°$. After this correction, the value of $\Delta S°$ (g, 298.15 K) for I→II is obtained to be about −3.8 J K^{-1} mol^{-1}. This is not far from the value −5.9 J K^{-1} mol^{-1}, calculated from the intrinsic entropies of the above compounds, which have been reported by O'Neal and Benson.[9] Hence there is a difference of *ca.* 9.3 J K^{-1} mol^{-1} in the experimental values of $\Delta S°$ (g, 298.15 K) for the reactions I→II and III→IV, although the entropy changes might be expected to be similar on account of apparently similar changes of structure in both reactions (the statistical factors of III and IV are equal). The reason for this difference is not clear, but it might be imagined that the methoxy groups are free to rotate about the O−C(sp^2) bond in the conjugated diene (IV) because of only a weak conjugation between the methoxy groups and the double bonds. This assumption seems, however, to be in disagreement with the previous discussion concerning the stabilizing effect of methoxy groups on III and IV, which was deduced to be equal in both cases.

Carbohydrate-dependent Enzymic Quinone Reduction during Lignin Degradation

ULLA WESTERMARK and KARL-ERIK ERIKSSON

Swedish Forest Products Research Laboratory, Box 5604, S-114 86 Stockholm, Sweden

Indications for the existence of a new enzyme were obtained when *Polyporus versicolor*, a white-rot fungus, was grown on lignin agar plates supplemented individually with glucose, cellobiose or cellulose. Formation of chromophoric structures occurred through the action of a polyphenol oxidase (laccase) but was effectively reversed when cellulose was present in the agar plates. Under these conditions the fungus produced an extracellular enzyme which, in the presence of cellobiose, reduced the stable quinone tested, namely 3-methoxy-5-*tert*-butylbenzoquinone-(1,2). The enzyme together with cellobiose inhibited phenolic coupling of guaiacol by laccase and although oxygen consumption proceded normally no polymeric products were formed.

It has long been known that the white-rot fungi readily degrade lignin in wood. Isolated lignin in submerged cultures seems, however, to be much more resistant to fungal attack. Under such conditions growth on lignin requires adaptation [1,2] to the polymer and even then it is questionable if depolymerization occurs to any large extent.

It seems likely that submerged cultures do not offer the right growth conditions when lignin is the carbon source, maybe due to insufficient localization of the necessary levels of a combination of several enzymes required for depolymerization. We therefore investigated the use of a solid medium with lignin in which the fungus could produce high local concentrations of enzymes and, hopefully, degrade lignin. To achieve conditions as similar to wood as possible, we also incorporated cellulose in the growth medium to observe if this could affect the lignin degradation. These experiments have led to the discovery of an enzyme, cellobiose: quinone oxidoreductase, which can reduce products of laccase oxidation and different quinones in a reaction in which cellobiose is required and simultaneously oxidized. The phenol-oxidizing enzyme laccase is induced in white-rot fungi both by lignin and simple phenols.[3] The precise role of laccase during lignin degradation is not yet elucidated.

A recent review [4] on lignin degradation concludes that whatever role phenol oxidases play, they can only be a part of the enzyme complex that catalyzes the complete decomposition of lignin.

This paper describes the experiments in which the quinone-reducing enzyme was found and the ability of the enzyme to stop phenolic coupling during laccase oxidation of guaiacol. An accompanying paper [5] describes the induction and some properties of the enzyme.

MATERIALS AND METHODS

Organism. Polyporus versicolor L. ex Fr. isolate Mad. was obtained from Prof. E. B. Cowling, North Carolina State University, Raleigh, North Carolina. USA.

Substrate. The lignin preparation used was a kraft lignin, Indulin AT (Westvaco, Polychemical Div., Charleston, West Virginia, USA). The lignin was dialyzed against a large volume of distilled water (2 × 20 l per 5 g Indulin AT for 20 h) in a dialysis bag with a pore size of 24 Å to remove low molecular weight compounds and impurities. Phosphoric acid swollen cellulose [6] was prepared from Munktell's cellulose powder No. 400.

Cultivation. A basal salt medium [7] was used with the supplement of evenly suspended lignin and different carbon sources and with 1.5 % Noble agar (Difco, Detroit, Mich., USA). Lignin was dissolved in a minimal volume of 0.1 M

KOH and filter-sterilized. The pH of the complete medium was adjusted to 5.6 with phosphoric acid. The plates were incubated at 25°C and 90 % relative humidity.

Enzyme. Laccase (O_2:*p*-diphenol oxidoreductase, E.C. 1.10.3.2) was obtained from *P. versicolor*.[8] The enzyme solution was concentrated to approx. 1/40 of the original volume by ultrafiltration (Amicon UM 10) and the laccase was precipitated with solid ammonium sulfate (90 % of saturation at 25°C). The precipitate was dissolved in a minimum volume of distilled water, dialyzed and partially purified on a Sephadex G-75 chromatography column.

Cellobiose-quinone oxidoreductase was prepared according to methods in the accompanying paper.[5]

Enzyme assays. Laccase activity was measured by following the production of colored material from guaiacol. The incubation mixture contained 25 μmol guaiacol, 50 μmol acetate buffer (pH 5.0) and the enzyme in a total volume of 5 ml. The color production was followed with a Klett colorimeter equipped with a blue filter ($\lambda = 400 - 465$) at 25°C.

The initial rate of formation of colored products was taken as a relative measurement of laccase activity.

Chemical determinations. Guaiacol was determined gas chromatographically with benzyl alcohol as an internal standard. Column: 10 % OV-1 on Chromosorb Q 100 – 120 mesh, 120°C. Retention times: guaiacol 8.9 min and benzyl alcohol 6.6 min.

Oxygen consumption was measured with an oxygen electrode (Rank Brothers, Bottisham, England) at 25°C.

Chemicals. The 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2) was kindly supplied by Dr. Augustine E. Opara of this laboratory.

RESULTS

Coloration of lignin agar plates by P. versicolor. *P. versicolor* was cultivated on agar plates containing 1 g/l of lignin individually supplemented with 3 g/l of glucose, cellobiose, or swollen cellulose as indicated. Fig. 1 shows plates (5 day cultivation time), where the surface mycelium has been removed. A few mm in front of the mycelium there was a reddening of the lignin in all plates. However, in those plates which contained cellobiose and cellulose this coloration started to disappear in the area in contact with the outermost edge of the mycelium and reappeared under the oldest mycelium in the center. The plates with lignin and lignin plus glucose had an even red color over the entire surface. The red color most likely originated from phenol oxidase oxidation of lignin or its degradation products. To test for laccase activity, the plates were flooded with a solution of 0.01 M guaiacol which gives an intense red to black color with laccase. The lower series of plates in Fig. 1 shows the plates after this staining. Laccase activity was found in all areas which were visibly red. The decolored areas in plates with lignin and cellulose or cellobiose gave no laccase staining with guaiacol.

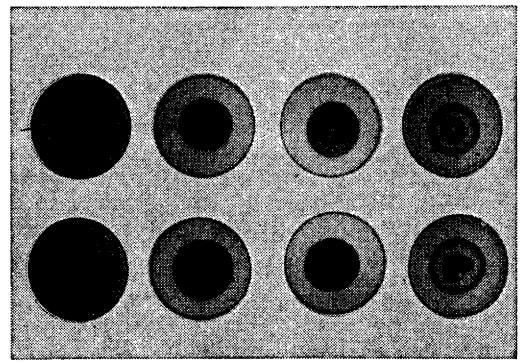

Fig. 1. P. versicolor grown on lignin agar plates supplemented with from left to right: nothing, glucose, cellobiose, and phosphoric acid swollen cellulose. The top row of plates shows the coloration caused by the fungus. The bottom row shows plates which have been flooded with guaiacol to stain for laccase activity.

Extraction of enzymes from lignin – cellulose agar plates. P. versicolor was grown for 5 days on plates containing lignin and cellulose. The surface mycelium was then removed and the plates were separated into three zones according to Fig. 2. Equal amounts of the three zones were extracted with 0.1 M acetate buffer (pH

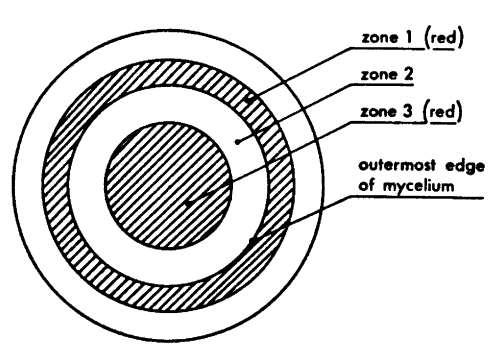

Fig. 2. Pattern of the lignin – cellulose agar plates used for extraction of enzymes from three zones.

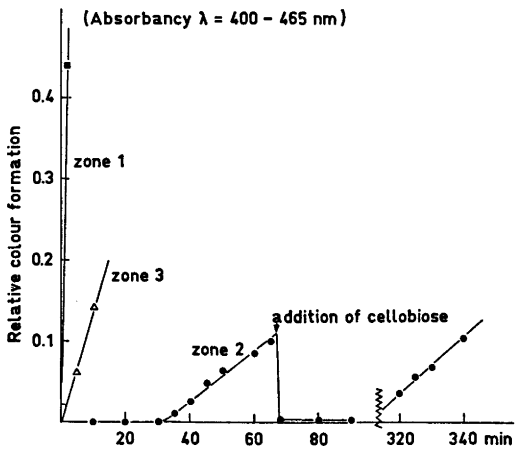

Fig. 3. Relative laccase activity in different zones of lignin – cellulose agar plates.

5.0) and centrifuged. Laccase activity was measured on the supernatants from the different zones. The results are shown in Fig. 3. The extract from zone 2 is of particular interest. Initially no color production from guaiacol was observed but after a while the color formation started and continued at a constant rate. If cellobiose was added, the color formation ceased and the colored products which had been formed disappeared. After a lag period depending upon the amount of cellobiose added, the formation of colored products was observed once more. It is obvious from these experiments that although laccase was present in zone 2, it did not react with guaiacol in the normal way. It is also clear that a reaction with cellobiose occurred in zone 2 and that this reaction inhibited the formation of colored products from laccase oxidation of guaiacol. If cellobiose was added to extracts from zone 3, a small decrease in the formation of colored products from guaiacol was found, but addition of cellobiose did not influence the laccase activity in extracts from zone 1.

Quinone reducing ability of the enzyme extracts from zone 2. The red products from laccase oxidation of both lignin or lignin degradation products and guaiacol are most likely due to quinoid structures.[9] To determine if the extract from zone 2 could reduce quinones, a ten-fold concentrated extract was incubated with a stable quinone, 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2). The quinone has an absorption maximum at 360 nm (acetate buffer, pH 5.0). The reduction of the quinone to the corresponding diphenol, was followed spectrophotometrically at this wave length. The enzyme extract from zone 2 could effectively reduce the quinone while boiled extract had no effect. It was also demonstrated that the reduction of the quinone was coupled to the oxidation of cellobiose. In an accompanying paper,[5] some properties of the enzyme from *C. lignorum* is described, and from these results the name cellobiose:quinone oxidoreductase is suggested. It appears likely that the cellobiose:quinone oxidoreductase caused the disappearence of the red color in zone 2 and also prevented the formation of colored products from guaiacol in this zone. The enzyme cannot use glucose which would explain why no decolored zones occurred in plates with lignin and glucose. The width of the zones may reflect both the amount of enzymes induced and the concentration of the carbohydrate co-substrate.

Inhibition of phenolic coupling by the quinone reducing enzyme. To study the effect of cellobiose:quinone oxidoreductase on the laccase oxidation of guaiacol, the concentration of guaiacol was followed by gas chromatography and laccase activity measured by following oxygen uptake. The reaction mixture contained 25 μmol guaiacol, 90 μmol cellobiose, 1 mmol acetate buffer (pH 5.0), 25 μmol benzyl alcohol (internal standard for gas liquid chromatography), laccase and cellobiose:quinone oxidoreductase in a total volume of 10 ml per sample. The control contained everything except cellobiose:quinone oxidoreductase. Samples and the controls were incubated at 25°C for different time periods after which the reaction mixture was extracted with 5 ml of ethyl acetate and the organic phase was analyzed for guaiacol and benzyl alcohol. Fig. 4 shows that all guaiacol in the control sample was polymerized in about 2 h. Under the same conditions less than 15 % of the guaiacol had been polymerized in the sample containing cellobiose:quinone oxidoreductase. Higher concentrations of oxidoreductase completely prevented the polymerization of guaiacol.

To determine if the laccase was inhibited by the solution of cellobiose:quinone oxidoreductase, the rate of oxygen consumption was

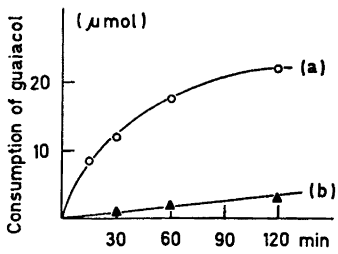

Fig. 4. Influence of cellobiose:quinone oxidoreductase on the consumption of guaiacol by laccase. The amount of guaiacol consumed is shown in (a) the control (laccase alone) and (b) sample containing both laccase and cellobiose: quinone oxidoreductase.

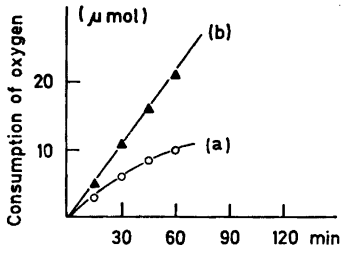

Fig. 5. Consumption of oxygen by laccase in the presence of cellobiose:quinone oxidoreductase. The samples are described in Fig. 4.

measured both in the sample and in the control. Fig. 5 shows that the initial rate of oxygen consumption was the same in both the sample and the control. The oxygen consumption in the control diminished with decreasing guaiacol concentration. In the sample containing cellobiose:quinone oxidoreductase the rate of oxygen consumption was constant. The oxygen consumption before addition of laccase was about the same for both the sample and the control and was subtracted from the readings. It is known that the preliminary product of laccase oxidation of phenols is the aryloxy radical and that the subsequent phenolic coupling is non-enzymatic.[10] Thus, the laccase as usual formed the guaiacoxy radicals but, instead of coupling, the radicals were reduced back to the phenolic state by the cellobiose:quinone oxidoreductase.

It is very likely that this is the same enzyme which reacts with quinones and with the laccase oxidation products. As described in the accompanying paper both of these hydrogen acceptors give the same oxidation product from cellobiose. Preliminary enzyme purification experiments with an ion exchanger and isoelectric focusing have not separated the activities.

DISCUSSION

The wood-degrading fungi are very specialized in the utilization of their substrate wood. In most cases, the white-rot fungi remove lignin and cellulose or hemicellulose simultaneously, perhaps implying that the enzymic degradation of the different wood components is linked. The cellobiose:quinone oxidoreductase requires both a carbohydrate and an oxidized phenol for its activity and both of these substrates are modified during the reaction. Thus, a study of the degradation of pure cellulose and pure lignin would probably not give the same products as from the degradation in wood.

When fungi are cultivated on lignin with or without added glucose they excrete large amounts of phenol oxidases which cause a polymerization of phenolic substances. The results in this paper show that in a more wood-like surrounding, quite different reactions can occur. The laccase functions as normal, but its initial products are effectively reduced back to the phenolic state and polymerization is prevented.

The ability of white-rot fungi to reduce quinones has been observed earlier.[11] In this case the white-rot fungus *Polystictus sanguineus* was cultivated on agar plates containing small amounts of phenols. The phenols were first oxidized to colored products (probably quinones) but this color began to disappear after ten or twelwe days. Agar plates containing preformed quinones were also slowly decolorized. It was suggested that this color change was due to a quinone reduction process.

Protocatechuate-3,4-oxygenase and catechol-1,2-oxygenase are the key enzymes in the catabolism of aromatic substances in most fungi.[12] It is known that these enzymes are inhibited by *o*- and *p*-benzoquinone.[13] If the lignin is degraded to simple phenols or quinones, it must be of importance for the fungus to keep the phenols in a reduced state to ensure the further breakdown of the aromatic nucleus. Cellobiose:quinone oxidoreductase can obviously serve this function.

Acknowledgement. We wish to thank Majlis Jansson for skilful technical assistance and Dr. A. Opara for supplying the quinone. We are also indebted to Dr. B. Lindgren and Dr. J. Gierer of this laboratory for stimulating discussions.

Cellobiose:Quinone Oxidoreductase, a New Wood-degrading Enzyme from White-rot Fungi

ULLA WESTERMARK and KARL-ERIK ERIKSSON

Swedich Forest Products Research Laboratory, Box 5604, S-114 86 Stockholm, Sweden

Production of an extracellular cellobiose: quinone oxidoreductase (cellobiose dehydrogenase) by *Polyporus versicolor* and *Chrysosporium lignorum** grown on cellulosic substrates was investigated. Highest yields of the enzyme occurred with powder cellulose as the carbon source. In *C. lignorum* development of oxidoreductase activity and cellulolytic enzymes were parallel.

The enzyme from *C. lignorum* was selected for further study. It was found to catalyze an oxidation – reduction reaction in which reduction of a quinone to the corresponding phenol was coupled to the conversion of cellobiose to cellobionic acid probably through cellobiono-δ-lactone. The enzyme has a high specificity for the oxidation of cellobiose. Lactose was oxidized at a slower rate but no other mono- or disaccharides tested served as substrate for the oxidoreductase. However, quinone requirement was less specific and the enzyme was able to reduce both *ortho* and *para* quinones. Optimum pH for oxidoreductase activity was approximately 4.5 – 5.0. An extracellular lactonase from *C. lignorum*, able to hydrolyze cellobiono-δ-lactone is also reported.

White-rot fungi utilize a number of extracellular hydrolytic enzymes for the degradation of cellulose.[1-3] In most studies of cellulose degradation, these enzymes are obtained by cultivation of fungi on pure cellulose. With cellulose and cellodextrins as substrates, the cellulolytic enzymes produce glucose and cellobiose as the final products of degradation. Results from these types of experiments are often extrapolated as description of the degradation of cellulose in wood. However, in this and in the accompanying paper,[4] we describe the occurrence of an extracellular enzyme which, in the presence of a suitable hydrogen acceptor, yields acidic sugars as breakdown products of cellulose. The enzyme can utilize reaction products of the phenol-oxidizing enzyme laccase and a suitable phenol, for example of lignin origin, as the hydrogen acceptor.

* Recent investigations have revealed that *C. lignorum* is identical with *Sporotrichum pulverulentum* Novobranova, and the latter name should be used.

EXPERIMENTAL

Organisms. *Chrysosporium lignorum* P 127-1 was obtained from Dr. T. Nilsson, Royal College of Forestry, Stockholm, Sweden. *Polyporus versicolor* L. ex Fr. isolate Madison, was obtained from Prof. E. B. Cowling, North Carolina State University, Raleigh, North Carolina, USA.

Cultivations. A basal salt medium [5] was used with 3 g of carbon source/liter.

To follow enzyme induction the fungi were grown in 250 ml Erlenmeyer flasks containing 80 ml culture solution on the following carbon sources: powder cellulose, wood meal, phosphoric acid-swollen cellulose, cellobiose, and sucrose. The flasks were incubated at 25°C on a reciprocal shaker at 135 rpm and two flasks were harvested every second day. The solid material was removed by filtration and the culture solution was concentrated 5-fold in a collodion tube before analysis.

For enzyme production, *C. lignorum* was cultivated in one-liter Erlenmeyer flasks on powder cellulose in 300 ml culture solution for 8 – 9 days at 25°C reciprocal shaking. The culture solution was filtered and then concentrated by ultrafiltration (membrane Amicon UM-10). The proteins were precipitated by addition of solid ammonium sulfate at room temperature to 90 % of saturation, redissolved and extensively dialyzed against distilled water before use.

Enzyme assays. Cellobiose dehydrogenase was assayed as follows: The reduction of 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2) was followed

spectrophotometrically at 360 nm at 25°C. The reaction mixture contained 300 μmol acetate buffer (pH 4.5), 1 μmol of the quinone, 2 μmol cellobiose and the enzyme in a total volume of 3 ml. Absorbancy was usually determined at one minute intervals. The decrease in absorbancy was linear with time until 90 % of the quinone was reduced. One enzyme unit was defined as the amount of enzyme that reduced 1 μmol quinone per min according to the Enzyme Commission.

Lactonase was assayed by measuring the decrease in the amount of cellobiono-δ-lactone. The lactone was determined colorimetrically as its hydroxamic acid derivative.[6] After incubation at 25°C for different times, hydroxylamine solution (pH 5.0) was added and the reaction mixture was allowed to stand at room temperature for 15 min before the ferric chloride solution was added. All assays were compared with a blank incubation mixture lacking enzyme to correct for the spontaneous hydrolysis of the substrate. Aryl-β-glucosidase activity was measured colorimetrically.[7]

Cellulase activity was determined viscosimetrically with CMC as a substrate [8] and colorimetrically with Avicel as a substrate. For the Avicelase measurement, the enzyme solution was incubated in a reaction mixture containing 20 mg of Avicel (American Viscose Co., Marcus Hook, Pennsylvania, USA) and 300 μmol acetate buffer (pH 5.0) in a total reaction volume of 3 ml. The sample was incubated for 2 h at 30°C with continuous shaking, filtered, and analyzed for reducing sugars.[9] Reduction of viscosity of CMC gives only a measurement of randomly-hydrolyzing endo-β-1,4-glucanases, while production of reducing sugars from Avicel, a crystalline cellulose, gives a measurement of both endo- and exo-β-glucanases.

Chemical determinations. The concentrations of quinones were measured spectrophotometrically. 3-Methoxy-5-*tert*-butyl-benzoquinone-(1,2) λ_{max}(nm) = 360 (ε = 2180) in 0.1 M acetate buffer (pH 4.5); 2-methoxybenzoquinone-(1,4) λ_{max}(nm) = 368 (ε = 1238) in 0.1 M acetate buffer (pH 4.5); cerulignone λ_{max}(nm) = 472 (ε = 19 180) in 0.1 M acetate buffer (pH 4.5) containing 50 % dioxan.

Lactones were measured colorimetrically [6] at pH 5.0. The hydroxamic acid derivative of cellobionolactone has an ε = 239 at λ = 500 nm. If a quinoid hydrogen acceptor was present the reaction mixture was extracted with chloroform to remove phenols and quinones before analysis for lactones.

Paper chromatography. Identification of reaction products were made by ascending paper chromatography on Whatman No. 1 chromatography paper. The samples were extracted with chloroform to remove phenols, concentrated by evaporation under vaccum, adjusted to pH 8 with NaOH, boiled for 2 min and finally treated with a strong cation exchanger (Dowex 50WX8).

Cellobionic acid had the following $R_{glucose}$: 0.29 in ethylacetate – pyridine – water (4:2:1 v/v/v), 0.55 in butanol – ethanol – water (10:3:5), and 0.87 in ethylacetate – acetic acid – water (3:1:1).

Gas chromatography. Gas-liquid chromatography was carried out on the trimethylsilyl ethers of cellobionic acid and cellobiono-δ-lactone. Column: QF-1 11 % on Cromosorb W 100 – 120 mesh, 235°. The samples were extracted with chloroform, adjusted to pH 8 and placed on an anion exchange column (Dowex 1-X4) (acetate form). The column was carefully washed with distilled water to remove neutral sugars and the acidic reaction products were eluted with 1 M acetic acid. The acetic acid was then removed by repeated evaporation and the residue was silylated both directly and as the Na-salt. *N,O*-bis(trimethylsilyl)-trifluoroacetamide and trimethylchlorosilane were used in the preparation of the silyl ethers. Retention time for the trimethylsilylated cellobionolactone was 12.15 min and 13.4 min for the trimethylsilylated cellobionic acid.

Chemicals. Cellobiono-δ-lactone was synthesized by chlorite oxidation of cellobiose.[10] Cellobionolactone had a m.p. of 181.7 – 182.4°C. No gluconic acid could be detected in the preparation. Hydrolysis of the synthetic cellobionolactone (100°C, 1 M HCl, 4 h) yielded glucose and gluconic acid as identified by paper chromatography. Cellobionic acid was prepared by alkaline hydrolysis at pH 8 of cellobionolactone. The free acid was obtained by cation exchange (Dowex 50W-X8).

Phosphoric acid-swollen cellulose was prepared from Munktell's Cellulose Powder No. 400.[11] The 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2) and cerulignone were kindly supplied by Dr. Augustine E. Opara of this department.

RESULTS

Induction of cellobiose dehydrogenase on different carbon sources

The production of cellobiose dehydrogenase from *C. lignorum* and *P. versicolor* was followed during a twenty day cultivation. *C. lignorum* was cultivated on wood meal, cellulose, phosphoric acid-swollen cellulose, cellobiose, and sucrose. *P. versicolor* was cultivated on cellulose and swollen cellulose. Fig. 1 shows the development of enzyme in the culture solution of *C. lignorum*. Cellulose induced the highest cellobiose dehydrogenase activity in the culture solution. The other cellulosic materials, wood meal and swollen cellulose, also induced enzyme activity. Very small amounts of enzyme were

produced with cellobiose and no activity was detected with sucrose. Cultivations of *P. versicolor* gave similar results but the maximal production was about 13 units/l culture solution compared with 18 units/l culture solution for *C. lignorum*. Therefore, the latter fungus was selected for further study.

Fig. 2 shows the development of cellulose-degrading enzymes in a culture solution of *C. lignorum* grown on powder cellulose. The development of cellobiose dehydrogenase was parallel to the cellulose-degrading enzymes. Cellobiose dehydrogenase, aryl-β-glucosidase, and avicelase activity all reached maximum after about ten days. CMC-ase activity reached maximum after about eight days. Without added cellobiose the quinone-reducing activity of the culture solution was very low during the whole cultivation period.

Properties of cellobiose dehydrogenase

(a) Isolation and identification of the reaction products. Quinone reduction. Treatment of 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2) with the enzyme in the presence of cellobiose yielded one single aromatic compound. It was identified as the corresponding reduced quinone, 3-methoxy-5-*tert*-butyl-catechol-(1,2). The ultraviolet spectrum of the product of the enzymic reduction was in agreement with the spectrum of the authentic catechol. The identity of the product was further confirmed by thin-layer chromatography using authentic material as a reference compound.

To identify the products of the enzymic oxidation of cellobiose, the following two mixtures were used: (I) 1 mmol cellobiose, 3 mmol acetate buffer (pH 5.0), 25 μmol guaiacol, the phenol-oxidizing enzyme laccase and the cellobiose dehydrogenase in a reaction mixture of 18 ml. The reaction proceeded for 5 h at 25°C with shaking to supply the laccase with oxygen. (II) 50 μmol cellobiose, 50 μmol 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2), 5 mmol acetate buffer (pH 5.0), and cellobiose dehydrogenase in a total volume of 50 ml. The reaction proceeded at 25°C until all the quinone was reduced.

The reaction products were indentified by paper chromatography with glucose, cellobiose gluconic acid, and cellobionic acid as reference compounds. Spots running the same as glucose, cellobiose, and cellobionic acid were identified from the reaction mixture but no gluconic acid was found. Part of the reaction mixture (I) was also analyzed by gas-liquid chromatography. The silylated samples from the reaction mixture gave peaks with the same retention time as the synthetic cellobiono-δ-lactone and cellobionic acid. The aldonic acids are in equilibrium with

Table 1. Stoichiometry of reaction. Reduction of 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2) by cellobiose dehydrogenase. The reaction mixture contained 300 μmol acetate buffer (pH 4.5), quinone and cellobiose according to the table, and the enzyme in a total volume of 3 ml.

Quinone μmol	Cellobiose μmol	Quinone reduced μmol
2.0	2.0	2.0
2.0	1.0	1.0
2.0	0.2	0.2
2.0	0	0
2.0	200	2.0

Table 2. Stoichiometry of reaction. Acid formation from the oxidation of cellobiose by cellobiose dehydrogenase. The reaction mixture contained cellobiose and 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2) according to the table together with enzyme in 18 ml distilled water. The initial pH was adjusted to 5 with nitric acid and the acid-formation was followed at pH 5 with a pH-stat.

Quinone μmol	Cellobiose μmol	Acid formed μmol
37	75	31
18	75	16
11	75	10
0	75	0
18	0	0

their lactones at acidic pH and the working up procedure did not ascertain whether cellobionic acid or cellobiono-δ-lactone was the primary product of the reaction. Direct analysis of the assay mixture (I) during the reaction failed to detect the presence of lactones. However, the enzyme preparations used contained high lactonase activities (see later).

(b) Stoichiometry of reaction. To evaluate the stoichiometry of the reaction, two series of experiments were run, one with cellobiose and one with quinone as the limiting substrate. Table 1 shows the reduction of the quinone when cellobiose was limiting and Table 2 the production of acid from cellobiose with limiting quinone.

The acid production was followed in a pH-stat at pH 5.0. Both Table 1 and Table 2 suggest that one mol of quinone is reduced when one mol of cellobiose is oxidized.

Table 3. Oxidation of different sugars. The reaction mixture contained 300 μmol acetate buffer (pH 4.5), 1 μmol 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2), 2 μmol of sugar and the enzyme in a total reaction volume of 3 ml. The reaction was measured by following the reduction of the quinone.

Substrate	Relative rate of oxidation
Cellobiose	100
Lactose	44
Maltose	0
Sucrose	0
Xylobiose	0
Glucose	0
Galactose	0
Mannose	0
Gluconolactone	0
Arabinose	0
Xylose	0

(c) Substrate specificity. (a) Carbohydrate oxidation. The relative rates of oxidation for a number of mono- and disaccharides were investigated and the results are presented in Table 3. The enzyme appears to have high specificity for the oxidation of cellobiose. Glucose was not oxidized at all by the enzyme and oligosaccharides could not be tested, since they would rapidly be degraded to cellobiose by contaminating enzymes.

(b) Quinone reduction. The specificity of the quinone-reducing ability of the enzyme appears to be less restricted and quinones used as sub-

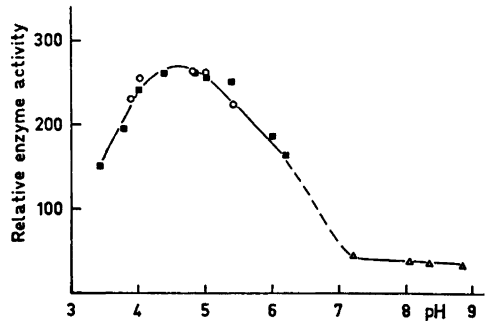

Fig. 3. Effect of pH on the activity of cellobiose dehydrogenase. The reaction mixture contained 300 μmol buffer, 1 μmol 3-methoxy-5-*tert*-butyl-benzoquinone-(1,2), 2 μmol cellobiose and the enzyme in a total volume of 3 ml. ■ Citrate buffer. ○ Acetate buffer. △ Tris buffer.

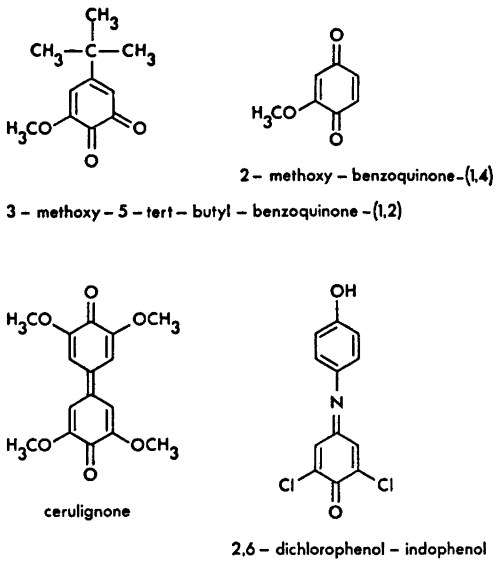

Fig. 4. Quinones which can be reduced by cellobiose dehydrogenase.

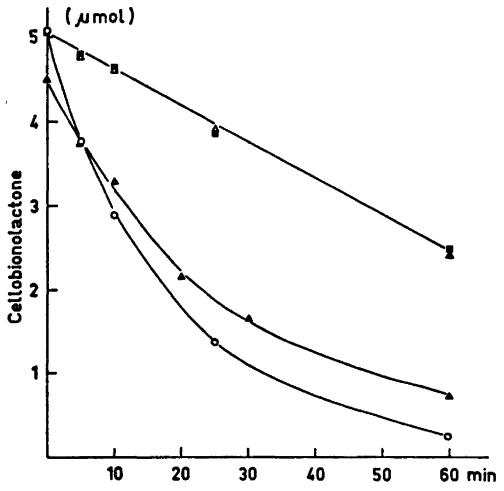

Fig. 5. Hydrolysis of cellobiono-δ-lactone. The reaction mixture contained 100 μmol of acetate buffer (pH 5.0), 5 μmol cellobiono-δ-lactone and the enzyme in a total volume of 1 ml. ○ 0.15 ml enzyme. ▲ 0.1 ml enzyme. △ Boiled enzyme control. ■ No enzyme (spontaneous hydrolysis).

strates for the enzyme are summarized in Fig. 4. The oxidoreductase can reduce both *ortho* and *para* quinones and also the artificial electron acceptor 2,6-dichlorophenolindophenol, but it cannot use molecular oxygen as hydrogen acceptor. What is more interesting from the point of view of wood degradation is that the enzyme can use reaction products of the phenol-oxidizing enzyme laccase and a suitable phenolic compound, for example lignin or lignin-degradation products, as hydrogen acceptor. As discussed in Ref. 4 the phenoxy radical formed from laccase oxidation of phenols is probably the substrate for the enzyme.

(d) pH-Optimum for the enzyme. The effect of pH on the enzymic activity was measured in citrate, acetate, and tris-buffers. The results given in Fig. 3 show that the enzyme has its optimal activity around 4.5 – 5. Phosphate buffer was somewhat inhibitory to the enzyme.

Enzymic hydrolysis of sugar lactones. It was expected that the primary product of cellobiose oxidation should be the cellobiono-δ-lactone if the enzyme reacted with the pyranoside form of cellobiose. However, all experiments to show the presence of the lactone failed. The cellobionolactone is spontaneously hydrolyzed at pH 5.0 (half life of about 58 min) but this could not explain the fact that no lactone could be detected in the reaction mixture after the oxidation of cellobiose.

To determine if enzymatic hydrolysis of lactones occurred, concentrated culture filtrates were assayed for lactonizing activity as described under methods. Fig. 5 shows the rate of hydrolysis of cellobionolactone by the culture solution. The concentrated culture solution also contained activity against glucono-δ-lactone but arabino-γ-lactone was not hydrolyzed by the enzyme solution. Thus, the first product of the cellobiose oxidation may be the cellobiono-δ-lactone which is immediately hydrolyzed by the lactonase, also secreted into the medium by the fungus.

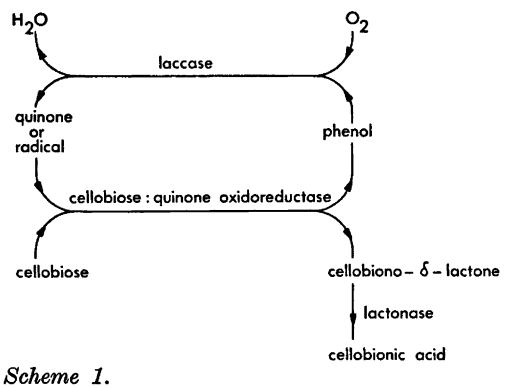
DISCUSSION

Certain bacteria, especially from the genus *Pseudomonas*,[12] can oxidize the disaccharides lactose and maltose to the corresponding aldobionic acids in the presence of a suitable hydrogen acceptor, without prior hydrolysis to monosaccharides. The enzyme responsible for the oxidation of lactose in *Pseudomonas graveolens* has been studied [13] and seems to have a similar mechanism of action as the *C. lignorum*

enzyme. However, the *P. graveolens* enzyme is intracellular, localized in the particulate fraction, while the *C. lignorum* is extracellular. Furthermore, the *P. graveolens* enzyme can oxidize several disaccharides including cellobiose, and also pentoses and hexoses, while the *C. lignorum* enzyme seems to be quite specific for cellobiose and fails to oxidize monosaccharides.

Cellobiose dehydrogenase may be involved in the enzymic degradation of both cellulose and lignin in wood. Several points suggest that carbohydrate oxidation is the important function of the enzyme. First, cellobiose dehydrogenase is induced by cellulose and cellulosic materials and is produced simultaneously with the cellulolytic enzymes in *C. lignorum*. The pH-optimum of the enzyme is in accordance with that of the cellulases from the same fungus.[14] Also, cellobiose dehydrogenase seems to have a high specificity for cellobiose which is an abundant product of cellulose degradation. It was impossible to determine if higher oligosaccharides and cellulose could also be oxidized by the enzyme, since the preparation contained cellulases. Finally, preliminary experiments indicate that cultivation of the fungus on xylan produces a similar enzyme specific for oxidation of xylan degradation products.

The function of laccase in white-rot fungi during wood degradation has been a topic of much discussion. It has been observed that some aromatic compounds stimulate the growth of white-rot fungi[15] and it was suggested that laccase participates in their electron-transport chain. The results in this paper indicate that laccase may, in fact, function as a link in an extracellular "electron-transport chain." A proposed mechanism for cellobiose dehydrogenase is given in Scheme 1.



Scheme 1.

Cellobionolactone could not be detected in the reaction but the presence of an extracellular lactonase which hydrolyzes cellobionolactone to cellobionic acid suggests that the primary product of the oxidation is the lactone. It is known that sugar lactones, especially gluconо-1,5-lactone, inhibit cellulases and β-glucosidases[16] so it is probably important for the fungus to hydrolyze immediately any lactones formed. In a study of the enzymic cleavage of cellobionic acid[17] it was found that enzymes in a commercial cellulase preparation and also an enzyme extract from *Aspergillus niger* could cleave cellobionic acid to glucose and gluconic acid.

Acknowledgements. We want to thank Majlis Jansson for skilful technical assistance.

Reaction of Diethyl Pyrocarbonate with Nucleophiles

S. OSTERMAN-GOLKAR, L. EHRENBERG and F. SOLYMOSY

Wallenberg Laboratory, Stockholm University, S-10405 Stockholm, Sweden and Biological Research Center, Hungarian Academy of Sciences, Szeged, Hungary

In order to clarify the kinetic background of the biochemical and biological action pattern of diethyl pyrocarbonate (diethyl oxydiformate) the rates of reaction of this compound with amines, thiols, and compounds with nucleophilic oxygen were studied at 25°. The nucleophilic strength within each series of compounds is correlated with the basicity. The primary amines are approximately five times as reactive as the thiols and thousand times as reactive as the oxygen anions, when compared at equal pK_a values.

Diethyl pyrocarbonate has been widely used as a food preservative because of its bactericidal action.[1] More recently it has been applied as a nuclease inhibitor in the preparation of undegraded high molecular weight RNA.[2-4]

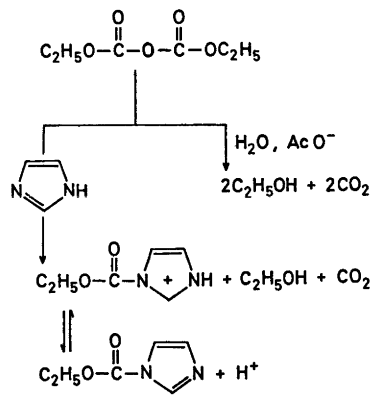
Diethyl pyrocarbonate can be regarded as the anhydride of ethoxyformic acid, and as such, although stabilized by the ethoxy group, it is very susceptible towards nucleophilic attack on a carbonyl carbon. There has been an extensive literature on the carbethoxylation by diethyl pyrocarbonate of amines, [5,6] thiols,[7] phenols,[8] amino acids,[5,9,10] and proteins.[11-13] Data on reaction rates, however, are at present very scanty.[12,14] Such data are needed for the understanding of the biological effects of diethyl pyrocarbonate,[15,16] for the optimization of the nucleic acid extraction method based on the use of diethyl pyrocarbonate, as well as for finding proper conditions for the use of diethyl pyrocarbonate in studies of the secondary structure of nucleic acids.[17]

MATERIALS AND METHODS

Diethyl pyrocarbonate was obtained from Schuchardt, München. Tris(hydroxymethyl)-aminomethane (Tris), glycylglycine, 2-mercaptoethanol, and 3-mercaptopropionic acid were purchased from Sigma, St. Louis, Mo. *p*-Nitrophenyl mercaptan was synthesized according to Augustinsson *et al.*[18] All other chemicals were obtained from Merck, Darmstadt, and were of reagent grade.

The reactions of diethyl pyrocarbonate were with a few exceptions followed in the presence of a large excess of the respective nucleophile to give pseudo first order kinetics. The temperature was maintained at $25 \pm 0.1°$ in a Hetotherm ultrathermostat. The ionic strength was kept constant ($I = 0.1$) by addition of NaCl, except in the study of buffer compounds.

Reaction with imidazole. Diethyl pyrocarbonate reacts rapidly with imidazole to form *N*-carbethoxyimidazole,[12] according to eqn. (1).



(1)

The rate of carbethoxylation was followed spectrophotometrically at 231 nm (λ_{max} for *N*-carbethoxyimidazole; $\varepsilon = 3 \times 10^3$ l mol^{-1} cm^{-1}). To a 10 – 20 mM solution of imidazole in acetate buffer (pH 4.4 – 4.9) diethyl pyrocarbonate dissolved in acetonitrile was added to give an initial concentration of 0.2 mM. The reaction was followed for ten half-lives to give the end-point A_∞. The half-time was determined from a plot of log $(A_\infty - A_t)$ against t, where A_t

is the absorbance at the time t. The observed first order rate constant was calculated from

$$k_{obs} = \ln 2/t_{1/2} \quad (2)$$

The pseudo first order rate constant for the reactions of diethyl pyrocarbonate with imidazole (IM) was obtained by subtracting the constants for hydrolysis and reaction with acetate (AcO^-), determined in separate experiments, from the observed rate constant; see eqn. (3). The second order rate constant was obtained by dividing the pseudo first order constant by the concentration of free base according to eqn. (4).

$$k_{obs} = k'_{H_2O} + k'_{AcO^-} + k'_{IM} \quad (3)$$

$$k_2 = k'_{IM}/[IM] \quad (4)$$

The fraction of base was calculated from

$$pH = pK'_a + \log \frac{[IM]}{[IMH^+]} \quad (5)$$

Reactions with water, CH_3COO^-, HPO_4^{2-}, Tris, and CO_3^{2-}. The rapid reaction with imidazole was used for the quantitative determination of diethyl pyrocarbonate. 0.1 ml samples were taken at appropriate intervals from a 2 – 3 mM solution of diethyl pyrocarbonate in the respective buffer and added to 5.0 ml of 5 mM imidazole in 0.035 M phosphate buffer (pH 8.0). The samples were carefully shaken and the absorption at 231 nm was measured after a few minutes. The errors due to parallel reaction of diethyl pyrocarbonate with water and buffers, change in background absorption of imidazole and hydrolysis of *N*-carbethoxyimidazole [12] were negligible under these conditions.

The reaction rates of the buffer compounds were studied at selected concentrations and pH in the following ranges: 0.05 – 0.2 M acetate buffer pH 4.5 – 5.0, 0.05 – 0.2 M phosphate buffer pH 6.5 – 7.5, 0.02 – 0.05 M Tris buffer pH 7.5 – 8.1, 0.05 – 0.1 M carbonate buffer pH 10.0. The rate constants were calculated from the stoichiometric composition of the buffer.

Reactions with glycylglycine, ammonia, ethanolamine, glycine, and β-alanine. The rate constants were determined by measuring the yield of *N*-carbethoxyimidazole in a solution of imidazole in the presence and absence of the amine under study.

The reactions were carried out in 0.02 M Tris or phosphate buffer at pH 8.0. Diethyl pyrocarbonate was dissolved in acetonitrile and added to the reaction mixture to give an initial concentration of 0.08 mM. The concentration of imidazole was 2 mM (4 mM in the reference experiment) and the amines were studied in the following concentration ranges: glycylglycine 1 – 2 mM, NH_4Cl 60 – 80 mM, ethanolamine 6 – 12 mM, glycine 5 – 20 mM, and β-alanine 15 – 50 mM. The absorption at 231 nm was measured after 5 min. The experiments were repeated for two of the compounds (glycylglycine and glycine) at pH 7.0 without buffer and with various concentrations of the amines (5 – 10 times higher than used at pH 8.0). The rate constants so determined were the same as those obtained at pH 8.0 within the limits of experimental error. The possibility of a general basic catalysis of the buffers or imidazole on the carbethoxylation of the investigated amines in the concentration ranges used could be disregarded. The stability of the *N*-carbethoxyimidazole in the presence of the amines was checked.

The concentration of the amines was large in comparison with the concentration of diethyl pyrocarbonate. Thus, the ratio of the pseudo first order rate constants could be determined directly from the ratio of the concentrations of the final products (*cf.*, *e.g.*, Ref. 19).

$$\frac{k'_{IM}}{k'_{RNH_2}} = \frac{k_{IM}[IM]}{k_{RNH_2}[RNH_2]} = \frac{[N\text{-carbethoxyimidazole}]}{[\text{urethan}]} \quad (6)$$

The second order rate constants refer to the concentrations of the free bases. The pK'_a values at $I = 0.1$ were taken from the literature (see Table 1).

Reaction with p-bromoaniline. The reaction was followed in an equimolar solution (3 – 4 mM) of diethyl pyrocarbonate and *p*-bromoaniline in 0.02 M phosphate buffer (pH 6.6). The amount of unreacted *p*-bromoaniline was determined by diazotation and coupling with histamine.[7] 0.1 ml samples were withdrawn every 10 sec and dispersed in 3.0 ml ice-cold $NaNO_2$-HCl (0.15 % $NaNO_2$, 0.1 M HCl, 1:3). After 15 min in ice-bath 1.0 ml 0.5 M borate buffer (pH 9.5) and 1.0 ml 0.01 M histamine dihydrochloride were added. The samples were carefully shaken after each addition. A yellow colour developed in 30 min at room temperature. Spectrophotometric readings were taken at 436 nm.

The second order rate constant k_2 was calculated from

$$1/c = k_2 t + C \quad (7)$$

where c is the concentration of *p*-bromoaniline (or diethyl pyrocarbonate) at time t.

Reactions with p-nitrophenyl mercaptan, 2-mercaptoethanol, and 3-mercaptopropionic acid. The reactions of diethyl pyrocarbonate with 2-mercaptoethanol and 3-mercaptopropionic acid were studied by three independent methods:

(a) By measuring the decrease of the concentration of diethyl pyrocarbonate. The reaction mixture was 1.5 mM with respect to diethyl pyrocarbonate and 15 mM with

respect to the SH compound in 0.05 M phosphate buffer (pH 7.0). 0.1 ml samples were taken at appropriate intervals and added to 3.0 ml 5 mM imidazole in phosphate buffer (pH 8). The *N*-carbethoxyimidazole was determined spectrophotometrically.

(b) By measuring the decrease of the concentration of the SH compound. The reaction between diethyl pyrocarbonate and the mercaptan in equal concentrations (2 – 4 mM) in 0.035 M phosphate buffer (pH 8.0) was followed by taking 0.1 ml samples every 7 sec and adding them to 5.0 ml of Ellman's reagent, 10^{-4} M 5,5′-dithiobis(2-nitrobenzoic acid) in 0.035 M phosphate buffer (pH 8).[20] The absorption was determined at 412 nm ($\varepsilon = 13\,600$ l mol^{-1} cm^{-1} for the liberated 4-nitro-3-carboxythiophenolate ion). A disturbing fading of the colour, possibly due to a reaction of the coloured anion with the remaining diethyl pyrocarbonate made it necessary to measure every sample several times and extrapolate the absorption to the time when the sample was taken. The rate constant was calculated from a plot of $1/c$ against time [eqn. (7)].

(c) By measuring the appearance of a peak in UV at 213 nm corresponding to the formation of an ethoxyformic acid thioester.[7] The reactions were carried out at pH 8.0 in 0.035 M phosphate buffer. The initial concentrations of diethyl pyrocarbonate and mercaptan were 0.1 mM and 1.1 mM, respectively. The increase in absorbance was measured directly at 213 nm. The reactions were followed for at least ten half-lives to get an accurate end-point determination. Log $(A_\infty - A_t)$ was plotted against time t to give a straight line from which the half-life was determined.

The reaction between diethyl pyrocarbonate and *p*-nitrophenyl mercaptan was followed by measuring the decrease of the absorption at 412 nm ($\varepsilon = 9000$ l mol^{-1} cm^{-1}; Ref. 18). The reaction conditions were the same as described under (b). The samples were diluted 50 times before reading.

The purity of the SH compounds was determined with the aid of Ellman's reagent.[20]

RESULTS AND DISCUSSION

The rate constants determined for the reaction of diethyl pyrocarbonate with the different nucleophilic reagents at 25° are summarized in Table 1. Good agreement was obtained with previous studies of the reaction rates with three of the nucleophiles, *viz.* the rate of the reaction with water [k (first order) = 0.0246 min^{-1}], determined by adding samples to diethylamine solutions and titrating the diethylamine in excess;[14] the rate of the reaction with imidazole ($k = 3240$ l mol^{-1} min^{-1}), determined spectrophotometrically at 231 nm, λ_{max} for *N*-carbethoxyimidazole;[12] and the rate of the reaction with ammonia ($k = 1600$ l mol^{-1} min^{-1}) determined by quantitative gas chromatographic analysis of the urethan formed (G. Löfroth, *personal communication*).

Table 1. Rate constants for reaction of diethyl pyrocarbonate with different nucleophiles at 25°. The given constants are mean values of 3 – 10 determinations; the error (95 % confidence interval) of the constants is mostly less than ± 10 %.

Nucleophile	pK_a	k l mol^{-1} min^{-1}
Water	−1.74[a]	4.3×10^{-4}
CH_3COO^-	4.8[a]	0.35
HPO_4^{2-}	6.9[a]	0.9
CO_3^{2-}	10.4[a]	0.6×10^2
Tris	8.1[a]	24
p-Bromoaniline	3.9[b]	2.2×10^2
Imidazole	7.0[c]	3.2×10^3
Ammonia	9.29[d]	1.7×10^3
Glycylglycine	8.09[e]	1.0×10^4
Ethanolamine	9.5[f]	2.7×10^4
Glycine	9.60[g]	4.0×10^4
β-Alanine	10.3[h]	5.4×10^4
p-Nitrophenyl mercaptan	5.1[i]	1×10^{2}[k]
2-Mercaptoethanol	9.5[a]	1.0×10^4
3-Mercaptopropionic acid	10.2[j]	1.2×10^4

A Brønsted plot of the data (Fig. 1) indicates that primary amines follow the relationship[19]

$$\log k = \beta \, pK_a + C \qquad (8)$$

where $\beta = 0.4$ gives the dependence of reaction rate on the basicity of the amino group. The rate constant for the tertiary amine, imidazole, falls on the same curve; a more detailed study on strictly defined structurally related imidazoles and primary amines is required to show whether imidazole truly belongs to the group of amines in this respect or the position of k_{IM} is the fortuitous resultant of mutually counteracting factors. The strong solvation of the ammonium ion which causes an abnormally high pK_a, and the low polarizability of NH_3 nitrogen, probably account for the relatively low reactivity of ammonia.[19,21] The slow reaction of tris(hydroxymethyl)aminomethane (Tris) as compared to other primary amines of

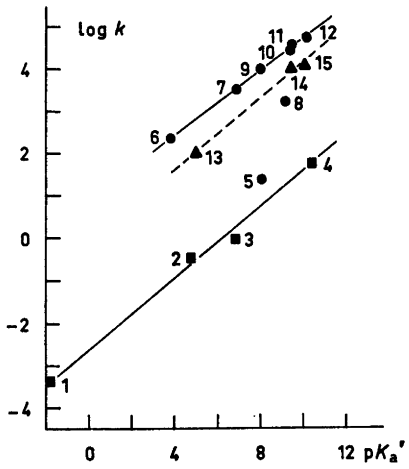

Fig. 1. Log k (k in 1 mol^{-1} min^{-1}), as a function of pK'_a of reactions of diethyl pyrocarbonate with nucleophiles at 25°. 1, water; 2, CH_3COO^-; 3, HPO_4^{2-}; 4, CO_3^{2-}; 5, Tris; 6, *p*-bromoaniline; 7, imidazole; 8, ammonia; 9, glycylglycine; 10, ethanolamine; 11, glycine; 12, β-alanine; 13, *p*-nitrophenyl mercaptan; 14, 2-mercaptoethanol; 15, 3-mercaptopropionic acid.

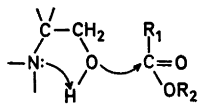
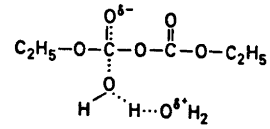
corresponding pK'_a may reflect steric hindrance at the nitrogen. It is probable, however, that this steric hindrance is comparatively large and that the reaction measured proceeds *via* an alternative mechanism, *viz.*, the intramolecular base-catalyzed attack by an oxygen according to formula (9), indicated to operate in the reactions of Tris and hydroxylamine with *p*-nitrophenyl acetate,[21] and suggested to explain the activation of the serine hydroxyl group at the active site of chymotrypsin.[22]



(9)

The three sulfhydryl compounds studied react more slowly with diethyl pyrocarbonate than primary amines with comparable dissociation constants. In this respect diethyl pyrocarbonate differs from the carefully investigated acylating agent, *p*-nitrophenyl acetate which is attacked somewhat more rapidly by thiol anions than by primary amines.[21] The difference in nucleophilic reactivity towards diethyl pyrocarbonate and *p*-nitrophenyl acetate seems to be the high reactivity of the primary amines towards diethyl pyrocarbonate, rather than the low reactivity of the thiols.

As expected, compounds with nucleophilic oxygen react slowly with diethyl pyrocarbonate. The rate constants for reaction of diethyl pyrocarbonate with water, acetate, hydrogen phosphate, and carbonate exhibit a dependence on pK_a which is approximately equal to that of the amines and the thiols. Kivinen [14] concluded that the neutral hydrolysis of diethyl pyrocarbonate in water takes place by a general base-catalyzed mechanism with water functioning as a base, and proposed the structure (10) for the transition state.



(10)

The acetate, hydrogen phosphate, and carbonate may serve either as general base catalysts or as real nucleophilic catalysts.

Preliminary studies of the carbethoxylation of RNA in phosphate buffer indicates that diethyl pyrocarbonate acts *via* a carbethoxy phosphate intermediate (which is certainly very unstable [23]), and accordingly the reaction mechanism would involve a nucleophilic attack of hydrogen phosphate on the carbonyl carbon (data to be published).

In biochemical studies, *e.g.* of enzyme inactivation with diethyl pyrocarbonate, its concentration, [DEP], decreases with time, t, according to

$$[\mathrm{DEP}] = [\mathrm{DEP}]_0 \, e^{-k't} \qquad (11)$$

where $[\mathrm{DEP}]_0$ is the initial concentration of diethyl pyrocarbonate and

$$k' = k_{H_2O}[H_2O] + \sum_i k_i c_i \qquad (12)$$

k_i and c_i being the rate constants and concentrations, respectively, of nucleophiles in the system. The rate constants of buffer components permit the calculation of k' in the reaction media and hence the dose, *i.e.* the time integral of the concentration of diethyl pyrocarbonate.

In reactions with proteins no absolute specificity, *e. g.* towards histidine, occurs. Reaction is expected to occur in a random fashion with various groups (*cf.* Ref. 24), if sterically accessible, and proportionally to the respective rate constants and the degrees of dissociation of these groups at the pH of the treatment. Fig. 2 illustrates the selectivity of the reaction with imidazole groups. It gives the expected total rates of carbethoxylation at pH 7 of amino ($\equiv N + \equiv NH^+$) and thiol ($-S^- + -SH$)

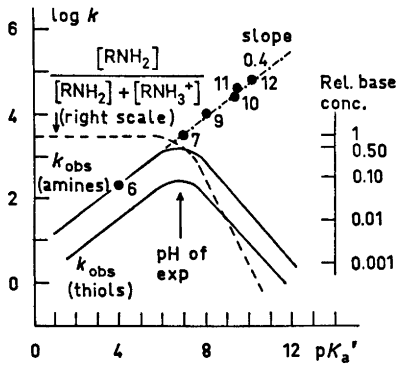


Fig. 2. The total observed reactivities at pH 7 (log k, scale to the left) of diethyl pyrocarbonate towards amines and thiols [solid lines marked k_{obs} (amines) and k_{obs} (thiols), respectively] as a function of pK'_a of the nucleophiles. For nucleophiles with $pK'_a <$ pH of the experiment (in the figure pH 7) the concentration of the reactive species, *i.e.* free base, approaches the total concentration of the nucleophile, whereas the relative concentration of the free base of nucleophiles with higher pK'_a approaches a line with slope -1 (shown for amines in curve – – – marked $[RNH_2]/([RNH_2]+[RNH_3^+])$; right scale). k_{obs} of weak bases ($pK'_a <$ pH) approach the respective Brønsted curve with slope 0.4 (–·–· curve for amines from Fig. 1). k_{obs} of strong bases approach the resultants of the Brønsted slope and the slope -1. *Cf.* Ref. 19 p. 84.

groups as a function of their dissociation constants. The rate of carbethoxylation of (total) imidazole exhibits a maximum aroung pK_a. For similar reasons, enzyme histidines will be carbethoxylated with a certain selectivity at or below pK_a (around 6.5).[12] The rate of inactivation of ribonuclease [13,15] by diethyl pyrocarbonate in the pH range 4 – 7 agrees well with the expected rate of reaction with histidine. The rate constants for inactivation of ATP-creatine phosphotransferase and ATP-L-arginine phosphotransferase [25] in 0.05 M phosphate buffer (pH 6.1) correspond to $k_{his} = 1000$ l mol^{-1} min^{-1} in agreement with expectation.

Lysine ε-amino groups (pK_a about 10) will react about 50 times slower than histidines in neutral solution but their reaction rates will increase rapidly with pH.

The second order rate constant for the reaction of diethyl pyrocarbonate with RNA was found to be about 0.003 l (mol nucleotide)$^{-1}$ min^{-1} in 0.05 M phosphate buffer (pH 6.5 – 7.5) and 25°. Since the reaction rate was found to depend on the concentration of phosphate, indicating a role of transcarbethoxylation *via* carbethoxy phosphate, the value of the constant is preliminary. It agrees acceptably with earlier data for the inactivation of virus RNA [26-28] and transfer RNA[29] by diethyl pyrocarbonate.

An RNA molecule containing 1000 nucleotides (in single-stranded regions [26-29]) will, under the conditions given, be inactivated at a rate of about 3 l (mol RNA)$^{-1}$ min^{-1}, *i.e.* two orders of magnitude more slowly than enzymes inactivated by carbethoxylation of histidine.

Changes in the ultraviolet spectra of diethyl pyrocarbonate-treated nucleic acids indicate [17,39] that diethyl pyrocarbonate reacts with single-stranded regions of RNA and DNA. Isotope studies using ^{3}H-labelled diethyl pyrocarbonate and homopolymers have revealed [40] that in the polynucleotide chain it is adenosine whose reaction rate with diethyl pyrocarbonate is the highest. If we now assume that in *E. coli* rRNA it is also adenosine which reacts fastest and that about 40 %[41] of its adenosine residues are in single-stranded regions, the rate constant at 25° for the reaction with RNA-adenosine will be about 0.03 l mol^{-1} min^{-1} in 0.05 M phosphate buffer and some three times higher in 0.2 M buffer. This rate is at least one order of magnitude lower than the value of 1.1 ($\pm$0.2) l mol^{-1} min^{-1} determined from ultraviolet spectral studies (our unpublished data *) for the reaction of

* Partly in collaboration with Prof. E. I. Budovskii (Shemyakin Institute for the Chemistry of Natural Products, Academy of Sciences, Moscow, U.S.S.R.) whose contribution is greatly acknowledged.

diethyl pyrocarbonate with adenosine in phosphate buffers, independently of buffer concentration. Adenosine residues in RNA are therefore less reactive towards diethyl pyrocarbonate than the free nucleoside and it remains to be shown whether the two reactions proceed by the same mechanism.

Acknowledgement. The investigation was supported by the *Swedish Natural Sciences* and *Atomic Research Councils*. The investigation was performed within the frame of collaboration between the Radiobiology Department, Stockholm University, and the Biological Research Center, Hungarian Academy of Sciences, Szeged.

We are indebted to Mrs. Inger Wennberg for skilful technical assistance, and to Mr. Felix Hultén for participation in certain parts of the investigation.

Studies on the Bacteriolytic Activity of *Streptomyces albus* Culture Filtrates. 3. Affinity for Chitin

L. AKSNES and A. GROV

The University of Bergen, School of Medicine, The Gade Institute, Department of Microbiology, N-5000 Bergen, Norway

The enzymes of *Streptomyces albus* G culture filtrates were absorbed to chitin and deaminated chitin, and desorbed quantitatively under mild conditions. The affinity was dependent on low ionic strength, whereas variation in pH between 4.5 and 9.0 had no effect. The similarity to the results obtained with carboxymethyl cellulose suggests a binding to substrate-analogous structures.

Earlier studies[1,2] have shown that culture filtrates of *Streptomyces albus* G contain a muramidase, an amidase, and several endopeptidase and caseinolytic activities. The two former activities were isolated in apparently pure states on carboxymethyl cellulose, whereas the latter activities were eluted together without detectable amidase and hexosaminidase activities. Further separation was not obtained either on gel filtration or electrophoresis.

Since the first report by Berger and Weiser[3] on degradation of chitin by egg-white lysozyme, the binding of this and other muramidases (E.C. 3.2.1.17) has been extensively studied using chitin as substrate.[4–8] This property of muramidases, *i.e.* reversible binding to a structural analog of its substrate, has also been utilized in isolation and purification of this type of enzyme.[9]

The intention of the present study was to test chitin as a possible adsorbent for the endo-*N*-acetylmuramidase of *Streptomyces albus* G culture filtrates.

MATERIALS AND METHODS

Chitin, a polymer of essentially non-branched chains of β-(1-4)-*N*-acetyl-D-glucosamine units, was obtained from Sigma Chemical Co., Mo. U.S.A. All other materials and chemicals used were described previously,[1,2] including the test bacteria abbreviated: Sa (*Staphylococcus aureus* Copenhagen), Sp (*Streptococcus pyogenes* A), Pc (*Planococcus* 2389), M-144 (*Micrococcus luteus* 144), M-84 (*M. conglomeratus* 84), Ml (*M. lysodeikticus* NCTC 2665), Sl (*Sarcina lutea*), and Bm (*Bacillus megaterium*).

The methods for testing of lytic activities, dialysis, concentration, determination and quantitation of free groups and *N*-acetylamino sugars, and estimation of enzymatic specificities were those described or referred to earlier.[1,2]

Preparation of chitin. Chitin was prepared and treated according to the description of Jensen and Kleppe[9]. Deamination was performed as described by Cherkasov and Kravchenko,[10] suspending chitin (10 ml) in a mixture of 1.27 ml 12 N HCl and 1 g $NaNO_2$ in 30 ml of water, incubating for 6 h at 0°C with continuous stirring, followed by washing in 1 % NaCl, 1 % acetic acid and finally distilled water.

Column fractionation. Columns (1.2 × 2 cm) of chitin and deaminated chitin, 50 – 100 mesh, were packed and equilibrated with buffer. Enzyme solutions were applied at a rate of about 5 ml/h followed by washing with buffer (100 ml). The columns were eluted with either (a) M acetic acid or (b) 0.01 M Tris-HCl pH 8.0, and a linear NaCl-gradient (200 ml) from 0 to 0.2 M. The elution rate was approximately 5 ml/h. Fractions (2 or 5 ml) were collected, dialyzed against 0.01 M Tris-HCl pH 8.0, and subjected to activity tests. All fractionation experiments were carried out at 4°C.

RESULTS

The various activities of crude enzyme preparation (CEP)[1] were apparently adsorbed to chitin. Only a slight caseinolytic activity was demonstrated in the effluent, but due to low activity there was uncertainty with respect to

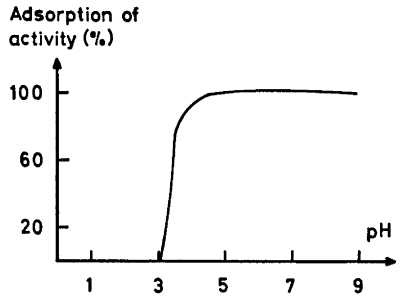

Fig. 1. Percentage adsorption to chitin of bacteriolytic activity (tested on *B. megaterium*) at various pH-values.

the amidase. The effect of pH on the binding to chitin was studied over a pH-range of 2.6–9.0 using the buffer systems: 0.01 M Na-citrate-HCl (pH 2.6–5.0), 0.01 M Na-phosphate (pH 5.0–8.0), and 0.01 M Tris-HCl (pH 8.0–9.0). CEP (10 ml), dialyzed against the appropriate buffer, was applied to the chitin column equilibrated with the same buffer. After washing with buffer, the activity adsorbed was eluted with M acetic acid and dialyzed against 0.01 M Tris-HCl, pH 8.0. Washings and eluates were tested for lytic activity on heat-killed cells of *B. megaterium* and for caseinolytic activity. The percentage of total lytic activity applied to the column which was bound at various pH-values is illustrated in Fig. 1. Above pH 4.2 complete adsorption of bacteriolytic activity was obtained. An abrupt drop in adsorption occurred below pH 4.2 and at approximately pH 3.2 the affinity of lytic enzymes for chitin was zero. Upon digestion of Sa mucopeptide, Bm cell wall, and casein with the eluates, free amino and reducing groups showed an increase in the same pH-range, as did also lysis of casein. The use of deaminated chitin as column material gave the same results as for chitin, and rubbed paper (Whatman No. 1 chromatography paper) at pH 8.0 (0.01 M Tris-HCl) behaved similarly as far as adsorbing capability is concerned.

Elution of enzyme-loaded (15 ml of the CEP) column with the NaCl-gradient and testing of every second fraction for bacteriolytic and caseinolytic activity gave the results shown in Figs. 2 and 3. To some extent the lytic activity of the material applied to the column seems, ac-

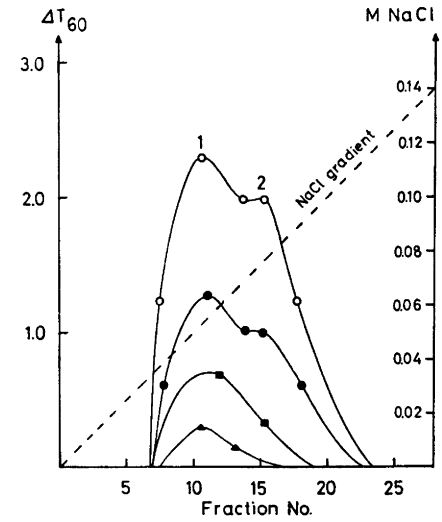

Fig. 2. Lytic activity in fractions (5 ml) from chitin column eluted with a linear NaCl-gradient, as tested on heat-killed Bm (○), Sa (●), Ml and Sl (■), and M-144, M-84 and Sp (▲). ΔT_{60} (reduction in turbidity after 60 min) = (ΔTt/t) × 60.

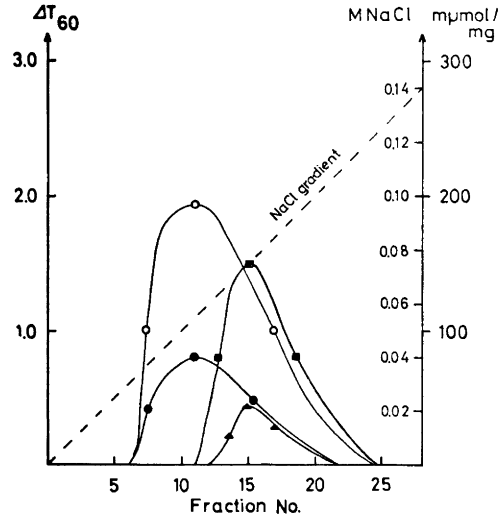

Fig. 3. Caseinolytic activity (●) and the increase in free amino groups on Sa mucopeptide (○), reducing groups (■) and *N*-acetylamino sugars (▲) of Bm cell wall upon digestion with fractions from the chitin column eluted with a linear NaCl-gradient. ΔT_{60}: See legend Fig. 2.

cording to the tests on Bm and Sa cells, to be divided into two peaks (Fig. 2). One of these peaks corresponds to the increase in free amino groups (tested on Sa mucopeptide) and the other to the increase in reducing groups (tested on Bm cell wall) (Fig. 3). The fractions showed no absorbance at 280 nm. Of the two activity peaks indicated, only the first showed lytic activity on all test bacteria and on casein within a digestion period of 90 min. The second peak lysed only Sa and Bm cells and increased the amount of reducing groups and *N*-acetylamino sugar. The recovery of bacteriolytic and caseinolytic activity was calculated to be about 80 % and 30 %, respectively. Deaminated chitin gave a similar elution pattern.

DISCUSSION

All the bacteriolytic enzymes of *Streptomyces albus* cultures seem to bind reversibly to chitin. The binding is apparently dependent on low ionic strength since elution of lytic material starts below 0.04 M NaCl (Fig. 2), but shows high affinity at pH-values above 4.2. The abrupt drop in binding affinity below pH 4.2, decreasing to zero at pH 3.2, is in accord with data reported for lysozymes.[7,9] In these reports the carboxyl groups localized to the "active sites" of the enzymes were supposed to be essential for binding to chitin. No difference between chitin and deaminated chitin was observed in the adsorption and elution pattern. Purified chitin contains some free amino groups revealed by deacetylation. These groups have been shown to exhibit ion-exchange effect,[5] but seem, according to the results with deaminated chitin, to be of no importance for adsorption.

Both endopeptidase and the endo-*N*-acetylmuramidase activity were demonstrated in the eluates from the chitin materials, the elution pattern being very similar to that of the carboxy methyl cellulose columns.[2] The binding of the muramidase to chitin is most probably due to a real enzyme-substrate affinity on account of analogy in the structures of glycan chains of mucopeptide and chitin, a specific binding of the endopeptidases being more doubtful. It has, however, previously been shown[11] that the endopeptidase activities of *Streptomyces albus* G to a certain degree depend on an intact glycan chain, and this may have a connection with a possible binding site of endopeptidases to the glycan chain.

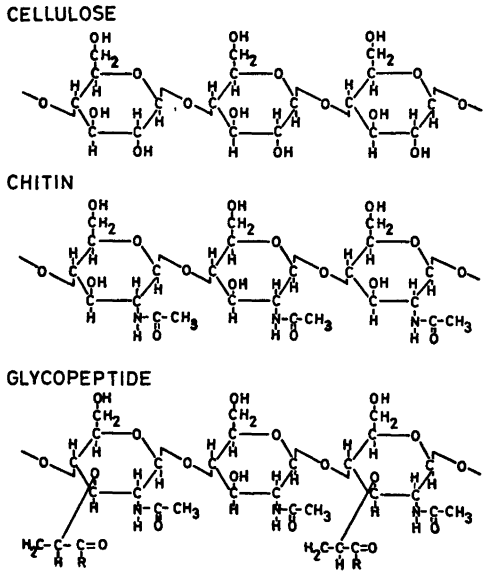

Fig. 4. The glycan chain of cellulose, chitin and mucopeptide (glycopeptide). R = OH or peptide.

The results of the present experiments with chitin are comparable with those obtained with carboxy methyl cellulose, and cellulose also with regard to adsorbing ability. This points to the possibility that binding of the lytic enzymes to the glycan chains is effected similarly in mucopeptides, cellulose, carboxy methyl cellulose and chitin (see Fig. 4 for a structural comparison), and that the introduced carboxyl groups have only a minor influence on this binding.

Acknowledgement. The authors wish to express their gratitude to Dr. H. B. Jensen, The Biochemical Institute, The University of Bergen, for advice and help in preparation of the chitin materials.

3,3-Dialkylindolin-2-ones and 3,3-Dialkylisoindolin-1-ones. 1. Hofmann Hypohalite Degradation of 4,4-Dialkyl-1,3-dioxo-1,2,3,4-tetrahydroisoquinolines (4,4-Dialkylhomophthalimides)

N. ÅKE JÖNSSON and PINCHAS MOSES

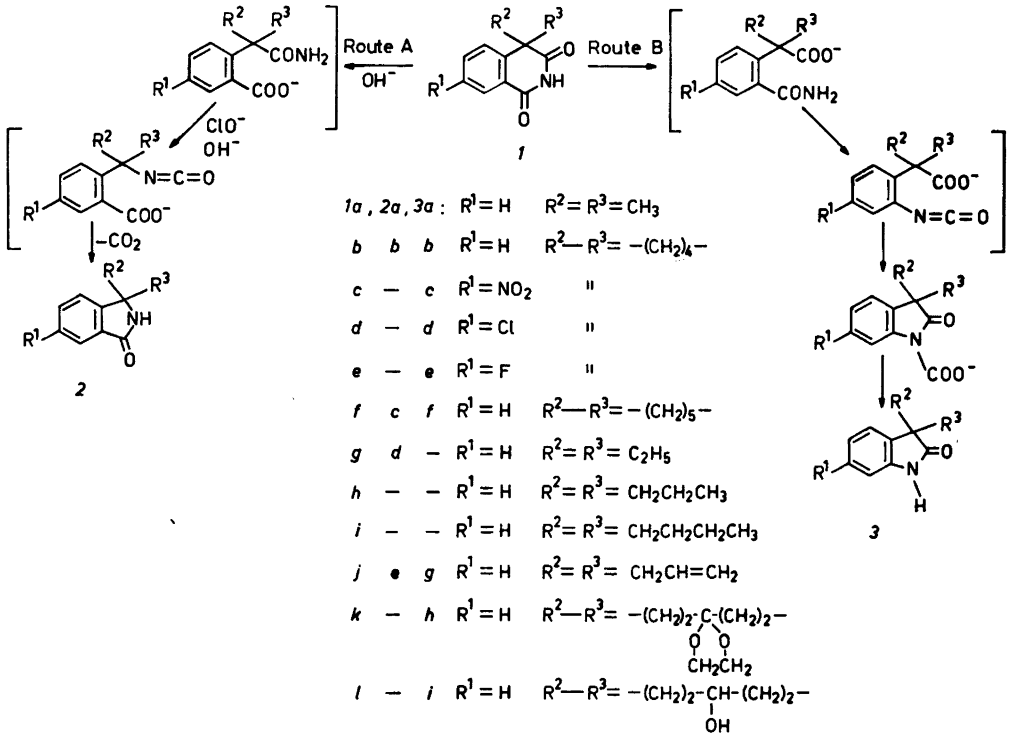
Department of Organic Chemistry, Research Department, AB Kabi, S-104 25 Stockholm, Sweden

Hofmann hypohalite degradation of certain 4,4-dialkyl substituted homophthalimides has been found to give a high yield of the corresponding 3,3-dialkylindolin-2-ones. If these homophthalimides are subjected to alkaline hydrolysis prior to treatment with hypohalite, isoindolin-1-ones are produced together with the indolin-2-ones.

In the course of an investigation on certain types of biologically active compounds, we required a number of 3,3-dialkylisoindolin-1-ones. Of the limited number of such compounds described in the literature, the 3,3-dimethyl derivative had been prepared by zinc dust distillation of "1,1-dimethyl-3-amino-ψ-isoindole"[1] and its *N*-phenyl derivative was reportedly formed when 3,3-dimethylphthalide was heated with aniline.[2] Hauser *et al.*[3] reported that a number of *o*-(*N*-alkylcarbamoyl)benzyl alcohols, including the α,α-pentamethylene derivatives, undergo ring-closure to isoindolinones when treated with strong acids. A reinvestigation of the structures of these reaction products by Bailey and De Grazia,[4] however, revealed that some of them are iminophthalides rather than isoindolinones. New routes had therefore to be developed for the preparation of our intermediates.

Since isoindolin-1-ones may be regarded as lactams of *o*-aminomethylbenzoic acids, our interest became focussed on the means of preparation of such acids dialkylated at the methylene carbon atom. Of the large number of methods generally available for the preparation of amines, very few are adaptable to the synthesis of derivatives fully alkylated at the α-carbon atom. Methods involving nucleophilic replacement reactions generally fail because eliminations prevail, many other methods fail because of the steric hindrance exerted by the α-substituents. The Hofmann degradation of amides,[5] however, is an exception and permits the synthesis of this sort of amine in high yields from amides of α,α-dialkyl fatty acids. One route to the desired isoindolin-1-ones would therefore use *o*-carboxy-α,α-dialkylphenylacetamides as intermediates. The facile preparation of 4,4-dialkylhomophthalimides from the readily available homophthalimide [6,7] or from suitably substituted homophthalic acids induced us to investigate the possibilities of this type of compound as start material for the acetamide derivatives. Although it has been reported [8] that homophthalimide itself is hydrolysed to *o*-carbamoylphenylacetic acid rather than to *o*-carboxyphenylacetamide (however, *cf.* Ref. 9) it was felt that because of the steric hindrance exerted by the alkyl groups in the *geminally* alkylated homologues the formation of phenylacetamide derivatives from these compounds would be favoured. Hofmann degradation of these acetamide derivatives followed by ring closure would then afford the desired products, according to the sequence outlined in Scheme 1, Route A.

For our investigation of this type of reaction, we used mainly 1′,3′-dioxo-1′,2′,3′,4′-tetrahydrospiro(cyclopentane-1,4′-isoquinoline), (4,4-



Scheme 1.

tetramethylenehomophthalimide*) (*1b*) as our model compound, since this derivative could be readily prepared in good yield [7] and also proved to be eminently suited for the isolation of the products of reaction with little loss.

Hydrolysis experiments with the homophthalimide derivative *1b* soon showed that whereas the unsubstituted homophthalimide could be completely hydrolysed within 3 days at room temp.[8], the 4,4-dialkyl derivatives were apparently very resistant to alkaline hydrolysis even at elevated temperatures. Thus when a solution of *1b* in excess of 2 N sodium hydroxide was kept at room temp. for various times up to 25 days and subsequently treated with hypochlorite solution, the maximum yield of the expected 1′-oxospiro(cyclopentane-1,3′-isoindoline) (*2b*) that could be isolated was about 35 %. An interesting observation was the fact that almost maximum yields were obtained already within the first few days, after which the rise in yield was almost imperceptible (Fig. 1). Using elevated temperatures (60° and 95°) did not improve the yield of *2b*, indeed, it became lower, probably because of the secondary hydrolysis of the amide group, as indicated by a distinct smell of ammonia noticeable at the higher temp.

In order to recover start material supposed to be present in the mother liquor after *2b* had been filtered off, the filtrate was acidified. Vigorous evolution of carbon dioxide ensued and a material precipitated out which was subsequently identified as the known 2′-oxospiro(cyclopentane-1,3′-indoline) (*3b*). When the alkaline reaction mixture was cooled strongly instead of being acidified, a sodium salt precipitated which, according to elemental analysis, was apparently sodium 2′-oxospiro(cyclopentane-1,3′-indoline)-1′-carboxylate. The structure was confirmed by esterification with dimethyl sulphate followed by pyrolysis to the known 1′-methylspiro(cyclopentane-1,3′-indolin)-2′-one.

* For convenience, the compounds are named as derivatives of homophthalimide when this can be done without risk of misunderstanding.

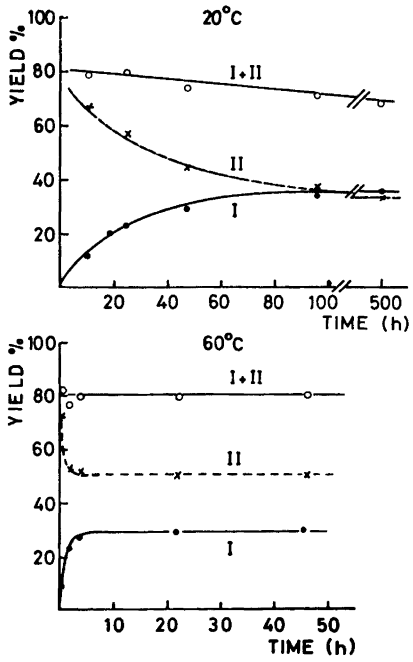


Fig. 1. Semiquantitative determination of the yields of 1′-oxospiro(cyclopentane-1,3′-isoindoline), I, and 2′-oxospiro(cyclopentane-1,3′-indoline), II, as functions of time and temp.

We later found that *3b* could be obtained in 89 % yield if the homophthalimide derivative was dissolved in aqueous alkali and immediately treated with the hypochlorite solution, even if the reaction was allowed to proceed at room temp. for as short a time as 1/2 h; under these conditions, none of the isoindolinone *2b* could be detected. This reaction, when applied to a variety of *geminally* disubstituted homophthalimides, afforded in high yields the disubstituted indolinones listed in Table 1, and thus offers a convenient route to several 3,3-dialkylated indolinones unsubstituted at the nitrogen atom, a class of compounds which has hitherto only been available through lengthy procedures and in unsatisfactory yields.[10–13]

When the reaction was carried out with 4,4-diallylhomophthalimide (*1j*) much longer reaction times were required (of the order of 24 h) and a mixture of the indolinone and the isoindolinone derivatives was isolated together with unreacted start material. 4,4-Diethylhomophthalimide failed to give any 3,3-diethylindolin-2-one but afforded up to 36 % of 3,3-diethylisoindolin-1-one when the homophthalimide derivative was allowed to react with alkaline hypochlorite solution for 3 days at room temp. 4,4-Dipropyl- and 4,4-dibutylhomophthalimide failed to react under any of the conditions tried. It thus appears that increasing steric hindrance prevents progressively first the reaction leading to an indolinone derivative and then that leading to an isoindolinone. Unsubstituted homophthalimide appears to give halogenated products with no indication of any rearrangement when treated with hypohalite solution.

Some comments on the modes of formation of the indolinones seem to be of interest. Although other mechanisms have been suggested [14] it is generally accepted [5,15,16] that the Hofmann degradation of imides is preceded by a hydrolytic opening of the imide ring to produce an "amic" acid intermediate which then rearranges. The formation of the isoindoline and indoline derivatives after pretreatment with alkali seems to be readily explicable by such ring opening mechanisms, Scheme 1. It is interesting that the yield of the isoindolinone *2b* levels off at about 35 % despite the fact that very little further hydrolysis to the dicarboxylic acid occurs, as is evident from Fig. 1. A possible explanation for this would be that the two hydrolysis routes, A and B in Scheme 1, compete with each other, finally resulting in an equilibrium mixture containing approx. 35 % of 1-(2-carboxyphenyl)cyclopentanecarboxamide.

However, it is much more difficult to envisage the mechanism by which the indolinones are formed when the homophthalimides are treated with alkaline hypochlorite solution without prehydrolysis. Since, under these conditions, the indolinones are formed very rapidly in almost quantitative yields, in contrast to the presumably very slow hydrolysis of the homophthalimide derivatives, it is extremely difficult to reconcile the rearrangement reaction with a mechanism involving a conventional ring opening of the homophthalimide derivative to the intermediate *o*-carbamoylphenylacetic acid. Because of this, we undertook a more extensive investigation of the mechanism

Table 1.

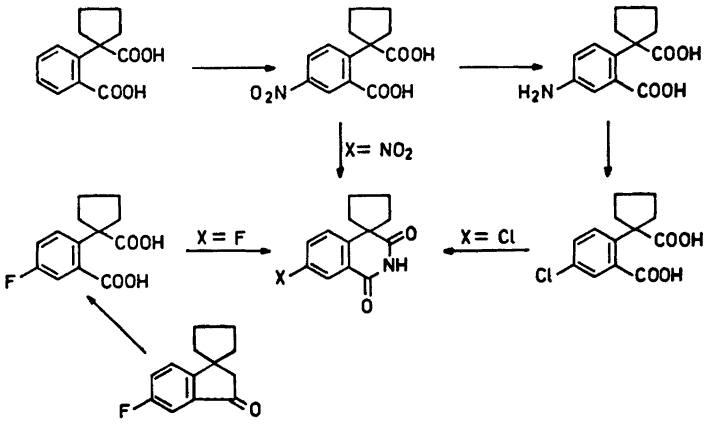

Scheme 2.

of this reaction, which will be the subject of a forthcoming paper.

Several of the substituted homophthalimides used as start material have been described in the literature.[6,7] The syntheses of the new compounds are described in the Experimental Part. The halogenated derivatives of 4,4-tetramethylenehomophthalimide were prepared according to Scheme 2.

The structures of the rearranged products were established by means of IR-, UV-, and NMR-spectroscopy. Especially the UV and NMR spectra were found to be very informative. In methanolic solution, all the indolinones investigated had a strong absorption band at 245 – 250 nm and only weak absorption around 225 nm. The isoindolinones, on the other hand, had a very strong, complex peak around 225 nm, almost no absorption around 250 nm but two small peaks at about 270 and 280 nm (cf. Ref. 20). In the NMR spectra of the indolinones the aromatic hydrogen atom *ortho* to the amino group is clearly distinguishable at τ 2.8 – 3.0 ppm ($CDCl_3$ solution), the corresponding atom appearing at τ 2.0 – 2.2 ppm in the isoindolinones. The IR spectra (in KBr) are less informative but there is a trend towards a shifting of the carbonyl frequences to higher values in the isoindolinones. (Thus the diallylindolinone derivative *3g* has two C=O absorption bands at 1675 and 1715 cm^{-1}, the corresponding bands in the isoindolinone derivative *2e* appearing at 1650 and 1700 cm^{-1}).

EXPERIMENTAL PART

Melting points were taken on a Heraeus Fus-O-Mat melting point apparatus. The structures of the compounds were determined by elemental analyses and by IR-, UV-, and NMR-spectroscopy. The microanalyses were carried out by Prof. K. J. Karrman, University of Lund, Lund, Sweden, and by Dr. Alfred Bernhardt, Mikroanalytisches Laboratorium, Elbach über Engelskirchen, Germany.

A. Preparation of homophthalic acid derivatives

1-(2-Carboxy-4-nitrophenyl)cyclopentanecarboxylic acid. 1-(2-Carboxyphenyl)cyclopentanecarboxylic acid [17] (355 g; 1.53 mol) was added portionwise to fuming nitric acid (sp. gr. 1.52; 1100 ml) under vigorous stirring, the temp. being kept at 5 – 10° by external cooling. After being stirred for 3 h, the mixture was poured onto crushed ice, the product was collected, washed copiously with water and dried, affording 400 g (93.5 %) of white crystals, m.p. *ca.* 200° (rapid heating). A sample crystallized from methanol-petroleum ether had m.p. 210°. (Found: C 55.7; H 4.72; N 5.00; O 34.4. $C_{13}H_{13}NO_6$ requires: C 55.9; H 4.70; N 5.02; O 34.4). If the reaction is carried out at 20°, the corresponding *anhydride* is obtained in 90 % yield, m.p. 132° (from benzene). (Found: C 59.9; H 4.17; N 5.36; O 30.4. $C_{13}H_{11}NO_5$ requires: C 59.8; H 4.24; N 5.36; O 30.6).

1-(4-Amino-2-carboxyphenyl)cyclopentanecarboxylic acid. The foregoing nitro compound (56 g; 0.2 mol) was dissolved in 150 ml of methanol, Raney nickel (20 g wet weight) was added and the mixture shaken in an atmosphere of hydrogen at an initial pressure of about

4 kg/cm². After 4 h, by when the theoretical quantity of hydrogen had been consumed, the grey precipitate was filtered off and sucked dry, the product was dissolved in conc. ammonia (50 ml), the solution filtered, cooled and neutralised with dil. hydrochloric acid. After acidification with acetic acid, the precipitate was collected, washed with cold water and dried, affording 46 g (92 %) of a grey-white powder of indefinite m.p. Recrystallization from water gave a product containing 1 mol of water. (Found: C 57.6; H 6.43; N 5.19; O 30.4. $C_{13}H_{15}NO_4.H_2O$ requires: C 58.4; H 6.41; N 5.24; O 29.9). Recrystallization from acetic acid gave the corresponding anhydride. (Found: C 67.1; H 5.64; N 5.84; O 21.4. $C_{13}H_{13}NO_3$ requires: C 67.4; H 5.67; N 6.06; O 20.8).

Note: It is important to observe that the starting material in this reaction contains no anhydride and that the reaction temp. is not allowed to rise to a level that will cause the diacid to be converted to the anhydride. If this is not rigorously followed, considerable quantities of polymeric products resulting from reaction between the anhydride and amino acid will be obtained.

1-(2-Carboxy-4-chlorophenyl)cyclopentanecarboxylic acid. The foregoing amino acid (31.8 g; 0.15 mol) in a mixture of 35 ml of conc. hydrochloric acid and 200 g of ice was diazotised at 5 – 10° with sodium nitrite (10.5 g; 0.15 mol) in 75 ml of water. After addition, the mixture was stirred for about 15 min and then added portionwise with vigorous stirring to an ice-cold solution of freshly prepared cuprous chloride (from 195 g of $CuSO_4.5H_2O$; 0.75 mol) in conc. hydrochloric acid (400 ml). This reaction should be carried out in a 3 litre beaker since copious effervescence occurs. After standing at ambient temp. for about 2 h the precipitate was collected, washed with dilute hydrochloric acid and water, and dried, giving 28.2 g (69.5 %) of a cream coloured product of indeterminable m.p. A sample warmed with acetic anhydride afforded an orange coloured product which was purified by column chromatography on alumina and subsequently crystallized from benzene-petroleum ether, affording the corresponding *anhydride* as bright orange crystals, m.p. 120 – 122°. (Found: C 62.9; H 4.38; Cl 13.5; O 19.2. $C_{13}H_{11}ClO_3$ requires: C 62.3; H 4.42; Cl 14.1; O 19.1).

1-(2-Carboxy-4-fluorophenyl)cyclopentanecarboxylic acid. 5'-Fluorospiro(cyclopentane-1,1'-indan)-3'-one [18] (41 g; 0.2 mol) in 0.5 N sodium hydroxide solution (800 ml; 0.4 mol) was warmed to 95° and treated portionwise with potassium permanganate (90 g; 0.55 mol) under stirring. After addition, the mixture was stirred on a water-bath for about 15 min by when the permanganate colour had become discharged. The mixture was filtered hot, the manganese dioxide cake was washed with hot water, the filtrate was cooled and acidified with conc. hydrochloric acid till crystals began to appear. Sodium bicarbonate was added, the mixture was warmed, filtered, cooled and acidified. The precipitate was collected, washed and dried giving 34 g (67.5 %) of crude diacid, m.p. 130 – 140°, with conversion to the *anhydride*, m.p. 83°. For analysis, a sample of the diacid was recrystallized from diisopropyl ether-petrol. ether and then melted at *ca.* 140°. (Found: C 61.9; H 5.20; F 7.53. $C_{13}H_{13}FO_4$ requires: C 61.9; H 5.19; F 7.53).

B. Preparation of homophthalimide derivatives

1',3'-Dioxo-7'-nitro-1',2',3',4'-tetrahydrospiro-(cyclopentane-1,4'-isoquinoline) (1c). 1-(2-Carboxy-4-nitrophenyl)cyclopentanecarboxylic acid (28 g; 0.1 mol) was treated with conc. ammonia (30 ml) and the mixture heated in an open flask over an open flame. The mixture darkened and eventually became converted to a high melting solid. On further heating, it melted with effervescence. Heating was continued until a clear dark melt was obtained which, after solidification, was pulverised and crystallized from 100 ml of dioxane, yielding 19.9 g (76.5 %) if the imide *1c*, m.p. 227°. (Found: C 59.9; H 4.65; N 10.7; O 24.6. $C_{13}H_{12}N_2O_4$ requires: C 60.0; H 4.65; N 10.8; O 24.6).

The following two compounds were prepared in a similar manner.

7'-Chloro-1',3'-dioxo-1',2',3',4'-tetrahydrospiro-(cyclopentane-1,4'-isoquinoline) (1d), hair-like needles from ethanol, m.p. 215 – 216°. Yield almost 100 %. (Found: C 62.7; H 4.87; Cl 13.8; N 5.63; O 13.2. $C_{13}H_{12}ClNO_2$ requires: C 62.5; H 4.87; Cl 14.2; N 5.61; O 12.8).

1',3'-Dioxo-7'-fluoro-1',2',3',4'-tetrahydrospiro(cyclopentane-1,4'-isoquinoline) (1e), white hair-like crystals from ethanol, m.p. 213°, yield 87 %. (Found: C 67.0; H 5.19; F 8.82; N 6.10; O 13.6. $C_{13}H_{12}FNO_2$ requires: C 66.9; H 5.19; F 8.15; N 6.01; O 13.7).

Ethylene glycol ketal of 1',3',4-trioxo-1',2',3',4'-tetrahydrospiro(cyclohexane-1,4'-isoquinoline) (1k). 1',3',4-Trioxo-1',2',3',4'-tetrahydrospiro-(cyclohexane-1,4'-isoquinoline) [17] (4.9 g; 0.02 mol) in toluene (250 ml) was treated with ethylene glycol (52 ml) and *p*-toluenesulphonic acid (200 mg). The mixture was distilled slowly from an oil-bath during 20 h, the volume of the reaction mixture being kept approximately constant by the periodic addition of dry toluene. After about 200 ml of distillate had been collected the mixture was cooled, the crystals were collected, washed with petroleum ether and water, and dried, giving 5.5 g (96 %) of stout, pale-yellow crystals, m.p. 220°. Crystallization from ethanol afforded a white product melting at 223 – 224°. (Found: C 66.1; H 6.10; N 4.89;

O 22.3. $C_{16}H_{17}NO_4$ requires: C 66.9; H 5.96; N 4.88; O 22.3).

1',3'-Dioxo-4-hydroxy-1',2',3',4'-tetrahydrospiro(cyclohexane-1,4'-isoquinoline) (11). 1',3',4-Trioxo-1',2',3',4'-tetrahydrospiro(cyclohexane-1,4'-isoquinoline) [17] (7.3 g; 0.03 mol) in abs. ethanol was treated at room temp. with sodium borohydride (0.6 g; 0.015 mol) under vigorous stirring. After 1.5 h, the clear yellow solution was treated with 2.0 ml of acetic acid, the volatile matter was removed under vacuum and the residual syrup was triturated with diisopropyl ether, causing it to become crystalline. The product was collected (8.2 g, m.p. *ca.* 170°) and crystallized from 100 ml of 50 % methanol, affording 4.8 g (64 %) of white crystals, m.p. 189 – 190°. (Found: C 68.6; H 6.16; N 5.70; O 19.7. $C_{14}H_{15}NO_3$ requires: C 68.6; H 6.16; N 5.71; O 19.6). The NMR spectrum in $(CD_3)_2SO$ reveals 1 aromatic H at τ 1.8 – 1.9 ppm, 3 aromatic H centered around τ 2.2 ppm. From the mother liquor there was isolated 0.75 g of white crystals melting at 247° after crystallization from dioxane, which gave a correct analysis for a *dihydro derivative* of compound 11. (Found: C 67.8; H 7.03; N 5.65; O 19.8. $C_{14}H_{17}NO_3$ requires: C 68.0; H 6.93; N 5.66; O 19.4). The IR-spectrum of this compound indicates two different hydroxyl groups. The NMR spectrum in $(CD_3)_2SO$ reveals 4 aromatic H centered around τ 2.9 ppm, indicating reduction of the aromatic carboxyl group. The compound thus is *1',4-dihydroxy-3'-oxo-1',2',3',4'-tetrahydrospiro(cyclohexane-1,4'-isoquinoline)*.

C. Simultaneous preparation of isoindolin-1-one and indolin-2-one derivatives

Spiro(cyclopentane-1,3'-isoindolin)-1'-one (2b) *and spiro(cyclopentane-1,3'-indolin)-2'-one* (3b). A stock solution of 1',3'-dioxo-1',2',3',4'-tetrahydrospiro(cyclopentane-1,4'-isoquinoline) [7] (65 g; 0.3 mol) in 2 N sodium hydroxide solution (600 ml; 1.2 mol) was prepared and stored at room temp. At regular intervals, an aliquot corresponding to 0.03 mol was withdrawn and treated with 1.08 M sodium hypochlorite solution (32 ml; 0.033 mol). After standing for 2 h, the solution was heated on a water bath for 15 min, cooled, and the precipitated spiro(cyclopentane-1,3'-isoindolin)-1'-one filtered off, washed and dried. The compound was analytically pure and melted at 179°. (Found: C 77.2; H 6.98; N 7.34; O 8.85. $C_{12}H_{13}NO$ requires: C 77.0; H 7.00; N 7.48; O 8.55). The filtrate from above was acidified with acetic acid, whereupon evolution of carbon dioxide ensued and a viscous oil fell out which gradually solidified on cooling. Recrystallization from aqueous methanol afforded spiro(cyclopentane-1,3'-indolin)-2'-one as colourless crystals, m.p. 114° (Lit.[11] m.p. 113°). The yields of these lactams varied as a function of time in the manner depicted in Fig. 1. The results of a similar series of experiments performed at 60° are likewise presented in Fig. 1.

3,3-Dimethylisoindolin-1-one (2a), *and 3,3-dimethylindolin-2-one* (3a). When the above reaction was carried out with 4,4-dimethylhomophthalimide at approximately 20°, yields of 3,3-dimethylisoindolin-1-one ranging from 10 % to 17 % and of 3,3-dimethylindolin-2-one ranging from 60 % to 44 % were obtained, the times of reaction with alkali varying from 18 to 67 h. Compound *3a* melted at 150° (Lit.[19] m.p. 150 – 151°), compound *2a* melted at 158 – 162° (Lit.[1] m.p. 162°).

3,3-Diallylisoindolin-1-one (2e) *and 3,3-diallylindolin-2-one* (3i). When a solution of 4,4-diallylhomophthalimide [6] in alkaline sodium hypochlorite solution was allowed to stand at room temp. for about 24 h, *3,3-diallylisoindolin-1-one* precipitated out in yields up to 43 %. Crystallization of the crude product from dilute ethanol gave beige crystals, m.p. 112°. (Found: C 78.3; H 7.06; N 6.57; O 7.79. $C_{14}H_{15}NO$ requires: C 78.8; H 7.09; N 6.57; O 7.50). When the alkaline filtrate was acidified, a crystalline precipitate was obtained which, after washing with dilute sodium hydroxide solution and water, afforded *3,3-diallylindolin-2-one*, m.p. 96° after crystallization from dilute ethanol. Yield 16 – 28 %. (Found: C 78.2; H 7.04; N 6.55; O 7.93. $C_{14}H_{15}NO$ requires: C 78.8; H 7.09; N 6.57; O 7.50).

3,3-Diethylisoindolin-1-one (2d). 4,4-Diethylhomophthalimide [6] was allowed to react with sodium hydroxide solution for 3 days at 20° and then treated with hypochlorite as described. The titel compound separated from the solution and was collected. White crystals from ethanol, m.p. 171 – 172°. Yield 36 %. (Found: C 76.2; H 8.01; N 7.31; O 18.1. $C_{12}H_{15}NO$ requires: C 76.2; H 7.99; N 7.40; O 18.5). When the alkaline filtrate was acidified, only unreacted start material was recovered with no evidence of any formation of the indolinone derivative.

Note: When 4,4-dipropyl- and 4,4-dibutylhomophthalimide were submitted to this treatment only unreacted start material could be recovered from the reaction mixtures even when the temp. in the hydrolysis step was as high as 90°.

D. Preparation of indolin-2-one derivatives unaccompanied by formation of isoindolin-1-one derivatives

The following procedure, used in the preparation of spiro(cyclopentane-1,3'-indolin)-2'-one, illustrates the method that was used for the synthesis of the indolin-2-ones listed in Table 1. 4,4-Dipropyl- and 4,4-dibutylhomophthalimide failed to react under these conditions and the start materials were recovered.

Sodium hypochlorite (1.08 M, 31 ml; 0.033 mol) was added to a cold solution of 1',3'-dioxo-1',2',3',4'-tetrahydrospiro(cyclopentane-1,4'-isoquinoline)[7] (6.5 g; 0.03 mol) in 2 N sodium hydroxide (60 ml; 0.12 mol) and the mixture stood at room temp. for 2 h. The clear solution was then warmed on a water bath for 15 min, cooled, and acidified with acetic acid, whereupon brisk evolution of carbon dioxide ensued and a viscous oily material fell out which became crystalline on cooling and scratching. The crystals were collected, washed with dilute sodium hydroxide and water and dried, affording 5.0 g (89 %) of the title compound *3b*, m.p. 114°. (Lit.[11] m.p. 113°).

Sodium 2'-oxospiro(cyclopentane-1,3'-indoline)-1'-carboxylate and *1'-methylspiro(cyclopentane-1,3'-indolin)-2'-one.* When the reaction mixture prepared as above was cooled strongly with ice-water before acidification with acetic acid, a white crystalline precipitate, approximately analysing for $C_{13}H_{12}NO_3Na$ and apparently consisting of *sodium 2'-oxospiro(cyclopentane-1,3'-indoline)-1'-carboxylate*, was isolated in about 50 % yield. This salt (7.6 g; 0.03 mol) was dissolved in water (40 ml) and the stirred solution treated dropwise with dimethyl sulphate (6.5 ml; 0.06 mol) at room temp. Dilute sodium hydroxide was added simultaneously at such a rate as to maintain an alkaline pH. The mixture was extracted with chloroform, the extract was washed with sodium bicarbonate solution and water, dried and the solvent evaporated, affording 6.1 g (83 %) of an oil assumed to be *methyl 2'-oxospiro(cyclopentane-1,3'-indoline)-1'-carboxylate.* Distillation at 110 – 120°/1.0 Torr caused decomposition and the product isolated was *1'-methylspiro(cyclopentane-1,3'-indolin)-2'-one,* m.p. 57 – 59° after crystallization from hexane (Lit.[21] m.p. 63°). (Found: C 77.1; H 7.50; N 6.96; O 7.72. $C_{13}H_{15}NO$ requires: C 77.6; H 7.51; N 6.96; O 7.95).

2',4-Dioxospiro(cyclohexane-1,3'-indoline). The ketal *3h* (1.04 g; 0.004 mol) was dissolved in a mixture of acetic acid (5 ml) and 2 N hydrochloric acid (5 ml) and the solution heated over a free flame for some minutes. After cooling, the product was collected, affording 0.66 g (78 %) of white crystals, m.p. 200 – 201°. (Found: C 72.2; H 6.11; N 6.45; O 15.1. $C_{13}H_{13}NO_2$ requires: C 72.5; H 6.09; N 6.51; O 14.9).

Arginase in Chang's Liver Cells

GUNILLA LARSSON, GEORGE BÖLCSFÖLDI and EVA ELIASSON

The Wenner-Gren Institute, University of Stockholm, Norrtullsgatan 16, S-113 45 Stockholm, Sweden

Arginase activity has been studied in lysates of Chang's liver cells, an established cell line derived from human liver. It was found that the enzyme of Chang cells differed only slightly from human liver arginase with respect to activation by manganese, pH dependence, Michaelis constant, and inhibition by basic amino acids. On the other hand there was a marked difference in electrophoretic mobility – the Chang cell enzyme moved towards the anode while liver arginase moved towards the cathode at pH 8.6. Furthermore, cell fractionation studies revealed, that the localization of the enzyme was different, the bulk of the Chang cell arginase being firmly bound to cytoplasmic particles sedimenting with mitochondria.

Arginase (L-arginine amidinohydrolase, EC 3.5.3.1) is a wide spread enzyme present in a variety of animal and plant cells.[1] By far the highest enzyme activity is found in the liver of ureotelic animals, where it mediates the final step in the ornithine-citrulline-urea cycle. When liver cells are maintained in cell culture the urea cycle is lost.[2] Thus, Chang's liver cells, an established cell line derived from human liver have no ornithine transcarbamylase activity [2] and consequently citrulline can not be formed from ornithine by these cells. However, arginase is still present but with a specific activity in the range of 0.1 % of the activity reported for intact liver.[3,4] The functional role of arginase in cells and tissues lacking the urea cycle has generally been ascribed to the catabolism of arginine and to the synthesis of proline by way of ornithine.[5]

Four isoenzymes with arginase activity present in varying amounts in different rat organs have been separated by means of chromatography.[6] It has also been shown that arginases isolated from rat kidney and liver differ in many properties.[7]

In human liver Bascur *et al.*[8] found two protein fractions with arginase activity, which could be separated by chromatography. Using immunological methods and electrophoresis Cabello *et al.*[9] compared purified liver arginase with arginase isolated from red blood cells. They found two, possibly identical isoenzymes in both preparations.

The aim of the present investigation was to compare arginase from Chang's liver cells with arginase from human liver. It seemed of interest to know whether the cultured cells contained the liver enzyme in reduced amounts or if they contained an arginase with different properties.

MATERIAL AND METHODS

Chang's liver is an established cell line originally derived from human liver.[10] Chang cells were grown as spinner cultures in Eagle's minimal medium for suspension cultures, containing 10 % horse serum.[11] The cultures were diluted with fresh medium three times a week and were routinely examined for bacterial contamination. (No contamination was found).

Arginase activity was determined according to the micromethod of Schimke,[12] using guanido labelled arginine as substrate followed by determination of $^{14}CO_2$ liberated by urease. Cell samples from the suspension cultures were centrifuged at 700 *g* for 3 min and resuspended in 50 mM Tris-HCl buffer, pH 7.8, at a density of approximately 10^8 cells per ml. The cell suspension was frozen and stored at −17°. As pointed out by Schimke [13] preparations made by freezing and thawing gave the same arginase activity as cell homogenates prepared in other ways. After thawing $MnCl_2$ was added to a concentration of 10 mM. The cell suspension was then heated to 55° for 5 min in order to activate arginase. 100 µl samples of the activated suspension were transferred to test tubes with screw caps. The reaction was started by the

addition of 100 µl 0.2 M guanido-^{14}C-arginine pH 9.7 (sp. act. 0.01 mC/mmol), the pH of the reaction mixture was 9.0. After incubation at 37° for appropriate times (usually 30 or 60 min) the reaction was stopped by the addition of 50 µl 0.4 M HCl. Strips of filterpaper were attached inside the screw caps with one end of the strip inserted under a plastic disc fitting into the bottom of the cap. 25 µl of hyamine hydroxide (1 M in methanol) was placed on the paper strip. Urease was dissolved in 0.2 M potassium phosphate buffer pH 6.3 to a concentration of 5 mg per ml. One ml of urease solution was added to the reaction mixture and the test tubes were immediately closed with the screw caps. The tubes were then placed in a rotating test tube rack at 37° for 45 min. The part of the paper strips containing hyamine was cut off and placed in scintillation vials. Radioactivity was determined, using Omnifluor (NEN) in toluene, in an Intertechnique SL 36 liquid scintillation spectrometer at 4°. The amount of enzyme added and the incubation time during the arginase reaction was modified so that the amount of urea formed did not exceed 0.5 µmol (2.5 % of the substrate). Standard solutions containing 0.02 to 0.6 µmol of ^{14}C labelled urea with a specific activity of 0.01 mC/mmol were used for incubations with urease under identical conditions. 1 µmol urea gave 16 000 cpm. One unit of arginase was defined as the amount of enzyme which produced 1 µmol urea per hour under the above conditions. Arginase activity was determined in the same way in subcellular fractions of Chang cells. For kinetic studies guanido-^{14}C-arginine with a specific activity of 0.02 mC/mmol was used.

Protein content was determined using Biuret reagent [14] or in clear supernatant fractions by the method of Warburg and Christian.[15]

Electrophoresis. Chang cell arginase activity could be removed from particulate cell fractions by a non-ionic detergent. Cells were washed in Hank's balanced salt solution [16] and suspended in 50 mM Tris buffer, pH 7.8. $MnCl_2$ and Lubrol (I.C.I.) were added to final concentrations of 10 mM and 0.5 %, respectively, and the cell suspension was shaken on a Vortex mixer. After adjusting the pH to 7.4 with Tris base the suspension was heated to 55° for 20 min and then centrifuged at 15 000 *g* for 20 min. Before electrophoresis the supernatant was concentrated 6 times by dialysis for 4 h against a 10 mM Tris-HCl buffer, pH 7.8, containing 10 mM $MnCl_2$, 10 mM NaCl, 1.5 mM $MgCl_2$, and 15 % polyethyleneglycol (MW 6000). After dialysis the preparation contained 5 to 10 units of arginase activity per ml.

Human foetal liver from a 20 – 25 week old foetus was washed in Hank's salt solution and homogenized in a Potter-Elvehjem homogenizer in 3 volumes cold 10 mM Tris-HCl buffer, containing 150 mM KCl, 20 mM $MnCl_2$, 10 mM NaCl, 1.5 mM $MgCl_2$, pH 7.8. The homogenate was then centrifuged at 15 000 *g*. The supernatant containing the entire arginase activity was finally heat activated for 20 min at 55° and centrifuged. Immediately before electrophoresis the liver enzyme was diluted 200 times with 10 mM Tris buffer, containing 10 mM $MnCl_2$, in order to obtain an arginase activity in the same order of magnitude as that of the Chang cell preparation.

Three identical 30 µl samples were applied to each glass slide covered with 1 % buffered agarose gel. Sodium barbital buffer, pH 8.6, ionic strength 0.1, was used. Potential difference at the electrodes was 100 V and the current intensity 3 mA. Electrophoresis was performed during 4 h. The agarose gel was sectioned in 3 stripes longitudinally, each containing one sample well, and in 13 cross sections giving pieces of gel approx. 100 µl in volume. These were transferred to test tubes, minced with a glass-rod, and 10 µl 0.1 M $MnCl_2$ was added. After heating for 5 min at 55° arginase activity was determined as described above.

Cell fractionation. Lysates of Chang cells were prepared according to Holtzman *et al.*[17] After washing the cells with cold Hank's salt solution, the cells were suspended in ice cold hypotonic buffer, 10 mM Tris pH 7.8, containing 10 mM NaCl and 1.5 mM $MgCl_2$, and allowed to swell at 0 – 4° for 20 min. The cells were then homogenized in a tight fitting Dounce homogenizer. Microscopic inspection showed very few intact cells. $MnCl_2$ and KCl were then added to the homogenate to final concentrations of 10 mM and 150 mM, respectively. Homogenate of foetal human liver was prepared as described above. Centrifugation at 15 000 *g* for 15 min gave pellets containing *nuclei and larger cytoplasmic particles*. For arginase activity determination pellets were suspended in 50 mM Tris, pH 7.8.

Separation of nuclei from cytoplasm was performed using the above mentioned hypotonic buffer but containing 0.05 mM spermine. Cells were washed, lysed, and homogenized as above. Nuclei were sedimented at 1600 *g* for 2 min. The nuclear pellet was resuspended in buffer and adhering cytoplasm was removed from the nuclei by pipetting several times with a narrow Pasteur pipett. After centrifugation at 1600 *g* the supernatant was added to the first supernatant. The combined supernatants, which did not contain any visible nuclei on microscopic inspection, were centrifuged at 15 000 *g* for 15 min. The resulting pellet, which contained *cytoplasmic particles, mainly mitochondria*, was suspended in 50 mM Tris, pH 7.8 and used for arginase activity and protein determinations.

The *nuclei* were further purified by suspension in 3.75 ml of 0.34 M sucrose in the above buffer containing spermine and layered over 1.25 ml of 1.35 M sucrose in the same buffer. After centrifugation at 15 000 *g* for 15 min the pellet was suspended in 2.5 ml of 2.1 M sucrose

and layered over 2.5 ml of the same sucrose solution. After centrifugation for 45 min at 75 000 *g* the nuclear pellet was washed with 5 ml of 0.34 M sucrose and sedimented at 15 000 *g* for 15 min. The pellet was suspended in 50 mM Tris buffer, pH 7.8. The majority of the nuclei looked intact, but some were severely fragmented. The suspension was used for arginase activity and protein determinations.

L-Arginine-(guanido)-^{14}C was obtained from The Radiochemical Centre, Amersham, Buckinghamshire, England. Hyamine hydroxide from the Packard Instrument Company Inc., Ill. USA. Omnifluor and urea-^{14}C from NEN Chemicals GmbH, Frankfurt, West Germany, urease (Jack bean type III) from Sigma Chemical Company, St. Louis, USA and Eagle's medium and horse serum from Statens Bakteriologiska Laboratorium, Solna, Sweden.

RESULTS AND DISCUSSION

Kinetic properties. Arginase is activated by bivalent cations.[1] Preincubation of Chang cell lysates at 55° for 5 min in the presence of 10 mM $MnCl_2$ increased the arginase activity by 70 %. Longer preincubation times did not increase the activity further. Fig. 1 shows the pH dependence of the reaction. Maximum activity was above pH 9, which is in agreement with results using arginase from ureotelic liver. On the other hand, Gasiorowska *et al.* obtained two pH optima at 7.5 and 9.5 for arginase from kidney, submaxillary gland and brain of the rat.[6]

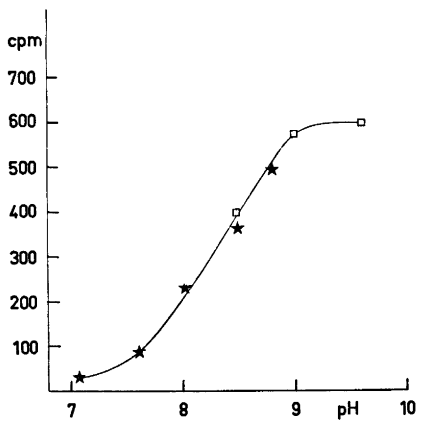

Fig. 1. pH dependence. Cell lysate in 5 mM Tris-HCl, pH 7.8, was activated by heating in the presence of 10 mM $MnCl_2$ prior to determination of arginase activities. Incubation mixtures contained 5 mM $MnCl_2$, 0.1 M ^{14}C-(guanido)-arginine (0.01 mC/mmol) and 50 mM Tris-HCl (pH 7.0 – 8.8 ★) or 50 mM glycine-NaOH (pH 8.5 – 9.6 □). Ordinate: pH, abscissa: arginase activity (cpm in $^{14}CO_2$, liberated by urease).

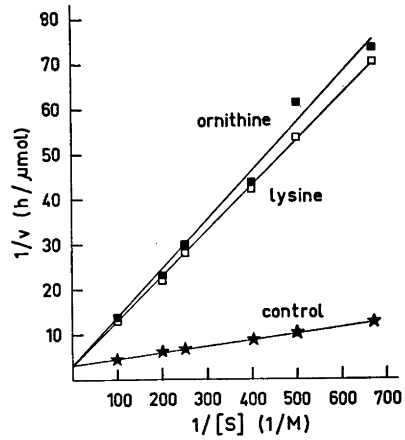

Fig. 2. Michaelis constant and inhibition by lysine and ornithine. Cell lysates were prepared as in Material and Methods, and arginase activated by heating in the presence of 10 mM $MnCl_2$. Incubation mixtures contained 2×10^7 lysed cells, 50 mM glycine-NaOH (pH 9.7), 25 mM Tris-HCl, 5 mM $MnCl_2$, 1.5 – 10 mM ^{14}C-(guanido)-arginine (0.02 mC/mmol). No addition or 10 mM lysine or 10 mM ornithine, respectively. Final pH in the reaction mixtures was 9.0.

K_m and $1/V$ were determined graphically. K_i's for lysine and ornithine were determined using the formula: slope $= (K_m/V)(1 + I/K_i)$ (Ref. 20).

The K_m for arginase as measured in crude Chang cell preparations varied in different experiments between 4 and 7 mM. Lysine and ornithine were both competitive inhibitors. A typical experiment is shown in Fig. 2 where the K_m was 4.5 mM, and the K_i values for lysine and ornithine were 1.6 mM and 1.5 mM, as calculated from the experimental results. With respect to substrate affinity and competitive inhibition by lysine, Chang cell arginase does not differ significantly from human liver arginase, as determined by Bascur *et al.*[8] These authors separated arginase, from human liver, by chromatography, into two components which differed with respect to their inhibition by ornithine. The larger component, corresponding to more than 90 % of the total activity, showed a mixed type of inhibition, while the

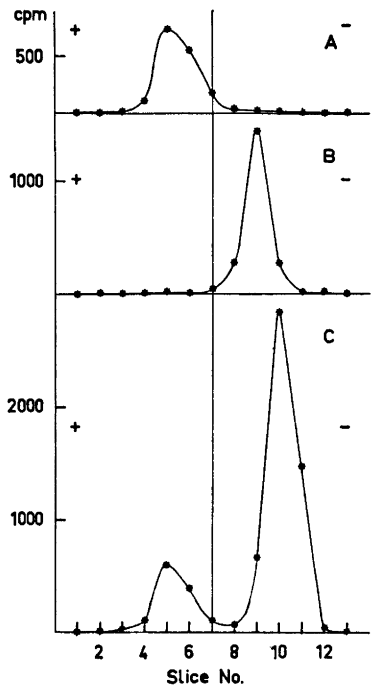

Fig. 3. Agar gel electrophoresis of arginase. A, 30 µl of Chang cell lysate prepared as in Material and Methods (1 mg protein/ml). B, 30 µl liver enzyme (0.03 mg protein/ml). C, Mixture of approx. 15 µl Chang cell arginase and 15 µl liver arginase. Ordinate: agar section, abscissa: arginase activity, adjusted to the total of 15 µl Chang cell enzyme (A), 15 µl liver enzyme (B), and 15 µl Chang cell enzyme + 15 µl liver enzyme (C).

smaller component was competitively inhibited, with a K_i of 3.1. Evidently the Chang cell arginase resembles the minor component of the liver enzyme with respect to inhibition by ornithine.

Electrophoretic mobility. Electrophoresis of Chang cell and foetal human liver preparations were carried out according to Material and Methods. The liver enzyme moved towards the cathode (Fig. 3B), which is in accordance with the results of Cabello *et al.*[9] using arginase from human liver and erythrocytes, where arginase from both sources moved towards the cathode at pH 8.6. Chang cell arginase on the other hand moved towards the anode (Fig. 3A). The activity from Chang cells recovered in the peak (Fig. 3A) corresponded to 100 % of the activity added. (Since Chang cell enzyme was prepared in the presence of 0.5 % Lubrol, a control experiment with human liver in the presence of Lubrol was performed which indicated that the electrophoretic mobility was unaffected). A mixture of the enzyme from human liver and Chang cells was separated into two peaks with maximum activities on the anodal side, corresponding to Chang cell arginase, and on the cathodal, corresponding to human liver arginase (Fig. 3C).

Therefore, the electrophoretic mobility of Chang cell arginase differs from that of human liver. Further studies using purified enzyme preparations may indicate whether this difference is due to the association of Chang cell arginase with some other molecule, thus altering the electrophoretic mobility, or if there is a true difference in the enzyme proteins.

Localization of the enzyme. Using standard procedures for extraction of arginase from liver, in the presence of 10 mM $MnCl_2$ and 150 mM KCl, the activity was found exclusively in the supernatant after centrifugation at 15 000 *g* for 15 min (Table 1). In order to homogenise Chang cells it was first necessary to swell the cells in hypotonic buffer. Immediately after homo-

genisation KCl was added to 150 mM and $MnCl_2$ to 10 mM, *i.e.* ion concentrations that completely remove arginase from the particulate fractions of liver.[18] After centrifugation 90 % of the arginase activity was consistently found in the pellet (Table 1). This was also true when the $MnCl_2$ concentration was increased to 50 mM. The enzyme could be released from the particulate fraction by treatment with a non-ionic detergent, *e.g.* Lubrol (Table 2).

In order to further clarify, whether arginase was bound to nuclei or to cytoplasmic particles, cells were lysed in a hypotonic buffer containing spermine, which maintains the integrity of the nuclear membrane.[19] One part of the lysate was centrifuged at 15 000 *g* yielding nuclei together with cytoplasmic particles. The other part was fractionated as described in Material and Methods, separating the cytoplasmic particles from the nuclei. 70 % of the arginase activity of the combined nuclear and mitochondrial pellet was found in the cytoplasmic particle fraction (Table 3). Attempts to purify the nuclei by centrifugation in hypotonic sucrose, yielded only 3 % activity in the pure nuclear fraction, while the remaining 25 % was lost during the purification procedure.

In summary, unlike liver, most of the arginase activity in Chang cells was firmly bound to cytoplasmic particles sedimenting with mitochondria. The activity cannot be removed from these particles by salt, but it can be released by non-ionic detergents. A similar localization of arginase activity in the mitochondrial fraction has been reported by Kaysen [7] for rat kidney.

Acknowledgments. The authors thank Professor Harold Strecker, Albert Einstein Coll. of Med., New York, for valuable discussions inspiring the initiation of this investigation. Thanks are also due to fil.lic. Marika Raftell for technical advice concerning electrophoresis experiments, and to Mrs. Mari Ann Westman for technical assistance. This investigation has been performed with financial support from *The Swedish Cancer Society*, project No. 260-B72-04XC.

Studies on Orchidaceae Alkaloids. XXXIX.* Isolation of (−)-Cryptostyline I, II, III and two Quaternary Salts from *Cryptostylis erythroglossa* Hayata. Biosynthetic Studies of (−)-Cryptostyline I

STIG AGURELL,[a] INGRID GRANELLI,[b] KURT LEANDER,[b] BJÖRN LÜNING[b] and JAN ROSENBLOM[b]

[a]Faculty of Pharmacy, Box 6804, S-113 86 Stockholm and [b]Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

(−)-Cryptostyline I, II and III, together with 1-(3,4-methylenedioxyphenyl)-6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium iodide and 1-(3,4-methylenedioxyphenyl)-6,7-dimethoxy-2-methylisoquinolinium chloride have been isolated from *Cryptostylis erythroglossa* Hayata.

The biosynthesis of (−)-cryptostyline I has been studied using radioactive precursors and the position of the radio-label determined by degradation. The biosynthetic results show that tyrosine and 3,4-dihydroxyphenylalanine as well as tyramine and dopamine are specifically incorporated. The finding that 3-hydroxy-4-methoxyphenethylamine is better incorporated than the isomeric 4-hydroxy-3-methoxyphenethylamine suggests that the ring closure to the tetrahydroisoquinoline skeleton is facilitated by a *para*-hydroxy group.

(+)-Cryptostyline I, II and III have been isolated by Leander *et al.*[2] from *Cryptostylis fulva* Schltr. The absolute configuration of these alkaloids has been established by two X-ray diffraction investigations.[3,4] In this paper we report the isolation of (−)-cryptostyline I, II and III from *C. erythroglossa* Hayata together with the immonium salt IV and the isoquinolinium salt V. Biosynthetic studies of (−)-cryptostyline I are also reported.

The structure of IV was established by comparing its iodide with an authentic sample of 1-(3,4-methylenedioxyphenyl)-6,7-dimethoxy-

* For number XXXVIII, see Ref. 1.

-isoquinolinium chloride
(V)

2-methyl-3,4-dihydroisoquinolinium iodide.[2] Identification of V was accomplished by comparison with a synthetic sample, obtained by dehydrogenation of 1-(3,4-methylenedioxyphenyl)-6,7-dimethoxy-3,4-dihydroisoquinoline[2] with selenium, followed by methylation.

The cryptostyline alkaloids are interesting from a biogenetic point of view since they are the first 1-phenyl-tetrahydroisoquinolines isolated from Nature. For this reason the biosynthesis of (−)-cryptostyline I in *C. erythroglossa* has been studied using radioactive precursors.

The potential precursors shown in Table 1 were administered to the plant and (−)-cryptostyline I was isolated. The results show that tyrosine and 3,4-dihydroxyphenylalanine as well as the corresponding amines, tyramine and dopamine, were specifically incorporated, but in low yields. The results of feeding experiments with the two isomeric compounds 3-hydroxy-4-methoxyphenethylamine and 4-hydroxy-3-methoxyphenethylamine suggest that only the former compound (which occurs in, *e. g.*, *Pachycereus pecten-aboriginum* (Eng.) Br&R.[5]) is a precursor of (−)-cryptostyline I.

The early steps in the formation of 1-benzyltetrahydroisoquinoline alkaloids have so far received scant attention,[6] whereas the formation of the tetrahydroisoquinoline skeleton of cactus alkaloids has been extensively studied.[7–9] The present results indicating alternative paths (Fig. 2) to dopamine from tyrosine *via* tyramine or from 3,4-dihydroxyphenylalanine are analogous to previous results on the biosynthesis of anhalamine and anhalonidine in the cactus *Lophophora williamsii* (Lem.) Coult.[9]

In the biosynthesis of, *e.g.*, anhalamine, which is a 6,7,8-trisubstituted tetrahydroisoquinoline, 3-hydroxy-4,5-dimethoxyphenethylamine is the immediate progenitor of the tetrahydroisoquinoline skeleton, thus providing an *ortho*-activation suitable for ring-closure.[9] The present results with (−)-cryptostyline I suggest that the ring-closure is facilitated by a *para*-hydroxy group (Fig. 2). The origin of the remaining C_6-C_1 moiety of (−)-cryptostyline I remains to be elucidated. It may possibly be derived from protocatechualdehyde or partially *O*-methylated derivates thereof as has been shown for some Amaryllidaceae alkaloids.[6]

The specificity in the incorporation of the precursors into (−)-cryptostyline I was established by degradation. The ^{14}C-labelled precursors would, if incorporated without extensive break-down, label (−)-cryptostyline I at C-3. This carbon atom was isolated as the dimedone derivative of formaldehyde (X), obtained as shown in Fig. 1. The extensive presence of radioactivity in this position (Table

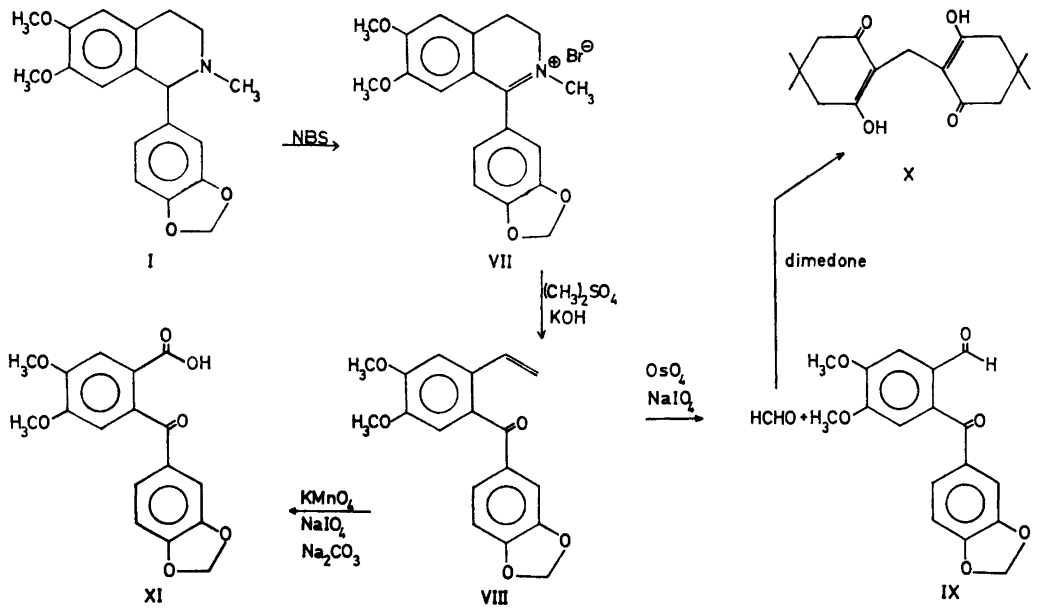

Fig. 1. Degradation of cryptostyline I.

1) indicates direct incorporation. The ^{3}H-labelled precursors would be expected to label the C_3 and C_4 positions in (−)-cryptostyline I. Degradation to compound XI showed predominant labelling in the expected positions (Table 1).

EXPERIMENTAL

Melting points are corrected. Mass spectra were measured on a Perkin-Elmer 270 instrument, the IR spectra on a Perkin-Elmer 257 instrument, the UV spectra on a Beckman DK 2 instrument and the NMR spectra on a Varian A-60A spectrometer. Elemental analyses were carried out at Alfred Bernhardt, Mikroanalytisches Laboratorium, Elbach über Engelskirchen, Germany, and Mikroanalyslaboratoriet, Lantbrukshögskolan, Uppsala, Sweden. Radioactivities were measured with a Packard Tri-Carb Model 3375 liquid scintillation spectrometer, in a solvent system consisting of 2 ml absolute ethanol and 10 ml Instagel® (Packard Instrument Corp.). External standardization was used for efficiency determination. Preparative thin-layer chromatography was carried out on alumina (1.5 mm) F-254 Type T (Merck) or silica gel (2 mm) 60F-254 (Merck).

(±)-Tyrosine-α-^{14}C, (±)-3,4-dihydroxyphenylalanine-α-^{14}C, tyramine-α-^{14}C, dopamine-α-^{14}C and 4-hydroxy-3-methoxy-5-^{3}H-phenethylamine were obtained from the Radiochemical Centre, Amersham, UK and New England Nuclear Corp., Boston, USA. The preparation of 4-hydroxy-3-methoxy-α,β-^{3}H-phenethylamine and 3-hydroxy-4-methoxy-α,β-^{3}H-phenethylamine has already been described.[10]

The plants were purchased from Chow Cheng Orchids, 194 Litoh-St. Taichung, Taiwan.

Feeding experiments. Each labelled precursor was dissolved in a minute quantity of water and injected into the stems of two plants of *C. erythroglossa*. After three weeks the alkaloid fraction was isolated as described below. Cryptostyline I ($R_F = 0.5$) was separated from the other alkaloids by preparative thin-layer chromatography on alumina plates with ether as eluent. The isolated alkaloid was diluted with 100 mg non-labelled (±)-cryptostyline I and recrystallized from ether to constant specific activity.

Isolation of the alkaloids. Fresh plants of *C. erythroglossa* (0.3 kg) were extracted with methanol (5 l). The extract was concentrated to 1 l, acidified (pH 3) with hydrochloric acid and washed with carbon tetrachloride (6 × 50 ml). The aqueous layer was made alkaline (pH 8) with sodium hydrogen carbonate and extracted with ether (3 × 50 ml). The combined ether solutions were treated as described earlier,[2] giving (−)-cryptostyline I (m.p. 101−102°; $[\alpha]_D^{22}$ −56°, *c* 0.4, chloroform), (−)-cryptostyline II (m.p. 116−117°; $[\alpha]_D^{22}$ −58°, *c* 0.4, chloroform) and (−)-cryptostyline III (m.p.

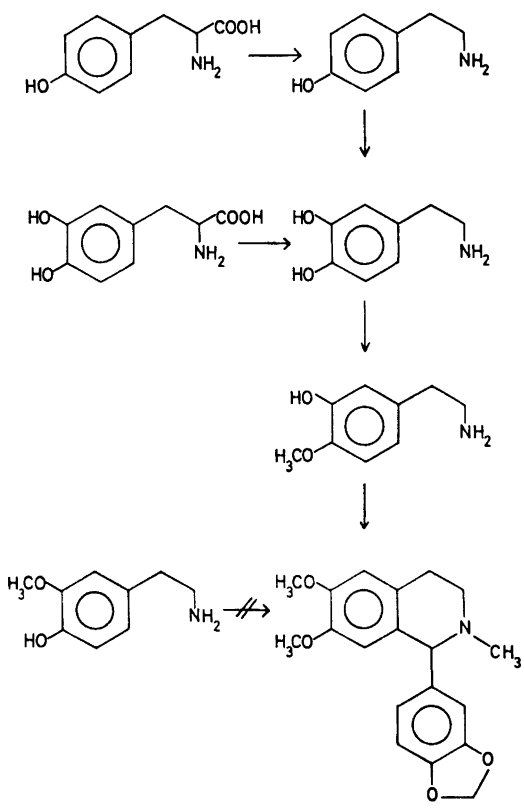

Fig. 2. Suggested pathway for the biosynthesis of (−)-cryptostyline I.

128 − 130°; $[\alpha]_D^{22}$ −52°, *c* 0.3, chloroform). The aqueous layer was then extracted with chloroform (8 × 50 ml). The chloroform extract was dried (Na_2SO_4) and evaporated to dryness. The residue was dissolved in water and filtered through a column of IRA-400 (Cl^-, 1 × 20 cm) irrigated with water, and the filtrate evaporated to dryness. This residue was separated into the crude chlorides IV ($R_F = 0.35$) and V ($R_F = 0.1$) by preparative thin-layer chromatography on alumina using chloroform/methanol (19:1) as eluent. The iodide corresponding to IV (5 mg), obtained by filtering the chloride through a column of IRA-400 (I^-, 1 × 15 cm) irrigated with water, was indistinguishable (m.p., TLC, IR) from an authentic sample of 1-(3,4-methylenedioxyphenyl-6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium iodide.[2] Purification of V by preparative thin-layer chromatography on silica gel using chloroform/methanol (2:1) as eluent yielded V as an amorphous solid (25 mg) indistinguishable (TLC, UV, NMR, m.p. of the picrate) from an authentic sample of 1-(3,4-methylenedioxyphenyl)-6,7-dimethoxy-2-methylisoquinolinium chloride (*vide infra*).

1-(3,4-Methylenedioxyphenyl)-6,7-dimethoxyisoquinoline (VI). 1-(3,4-Methylenedioxyphenyl)- 6,7- dimethoxy- 3,4-dihydroisoquinoline [2] (0.40 g) and selenium (0.48 g) were heated under nitrogen at 220 − 230° for 15 min. The reaction mixture was dissolved in methanol and filtered through a column of silica gel. The eluate was chromatographed on neutral alumina using chloroform as eluent. The first fraction contained VI and unreacted imine, which were separated by preparative thin-layer chromatography on silica gel plates developed with ether. Recrystallization from methanol gave VI (0.10 g), m.p. 129 − 132°. (Found: C 69.8; H 5.1; N 4.4 Calc. for $C_{18}H_{15}NO_4$: C 69.9; H 4.9; N 4.5). UV spectrum, nm (ε): λ_{max} (ethanol) 329 (8000), 292 (8000), 238 (46 000); $\lambda_{shoulder}$ 245 (43 000). NMR spectrum ($CDCl_3$): τ 1.53 (d, 1 H, $J = 5$ Hz), 2.43 − 3.20 (m, 6 H); 3.95 (s, 2 H), 5.98 (s, 3 H), 6.12 (s, 3 H).

1-(3,4-Methylenedioxyphenyl)-6,7-dimethoxy-2-methylisoquinolinium chloride. An excess of methyl iodide was added to a solution of VI in acetone. The mixture was refluxed for 1.5 h, cooled and evaporated to dryness. The residue was filtered through a column of IRA-400 (Cl^-, 1 × 20 cm) irrigated with water. Evaporation of the eluate to dryness and purification of the residue by preparative thin-layer chromatography on silica gel using chloroform/methanol (2:1) as eluent gave the title compound as an amorphous solid. UV spectrum, nm (ε): λ_{max} (ethanol) 319 (4500), 290 (3500), 258 (25 100); $\lambda_{shoulder}$ 348 (2900). NMR spectrum ($CDCl_3$): τ 1.36 and 1.61 (AB spectrum, 2 H, $J = 6.5$ Hz), 2.22 (s, 1 H), 2.78 (s, 3 H), 3.00 (s, 1 H), 3.77 (s, 2 H), 5.77 (s, 3 H), 5.87 (s, 3 H), 6.17 (s, 3 H).

The *picrate*, m.p. 218 − 223°, was recrystallized from methanol-water. (Found: C 54.2; H 3.6; N 9.8. Calc. for $C_{25}H_{20}N_4O_{11}$: C 54.4; H 3.7; N 10.1).

1-(3,4-Methylenedioxyphenyl)-6,7- dimethoxy-2-methyl-3,4-dihydroisoquinolinium bromide (VII). *N*-Bromosuccinimide (75 mg) was added with stirring to a solution of cryptostyline I (100 mg) in absolute ether (20 ml). During the addition, a yellow precipitate appeared. After 1 h acetone (3 ml) was added and the reaction mixture was refluxed for 4 h to give the crude immonium salt (VII) as a light yellow crystalline precipitate. The precipitate was washed with a mixture of ether-acetone (7:1) to remove succinimide, giving VII (118 mg), m.p. 207 − 208°. (Found: C 56.0; H 4.8; Br 19.9; N 3.5; O 15.8. Calc. for $C_{19}H_{20}BrNO_4$: C 56.2; H 4.9; Br 19.7; N 3.5; O 15.8). IR spectrum: σ_{max} (KBr) 1640 (m) cm^{-1}. UV spectrum, nm (ε): λ_{max} (ethanol) 367 (13 400), 315 (11 500), 252 (22 000). NMR spectrum (CD_3OD): τ 2.78 − 2.95 (m, 4 H), 3.42 (s, 1 H), 3.85 (s, 2 H), 5.60 − 6.05 (m, 2 H), 6.50 − 6.85 (m, 2 H), 6.02 (s, 3 H), 6.38 (s, 6 H).

2-(3,4-Methylenedioxybenzoyl)-4,5-dimethoxystyrene (VIII). A mixture of VII (118 mg), dimethyl sulphate (0.06 ml), ethanol (0.12 ml) and aqueous potassium hydroxide (0.40 ml, 20 %) was refluxed for 3 h. Water (10 ml) was added and the cold solution was extracted with chloroform (5 × 10 ml). The combined chloroform solutions were dried (Na_2SO_4) and evaporated to dryness. The residue was purified by preparative thin-layer chromatography on silica gel using ethanol as eluent ($R_F = 0.9$). Recrystallization from ethanol gave VIII (77 mg), m.p. 98–99°. (Found: C 69.4; H 5.2; O 25.6 Calc. for $C_{18}H_{16}O_5$: C 69.2; H 5.1; O 25.6). IR spectrum: σ_{max} (KBr) 1620 (m), 1655 (s) cm^{-1}. UV spectrum, nm (ε): λ_{max} (ethanol) 314 (13 800), 258 (22 900), 237 (28 200). NMR spectrum ($CDCl_3$): τ 2.60–3.53 (m, 6 H), 3.95 (s, 2 H), 4,45 (q, 1 H, $J_1 = 1$ Hz, $J_2 = 17$ Hz), 4.85 (q, 1 H, $J_1 = 1$ Hz, $J_2 = 11$ Hz), 6.05 (s, 3 H), 6.15 (s, 3 H). MS: M^+ 312.

2-(3,4-Methylenedioxybenzoyl)-4,5-dimethoxybenzaldehyde (IX). A catalytic amount of osmium tetroxide (2 mg) was added to a solution of the alkene VIII (77 mg) in water-dioxane (1:4, 5 ml). After 0.5 h sodium periodate (145 mg) was added and the mixture was heated at 80° for 2 h. The solvent was evaporated and the residue was suspended in water and extracted with chloroform (5 × 25 ml). The combined chloroform solutions were dried (Na_2SO_4) and evaporated to dryness. The residue was purified by preparative thin-layer chromatography on silica gel using ethanol as eluent ($R_F = 0.7$). Crystallization from chloroform-ether gave IX (55 mg), m.p. 162–163°. (Found: C 64.8; H 4.5; O 30.4. Calc. for $C_{17}H_{14}O_6$: C 65.0; H 4.5; O 30.6). IR spectrum: σ_{max} (KBr) 1635 (m), 1685 (s) cm^{-1}. UV spectrum, nm (ε): λ_{max} (ethanol) 316 (12 600), 268 (10 800), 237 (21 700). NMR spectrum ($CDCl_3$): τ 1.23 (s, 1 H), 2.40–3.32 (m, 5 H), 3.92 (s, 2 H), 6.03 (s, 3 H), 6.06 (s, 3 H). MS: M^+ 314.

The formaldehyde formed in the reaction was trapped in a solution of dimedone (100 mg) in water (40 ml). The precipitate was recrystallized twice from ethanol giving methylenebisdimedone (X, 30 mg), m.p. 191° (Lit.[11] m.p. 191°).

2-(3,4-Methylenedioxybenzoyl)4,5-dimethoxybenzoic acid (XI). *t*-Butanol (4 ml) and 2-(3,4-methylenedioxybenzoyl)-4,5-dimethoxystyrene (VII, 55 mg) were added to a solution of sodium periodate (0.70 g) and potassium permanganate (0.35 g) in water (12 ml). The pH of the solution was adjusted to 8.5 by the addition of solid sodium carbonate. The mixture was stirred for 15 h at 25°, and then acidified (pH 4) with aqueous sulphuric acid. The excess of permanganate was destroyed with sodium sulphite and the solution extracted with chloroform (5 × 25 ml). The combined chloroform solutions were dried and evaporated to dryness. The residue was chromatographed on silica gel (3 × 10 cm, 70–230 mesh). Unreacted alkene (VII) was eluted with chloroform. Exchange of the solvent to ethanol eluted the acid (XI), which was further purified by preparative thin-layer chromatography on silica gel using ethanol as eluent ($R_F = 0.6$). Recrystallization from ethanol gave XI, m.p. 206–207°. (Found: C 61.8; H 4.4; O 33.8. Calc. for $C_{17}H_{14}O_7$: C 61.8; H 4.2; O 33.9). IR spectrum: σ_{max} (KBr) 1655 (m), 1665 (m), 3300–2500 (m) cm^{-1}. UV spectrum, nm (ε): λ_{max} (ethanol) 312 (9200), 275 (8400), 232 (24 300). NMR spectrum (CD_3OD): τ 2.16–3.27 (m, 5 H), 3.94 (s, 2 H), 6.02 (s, 3 H), 6.12 (s, 3 H).

Acknowledgement. We are indebted to Dr. Jörgen Lönngren for measuring the mass spectra and to the *Swedish Natural Science Research Council* for support.

C_{50}-Carotenoids. 12.* Steric Effects on the Intensity Ratios of the (M − 92)/(M − 106) Ions in the Mass Spectra of Carotenoids

GEORGE W. FRANCIS,[a] SISSEL NORGÅRD and [b] SYNNØVE LIAAEN-JENSEN [b]

[a] Chemistry Department, University of Bergen, N-5000 Bergen, Norway and [b] Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim, Norway

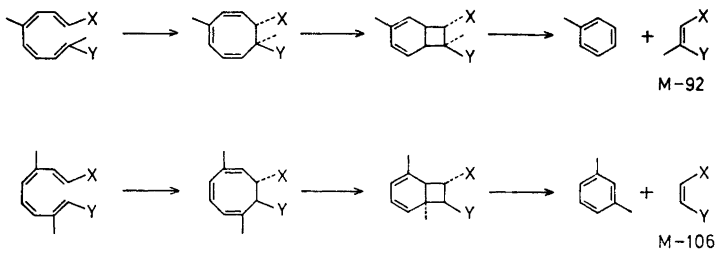
Steric factors are shown to allow rationalisation of hitherto unexplained variations of the ratio (R) of the (M − 92)/(M − 106) ions in the mass spectra of C_{50}-carotenoids. It is suggested that this ratio may be used to provide information about the position of the extra prenyl groups relative to the chromophoric system in acyclic C_{50}-carotenoids.

Characteristic ions at M − 92 and M − 106 mass units are observed in the mass spectra of virtually all carotenoids.[1-4] These ions are attributed to species where six consecutive carbon atoms of the conjugated chain and the substituents carried by these atoms have been extruded. The mechanism shown in Scheme 1 has been proposed for the formation of both M − 92 and M − 106 mass unit species and may be applied to their genesis by either direct electron bombardment or through the intermediacy of prior thermal decomposition.[5,6]

The values obtained for the intensity ratio (R) of the (M − 92)/(M − 106) ions can be related to the chromophoric system present in most cases.[2,6] In particular, in the case of C_{40}-carotenoids lacking substituents directly conjugated to the acyclic chromophore, the R-values found decrease as the number of double bonds in the acyclic chromophore (DB) increases from 9 to 13; representative examples and the observed limits for R are cited in Scheme 2.[2] The R-values found when carbonyl or aromatic functions are directly conjugated to the acyclic chromophore vary from those found in the above case, but may be rationalised in terms of the type of substitution present.[6] The ratio R may thus be used to obtain information about the chromophore of C_{40}-carotenoids.

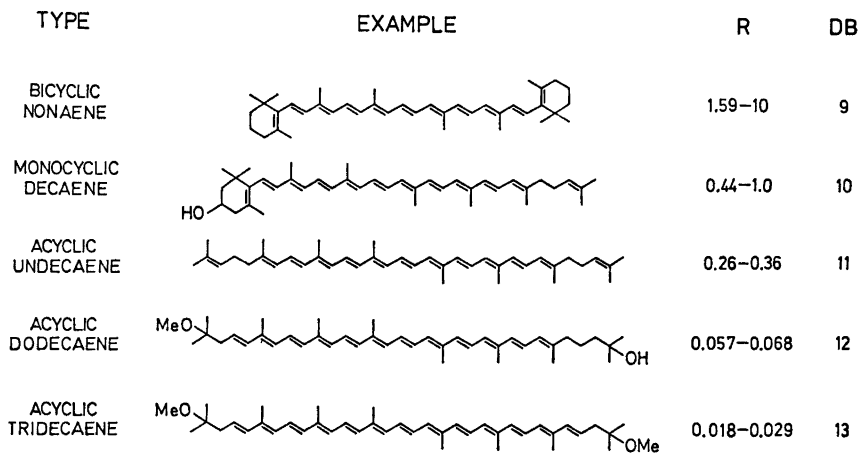
RESULTS AND DISCUSSION

The R-values found with C_{45}- and C_{50}-carotenoids are often markedly different from those obtained with C_{40}-carotenoids having the same chromophore.[7] Consideration of work [8] on the responsibility of steric factors, particularly



Scheme 1. Proposed mechanism for the formation of M − 92 and M − 106 mass unit species found in the mass spectra of carotenoids.[5,6]

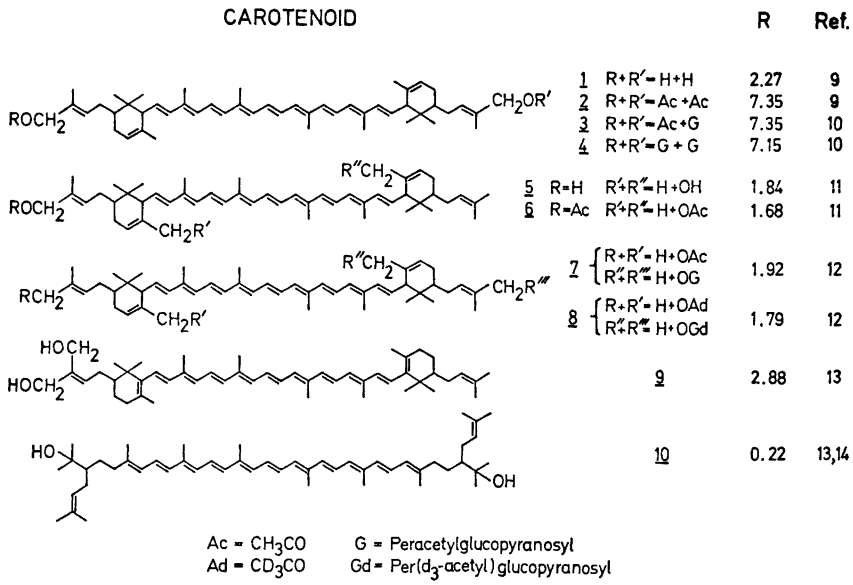
* Part 11, *Acta Chem. Scand. 27* (1973) 2321.



Scheme 2. Range of values for the intensity ratio (R) of the $(M-92)/(M-106)$ ions in the mass spectra of C_{40}-carotenoids having various numbers of double bonds (DB) in the acyclic chromophore. A typical example of each structural type is shown.[2]

end group bulk (see Fig. 1), for variations in this intensity ratio in the case of C_{40}-carotenoids suggested that steric effects might also be of decisive importance in the present case.

The end groups found in carotenoids with supernumerary carbon atoms may be categorised according to whether the additional prenyl unit is immediately adjacent to the acyclic chromophore or not. Those compounds (*1–10*) shown in Scheme 3 have only end



Scheme 3. Observed values for the intensity ratio (R) for C_{50}-carotenoids showing R-values similar to those found in C_{40}-carotenoids. The compounds *1–9* have nine double bonds in the acyclic chromophore ($DB=9$), while the compound *10* has $DB=11$.

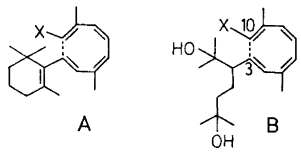


Fig. 1. Steric conflict in the cyclisation process required to provide M − 106 mass unit species by rearrangement of the terminal double bond of the acyclic chromophore in the presence of (*A*) cyclic end groups,[8] and (*B*) acyclic end groups carrying an additional prenyl group.

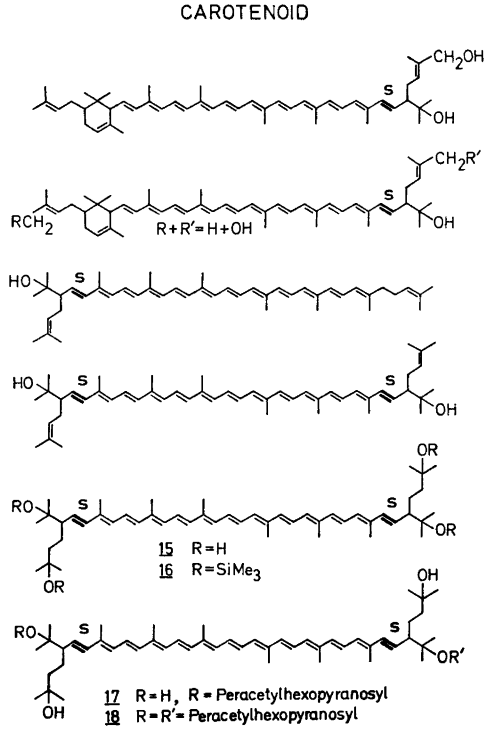
groups belonging to the latter category and all show values [9–14] of the ratio (*R*) close to those found with C_{40}-carotenoids having the same *DB*-values, *cf.* Scheme 2. The *R*-values are thus normal and in agreement with the structural classification of these compounds (*1 – 10*) as remotely-substituted C_{40}-carotenoids.

The compounds *11 – 18*, shown in Scheme 4, all contain at least one end group where the extra prenyl group is carried by the carbon atom immediately adjacent to the terminus of the conjugated chain. Before examining the observed *R*-values [7,13–15] for these compounds it should be noted that the position of the methyl groups carried by the conjugated chain is known to be critical in determining these values.[8,16] The compounds *11* and *12* [7,18] are thus not directly comparable to the usual C_{40}-carotenoid undecaenes which have symmetric chromophoric systems carrying six methyl groups, and must be compared with monocyclic undecaenes carrying five methyl groups on the aliphatic polyene chain. Available data [17,18] for monocyclic C_{40}-carotenoids with $DB = 11$ are compiled in Scheme 5 with *R*-values (0.052 – 0.081) considerably lower than for the acyclic undecaenes (0.26 – 0.36).

Examination of the *R*-values [7,13–15] for the compounds *11 – 18* reveals that in all cases the observed values are considerably higher than



CAROTENOID	DB	R	RA	RB	Ref.

those found for C_{40}-carotenoids with the same chromophore. Thus, the formation of the M − 106 species is less favourable than would be expected by analogy with C_{40}-carotenoids with the same chromophoric system.

The critical factor in extrusion reactions leading to M − 92 and M − 106 mass unit species is believed to be the initial new bond formation.[6] Where the C-2 carbon atom in an acyclic end group carries an extra prenyl group, as with the compounds in Scheme 4, the approach of C-3 and C-10 will be more difficult than in the absence of such substituents. The extrusion modes at more distant sites would be little affected. Thus, the only mode affected by this cause of steric hindrance is one leading to an M − 106 mass unit species and this steric factor may thus be applied to explain the observation that the *R*-values for the compounds *11* − *18* are only slightly lower than those expected for C_{40}-carotenoids lacking the 3,4-double bond. The somewhat lower values may in fact be the result of the higher temperatures needed for volatilisation of C_{45} and C_{50}-carotenoids as compared with those for the C_{40}-compounds: the contribution of thermal genesis is less for the M − 92 than for the M − 106 mass unit species.[16]

The above argument allows rationalisation of the recorded *R*-values for carotenoids with extra prenyl groups. It should thus be possible to use *R*-values for acyclic carotenoids with extra prenyl groups to indicate the position of these extra groups relative to the chromophore. The *R*-values used in this study were obtained from spectra previously published or recorded during previous work on C_{45} and C_{50}-carotenoids.[7,9–15]

EXPERIMENTAL

The spectra of the C_{45} and C_{50}-carotenoids were recorded on an AEI MS 902 mass spectrometer using the direct insertion probe. All spectra were recorded at 70 eV, 4 or 8 KV, and with the ion source at the minimum temperature required to achieve volatilisation (190 − 290 C). The time elapsing between insertion of the probe into the ion source and recording of the spectra was kept to a minimum in order to reduce thermal decomposition as much as possible.

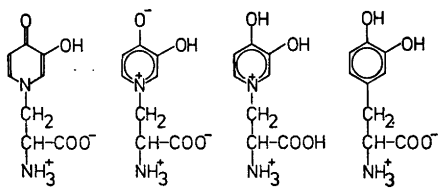
The Crystal Structure of L-Mimosine Sulphate Hydrate

ARVID MOSTAD,[a] EINAR ROSENQVIST [b] and CHRISTIAN RØMMING [a]

[a] Department of Chemistry and [b] Institute of Pharmacy, University of Oslo, Oslo 3, Norway

The structure of L-mimosine sulphate hydrate, $C_5H_3(OH)_2NHC_2CH(NH_3)COOH.SO_4.(H_2O)_{1.5}$ has been determined by X-ray methods using 2451 observed reflections collected by counter methods. The crystals are orthorhombic, space group $P2_12_12_1$, with unit cell dimensions $a = 6.42_3$ Å; $b = 13.88_6$ Å; $c = 14.48_7$ Å. The refinements yielded a conventional R-factor of 0.051. The crystal structure is discussed and the bond lengths and angles are compared to those found in the un-protonized mimosine molecules.[1] The conformation of the amino acid is similar to that of L-tyrosine, the α hydrogen atom being in *trans* position relative to the aromatic part.

A previous structure determination [1] showed the anhydrous form of L-mimosine to exist in the crystals as an intermediate between the structures I and II of Fig. 1.



I II III DOPA

Fig. 1.

L-Mimosine forms a dibasic salt with sulphuric acid.[2] The protonized form is assumed to have the structure indicated by III which closely corresponds to the structure of L-DOPA. In order to investigate a molecule of this kind we have studied the sulphate of L-mimosine which is reported to crystallize with 1.5 molecule H_2O per formula unit and to have a melting point nearly 100°C below that of mimosine itself.[2]

A sample of L-mimosine was kindly given to us by Dr. M. P. Hegarty (The Cunningham Laboratory, CSIRO, Australia).

EXPERIMENTAL

Single crystals of the compound were formed by slow evaporation of a solution of L-mimosine in diluted sulphuric acid. A single crystal of approximate dimensions $0.3 \times 0.3 \times 0.17$ mm³ was used in all the X-ray experiments.

Weissenberg photographs indicated orthorhombic symmetry; systematically absent reflections proved the space group to be $P2_12_12_1$. Unit cell dimensions were determined from diffractometer measurements on 15 general reflections using Mo$K(\alpha_1 + \alpha_2)$ radiation ($\lambda = 0.71069$ Å).

The intensity data were recorded with the use of a SYNTEX $P\bar{1}$ diffractometer with graphite crystal monochromated MoK radiation. 3269 independent reflections with $2\theta < 70°$ were measured using the $\omega - 2\theta$ scanning mode with the 2θ scan speed varying from 2 to 12° min^{-1} depending on the intensity. The scan range was from 1° below $2\theta(\alpha_1)$ to 1° above $2\theta(\alpha_2)$ and background counts were taken for half the scan time at each of the scan range limits. Three standard reflections were measured after every 50 reflections; they showed no systematic variation during the experiment.

The estimation of the standard deviation of the intensities was based on counting statistics with 2.5 % addition in order to account for other errors. The 2451 reflections with intensity larger than $2.5\sigma(I)$ were considered to be observed; the remaining data were excluded from the structure refinement procedure.

The structure was determined by the use of the program MULTAN written by P. Main, M. M. Woolfsen and G. Germain. All other computer programs applied are described in Ref. 3. Atomic form factors applied were those of Doyle and Turner [4] for sulphur, oxygen, nitrogen, and carbon atoms and of Stewart, Davidson and Simpson [5] for hydrogen.

CRYSTAL DATA

L-Mimosine sulphate hydrate, $C_8H_{19}N_2O_4.H_2SO_4.1.5H_2O$, m.p. 143 – 143.5°C, with decom-

position.[3] Orthorhombic; $a = 6.423(0.001)$ Å, $b = 13.886(3)$ Å, $c = 14.487(3)$ Å. Figures in parentheses are estimated standard deviations. $V = 1292.1$ Å^3; formula weight 323.29; $F(000) = 676$; $Z = 4$; $D_{calc} = 1.662$ g cm^{-3}. Absent reflections: (h00) for h odd, (0k0) for k odd, (00l) for l odd; space group $P2_12_12_1$.

STRUCTURE DETERMINATION

After being corrected for Lorentz and polarization effects the data were put on an approximate absolute scale by Wilson's statistical method and normalized structure amplitudes were calculated. 472 reflections with E-values greater than 1.25 were used as input in the program assembly MULTAN.[6] Of the solutions obtained the one with the highest absolute figure of merit was used as the basis for an E-map in which all except three of the non-hydrogen atoms were localized. After one Fourier refinement cycle two of the missing heavy atoms appeared in the electron density map. The trial structure was refined by a few least-squares cycles and the approximate positions of the hydrogen atoms bonded to carbon were calculated. A couple of cycles of alternating least-squares refinements and difference Fourier syntheses yielded the positions of the oxygen atom of the "half" water molecule as well as the remaining hydrogen atoms of the mimosine ion and the other water molecule.

In the subsequent full-matrix least-squares refinement the 2451 observed reflections were included; the function minimized was $\sum w(F_o - F_c)^2$, the weight assigned to each reflection was

Table 1. Fractional coordinates and thermal parameters ($\times 10^5$) with estimated standard deviations (in parentheses). The temperature factor is given by exp $-(B11h^2 + B22k^2 + B33l^2 + B12hk + B13hl + B23kl)$.

taken as the inverse of the variance of the observed structure factor. The parameters refined were the scale factor, 105 positional parameters, 189 anisotropic thermal parameters for the heavy atoms, and 14 isotropic thermal parameters for the hydrogen atoms.

L-Mimosine sulphate was reported to contain 1.5 molecules of water per formula unit.[3] The X-ray crystallographic study revealed the position of one water molecule which is firmly hydrogen bonded to mimosine ions and for which the hydrogen positions were determined. Another position was found for an additional water molecule where only weak interactions with the surrounding molecules are possible; the occupancy for this water molecule is probably less than one per position. When allowed to vary during the least-squares refinement the occupancy factor for the oxygen atom of this water molecule (OV1) refined to 0.6. The thermal parameters associated with the atom were rather large, however, and highly correlated with the occupancy factor. When fixing the occupancy factor at 0.5 the thermal parameters refined to values comparable to those of the other water molecule (*cf.* Table 4). Because of the correlation we cannot decide whether this is correct or if the molecule has larger fractional population and thermal parameters.

The refinement converged with a final conventional R-factor of 0.051 ($R_w = 0.050$). The corresponding atomic parameters are listed in Tables 1 and 2. A comparison of observed and calculated structure factors is given in Table 3.

Magnitudes and directions of the principal axes of vibration for the heavy atoms are given in Table 4. As may be seen from these values the amplitudes of thermal vibration along the main axes for the oxygen atoms of the sulphate ion are quite large. A rigid-body analysis showed that the thermal motion of the ion could to a good approximation be interpreted in terms of translational and librational oscillations. A corresponding analysis for the entire mimosine ion was far less satisfactory; omitting the alanine part of the ion in the analysis seemed to give adequate agreement between observed and calculated U-values.

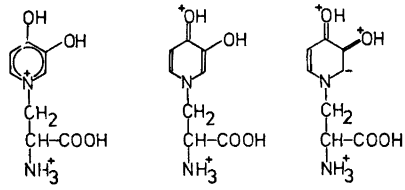
Bond lengths and angles, and some intermolecular distances are given in Table 5. Bond lengths corrected for thermal librations are given where such corrections seem to be justified.

Standard deviations in distances and angles were calculated from the correlation matrix.

DISCUSSION OF THE STRUCTURE

A drawing of the protonized form of L-mimosine as found in the crystals of the sulphate is presented in Fig. 2 where also the numbering of the atoms is indicated. The bond lengths and angles arrived at in the present analysis are indicated in this figure and may also be found in Table 5. The standard deviations in the bond lengths are 0.003 Å for S–O bonds, 0.004–0.005 for bonds between C, N, and O atoms, and 0.04–0.05 Å for bonds involving hydrogen atoms. The standard deviations in angles are 0.2–0.3°.

The six-membered ring of the hydroxypyridyl part of the molecule is planar. The distances from various atoms to a least-squares plane through the ring atoms are indicated in Fig. 2c. O1 and O2 are situated slightly out of the plane and the N1–C6 bond is bent out from the C3–N1 direction. The two C–N bonds in the pyridyl ring are of equal lengths (1.354 Å and 1.358 Å) and comparable to the mean value (1.356 Å) of the corresponding bonds in mimosine.[1] For the latter structure it was concluded that the contributions from the two resonance structures I and II of Fig. 1 are about equal. If an analogous simple valence bond picture is applied to the doubly protonized form the contributions from the structures IV–VI seem to be of importance.



IV V VI

The contribution from VI explains the rather short C–O bonds (1.339 Å and 1.317 Å, as compared to the C–O bonds in phenols, 1.36–1.38 Å) and also that C4–C5 (1.347 Å) is shorther than C1–C2 (1.375 Å). The difference between the C–O bond lengths may be explained by the contribution from V, which also

Table 5. Bond lengths (Å), bond angles (°) and some intermolecular distances in mimosine sulphate hydrate. Distances given in parentheses are corrected for thermal libration.

Bond		Corr.	Angle		Hydrogen bonds

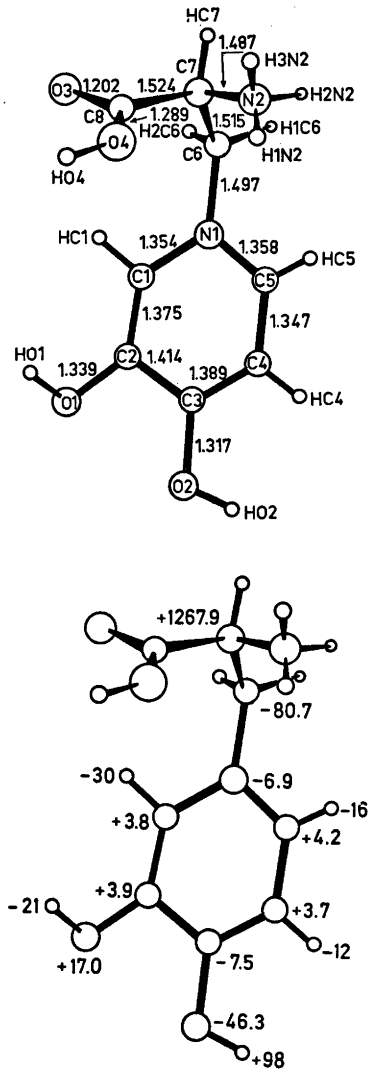

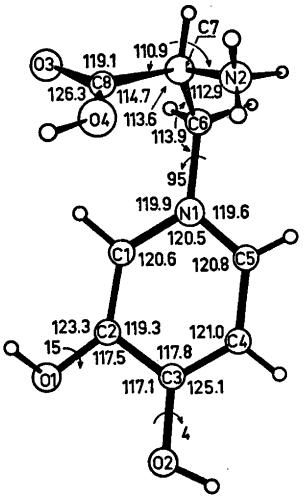

Fig. 2. a. Bond lengths (Å) and *b.* bond angles (°) in the mimosine ion. *c.* Deviations ($\times 10^3$ Å) from the best plane through the pyridine ring.

accounts for the shortness of the C1 – C2 and the C4 – C5 bonds relative to the aromatic C – C bond as found in pyridine. In accordance with the resulting charge distribution the two phenolic oxygen atoms act as hydrogen donors in fairly short hydrogen bonds (2.601 Å and 2.577 Å to oxygen atoms of the sulphate ion).

The external angles at the carbon atoms carrying the hydroxyl groups exhibit the characteristics commonly found in hydrogen bonded phenols and catechols: the angles "*cis*" to the hydrogen atoms are greater than 120° (123.3° and 125.1° for O1 and O2, respectively) whereas the angles "*trans*" are less than 120° (117.5° and 117.1°), even if the consequence is a rather small O – O nonbonded separation. The phenolic hydrogen atoms are close to the plane of the pyridyl ring, the dihedral angles C – C – O – H being 15° (O1) and 4° (O2).

The N1 – C6 bond connecting the hydroxypyridyl ring to the alanine moiety is found to be somewhat longer (1.497 Å) than in mimosine (1.478 Å). The bond lengths found within the alanine part of the ion correspond closely to

those given by Sundaralingam and Putkey [7] as the mean values for a number of protonized amino acids. As for the bond angles the agreement is also good with the exception of the two C – C – O angles which show a significant difference. Their figures are based on amino acids having the normal conformation, however, with the nitrogen atom situated close to plane of the carboxyl group and in the *anti* position relative to the hydroxyl oxygen atom. In the present structure the conformation is *syn*, resulting in a 3.5° opening of the C – C – OH angle and a corresponding decrease in the C – C = O angle relative to the values given in the paper referred to; the O – C – O angle remains unchanged. The nitrogen atom is situated close to the plane through $C_\alpha - CO_2$ (0.13 Å); the dihedral angle O(H) – C – C – N is 5.6°. The conformation about the C – N bond is staggered.

The conformation of the mimosine ion with respect to the $C_\alpha - C_\beta$ bond is different from that found for L-mimosine but is the same as that reported for L-tyrosine.[8] The carboxyl and the amino groups are both in *gauche* positions relative to the pyridyl-ring with torsional angles N1 – C6 – C7 – N2 and N1 – C6 – C7 – C8 equal to 64.6° and – 62.8°, respectively. The angle between the ring plane and the plane through N1, C6, and C7 is 85.0° in good agreement with the corresponding angles in several phenylalanine derivatives with this specific conformation (83 – 86°).

The oxygen atoms of the sulphate ion are tetrahedrally arranged around the sulphur atom with O – S – O bond angles in the range 107.4° to 110.7°. The S – O bond lengths are equal, mean value 1.466 Å (1.482 Å corrected for thermal motion). This agrees well with the average S – O bond length of 1.473 Å (1.486 Å corrected) as given by Taesler and Olovsson from a number of structure determinations of the sulphate ion.[9]

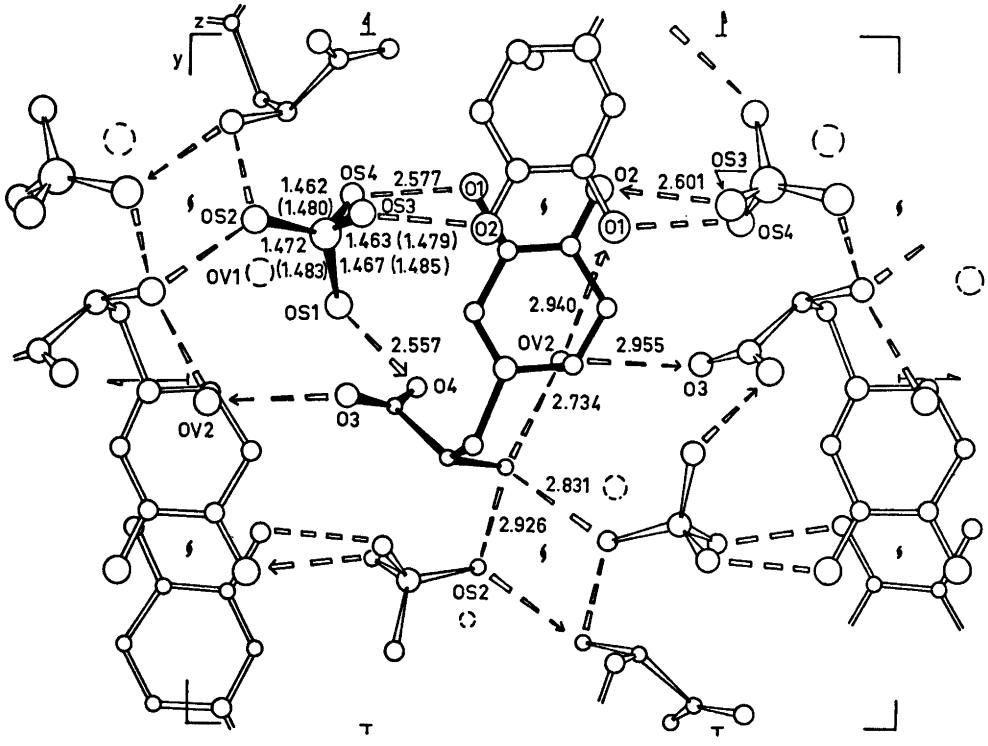

Fig. 3. The crystal structure of mimosine sulphate hydrate as seen down the *a* axis. Hydrogen bonds are indicated by broken lines, arrows indicate hydrogen bonds to atoms in another unit cell.

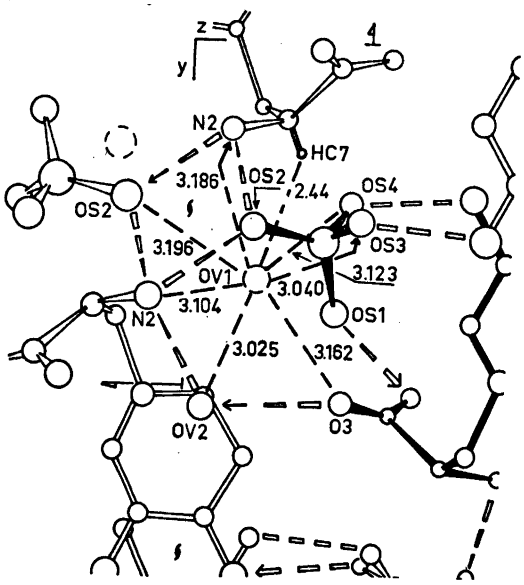

Fig. 4. The cavity containing the "half" water molecule.

The positions of the water molecules may be seen from Fig. 3. OV2 is involved in three hydrogen bonds; two as a hydrogen donor and one (to an ammonium nitrogen atom) as an acceptor. Fig. 4 illustrates the cavity containing the "half" water molecule. The molecule is surrounded by three sulphate ions, two ammonium groups, one water molecule and a carboxyl oxygen atom; there are eight oxygen or nitrogen atoms in distances between 3.0 and 3.2 Å from the OV1 atom. Four of these have lone pairs available for hydrogen bond formation. Since we were not able to localize the hydrogen atoms in this water molecule we are unable to determine which of the hydrogen bonds are established, and there may indeed exist different bonds in different unit cells in a statistical disordered way.

The crystal structure, packing and hydrogen bonding is illustrated in Fig. 3. From this drawing it may be seen that each mimosine ion is coordinated to five sulphate ions in a distorted trigonal bipyramidal arrangement. Each sulphate ion is surrounded by and hydrogen bonded to five mimosine residues. There is no direct contact between mimosine ions.

The molecular units are tied together in the crystal in an extensive three-dimensional hydrogen bond network, with the possible exception of the "half" water molecule. All hydrogen atoms bonded to hetero atoms are engaged in hydrogen bonds. The strongest of these occur between the oxygen atoms of the sulphate ion and the three hydroxyl groups in the mimosine ion, 2.557 Å (OS1 – O4), 2.577 Å (OS4 – O1) and 2.601 Å (OS3 – O2). The carbonyl oxygen atom is rather weakly hydrogen bonded to the water molecule (2.955 Å). The other hydrogen atom of this water molecule is engaged in a weak hydrogen bond to the phenolic oxygen atom O1 (2.940 Å). The N2 atom is involved as a hydrogen donor in three hydrogen bonds, one of 2.940 Å to one sulphate oxygen atom, one of 2.831 Å to another and a third of 2.734 Å to the oxygen atom of the water molecule.

Short Communications

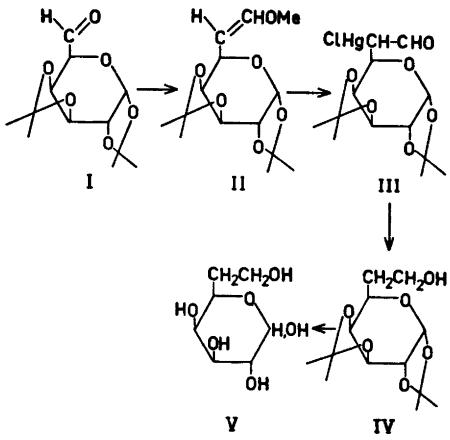
Synthesis of 6-Deoxy-D-*galacto*-heptose

KARIN EKLIND, PER J. GAREGG, BENGT LINDBERG and ÅKE PILOTTI

Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

We recently established that 6-deoxy-D-*manno*-heptose is a component sugar of the *Yersinia (Pasteurella) pseudotuberculosis* group IIa lipopolysaccharide.[1] The identification of this sugar was confirmed by synthesis.[2] Several isomeric 6-deoxyhexoses have been found in Nature,[3] and are synthesized from nucleoside hexoses *via* the corresponding 6-deoxyhexos-4-ulose derivatives. It seems most probable that the 6-deoxy-D-*manno*-heptose is likewise synthesized from a nucleoside heptose. Other 6-deoxy-heptoses may also be found in Nature and the syntheses of these sugars is therefore a matter of some interest. 6-Deoxy-D-*gluco*-heptose, as the 1,2-*O*-isopropylidene derivative, was recently synthesized by Rosenthal and Kan [5] *via* the hydroformylation of 5,6-anhydro-1,2-*O*-isopropylidene-α-D-glucofuranose. We now report the synthesis of 6-deoxy-D-*galacto*-heptose.

The 6-deoxy-D-*galacto*-heptose was synthesized by a Wittig reaction, analogous to that used for the synthesis of the corresponding D-*manno* derivative.[2] The various synthetic transformations are outlined in Scheme 1. 1,2:3,4-Di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose [6] was treated with methoxymethylenetriphenylphosphorane to afford the vinylic derivative II, which was transformed into the 7-aldehydo sugar III by treatment with mercuric chloride and mercuric oxide.[7] Reduction of III with sodium borohydride afforded the heptose derivative IV in an over-all yield of 10 % from I. Acid hydrolysis of IV produced 6-deoxy-D-*galacto*-heptose.



Scheme 1.

Experimental. General methods were the same as those described in a previous paper [2] NMR spectra, recorded for all compounds, except for III, were in accordance with the presumed structures.

*6-Deoxy-1,2:3,4-di-*O*-isopropylidene-α-*D*-galacto-heptopyranose (IV).* Methoxymethyltriphenylphosphonium chloride (6.7 g) in dry diethyl ether (44 ml) was enclosed in a serum bottle with a magnetic stirrer under nitrogen and cooled to −10°. Butyllithium (9.2 ml, 30 % in hexane) was added by syringe. The mixture was allowed to stand with stirring for 20 min. 1,2:3,4-Di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose (I) [6] (2.5 g) in dry diethyl ether (25 ml) at −10° was added by syringe and the mixture was allowed to stand with stirring under nitrogen for 1 h at −10° and then at room temperature for 18 h. Partitioning between diethyl ether and water, drying the diethyl ether solution over sodium sulphate, filtration and concentration afforded a crude syrup (II).

Crude, syrupy II was dissolved in acetone-water (10:1, 12 ml). Mercuric oxide (360 mg) was added with magnetic stirring and then, dropwise, with stirring, mercuric chloride (360 mg) in acetone-water (10:1, 4.0 ml).[7] The reaction was monitored by TLC and interrupted after about 5 min at room temperature. The mixture was filtered, concentrated to dryness to yield syrupy, crude III which immediately was dissolved in ethanol (15 ml); the ethanol solution was diluted with water to near turbidity. Exess sodium borohydride was added and the solution was allowed to stand at room temperature overnight. Sodium cations were removed with Dowex 50 (H^+ form). Filtration, concentration and repeated concentrations with methanol in order to remove boric acid as methyl borate afforded a syrup which after purification on silica gel [diethyl ether-light petroleum (40 – 60°)] gave chromatographically pure IV (260 mg), $[\alpha]_D$ −44° (*c* 0.6, $CHCl_3$). (Found: C 56.8; H 8.28, $C_{13}H_{22}O_6$ requires: C 56.9; H 8.08).

6-Deoxy-D-galacto-*heptose (V)*. The above di-*O*-isopropylidene derivative IV (39 mg) was treated with trifluoracetic acid-water [8] (9:1, 10 ml) at room temperature for 5 min. The solution was concentrated and the product dissolved in water, filtered and concentrated to a syrup (27 mg) $[\alpha]_D + 75°$ (*c* 0.9, H_2O). An aliquot of the material was transformed into 6-deoxy-D-*galacto*-heptitol hexaacetate by reduction with sodium borohydride followed by acetylation.[9] The GLC retention time relative to that of D-glucitol hexa-acetate (3 % ECNSS-M on Gas-Chrom Q at 180° and a flow rate of 30 ml/min) was 1.35. Another aliquot was reduced with sodium borodeuteride and then converted into the hexamethyl ether. The MS of the resulting 6-deoxy-1-deuterio-1,2,3,4,5,7-hexa-*O*-methyl-D *galacto*-heptitol showed the following (primary) fragments: *m/e* 235, 191, 178, 147, 134, 103, 90, 46, and 45. The remainder of the spectrum was in accordance with the presumed structure. The above 6-deoxy-D-*galacto*-heptitol hexaacetate crystallized, m.p. 123–125°, $[\alpha]_D$ −9° (*c* 0.4, $CHCl_3$). (Found: C 50.7; H 6.29. $C_{19}H_{28}O_{12}$ requires: C 50.9; H 6.29).

The Structure of Methyl β-D-Ribopyranoside

ASBJØRN HORDVIK

Department of Chemistry, University of Bergen, N-5000 Bergen, Norway

X-Ray crystallographic studies on the pyranose form of aldopentoses [1–6] have shown that the structures agree with those predicted by Reeves.[7] Thus, β-arabinose,[1–3] β-lyxose,[4] and α-xylose,[5,6] are found to have the conversion forms 1*a*2*e*3*e*4*a*, 1*e*2*a*3*e*4*e*, and 1*a*2*e*3*e*4*e*, respectively.

As regards the fourth aldopentose, ribose, preliminary crystallographic data only have been reported.[8] However, a structure study of 2-deoxy-β-ribose has been carried out.[9]

The conversion form 1*a*3*e*4*a* which 2-deoxy-β-ribose has in the crystalline state, does not agree with Reeves' predictions, and it has been proposed in this connection that an axial substituent on C(1) should be regarded as an element of stability rather than an element of instability.[9] An X-ray structure study of methyl β-ribopyranoside which may occur as 1*a*2*a*3*e*4*a* or 1*e*2*e*3*a*4*e*, was therefore thought of interest.

The results from this study show, *cf.* Fig. 1, that methyl β-D-ribopyranoside in the crystalline state has the conversion form 1*a*2*a*3*e*4*a*, which from Reeves' stability scheme [7] is supposed to be the least stable one.

One may query, however, whether the assumed stabilizing effect of the 1*a* substituent has been decisive for the structure in this case. There is namely an intramolecular hydrogen bond between O(2) and O(4) which at least to some degree stabilizes the molecule. Similar intramolecular hydrogen bonds occur in methyl 1-thio-β-D-ribopyranoside and methyl 1,5-dithio-β-D-ribopyranoside,[10] and the possibility for such bonding should therefore be taken into account when judging about the stability of the conversion forms of pyranoses. It should be mentioned in this connection that methyl 5-thio-β-D-ribopyranoside occurs as 1*e*2*e*3*a*4*e* in the crystalline state.[11]

The C–O and C–C bond lengths in methyl β-D-ribopyranoside, as derived from the coordinates in Table 1, are shown in Fig. 1. The values agree with those reported by James and Stevens from an independent X-ray study of the compound,[12] and also with those previously reported for glycoside structures.[13,14]

The three hydroxyl hydrogens participate in hydrogen bonds. They are, O(2)···O(4) = 2.77 Å with H(O2)···O(4) = 2.09 Å, O(3)···O(2)′ = 2.85 Å with H(O3)···O(2)′ = 2.03 Å, and O(4)···O(3)′ = 2.87 Å with H(O4)···O(3)′ = 2.22 Å. Thus each of the hydroxyl oxygens donates as well as accepts a hydrogen bond.

Methyl β-D-ribopyranoside crystallizes from ethyl acetate,[15] as orthorhombic prisms elon-

6-Deoxy-D-galacto-*heptose (V)*. The above di-*O*-isopropylidene derivative IV (39 mg) was treated with trifluoracetic acid-water [8] (9:1, 10 ml) at room temperature for 5 min. The solution was concentrated and the product dissolved in water, filtered and concentrated to a syrup (27 mg) $[\alpha]_D + 75°$ (*c* 0.9, H_2O). An aliquot of the material was transformed into 6-deoxy-D-*galacto*-heptitol hexaacetate by reduction with sodium borohydride followed by acetylation.[9] The GLC retention time relative to that of D-glucitol hexa-acetate (3 % ECNSS-M on Gas-Chrom Q at 180° and a flow rate of 30 ml/min) was 1.35. Another aliquot was reduced with sodium borodeuteride and then converted into the hexamethyl ether. The MS of the resulting 6-deoxy-1-deuterio-1,2,3,4,5,7-hexa-*O*-methyl-D *galacto*-heptitol showed the following (primary) fragments: *m/e* 235, 191, 178, 147, 134, 103, 90, 46, and 45. The remainder of the spectrum was in accordance with the presumed structure. The above 6-deoxy-D-*galacto*-heptitol hexaacetate crystallized, m.p. 123–125°, $[\alpha]_D$ −9° (*c* 0.4, $CHCl_3$). (Found: C 50.7; H 6.29. $C_{19}H_{28}O_{12}$ requires: C 50.9; H 6.29).

The Structure of Methyl β-D-Ribopyranoside

ASBJØRN HORDVIK

Department of Chemistry, University of Bergen, N-5000 Bergen, Norway

X-Ray crystallographic studies on the pyranose form of aldopentoses [1–6] have shown that the structures agree with those predicted by Reeves.[7] Thus, β-arabinose,[1–3] β-lyxose,[4] and α-xylose,[5,6] are found to have the conversion forms 1*a*2*e*3*e*4*a*, 1*e*2*a*3*e*4*e*, and 1*a*2*e*3*e*4*e*, respectively.

As regards the fourth aldopentose, ribose, preliminary crystallographic data only have been reported.[8] However, a structure study of 2-deoxy-β-ribose has been carried out.[9]

The conversion form 1*a*3*e*4*a* which 2-deoxy-β-ribose has in the crystalline state, does not agree with Reeves' predictions, and it has been proposed in this connection that an axial substituent on C(1) should be regarded as an element of stability rather than an element of instability.[9] An X-ray structure study of methyl β-ribopyranoside which may occur as 1*a*2*a*3*e*4*a* or 1*e*2*e*3*a*4*e*, was therefore thought of interest.

The results from this study show, *cf.* Fig. 1, that methyl β-D-ribopyranoside in the crystalline state has the conversion form 1*a*2*a*3*e*4*a*, which from Reeves' stability scheme [7] is supposed to be the least stable one.

One may query, however, whether the assumed stabilizing effect of the 1*a* substituent has been decisive for the structure in this case. There is namely an intramolecular hydrogen bond between O(2) and O(4) which at least to some degree stabilizes the molecule. Similar intramolecular hydrogen bonds occur in methyl 1-thio-β-D-ribopyranoside and methyl 1,5-dithio-β-D-ribopyranoside,[10] and the possibility for such bonding should therefore be taken into account when judging about the stability of the conversion forms of pyranoses. It should be mentioned in this connection that methyl 5-thio-β-D-ribopyranoside occurs as 1*e*2*e*3*a*4*e* in the crystalline state.[11]

The C–O and C–C bond lengths in methyl β-D-ribopyranoside, as derived from the coordinates in Table 1, are shown in Fig. 1. The values agree with those reported by James and Stevens from an independent X-ray study of the compound,[12] and also with those previously reported for glycoside structures.[13,14]

The three hydroxyl hydrogens participate in hydrogen bonds. They are, O(2)···O(4) = 2.77 Å with H(O2)···O(4) = 2.09 Å, O(3)···O(2)′ = 2.85 Å with H(O3)···O(2)′ = 2.03 Å, and O(4)···O(3)′ = 2.87 Å with H(O4)···O(3)′ = 2.22 Å. Thus each of the hydroxyl oxygens donates as well as accepts a hydrogen bond.

Methyl β-D-ribopyranoside crystallizes from ethyl acetate,[15] as orthorhombic prisms elon-

gated along the *c*-axis. The crystals belong to the space group $P2_12_12_1$ with $Z=4$.

Unit cell dimensions were determined by measuring the 2θ settings for eight reflections on a Picker four-angle automatic diffractometer, with Cu$K\beta$ radiation ($\lambda=1.39217$ Å). From a least squares treatment, the cell dimensions are, $a=6.415(2)$ Å, $b=19.994(3)$ Å, and $c=5.747(2)$ Å. The calculated density is 1.479 g/cm³, as compared with the density 1.48 g/cm³ found by flotation.

Intensity data were collected on the diffractometer, using Cu$K\alpha$ radiation and omega scan. 660 reflections, measured within $\sin\theta=0.865$, were reduced to structure factors in the usual way. The crystal used for data collection had the dimensions $0.2\times0.2\times0.4$ mm in the three axial directions. Absorption corrections were not applied.

The structure was solved by direct methods [16] and refined by full matrix least squares to a final *R* factor of 0.07. The scattering factors used for oxygen and carbon were those given in *International Tables*.[17] For hydrogen the scattering factor curve given by Stewart *et al.*[18] was used.

Final atomic coordinates are listed in Table 1. The final list of structure factors is available on request.

This work has been carried out at the University of Pittsburgh (1968) and at the University of Bergen. The author wishes to thank Professor George A. Jeffrey and his staff members at the Crystallography Laboratory, University of Pittsburgh, for great hospitality.

Electroörganic Preparations. XXXVI. Stepwise Reduction of Benzotrifluoride

HENNING LUND and NIELS J. JENSEN

Department of Chemistry, University of Aarhus, DK-8000 Aarhus C, Denmark

Electrochemical reduction of trifluoromethyl compounds has been observed in some instances.[1–4] In most cases reported the reduction has been performed in protic solvents, and under these conditions a complete reduction involving 6 F/mol to a methyl group is generally observed;[1–3] the only exception seems to be the reduction of 2,2,2-trifluoroacetophenone to acetophenone in 80 % aqueous ethanol during which monofluoroacetophenone was detected as an intermediate.[3]

In *N*,*N*-dimethylformamide (DMF) some trifluoromethylbenzenesulphonamides have been investigated polarographically [4] and a stepwise reduction was found in some cases; the electrode reaction corresponded to a reductive cleavage of the carbon-sulphur bonds, and the resulting benzotrifluoride was reported to give a single polarographic wave.

In the present work the electrochemical behaviour of benzotrifluoride and some other α-halogenated toluenes have been investigated by means of cyclic voltammetry (CV) and controlled potential electrolysis (CPE).

Results and discussion. In Table 1 are given the peak potentials of benzotrifluoride (I), α,α-difluorotoluene (II), α-fluorotoluene (III), benzotrichloride (IV), α,α-dichloro-α-fluorotoluene (V), α-chloro-α,α-difluorotoluene (VI), benzal chloride (VII), α-chloro-α-fluorotoluene (VIII), and benzyl chloride (IX). None of the electrode reactions are reversible on CV.

Whereas the peak potentials of II and III are very nearly equal, the potential of I is more than 200 mV less negative than that of II, and a reduction of I to II should be possible with a reasonable selectivity. The half-peak potential of II is about 0.05 V less negative than that of III which might indicate that the signal from II is a composite wave due to poorly separated peaks of the reduction of II to III and III to toluene. A reduction of II to III would thus be expected to be less selective than a reduction of I to II.

Cyclic voltammograms of I in DMF with added water showed that the peak potentials of the first and second peak were not affected by addition of up to 2 % of water. The background current raised and at a water content higher than about 2 % the waves merged with the background current.

The difference in reduction potential between that of the carbon-chlorine bond and that of the carbon-fluorine bonds in VI is about 0.7 V, sufficiently for a selective reduction; this was confirmed by a preparative reduction of VI to II in good yield. The potential difference between the reduction of the first and second carbon-chlorine bond in V is about 0.4 V; a selective reduction of V to VIII was shown to be possible.

The reduction of I was investigated in more detail; in Fig. 1 is shown the dependence of the concentrations of I, II, III, and toluene (X) on the electron consumption. The samples with-

Electroörganic Preparations. XXXVI. Stepwise Reduction of Benzotrifluoride

HENNING LUND and NIELS J. JENSEN

Department of Chemistry, University of Aarhus, DK-8000 Aarhus C, Denmark

Electrochemical reduction of trifluoromethyl compounds has been observed in some instances.[1–4] In most cases reported the reduction has been performed in protic solvents, and under these conditions a complete reduction involving 6 F/mol to a methyl group is generally observed;[1–3] the only exception seems to be the reduction of 2,2,2-trifluoroacetophenone to acetophenone in 80 % aqueous ethanol during which monofluoroacetophenone was detected as an intermediate.[3]

In *N*,*N*-dimethylformamide (DMF) some trifluoromethylbenzenesulphonamides have been investigated polarographically [4] and a stepwise reduction was found in some cases; the electrode reaction corresponded to a reductive cleavage of the carbon-sulphur bonds, and the resulting benzotrifluoride was reported to give a single polarographic wave.

In the present work the electrochemical behaviour of benzotrifluoride and some other α-halogenated toluenes have been investigated by means of cyclic voltammetry (CV) and controlled potential electrolysis (CPE).

Results and discussion. In Table 1 are given the peak potentials of benzotrifluoride (I), α,α-difluorotoluene (II), α-fluorotoluene (III), benzotrichloride (IV), α,α-dichloro-α-fluorotoluene (V), α-chloro-α,α-difluorotoluene (VI), benzal chloride (VII), α-chloro-α-fluorotoluene (VIII), and benzyl chloride (IX). None of the electrode reactions are reversible on CV.

Whereas the peak potentials of II and III are very nearly equal, the potential of I is more than 200 mV less negative than that of II, and a reduction of I to II should be possible with a reasonable selectivity. The half-peak potential of II is about 0.05 V less negative than that of III which might indicate that the signal from II is a composite wave due to poorly separated peaks of the reduction of II to III and III to toluene. A reduction of II to III would thus be expected to be less selective than a reduction of I to II.

Cyclic voltammograms of I in DMF with added water showed that the peak potentials of the first and second peak were not affected by addition of up to 2 % of water. The background current raised and at a water content higher than about 2 % the waves merged with the background current.

The difference in reduction potential between that of the carbon-chlorine bond and that of the carbon-fluorine bonds in VI is about 0.7 V, sufficiently for a selective reduction; this was confirmed by a preparative reduction of VI to II in good yield. The potential difference between the reduction of the first and second carbon-chlorine bond in V is about 0.4 V; a selective reduction of V to VIII was shown to be possible.

The reduction of I was investigated in more detail; in Fig. 1 is shown the dependence of the concentrations of I, II, III, and toluene (X) on the electron consumption. The samples with-

Compound		E_p (1)	E_p (2)	E_p (3)	V *vs.* aq. SCE
I	$C_6H_5CF_3$	2.61	2.84		
II	$C_6H_5CHF_2$	2.83_5			
III	$C_6H_5CH_2F$	2.84			
IV	$C_6H_5CCl_3$	1.77	2.13	2.35	
V	$C_6H_5CCl_2F$	1.90	2.34	2.84	
VI	$C_6H_5CClF_2$	2.11	2.84		
VII	$C_6H_5CHCl_2$	2.12	2.36		
VIII	C_6H_5CHClF	2.36	2.84		
IX	$C_6H_5CH_2Cl$	2.35			

drawn during the electrolysis were analyzed by GLC; the retention times of the compounds were I < X < II < III. The electron consumption is somewhat higher (~20 %) than the theoretical one reflecting a certain reduction of background components (*e.g.* supporting electrolyte) due to the very negative potential.

The cyclic voltammetry indicated the possibility of a reasonably selective reduction of I to II, but it seems somewhat more surprising that III is found in a rather high concentration during the latter part of the reduction, although the half-peak potential of III is only 0.05 V more negative than that of II. From the peak potentials a reduction of II to X could be expected.

Trifluoromethylbenzene (I) is thus in DMF reduced stepwise to toluene in a manner similar to other α,α,α-trihalotoluenes, although the differences in potential of the three steps are very small for I compared with the other trihalotoluenes. In protic media the trifluoromethyl compounds, when reducible, have mostly been found to be reduced to the toluenes without detection of any partly dehalogenated intermediates. The reason for this difference is not apparent, possibly the difference in ability of the fluoride ion to act as a leaving group in protic solvents, where it is highly solvated, and in DMF, where fluoride ions are less solvated, may play a role.

Reduction of I in protic solvents has not been attempted, as no voltammetric waves were observed; reduction of methyl *p*-trifluoromethylbenzoate in methanol produced the methyl toluate;[2] cyclic voltammetric and coulometric studies in DMF pointed, however, to a primary two-electron reduction.[5]

Cyclic voltammetric data in DMF of other substituted trifluoromethyl benzenes point to a stepwise reduction of these compounds; further studies with controlled potential reduction may show whether a stepwise reduction of the trifluoromethyl group is the general reduction mode in aprotic media.

Experimental. Apparatus. A Juul-electronics potentiostat, a F&M Research Chromatograph Model 810 with a Hewlett-Packard 3370B electronic integrator, and a CEC 21 – 104 Mass Spectrometer were used.

Materials. Benzotrifluoride (I), benzyl fluoride (III), benzotrichloride (IV), benzal chloride (VII), and benzyl chloride (IX) were commercially available. α,α-Dichloro-α-fluorotoluene (V) and α-chloro-α,α-difluorotoluene (VI) were prepared according to Swarts,[6] V (b.p. 178 – 180°C) was purified by preparative GLC on a 25 % SE 52 column, $t = 80$°C; $n_D^{23} = 1.5109$.

α,α-Difluorotoluene (II). 5 ml of α-chloro-α,α-difluorotoluene (VI) were reduced in 150 ml of DMF containing 5 % of water and 0.1 m tetrabutylammonium iodide (TBAI) at −1.80 V *vs.* Ag/AgI (DMF), $n = 1.87$. The reduction completed the DMF was diluted with 1 l of water and extracted 3 times with 50 ml petrol ether. The petrol ether was washed 5 times with water to remove DMF and dried on "Sikkon Fluka". After removal of the petrol ether through a short column the residue, 3.6 g, was purified by preparative GLC on a 10 % FFAP column at 50°C, 1.24 g. $n_D^{22} = 1.4550$. NMR-spectrum (neat): $\delta = 6.42$, 1 H, triplet, $J_{HF_2} = 57$ Hz; $\delta = 7.1 - 7.5$, 5 H, multiplet. Mass spectrum, *m/e* (%): 39 (3), 41 (3), 43 (3), 50 (7), 51 (14), 55 (6), 57 (5), 63 (3), 69 (3), 74 (4), 75 (3), 77 (10), 78 (32), 79 (3), 81 (4), 83 (7), 101 (3), 107 (5), 109 (23), 126 (3), 127 (100), 128 (59), 129 (5).

α-Chloro-α-fluorotoluene (VIII). α,α-Dichloro-α-fluorotoluene (V) (2.7 g) was reduced in 150 ml of DMF containing 5 ml of water and 0.1 m TBAI at −1.3 V *vs.* Ag/AgI (DMF), $n = 2.03$. The catholyte was treated as described above for II, and the residue purified on a 10 % FFAP-column at 70°C; 1.34 g. NMR (CCl_4): $\delta = 5.30$, 1 H, doublet, $J_{HF} = 48$Hz. $\delta = 7.28$, 5 H, singlet. Mass spectrum, *m/e* (%): 27 (7), 29 (9), 39 (7), 41 (21), 42 (16), 43 (27), 50 (8), 51 (8), 56 (23), 57 (38), 63 (8), 83 (17), 89 (6), 107 (9), 109 (100), 110 (13), 125 (2.4), 127 (0.9), 144 (29), 146 (11).

Reduction of benzotrifluoride (I). A. I (34 mg) was reduced in 45 ml DMF containing 0.1 m TBAI at −2.0 – −2.3 V *vs.* Ag/AgI. During the reduction samples were withdrawn, the electricity consumption noted, and the samples

analyzed by GLC on a 2.5 % diisodecylphthalate (DIDP)-column, programmed 4°/min from 40° to 150°, injection temperature 140°. The retention times (sec) were: I 470, toluene 603, II 900, III 967. The results are presented in Fig. 1.

B. I (2.0 ml) was reduced in 235 ml DMF containing 0.1 m TBAI at −1.95 Ag/AgI (DMF). After an electron consumption of 1.86 F/mol the reduction was stopped. Analysis by GLC gave I (11 %), II (82 %), and III (7 %). The catholyte was divided in two parts; one was treated as described above for the reduction of VI. Analysis of the residue showed a relative content of I, II, and III of 8:87:5.

The other part of the catholyte was reduced further at −2.1 V (the foot of the wave of II); after further 2 F/mol the catholyte was analyzed by GLC; II 13 %, III 72 %, and toluene 14 %.

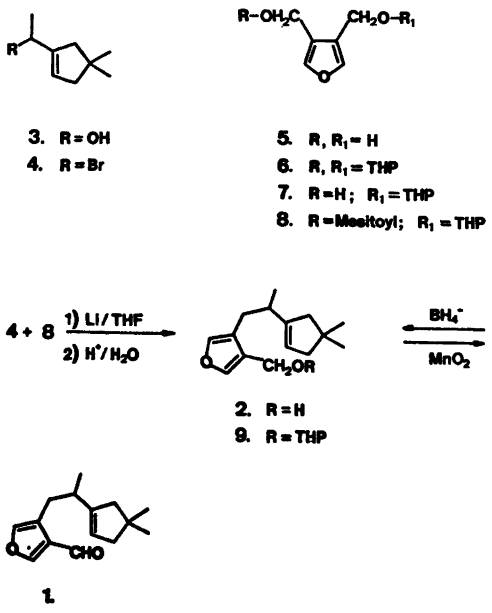
Fungal Extractives. VII.* A Formal Synthesis of (±)-Lactaral

J. FROBORG, G. MAGNUSSON and S. THORÉN

Organic Chemistry 2, Chemical Center, The Lund Institute of Technology, P.O. Box 740, S-220 07 Lund, Sweden

The structure of lactaral (*1*), a new sesquiterpene furan-3-aldehyde from *Lactarius vellereus* and *L. pergamenus* (Russulaceae), has been described.[1] We now report a formal synthesis of lactaral confirming structure *1*.

A direct reductive cross-coupling of the allylic alcohol *3* and the 3-furyl alcohol *7* with $TiCl_4$/butyllithium (or methyllithium) in monoglyme [2] was unsuccessful. However, a lithium-promoted coupling reaction between the mesitoate *8* of the furyl alcohol *7* and the allylic bromide *4* [3] gave the tetrahydropyranyl ether (THP) *9* of lactarol in low yield. Hydrolysis of compound *9* afforded racemic (±)-lactarol (*2*). This synthetic alcohol was spectroscopically identical with an authentic sample prepared from native lactaral by borohydride reduction (MS, IR and NMR). (−)Lactarol was reoxidized to lactaral with active manganese dioxide thus formally completing the total synthesis.



Experimental. The NMR spectra were recorded on a Varian T-60 spectrometer. Mass spectra were recorded on an LKB 1100 instrument.

4,4-Dimethyl-1-(1-bromo)ethylcyclopentene(4). The allylic alcohol *3* [1] was brominated with triphenylphosphine-carbon tetrabromide in ether.[4] After reflux for 24 h the reaction mixture was worked up to give the *bromide 4* in 73 % yield. B.p.$_{20}$ 78−81°; n_D^{26} 1.5250; ν_{max}(neat) 3050, 1640, 1380, 1370, 820 cm^{-1}; NMR: δ_{TMS}($CDCl_3$) 5.62 (1 H, s broad), 4.83 (1 H, q, J=7 Hz), 2.25 2.15 (2 H each, s broad), 1.80 (3 H, d, J=7 Hz), 1.10 (6 H, s) ppm; MS: *m/e* 122 (24 %) (M^+−HBr), 107 (100 %), 91 (31 %), 79 (19 %).

3,4-Bis(hydroxymethyl)furan (5). The diol *5* was prepared by lithium aluminium hydride reduction of the corresponding commercially available diethyl ester according to the literature.[5] Yield 84 % (lit. 83 %). B.p. 100−102°/0.2 mmHg (lit. 129−130°/2 mmHg); n_D^{22} 1.5103 (lit. n_D^{20} 1.5080).

Reaction of diol 5 with 3,4-dihydro-2H-pyran. A mixture of diol *5* (1.28 g, 0.0100 mol), 3,4-

* Part VI see Ref. 1.

analyzed by GLC on a 2.5 % diisodecylphthalate (DIDP)-column, programmed 4°/min from 40° to 150°, injection temperature 140°. The retention times (sec) were: I 470, toluene 603, II 900, III 967. The results are presented in Fig. 1.

B. I (2.0 ml) was reduced in 235 ml DMF containing 0.1 m TBAI at −1.95 Ag/AgI (DMF). After an electron consumption of 1.86 F/mol the reduction was stopped. Analysis by GLC gave I (11 %), II (82 %), and III (7 %). The catholyte was divided in two parts; one was treated as described above for the reduction of VI. Analysis of the residue showed a relative content of I, II, and III of 8:87:5.

The other part of the catholyte was reduced further at −2.1 V (the foot of the wave of II); after further 2 F/mol the catholyte was analyzed by GLC; II 13 %, III 72 %, and toluene 14 %.

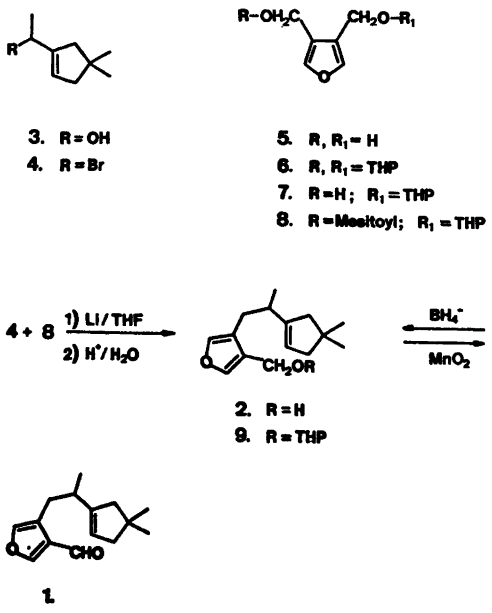
Fungal Extractives. VII.* A Formal Synthesis of (±)-Lactaral

J. FROBORG, G. MAGNUSSON and S. THORÉN

Organic Chemistry 2, Chemical Center, The Lund Institute of Technology, P.O. Box 740, S-220 07 Lund, Sweden

The structure of lactaral (*1*), a new sesquiterpene furan-3-aldehyde from *Lactarius vellereus* and *L. pergamenus* (Russulaceae), has been described.[1] We now report a formal synthesis of lactaral confirming structure *1*.

A direct reductive cross-coupling of the allylic alcohol *3* and the 3-furyl alcohol *7* with $TiCl_4$/butyllithium (or methyllithium) in monoglyme [2] was unsuccessful. However, a lithium-promoted coupling reaction between the mesitoate *8* of the furyl alcohol *7* and the allylic bromide *4* [3] gave the tetrahydropyranyl ether (THP) *9* of lactarol in low yield. Hydrolysis of compound *9* afforded racemic (±)-lactarol (*2*). This synthetic alcohol was spectroscopically identical with an authentic sample prepared from native lactaral by borohydride reduction (MS, IR and NMR). (−)Lactarol was reoxidized to lactaral with active manganese dioxide thus formally completing the total synthesis.



Experimental. The NMR spectra were recorded on a Varian T-60 spectrometer. Mass spectra were recorded on an LKB 1100 instrument.

4,4-Dimethyl-1-(1-bromo)ethylcyclopentene(4). The allylic alcohol *3* [1] was brominated with triphenylphosphine-carbon tetrabromide in ether.[4] After reflux for 24 h the reaction mixture was worked up to give the *bromide 4* in 73 % yield. B.p.$_{20}$ 78−81°; n_D^{26} 1.5250; ν_{max}(neat) 3050, 1640, 1380, 1370, 820 cm^{-1}; NMR: δ_{TMS}($CDCl_3$) 5.62 (1 H, s broad), 4.83 (1 H, q, J=7 Hz), 2.25 2.15 (2 H each, s broad), 1.80 (3 H, d, J=7 Hz), 1.10 (6 H, s) ppm; MS: *m/e* 122 (24 %) (M^+−HBr), 107 (100 %), 91 (31 %), 79 (19 %).

3,4-Bis(hydroxymethyl)furan (5). The diol *5* was prepared by lithium aluminium hydride reduction of the corresponding commercially available diethyl ester according to the literature.[5] Yield 84 % (lit. 83 %). B.p. 100−102°/0.2 mmHg (lit. 129−130°/2 mmHg); n_D^{22} 1.5103 (lit. n_D^{20} 1.5080).

Reaction of diol 5 with 3,4-dihydro-2H-pyran. A mixture of diol *5* (1.28 g, 0.0100 mol), 3,4-

* Part VI see Ref. 1.

dihydro-2*H*-pyran (1.00 ml, 0.0109 mol) and a few crystals of *p*-toluenesulfonic acid was stirred at room temperature for 24 h. The products were then separated on a silica gel (100 g) column with methylene chloride-ethyl acetate (3 : 1) as eluent. 15 ml fractions were collected. From fr. 9–18.

3,4-Bis[(2-tetrahydropyranyl)oxymethylene]-furan (6) (0.81 g, 28 %) was obtained as a colourless oil which had: n_D^{21} 1.4911; IR (neat): ν_{max} 1550, 1120, 1025, 880, 870 cm^{-1}; NMR ($CDCl_3$, TMS): δ 7.40 (2 H, s; two fur-*H*), 4.70, 4.40 (2 H each, d, $J = 12$ Hz; two fur–*HCH*–O), 4.70 (2 H, s broad; two O–C*H*–O), 3.25–4.15 (4 H, m; two O–CH_2–CH_2) ppm; MS *m/e*: 296 (M^+, 1 %) ($C_{16}H_{24}O_5$), 111 (18 %), 95 (20 %), 94 (81 %), 85 (100 %; base peak). It was distilled *in vacuo* for analysis. (Found: C 64.9; H 8.3. $C_{16}H_{24}O_5$ requires: C 64.8; H 8.2). From fr. 20–41 *3-hydroxymethyl-4-(2-tetrahydropyranyl)-oxymethylene-furan (7)* (1.06 g, 50 %) was obtained. The compound, a colourless oil, had: n_D^{21} 1.4957; IR (neat): ν_{max} 3400–3600 (OH), 3150 3120 1555 (furan), 1120, 1020, 905, 875 (furan), 805 cm^{-1}; NMR ($CDCl_3$, TMS): δ 7.40 (2 H, s; two fur–*H*), 4.73 4.43 (1 H each, d, $J = 12$ Hz; fur–*HCH*–OTHP), 4.72 (1 H, s broad; O–C*H*–O), 4.51 (2 H, s; fur-CH_2–OH), 3.25–4.15 (2 H, m; O–CH_2–CH_2) ppm; MS *m/e*: 212 (M^+; 5 %) ($C_{11}H_{16}O_4$), 128 (11 %), 112 (54 %), 111 (100 %; base peak), 110 (47 %), 85 (60 %). It was distilled *in vacuo* for analysis. (Found: C 62.3; H 7.7. $C_{11}H_{16}O_4$ requires: C 62.3; H 7.6). The terminal fractions yielded smaller amounts of unreacted *diol 5* (0.05 g).

3-(2-Tetrahydropyranyl)oxymethylene-4-(2,4,6-trimethylbenzoyl)oxymethylenefuran (8). The 3-furyl alcohol *7* was esterified with mesitoyl chloride [6] in ethanol-free chloroform.[3] Column chromatography of the crude product on silica gel with methylene chloride-ethyl acetate (4 : 1) as eluent gave the *mesitoate 8* in 82 % yield. It had: ν_{max}(neat) 3150, 3120, 1730, 1265, 1080, 875 cm^{-1}; NMR: δ_{TMS}($CDCl_3$) 7.54 (1 H, d, $J = 2$ Hz; fur–*H*), 7.40 (1 H, s broad; fur–*H*), 6.84 (3 H, s broad; ϕ–*H*), 5.14 (2 H, s; fur–CH_2–OCO–), 4.74 4.42 (1 H each, d, $J = 12$ Hz; fur–*HCH*–OTHP), 4.65 (1 H, s broad; O–C*H*–O–), 3.28–4.10 (2 H, m; –O–CH_2–CH_2–), 2.27 (9 H, s; three ϕ–CH_3); MS: *m/e* 358 (1 %) (M^+; $C_{21}H_{26}O_5$), 279 (6 %), 256 (5 %), 167 (20 %), 149 (63 %), 147 (100 %), 146 (25 %). It was distilled *in vacuo* for analysis. (Found: C 70.5; H 7.4. Calc. for $C_{21}H_{26}O_5$: C 70.4; H 7.3).

Reaction between 4 and 8 to give (±)-lactarol (2). Lithium (345 mg; 50 mmol) was added to a stirred, ice-cold solution of the mesitoate *8* (1790 mg; 5 mmol) and the bromide *4* (1015 mg; 5 mmol) in dry tetrahydrofuran (25 ml) under nitrogen.[3] When the solution turned deep brown-red in colour (15 min) the reaction was quenched with water (0.5 ml). Work-up of the reaction mixture gave mesitoic acid (315 mg). The neutral fraction was chromatographed on a silica gel (100 g) column with ethyl acetate (2 %) in methylene chloride as eluent. A small amount of the crude *tetrahydropyranyl ether 9* (IR, NMR) (230 mg) was obtained. Hydrolysis of the crude ether *9* (115 mg) was accomplished with 1 M sulphuric acid (1 ml) in dimethoxyethane (5 ml). After 48 h the partially hydrolyzed mixture was worked up. Column chromatography on silica gel (10 g) with ethyl acetate (2 %) in methylene chloride as eluent gave (R,S)-*lactarol (2)* (22 mg). This compound gave spectra (IR, NMR, MS) identical with those of an authentic sample of lactarol (*vide infra*). *(–)-Lactarol (2)*. Lactaral (*1*) was reduced with potassium borohydride in water-ethanol to give an almost quantitative yield of *lactarol (2)*. It had: $[\alpha]_D^{22} - 3.5°$ (*c* 0.9 in chloroform); ν_{max}(neat) 3350 (broad), 1610, 1545, 1385, 1380, 1055, 885, 795 cm^{-1}; NMR: δ_{TMS}($CDCl_3$) 7.36, 7.20 (1 H each, s broad; two fur–*H*), 5.28 (1 H, s broad; –C=C*H*–CH_2–), 4.55 (2 H, s; fur–CH_2–OH), 2.20–2.70 (3 H, m; allylic protons), 2.12 (4 H, s; two –CH_2–C=C–), 1.08 (6 H, s; two *gem*-CH_3), 1.05 (3 H, d, $J = 7$ Hz; –CH–CH_3); MS: *m/e* 234 (18 %) (M^+; $C_{15}H_{22}O_2$), 217 (20 %), 201 (18 %), 160 (13 %), 123 (100 %), 81 (60 %).

(–)-Lactarol was reoxidized with active manganese dioxide [7] in methylene chloride-pentane (1 : 1) to lactaral which was identical in all respects with the original aldehyde.

Intramolecular Coupling of Diarylpropanes. Evidence for the Phenoxonium Ion Mechanism

ULF PALMQUIST,[a] ALVIN RONLÁN*,[a] and VERNON D. PARKER[b]

[a] Organic Chemistry 2, Chemical Center, The Lund Institute of Technology, P.O. Box 740, S-220 07 Lund 7, Sweden and [b] Department of General and Organic Chemistry, The H. C. Ørsted Institute, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark

Spirodienones (cyclohexa-2,5-dienone derivatives like V) are important in biosynthesis and occur widely in nature.[1] Biosynthetically they are believed to be formed *via* coupling of a diphenolic precursor.[1] However, attempts to make spirodienones *in vitro* by oxidation of diphenols with conventional reagents have generally been unsuccessful,[1] probably due to the inability of these reagents to oxidize both phenolic moieties of the diphenol simultaneously and because free phenoxy radicals are involved in these reactions. Recently, spirodienones have been obtained from diphenolic precursors by using a vanadium oxytrichloride reagent[2] or a ferric chloride dimethylformamide complex,[3] which are able to oxidize both phenolic moieties simultaneously.

In a previous communication [4] we demonstrated that phenoxonium ions derived from hindered phenols by anodic oxidation react with anisole to give 4-(*p*-anisyl)-cyclohexa-2,5-dienones in high yield. We now report an application of the same principle to intramolecular cyclization of diarylpropanes, which gives spirodienones in high yield, and present evidence for the involvement of phenoxonium ions.

Phenols are more easily oxidized than the corresponding methyl ethers. Oxidation at the potential of the first oxidation stage of I (R = H) therefore occurs in the phenolic group without competition from oxidation of the other ring. The initial electron transfer produces the acidic cation radical (II) which deprotonates instantaneously in neutral or basic media.

In principle the cation radical (II) could also dimerize or cyclize (*via* electrophilic attack on the ether moiety or I). An investigation of the anodic oxidation of the methyl ether of I (R = OMe) has shown [5] that the stereochemistry of the diarylpropanes is in fact very favourable for the latter kind of reaction. However, on the basis of the following argument we believe that reactions other than deprotonation of the cation radical II can be ruled out. Electronically, 3-methylanisole and *p*-cresol are very similar and therefore would be expected to have similar oxidation potentials. Thus the observed difference in peak potentials (= 0.4 V)[4,8] must depend on a very rapid deprotonation of the *p*-cresol cation radical (the pK of cation radicals derived from monohydric phenols is about −5 (Ref. 6)). The deprotonation rate can be estimated [7] to be at least 10^7 times faster than dimerization of the *p*-cresol or 3-methylanisole cation radical (assuming that these two species have similar rates of dimerization). The potential of the first oxidation stage of I (R = H) is 1.30 V (standard calomel electrode) just as for *p*-cresol. This means that if cyclization is the preferred reaction for II it should be 10^7 times faster than dimerization of the *p*-cresol cation radical which is improbable (by analogy with phenol ethers,[8] we believe that the most likely reaction (next to deprotonation) of cation radicals derived from phenols is dimerization).

Any chemical reaction following electron transfer must then involve either the radical III or the phenoxonium ion IV. Reactions in which phenoxy radicals participate generally result in a mixture of products due to the delocalisation of the unshared electron over the oxygen atom and the carbon atoms of the ring. On the other hand, the positive charge of the phenoxonium ion is concentrated in the ring,[9] favouring reactions with bond formation to carbon. Thus, controlled anodic conditions ensure that the phenolic part of the molecule undergoes oxidation and an analysis of the products formed will distinguish between the phenoxonium ion and the phenoxy radical mechanisms.

The anodic oxidation of I (R = H) (0.1 mmol) in acetonitrile (50 ml) containing sodium perchlorate (0.1 M) and sodium carbonate (1 g) in a three compartment cell was monitored by peak voltammetry during constant current coulometry.[10] Precisely 2.0 Faradays per mol of I (R = H) were consumed during exhaustive electrolysis. When the oxidation was complete, the sodium carbonate was filtered off. For analysis of the product, trifluoroacetic acid (TFA) (5 ml) was added to the electrolysis mixture to convert the electro-inactive spirodienone (V, R = H) to the corresponding phenol (VII, R = H). The reaction was monitored by the appearance of an oxidation peak at 0.95 V and was complete in less than 30 min at room temperature. The height of the oxidation peak at 0.95 V indicated that the overall result of the reaction was quantitative conversion of V (R = H) to VII (R = H).

A series of preparative experiments were carried out, and the results are shown in Table 1. The formation of the compound VI represents an interesting electrochemical analogy (the reduction step in this transformation takes place at the cathode of the undivided cell) to the dienone-benzene rearrangement which is frequently encountered in alkaloid biosynthesis.[12]

While it is clear that only the phenolic ring undergoes oxidation in the case of I (R = H)

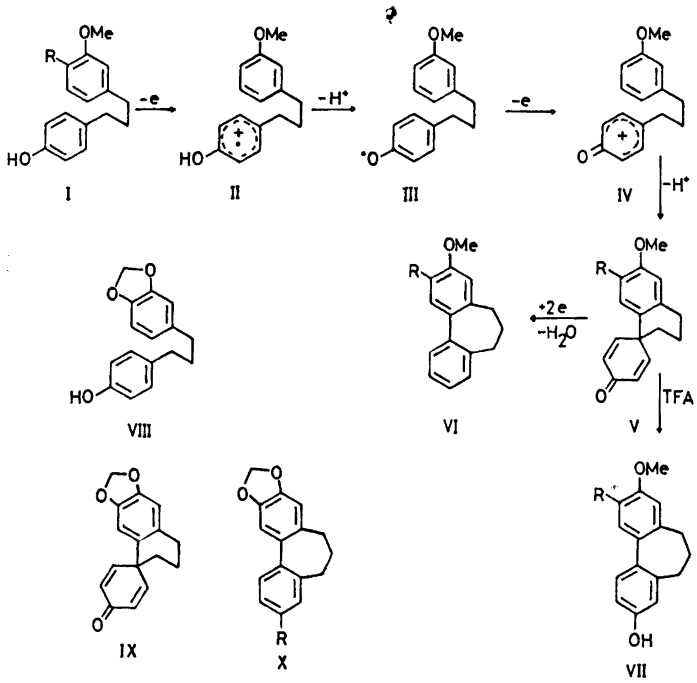

Table 1. Anodic oxidation of various diarylpropanes on a platinum anode in acetonitrile.[a]

Substrate	Products, yield (%)	TFA[b] → Phenol
I (R=H)	VI (R=H) (17): V (R=H) (68)	VII (R=H)[c]
I (R=OMe)	VI (R=OMe) (20); V (R=OMe) (73)	VII (R=OMe)[c]
VIII[d]	X (R=H) (21); IX (75)	X (R=OH)[c]

[a] These oxidations were carried out in an undivided cell (nickel cathode) on 2 mmol [0.2 mmol in case of I (R=H)] of substrate in acetonitrile (100 ml) containing sodium perchlorate (0.1 M). The potential was controlled at 1.25 V and the electrolysis was interrupted when 2 Faradays per mol of substrate had been passed. The products were isolated by chromatography on alumina and characterized by their NMR, mass spectrum and elemental analysis. [b] Compound obtained by treatment of the spirodienone with TFA. [c] Identified as its methyl ether by comparison with an authentic sample obtained from anodic coupling of the corresponding methoxylated diarylpropane.[5] [d] This compound has been oxidized to IX in 87 % yield with thallium trifluoroacetate.[11]

the same cannot be said with certainty for the oxidation of I (R=OMe) or of VIII since the additional ether group in these compounds lowers the oxidation potential of the second ring and it is expected that both aryl groups should undergo oxidation at about the same potential. Thus a dication diradical mechanism similar to that demonstrated for the anodic cyclization of methoxybibenzyls [13] cannot be ruled out for these reactions.

The absence of intermolecular coupling products and products involving carbon-oxygen bond formation from the oxidation of I (R=H) shows that the radical III is oxidized anodically as soon as it is formed. The nature of the products obtained (V and VI) strongly suggests that the phenoxonium ion IV is the result of this oxidation.

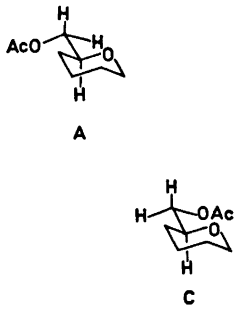
Molecular Structure of Methyl 6-*O*-Acetyl-β-D-glucopyranoside

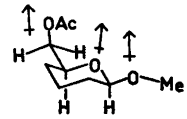
PER J. GAREGG,[a] K. BÖRJE LINDBERG[b] and CARL-GUNNAR SWAHN[a]

[a]Department of Organic Chemistry and [b]Department of Structural Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

In our attempts to correlate the circular dichroism of glycoside acetates with molecular geometry, we find that the single, negative CD band observed for methyl 6-*O*-acetyl-β-D-glucopyranoside is best explained by assuming that rotamer C predominates in ethanol solution.

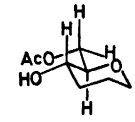


This contrasts with the results obtained for the corresponding α-anomer, for which a double CD band was observed, and which led to the suggestion that both rotamers B and C contributed to the observed CD. We suggested that for the β-anomer an unfavourable dipolar interaction for rotamer B would lead to the presence of



rotamer C only. Since this interaction is absent in the corresponding α-anomer, both rotamers B and C can be present.[1] Lemieux and coworkers have suggested, on the basis of NMR studies, as well as from considerations of optical rotation, that for D-*erythro*-hexopyranosides, rotamer C predominates over A and B.[2,3]

We have previously reported an X-ray crystallographic study on methyl 6-*O*-acetyl-β-D-galactopyranoside.[4] This showed that in the crystalline state rotamer A predominated. In the D-*gluco* series, however, this rotamer is unimportant, due to an unfavourable 1,3 interaction.



The present study, summarized in Fig. 1 and Table 1 establishes that for methyl 6-*O*-acetyl-β-D-glucopyranoside the conformation in the crystalline state corresponds to rotamer C, in agreement with the interpretation of the results from the CD investigation. The compound crystallized in space group $P2_1$, $a = 10.201$, $b = 7.239$, $c = 7.863$, $Z = 2$. The X-ray data were obtained on a Philips PW 1100 computer-controlled single-crystal diffractometer with graphite monochromatized Cu$K\alpha$ radiation. The phase

Synthesis of Asterosterol, a Novel C_{26} Marine Sterol

PER M. BOLL

Department of Chemistry, Odense University, DK-5000 Odense, Denmark

Recently Kobayashi *et al.*[1,2] suggested structure *1a* for a new marine C_{26} sterol, asterosterol, isolated from several asteroids [3] and stated [1] that they had synthesized a 22-*cis* and -*trans* mixture of 24-*nor*-cholesta-7,22-dien-3β-ol, resistant to separation. Through the investigation of the sterol components of the marine sponge *Halicondria panicea* we have now found the same sterol present as a minor component.

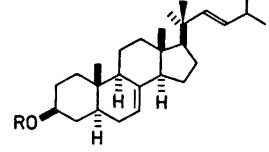
Synthesis of Asterosterol, a Novel C_{26} Marine Sterol

PER M. BOLL

Department of Chemistry, Odense University, DK-5000 Odense, Denmark

Recently Kobayashi *et al.*[1,2] suggested structure *1a* for a new marine C_{26} sterol, asterosterol, isolated from several asteroids [3] and stated [1] that they had synthesized a 22-*cis* and -*trans* mixture of 24-*nor*-cholesta-7,22-dien-3β-ol, resistant to separation. Through the investigation of the sterol components of the marine sponge *Halicondria panicea* we have now found the same sterol present as a minor component.

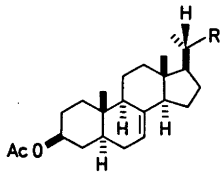


1a : R = H
1b : R = Ac

Due to the uncertainties associated with the stereochemistry at C-20 as well as the biogenetic novelty of the sidechain structure a final proof

of structure was desirable and a partial synthesis of asterosterol from 5α,6-dihydroergosterol has been developed.

5α,6-Dihydroergosterol acetate (*2b*) was ozonized at −70° in methylene chloride in the presence of pyridine followed by reductive work-up (Zn-AcOH). Preparative layer chromatography (hexane-ethyl acetate 9:1) gave 19 % unchanged starting material (*2b*) and 28 % of the pure aldehyde (*2a*) which showed, in the



2a : R = CHO
2b : R = trans-CH:CH·CHEt·CHMe$_2$

NMR spectrum,* the aldehyde proton as a doublet at 9.54 ppm. Acid work-up gives according to Barton *et al.*[4] an epimerized product with the aldehyde proton as two doublets at 9.55 and 9.60 ppm in the ratio of 4:1. Wittig reaction of the (20*S*)-aldehyde with isobutyltriphenylphosphonium bromide (butyllithium, heptane-ether 3:1) gave 46 % of the acetates of 22-*trans*-24-*nor*-5α-cholesta-7,22-dien-3β-ol (*1b*) and its 22-*cis*-isomer in the proportions 1:5. The separation of the two isomers was accomplished by TLC in hexane-benzene (3:1) on SiO_2-20 % $AgNO_3$.

The NMR spectrum of the synthetic 22-*trans*-isomer (*1b*), m.p. 171 − 173°, $[\alpha]_D^{25}$ −21.0° (lit.[2] m.p. 134 − 136.5°, $[\alpha]_D$ −2.8°), showed signals of 18-H_3 (δ 0.533, s), 19-H_3 (0.803, s), 26,27-H_6 (0.903, d, *J* 6.7), 21-H_3 (1.01, d, *J* 6.7), acetyl (2.00), 3-H (4.67, m) and 7-H, 22-H and 23-H (5.14, ill-defined). All NMR values were within the experimental error of those reported by Kobayashi *et al.*[2] The mass spectrum of the synthetic compound (*1b*) was identical with that published [2] and the IR spectrum, also as reported, was superimposable on that of 5α,6-dihydroergosterol acetate including the finger print region and showed absorption at 965 cm^{-1} (*trans*-disubstituted sidechain double bond). Hydrolysis of *1b* gave *1a* as needles from MeOH, m.p. 171 − 172°, $[\alpha]_D^{25}$ −23.9°, which displayed physical constants distinctly different from those reported (lit.[2] 129 − 130°, $[\alpha]_D \pm 0°$). Even taken into consideration the discrepancies in m.p. and specific rotation, the synthesis just reported clearly indicates that the structure assigned to asterosterol by Kobayashi *et al.*[2] is correct.

* Chloroform was used for NMR and optical rotation measurements. IR spectra were measured in KBr. All new compounds gave correct analyses.

The synthetic sterol acetate (*1b*) was identical with the acetylated natural material isolated from *Halicondria panicea*.

The mass spectrum of the 22-*cis* C_{26} sterol acetate, m.p. 145 − 145.5°, $[\alpha]_D^{25}$ −31.3°, showed the expected molecular ion at *m/e* 412. The fragmentation was the same as that of *1b*, also with respect to the side chain-fragments. The IR spectrum is in agreement with the *cis*-structure (766 cm^{-1}). The only differences observed between the NMR spectra of *1b* and its *cis*-isomer are related to 18-H_3 (0.559), 21-H_3 (0.969, d, *J* 6.4), 26, 27-H_6 (0.927, d, *J* 6.4), 22-H and 23-H (AB, 4.95, 5.07, *J* 2.1). Hydrolysis gave the free sterol, m.p. 137 − 138.5°, $[\alpha]_D^{25}$ −35.9°.

Reduction (H_2-Pd) of *1b* or its isomer leads to the same compound, the corresponding stanol, m.p. 129 − 134°, $[\alpha]_D^{25}$ +8.6° (lit.[5] 128 − 135°). The observed differences in the rotatory powers of *1b* and its isomer are thus related to the stereochemistry at C-22 and C-23.

Acknowledgement. The author is grateful to Dr. E. Caspi for helpful discussions during this work, which was carried out at the Worcester Foundation of Experimental Biology, Shrewsbury, Mass. He is also thankful to the Worcester Foundation and the Danish Science Research Council for support.

Synthesis of 11,11′-Deuterated ε-Carotene and Lycopene

ÅSE EIDEM and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034-Trondheim-NTH, Norway

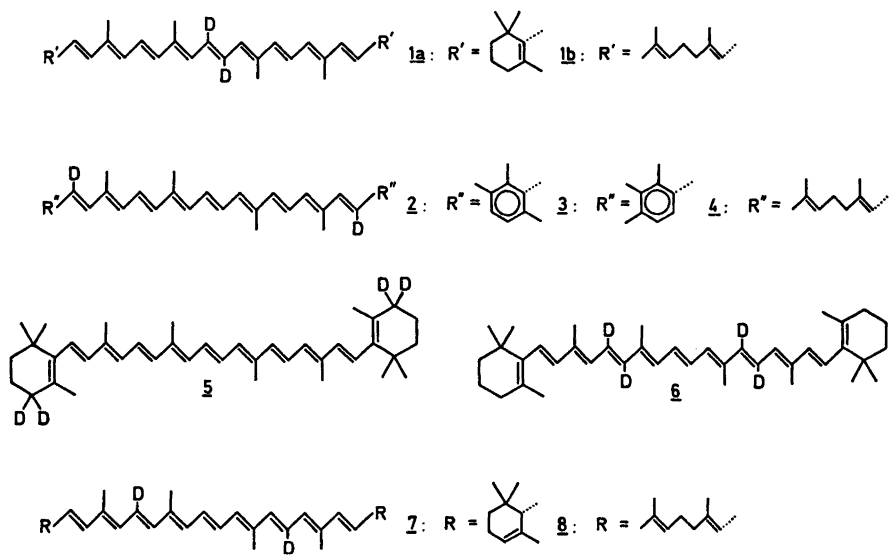
The synthesis of 11,11′-deuterated ε-carotene (*7*) and 11,11′-deuterated lycopene (*8*) by a combination of routes previously used for the unlabelled carotenes, are reported.

The deuterium was introduced by lithium aluminium deuteride reduction of the intermediate C_{15}-esters (*10* and *15*).

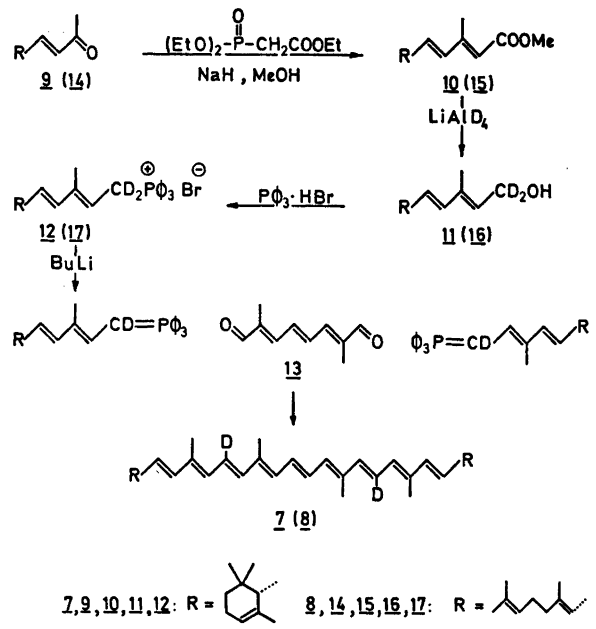
Specifically deuterated carotenes are of special interest for a systematic study of the electron impact induced fragmentation of carotenoids.

The preparation of only few specifically deuterated carotenes has been reported. Schwieter *et al.*[1] have synthesized 15,15′-dideuterio-β,β-carotene (*1a*, Scheme 1) and 15,15′-dideuterio-lycopene (*1b*) by selective deuteration of the acetylenic analogues. Some 7,7′-deuterated carotenes (*2,3,4*) have been previously prepared by our group,[2] the deuterium atoms being introduced by lithium aluminium deuteride reduction of intermediate C_{10}-carboxylic acids. More recently the partial synthesis of 4,4′-tetradeuterio-β-carotene (*5*) from canthaxanthin by reduction with lithium aluminium deuteride in the presence of aluminium chloride has been described by Brzezinka.[3] The same author also prepared 11,12,11′,12′-tetradeuterio-β-carotene (*6*) by total synthesis; in principle by selective deuteration of an acetylenic intermediate.

We now report the synthesis of 11,11′-deuterated ε-carotene (*7*) and 11,11′-deuterated lycopene (*8*).



Scheme 1.



Scheme 2.

RESULTS AND DISCUSSION

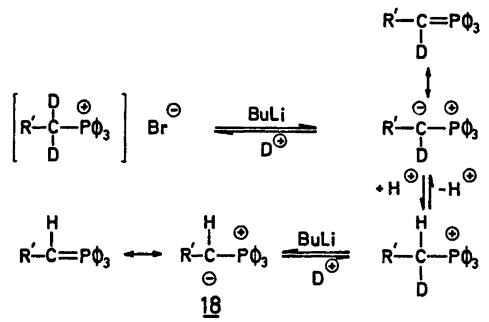
The route employed, given in Scheme 2, was based on a combination of the routes previously described by Weedon and co-workers [4] for undeuterated ε-carotene by a $C_{15}+C_{10}+C_{15}=C_{40}$ approach.

Racemic α-ionone (*9*) was condensed in a Horner reaction with the carbanion of ethyl diethylphosphonoacetate, obtained with sodium hydride, to the C_{15}-ester (*10*). The C_{15}-ester (*10*) was reduced with lithium aluminium deuteride to the allylic alcohol (*11*), which was converted to the corresponding phosphonium salt (*12*) with triphenylphosphine hydrobromide. In the final Wittig reaction the ylid of the phosphonium salt (*12*) was reacted with C_{10}-dial (*13*) to give 11,11′-deuterated ε-carotene (*7*).

Pseudo-ionone (*14*) gave 11,11′-deuterated lycopene (*8*) by the same route *via* *15*, *16* and *17*.

On first attempt the deuterium incorporation was low in ε-carotene. According to the PMR-spectra the allylic alcohol (*11*) as well as the phosphonium salt (*12*) had complete deuterium incorporation. The ylid formation and/or subsequent condensation consequently represented the crucial steps.

According to the accepted mechanism of ylid formation,[5a] given in Scheme 3, deuterium-hydrogen exchange of the ylid is expected to occur in protic media, resulting in unlabelled ylid (*18*).



Scheme 3.

Using diethyl ether, dried over metallic sodium and distilled over lithium aluminium hydride, the following incorporation was obtained: 11,11′-deuterated ε-carotene (*7*), 87 % deuterium incorporation, $D_0:D_1:D_2=3:23:76$ and for 11,11′-deuterated lycopene (*8*), 80 % deuterium incorporation, $D_0:D_1:D_2=8:25:67$, judged by the intensity of the molecular ions observed on electron impact. Percentage deuteration

reflects average number of deuterium atoms incorporated relative to the theoretically possible incorporation. The ratio of deuterated species is calculated as in previous work,[2] taking into account ^{13}C isotope contributions, *cf.* Ref. 5b.

The deuterated carotenes were characterized by means of electronic spectra, IR-spectra, and mass spectra (*7* and *8*) and PMR-spectrum (*7*), melting points and chromatographic behaviour. Undeuterated ε-carotene was prepared for comparison. Mixed melting points of the deuterated carotenes (*7* and *8*) with the corresponding undeuterated carotenes gave no depression. No chromatographic separation from undeuterated analogs was obtained. The deuterium incorporation, judged from mass spectra, was retained on chromatography and recrystallization. Extinction coefficients lower than predicted[4,6] are ascribed to sterically inhomogeneous products (*cis* and *trans*).

The mass-spectrometric results will be discussed separately in a communication also comprising other deuterated carotenes.[7]

EXPERIMENTAL PART

Materials and methods were as generally used in this laboratory.[2] For column chromatography neutral alumina activity grade 2 was used. Only diagnostically useful spectroscopic properties of the intermediates are quoted.

Methyl α-ionylideneacetate (*10*) was prepared from α-ionone (*9*, 4 g) and ethyl diethylphosphonoacetate (4.5 g) by the procedure of Manchand *et al.*[4] Column chromatography on alumina (eluent pet.ether) gave a mixture of *10* (*ca.* 80 %) and the ethyl ester (*ca.* 20 %); yield 6.2 g (70 %); τ ($CDCl_3$) 9.17 s and 9.08 s (*gem.* dimethyl), 8.42 s (ring methyl), 7.71 s (on-chain methyl), 6.33 s (ester methyl), 8.72 t and 5.8 q (ester ethyl) and olefinic signals; used without further purification.

Deuterated α-ionylidene-ethanol (*11*) was prepared by adding dropwise a suspension of $LiAlD_4$ (0.5 g) in anhydrous ether (25 ml) to *10* (4.0 g) in anhydrous ether at 0°C. After 1 h excess reagent was destroyed with ethyl acetate (2 ml) and the reaction mixture poured on ice and 1 N H_2SO_4. *11* was extracted with ether in the usual manner; yield 3.0 g (90 %) *11*; τ ($CDCl_3$) 9.17 s and 9.08 s (*gem.* dimethyl), 8.42 s (ring methyl), 8.20 s (on-chain methyl), and 4.8 – 3.8 (olefinic protons), but no signal at τ 5.73; used without further purification.

The undeuterated analogue was similarly prepared using $LiAlH_4$; yield 3.1 g (90 %); τ ($CDCl_3$) as for *11* above and 5.73 d ($J = 7$ cps, CH_2OH).

Deuterated α-ionylidene-ethyltriphenylphosphonium bromide (*12*). *11* (2.0 g) and triphenylphosphonium bromide (2.3 g) in dry methanol (30 ml) was kept at room temperature for 56 h. The solvent was removed under vacuum, and the residue washed with water. The crude, colourless solid *12*, yield 3.5 g (81 %); τ ($CDCl_3$) 9.23 s and 9.13 s (*gem.* dimethyl), 2.5 – 2 (aromatic protons), no signals at τ 6 – 5 for CH_2P; was used without further purification.

The undeuterated phosphonium salt was similarly prepared from undeuterated α-ionylidene-ethanol; yield 3.8 g (88 %); τ ($CDCl_3$) 9.23 s and 9.13 s (*gem.* dimethyl), 6 – 5 m (CH_2P), 2.5 – 2 (aromatic protons).

2,7-Dimethylocta-2,4,6-trienedial[8] (*13*). 2,7-Dimethylocta-2,6-dien-4-ynedial (1.0 g) in ethyl acetate (50 ml) was hydrogenated in the presence of Lindlar catalyst (0.7 g) until one equivalent of hydrogen was absorbed. The catalyst was removed by filtration and the solvent evaporated. Recrystallization from methanol gave *cis* and *trans* *13* (0.5 g, 50 %); λ_{max} (methanol) 323 nm; τ ($CDCl_3$) 8.05 s (6H, methyl), 3.3 – 2.5 m (4H, olefinic), 0.35 s (2H, aldehydic).

11,11'-Deuterated ε-carotene (*7*). To a suspension of *12* (920 mg) in anhydrous ether (75 ml, dried over Na and distilled over $LiAlH_4$) was added dropwise a 1 N solution of BuLi in anhydrous ether until the red phosphorane was prepared. Excess BuLi was destroyed by addition of CH_2Cl_2 (3 ml). C_{10}-dial (*13*, 124 mg) in CH_2Cl_2 (10 ml) was added dropwise and the reaction mixture left at room temperature over night. The solvent was removed and the residue dissolved in 90 % aqueous methanol. The pigments were transferred to pet. ether in the usual manner, chromatographed on alumina (eluent pet. ether) and *7* crystallized and recrystallized from benzene-methanol; yield 25 mg (10 %); m.p. 194 – 196°C, undepressed on admixture with undeuterated ε-carotene of m.p. 189 – 190°C; $R_F = 0.83$ (alumina paper, petroleum ether, no separation from undeuterated ε-carotene; λ_{max} (pet. ether) 413, 437 ($E_{1\%,1cm} = 2600$) and 467 nm, % III/II[9] = 93; ν_{max} (KBr) 3030, 2960, 2920, and 2860 (CH), 1450 and 1435 (CH_2), 1385, 1375 and 1365 (methyl, *gem.* dimethyl) 1270, 1215, 1080, 1030, 1015, 965 (*trans* disubst. double bonds), 920 (medium, *trans*-CD=CH–, see Ref. 10), 825 (trisubst. double bonds), 800 and 730 cm^{-1}; τ ($CDCl_3$) 9.17 s and 9.08 s (12 H, *gem.* dimethyl), 8.42 s (6 H, 18,18'-methyl), 8.10 s (6 H, 19,19'-methyl), 8.05 s (6 H, 20,20'-methyl) and 4.6 – 3.0 m (olefinic protons); *m/e* 538 (MD_2), 537 (MD_1), 536 (MD_0), 482 ($MD_2 - 56$), 446 ($MD_2 - 92$), 445 ($MD_2 - 93$), 431 ($MD_2 - 107$), 379 ($MD_2 - 159$) with intensity ratios ($MD_2 - 92$):($MD_2 - 93$):($MD_2 - 94$) = 37:63:0, ($MD_2 - 106$):($MD_2 - 107$):($MD_2 - 108$) = 0:100:0, ($MD_2 - 158$):($MD_2 - 159$):($MD_2 - 160$) = 0:100:0; MD_0:MD_1:MD_2 = 3:23:74; 86 % deuterium incorporation.

Undeuterated ε-carotene was prepared in the

corresponding manner from the undeuterated phosphonium salt; yield 60 mg (17 %); m.p. 189 – 190°C; λ_{max} (pet. ether) 413, 437 ($E_{1\%,1cm}$ = 2400) and 467 nm, % III/II = 87, spectrum conform with that of *7*; ν_{max} (KBr) close to those of *7*, but band at 920 cm^{-1} absent; τ ($CDCl_3$) 9.17 s and 9.08 s (12H, *gem*.dimethyl), 8.42 s (6 H, 18,18′-methyl), 8.08 s (19,19′-methyl), 8.04 s (20,20′-methyl) and 4.6 – 3.0 m (olefinic protons); *m/e* 536 (M), 480 (M – 56), 444 (M – 92), 430 (M – 106), 388 (M – 56 – 92), 378 (M – 158) with intensity ratio (M – 92):(M – 106) = 8.9.

Methyl ψ-ionylideneacetate (*15*) was prepared from *14* (4 g) by the same procedure as for *9*; yield 6.5 g (87 %) of a mixture of the methyl ester *15* (*ca.* 75 %) and the ethyl ester (*ca.* 25 %); τ ($CDCl_3$) 8.39 s and 8.32 s (isopropylidene methyl), 8.19 s (end-of-chain methyl), 7.68 s (in-chain methyl), 6.34 s (ester methyl), 8.72 t and 5.85 q (ester ethyl), 5 – 2 m (olefinic protons); used without further purification.

Deuterated ψ-ionylidene-ethanol (*16*) was prepared from *14* (4 g) by the same procedure as *11* above, avoiding work-up in the presence of H_2SO_4; yield 2.5 g (74 %); τ ($CDCl_3$) 8.40 s and 8.32 s (isopropylidene methyl), 8.20 s and 8.12 s (on-chain methyl) and 5.0 – 2.5 (olefinic protons), but no signal at τ 5.7 for CH_2OH.

Deuterated ψ-ionylidene-ethyltriphenylphosphonium bromide (*17*) was prepared by the same procedure as *12* above. *16* (2.0 g) gave *17* (3.7 g) as a solid; τ ($CDCl_3$) 8.40 s and 8.32 s (isopropylidene methyl), 8.26 (end-of-chain methyl), 4.9 (isopropylidene H), 4.5 – 3.8 (olefinic protons) and 2.5 – 2 (aromatic protons); used without further purification.

11,11′-Deuterated lycopene (*8*). The same procedure as for *7* was used. *13* (40 mg) and *17* (273 mg) gave *8* (*cis*+*trans*, 5 mg, yield 4 %); m.p. 167 – 169°C, undepressed on admixture with undeuterated lycopene of m.p. 172°C; R_F = 0.50 (alumina paper, 1 % acetone in pet.ether); λ_{max} (pet.ether) 440, 468 and 500 nm; *m/e* 538 (MD_2), 537 (MD_1), 536 (MD_0), 469 ($MD_2 - 69$), 446 ($MD_2 - 92$), 445 ($MD_2 - 93$), 431 ($MD_2 - 107$), 379 ($MD_2 - 159$) with intensity ratios ($MD_2 - 92$):($MD_2 - 93$):($MD_2 - 94$) = 38:62:0, ($MD_2 - 106$):($MD_2 - 107$):($MD_2 - 108$) = 0:100:0 and ($MD_2 - 158$):($MD_2 - 159$):($MD_2 - 160$) = 0:100:0; MD_0:MD_1: MD_2 = 8:25:67, 80 % deuterium incorporation. Synthetic undeuterated lycopene (Roche) recorded for comparison had λ_{max} (pet.ether) 462, 470, and 502 nm; *m/e* 536 (M), 467 (M – 69), 444 (M – 92), 430 (M – 106), 399 (M – 137), 378 (M – 158).

Acknowledgements. Undeuterated lycopene, 2,7-dimethylocta-2,6-dien-4-ynedial and Lindlar catalyst were gifts from Hoffmann-La Roche, Basel and Nutley. Å. E. was partly supported by a grant from the Norwegian Research Council of Science and Humatities to S.L.J.

Intestinal Glycoproteins of Germfree Rats. III. Characterization of a Water-soluble Glycoprotein Fraction*

JENS K. WOLD,[a] TORE MIDTVEDT [b] and ROGER W. JEANLOZ [c]

[a] Institute of Pharmacy, University of Oslo, Oslo 3, [b] Kaptein W. Wilhelmsen og Frues Bakteriologiske Institutt, Rikshospitalet, Oslo 1 and [c] Laboratory for Carbohydrate Research, Departments of Biological Chemistry and Medicine, Harvard Medical School and Massachusetts General Hospital, Boston, Mass. 02114, U.S.A.

A water-soluble glycoprotein fraction was obtained by fractionation of crude intestinal or fecal extracts from germfree rats. This procedure involved proteolytic digestion with pronase, precipitation of the acidic glycoprotein with cetyltrimethylammonium bromide (CTAB), and chromatography on DEAE-Sephadex and on Sepharose 4 B. The purified fractions obtained from intestinal and fecal material, respectively, were very similar in chemical composition and properties. The mucin-type glycoprotein contained 23 % of galactose, 8.6 % of fucose, 18.6 % of *N*-acetylgalactosamine, 18.2 % of *N*-acetylglucosamine, 13.5 % of sialic acid, 1.3 % of sulphate groups, and *ca.* 15 % of amino acids of which threonine, serine, and proline were the predominant ones. The results of gel electrophoresis and of sedimentation equilibrium indicated some polydispersity, consistent with previous findings for mucin glycoproteins. Incubation of the glycoprotein with a neuraminidase from *Clostridium perfringens* removed 57 % of the sialic acid, and an α-(1→2)-L-fucosidase isolated from the same bacterium released 71 % of the fucose residues. The glycoprotein was shown to possess blood-group A and H activity but was virtually free of B activity.

The epithelial surface of the mammalian intestinal tract is protected by a flowing layer of mucus continuously produced by secretory cells of the intestinal mucosa. This viscous layer not only serves as a mechanical protective barrier, but also contributes to maintain a relatively constant pH and ion concentration in the environment of the tender microvilli.

The intestinal mucin secretions are extensively degraded by the microflora of the digestive tract,[1,2] a fact which complicates the isolation and the study of the native product. Furthermore, mucin-containing extracts from mucosal scrapings and especially from intestinal contents are contaminated with other high-molecular-weight components. But, despite the difficulty in obtaining pure and undegraded mucin preparations, it has been demonstrated that mammalian intestinal mucins are composed of glycoproteins [3,4] that contain, like other glycoproteins obtained from mammalian mucins, carbohydrate residues linked by an *N*-acetylgalactosamine residue to serine and threonine residues in the polypeptide chain.[5]

By the use of animals devoid of any microflora in the digestive tract it is possible to obtain the intestinal glycoprotein in a yield better than that obtained from conventional animals. In addition, feeding the animals an entirely synthetic diet [6] consisting only of low-molecular-weight substances reduces the amount of exogenous macromolecules in the intestinal contents, *e.g.* from food components, to an insignificant level. Under germfree conditions one might expect the intestinal mucin to pass essentially unaltered through the digestive tract, which results in an excretory fecal mucin of a composition similar to the intestinal one. The present report describes the purification and characterization of a water-soluble, intestinal glycoprotein fraction and a corresponding fecal glycoprotein fraction, obtained from germfree rats fed a chemically defined diet.

* Part II. See Ref. 7.

RESULTS

The successive steps of the purification procedure are given in Fig. 1. The water-soluble, non-dialysable extract initially obtained,[6] still contained lipid material that was removed by exhaustive extraction with chloroform-methanol mixtures. This treatment was found to facilitate the subsequent fractionation steps. Incubation with pronase resulted in the degradation of contaminating protein, whereas the mucin appeared unaffected by the proteolysis since no retardation of the major carbohydrate-containing material was observed by gel chromatography on Sepharose 4 B, as compared with the non-proteolysed material. Addition of cetyltrimethylammonium bromide (CTAB) to a solution of the pronase-treated, non-dialysable fraction precipitated a large proportion of the mucin glycoprotein, leaving less acidic material in solution. This step removed most of the pentose-containing glycan which is thought to stem from previously given diet.[7] After dissociation of the methanol-soluble, CTAB-glycoprotein complex, the recovered material was subjected to chromatography on DEAE-Sephadex A 25 and, finally, on Sepharose 4 B (Figs. 2 and 3).

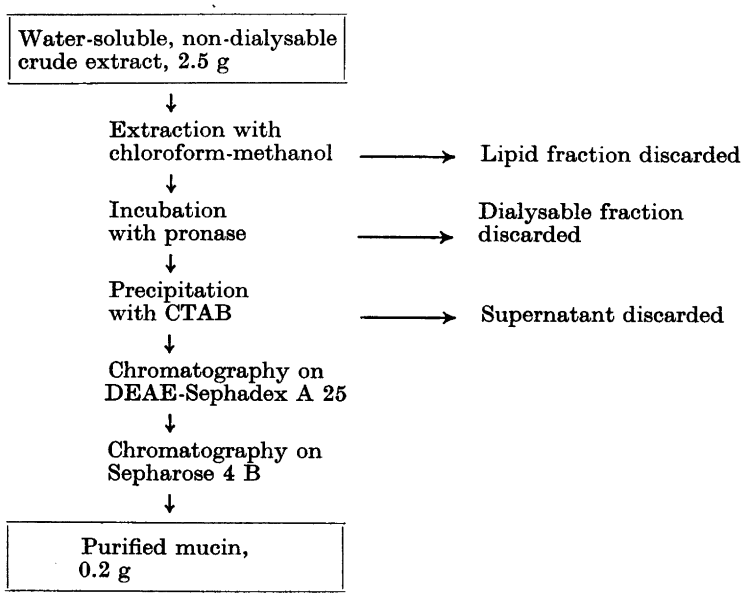

Fig. 1. Schematic diagram of the purification of germfree rat intestinal mucin.

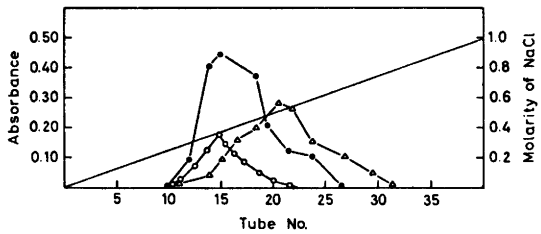

Fig. 2. Chromatography on DEAE-Sephadex A 25 of the material precipitated by CTAB. Effluent fractions were analysed for neutral sugar (●), sialic acid(○), and protein (△). Fractions 11 to 19 were pooled, concentrated, and subjected to gel chromatography on Sepharose 4 B. Experimental details are given in the text.

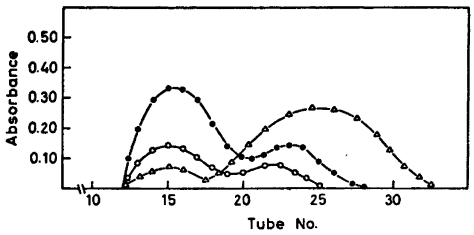

Fig. 3. Chromatography on Sepharose 4 B of fractions 11 to 19 from the DEAE-Sephadex column (Fig. 2). The effluent was analysed for neutral sugar (●), sialic acid (○), and protein (△). Fractions 13 to 17 were pooled, dialysed and lyophilized. Experimental details are given in the text.

The front peak eluted from the Sepharose 4 B column (Fractions 13 – 17) contained the purified glycoprotein; its carbohydrate composition and sulphate content are given in Table 1 and its amino acid composition in Table 2. The second peak obtained from the Sepharose column (Fractions 20 – 25) contained, in addition to the sugars present in the first peak (Table 1), mannose *ca.* 1 %, and smaller amounts of arabinose and xylose. The supernatant solution left after the precipitation with CTAB also contained glycoprotein material that could be recovered by chromatography on Sepharose 4 B, the glycoprotein fraction appearing in the front peak. It had a carbohydrate and amino acid composition similar to that of the purified glycoprotein, but was less acidic and contained some mannose, arabinose, and xylose (Table 3).

The infrared spectrum of the purified glycoprotein showed absorption bands at 3400 cm^{-1} (broad, O – H stretching), at 1640 and 1540

Table 1. Carbohydrate and sulphate content of purified glycoprotein from intestinal and fecal extract.

Residues	Intestinal glycoprotein			Fecal glycoprotein

cm^{-1} (acetamido group), at 1240 cm^{-1} (S=O stretching in sulphate group), and at 820 cm^{-1} (C–O–S vibration), indicative of primary alcohol sulphate ester groups.

Gel electrophoresis of the purified glycoprotein in 2 % polyacrylamide – 0.5 % agarose or in 1 % agarose, either in the presence or the absence of sodium dodecyl sulphate, resulted in a single, broad band. At a polyacrylamide concentration of 7.5 %, the whole glycoprotein sample remained at the sample-running gel interphase, whereas a more porous gel containing 5 % polyacrylamide allowed a partial penetration of the glycoprotein into the running gel. The glycoprotein gave a strong reaction for carbohydrate with the periodic acid-Schiff reagent; it could also be detected with Toluidine Blue, owing to its content of sialic acid and sulphate residues, but no bands were revealed with Coomassie Brilliant Blue or with Amido Black under standard conditions for protein staining; this would preclude any significant protein contamination. The failure of carbohydrate-rich glycoproteins to react with protein-stain reagents in polyacrylamide and agarose gels has been observed previously.[8] Treatment of the glycoprotein with dithioerythritol in a 0.05 M Tris chloride buffer of pH 7.8 and subsequent Sepharose gel chromatography in the same buffer, with or without 7 M urea, gave no change in the usual chromatographic elution pattern. Thus, the possibility of polypeptide chains linked by disulphide bridges seems to be ruled out; this is consistent with the absence of cysteine residues in the glycoprotein. The molecular weight was estimated by determination of the sedimentation equilibrium. After the sample had been for 24 h in the ultracentrifuge, an almost straight line was obtained when log c was plotted against r^2; the extrapolation of the curve indicates a molecular weight of 550 000 dalton. After a 48 h run, the curve showed a sharp deflection towards the bottom of the cell, corresponding to a M. W. value in the 1.5 to 2 million range; however, this part of the curve is bound to indicate inaccurate molecular weights. The lower M. W.-limit value calculated after the 48 h run was 390 000. A glycoprotein sample not treated with pronase was subjected to the same procedure, and the curves obtained for the proteolysed and non-proteolysed material were very similar, both in 24 and 48 h ultracentrifuge runs, revealing no essential difference in molecular weight values.

Incubation of the glycoprotein with a *Clostridium perfringens* neuraminidase decreased the sialic acid content from 13.5 to 5.8 %; repeated treatment with the same enzyme failed to liberate any additional sialic acid. Paper chromatographic examination of the sialic acid released showed the presence of approximately equal proportions of *N*-acetyl- and *N*-glycolyl-neuraminic acid. Incubation with trypsin or renewed incubation with pronase of the neuraminidase-treated glycoprotein was followed by chromatography on Sepharose 6 B. No change of the

chromatographic elution curve was observed after proteolysis.

Treatment of the glycoprotein with a *Clostridium perfringens* α(1→2)-L-fucosidase and subsequent fractionation of the digest on Sepharose 6 B yielded a glycoprotein fraction having a fucose content of 2.5 %, a reduction from the value of 8.6 % observed for the original compound. The low-molecular-weight fraction eluted from the Sepharose column contained fucose and a minute proportion of galactose, as shown by GLC.

The glycoprotein was tested for blood-group activity by the hemagglutination-inhibition technique. At a concentration of 1 mg/ml, the glycoprotein inhibited the agglutination of human red A cells by human anti-A serum and the agglutination of human red O cells by human anti-H serum or by *Ulex europeus* H-lectin. Thus A- and H-blood-group activity was clearly demonstrated. On the other hand, the mucin had almost no inhibitory effect in the human red B cell – anti-B cell system.

DISCUSSION

Preparation and characterization of glycoproteins presents a major problem in view of the known microheterogeneity of these polymers.[9] All mucin-type glycoproteins studied so far appear to possess microheterogeneity, both with respect to molecular weight and charge, and the purification of these compounds leads to fractions comprising closely related but mostly nonidentical molecules.

The purified glycoprotein obtained (*ca.* 8 %) is only a part of the total mucin content of the original crude extract, namely the final product of the particular fractionation scheme employed. The use of a different purification procedure would probably have given fractions with compositions different from those observed. Like other mucin-type glycoproteins studied,[5,8,10] the germfree-rat intestinal glycoprotein was clearly polydisperse. It gave a broad band on gel electrophoresis and a broad peak on Sepharose 4 B gel chromatography (Fig. 3). The result of the 48 h sedimentation equilibrium experiment indicated a polydispersity greater than expected. However, aggregation may occur to some extent during prolonged periods of centrifugation and it is difficult to ascertain the effect of molecular aggregation in evaluating the polydispersity.[11]

The present study demonstrates a close similarity between the purified glycoprotein preparations of the intestinal and the fecal extracts. No difference could be observed in the chromatographic elution curves from columns of DEAE-Sephadex or Sepharose, and identical bands were obtained on gel electrophoresis. The carbohydrate and amino acid composition of the two products were strikingly similar (Table 1 and 2). These data suggest that the soluble or brush border-bound enzymes which may degrade or modify the glycoprotein during its passage through the intestinal tract had no effect, in agreement with the observation that the glycoprotein is resistant to trypsin and pronase, even after partial removal of sialic acid residues. In addition to the content of carbohydrate and protein the purified glycoprotein fractions invariably contained *ca.* 1 % of sulphate groups. Since uronic acid residues were absent, contamination with sulphate-containing polysaccharides was precluded. The infrared spectrum of the glycoprotein showed absorption bands characteristic of sulphate ester groups. The presence of a band at 820 cm^{-1} and the absence of the band at 850 cm^{-1} suggested [12] that the sulphate groups were most probably located at C-6 of the galactose or hexosamine residues. Bella and Kim [5] have recently suggested that nearly 40 % of the sulphate groups present in an acidic glycoprotein of the small intestine of the rat were *N*-linked, since they were released by mild acid hydrolysis. When the glycoprotein of the germfree rat was analysed for *N*-sulphate groups by the nitrous acid procedure [13] no such groups could be detected, in agreement with a similar observation made on a glycoprotein of dog gastric mucosa by Pamer *et al.*[14]

Repeated neuraminidase treatment released only 57 % of the total sialic acid present in the glycoprotein. The resistance to neuraminidase may possibly be due to *O*-acetyl groups at C-4 of the sialic acid residues, since Schauer and Faillard [15] have shown that the *N*-acetyl-4-*O*-acetylneuraminic acid groups of horse submaxillary glycoprotein were not split off by *Clostridium perfringens* neuraminidase. In contrast, the authors found that *N*-acetyl-7-*O*-acetyl-, *N*-acetyl-8-*O*-acetyl-, and *N*-acetyl-7,8-

di-*O*-acetylneuraminic acid residues of bovine submaxillary glycoprotein were all released by the same enzyme.

One incubation of the glycoprotein with a specific α-(1→2)-L-fucosidase [16] removed 71 % of the total fucose content. Studies on hog submaxillary [17] and gastric [18] glycoproteins have established that an α-L-fucopyranosyl residue is linked to C-2 of a β-D-galactose residue. Since a terminal *O*-α-L-fucopyranosyl-(1→2)-β-D-galactose moiety is a prerequisite for blood-group H activity, this disaccharide unit probably constitutes the nonreducing end group of, at least, some of the carbohydrate chains in the intestinal glycoprotein of the germfree rat. Further, the serological demonstration of blood-group A activity of the glycoprotein suggests also the presence of chains terminated with the sequence *O*-2-acetamido-2-deoxy-α-D-galactopyranosyl-(1→3)-[*O*-α-L-fucopyranosyl-(1→2)]-β-D-galactose.

EXPERIMENTAL

Prior to analysis, samples were dried in the presence of phosphorus pentaoxide *in vacuo;* solutions were concentrated under reduced pressure with an outside bath temperature of 35 – 40°.

Analytical methods. Quantitative carbohydrate analysis was performed by gas-liquid chromatography (GLC) on a Perkin-Elmer 900 gas chromatograph. After methanolysis the methyl glycosides were converted into the per-(trimethyl)-silyl ethers and separated on a column (150 × 0.3 cm) packed with 0.1 % OV-17 on glass beads (No. GLC 110, 120/140 mesh), as described by Reinhold.[19] Methanolysis of the mucin sample (1 mg) with *myo*-inositol (40 μg) as the internal standard was effected with 1 M hydrogen chloride in methanol (1 ml) at 85° for 20 h. For simultaneous estimation of *N*-acetyl- and *N*-glycolylneuraminic acid, methanolysis was performed with 0.5 M hydrogen chloride in methanol at 65° for 1 h. Sialic acid, free or glycosidically bound, was also estimated by the periodate-resorcinol method of Jourdian *et al.*[20] with the following modification: After the oxidation step, 0.2 ml of 0.1 M sodium arsenite was added and the solution kept for 2 – 3 min at room temperature until the brown colour had disappeared. Then the resorcinol reagent was added and the assay completed as described. The original procedure [20] led to coloured blanks and unsatisfactory reproducibility; however, conversion of the excess of periodate into iodate prior to the hydrochloric acid-resorcinol treatment resulted in colourless blanks and reproducible results.

Amino acids were estimated by GLC of the derived *N*-trifluoroacetyl 1-butyl esters on a column of 0.325 % EGA on Chromosorb W;[21] 1-butyl stearate was used as the internal standard. The glycoprotein sample (2 mg) was hydrolysed with 6 M hydrochloric acid (1 ml) at 110° for 18 – 20 h under nitrogen. After evaporation of the hydrolysate under a stream of nitrogen, the residue was dissolved in water and the insoluble material centrifuged off. The clear supernatant was concentrated to dryness, and the amino acid hydrochlorides converted into the *N*-trifluoroacetyl 1-butyl esters.[21]

Total sulphate groups were determined by the barium chloroanilate method of Spencer,[22] and *N*-sulphate groups by the method of Lagunoff and Warren.[13]

The elution of columns of DEAE-Sephadex and Sepharose was monitored by the phenol-sulphuric acid test,[23] by the method of Lowry *et al.*,[24] and by the periodate-resorcinol test [20] for neutral sugars, protein, and sialic acid, respectively.

Gel electrophoresis of glycoprotein samples (0.1 mg) was performed in 0.09 M Tris-borate buffer, pH 8.2, in 0.5 % agarose – 2 % polyacrylamide or in 1 % agarose (Agarose for electrophoresis, General Biochemicals), as described by Holden *et al.*,[8] some experiments being done in gels containing 0.1 % sodium dodecyl sulphate. In addition gels were stained with 0.2 % Toluidine Blue in 0.1 M acetic acid.[25]

Infrared spectra were recorded for glycoprotein samples (1.5 – 2 mg) in potassium bromide discs with a Perkin-Elmer Model 237 spectrophotometer.

Incubation with neuraminidase (Type V, Sigma, purified from *Clostridium perfringens*) was performed by adding 0.02 units of the enzyme to the sample (20 mg) in 0.05 M sodium acetate buffer, (5 ml) pH 5.4, and keeping the digest at 35° for 24 h under toluene. The same amount of enzyme was added and the incubation continued for 24 h. The digest was then concentrated to 1 ml, applied to a column (1.2 × 45 cm) of Sepharose 6 B and eluted with 0.01 M pyridine – acetate buffer, pH 4.8, 2 ml fractions being collected. The glycoprotein fraction was eluted in the front peak and isolated by lyophilization; the following low-molecular-weight fraction obtained was deionized by passage through a column of Dowex 50 (H^+), and the acidic eluate concentrated at room temperature. The resulting syrup was analysed by paper chromatography in the solvent system 1-butanol-1-propanol-0.1 M hydrochloric acid, 1:2:1 (v/v), and the spots were stained with the thiobarbituric acid spray reagent.[26]

Incubation with α-L-fucosidase purified from *Clostridium perfringens* was kindly performed by Dr. D. Aminoff according to the conditions of Aminoff and Furukawa.[16] The lyophilized enzyme digest (2 mg) was dissolved in 0.01 M pyridine-acetate buffer, pH 4.8, (0.3 ml), applied on a Sepharose 6 B column (1.2 × 29 cm) and

eluted with the same buffer, fractions of 1.5 ml being collected. The glycoprotein-containing front peak was dialysed and lyophilized. The material of the final, phenol-sulphuric acid-positive peak was deionized on columns of Dowex 50 (H^+) and Dowex 1 formate. The carbohydrate composition of the two products was analysed by GLC.

Incubation with trypsin (Type I, Sigma, 2 × crystallized) was performed by dissolving the sample (10 mg) in 0.05 M Tris-chloride buffer containing 0.01 M calcium chloride, pH 7.9, (2 ml) and incubating with the enzyme (0.5 mg) at 35° for 8 h. The digest was immersed briefly in a boiling water bath, applied to a Sepharose 6 B column (1.2 × 45 cm) and eluted with 0.025 M Tris-chloride buffer, pH 7.3, 2 ml fractions being collected.

For the determination of blood group activity the glycoprotein was serologically typed by its ability at a concentration of 1 mg/ml, to inhibit the agglutination of human red cells in the presence of the appropriate antiserum. In addition to human anti-H serum, *Ulex europeus* H-lectin was used as anti-H substance.

The molecular weight determination was performed by sedimentation equilibrium. The sample (4 mg), dissolved in 1 ml of 0.1 M acetate buffer, pH 5.7, was dialysed against the same buffer at 4° for 18 h. The solution was analysed by low-speed equilibrium at 3000 rpm for 48 h at 20° in a Spinco Model E analytical ultracentrifuge. Optical registration was done by a photoelectric scanner at 280 nm. The partial specific volume ($\bar{V}$, 0.64) was calculated from the carbohydrate and amino acid composition of the glycoprotein sample.

Preparation of purified glycoprotein fraction. The crude, nondialysable intestinal or fecal extract was isolated as described previously.[6] The extract (2.5 g) was stirred at room temperature for 24 h with chloroform – methanol, 2:1 (v/v), and then 1:2 (v/v), 300 ml each time. After filtration the remaining material (2.4 g) was dissolved in 0.05 M Tris – chloride buffer, pH 7.9 (300 ml) containing 0.01 M calcium chloride, and incubated with pronase (B grade, Calbiochem.) (25 mg) at 35° for 24 h under toluene. The same amount of pronase was again added and the incubation continued for a further 24 h. The resulting proteolysate was dialysed exhaustively against distilled water, concentrated, and lyophilized to yield 1.8 g. The pronase-resistant material (1.8 g) was dissolved in water (360 ml) to which an aqueous 1 % solution of CTAB (180 ml) was added slowly with stirring. The precipitate was allowed to settle for 4 h at 4°, and was then centrifuged off and dissolved in methanol (400 ml) by stirring at room temperature overnight. A small amount of undissolved dark material was centrifuged off and discarded. To dissociate the CTAB-glycoprotein complex, a solution of equimolar proportions of sodium acetate trihydrate (5.0 g) and acetic acid (2.2 g) in 50 ml of methanol was added with stirring to the clear supernatant.

The precipitated glycoprotein was centrifuged off, dissolved in water, dialysed, and recovered by lyophilization to yield 0.9 g. A portion of this material (0.45 g) dissolved in 0.05 M Tris-chloride buffer, pH 7.3, was applied to a column (2.5 × 30 cm) of DEAE-Sephadex A 25 equilibrated with the same buffer. The column was eluted with a linear gradient of sodium chloride in 0.05 M Tris buffer pH 7.3, from 0 to 1.0 M sodium chloride in a total volume of 400 ml. Fractions of 10 ml were collected and aliquots analysed for hexose, protein, and sialic acid. The fractions containing the glycoprotein (Fractions 11 to 19, Fig. 2) were pooled, dialysed, and lyophilized to afford 0.25 g. The combined fractions obtained from two separations on the DEAE-Sephadex column (0.5 g) were dissolved in 0.025 M Tris-chloride buffer, pH 7.3, and the solution was applied to a 2.5 × 80 cm column of Sepharose 4 B, and eluted with the same buffer; 8 ml fractions were collected and analysed as described for the DEAE-Sephadex column. The fractions containing the glycoprotein (Fractions 13 to 17, Fig. 3) were pooled, dialysed, and lyophilized to yield 0.2 g.

Acknowledgements. The authors are indebted to Dr. D. Aminoff for carrying out the fucosidase incubation, to Dr. T. B. Christensen for the sedimentation equilibrium analysis, and to Dr. R. Nordhagen for the hemagglutination inhibition test.

This investigation was supported in part by a U. S. Public Health Service International Postdoctoral Research Fellowship (number 1 FO 5 TW 1769 – 01) and by a research grant (AM-03564) from the National Institute of Arthritis, Metabolism, and Digestive Diseases, National Institutes of Health, U. S. Public Health Service. This is publication No. 622 of the Robert W. Lovett Memorial Group for the Study of Diseases Causing Deformities, Harvard Medical School at the Massachusetts General Hospital.

Tobacco Chemistry. 24. (9*R*)-9-Hydroxy-4-megastigmen-3-one, a New Tobacco Constituent

ARNE J. AASEN, JOSEPH R. HLUBUCEK and CURT R. ENZELL *

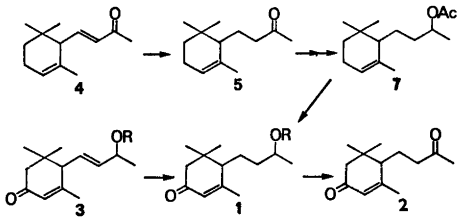
Research Department, Swedish Tobacco Co., Box 17 007, S-104 62 Stockholm, Sweden

(9*R*)-9-Hydroxy-4-megastigmen-3-one has been isolated from Greek tobacco. Its absolute configuration was determined by correlation with derivatives of (9*R*)-9-hydroxy-4,7*E*-megastigmadien-3-one.

Some time ago we reported on the presence in Greek tobacco, *Nicotiana tabacum* L., of (9*R*)-9-hydroxy-4,7*E*-megastigmadien-3-one** (*8*, R=H, 3-oxo-α-ionol),[1] the absolute configuration of which has recently been established.[2] In the present communication we discuss the absolute configuration and synthesis of a closely related compound not previously encountered in tobacco.

The new compound, $C_{13}H_{22}O_2$, was isolated as its acetate from a complex, medium volatile fraction [3] of an extract [4] of Greek tobacco. The presence of a secondary hydroxyl group was apparent from an NMR deacylation shift [5] (1.1 ppm) observed on hydrolysis, and the formation of a methyl ketone when subjecting the resulting alcohol to oxidation. The second oxygen atom is part of a β,β-disubstituted, conjugated ketone grouping judging from its UV (237 nm), IR (1667 cm^{-1}) and NMR (one-proton multiplet at δ 5.84) spectra. Spin-spin decoupling experiments revealed that the single olefinic proton is coupled to a vinylic methyl group (δ 1.99, *J* 1.4 Hz) thereby unveiling one of the β-substituents. An AB-system at δ 2.02 and 2.36 (*J* 17 Hz) ascribed to a methylene group flanked by a carbonyl group and a fully substituted carbon atom, revealed the partial structure $-C\text{-}CH_2\text{-}CO\text{-}CH=C(CH_3)-$. The above evidence, and the fact that the NMR spectrum also disclosed the presence of two non-coupled methyl groups (singlets at δ 1.03 and 1.06) made structure *1* (R=H) appear likely for this new tobacco constituent.***

Its gross structure was confirmed synthetically by comparison of the acetate *9* (R=Ac) with corresponding racemic material obtained both on selective hydrogenation of (±)-9-acetoxy-4,7*E*-megastigmadien-3-one [2] (*3*, R=Ac), and on selective hydrogenation of (±)-*trans*-α-ionone (*4*), followed by hydride reduction, acetylation, and allylic oxidation.



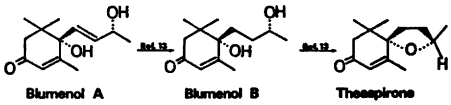
Galbraith and Horn [6] have recently isolated from *Podocarpus blumei* Endl. three structurally related compounds designated blumenol A, B, and C, the first one probably being identical to vomifoliol [9] (*Rauwolfia vomitoria*), and the last being identical to or stereoisomeric with the new tobacco compound. The structures of the blumenols were deduced from spectral data

** Nomenclature and stereochemistry as defined in Ref. 6.

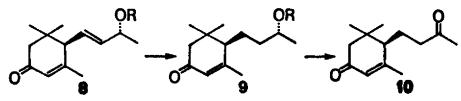
*** Dr. D. L. Roberts, R. J. Reynolds Tobacco Co., Winston-Salem, has simultaneously and independently identified *1* (R=H) as a new tobacco compound (private communication). Racemic *1* (R=H) has previously been reported as an intermediate in a synthesis of a tobacco additive, however without characterization.[7]

(molecular weight given for blumenol C, 208, is a misprint for 210; private communication), and in the cases of blumenol A and B, confirmed synthetically. Based on a comparison of the ORD curve of blumenol C with those of (+)-α-ionone [10] and lutein [11] the absolute configuration at C-6 was proposed as *R* which is consistent with the C-6(*S*) configurations of blumenols A and B very recently established chemically.[12,13]

Weiss *et al.*[13] also demonstrated chemically that the configuration at C-9 of blumenol A and B is *R* by converting (with stereospecific inversion at C-9) blumenol B into theaspirone of known absolute configuration (9*S*). However, contradictory to these results, Galbraith and Horn [12] have simultaneously suggested, on the basis of an assumed biogenetic relationship between the blumenols and theaspirone, that the absolute configuration of all the blumenols is *S* at C-9. It was therefore considered necessary to elucidate the absolute configurations of the new tobacco compound through correlation with synthetic material of known absolute stereochemistry.



The natural compound and its acetate displayed optical rotations somewhat higher than those of the corresponding material which could be prepared from (9*R*)-9-hydroxy-4,7*E*-megastigmadien-3-one (*8*, R = H, *cf.* Table 1) and it was therefore imperative to examine the two chiral centres, C-6 and C-9, separately. The absolute configuration at C-6 was established as *R* by comparison of two samples of the diketone *10* derived on the one hand from the natural product *9* (R = H) and on the other from (9*R*)-9-hydroxy-4,7*E*-megastigmadien-3-one (*8*, R = H), which both exhibited rotations of the same sign and similar magnitude (*cf.* Table 1). The somewhat lower optical activity of the latter material is presumably due to partial epimerization at C-6 during isolation which required basic conditions.



The absolute configuration at C-9 was disclosed by comparing the optical activities of the epimeric mixtures obtained after subjecting the natural alcohol *9* (R = H) and the correponding synthetic specimen obtained on hydrogenation of (9*R*)-9-hydroxy-4,7*E*-megastigmadien-3-one (*8*, R = H) to alkali treatment. Depending on the configuration at C-9, the resulting equilibrium mixtures of epimers would comprise either the 6*R*,9*R* and 6*S*,9*R* or the 6*R*,9*S* and 6*S*,9*S* isomers. Since the components of one mixture would be the enantiomers of those in the other, the equilibrium constants have to be the same in both cases, and hence, the signs of the resulting rotations would reveal whether the configuration at C-9 is *R* or *S*. The two mixtures were found to exhibit optical activities of the same sign and similar magnitude thereby establishing the absolute configuration at C-9 of the new compound as *R*, which is the same as that found by Weiss *et al.*[13] for blumenol A and B. If, as assumed previously,[12] the blumenols are biogenetically interrelated it is considered likely that blumenol C has 9*R* configuration rather

Table 1. Optical activities, [α], of specimens of the natural product (9*R*)-9-hydroxy-4-megastigmen-3-one (*9*, R = H) and its derivatives, and of corresponding authentic compounds derived from (9*R*)-9-hydroxy-4,7*E*-megastigmadien-3-one (*8*, R = H).

than 9*S* as suggested by Galbraith and Horn.[12]

The structural relationship, including absolute configurations, between the two tobacco compounds (9*R*)-9-hydroxy-4-megastigmen-3-one (*9*, R=H) and (9*R*)-9-hydroxy-4,7*E*-megastigmadien-3-one (*8*, R=H) indicates that they are biogenetically interrelated and likely to be derived from a common carotenoid precursor, *e.g.* lutein and/or α-carotene which are known tobacco carotenoids [14] possessing the same absolute configuration in the position corresponding to C-6.[10,11] The new compound *9* (R=H) might in turn be the precursor of two stereomers of 1,3,7,7-tetramethyl-2-oxa-bicyclo[4.4.0]-decan-9-one which were isolated recently from tobacco.[15] The conversion of *1* (R=H) to the latter compounds has been achieved chemically.[7]

EXPERIMENTAL

NMR, IR, UV, and mass spectra were recorded on Varian XL-100, Digilab FTS-14, Beckmann DK-2A, and LKB 9000 (70 eV) instruments, respectively. Optical activities were recorded on a Perkin-Elmer 141 polarimeter. Accurate mass determinations were carried out at the Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm.

Isolation. (9*R*)-9-Hydroxy-4-megastigmen-3-one (9, R=H) was isolated as its acetate (*9*, R=Ac, 25 mg) from a medium-volatile fraction of an extract from 295 kg Greek tobacco, *Nicotiana tabacum* L., using liquid chromatography. The sub-fractionation of this medium-volatile material will be described later.[3]

(9R)-9-Acetoxy-4-megastigmen-3-one (9, R=Ac). $[\alpha]_{20}$: see Table 1; λ_{max} (EtOH): 237 nm (ε 6940); ν_{max} (film): 2965 (s), 2940 (s), 2873 (m), 1737 (s), 1667 (s), 1376 (m), 1245 (s), 1134 (w), 1074 (w), 1023 (w), 949 (w), 896 (w), 844 (w), 671 (w), 611 (w) cm^{-1}; MS: *m/e* 252 (M^+, 30), 177 (26), 150 (35, 138 (36), 136 (33), 135 (50), 123 (24), 121 (29), 109 (29), 108 (62), 93 (42), 55 (29), 43 (100), 41 (45); accurate mass determination: $C_{15}H_{24}O_3$: Found: 252.1732, Calc.: 252.1725; δ ($CDCl_3$): 1.03 (3 H, s), 1.06 (3 H, s), 1.23 (3 H, d, *J* 6.3 Hz), 1.99 (3 H, d, *J* 1.4 Hz), 2.04 (3 H, s), 2.02 and 2.36 (2 H, AB-system, *J* 17 Hz), 4.86 (1 H, m), 5.84 (1 H, m); irradiation at δ 5.84 collapsed the doublet at δ 1.99 to a singlet.

(9R)-9-Hydroxy-4-megastigmen-3-one (9, R=H). The acetate (*9*, R=Ac, 12 mg) was dissolved in 1 % KOH/MeOH (6 ml) and left at room temperature for 2 h. The mixture was diluted with water and extracted with ether. Removal of the solvent left a colourless, TLC-pure oil (9 mg). $[\alpha]_{20}$: see Table 1; ν_{max} (film): 3420 (broad), 2967 (s), 2937 (s), 2872 (m), 1660 (s), 1419 (w), 1379 (m), 1325 (w), 1300 (m), 1258 (m), 1180 (w), 1122 (m), 1081 (w), 989 (w), 945 (w), 898 (w), 840 (w) cm^{-1}; MS: *m/e* 210 (M^+, 41), 150 (48), 135 (76), 123 (47), 109 (70), 108 (86), 95 (62), 93 (59), 69 (55), 55 (51), 45 (49), 43 (100), 41 (88); δ ($CDCl_3$): 1.02 (3 H, s), 1.07 (3 H, s), 1.20 (3 H, d, *J* 6.2 Hz), 2.0 (3 H, d, *J* 1.2 Hz), 2.01 and 2.40 (2 H, AB-system, *J* 17 Hz), 2.75 (OH), 3.76 (1 H, m), 5.83 (1 H, m).

4-Megastigmen-3,9-dione (10). The alcohol (*9*, R=H, 9 mg) was oxidised with CrO_3 to the diketone (*10*, 8 mg) employing the two-phase system described by Brown *et al.*[16] The conversion to the ketone was complete in 30 min, after which the aqueous phase was extracted with ether, washed with $NaHCO_3$, and concentrated leaving a colourless, TLC-pure oil. $[\alpha]^{20}$, see Table 1; ν_{max} (film): 2967 (s), 2938 (m), 2876 (m), 1718 (s), 1662 (s), 1441 (m), 1418 (m), 1379 (m), 1370 (m), 1291 (w), 1252 (m), 1180 (w), 1163 (w), 1121 (w), 1070 (w), 1024 (w), 971 (w), 953 (w), 869 (w), 838 (w) cm^{-1}; MS: *m/e* 208 (M^+, 40), 151 (73), 138 (25), 136 (71), 123 (31), 109 (67), 108 (31), 107 (21), 95 (40), 81 (23), 67 (23), 55 (23), 43 (100), 41 (40); δ ($CDCl_3$): 1.04 (3 H, s), 1.08 (3 H, s), 2.02 (3 H, d, *J* 1.1 Hz), 2.16 (3 H, s), *ca.* 2.28–2.57 (4 H, m), 5.85 (1 H, m), irradiation at δ 5.85 simplified the doublet at δ 2.02 to a singlet.

Preparation of (±)-9-acetoxy-4-megastigmen-3-one (1, R=Ac). (a): (±)-9-Acetoxy-4,7*E*-megastigmadien-3-one [3] (*3*, R=Ac, 60 mg) in dry dioxane (0.25 ml) was added to a suspension of Pd/C (10 %, 14 mg) in dioxane [17] (10 ml) which had been saturated with H_2. The theoretical amount of H_2 was consumed at atmospheric pressure in 40 min, after which the mixture was diluted with water, extracted with ether and concentrated. The colourless oil was chromatographed on silica gel furnishing pure acetate (*1*, R=Ac, 29 mg); its spectral data were identical to those of the acetate derived from the natural alcohol (*9*, R=H). (b): (±)-*trans*-α-Ionone (*4*, 12 g) dissolved in 0.25 N NaOH/EtOH (100 ml) was hydrogenated [18] at atmospheric pressure and room temperature using Pd/C (10 %, 250 mg) as catalyst. One equivalent of H_2 was taken up in 2.5 h after which water was added and the product (*5*, 12 g) extracted with pentane; δ ($CDCl_3$): 0.87 (3 H, s), 0.92 (3 H, s), 1.67 (3 H, d, *J* 1.0 Hz), 2.11 (3 H, s), 2.46 (2 H, t, *J* *ca.* 7 Hz), 5.33 (1 H, m). The dihydroionone (*5*, 1 g) was treated with $NaBH_4$ (300 mg) in EtOH (25 ml) for 1 h. The mixture was diluted with water and extracted with ether. Removal of the solvent left a colourless oil (6, 950 mg); δ ($CDCl_3$): 0.83 (3 H, s), 0.88 (3 H, s), 1.14 (3 H, d, *J* 6 Hz), 1.62 (3 H, d, *J* 1 Hz), *ca.* 1.9 (2 H, m), 2.6 (OH), 3.62 (1 H, m), 5.24 (1 H, m). The alcohol (*6*, 950 mg) was acetylated using acetic anhydride (1 g) in pyridine (10 ml). After 3 h at ambient temperature excess anhydride was destroyed with MeOH, diluted with aqueous sulphuric acid and extracted with ether. Removal of the solvent left the acetate (*7*, 980 mg) as a colourless oil:

δ ($CDCl_3$): 0.86 (3 H, s), 0.90 (3 H, s), 1.19 (3 H, d, J 6 Hz), 1.66 (3 H, d, J 1 Hz), 2.0 (3 H, s), 4.84 (1 H, m), 5.30 (1 H, m). The acetate (*7*, 950 mg) dissolved in acetic acid (5 ml) was added to a solution of CrO_3 (1 g) in acetic acid (15 ml) and stirred at room temperature for 3 h. Water was added and the mixture extracted with ether which was washed with $NaHCO_3$ and water. The residue obtained after distillation of the solvent was chromatogaphed on silica gel furnishing starting material (169 mg) and the ketoacetate (*1*, R=Ac, 177 mg), respectively. The spectral data of the product were indistinguishable from those of the acetate derived from the natural alcohol (9, R=H).

Preparation of (±)-9-hydroxy-4-megastigmen-3-one (1, R=H) and (±)-4-megastigmen-3,9-dione (2). The racemic acetate, prepared above, was hydrolyzed to the corresponding alcohol (*1*, R=H) which subsequently was oxidised to the diketone (*2*) as described above for the natural compound. The physical properties except for optical activity of the products *1* (R=H) and *2* were identical to those of the tobacco-isolate and its oxidation product.

Partial syntheses of (9R)-9-acetoxy-4-megastigmen-3-one (9, R=Ac), (9R)-9-hydroxy-4-megastigmen-3-one (9, R=H) and 4-megastigmen-3,9-dione (10). (9*R*)-9-hydroxy-4,7*E*-megastigmadien-3-one [3] (*8*, R=H, 93 mg) was acetylated, selectively hydrogenated, hydrolyzed, and oxidized as described above. The products were indistinguishable from the natural alcohol, its acetate and oxidation product except for having somewhat lower specific rotations; see Table 1.

Epimerization of authentic (9R)-9-hydroxy-4-megastigmen-3-one (9, R=H). The authentic ketol *9* (R=H, 6.3 mg) was dissolved in MeOH, a small amount of $NaOCH_3$ (2 drops of a 3 % solution in MeOH) was added and the change in optical acitivity was followed. After about 10 h no further change in the activity could be observed; 436 nm: −5.2°, 456 nm: −3.8°, 578 nm: −3.5°, 589 nm: −3.2°.

Epimerization of natural (9R)-9-hydroxy-4-megastigmen-3-one (9, R=H): The natural ketol *9* (R=H, 5.7 mg) was treated as described above for the authentic ketol. Optical activity of the equilibrium mixture: 436 nm: −7.7°, 546 nm: −5.4°, 578 nm: −4.7°, 589 nm: −4.7°. Dilution with water and extraction with ether yielded 4.3 mg which were dissolved in $CHCl_3$ (1 ml): 436 nm: −7.7°, 546 nm: −6.0°, 578 nm: −5.1°, 589 nm: −3.3°.

Acknowledgements. The authors are indebted to Miss A.-M. Eklund for skilful technical assistence, Dr. D. L. Roberts, R. J. Reynolds Tobacco Co., Winston-Salem, for disclosing his results prior to publication, Professor O. Theander, Agricultural College of Sweden, Uppsala, for placing the NMR instrument at their disposal, and Mr. S.-O. Almqvist for recording NMR spectra.

Added in proof: Comparison of the optical properties of the new tobacco constituent with those of blumenol C leaves no doubt about their identity (M. N. Galbraith, private communication). Dr. A. Demole, Firmenich SA, Geneva, has recently independently identified the title compound as a burley tobacco constituent (private communication).

Tobacco Chemistry. 25. Two New Drimane Sesquiterpene Alcohols from Greek *Nicotiana tabacum* L.

JOSEPH R. HLUBUCEK, ARNE J. AASEN, SVEN-OLOF ALMQVIST and CURT R. ENZELL *

Research Department, Swedish Tobacco Co., Box 17 007, S-104 62 Stockholm, Sweden

Two new sesquiterpene alcohols, isolated from Greek tobacco, were shown to be driman-8-ol (*3*) and driman-8,11-diol (*5*) on the basis of spectral data and confirmatory synthesis from drim-7-en-11-ol.**

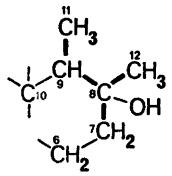
Our continued investigation of the neutral fractions from the volatile extracts of Greek tobacco [1,2] has led to the isolation of two new bicyclic sesquiterpene alcohols.

The first compound, $C_{15}H_{28}O$, was isolated by a combination of liquid and preparative gas chromatography from a fraction of medium polarity (B-5).[2] The presence of a tertiary methyl carbinol group ($>C(OH)CH_3$) followed from IR (3400 cm^{-1}) and NMR data, *i.e.* a methyl singlet at 1.11 ppm and absence of signals downfield of 2.0 ppm. Singlets for three methyl groups at 0.82, 0.82, and 0.88 ppm and a doublet for a methyl group at 0.89 ppm (J 7 Hz) were also observed and with no evidence for unsaturation, these results indicated a bicyclic structure.

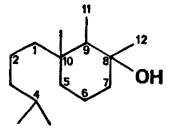
On addition of $Eu(dpm)_3$-d_{27}, the three-proton singlet due to the methyl on the hydroxylated carbon suffered the strongest downfield shift. Three one-proton multiplets also moved downfield strongly and must correspond to three protons on the two carbons, vicinal to the hydroxylated carbon. One of these appeared as a distinct quartet (J 7 Hz) and, as shown by spin decoupling, was attached to the same carbon as the methyl group which gave rise to the doublet (7 Hz). The absence of any other measurable couplings to this proton suggested that both carbons adjacent to the carbon carrying it were quaternary. The other two strongly downfield-shifted one-proton multiplets were assigned to the protons of a methylene group. These were mutually coupled (J_{gem} 12 Hz) and since they were both further coupled to two other vicinal protons, there must be an ethylene group linked to the methyl carbinol group. These results furnished the partial structure *1*.

Available evidence, including the fact that the C_5-unit shown in *1* by heavy lines corresponds to a terminal isoprene unit, indicated that this C_{15}-compound was derived from a normal, head-to-tail linked sesquiterpenoid precursor and hence suggested the partial structure *2*. The ring closure between C(9) and C(10) in *2* (numbering as in the final structure *3*) to incorporate the partial structure *1* is directed by

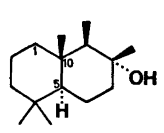
** Nomenclature and stereochemistry as defined in Ref. 3.



1



2



3

the NMR spectral requirements of (i) a secondary carbon atom at C(9) adjacent to a quaternary carbon atom at C(10), and (ii) that the remaining methyl groups not characterized in the partial structure *1* are at quaternary carbon atoms. The location of the methyl at C(10) is supported by the relative LIS (1.0) observed for a methyl singlet in the NMR spectrum. Cyclisation of *2* at C(4)–C(5) to yield the drimane [3] sesquiterpenoid *3* (no stereochemistry implied) maintains the necessary quaternary centre at C(4) and is preferred to the two remaining alternatives, *i.e.* the bicyclic structures derived by cyclisation of C(4) to C(1) or C(2), because of the mass spectrometric fragmentation pattern. Thus readily explained on the basis of structure *3* are the base peak at *m/e* 71, mainly due to a $C_4H_7O^+$ fragment evidently formed as shown [4] in Scheme 1 through initial α-cleavage of the C(8)–C(9) bond, and the prominent peak at *m/e* 137, characteristic [5] for structurally related labdane diterpenoids (ring A fragment 4). Fragments expected to be prominent on the basis of the alternative structures are insignificant or absent, *e. g.* ions derived by C(1)–C(10) cleavage or formed by reactions initiated by α-cleavage of the C(7)–C(8) bond.

The stereochemical assignments shown in *3* were derived from an analysis of the NMR spectrum after the addition of $Eu(dpm)_3$-d_{27}. C(9)H is coupled only to $C(11)H_3$ and the absence of any long-range W-coupling [6] to the equatorial proton at C(7) indicates that C(9)H is axial. The observed LIS for the methyl groups at C(8), C(9), and C(10) are in the order 2.6:1.8:1.0 and this can be rationalized only by co-ordination of the lanthanide complex to an equatorial C(8)OH group. The relatively weak LIS observed for the methyl groups at C(4) (0.4 axial; 0.2 equatorial) relative to the LIS (1.0) measured for the $C(10)CH_3$ support a *trans*-fused geometry of the rings. The synthesis of *3* (*vide infra*) from drim-7-en-11-ol (*9*) confirms the structure *3*, with stereochemistry as shown, for this tobacco compound.

The second compound was isolated by liquid chromatography from a less volatile, neutral fraction of the Greek tobacco extract and purified as the acetate. The latter was the monoacetate of a diol, $C_{15}H_{28}O_2$, as shown by IR absorption at 3470, 1740, and 1243 cm^{-1} and NMR signals at 2.04 ppm (3 H, s) and 5.4 ppm (1 H, broad s, removed by D_2O). Resonances at 4.26 ppm (1 H, dd, *J* 5.5 and 12 Hz) and 4.36 ppm (1 H, dd, *J* 4.5 and 12 Hz), shifted upfield to 3.90 ppm (2 H, m) in the diol, showed the presence of a primary acetate [7] attached to a secondary carbon ($>CH\text{-}CH_2OCOCH_3$). The NMR spectrum of the diol also exhibited singlets for three methyl groups at 0.81, 0.81, and 0.88 ppm and a downfield singlet at 1.33 ppm for a methyl attached to a tertiary carbinol group. With no evidence of unsaturation, these data implied a C_{15} compound having five C_1-substituents on a bicyclic C_{10}-nucleus and hence a drimane skeleton, which made only two alter-

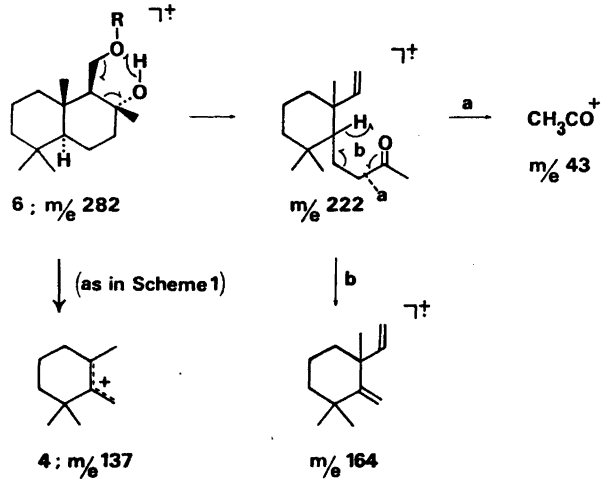
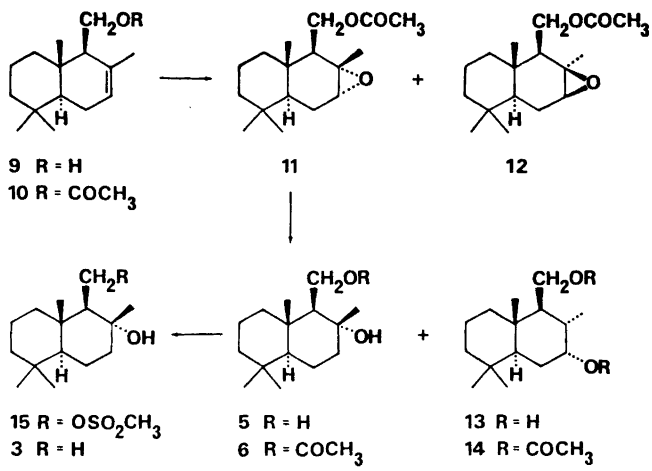
native structures, neglecting stereochemistry, worthy of consideration, namely driman-8,11-diol (*5*) and driman-9,12-diol (*7*). The mass spectra of the diol and the acetate – both displaying the expected *m/e* 137 ion ($C_{10}H_{17}$) corresponding to the drimane ring A fragment 4 – allowed these to be distinguished. Thus the *m/e* 222 ion, due to a $C_{15}H_{26}O$ fragment formed by loss of CH_3COOH from the acetate and water from the diol, underwent loss of acetone to give a *m/e* 164 ion ($C_{12}H_{20}$, m*), a reaction only readily explained in terms of structure *5* (Scheme 2). Moreover, the structures given for the *m/e* 222 and 164 species in Scheme 2 are supported by the fact that the spectra of the diol and the acetate below *m/e* 222 are very similar, except for the *m/e* 137 peak, to that of the ketone *8*. The structure 5, with stereochemistry as shown, was established by synthesis.

It was envisaged that a successful synthesis of the diol *5* would in turn permit the convenient preparation of the alcohol *3* and the synthetic routes to these compounds from drim-7-en-11-ol (9) are outlined in Scheme 3. 11-Acetoxydrim-7-ene (*10*) was treated with *m*-chloroperbenzoic acid in methylene chloride at $-30°$ for three days to give an excellent yield of the desired α-epoxide *11*, formed by preferential attack from the sterically less hindered α-side, and minor amounts of the less polar, and chromatographically readily removed, β-epoxide *12*. Reductive opening of the α-epoxide *11* with excess $LiAlH_4$ in refluxing ether (36 h) gave the diol *5*, identical in all respects with the natural product. However, the yield of the diol *5* was low and the major product was the previously prepared [3] diol *13*, the result of preferred *trans*-diaxial opening of the oxirane ring. Since Ohloff *et al.*[11] have recently shown that in the corresponding 11-nor compound steric hindrance by the $C(10)CH_3$ leads preferentially to abnormal ring opening (nucleophilic attack at C(7) giving the equatorial 8 α-alcohol), it seems that in the acetoxyepoxide



Scheme 2.



Scheme 3.

11 this steric effect is outweighed by a directing influence of the primary oxygen function on the nucleophile. An anchimeric assistance by the hydroxyl group in the ring cleavage reaction such as recently observed by Barton *et al.*[12] for 4α,5α-epoxy-7α-hydroxy steroids, which would also favour the abnormal opening, is unlikely to be of importance in the present case.

Overnight reaction of the diol *5* with excess methanesulphonyl chloride in pyridine at 0° gave a quantitative yield of the monomesylate *15*. Subsequent reduction with $LiAlH_4$ furnished in good yield the alcohol *3*, identical in all respects with the corresponding natural product.

We have previously isolated from Greek tobacco a number of compounds which may be degradation and/or rearrangement products of terpenoid precursors.[8,9,13] The two new compounds (*3* and *5*) are of interest in this context as they both represent potential precursors of the vinylketone *8*, previously also obtained by us from Greek tobacco;[8] *i.e.* from driman-8,11-diol (*5*) by 1,3-diol-rearrangement, and/or from driman-8-ol (*3*) by oxidative fragmentation. Attempts to prepare the vinylketone *8* by oxidation of driman-8-ol (*3*) in refluxing cyclohexane in the presence of calcium carbonate gave, however, only a small quantity of *8*, as detected by GC-MS and TLC.

EXPERIMENTAL

NMR, IR, and mass spectra were recorded on Varian HA100D and XL-100, Digilab FTS-14 and Perkin-Elmer 257, and LKB 9000 (70 eV) instruments, respectively. Rotations were measured on a Perkin-Elmer 141 instrument and accurate mass determinations were carried out at the Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm.

Isolations. Driman-8-ol (*3*) (12 mg) was isolated by column chromatography on silica and silica impregnated with 20 % $AgNO_3$ followed by preparative gas chromatography (3 m × 3.2 mm glass column packed with 5 % Carbowax 20 M on Chromosorb G) from the volatile neutral fraction B-5 of an extract of the leaves of sun-cured Greek *Nicotiana tabacum* L.[1] Driman-8,11-diol (*5*) was isolated as the acetate derivative (*6*) (11 mg) (after acetylation of a complex sub-fraction with excess acetic anhydride in pyridine for 24 h at room temperature) by liquid chromatography on silica from a medium-volatile neutral fraction of the leaves of sun-cured Greek *N. tabacum L.* The fractionation of this medium-volatile material will be described later.[2]

Driman-8-ol (*3*). Colourless needles m.p.73–75° (early softening). MS: 224 (M^+, 8 %), 71 (100), 69 (70), 83 (70), 97 (66), 43 (63), 109 (62), 55 (61), 41 (60), 95 (56); accurate mass measurement: $C_{15}H_{28}O$, found 224.2140, calc. 224.2140; $C_{10}H_{17}$, found 137.1320, calc. 137.1330; C_4H_7O, found 71.0499, calc. 71.0497; C_5H_{11}, found 71.0863, calc. 71.0861, *m/e* 71.0499 and 71.0863 peaks are of approximately equal intensities; $\delta(CDCl_3)$ 0.82 (6 H, s, C(4β)CH_3 and C(10β)CH_3), 0.88 [3 H, s, C(4α)CH_3], 0.89 [3 H, d, J ~7 Hz, C(9β)CH_3], 1.11 [3 H, s, C(8β)CH_3]; on addition of Eu(dpm)$_3$-d_{27}, r (relative induced shift ra-

tio) = 0.2 [3 H, s, C(4α)CH_3], 0.4 (3 H, s, C(4β)CH_3), 1.0 [3 H, s, C(10β)CH_3], 1.8 (3 H, d, J 7 Hz, C(9β)CH_3), 2.6 (3 H, s, C(8β)CH_3, 3.6 (1 H, q, J 7 Hz, C(9α)H), 3.4 (1 H, d of t, J ~3, 12 Hz, C(7β)H), ~4.0 (1 H, broad t of d, J ~4, 12 Hz, C(7α)H); ν_{max}(KBr) 3400 (broad), 1078 (m), 1058 (w), 940 (w) cm^{-1}; $[\alpha]_D^{20}$ −18.2° (c 0.56, $CHCl_3$).

11-Acetoxydriman-8-ol (*6*). M.p. 77 – 79° (early softening): MS: 282 (M^+, 3 %), 43 (100), 41 (30), 95 (28), 109 (28), 69 (26), 55 (24), 82 (23), 81 (22), 123 (18); accurate mass measurement: $C_{17}H_{30}O_3$, found 282.2202, calc. 282.2195; $C_{15}H_{26}O$, found 222.1986, calc. 222.1984; $C_{12}H_{20}$, found 164.1568, calc. 164.1565; C_5H_6O, found 82.0415, calc. 82.0419; C_6H_{10}, found 82.0785, calc. 82.0782; δ ($CDCl_3$) 0.82 (3, H, s), 0.87 (3 H, s), 0.89 (3 H, s), 1.18 (3 H, s), 2.04 (3 H, s), 4.26 (1 H, dd, J 5.5, 12 Hz), 4.36 (1 H, dd, J 4.5, 12 Hz), 5.4 (1 H, broad); ν_{max}(film) 3470 (broad), 1740 (s), 1243 (s), 1030 (w) cm^{-1}; $[\alpha]_D^{20}$ −9° (c 0.53, $CHCl_3$).

Driman-8,11-diol (*5*). Colourless crystals m.p. 119 – 120°. MS: 240 (M^+, 0.5 %), 43 (100), 95 (84), 109 (79), 69 (72), 82 (72), 123 (60), 164 (60), 41 (58), 81 (56), 55 (54); δ($CDCl_3$) 0.81 (6 H, s), 0.88 (3 H, s), 1.33 (3 H, s), 3.9 (2 H, m); ν_{max} (KBr) 3360 (broad), 1076 (w), 1053 (w), 1023 (m), 1015 (w), 994 (w), 940 (w), 913 (w) cm^{-1}; $[\alpha]_D^{20}$ 1.6° (c 0.63, $CHCl_3$).

7α,8-Epoxy-11-acetoxydrimane (*11*). 11-Acetoxydrim-7-ene (*10*) was prepared by overnight reaction of drim-7-en-11-ol (*9*) (1.1 g) with excess acetic anhydride (2.4 g) in pyridine solution (7 ml) at room temperature. TLC showed the crude acetylated product *10* (1.27 g) to be essentially pure and it was used in the next step without further purification. A solution of *m*-chloroperbenzoic acid (1.1 g) in methylene chloride (20 ml) was added dropwise over 2 h to a cold (−30°) stirred solution of *10* (1.27 g) in methylene chloride (50 ml). After 3 days at −30° TLC showed the reaction mixture contained no unreacted *10* and the reaction mixture was diluted with ether, washed with saturated $NaHCO_3$ solution, water and dried (Na_2SO_4). Evaporation of the solvent gave a colourless oil (1.36 g) which crystallized slowly on standing and TLC (SiO_2; 40 % ether/hexane) revealed a mixture of two products (R_F 0.33 and 0.36) in the ratio 9:1. The more polar major product, the α-epoxide *11*, was purified by chromatography on silica: m.p. 55 – 57°; MS: 280 (M^+, 5 %), 99 (100), 43 (91), 123 (42), 69 (42), 41 (41), 85 (38), 124 (38), 71 (36), 55 (32), 73 (28); δ($CDCl_3$) 0.83 (3 H, s), 0.87 (3 H, s), 0.89 (3 H, s), 1.36 (3 H, s), 2.07 (3 H, s), 3.00 (1 H, m, $w_{1/2}$ 4 Hz), 4.0 (1 H, dd, J 9.5, 12 Hz), 4.4 (1 H, dd, J 3, 12 Hz); ν_{max} (KBr) 1740 (s), 1240 (s), 1045 (m), 1036 (m) cm^{-1}; $[\alpha]_D^{20}$ 29.3° (c 0.41, $CHCl_3$).

11-Acetoxydriman-8-ol (*6*) and *7α,11-diacetoxy-8α-drimane* (*14*). Excess $LiAlH_4$ (0.6 g) was added to a solution of the α-epoxide *11* (1.3 g) in dry ether (100 ml) and the mixture was heated under reflux for 30 h. The cooled reaction mixture was treated with ethyl acetate to decompose unreacted $LiAlH_4$, diluted with ether and washed with 1 M HCl, saturated $NaHCO_3$ solution, brine and dried (Na_2SO_4). Evaporation of the solvent gave a crystalline residue (1.1 g) which was treated overnight at room temperature with acetic anhydride (3 g) in pyridine solution (6 ml). Methanol (0.5 ml) was added (at 0°) to decompose excess acetic anhydride (15 min) and the reaction mixture was diluted with ether and washed with 1 M HCl, saturated $NaHCO_3$ solution, brine and dried (Na_2SO_4). Evaporation of the ether gave a colourless oil (1.3 g) which TLC (SiO_2; 60 % ether/hexane) indicated contained some unreacted starting material (*11*) and two products R_F 0.59 and 0.35). Column chromatography on silica (110 g) recovered unreacted *11* (190 mg) and separated the reaction products. The less polar major product (800 mg) was the diacetate *14* isolated as a low-melting crystalline solid. MS: M^+ not visible, 43 (100 %), 204 (84), 189 (61), 119 (38), 69 (34), 121 (30), 55 (28), 41 (26), 81 (26), 109 (16); δ($CDCl_3$) 0.80 (3 H, s), 0.82 (3 H, s), 0.89 (3 H, d, J 6.5 Hz), 0.90 (3 H, s), 2.02 (3 H, s), 2.06 (3 H, s), 4.06 (1 H, dd, J 3, 12 Hz), 4.18 (1 H, dd, J 3, 12 Hz), 5.04 (1 H, m, $w_{1/2}$ 6 Hz); ν_{max} (KBr) 1740 (s), 1240 (s), 1025 (m) cm^{-1}; $[\alpha]_D^{20}$ −37.6° (c 0.51, $CHCl_3$).

The more polar product (97 mg) was the acetate *6*, isolated as a colourless oil that crystallised on standing and identical in all respects to the acetate *6* of the tobacco compound *5*.

Driman-8,11-diol (*5*). Hydrolysis of the synthetic acetate *6* in 10 % methanolic KOH (10 min) and work-up as described above gave synthetic *5* indistinguishable from the diol *5* isolated from the tobacco.

Driman-8-ol-11-yl methane sulphonate (*15*). A cold (0°) solution of the diol *5* (18 mg) in dry pyridine (1 ml) was treated with methanesulphonyl chloride (25 mg) and after 18 h at 0 – 5° excess methanesulphonyl chloride was decomposed with a few drops of water, the reaction mixture was diluted with ether and washed with 1 M HCl, saturated $NaHCO_3$ solution, brine, dried (Na_2SO_4) and the solvent evaporated to leave a pale yellow oil (24 mg). This product showed a single spot on TLC (SiO_2; 80 % ether/hexane) and was used in the next step without further purification. δ($CDCl_3$) 0.82 (3 H, s), 0.90 (6 H, s), 1.15 (3 H, s), 2.1 (1 H, broad s), 3.02 (3 H, s), 4.32 (2 H, dd, J 6, 11 Hz), 4.55 (2 H, dd, J 3, 11 Hz); ν_{max} (film) 3500 (broad), 1355 (s), 1175 (s), 945 (s) cm^{-1}.

Driman-8-ol (*3*). The crude mesylate *15* (24 mg) in dry ether solution (5 ml) was treated with $LiAlH_4$ (40 mg) and the mixture refluxed for 18 h. Ethyl acetate was added to the cooled reaction mixture to decompose excess $LiAlH_4$ and the mixture was diluted with ether and washed with 1 M HCl, saturated $NaHCO_3$ solution, brine and dried (Na_2SO_4). The solvent was evaporated to leave a crystalline residue (18 mg) which was chromatographed on silica to recover

diol *5* (7 mg), and isolate synthetic *3* (11 mg) which was identical in all respects to the tobacco compound *3*.

Oxidation of driman-8-ol (3). Driman-8-ol (4 mg) was added to a mixture of $CaCO_3$ (5 mg) and $Pb(OAc)_4$ (20 mg) in cyclohexane (2 ml) and the mixture heated under reflux for 24 h. Direct analysis of the reaction mixture by GLC-MS revealed about 70 % unreacted *3* and a minor component (~5 %) with a mass spectrum and retention time (50 m × 0.3 mm glass column coated with HB 5000) identical to that of authentic vinylketone *8*.

Acknowledgements. The authors are indebted to Miss A.-M. Eklund for skilful technical assistance, Professor H. H. Appel and Professor K. H. Overton for the generous gifts of drim-7-en-11-ol and Professor K. Olsson, Agricultural College of Sweden, Uppsala, for placing the NMR spectrometer at their disposal.

Alkylation of Indenyllithium and Alkylindenyllithium Compounds

LENNART MEURLING

Department of Organic Chemistry, University of Uppsala, Box 531, S-751 21 Uppsala, Sweden

The reactions between indenyllithium and various halides (methyl, ethyl, isopropyl, *t*-butyl, benzyl, benzhydryl, and triphenylmethyl) gave almost exclusively the corresponding 1-alkylindene (Ia) in good yields. Methylindenyllithium gave a mixture of 1-alkyl-3-methylindene (IIb) and 1-alkyl-1-methylindene (IIc) when treated with alkyl halide in ether. Methylation of alkylindenyllithium compounds methyl-, ethyl-, *t*-butyl- and benzyl-) with methyl iodide gave the corresponding 1-methyl-3-alkylindenes (IIa) in good yields and only slightly contaminated with 1-alkyl-1-methylindene (IIc). The reactions offer a convenient synthetic route from indene to 1,3-dialkylindenes and especially to the least stable tautomer (IIa).

As a part of investigations on the tautomerism of indene and indene derivatives,[1] a good preparative method for the synthesis of 1-, and especially, 1,3-disubstituted, indenes was required. The fact that the methylene moiety of indene is slightly acidic ($pK_a = 21$) has enabled several workers to prepare metal compounds of indene.[2–5] These compounds could then be used to prepare alkylated indenes.[5,6] However, in most cases in the earlier literature, there is some doubt as to whether a 1- or a 3-substituted indene has been formed. The reaction conditions have sometimes been too vigorous and led to a mixture of products. High temperature or prolonged heating leads to the more stable 3-substituted isomer. However, high temperature is often needed with sluggish reacting reagents such as sodium, sodamide, and alkali-hydroxides in the first step and secondary and tertiary halides in the second step. 1-Substituted indenes have also been prepared in an essentially isomeric pure state from indenylmagnesium bromide and an alkyl halide.[7] This reaction is, however, restricted to the more reactive halides such as benzyl chloride and gives rather poor yields.

With ethyllithium in ether in an inert atmosphere, indene forms a compound, which can be isolated as yellowish crystals. Schlenk and Bergmann [4] used this compound to prepare benzhydrylindene (m.p. 158°C) by reacting it with benzhydryl chloride. When this indene-derivative was treated with methanolic potassium hydroxide, a compound with a melting point of 108 – 109°C was found. They concluded that the compound first isolated was the 1-substituted isomer, which was rearranged to 3-benzhydrylindene in the base-catalyzed reaction. This finding has been confirmed in the present paper by means of NMR data. The metalation and alkylation procedures used by these authors were thus mild enough to permit isolation of the least stable isomer.

In these laboratories preparations of pure 1-substituted and 1,3-disubstituted derivatives have been achieved. Thus, 1,3-dideuterio-indene has been prepared by heating 1,1,3-trideuterio-indene with a sodium dispersion, followed by quenching the reaction mixture with H_2O.[9] Ahlberg *et al.* prepared 1-α-hydroxyisopropyl-indene by reacting indenyllithium with acetone.[6] Isomeric pure 1-deuterio-2-ethylindene has also been prepared and these results will be published elsewhere.[10]

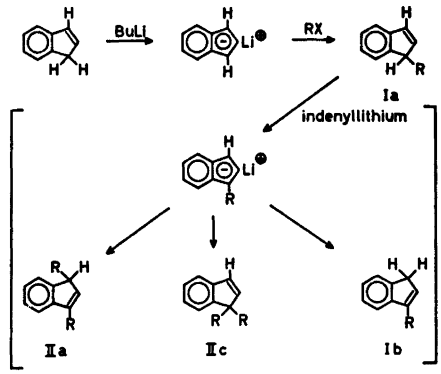
A few years ago, Meth-Cohn and Gronowitz prepared indene-1-carboxylic acid from carbon dioxide and indenyllithium.[11] Quite recently Cedheim and Eberson have reported the preparation of several 1-alkylindenes from indenyl-

lithium.[12] As quoted in their paper indenyllithium had earlier been used for the preparation of 1-benzyl-, 1-benzhydryl-, and 1-triphenylmethylindene. This paper describes the use of indenyllithium compounds for the preparation of both 1- and 1,3-alkylsubstituted indenes. Contrary to the findings of others,[12] no need was found for using the method of reversed addition of reagents.

RESULTS AND DISCUSSION

The metalation of indene was performed by treating indene with a 50 % excess of butyllithium in pentane or ether. The reaction was exothermic and was controlled by external cooling. The metalation was complete within 15 min, since quenching with D_2O, followed by rapid acidification, showed more than 98 % monodeuteration in the indene isolated, as judged from the NMR-spectrum. In one experiment the ether was removed after adding a two-fold excess of butyllithium, xylene was added and the reaction mixture heated for 12 h. After quenching with D_2O and conventional work-up, the NMR-spectrum of the product was examined. The spectrum showed only monodeuteration (*i.e.* one equivalent of butyllithium had reacted) which is opposite to the results obtained by others under similar conditions.[13]

The alkylation was performed by adding an excess of alkyl halide to a cooled ethereal



Scheme 1.

solution of indenyllithium in a nitrogen atmosphere. After standing for the appropriate time and temperature (see Table 1) with stirring, the reaction mixture was poured into ice-cooled, 2 M hydrochloric acid. After work-up and preparative GLC, the product was analyzed with NMR and analytical GLC. This showed that the reaction mixture consisted of the starting material and isomeric pure 1-alkylindene in different proportions, depending on the alkyl halide used. A complication in these syntheses is that excessively high temperature and/or prolonged reaction time lead to 3-alkylindenes or dialkylation (1,3-dialkylation and 1,1-dialkylation) presumably according to scheme 1. Thus when indenyllithium was

Table 1. Alkylation of indenyllithium in ether with various alkylhalides (*cf.* Scheme 1). Retention times are given for the analytical column described in the experimental part. Retention time for indene: 9.0 min.

Alkylating agent	Reaction temp.°C	Reaction time h.	Yield of Ia (%)	Retention time of Ia (min)	Retention time of rearranged prod. Ib (min)

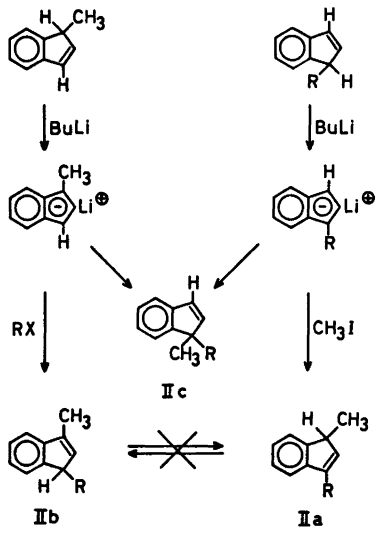
[a] Equimolar amount of DMSO added.

methylated at room temperature and the solution left for 18 h, the product consisted of 78 % 1-methylindene, 12 % 3-methylindene, and 10 % dimethylated indenes. Bosch and Brown [5] reported similar results except that they found a larger portion of 3-methylindene. However, if the temperature is kept below −20°C in the alkylation step, 93 % 1-methylindene, about 0.5 % 3-methylindene, and 1.5 % dimethylated products are obtained. Even if a low reaction temperature is necessary, it was found that heating can increase the yield of the 1-substituted indene. Thus heating a mixture of indenyllithium and *t*-butyl bromide increased the yield of 1-*t*-butylindene from 35 to 45 % without isomerization.



Scheme 2.

Alkylation of alkyl-indenyllithium compounds is supposed to occur in both the 1- and the 3-position and result in the formation of 1,1- and 1,3-dialkylindenes (Scheme 2). However, the distribution and yields of these two species vary considerably depending on the substituent in the indene nucleus and the type of alkyl halide used. Methylation of methylindenyllithium thus gave about 10 % 1,1-disubstitution while the same reaction with *t*-butylindenyllithium gave no 1,1-disubstituted product. Ethyl- and isopropylindenyllithium gave yields between these two extremes, while 1-benzylindenyllithium gave about the same amount of the 1,1-disubstituted products as methylindenyllithium (Table 2). However, when methylindenyllithium was alkylated with various alkyl halides (Table 3), the amount of 1,1-disubstitution increased with the bulkiness of the alkylating agent. Thus, *t*-butylbromide gave 55 % 1,1-disubstitution (calculated on the total amount of the disubstituted product), while methyl iodide gave only 10 %. When dimethoxyethane was used as solvent, the relative amount of 1,1-disubstitution was diminished to about 45 %. Benzyl chloride gave about the same amount of 1,1-disubstitution as *t*-butyl bromide. The varying amounts of 1,1-disubstitution is, of course, a disadvantage but, since separation is fairly easy with preparative GLC, the method can be of synthetic value since the previous routes to 1,3-dialkylindenes have been long and tedious. It should also be mentioned that the synthesis of IIa, the least stable isomer, gives the desired product in high yield, only slightly contaminated with 1,1-dialkylated product. No tautomeric mixture (IIa+IIb) is formed in either case (Tables 2 and 3).

For comparison it may be mentioned that quenching of methylindenyllithium with water under controlled conditions, *i.e.* so that no rearrangement can occur, gave exclusively 3-methylindene.

The different trends observed in the proportion of 1,1-dialkylated product (IIc in Scheme 2) obtained in the methylation procedure (Table 2) compared to the alkylation procedure (Table 3) are difficult to account for. In the methylation experiments, the benzyl substituent gives a result which resembles that found for the methyl substituent rather than for the higher alkyls (Table 2). Thus, a simple steric effect cannot account for the results. In the alkylation of methylindenyllithium, benzyl chloride shows, however, more similarity to the higher alkyl halides than to methyl iodide (Table 3). The entire trend in these experiments is thus opposite to that expected if simple steric hindrance between methyl and alkyl is considered. A more detailed study, especially regarding the structure of the indenyllithium compounds, is probably needed before any safe explanation can be given for the above-mentioned facts. This is beyond the scope of the present paper although a few further comments seem appropriate.

Table 2. Methylation of various alkylindenyllithium compounds in ether with methyl iodide (*cf.* Scheme 2). Reaction time 18 h. Reaction temperature 25°C. Retention times were obtained under the conditions given in the experimental part.

The fact that tautomeric mixtures (IIa + IIb) are not formed in any of the alkylation procedures (Scheme 2, Tables 2 and 3) and that formation of 3-alkylindenes (Ib, Scheme 1 and Table 1) can be avoided, indicates that the indenyllithium compounds must be present in the form of covalent species or contact ion pairs. Solvent separated ion pairs or indenyl anions would bring about a fast isomerization of the alkylindenes formed.[1]

The bonding in delocalized organolithiums varies considerably depending on the stability of the carbanion and the nature of the solvent.[14] Fluorenyllithiums in dioxane occur in the form of contact ion pairs exclusively and in tetrahydrofurane as a mixture of contact and solvent-separated ion pairs.[15] In cyclohexylamine-diethylamine indenyllithium exists as 65 % solvent-separated ion pairs and 35 % contact ion pairs at room temperature.[16] Compared to the fluorenyl anion, the indenyl anion has a more concentrated negative charge and forms a relatively more stable contact ion pair.[16] These data suggest that indenyllithium in ether should exist mainly as contact ion pairs (*cf.* Ref. 17). Alkyl substituted fluorenyllithiums show a greater proportion of solvent separated ion pairs as compared to the fluorenyllithium itself.[14,16] Whether this is true for the indenyllithiums cannot be decided since in this allylic system there may be an equilibrium between two contact ion pairs, with the lithium ion situated above either the 1- or the 3-position. Indenyllithium in tetrahydrofuran has an NMR-spectrum in which H_1 and H_3 are magnetically equivalent. This has been explained as the result of a rapid equilibrium between two covalent structures.[16] The spectrum can, however, also be accounted for as a result of a contact ion pair or an equilibrium between two

such ion pairs in view of the facts mentioned above and of other studies of allyllithium compounds.[14]

The situation in the relatively concentrated solutions used in the preparative procedures is certainly rather complex, since it is known that allyllithium is highly aggregrated in concentrated ether solution.[14] However, if we may use the simple hypothesis that contact ion pairs and high polarity of the solvent are favourable for the desired outcome of the alkylation reactions, the use of a larger cation than lithium should be preferred,[15] although the use of such cations will present larger preparative problems.

EXPERIMENTAL

General. Preparative GLC was performed on a Varian Aerograph 90-P, equipped with a 4 m × 3/8″ column filled with 15 % Apiezon L on Chromosorb 80/100 mesh with a gas-flow of about 100 ml/min. The column temperature was held constant at a temperature between 120 and 150°C depending on the indene being examined. Tests of indene purity were made on a Perkin-Elmer 900 gas-chromatograph with a flame ionization detector on a 8 m × 1/8″ column filled with 8 % Apiezon L on Varaport 30, 100/120 mesh. The column temperature was 150°C and the initial pressure 1 kg/cm². The NMR-spectra were run on a Varian A 60 D NMR-spectrometer. The samples were about 20 % in CCl_4 and run at 35°C with tetramethylsilane as an internal standard. The aralkylindenes were run in benzene-d_6.

Alkylation procedure. Butyllithium[19] (15 mmol) in 10 ml of pentane was added to a cooled solution of indene (or 1-alkylindene) (10 mmol) in 50 ml of dry ether in an atmosphere of dry nitrogen, purified over a solution of triphenylmethanide anion in pyridine.[20] The resulting solution was stirred at room temperature for about 30 min. The appropriate alkyl halide, bromide or iodide, (20 mmol) in 10 ml of ether was added with cooling to the reaction mixture. Samples were withdrawn and analyzed on the gas chromatograph. After standing at the appropriate temperature for the time scheduled in Tables 1 – 3, the brown-coloured solution was poured on to 100 ml of ice-cooled 2 M hydrochloric acid. The ether phase was separated, the aqueous phase extracted with ether and the combined ether extracts washed with aqueous NaCl sat. and dried over $MgSO_4$. The ether extracts were decolourized with charcoal and the ether evaporated. The residue was purified with preparative GLC in 250 μl portions. In most cases sufficient purity, ≤1 % impurities, was

obtained with a spinning band column, if the reactions were run in larger batches.

1-Benzylindene was prepared from 100 mmol of indenyllithium and 200 mmol of benzyl chloride and the product subjected to fractional destillation. Since none of the aralkylindenes can be purified *via* GLC, 1-benzhydrylindene and 1-triphenylmethylindene were recrystallized from isopropanol. 3-Aralkylindene was isolated from equilibrium mixtures after isomerization experiments, the results of which will be published separately.[21] The equilibrium constant was larger than 50 and the 3-aralkylindenes were purified by destillation (3-benzylindene) or recrystallization from isopropanol. Melting points and NMR-data are shown in Table 4. NMR-data for 1,1-dialkylindenes are given in Table 5.

Synthesis of 7,7′-Deuterated Lycopene, 7,7′-Deuterated Rhodopin, and 7-Deuterated Apo-8′-lycopenal

JON EIGILL JOHANSEN and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway

The synthesis of 7,7′-deuterated lycopene (*8*), 7,7′-deuterated rhodopin (*9*), and 7-deuterated apo-8′-lycopenal (*7*) is described. Deuterium was incorporated into geranyltriphenylphosphonium bromide (*2*) and (7-hydroxy-3,7-dimethyloct-2-en-1-yl) triphenylphosphonium bromide (*3*) through a base catalyzed exchange reaction.

As a model for the exchange reaction was studied the synthesis of undeuterated and deuterated 4,8-dimethyl-1-phenylnona-1,3,7-triene (*14* and *15*), followed by GLC-, PMR-, and IR characterization of the *cis-trans* isomeric products (*14A*, *14C*, *15A* and *15C*).

Spectroscopic and other physical properties of intermediates, products and model compounds are reported.

IR absorption at 920 and 730 cm^{-1} in deuterated carotenoids is on an empirical basis ascribed to out-of-plane deformation of *trans*-CH=CD.

A number of deuterium labelled carotenoids have been prepared recently by partial or total synthesis.[1–5] Furthermore, fully deuterated carotenes have been isolated from algae grown in heavy water.[6] Spectrometric studies on deuterated carotenoids have provided useful information especially on mass spectrometric fragmentations.[1–8]

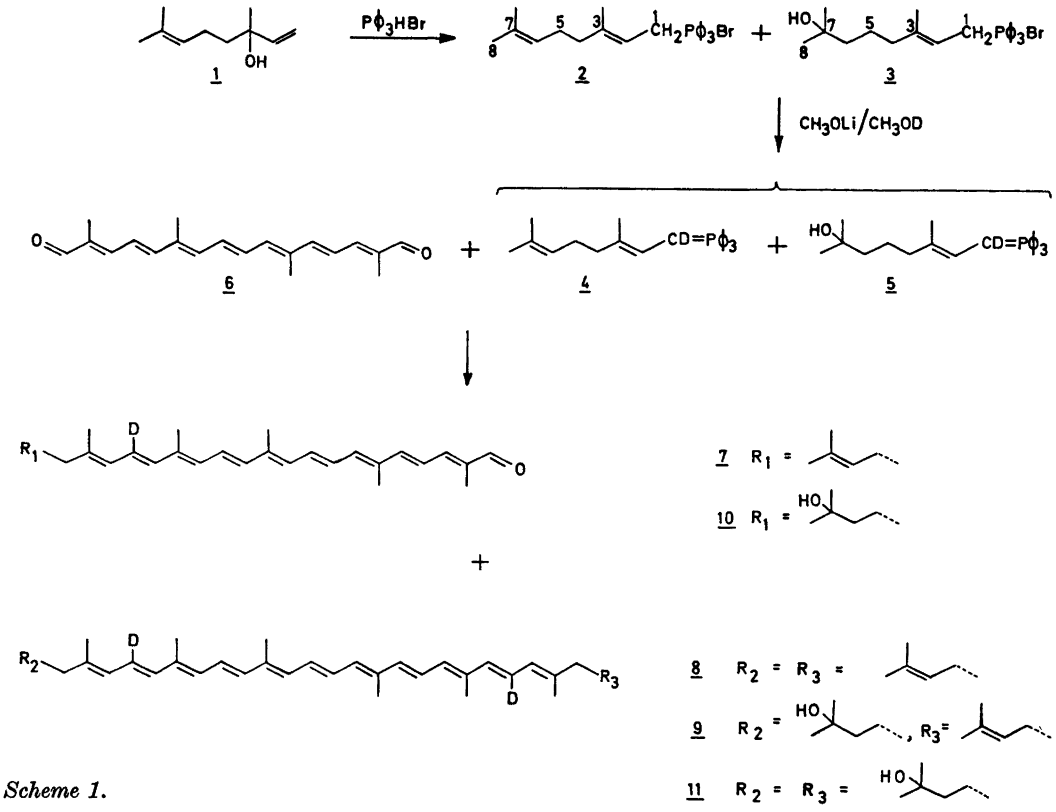
Generally two approaches are used for chemical synthesis of deuterium labelled organic compounds: reduction or hydrogen-deuterium exchange.[9a] Reduction reactions have been used in all previous preparations of deuterium labelled carotenoids. In the present paper we report the first syntheses of deuterium labelled carotenoids using the exchange technique, in principle as discussed in the previous paper.[5] The same type of exchange reaction has recently independently been used by Bestmann *et al.* for the preparation of a tritium labelled phosphorane.[9b] The following paper [10] deals with a related exchange reaction of enolizable hydrogen.

RESULTS AND DISCUSSION

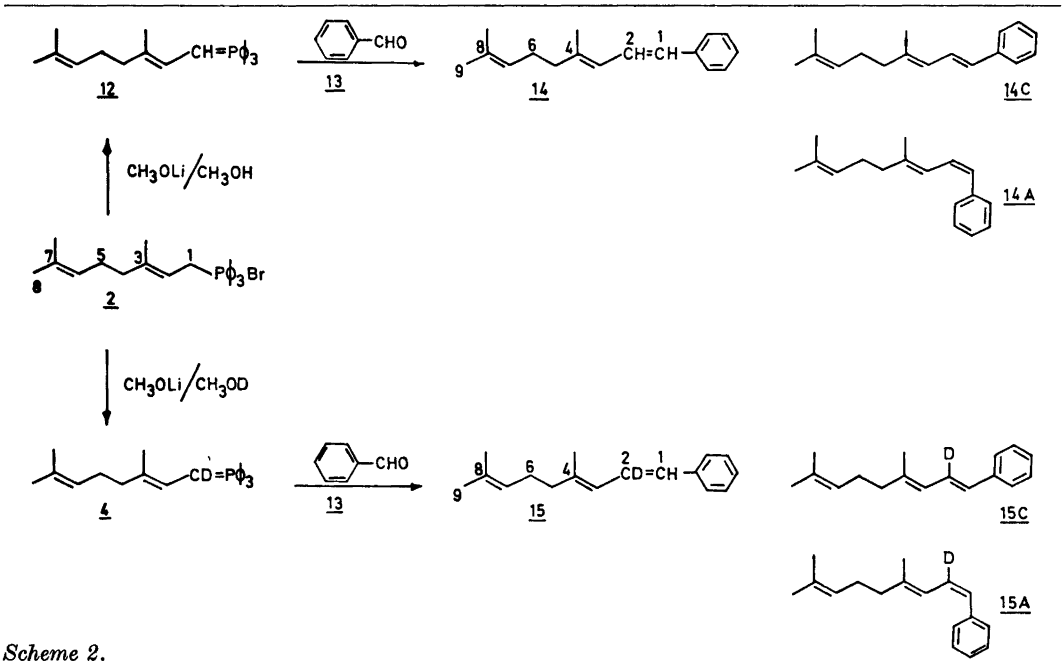
The synthesis of 7,7′-deuterated lycopene (*8*), 7,7′-deuterated rhodopin (*9*), and 7-deuterated apo-8′-lycopenal (*7*) was accomplished [11] by the route shown in Scheme 1 from linalool (*1*).

Hydrogen bromide catalyzed addition of methanol to the isopropylidene group of linalool (*1*) or geraniol has been reported.[12] Chloroform was therefore used as solvent in the first step. However, it is also known that geranyltriphenylphosphonium bromide (*2*) readily adds water.[13] Since water is produced on formation of geranyltriphenylphosphonium bromide (*2*) from linalool (*1*) it is conceivable that water was subsequently added to the phosphonium salt *2*, resulting in a mixture of geranyltriphenylphosphonium bromide (*2*, 76 %) and 7-hydroxy-3,7-dimethyloct-2-enyl)triphenylphosphonium bromide (*3*, 24 %), judged by the PMR spectrum.

Suitable conditions for the following exchange reaction of the mixed phosphonium salts (*2* and *3*) with deuteriomethanol and lithium methylate was studied by a model reaction (Scheme 2). Only products obtained from geranyltriphenylphosphonium bromide (*2*) were examined. In undeuterated methanol/lithium methylate the phosphorane *12* was readily obtained, judged by its further reaction with benzaldehyde (*13*) to the condensation product *14*. Hydrogen-deuterium exchange during phosphorane (*4*)



Scheme 1.



Scheme 2.

formation from *2*, followed by condensation with benzaldehyde (*13*) provided the deuterated hydrocarbon *15*. Under the conditions used 80 % deuterium incorporation was achieved after 5 min. The stereochemistry of the model compounds prepared is discussed below.

The mixed deuterated phosphoranes *4* and *5* (Scheme 1) gave with crocetindial (*6*) the monocondensation product *7* (15 % of carotenoid products) and 7,7′-deuterated lycopene (*8*, 59 %) and 7,7′-deuterated rhodopin (*9*, 26 %) as dicondensation products. The predicted minor condensation products 7-deuterated apo-8′-rhodopinal (*10*) and the diol *11* were not isolated. Large excess of phosphorane was required to obtain high yield of dicondensation products (*8* and *9*) relative to the monocondensation product (*7*). Physical properties of the products *7*, *8*, and *9* are given in the Experimental Part.

Judged by electronic spectra crystalline *8* was the all-*trans* compound. *cis*-Bond formation during the Wittig reaction [14] is in this case of 7(7′) double bond(s) less favourable due to steric hindrance. Prior to crystallization two *cis* isomers of 7,7′-deuterated lycopene (*8*) were isolated. However, these *cis* isomers were identical, juded by R_F-values and electronic spectra, to those present in the iodine catalyzed stereomutation mixture of all-*trans* *8*, known to contain no isomers with sterically hindered double bonds.[15] It consequently appears that the Wittig reactions leading to *7*, *8*, and *9* had *trans* stereospecificity.

7,7′-Deuterated lycopene (*8*) prepared here had 92 % deuterium incorporation (D_0:D_1:D_2 = 3:10:87, calculated from the mass spectrum as in a preceding paper [5]) when using 160 times excess of CH_3OD and 87 % incorporation (D_0:D_1:D_2 = 5:16:79) when using 40 times excess of CH_3OD relatively to exchangeable hydrogen in the phosphonium bromide. A previously synthesized 7,7′-deuterated lycopene (*8*) obtained *via* a different route involving lithium aluminium deuteride reduction had 80 % incorporation (D_0:D_1:D_2 = 5:30:65).[4]

Relatively few IR data are available for deuterated carotenoids.[4-6] IR data for products *7*, *8*, and *9* are discussed in connection with data for the products of the model reaction, Scheme 2.

The olefinic region in the PMR spectra of hydrocarbons *14* and *15* were very complex due to a mixture of *cis* and *trans* isomers. GLC analysis revealed three components for *14*

a = C−H out-of-plane deformation of *trans*-CH=CH.
b = C−H(D) out-of-plane deformation of *trans*-CD=CH.
c = C−H out-of-plane deformation of *cis*-CH=CH.
d = C−H(D) out-of-plane deformation of *cis*-CD=CH.
s = strong, m = medium, w = weak.
Parentheses indicate that these absorptions might be explained by incomplete separation on GLC or incomplete deuteration.

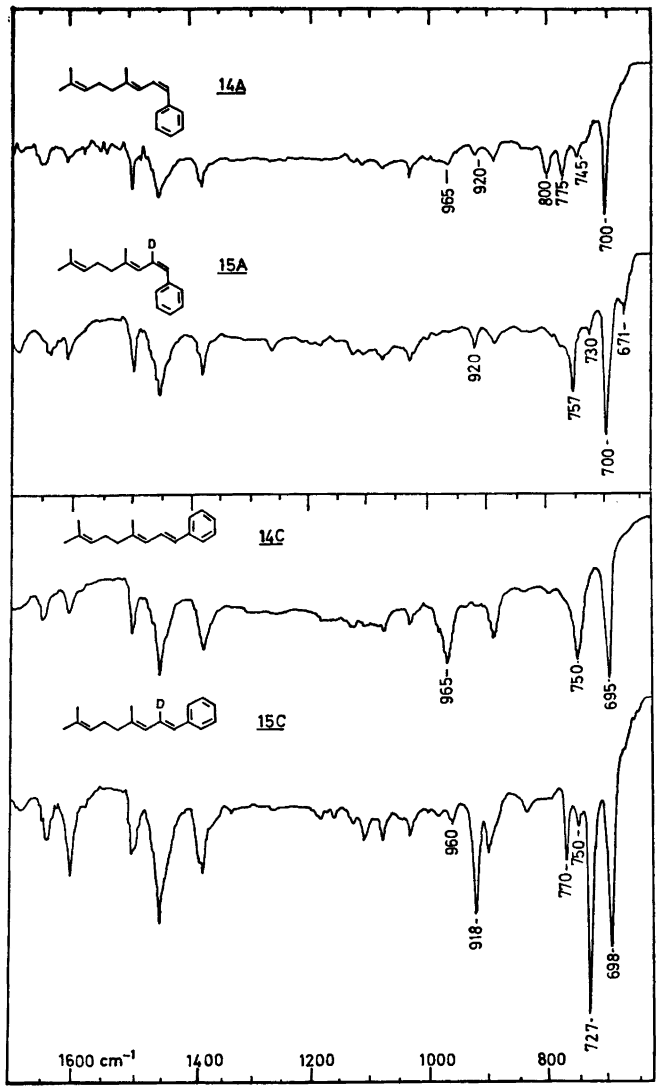

Fig. 1. Infrared spectra (liq.) of 1-*cis*-4,8-dimethyl-1-phenylnona-1,3,7-triene (*14A*), 1-*trans*-4,8-dimethyl-1-phenylnona-1,3,7-triene (*14C*), 1-*cis* 2-deuterated 4,8-dimethyl-1-phenylnona-1,3,7-triene (*15A*), and 1-*trans* 2-deuterated 4,8-dimethyl-1-phenylnona-1,3,7-triene (*15C*).

(*14A – C*) and four for *15* (*15A – D*). By preparative GLC *14A* and *14C*, and *15A* and *15C* were separated and isolated. IR data and PMR spectra revealed that *14A* and *15A* had *cis* configuration and *14C* and *15C* had *trans* configuration around the disubstituted double bond. The interpretation was supported by a computer-simulated (Program NMR 01 [16]) ABC spectrum with assumed chemical shifts and coupling constants. Available data do not permit definition of the stereochemistry of the adjacent double bond in these isomers (arbitrarily presented as *trans* in Scheme 2).

Characteristic IR data for the hydrocarbons *14* (stereoisomeric mixture), *14A*, *14C*, *15* (stereoisomeric mixture), *15A* and *15C* are given in Table 1, together with relevant data for the deuterated all-*trans* carotenoids here or previously prepared (*7*, *8*, and *9*) and undeuterated analogues. Assignments of the

~920 and ~730 cm^{-1} absorptions in deuterated carotenoids to *trans*-CD=CH is supported by data for the *trans* model compounds *14C* (undeuterated) and *15C* (deuterated). Absorption at 920–927 cm^{-1} has previously been considered characteristic of a monodeuterated *trans* double bond whereas absorption at 727–730 cm^{-1}, first considered due to an impurity,[4] later has been ascribed to this same group.[17] Data for the model compounds further suggest that absorption at 775 cm^{-1} (*14A*) is connected with C–H out-of-plane deformation of *cis*-CH=CH, whereas the corresponding vibration for *cis*-CD=CH occurs at 671 cm^{-1} (*14C*). Absorption at 641 cm^{-1} in *cis* EtCD=CHEt has previously been ascribed to such deformation at *cis*-CD=CH.[18]

The PMR spectra of 7,7'-deuterated lycopene (*8*), 7,7'-deuterated rhodopin (*9*), and 7-deuterated apo-8'-lycopenal (*7*) were as expected.

Discussion of the mass spectrometric data will be published separately.[19]

EXPERIMENTAL

Materials and methods. Methylene chloride (Merck *p.a.*) used in the exchange reactions had passed through a column of Al_2O_3 (Merck basic, activity grade 1 [20]). Ether had passed through a column of Al_2O_3 (Spence type H, activity grade 1 [20]). Technical grade acetone was distilled. Technical grade petroleum ether was distilled (b.p. 40–65°C) and then passed through a column of Al_2O_3 (Merck neutral, activity grade 1 [20]). Deuterated methanol (CH_3OD) was from Koch-Light (>99 % deuterated). Other solvents used were of analytical grade.

For column chromatography was used Merck, Spence or Woelm Al_2O_3, activity grade 1–3,[20] and Merck kieselgel (0.05–0.2 mm). TLC was performed on Merck Al_2O_3 or kieselgel (type 60) with or without indicator as stated in each case. Paper chromatography was carried out on Schleicher and Schüll Nos. 287 (kieselguhr) and 288 (aluminium oxide).

GLC was carried out on a Perkin Elmer F 11 flame ionization gas chromatograph. Other instruments used were as specified previously.[21] Complete spectra are available elsewhere.[11]

Deuterated carotenoids

Geranyltriphenylphosphonium bromide (2) and (7-hydroxy-3,7-dimethyloct-2-enyl)triphenylphosphonium bromide (3). Linalool (*1*, 145 g) and triphenylphosphonium bromide [286 g; m.p. 187–193°C; δ ($CDCl_3$) 7.50–8.15 (15 aromatic H) and 12.15 s (1 H); prepared by the procedure of Schwieter *et al.*[22]] in chloroform (0.7 l) were stirred at room temperature for 20 h. This gave a mixture of *2* (76 %) and *3* (24 %), yield 358 g (77 % based on *1*), on crystallization from methylene chloride-ethyl acetate; m.p. 164–165°C; λ_{max} (MeOH) 214, 261, 267, and 274 nm [*E*(1 %, 1 cm) 575, 31, 37 and 30]; ν_{max} (KBr) 3040–2770 (CH), 1660 (C=C), 1585, 1480 and 1445 (phenyl, CH_2, CH_3), 1435 (P-phenyl), 995 (*trans*-CH=CH), 750, 725 and 690 cm^{-1} (monosubst. phenyl and bromine); δ ($CDCl_3$) 1.17 s (H-8, CH_3-7 in *3*), 1.35 s and 1.42 s (3 H, CH_3-3 in *2* and *3*), 1.52 s and 1.59 s (H-8, CH_3-7 in *2*), 1.17, 1.52, and 1.59 counting for 6 H, 1.77 (H-6 in *2*?), 1.9–2.0 (4 H, H-3,4), 2.52 s (*ca.* 1/4 H, OH in *3*), 4.54 dd (2 H, J_{P-1}=14 Hz, J_{1-2}=8 Hz, H-1), 5.00 m (H-6 in *2*?), 5.08 t (J_{1-2}=8 Hz, H-2?) and 7.7–8.05 (15 aromatic H). An aliquot, after recrystallization from methylene chloride-ethyl acetate, melted at 177–178°C (reported 189°C for *2* [13] and 194°C for *3* [13]).

7-Deuterated apo-8'-lycopenal (7), 7,7'-deuterated lycopene (8) and 7,7'-deuterated rhodopin (9). Conditions for formation of the deuterated phosphoranes were investigated in model experiments described below.

(i). A solution of the phosphonium bromides *2* and *3* (35 mg) in CH_3OD (1.1 ml) and 0.28 N CH_3OLi (see below) was stirred at room temperature for 5 min. Crocetindial (*6*, 10 mg) in methylene chloride (5 ml) was added slowly, and the reaction mixture stirred at 30°C for 3 h. The reaction mixture was taken to dryness, the residue dissolved in chloroform and chromatographed by TLC on kieselgel G (chloroform), yield 0.34 mg (2 % based on *6*) of *8*; λ_{max} (acetone) 446, *472*, and 504 nm (most intense maximum is italicized); *m/e* (200°C) 538 (M); D_0:D_1:D_2=3:10:87; 92 % deuterium incorporation and 7.8 mg (52 % based on *6*) of *7*; λ_{max} (acetone) *446* nm; *m/e* (200°C) 417 (M); D_0:D_1=6:94; 94 % deuterium incorporation.

(ii). To a mixture of *2* and *3* (1.44 g) in CH_3OD (10.8 ml) and 0.28 N CH_3OLi, stirred for 5 min at room temperature, was added methylene chloride (3 ml). Crocetindial (*6*, 20 mg) in methylene chloride (4 ml) was added slowly, and the mixture stirred at 30°C for 3 h. The mixture was taken to dryness, the residue dissolved in 90 % methanol, extracted with petroleum ether and washed with aqueous 5 % NaCl-solution and water. The solution was taken to dryness, dissolved in ether, and the pigments purified by TLC on kieselgel G (15 % acetone in petroleum ether=15 % APE). This gave 7,7'-deuterated lycopene (*8*); yield 12.1 mg (31 % based on *6*), 7,7'-deuterated rhodopin (*9*); yield 5.6 mg (14 % based on *6*) and 7-deuterated apo-8'-lycopenal (*7*); yield 2.5 mg (8 % based on *6*).

7-Deuterated apo-8'-lycopenal (7) was rechromatographed by TLC on kieselgel G (15 % APE). Chromatography on paper (SS 287, 5 % APE) gave two zones: neo [15] a; R_F=0.90; λ_{max}

(acetone) 348 and *357* nm and all-*trans*; R_F = 0.76; λ_{max} (acetone) *466* nm. *7* was crystallized from acetone; m.p. 122–124°C (reported 141°C for the undeuterated analogue[23]); λ_{max} (acetone) 350 and *469* nm (reported λ_{max} (acetone) *470* nm[24]); ν_{max} (KBr) 3030–2850 (CH), 1670 (conj. CH=O), 1610 (CH_3), 1185, 1005, 966 (*trans*-CH=CH), 920 and 729 cm^{-1} (*trans*-CD=CH); δ ($CDCl_3$) 0.88 and 1.28 (imp.), 1.64 s and 1.70 s (isopropylidene CH_3), 1.85 s (end-of-chain CH_3), 1.90 (end-of-chain CH_3 at CHO), 2.02–2.40 (allylic CH_2) and 9.42 (aldehyde H); *m/e* (190°C), 417 (M), 348 (M–69), 325 (M–92), 322 (M–95) and 311 (M–106); D_0:D_1 = 12:88; 88 % deuterium incorporation.

7,7'-Deuterated lycopene (*8*) was rechromatographed by TLC on kieselgel G (5 % APE). Paper chromatography (SS 287, 2 % APE) gave three zones: neo b, R_F = 0.90, λ_{max} (ether) 361, (440), *464*, and 493 nm; neo a, R_F = 0.80, λ_{max} (ether) 360, 442, *467*, and 497.5 nm, and all-*trans* R_F = 0.73, λ_{max} (ether) 360, 445, *471*, and 503.5 nm. The all-*trans* isomer was inseparable from authentic lycopene. The same isomers were obtained on iodine catalyzed stereomutation of each isomer.[25] *8* was crystallized from acetone-petroleum ether, yield 6.0 mg; m.p. 157–158°C (reported 140–160°C for the deuterated[4] and 171°C for the undeuterated analogue[13]), undepressed on admixture with authentic lycopene; λ_{max} (acetone) 446, *473*, and 505 nm; % D_B/D_{II}[26] = 6, % III/II[26] = 78 (reported λ_{max} (acetone) 363, 446.5, *475*, and 506 nm[25] for undeuterated lycopene); ν_{max} (KBr) 3040–2855 (CH), 1625 (C=C), 1450 (CH_2), 1375 (CH_3), 961 (*trans*-CH=CH), 927 (*trans*-CD=CH), 825 (>C=CH–) and 730 (*trans*-CD=CH); δ ($CDCl_3$) 1.62 and 1.70 (4 isopropylidene CH_3), 1.83 (2 end-of-chain CH_3), 1.97 (4 in-chain CH_3), 2.10 and 2.15 (4 allylic CH_2), 5.13 (2 H, H-2,2'), 5.96 (2 H, H-6,6') and 6.78–6.25 (12 olefinic H); *m/e* (190°C) 538 (M), 469 (M–69), 446 (M–92), and 432 (M–106); D_0:D_1:D_2 = 5:16:79; 87 % deuterium incorporation.

7,7'-Deuterated rhodopin (*9*) was rechromatographed by TLC on kieselgel G (15 % APE). Paper chromatography (SS 287, 2 % APE) gave three zones: neo b, R_F = 0.69, neo a, R_F = 0.66, and *trans* R_F = 0.46. The *trans* isomer could not be separated from synthetic undeuterated rhodopin.[23] *9* had λ_{max} (ether), 360, 441, *467*, and 498; λ_{max} (acetone) 446, *471*, and 502 nm (reported λ_{max} (acetone) 365, 447.5, *477*, and 508 nm for the *trans* isomer[25]); ν_{max} (KBr) 3420 (OH), 3030–2850 (CH), 1630, 1450 (CH_2), 1375 (CH_3), 960 (*trans*-CH=CH), 925 and 728 cm^{-1} (*trans*-CD=CH); δ ($CDCl_3$) 0.88 and 1.27 (imp.), 1.60 and 1.67 s (isopropylidene CH_3), 1.82 s (end-of-chain CH_3), 1.96 s (in-chain CH_3), 2.10–2.15 (allylic CH_2), 5.13 m (isopropylidene), 5.96 (H-6,6'), and 6.0–6.9 (olefinic H); *m/e* (200°C) 556 (M), 538 (M–18), 464 (M–92), and 450 (M–106); D_0:D_1:D_2 = 7:13:80; 87 % deuterium incorporation.

Model compounds

Conditions for formation of undeuterated and deuterated phosphoranes. A 0.28 N solution of CH_3OLi in CH_3OH was prepared by addition of 20 % BuLi in hexane (9.6 ml) to CH_3OH (100 ml).

A 0.28 N solution of CH_3OLi in CH_3OD was prepared by addition of 20 % BuLi in hexane (1.2 ml) to CH_3OD (10 g).

Equivalent amounts of base and phosphonium bromide were used for phosphorane formation, unless otherwise stated. The reactions were monitored by TLC.

4,8-Dimethyl-1-phenylnona-1,3,7-triene (*14*). To a mixture of the phosphonium salts *2* and *3* (0.72 g) in CH_3OH (5.5 ml) and 0.28 N CH_3OLi, stirred for 5 min at 20°C, was added freshly distilled benzaldehyde (*13*, 0.16 g). The mixture was stirred at 20°C for 2 h and taken to dryness. TLC twice on kieselgel PF 254+366 (petroleum ether) gave *14*; yield 0.162 g (63 % based on *2*); λ_{max} (hexane) 287 nm; ν_{max} (liq.) 3080–2710 (CH), 1675, 1637 (conj. phenyl), 1598 (conj. C=C), 1491, 1448 (CH_2), 1374 (CH_3), 1180–1030 (phenyl), 960 (*trans*-CH=CH), 885, 827 (>C=CH–), 800, 772 (*cis*-CH=CH), 748 and 698 cm^{-1} (monosubst. benzene); δ ($CDCl_3$) 1.61 s, 1.70 s (6 H, H-9, CH_3-8), 1.84 s (3 H, CH_3-4), 2.11–2.24 (4 H, H-5,6), 5.13 m (1 H, H-7), 5.90–7.15 (3 H, H-1,2,3, complex coupling) and 7.15–7.42 (5 aromatic H); *m/e* (110°C) 226 (M), 157 (100 %) and 69 (98 %). *14*, analyzed on GLC (column OV-17) gave three peaks (*14A*, *14B* and *14C*) with retention time (210°C) 15, 17, and 22 min and relative integral 45:12:43, respectively. *14A* and *14C* were separated preparatively in the same GLC system.

1-cis-*4,8-Dimethyl-1-phenylnona-1,3,7-triene* (*14A*) had ν_{max} (liq.) 3080–2730 (CH), 1640 (conj. phenyl), 1600 (conj. C=C), 1570, 1490, 1450 (CH_2), 1375 (CH_3), 1180–1030 (phenyl), 965 (imp. from *6b*, *c*?), 885, 825 (>C=CH–), 800, 775 (*cis*-CH=CH), 745 and 700 cm^{-1} (monosubst. benzene); δ ($CDCl_3$) 1.61 s and 1.70 s (6 H, H-8, CH_3-8), 1.83 s (3 H, CH_3-4), 2.11–2.24 (4 H, H-5,6), 5.12 m (1 H, H-7), 6.39 (3 H, H-1,2,3) and 7.20–7.40 (5 aromatic H).

1-trans-*4,8-Dimethyl-1-phenylnona-1,3,7-triene* (*14C*) exhibited ν_{max} (liq.) 3080–2720 (CH), 1640 (conj. phenyl), 1598 (conj. C=C), 1575, 1495, 1449 (CH_2), 1375 (CH_3), 1180–1030 (phenyl), 965 (*trans*-CH=CH), 890, 845, 805, 750 and 695 cm^{-1} (monosubst. benzene); δ ($CDCl_3$) 1.63 s and 1.70 s (6 H, H-9, CH_3-8), 1.87 s (3 H, CH_3-4), 2.13–2.25 (4 H, H-5,6), 5.17 m (1 H, H-7), 5.92, 6.09, 6.28, 6.53, 6.82, 6.99, 7.12 (3 H, H-1,2,3), and 7.2–7.4 (5 aromatic H); the spectrum showed good agreement with a computer-simulated ABC spectrum assuming the given coupling constants and chemical shifts of the H-1, H-2, and H-3, protons, confirming the *trans* 1-double bond.

2-Deuterated 4,8-dimethyl-1-phenylnona-1,3,7-

triene (*15*). (i). To a mixture of the phosphonium bromides *2* and *3* (0.72 g) in CH_3OD (5.5 ml) and 0.28 N CH_3OLi stirred for 1 h at 20°C was added freshly distilled benzaldehyde (*13*, 0.16 g). The reaction mixture was stirred for 2 h at 30°C, and taken to dryness under vacuum. TLC as above gave 0.029 g (11 % based on *2*) of *15*; D_0:D_1 = 20:80; 80 % deuterium incorporation.

(ii). To a mixture of *2* and *3* (0.72 g) in CH_3OD (5.5 ml) and 0.28 N CH_3OLi stirred for 5 min at 20°C was added freshly distilled benzaldehyde (*13*, 0.16 g) and then treated as above. This gave *7*, yield 0.202 g (78 % based on *2*); λ_{max} (hexane) 287 nm; ν_{max} (liq.) 3080–2710 (CH), 2250 (CD), 1715, 1680, 1633 (conj. phenyl), 1595 (conj. C=C), 1491, 1447 (CH_2), 1376 (CH_3), 1180–1030 (phenyl), 960 (imp. from *14*?), 918 (*trans*-CD=CH), 899, 837 (>C=CH–), 770 (imp. from *14*?), 756, 727 (*trans*-CD=CH), 702–692 (monosubst. benzene), and 671 cm^{-1} (*cis*-CD=CH); δ ($CDCl_3$) 1.63 s, 1.69 s (6 H, H-9, CH_3-8), 1.82 (3 H, H-4), 2.10–2.23 (4 H, H-5,6), 5.13 m (1 H, H-7), 6.00 and 6.39 (2 H, H-1,3) and 7.05–7.35 (5 aromatic H); *m/e* (110°C) 227 (M), 158 (96 %) and 69 (100 %); D_0:D_1 = 18:82; 82 % deuterium incorporation. *15* was analyzed by GLC (column OV-17) and gave four peaks (*15A*, *15B*, *15C* and *15D*) with retention time (210°C) 15, 18, 24, and 27 min and relative integrals 28:19:43:10, respectively. *15A* and *15C* were separated preparatively in the same GLC system.

1-cis *2-Deuterated 4,8-dimethyl-1-phenylnona-1,3,7-triene* (*15A*) showed ν_{max} (liq.) 3080–2720 (CH), 2240 (CD), 1680, 1630 (conj. phenyl), 1600 (conj. C=C), 1492, 1447 (CH_3), 1376 (CH_2), 1180–1030 (phenyl), 920 (imp. from *15B*, *C*?, 885, 840 (>C=CH–), 757, 730 (imp. from *15B*, *C*?), 700 (monosubst. benzene), and 671 cm^{-1} (*cis*-CD=CH); δ ($CDCl_3$) 1.60 s and 1.68 s (6 H, H-9, CH_3-8), 1.83 (3 H, H-4, 2.06–2.25 (4 H, H-5,6), 5.16 (1 H?, H-7), 6.32–6.39 (2 H?, H-1,3) and 7.25–7.50 (5 aromatic H).

1-trans *2-Deuterated 4,8-dimethyl-1-phenylnona-1,3,7-triene* (*15C*) had ν_{max} (liq.) 3080–2720 (CH), 2250 (CD), 1680, 1630 (conj. phenyl), 1595 (conj. C=C), 1496, 1447 (CH_2), 1376 (CH_3), 1180–1030 (phenyl), 918 (*trans*-CD=CH), 895, 835 (>C=CH–), 770, 750, 727 (*trans*-CD=CH), and 693 cm^{-1} (monosubst. benzene); δ ($CDCl_3$) 1.65 s and 1.71 s (6 H, H-9, CH_3-8), 1.87 s (3 H, CH_3-4), 2.10–2.25 (4 H, H-5,6), 5.13 m (1 H, H-7), 5.87 s (1 H, H-3), 6.45 s (1 H, H-1), and 7.2–7.5 (5 aromatic H).

Acknowledgement. Crocetindialdehyde was provided by Dr. J. D. Surmatis, Hoffman-La Roche, Nutley, New Jersey.

Organic Hydroxylamine Derivatives. IX.* Structural Analogues of GABA of the Isoxazole Enol-betaine Type. Improved Synthesis and the Crystal Structure of 3-Hydroxy-5-(2-aminoethyl)isoxazole Zwitterion (Homomuscimol)

LOTTE BREHM, POVL KROGSGAARD-LARSEN and HANS HJEDS

The Royal Danish School of Pharmacy, Chemical Laboratory C, DK-2100 Copenhagen, Denmark

An improved synthesis and the crystal structure determination of homomuscimol, 3-hydroxy-5-(2-aminoethyl)isoxazole zwitterion (IV), which is a structural analogue of δ-aminovaleric acid, are described. The synthesis is based on a reaction sequence in which a carboxylic acid is converted into the corresponding methoxycarbonylamino derivative without isolation of intermediate products. The pK_A values of homomuscimol have been determined to 5.12 ± 0.03 and 9.46 ± 0.02.

Crystals of homomuscimol, $C_5H_8N_2O_2$, are monoclinic, space group $P2_1/n$, $a = 11.530(1)$, $b = 6.203(1)$, $c = 8.782(2)$ Å, $\beta = 104.20(1)°$, $Z = 4$. The structure has been solved by a direct phasing technique using X-ray diffraction data and has been refined by full-matrix least-squares methods. The final R value is 0.042. The crystal structure is made up of homomuscimol zwitterions and is stabilized by a network of hydrogen bonds.

As part of our investigations of GABA analogues of the isoxazole enol-betaine type X-ray analyses of two crystal forms of muscimol have been performed.[1,2] This paper presents an improved synthesis and the crystal structure determination of homomuscimol, 3-hydroxy-5-(2-aminoethyl)isoxazole zwitterion (IV). Homomuscimol (IV) is a structural analogue of δ-aminovaleric acid, which exhibits a physiological activity very similar to that of GABA.[3,4] To our knowledge homomuscimol (IV) has not yet been examined for GABA activity. However, investigations of the biological properties of this compound will be initiated in the near future.

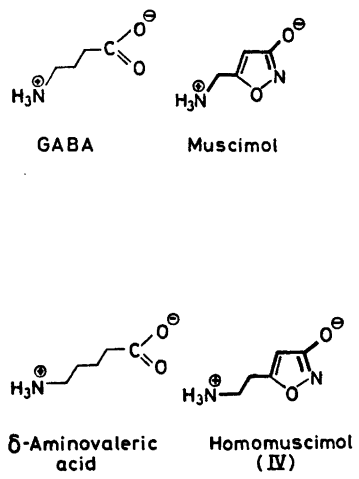

Fig. 1. Some common structural features of GABA/muscimol and δ-aminovaleric acid/homomuscimol.

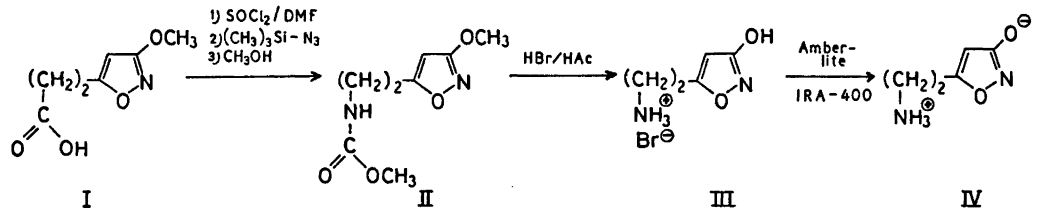
RESULTS AND DISCUSSION

Homomuscimol (IV) was synthesized by Bowden *et al.*[5] The preparation described by these authors is based on 3-(3-methoxyisoxazolyl-5)-propionic acid (I) and proceeds through several steps, including a Curtius reaction. The reported yield of homomuscimol (IV) is rather low and, since several attempts made at the start of this investigation using the same reaction sequence confirmed this, we were prompted to develop and improve the synthesis. The present synthesis of homomuscimol is also based on 3-(3-

* Part VIII. *Acta Chem. Scand.* 27 (1973) 3251.



methoxyisoxazolyl-5)propionic acid (I). It is converted into 3-methoxy-5-(*N*-methoxycarbonyl-2-aminoethyl)isoxazole (II) without isolation of intermediate compounds. The reaction is an extension of the general sequence for the preparation of isocyanates,[6] in which acid chlorides are reacted with trimethylsilyl azide to isocyanates without isolation of the acyl azide intermediates. As the acid chloride of 3-(3-methoxyisoxazolyl-5)propionic acid (I) seemed to be very unstable it is allowed to react with trimethylsilyl azide without purification. The intermediate acyl azide is transformed into the corresponding isocyanate, and the reaction sequence is completed by addition of methanol to the reaction mixture to give 3-methoxy-5-(*N*-methoxycarbonyl-2-aminoethyl)isoxazole (II) in good yields. This is then cleaved by hydrogen bromide in glacial acetic acid to give 3-hydroxy-5-(2-aminoethyl)isoxazole hydrobromide (III). Homomuscimol (IV) is isolated from (III) in good yields and in a pure state using a strongly basic ion exchange resin. The stoichiometric pK_A values of homomuscimol are 5.12 ± 0.03 and 9.46 ± 0.02.

The X-ray diffraction analysis of homomuscimol confirms the zwitterionic structure. The molecular dimensions and the conformation of the molecule are shown in Figs. 2a and 2b.

The isoxazole ring is planar within the limits of experimental error; Table 1 lists the displacements of some atoms from the least-squares plane through the ring. The exocyclic oxygen atom O(2) is in this plane, but the exocyclic carbon atom C(6) is 0.055Å out of it. The plane of the aminoethyl side chain makes an angle of 83.1° with the isoxazole ring plane. The torsion angle τ_1, O(1)−C(5)−C(6)−C(7), is ±51.7° and τ_2, C(5)−C(6)−C(7)−N(1), is ±70.3°. The hydrogen atoms are tetrahedrally

Table 1. Distances of atoms from least squares plane (Å). The equation of the plane is in direct (unit-cell) space.

Isoxazole ring

arranged about the nitrogen atom. Their positions correspond to a 10–20° rotation about the C–N bond relative to that for a strictly staggered conformation.

Tables 2 and 3 and Figs. 2a and 2b show the *intra*-molecular distances and angles found. The bond lengths and angles agree well with their equivalents in other isoxazole compounds.[2,7-11] Thus, it is evident that there is significant resonance within the isoxazole ring, all the bonds except the N–O bond having a significant partial double bond character. The geometry of the aminoethyl side chain does not exhibit unusual

features. The *intra*-molecular distance $N(1)^+\cdots O(2)^-$ is 5.979 Å.

The anisotropic thermal parameters of the non-hydrogen atoms are given in Table 5 and are drawn schematically in Fig. 2a.

Figs. 3 and 4 illustrate the packing of the homomuscimol molecules in the crystals. The crystal structure is made up of homomuscimol zwitterions and is stabilized by a network of hydrogen bonds, one for each hydrogen atom covalently bonded to nitrogen. Hydrogen bonded pairs result from the formation of bonds $[N(1)-H(12)\cdots O(2)_{II}$; $O(2)\cdots H(12)_{II}-N(1)_{II}]$ between pairs of molecules related by a centre of symmetry. The n-glideplane-related molecules are bound head to tail by the hydrogen bond $N(1)-H(13)\cdots O(2)_{III}$, thereby forming infinite chains in the [101] direction. These chains are connected in the b direction by the hydrogen bond $N(1)-H(11)\cdots N(2)_{IV}$. Thus, each molecule is involved in six hydrogen bonds to five different neighbouring molecules. A summary of the geometry of the hydrogen bonding between molecules together with a few other close contacts is shown in Table 4.

EXPERIMENTAL

The determination of melting points, the recording of IR, UV, and ^1H NMR spectra, and the performance of microanalyses were accomplished as described in a previous paper.[12] The pH values were measured on a Radiometer pH meter 26.

The computations were performed on a GIER computer and an IBM 360/75 computer using *INDIFF*,[13] a local version of *The N.R.C. 2A Picker Data Reduction Program*,[14] *The X-Ray System*,[15] and *ORTEP*.[16] The X-ray atomic scattering factors used were those of Cromer and Mann [17] for oxygen, nitrogen, and carbon, and of Stewart, Davidson, and Simpson [18] for hydrogen.

Synthesis

3-Methoxy-5-(N-methoxycarbonyl-2-aminoethyl)isoxazole (II). To a mixture of 1.71 g (10 mmol) of 3-(3-methoxyisoxazolyl-5)propionic acid (I) [19] and thionyl chloride (8 ml) 0.5 ml of *N,N*-dimethylformamide was added dropwise and with stirring. After stirring for further 2 min the solution was evaporated *in vacuo* to give an oil, which was extracted with three 6 ml portions of ether. The combined ether phases were evaporated *in vacuo* to give a brownish oil, which was dissolved in tetrachloromethane (6 ml), and upon addition of 1.27 g (11 mmol) of trimethylsilyl azide the solution was refluxed for 90 min. After cooling to room temperature 1.60 g (50 mmol) of methanol were added, and the solution was refluxed for further 90 min. After cooling to room temperature the solution was concentrated *in vacuo* to give an oil, which was dissolved in ether (15 ml). To the ethereal solution was added with stirring petroleum ether (5 ml) and diatomaceous earth

(0.5 g). After filtration the solution was evaporated *in vacuo* to give 1.7 g of a crystalline product. Recrystallization (ether-petroleum ether) afforded 1.21 g (61 %) of compound (II) as colourless crystals, m.p. 56.5 – 57.5°C. (Found: C 48.05; H 6.09; N 14.04. Calc. for $C_8H_{12}N_2O_4$: C 47.99; H 6.04; N 13.99). λ_{max} 212 nm ($\varepsilon = 6.50 \times 10^3$). IR data (KBr) cm^{-1}: 3265 (s, NH); 1708 and 1680 (both s, monosubstituted urethane C=O); 1618 and 1560 (both s, isoxazole-ring). ^1H NMR data (CCl_4) δ: 5.8 – 5.3 (broadened signal, 1 H, N*H*); 5.59 (s, 1 H, C=C*H*–C); 3.83 (s, 3 H, O–CH_3); 3.55 (s, 3 H, CO–OCH_3); 3.5 – 3.2 (t, 2 H, NH–CH_2–CH$_2$); 3.0 – 2.6 (t, 2 H, CH$_2$–CH_2–C=).

3-Hydroxy-5-(2-aminoethyl)isoxazole hydrobromide (III). A solution of 1.32 g (6.6 mmol) of (II) in 13 ml of glacial acetic acid containing 43 % of hydrogen bromide was heated in an oil bath (bath temperature: 90°C) for 45 min. After cooling to room temperature the reaction mixture was evaporated *in vacuo* to give an oil, which was dissolved in methanol (10 ml), filtered and evaporated *in vacuo* to give an oil, which crystallized after having been dried *in vacuo* over potassium hydroxide for 1 h. Recrystallization (methanol-ether) gave 1.13 g (82 %) of compound (III) as colourless crystals, m.p. 171 – 173°C (decomp.). (Found: C 28.60; H 4.29; N 13.33; Br 38.20. Calc. for $C_5H_9N_2O_2Br$: C 28.72; H 4.34; N 13.40; Br 38.22). λ_{max} 209 nm ($\varepsilon = 7.13 \times 10^3$). IR data (KBr) cm^{-1}: 3600 – 2100 and 1980 (s and w, respectively, NH_3^+); 1623 and 1535 (both s, isoxazole-ring). ^1H NMR data (DMSO-d_6) δ: 11.7 – 9.7 (broad signal, 1 H, O*H*); 8.5 – 7.4 (broad signal, 3 H, NH_3^+); 5.95 (s, 1 H, C=C*H*–C); 3.4 – 2.6 (m, 4 H, NH_3^+–CH_2–CH$_2$ and CH$_2$–CH_2–C=).

3-Hydroxy-5-(2-aminoethyl)isoxazole zwitterion (IV). 1.48 g (7.1 mmol) of (III) were dissolved in water (10 ml) and passed through a column containing an ion exchange resin (Amberlite IRA 400, (OH), 130 ml) using acetic acid (1 N) as an eluent. The fractions containing compound (IV) were collected and evaporated to dryness *in vacuo*. The residue was dissolved in water (10 ml) and the solution was treated with a mixture of activated charcoal and diatomaceous earth, filtered, and evaporated *in vacuo* to give an oil. Crystallization from water-ethanol gave 564 mg (62 %) of homomuscimol (IV) as colourless crystals, m.p. 167°C (decomp.) [Ref. 5, m.p. 158 – 160°C (decomp.)]. λ_{max} 210 nm ($\varepsilon = 6.05 \times 10^3$). The IR spectrum is identical with that of a sample prepared according to the method described by Bowden *et al.*[5]

Determination of the stoichiometric pK_A values

The stoichiometric pK_A values of homomuscimol (IV) have been determined according to the method described by Albert and Serjeant.[20]

Solutions of homomuscimol hydrobromide (III) 0.005 M and of homomuscimol (IV) 0.005 M were titrated with 0.1 N sodium hydroxide. pH Values were recorded after nine different additions of titrant between 10 and 80 % of neutralization, and the pK_A values were calculated using the formula:

$$pK_A = pH - \log \frac{[Base] + [H^+] - [OH^-]}{[Acid] - [H^+] + [OH^-]};$$

[Base] = the stoichiometric concentration of base, [Acid] = the stoichiometric concentration of acid. The final average stoichiometric pK_A values for homomuscimol (IV) are 5.12 ± 0.03 and 9.46 ± 0.02.

X-Ray analysis

The homomuscimol used for the X-ray examination was recrystallized by diffusion at room temperature of absolute ethanol into an aqueous solution of the compound. Colourless prisms somewhat elongated in the *c* direction were formed.

Crystal data. 3-Hydroxy-5-(2-aminoethyl)isoxazole (homomuscimol), $C_5H_8N_2O_2$, M = 128.14. Monoclinic, $a = 11.530(1)$, $b = 6.203(1)$, $c = 8.782(2)$ Å, $\beta = 104.20(1)°$, $U = 608.9$ Å^3, $D_m = 1.39$ g cm^{-3}, $Z = 4$, $D_c = 1.398$ g cm^{-3}. Linear absorption coefficient for X-rays [λ(Mo$K\alpha$) = 0.7107 Å], $\mu = 1.18$ cm^{-1}. Number of electrons per unit cell, $F(000) = 272$. Systematically absent reflections: $h0l$ when $h+l$ odd, $0k0$ when k odd; space group $P2_1/n$.

The unit-cell parameters were refined by least-squares techniques from the diffractometer-measured θ angles observed for 35 reflections well distributed in reciprocal space. The crystal density was measured by flotation in a chlorobenzene/bromobenzene mixture.

Data collection. Three-dimensional diffraction data were measured at room temperature on a Nonius three-circle automatic diffractometer using graphite monochromated Mo$K\alpha$ radiation. The ω scan technique with a scan speed of 1.2° min^{-1} was employed. Background counts were taken for half the scanning time at each of the scan range limits. One standard reflection was measured after every 25 reflections.

All the data were measured from a single crystal with approximate dimensions $0.25 \times 0.29 \times 0.39$ mm. The crystal was mounted with [001] along the ϕ axis of the goniostat.

Out of the 1323 independent reflections measured in the range $2.5° \leq \theta \leq 27°$, 996 had $I_{net} \geq 3.0\sigma(I)$, where $\sigma(I)$ is the standard deviation from counting statistics. These were regarded as observed reflections, whereas the remaining reflections were regarded as unobserved and excluded from the refinement procedure. Lorentz and polarization corrections were applied, but no absorption corrections were made owing to the low absorption coefficient.

Table 5. Final positional and thermal (Å²) parameters for non-hydrogen atoms. The estimated standard deviations of positional ($\times 10^4$) and thermal ($\times 10^2$) parameters are given in parentheses. The temperature expression is of the form:

$$\exp -\tfrac{1}{4}[(h^2a^{*2}B_{11}+k^2b^{*2}B_{22}+l^2c^{*2}B_{33}+2hka^*b^*B_{12}+2hla^*c^*B_{13}+2klb^*c^*B_{23})]$$

Structure determination. The observed structure amplitudes were brought onto an absolute scale by Wilson statistics and normalized structure amplitudes, $|E(hkl)|$, were calculated.

The phase problem was solved in a straightforward way by direct methods using the programs of the X-Ray System, 1972 edition.[16]

In an E map based on 100 $E(hkl)$'s with $|E(hkl)| \geq 1.5$ the nine highest peaks formed a recognizable molecule and in fact all the peaks corresponded to the positions of the nine nitrogen, oxygen, and carbon atoms. Individual atomic parameters of this model were refined, first with isotropic and then anisotropic thermal parameters using the full-matrix least-squares method. On convergence the R value was 0.084. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, where weights were initially taken as unity.

A three-dimensional difference Fourier synthesis then showed maxima with peak heights of 0.5 − 0.7 e Å^{-3} in positions expected for all the hydrogen atoms, and there was no extraneous peaks greater than the lowest hydrogen atom. Introduction of the hydrogen atoms in the refinement, with the isotropic temperature factors of the connected non-hydrogen atoms as constant parameters, reduced the R value to 0.047.

The least-squares refinement was completed with the introduction of a weighting scheme of the form: $w = 1/(1+[(|F_o|-b)/a]^2)$, where $a = 3.5$e and $b = 6.0$e. On the last cycle of least-squares refinement shifts of all the parameters were less than one tenth of their estimated standard deviations and the final R value is 0.042. Tables 5 and 6 list the final positional and thermal parameters for the non-hydrogen atoms and hydrogen atoms, respectively. From these parameters the terminal set of structure factors, listed with the observed data in Table 7, was computed. Comparison of the 100 signs determined by direct methods with the corresponding phases computed from the refined structure shows that all had been correctly assigned.

Table 6. Final positional and thermal (Å²) parameters for hydrogen atoms. The estimated standard deviations ($\times 10^3$) of the coordinates are given in parentheses.

Synthesis and Resolution of Vinylglycine, a β,γ-Unsaturated α-Amino Acid

PALLE FRIIS, PER HELBOE * and PEDER OLESEN LARSEN

Department of Organic Chemistry, Royal Veterinary and Agricultural University, DK-1871 Copenhagen, Denmark

DL-Vinylglycine (2-amino-3-butenoic acid) has been synthesized for the first time from ethyl 2-bromo-3-butenoate by amination and saponification, and by a Strecker synthesis from acrolein. D-Vinylglycine has been produced by treatment of the racemate with L-amino acid oxidase or baker's yeast. The spectroscopic properties and chemical stability of vinylglycine have been determined. Vinylglycine, the simplest β-γ-unsaturated α-amino acid, has previously been postulated as an intermediate in various enzymatic processes. The natural occurrence of other β-γ-unsaturated α-amino acids is briefly discussed.

A number of aliphatic α-amino acids possessing β,γ-unsaturation have been found in natural sources in recent years as indicated in Table 1. Several biological actions have been ascribed to this type of amino acid, and a potential role as amino acid antagonists can be envisioned. Thus, (*E*)-2(*S*)-amino-4-methoxy-3-butenoic acid (Ie, Table 1) is an antimetabolite, inhibiting growth of a *Bacillus* species [4,5] and of *Escherichia coli*.[5] Rhizobitoxine (If, Table 1) in low concentrations strongly inhibits ethylene production by *Sorghum* seedlings and induces chlorosis in new leaf tissues in many plants,[7] whereas the saturated analogue, dihydrorhizobitoxine,[8] does not seem to induce any chlorosis.[9]

Vinylglycine is the simplest β,γ-unsaturated α-amino acid. It has been postulated as an intermediate in the enzymatic conversion of homoserine to threonine [10] and α-ketobutyrate [11] but has not so far been encountered as a compound of natural derivation, and no report of its synthesis has appeared. It is the purpose of the present paper to describe a synthesis of DL- and D-vinylglycine and the chemical and spectroscopic properties of these compounds.

RESULTS

Syntheses. Synthesis of vinylglycine in reasonable yields was impeded by the instability of the compound upon treatment with heat, acid, or base (see below). Even if substantial amounts of vinylglycine could be produced, the isolation of pure material was always accompanied by great losses. The most satisfactory yields were obtained by stirring ethyl 2-bromo-3-butenoate with concentrated aqueous ammonia, followed by cold saponification and isolation of vinylglycine by use of a cation exchange resin. The synthesis of ethyl 2-bromo-3-butenoate has been reported previously.[12] Later an improved version of this synthesis has been described and it has been shown that on treatment of this substance with diethyl sodiomalonate it undergoes displacement of bromine without rearrangement.[13] Vinylglycine was also produced in a Strecker reaction performed essentially as described in an analogous synthesis of β-methylene-DL-norvaline (Ia, Table 1).[1] The dark brown reaction mixture contained six components reacting with ninhydrin besides vinylglycine. However, after a cumbersome isolation procedure involving ion exchange chromatography, pure vinylglycine was obtained in a yield of 1.1 %.

* Present address: National Health Service Pharmaceutical Laboratories, Frederikssundsvej 378, DK-2700 Brønshøj, Denmark.

Table 1. Naturally occurring β,γ-unsaturated α-amino acids with the general formula $R_3(R_2)C=C(R_1)CH(NH_3^+)COO^-$ (I).

Double bonds can be produced by elimination reactions from sulphonium compounds [14] and sulphoxides.[15] Therefore production of vinylglycine was attempted by thermal decomposition of *S*-methylmethionine, *S*-adenosylmethionine and methionine sulphoxide. However, homoserine, probably produced *via* the lactone, was the only reaction product which could be identified in a number of experiments under varying conditions of temperature and solvent. This negative result is in agreement with previous experiments on the degradation of these compounds. Thus *S*-methylmethionine on heating gives homoserine and dimethyl sulfide. [16,17] Vinylglycine has been postulated as an intermediate in the acid degradation of methionine sulphoxide but has not been identified in the reaction mixture.[18]

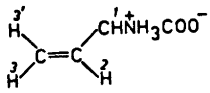
Resolution. Because of the instability of vinylglycine (see below) difficulties could be expected in attempts at chemical resolution of the racemate. Therefore the racemate was subjected to the action of L-amino acid oxidase,[19] which resulted in production of the levorotatory D-amino acid. However the optical purity obtained in this preparation was less than 25 % as indicated by the subsequent experiments.

Better results were obtained by subjecting racemic vinylglycine to the asymmetric action of baker's yeast during fermentation of sucrose. In this way a sample of D-vinylglycine was obtained possessing an $[\alpha]_D$ of $-94°$ in water. This product was hydrogenated to give a sample of 2-aminobutyric acid, $[\alpha]_D - 16.6°$ in hydrochloric acid. If it is assumed that the reduction proceeded without racemization, the D-vinylglycine must have contained about 9 % of the L-isomer, since a rotation of $+20.1°$ in hydrochloric acid is reported for L-2-aminobutyric acid (*cf.* Ref.[20], p. 116).

The D-configuration of the levorotatory stereoisomer is established by its production in the action of L-amino acid oxidase on the racemate and its reduction to D-2-aminobutyric acid. Furthermore the amino acid obeys the Clough-Lutz-Jirgensons rule (*cf.* Ref.[20], p. 85), showing a negative shift in $[\alpha]_D$ on acidification. Circular dichroism measurements (see below) also agree with the assignment of configuration.

Properties of vinylglycine. The UV-spectrum of vinylglycine in water shows a shoulder at about 210 nm, which can be attributed to the carboxylate group, and increasing absorption towards 190 nm due to the C=C bond. In hydrochloric acid the position of the shoulder is shifted to about 220 nm, in agreement with the change of the carboxylate group into a free carboxyl group. Measurements of CD-curves for the D-isomer (with optical purity more than 90 %, see above) demonstrated a negative Cotton effect at 208 nm in water and

212 nm in hydrochloric acid. No indication of additional Cotton effects could be observed down to 192 nm in water and 197 nm in hydrochloric acid. The strong UV-absorption prevented measurements at lower wavelengths. The Cotton effects observed must be attributed to the carboxylate and carboxyl groups. The numerically rather high $\Delta\varepsilon$-values found (−6.7 in water, −4.9 in hydrochloric acid) indicate, however, an influence from the C=C bond (*cf.* Ref. 21).



The ^{1}H NMR-spectrum of vinylglycine shows as expected the α-proton as a doublet and the three vinylic protons as a complex pattern. The spectrum was simulated using the LAOCN3 program.[22] With the following values for chemical shifts and coupling constants, agreement was obtained with the measured spectrum both with regard to position and intensity of the peaks (for designation of atoms see formula): δ_1 4.29 ppm; δ_2 5.97; δ_3 5.48; $\delta_{3'}$ 5.48; $J_{1,2}$ 7.1 cps; $J_{2,3}$ 10.8 cps; $J_{2,3'}$ 16.7 cps; $J_{3,3'}$ −1.2 cps.

On chromatograms vinylglycine produces with ninhydrin a yellow colour which changes through a brownish shade into the normal purple. The colour change is that expected for an α-amino acid with an electrophilic substituent in the β-position.[23]

When heated in water vinylglycine is slowly decomposed with the concomitant production of 2-aminobutyric acid and ammonia. However traces of vinylglycine can still be observed after 168 h at 100° or 68 h at 120°. In 1 N hydrochloric acid vinylglycine is decomposed without the production of other ninhydrin-reactive compounds. After 50 h at 100° no vinylglycine remained. When heated in aqueous ammonia vinylglycine is decomposed with the production of unidentified ninhydrin-reactive compounds. After 22 h at 100° in 2 N ammonia all vinylglycine had disappeared, whereas no decomposition was observed during 168 h in 2 N ammonia at room temperature.

When vinylglycine was heated in aqueous solution with 2-keto-4-methylpentanoic acid, leucine could be identified in the reaction mixture by paper chromatography. This result indicates that the production of 2-aminobutyric acid from vinylglycine in water takes place by production of 2-ketobutyric acid followed by transamination.

EXPERIMENTAL

^{1}H NMR spectra were measured on a JEOL-C-60 HL instrument. Chemical shifts are given in ppm downfield from sodium 2,2,3,3-tetradeuterio-3-(trimethylsilyl)-propionate. Infra-red spectra (in KBr) were recorded on a Perkin-Elmer Model 337 instrument. UV-spectra were measured in 1 mm cells on a Perkin-Elmer Model 402 instrument. Optical rotations were determined on a Perkin-Elmer Model 141 polarimeter in 1 dm tubes. CD-curves were recorded on a Roussel-Jouan Dichrograph CD 185 using 2 mm cells and concentrations of approximately 0.3 mg/ml. Microanalyses were performed by Mr. G. Cornali and his staff.

Paper chromatography was performed by the descending technique on Whatman No. 1 paper in A, BuOH−HOAc−H_2O [12 : 3 : 5 (v/v/v)], and B, PhOH−H_2O−conc. NH_3 [120 : 30 : 1 (w/v/v)]. The following R_F-values were found: Vinylglycine: A, 0.35; B, 0.66. 2-Aminobutyric acid: A, 0.47; B, 0.71.

DL-*Vinylglycine by Strecker synthesis.* The synthesis was performed as a modification of a standard procedure.[1,24] A solution of acrolein (28 g), NH_4Cl (64 g), and KCN (25 g) in water (270 ml) was kept at 5° for 30 min and at room temperature for 2 1/2 h. Conc. HCl (200 ml) was added and the solution concentrated by heating under a stream of nitrogen. After cooling, filtration, further concentration to 150 ml and filtration (to remove inorganic salts) the solution was applied to a strongly acidic cation exchange resin (Amberlite IR 120, 1 × 37 cm, H^+-form). After washing with water (300 ml) the column was eluted with ammonia (250 ml, 2 N). The eluate was concentrated to dryness (2.0 g), dissolved in water and passed through a column of deactivated carbon (1 × 5 cm). The effluent from the carbon was evaporated to dryness (1.75 g), the residue dissolved in water and the solution applied to a strongly acidic cation exchange resin (Dowex 50W × 8, 1.2 × 75 cm, particle size 45−70 μ, 3-chloropyridinium form). The column was washed with water (150 ml) and eluted with aqueous 3-chloropyridine (0.25 M). Fractions of 12 ml each were collected. Fractions 91−109 were concentrated to dryness to give chromatographically pure vinylglycine (480 mg, 1.1 %). Final purification was accomplished by passage of an aqueous solution through a small carbon column, concentration to dryness, redissolution in water (0.5 ml) and precipitation with ethanol (2 ml) to give colourless DL-vinylglycine (58 mg). (Found: C 47.51; H 6.99; N 13.70. Calc. for $C_4H_7NO_2$: C 47.52; H 6.98; N 13.85). IR:

ν_{max}(KBr) 2080 cm^{-1} (medium), 1660 (very strong), 1585 (vs), 1520 (vs), 1420 (vs), 1395 (vs), 1340 (vs), 1280 (strong), 1160 (m), 1120 (s), 1080 (m), 1040 (m), 990 (s), 935 (vs), 915 (vs), 880 (m), 790 (vs), 660 (s), 610 (m), 515 (m), 470 (s).

DL-*Vinylglycine from ethyl 2-bromo-3-butenoate.* Ethyl 2-bromo-3-butenoate [12,13] (74 g) was stirred with concentrated aqueous ammonia (450 ml) for 20 h. After addition of NaOH (30 %, 45 ml) the solution was kept at 5° for 14 days and at −15° for another 14 days. The solution was then applied to a cation exchange resin (Amberlite IR 120, 5 × 40 cm, H^+-form). The resin was washed with water (15 l). and eluted with aqueous pyridine (1 M, 2 l) All fractions showing a positive reaction with ninhydrin were pooled and evaporated to dryness, leaving a brown residue (13.6 g) which was dissolved in water (100 ml) and passed through a column of Sephadex G-10 (2.5 × 90 cm). The column was eluted with water, 6 ml fractions being collected. Fractions 25 – 51 contained vinylglycine as the major component. The residue (8.5 g) from fractions 36 – 51 was dissolved in a small amount of water and absolute ethanol was added. On storage in the icebox overnight a slightly yellow product precipitated (1.3 g). A second crop (1.2 g, total yield 6.6 %) was obtained on concentration of the mother liquor to near dryness followed by addition of absolute ethanol. The product was identical with the product from the Strecker synthesis as judged by paper chromatography and IR- and ^1H NMR-spectroscopy.

Production of partially racemic D-*vinylglycine by the action of* L-*amino acid oxidase on the racemate.* DL-Vinylglycine (200 mg) was dissolved in 500 ml of 0.2 M Tris (pH 7.5), and L-amino acid oxidase [50 mg, from *Crotalus adamanteus* venom (Sigma No. A-9378)] was added. The flask was stoppered and placed in a water bath at 37°. After shaking for 17 h, the stopper was removed and the shaking continued for 3 h. The solution was concentrated and applied to a cation exchange resin (Amberlite IR 120, 2.5 × 30 cm, H^+-form). The resin was washed with water (1100 ml) and eluted with aqueous pyridine (0.5 M). The fractions containing the amino acid were pooled and concentrated to a brown, sticky residue. Further purification was accomplished by ion exchange on a small column of Dowex 50W × 8 resin, preparative paper chromatography (solvent A) and passage through a small carbon column to give a colourless sample (136 mg), $[\alpha]_D^{23} - 23°$ (*c* 0.93, H_2O).

Production of D-*vinylglycine by the action of baker's yeast on the racemate.* DL-Vinylglycine (200 mg) and sucrose (7 g) were dissolved in water (50 ml), and baker's yeast (5 g) was suspended in the mixture by stirring. The suspension was set aside at room temperature for two days, and the liquid was decanted through a 1 cm layer of Filtercel. The filtrate was concentrated and applied to a cation exchange resin (Amberlite IR 120, 1.3 × 17 cm, H^+-form). The column was rinsed with water, and vinylglycine was eluted with aqueous pyridine (0.5 M), 5 ml fractions being collected. Fractions 8 – 12, which contained vinylglycine, were combined and evaporated to dryness. The residue (104 mg) was dissolved in a few ml of water and passed through a filter having a small layer of carbon. The filtrate was evaporated to dryness, leaving a colourless sample of D-vinylglycine (78 mg), m.p. 216 – 218° (decomp.), $[\alpha]_D^{22} - 93.8°$ (*c* 1.5, H_2O). The paper-chromatographic behaviour and IR- and ^1H NMR-spectra were identical with those observed for the racemate. A sample of D-vinylglycine with $[\alpha]_D^{22} - 83.1°$, produced in a preliminary experiment, revealed, dissolved in hydrochloric acid, an $[\alpha]_D^{22} - 95°$ (*c* 0.3, 2 M HCl).

D-*2-Aminobutyric acid by reduction of* D-*vinylglycine.* An aqueous solution of D-vinylglycine (29 mg) $[\alpha]_D - 93.8°$ was hydrogenated with platinum on carbon (30 mg, 10 % Pt) as a catalyst. Hydrogen uptake was completed in less than one hour, as demonstrated by paper chromatography. The catalyst was removed by filtration, and the filtrate was evaporated to dryness to give colourless and chromatographically pure D-2-aminobutyric acid (33 mg), $[\alpha]_D^{21} - 16.6°$ (*c* 0.9, 2 N HCl).

DL-*2-Aminobutyric acid and ammonia by heating an aqueous solution of* DL-*vinylglycine.* DL-Vinylglycine (100 mg) in water (10 ml) was heated in a sealed tube for 4 days at 120°. Ammonia could be identified in the reaction mixture by the use of Nessler's reagent. The solution was taken to dryness, dissolved in water and applied to a small column of cation exchange resin (Dowex 50W × 8, H^+-form). After flushing with water, neutral amino acids were eluted with aqueous pyridine (1 M). 2-Aminobutyric acid, which was the main component, was purified by passage through a small carbon column, preparative paper chromatography and a second carbon treatment. A colourless, crystalline sample (18 mg) was obtained. The paper-chromatographic behaviour and ^1H NMR-spectrum were identical with those observed for an authentic sample of L-2-aminobutyric acid. Small deviations in the IR-spectra must have been due to the difference between the racemate and the enantiomer.

Acknowledgements. The authors are indebted to Dr. P. Laur, Danish Technical University, for the recording of the CD-curves. We are further indebted to Professor M. G. Ettlinger, University of Copenhagen, for valuable discussions and suggestions, for calling our attention to Ref. 13, and for providing us with a copy. The simulation of the ^1H NMR-spectrum of vinylglycine was kindly performed by Dr. C. E. Olsen of this department.

The Mechanism of the Nitrodeiodination of 2-Iodo-1,3,5-trineopentylbenzene

KÅRE OLSSON

Department of Organic Chemistry, University of Göteborg and Chalmers University of Technology, Fack, S-402 20 Göteborg 5, Sweden

When 2-iodo-1,3,5-trineopentylbenzene is nitrated in nitromethane with 90 % nitric acid, it undergoes nitrodeprotonation, as well as nitrodeiodination. The latter reaction was found to be a direct substitution of the iodine atom by a nitro group in analogy with the mechanism of the former reaction.

Results concerning the reaction between various alkyl-substituted iodobenzenes and fuming nitric acid in nitromethane were presented in a previous publication.[1] Two different reactions occurred with substrates having a hydrogen, as well as an iodine, atom attached to the benzene nucleus. These reactions were the usual nitrodeprotonation and a reaction in which the iodine atom is exchanged for a nitro group. The latter reaction was thought to be a direct nitrodeiodination.

Butler and Sanderson [2] showed recently that for the reaction between nitric acid and 4-iodoanisole in acetic acid, the observed nitrodeiodination takes place *via* an initial nitrosodeiodination and a subsequent oxidation. In Ref. 1, that mechanism was rejected for alkyl-substituted iodobenzenes since the rate of nitrodeiodination was not reduced when urea had been added to the reaction solution. As pointed out by Butler and Sanderson, such an experiment may not be completely conclusive and the dependence of the rate of nitrodeiodination on addition of nitrate may give more accurate information.

The present paper deals with the reaction between fuming nitric acid and 2-iodo-1,3,5-trineopentylbenzene (ITNB) in nitromethane solution, and evidence is presented for the view that the observed nitrodeiodination is a direct one.

ITNB was treated in nitromethane with 90 % nitric acid which was prepared with particular attention paid to minimizing the content of lower nitrogen oxides. The two products obtained were 2-iodo-1,3,5-trineopentyl-4-nitrobenzene (INO_2TNB) and 1,3,5-trineopentyl-2-nitrobenzene (NO_2TNB), resulting from nitrodeprotonation and nitrodeiodination, respectively.

From the composition of the product mixture, a quantity a was calculated; a is defined as twice the amount of NO_2TNB divided by the amount of INO_2TNB. In Ref. 1, it was reported that the value of a did not change during the course of reaction, and this result has been confirmed in the present work. It can thus be concluded that the value of a represents the ratio between the rates per available position of nitrodeiodination and nitrodeprotonation. The reaction was repeated several times with different amounts of sodium nitrite added to the reaction solution, and the value of a was determined in each case (see Table 1).

The a values increase with increasing molar ratio between added nitrite and ITNB, and a fairly good linear correlation can be found. The slope of the line is small, however, and the increase in a over the entire interval studied is less than half the value without addition of nitrite.

The observed nitrodeiodination could not be the result of a nitrosodeiodination followed by an oxidation because of the relatively high value of a in the case in which no nitrite was added and the small value of the slope of the correlation

Table 1. Nitration of 2-iodo-1,3,5-trineopentylbenzene (ITNB) with an excess of nitric acid containing varying amounts of sodium nitrite. For conditions, see Experimental section. The quantity a is defined as twice the ratio between the amounts of 1,3,5-trineopentyl-2-nitrobenzene and 2-iodo-1,3,5-trineopentyl-4-nitrobenzene.

mol $NaNO_2$ / mol ITNB	mol $NaNO_2$ / mol HNO_3	a
0	0	0.56
1.2	0.001	0.57
3.4	0.004	0.60
6.6	0.007	0.62
10.5	0.012	0.66
12.0	0.013	0.66
18.7	0.021	0.71
26.5	0.030	0.82
30.9	0.034	0.82

line. If this were the case, the nitric acid itself would have contained 7 mol % of nitrous acid, as can be found by extrapolation. The nitric acid prepared was not found to contain any detectable amounts of nitrous acid, within an experimental accuracy of 1 mol %.

The small increase in the a value observed when nitrite was added may be due to nitrodeiodination *via* a nitrosodeiodination, or to relative rate differences caused by medium effects. Neither of these possibilities can be ruled out.

The possibility that a catalytic effect of nitrite on the rate of nitrodeiodination may be hidden by a similar effect on the rate of nitrodeprotonation can be ruled out by means of the results from an estimate of the rate constants. In fact, the overall reaction rate decreased when sodium nitrite was added; see Experimental section.

A possible reaction sequence consisting of a protodeiodination followed by a nitrodeprotonation, leading to an overall nitrodeiodination has been ruled out.[1,3]

The reason for a difference between the mechanism found in the present case and that in the case of 4-iodoanisole may to some extent be rationalized in the following way. Butler and Sanderson [2] found a very low *ortho*:*para* ratio for the nitrosodeiodination reaction. Since the iodine in ITNB is placed between two *ortho* substituents the nitrosodeiodination may be hampered in this case, and the direct nitrodeiodination becomes the dominating path for the replacement of iodine by the nitro group.

EXPERIMENTAL

The NMR analyses were performed on a Varian A 60 NMR spectrometer. Gas chromatographic (GLC) analyses were made on a Perkin-Elmer 900 instrument fitted with SE-30 columns.

2-Iodo-1,3,5-trineopentylbenzene (ITNB) was prepared according to a method previously described.[3] The fuming nitric acid used was obtained according to Bennett *et al.*[4] The concentration was adjusted to 90 % by mixing with a proper amount of concentrated nitric acid. The acid was finally tested for nitrous acid according to a method based on reaction with *N*-chloro-4-toluenesulphonamide, described by Bennett *et al.*[4] No nitrous acid could be detected within the experimental accuracy of 1 mol %.

Nitration of ITNB with nitric acid. ITNB (100 mg, 0.24 mmol) was dissolved in 65 ml of nitromethane and the solution was cooled to 0°C. Fuming nitric acid (90 %, 10 ml, 215 mmol) at 0°C was added, and the reaction solution was kept at 0°C for 2 days. A small amount (ca. 10 ml) of water was added, and the new solution was extracted three times with cyclohexane. The combined cyclohexane phases were washed with water and dried with magnesium sulphate. The drying agent was removed and the solvent was evaporated. The residue was dissolved in carbon tetrachloride and analysed by means of NMR spectroscopy. The relative amounts of the two products, 1,3,5-trineopentyl-2-nitrobenzene and 2-iodo-1,3,5-trineopentyl-4-nitrobenzene, were determined by comparing the intensities of the peaks due to the different aromatic protons.

The experiment was repeated with varying amounts of sodium nitrite added to the nitric acid before the acid was added to the nitromethane solution. The results are summarized in Table 1.

When more than approximately 300 mg of sodium nitrite was added to the acid, a precipitate appeared when the acid was poured into the nitromethane solution. This precipitate was analysed by conventional chemical tests and was found to consist of sodium nitrate.

Estimate of the rate of reaction of ITNB with nitric acid with and without sodium nitrite. ITNB (20.0 mg, 0.048 mmol) was dissolved in 10.0 ml of nitromethane and the solution was cooled to 0°C. Fuming nitric acid (90 %, 2.0 ml, 43 mmol) at 0°C was added. The reaction mixture was kept at 0°C, and aliquots were withdrawn at proper time intervals. The aliquots were added to some water and the resulting solution was extracted with cyclohexane. The cyclohexane solution was analysed by means of GLC, and the relative amounts of the starting material and the two products were obtained as the

ratios of the peak heights. The value of the pseudo first-order rate constant for the consumption of ITNB was 2.1×10^{-4} s^{-1}.

The experiment was repeated with 64.6 mg (0.94 mmol) of sodium nitrite dissolved in the nitric acid before the addition to the nitromethane solution. In this case the value of the rate constant was 9.0×10^{-5} s^{-1}. The accuracy of these rate constants can be estimated at ± 10 %. Both experiments were repeated, and the values of the rate constants were found to be within the given error limits.

The relative amounts of the two products, NO_2TNB and INO_2TNB, determined by means of GLC as just described, were found to be constant throughout the reactions.

Studies on Intermediates Involved in the Syntheses of Pentaerythritol and Related Alcohols. V.* On the Kinetics of the Base-catalyzed Aldol Condensation Reactions of Intermediate Aldehydes with Formaldehyde

JAN-ERIK VIK **

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack S-402 20 Göteborg 5, Sweden

Rate constants for the base-catalyzed aldol condensation reactions of 3-hydroxypropanal, 2-propenal, 2-hydroxymethyl-2-propenal, 2-methyl-2-propenal, and 2-ethyl-2-propenal, respectively, with formaldehyde have been obtained from kinetic experiments.

In alkaline, dilute aqueous solutions the unsaturated aldehydes mentioned undergo hydration to give equilibrium mixtures with their saturated, α-hydroxymethyl-substituted counterparts. In these mixtures the unsaturated aldehyde dominates except in the pair 2-propenal ⇌ 3-hydroxypropanal. The hydration ⇌ dehydration reactions are rather rapid. By studying UV-spectrophotometrically the rates of disappearance of the latter three of the unsaturated aldehydes enumerated above, it was therefore thought possible indirectly to determine the rates whereby the corresponding three saturated aldehydes 3-hydroxy-2 hydroxymethylpropanal, 3-hydroxy-2-methyl propanal, and 2-ethyl-3-hydroxypropanal are converted into aldol condensation products with formaldehyde. Experimentally, however, the observed rates of condensation at higher formaldehyde concentrations were found to be faster than the known rates of hydration and this in spite of the activation energies for the condensations being higher. The explanation for this latter observation seems to be that the activation energy for dehydration of methylene glycol with formation of free formaldehyde, the reacting species, is included in the activation energies for the aldol condensations. The experimental findings thus indicate that the rate of condensation of each of the unsaturated aldehydes may differ from the corresponding rate for its saturated, hydrated counterpart and that equilibrated mixtures of these two aldehydes probably only are formed when the condensation reactions are carried out at relatively low concentrations of formaldehyde.

The condensation reactions with formaldehyde of 3-hydroxypropanal and of 2-propenal were followed by means of a gas chromatographic determination method. The sum of the concentrations of 2-propenal and of 3-hydroxypropanal was determined as an apparent concentration of 2-propenal after quantitative dehydration of 3-hydroxypropanal in the injection block. Both aldehydes were found, within experimental errors, to react with formaldehyde at the same rate. Furthermore, at higher formaldehyde concentrations, the reactions of these two aldehydes with formaldehyde, like those of the other aldehydes examined, are faster than their hydration and dehydration reactions.

This work is a sequel to a study [1] dealing with the base-catalyzed aldol condensations of the lowest molecular weight members of the alkanal series with formaldehyde. The hydroxyaldehydes 3-hydroxypropanal (I, monomethylolacetaldehyde, hydracrolein) and 3-hydroxy-2-hydroxymethylpropanal (II, dimethylolacetaldehyde) constitute the first and the second intermediate in the reaction sequence forming pentaerythritol, ultimately, from acetaldehyde and formaldehyde. Likewise, 3-hydroxy-2-methylpropanal (III, monomethylolpropionaldehyde) and 2-ethyl-3-hydroxypropanal (IV, monomethylolbutyraldehyde) are the first intermediates in

* Part IV: *Acta Chem. Scand.* 27 (1973) 251.

** Present address: Perstorp AB, S-284 00 Perstorp, Sweden.

the reaction series leading to trimethylolethane and to trimethylolpropane as products of the corresponding reactions of propionaldehyde and of butyraldehyde with formaldehyde:

$$CH_3CHO \xrightarrow[OH^-]{CH_2O} \underset{I}{HOCH_2CH_2CHO} \xrightarrow[OH^-]{CH_2O}$$

$$\underset{II}{(HOCH_2)_2CHCHO} \xrightarrow[OH^-]{CH_2O} (HOCH_2)_3CCHO$$

$$\xrightarrow{CH_2O,\ OH^-} C(CH_2OH)_4 + HCOO^-$$

$$CH_3CH_2CHO \xrightarrow[OH^-]{CH_2O} \underset{III}{HOCH_2CHCHO} \xrightarrow[OH^-]{CH_2O}$$

$$\underset{CH_3}{|}$$

$$(HOCH_2)_2CCHO \xrightarrow{CH_2O,\ OH^-}$$

$$\underset{CH_3}{|}$$

$$CH_3C(CH_2OH)_3 + HCOO^-$$

$$CH_3CH_2CH_2CHO \xrightarrow[OH^-]{CH_2O} \underset{IV}{HOCH_2CHCHO} \xrightarrow[OH^-]{CH_2O}$$

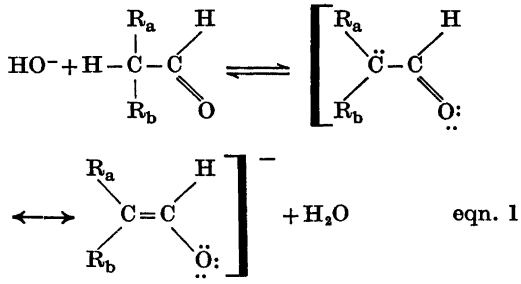
$$(HOCH_2)_2CCHO \xrightarrow{CH_2O,\ OH^-}$$

$$\underset{CH_2CH_3}{|}$$

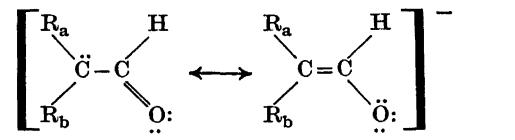
$$CH_3CH_2C(CH_2OH)_3 + HCOO^-$$

One of these reactions, namely the one between I and formaldehyde, has been the subject of a study by Ogata, Kawasaki, and Yokoi,[2] who in the same paper also present data concerning the aldol condensation between acetaldehyde and formaldehyde. Since some aspects of their method seem questionable, independent methods to study these reactions, preferably in a more direct way, have been sought. In the reaction with acetaldehyde its rate of disappearance could be followed by direct gas chromatographic analysis under reaction conditions where its rate of self-condensation was negligible.[1] 3-Hydroxypropanal, on the other hand, is not sufficiently thermally stable to allow direct determination by this method. It has now been found, however, that if a thin glass tube, the walls of which are covered with a mixture of acid sodium and potassium phosphates, is inserted into the heated injection block of the gas chromatograph, 3-hydroxypropanal, present in a neutralized reaction mixture, on injection is instantaneously converted into 2-propenal (V, acrolein) and can be quantitatively determined as such. It had to be ascertained, by separate experiments with no formaldehyde present, that the apparent rate of disappearance of V was negligibly small in aqueous solutions of the same nominal alkalinity as used in the experiments with formaldehyde present. Since it is known that in such solutions an equilibrium between I and V, in which I dominates, is rather rapidly established,[3] it follows that the mixture of I with V was quantitatively determined as V. Likewise, in an alkaline solution of the aldehyde I, its concentration, as measured by this method in the form of an apparent concentration of V, was found to be reasonably constant for a few hours in the temperature range investigated (20 – 40°C). In experimental kinetic runs performed in the presence of formaldehyde by this method, approximately straight pseudo first-order plots of the disappearance of aldehyde I (or V) were always obtained, the plot from a typical run being shown in Fig 1.

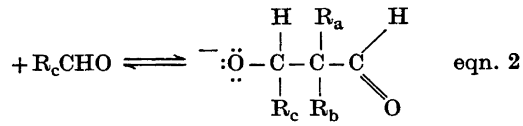
The problem to determine the rates of condensation with formaldehyde of the aldehydes II, III, and IV was more complicated, since so far attempts to work out similar gas chromato-



eqn. 1



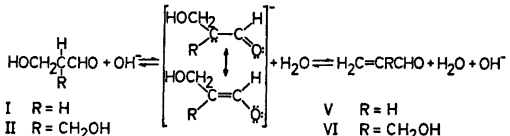
eqn. 2



eqn. 3

graphic determination methods have been unsuccessful. It could be expected, however, that these reactions follow the commonly accepted scheme for aldol condensations.[4]

Previous work,[3] made possible by the development of methods to obtain the aldehydes I, II, III, and IV,[5] had shown that II, III, and IV, in alkaline aqueous media, are rather rapidly converted into their dehydrated, unsaturated counterparts, 2-hydroxymethyl-2-propenal (VI), 2-methyl-2-propenal (VII, methacrolein), and 2-ethyl-2-propenal (VIII), respectively, until dynamic equilibria are established. In dilute aqueous solutions, at temperatures above 20°, the unsaturated aldehyde constitutes more than 90 mol % of each of these equilibrium mixtures.



eqn. 4

The equilibria presented in eqn. 4 therefore must be taken into consideration when aldol condensations with formaldehyde are investigated kinetically with compounds II, III, and IV.

At lower formaldehyde concentrations the second reaction step, presented in eqn. 2, can be assumed to be rate determining for the aldol condensations. Under these conditions the initial rate of formation of the aldol condensation product is not necessarily the same for the two possible reactants, the saturated and the unsaturated aldehyde, since the steady state concentrations of enolate ions they give rise to may well differ. After a period of time, however, an equilibrium is expected to be attained between the two aldehydes and from then on the same rate of formation of product must be observed, irrespective of which of the two aldehydes was chosen as starting material. A change in observed rate "constant" during the initial stage of the reaction is therefore not unexpected.

At higher formaldehyde concentrations the reaction given in eqn. 1, *i.e.* the formation of enolate ions, is expected to be rate determining. Again the saturated and the unsaturated aldehyde may show different rates of disappearance depending on their rates of formation of enolate ions. Besides, since the formaldehyde hydrates, methylene glycol and oligomers, buffer alkaline solutions, the maximum rates of condensation for a certain amount of sodium hydroxide added, would be expected to be lower than the rates of enolate ion formation in mixtures of the same nominal alkalinity, but with no formaldehyde present.

Unfortunately, as mentioned, it has so far not been possible to carry out kinetic investigations on the condensation reactions with formaldehyde of compounds II, III, and IV due to lack of analytical methods to follow the reactions. It then seemed of interest at least to determine the corresponding rates of reaction of the unsaturated aldehydes VI, VII, and VIII. In this way it would be possible to get rate constants for the formation of product from the equilibrium mixtures present at low formaldehyde concentrations. Analytically, it should be possible easily to follow the rates of disappearance of the unsaturated aldehydes by means of UV-spectrophotometry in the same way as the dehydration⇌hydration reactions were followed.[3]

In this earlier investigation it was observed that the addition of a small amount of hydroxide ion to a 10^{-4} M solution of any of the aldehydes VI, VII, or VIII caused a rapid decrease by less than 10 % of the UV-absorption, further changes occurring only comparatively slowly. By contrast, in similar experiments now performed with formaldehyde present, a rapid decrease in concentration of the unsaturated aldehyde, starting at once and continuing until this aldehyde had completely disappeared, was observed. In each run the rate "constant" was higher in the beginning of the reaction than later on but reached a fairly stable value after part of the unsaturated aldehyde had disappeared. In Fig. 2 this is illustrated with 2-hydroxymethyl-2-propenal (VI) and formaldehyde.

The assumption that the initial rate deviations could be ascribed to a change in temperature during the first few minutes of reaction can be ruled out, since the rate "constant" was always found to decrease, also at temperatures above ambient. The rate change observed for the disappearance of the unsaturated starting material is probably influenced by the rate change for formation of product expected, when

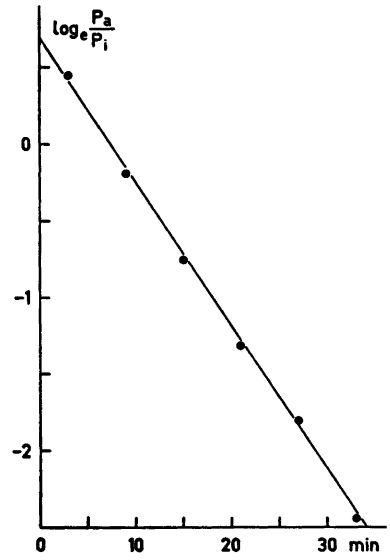


Fig. 1. Pseudo first-order disappearance of acrolein (V) in 0.25 M CH_2O. P_a/P_i: Peak area of signal from acrolein relative to that of 1-propanol. Nominal concentration of NaOH 0.0030 M. Temperature 20°C.

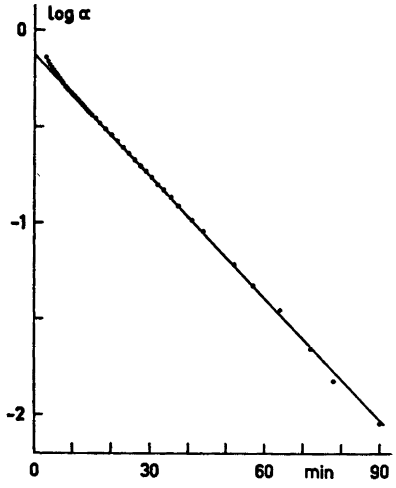

Fig. 2. Condensation of 2-hydroxymethyl-2-propenal (VI) with formaldehyde followed by UV-spectrophotometric measurement of the decreasing absorbance at 213.5 nm. Temperature 20.0° and nominal NaOH-concentration 0.0100 M.

part of this starting material is converted into the saturated aldehyde in their equilibrated mixture, as was discussed earlier. This hydration reaction in itself of course also contributes to the initial faster rate of disappearance of the unsaturated aldehyde but gives no direct contribution to the rate of formation of the aldol condensation product. Moreover, not only water can be reversibly added to the unsaturated aldehyde. Alcohol addition⇌elimination reactions also take place under alkaline conditions.[6] The rates of addition of some alcohols to the unsaturated aldehydes in question have been investigated in a separate study, which will be the subject of a forthcoming paper. These rates have been found to be considerably faster than the rates of addition of water, even in rather dilute aqueous solutions. Under the conditions used in the present work not only methanol, present in a low concentration in the formalin used, but also, and more important, methylene glycol and oligomeric formaldehyde hydrates may add in reversible reactions:

$$ROH + OH^- \rightleftharpoons RO^- + H_2O \qquad \text{eqn. 5}$$

$$RO^- + H_2C{=}CR'CHO \rightleftharpoons [ROCH_2\bar{C}R'CHO \leftrightarrow ROCH_2CR'{=}C\bar{H}O] \qquad \text{eqn. 6}$$

$$[ROCH_2\bar{C}R'CHO \leftrightarrow ROCH_2CR'{=}C\bar{H}O] + H_2O \rightleftharpoons ROCH_2CHR'CHO + OH^- \qquad \text{eqn. 7}$$

Since the reactions with methanol are known to be fast and the corresponding reactions with methylene glycol presumably are so too, such equilibrium reactions may well be part of the explanation for the initial faster rates observed. The curvatures of the pseudo first-order plots were also found to be more pronounced for experiments carried out at higher formaldehyde concentrations, where the reversible addition of methylene glycol can be expected to be of increasing importance. This state of things made it more difficult to graphically evaluate the rate constants "after stabilization" in these runs. Whereas the values of the rate constants obtained at lower formaldehyde concentrations were within ± 5 % of the mean value, reproducibility was only ± 10 % at higher formaldehyde concentrations.

If thus the observed rates of disappearance of the unsaturated aldehydes during the initial

period of each run do not represent the rate of any single reaction, once the various equilibria are attained, further changes must be due to the condensation reaction with formaldehyde. It is therefore assumed that the rate constants "after stabilization" represent the true rate of the condensation reaction with formaldehyde of the mixture of unsaturated and saturated aldehyde present at this stage of the reaction. These rate constants, like the ones obtained for the reactions of I and of V, were found to be directly proportional to the amount of NaOH added to the reaction mixtures. Second-order rate constants, k', may therefore be calculated referring to the rate expression:

$$-\mathrm{d[A]}/\mathrm{d}t = k'[\mathrm{A}][\mathrm{NaOH}]_{\mathrm{added}}$$

Here [A] denotes the concentration of the aldehyde under study, and k' times $[\mathrm{NaOH}]_{\mathrm{added}}$ is equal to k_{obs} for the pseudo first-order disappearance of A. The constants, k', were found to depend on the formaldehyde concentration in a manner somewhat similar to what was found for acetaldehyde and its homologs in the study referred to previously [1] (Fig. 3 and Table 1).

With the normal aldol condensation reaction mechanism operating one expects reaction step 1 (eqn. 1), that is the rate of formation of enolate ions, to become rate determining at higher formaldehyde concentrations. This simple picture is, however, partly obscured due to the behaviour of formaldehyde in alkaline, aqueous solutions. Firstly, the concentration of the reacting species, free, monomeric formaldehyde, is not linearly increasing with the total concentration of formaldehyde due to extensive formation of mono- and oligomeric hydrates. Secondly, because these hydrates are weakly acidic they buffer alkaline solutions increasingly with increasing concentration of formaldehyde. Of course it is still possible with the help of a pH-meter to adjust the hydroxide ion activity to the same value at the different formaldehyde concentrations. This would still leave open the question, however, to what extent the different amounts of anions of methylene glycol and oligomers present catalyze the condensation reaction. Furthermore, from an industrial viewpoint the interesting question is which rate is to be expected with a certain amount of alkali added, an amount determinable by titration. Anyhow, both the factors mentioned contribute to cause a less than proportional increase in rate constant for a certain increase in formaldehyde concentration. The levelling off of the values of the rate constants at concentrations of formaldehyde higher than about 1 M observed for the aldehydes VI, VII, and VIII does therefore not necessarily imply that the rates of enolate ion formation are becoming rate determining at this particular concentration.

In order to examine this, experiments have also been performed using the corresponding saturated aldehydes as starting materials for the condensations with formaldehyde. In these runs

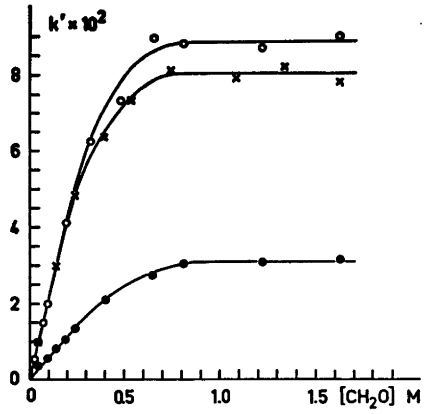

Fig. 3. Pseudo first-order rate constants for the condensation reactions of 2-hydroxymethyl-2-propenal (VI, ×), 2-methyl-2-propenal (VII, ○), and 2-ethyl-2-propenal (VIII, ●), respectively, with formaldehyde.

too the concentration of the unsaturated aldehyde in the equilibrium couple was followed by means of UV-spectrophotometry. The UV-absorptions of the unsaturated aldehydes were found at first to increase to a maximum and then to decrease to zero. This was the case both at lower and, more remarkably, also at higher formaldehyde concentrations in the region where the rates of the condensation reactions of the unsaturated aldehydes had been found to be unaffected by further increase of the formaldehyde concentration. The maximum concentration reached by the unsaturated aldehyde was highest with II as the starting material at equal formaldehyde concentrations. It was also higher when this concentration was low. This seems reasonable since the difference in rate between the dehydration of the saturated aldehyde and the condensation reaction of the unsaturated is greatest for the couple II and VI and also must be greater at lower formaldehyde concentrations. The very fact that unsaturated aldehyde is formed also at the higher of the formaldehyde concentrations used shows, anyhow, that not all enolate ions formed condense with formaldehyde even at these concentration levels. For this reason the rates of enolate ion formation cannot be completely rate determining even under these conditions.

The aldehydes I and V have a very pronounced rate maximum in about 0.25 M formaldehyde solutions, the rate constant having a four times smaller value for the reaction in 4.0 M solutions. The dehydration⇌hydration reactions cannot, as discussed earlier, give contributions to the experimentally observed rates of disappearance in these cases, since the analytical method used did not distinguish between I and V. The same is probably true for the alcohol addition ⇌ elimination reactions as well, β-alkoxyaldehydes being split when introduced into the injection block. Experimentally I and V were found to react with the same rate under the different concentration and temperature conditions used and this also helps to explain why changes in rate constant during a single run were not observed with these aldehydes. Their equality of rates is probably incidental since there seems to be no reason why this should be so for the unsaturated and saturated aldehyde in any given equilibrium couple, except under conditions where equilibrium already is attained.

The Arrhenius activation energies calculated from the experimental data are 17.3, 13.1, 13.1, and 12.6 kcal mol^{-1} for I (and V), VI, VII, and VIII, respectively. The experimental errors are estimated to be in the order of ± 0.4 kcal mol^{-1} for I (and V) and ± 0.8 kcal mol^{-1} for the others.

Since both the aldol condensation reactions and the hydration ⇌ dehydration reactions are believed to proceed *via* enolate ions it is of obvious interest to compare both rate constants and activation energies obtained.[3] It is then seen, that the condensation reactions have both the highest rates and, remarkably, the highest activation energies. At first sight this seems hard to reconcile with the assumption that all these reactions involve enolate ions. One must bear in mind, however, that only a very small part of the formaldehyde is present in reactive form, monomeric and unhydrated. The activation energies calculated for the condensation reactions thus reflect not only the activation energy for formation of the transition state from a formaldehyde molecule and the enolate ion. At least at lower formaldehyde concentrations, where the second reaction step (eqn. 2) is rate determining, they also contain the enthalpy and entropy changes for dehydration of methylene glycol, 5.7 kcal mol^{-1} and 5.4 e.u. according to Gruen and McTigue.[7] Thus, for all the aldehydes V to VIII the activation energies for the actual condensation reaction with formaldehyde are lower or about equal to the activation energies for the corresponding hydration reactions. For aldehyde II it is lower even without considering the influence due to dehydration of methylene glycol.

Ogata *et al.* in their paper report an activation energy of 22.9 kcal mol^{-1} for the aldol condensation of I with formaldehyde and the value of 22.1 kcal mol^{-1} for the corresponding reaction of acetaldehyde. As is evident from the spread in their presented primary rate data there is a considerable uncertainty inherent in their method. Besides, the temperature range they have investigated is rather narrow. Their values thus seem somewhat doubtful and they also seem high for normal aldol condensations. The rate constants one can calculate from their reported data for runs at 20° are very scattered. For acetaldehyde they are higher by factors between 1.5 to 3.5 but for I they are seven to ten times

smaller than the values reported in this series. It is believed, however, that the methods used in this work allow more accurate determinations with less sources of errors.

When comparing the rate constants and activation energies obtained for the aldehydes examined in this and the preceding study,[1] some notable differences can be observed. 3-Hydroxypropanal and 2-propenal are by far the most reactive ones of all the aldehydes investigated and react at 20° more than ten times faster than acetaldehyde, their precursor in the reaction series leading to pentaerythritol. 2-Methyl-2-propenal reacts in 1 M formaldehyde solutions at 20° with about the same rate as its precursor, propionaldehyde, but at formaldehyde concentrations lower than about 0.5 M this latter aldehyde reacts appreciably faster. 2-Hydroxymethyl-2-propenal and 2-ethyl-2-propenal, finally, react noticeably slower than their respective precursors, 3-hydroxypropanal and butyraldehyde, at all formaldehyde concentrations. The lowest molecular weight compounds among the alkanals and 3-hydroxypropanals, that is acetaldehyde and 3-hydroxypropanal, have distinctly higher activation energies than the other aldehydes. There does not seem to be any single factor causing this order of reactivities. The explanation must rather be sought in a combination of sterical and inductive effects of the various substituents. It could be that a 3-hydroxy group also has a neighbouring group effect in hydrogen bonding the formaldehyde molecule undergoing condensation.

EXPERIMENTAL

Materials. The formaldehyde used was of the LM-42 grade of Perstorp AB. This grade is an aqueous solution containing 42.0 ± 0.5 % of formaldehyde, 0.3 to 0.5 % of methanol, and 0.015 to 0.020 % of acid (calculated as formic acid; all percentages by weight). Acrolein and methacrolein were commercial practical grade chemicals. 2-Ethyl-2-propenal was prepared by the method of Marvel *et al.*[2] These three aldehydes were redistilled each day before use. 2-Hydroxymethyl-2-propenal and 3-hydroxypropanal were prepared in the form of their acetals, and 10^{-3} M stock solutions of the free aldehydes were prepared by the method described in an earlier paper [3] and used with the same precautions. 1-Propanol, used as internal standard in the gas chromatographic determinations, was of Fischer reagent grade. Sodium hydroxide stock solutions were freshly prepared each week from Merck Titrisol ampoules. These and all other aqueous solutions were made up with boiled, CO_2-free, distilled water.

The following stock solutions were prepared: of formaldehyde 1.00 and 10.0 M for use in the runs with I and V, 0.5 and 8.2 M for use in the runs with VII and VIII, and 0.5 and 10.9 M for use in the runs with VI; of I and V about 10^{-2} M and of VI, VII, and VIII about 10^{-3} M stock solutions were used; of NaOH 0.100 M and of 1-propanol about 0.08 % by weight solutions. The formaldehyde stock solutions were neutralized to pH 7.0.

Apparatus. The reaction mixtures were prepared in volumetric flasks and kept in a thermostatted bath controllable to within ± 0.05°C. Vapour phase chromatography was performed using a Varian 1740 gas chromatograph equipped with FI-detector and connected with an electronic integrator of type Varian 480. The UV-measurements were made using a Beckman DU instrument with cell compartment thermostatted by circulating water from the water bath.

General procedure. In the gas chromatographic runs this was identical with the one reported in the study on acetaldehyde and its homologs [1] and in the UV-spectrophotometric runs with the one used in the study on the hydration $\rightleftharpoons$ dehydration reactions of some 2-propenals and their saturated counterparts,[3] with the exception that formaldehyde was added to the mixtures used in the present study.

Gas chromatographic runs. At the start of the experimental runs, the reaction mixtures were about 0.001 M in I (or V) and about 0.004 % in 1-propanol, which was used as internal standard. The NaOH-concentration ranged from 0.001 to 0.005 M and the formaldehyde concentration from 0.10 to 4.0 M. The injection block was glass lined by insertion of a thin glass tube of commercial type to be used for this purpose. The inner wall of this tube was covered with a thin layer of a mixture of acid sodium-potassium phosphates. A syrupy aqueous solution of phosphoric acid and mono- and disodium and potassium phosphates had been prepared and was repeatedly deposited on the inner wall, the tube being dried in an oven after each treatment, until the wall was completely covered. The column was of stainless steel, 2 m × 0.22 cm. Stationary phase Chromosorb 101 80/100 mesh. Injection temperature 180°, column temperature 140°, detector temperature 150°. Carrier gas 30 ml per minute of N_2, attenuation 2×10^{-11} on the chromatograph and 1 on the integrator. Injected volume 1.0 µl.

UV-spectrophotometric runs. At the start of the experimental runs the reaction mixtures were about 10^{-4} M in VI, VII, or VIII, respectively. The concentration of formaldehyde was varied from 0.05 to 1.64 M. The NaOH-con-

centration was varied from 0.005 to 0.040 M in the runs with VI, from 0.005 to 0.030 M in the runs with VII, and from 0.010 to 0.080 M in the runs with VIII. A 1.000 cm quartz cell was used.

Acknowledgements. Generous financial support from Perstorp AB, Perstorp, Sweden, and from the Swedish Board for Technical Development is gratefully acknowledged. The author also wants to express his thanks to Professor Erich Adler for his kind interest and help, and to Mrs. Marianne Frantsi, Mrs. Ulla-Britt Persson, and Mr. Börge Samevall for skilful laboratory assistance.

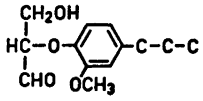
Synthesis of Lignin Model Compounds for the Glyceraldehyde-2-aryl Ether Type of Structure

LISSELA BERNDTSON, KENNETH HEDLUND, LENNART HEMRÅ and KNUT LUNDQUIST

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

The preparation of lignin model compounds for the glyceraldehyde-2-aryl ether type of structure (I) is described. The occurrence of structural elements in lignin of type I is discussed on the basis of results from studies of lignin degradation products.

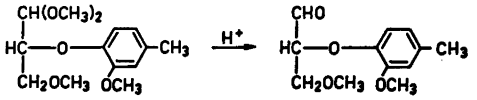
The occurrence of glyceraldehyde-2-aryl ether structures (I) in lignin has been suggested on the basis of the formation of pyruvaldehyde on "acidolysis" of lignin and model compounds.[1] Later studies [2-4] have supported the presence of such structures in lignin and some additional evidence is given in the present paper. Moreover, recent results from studies on the enzymatic oxidation of lignin model compounds [5] have provided indirect support for the occurrence of lignin structures of type I. Structure I contains a "detached side chain". The



I

role of oxidative side chain detachment in lignin chemistry has been discussed extensively the past few years (see Refs. 6 and 7). In the present paper, the synthesis of model compounds for the glyceraldehyde-2-aryl ether type of structure is described. Some aspects concerning the occurrence of "detached side chains" in lignin are also discussed.

Model compound II (liquid) was obtained by heating the sodium salt of 2-methoxy-4-methylphenol with 2-bromo-1,1,3-trimethoxypropane



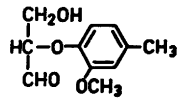
II III

Fig. 1. Preparation of aldehyde III by hydrolysis of acetal II.

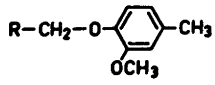
in ethanol solution. Although the yield was low, the product could be conveniently separated from the reaction mixture. Mild acidolysis of compound II gave aldehyde III (Fig. 1). This compound was obtained in a crystalline state (m.p. 44–46°). Aldehyde III is soluble in sulphite liquor and has been used as a model for structures of type I by Christofferson [4] in studies concerning the origin of pyruvaldehyde present in spent sulphite liquor (the formula given for the model compound in Ref. 4 is erroneous).

As reported previously,[1] attempts to prepare model compound IV by condensation of aldehyde VI with formaldehyde have been made. The product obtained gave 2-methoxy-4-methylphenol and pyruvaldehyde on "acidolysis", showed no infrared carbonyl absorption, and had a molecular weight which corresponded to a dimer of IV. On the basis of these properties, the product was suggested [1] to be a cyclic dimer of IV (in which the carbonyl groups take part in hemiacetal or acetal groups). The present paper describes experiments to prepare and characterize this product.

Starting material VI was prepared by hydrolysis of acetal V (obtained from the sodium



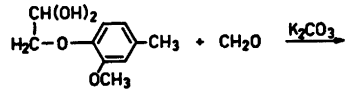
IV



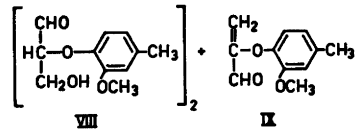
V R = $CH(OC_2H_5)_2$
VI R = CHO

salt of 2-methoxy-4-methylphenol and 2-bromo-1,1-diethoxyethane; *cf.* Ref. 8). The compound was obtained as a crystalline monohydrate (VII; m.p. 74 – 75°) and this was used in the condensation experiments with formaldehyde (Fig. 2). Distillation *in vacuo* of hydrate VII gave aldehyde VI (m.p. 50 – 52°).

The above discussed product, suggested to be a dimer of IV (VIII) (Fig. 2), was separated from reaction mixtures obtained in condensation experiments and examined. The NMR spectrum revealed the presence of a 2-methoxy-4-methylphenoxy group, but otherwise showed no clearly discernible signals. Gel filtration properties were in accord with a dimer of IV. Additional structural evidence for compound VIII was provided by the fact that borohydride reduction gave glycerol ether X (TLC) (Fig. 3) (*cf.* Ref. 9). The conversion of VIII into compound X was demonstrated by acetylation of the reaction product and identification of the acetate derivative with the independently prepared diacetate XII. For the preparation of X and XII, see Experimental.

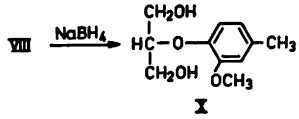


VII



VIII IX

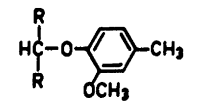
Fig. 2. Preparation of dimer VIII and aldehyde IX by condensation of compound VII with formaldehyde.



X

Fig. 3. Formation of glycerol ether X on reduction of dimer VIII with sodium borohydride.

In the preparation of dimer VIII an additional product was obtained, namely aldehyde IX. This compound is a likely intermediate in the acidolytic degradation [1] of compounds II – IV. In accord with expectations, it was found that compound IX gave pyruvaldehyde and 2-



XI R = $COOC_2H_5$
XII R = CH_2OCOCH_3

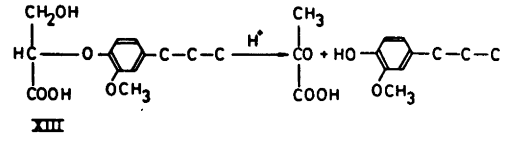
methoxy-4-methylphenol in high yields on brief "acidolysis". The fact that compound VI was stable during "acidolysis" [1] is also in accord with the assumption that an enol ether of type IX is an intermediate in the acidolytic cleavage of glyceraldehyde-2-aryl ethers.

In connection with studies of the formation of pyruvaldehyde on acidolysis of lignin, it was found that negligible amounts were formed from borohydride-reduced lignin (Ref. 3 and unpublished data). This is in accord with the proposal that the pyruvaldehyde originates from glyceraldehyde-2-aryl ethers, since such structures should be converted into glycerol-2-aryl ether structures on reduction with borohydride (*cf.* above and Ref. 9). The latter type of structure can be expected to give glycerol on "soda cooking".[10] In fact, borohydride treated lignin (but not nontreated lignin) gave glycerol on "soda cooking" (2 M NaOH, 170°, 2 h). The amount was somewhat smaller than expected from the studies of the pyruvaldehyde formation from nontreated lignin. Rather unexpectedly, it was found that glycerol was destroyed to a great extent during "soda cooking"; this makes quantitative evaluations of the results uncertain.

Comparison of the yields of pyruvaldehyde on "acidolysis" of lignin and model compounds suggests that about 2 % of the units in lignin are linked to glyceraldehyde with a 2-aryl ether bond. Calculations based on results from sulphite cooking studies [4] suggest a somewhat higher value.

During sulphite cooking structures of type I may be formed from arylglycerol-β-aryl ether structures in electrophilic displacement reactions.[10b] To what extent such or originally present structures of type I give rise to the pyruvaldehyde formed on sulphite cooking might be elucidated by sulphite cooking experiments with model compounds of the arylglycerol-β-aryl ether type and borohydride reduced lignin. In any case, it seems very likely that pyruvaldehyde (and pyruvic acid) present in sulphite liquor [4] arises from cleavage of glyceraldehyde-2-aryl ether groups.

Recent studies on lignin degradation products have demonstrated the occurrence of several types of structural elements containing units lacking propyl side chains (Refs. 7 and 11, see also Ref. 12). Based on yields of degradation products,[13,14] it seems that one of these types, namely the 1,2-diaryl-1,3-propanediol structure, is rather frequent in lignin. The figure obtained in the above-mentioned estimation of the frequency of "detached side chains" of the glyceraldehyde-2-aryl ether type therefore seems to be too low to fit with the number of units lacking side chains.



XIII

Fig. 4. Acidolytic cleavage of the proposed lignin structure XIII.

One explanation could be the occurrence of "detached side chains" of the glyceric acid-2-aryl ether type (XIII) (possibly with an esterified carboxylic group).[15] In connection with attempts to detect such structures in lignin the reaction shown in Fig. 4 was investigated. Model studies showed that ethers of type XIII were stable during "acidolysis". As expected, no pyruvic acid was formed on "acidolysis" of lignin. Additional model experiments showed that the reaction in Fig. 4 occurred to some extent on "acidolysis" at elevated temperature (140°) as indicated by the formation of pyruvic acid.

EXPERIMENTAL

IR spectra were recorded using KBr pellets (solids) or NaCl discs (liquids), with a Beckman IR 9 instrument. *NMR spectra* were recorded on a Varian A-60 instrument with TMS as internal standard. *Mass spectra* were taken on an AEI model MS 902 instrument. This equipment was also used for precise mass measurements of molecular ions. Elemental compositions were determined from these measurements using the tables of Beynon-Williams.[16]

Thin layer chromatography (TLC) was performed on silica gel plates. Eluents were benzene-ethyl acetate (1:1) (R_F values: X, 0.12; VIII, 0.17; 2-methoxy-4-methylphenol, 0.47; IX, 0.48; XII, 0.51) and benzene-ethyl acetate (4:1) (R_F values: III, 0.28; II, 0.36; 2-methoxy-4-methylphenol, 0.44). As developing agents iodine vapour (brown spots) and formalin-H_2SO_4 (1:9) were used (black spots after heating). Compounds VIII and IX were also made visible as purple spots by spraying with 2-methylindole in hydrochloric acid/ethanol and subsequent heating.

1,1,3-Trimethoxy-2-(2-methoxy-4-methylphenoxy)propane (II). 2-Methoxy-4-methylphenol (18.5 g) and 2-bromo-1,1,3-trimethoxypropane [17] (26.7 g) were added to a solution of 2.6 g Na in 50 ml ethanol and the mixture was heated in a steel autoclave at 150° for 5 h. After the NaBr which had formed was filtered off, the reaction mixture was diluted with dichloromethane, washed with 1 M NaOH and water, and dried over Na_2SO_4. Removal of the solvent by film evaporation gave an oil weighing 24.5 g. The product was chromatographed on a silica gel column (5 × 40 cm, 300 g SiO_2) with benzene-ethyl acetate (3:1) as eluent. The eluate fraction 700 – 950 ml contained compound II (TLC). The eluted material dissolved in ether was washed with 1 M NaOH and an essentially pure product (TLC) weighing 2.0 g was obtained. Final purification was made by distillation *in vacuo* (0.05 torr = 7 Pa) at 90°.

Precise mass measurements of the molecular ion gave *m/e* 270.14738. Calc. for $C_{14}H_{22}O_5^+$: *m/e* 270.146713. The molecular ion was 34 % of the base peak, *m/e* 75, which is attributed to the fragment ion $(CH_3O)_2CH^+$.

NMR spectrum (δ units; solvent, CCl_4): 2.24 (3 H, singlet; Ar-CH_3), 3.30 (3 H, singlet) and 3.33 (3 H, singlet) [$-CH(OCH_3)_2$], 3.41 (3 H, singlet; $-CH_2-O-CH_3$), 3.71 (1 H, doublet, $J = 4.8$ Hz) and 3.73 (1 H, doublet, $J = 3.4$ Hz) ($-CH_2-$), 3.78 (3 H, singlet; $Ar-O-CH_3$), 4.12 (1 H, doublet of triplets, $J = 3.4$ Hz and about 5 Hz; $Ar-O-CH<$), 4.42 (1 H, doublet, $J = 5.1$; $-CH(OCH_3)_2$), 6.49 – 6.91 (3 H, multiplet; aromatic protons).

3-Methoxy-2-(2-methoxy-4-methylphenoxy)propanal (III). Acetal II (0.33 g) was refluxed with 10 ml 0.2 M HCl in dioxan-water (9:1) for 10 min. The reaction mixture was neutralized with 10 ml 0.2 M $NaHCO_3$ and extracted with chloroform (20 + 2 × 10 ml). The extract was dried over Na_2SO_4. The amount of solvent was reduced to 10 ml by film evaporation. TLC showed one predominating spot. The solution was chromatographed on a silica gel column

(32 × 2 cm; 50 g SiO_2) with benzene-ethyl acetate (4:1) as eluent. From the eluate fraction 140 – 195 ml 0.21 g of an oil was obtained. Distillation (60 – 70°, 0.05 torr = 7 Pa) gave 0.12 g of an oil which crystallized on cooling (m.p. 44 – 46°). The IR spectrum showed a strong band at 1725 cm^{-1} (C = O). The molecular ion (*m/e* 224) was the base peak in the mass spectrum. Precise mass measurements of the molecular ion gave *m/e* 224.1038. Calc. for $C_{13}H_{16}O_4^+$: *m/e* 224.104851.

NMR spectrum (δ units; solvent, chloroform-*d*): 2.30 (3 H, singlet; $Ar-CH_3$), 3.39 (3 H, singlet; $-CH_2-O-CH_3$), 3.82 (3 H, singlet; $Ar-O-CH_3$), 3.82 (2 H, doublet, $J = 4.3$ Hz; $-CH_2-$), 4.45 (1 H, doublet of triplets, $J = 4.3$ and 1.5 Hz; $Ar-O-CH<$), 6.54 – 6.98 (3 H, multiplet; aromatic protons), 9.88 (1 H, doublet, $J = 1.5$ Hz; $-CHO$).

1,1-Diethoxy-2-(2-methoxy-4-methylphenoxy)-ethane (V) was prepared from 2-bromo-1,1-diethoxyethane and 2-methoxy-4-methylphenol according to a procedure (method B) described by Julia and Tchernoff [8] for the synthesis of similar compounds. The product was purified by distillation (4 torr = 500 Pa, bath temperature 147°). Yield: 59 %. (Found: C 66.51; H 8.89. Calc. for $C_{14}H_{22}O_4$: C 66.12; H 8.72.) NMR spectrum (δ units; solvent, chloroform-*d*): 1.21 (6 H, triplet, $J = 7.0$; $-CH_2-CH_3$), 2.26 (3 H, singlet; $Ar-CH_3$), 3.66 (2 H, quartet, $J = 7.0$) and 3.70 (2 H, quartet, $J = 7.1$) ($-CH_2-CH_3$), 3.80 (3 H, singlet; $-O-CH_3$), 4.01 (2 H, doublet, $J = 5.2$; $Ar-O-CH_2-$), 4.84 (1 H, triplet, $J = 5.2$ Hz; $>CH-$), 6.53 – 6.91 (3 H, multiplet; aromatic protons).

1,1-Dihydroxy-2-(2-methoxy-4-methylphenoxy)-ethane (VII). Acetal V (8.0 g) was refluxed with 100 ml 0.2 M HCl in dioxan-water (4:1) for 10 min. The reaction mixture was neutralized with 0.4 M $NaHCO_3$ to pH 6 and extracted with a total of 200 ml chloroform. The extract was dried over Na_2SO_4 and the solvent removed by film evaporation. The residual oil weighed 6.35 g. From ether saturated with water, 4.9 g crystals (m.p. 74 – 75°) was obtained. (Found: C 60.70; H 7.07; OCH_3 15.79. Calc. for $C_{10}H_{14}O_4$: C 60.59; H 7.12; OCH_3 15.66.)

NMR spectrum (δ units, 20°; solvent, DMSO-d_6): 2.24 (3 H, singlet; $Ar-CH_3$), 3.75 (3 H, singlet; $-O-CH_3$), 3.88 (2 H, doublet, $J = 5.2$ Hz; $-CH_2-$), 5.13 (1 H, approximately quintet, $J = 6.3$ and 5.2 Hz), 5.97 (2 H, doublet, $J = 6.3$ Hz; $-OH$), 6.43 – 6.91 (3 H, multiplet, aromatic protons). When the spectrum was recorded at higher temperatures, the presence of aldehyde VI was indicated.

2-(2-Methoxy-4-methylphenoxy)acetaldehyde (VI) was obtained upon distillation (0.04 torr = 5 Pa, 50 – 60°) of compound VII. The product melted at 51 – 52°. (Found: C 66.28; H 6.59; OCH_3 17.33. Calc. for $C_{10}H_{12}O_3$: C 66.65; H 6.71; OCH_3 17.22.) The IR spectrum showed a strong band at 1735 cm^{-1} (C = O). NMR spectrum (δ units; solvent chloroform-*d*): 2.29 (3 H, singlet; $Ar-CH_3$), 3.83 (3 H, singlet; $-O-CH_3$), 4.50 (2 H, doublet, $J = 1.3$ Hz; $-CH_2-$), 6.66 – 6.73 (3 H, multiplet; aromatic protons), 9.84 (1 H, triplet, $J = 1.3$ Hz; $-CHO$).

The compound gave a semicarbazone melting at 174 – 176° after recrystallization from ethanol-water. (Found: C 55.89; H 6.29; O 20.74; N 17.85; OCH_3 13.15. Calc. for $C_{10}H_{12}O_2N_3(OCH_3)$: C 55.69; H 6.37; O 20.23; N 17.71; OCH_3 13.08.)

Dimer (VIII) of 3-hydroxy-2-(2-methoxy-4-methylphenoxy)propanal (IV). Compound VII (5.0 g) was dissolved in 20 ml DMSO and 100 mg K_2CO_3 and 10 ml 37 % formaldehyde solution were added. The mixture was stirred for 20 min at room temperature. After the addition of 170 ml 0.1 M KH_2PO_4, the reaction mixture was extracted with chloroform (100 + 3 × 75 ml). The extract was dried over Na_2SO_4 and solvent removed by film evaporation. The residue, according to TLC, contained two components which gave purple spots with 2-methylindole in hydrochloric acid/ethanol, *i.e.* liberated pyruvaldehyde on acid treatment, *cf.* Ref. 1. The components were separated by chromatography on a silica gel column (2.5 × 40 cm; 170 g SiO_2) with benzene-ethyl acetate (1:1) as eluent. It may be noted that DMSO present in the residue was adsorbed at the top of the column. Eluate fraction 120 – 150 ml gave 0.78 g product (*fraction A*). Eluate fraction 190 – 260 ml gave 0.95 g product (*fraction B*).

Fraction A consisted essentially of 2-(2-methoxy-4-methylphenoxy)acrolein (IX). This was separated by chromatography on silica gel with dichloromethane as eluent. A product weighing 0.57 g was obtained. Purification by distillation (0.01 torr = 1 Pa, 55 – 63°) gave 0.40 g of an oil.

Mass measurements of the molecular ion gave *m/e* 192.077100. Calc. for $C_{11}H_{12}O_3^+$: *m/e* 192.078638.

The IR spectrum showed a strong band at 1705 cm^{-1} (C = O).

NMR spectrum (δ units; solvent, chloroform-*d*): 2.39 (3 H, singlet, $Ar-CH_3$), 3.93 (3 H, singlet; $-O-CH_3$), 5.03 (1 H, doublet, $J = 2.6$ Hz) and 5.21 (1 H, doublet, $J = 2.6$ Hz) ($=CH_2$), 6.61 – 6.98 (3 H, multiplet, aromatic protons), 9.43 (1 H, singlet, $-CHO$).

Fraction B was subjected to column chromatography on silica gel using gradient elution according to the previously described standard procedure [14a] to isolate the major component, which was subsequently purified by distillation (80 – 110°, 0.05 torr = 7 Pa). It has previously been suggested [1] that the product obtained in this way is a dimer of IV, in this paper denoted VIII. This was derived from the facts that no carbonyl band appeared in the IR, the molecular weight determined by osmometry fitted very well with a dimer of IV, and pyruvaldehyde and 2-methoxy-4-methylphenol were formed on "acidolysis".[1] We have made further studies which support the assumption that the product

is a dimer of IV. Thus gel filtration on Sephadex G-25 with dioxan-water (1:1) as eluent[18] supported a dimeric structure ($K_d' = 0.4$; K_d' values for compounds III and X were about 0.7). Furthermore, reduction with $NaBH_4$ gave glycerol ether X (see below). The NMR spectrum showed the presence of a 2-methoxy-4-methylphenoxy group, but was otherwise too complex to permit interpretation; possibly the product is a mixture of isomeric dimers. The mass spectrum corresponded to monomer IV. Mass measurements of the molecular ion gave *m/e* 210.091. Calc. for $C_{11}H_{14}O_4^+$: *m/e* 210.089 202. The molecular ion was 84 % of the base peak, *m/e* 138, which is proposed to be due to fragment ion (2-methoxy-4-methylphenol)$^+$.

Diethyl 2-(2-methoxy-4-methylphenoxy)-malonate (XI). Diethyl chloromalonate (35 g) was refluxed with the sodium salt of 2-methoxy-4-methylphenol (29 g) in 100 ml ethanol for 6 h (*cf.* Ref. 10a). The reaction mixture was poured into water and extracted with ether. The ether layer was dried over Na_2SO_4 and the ether removed by film evaporation. The residual oil was distilled (b.p. 116–120°/1 torr = 100 Pa). Yield: 24.5 g (46 %).

NMR spectrum (δ units, chloroform-*d*): 1.26 (6 H, triplet, $J = 7.1$; $-CH_2CH_3$), 2.26 (3 H, singlet; $Ar-CH_3$), 3.78 (3 H, singlet; $Ar-O-CH_3$), 4.26 (4 H, quartet, $J = 7.1$; $-CH_2-$), 5.16 (1 H, singlet, $-CH<$), 6.52–7.01 (3 H, multiplet; aromatic protons).

2-(2-Methoxy-4-methylphenoxy)-1,3-propanediol (X) was prepared by reduction of ester XI with $LiAlH_4$ (*cf.* Ref. 10a). The crude product was purified by chromatography on a silica gel column with ethyl acetate as eluent followed by distillation (110°, 0.02 torr = 3 Pa). The product was obtained as a colorless oil.

Precise mass measurements of the molecular ion gave *m/e* 212.101946. Calc. for $C_{11}H_{16}O_4^+$: *m/e* 212.104851.

NMR spectrum (δ units; solvent, chloroform-*d*): 2.27 (3 H, singlet; $Ar-CH_3$), 3.54 (2 H, singlet; $-OH$), 3.78 (3 H, singlet; $-O-CH_3$), 3.76 (4 H, doublet, $J = 4$ Hz; $-CH_2-$), 3.99 (1 H, multiplet; $-CH<$), 6.47–7.01 (3 H, multiplet; aromatic protons).

Diacetate (XII) of compound X. Compound X was acetylated with acetic anhydride-pyridine. Excess reagent was removed by distillation and the residual product purified by distillation *in vacuo*. (Found: C 61.10; H 6.63. Calc. for $C_{15}H_{20}O_6$: C 60.80; H 6.80.) The IR spectrum showed a strong band at 1745 cm^{-1} (C=O). NMR spectrum (δ units; solvent, chloroform-*d*): 2.03 (6 H, singlet; $-CO-CH_3$), 2.28 (3 H, singlet; $Ar-CH_3$), 3.79 (3 H, singlet; $-O-CH_3$), 4.3 (5 H, multiplet; $-CH_2-CH(OAr)-CH_2-$), 6.55–6.95 (3 H, multiplet; aromatic protons).

Reduction of compound VIII (dimer of IV). Compound VIII (100 mg) was dissolved in 5 ml dioxan and 2–3 ml $NaBH_4$ solution was added (2 g $NaBH_4$ in 100 ml 0.25 M NaOH). After 1 h the solution was extracted with chloroform. The extract was dried over Na_2SO_4 and the solvent evaporated. Examination by TLC indicated that the product was compound X (small amounts of contaminants were present). The product was acetylated with acetic anhydride-pyridine and the resulting acetate was purified by chromatography on silica gel with benzene-ethyl acetate (4:1) as eluent. A pure product (TLC) weighing 105 mg was obtained. This was shown to be identical with authentic diacetate XII by IR and NMR analyses.

Acidolysis of aldehyde IX. Aldehyde IX (6.0 mg) was acidolysed for 5 min in 10 ml 0.2 M HCl in dioxan-water (9:1). Five ml 0.4 M $NaHCO_3$ was added and the mixture extracted with chloroform ($10 + 2 \times 5$ ml). It was demonstrated that the major part of the pyruvaldehyde remains in the aqueous layer during this work up procedure. To the aqueous layer 50 ml 2,4-dinitrophenylhydrazine solution was added (3 g 2,4-dinitrophenylhydrazine was dissolved in 100 ml 72 % $HClO_4$ and 100 ml H_2O added). After 1 h the precipitate was filtered off and washed with 12 % $HClO_4$, water, and ethanol. The precipitate (11.6 mg) was identified as the bis[(2,4-dinitrophenyl)hydrazone] of pyruvaldehyde. The formation of 2-methoxy-4-methylphenol was demonstrated by examination of the organic layer with TLC.

Acknowledgements. The authors thank Prof. E. Adler and Prof. M. Nilsson for their kind interest in this work. We wish to thank Civ.ing. M. Björklund for performing the experimental work concerning structures of type XIII.

On the Reaction of Methylthio- and Methoxythiophenes with Tetracyanoethylene Oxide

SALO GRONOWITZ and BENGT UPPSTRÖM *

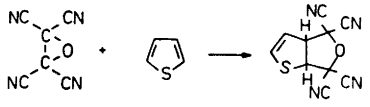
Division of Organic Chemistry, University of Lund, Chemical Center, P.O. Box 740, S-220 07 Lund 7, Sweden

The reaction between methoxythiophenes or methylthiothiophenes and tetracyanoethylene oxides gives methoxy- or methylthiosubstituted thenoyl cyanides in low yields. A probable reaction mechanism for the formation of the thenoyl cyanides is given.

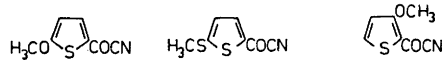
The mass spectra of the thenoyl cyanides are briefly discussed.

In connection with our work [1] on the effect of substituents on the cycloaddition of tetracyanoethylene oxide (I) to thiophene (II) [2] we used methoxy- and methylthiothiophenes as substrates. However, in these cases the normal substituted 1,1,3,3-tetracyano-1,3,3a,6a-tetrahydrothieno[2,3-*c*]furans (III) [2] were not obtained. Reacting for instance 2-methoxythiophene with I in benzene at 150° gave a crystalline compound, m.p. 68°C, which elemental analysis and mass spectrum showed to have the composition $C_7H_5NO_2S$. The IR spectrum indicated the presence of C≡N (2230 cm^{-1}) and C=O stretchings (1675, 1640 cm^{-1}) and the NMR spectrum showed aromatic methoxyl at δ 4.05 and two doublets at δ 6.44 and δ 7.87 with couplings of 4.5 Hz characteristic of a disubstituted thiophene. All these facts clearly show that the compound obtained is 5-methoxy-2-thenoyl cyanide (IV). 2-Thenoyl cyanide has recently been studied by Roques and Robba.[3] Using their substituent shifts in the proton NMR spectra and those earlier obtained by Gronowitz and Hoffman [4] for 2-methoxythiophene and assuming additivity, shifts of δ 7.67 and δ 6.34 for the 3- and 4-hydrogen were calculated for 5-methoxy-2-thenoyl cyanide, which are in good accordance with the observed values. Roques and Robba [3] also observed two carbonyl stretching frequencies at 1661 and 1683 cm^{-1} which they assigned to the presence of *s-cis* and *s-trans* conformers. This may also be the case in the 5-methoxy-substituted derivative, the somewhat lower frequencies being due to higher single bond character due to through-conjugation between the methoxy and the carbonyl cyanide group.[5]

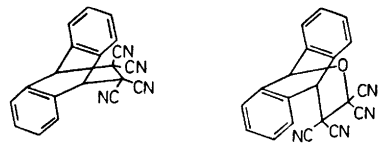
2-Methylthiothiophene reacted in the same way, although the yield of 5-methylthio-2-thenoyl cyanide (V) was only 6 %. Also in this case the structure followed from spectroscopic data and good accordance between the experimental chemical shifts (δ_3 = 8.03 ppm, δ_4 = 7.20 ppm) and those calculated by assuming additivity of



I II III



IV V VI



VII VIII

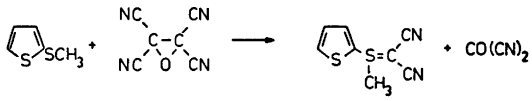
* Taken in part from the Ph.D. thesis of B. Uppström, University of Lund 1973.

substituent shifts ($\delta_3 = 7.92$ ppm, $\delta_4 = 7.25$ ppm) was observed.

In the reaction of I with 3-methoxythiophene, 12 % of 3-methoxy-2-thenoyl cyanide (VI) was obtained. In this case larger deviations of the shifts from additivity were obtained. The observed shifts were 7.22 and 8.20 for the 4- and 5-hydrogen resonance, while the calculated values were δ 6.90 and δ 7.77, respectively. The deviation is probably due to steric interaction between the substituents.

It is known [3,6] that electron-rich olefins do not give normal adducts with I. Thus 2,3-dimethylbutene and I gave 2,3-dimethyl-2-butene epoxide. Anthracene and I gave a complex mixture of anthrone, anthraquinone, and bianthrone in addition to the anomalous adducts VII and VIII.[6] The side-reaction observed by us is most probably of another type. It has been found that I reacts with dimethyl sulphide to give dimethylsulphonium dicyanomethylide and carbonyl cyanide.[7] The corresponding reaction with dibutyl sulphide is indeed one of the most convenient methods for the preparation of carbonyl cyanide.[8] This reaction also occurs with aromatic sulphides. Thus *p*-anisyl methyl sulphide gave *p*-anisylmethylsulphonium dicyanomethylide in 67 % yield.[9]

It therefore seems likely that 2-methylthiothiophene first reacts with I to give the sulphonium dicyanomethylide and carbonyl cyanide, and the latter then reacts with excess of 2-methylthiothiophene to give V (*cf.* Formula Scheme).



V

An analogous route for the formation of IV and VI could be possible. However, the corresponding carbonyl ylide must be much less stable and more reactive than the sulphur analogue due to the absence of d-orbital stabilization. The formation of large amount of tars

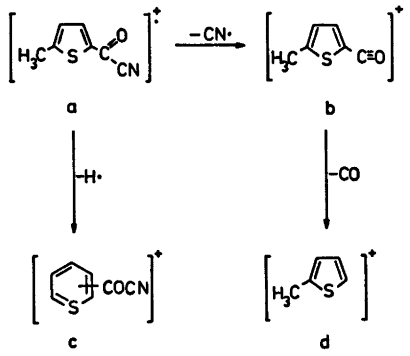


Fig. 1. Mass spectral fragmentation pattern for 5-methyl-2-thenoyl cyanide.

in this reaction could be due to the decomposition of the ylides.

The hypothesis that methylthio- and methoxythiophenes react with carbonyl cyanide at 130° to give thenoyl cyanides was confirmed with 2-methylthiothiophene and 3-methoxythiophene, which gave 33 % and 55 % yield of V and VI, respectively. Also less activated thiophenes such as 2-methylthiophene reacted with carbonyl cyanide to give the thenoyl cyanide, albeit in lower yield.

This way of introducing the COCN group into thiophenes appears to be more convenient than the $AlCl_3$-catalyzed reaction utilized earlier.[10]

We have also studied the mass spectral fragmentation of the thenoyl cyanides to some extent. The structures and mechanisms which are suggested should be considered as tentative. The simplest pattern is obtained for 5-methyl-2-thenoyl cyanide, Fig. 1. The molecular ion (a) loses a cyanogen radical to give the stable acylium ion (b) which further loses CO to give the ion (d). As with other methylthiophenes the molecular ion also loses hydrogen to give the thiopyrylium ion (c).[11]

Also in the mass spectra of the two methoxy-substituted thenoyl cyanides, the molecular ion is the most intense (Figs. 2 – 3). Fragmentation then occurs for IV by loss of either a cyanogen or a methyl radical to give the ion (f) (48 %) and (g) (60 %) of about equal intensity. For VI the loss of methyl is of much less importance, as the ion (o) has only an intensity of 5 %. The suggestion that the ions (g) (Fig. 2) and (o) (Fig. 3) lose the ring-carbonyl group as C=O

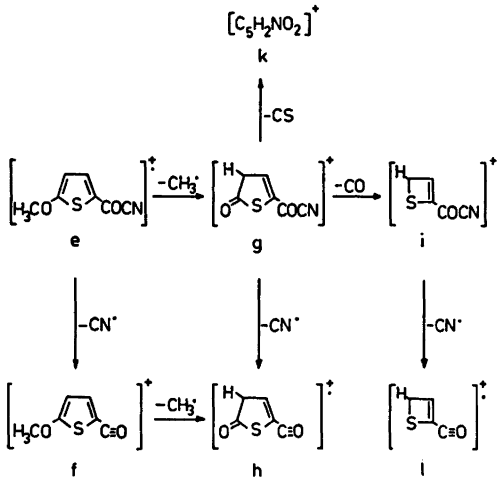

Fig. 2. Mass spectral fragmentation pattern for 5-methoxy-2-thenoyl cyanide.

is supported by the fact that the ion (x) does not lose CO but CS to give (y) (Fig. 4) and that ion (a) (Fig. 1) does not lose CO. The fragmentation with loss of ring-carbonyl groups is also observed in methoxythiophenes, which show step-wise loss of CH_3 and CO from the molecular

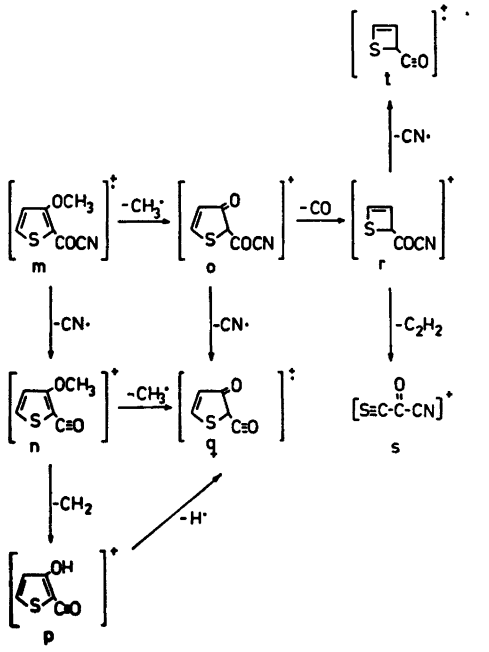

Fig. 3. Mass spectral fragmentation pattern for 3-methoxy-2-thenoyl cyanide.

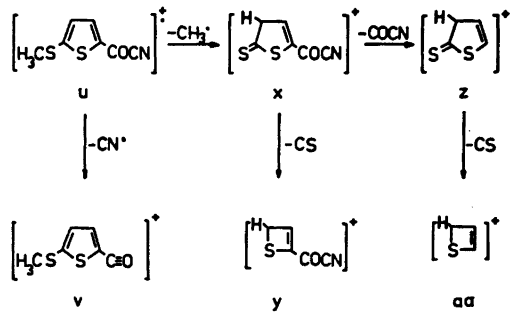

Fig. 4. Mass spectral fragmentation pattern for 5-methylthio-2-thenoyl cyanide.

ions.[13] The ion (i) (*m/e* 124) loses a fragment with mass 26 which could indicate loss of either a cyanogen radical or acetylene or both. High-resolution mass spectroscopy showed that the ion (l) had the composition C_4H_2OS. Thus the ion (i) loses only a cyanogen radical. On the other hand, the ion (r) (Fig. 3) loses both cyanogen and acetylene as with high-resolution mass spectroscopy both ion (s) and (t) could be observed. They had approximately the same intensity. Also the composition of ions (e), (g), (h), (i), (m), (n), (p), (q), and (r) was determined by high-resolution mass spectrometry. Further fragmentation is indicated in Figs. 2 – 3.

The mass spectrum of anisole shows the elimination of formaldehyde from the molecular ion.[12] This fragmentation path was not observed for IV and VI.

The fragmentation pattern of 5-methylthio-2-thenoyl cyanide is shown in Fig. 4. The loss of the cyanogen radical from the molecular ion is more important than the loss of methyl. No elimination of SH or CH_2S, which is characteristic for 2-fluoro-5-methylthiothiophene,[13] was observed. Neither was any intermediate ion observed on the path from the ion (x) to the ion (z) which might indicate the direct elimination of COCN.

EXPERIMENTAL

Reaction of methoxythiophenes with tetracyanoethylene oxide. 11.4 g (0.10 mol) of 2-methoxythiophene,[14] and 5.0 g (0.035 mol) of tetracyanoethylene oxide [15] in 100 ml of anhydrous benzene were heated in a glass ampoule at 150°C for 5 h. The mixture was filtered hot and evaporated to a volume of 20 ml. This

solution was chromatographed on silica gel, using benzene as eluent, and yielding 1.4 g (24 %) of 5-methoxy-2-thenoyl cyanide after recrystallization from 1,2-dichloroethane, m.p. 67 – 69°C. NMR ($CDCl_3$) $\delta_3 = 6.44$ ppm, $\delta_4 = 7.87$ ppm, $\delta_{CH_3} = 4.05$ ppm, $J_{3,4} = 4.5$ Hz. IR (KBr) C≡N: 2230 cm^{-1}, C=O: 1675, 1640 cm^{-1}. Mass spectrum (*m/e*, %): 169, 5; 168, 10; 167, 100; 153, 20; 152, 60; 141, 48; 126, 5; 124, 10; 108, 65; 98, 70; 96, 12; 70, 48; 69, 35; 64, 8; 57, 6; 54, 10; 53, 8; 45, 14; 38, 11; 37, 9. [Found: C 51.30; H 3.15; N 8.21; O 18.58; S 18.74. Calc. for $C_7H_5NO_2S$ (167.2): C 50.29; H 3.01; N 8.38; O 19.14; S 19.18].

From 11.4 g (0.10 mol) of 3-methoxythiophene,[16] 5.0 g (0.035 mol) of tetracyanoethylene oxide and 100 ml of benzene, 0.70 g (12 %) of the title compound, m.p. 134 – 135°C after recrystallization from 1,2-dichloroethane/cyclohexane, was obtained in the same way as described above. NMR ((CD_3COCD_3): $\delta_5 = 8.20$ ppm, $\delta_4 = 7.22$ ppm, $\delta_{CH_3} = 4.13$ ppm, $J_{45} = 5.5$ Hz. IR (KBr) C≡N: 2210 cm^{-1}, C=O: 1610 cm^{-1}. Mass spectrum (*m/e*, %): 169, 5; 168, 10; 167, 100; 152, 5; 150, 12; 142, 5; 141, 60; 140, 25; 139, 6; 138, 12; 137, 5; 128, 5; 127, 60; 126, 45; 124, 12; 113, 8; 112, 25; 111, 60; 110, 10; 109, 25; 98, 30; 96, 12; 85, 6; 84, 5; 83, 12; 82, 10; 81, 5; 73, 13; 69, 12; 64, 5; 58, 7; 56, 5; 54, 28; 53, 9; 45, 35; 44, 10; 41, 10; 39, 12; 38, 7; 37, 2. 2-Methylthiothiophene. This compound was prepared in a manner analogous to that described for 3-methylthiothiophene.[17] To 42.0 g (0.50 mol) of thiophene in 450 ml of anhydrous ether, 0.55 mol of 1.64 N butyllithium in hexane was added dropwise. The solution was cooled to −70°C and 47.1 g (0.50 mol) of dimethyl disulphide was added dropwise. The mixture was left over night at room temperature and then poured into ice-water. The ether phase was separated, the aqueous layer extracted with ether and the combined organic phases washed with water, sodium hydroxide solution and water. The organic layer was dried over magnesium sulphate, the ether and hexane evaporated and the residue distilled in vacuo to yield 50.0 g (77 %) of 2-methylthiothiophene, b.p. 65 – 70°/15 mmHg. Literature value[18] b.p. 80 – 82°/22 mmHg.

Reaction of 2-methylthiothiophene with tetracyanoethylene oxide. From 13.0 g (0.10 mol) of 2-methylthiothiophene, 5.0 g (0.035 mol) of tetracyanoethylene oxide and 100 ml of anhydrous benzene, 0.40 g (6 %) of the title compound, m.p. 69 – 70°C after recrystallization from 1,2-dichloroethane/cyclohexane mixture was obtained in the same way as described above. NMR ($(CD_3)_2CO$): $\delta_3 = 8.03$ ppm, $\delta_4 = 7.20$ ppm, $\delta_{CH_3} = 2.75$ ppm, $J_{34} = 4.4$ Hz. IR (KBr) CN: 2220 cm^{-1}, C=O: 1640 cm^{-1}. Mass spectrum (*m/e*, %): 185, 7; 184, 8; 183, 100; 168, 15; 159, 6; 158, 5; 157, 90; 124, 5; 114, 62; 108, 5; 96, 5; 88, 5; 85, 28; 82, 9; 81, 7; 70, 30; 69, 55; 57, 10; 54, 8; 53, 5; 45, 52; 41, 5; 38, 10; 37, 5. [Found: C 45.97; H 3.12; N 7.54; O 8.38; S 35.10. Calc. for $C_7H_5NOS_2$ (183.2): C 45.88; H 2.75; N 7.64; O 8.73; S 34.99].

3-Methoxy-2-thenoyl cyanide. To a solution of 2.6 g (0.033 mol) of carbonyl cyanide,[8] in 50 ml of anhydrous benzene, 9.5 g (0.083 mol) of 3-methoxythiophene was added, and the solution heated to 130°C for 2 h in a glass ampoule. The reaction mixture was worked up as described in method A yielding 1.8 g (33 %) of the title compound, m.p. 133 – 134°C and with the same spectroscopic data as the sample described above.

5-Methylthio-2-thenoyl cyanide. To a solution of 2.3 g (0.029 mol) of carbonyl cyanide [8] in 50 ml of anhydrous benzene 12.0 g (0.092 mol) of 2-methylthiothiophene was added and the solution heated in a glass ampoule to 130°C for 2 h. The reaction mixture was worked up as described above yielding 3.0 g (55 %) of the title compound, m.p. 68 – 69°C, having the same spectroscopic properties as the sample described above.

5-Methyl-2-thenoyl cyanide. To a solution of 1.8 g (0.023 mol) of carbonyl cyanide [8] in 50 ml of anhydrous benzene, 13.0 g (0.13 mol) of 2-methylthiophene [19] was added and the solution heated in a glass ampoule to 130°C for 3 h. The reaction mixture was filtered, evaporated almost to dryness and the residue chromatographed on silica gel using benzene as eluent. The product was recrystallized from carbon tetrachloride, yielding 0.6 g (17 %) of the title compound, m.p. 73 – 74°. NMR ($(CD_3)_2CO$): $\delta_3 = 8.03$ ppm, $\delta_4 = 7.12$ ppm, $\delta_{CH_3} = 2.68$ ppm, $J_{34} = 4.0$ Hz, $J_{CH_3-4} = 1.0$ Hz, $J_{CH_3-3} = 0.6$ Hz. IR (KBr) CN: 2220 cm^{-1}, C=O: 1640 cm^{-1} (broad). Mass spectrum (*m/e*, %): 153, 5; 152, 10; 151, 100; 150, 15; 127, 5; 126, 8; 125, 95; 122, 8; 98, 5; 97, 58; 96, 8; 95, 8; 93, 5; 82, 5; 71, 8; 70, 10; 68, 22; 63, 5; 59, 7; 58, 7; 57, 12; 54, 30; 53, 40; 52, 5; 51, 12; 50, 10; 45, 32; 39, 18; 38, 13; 37, 10. [Found: C 54.81; H 3.36; N 9.10; S 20.94. Calc. for C_7H_5NOS (151.2): C 55.61; H 3.33; N 9.26; S 21.21].

IR spectra were recorded on a Perkin-Elmer 257 Grating Infrared Spectrophotometer, NMR spectra on a Varian A-60 spectrometer and mass spectra on an LKB 9000 mass spectrometer. The compounds were injected through a direct inlet at approximately 25°C. The energy of the ion beam was 70 eV and the electron current was set to 60 μA. High-resolution mass spectra were obtained with an MS 902 AEI spectrometer.

Acknowledgements. The authors are grateful to Professor K. Undheim, University of Oslo, for the high-resolution mass spectra. Grants from the Swedish Natural Science Research Council to S. G. and from the Royal Physiographic Society in Lund to B. U. are gratefully acknowledged.

The Synthesis and Stereochemistry of 3-Alkyl-1,2-indandiol Diacetates

LARS CEDHEIM and LENNART EBERSON *

Division of Organic Chemistry 1, Chemical Center, University of Lund, P.O. Box 740, S-220 07 Lund 7, Sweden

A series of alkylindenes, with the alkyl group methyl, ethyl, propyl, isopropyl, butyl, and *t*-butyl has been subjected to (a) permanganate oxidation and (b) oxidation by iodine/silver acetate under "wet" and "dry" conditions, These methods, in combination with acetylation by acetic anhydride/pyridine, give access to the four possible 3-alkyl-1,2-indandiol diacetates from each 1-alkylindene (except for the *t*-butyl compound, where the all-*trans*-isomer is not available by these methods). Structures have been assigned to all compounds by synthetic, mechanistic, and NMR spectral considerations.

Studies on the stereochemistry of the anodic side-chain acetoxylation of 2-*t*-butylindan [1] and 1-*t*-butylacenaphthene [2] have indicated that the anodic surface might exert a certain degree of steric control on the reaction. In order to extend these studies to other reaction types we have chosen to investigate the anodic addition of two acetoxy groups to 1-alkylindenes (eqn. 1). Since the steric relationships among the

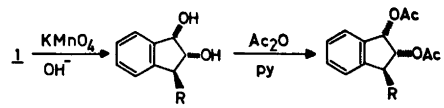
1 2

R = CH_3, C_2H_5, C_3H_7, i-C_3H_7, C_4H_9, and *t*-C_4H_9

four possible isomeric 3-alkyl-1,2-indandiol diacetates (*2*) are not known, it was first necessary to establish these by independent methods. This paper is a report of the synthesis and elucidation of the structures of all possible diacetates of the type *2* with R defined as in eqn. 1.

RESULTS AND DISCUSSION

It is known that potassium permanganate will oxidize alkenes to *cis* glycols in alkaline solution,[3] as exemplified for a 1-alkylindene in eqn. 2. It has also been shown that potassium permanganate will attack a properly substituted alkene preferentially from the sterically least hindered side and thus should give the less hindered *cis* glycol (*3*) from a 1-alkylindene [4–7] (eqn. 2). From *3*, the corresponding diacetate (*4*) should be easily available by reaction with acetic anhydride/pyridine.



(2)

3 4

Another method of preparing *cis* glycols is the reaction between an alkene and iodine/silver acetate in "wet" acetic acid.[8] Again exemplifying with a 1-alkylindene, this reaction should give a mixture of *cis* glycol monoacetates from which the two possible *cis* diacetates *4* and *5* should be easily available (eqn. 3). The same reaction in "dry" acetic acid, [5b] known to give *trans* glycol monoacetates, should in the case of a 1-alkylindene directly give access to the two possible *trans* glycol diacetates *6* and *7* (eqn. 4).

The more often used method of preparing glycols from alkenes by peracid oxidation cannot be used here, since one usually obtains a mixture of *cis* and *trans* glycols [9,10] unless the reaction conditions are controlled very carefully.[11]

Table 1. Yields and physical data of *4*, synthesized *via* permanganate oxidation of 3-alkylindenes (*1*) and subsequent acetylation of the product (eqn. 2).

R	Yield of *4*, %	B.p. °C at mmHg	Retention time, min[a]
CH_3	35	117–120/0.8	15.0
C_2H_5	75	130–132/1.5	20.1
C_3H_7	73	137–139/1.0	15.0
i-C_3H_7	68	127–128/0.7	13.6
C_4H_9	47	135–137/0.8	19.0
t-C_4H_9	60	125–120/1.0	17.0

[a] 2 m × 0.3 mm 5 % neopentylglycol succinate on Chromosorb W column at 180°C; carrier gas N_2, flow rate 20 ml/min.

In the oxidation of 1-alkylindenes (*1*) with potassium permanganate/water only one of the possible *cis* glycols is formed in each case. In line with the known stereochemistry of the reaction (see eqn. 2) structure *3* is assigned to these glycols. Table 1 gives overall yields of the reaction sequence (eqn. 2) and some physical data for identification of the diacetates *4*, R = CH_3, C_2H_5, C_3H_7, i-C_3H_7, C_4H_9, and *t*-C_4H_9.

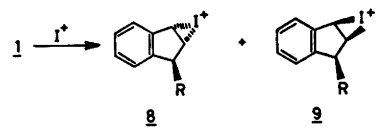
The reaction of 1-alkylindenes (*1*) with silver acetate/iodine in "wet" acetic acid, followed by acetylation of the monoacetates formed, gives a mixture of two *cis* diacetates, one of them being identical to *4* and the other one accordingly assigned structure *5*. By using GLC and/or NMR analysis it was possible to determine the relative amounts of *4* and *5* in the product mixtures (Table 2).

Table 2. Yields and retention times of products from the reaction between 1-alkylindenes (*1*) and iodine/silver acetate in "wet" acetic acid and subsequent acetylation (eqn. 3).

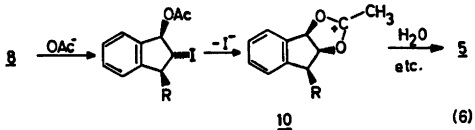
R	Yield of *4*+*5*, %	Relative yields, %		Retention time, min[a]	
		4	*5*	*4*	*5*
CH_3	52	69	31	15.0	17.2
C_2H_5	55	65	35	20.1	22.2
C_3H_7	72	65	35	15.0	15.5
i-C_3H_7	57	29	71	13.6	15.2
C_4H_9	49	72	28	19.0	20.1
t-C_4H_9	59	< 0.1	100	17.0	20.1

[a] 2 m × 0.3 mm 5 % neopentylglycol succinate on Chromosorb W column at 180°C; carrier gas N_2, flow rate 20 ml/min.

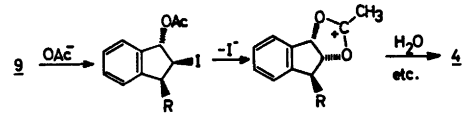
The reaction between an alkene and iodine/silver acetate in "wet" acetic acid is supposed [12] to follow the mechanism given in eqns. 5 – 7 for a 1-alkylindene:



(5)



(6)



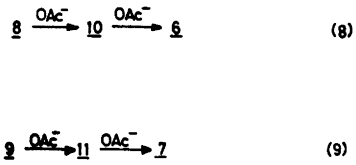
(7)

The initial step is the formation of iodonium ions *8* and *9* which then undergo S_N2 displacement by acetate ion followed by internal nucleophilic displacement of iodide ion to give acetoxonium ions *10* and *11*. These hydrolyze to give a mixture of *cis* hydroxy acetates, from which a mixture of diacetates *4* and *5* are prepared by treatment with acetic anhydride/pyridine. In the first step which controls the overall stereochemistry of the reaction sequence,

an increase in the steric demands of R should increase the percentage of iodonium ion *8* and hence the proportion of *5* in the final product. The results given for $R=C_2H_5$, i-C_3H_7 and *t*-C_4H_9 in Table 2 show this prediction to be correct.

The same reaction, run in "dry" acetic acid, gave a mixture of diacetates which by GLC and/or NMR spectral analysis were not identical with either *4* or *5*. Accordingly, the product mixture must consist of *trans* diacetates *6* and *7*. The assignment of structures to *6* and *7* is based on predictions from mechanistic considerations in the following way: Under "dry" conditions the mechanism is identical to that given in eqns. 5–7, except for the hydrolysis step which is exchanged for an S_N2 attack at the benzylic carbon of acetoxonium ions *10* and *11* by acetate ion [5b, 12] (eqns. 8 and 9). Since the first part of the reaction is performed in the same way under both "wet" and "dry" condition, *8* and *9* and hence *10* and *11* should be formed in approximately the same ratios in both cases. From this it follows that the *4*/*5* ratio should be approximately equal to the *7*/*6* ratio, and this prediction has been the basis of the structural assignments of Table 3.

The NMR spectra of compounds *4*–*7* are in good agreement with the general structure *2* but cannot be reliably used for detailed stereostructural assignments due to the irregularities of vicinal coupling constants in the indan system.[1,13,14] Table 4 illustrates these difficulties



(8)

(9)

for two representative sets of compounds *4*–*7*, $R=CH_3$ and C_4H_9. In these cases there is no possibility of assigning *cis* or *trans* stereochemistry of H_a, H_b and H_c from the relative magnitudes of the coupling constants J_{ab} and J_{bc}.

The mass spectra of diacetates *4*–*7* are closely similar. (For an example, see Table 5). No molecular ion is detectable, the fragment with highest mass being formed by elimination of acetic acid from M^+.

Further evidence for the correctness of the structural assignments above was obtained by studying the pseudocontact shifts in the NMR

Table 3. Yields and retention times of products from the reaction between 1-alkylindenes and iodine/silver acetate in "dry" acetic acid (eqn. 4).

R	Yield of *6*+*7*, %	Relative yields, %		Retention time, min[a]

spectrum of *4* – *7*, R = *t*-Bu, caused by the addition of tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-4,6-dionato)europium(III), Eu(fod)$_3$. Since Eu(fod$_3$) is sterically very demanding, one would expect it to complex at the 3-acetoxy group of the sterically most crowded diacetate, the all-*cis* isomer *5*. Hence the 3-acetoxy methyl should be more shifted than that of the 2-acetoxy group, and H_a and the methyl groups should be affected to a relatively low extent (see Table 6). The second isomer with *cis* acetoxy groups, *4*, should have nearly equivalent acetoxy groups from the steric point of view, resulting in nearly equal shifts of the acetoxy methyl signals. On the other hand, both the H_a and the R methyl signal should be relatively more shifted than in *5*.

Isomer *6*, with the 2-acetoxy group *cis* to the *t*-butyl group, again should have the 3-acetoxy group sterically more accessible for complexing with Eu(fod)$_3$. On the other hand, the all *trans* isomer *7* should have nearly equivalent acetoxy groups and hence show similar shifting of the acetoxy methyl signals.

A study of the anodic addition of two acetoxy groups across the double bond of 1-alkylindenes will be reported later.[15]

Table 6. Pseudocontact shifts in the NMR spectra of *4* – *7*, R = *t*-C_4H_9 by addition of Eu(fod)$_3$; solvent $CDCl_3$.[a]

Compound	Shift, Hz CH_3 in *t*-C_4H_9	CH_3 in 3-acetoxy	CH_3 in 2-acetoxy	H_a	[Eu(fod)$_3$]/[substrate]

7	68	148	137	154	0.36

[a] Recorded on a Varian T-60 NMR spectrometer.

EXPERIMENTAL

1-Alkylindenes. These compounds were prepared as described earlier.[16]

trans,cis-*3-Alkyl-1,2-indandiol diacetates* (*4*). To a cooled solution of 1-alkylindene (10.0 mmol) in acetone-water (80 + 20 ml) a solution of potassium permanganate (1.5 g) and potassium hydroxide (0.3 g) in water (30 ml) was added at a rate allowing for the purple colour caused by one drop to disappear before the next drop was added. The temperature was not allowed to exceed 0°C during the addition. After 2 h the manganase dioxide was filtered off and the solvent removed from the filtrate in a rotating-film evaporator. The residue was treated with a mixture of acetic anhydride (25 ml) and pyridine (1 ml) and refluxed for 5 min. After cooling and addition of water (100 ml) the organic material was extracted into pentane. The pentane solution was then worked up by distillation, giving the pure isomers *4* (see Table 1).

Mixtures of trans,cis- *and all*-cis-*3-alkyl-1,2-indandiol diacetates* (*4 and* 5). Iodine (6.5 g) was added all at once at room temperature to a mixture of acetic acid (125 ml), silver acetate (8.6 g, 96 %) and 1-alkylindene (25 mmol). The solution was stirred for 1 h at 20°C and water (2 ml) was added. The solution was then stirred at 80 – 90° for 2 h. From the cooled solution silver iodide was removed by filtration and acetic acid by evaporation. The residue was refluxed for 5 min with acetic anhydride (25 ml) and pyridine (1 ml). The same work-up procedure as above yielded a mixture of *4* and *5* (see Table 2; for R = *t*-Bu, only *5* is formed).

Mixtures of cis-trans- *and all*-trans-*3-alkyl-1,2-indandiol diacetates* (*6 and* 7). This reaction was carried out exactly as described in the preceding case, except that the water was replaced with acetic anhydride (5 ml) and the acetylation procedure was omitted.

Synthesis of 19,19′-D_6-β-Carotene

JON EIGILL JOHANSEN and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway

The total synthesis of 19,19′-D_6-β-carotene (*10*) with two fully deuterated in-chain methyl groups is described. The deuterium was introduced by base-catalyzed deuterium exchange of enolizable hydrogen. Two alternative routes were investigated for optimum deuterium incorporation in the final product.
Spectroscopic and other physical properties of intermediates and products are reported.

Previous reports on the preparation of deuterated carotenoids by reduction methods have just been summarized.[1] In the preceding paper we reported the first synthesis of deuterated carotenoids using the exchange technique on a phosphonium salt to give a deuterated phosphorane.[2]

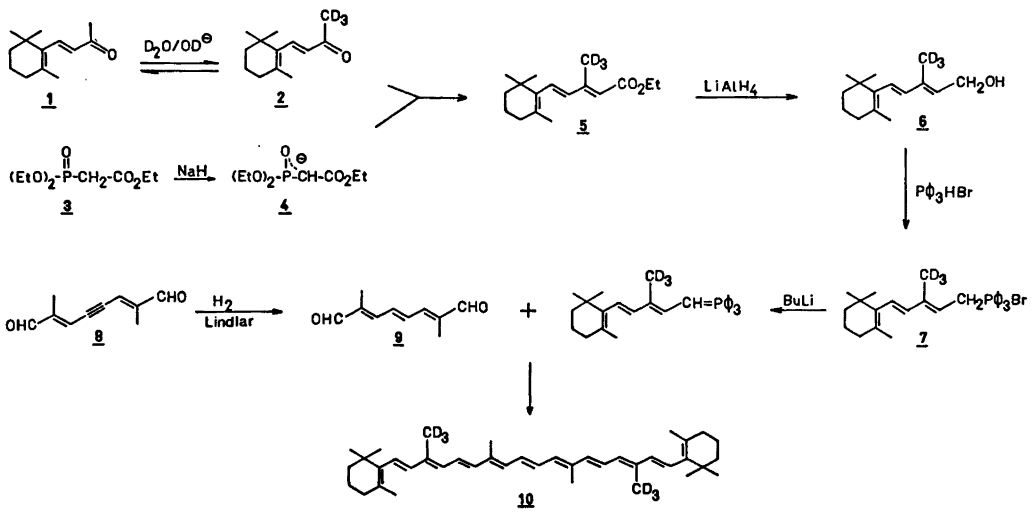
We now report the synthesis of β-carotene with two fully deuterated in-chain methyl groups, involving base-catalyzed deuterium exchange of enolizable hydrogen.

The present work forms part of a larger project comprising synthesis of specifically deuterated carotenoids for mass-spectrometric studies.[3]

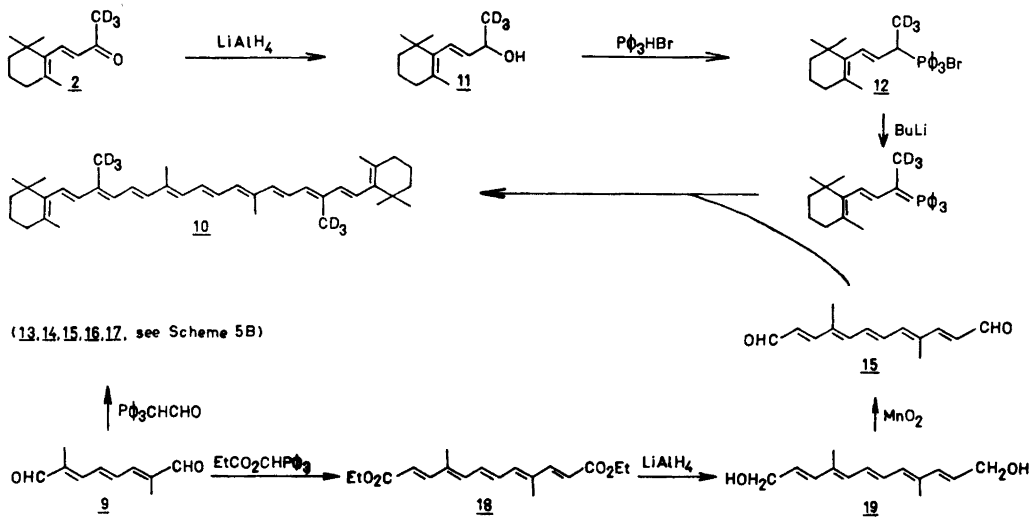
RESULTS AND DISCUSSION

Two alternative approaches were considered for the synthesis of 19,19′-D_6-β-carotene (*10*), shown in Schemes 1 and 2. Both routes involved labelling of β-ionone (*1*) in a base-catalyzed exchange reaction as briefly described by Thomas *et al.*[4]

The shortest, but also least safe route (Scheme 1, route 1), was first pursued. Horner reaction between α,α,α-D_3-β-ionone (*2*, Scheme



Scheme 1.

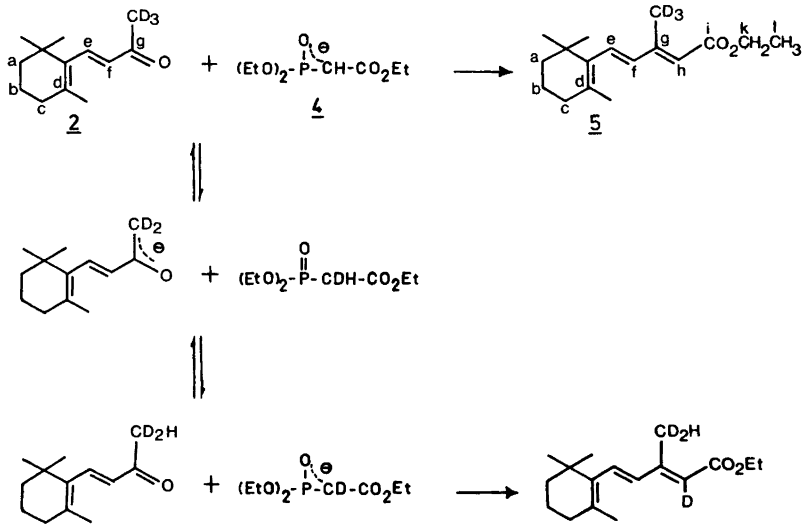


Scheme 2.

2) and triethylphosphonoacetate (*3*) resulted in scrambling of the deuterium. To prevent scrambling *via* enolization of α,α,α-D_3-β-ionone (*2*), route 2 (Scheme 2) involved reduction of the deuterated ketone *2*.

Route 1. Labelled β-ionone (*2*) was obtained by using 0,1 % NaOD in D_2O/pyridine; 1 % NaOD in D_2O/dioxane was employed by Thomas *et al.*[4,5] Also 0.28 N CH_3OLi in CH_3OD effected the same. Maximal incorporation was obtained within 18 min in the NaOD case, while few seconds were sufficient in the latter system. Three deuterium atoms only were incorporated in both cases.[4]

The attempted synthesis of D_3-β-ionylidene acetate (*5*) was performed from α,α,α-D_3-β-ionone (*2*) and triethylphosphonoacetate (*3*).[6] The anion of *3* (*4*) was generated *in situ* with equivalent amount of base (NaH) to prevent enolization of *2*. The resulting ester *5a* was reduced with $LiAlH_4$, and the corresponding alcohol *6a* converted to the phosphonium salt *7a*.



Scheme 3.

Examination of the PMR spectra of the ester *5a* and the alcohol *6a* revealed that some deuterium was lost from the methyl group and present at position *h* (Scheme 3). Thus the phosphonate anion *4* was a sufficiently strong base to effect enolization of α,α,α-D_3-β-ionone (*2*), and served as a deuterium acceptor as shown in Scheme 3. Compounds *5a*, *6a*, and *7a* thus represent mixtures with deuterium in both positions *g* and *h* (Scheme 3; *5*, *6*, *7* and *7*-phosphorane also considered to comprise *cis*-isomers as to the trisubstituted double bond).

The trienedial *9*, obtained by selective, catalytic hydrogenation [7,8] of the corresponding acetylene *8*, was condensed with the phosphorane of the phosphonium bromide *7a* to give deuterated β-carotene (*10a*) with uneven and unsatisfactory deuterium incorporation (D_0:D_1:D_2:D_3:D_4:D_5:D_6:D_7:D_8 = 2:5:12:20:24:21:13:3:0).

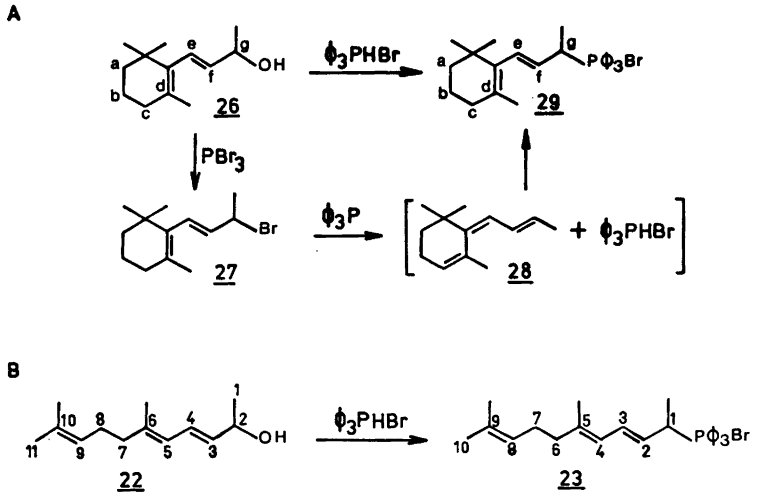
Route 2. On formation of phosphonium salts by S_N2 mechanism primary substrates are favoured.[9] Synthesis of the secondary phosphonium bromide *29* (Scheme 4A) either from the corresponding alcohol *26* [10] or bromide *27* [11] are described in patents only. In the latter case the reaction is presumed to occur *via* the triene *28* intermediate.[12]

As a model was checked the reaction of ψ-ionol (*22*, Scheme 4B) with triphenylphosphonium bromide, which gave the corresponding phosphonium bromide *23* without complications.

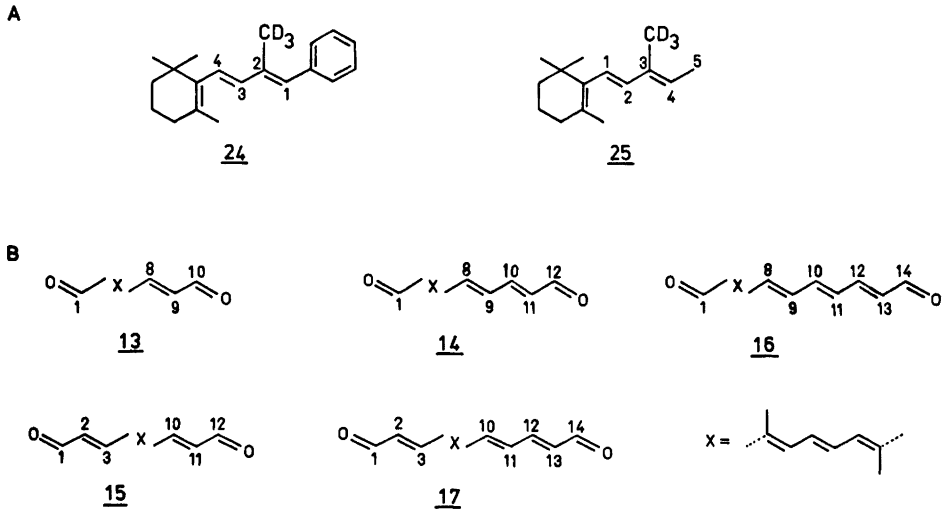
α,α,α-D_3-β-Ionone (*2*) from Route 1 was reduced with $LiAlH_4$, and the corresponding alcohol *11* converted to the phosphonium salt *12* with triphenylphosphonium bromide in like manner and in good yield.

The PMR spectrum of the phosphonium salt *12* showed unexpectedly two singlets at δ 0.70 and 0.88 (6 H), attributed to the *gem.* dimethyl group. Normally the *gem.* dimethyl in an unsubstituted β-end group give rise to a singlet around δ 1.1.[13] The compounds *24* and *25* (Scheme 5A), also prepared, showed singlets at δ 1.02 and 1.05 and δ 1.00 and 1.03, respectively. The abnormal chemical shift of the *gem.* dimethyl group in the phosphonium salt *12* is ascribed to the anisotropic effect of the triphenylphosphonium group, whereas the magnetic non-equivalence may be due to *cis* and *trans* isomerism.

The C_{14}-dialdehyde *15*, used as the central component, was synthesized from the C_{10}-dial *9*. Condensation of the C_{10}-dial *9* with formylmethylene triphenylphosphorane [14] gave a mixture of different products (Schemes 2 and 5B), not readily separable. However, condensation of the C_{10}-dial *9* with carbethoxymethyl triphenylphosphonium bromide to the diethyl ester *18*, followed by reduction with $LiAlH_4$ to the corresponding diol *19*, and allylic oxidation with activated MnO_2 gave the desired C_{14}-dialdehyde *15*.



Scheme 4.



Scheme 5.

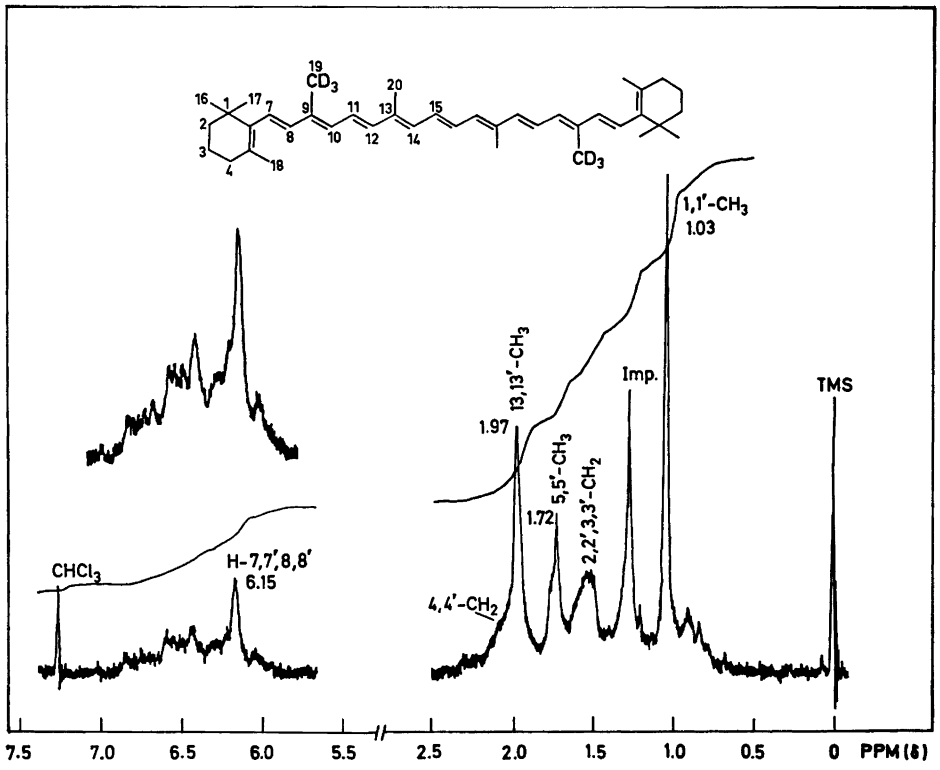


Fig. 1. ^{1}H NMR spectrum ($CDCl_3$) of 19,19'-D_6-β-carotene.

19,19'-D_6-β-Carotene (*10*) was obtained by condensation of the dialdehyde *15* and the phosphorane of the phosphonium bromide *12*. Deuterated β-carotene (*10*) thus prepared had 85 % deuterium incorporation (D_0:D_1:D_2:D_3:D_4:D_5:D_6 = 0:1:2:4:10:42:41). The PMR spectrum of *10* is given in Fig. 1. Specific deuterium incorporation in 19,19' is consistent with the integral for the in-chain methyl signal at δ 1.97 (6 rather than 12 hydrogens). IR absorption at 2110 and 2160 cm^{-1} was ascribed to C–D stretching vibrations.

For the deuterated β-carotene (*10a*), prepared by Route 1, labelled at C-10,10', absorption at 761 cm^{-1} was also observed, compatible with C–D out-of-plane vibration of a trisubstituted double bond (>C=CD–).

The mass spectrum of 19,19'-D_6-β-carotene (*10*) is discussed elsewhere.[3]

EXPERIMENTAL PART

Materials and methods were as described elsewhere.[2,15]

Heavy water was from Norsk Hydro (>99.8 % deuterated). Pyridine *p.a.* (Merck) was distilled and kept over barium oxide. NaH (50 %), delivered in mineral oil, was washed with petroleum ether prior to use. NaOD was from Merck (40 % in D_2O). β-Ionone (Firmenich, synthetic) contained 13 % α-ionone, judged by the ^1H NMR integral.

Complete spectra of the compounds prepared are available elsewhere.[16]

Deuterium incorporation is calculated from the mass spectra, taking naturally occurring isotopes into account, *cf.* Ref. 1.

Route 1

α,α,α-D$_3$-β-Ionone (*2*). β-Ionone (*1*, 9.0 g), D_2O (28.1 g) and pyridine (60 ml) were mixed, 10 drops NaOD added and the mixture stirred at room temperature for 1 h. The product was extracted with ether, washed thoroughly with H_2O (7 times), dried (Na_2SO_4) and evaporated. This gave *2*; yield 8.95 g (98 %); n_D^{20} = 1.5173; λ_{max} (hexane) 281 nm [*E*(1 %, 1 cm) = 400]; ν_{max}(liq.) 3015–2730 (CH), 2227 and 2212 (CD), 1690, 1665 (conj. C=C), 1460–1365 (CH_2,CH_3), 1265, 980 (*trans*-CH=CH), 920 and 735 cm^{-1} (the two last absorptions were absent or very weak in the spectrum of undeuterated β-ionone (*1*)); δ ($CDCl_3$, Scheme 3) 0,87 s and 0.94 s (*gem.* dimethyl in α,α,α-D_3-α-ionone), 1.08 s (6 H, *gem.* dimethyl), 1.77 s (3 H, CH_3-*d*), 1.98–2.13 (2 H, H-*c*), 6.12 d (1 H, J_{e-f} = 16.5 Hz, H-*e*) and 7.31 (1 H, J_{e-f} = 16.5 Hz, H-*f*); *m/e* (130°C) 195 (M), 180 (M–15, 100 %) and 139 (M–56); D_0:D_1:D_2:D_3 = 0:3:21:76; 90 % deuterium incorporation.

Deuterated ethyl β-ionylidene acetate (*5a*). To triethylphosphonoacetate (*3*, 7.5 g) was slowly added NaH (50 %, 1.6 g) in dry ether (20 ml) and the mixture stirred at room temp. for 1 h. *2* (5 g) in dry ether was added during 30 min, and the mixture stirred for 24 h; 80 % conversion judged by TLC. The mixture was transferred to water (1 l), extracted with ether, washed with water, dried (Na_2SO_4) and evaporated; yield 6.12 g *2* and *5a*, plus *ca.* 13 % α-isomers. The reaction was repeated with the product mixture, and the same amount of reagent *4* generated *in situ* as above. The mixture, worked up as above after 2 h, gave *5a*, yield 6.48 g (95 %); n_D^{20} = 1.5361; λ_{max} (hexane) 262 [*E*(1 %, 1 cm) = 550] and (290) nm; ν_{max} (liq.) 3015–2725 (CH), 2210, 2165, 2110, and 2060 (CD), 1715 (C=O), 1605 (conj. C=C), 1455=1360 (CH_2,CH_3), 1235 (C–O), 1215 [not in the undeuterated analogue *20* prepared below, 1150 (C–O), 1080 (not in *20*) and 970 (*trans*-CH=CH); δ (CCl_4), Scheme 3] 0.82 s and 0.92 s (*gem.* dimethyl in the α-isomer), 1.02 s (6 H, *gem.* dimethyl), 1.25 t (3 H, J_{k-l} = 7 Hz, H-*l*), 1.68 s (3 H, CH_3-*d*), 2.29 (*ca.* 1 H, CH_3-*g*), 4.11 k (2 H, J_{k-l} = 7 Hz, H-*k*), 5.66 s (0.7 H, H-h), 6.02 d (1 H, J_{e-f} = 16 Hz, H-*f*) and 6.53 d (1 H, J_{e-f} = 16 Hz, H-*e*); *m/e* (130°C) 266 (M+1), 265 (M), 264 (M–1), 263 (M–2), 262 (M–3), 250 (M–15), 236 (M–29), 220 (M–45), and 59 (100 %); D_0:D_1:D_2:D_3:D_4 = 13:21:31:28:7; 63 % deuterium incorporation (assuming 3 exchangeable H).

Deuterated β-ionylidene ethanol (*6a*). To a mixture of *5a* (5.5 g) in dry ether (10 ml) was added $LiAlH_4$ (0.85 g) in dry ether (50 ml) at 0°C during 30 min. Excess $LiAlH_4$ was destroyed with moist ether and water after 1 h stirring. The mixture was poured into 1 N H_2SO_4 (0°C) and the product extracted with ether. The extract was washed with water, aqueous $NaHCO_3$ solution and water, dried (Na_2SO_4) and evaporated. This gave *6a* plus *ca.* 13 % α-isomer; yield 4.2 mg (91 %); $n_D^{20.5}$ = 1.5363; λ_{max} (hexane) 239 [*E*(1 %, 1 cm) = 560] and (265) nm (reported λ_{max} 237 and 265 in methanol[17]); ν_{max} (liq.) 3320 (OH), 3020–2725 (CH), 2240, 2210, 2155, 2110, and 2065 (CD), 1455–1360 (CH_2, CH_3), 970 (*trans*-CH=CH), 915 and 735 cm^{-1}; δ ($CDCl_3$, reference letters as for *5a* in Scheme 3) 0.82 s and 0.90 s (*gem.* dimethyl in the α-isomer), 1.02 s (6 H, *gem.* dimethyl), 1.68 s (3 H, CH_3-*d*, 2.08 (–OH), 4.27 s and 4.27 d (2 H, J_{h-i} = 7 Hz, H-*i*), 5.62 s and 5.62 t (*ca.* 0.8 H, J_{h-i} = 7 Hz, H-*h*) and 6.07 (2 H, H-*e*, *f*); *m/e*(130°C) 224 (M+1), 223 (M), 222 (M–1), 221 (M–2), 220 (M–3), 179 (M–44), 149 (M–74), 136 (M–87), and 41 (100 %), D_0:D_1:D_2:D_3:D_4 = 14:23:28:27:8; 61 % deuterium incorporation (assuming 3 exchangeable H).

Deuterated β-ionylidene triphenylphosphonium bromide (7a). To triphenylphosphonium bromide (6.15 g) in methanol (65 ml) was added *6a* (4.0 g), and the mixture was stirred for 48 h. The solvent was removed, and the residue washed with ether and ethyl acetate gave *6a* plus *ca.* 13 % α-isomer; yield 5.1 g (51 %). Recrystallization three times from CH_2Cl_2-ethyl acetate gave white, cubic crystals; m.p. 157–158°C (reported 123°C [17]); λ_{max} (methanol) 204, 225, 261, 267, and 274 nm with E(1 %, 1 cm) = 1060, 730, 212, 221, and 208, respectively; ν_{max} (KBr) 3020–2775 (CH), 1440, 1115, 995, 975 (*trans*-CH=CH) and 760–685 (phenyl and bromine); δ ($CDCl_3$, reference letters as for *5a* in Scheme 3) 0.96 (6 H, *gem.* dimethyl), 1.64 (3 H, CH_3-*d*), *ca.* 1.9 (2 H, H-*c*), 4.78 dd (J_{H-P} = 16 Hz, J_{h-i} = 7 Hz, =CH–CH_2P), 4.78 d (J_{H-P} = 16Hz, =CD–CH_2P), 4.78 (total 2 H), 5.29 t (*ca.* 0.6 H, J_{h-i} = 7 Hz, H-*h*), 5.99 (2 H, H-*e,f*) and 7.6-8.1 (15 aromatic H).

2,7-Dimethylocta-2,4,6-triene-1,8-dial (9). 2,7-Dimethylocta-2,6-diene-4-yne-1,8-dial (*8*, 5 g) in ethyl acetate (150 ml) was hydrogenated in the presence of Lindlar catalyst [7] (3.5 g) until one equivalent of hydrogen was absorbed as described by Mildner and Weedon.[8] The catalyst was removed by filtration, the solvent evaporated, and the product crystallized from benzene; *9* had m.p. 133–135°C (reported 135–140°C[8]); λ_{max} (MeOH) 236, 3235 [E(1 %, 1 cm) = 2800] and 334 nm; ν_{max} (KBr) 2810, 2710 (CH), 1655 (C=O), 1600 (conj. C=C), 1435–1330 (CH_3), 1225, 1010, 900, 830, 800, 730, and 670 cm^{-1}; δ($CDCl_3$) 1.95 s (6 H, 2 CH_3), 6.75–7.52 (4 olefinic H, complex coupling) and 9.63 s (2 aldehyde H); *m/e* (75°C) 164 (M).

10,10',19,19'-Deuterated β-carotene (10a). To a suspension of deuterated β-ionylidenethyltriphenyl-phosphonium bromide (*7a*, 0.262 g) in dry ether (20 ml) was added dropwise a solution of 0.06 N BuLi in dry ether (20 ml). Excess BuLi was destroyed by addition of CH_2Cl_2 (3 ml). After 10 min C_{10}-dial (*9*, 33 mg) in CH_2Cl_2 (3 ml) was dropwise added over a period of 20 min, and the mixture stirred at room temp. for 5 h. The solvent was removed and the residue dissolved in 90 % aqueous methanol. The pigments were extracted with petroleum ether, washed with water, dried (Na_2SO_4) and the solvent removed. Chromatography on alumina (Woelm neutral, grade 2 [18]) and elution with benzene gave *10a* yield 15.0 mg (7 %); δ ($CDCl_3$) 0.84 s, 0.92 s (imp. or *gem.* dimethyl in α-carotene), 1.03 s (12 H, CH_3-1,1'), 1.27 s (imp.), 1.49–1.54 (8 H, H-2,2',3,3'), 1.72 s (6 H, CH_3-5,5'), 1.97 s (6 H, CH_3-13,13'), 2.09 (4 H, H-4,4'), 6.14 (H-7,7',8,8'), and 6.0–6.8 (olefinic H). Crystallization from $CHCl_3$-petroleum ether yielded 8.8 mg; m.p. 150–151°C (reported 178–179°C for undeuterated β-carotene [19]), undepressed on admixture with authentic β-carotene; λ_{max} (petroleum ether) 340, 424, *447*, and 474 nm; % D_B/D_{II}[20] = 9.5, % III/II[20] = 42 (reported λ_{max} (petroleum ether, b.p. 80–105°C) *453* and 481 nm[21]); ν_{max} (KBr) 3020–2820 (CH), 2220 (?), 1550 (C=C), 1450 (CH_2), 1395–1360 (CH_3), 1212, 1174, 966 (trans-CH=CH), 761 (>C=CD–?), and 710 cm^{-1}; *m/e* (190°C) 543–536 (M); D_0:D_1:D_2:D_3:D_4:D_5:D_6:D_7:D_8 = 2:5:12:20:24:21:13:3:0; 64 % deuterium incorporation (assuming 6 exchangeable H).

Route 2

α,α,α-D$_3$-β-Ionol (11). α,α,α-D_3-β-ionone (*2*, 3.5 g) in dry ether was reduced with $LiAlH_4$ (0.60 g) in dry ether (50 ml) by the procedure used above for the synthesis of *6a* yield 3.1 g (88 %); n_D^{17} = 1.4923; λ_{max} (hexane) and 233 [E (1 %, 1 cm) = 245]; ν_{max} (liq.) 3300 (OH), 3020–2720 (CH), 2215, 2120 and 2060 (CD), 1445 (CH_2), 1380, 1370 and 1360 (CH_3), 1115, 1045, 1030 (C–O) and 970 cm^{-1} (*trans*-CH=CH); δ (CCl_4, Scheme 4A) 0.80 s and 0.88 s (*gem.* dimethyl in the α-isomer), 0.99 s (6 H, *gem.* dimethyl), 1.64 s (3 H, CH_3-*d*), 2.78 s (1 H, –O*H*), 4.25 d (1 H, J_{f-g} = 6 Hz, H-*g*), 5.40 dd (1 H, J_{f-g} = 6 Hz, J_{e-f} = 16 Hz, H-*f*) and 5.99 d (1 H, J_{e-f} = 16 Hz, H-*e*); *m/e* (110°C) 197 (M), 179 (M–18), 164 (M–33), 141 (M–56), 136 (M–61), 123 (M–74) and 121 (M–76, 100 %); D_0:D_1:D_2:D_3 = 2:5:24:69; 87 % deuterium incorporation.

α,α,α-D$_3$-β-Ionyl-triphenylphosphonium bromide (12). A mixture of α,α,α-D_3-β-ionol (*11*, 2.95 g) and triphenylphosphonium bromide (5.14 g) in methanol (65 ml) was stirred at room temperature for 48 h. The solvent was removed and the residue washed with ether. The product (*12*) yield 6.4 mg (80 %) had λ_{max} (methanol) 207.5, (225), 261, 267, and 274 nm with E(1 %, 1 cm) = 577, 426, 130, 134, and 107, respectively; ν_{max} (KBr) 3050–2830 (CH), 2225 (CD), 1435 (CH_2), 1110, 995, 975 (*trans*-CH=CH), 755, 725 and 695 cm^{-1} (bromide and monosubst. benzene; δ($CDCl_3$, Scheme 4A) 0.70 s and 0.88 s (6 H, *gem.* dimethyl), 1.43 s and *ca.* 1.90 (9 H, H-*a*, *b*, *c*, CH_3-*d*), 4.87–5.37 (1 H, H-*g*, complex coupling), 5.97–7.01 (2 H, H-*e,f*, complex coupling, *cis-trans*?) and 7.6–8.3 (15 aromatic H).

2,7-Dimethyldeca-2,4,6,8-tetraene-1,10-dial (13), 2,7-dimethyldodeca-2,4,6,8,10-pentaene-1,12-dial (14), 4,9-dimethyldodeca-2,4,6,8,10-pentaene-1,12-dial (15), 2,7-dimethyltetradeca-2,4,6,8,10,12-hexaene-1,14-dial (16) and 4,9-dimethyltetradeca-2,4,6,8,10,12-hexaene-1,14-dial (17). A mixture of C_{10}-dial (*9*, 1.52 g) and formylmethylenetriphenylphosphorane (5.69 g) in benzene (300 ml) was refluxed for 22 h as described by Trippett and Walker.[14] An aliquot of the reaction mixture was submitted to TLC on alumina G 254 (20 % acetone in petroleum ether = 25 % APE) giving *8:13:(14+15):(16+17)* = 57:37:5:1, calculated from the electronic spectra using extinction coefficients based on those reported for *9*, *14* and crocetindial.[22]

13 had $R_F = 0.32$; λ_{max} (ether) *ca.* 335, 349 and 369 nm; δ ($CDCl_3$) 1.92 s and 1.94 s (3 H, CH_3-2), 2.05 (3 H, CH_3-7), 6.0–7.5 (6 olefinic H) and 9.0–9.7 (2 H, aldehyde). *14* + *15* had $R_F = 0.28$; λ_{max} (ether) 360, 378, and 401 nm; δ ($CDCl_3$) 1.93 s (CH_3-2 in *14*), 2.05 (CH_3-7 in *14* and CH_3-4,9 in *15*), 6.0–7.5 (8 olefinic H) and 9.0–9.7 (2 H, aldehyde); *14*:*15* = 1:1, calculated from the ^{1}H NMR spectrum. *16* + *17* exhibited $R_F = 0.24$; λ_{max} (ether) 381, 403, and 427 nm; δ ($CDCl_3$) 1.26 (imp.), 1.90 s (CH_3-2 in *16*), 2.02 s (6 H, CH_3-7 in *16* and CH_3-4 in *17*), 6.0–7.5 (10 olefinic H) and 9.5–9.7 (2 H, aldehyde); *16*:*17* = 1:4, calculated from the ^{1}H NMR spectrum.

Diethyl 4,9-dimethyldodeca-2,4,6,8,10-pentaene-1,12-dioate (18). A mixture of C_{10}-dial (*9*, 0.55 g) and carbethoxymethylenetriphenylphosphorane (8.5 g) in $CHCl_3$ (60 ml) was stirred at room temp. for 12 h. Chromatography twice on kieselgel (eluent 25 % benzene in $CHCl_3$) gave *18*; yield 1.02 g (100 %); λ_{max} (ether) 272, 352, *370*, and 392 nm; ν_{max}(KBr) 2980–2850 (CH), 1705 (conj. ester), 1605 (conj. C=C), 1365 (CH_3), 1300, 1175, 1035, 980–970 (*trans*-CH=CH), 850 and 800 cm^{-1}; δ ($CDCl_3$) 1.32 t (6 H, $J = 7$ Hz, 2 CH_3 in ethyl), 1.95 s (6 H, CH_3-4,9), 4.23 q (4 H, $J = 7$ Hz, 2 CH_2 in ethyl) and 5.75–7.60 (8 olefinic H, complex coupling); *m/e* (140°C) 304 (M), 259 (M–45) and 157 (100 %).

4,9-Dimethyldodeca-2,4,6,8,10-pentaene-1,12-diol (19). The C_{14}-diester *18* (1.0 g) in dry ether (50 ml) was reduced with $LiAlH_4$ (0.30 g) in dry ether (50 ml) by the procedure described above for preparation of *6a*. This gave crude *19*; yield 0.47 g (65 %). An analytical amount, purified by TLC on kieselgel (30 % APE), exhibited λ_{max}(ether) 248, 324, 340, and 359 nm; δ ($CDCl_3$) 1.25 (imp.), 1.90 s (6 H, CH_3-4,9) 2.62 s (2 H, -O*H*), 4.23 d (4 H, $J_{1-2(11-12)} = 6$ Hz, H-1,12) and 5.7–6.5 (8 olefinic H, complex coupling); *m/e* (130°C) 220 (M) and 95 (100 %).

4,9-Dimethyldodeca-2,4,6,8,10-pentaene-1,12-dial (15). A mixture of crude *19* (140 mg) and activated MnO_2 (1.40 g) in acetone (75 ml) was kept at room temp. for 12 h. TLC on kieselgel G (20 % APE) gave *15*; yield 41 mg (29 %); λ_{max}(ether) 280, 362, *379*, and 401 nm (previously found λ_{max} (petroleum ether) 358, *378*, and 400 [22]), ν_{max} (KBr) 3040–2710 (CH), 1665 (conj. C=O), 1585 (conj. C=C), 1385 and 1370 (CH_3), 1170, 1125, and 975 cm^{-1} (*trans*-CH=CH); δ ($CDCl_3$) 2.02 s (6 H, $CH_3-4,9$), 6.05–7.35 (8 olefinic H, complex coupling) and 9.64 d (2 H, $J_{1-2(11-12)} = 7.5$ Hz, H-1,12); *m/e* (140°C) 216(M).

19,19′-D_6-β-Carotene (10). To a suspension of α,α,α-D_3-β-ionyl-triphenylphospohonium bromide (*12*, 389 mg) in a dry ether (20 ml) was added dropwise a solution of 0.06 N BuLi in dry ether (30 ml). Excess BuLi was destroyed by addition of CH_2Cl_2 (3 ml). After 10 min was C_{14}-dial (*15*, 40 mg) in CH_2Cl_2 (10 ml) added slowly during 20 min, and the mixture stirred at room temperature for 3 h. The solvent was removed and the residue dissolved in 90 % aqueous methanol. The pigments were extracted with petroleum ether, washed with water, dried (Na_2SO_4) and the solvent removed. Chromatography on alumina (Merck neutral, grade 2 [18]) and elution with 10 % ether in petroleum ether gave *10*; yield 41.2 mg (41 %). Paper chromatography of *10* on Schleicher & Schüll No. 288 paper (1 % ether in petroleum ether) gave two zones: neo a $R_F = 0.61$; λ_{max} (petroleum ether) *442* and 475 nm and all-*trans* $R_F = 0.54$; λ_{max} (petroleum ether) *447* and 471 nm. The *trans* isomer was inseparable from authentic β-carotene, whereas both zones were separated from authentic α- and ε-carotene, also theoretically present. *10* exhibited δ ($CDCl_3$, Fig. 1) 0.85 s (imp.), 0.91 (imp.), 1.03 s (12 H, *gem.* dimethyl), 1.27 s (imp.), 1.5–1.6 (8 H, H-2,2′,3,3′), 1.72 s (6 H, end-of-chain CH_3), 1.97 (6 H, in-chain 13,13′-CH_3), 6.15 (H-7,7′,8,8′) and 6.05–6.85 (14 olefinic H). Crystallization from acetone gave 2.3 mg, *m.p.* 163–164°C (reported 178–179°C for undeuterated β-carotene [19]), undepressed on admixture with authentic β-carotene; λ_{max} (petroleum ether) 339, *447.5* and 474 nm, % D_B/D_{II}[20] = 13, % III/II[20] = 28 (reported λ_{max} in petroleum ether *453* and 481 nm[21]); ν_{max} (KBr) 3020–2820 (CH), 2110 and 2060 (CD), 1705, 1623, 1556 (C=C), 1455 (CH_2), 1395–1360 (CH_3), 967 (*trans*-CH=CH) and 830 (>C=CH–); *m/e* (200°C) 542 (M), 463 (M–79), 450 (M–92), 433 (M–109), 406 (M–136) and 481 (M–161), D_0:D_1:D_2:D_3:D_4:D_5:D_6 = 0:1:2:4:10:42:41; 85 % deuterium incorporation.

Model compounds

Ethyl β-ionylidene acetate (20) was prepared from triethylphosphonoacetate (*3*, 1.5 g), NaH (50 %, 0.32 g) and β-ionone (*1*, 1.0 g) by the same procedure as for *5a* above; conversion 70 %, judged by TLC. Preparative TLC on kieselgel HF 254 + 366 (10 % ether in petroleum ether) gave *5a*, yield 0.65 g (48 %); $n_D^{20.5}$ = 1.5361; λ_{max} (hexane) and ν_{max} (liq.) see *5a* above; δ (CCl_4, Scheme 5A) 2.29 s (3 H, CH_3-*g*) and 5.66 s (1 H, H-*h*), otherwise as for 5a above.

ψ-Ionol (22). A solution of ψ-ionyl acetate [23] (*21*, 8.5 g) in 10 % KOH in methanol (0.5 l) and ether (0.5 l) was stirred for 12 h. Water was added and the product transferred to ether. The ether extract was washed, dried (Na_2SO_4) and the solvent evaporated. This gave *22* yield 6.5 g (93 %); $n_D^{17} = 1.5059$; λ_{max} (hexane) 241 [*E*(1 %, 1 cm) = 1210]; ν_{max} (liq.) 3330, 3020–2725, 1665, 1448, 1375, 1138, 1057, and 965; δ (CCl_4, Scheme 4B) 1.20 d (3 H, $J_{1-2} = 6.5$ Hz, H-1), 1.58 s, 1.65 s and 1.73 s (3 × 3 H, H-11, CH_3-6,10), 2.23 s (1 H, -O*H*), 4.21 dq (1 H, $J_{1-2} = 6.5$ Hz, $J_{2-3} = 6$ Hz, H-2), 5.04 (1 H, H-9), 5.47 dd (1 H, $J_{2-3} = 6$ Hz, $J_{3-4} = 15$ Hz, H-3), 5.71 d (1 H, $J_{4-5} = 10.5$

Hz, H-5) and 6.27 dd (1 H, $J_{3-4}=15$ Hz, $J_{4-5}=10.5$ Hz, H-4); *m/e* (110°C) 194 (M), 176 (M − 18), 151 (M − 43), and 133 (M − 43 − 18).

ψ-Ionyl-triphenylphosphonium bromide (23). A mixture of *ψ*-ionol (*22*, 3.0 g) and triphenylphosphonium bromide (5.3 g) in methanol (40 ml) was stirred at room temp. for 24 h. The solvent was removed and the product washed with ether and water. This gave *23* yield 4.4 g (53 %); λ_{max} (MeOH) 204.5, (225), 261, 267, and 274 [*E*(1 %, 1 cm) = 1050, 630, 192, 184, and 121]; ν_{max}(KBr) 3050 − 2850, 1435, 1375, 1110, 995, 755, 725 and 695 cm^{-1}; δ ($CDCl_3$), Scheme 4B) 1.58, 1.63 (H-10, CH_3-1,5 and 9), 4.70 − 6.50 (H-1,2,3,4, and 8, complex coupling) and 7.60 − 8.20 (aromatic H).

2-D_3-Methyl-1-phenyl-4-(2,6,6-trimethyl-cyclohex-1-enyl)-1,3-butadiene (24). To a mixture of α,α,α-D_3-*β*-ionyl-triphenylphosphonium bromide (*12*, 0.52 g) in dry ether (10 ml) was added 0.06 N BuLi in dry ether (20 ml). Excess BuLi was destroyed by addition of CH_2Cl_2 (3 ml) after 10 min. Freshly distilled benzaldehyde (0.11 mg) was added and the mixture stirred for 2 h at 35°C. TLC twice on kieselgel HF 254 + 366 (petroleum ether) gave *24* (0.11 g, 41 %); λ_{max} (hexane) 288 [*E*(1 %, 1 cm) = 730]; ν_{max} (liq.) 3020 − 2830, 2140, 1595, 1490, 1445 − 1360, 975, 965, 920, 740, and 700; δ ($CDCl_3$, Scheme 5A) 1.02 s and 1.05 s (6 H, *gem.* dimethyl), 1.45 − 1.63 (4 H, H-4′,5′), 1.70 (s?, 3 H, 2′-CH_3), 2.00 m (2 H, H-3′), 6.09 − 6.73 (3 H, H-1,3,4, complex coupling, *cis-trans* around double bonds 1,2 and 3,4?) and 7.22 − 7.37 (5 aromatic H); *m/e* (110°C) 269 (M, 100 %), D_0:D_1:D_2:D_3 = 2:6:21:71; 88 % deuterium incorporation.

3-D_3-Methyl-1-(2,6,6-trimethylcyclohex-1-yl)-1,3-pentadiene (25) was made by the above procedure, using large excess of acetaldehyde (2 ml) instead of benzaldehyde. This gave *25*; yield 0.10 g (48 %); λ_{max} (hexane) 363 [*E*(1 %, 1 cm) = 620]; ν_{max} (liq.) 3020 − 2720, 2230, 2200, 2110, 2060, 1445 − 1360, 970, and 735 cm^{-1}; δ ($CDCl_3$), Scheme 5A) 1.00 s and 1.03 s (6 H, *gem.* dimethyl), 1.72 (s?, CH_3-2′, 1.73 d (H-5, $J_{4-5}=6.5$ Hz), 2.00 m (2 H, H-3′), 5.43 p or dq (1 H, $J_{4-5}=6.5$ Hz, H-4, *cis-trans*?), 6.00 s (H-1,2, *trans*), 6.06 d and 6.50 d ($J_{1-2}=16.5$ Hz, H-1,2, *cis*), *m/e* (110°C) 207 (M), 180 (M − 27), and 46 (100 %), D_0:D_1:D_2:D_3 = 3:9:29:59; 82 % deuterium incorporation.

Acknowledgements. 2,7-Dimethylocta-2,6-dien-4-ynedial and Lindlar catalyst were provided by Dr. J. D. Surmatis, Hoffmann-La Roche, Nutley, New Jersey, and *β*-ionone by Dr. A. F. Thomas, Firmenich, Geneve, through Docent C. R. Enzell, Stockholm.

Thermodynamics of Vinyl Ethers. VIII.* A Study of the Relative Ring Strain Energies and Relative Ring Entropies of Three- to Eight-membered Carbocyclic Rings with One or No sp^2-Hybridized Carbon Atom

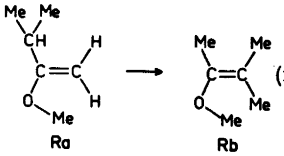
ESKO TASKINEN

Department of Chemistry, University of Turku, 20500 Turku 50, Finland

The relative stabilities of three- to eight-membered 1-methoxyvinylcycloalkanes and 1-methoxyethylidenecycloalkanes have been studied by means of chemical equilibration at several temperatures. The thermodynamic functions of isomerization, in comparison with the corresponding functions for the isomerization of 2-methoxy-3-methyl-1-butene to 2-methoxy-3-methyl-2-butene, allowed an estimation of the relative ring strain energies and relative ring entropies of carbocyclic rings with one or no sp^2-hybridized carbon atom.

Although the values of ring strain energy have been established for a great number of saturated and unsaturated cyclic hydrocarbons (cycloalkanes and cycloalkenes, respectively), relatively few reliable data exist of ring strain energies in carbocyclic hydrocarbons with an sp^2-hybridized carbon atom in the ring.[1–4] This is mainly due to a lack of appropriate thermochemical data for such compounds; in fact, in the case of methylenecycloalkanes the standard enthalpy of formation in the ideal gas state at 298.15 K is known only for methylenecyclobutane.[4,5] In addition, the values of ΔH_f° (l, 298.15 K) are known for methylenecyclopentane, ethylidenecyclopentane, and the corresponding cyclohexanes,[4] but no actual enthalpy of vaporization measurements have been reported for these compounds. This lack is not very severe since the standard enthalpy of vaporization can be estimated with good accuracy from the normal boiling point.[6] For other cycloalkanes with an *exo*-cyclic double bond, the enthalpy of formation must be estimated indirectly, which of necessity brings about additional uncertainty in the values of derived quantities, such as ring strain energy. Moreover, there are no gas-phase entropy data for alkylidenecycloalkanes. Gas-phase entropies of many organic compounds can be estimated by the group increment scheme described by Benson *et al.*[7] but, unfortunately, the values of "ring corrections" for carbocyclic rings with an sp^2-hybridized carbon atom are not known.

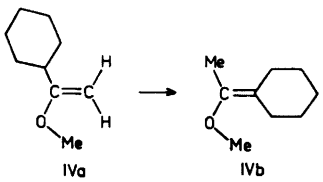
This paper reports the results of an approach to the evaluation of the relative ring strain energies and relative ring entropies of three- to eight-membered carbocyclic rings with one or no sp^2-hybridized carbon atom. The work is based on the assumption that comparison of the values of the standard enthalpy change, ΔH° (g, 298.15 K), and standard entropy change, ΔS° (g, 298.15 K), of the reactions (1) and (2) should reflect the changes in ring strain energy and ring entropy on going from the saturated ring to one containing an sp^2-hybridized carbon atom:



(reference reaction) (1)

* Part VII. *Acta Chem. Scand. B 28* (1974) 201.

and, for example,



IVa IVb (2)

The degree of double bond substitution by alkyl groups undergoes similar changes in each reaction, and as the stabilizing effect of alkyl groups on olefinic double bonds is virtually independent of the alkyl group,[8] the difference $\Delta H°$ (reference reaction) − $\Delta H°$ [reaction (2)] should indeed reflect the change in ring strain energy for the six-membered ring on going from IVa to IVb, provided that the effects of steric factors across the double bond are equal in both reactions. This is a critical point, and certain corrections are necessary for small-ring compounds up to cyclopentane.

EXPERIMENTAL

NMR spectra. The NMR spectra of the vinyl ethers were recorded on a 60 MHz Perkin Elmer R10 spectrometer at 307 K. Carbon tetrachloride was used as solvent and tetramethylsilane as internal standard. In many cases the spectra were recorded from a mixture of isomers containing mainly one of the two isomers and hence the signals due to the protons of the minor component could not always be detected. The spectra are shown in Tables 1 and 2.

Materials. 1-Methoxyvinylcyclopropane (Ia) and its isomer (Ib). A mixture of cyclopropyl methyl ketone (0.225 mol, Fluka AG), trimethylorthoformate (0.236 mol), and methanol (0.63 mol) was allowed to stand five days at room temperature in the presence of a small amount of *p*-toluenesulfonic acid, after which the mixture was made alkaline by adding a small volume of sodium methoxide in methanol.[9] Fractionation of the mixture at reduced pressure gave the dimethyl acetal of cyclopropyl methyl ketone (b.p. 312.7 – 313.2 K at 3.3 kPa) in 40 % yield. The acetal was distilled from a small amount of *p*-toluenesulfonic acid at atmospheric pressure to give a mixture of methanol and the desired vinyl ethers, boiling temperature 336 – 371 K. The mixture was extracted with water to remove the methanol, after which the organic layer was dried over K_2CO_3. Distillation from $LiAlH_4$ gave pure Ia (b.p. 377.0 K at 99.3 kPa) in 44 % yield.

1-Methoxyvinylcyclobutane (IIa) and its isomer (IIb). The preparation was analogous to that of Ia except that the acetal of cyclobutyl methyl ketone (the ketone was from Ash Stevens Inc., Mich.) was not isolated but the acid reaction mixture was directly subjected to fractional distillation. After a forerun below *ca.* 380 K, a mixture of IIa and IIb (in the mol ratio of 21 to 1) could be collected at 397.8 – 398.2 K at 101.1 kPa. The yield was 85 %.

1-Methoxyvinylcyclopentane (IIIa) and its isomer (IIIb). 1-Cyclopentylethanol (Aldrich) was oxidized with sodium dichromate in aqueous sulfuric acid to cyclopentyl methyl ketone using the procedure described by Brown and Garg.[10] The yield of the product boiling at 431.7 – 432.7 K at 102.5 kPa was 71 %. The ketone was converted to the desired vinyl ethers as described above for IIa and IIb. An approximately equimolar mixture of IIIa and IIIb was collected at 426 – 431 K at 103.3 kPa. The yield was 82 %.

1-Methoxyvinylcyclohexane (IVa) and its isomer (IVb). The preparation was analogous to that of IIIa and IIIb. The ketone (b.p. 340 – 341 K at 1.7 kPa) was obtained in 79 % yield from 1-cyclohexylethanol (Aldrich). A

Table 1. NMR data for some 1-methoxyvinylcycloalkanes in CCl_4 solution. Peak positions are given in τ values (ppm) and the coupling constant in Hz.

Ring size	H *cis* to MeO	H *trans* to MeO	Me in MeO	Ring protons	$J(=CH_2)$
C_3	6.20	6.26	6.44	8.4 – 8.9, 9.3 – 9.6	2.2
C_4	6.21	6.21	6.51	6.8 – 7.4, 7.7 – 8.4	0.0
C_5	6.16	6.32	6.50	7.4 – 8.0, 8.2 – 8.6	2.0
C_6	6.23	6.33	6.54	7.8 – 9.0	2.3
C_7	6.20	6.37	6.53	? [a]	2.0

[a] The spectrum was recorded from a mixture of isomers containing only 30 % of the isomer in question; hence the signals of the major component eclipsed those of the isomer concerned.

Table 2. NMR data for some 1-methoxyethylidenecycloalkanes in CCl_4 solution. Peak positions are in τ values (ppm).

Ring size	Me	Me in MeO	Ring protons
C_5	8.25	6.56	7.6 – 8.1, 8.2 – 8.6
C_6	8.28	6.64	7.6 – 8.2, 8.3 – 8.6
C_7	8.26	6.59	7.6 – 8.1, 8.2 – 8.6
C_8	8.26	6.58	7.6 – 8.1, 8.2 – 8.6

93 % yield of IVa and IVb (in the mol ratio of 4 to 1) was collected at 449 – 451 K at 102.1 kPa.

1-Methoxyvinylcycloheptane (Va) and its isomer (Vb). Cycloheptylmagnesium chloride was prepared from cycloheptyl chloride (0.50 mol, Aldrich) and magnesium (0.55 mol) in 250 cm^3 of dry ether. The Grignard reagent was cooled to *ca.* 263 K, after which 0.50 mol of acetaldehyde in 70 cm^3 of ether was added to the Grignard reagent during about 0.3 h. The product was allowed to warm to room temperature, after which it was poured on ice. Dilute sulfuric acid was added to dissolve the precipitate. The organic layer was separated, and the aqueous layer was extracted with ether. The combined extracts and the original organic layer were washed with sodium bicarbonate solution and water. After drying over K_2CO_3, the ether was evaporated and the residue fractionated to give 1-cycloheptylethanol, b.p. 367 – 369 K at 1.3 kPa, in 37 % yield. The alcohol was oxidized to cycloheptyl methyl ketone as described above for cyclopentyl methyl ketone. The yield of the product boiling at 355 – 357 K at 1.5 kPa was 69 %. The ketone was converted into a mixture of Va and Vb in the usual manner. The yield was 46 %, and the mixture of isomers containing 75 mol % of Vb was collected at 351 – 353 K at 1.2 kPa.

1-Methoxyvinylcyclooctane (VIa) and its isomer (VIb). Cyclooctanol (0.34 mol, Fluka AG) was dissolved in chloroform (150 cm^3), after which thionyl chloride (0.39 mol) was added with stirring so that the chloroform refluxed gently. Refluxing was continued for an hour, or until the evolution of gas ceased. The mixture was poured into water, the layers were separated, and the organic layer was washed with saturated sodium bicarbonate solution and water. The product was dried over $MgSO_4$ and distilled to give a 55 % yield of cyclooctyl chloride, b.p. 345.2 – 346.2 K at 1.1 kPa. 1-Cyclooctylethanol was then prepared from cyclooctylmagnesium chloride and acetaldehyde as described above for 1-cycloheptylethanol. The product, obtained in 15 % yield, was collected at 376 – 378 K at 0.9 kPa. It was oxidized to cyclooctyl methyl ketone (b.p. 362 – 364 K at 0.8 kPa) in 63 % yield. The ketone was converted into a mixture of VIa and VIb (in the mol ratio of 1 to 20, respectively) in the usual manner. The product boiled at 358 – 359 K at 0.8 kPa, and the yield was 62 %.

Purification of the vinyl ethers. Prior to the equilibrations, the mixtures of the isomeric vinyl ethers were purified by preparative GLC using a Carbowax 20M column.

Determination of normal boiling points. The normal boiling points of the isomeric vinyl ethers were determined by the gas-chromatographic method described earlier.[6] The following compounds were used as the reference compounds (compound, normal boiling point): isobutyl vinyl ether (R1), 356.2 K; isobutylidene ethyl ether (R2), 366.7 K; 1-methoxycyclopentene (R3), 387.0 K; 1-ethoxycyclopentene (R4), 409.0 K; 1-methoxycyclohexene (R5), 417.1 K; 1-ethoxycyclohexene (R6), 435.0 K; 1-propoxycyclohexene (R7), 455.9 K; 1-cyclopentoxycyclopentene (R8), 479.7 K. The normal boiling points of IIa and IIb were determined by means of the following reference compounds (compound, relative retention time): R1, 0.255; R2, 0.286; R3, 0.417; R4, 0.574; R5, 0.708; R8, 1.000. The relative retention times of IIa and IIb were 0.501 and 0.656, respectively, corresponding to normal b.p.'s of 399.0 and 413.9 K. *IIIa and IIIb*, reference compounds and their relative retention times: R2, 0.149; R3, 0.226; R5, 0.411; R6, 0.604; R7, 1.000. The relative retention times of IIIa and IIIb (0.461 and 0.633, respectively) led to normal b.p.'s of 422.6 and 437.4 K. *IVa and IVb*, reference curve: R2, 0.180; R3, 0.262; R5, 0.440; R6, 0.619; R7, 1.000. The relative retention times of IVa and IVb (0.817 and 0.971, respectively) corresponded to normal b.p.'s of 447.5 and 454.6 K. *Va and Vb*, reference curve: R2, 0.153; R3, 0.202; R5, 0.303; R6, 0.393; R7, 0.573; R8, 1.000. The relative retention times of Va and Vb (0.844 and 0.985, respectively) led to normal b.p.'s of 473.0 and 479.2 K. *VIa and VIb*, reference curve: R2, 0.187; R3, 0.239; R5, 0.341; R6, 0.429; R7, 0.604; R8, 1.000. The relative retention times of VIa and VIb were 1.420 and 1.547 corresponding to normal boiling points of *ca.* 493.0 and 496.0 K, respectively.

Procedure. Details of the experimental performance of the equilibrations have been described previously.[6] Iodine was used as catalyst and cyclohexane as solvent. The purities of the vinyl ethers were checked by GLC (Carbowax 20 M and SE-30 columns) and NMR spectra.

Table 3. Values of the mean equilibrium constant K and its standard error for the iodine-catalyzed reaction 1-methoxyvinylcycloalkane (a) ⇌ 1-methoxyethylidenecycloalkane (b) in cyclohexane solution at various temperatures. The time of equilibration varied from a few days at the lowest temperatures to a few tens of minutes at the highest temperatures employed; n denotes the number of independent determinations.

Peak separation was good, and the compounds were eluted in the sequence a,b. Peak areas, which were considered to be proportional to the molar amounts of the vinyl ethers,[6] were integrated by means of a Hewlett-Packard 3370B integrator.

In cases when the synthetic product contained only a small amount of the less stable isomer, the isomers were not separated by preparative GLC, and then only one initial mixture of isomers was used in the equilibrations. To be sure that true equilibrium had been reached, equilibration times were extended well beyond the time necessary for the isomer ratio to become constant. Moreover, the studied compounds are fairly reactive under the experimental conditions employed so that the state of equilibrium is readily attained without noteworthy side-reactions except for the formation of small amounts of hydrolysis products [$R(MeO)C=CH_2 + H_2O \rightarrow RCOMe + MeOH$; $MeOH + R(MeO)C=CH_2 \rightarrow RMeC(OMe)_2$].

If the less stable isomer could not be separated for its spectral characterization, it was identi-

fied by its retention time in the gas-chromatographic analyses, and by its behavior in the equilibrations. In no cases did the identification provide any difficulty since in addition to the peaks of the two isomers, the only noteworthy peaks could be shown to be due to the hydrolysis products.

Equilibrium constants could not be determined for the reaction Ia⇌Ib, since the position of equilibrium lay so far to the left that the peak of Ib could not be detected in the gas chromatogram.

RESULTS

The values of the mean equilibrium constant K and its standard error at various temperatures are shown in Table 3. As mentioned earlier (see EXPERIMENTAL), equilibrium constants could not be determined for the reaction Ia⇌Ib because of the low thermodynamic stability of the b isomer. For each isomerization reaction the standard Gibbs free energy change $\Delta G°$, calculated from the mean equilibrium constant, proved to be a linear function of temperature (within experimental error, of course). The values of the standard enthalpy change $\Delta H°$ and standard entropy change $\Delta S°$ were obtained by a least-squares treatment of $\Delta G°$ against temperature T ($\Delta G° = \Delta H° - T\Delta S°$). The values of $\Delta G°$, $\Delta H°$, and $\Delta S°$ in the liquid phase at 298.15 K are collected in Table 4. The normal boiling points of the isomeric compounds (see EXPERIMENTAL) were then used for the evaluation of the values of the standard enthalpy and standard entropy of vaporization at 298.15 K.[6] Table 5 gives the values of $\Delta H°$ and $\Delta S°$ in the gas phase at 298.15 K. The calculations have been described in more detail in Refs. 6 and 11.

DISCUSSION

Both molecular models and the available thermochemical data suggest that the compounds studied in this work can be divided into two groups according to the extent of steric *cis* interactions across the double bond in the b isomer: (i) compounds in which the steric interactions can be assumed to be equal to those in the reference compound Rb, and (ii) compounds in which this is not the case. The latter group includes the three-, four-, and five-membered compounds, whereas all the other ring compounds belong to the former group. This can be verified by means of thermochemical data as follows.

From available enthalpy of hydrogenation data,[12] the enthalpy of isomerization of methylenecyclopentane to 1-methylcyclopentene is *ca.* -16.2 kJ mol^{-1} in acetic acid at 298.15 K, but the corresponding value for the isomerization of ethylidenecyclopentane to 1-ethylcyclopentene is -5.4 kJ mol^{-1}. The difference in these values shows that the methyl group of ethylidenecyclopentane stabilizes the *exo*-cyclic double bond by 10.8 kJ mol^{-1}, which is practically equal to the hyperconjugative stabilization (11.3 kJ mol^{-1}) in propene,[8] an apparently "strain-free" molecule. The similarity of these two stabilization energies indicates that there is no measurable destabilization between the methyl group and ring hydrogens of ethylidenecyclopentane. This is supported by the fact that the enthalpy of isomerization of isopropylidenecyclopentane to 1-isopropylcyclopentene is 4.3 kJ mol^{-1} in acetic acid at 298.15 K,[13] which shows that the second *exo*-cyclic methyl group in isopropylidenecyclopentane causes an additional stabilization (relative to ethylidenecyclopentane) of $4.3 - (-5.4) = 9.7$ kJ mol^{-1}, *i.e.*, not significantly less than the first

Table 4. Thermodynamic data for the reaction 1-methoxyvinylcycloalkane → 1-methoxyethylidenecycloalkane in cyclohexane solution at 298.15 K. The errors are twice the standard errors.

Ring size	$\Delta G°$/kJ mol^{-1}	$\Delta H°$/kJ mol^{-1}	$\Delta S°$/J K^{-1} mol^{-1}
C_4	6.271 ± 0.046	9.02 ± 0.26	9.2 ± 0.8
C_5	-0.654 ± 0.012	1.27 ± 0.07	6.46 ± 0.21
C_6	6.211 ± 0.040	10.98 ± 0.30	16.0 ± 0.9

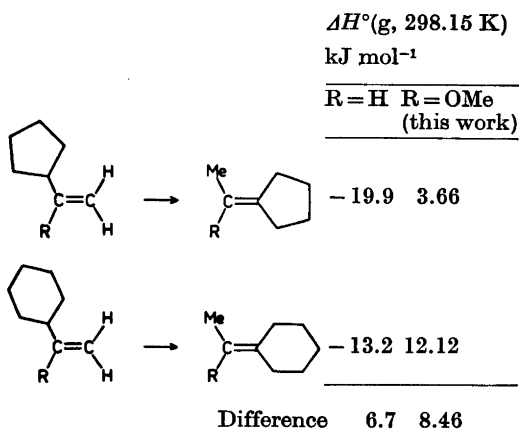
methyl group. Hence it appears that in alkylidenecycloalkanes with three-, four-, and five-membered rings the hydrogen atoms of the *exo*-cyclic methyl groups are not capable of interacting with the hydrogen atoms of the ring.

On the other hand, the enthalpy of isomerization of methylenecyclohexane to 1-methylcyclohexene (acetic acid, 298.15 K) is only 5.0 kJ mol^{-1} more negative than that of ethylidenecyclohexane to 1-ethylcyclohexene,[12] which shows that there are considerable destabilizing interactions between the *exo*-cyclic methyl group and ring hydrogens in ethylidenecyclohexane. As the methyl group of ethylidenecyclopentane brings about a stabilization of 10.8 kJ mol^{-1} relative to methylenecyclopentane, the strain between the methyl group and ring hydrogens of ethylidenecyclohexane is about 10.8 − 5.0 = 5.8 kJ mol^{-1}. This is somewhat higher than the strain in (*Z*)-2-butene, 4.2 − 4.5 kJ mol^{-1},[14] but Skinner [1] has pointed out that for compounds like 2-methyl-2-butene (and, by analogy, ethylidenecyclohexane) carrying two alkyl groups on one of the two sp^2-hybridized carbon atoms and one alkyl group on the other, steric crowding is enhanced so that the total strain between the three alkyl groups amounts to *ca.* 5.8 kJ mol^{-1}, or exactly the same that was found to exist between the methyl group and ring hydrogens of ethylidenecyclohexane. This strain is released when the *cis* interaction is absent, as in ethylidenecyclopentane and the other small-ring compounds.

Moreover, it can be deduced by means of molecular models that the strain between the methyl group and ring hydrogens of ethylidenecycloalkanes larger than ethylidenecyclohexane should be close to that in ethylidenecyclohexane.

Applied to the present compounds, in addition to the disappearance of the destabilizing interaction between the *exo*-cyclic methyl group and ring hydrogens on going from 1-methoxyethylidenecyclohexane (IVb) to IIIb, IIb, and Ib, there remains the question of the possible change in the interaction energy between the methoxy group and ring hydrogens in the same process. This problem can be solved as follows. From available data,[4] the values of $\Delta H°_f$(l, 298.15 K) of vinylcyclopentane and ethylidenecyclopentane are −34.8 and −56.7 kJ mol^{-1}, respectively. The normal boiling points of the above compounds are 373.5 and 385.8 K, respectively.[15] Thus the standard enthalpy of vaporization at 298.15 K of vinylcyclopentane is calculated [6] to be about 36.7 and that of ethylidenecyclopentane 38.7 kJ mol^{-1}. Hence the values of $\Delta H°_f$(g, 298.15 K) of the above compounds are calculated to be about 1.9 and −18.0 kJ mol^{-1}, respectively. Similarly, for vinylcyclohexane and ethylidenecyclohexane, the values of $\Delta H°_f$(l, 298.15 K) are −88.7 and −103.5 kJ mol^{-1}, respectively. The normal boiling points of vinylcyclohexane [15] (400.2 K) and ethylidenecyclohexane [15] (410.0 K) lead to the standard enthalpies of vaporization at 298.15 K of 41.0 and 42.6 kJ mol^{-1}, respectively. Hence the values of $\Delta H°_f$(g, 298.15 K) of vinylcyclohexane and ethylidenecyclohexane are *ca.* −47.7 and −60.9 kJ mol^{-1}, respectively. Now the following standard enthalpies of isomerization can be written:



The difference $\Delta H°$(6-membered ring) − $\Delta H°$(5-membered ring) is *ca.* 1.8 kJ mol^{-1} more positive in the case R = OMe. Hence the destabilizing

interaction energy between the methoxy group and ring hydrogens increases slightly on going from the 5-membered to the 6-membered ring compound.

To summarize, the following discussion of ring strain energies is based on three assumptions: (i) in the 6-, 7-, and 8-membered ring compounds IVb, Vb, and VIb, the strain between the *exo*-cyclic substituents (Me and MeO) and ring hydrogens is taken to be equal to that in the reference compound Rb, (ii) this strain (fixed at $5.8+1.8=7.6$ kJ mol^{-1}) is absent in the 3-, 4-, and 5-membered compounds Ib, IIb, and IIIb, and, (iii) the strain in the a isomers (excluding the strain of the saturated ring) is equal to that in the reference compound Ra.

As to the values of $\Delta H°$(g, 298.15 K) and $\Delta S°$(g, 298.15 K) for the reference reaction, the liquid phase data given in Ref. 11 lead to the following values for the thermodynamic functions in question, if the standard enthalpies and standard entropies of vaporization at 298.15 K are estimated from the appropriate equations given in Ref. 6: $\Delta H°$(g, 298.15 K) $= 9.46 \pm 0.40$ kJ mol^{-1}, $\Delta S°$(g, 298.15 K) $= 17.9 \pm 0.9$ J K^{-1} mol^{-1}.

Relative ring strain energies. Three-membered ring compounds. In this case only a qualitative result was achieved since the peak of Ib could not be detected by GLC, owing to the low thermodynamic stability of the three-membered ring with an sp^2-hybridized carbon atom. Hence the following discussion is based on literature data. From available data,[4] the value of $\Delta H°_f$(g, 298.15 K) of methylenecyclopropane is found to be *ca.* 175 kJ mol^{-1} higher than that of a strain-free methylenecyclopropane molecule calculated from the group increments given by Cox and Pilcher.[4] On the other hand, the experimental enthalpy of formation of gaseous cyclopropane [4] is 115 kJ mol^{-1} higher than the calculated value. Hence the introduction of an sp^2-hybridized carbon atom into the three-membered saturated ring leads to an increase of ring strain of *ca.* 60 kJ mol^{-1}, which causes Ib to be highly unfavored at equilibrium.

Four-membered ring compounds. The enthalpy change $\Delta H°$(g, 298.15 K) for the reaction 1-methoxyvinylcyclobutane → 1-methoxyethylidenecyclobutane is 1.96 kJ mol^{-1} more positive than that for Ra → Rb. If the correction term of 7.6 kJ mol^{-1} (due to the absence of steric interactions across the double bond in IIb) is taken into account, the introduction of an sp^2-hybridized carbon atom into the cyclobutane ring is seen to increase the ring strain by $1.96 + 7.6 \simeq 9.6$ kJ mol^{-1}. This may be compared with the value obtainable from literature data as follows. The experimental enthalpy of formation of gaseous cyclobutane [4] and the group increments of Cox and Pilcher lead to a strain energy of *ca.* 111 kJ mol^{-1} for the cyclobutane ring. The enthalpy of formation of methylenecyclobutane has not been determined experimentally but it can be estimated as follows. The enthalpy of hydrogenation data by Turner and Garner [12] reveal that the enthalpy of 1-methylcyclobutene is *ca.* 3.8 kJ mol^{-1} lower than that of methylenecyclobutane in acetic acid at 298.15 K. Methylenecyclobutane is reported to boil *ca.* 5 K higher than 1-methylcyclobutene,[16,17] and thus the standard enthalpy of vaporization (at 298.15 K) of the latter should be about 0.80 kJ mol^{-1} lower than that of the former.[6] Accordingly, the standard enthalpy change in the reaction methylenecyclobutane → 1-methylcyclobutene is about -4.6 kJ mol^{-1} in the gas phase at 298.15 K, if it is assumed that both isomers have equal enthalpies of solution in acetic acid. The standard enthalpy of formation in the gas phase at 298.15 K of 1-methylcyclobutene can be estimated by assuming that the difference in the values of $\Delta H°_f$(g, 298.15 K) between 1-methylcyclobutene and cyclobutene is equal to that between 1-methylcyclopentene and cyclopentene. The value of $\Delta H°_f$(l, 298.15 K) of 1-methylcyclopentene is -36.2 kJ mol^{-1},[4] and as the normal boiling point [19] (348.7 K) corresponds to a standard enthalpy of vaporization of 32.7 kJ mol^{-1} at 298.15 K,[6] the value of $\Delta H°_f$(g, 298.15 K) of 1-methylcyclopentene is obtained as -3.5 kJ mol^{-1}. As the corresponding value for cyclopentene is 32.4 kJ mol^{-1},[4] the difference in the values of $\Delta H°_f$(g, 298.15 K) between cyclopentene and 1-methylcyclopentene is about 35.9 kJ mol^{-1}. For cyclobutene, $\Delta H°_f$(g, 298.15 K) is *ca.* 156.7 kJ mol^{-1},[4] which leads to a $\Delta H°_f$(g, 298.15 K) of $156.7 - 35.9 = 120.8$ kJ mol^{-1} for 1-methylcyclobutene. Hence the standard enthalpy of formation of gaseous methylenecyclobutane is calculated to be $120.8 + 4.6 = 125.4$ kJ mol^{-1} at 298.15 K. The group increments suggest a standard enthalpy of formation of 5.1 kJ mol^{-1} for a strain-free

methylenecyclobutane, and thus the strain in methylenecyclobutane is obtained as 120 kJ mol^{-1}, which is 9 kJ mol^{-1} higher than the strain in cyclobutane. The result achieved is practically equal to that obtained in this study.

Five-membered ring compounds. If the correction term of 7.6 kJ mol^{-1} is added to the difference (−5.80 kJ mol^{-1}) between the gas phase standard enthalpies of isomerization of 1-methoxyvinylcyclopentane (IIIa) to 1-methoxyethylidenecyclopentane (IIIb) and Ra to Rb, the introduction of an sp^2-hybridized carbon atom into the cyclopentane ring is seen to cause a slight increase (1.8 kJ mol^{-1}) in ring strain energy. This result is in good agreement with the value obtainable from literature data. The standard enthalpy of formation of liquid methylenecyclopentane is −20.1 kJ mol^{-1} at 298.15 K,[4] and the standard enthalpy of vaporization at 298.15 K is estimated to be *ca.* 32.7 kJ mol^{-1} (normal boiling point 348.8 K [15]) leading to a $\Delta H°_f$(g, 298.15 K) of 12.6 kJ mol^{-1}, which is 28.1 kJ mol^{-1} more positive than the value −15.5 kJ mol^{-1}, calculated by means of the group increments. On the other hand, the strain in cyclopentane is obtained to be 25.8 kJ mol^{-1} from its experimental [4] and estimated enthalpy of formation. Thus the literature data lead to an increase of *ca.* 2 kJ mol^{-1} in ring strain energy on going from cyclopentane to methylenecyclopentane.

Six-membered ring compounds. The enthalpy of isomerization of 1-methoxyvinylcyclohexane (IVa) to 1-methoxyethylidenecyclohexane (IVb) is 2.66 kJ mol^{-1} more positive than that of Ra to Rb showing that the introduction of an sp^2-hybridized carbon atom into the saturated six-membered ring increases the strain by this amount. The data of Turner and Garner [12] show that the enthalpy of methylenecyclohexane is *ca.* 10.0 kJ mol^{-1} higher than that of 1-methylcyclohexene in acetic acid at 298.15 K. The value of $\Delta H°_f$(l, 298.15 K) of 1-methylcyclohexene is about −81.2 kJ mol^{-1},[4] and thus the standard enthalpy of formation of liquid methylenecyclohexane is about −71.2 kJ mol^{-1} at 298.15 K. The normal boiling point of methylenecyclohexane is 376.5 K [15] corresponding to a standard enthalpy of vaporization at 298.15 K of about 37.2 kJ mol^{-1}, and hence the value of $\Delta H°_f$(g, 298.15 K) of methylenecyclohexane is *ca.* −34.0 kJ mol^{-1}. The group increments [4] suggest a $\Delta H°_f$(g, 298.15 K) of −36.1 kJ mol^{-1} for a strain-free methylenecyclohexane. Thus the strain in this compound is about 2 kJ mol^{-1}. From the experimental enthalpy of formation of gaseous cyclohexane [4] the strain of the saturated six-membered ring is calculated to be about 0 kJ mol^{-1} which is 2 kJ mol^{-1} less than the strain in methylenecyclohexane. This result is in reasonable agreement with the value 2.7 kJ mol^{-1} achieved in this study.

Seven-membered ring compounds. The enthalpy of isomerization of 1-methoxyvinylcycloheptane (Va) to 1-methoxyethylidenecycloheptane (Vb) is 1.73 kJ mol^{-1} while that of Ra to Rb is 9.46 kJ mol^{-1}. Hence the seven-membered ring containing an sp^2-hybridized carbon atom is about 7.7 kJ mol^{-1} less strained than the saturated ring. From enthalpy of hydrogenation measurements,[12] the enthalpy of isomerization of methylenecycloheptane to 1-methylcycloheptene is *ca.* −9.6 kJ mol^{-1} in acetic acid at 298.15 K. As the normal boiling point of the former is about 1 K lower than that of the latter,[12] the enthalpy difference is about −9.4 kJ mol^{-1} in the gas phase. Moreover, if it is assumed that the difference in the values of $\Delta H°_f$(g, 298.15 K) between cycloheptene [$\Delta H°_f$(g, 298.15 K) = −9.2 kJ mol^{-1}, Ref. 4] and 1-methylcycloheptene is the same as the corresponding difference between cyclohexene and 1-methylcyclohexene, 38.7 kJ mol^{-1},[4] the value of $\Delta H°_f$(g, 298.15 K) for 1-methylcycloheptene is obtained as −9.2 −38.7 = −47.9 kJ mol^{-1}. Hence for methylenecycloheptane, $\Delta H°_f$(g, 298.15 K) = −47.9 + 9.6 = −38.3 kJ mol^{-1}, which is *ca.* 18 kJ mol^{-1} more positive than the value −56.7 kJ mol^{-1} calculated from the group increments. On the other hand, the experimental standard enthalpy of formation of gaseous cycloheptane [4] is 26 kJ mol^{-1} more positive than the calculated value. Thus the decrease in ring strain energy on going from cycloheptane to methylenecycloheptane is about 8 kJ mol^{-1}, in agreement with the result (7.7 kJ mol^{-1}) obtained in this study.

Eight-membered ring compounds. The results of the present work indicate that the introduction of an sp^2-hybridized carbon atom into cyclooctane decreases the ring strain energy by 9.46 − (−3.41) ≃ 12.9 kJ mol^{-1}. In the absence of suitable literature data, a comparison cannot be made.

Summary of the changes of ring strain energy. From the above discussion it appears that on going from a cycloalkane to the corresponding alkylidenecycloalkane, the values of ring strain energy undergo the following changes:

Ring size	Increase of ring strain energy/kJ mol^{-1}
C_3	60 from literature data
C_4	9.6
C_5	1.8
C_6	2.7
C_7	−7.7
C_8	−12.9

These results have been combined with some literature data in Table 6, which shows the values of ring strain energy in carbocyclic rings with no, one, or two sp^2-hybridized carbon atoms. The literature data are based on the difference between the experimental [4] and estimated standard enthalpies of formation of the gaseous compounds at 298.15 K.

The increase of ring strain energy in the three- and four-membered rings with increasing unsaturation of the ring carbons is undoubtedly due to increased bending of the carbon-carbon bond angles from their normal values. On the other hand, the decrease of ring strain in the large-ring compounds (C_7 and C_8) in the same sequence points to decreased destabilizing interactions between incompletely staggered adjacent bonds, or/and to decreased transannular interactions (see, for example, Ref. 18).

Relative ring entropies. For each isomerization reaction studied in this work, the value of $\Delta S°$(g, 298.15 K) is less positive than the entropy change in the reference reaction. As the differences in the values of $\Delta S°$ for the reference reaction and the a → b reactions must be due to differences in ring entropy between a saturated carbocyclic ring and the corresponding ring containing an sp^2-hybridized carbon atom the entropy data show that the saturated ring has a greater entropy value. This result is in agreement with the decreasing values of intrinsic entropy [7,19] on going from cycloalkanes to cycloalkenes or to more highly unsaturated cyclic olefins. O'Neal and Benson [19] have described a method for estimating gas phase entropies of carbocyclic compounds with one or more *endo*-cyclic double bonds from the entropies of the corresponding cycloalkanes by making certain corrections the most important of which is the "double bond tightness correction". This correction is negative for cycloalkenes up to cyclooctene except for cyclopropene for which it is zero. It is of interest to compare the value of the "*endo*-cyclic double bond tightness corrections" of O'Neal and Benson with the "*exo*-cyclic double bond tightness corrections" obtainable from this study by subtracting 17.9 J K^{-1} mol^{-1} (the value of $\Delta S°$ for the reference reaction) from the entropy changes in the a − b reactions involving four- to eight-membered carbocyclic rings:

Ring size	*Exo*-cyclic *vs.* *endo*-cyclic double bond tightness correction /J K^{-1} mol^{-1}
C_4	−6.0/−7.9
C_5	−8.9/−16.3
C_6	−0.8/0.0
C_7	−6.2/−10.4
C_8	−7.6/−13.4

The negative values of the double bond tightness corrections show that in general, increasing unsaturation of the ring carbons leads to increased rigidity of the ring. This effect is least marked for the six-membered ring; on the other hand, it attains a maximum value for the five-membered ring. Hence, on going from cyclohexane to methylenecyclohexane, the rigidity of the ring undergoes only a slight increase. This is understandable since methylene-

Table 6. Values of ring strain energy (in kJ mol^{-1}) in some saturated and unsaturated carbocyclic rings.

Ring size	Ring strain energy in cycloalkane	alkylidene-cycloalkane	cycloalkene
C_3	115	175	225
C_4	111	120	126
C_5	26	28	24
C_6	0	3	5
C_7	26	18	21
C_8	40	27	24

cyclohexane exists in a chair conformation,[20] and thus there is no change in conformation on going from cyclohexane to methylenecyclohexane. However, on going from cyclopentane to methylenecyclopentane, the flexible envelope conformation of cyclopentane is changed to a more rigid half-chair conformation in methylenecyclopentane.[18]

As an application of the *exo*-cyclic double bond tightness corrections given above, the entropy change $\Delta S°$(g, 298.15 K) for the reaction methylenecyclopentane → 1-methylcyclopentene is estimated by means of the group increment method proposed by Benson *et al.*[7] For cyclic compounds, a ring correction term is necessary. This is obtained as 105.3 J K^{-1} mol^{-1} for the five-membered ring in methylenecyclopentane by summing the ring correction term for a saturated five-membered carbocyclic ring (114.2 J K^{-1} mol^{-1}) given by Benson *et al.*, and the *exo*-cyclic double bond tightness correction term (−8.9 J K^{-1} mol^{-1}) for a five-membered ring. Now the entropies $S°$(g, 298.15 K) of methylenecyclopentane (symmetry number = 2) and 1-methylcyclopentene (external symmetry number = 1) are estimated to be 322.9 and 327.7 J K^{-1} mol^{-1}, respectively. Hence the entropy change for the reaction in question is calculated to be about 4.8 J K^{-1} mol^{-1}. From equilibrium [21] and enthalpy of hydrogenation [12] studies in acetic acid at 298.15 K, the values of $\Delta G°$ and $\Delta H°$ are −17.45 and −16.2 kJ mol^{-1}, respectively, and hence the standard entropy change $\Delta S°$(l, 298.15 K) is obtained as 4.2 J K^{-1} mol^{-1}. Since the normal boiling points of the compounds in question are equal within 1 K,[15,22] they are expected [6] to have practically equal standard entropies of vaporization at 298.15 K, and hence the value of $\Delta S°$(g, 298.15 K) is *ca.* 4.2 J K^{-1} mol^{-1}, in agreement with the estimated value.

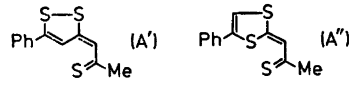
Short Communications

Formation of α-(5-Phenyl-1,3-dithiol-2-ylidene)propanethione from Thioacetic Acid and Phenylacetylene

CARL TH. PEDERSEN

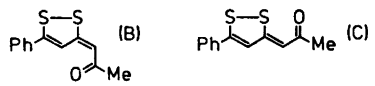
Department of Chemistry, Odense University, DK-5000 Odense, Denmark

It has been reported that the reaction of thioacetic acid with phenylacetylene in the presence of anhydrous sodium acetate resulted in the formation of an intensely coloured compound, $C_{12}H_{10}S_3$, (A).[1] This compound has later been assigned the *trans* trithiapentalene structure (A').[2-4]

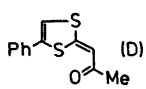


We want to present evidence which conclusively establishes the structure α-(5-phenyl-1,3-dithiol-2-ylidene)propanethione (A'') for this substance.

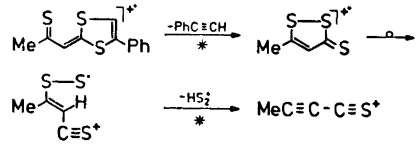
If compound (A) is dissolved in concentrated sulfuric acid a compound with the composition $C_{12}H_{10}OS_2$ can be isolated after dilution with water. The compound has been assigned the structure (B).[2-4]



This structure is unlikely since dithiolylidene ketones (C) have been shown to photoisomerize to *trans* compounds of the same type as (B).[5,6] These *trans* isomers, however, are not stable but revert to starting material *via* a thermal process. The lifetime of the *trans* isomers varies from milliseconds to some minutes. The compound obtained by partial desulfurization is actually α-(5-phenyl-1,3-dithiol-2-ylidene)propanone (D).[7]



The mass spectrum of (A), Fig. 1, is fully in accordance with structure (A''). The dominant fragmentation is loss of phenylacetylene from the molecular ion, a metastable peak corresponding to this fragmentation being present. The loss of acetylenes has been observed to be a general for 1,3-dithioles of the same type as (A'').[8] The $[M-PhC{\equiv}CH]^{+}$ ion further loses $HS_2^{\cdot}$ to give rise to the abundant ion *m/e* 83. These fragmentations can be rationalized for structure (A'') in the following way.



The loss of HS_2 is caracteristic for 5-substituted 1,2-dithiol-3-thiones.[9]

When compound (A) is refluxed for several hours in xylene very little isomerisation to the corresponding 2-methyl-5-phenyl-1,6,6a^{IV}*S*-trithiapentalene occurs; however, if thioacetamide is added to the refluxing solution rapid isomerisation takes place in accordance with previous observations.[10-12]

1,2-Dithiol-3-thiones react with activated acetylenes in a cycloaddition reaction forming α-(1,3-dithiol-2-ylidene)thioketones.[10,13,14] We have succeeded in preparing a compound identical with (A) by reacting 5-methyl-1,2-dithiol-3-thione with phenylacetylene in boiling xylene. By partial desulfurization in concentrated sulfuric acid a compound identical to the compound which had been assigned structure (D) was obtained.

We have observed, that 5-methyl-1,2-dithiol-3-thione is formed in a refluxing solution of anhydrous sodium acetate in thioacetic acid. It has further been observed that the amount of 5-methyl-1,2-dithiol-3-thione is augmented by addition of diacetyl disulfide. We therefore propose that diacetyl disulfide is a precursor for the thione which reacts in a cycloaddition forming (A). This is further substantiated by the observation that the yield of (A) increased in proportion to the amount of diacetyl disulfide added to the reaction mixture.

Experimental. *α-(5-Phenyl-1,3-dithiol-2-ylidene)propanethione(A'').* Phenylacetylene (10 g), thioacetic acid (40 g), and anhydrous sodium acetate (1 g) were refluxed for 3 h, and the

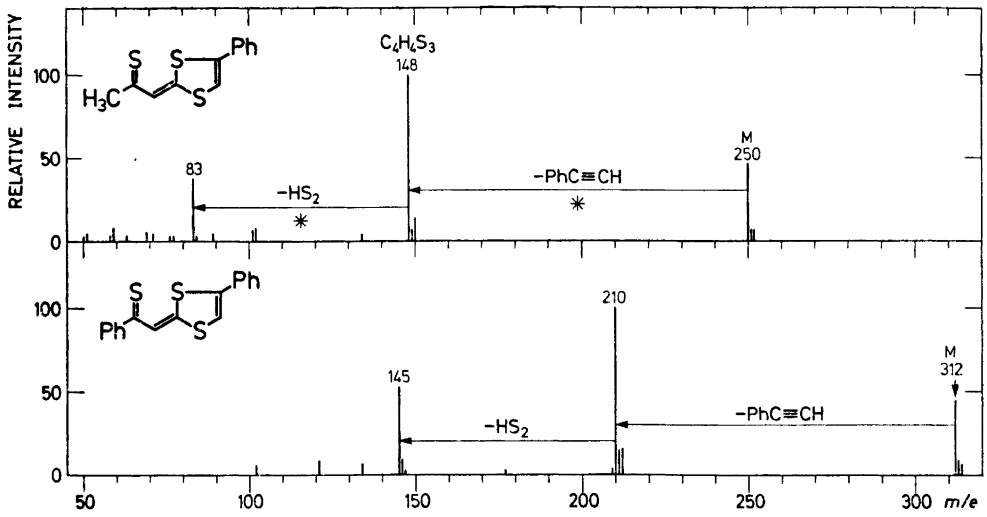


Fig. 1. Mass spectra of α-(5-phenyl-1,3-dithiol-2- ylidene) propanethione, and α-(5-phenyl-1,3-dithiol-2-ylidene)thioacetophenone.

reaction mixture was left over-night. The crystals that separated were washed with water. Yield 1.8 g, 7 % based on phenylacetylene. Recrystallized from glacial acetic acid; m.p. 185 – 187 °C (isomerization). M^+ 249.9945; calc. for $C_{12}H_{10}S_3$ 249.9904, M – 102 148.0060; calc. for $C_4H_4S_3$ 148.0071. (Found: C 57.55; H 4.13; S 38.43. Calc. for $C_{12}H_{10}S_3$: C 57.60; H 4.03; S 38.37).

α-(5-Phenyl-1,3-dithiol-2-ylidene)propanone (D) (A″) (500 mg) was dissolved in cold concentrated sulfuric acid (10 ml); after 10 min at room temperature the yellow solution was warmed for 5 min on the water bath. After cooling the solution was poured into ice. The product was extracted with chloroform. After evaporation the compound was recrystallized from ethanol. Yield 300 mg; m.p. 157 – 158 °C, (lit. 157 – 158 °C,[4] 152 – 154 °C [7]).

2-Methyl-5-phenyl-1,6,6a^{1V}*S-trithiapentalene.* Compound (A″) (300 mg) was refluxed in xylene (25 ml). After 4 h small amounts of trithiapentalene were detectable by means of TLC. Thioacetamide (300 mg) was added, and the solution was refluxed for a further 4 h, after which (A″) was 75 % converted to trithiapentalene. After evaporation and chromatography on alumina 100 mg of crystals were isolated, Recrystallized from cyclohexane, m.p. 168 – 169 °C, (lit. 169 °C [15]).

On the Rearrangement of 1-Aralkylindenes

LENNART MEURLING

Department of Organic Chemistry, University of Uppsala, Box 531, S-751 21 Uppsala 1, Sweden

In connection with studies [1,2] on the tautomerism of indene, an unusual effect of the triphenylmethyl group on the base-catalyzed prototropic rearrangement has been observed. 1-Benzyl-, 1-benzhydryl-, and 1-triphenylmethylindene were rearranged to the corresponding 3-substituted indenes in benzene with diazabicylo[2.2.2]octane (DABCO) as catalyst. The rate constants observed are given in Table 1, together with that found for the rearrangement of 1-methylindene. The trend of moderate increase in the rate constant observed on substituting the hydrogens in the methyl group by one and two phenyl groups is drastically changed for 1-triphenylmethylindene. This compound rearranges 30 times slower than 1-benzhydrylindene and about 5 times slower than 1-methylindene.

If one of the hydrogens in the methyl group of 1-methylindene is substituted, the transition state for proton abstraction (which is rate-determining in the rearrangement of 1-substituted indenes) can adopt a conformation in which steric hindrance between the catalyst is of minor importance. Thus, in this case, the retarding effect of a methyl substituent (1-ethylindene) as well as the accelerating effect of the methoxy-, acetoxy-, and thioacetoxy groups can be qualitatively understood on the basis of electronic effects as shown by Ahlberg.[3] Furthermore, in benzhydrylindene, rotation about the bond between the indenyl ring and benzylic carbon can minimize the steric interaction between the catalyst and the substrate, and electronic factors may thus account for the moderate rate acceleration found when going from 1-methylindene to benzhydrylindene (*cf.* Tafts' σ^*-substituent constants [4]).

The abrupt drop in the rearrangement rate which is observed when going to 1-triphenylmethylindene (Table 1) must to a large extent be ascribed to the lack of a conformationally favourable transition state. The series methyl-, benzyl-, benzhydryl-, and triphenylmethylindene is very suitable for the study of such effects, since the fully substituted compound deviates from the trend in the series. Successive substitution of the hydrogens of methylindene by methyl groups gives a monotonic decrease in the rate constant.

As regards the equilibrium constant between the 3- and the 1-substituted indene isomer, the triphenylmethyl group differs from the *t*-butyl group. The equilibrium constant, [3-*t*-butylindene]/[1-*t*-butylindene], is 33 $\pm$1,[5] a value smaller than that found for [3-methylindene]/[1-methylindene] (about 100).[5] This effect can, at least partly, be accounted for by the increased *peri*-interaction between the substituent and the aromatic hydrogen in the 3-isomer on going from methyl- to *t*-butylindene. In an analogous way, the equilibrium constant [3-triphenylmethylindene]/[1-triphenylmethylindene] would be expected to be smaller than 33, but it is in fact larger than 50. It is possible that steric interactions also in the 1-isomer in this case may be responsible for this observation. However, all peculiarities of the triphenylmethyl-group are still not understood.

Experimental. The aralkylindenes were prepared and purified according to procedures previously recorded.[2] Stock solutions of diazabicyclo[2.2.2]octane (Kebo), m.p. 158 – 159 °C, recrystallized twice from hexane, in benzene (Mallinckrodt), dried over molecular sieves and distilled, were prepared. The aralkylindenes were weighed into 10 ml flasks and base solution added, so that the substrate concentration was about 0.3 M. The flask was placed in a thermostat at a temperature of 35.0 $\pm$ 0.1 °C. Samples were withdrawn at intervals, quenched with 2 M hydrochloric acid and analyzed in the NMR-apparatus. The signals of the *x*-protons (*cf.* Ref. 1) of 1- and 3-aralkylindenes were examined and the corresponding integrals re-

Table 1. Comparison of the isomerization rates of 1-methylindene and some 1-aralkylindenes with diazabicylo[2.2.2]octane in benzene at 35 °C.

Substrate	Conc. of catalyst [B] (mol/l)	k_1 pseudo-first order $\times 10^5$ (sec^{-1})	$k_1 \times 10^3$/[B] (l mol^{-1} sec^{-1})
1-Methylindene	2.41×10^{-2}	11.3 $\pm$0.2	4.69 $\pm$ 0.09
1-Benzylindene	4.15×10^{-3}	2.56 $\pm$ 0.12	6.17 $\pm$ 0.35
1-Benzhydrylindene	4.40×10^{-3}	12.1 $\pm$0.6	27.5 $\pm$1.4
1-Triphenylmethylindene	2.64×10^{-2}	2.40 $\pm$ 0.15	0.91 $\pm$ 0.05

corded. The reaction was followed for at least 3 half-life times. No 1-substituted indene could be detected at equilibrium. From the equilibrium solutions, the 3-substituted indenes were isolated and recrystallized from isopropanol. The distinct melting points of the indenes isolated and the NMR-spectra showed that the products were uniform in character. The equilibrium constants were determined by the NMR-technique with the aid of a computer of average transients. All equilibrium constants were larger than 50. The experimental technique did not allow a more precise determination.

Isoelectric Focusing in Deuterium Oxide Density Gradient

STIG FREDRIKSSON and SUNE PETTERSSON

Department of Physical Chemistry, Chalmers Institute of Technology and University of Gothenburg, S-402 20 Gothenburg, Sweden

The present paper is a preliminary report on the use of deuterium oxide as a substitute for sucrose when preparing density gradients for small isoelectric focusing columns. Full details of the technique used and the results obtained will be given elsewhere.

The isoelectric focusing column utilized in the present work is a modification of the 1.5 ml column described by Jonsson *et al.*[1] *Inter alia*, the bottom electrode of platinum wire has been exchanged for a sheet of palladium covering the bottom of the focusing chamber.

The D_2O density gradient has been created directly in the column by free interdiffusion of three D_2O solutions for 3 min.[2] The resulting D_2O concentration course, as obtained by measurement of the refractive index gradient,[2] has a very high degree of linearity. The initial D_2O density gradient (0.018 g cm^{-4}) is as strong as the initial sucrose density gradient used by Jonsson *et al.* As expected, the stability in time is less for the D_2O density gradient than for the sucrose density gradient. However, the D_2O density gradient remaining after the column has been standing in an upright position for two hours (0.016 g cm^{-4}), is still more than twice as strong as the sucrose density gradient obtainable in an LKB 110 ml column with 500 g of sucrose per litre as initial bottom concentration. Thus, the D_2O density gradient described should normally be quite sufficient for stabilization of protein zones. This conclusion is supported by results obtained in this laboratory at isoelectric focusing of β-lactoglobulin (*cf.* Fig. 1) and sperm whale myoglobin.

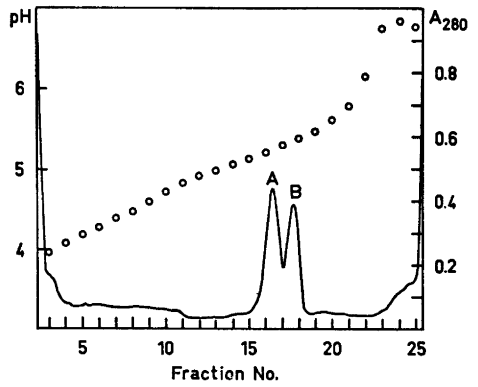

Fig. 1. Scan of 1.5 ml column [1] at 280 nm (solid curve) obtained after D_2O density gradient isoelectric focusing of 100 μg β-lactoglobulin in 1 % Ampholine pH 4 – 6 for 75 min. Average field strength 30 V cm^{-1}. Superimposed are pH values of 60 μl fractions of the column contents (circles).[3] (A represents β-lactoglobulin A, and B β-lactoglobulin B.)

Isoelectric points evaluated from isoelectric focusing runs in D_2O density gradients were found to be about 0.1 pH unit higher than those obtained in sucrose density gradients. This increase seems to be the net result of two effects: the intrinsic pK_a values of the protolytic groups in proteins are higher in D_2O than in H_2O but simultaneously the pH meter reading in D_2O solution is lower than in H_2O solution for solutions of comparable acidity.

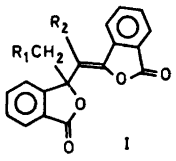
High Resolution Mass Spectra of Aromatic γ-Dilactones

PER KOLSAKER

Department of Chemistry, University of Oslo, Blindern, Oslo 3, Norway

The mass fragmentation of some α,β-unsaturated γ-dilactones formed by condensation of certain γ-keto-acids [1] was recently reported on.[2] When aromatic γ-keto-acids were condensed similar γ-dilactones were formed where the aromatic ring constitutes the α,β-unsaturation (I). The availability of the proper aromatic γ-keto-acids [1] gave in hand γ-dilactones well suited for a study of the effect of other substituents (*i.e.* at the double bond connecting the two lactone rings and at the sp^3 ring-carbon-atom) on the fragmentation of such systems. The main fragments in the high mass region are given in Table 1.

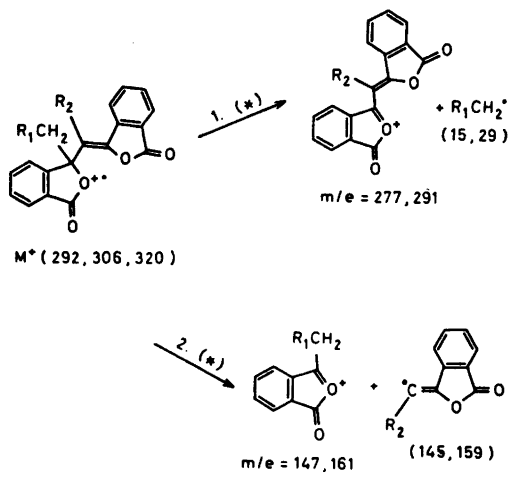


I

a : $R_1 = R_2 = H$
b : $R_1 = H$, $R_2 = Me$
c : $R_1 = R_2 = Me$

The molecular ions are involved in two simple bond cleavage processes, both being associated with a change in hybridization at the only sp^3 ring-carbon atom in the molecules (Scheme 1). The first involves splitting off the R_1CH_2-radical and the other route leads to the carbonium ion believed to be one of the key intermediates in the selfcondensation of the γ-keto-acids.[1]

Scheme 1 is interesting in many respects. The structural difference between Ib and Ic lies in the substituent R_1 and therefore the observed



Scheme 1. Consecutive ejection of carbon monoxide (or C_2O_2) leading to fluorenyl cations. Ia. Preferred route: 1. Ib. Preferred route: 2. Ic. Preferred route: 1.

variation in fragmentation must be due to the difference in stabilities of the radicals R_1CH_2· and/or the relative stabilities of the carbonium ions formed by route 2. From measurements of ionization potentials an ethyl group is found to stabilize a carbonium ion better than a methyl group by about 1.9 kcal/mol,[3] and thus the carbonium ion formed by route 2 should be more stable from Ic than from Ib. However, the limit of error of the ionization potential measurements was estimated to 1.2 kcal/mol. On the other hand, most values for stabilities of radicals favor the ethyl radical in comparison to the methyl radical by 3 – 6 kcal/mol. Thus this greater difference in radical stabilities explains the preference for route 1 for Ic and

Table 1. Relative intensities of main high masses in the fragmentation of I.

route 2 for Ib. The different fragmentation preference for Ia and Ib must lie in the relative stabilities of the entities carrying the substituent R_2. Again the radical stabilities seems to be more important, *i.e.* a methyl group (compared to a hydrogen atom at a double bond) must be more effective in stabilizing radicals than carbonium ions.

Similar to the aliphatic analogues, fragmentations involving consecutive losses of carbon monoxide are observed. The metastable defocusing technique once again revealed that two molecules of carbon monoxide (or C_2O_2) are ejected simultaneously. These fragmentations leading to fluorenyl cations are dealt with in Scheme 2. The rearrangement of $[M-R_1CH_2]^+$ and the intermediate formation of α-diketones before ejection of C_2O_2 are processes discussed earlier.[2]

As seen from Table 1 the path through $m/e=221$ (Ia) or $m/e=193$ (Ia) and 207 (Ib and Ic) is preferred only to some extent. In fact, the fragmentation route in Scheme 1 is very prominent only for Ia. When $R_2=Me$ (Ib and Ic) another route seems to be of more importance. Here fragmentation of $M-R_1CH_2$ directly to $m/e=143$ is preferred, demonstrated by the observation of the proper metastable peak (Scheme 3).

As for the aliphatic analogues,[2] metastable peaks indicating the elimination of ketenes from I are observed. In these aromatic dilactones such processes must involve rearrangements destroying the aromatic structure in one of the aromatic rings.

However, compared with other processes, only for Ia this represents a major fragmentation path.

Experimental. Mass spectra (70 eV, ion source temperature 230 °C) were obtained on an AEI MS 902 mass spectrometer connected to an AEI DS 30/64/H data system. Peak compositions were within 4 ppm of calculated values. Metastable peaks were observed in the spectra and confirmed by the metastable defocusing technique.

The Dimerization of Coniferyl Alcohol in Aqueous Sodium Hydroxide*

HELENA AMINOFF,[a] GÖSTA BRUNOW,[a] KIRSTI FALCK[a] and GERHARD E. MIKSCHE[b]

[a] Department of Organic Chemistry, University of Helsinki, SF-00100 Helsinki 10, Finland and [b] Organic Chemistry 2, Chemical Center, Box 740, S-220 07 Lund, Sweden

p-Hydroxyarylglycerol β-aryl ether structures (*1*), present originally as such or formed during degradation, have been shown to be the major site of lignin fragmentation in kraft pulping.[1] Structures of type *1* fragment to give predominantly *trans*-coniferyl alcohol (*2*).[2] This undergoes further transformation, in part via its extended quinone methide *3*. By this process the side chains of units derived from *2* and *3* condense to the final product, kraft lignin. The present paper is concerned with the elucidation of some of the reactions by which *2* reacts with the kraft lignin being formed.

Heating of *2* in dilute aqueous sodium hydroxide for 2 h at 170 °C gives a polymer.[2a,3] Little monomeric or dimeric material remains. The most characteristic feature of this polymer (in a strict sense it should be termed a telomer) is the absence of the γ-hydroxymethyl group present in its precursor *2*. This was demonstrated by recording the NMR-spectrum of the acetylated polymer. A similar polymer can be made by alkaline treatment of γ-coniferyl benzoate, which is believed to give primarily the quinone methide *3*.[4]

Suitable choice of the conditions of heating coniferyl alcohol in dilute sodium hydroxide (120 °C 1 h) afforded considerable amounts of dimeric material. Gas chromatography of the trimethylsilylated reaction mixture [bis(trimethylsilyl)trifluoracetamide in pyridine] showed that the dimer fraction has two major components (*A* and *B*). Small amounts of these were collected and analyzed by high resolution mass spectroscopy. The fragmentation pattern and determinations of exact masses of the molecular ion (*B*) and of a prominent fragment (*A*) suggested structures *4* and *5* for *A* and B, respectively. Compound *4* is the 1,8-addition product of the carbanion of *2* to the quinone methide *3*. Proton abstraction from solvent by the anion of *4* gives a quinone methide (*6*) which undergoes cyclization with preferential reaction by the less hindered primary hydroxyl group, yielding *5*.

p-Coumaryl alcohol reacted in the same way as *2*, giving major amounts of the non-meth-

The Dimerization of Coniferyl Alcohol in Aqueous Sodium Hydroxide*

HELENA AMINOFF,[a] GÖSTA BRUNOW,[a] KIRSTI FALCK[a] and GERHARD E. MIKSCHE[b]

[a] Department of Organic Chemistry, University of Helsinki, SF-00100 Helsinki 10, Finland and [b] Organic Chemistry 2, Chemical Center, Box 740, S-220 07 Lund, Sweden

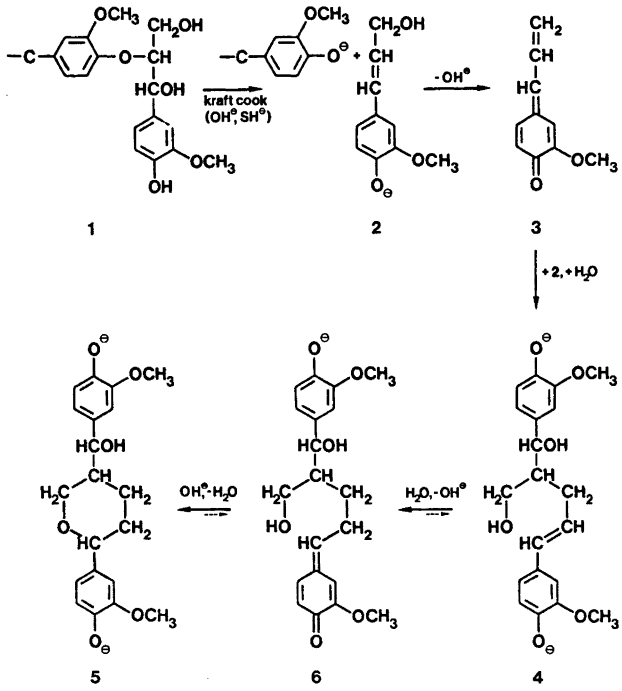
p-Hydroxyarylglycerol β-aryl ether structures (*1*), present originally as such or formed during degradation, have been shown to be the major site of lignin fragmentation in kraft pulping.[1] Structures of type *1* fragment to give predominantly *trans*-coniferyl alcohol (*2*).[2] This undergoes further transformation, in part via its extended quinone methide *3*. By this process the side chains of units derived from *2* and *3* condense to the final product, kraft lignin. The present paper is concerned with the elucidation of some of the reactions by which *2* reacts with the kraft lignin being formed.

Heating of *2* in dilute aqueous sodium hydroxide for 2 h at 170 °C gives a polymer.[2a,3] Little monomeric or dimeric material remains. The most characteristic feature of this polymer (in a strict sense it should be termed a telomer) is the absence of the γ-hydroxymethyl group present in its precursor *2*. This was demonstrated by recording the NMR-spectrum of the acetylated polymer. A similar polymer can be made by alkaline treatment of γ-coniferyl benzoate, which is believed to give primarily the quinone methide *3*.[4]

Suitable choice of the conditions of heating coniferyl alcohol in dilute sodium hydroxide (120 °C 1 h) afforded considerable amounts of dimeric material. Gas chromatography of the trimethylsilylated reaction mixture [bis(trimethylsilyl)trifluoracetamide in pyridine] showed that the dimer fraction has two major components (*A* and *B*). Small amounts of these were collected and analyzed by high resolution mass spectroscopy. The fragmentation pattern and determinations of exact masses of the molecular ion (*B*) and of a prominent fragment (*A*) suggested structures *4* and *5* for *A* and B, respectively. Compound *4* is the 1,8-addition product of the carbanion of *2* to the quinone methide *3*. Proton abstraction from solvent by the anion of *4* gives a quinone methide (*6*) which undergoes cyclization with preferential reaction by the less hindered primary hydroxyl group, yielding *5*.

p-Coumaryl alcohol reacted in the same way as *2*, giving major amounts of the non-meth-

* Part IV of the series "Degradation of Lignin by Kraft Cooking", Part III, Ref. 2a.



Compounds *2*, *4*, *5*, and *6* are shown as anions.

oxylated dimers corresponding to *4* and *5* (at a slightly higher reaction temperature, 135 °C).

The structural assignment for *4* was confirmed by the reaction of γ-coniferyl benzoate with an excess of *2* in aqueous NaOH at room temperature. Apart from some polymeric material the major product of this reaction was *4*. The absence of *5* (GLC) is due to the low rate at room temperature of the protonation of the carbanion of *4* leading to formation of *6*.

These experiments indicate that the dominant reactions in the base-catalyzed transformation of *2* to dimeric and polymeric products are Michael-type additions, in which *3* provides the unsaturated carbonyl substrate (1,8-addition being preferred to 1,6-addition), and *2* reacts as a carbanion with attack via C_β. The condensation products can react in much the same way as do *2* and *3*. It should be noted, however, that in contrast to the experiments described here, under the conditions of a kraft cook of lignin, *2* is present in a low, approximately steady-state concentration. Thus dimerization of *2* should be suppressed in favour of Michael-type addition to other enone structures, and of addition to *3* of other carbanions present.

Precise mass measurement. Tetrakis(trimethylsilyl)ether of *1,5-bis(4-hydroxy-3-methoxyphenyl)-2-hydroxymethyl-4-penten-1-ol* [*tetrakis(trimethylsilyl)ether* of *4*]. Peak at $m/e = 558$ [molecular ion at $m/e = 648 - (CH_3)_3SiOH$]. Found: 558.2659 ± 3 mmu. Calc. for $C_{29}H_{46}O_5Si_3$: 558.2653.

Tris(trimethylsilyl)ether of *2-(4-hydroxy-3-methoxyphenyl)-5-[(4-hydroxy-3-methoxyphenyl)-hydroxymethyl]-tetrahydropyran* [*tris(trimethylsilyl)ether* of *5*]. Molecular ion. Found: 576.2749 ± 3 mmu. Calc. for $C_{29}H_{48}O_6Si_3$: 576.2759.

Strained Heterocyclic Compounds. 5. The Synthesis of [Bromochloro(*N*,*N*-pentamethylenecarbamoyl)methyl]-phenylmercury and Its Thermal Decomposition to a Chloro-β-lactam

BJÖRN ÅKERMARK, STYRBJÖRN BYSTRÖM EBBA FLORIN, NILS-GUNNAR JOHANSSON and INGER LAGERLUND

Department of Organic Chemistry, Royal Institute of Technology, S-100 44 Stockholm 70, Sweden

In the last few years considerable efforts have been devoted to the synthesis of compounds related to penicillin.[1] Our own efforts have been directed towards the synthesis of penicillin analogues in which the thiazolidine nucleus has been modified. We have recently been able to synthesize bromo-β-lactams like *3* and *4* by thermolysis of phenylmercury compounds of the type *2* in boiling bromobenzene.[2] While the compound *3* could be prepared in good yield,[2b] only a low yield of the compound *4* was obtained.[2c] One reason for this is the low thermal stability of the compound *4*. Since the analogous chloro compound *4a* is considerably more stable,[3] attempts were made to prepare a chloro-β-lactam by thermolysis of the dichloro compound *2b*. However, due to the sluggishness of this reaction, the product chloro-β-lactam was extensively decomposed despite its relative stability.[2b] To circumvent these difficulties we have now prepared the bromochloro compound *2a*, which on thermolysis gave the desired chloro-β-lactam *3a* in good yield.

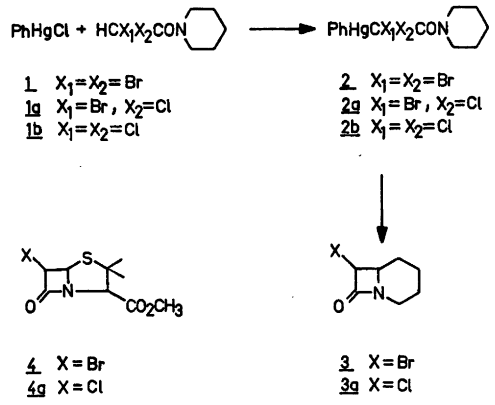

Fig. 1.

The phenylmercury compound *2a* was prepared essentially as the compounds *2* and *2b*. Bromochloroacetyl chloride, prepared by distillation of 1,2-dibromo-1,2-dichloro-1-ethoxyethane,[4] was reacted with piperidine to give the amide *1a*. This was condensed with phenylmercury chloride in THF using potassium *t*-butoxide as a base.[2] Interestingly, the condensation of the bromochloroamide *1a* and phenylmercury chloride gave lower yields than the corresponding reactions with either of the dichloro- and dibromoamides *1b* and *1*. Also, it is much more important that the reaction temperature is kept low with the bromochloroamide *1a*. A maximum yield of about 50 % of the compound *2a* was obtained when phenylmercury chloride and the bromochloroamide *1a* in THF solution were added rapidly from two dropping funnels to a cooled (−75°C) solution of the potassium *t*-butoxide in THF. If the butoxide and phenylmercury chloride are first mixed, the yield of condensation product is negligible. If the base and the bromochloroamide are first mixed, the yield of the mercury compound *2a* is lowered to about 20 %.

The thermal generation of the chloro-β-lactam *3a* from the mercury compound *2a* proceeded 10 times faster than the corresponding reaction from the dichloro analogue *2b*.[2b] In the reaction of the bromochloro compound *2a*, both phenylmercury chloride and bromide could be formed, although the elimination of phenylmercury bromide should be favoured (*cf.* Ref. 4b). Mass spectrometric analysis of the products gave no indication of the formation of phenylmercury chloride or bromo-β-lactam *3*.

The yield of the chloro-β-lactam *3a* from the compound *2a* is only slightly higher than the yield of the bromo-β-lactam *3* from the compound *2*. However, the exclusive generation of the *trans*-isomer of the chloro-β-lactam (*trans*:*cis* > 15:1) is an advantage since the correct configuration should be obtained on introduction of the proper side-chain (*cf.* Ref. 2). Furthermore, the facile generation of a relatively stable halogen derivative may be advantageous when labile systems of structures similar to *4a* are involved.

Experimental. All melting points were determined on a micro hot stage and are uncorrected. Elemental analyses were carried out by Centrala Analyslaboratoriet, Uppsala, Sweden, and by Alfred Bernhardt, Mikroanalytisches Laboratorium, 5251 Elbach über Engelskirchen, West Germany. IR spectra were recorded on a Perkin-Elmer No. 421 spectrophotometer, solids were measured in KBr discs, and oils as liquid films. The numbers are given in cm^{-1}. NMR spectra were recorded on a Varian A 60 instrument, the spectra refer to $CDCl_3$-solutions and the chemical shifts are given as δ-values relative to TMS as internal standard. Mass spectra were recorded on an LKB 9000 instrument. All THF used was freshly distilled from potassium metal/benzophenone under a N_2-atmosphere. Column chromatography was made on silica (Merck 0.05 – 0.2 mm) using increasing amounts of dry ether in distilled light petroleum as eluent.

N-(Bromochloroacetyl)piperidine (1a). Bromochloroacetyl chloride (38.4 g, 0.2 mol) in 200 ml of dry ether was added during 15 min from a dropping funnel to a magnetically stirred, ice-cooled solution of piperidine (34 g, 0.4 mol) in 800 ml dry ether. The reaction mixture was left for 3 h at room temperature and the precipitate of piperidine hydrochloride was filtered off. The ether solution was washed with two portions of 2 M HCl, two portions of saturated $NaHCO_3$-solution and one portion of water, then dried over Na_2SO_4 and evaporated. Recrystallization of the crude product from diethyl ether gave white crystals, m.p. 60–62°C. Yield 31.7 g (66 %). (Found: C 35.08; H 4.63; Br 33.07; Cl 14.61; N 5.77. Calc. for $C_7H_{11}BrClNO$: C 35.14; H 4.60; Br 33.05; Cl 14.64; N 5.85.) IR: CO 1635 cm^{-1}. NMR 1.68 (S, CH_2); 3.64 (S, $N-CH_2$); 6.34 (S, CHBrCl). MS: *m/e* 239, 241, 243 (M).

[Bromochloro(N,N-pentamethylenecarbamoyl)methyl]phenylmercury (2a). Phenylmercury chloride (3.1 g, 0.01 mol) in THF (80 ml) and *N*-(bromochloroacetyl)piperidine (2.4 g, 0.01 mol) in THF (50 ml) were added rapidly and simultaneously from two dropping funnels to a magnetically stirred solution of unsolvated *t*-BuOK (0.01 mol) in THF (100 ml), which was maintained at −75°C during the reaction. During the addition there was always a small excess of the amide over the phenylmercury chloride. When the addition was complete the reaction mixture was kept at −75 °C for an additional 45 min. The temperature was quickly raised to +10°C, and the solvent was evaporated on a rotatory evaporator at room temperature. The residue was dissolved in benzene (200 ml), washed with distilled water (40 ml) and dried over $MgSO_4$. Crystallization from dry diethyl ether gave [bromochloro(*N,N*-pentamethylenecarbamoyl)-methyl]phenylmercury (*2a*) 2.46 g (48 %), m.p. 111–113 °C (dec.). When the reaction was performed at −40 °C, the yield was lowered to 0.55 g (11 %). A longer reaction time also lowered the yield; thus, 75 min gave 1.26 g (27 %), 120 min gave 0.94 g (18 %). (Found: C 30.7; H 3.00; Br 16.0; Cl 7.14; N 2.69. Calc. for $C_{13}H_{15}BrClHgNO$: C 30.2; H 2.94; Br 15.5; Cl 6.85; N 2.71). IR: CO 1615 cm^{-1}. NMR: 1.75 (S, CH_2); 3.90 (S, $N-CH_2$); 7.60 (S, aromatic protons).

Thermolysis of [bromochloro(N,N-pentamethylenecarbamoyl)methyl]phenylmercury (2a). 0.8 g (1.55 mmol) of *2a* was refluxed in 240 ml freshly distilled bromobenzene. The decomposition of *2a* was followed by the use of IR spectrometry (β-lactam absorption at 1760 cm^{-1}) with samples removed after 1.3 h, 1.7 h, 2 h, 2.3 h, and 3.5 h. The best result was obtained at 2.3 h. The solvent was removed *in vacuo*, ether was added and the insoluble phenylmercury bromide was filtered off. Separation of the ether soluble products was accomplished by chromatography on a column of silica gel, cooled to −20 °C by cold circulating ethanol. Elution with increasing amounts of diethyl ether in light petroleum afforded 7-chloro-8-oxo-1-azabicyclo[4.2.0]octane (*3a*) (0.125 g, 54 %). Only the *trans*-isomer of *3a* could be detected by NMR: 1.2–1.3 (M, H-3, H-5); 2.6–4.1 (M, H-2, H-6); 4.45 (D, $J = 1.3$ Hz, H-7, *cf. cis*-isomer 4.95 (two D, $J = 1.4$ and 4.4 Hz, H-7).

Acknowledgements. This work has been supported by The Swedish Board for Technical Development. Miss Gurli Hammarberg recorded the spectra.

Synthesis of Bradykinin by Fragment Condensation on a Solid Support

SUNE M. KARLSSON and ULF RAGNARSSON

Biokemiska Institutionen, Uppsala Universitet, Box 531, S-751 21 Uppsala 1, Sweden

Solid phase peptide synthesis (SPPS) was introduced by Merrifield.[1] In a series of papers he developed the technique further and demonstrated the exceptional scope of his method.[2]

To simplify purification, which is the crucial step of this method, Weygand and one of the present authors [3] attempted to couple a peptide fragment instead of an amino acid derivative, *i.e.*, to use fragment condensation instead of a step-wise approach in analogy with common strategy in conventional peptide synthesis. We found that a peptide could be coupled satisfactorily with respect to the yield and with a very low degree of racemization when *N,N'*-dicyclohexylcarbodiimide (DCC) plus *N*-hydroxysuccinimide (HOSu) together [4] were used in CH_2Cl_2, the solvent of choice in SPPS, although admittedly the evidence concerning the yield was weak. Both considerations are of equally fundamental importance in this context. Since our initial work in this area, a couple of papers

N-(Bromochloroacetyl)piperidine (1a). Bromochloroacetyl chloride (38.4 g, 0.2 mol) in 200 ml of dry ether was added during 15 min from a dropping funnel to a magnetically stirred, ice-cooled solution of piperidine (34 g, 0.4 mol) in 800 ml dry ether. (Found: C 30.7; H 3.00; Br 16.0; Cl 7.14; N 2.69. Calc. for $C_{13}H_{15}BrClHgNO$: C 30.2; H 2.94; Br 15.5; Cl 6.85; N 2.71). IR: CO 1615 cm^{-1}. NMR: 1.75 (S, CH_2); 3.90 (S, $N-CH_2$); 7.60 (S, aromatic protons).

Thermolysis of [bromochloro(N,N-pentamethylenecarbamoyl)methyl]phenylmercury (2a). 0.8 g (1.55 mmol) of *2a* was refluxed in 240 ml freshly distilled bromobenzene. The decomposition of *2a* was followed by the use of IR spectrometry (β-lactam absorption at 1760 cm^{-1}) with samples removed after 1.3 h, 1.7 h, 2 h, 2.3 h, and 3.5 h. The best result was obtained at 2.3 h. The solvent was removed *in vacuo*, ether was added and the insoluble phenylmercury bromide was filtered off. Separation of the ether soluble products was accomplished by chromatography on a column of silica gel, cooled to −20 °C by cold circulating ethanol. Elution with increasing amounts of diethyl ether in light petroleum afforded 7-chloro-8-oxo-1-azabicyclo[4.2.0]octane (*3a*) (0.125 g, 54 %). Only the *trans*-isomer of *3a* could be detected by NMR: 1.2–1.3 (M, H-3, H-5); 2.6–4.1 (M, H-2, H-6); 4.45 (D, $J = 1.3$ Hz, H-7, *cf. cis*-isomer 4.95 (two D, $J = 1.4$ and 4.4 Hz, H-7).

Synthesis of Bradykinin by Fragment Condensation on a Solid Support

SUNE M. KARLSSON and ULF RAGNARSSON

Biokemiska Institutionen, Uppsala Universitet, Box 531, S-751 21 Uppsala 1, Sweden

Solid phase peptide synthesis (SPPS) was introduced by Merrifield.[1] In a series of papers he developed the technique further and demonstrated the exceptional scope of his method.[2]

To simplify purification, which is the crucial step of this method, Weygand and one of the present authors [3] attempted to couple a peptide fragment instead of an amino acid derivative, *i.e.*, to use fragment condensation instead of a step-wise approach in analogy with common strategy in conventional peptide synthesis. We found that a peptide could be coupled satisfactorily with respect to the yield and with a very low degree of racemization when *N,N'*-dicyclohexylcarbodiimide (DCC) plus *N*-hydroxysuccinimide (HOSu) together [4] were used in CH_2Cl_2, the solvent of choice in SPPS, although admittedly the evidence concerning the yield was weak. Both considerations are of equally fundamental importance in this context. Since our initial work in this area, a couple of papers

on the use of fragment condensation in SPPS have appeared,[5] but to date progress has been slow.

This communication describes the preparation of bradykinin on a solid support from three protected peptide fragments (I – III below). The coupling procedure used was DCC plus HOSu when there was a risk for racemization and DCC only when that risk was absent. However, only one equivalent of HOSu was used as compared with two earlier,[3] when much more dilute solutions were used. When possible, completeness of coupling was verified using the 2-hydroxy-1-naphthaldehyde procedure [6] before proceeding to the next step. The loss in time was more than compensated for by the information gained.

The three protected peptide fragments used, Z-Arg(NO_2)-Pro (I), Z(OCH_3)-Pro-Gly-Phe (II) and Z(OCH_3)-Ser(Bzl)-Pro-Phe (III),* were prepared in step-wise fashion by the mixed anhydride procedure without a carboxyl protecting group. They all gave only one spot on thin-layer chromatography and satisfactory elemental analyses as well as, after hydrolysis, amino acid analyses. II and III are amorphous solids. The reason for selecting two peptide fragments with C-terminal phenylalanine was that racemization, if any, could be simply established and consequently compared with that obtained earlier.[3]

We started our synthesis from 1.32 g of Boc-Arg(NO_2)-resin with a substitution degree of 0.151 mmol/g of Arg. All operations were performed manually in a sintered glass vessel, and apart from those explicitly mentioned below consisted of washings with proper solvents and neutralizations of amine trifluoroacetates. Initially, Boc was removed with 50 % trifluoroacetic acid (TFA) in CH_2Cl_2. Coupling was effected in 99.5 % yield, determined as described above, with 2.5 equiv. of III, DCC and HOSu each in CH_2Cl_2 for 4 h. Z(OCH_3) was removed using 10 % TFA in CH_2Cl_2.[7] The following coupling was effected also in 99.5 % yield as before with II substituted for III. After removal of Z(OCH_3), I was attached. In this case HOSu was omitted. This coupling step was repeated once, since a preliminary experiment indicated some residual heptapeptide. Finally, the peptide was split off from the resin using HF.[8]

Crude bradykinin was obtained in 81 % yield. After hydrolysis in 6 N HCl at 110 °C for 24 h it gave the following amino acid analysis: Arg 2.00 (2), Gly 1.03 (1), Phe 2.06 (2), Pro 2.93 (3) and, after correction for decomposition during hydrolysis, Ser 0.98 (1). Another sample was hydrolyzed as just mentioned and coupled with Leu-*N*-carboxyanhydride.[9] In a parallel experiment, analytically pure, biologically fully active bradykinin was carried through the same procedure as a control. On analysis the D-Phe/L-Phe ratio was found to be 3.76 % compared to 2.91 % for the control. These determinations were performed under such conditions that the L-Leu-D-Phe peaks could be properly integrated. The difference, 0.85 %, reflects the average racemization taking place during the coupling of the two fragments II and III to the resin. The original sample of phenylalanine used in this work contained less than 0.10 % D-Phe.

The crude bradykinin was purified by ion-exchange chromatography on carboxymethyl cellulose. The recovery of pure bradykinin in this step was 87 %. This is at least 25 % higher than the average we have obtained using step-wise procedure. Less than 5 % of the total material was obtained in two minor peaks, the rest we believe are inevitable losses. Amino acid analysis after hydrolysis now gave: Arg 2.00, Gly 1.02, Phe 2.03, Pro 2.98, and Ser 0.98. Purity was further established by high voltage paper electrophoresis at pH 6.46 and elemental analysis.

The conclusions reached in the earlier paper [3] have now been further verified. DCC together with HOSu in CH_2Cl_2 gives a very efficient coupling to the resin for the two tripeptides II and III. This might not always be the case.[5bf] As concerns racemization, the conditions used are certainly not perfect. However, a value as low as ours can in most cases, we believe, be tolerated. It may have been lower if we had used more than one equivalent of HOSu.

Many more experiments are needed to establish the scope of this approach to SPPS. Steric hindrance or an enhanced degree of racemization may in some cases exclude its general use. Even so, however, cases can be envisaged where it would be possible to incorporate a difficult amino acid into the interior of a fragment which could then be coupled to the resin by the proposed procedure. A mixed procedure, in which some amino acids are coupled step-wise and others as oligopeptides, may in other cases be a practical alternative.

Small protected peptides with a free C-terminal carboxyl group, as needed in the present scheme, are generally simple to prepare in satisfactory quality and quantity by conventional solution procedures. Somewhat larger ones, if needed, can perhaps be made as proposed recently.[5g] A definite disadvantage of any fragment condensation approach is that time is lost in the preparation of the partial sequences. For bradykinin,[10] which is small enough to be easily purified, our procedure is hardly an improvement. Nevertheless, our experiences with this synthesis as concerns the near absence of smaller peptides in the crude product make us believe that for larger peptides the purification will be much less time-consuming, *i.e.*, make a fragment condensation approach competitive even as regards the time needed.

* All amino acids used were of L-configuration except glycine.

The Oligomerization of Ethylene Oxide to Macrocyclic Ethers, Including 1,4,7-Trioxacyclononane

JOHANNES DALE, GERD BORGEN and KARI DAASVATN

Kjemisk Institutt, Universitetet i Oslo, Oslo 3, Norway

Cyclic homologues of ethylene oxide, $-[-CH_2-CH_2-O-]-_n$, have attracted much attention due to their remarkable complexing power for alkali and other cations.[1-3] Laboratory methods for the preparation of the higher members ($n > 4$) have been described [2] which involve several steps and use di-, tri-, or tetraethylene glycol as starting materials; these methods fail to yield the medium rings ($n = 3$ and 4). Clearly, the simplest conceivable way to prepare this class of cyclic ethers is the direct oligomerization of ethylene oxide. In fact, it has been reported [4] that the cyclic tetramer (1,4,7,10-tetraoxacyclododecane) is obtained together with mainly dioxan and polymer from ethylene oxide in the presence of trialkylaluminium. On the other hand, although BF_3 is reported [5] to catalyse the conversion of propylene oxide to isomeric cyclic tetramers and pentamers, ethylene oxide under the same conditions gave only dioxan and polymers.

We can now report that a mixture of all the possible cyclic oligomers, including the hitherto unknown trimer 1,4,7-trioxacyclononane, m.p. 0 °C, and unaccompanied by open-chain oligomers and polymers, can be easily obtained from ethylene oxide at room temperature and atmospheric pressure in the presence of BF_3 or similar acidic fluorine compounds (PF_5, SbF_5). The important point is to exclude any substance capable of furnishing permanent end groups to polymeric chains. Thus, the common practice of using BF_3 as its etherate leads to a mixture of the rings and open-chain compounds terminated by ethoxy groups. Another common practice, to add water as a cocatalyst to speed up the reaction,[6] leads to hydroxyl-terminated open-chain compounds. Only dry HF gas proved acceptable as a cocatalyst, in accordance with the low nucleophilicity of fluoride ion. Likewise, any solvent must be inert (benzene, saturated hydrocarbons); even diethyl ether suppresses totally the formation of macrocyclic compounds, while dioxan, being one of the products, is a suitable solvent.

Other Lewis acids are either ineffective as catalysts ($AlCl_3$, $FeCl_3$) or give waxy polymers ($SnCl_4$, $SbCl_3$), while oxygen acids ($HClO_4$, *p*-toluene sulfonic acid) are rapidly transformed to half-esters of ethylene glycol.

Surprisingly, the product composition is little dependent on the concentration of monomer, so that similar products are obtained from

The Oligomerization of Ethylene Oxide to Macrocyclic Ethers, Including 1,4,7-Trioxacyclononane

JOHANNES DALE, GERD BORGEN and KARI DAASVATN

Kjemisk Institutt, Universitetet i Oslo, Oslo 3, Norway

Cyclic homologues of ethylene oxide, $-[-CH_2-CH_2-O-]-_n$, have attracted much attention due to their remarkable complexing power for alkali and other cations.[1-3] Laboratory methods for the preparation of the higher members ($n > 4$) have been described [2] which involve several steps and use di-, tri-, or tetraethylene glycol as starting materials; these methods fail to yield the medium rings ($n = 3$ and 4). Clearly, the simplest conceivable way to prepare this class of cyclic ethers is the direct oligomerization of ethylene oxide. In fact, it has been reported [4] that the cyclic tetramer (1,4,7,10-tetraoxacyclododecane) is obtained together with mainly dioxan and polymer from ethylene oxide in the presence of trialkylaluminium. On the other hand, although BF_3 is reported [5] to catalyse the conversion of propylene oxide to isomeric cyclic tetramers and pentamers, ethylene oxide under the same conditions gave only dioxan and polymers.

We can now report that a mixture of all the possible cyclic oligomers, including the hitherto unknown trimer 1,4,7-trioxacyclononane, m.p. 0 °C, and unaccompanied by open-chain oligomers and polymers, can be easily obtained from ethylene oxide at room temperature and atmospheric pressure in the presence of BF_3 or similar acidic fluorine compounds (PF_5, SbF_5). The important point is to exclude any substance capable of furnishing permanent end groups to polymeric chains. Thus, the common practice of using BF_3 as its etherate leads to a mixture of the rings and open-chain compounds terminated by ethoxy groups. Another common practice, to add water as a cocatalyst to speed up the reaction,[6] leads to hydroxyl-terminated open-chain compounds. Only dry HF gas proved acceptable as a cocatalyst, in accordance with the low nucleophilicity of fluoride ion. Likewise, any solvent must be inert (benzene, saturated hydrocarbons); even diethyl ether suppresses totally the formation of macrocyclic compounds, while dioxan, being one of the products, is a suitable solvent.

Other Lewis acids are either ineffective as catalysts ($AlCl_3$, $FeCl_3$) or give waxy polymers ($SnCl_4$, $SbCl_3$), while oxygen acids ($HClO_4$, *p*-toluene sulfonic acid) are rapidly transformed to half-esters of ethylene glycol.

Surprisingly, the product composition is little dependent on the concentration of monomer, so that similar products are obtained from

undiluted liquid ethylene oxide as from 5 % solutions. The most convenient procedure is to add cooled liquid ethylene oxide gradually to a small volume of dioxan containing initially about 1 % BF_3/HF (1:1). The catalyst is destroyed with NH_3 gas.

A typical product distribution as determined by distillation and gas chromatography is:

n:	2	3	4	5	6	7	8	9	10	11	higher
%:	40	1	15	5	4	3	2	2	1	1	25

With PF_5 and SbF_5 the distribution of ring sizes is similar, except that relatively more trimer and pentamer are formed.

The composition of the mixture does not change with reaction time, although for entropy reasons the smallest unstrained ring, dioxan, corresponding to the largest number of molecules, must be the thermodynamically stable end product. Since furthermore the isolated products are stable in the presence of the catalyst, one might be led to the conclusion that the reaction is kinetically controlled. In the presence of ethylene oxide and catalyst, however, the larger rings are degraded to dioxan. The product composition seems therefore to be determined by the balancing rates of oligomerization and of degradation of the products to dioxan, both dependent on ethylene oxide concentration. This is in accord with observations [6] on the degradation of the polymer.

Ethylene oxide may in part be dehydrated by BF_3 in the gas phase, in non-basic solvents (hexane), and generally at higher temperatures. Dark-coloured tars are then formed and the resulting hydrated catalyst gives rise also to open-chain polyethers.

Only very little of cyclic acetals are observed. 2-Methyl-1,3-dioxolan is present in the dioxan fraction only when the reaction is carried out at higher temperatures. 2-Methyl-1,3,6-trioxacyclooctane occurs as impurity in the cyclic trimer fraction and must be removed by mild hydrolysis.

Experimental. Example of oligomerization procedure. A stock solution of catalyst is prepared by absorbing first gaseous BF_3 (7 g), thereafter gaseous HF (2 g), in dioxan (50 ml). This solution does not attack glass and is stable for months at room temperature. A portion of this solution (2 ml) was diluted with dioxan (40 ml) and cooled liquid ethylene oxide (250 g) added, with vigorous stirring, at a rate slow enough to prevent the temperature to rise above 30 °C. After 18 h, the solution was neutralized with gaseous NH_3 and fractionally distilled. Unreacted ethylene oxide (20 – 40 %) and dioxan distilled at atmospheric pressure, the trimer and most of the tetramer at 10 mmHg, and the remaining tetramer and the higher fractions including the octamer at 0.1 mmHg; in the last fractions at 200 °C rings up to the undecamer were identified.

Purification of 1,4,7-trioxacyclononane. The trimer fraction (100 mg), b.p. 110 °C/10 mmHg, was dissolved in ether (10 ml) containing water (0.1 ml) and a trace of *p*-toluenesulfonic acid, and the solution refluxed for one hour. After evaporation of the ether, the residue was taken up in pentane, stirred with basic alumina and filtered. The filtrate was concentrated and distilled to give pure 1,4,7-trioxacyclononane, b.p. 168 – 172 °C/760 mmHg, m.p. 0 °C. The NMR-spectrum in $CDCl_3$ showed a single line at δ 3.77 at room temperature, showed the molecular ion in MS, and had the following main infrared bands in the liquid: 2910, 2890, 2840, 1385, 1370, 1305, 1285, 1275, 1260, 1155, 1145, 1135, 1120, 1065, 1005, 910, 885, 835, 525 and 505 cm^{-1}.

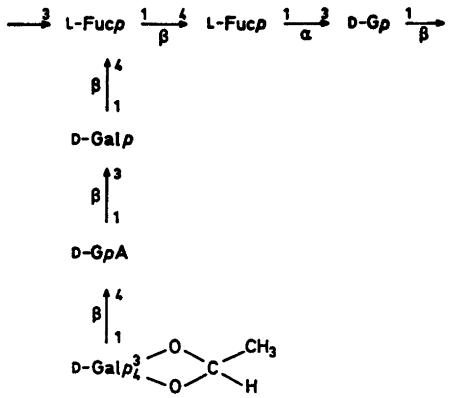
Synthesis and Configurational Assignment of the Two Stereoisomeric Methyl 3,4-*O*-Ethylidene-β-D-galactopyranosides

PER J. GAREGG,[a] K. BÖRJE LINDBERG [b] and CARL-GUNNAR SWAHN [a]

[a] Department of Organic Chemistry and [b] Department of Structural Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

The two stereoisomers of methyl 3,4-*O*-ethylidene-β-D-galactopyranoside have been prepared. Their configurations have been assigned from an X-ray crystallographic structural determination of one of them and correlated with the observed chemical shift of the ethylidene methine proton for each of the stereoisomers.

Previous structural studies on the extracellular M-antigen which can be isolated from the mutant *Salmonella typhimurium* 395 MRO-M1 have demonstrated the following polysaccharide frame-work.[1,2]



The configuration at the asymmetric acetal carbon of the ethylidene group linked to the terminal D-galactose residues is so far not known.

In the present paper, we report the synthesis of the two stereoisomeric methyl 3,4-*O*-ethylidene-β-D-galactopyranosides. These were required as reference compounds for the determination of the configuration at the above 3,4-*O*-ethylidene groups. We have determined the configuration of the ethylidene group in one of these acetals by X-ray crystallography. This has made it possible for us to correlate the NMR chemical shifts of the acetal methine protons with the structures of the two possible stereoisomers.

We have recently reported a method of benzylidenation, whereby the appropriate diol is treated with a benzal halide in pyridine at reflux temperature. The method is applicable in the presence of acetyl or trityl groups on other positions of a pyranose ring.[3,4] It therefore gives easy access to methyl 3,4-*O*-benzylidene-β-D-galactopyranoside (I),[4] which was the starting material in the present synthetic work. Benzylation of I produced II, the stereoisomers of which (IIa and IIb) were obtained by chromatography. Removal of the benzylidene group from II under mild acidic conditions produced methyl 2,6-di-*O*-benzyl-β-D-galactopyranoside III. This, on treatment with excess 1,1-dimethoxyethane and a catalytic amount of sulphuric acid afforded the 3,4-*O*-ethylidene acetal IV, the stereoisomers of which, IVa and IVb, were obtained by chromatographic separation. Catalytic hydrogenation of IVa and IVb yielded the stereoisomeric methyl 3,4-*O*-ethylidene-β-D-galactopyranosides Va and Vb, respectively.

The assignments of configuration at the asymmetric benzylidene acetal carbons for compounds Ia, Ib, IIa, and IIb described in the experimental part, are based on the observations of Baggett and co-workers that the benzylic proton in a dioxolane ring fused to a

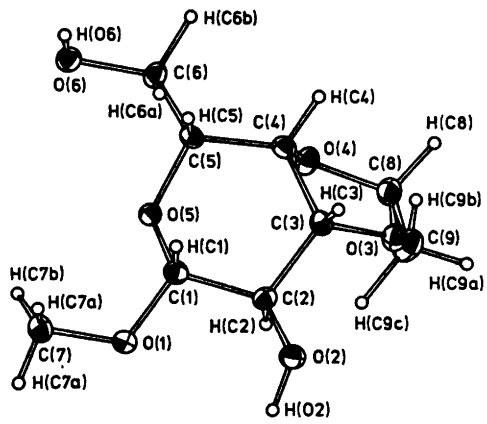


Fig. 1. Molecular structure of methyl 3,4-*O*-ethylidene-β-D-galactopyranoside, isomer Vb.

pyranoside (of Ia and Ib) has different chemical shifts depending on the configuration. An *exo*-benzylidene proton resonates at a higher field than does an *endo* one, and this was used in the structural assignment of benzylidene acetals previously described.[5,6] By similar reasoning the ethylidene acetals IVa and Va have an *endo* acetalic hydrogen and IVb and Vb correspondingly an *exo* one. In view of the fact that such correlations for pyranoside ethylidene acetals do not seem to have been made, we decided to determine the structure of one of the acetals, Vb, by X-ray crystallography. The molecular structure is shown in Fig. 1. Intramolecular distances and angles are listed in Table 1. Having thus determined the configuration at the ethylidene carbon in Vb, the corresponding configuration in Va, IVa, and IVb follows. The results (*cf.* Table 2) clearly indicate the possibility of applying the NMR correlations of Baggett and co-workers (for the configuration of benzylidene acetals) to ethylidene acetals. However, no such correlation for the chemical shift of the methyl protons of the ethylidene group with the configuration at the ethylidene acetal carbon was found.

EXPERIMENTAL

General methods were the same as those described in a previous paper.[4] Unless otherwise stated, chemical shifts are measured in ppm downfield from tetramethylsilane (internal).

Methyl 2,6-di-O-benzyl-3,4-O-benzylidene-β-D-galactopyranoside (IIa, IIb). Methyl 3,4-*O*-benzylidene-β-D-galactopyranoside (Ia, m.p. 139–141°, 530 mg) was converted into the 2,6-di-*O*-benzyl ether by treatment with benzyl bromide (3.25 g) and sodium hydride (from 0.91 g 50 % suspension in oil, thoroughly washed with light

petroleum) in dry dimethylformamide (30 ml), essentially as described by Brimacombe and co-workers.[7] Excess benzyl bromide was converted into benzyl methyl ether by adding methanol (15 ml) and continuing the reaction at room temperature for 3 h. The product was partitioned between benzene and water and concentrated. The resulting syrup was purified by TLC to yield syrupy II (580 mg) $[\alpha]_D$ +11° (*c* 0.9, $CHCl_3$). (Found: C 72.5; H 6.37. $C_{28}H_{30}O_6$ requires: C 72.7; H 6.54).

An NMR spectrum showed that although the starting material contained one stereoisomer only (Ia), the product contained approximately equal quantities of the isomers IIa and IIb. A small-scale benzylation of Ia with benzyl bromide and silver oxide in dimethyl formamide essentially as described by Kuhn and co-workers,[8] however yielded pure IIa. Benzylation of a mixture of Ia and Ib (4.2 g) with benzyl bromide and sodium hydride in dimethyl formamide as described above afforded an 80 % yield of a stereoisomeric mixture of IIa and IIb, used in the subsequent synthesis. A small quantity of this mixture was separated by TLC ($CHCl_3$ – Et_2O 9:1) yielding pure, syrupy, IIa (faster-moving isomer), $[\alpha]_D$ +10° (*c*, 0.6, $CHCl_3$) and IIb, $[\alpha]_D$ +13° (*c* 0.3, $CHCl_3$). (Found: IIa: C 72.6; H 6.36. IIb: C 72.9; H 6.69. $C_{28}H_{30}O_6$ requires: C 72.7; H 6.54). NMR, IIa ($CDCl_3$): δ 3.60 (s and broad one-proton signal, 4 H), methoxyl and one ring proton; δ 4.62 (2 H) and 4.90 (2 H), benzylic protons; δ 5.98 (s, 1 H), benzylidene proton. NMR, IIb ($CDCl_3$): δ 3.57 (s and broad one-proton signal, 4 H), methoxyl and one ring proton; δ 4.67 (2 H) and 4.75 (2 H), benzylic protons; δ 5.92 (s, 1 H), benzylidene proton.

Methyl 2,6-O-benzyl-β-D-galactopyranoside (III). A mixture of the stereoisomers IIa and IIb (9.2 g) was treated with 85 % aqueous trifluoroacetic acid (100 ml) at room temperature for 15 min. The solution was concentrated and the product purified on a silica gel column, ($CHCl_3$, $CHCl_3$ – Et_2O 9:1 and 1:1, EtOAc in sequence), to yield III (4.7 g), which after recrystallization from cyclohexane had m.p. 78 – 80°, $[\alpha]_D$ +10° (*c* 0.4, $CHCl_3$). (Found: C 67.1; H 7.16. $C_{21}H_{26}O_6$ requires: C 67.4; H 7.00). NMR ($CDCl_3$): δ 3.54 (s, 3 H), methoxyl protons; δ 4.58 (2 H) and 4.73, 4.87 (2 H), benzylic protons.

Methyl 2,6-di-O-benzyl-3,4-O-ethylidene-β-D-galactopyranoside (IVa, IVb). The dibenzyl ether II (100 mg) in 1,1-dimethoxyethane (1.5 ml) containing sulphuric acid (1 drop) was allowed to stand at room temperature for 15 min. Excess chloroform was added and the resulting solution was shaken with aqueous sodium bicarbonate. The chloroform layer was dried (Na_2SO_4), filtered, and concentrated to a syrup (IVa and IVb, 78 mg) $[\alpha]_D$ +19° (*c* 0.5, $CHCl_3$). (Found: C 69.8, H 6.91, $C_{23}H_{28}O_6$ requires: C 70.0; H 7.05). The syrup was subsequently fractionated by TLC (light petrol (40 – 60°) – Et_2O – EtOAc 5:2:1) to yield IVa (minor component), $[\alpha]_D$ +13° (*c* 0.3, $CHCl_3$), and IVb (major component), $[\alpha]_D$ +12° (*c* 0.3, $CHCl_3$). These substances were not quite pure and tended to decompose on standing which may account for the rotations being lower than that recorded above for the mixture. NMR, IVa, ($CDCl_3$): δ 1.33 (d, J = 5 Hz, 3 H), ethylidene methyl protons; δ 3.58 (s, 3 H), methoxyl protons; δ 4.65 (2 H) and 4.83 (2 H), benzylic protons; δ 5.25 (q, J = 5 Hz, 1 H), ethylidene methine proton. NMR IVb, ($CDCl_3$): δ 1.30 (d, J = 5 Hz, 3 H), ethylidene methyl protons; δ 3.54 (s, 3 H), methoxyl protons; δ 4.62 (2 H) and 4.82 (2 H), benzylic protons; δ 5.13 (q, J = 5 Hz, 1 H), ethylidene methine proton.

Methyl 3,4-O-ethylidene-β-D-galactopyranoside (Va, Vb). The above dibenzylated ethylidene acetals, IVa and IVb, were hydrogenated in ethanol using 5 % palladium on charcoal as catalyst to give, in quantitative yields, respectively, Va, $[\alpha]_D$ +13° (*c*, 0.3, H_2O), m.p. 169 – 171° (recrystallized from ethanol), and Vb, $[\alpha]_D$ +8° (*c*, 0.3, H_2O), m.p. 193 – 196° (recrystallized from ethanol). (Found, Va: C 49.2; H 7.48. Vb: C 49.0; H 7.27. $C_9H_{16}O_6$ requires: C 49.1; H 7.32). NMR, Va (D_2O, δ values in ppm downfield from sodium 3-(trimethylsilyl)-propane sulphonate: δ 1.35 (d, J = 5 Hz, 3 H), ethylidene methyl protons; δ 3.57 (s, 3 H), methoxyl protons; δ 5.45 (q, J = 5 Hz, 1 H), ethylidene methine proton. NMR, Vb (D_2O, δ values in ppm downfield from sodium 3-(trimethylsilyl)propane sulphonate: δ 1.45 (d, J = 5 Hz, 3 H), ethylidene methyl protons; δ 3.58 (s, 3 H), methoxyl protons; δ 5.25 (q, J = 5 Hz, 1 H), ethylidene methine proton.

Crystallography. Vb crystallized in space groups $P2_12_12_1$, $a=16.678$ (1), $b=12.828$ (2), $c=4.9165(9)$, $Z=4$. The X-ray data were collected using a Philips PW 1100 computer-controlled single-crystal diffractometer with graphite monochromatized Cu$K\alpha$ radiation. The determination of the phases were carried out by a computerized application of direct methods using the weighted phase-sum formula described by Norrestam.[9]

Several cycles of full-matrix least-squares refinements (anisotropic non-hydrogen and fixed isotropic hydrogen temperature parameters) gave an R-value of 0.052. Full details of the X-ray diffraction investigation will be published elsewhere.[10]

Mass Spectrometry of Carotenoids— In-chain Fragmentations of Deuterium Labelled Carotenoids

JON EIGILL JOHANSEN, ÅSE EIDEM and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway

In-chain fragmentations of specifically labelled 7,7′-D_2- (*1*—*3*), 11,11′-D_2- (*4*—*6*) and 19,19′-D_6- (*7*) carotenoids have been studied.

The data support the modified Edmunds-Johnstone mechanism for in-chain eliminations of toluene, xylene, and dimethylcyclodecapentaene, and the previously given ranges for the sites of these eliminations.

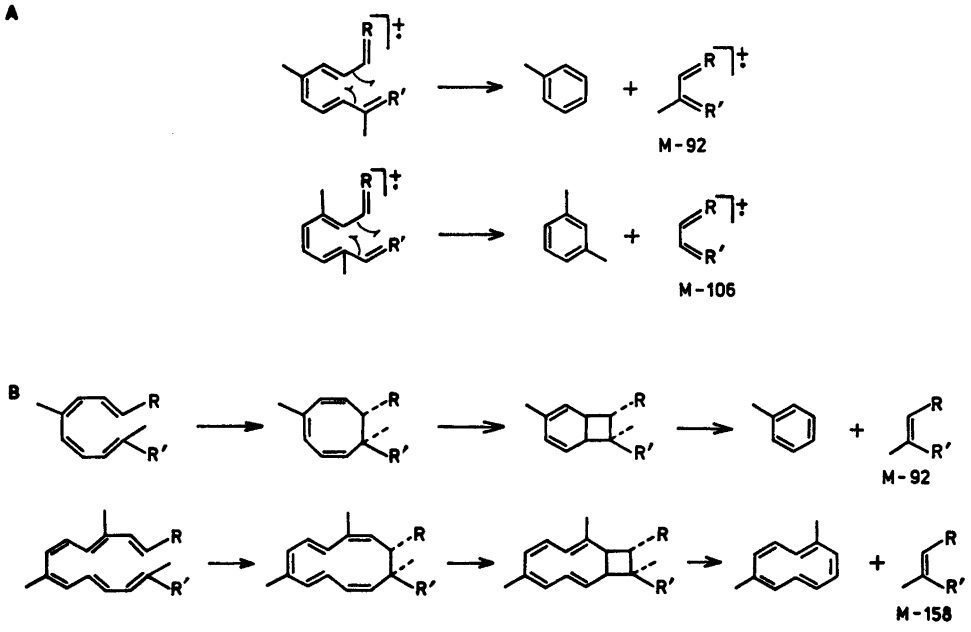
In bicyclic carotenoids the expulsion of dimethylcyclodecapentaene is restricted to the C(10)—C(10′) range.

Rationalization by others of a common M − 79 ion as elimination of a cyclopentadienyl radical from the polyene chain seems valid and appears to be restricted to the C(11)—C(11′) range for bicyclic carotenoids.

Formal loss of methylbenzyne instead of toluene may be general for bicyclic 15,15′-didehydro carotenoids.

Evidence for some in-chain cleavages with hydrogen transfer was also obtained.

Fragmentations leading to losses of 92 (toluene), 106 (xylene), and 158 (dimethylcyclodecapentaene) from the polyene chain due to electron impact induced and thermal processes are con-



Scheme 1.

sidered characteristic of carotenoid mass spectra.[1,2] A comprehensive review on carotenoid mass spectrometry was recently published.[3] Further systematic studies have since appeared.[4–9]

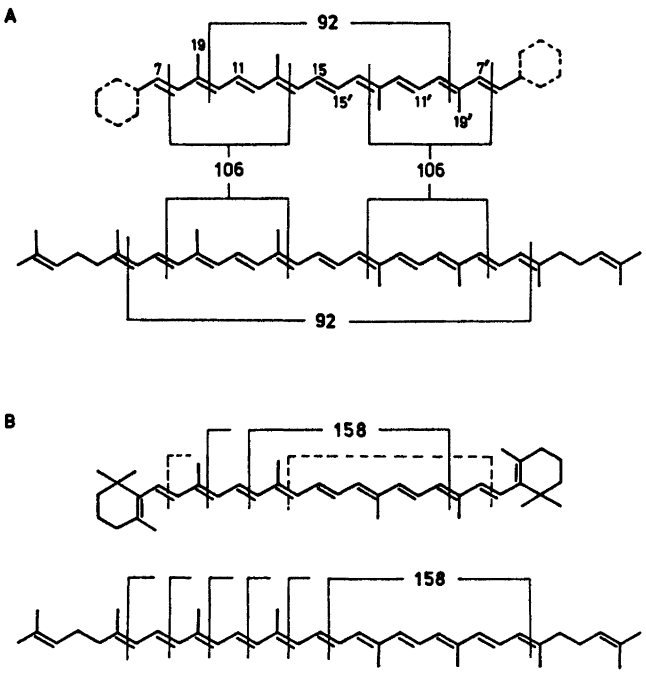
For the eliminations from the polyene chain the alternative mechanisms A[1] and B[4] have been considered. Mechanism A, exemplified in Scheme 1A for the loss of toluene and xylene involves rupture of single bonds, whereas mechanism B implies cleavage of double bonds in the original carotenoid. Mechanism B, as recently indepently modified by Vetter *et al.*[3] and Francis [6] according to the principle of conservation of orbital symmetry,[10] is illustrated for the expulsion of toluene in Scheme 1B. As dicussed by others [6,7] this modification involves an eight-electron conrotatory electrocyclic reaction followed by a disrotatory six-electron electrocyclic reaction and scission of the four-membered transition state. The formation of toluene and dimethylcyclodecapentaene may be envisaged by analogous reactions; transitions through twelve- and ten-electron electrocyclic reactions [3,6,7] being involved in the latter case as illustrated in Scheme 1B.

From consideration of the fragmentation pattern of 15,15′-D_2- and 7,7′-D_2-carotenes mechanism B has been favoured, and the origin of toluene, xylene, and dimethylcyclodecapentaene from acyclic and bicyclic carotenoids has been proposed.[11,12] Scheme 2A, B gives the presumed range for these eliminations. Several modes of elimination are considered involved [4,11,13] as illustrated for the M − 158 elimination in Scheme 2B.

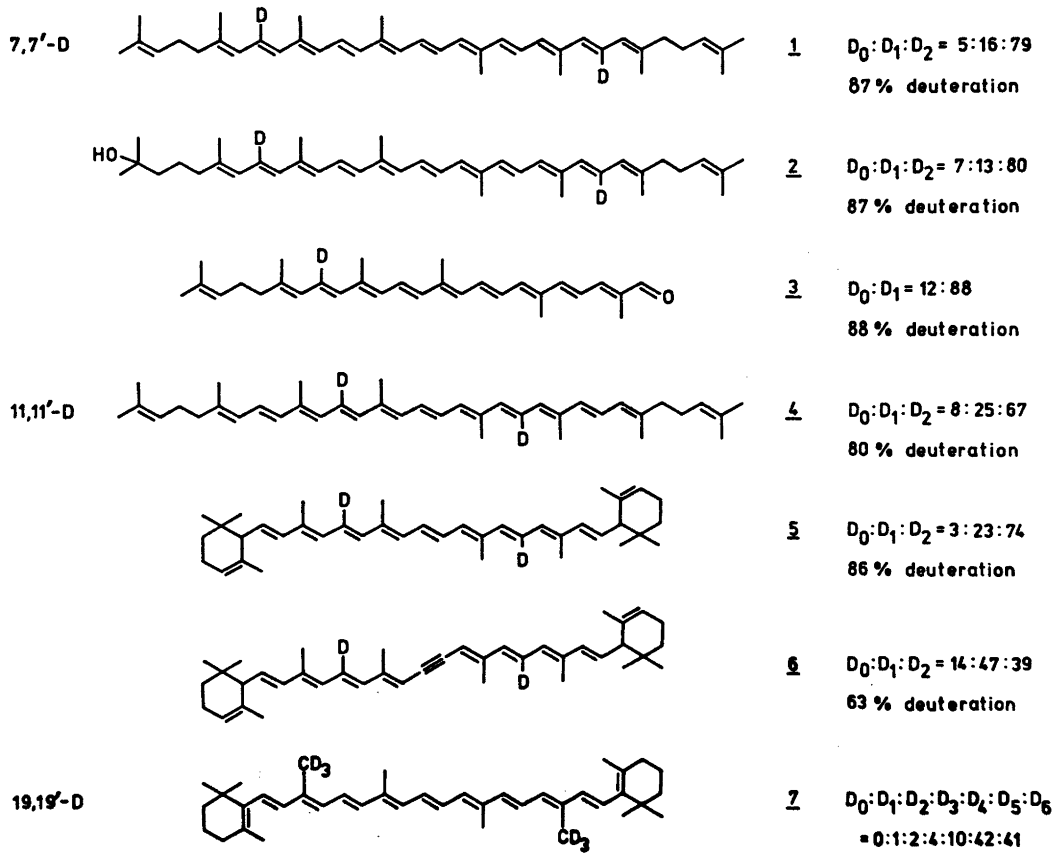
RESULTS AND DISCUSSION

In order to obtain further evidence for these in-chain eliminations 7,7′-D_2-[13], 11,11′-D_2-[14] and 19,19′-D_6-carotenoids [15a] have been synthesized. The carotenoids here studied and their degree of deuteration estimated by mass spectrometry are given in Scheme 3. The ratio of deuterated species has been calculated taking into account ^{13}C isotope contributions, *cf.* Ref. 15b. Percentage deuteration reflects average number of deuterium atoms incorporated relative to the theoretically possible incorporation.

In the following considerations are made as to



Scheme 2.



Scheme 3.

the preferred mechanism (A or B) and sites of in-chain eliminations. The ratio of eliminated, labelled, and unlabelled species, calculated theoretically on the basis of a valid mechanism, should within experimental error agree with values calculated from observed spectra. Conclusions provide that the rate of elimination be the same from all parts of the aliphatic polyene chain. Also hydrogen-deuterium scrambling through sigmatropic shifts in the mass spectrometer should not take place. This has been considered and rejected.[7,11]

Steric conflicts in the intermediate are considered responsible [1,6,12] for the reduction of the theoretically possible modes of elimination of toluene [11] and dimethylcyclodecapentaene [5] in bicyclic carotenoids. Such limits become obvious when figures obtained for a given compound do not fit a generally preferred mechanism.

Mechanism and range for elimination of toluene, xylene and dimethylcyclodecapentaene. Taking into consideration all possible modes of elimination of toluene, xylene, and dimethylcyclodecapentaene by mechanisms A and B the calculated and observed ratios of deuterium incorporation in the expelled fragments from *1*, *2*, *4*, *5*, and *7* are given in Table 1.

For the 7,7'-D_2-compounds *1* and *2* the results for toluene and xylene formation is consistent with those previously obtained for acyclic 7,7'-D_2-carotenoids [11] in favour of mechanism B. The deuterium incorporation in the expelled toluene and xylene from the 11,11'-D_2-carotenes *4* and *5* also shows a clear preference for

Table 1. Calculated and observed ratios for deuterated and non-deuterated toluene, xylene, and dimethylcyclodecapentaene, based on examination of ions derived from the molecular ions of carotenoids *1*, *2*, *4*, *5*, and *7* by loss of these fragments.

[a] Assuming C(8)—C(8′) range of elimination. [b] Assuming C(10)—C(10′) range of elimination.

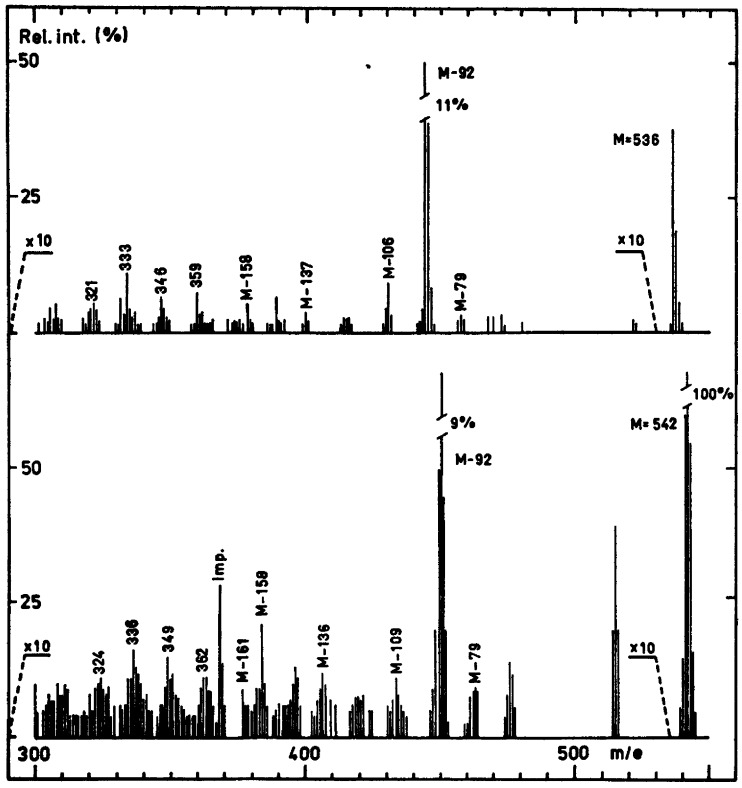

Fig. 1. Mass spectra of 19,19′-D_6-β-carotene (*7*, lower curve) and undeuterated β-carotene (upper curve).

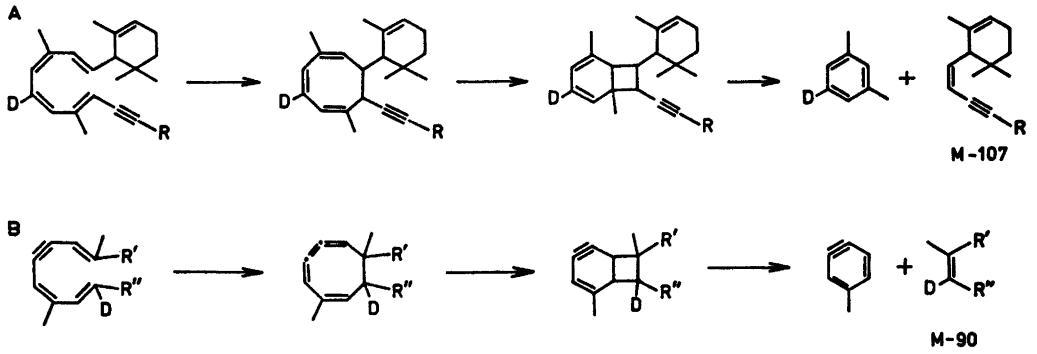
mechanism B. The preference is still more obvious for the most heavily deuterated test compound, 19,19′-D_6-β-carotene (*7*), judged by the data for toluene and xylene in Table 1 and Fig. 1.

Considered jointly these results for toluene and xylene clearly support mechanism B, rather than A, and the previously assumed ranges for the origin of these species.

Regarding the origin of the less abundant M − 158 ion the possible modes of elimination by mechanism B are given in Scheme 2B. Satisfactory agreement is observed (Table 1) for mechanism B and the C(6) − C(6′), range for acyclic carotenoids. However, the range appears to be limited to C(10) − C(10′) in the bicyclic series, if the reasonable assumption is made that mechanism B also is valid here. Thus no loss of trideuterio-dimethylcyclodecapentaene (161 mass units) is observed from 19,19′-D_6-β-carotene (*7*). This situation was already suggested in previous work [11] and is later documented by Brzezinka [5] on the basis of results for 11,12,-11′,12′-deuterated carotenoids. The steric argument previously advanced [12] and further elaborated [3,6,7] is likely to be valid in this case, see Scheme 1B.

Eliminations from 15,15′-didehydrocarotenoids. The fragmentation pattern of the acetylenic analogue *6* of 11,11′-dideuterio-ε-carotene (*5*) was studied. It has previously been claimed that a triple bond in 15,15′-position totally inhibits the loss of toluene and xylene.[3] According to mechanism B and the ranges given in Scheme 2 for toluene and xylene eliminations, this should be true only for the toluene case (Scheme 4A). However, a small peak at M − 90, ascribed to the loss of methylbenzyne has previously been observed.[3,16,17] This loss may also be rationalized by mechanism B, although this implies a



Scheme 4.

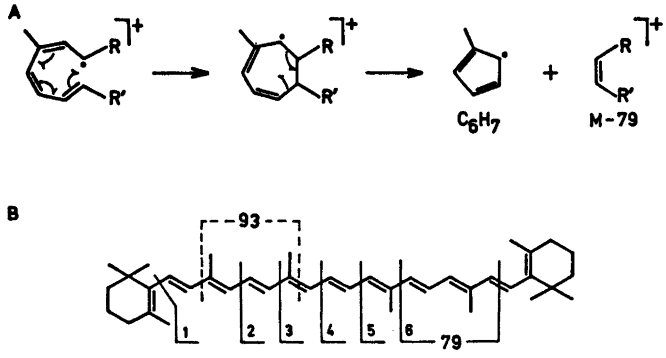
strongly deformed, energetically unfavourable transition state (Scheme 4B). The 11,11'-labelled acetylenic compound *6* should according to mechanism B and the ranges given in Scheme 2 give rise to monodeuterated xylene and undeuterated methylbenzyne. Indeed M − 107 and M − 90 ions were observed.

An M − 156 peak has previously been reported for undeuterated 15,15'-didehydro-β-carotene,[5] and the expected M − 158 peak for the 11,11'-D_2-15,15'-didehydro compound *6* was observed. It is also mentioned that the M − 15 peak, usually encoutered in the spectra of 15,15'-didehydro compounds,[5] was also observed for *6*.

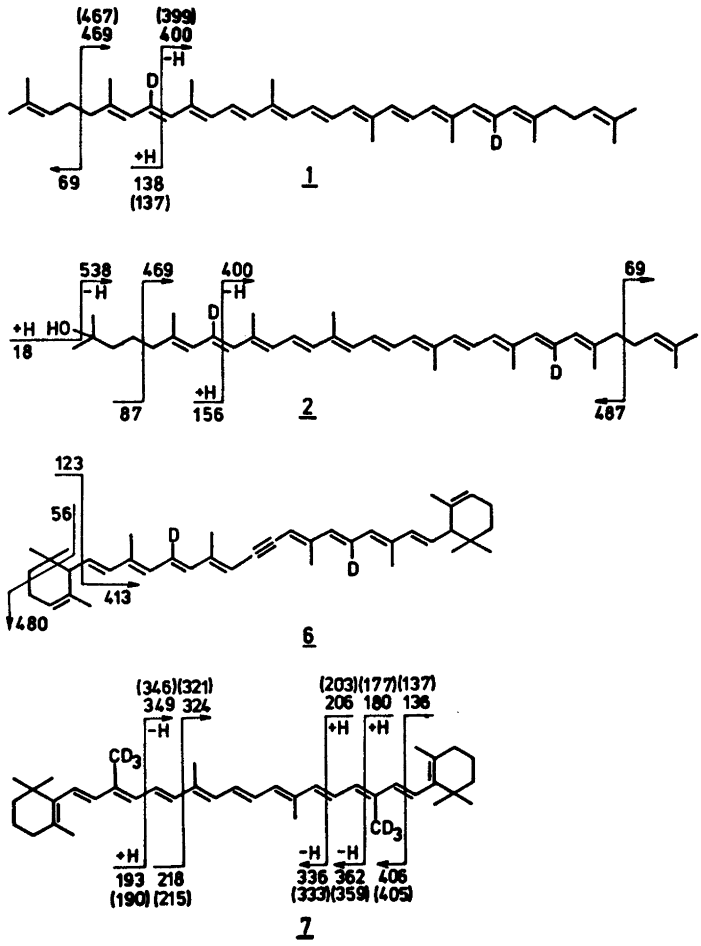
Apo-carotenoids. Apo-carotenoids, here represented by 7-D-8'-apolycopenal (*3*), Scheme 3, are known to give weak and inconsistent M − 92 and M − 106 ions.[16] Only very weak M − 92 and M − 106 ions were observed for *3*, not suitable for mechanistic considerations.

Mechanism for elimination of methylcyclopentadienyl radical. It was early recognized that in addition to M − 92, M − 106 and M − 158 ions a less abundant M − 79 ion is characteristic of carotenoid mass spectra. A methylcyclopentadienyl radical was considered the species involved.[2] Kjøsen [7] has recently rationalized the formation of this common M − 79 ion as loss of a methylcyclopentadienyl radical from the polyene chain, also explaining the formation of M − 78 and M − 80 ions from a common seven-membered transition state (*8*), here cited in Scheme 5A for the loss of 79 mass units.

Six alternative modes of eliminations by this mechanism for the bicyclic case are illustrated in Scheme 5B. Particularly modes 1 and 6 are considered less likely due to steric hindrance, leaving the C(11) − C(11') range as likely site of elimination. Only the D_6-model compound has sufficient number of labels to provide information in this case. It appears from the mass spectrum of 19,19'-D_6-β-carotene (*7*), as compared with that of undeuterated β-carotene, Fig. 1, that the fragment lost is undeuterated. This



Scheme 5.



Scheme 6.

may support the origin suggested by Kjøsen [7] of the M − 78, M − 79, and M − 80 ions, and the C(11) − C(11′) range of expulsion in the bicyclic case.

In acyclic undecaenes such as lycopene the entire C(6) − C(6′) range is expected to serve as sites for these eliminations.

In-chain cleavages. In-chain cleavages are not abundant amongst carotenoids of type *1*, *2*, *4* − *7*.[3] However, unlabelled *β*-carotene and 19,19′-D_6-*β*-carotene (*7*) showed fragment ions consistent with the in-chain cleavages given in Scheme 6, generally occurring with hydrogen transfer. Values in parenthesis refer to unlabelled compounds. Some of these cleavages have not been previously reported.[3,8] Cleavage of the 7-double bond with hydrogen transfer to the smaller, uncharged fragment was also confirmed for unlabelled and labelled lycopene (*1*) and indicated for labelled rhodopin (*2*).

EXPERIMENTAL

The syntheses of the compounds studied are described elsewhere.[13–15] 11,11′-D_2-15,15′-didehydro-*ε*-carotene (*6*) was here prepared in small scale by a procedure analogous to that used for *7*, using an acetylenic center-piece. *6* had *m/e* 536 (M), M − 15, M − 56, M − 90, M − 107 M − 123 (*cf.* Scheme 6), M − 158 and no M − 91, M − 92 or M − 93 ions.

Mass spectra were recorded on an AE1 MS 902 mass spectrometer with direct insertion probe. Spectra were recorded at 70 eV, 6 kV

and with the ion source at minimum temperature required to achieve vapourization (190 – 200°C).

The accuracy of the present intensity ratio calculations depends on absolute peak intensity and is estimated to *ca.* ± 5 % in most cases.

A New One Step Indole Synthesis

J. BAKKE,* H. HEIKMAN and E. B. HELLGREN

AB Bofors, Nobelkrut, Bofors, Sweden

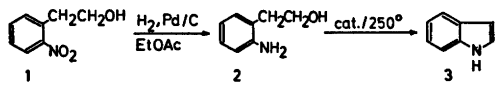
A simple conversion of 2-(*o*-nitrophenyl)ethanol to indole in the gas phase over a copper catalyst was presented. The probable way of formation of indole was discussed. The most probable intermediates were thought to be 2-(*o*-aminophenyl)-ethanol (*2*) and 2,3-dihydroindole (*8*). Part of the reaction might proceed *via* *o*-aminophenylacetaldehyde (*9*).

Most of the methods for the synthesis of indole (*3*) result primarily in substituted indoles.[1] Lately an interest in simple, direct methods for the synthesis of indole itself has been noted. Thus, a number of groups have been working on the high temperature conversion of *o*-aminoethylbenzene to indole,[2,3] and lately Suvorov, Avramenko, Shilkova and Zamyshlyaeva [4] were able to convert acetaldehyde phenylhydrazone to indole in 60 % yield by catalytic reaction in the vapour phase.

Some time ago, we reported the addition of mononitrotoluenes to aldehydes.[5] The products from the reaction between some *o*-nitrotoluenes and various aldehydes have been used to synthesize both substituted and unsubstituted indoles and 2,3-dihydroindoles.[6] 2-(*o*-Nitrophenyl)ethanol (*1*), readily available from *o*-nitrotoluene and formaldehyde, gave indole (*3*) or 2,3-dihydroindole (*8*) by that reaction sequence. Although the yields in each step were high, the number of steps necessary made it desirable to find a more direct synthesis of indole and 2,3-dihydroindole.

By running reactions in gas phase it is sometimes possible to carry out several consecutive synthetic steps without isolation and purification of the intermediate products. The possibility of a gas phase conversion of 2-(*o*-nitrophenyl)-ethanol to indole was therefore investigated.

Several years ago, Ufer and Breuers [7] described the formation of indole from 2-(*o*-aminophenyl)ethanol (*2*) by gas phase reaction over a copper catalyst. As 2-(*o*-aminophenyl)ethanol was readily available from the nitro analogue this method was tried:



1 2 3

No yield was stated in the German patent, and our reproduction indicated the catalyst to have a rather short working life (less than 10 min). Ufer *et al.*[7] had prepared the catalyst by shaking bauxite with dry copper carbonate, followed by reduction. In that way, copper would be present only on the outer surface of the catalyst particles, and not in the internal pore structure.

A far superior catalyst was made by soaking silica gel in a solution of copper nitrate, drying and reducing with hydrogen. This is a well known method for the preparation of metal catalysts on carriers, and in this way even the inner pores of the carrier will contain metal catalyst. By using this type of preparation, catalysts with a working life of several hundred hours were obtained. The yield (95 %) and purity (96 %) of the indole produced was high. We had thus obtained a two step synthesis of indole from 2-(*o*-nitrophenyl)ethanol: reduction of the nitro group to an amino group in the liquid phase, followed by the vapour phase synthesis of indole.

* Author to whom correspondence should be adressed at University of Trondheim, Department of Chemistry, NLHT, 7000 Trondheim, Norway.

However, the vapour phase reduction of aromatic nitro compounds to the corresponding amines is a well known process.[8] If therefore 2-(*o*-nitrophenyl)ethanol could be reduced in the vapour phase without decomposition, the reaction would proceed directly to indole, and a one step synthesis of indole from 2-(*o*-nitrophenyl)-ethanol would be obtained.

When 2-(*o*-nitrophenyl)ethanol was passed over the copper catalysts used for the reaction of 2-(*o*-aminophenyl)ethanol, indole was obtained and the yield was almost as high (90 – 95 %) as in the case of 2-(*o*-aminophenyl)-ethanol. The catalysts and reaction conditions could be varied as shown in Table 2. The table indicates the catalysts containing copper to be of advantage as compared to those with other metals. Hydrogen was used for the reduction in most of the experiments, but other reducing gases, *e.g.* ammonia (run 12), could be used.

A typical run with copper chromite as catalyst gave indole in 90 % yield, and with the by-products given in Table 1.

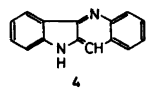
Table 1. Formation of indole and byproducts from 2-(*o*-nitrophenyl)ethanol over copper chromite at 250°, with hydrogen [12 mol/mol 2-(*o*-nitrophenyl)ethanol)] as reducing gas.

Products	Yields (%)[a]
Aniline	0.1
o-Toluidine	2.6
o-Aminoethylbenzene	2.1
2,3-Dihydroindole	4.4
Indole	90
Unidentified	0.8

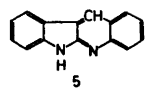
[a] Determined by GLC.

The byproducts are readily accounted for by expected side reactions: retro-Knoevenagel condensation of 2-(*o*-nitrophenyl)ethanol would give *o*-nitrotoluene which would be reduced to *o*-toluidine. Dehydration of 2-(*o*-nitrophenyl)ethanol followed by hydrogenation of the *o*-nitrostyrene formed would give *o*-aminoethylbenzene, and incomplete dehydrogenation of 2,3-dihydroindole shows up in the presence of this compound. That this is the probable source of 2,3-dihydroindol and not hydrogenation of indole, was indicated by an increase in the content of 2,3-dihydroindole as the catalyst aged.

One byproduct which showed up in a very low yield (less than 10^{-2} %) was a crystalline, high melting compound, almost insoluble in common solvents. The IR spectrum indicated a strongly hydrogen bonded hydrogen to be present and the electronic spectrum that it contained a longer chromophore than indole itself. The mass spectrum indicated an elemental formula of $C_{18}H_{10}N_2$. From these indications both structures *4* and *5* (or the 5H-isomers) seemed possible for the compound. Compound *4* is quindoline, synthesized by Fichter and Boehringer,[9] and compound *5* quinindoline, synthesized by Gabriel and Eschenbach.[10]



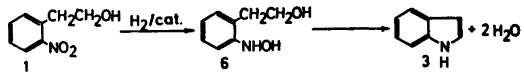
4



5

M.p. of the substance from the indole synthesis indicated it to be quinindoline (*5*), and comparison of the IR spectrum with that of an authentic sample [10] together with mixed m.p. showed the substance to be quinindoline.

The formation of indole from 2-(*o*-nitrophenyl)ethanol (*1*) probably proceeds *via* 2-(*o*-aminophenyl)ethanol (*2*) as indicated above. However, 2-(*o*-hydroxylaminophenyl)ethanol (*6*) can not be excluded as an intermediate. The hydrogenation conditions used would normally give the amino compound in high yield.[8] However, in the present case, the hydroxylamine (*6*) might be trapped in the cyclization reaction before further reduction could take place.

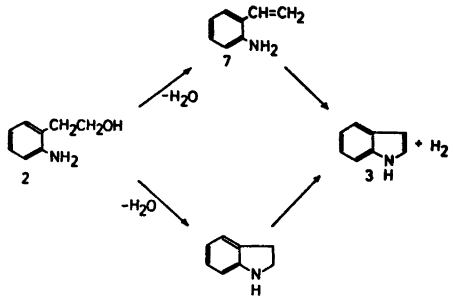


1 6 3

This posibility has not been investigated further. However, because of the ready reduction of nitro aromatics to the corresponding amines [8] it seems reasonable to assume that at least part of the indole was formed *via* 2-(*o*-aminophenyl)-ethanol.

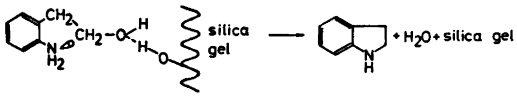
The formation of indole from 2-(*o*-aminophenyl)ethanol can be envisaged by several routes. One possibility is by *o*-aminostyrene (*7*) followed by cyclisation and dehydrogenation,

another by cyclisation to 2,3-dihydroindole (*8*) followed by dehydrogenation:



Experiments were undertaken to investigate these and other ways of formation. The route *via* o-aminostyrene was excluded by an experiment showing that this compound did not give indole at the comparatively low temperature (250°) used for the reaction of 2-(*o*-aminophenyl)ethanol.

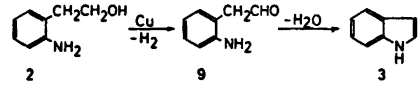
On the other hand, dihydroindole gave indole in high yield (98 %) under the reaction conditions. Further, if 2-(*o*-aminophenyl)ethanol vapour was passed over silica gel without copper metal, dihydroindole was obtained (98 % yield). This cyclisation of aminophenylethanol was shown to be catalyzed by silica gel, since no cyclisation took place over Vycor chips under the same reaction conditions. The catalytic effect of silica gel may be explained by the hydroxyl groups present.



From these results, it seemed plausible to assume that the indole had been formed by cyclisation of 2-(*o*-aminophenyl)ethanol followed by dehydrogenation of 2,3-dihydroindole.

However, another possible reaction path was revealed when metallic copper alone (from copper oxide) was used as catalyst. Again, indole in high yield was obtained from 2-(*o*-aminophenyl)ethanol. In the case of metallic copper, the catalytic cyclisation above is harder to envisage as the copper has no hydroxyl groups like silica gel.

A possible path for the formation of indole over metallic copper would be by dehydrogenation of the alcohol group of 2-(*o*-aminophenyl)-ethanol to an aldehyde group. The product *o*-aminophenylacetaldehyde (*9*) would probably cyclize to indole under the reaction conditions.



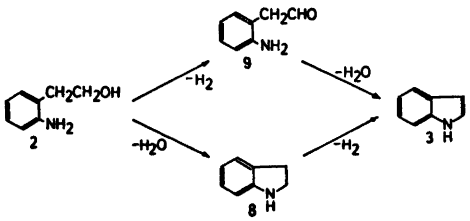
The catalytic dehydrogenation of alcohols to the corresponding aldehydes is a well known reaction: $RCH_2OH \xrightarrow{cat.} RCHO + H_2$.[11] The equilibrium is usually displaced towards the aldehyde by trapping the hydrogen formed. In the present reaction, the equilibrium would be displaced by the removal of *o*-aminophenylacetaldehyde (to indole).

To test the hypothetical reaction path *via* the aldehyde, 2-(*p*-aminophenyl)ethanol vapour was passed over silica gel and metallic copper catalysts. With 2-(*p*-aminophenyl)ethanol, no cyclization reaction would be possible, and *p*-aminostyrene was expected from the reaction over silica gel (by catalytical dehydration). From the reaction over copper it was hoped to identify traces (due to ready polymerization) of *p*-aminophenylacetaldehyde.

However, from both experiments, only unreacted 2-(*o*-aminophenyl)ethanol was isolated and in low yields, indicating polymerization of the products in the reactor. No conclusions as to presence of an aldehydic intermediate (*9*) in the indole synthesis could thus be drawn.

To test if an aldehyde nevertheless could be formed under the reaction conditions, 2-phenylethanol vapour was passed over copper at 250° in a nitrogen stream. The main product was indeed phenylacetaldehyde (50 % yield). Maihle [12] had earlier obtained phenylacetaldehyde from 2-phenylethanol over copper at 300°. Our result thus indicates that the copper catalyzed synthesis of indole from 2-(*o*-aminophenyl)ethanol might proceed *via* *o*-aminophenylacetaldehyde.

The reaction path *via* 2,3-dihydroindole was obviously not excluded by the results, and the only conclusion possible was that the reaction might proceed by both paths.



By the method presented here, it has thus been possible to synthezise indole in one step and in high yield from 2-(*o*-nitrophenyl)ethanol. This should be compared to the three steps necessary if a synthetic route in liquid phase is used.[1] On the other hand, the synthesis in liquid phase is probably more advantageous for the synthesis of substituted indoles.[6] The presented synthesis in vapour phase has not yet been investigated in the case of substituted indoles.

EXPERIMENTAL

The IR spectra were recorded on a Perkin-Elmer infrared spectrophotometer Model 257 and the electronic spectra on a Beckman DK-2 spectrophotometer. Gas chromatographic separations were made on a Perkin-Elmer F-11 gas chromatograph, equipped with a hydrogen flame ionisation detector and a 10 % SE-30 column. Mass spectra were recorded on an A. E. I. M. S. 902 mass spectrometer.

The gas phase reactor was made of a 60 cm long Vycor tube (o.d. 18 mm) equipped with a thermocouple well (o.d. 8 mm). The reactor was heated in an electrically heated fluidized bed with silicon carbide as heat transferring medium.[18] The reactor was half filled with catalyst (catalyst volume 30 ml) and the rest of reactor filled with Vycor chips (to heat reactants before reaching the catalyst). The liquid reactants were passed onto the top of the reactor by a syringe pump, together with the appropriate gas. The effluents from the reactor were analyzed by GLC. The stated percentages of the various components in the reaction mixtures were calculated from the gas chromatograms after corrections had been made for differences in the ionizing power of the various components.

Reactions of 2-(o-aminophenyl)ethanol in the vapour phase. Indole synthesis. When the experiment of Ufer *et al.*[7] was reproduced, indole was formed in 70 % yield during the first 10 min. The catalyst deteriorated rapidly, and later indole was found in low yield together with 2,3-dihydroindole and unreacted starting material. The reaction was then tried with a catalyst made by soaking silica gel in an aquous solution of copper nitrate, evaporating the water, drying the silica gel at 100°, heating it at 250° until the evolution of nitrous gasses ceased and finaly reducing it with hydrogen at 250°. The catalyst contained 7 % copper. With this catalyst (30 ml) in the reactor, 2-(*o*-aminophenyl)ethanol (10 g/h) was evaporated in a stream of hydrogen (200 ml/min) and passed over the catalyst. The yield of indole was 95 % and the main byproducts were 2,3-dihydroindole (2 %) and *o*-aminoethylbenzene (1.5 %). The indole from the reactor was 96 % pure and had m.p. 45–47°. Several commercial copper or copper chromite catalysts were tried and gave essentially the same result. The working lives of the catalysts were several hundred hours. A copper metal catalyst made by hydrogen reduction of copper oxide (Merk AG, Kupferoxid Draht Form) gave the same result.

2,3-Dihydroindole from 2-(o-aminophenyl)ethanol. 2-(*o*-Aminophenyl)ethanol (10 g/h) and hydrogen (200 ml/min) were passed through the reactor containing silica gel as catalyst at 250°. The yield of 2,3-dihydroindole was 98 %.

Gas phase reaction of 2-(o-aminophenyl)ethanol without catalyst. This reaction was carried out as the previous one, except that the reactor was filled with Vycor chips alone. The product consisted of unreacted starting material. No 2,3-dihydroindole was detected.

Gas phase reaction of o-aminostyrene. o-Aminostyrene (10 g/h, prepared by reduction of *o*-nitrostyrene with iron turnings) together with hydrogen (200 ml/min) was passed through the reactor containing silica gel (30 ml) as catalyst at 250°. The product consisted of unreacted *o*-aminostyrene. No 2,3-dihydroindole was detected. When 7 % copper on silica gel was used as catalyst, *o*-aminoethylbenzene was obtained in 97 % yield.

Gas phase reaction of 2,3-dihydroindole. When 2,3-dihydroindole was vapourized and passed with hydrogen over the copper/silica gel catalyst, as described for 2-(*o*-aminophenyl)ethanol, indole was obtained in 98 % yield.

Reactions of 2-(p-aminophenyl)ethanol in the vapour phase. 2-(*p*-Aminophenyl)ethanol (2.5 g) was dissolved in 1,2-dimethoxyethane (37.5 g) and the solution (19.6 g/h) pumped into the reactor at 250° together with N_2 (30 ml/min). When silica gel (30 ml) was used as catalyst, 21.10 g solution was reacted (containing 1.9 g *p*-aminophenylethanol).

The product (0.1 g concentrated, 5 % of starting material) gave 8 peaks on GLC, one of which was possibly 2-(*p*-aminophenyl)ethanol. By extracting the catalyst for 6 h with a 1:1 mixture of chloroform:methanol, 0.3 g of a product consisting mainly of starting material (as judged by TLC) was obtained.

When copper metal (from copper oxide) was used as catalyst and the other conditions retained as described above, 31.5 g of the *p*-aminophenylethanol solution (containing 2.06 g of *p*-aminophenylethanol) was reacted. A certain amount of product was isolated (*ca.* 450 mg),

consisting mainly of unreacted starting material, (GLC).

As the conditions for the reactions of *p*-aminophenylethanol (due to the crystallinity of the substance) were slightly different from those originally used for *o*-aminophenylethanol, control experiments were run: A solution of 2-(*o*-aminophenyl)ethanol (3.5 g) in 1,2-dimethoxyethane (50 g) was reacted at the same rate and under the same conditions as those for the *p*-isomer described above. When silica gel was used as catalyst, 2,3-dihydroindole was obtained. When copper was used as catalyst, indole was the product. Both substances were obtained in the same yields and purities as described for the reaction without solvent and with H_2 as carrier gas.

Formation of 2-phenylacetaldehyde. 2-Phenylethanol (1.85 g/h) was pumped into the reactor at 250° together with nitrogen (85 ml/min). The reactor contained copper (from copper oxide) (13 ml) and Vycor chips (10 ml). Totally 3.7 g of phenylethanol was reacted. The condensate from the reactor (3.05 g) contained phenylacetaldehyde (35 %), ethylbenzene (26 %), and phenylethanol (31 %) (analyzed by GLC, internal standard method). This corresponded to a yield of phenylacetaldehyde of 50 % (calculated on basis of reacted alcohol). Phenylacetaldehyde was identified after isolation by column chromatography, by comparison of IR and TLC with those of an authentic sample.

Indole from 2-(o-nitrophenyl)ethanol. 2-(*o*-nitrophenyl)ethanol (5.6 g/h) was pumped into the reactor containing 30 ml of catalyst and 30 ml of Vycor chips together with a reducing gas. The products were analyzed by GLC. Results and reaction conditions are given in Table 2. From the reaction mixture with copper chromite as catalyst, 0.01 % of a crystalline compound was isolated. The compound had mp. 341 – 343°, IR (KBr) 3140 (broad, from 3300 to 2300 cm^{-1}), 1640, 1610, 1580, 1490, 1480, 1460, 1410, 1330, 1280, 1260, 1230, 1130, 1020, 990, 950, 910, 880, 860, 820, 790, 760, 740, 700, 640 cm^{-1}. The electronic spectrum (in ethanol) had maxima (in nm) numbers in parantheses give ε_{max} (l mol^{-1} cm^{-1}): 368 (3600), 331 (17 000), 317 (12 000), 270 (52 000), 265 (shoulder) (45 000). The mass spectrum indicated an elemental formula of $C_{15}H_{10}N_2$ with the molecular ion giving the base peak.

The isolated compound was in every respect identical with an authentic one synthesized by the method of Gabriel *et al.*[10] (In the synthesis,[10] catalytic reduction was used instead of the sulfide reduction used by these authors).

Table 2. Synthesis of indole from 2-(*o*-nitrophenyl)ethanol (ONPE) in the vapour phase, (5.6 g ONPE/h reacted). Reducing gas H_2.

Run	Catalyst	Reaction temperature °C	Mol reducing gas/mol ONPE	Yield of indole %
1	7 % Cu/silica gel	250	12	99

Effects of Alkyl-substitution on the Base-catalysed 1,3-Proton Transfer in the Indene System

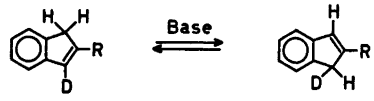
LENNART MEURLING

Department of Organic Chemistry, University of Uppsala, Box 531, S-751 21 Uppsala, Sweden

Syntheses of 2-alkyl substituted, deuterated indenes and their isomerization catalyzed by some tertiary aliphatic amines in pyridine solution, have been studied. Optically active 1,2-dimethylindene has been prepared and its rearrangement to 2,3-dimethylindene has been studied polarimetrically. Some steric and electronic consequences of substitution in the indene nucleus are discussed. The substitution pattern of the indene and the nature of the catalyst seem to influence the reaction rate in a complex way. Rate constants and activation parameters for the isomerization reactions are given.

The prototropic 1,3-shift in the indene system has been investigated in detail.[1–19] Base-catalyzed isomerization of 1-,[1–7] 1,2-,[9] and 1,3 [10]-alkyl substituted indenes have been studied with regard to stereospecificity,[2,19] intramolecularity and deuterium isotope effect.[1,20,21] Recently, a report has been published [22] concerning the influence of some β-substituents in alkylsubstituted methylindenes on the isomerization rate.

This communication reports the results of some experiments with 2-alkyl substituted indenes. The isomerization *1* ⇌ *2* (Scheme 1), where R is a methyl or an ethyl group, was studied by the NMR-technique. Further, optically active 1,2-dimethylindene *7* (Scheme 3)

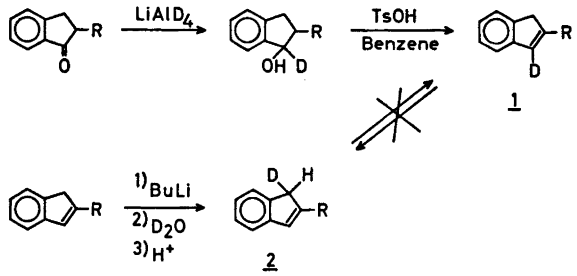


1 2

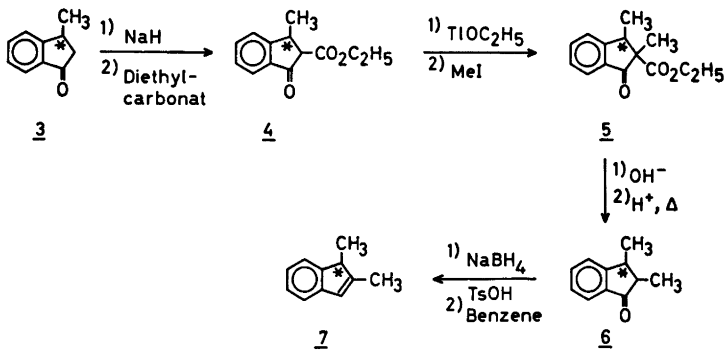
Scheme 1.

was synthesized and its mutarotation to the non-chiral 2,3-dimethylindene was studied polarimetrically. As in previous investigations, aliphatic amines were used as catalysts and the reactions were run in pyridine solutions. The catalytic effect of 1,4-diazabicyclo[2.2.2]-octane (DABCO) and triethylamine (TEA) were investigated. Earlier, it was found that the rearrangements under these conditions in the indene system were completely intramolecular and highly stereospecific.[1,21]

In order to kinetically follow the reaction by NMR it was necessary to label the 2-alkylindenes with deuterium in position 1 or 3. The 2-alkyl-3-deuterioindenes *1* were prepared by reducing the corresponding 2-alkylindanones



Scheme 2.



Scheme 3.

with lithium aluminium deuteride, followed by dehydration with *p*-toluenesulphonic acid of the indanol obtained (Scheme 2). In order to get access to the 2-alkyl-1-deuterioindenes *2*, 2-methylindene (or 2-ethylindene) was treated with butyllithium in dry ether at −30°C and the indenyllithium thus formed was decomposed with D_2O, followed by rapid acidification (Scheme 2). As judged from the NMR-spectrum, no rearranged product *1* was formed during this synthesis.

In the case of the 1,2-dialkylindene, the isomerization [9] can be followed more accurately by the polarimetric technique since the indene mutarotates with the same rate as it isomerizes. The conventional synthesis of an optically active 1,2-substituted indene starts with the resolution of an α-alkyl-β-phenyl substituted alkanoic acid. This may be a complicated procedure since the molecule contains two asymmetric carbon atoms. An alternative route to the optically active indene was therefore undertaken. Optically active 3-methylindanone *3* was acylated in the 2-position with diethylcarbonate and the thallium salt of 2-carbethoxy-3-methylindanone *4* was prepared by treatment of *4* with thallous ethoxide. Alkylation with methyl iodide gave almost exclusively C-alkylation of the carbethoxy-indanone in good yield. Alkaline hydrolysis and decarboxylation gave the 1,2-dimethylindene *7* after some conventional steps (Scheme 3).

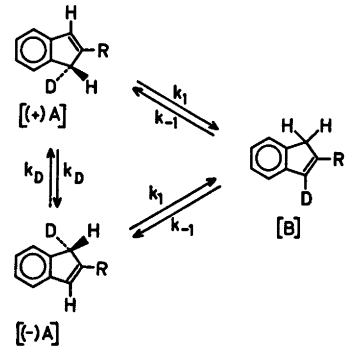
TREATMENT OF RATE DATA

The course of the reaction in Scheme 1 was measured by integration of the NMR-signals from the vinylic proton and/or the saturated ring protons. The signal from the 2-alkyl group was used as an internal standard. In discussing the rate and equilibrium properties of the system, it should be remembered that the equilibrium constant *2/1* is equal to 2, due to the asymmetry of *2* (*cf.* Scheme 1). Using the notations given in the phenomenological reaction Scheme 4, we get the following rate equations:

$$\frac{d[(+)A]}{dt} = -(k_1+k_D)[(+)A]+k_D[(-)A]+k_{-1}[B] \quad (1)$$

$$\frac{d[(-)A]}{dt} = k_D[(+)A]-(k_1+k_D)[(-)A]+k_{-1}[B] \quad (2)$$

$$\frac{d[(B)]}{dt} = k_1[(+)A]+k_1[(-)A]-2k_{-1}[B] \quad (3)$$



Scheme 4.

If $[A]=[(+)A]+[(-)A]$, these equations can be written as:

$$\frac{d[A]}{dt} = -k_1[A]+2k_{-1}[B] \quad (4)$$

$$\frac{d[B]}{dt} = k_1[A] - 2k_{-1}[B] \quad (5)$$

[The (+)- and (−)-signs have no configurational relevance.] Thus, deuterium migration, which brings (+)A to (−)A and *vice versa*, does not influence our kinetic measurements. Furthermore, if secondary isotope effects are neglected, *i.e.* if $k_{-1}=k_1$, the rate equations, in integrated form, will be:

$$[A] = ([A]_0 - [A]\infty) \exp(-3k_1t) + [A]\infty \quad (6)$$

$$[B] = ([B]_0 - [B]\infty) \exp(-3k_1t) + [B]\infty \quad (7)$$

If x and y denotes the area of the saturated and the vinylic protons, respectively, and λ is a proportionality constant we have

$$x = \lambda([A] + 2[B]) \quad (8)$$

$$y = \lambda[A] \quad (9)$$

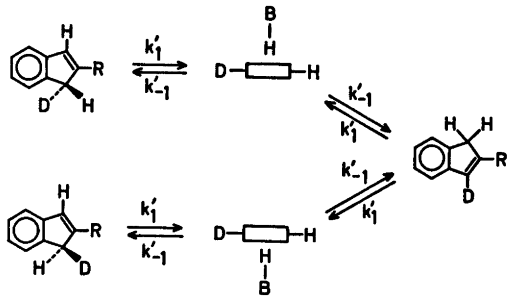
Combining eqns. (6 – 7) with eqns. (8 – 9) we get:

$$x = (x_0 - x\infty) \exp(-3k_1t) + x\infty \quad (10)$$

$$y = (y_0 - y\infty) \exp(-3k_1t) + y\infty \quad (11)$$

Thus, the observed rate constant is $3k_1$. This fact is of importance for the comparison of the rate constants obtained for alkylindenes with different substitution pattern. Thus, if we consider a phenomenological reaction scheme equivalent to Scheme 4 for a 1- or a 1,2-substituted indene, the observed rate constant will be k_1,[1,9] since the collapse ratio is large and for the symmetrically substituted 1,3-dimethylindene [10] the observed rate constant will be exactly $2k_1$.

As pointed out before,[14] however, the rearrangements proceed most probably *via* an ion-pair intermediate as in mechanistic reaction, Scheme 5.



Scheme 5.

In this case, a proper comparison should involve the mechanistic rate constant k'_1, and it is easily shown that $k_{obs}=3k'_1/2$ for 2-substituted indenes and that $k_{obs}=k'_1$ in other cases of interest, *i.e.* the last expression is exactly valid for 1,3-dimethylindene and approximately valid for the 1-methylindene since the collapse ratio is large. The comparisons should thus be made according to the directions given in Table 1. These considerations should

Table 1.

Substrate:	Phenomenological Scheme 4 k_1	Mechanistic Scheme 5 k'_1
	$\frac{1}{3}k_{obs}$	$\frac{2}{3}k'_{obs}$
	k_{obs}	k_{obs}
	$\frac{1}{2}k_{obs}$	k_{obs}

be kept in mind when rate constants are to be compared. Enthalpies of activation can of course be calculated and compared directly, using k_{obs}. The entropies of activation will depend on which rate constant is chosen, but the experimental error will, in most cases, be larger than the difference between the entropy values calculated using different rate constants (*i.e.* k_{obs}, k_1 or k'_1). Finally, it should be noted that k_{obs} used in the present discussion is the second order rate constant, obtained by multiplying the experimentally observed pseudo-first order constant with 1/[Base].

RESULTS AND DISCUSSION

It was found earlier that the introduction of a methyl group in position 1 of the indene nucleus slows the TEA-catalyzed reaction at 30°C by a factor of 5.8.[6] Introduction of a substituent in the 2-position of 1-methylindene further shows the reaction by a factor of 25.[9] The retarding effect of a substituent in the 2-position is thus considerable. If 1-methylindene is substituted with a methyl group in the 3-

position, only a very slow rearrangement occurs with TEA.[10]

Turning to the DABCO-catalyzed reactions, it can be found from the present investigation and from earlier results in this field [6] that 1-methylindene rearranges about 25 % slower than indene itself, but a further substitution to 1,2-dimethylindene slows the reaction rate by a factor about 7.[9] Alkyl substitution to 1,3-dimethylindene shows that the mechanistic rate constant is about 40 times smaller than that for indene. The effect of alkyl-substitution on the reaction rate is thus markedly dependent on the situation of the substituent.

In the ground state, a 2-alkylindene should be more stable than a 1-alkylindene, due to hyperconjugation between the double bond and the methyl group, as well as between the double bond and the CH_2-group in position 1. In the transition state, the indene part is probably very much like the indenyl anion. In this anion, positions 1 and 3 have higher electron densities than position 2 [12] and a 2-substituted indenyl anion is therefore expected to be more stable than a 1-substituted anion.

Starting with indene, the introduction of an alkyl substituent in the 1-position would thus raise the energy level of the ground state but also increase the energy level of the transition state (Fig. 1). In accordance with this view, the situation in the 2-alkylindene case should be a lower ground state energy level, but with a transition state of about the same magnitude as in indene. The introduction of a methyl group in the 1-position of 2-methylindene should also raise the energy of the ground state to about the same extent as a 1-methyl group does on substitution in indene. In the transition state, a 1-methyl substituent would act in the same direction, *i.e.* raising the energy level.

The introduction of a methyl group in the 1-position does not always retard the proton abstraction rate (k'_1) when DABCO is used as a catalyst. This might seem puzzling since a retardation in reaction rate is quite obvious with TEA as catalyst. TEA should of course be sterically more hindering in the transition state than DABCO. However, a retardation in reaction rate would be expected also in the DABCO-case when a methyl group is introduced in the 1-position of 2-methylindene. Thus if $\Delta G^{\ddagger}_0$, $\Delta G^{\ddagger}_1$, $\Delta G^{\ddagger}_2$, and $\Delta G^{\ddagger}_{12}$ denote the free energies of activation (as calculated from the k'_1-values) for indene, 1-methylindene, 2-methylindene, and 1,2-dimethylindene, we get, using the values given in Table 2:

$(\Delta G^{\ddagger}_1 - \Delta G^{\ddagger}_0)_{\mathrm{DABCO}} = +0.1$ kcal mol^{-1};
$(\Delta G_1^{\ddagger} - \Delta G^{\ddagger}_0)_{\mathrm{TEA}} = +1.0$ kcal mol^{-1}

$(\Delta G^{\ddagger}_{12} - \Delta G^{\ddagger}_2)_{\mathrm{DABCO}} = -0.1$ kcal mol^{-1};
$(\Delta G^{\ddagger}_{12} - \Delta G_2^{\ddagger})_{\mathrm{TEA}} = +1.1$ kcal mol^{-1}

Thus, in the case of TEA the 1-methyl substituent increases the free energy of activation by 1.1 kcal mol^{-1} whether or not a methyl group is present in the 2-position. With DABCO the introduction of a methyl substituent in the 2-position has little or no influence on the reaction rate, the average value for the difference in free energy of activation being 0.0 kcal mol^{-1}.

The difference between these values, 1.1 kcal mol^{-1}, may be ascribed to the difference in steric hindrance in the transition state (steric hindrance in the ground state being equal and negligible) between the 1-methyl and TEA and DABCO, respectively. If y'_1 denotes the steric hindrance in kcal mol^{-1} between the 1-methyl group and the catalyst in the transition state, we get:

$(y'_1)_{\mathrm{TEA}} - (y'_1)_{\mathrm{DABCO}} = +1.1$ kcal mol^{-1}

In the same way, one may use the activation energy differences between 2-methylindene (and 1,2-dimethylindene) and indene to estimate the difference in steric effects in the transition state between a 2-methyl group and TEA and DABCO, respectively. If y'_2 denotes the steric hindrance between the 2-methyl group and the catalyst in the transition state, we get:

$(y'_2)_{\mathrm{TEA}} - (y'_2)_{\mathrm{DABCO}} = (\Delta G_2^{\ddagger} - \Delta G^{\ddagger}_0)_{\mathrm{TEA}} - (\Delta G_2^{\ddagger} - \Delta G^{\ddagger}_0)_{\mathrm{DABCO}}$

and

$(y'_2)_{\mathrm{TEA}} - (y'_2)_{\mathrm{DABCO}} = (\Delta G^{\ddagger}_{12} - \Delta G^{\ddagger}_0)_{\mathrm{TEA}} - (\Delta G^{\ddagger}_{12} - \Delta G^{\ddagger}_0)_{\mathrm{DABCO}} - \{(y'_1)_{\mathrm{TEA}} - (y'_1)_{\mathrm{DABCO}}\}$

The right hand sides of these equations are, using the previously deduced value for the y'_1-difference and the $\Delta G^{\ddagger}$-values of Table 2, +0.4 and +0.6 kcal mol^{-1}. As an average value +0.5 kcal mol^{-1} can be chosen and thus

$(y'_2)_{\mathrm{TEA}} - (y'_2)_{\mathrm{DABCO}} = +0.5$ kcal mol^{-1}

A 2-methyl group thus causes a less pronounced selectivity between different catalysts than a

1-methyl substituent, and TEA exhibits a larger steric hindrance than DABCO. These conclusions are quite reasonable from the chemical point of view.

The above analysis invites an attempt to describe the substituent effects, both steric and electronic, by a linear model. This cannot lead anywhere, however, without further data. Important information can be obtained from the previous study of the rearrangement of 1,3-dimethylindene with DABCO. We may assume that the transition state is unsymmetrical, so that only one of the methyl groups gives rise to steric repulsion. Both methyl groups have other effects, however, which are mainly electronic on the ground state as well as on the transition state. Another important fact is the equilibrium constant between 3-methylindene and 1-methylindene. It has been found that 1-methylindene is present to about 1 % in equilibrium. The free energy difference between the ground states of these two indenes must therefore be close to 2.8 kcal mol^{-1}. This difference is caused by substituent effects on the ground states, which for simplicity one may interpret as electronic (hyperconjugative) effects. Introducing the symbols given below, one gets the energy levels given in Fig. 1. The rate determining transition state for 3-methylindene is, of course, the same as for 1-methylindene. Referring to Fig. 1 we obtain the equations:

$$\Delta G^{\ddagger}_1 - \Delta G^{\ddagger}_0 = x'_1 + y'_1 + x^0_0 \quad (12)$$

$$\Delta G^{\ddagger}_{13} - \Delta G^{\ddagger}_0 = 2x'_1 + y'_1 + x^0_0 - x^0_1 \quad (13)$$

$$\Delta G_0 = x^0_0 + x^0_1 \quad (14)$$

$$\Delta G^{\ddagger}_2 - \Delta G^{\ddagger}_0 = x'_2 + y'_2 - x^0_1 \quad (15)$$

$$\Delta G^{\ddagger}_{12} - \Delta G^{\ddagger}_0 = x'_1 + y'_1 + x'_2 + y'_2 + x^0_0 - x^0_1 \quad (16)$$

The symbols have the following meaning:

x^0_0 = effect on the ground state of introducing a ring-CH_2-group

x^0_1 = effect on the ground state of introducing a CH_3-group in hyperconjugation with a double bond

x'_1 = effect on the transition state of introducing a CH_3-group in the 1- or 3-position

x'_2 = effect on the transition state of introducing a CH_3-group in the 2-position

y'_1 = steric effect on the transition state of a CH_3-group in the 1-position

y'_2 = steric effects on the transition state of a CH_3-group in the 2-position

$\Delta G_0 = -RT \ln K_{eq.}$, where $K_{eq.}$ is the equilibrium constant between 3-methylindene and 1-methylindene.

It should be noted, that x^0_0, x^0_1, x'_1 and x'_2 are independent of the nature of the catalyzing base, whereas y'_1 and y'_2 are, of course, different for DABCO and TEA, as explained above.

Eqns. (12), (13), and (14) can be solved for y'_1, and we get:

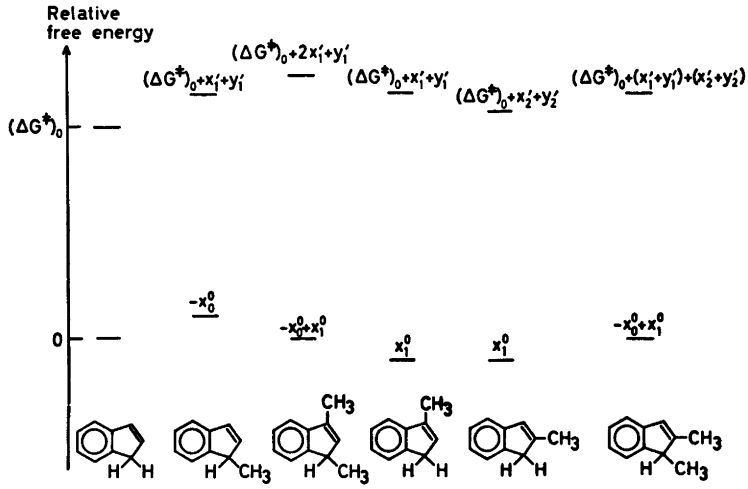

Fig. 1. Relative free energies between ground state and transition state for alkylindenes. The symbols are explained in the text.

$$y'_1 = 2\Delta G^{\ddagger}_1 - \Delta G^{\ddagger}_{13} - \Delta G^{\ddagger}_0 - \Delta G_0 \quad (17)$$

The rate constant (7.65×10^{-4} l mol^{-1} sec^{-1}) reported previously for the DABCO-catalyzed reaction for 1,3-dimethylindene, gives $\Delta G^{\ddagger}_{13} =$ 22.1 kcal mol^{-1}. Using this value and the $\Delta G^{\ddagger}$-values reported in Table 2 (together with $\Delta G_0 = -2.8$ kcal mol^{-1} as given above), we find that $(y'_1)_{DABCO} = +0.8$ kcal mol^{-1}. Since we already have concluded that $(y'_1)_{TEA} - (y'_1)_{DABCO}$ was +1.1 kcal mol^{-1}, we now get $(y'_1)_{TEA} = +1.9$ kcal mol^{-1}.

Combination of eqns (12), (15), and (16) gives:

$$\Delta G^{\ddagger}_1 - \Delta G^{\ddagger}_0 = \Delta G^{\ddagger}_{12} - \Delta G^{\ddagger}_2 = x'_1 + y'_1 + x^0_0 \quad (18)$$

Using the average value for the free energy differences used above for the DABCO-case and the value +1.1 kcal mol^{-1} for the TEA catalyzed reaction together with the y'_1-values just obtained, we get $x'_1 + x^0_0 = -0.8$ kcal mol^{-1}. With the parameter values thus obtained, eqns (15) and (16) are best satisfied using $x'_2 - x^0_1 + (y'_2)_{DABCO} = +1.4$ kcal mol^{-1}

Thus, the data now available gives us the following parameters:

$(y'_1)_{DABCO} = +0.8$ kcal mol^{-1}
$(y'_1)_{TEA} = +1.9$ kcal mol^{-1}
$x'_1 + x^0_0 = -0.8$ kcal mol^{-1}
$x^0_0 + x^0_1 = -2.8$ kcal mol^{-1}
$(x'_2 - x^0_1) + (y'_2)_{DABCO} = +1.4$ kcal mol^{-1}

Table 3 summarizes the activation free energy differences calculated using these parameter values and compares them with experimental results.

Thus, the eight parameters used in the model [eqns. (12)–(16)] have been fixed to six numerical values. An attempt can now be made, using chemical intuition, to create a set for all eight parameters. The steric parameters already given

Table 3.

	DABCO		TEA	
	Exp.	Calc.	Exp.	Calc.
$\Delta G^{\ddagger}_1 - \Delta G^{\ddagger}_0$	0.1	0	1.0	1.1
$\Delta G^{\ddagger}_{13} - \Delta G^{\ddagger}_0$	2.2	2.0	–	3.1
$\Delta G^{\ddagger}_2 - \Delta G^{\ddagger}_0$	1.4	1.4	1.8	1.9
$\Delta G^{\ddagger}_{12} - \Delta G^{\ddagger}_0$	1.3	1.4	2.9	3.0

makes it plausible to set $(y'_2)_{DABCO} = 0$, and the steric parameters would then be as follows:

$(y'_1)_{DABCO} = +0.8$ kcal mol^{-1};
$(y'_1)_{TEA} = +1.9$ kcal mol^{-1}

$(y'_2)_{DABCO} = 0.0$ kcal mol^{-1};
$(y'_2)_{TEA} = +0.5$ kcal mol^{-1}

Using this value for $(y'_2)_{DABCO}$, we see that $x'_1 - x'_2 = +0.6$ kcal mol^{-1}. As long as $(y'_2)_{DABCO}$ is greater than -0.6 kcal mol^{-1}, which it seems safe to assume, the difference between x'_1 and x'_2 will be greater than zero. Thus, a 1-methyl group will have a more destabilizing effect on the transition state than a methyl group in the 2-position. This agrees well with the fact that the indenyl anion has a larger negative charge on the 1-carbon atom than on the 2-carbon atom. As mentioned before, the indene part of the transition state is probably very much like the indenyl anion.

A complete set of reasonable electronic parameters may be constructed if it is assumed that the stabilizing effect of the ground state (hyperconjugation) of the ring methylene group is equal to the stabilization between a methyl group and a double bond in the ground state. If this is true, we get the following values of the individual x-parameters:

$x^0_0 = -1.4$ kcal mol^{-1};
$x^0_1 = -1.4$ kcal mol^{-1}

$x'_1 = +0.6$ kcal mol^{-1};
$x'_2 = 0.0$ kcal mol^{-1}

Steric repulsion between the catalyzing base and the substrates, as judged from models, seems to be approximately the same for 1- and 2-substituted indenes. However, Plenat and Bergson found [9] that the relative catalytic effect of TEA was more sensitive to the nature of the substrates, *i.e.* the substituted indenes, than that of DABCO. For instance the ratio k_{DABCO}/k_{TEA} was found to be 19:1 for 1-methylindene and 66:1 for 1,2-dimethylindene. In this investigation we found the corresponding ratio for 2-methylindene to be 8:1 and for indene 4:1. The introduction of a substituent in the nucleus of indene should of course present increased interaction between the substrate and TEA and it is obvious that a 1-methylsubstituent is more hindering than a 2-methyl group. However, it can be concluded from the

above mentioned considerations, that it is not the 1- or 2-substituents separately which are causing the substrate sensitivity for TEA, but a combination as reflected in the 1,2-dimethylindene case.

From Table 2 it can be seen that the enthalpies of activation are about the same for 1-methyl- and 2-methylindene; 10.9 and 11.4 kcal mol^{-1} for the DABCO-catalyzed reactions and 9.6 and 9.8, respectively, for the TEA-catalyzed reaction. The activation enthalpies of the disubstituted indenes were significantly higher, 12.7 kcal mol^{-1} for 1,2-dimethylindene and 13.6 kcal mol^{-1} for 1,3-dimethylindene in the DABCO-catalyzed reaction. As expected, there is no difference in $\Delta S^{\ddagger}$ between 1-, 1,2- and 1,3-dimethylindene (−30, −28, and −28 e.u.). Much of the difference in reactivity between these substrates can thus be attributed to differences in $\Delta H^{\ddagger}$. For this reason, it seems confusing that $\Delta S^{\ddagger}$ for the DABCO and TEA-catalyzed isomerization of 2-methylindene is larger than the corresponding reactions with 1-methylindene as a substrate. Even if the experimental errors are large, it must be concluded that the lower reacting power of the 2-substituted compounds is probably due to these differences in activation entropy. The origin of this difference is not clear at present.

EXPERIMENTAL

Instrumental. Melting points and boiling points are uncorrected. The NMR-spectra were recorded in CCl_4 at 34 ± 1°C on a Varian A 60 D spectrometer. Preparative GLC of the indenes was performed on a Varian Aerograph Model 90-P4 with helium as carrier gas. The column used for purification was 0.6 m × 3/8″, packed with 20 % Apiezon L on Chromosorb W, 60/80 mesh. The purities of the indenes were checked on a Perkin-Elmer 900 gas chromatograph, equipped with a flame ionization detector, and with a 3 m × 1/8″ column, packed with 5 % Apiezon L on 100/120 mesh Varaport. The polarimetric measurements were made with a Perkin-Elmer polarimeter 141 M and the infra-red spectra with a Perkin-Elmer Model 237 spectrophotometer.

Syntheses

2-Alkylindanones were prepared according to Cologne and Weinstein [24] by condensation of the appropriate arylalkylketone with formaldehyde and subsequent dehydration of the ketols obtained with sulphuric acid. 2-Methylindanone-1: $b.p._{11} = 112-113°C$, $n_D^{22} = 1.5520$ (Lit.[24] $b.p._{15} = 120°C$, $n_D^{22} = 1.5511$). 2-Ethylindanone-1: $b.p._{11} = 125-126°C$, $n_D^{22} = 1.5465$ (Lit.[24] $b.p._{12} = 127°C$, $n_D^{22} = 1.5457$).

2-Alkyl-3-deuterioindenes (1) Alkylindanone (0.05 mol) in 50 ml of dry ether was slowly dropped into a solution of 0.03 mol of $LiAlD_4$ (Merck, deuterium content min. 99 %) in 20 ml ether. After refluxing for 2 h and after the usual work-up procedure,[5] the resulting indanols were dehydrated without further purification with 0.01 g of *p*-TsOH in 200 ml of dry benzene, using a Soxhlet extractor, filled with molecular sieves (Union Carbide, 5 Å). After half an hour of reflux the solution was chilled, extracted with 5 % aq. $NaHCO_3$ and then with a saturated NaCl solution and dried. The indenes were distilled in vacuum and purified by preparative GLC. The deuterium content in the 3-position was 97 ∓ 1 % as judged by the NMR-spectrum.

2-Methyl-3-deuterioindene (1a). Yield 68 % (calc. on the ketone) $b.p._{11} = 76-77°C$, $n_D^{22} = 1.5637$ (Lit.[25] gives for 2-methylindene $b.p._{2,3} = 64-65°C$, $n_D^{20} = 1.5645$). NMR: (Shifts in δ) 6.7 − 7.3, 4 H, complex; 3.11, 2 H, s (singlet); 2.09, 3 H, s.

2-Ethyl-3-deuterioindene (1b). Yield 76 % (calc. on ketone) $b.p._{11} = 82-85°C$, $n_D^{22} = 1.5590$ (Lit.[25] gives for 2-ethylindene $b.p._{1,1} = 62°C$, $n_D^{20} = 1.5598$). NMR: 6.7 − 7.3, 4 H, complex; 3.09, 2 H, s; 2.32, 2 H, q, $J = 7.5$ cps; 1.15; 3 H, t, $J = 7.5$ cps.

2-Alkyl-1-deuterioindenes (2). 2-Alkylindene [25] (0.02 mol) in 10 ml of dry ether was treated with 0.03 mol of butyllithium in ether solution at −30°C and held at this temperature for 1.5 h. D_2O, 5 ml (Norsk Hydro, 99.8 % D) was added with vigorous stirring during 5 min. The temperature was never allowed to exceed −15°C. After acidification with 2 M HCl, the ether layer was separated and the acidic phase extracted with ether. After drying of the extracts, the solvent was evaporated and the residue distilled in vacuum. The indenes were further purified by preparative GLC. No rearrangement occurred during the synthesis, since the deuterium content was more than 96 % in the 1-position as judged by the NMR-spectrum.

2-Methyl-1-deuterioindene (2a). Yield 82 %, $b.p._{10} = 74-75°C$, $n_D^{22} = 1.5643$. NMR: 6.7 − 7.3, 4 H, complex; 6.42, 1 H, t, $J = 2.5$ cps; 3.07, 1 H, complex; 2.08, 3 H, d, $J = 2.5$ cps.

2-Ethyl-1-deuterioindene (2b). Yield 77 %, $b.p._{10} = 81-83°C$, $n_D^{22} = 1.5592$. NMR: 6.7 − 7.3, 4 H, complex; 6.39, 1 H, t, $J = 2.5$ cps; 3.05, 1 H, complex; 2.30, 2 H, q, $J = 7.5$ cps; 1.15, 3 H, t, $J = 7.5$ cps.

An interesting fact is that in the spectra of 2-alkyl-3-deuterioindenes, the signal from the X-protons (methylene) appeared at a shift which was 0.04 ppm higher than the corresponding signal from the 1-deuterium-substituted

analogues. This effect was also demonstrated in the rearrangement, since at equilibrium, the amount of *1a* and *2a* (or *1b* and *2b*) could be seen as separate entities. This isotope effect is not unusual,[26] and still larger shifts are found in ^{19}F spectroscopy. Bovey [27] reports that in the spectrum of a 1:16 v/v mixture of cyclohexane and cyclohexane-d_{11}, the signal from the remaining H appeared at a shift 0.057 ppm from the sharp resonance of cyclohexane. The same effect, although to a lower extent, can be observed when the spectra from 1-deuterio- and 3-deuterioindenes are examined. The origin of this isotope effect is thought to result from differences in zero point vibrational functions, which are associated with different isotopic masses. A more extensive theoretical treatise is given elsewhere.[28]

(−)-3-Methyl-2-carbethoxy-indanone-1 (4). (−)-3-Methylindanone-1 (*3*) {$[\alpha]_D^{25} = +1.8°$, ($c = 31.6$, benzene)}, 10 g (69 mmol), obtained by ring-closure of (+)-β-phenyl-butyric acid, {$[\alpha]_D^{25} = +57.6°$ ($c = 2.8$, benzene)}[5] in 75 ml of dry benzene, was dropped into 6.5 g (270 mmol) of NaH (BDH, puriss) and 75 g (630 mmol) of diethyl carbonate in 50 ml of dry benzene at +65°C for 2 h, and maintained at that temperature for another hour. The solution was chilled to +10°C, acetic acid was added to pH 6, the mixture chilled to ±0°C and the pH adjusted to 1 with hydrochloric acid. The organic phase was extracted twice with 5 % $NaHCO_3$ and with NaCl aq. sat., After evaporation of the benzene, the residue was distilled under vacuum, yield: 83 % b.p.$_{0,5}$ = 131 − 133°C, $n_D^{22} = 1.5435$, $[\alpha]_D^{25} = -105°C$ ($c = 2.0$, benzene). NMR: About 30 % of the product was present as the enol. Shifts: 10.52, s; 6.7 − 7.3, complex; 4.23, q; 3.14, d; 1.21, d; 1.23, complex. IR: C=O, 1720 cm^{-1} (ester), 1670 cm^{-1} (ketone)

(−)-2,3-Dimethyl-2-carbethoxyindanone (5). (−)-3-Methyl-2-carbethoxyindanone-1, 12 g (0.054 mol) in 100 ml of dry ether was treated dropwise with 13.4 g (0.054 mol) of thallous ethoxide at room temperature. After 5 min, the thallium salt of 3-methyl-2-carbethoxy-indanone-1 precipitated as a yellow powder, which was filtered and washed with a small amount of ether. Yield: quantitative, m.p. 156 − 157°C. The salt was boiled under reflux with 50 g (0.350 mol) of methyl iodide (Kebo, puriss.). After filtration of the thallium(III), iodide obtained, the residue was distilled under vacuum. Yield: 87 %, $n_D^{23} = 1.5282$, b.p.$_1$ = 135 − 136°C, $[\alpha]_D^{25} = -67°$ ($c = 2.6$, benzene). NMR: 6.7 − 7.3, 4 H, complex; 3.52, 1 H, q; 3.86, 2 H, complex; 1.31, 3 H, d; 1.20, 6 H, complex. IR: C=O 1745 cm^{-1} (ester), 1690 cm^{-1} (ketone).

(−)-2,3-Dimethylindanone-1 (6). (−)-2,3-Dimethyl-2-carbethoxyindanone (*5*) 8 g (0.034 mol) was stirred at room temperature with 100 ml of 5 % NaOH for 24 h. To the homogeneous solution 100 ml of 4 M H_2SO_4 was added and the mixture refluxed for 2 h. After ether extraction and evaporation of the solvent the residue was distilled. Yield: 87 %, b.p.$_{10}$ = 118 − 119°C, $n_D^{22} = 1.5428$. (Lit.[9] gives for the racemic compound b.p.$_{13}$ = 121°C, $n_D^{17} = 1.5548$), $[\alpha]_D^{25} = +3.0°$ ($c = 10.0$ benzene) NMR: 6.7 − 7.3, 4 H, complex; 2.31, 1 H, p; 1.72, 1 H, 1.10, 3 H, d; 0.95, 3 H, d. IR: C=O 1725 cm^{-1} (ketone).

(+)-1,2-Dimethylindene (7). (+)-2,3-Dimethylindanone, 4.0 g (0.025 mol) was dissolved in 50 ml of methanol and sodium borohydride, 1.0 g (0.027 mol) in 75 ml 0.1 M NaOH was added slowly to the solution maintained at 20 − 25°C by external cooling. After evaporation of the solvent, 100 ml of water was added, the mixture extracted with ether, the ether phases dried over anhydrous $MgSO_4$ and the solvent evaporated. Without any further purification, the indanol was dissolved in 150 ml of dry benzene and dehydrated by the same route as the 2-alkyl-3-deuterioindenes. The crude indene was flash-distilled and purified *via* preparative GLC. Yield: 2.5 g, 69 %, b.p.$_{11}$ = 82 − 86°C, $n_D^{22} = 1.5655$ (lit. gives for the racemic compound b.p.$_{13}$ = 86 − 87°C, $n_D^{25} = 1.5642$). $[\alpha]_D^{25} = +115°$ ($c = 2.0$, benzene). NMR: 6.6 − 7.3, 4 H, complex; 6.25, 1 H, p; 3.01, 1 H, p; 1.96, 3 H, q; 1.18, 3 H, d.

Kinetics

The kinetic experiments were performed in a thermostat having an accuracy of ±0.05°C. Diazabicyclooctane (KEBO), m.p. 156 − 158°C, was recrystallized twice from hexane (spectrograde). Triethylamine (Merck) was distilled over sodium. Pyridine (Mallinckrodt) was dried over calcium hydride and distilled and degassed with oxygen-free N_2. Stock solutions of the aliphatic amines were prepared and added to the substrate, such that the indene concentration was 2 M. At specific intervals, samples were withdrawn from the reaction bottle, quenched with dilute hydrochloric acid and the indenes extracted with carbon tetrachloride. The samples were diluted with carbon tetrachloride to give concentrations approximately 2 M in indene. The NMR-spectra were recorded and the average of at least three integrals of A- and X-protons was recorded. The internal standard was the CH_3-group of 2-methylindene or the $-CH_2-$group in 2-ethylindene. About 15 observations during 3 halflives were recorded. The rate constants were calculated by means of a least-squares plot. The isomerizations were studied at 20.0, 30.0, and 40.0°C.

In a test run the isomerization of 1-methylindene and 3-deuterioindene, respectively, with DABCO as a catalyst was studied. These runs were undertaken at 30.0°C. The internal standard was *t*-BuOH, 0.1 M, which has a very small retarding effect on the reaction rate.

The polarimetric measurements were performed with 0.5 M optically active 1,2-dimethyl-

indene and inactive 1,2-dimethylindene added so that the total concentration was 2 M. The mutarotation was followed by means of an automatic data collecting system, equipped with a paper tape punch. About 200 observations were made over at least 3 half-life times. The rate constants were calculated *via* a least-squares plot performed by the computer programme PROGAEXP.[14]

Specific Heat Measurements on Lysozyme, Chymotrypsinogen, and Ovalbumin in Aqueous Solution and in Solid State

J. SUURKUUSK

Thermochemistry Laboratory, Chemical Center, University of Lund, S-220 07 Lund, Sweden

Specific heats on solid lysozyme, chymotrypsinogen, and ovalbumin with different amount of water have been measured as a function of the water content. The $\bar{c}p°$ values obtained from extrapolation to zero water content are 1.192 ± 0.005 (lysozyme), 1.223 ± 0.004 (chymotrypsinogen) and 1.231 ± 0.005 (ovalbumin) in J K^{-1} g^{-1}. The specific heat for the water associated with the proteins is 30 % larger than the value for pure water.

Specific heat measurements were also carried out on aqueous protein solutions at different concentrations in order to obtain partial specific heat values at infinite dilution. The values found are 1.494 ± 0.007, 1.529 ± 0.015, and 1.534 ± 0.014 in J K^{-1} g^{-1} for lysozyme, chymotrypsinogen, and ovalbumin, respectively.

Specific heat values were calculated for solid lysozyme, chymotrypsinogen and insulin from the sum of the heat capacity values of the amino acids, corrected for the heat capacity contributions for the formation of the peptide bonds. The calculated values are within a few percent of the experimentally obtained values.

A similar analysis of the results from specific heat measurements on aqueous protein solutions indicates that a substantial part of the non-polar amino acid side groups are solvated by water.

The biochemical properties of protein are to a large extent governed by the mutual interaction between protein and water. One of the most important factors which stabilizes native proteins seems to be the interactions between water and the non-polar groups of the protein. Kauzmann [1] proposed that the stabilization effect is caused by the entropy gain when non-polar groups are taken out of contact with water to the inside of the protein. It was assumed that the hydrophobic side chains are buried in the interior of the protein. Klotz,[2] on the other hand, pointed out that the favourable enthalpy contribution from the solvation of non-polar groups could be an important stabilization factor. X-Ray investigations on several proteins have shown that nearly all ionic side-chains are exposed to solvent, and a substantial number of hydrophobic groups are accessible to solvent.[3]

There is an increasing interest for a quantitative characterization of these interactions and thermodynamic methods seem to be among those which are best suited for the purpose. From experiments with low molecular weight compounds it has been shown that hydrophobic groups in contact with water are associated with very large apparent heat capacity values. It is believed that the "excess" heat capacity is due to enthalpy of melting of water structures formed under the influence of the hydrophobic groups. Recent model compound experiments [4,5] indicate that the heat capacity values can be accounted for by simple additivity rules.

The analysis of the heat capacity of a protein in terms of the contributions from amino acid side groups, the effect of solvation and the polypeptide back bone can be shown to give information about the distribution of the non-polar groups between the interior and surface of a protein. Unfortunately, there are only a few globular proteins for which absolute specific heats are measured in aqueous solution or in the solid state.[6-9] Furthermore, most of the available heat capacity values are not precise enough to attempt to predict structural features.

The long range goal of this work is to make

correlations between heat capacities and structural features for proteins and protein constituents. Here we present a first exploratory study on the specific heats for a few globular proteins. The measurements have been made by a novel double drop heat capacity calorimeter.[10]

Specific heat measurements were made on ovalbumin, chymotrypsinogen, and lysozyme in dilute aqueous solutions at different concentrations. From these measurements partial specific heats at infinite dilution, $\bar{c}p^{\circ}_2$, were derived for the proteins. Measurements were also made on the proteins in their solid states at different water contents.

The observed cp° values of the solid proteins are compared with calculated cp values and the $\bar{c}p^{\circ}_2$ values obtained in aqueous solution are used to estimate the per cent of solvated hydrophobic residues which are solvated on proteins in aqueous solution.

EXPERIMENTAL PROCEDURE AND CALCULATIONS

Materials. Lysozyme (LYSF OCC, salt free) was obtained from Worthington Biochemical Corp. Ovalbumin was obtained from Miles-Servac (PTY) Ltd. Chymotrypsinogen (3× crystallized, salt free) was obtained from Nutritional Biochemical Corp. All proteins were used without further purification. Glass distilled water was used with dissolved gases removed by boiling.

Calorimetry. A newly developed double drop calorimetric method was used.[10] The calorimeter consists of two main parts: (1) a "furnace" for temperature equilibration of the sample ampoule and reference ampoule and (2) a receiver twin calorimeter of the heat conduction type. The calorimetric unit was kept at about 29.7°C and the furnace at 20.3°C. The ampoules were equilibrated in the furnace for about 30 min, after which they are dropped into the receiver calorimetric unit and the difference between the heat quantities transferred by the two ampoules measured. From the difference obtained with the sample ampoule filled and empty, and the measured temperature difference ($\pm 2 \times 10^{-4}$ °C) between the furnace and calorimeter, the mean specific heat (cp) for the temperature interval 20.3 – 29.7°C can be calculated.

Calibration of the calorimeter was performed with water. Results from test experiments indicate systematic errors to be less than 0.1 %.[10]

Heat capacity studies on proteins performed with scanning calorimeters [9,11] show that the partial specific heat values vary almost linearly with the temperature in the interval here concerned. Therefore the specific heat values given in the present study may be assumed to refer to the mean temperature 25°C. Variations in the mean temperature were small, ±0.01°C, and any corrections to 25°C were insignificant. The only correction applied on the experimental specific heat values was the effect caused by the displaced air,[12] which was of the same order of magnitude as the precision of the measurements.

Uncertainties given for the cp values are twice the standard deviation of the mean $s = 2\langle\delta^2\rangle^{\frac{1}{2}}/\{n(n-1)\}^{\frac{1}{2}}$. The partial cp values were calculated by using the linear regression analytical method.[13]

Procedure. All aqueous protein solutions were prepared from dry proteins, which had been stored in vacuum ($< 10^{-3}$ mmHg) over P_2O_5, at room temperature, for at least 4 days. The concentrations were determined on the weight basis. During the preparation of the solutions care was taken to avoid unwanted hydration of the dry proteins. Even short exposure of the proteins to the air gives errors in the partial specific heat of the proteins of the order of a few percent. All manipulations with the dry proteins were therefore performed under dry nitrogen atmosphere.

About 0.6 g of the protein solution was filled into the ampoule immediately after preparation. The sample ampoule and the reference ampoule, which in the present study was always empty, were placed in the calorimeter. The order of selection of the concentrations studied was random. 4 – 8 consecutive determinations were performed at each concentration.

Various desired water contents for the hydration of the solid proteins were obtained by placing the dry proteins in evacuated vacuum desiccators over aqueous sulfuric acid of the appropriate concentration. The proteins were allowed to equilibrate for at least 24 h. The hydrated samples (0.2 – 0.05 g) were then filled into an ampoule, which was sealed by a plunger system. The plunger could be pressed against the proteins to achieve a minimum of vapor space without compression of air. After 4 – 8 consecutive cp measurements on each sample, the water contents were determined by weight difference before and after drying in an oven at atmospheric pressure and 105°C for 24 h.

Calculations. Specific heats were measured for the aqueous protein solutions at several concentrations and for the solid proteins at several water contents. From the measured cp values as a function of the concentration the contributions to the total cp from water and protein were calculated. The relationship between the partial specific heats is given by eqn. 1 (*cf.* Ref. 7)

$$(1 + W_2)cp = \bar{c}p_1 + W_2\bar{c}p_2 \qquad (1)$$

where W_2 is the quotient between the masses of the solute and the solvent ($W_2 = m_2/m_1$). Index 1 stands for the solvent and index 2 for the solute. In the solid samples the solvent is the protein and the solute is the water. cp is the measured specific heat, and $\bar{c}p_1$ and $\bar{c}p_2$ are the partial specific heats for the solvent and solute, respectively. Eqn. 1 shows that a plot of $(1+W_2)$cp against W_2 gives the $\bar{c}p_1$ value as the ordinate intercept and the $\bar{c}p_2$ value as the slope.

RESULTS

Measurements on lysozyme in aqueous solution were made at 14 different concentrations from 1.11 to 27.12 weight % lysozyme. The results are summarized in Table 1. The pH in this concentration range varied between 4.56 and 4.58. In Fig. 1a the results are plotted as described above. The experimental points were best fitted using two straight lines with a break between 9.5 and 10.1 weight %. According to eqn. 1 the partial specific heats for lysozyme and water are constant on both sides of the 10 % region. At that concentration there is a 2.1 % increase of the $\bar{c}p_2$ value and an increase of 0.05 % for the $\bar{c}p_1$ values.

The same effect occurs for aqueous ovalbumin solutions, which were measured in the range 0.58 – 12.44 weight % ovalbumin (Fig. 1b). The partial cp values are constant up to 4.3 – 4.8 %, after which an increase of 1.4 % and 0.04 % occurs for ovalbumin and water, respectively.

Table 1. Specific heat for aqueous lysozyme solutions at different concentrations and calculated apparent specific heat [a] for lysozyme.

Weight-% lysozyme	cp/J K^{-1} g^{-1}	ϕ_{cp_2}/J K^{-1} g^{-1}
1.11	4.1497 ± 0.0005	1.470 ± 0.045
2.45	4.1135 ± 0.0004	1.473 ± 0.016
3.63	4.0818 ± 0.0005	1.476 ± 0.013
4.79	4.0499 ± 0.0004	1.466 ± 0.009
6.11	4.0154 ± 0.0004	1.489 ± 0.006
6.60	4.0014 ± 0.0005	1.476 ± 0.007
9.47	3.9253 ± 0.0004	1.492 ± 0.004
10.11	3.9128 ± 0.0004	1.538 ± 0.004
13.08	3.8322 ± 0.0004	1.528 ± 0.003
17.18	3.7263 ± 0.0004	1.540 ± 0.002
21.90	3.6001 ± 0.0004	1.533 ± 0.002
27.12	3.4606 ± 0.0003	1.528 ± 0.001

[a] $\phi_{cp_2} = \dfrac{Cp - m_1\bar{c}p^\circ_1}{m_2}$; where Cp is the total heat capacity and $\bar{c}p^\circ_1$ is the specific heat for pure liquid water.

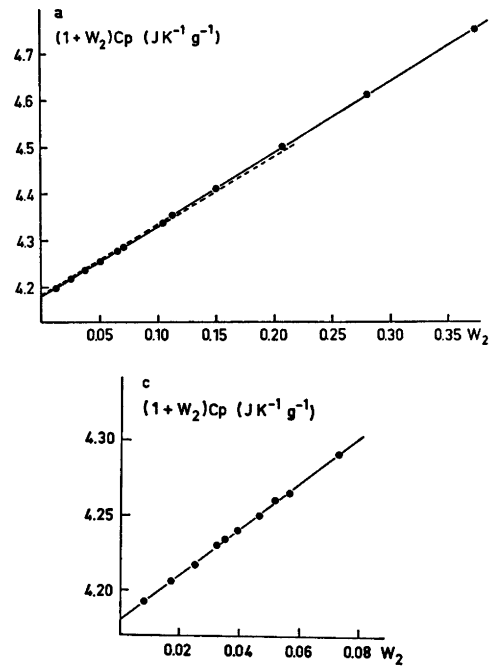

Fig. 1. Result of specific heat measurements on aqueous protein solutions as a function of the concentration: (a) lysozyme, (b) ovalbumin, (c) chymotrypsinogen.

In the measured concentration range there was a decrease of the pH from 6.3 to 6.1.

Fig. 1c shows the results from cp determinations on aqueous chymotrypsinogen in the interval 0.78 – 6.79 weight %, with a pH change from 4.06 to 4.10. In this region the $\bar{c}p$ values were constant, within the experimental errors.

Results from aqueous protein measurements extrapolated to zero concentration and the values found in the literature are summarized in Table 2.

Measurements on solid protein samples were carried out at six different water contents on each protein. Fig. 2 a, b, and c show the results for lysozyme, ovalbumin, and chymotrypsinogen, respectively. It is seen that the three curves show the same characteristic pattern: the experimental results from samples with less than 5 % and more than 15 % water fall on the same straight line, but the values between these limits fall below the extrapolated lines. The deviation from linearity is more pronounced for ovalbumin (*ca.* 3 %), than for lysozyme and chymotrypsinogen (*ca.* 2.0 – 1.5 %). Partial specific heats for the three proteins are the same on both sides of this interval.

The partial specific heat values extrapolated to zero water content from the solid protein experiments together with values found in the literature are summarized in Table 3.

Table 2. Partial specific heats of infinite aqueous dilution of lysozyme, chymotrypsinogen and ovalbumin at 25°C.

DISCUSSION

Hutchens *et al.*[8] suggested that it is possible to calculate the standard entropies for proteins from their amino acid composition and gave entropy calculations on solid proteins. The specific heats for the solid proteins (Table 3) and for the crystalline amino acids [14] on the average differ only slightly from each other, which seems to support the idea that heat capacities can also be calculated from the amino acid composition. With use of eqn. 2

$$n \text{ amino acids (c)} \rightarrow \text{protein (s)} + (n-i)H_2O \text{ (l)} \quad (2)$$

where n is the total number of amino acids and i is the number of polypeptide chains in the protein, it is possible to calculate the contributions from the peptide bonds to the total heat capacity of the protein. If ΔCp stands for the average molar heat capacity contribution from one peptide bond, then the ΔCp can be written by use of eqn. 2 as

$$\Delta C\text{p} = C\text{p}°(\text{protein}) + (n-i)C\text{p}°(H_2O) - \sum_i^n C\text{p}_i(\text{amino acids})/(n-i) \quad (3)$$

ΔCp values for three dipeptides, lysozyme, and chymotrypsinogen were calculated by use of eqn. 3. The heat capacity values for the amino acids and the dipeptides were taken from Ref. 14, where the data for L-Lys and L-His were estimated from the values given for L-Lys.HCl and L-His.HCl by subtracting 34.14 J K^{-1} mol^{-1}, which is the difference between D-Glu.HCl and L-Glu. The amino acid compositions for lysozyme and chymotrypsinogen given in Ref. 15 were used. The ΔCp values calculated in this study and the corresponding entropy data by Hutchens [8] are summarized in Table 4. In both cases a relative constant value for ΔCp or ΔS can be ascribed to the formation of the peptide bond. This points out that it may be possible to calculate the heat capacity for a solid protein from its amino acid composition with an accuracy of a few percent. Rearranging eqn. 3, using the ΔCp = 40.6 J K^{-1} mol^{-1} calculated from the two proteins and the Cp° = 75.3 J K^{-1} mol^{-1} for water leads to eqn. 4

Table 4. Calculated heat capacity and entropy changes [a] for forming peptide bond in the solid state at 25°C.

	ΔCp[b]	ΔS[b]
Lysozyme	40	
Chymotrypsinogen	43	38
Insulin		39
Gly-Gly	41	43
Ala-Gly	36	51
Leu-Gly	32	36

[a] Values taken from Hutchens *et al.*[8] [b] In J/K × (peptide bond).

$$c\text{p}°(\text{protein}) = \sum C\text{p}(\text{amino acid}) - (n-i)34.7 \text{ (J K}^{-1}\text{ g}^{-1})/\text{M} \quad (4)$$

The eqn. 4 was used to calculate the specific heat for insulin from its amino acid composition. The value obtained was 1.213 J K^{-1} g^{-1} compared with the measured value of 1.255.[8] This agreement is not surprising because if one calculates specific heat using eqn. 4 for all the various polypeptides made up of single amino acid units, the mean value falls within 1.2 ± 0.2 J K^{-1} g^{-1}. From this it can be assumed that the specific heat for most solid proteins is close t 1.2 J K^{-1} g^{-1}.

The specific heat for water bound on the solid proteins (Table 3) is about 30 % higher than for pure liquid water. This large value is surprising, because the specific heat of pure water is by itself "abnormally" high, caused by the gradual rupture of the hydrogen bonds with increasing temperature. The qualitative explanation could be that the water bound to the protein makes double hydrogen bonds at specific hydrophilic sites on the protein, such as was found in the collagen-water system by NMR-studies,[16] and that the rupture of the hydrogen bonds between water and protein falls off more rapidly than in pure liquid water with increasing temperature.

The specific heat decrease in the middle adsorption range (Figs. 2a, b, c) is probably due to specific heat change of the bound water, since from the argument above the specific conformation in the solid protein does not seem to affect the heat capacity values significantly. According to the adsorption mechanism proposed by Berlin *et al.*[17] the water is bound in double layers in the middle range due to the saturation of the specific water sites. This could lead to the decrease of the specific heat of bound water to a value closer to that of pure liquid water. The adsorption of more water was proposed to induce a conformational change which leads to an increase of available water sites, and the specific heat of water therefore increases to the same value as that found at low water content.

Partial specific heat of the protein in aqueous solution. In Fig. 1a, b, and c it can be seen that the partial specific heats are constant up to a rather high concentration. No obvious explanation can be offered for the abrupt changes in the c_p values for lysozyme and ovalbumin in the middle range. For the following discussion the $\bar{c}p^\circ$ values are obtained from the data below the breaking points (Table 3).

The derived $\bar{c}p_2^\circ$ values could be affected due to association reactions, which have been found to occur at higher pH from several sedimentation and chromatographic investigations on lysozyme [18-24] and chymotrypsinogen.[25-27] The effect on C_p caused by the association can be separated in two components: (1) direct changes in the specific heat caused by aggregation, and (2) change in the equilibrium of the association reaction induced by the temperature change. The effect 1 can be assumed to decrease the total specific heat due to the hydrophobic character found for the association reaction, whereas effect 2 always causes a positive c_p effect since an increase of temperature must cause a shift in equilibrium in the endothermic direction, requiring a positive absorption of heat. Since the observed $\bar{c}p_2$ is independent of concentration it is reasonable to assume that effects 1 and 2 are too small to be significant, and the observed $\bar{c}p_2^\circ$ values are equal to the true inifinitely dilute value.

The most striking result from the c_p measurements is the large Δc_p for the transferring of a solid protein to aqueous solution. The Δc_p°(solv) values for the proteins are 0.302 ± 0.008, 0.306 ± 0.015, and 0.303 ± 0.015 J K^{-1} g^{-1} for lysozyme, chymotrypsinogen, and ovalbumin, respectively, or an increase of 25 % in c_p for the process of solvating a protein. It is seen that nearly identical Δc_p°(solv) values were obtained for the three proteins.

Calculation of partial specific heats of proteins. In this section an attempt is made to analyse the obtained $\bar{C}p^\circ_2$ values by use of model compound data and simple additivity rules. In simple terms the different contributions to the $\bar{C}p^\circ_2$ values can be separated into several groups and are tabulated in Table 5.

A. Contributions from the back bone. From the observed independency of the heat capacities of the solid proteins on degree of hydration, it is assumed that the C_p contributions from the back bone do not change with the solvation of the protein. The C_p° for the back bone is estimated by using eqn. 4 on n glycine residues. The ΔC_p for solvating the terminal amino and carboxylic acid is taken to be zero.[4]

B. Contributions from solvated polar groups. All polar groups are assumed to be solvated.[3] The $\bar{C}p^\circ_2$ values for alcohol, amino, carboxylic, and amide groups given in Ref. 4 are used. The $\bar{C}p^\circ_2$ value for guanidine and imidazole groups are estimated by simple additivity rules from the values of the functional groups in Ref. 4. The phenolic group on tyrosine is estimated from values given in Ref. 28.

C. Contributions from non-polar groups. This group includes all the non-polar amino acid side chains, indole, mono- and disulfide groups, and

the non-polar parts of the polar side chains. The $Cp°_2$ values from these groups can be written as follows

$$\bar{C}p°_2 = Cp° + \alpha \Delta Cp(solv) \quad (5)$$

where $Cp°$ value is calculated from solid amino acid values [14] by subtracting the value for glycine, $\Delta Cp(solv)$ is the change when the non-polar groups are transferred to aqueous solution and α is the degree of solvation of the non-polar groups ($\alpha = 1$, when complete solvation). The ΔCp values were calculated for the different species through simple additivity rules from values given in Refs. 4, 14, 28. The ΔCp values for mono- and disulfide groups are not possible to estimate, but as the groups are probably not hydrated, the ΔCp is assumed to be zero. The ΔCp for the NH in indole is estimated to be zero.[4]

D. Contributions from ionisation. The $\bar{C}p°_2$ values for the polar groups all refer to the non ionic forms.[4] It is known that ionisation reactions occur with a decrease in the heat capacity.[29] Corrections for the ionisation of groups in the dissolved proteins were estimated from the expected pK values for the different side groups, the pH of the solution, and a mean ΔCp for ionisation reactions given in Ref. 30. It was assumed that lysozyme has 25 ionic groups at pH = 4.6 and chymotrypsinogen 27 at pH = 4.1.

The estimated contributions to the total $\bar{C}p°_2$ are summarized in Table 5.

The $\bar{C}p°_2$ can be written as the sum of all the different contributions

$$\bar{C}p°_2 = Cp(backbone) + \bar{C}p°_2(polar) + Cp° (non\text{-}polar) + \alpha \Delta Cp(solv) + \Delta Cp(ion) \quad (6)$$

The eqn. 6 with $\alpha = 1$, assuming all of the non-polar groups solvated, is used to calculate the theoretical heat capacities for completely solvated lysozyme and chymotrypsinogen (Table 6). From Table 6 it is seen that the calculated values exceed the experimentally obtained values with 70 – 80 %. This result suggests that the actual degree of solvation, α, is

The degree of solvation, α.	0.27	0.20

much less than 1. The difference between the calculated ($\alpha = 1$) and the observed heat capacity values can be used to estimate the degree of hydration of the non-polar groups from

$$\alpha = 1 - \frac{\bar{C}p^\circ_2(\text{calc},\alpha=1) - \bar{C}p^\circ_2(\text{obs})}{\Delta Cp(\text{solv})} \qquad (7)$$

Values for α were calculated for lysozyme and chymotrypsinogen and the results are summarized in Table 6. For lysozyme the value for α was found to be 0.27. This value agrees with the proposed solvation picture given by Klotz.[3] The value of $\alpha = 0.26$ for lysozyme obtained from static accessibility calculation from X-ray data made by Lee and Richards [31] seems to be surprising since the solvation of polar groups is calculated to be only 0.49, whereas in above calculation a value of 1 has been assumed. The value of α obtained for chymotrypsinogen in this study is 0.20 which is smaller than found for lysozyme, which seems to be reasonable from the fact that larger molecules can easily bury greater fractions of the non-polar groups.

With the above method it is also possible to estimate the change of solvation upon denaturation. The ΔCp values found for the thermal denaturation of lysozyme [11] and chymotrypsinogen [9] indicate that the solvation increases to the values 0.35 and 0.34 for the respective proteins.

Finally, the values calculated above for the degree of solvation, α, can also be compared with the values derived from the very approximate α_i values given by Tanford.[32] Tanford gives values of the degrees of solvation of 0.3 for native and 0.4 for incomplete (thermal) denaturation of small protein molecules. The above results confirm these estimates.

Acknowledgements. I express my sincere thanks to Dr. Ingemar Wadsö, who suggested this work, for many helpful discussions. I also want to acknowledge the very valuable suggestions and criticism I have received from Prof. Stanley J. Gill and Prof. Charles H. Spink.

Intramolecular Cyclizations of Thioureas Derived from Sulphoraphene: a Case of Asymmetrically Induced Additions to Vinylic Sulphoxides*

JAN JØRN HANSEN and ANDERS KJÆR**

Department of Organic Chemistry, Technical University of Denmark, DK-2800 Lyngby, Denmark

Sulphoraphene *1*, isolated from radish seeds, yields a thiourea *3a* on controlled reaction with ammonia. Upon more severe treatment, *3a* undergoes intramolecular cyclization to the epimeric $(R)_S$-4-methylsulphinylmethyl-tetrahydropyrimidine-2-thiones, *4a* and *4b*. The absolute configurations of the latter are established by stereospecific synthesis of one of the reduced isomers, *5b*, starting from (*R*)-β-methionine *6*. The degree of asymmetric induction in the cyclization of *3a* is determined and the mechanism discussed. The *N*-phenyl (*3b*) and *N*-methyl thiourea (*3c*) undergo similar cyclizations.

2

Scheme 1.

Sulphoraphene ((*R*)-4-methylsulphinyl-3(*E*)-butenyl isothiocyanate) *1*,[1-3] derivable, by enzymic hydrolysis, from a glucosinolate (*cf.* Ref. 4) present in seeds of radish (*Raphanus sativus* L.),[1] possesses the notable property of being the first naturally derived compound that is optically active solely by virtue of an asymmetric sulphur atom. Upon prolonged treatment with alcoholic ammonia at 37°, sulphoraphene was converted by Schmid and Karrer,[1] its discoverers, into a levorotatory, crystalline compound, $C_6H_{12}N_2OS_2$, m.p. 219 – 220°, formulated as "sulphoraphene thiourea" *2*. We have investigated the structure and formation of this product and present the results.

When a chloroform solution of sulphoraphene, produced by enzymic hydrolysis of the glucosinolate fraction from radish seed extracts, was treated with ammonia-saturated methanol for 4 h at room temperature, the thiourea *3a*, m.p. 88 – 89°, was formed in an unexceptional reaction. Its composition and spectroscopical properties, including NMR-signals from its two vinylic protons, were in accord with the linear thiourea-structure *3a*.

Prolonged treatment of *3a*, or sulphoraphene itself, with methanolic ammonia, followed by repeated recrystallization of the product mixture, afforded an apparently homogeneous substance, possessing the properties previously attributed to "sulphoraphene-thiourea"[1] and, in fact, indistinguishable from the latter on comparison.* The composition, chemical properties, and spectroscopic characteristics all support the structure *4a*, or *4b*, for this product. With the multiple purpose of substantiating the proposed

structure, establishing its absolute configuration, and assessing the degree of asymmetric induction in the cyclization reaction, the cyclic sulphoxide was reduced to the monochiral sulphide *5a*, the enantiomer of which was synthesized, in a stereospecific fashion, from (*R*)-*β*-methionine *6* through the sequence of reactions shown in Scheme 3.

(*R*)-*β*-Methionine *6*, in its turn, was synthesized by Arndt-Eistert homologization [5,6] of (*R*)-*N*-phthaloyl-*S*-benzylcysteine [7] *9*, followed by dephthaloylation to (*R*)-*S*-benzyl-*β*-homocysteine [6] *8*, debenzylation, and, finally, S-methylation:

Production of (*R*)-*N*-phthaloyl-*S*-benzylcysteine *9* by phthaloylation of (*R*)-*S*-benzylcysteine, in acceptable yield and with stereochemical integrity, is not straightforward, however. The proposed application of *o*-carbethoxythiobenzoic acid for this purpose [9] failed in our hands, whereas heating of *S*-benzylcysteine with phthalic anhydride at 110° for 30 min [7,10] led to low yields of slightly racemized product. Adoption of the Nefkens procedure,[11] however, involving *N*-carbethoxyphthalimide, permitted the preparation, in 90 % yield and high optical purity, of amorphous *9*, easily converted into its crystalline methyl ester. The chain-lengthening *9*→*8* proceeded through a sequence of unexceptional steps, essentially according to directions in the literature.[6,12] Further processing of *8* into (*R*)-*β*-methionine *6*,[8] and thence into its methyl ester hydrochloride,[13] went smoothly, as did the ammonolysis of the latter, followed by $LiAlH_4$-reduction to the diamine *7*, characterized as its dipicrate. An attempt to circumvent the described sequence by subjecting the hitherto unknown methyl ester hydrochloride of (*R*)-*S*-benzyl-*β*-homocysteine to treatment with Na/NH_3, followed by MeI, in order to arrive directly at (*R*)-*β*-methionine amide, proved of no avail.

Known methods for converting 1,3-diamines, such as *7*, into tetrahydropyrimidine-2-thiones include thermolysis at 125 – 160° of dithiocarbamates, formed upon reaction with CS_2,[14,15] or,

alternatively, heating of the diamines at high temperature with thiourea [16] or thiocyanic acid.[17] In attempts to achieve ring-formation under milder conditions the reaction of aliphatic 1,3-diamines with thiocarbonyl chloride, a reaction apparently without literature precedent, was studied. Despite extensive variation of reaction conditions, yields never exceeded 27 % of the desired, cyclic products. On this background, it was unexpected to find the dithiocarbamate of (*R*)-1,3-diamino-4-methylthiobutane *7* undergoing quantitative and facile ring-closure in ethanol suspension at 25° to supposedly optically pure (*R*)-4-methylthiomethyl-tetrahydropyrimidine-2-thione *5b*, $[\alpha]_D$ −168°. The enantiomeric relationship of the latter to a repeatedly recrystallized, dextrorotatory, cyclic sulphide-thiourea of natural derivation was established by rotation measurements and mirror-image CD curves. On admixture, equal proportions of the enantiomers formed a lower-melting racemic compound.

A preparation of the cyclic sulphoxide, with $[\alpha]_D$ −65°, produced from sulphoraphene according to literature directions,[1] afforded on reduction an analytically pure, non-fractionated, cyclic sulphide-thiourea with the rotation value $[\alpha]_D$ +145°, consequently representing an optical purity of 86 %. Assuming optical purity of naturally derived sulphoraphene *1*, and steric stability of the chiral S-atom during treatment with ammonia, the observed rotation signifies the composition 93 % R_SS_C- (*4a*) and 7 % R_SR_C-isomer (*4b*) for the thiourea with $[\alpha]_D$ −65°. The previously reported rotation, $[\alpha]_D$ −72°,[1] hence represents a 88:12 composition of the same two diastereoisomers.

The rotation, $[\alpha]_D$ +24°, of the cyclic sulphide thiourea, obtained upon quantitative reduction of a non-fractionated mixture of cyclic sulphoxides, $[\alpha]_D$ −119°C, reveals an asymmetric induction of 14 % in the cyclization of the linear sulphoxide thiourea *3a*, with the (R_SS_C)-isomer *4a* being the predominant one. The combined experimental data permit calculations of the rotation values: $[\alpha]_D$ −54° and $[\alpha]_D$ −205° for the pure (R_SS_C)- (*4a*) and (R_SR_C)-isomer, *4b*, respectively.

The observed cyclization is hardly trivial. Intramolecular nucleophilic addition of a thiourea grouping across the double bond should expectedly yield 2-amino-1,3-thiazine-derivatives rather than, as observed, pyrimidine-2-thiones. Addition-elimination reactions, involving ammonia, can be ruled out in view of the following observations: (i) identical cyclization takes place thermally, in the presence or absence of ethanol, but considerably faster in soda glass than in Pyrex glass: (ii) cyclization proceeds rapidly in aqueous base; (iii) methylamine, instead of ammonia, causes *competitive* formation of linear adducts, *10a*, and *non-methylated*, cyclic diastereomers *11a*. A controlling experiment revealed no aptitude for the linear sulphoxide thiourea to react with extraneous thiourea.

12

Scheme 5.

A base-catalyzed, intramolecular attack of the terminal nitrogen at the vinylic β-carbon atom, accompanied or followed by protonation of the resulting α-sulphinylcarbanion, hence seems to be best in accord with the experimental results. It deserves attention that no cyclization is observed when the linear thiourea is treated with ammonia in chloroform solution. Hydrogen bonding, possibly *via* solvent bridges, between the sulphoxide and the reacting NH_2-grouping, as suggested in *12*, may conceivably be instrumental in facilitating and governing the cyclization reaction.

Noticeable stereoselectivity in kinetically controlled, nucleophilic additions to vinylic sulphoxides is not without precedent. Thus, additions of piperidine,[18] or diethyl malonate and ethyl acetoacetate [19] to vinylic sulphoxides have been shown to proceed with a considerable degree of asymmetric induction. Additional re-

sults from this laboratory [20] confirm and extend these results.

Cyclizations, as described above, also occur with terminally substituted thioureas. Thus, the phenylthiourea *3b*, obtained, as described,[1] from sulphoraphene *1* and aniline, undergoes cyclization on prolonged exposure to aniline in ethanol at 37° to give a mixture of diastereomers *11b*, $[\alpha]_D$ +12°, from which a supposedly homogeneous isomer, $[\alpha]_D$ +22°, was obtained after repeated recrystallizations. A similarly composed mixture was rapidly produced on heating the thiourea *3b* in ethanol at 80° in a soft glass vessel; in Pyrex glass, the reaction proceeded at a greatly diminished rate. With methylamine, under carefully controlled conditions, sulphoraphene affords the expected *N*-methylthiourea *3c*. This, on treatment with aqueous base or ethanolic ammonia, undergoes cyclization to a mixture of diastereomers, *11c*, from which an apparently homogeneous isomer could be obtained after several recrystallizations. Exposed to methylamine for a prolonged period of time, the *N*-methylthiourea affords, as with other bases, a mixture of two cyclized epimers *11c*, but in addition, another product mixture, *10b*, arising from competitive addition of methylamine across the double bond of the linear thiourea.

The observed reactions provide interesting synthetic perspectives which are presently being pursued in this laboratory.

EXPERIMENTAL

Melting points are uncorrected and determined in capillary tubes in a heated bath. Paper chromatography (PC) was conducted by the descending technique on Schleicher and Schüll paper 2043b, with the upper layer of the system BuOH:EtOH:H_2O (4:1:4) as the mobile phase.

Rotations are measured on a Perkin-Elmer 141 polarimeter; CD curves on a Jouan CD-185 Dicrographe. UV-Spectra are recorded on a Perkin-Elmer 402 spectrophotometer, IR spectra (in KBr when not otherwise indicated) on a Perkin-Elmer 421 grating instrument, and mass spectra on the Perkin-Elmer 270 mass spectrometer at 70 eV. ^{1}H NMR-Spectra are determined at 60 MHz or 100 MHz on Varian instruments, with TMS, or, for D_2O-solutions, the Na-salt of DSS as internal standards. ^{13}C NMR-Spectra are measured as proton-noise decoupled spectra on a Bruker WH-90 instrument with Fourier Transform pulse technique, and are reported as δ-values in ppm downfield from TMS.

Microanalyses were performed by Mr. G. Cornali and his staff.

Sulphoraphene 1. Commercial radish seeds (66 g) were finely ground and defatted by extraction with two 2 l portions of hot petroleum ether. The glucoside fraction was removed by boiling the residue with two 2 l portions of 70 % MeOH. MeOH was removed from the filtrate by concentration *in vacuo*, and the aqueous solution was diluted with 1 l of H_2O, filtered through Hyflo-Supercel, and extracted once with ether (200 ml) and once with $CHCl_3$ (200 ml). The organic phases were discarded. Residual organic solvents were removed *in vacuo*, and the aqueous solution was buffered at pH 6.5 by adding a saturated Na_2HPO_4 -solution. Enzymic hydrolysis was accomplished by adding a crude cell-free myrosinase solution (18 ml), produced from yellow mustard, and a few mg's of ascorbic acid. After being kept at 40° for 3.5 h, the solution was extracted with five 150 ml portions of $CHCl_3$. The combined extracts (800 ml), containing sulphoraphene *1*, were dried over Na_2SO_4 and used for production of the various thioureas described in the sequel.

(R)-1-(4-Methylsulphinyl-3(E)-butenyl)-thiourea 3a. An aliquot of the $CHCl_3$-solution of sulphoraphene (300 ml) was treated with MeOH (12 ml), saturated at 0° with NH_3, for 4 h at 25°. The solution was concentrated in vacuum to an oily residue.

Paper chromatography revealed the contents in this solution of one major (R_F 0.56) and two minor (R_F 0.51 and 0.39) thioureas, the latter of which represents the cyclized product(s) described below. The thiourea with R_F 0.51, present only in trace amounts, is believed to represent the saturated counterpart of the thiourea derived from sulphoraphene, *i.e.* (*R*)-1-(4-methylsulphinylbutyl)-thiourea, on the basis of coinciding chromatographic behaviour in three solvent systems with an authentic specimen. Undoubtedly, this thiourea derives from sulphoraphane originating from trace amounts of the saturated glucosinolate, known from other sources,[21] in radish seeds.

The crude thiourea mixture was chromatographed on a silica gel column (60 g), with $CHCl_3$, containing a gradient of EtOH from 0 to 10 %, as the eluent. The thiourea-containing fractions, revealed by the production of a blue colour with Grote's reagent, were combined and evaporated to dryness (118 mg). The crystalline residue was recrystallized twice from MeOH:Et_2O to give an analytical specimen of *3a* as colourless crystals, homogeneous on chromatography, m.p. 88–89°; $[\alpha]_D^{22}$ −70° (*c* 0.7, H_2O) (Found: C 37.28; H 6.34; N 14.27. Calc. for $C_6H_{12}N_2OS_2$: C 37.47; H 6.29; N 14.57). Spectroscopic characteristics: UV: λ_{max} (EtOH) 243 nm (ε 15 000), 205 nm (13 740); IR: 3210 (vs), 3110 (vs), 1645 (vs,) 1540 (vs), 1450 (m), 1410 (m), 1350 (m), 1318 (s), 1295 (s), 1270 (s), 1195 (s), 1130 (s), 1060 (w), 1030 (vs), 963 (m), 950 (s), 818 (m), 765 (s), and 690 cm^{-1} (s). MS: *m/e*

192 (M^+). ^{1}H NMR ,in $(CD_3)_2SO$: δ 2.4 (2 H, m), 2.61 (3 H, s), 3.4 (2 H, m), 6.35 (1 H, dt, J 16 and 7 Hz), 6.75 (1 H, d, J 16 Hz), and 7.1–7.9 ppm (3 H, exchangeable).

In keeping with its structure as a vinylic thioether, *3a* decomposes readily in acid to give MeSH.

C-Epimers of 4-((R)-methylsulphinylmethyl)-tetrahydropyrimidine-2-thione, 4a and 4b. A solution of the linear thiourea *3a* (55 mg) in EtOH (5 ml), to which was added a saturated EtOH-solution of NH_3 (3 ml), was kept for 8 days at 40°, when PC revealed virtually complete transformation of *3a* (R_F 0.56) into a new type of product (R_F 0.39). Trace amounts of starting material and more polar by-products were removed by chromatography on a silica gel column (10 g), with EtOAc:MeOH (1:1) as the eluent. The chromatographically homogeneous epimer mixture (40 mg), $[\alpha]_D^{23}$ −119° (*c* 1.1, H_2O), was subjected to five recrystallizations from MeOH:Et_2O to give what is supposedly the almost homogeneous (R_SS_C)-epimer *4a*, m.p. 223–224°, $[\alpha]_D^{25}$ −61° ±4° (*c* 0.4, H_2O). (Found: C 37.63; H 6.34; N 14.31; S 33.02. Calc. for $C_6H_{12}N_2OS_2$: C 37.47; H 6.29; N 14.57; S 33.34). Spectroscopic characteristics, UV: λ_{max}(EtOH) 247 nm (ε 15 500), 208 nm (11 100); IR: 3300 (s), 3200 (vs), 1550 (vs), 1510 (vs), 1460 (m), 1430 (s), 1355 (s), 1335 (s), 1320 (s), 1260 (m), 1230 (m), 1195 (vs), 1180 (s), 1105 (w), 1065 (m), 1025 (m), 998 (vs), 963 (s), 938 (m), 920 (w), 892 (w), 872 (w), 832 (w), and 705 (br.) cm^{-1} MS: *m/e* 192 (M^+). ^{1}H NMR, in $(CD_3)_2SO$: δ 1.9 (2 H, m) (C-5), 2.61 (3 H, s), 2.95 (2 H, d, J 6.5 Hz) (−S(O)CH_2)−, 3.2 (2 H, m) (C-6), 3.75 (1 H, m) (C-4), and 7.8–8.1 ppm (2 H, exchangeable).

No methanethiol was produced on heating the epimer mixture with acid.

In contrast to the above described behaviour, a *chloroform* solution of the linear thiourea *3a*, saturated with NH_3, underwent no changes within 30 days at 25°, as estimated from PC.

Though unchanged in aqueous solution after 4 weeks, the thiourea *3a* undergoes quantitative cyclization in less than 30 min in 0.5 M NaOH at 25° to a mixture of the epimers, *11a*.

In ethanolic $MeNH_2$, *3a* reacts to a mixture of products within 1 h at 25°. Separation by preparative TLC on silica gel (eluent MeOH) affords a more lipophilic fraction (60 %), m.p. 195–203°, identified as the mixture *11a*, and a more polar, basic component (40 %), yielding a red colouration with ninhydrin. This very hygroscopic material possesses spectroscopical characteristics supporting its identity as a mixture of adducts, *10a*. UV: λ_{max}(EtOH) 245 nm ($\varepsilon \sim 10^4$); ^{1}H NMR (in CD_3OD): δ 1.8–2.0 (2 H, m) (−C−CH_2−C), 2.41 and 2.43 (3H, 2s) (CH_3−NH−C−, in the epimers, *10a*), 2.73 (3 H, s) [MeS(O)], 2.8–3.2 (2 × 2 H, m) [−S(O)-CH_2− and −CH_2−NH−], 3.5–3.7 (1 H, m) [−C*H*(NHMe)−], and 4.73 ppm (*ca.* 3 H, s) (−NH and −NH_2) (the cyclized product *11c*, containing the Me−N−CS-grouping, should exhibit CH_3−N-absorption at δ 3.0–3.5 ppm [22]). The mixture of adducts remained unchanged on standing at 40° in ethanolic methylamine for 8 days, excluding its role as an intermediate in the production of the cyclic products.

Heating *3a* to 90° for 86 h in a capillary, made of soft glass, brings about extensive cyclization to *11a*. In Pyrex glass, very little cyclization is observed. Heating in EtOH at 80°, in soft glass, quantitatively converts *3a* into *11a* in the course of 63 h.

(R)-S-Benzyl-N-phthaloylcysteine methyl ester. *(R)-S*-Benzylcysteine (22.6 g) and Na_2CO_3. $10H_2O$ (32.7 g) were dissolved in hot water (175 ml). After cooling to 25°, *N*-carbethoxyphthalimide [11] (26 g) was added. After 1 h, the solution was acidified with 6 N HCl, when a colourless syrup separated. Next day, $CHCl_3$ (400 ml) was added, and unreacted *S*-benzylcysteine (2 g) was removed by filtration. The filtrate was extracted with three 75 ml portions of water to remove most of the unreacted urethan. After drying and removal of $CHCl_3$, a colourless syrup remained, consisting of *(R)-S*-benzyl-*N*-phthaloylcysteine *9* (34.7 g, 90 % yield, on the basis of non-recovered starting material) with a maximum content of 10 % urethan according to ^{1}H NMR-analysis. This product, $[\alpha]_D^{25}$ −154° (*c* 1, MeOH) [reported:[7] $[\alpha]_D^{25}$ −167° (*c* 0.6, MeOH)], was used for the subsequent synthesis without further purification.

The above acid (66 mg), dissolved in Et_2O (3 ml), was treated with excess CH_2N_2. Next day, the solvent was removed and the crystalline methyl ester was recrystallized thrice from MeOH before analysis, m.p. 66°, $[\alpha]_D^{24}$ −162°. (*c* 0.8, C_6H_6). (Found: C 63.81; H 4.92; N 3.83. Calc. for $C_{19}H_{17}NO_4S$: C 64.21; H 4.82; N 3.94).

(R)-S-Benzyl-β-homocysteine 8. The above cysteine derivative *9* was converted into its acid chloride, $[\alpha]_D^{22}$ −140° (*c* 1.2, C_6H_6) [reported: $[\alpha]_D^{16}$ −136° [7]], and thence into the corresponding diazoketone, $[\alpha]_D^{23}$ −188° (*c* 0.3, C_6H_6) [reported for a benzene solvate: $[\alpha]_D^{16}$ −170° (*c* 0.4, C_6H_6) [7]], essentially as described.[6,7,12] Again, further processing of the latter into *(R)-S*-benzyl-*N*-phthalimido-homocysteine methyl ester, a syrup with $[\alpha]_D^{25}$ −59° (*c* 2, C_6H_6) [reported: m.p. 67°, $[\alpha]_D^{20}$ −80° (*c* 1.12, C_6H_6) [6]], the corresponding free acid, also a syrup, $[\alpha]_D^{22}$ −83° (*c* 2.3, C_6H_6) [reported: $[\alpha]_D^{14}$ −78° (*c* 1.8, C_6H_6) [6]], and *S*-benzyl-*β*-homocysteine *8*, m.p. 182–183° (dec.), $[\alpha]_D^{23}$ −58° (*c* 1.1, 1 N HCl) [reported: m.p. 173° (dec.),[6] $[\alpha]_D^{19}$ −57° (*c* 1.19, 1 N HCl),[6] m.p. 171–174° (dec.),[23] $[\alpha]_D^{23}$ −64° (*c* 1.16, 1 N HCl)[23]], took place with little deviation from the reported procedures.

(R)-S-Benzyl-β-homocysteine methyl ester hydrochloride. The amino acid above was converted into its methyl ester hydrochloride on treatment with anhydrous HCl in MeOH in the usual way. After two recrystallizations from MeOH/Et_2O an analytical sample was obtained,

m.p. 116–117°, $[\alpha]_D^{25}$ −37° (*c* 0.5, MeOH). (Found: C 52.00; H 6.64; N 11.68. Calc. for $C_{12}H_{18}NO_2SCl$: C 52.25; H 6.58; N 11.62).

(R)-β-Methionine amide hydrochloride. (*R*)-*S*-Benzyl-β-homocysteine, described above, was converted into (*R*)-β-methionine as reported,[8] in 79 % yield. Esterification with MeOH and anhydrous HCl yielded the hygroscopic (*R*)-β-methionine methyl ester hydrochloride, m.p. 86–87°, $[\alpha]_D^{25}$ −14.5° (*c* 0.8, H_2O) [reported: m.p. 88–90°, $[\alpha]_D$ −14.3° (*c* 5, H_2O) [13]]. On treatment of the ester hydrochloride (730 mg), dissolved in anhydrous MeOH (40 ml) saturated at 0° with dry NH_3, for 14 days at 5°, a quantitative yield of (*R*)-β-methionine amide hydrochloride was obtained. An analytical specimen was obtained by recrystallization from MeOH/Et_2O, m.p. 161–163°, $[\alpha]_D^{25}$ −2° ± 0.5° (*c* 1.1, MeOH), −17° (*c* 0.5, 2 N NH_3). (Found: C 32.52; H 7.05; N 14.48; S 17.56. Calc. for $C_5H_{13}N_2OSCl$: C 32.52; H 7.10; N 15.17; S 17.36).

(R)-1,3-Diamino-4-methylthio-butane 7. To the above amide hydrochloride (128 mg), suspended in anhydrous Et_2O (50 ml), was added $LiAlH_4$ (390 mg), and the mixture was refluxed for 26 h, when an additional amount of $LiAlH_4$ (100 mg) was added; the refluxing was continued for 45 h. After cooling, water-saturated ether, followed by a saturated solution of KNa-tartrate, were added to the reaction mixture. The combined ether extracts were dried over KOH. On evaporation, the diamine was obtained as a colourless syrup.

For characterization, the amine was converted into its crystalline dipicrate, recrystallized, before analysis, from MeOH/Et_2O, m.p. 185–186° (dec.), $[\alpha]_D^{25}$ +2.9° (*c* 0.6, MeOH), $[\alpha]_{546}^{25}$ +5.6° (*c* 0.6, MeOH). (Found: C 34.42; H 3.45; N 18.83; S 5.80. Calc. for $C_{17}H_{20}N_8O_{14}S$: C 34.46; H 3.40; N 18.91; S 5.41).

(R)-4-Methylthiomethyl-tetrahydropyrimidine-2-thione 5b. The above diamine, resulting from the reduction of β-methionine amide hydrochloride (118 mg), was dissolved in EtOH (5 ml). The solution was slowly added to a mixture of CS_2 (3 ml) and EtOH (5 ml). The suspension of the dithiocarbamate was stirred at 25° for 24 h when no more precipitate was present. Evaporation to dryness gave a crystalline residue, which, after treatment with charcoal in $CHCl_3$, was recrystallized twice from MeCN to give an analytical specimen, m.p. 178–179°, $[\alpha]_D^{25}$ −168° (*c* 0.5, $CHCl_3$). (Found: C 40.97; H 6.72; N 15.99; S 36.26. Calc. for $C_6H_{12}N_2S_2$: C 40.88; H 6.86; N 15.89; S 36.38). Spectroscopic characteristics: λ_{max}(EtOH) 249 nm (ε 14 800), λ_{max} (MeCN) 255 nm (ε 17 300), 222 nm (sh.); ^1H NMR in $CDCl_3$: δ 1.8–2.2 (2 H, m), 2.15 (3 H, s), 2.5–2.7 (2 H, m), 3.3–3.8 (2+1 H, m), and 6.9 (2 H, "s", exchangeable) ppm. ^{13}C NMR, in $CDCl_3$: δ 15.7 (CH_3-S-), 25.5 ($-C-CH_2-C$), 39.2 (or 39.7) ($-S-CH_2-$), 39.7 (or 39.2) ($-NH-CH_2$), 49.2 ($N-C(H)-C$), and 176.8 ($-N-CS-N$) ppm.

Reduction of cyclic sulphoxide(s) 11a. A cyclic sulphoxide fraction (21 mg), $[\alpha]_D^{23}$ −65° (*c* 1.0, H_2O), obtained by ammonia-induced cyclization of *3a* as described above, was dissolved in AcOH (7 ml). Solid $NaHCO_3$ (1 g) was added (to dispel dissolved O_2) and a 0.11 N $TiCl_3$-solution (5 ml) was added. After standing at 80° for 90 min, excess $TiCl_3$ was removed with 0.5 N $Fe^{III}NH_4$-sulphate (5 ml). Water was added to a volume of 30 ml and pH was adjusted to 7 with solid Na_2CO_3. The organic product was removed by extraction with $CHCl_3$ (3 × 30 ml). After drying, the combined extracts were evaporated to give a crystalline product (17 mg, 90 %), $[\alpha]_D^{27}$ +145° (*c* 0.7, $CHCl_3$), which, according to TLC, was homogeneous. After recrystallization from MeOH a product was obtained with m.p. 176–178°, $[\alpha]_D^{27}$ +142 (*c* 1.0, $CHCl_3$). On comparison, its MS-, ^1H NMR- and IR-spectrum (in $CDCl_3$) proved indistinguishable from those of the above described synthetic compound *5b*.

Upon two recrystallizations from MeCN, the reduced product afforded a crystalline fraction, m.p. 178–179°, $[\alpha]_D^{25}$ + 168° (*c* 0.6, $CHCl_3$), supposedly representing the homogeneous (*S*)-enantiomer *5a*.

On measuring the CD-curves in MeCN, the following $\Delta\varepsilon$-values were obtained:

λ nm	(*R*)-isomer *5b*	(*S*)-isomer *5a*
206	−8.3	+8.8
228	+1.1	−1.7
249	−1.2	+0.8
273	+0.33	−0.41

On mixing equal amounts of the enantiomers in $CHCl_3$ and recrystallizing the residue from MeCN, the racemic compound was obtained, m.p. 142–143°, $[\alpha]_D \sim 0°$.

Cyclization of the linear N-phenylthiourea 3b. When the phenylthiourea *3b* (34 mg), obtained from sulphoraphene and aniline,[1] was left in ethanol (5 ml), saturated with NH_3, for 24 h, it was converted into a chromatographically homogeneous, new product, $[\alpha]_D^{25}$ +12° (*c* 0.4, $CHCl_3$), which could be recrystallized from EtOH/Et_2O to constant rotation, m.p. 208–209°, $[\alpha]_D^{25}$ +22° (*c* 0.5, $CHCl_3$). (Found: C 53.66; H 6.24; N 10.19; S 23.74. Calc. for $C_{13}H_{16}N_2OS_2$: C 53.78; H 6.02; N 10.45; S 23.93). Spectroscopic data: λ_{max}(EtOH) 253 nm (ε 7 000), 238 nm (sh); ^1H NMR, in $CDCl_3$: δ 2.1–2.7 (2 H, m), 2.54 (3 H, s), 3.00 (2 H, "d"), 3.3–3.7 (2 H, m), 4.2–4.6 (1 H, m), 7.3–7.5 (5 H, m), and 7.9 (1 H, "s", exchangeable) ppm; MS: 268 (M^+).

The stability to alkali, blue colour with Grote's reagent, and absence of IR-absorption in the 1600–1650 cm^{-1} range,[24] all are in agreement with the structure *11b* for the cyclization product rather than the isomeric 1,3-thiazine isomer.

Heating an EtOH-solution of *3b* in a soda-glass tube at 40° brings about a slow conversion

into cyclic products; after 10 days, non-cyclized thiourea remains. At 80°, however, the cyclization reaction is complete within less than 24 h, whereas, in borosilicate glass, the greater part of the linear thiourea *3b* is unchanged after 5 days under the same conditions.

Cyclization of the linear N-*methylthiourea 3c.* To a $CHCl_3$-solution (45 ml) of sulphoraphene, arising from 32 g of radish seeds, 12 drops of a saturated solution of $MeNH_2$ in EtOH were gradually added, in the course of 3 h. The residue from evaporation of the mixture was chromatographed on a silica gel column, using first EtOAc:MeOH (9:1), later MeOH as the eluent. The Grote-positive fractions were evaporated to dryness to give a colourless syrup, homogeneous on PC (R_F 0.68) and giving the ^1H NMR-spectrum expected for the linear *N*-methylthiourea *3c*: (in $CDCl_3$): δ 2.4 – 2.8 (2 H, m), 2.70 (3 H, s), 3.02 (3 H, d), 3.74 (2 H, "q"), 6.4 – 6.6 (2 × 1 H, m) and 7.1 (2 H, "s", exchangeable) ppm.

The thiourea (57 mg) was kept at 20° for 48 h in EtOH, saturated with NH_3. The solid residue proved homogeneous on PC (R_F 0.48), After three recrystallizations from EtOH, a colourless, crystalline product (16 mg) m.p. 232 – 238°, $[\alpha]_D \sim -87°$ (*c* 0.2, MeCN), was obtained, giving a typical blue Grote-reaction and exhibiting spectroscopic characteristics in accord with the cyclic structure *11c*. UV: λ_{max}(EtOH) 248 nm (ε 10 000); MS: *m/e* 206 (M^+); IR: no absorption within the range 1610 – 1630 cm^{-1}; ^1H NMR: (in CD_3CN + 25 % D_2O): δ 1.9 – 2.3 (2 H, m) 2.71 (3 H, s) 3.0 – 3.5 (2 × 2 H, m), 3.39 (3 H, s), and 3.9 – 4.3 (1 H, m) ppm.

A similar product was obtained when the linear thiourea *3c* was kept at 25° in 0.5 N NaOH for 1 h.

When treated with ethanolic $MeNH_2$ at 25° for 2 h, the methylthiourea *3c* (23 mg) afforded two Grote-positive products, which were separated on a silica gel column, with MeOH as an eluent. The fastest moving component (11 mg) proved identical with the cyclic product(s) *11c* discussed above. The slower-moving product (4 mg) possessing an R_F-value of 0.39 in PC, was identified as the adduct(s) *10b*, mainly on the basis of its UV-spectrum, λ_{max}(EtOH) 243 nm, typical for a non-cyclic thiourea, its MS (*m/e* 223, M^+), and IR-spectrum. On prolonged treatment with $MeNH_2$ in EtOH, the adduct showed no signs of undergoing reaction as estimated from chromatographic analysis.

Acknowledgements. The authors are grateful to Miss A. Schuster for skillful technical assistance and to Dr. P. Laur for help in recording the CD-curves.

Conformations and ^{1}H NMR Spectra of 5-Alkoxy-, 5-Hydroxy-, and 5-Amino-Δ^2-1,2,3-triazolines

CARL ERIK OLSEN

Department of Organic Chemistry, Royal Veterinary and Agricultural University, DK-1871 Copenhagen, Denmark

^{1}H NMR spectroscopy (and in a single case X-ray results) shows that 5-alkoxy- and 5-hydroxy-Δ^2-1,2,3-triazolines prefer an envelope conformation with the hetero substituent at C-5 pseudo-axial at the flap and the N-1 substituent pseudoequatorial, probably due to the anomeric effect.

1-(*p*-Nitrophenyl)-5-amino-Δ^2-1,2,3-triazolines with $R^5 = H$ prefer the same conformation, but for $R^5 \neq H$ there seems to be more than one important conformation. In aminotriazolines steric effects, rather than the anomeric effect, seem to be dominating.

5-Amino-Δ^2-1,2,3-triazolines unsubstituted in the amino group have been prepared for the first time.

During ^{1}H NMR investigations on 5-hydroxy- and 5-amino-Δ^2-1,2,3-triazolines we observed that the chemical shifts of protons and methyl groups at C-4 depend in a characteristic manner on the orientation relative to the hetero substituent (X) at C-5. This was extensively used by us for assignments of relative configurations at C-4 and C-5 in both 5-hydroxy- and 5-amino-Δ^2-1,2,3-triazolines,[1-3] and subsequently by other authors [4] in some 5-dialkylamino-Δ^2-1,2,3-triazolines.

For all hydroxytriazolines and most aminotriazolines one observes that a *cis* * oriented proton (or methyl group) at C-4 resonates at lower field than that in *trans*. This may be due to a non-planar conformation of the triazoline ring. Thus with Δ^1-pyrazolines ring-puckering has been assumed to explain chemical shift differences for protons or methyl groups adjacent to the N=N double bond.[5-7] These differences have been proposed to stem from the different positions of the protons in the strongly anisotropic field due to the N=N bond.[8] The anisotropy of single bonds (C−C, C−H, and C−N) cannot be ignored, however, and we prefer to consider only the sum of these contributions, the total anisotropy of the ring. Quantitative calculations on this [9] (*cf.* Refs. 10−12) seems unjustified in view of the difficulties encountered even in simple hydrocarbons. The total effect seems to be consistent; a pseudo-axial proton or methyl group resonates at higher field than a pseudo-equatorial (henceforth abbreviated to axial and equatorial). By analogy the chemical shift differences of C-4 groups in Δ^2-1,2,3-triazolines might be due to folding of the ring system so as to shield the axial relative to the equatorial group.

A near planar ring probably represents an energy maximum due to eclipsing of the C-4 and C-5 substituents; however, the eclipsing energy may be smaller than in straight-chain hydrocarbons, since the small ring angles at C-4 and C-5 must result in larger distances between the interfering substituents. The preference of nitrogen (N-1) for being in the sp^3 state, rather than in the sp^2 state,[13] would further destabilize the planar structure. The planar conformation of cyclopentene represents an energy barrier of 0.6 kcal/mol [14] between the two equivalent folded conformations, but the barrier might well be higher in the triazolines.

Four non-planar ring conformations are possible (Fig. 1), and at room temperature they might equilibrate so fast as to give time-

* Used without specification *cis* and *trans* refer to position relative to X.

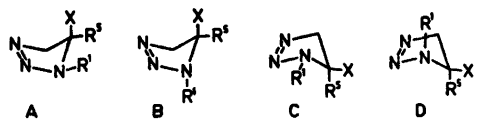

Fig. 1.

averaged NMR spectra. The factors that determine the preferred conformation may be divided into electronic effects, steric effects, and hydrogen bonding. The electronic effects include stabilization by conjugation in the triazene part of the ring. This does not necessarily involve strong preference for a planar arrangement of the ring atoms and R^1; but is should favor A and C over B and D, since in the lone-pair orbital of N-1 the *p* orbital component that is in a position to overlap with the N-2 *p* orbital is largest when the lone-pair is axial.[13]

The electronegativity of R^1 determines the electron density in the N-1 lone-pair orbital, which in turn must influence the degree of conjugation within the triazene part (*cf.* Ref. 15) and possibly also the interaction with X. This latter interaction is reminiscent of the anomeric effect (rabbit ear effect, dipolar effect [16–19]) and would act so as to favor conformation A. Other authors [20] have also suggested the operation of an anomeric effect between a hydroxy group and a nitrogen atom of a five-membered heterocylic ring. n-π Repulsive forces [21] between X and the N=N π-system would tend to place X equatorially.

Steric effects must play an important role. The interactions of the C-5 substituents with the N=N π-system are probably smaller than with the C-4 substituents, and the axial position of the larger C-5 group may thus be favored.

Interaction of R^1 with the C-4 substituents would be expected to favor an equatorial position of R^1, whereas its interaction with the C-5 substituents would favor an axial position, particularly if both C-5 groups are very bulky.

Hydrogen bonding between X and the N=N π-system [22] would favor an axial position of X.

The data used to solve the conformational problem include vicinal coupling constants, chemical shifts, and one X-ray structure. Most NMR data have been gathered from the literature; only the section on aminotriazolines contains mostly new NMR data.

5-Alkoxy-Δ^2-1,2,3-triazolines. The conformation of the triazoline ring in 5-alkoxytriazolines may be inferred from vicinal coupling constants. Table 1 reveals that the *cis* and *trans* coupling constants are very constant, being 7.0–7.5 Hz and 2.0–2.8 Hz, respectively. The small value of the *cis* coupling constant is not compatible with a planar triazoline ring, since J^0 would then be expected to be 13 Hz or larger, based on the *cis* coupling constant in 1-phenyl-4-carbomethoxy-Δ^2-1,2,3-triazoline (J_{cis} = 13.03 Hz, J_{trans} = 9.87 Hz [25]). Further, in a non-planar structure (Fig. 1) the alkoxy group cannot take the equatorial position (as in C or D), since this should give rise to a *trans* coupling constant much larger than 3 Hz, the dihedral angle being considerably larger than 120°. The alkoxy group must therefore occupy the axial position, and one or both of such conformations (A or B) predominate.

Three alkoxytriazolines deserve special mention. With Ic (Table 1) there is no *trans* coupling on which to base assumptions as to the

Table 1. ^{1}H NMR data of 1-(*p*-nitrophenyl)-5-alkoxy-Δ^2-1,2,3-triazolines ($CDCl_3$).

	R^4_{cis}	R^4_{trans}	R^5	X	R^4_{cis}	R^4_{trans}	J_{cis} [a]	J_{trans} [a]	Ref.

Ie	H	H	Me	OEt	4.72	4.19			23

[a] J_{cis} is the coupling constant between R^4_{trans}=H and R^5=H, J_{trans} that between R^4_{cis}=H and R^5=H.

conformation. The degree of ring folding seems nevertheless to be approximately the same in Ic as in Ia or Ib, as judged from the nearly identical *cis* vicinal coupling constants.

In Id conformation C would be expected on steric grounds, since here both R^1 and R^4_{trans}=Me are equatorial. However, even here X and consequently also R^4_{trans} must be preferentially axial, the *trans* coupling constant being only 2.0 Hz. Hence the axial position of R^4_{trans}=Me does not seem to be particularly unfavorable or, alternatively, the tendency of X to be axial must be very strong. The axial position of R^4_{trans} is best compatible with an equatorial position of R^1, *i.e.* Id presumably adopts conformation A.

In the triazoline [23] prepared from *p*-nitrophenyl azide and 3,4-dihydro-2H-pyran we have measured the coupling constants of R^4_{trans}=H with the two adjacent methylene protons of the tetrahydropyran ring to be 5.4 and 2.8 Hz. This indicates a *gauche* relationship to both methylene protons, which in turn implies that the oxygen atom at C-5 is axially oriented, if the tetrahydropyran ring is to adopt the usual chair conformation. The *cis* vicinal coupling constant between R^4_{trans}=H and R^5=H is 7.1 Hz, *i.e.* of the same magnitude as for the examples in Table 1.

Chemical shifts of the C-4 protons in the 1-*p*-nitrophenyltriazolines clearly distinguish a *cis* (4.61 – 4.72 ppm) from a *trans* proton (4.19 – 4.29 ppm).

In all discussed examples conformation A seems to predominate at equilibrium. Since the chemical shift between the C-4 protons is not diminished by the introduction of a methyl group at C-5 (Ie), conformation A seems to be favored by an anomeric effect rather than by steric effects involving the C-5 substituents. Unfortunately, two experiments designed to verify this were inconclusive. Thus the conformation (or predominating conformation) of Ia seemingly did not change on going from $CDCl_3$ to the much more polar solvent acetonitrile, the coupling constants remaining largely unaltered (7.9 and 2.9 Hz). Also, reduction of the nitro group in Ia to an amino group did not lead to a change in coupling constants or chemical shift difference between the C-4 protons (NMR data for the reduced compound: 4.42 and 4.10 ppm; 7.5 and 2.8 Hz). Both experiments suggest that the degree of folding of the triazoline ring remains the same.

5-Hydroxy-Δ^2-1,2,3-triazolines. An X-ray crystallographic investigation [26] on 1,4-dimethyl-5-ethyl-5-hydroxy-Δ^2-1,2,3-triazoline confirmed that there was a significant degree of conjugation within the triazene chain, as evidenced by a substantial shortening of the N-1···N-2 bond (1.357 Å as opposed to 1.44 Å for a normal N – N single bond [27]). In spite of this the triazoline ring was strongly puckered, the angle between the plane containing N-1, N-2, N-3, and C-4 and that defined by C-4, C-5, and N-1 being 27.5°. The molecule adopted conformation A, the OH group being axial and R^1 equatorial. Of course, the conformation is not necessarily the same in solution and crystal, even when there are no exceptionally strong interactions between the individual molecules. But it is presumably the more common and has often been assumed by other authors (*cf.* references given in Refs. 17 and 28).

Unfortunately, data for vicinal coupling constants in hydroxytriazolines are not available, since hydroxytriazolines with R^5=H are unknown. However, support for a puckered triazoline ring may be obtained indirectly from the coupling constants of R^4_{cis}=H in 4,5-tetramethylene-5-hydroxy-Δ^2-1,2,3-triazolines.[1,2] The cyclohexane ring is likely to adopt a chair conformation, thus excluding a planar structure of the triazoline ring. The chair conformation may be attained in two ways, as shown in Fig. 2. The coupling constants between R^4_{cis}=H and the adjacent methylene protons of the cyclohexane ring are 7.2 and 10.2 Hz for R^1 being methyl or benzyl; for R^1 being phenyl they are 7.2 and 8.5 Hz. These coupling constants may easily be interpreted in terms of conformation E and are incompatible with conformation F, which should give coupling constants below 6 Hz,[29] these dihedral angles being around 60°. Since R^1 (methyl or benzyl) has the same chemical shift in these molecules as in those where R^4_{trans} is

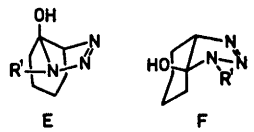

Fig. 2.

not part of a cyclohexane ring (the same applies to pyridine solvent shifts for R^1 and R^4_{cis}),[1,2] the conformation is probably the same in all these cases, *i.e.* puckered in such a way as to place the hydroxy group axially.

Also chemical shift data, and particularly their systematic variations with substituents, provide evidence for a non-planar conformation in solution. The effect on equal substituents at C-4 of changing R^1 (Table 2) would not be

Table 2. Chemical shifts of methyl groups at C-4 in 4,4-dimethyl-5-hydroxy-5-isopropyl-Δ^2-1,2,3-triazolines ($CDCl_3$).[1,2]

R^1	R^4_{cis}=Me	R^4_{trans}=Me
Me	1.52	1.13
Benzyl	1.55	1.21
p-NH_2-Ph	1.60	1.29
p-MeO-Ph	1.60	1.30
Ph	1.58	1.33
p-Br-Ph	1.58	1.33
p-NO_2-Ph	1.56	1.44

understandable on the basis of a planar arrangement of the ring and N-1···R^1 bond. R^4_{cis}=Me is seen to be largely unaffected, whereas R^4_{trans}=Me varies monotonically with the electronegativity of R^1. This variation is probably caused by electronic effects, possibly involving the N-1 lone-pair, since steric variations in R^1 are negligible, at least in the aromatic series.

The remarkably constant chemical shift of R^1=Me in 1-methyl-5-hydroxy-Δ^2-1,2,3-triazolines (3.26 ± 0.02 ppm, unless R^5 is particularly bulky (Bu^t) or anisotropic (Ph)[1,2] points to a constant conformation of the ring in these triazolines. Again, this conformation cannot be planar, since this would involve eclipsing of vicinal alkyl groups in the cases where R^4_{trans} is methyl. In addition, the insensitivity of the chemical shift of R^1 to variations in the C-4 substituents indicates that R^1 is well separated from these. This is also supported by the fact that the equilibrium position between diastereomeric hydroxytriazolines ($R^4_{cis} \rightleftharpoons R^4_{trans}$) is rather indifferent to the steric requirements of R^1.[1,2] Therefore R^1 must be equatorially disposed, and conformation A is most probable on the reasonable assumption that the OH group is axial.

The effect of varying the size of R^5 is shown in Table 3. The constant chemical shift of R^4_{cis}=Me is yet another indication that the triazoline ring has a constant conformation.

Table 3. Chemical shift variations in some 1,4-dimethyl-5-hydroxy-Δ^2-1,2,3-triazolines as a function of R^5.[1,2]

R^5	R^4_{cis}=Me	R^4_{trans}=H	R^1=Me
Me	1.44	3.63	3.27
Et	1.44	3.78	3.24
Pr^i	1.44	3.84	3.24
Bu^t	1.41	4.10	3.37

The fact that R^4_{trans}=H is influenced by the steric requirements of the proximate R^5 is quite reasonable (*cf.* Ref. 30).

In summary, conformation A seems to predominate with hydroxytriazolines in solution. We propose the anomeric effect to be responsible for this. The fact that R^5 is larger than the OH group does probably not stabilize conformation A. Intramolecular OH···π bonding[22] is also presumed to be of minor importance. The free OH stretching frequency is rather low (3580 − 3595 cm^{-1} in $CHCl_3$, as opposed to the normal 3625 cm^{-1} [22]), but this may well be due to the nitrogen atom attached to C-5. The intensity of the free OH band varies with the concentration, thus excluding any exceptionally strong OH···π interaction;[21] the puckering of the ring is probably too small.[22] The occasional appearance of the OH stretching frequency as a doublet or asymmetric band is probably better explained in terms of rotational isomerism around the C-5···O bond.[31]

With regard to the conformation at the N-1···R^1 bond, it was observed that the diastereotopic benzylic protons in 1-benzyl-5-hydroxy-Δ^2-1,2,3-triazolines appeared in two

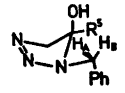

Fig. 3.

ranges, 4.6 – 4.7 ppm and 4.8 – 5.0 ppm, provided that $R^5 \neq Ph$. This is consistent with conformation A. Of the three possible rotational isomers the one with the benzylic phenyl group pointing away from R^5 and OH (Fig. 3) is most likely, and the observed shielding by $R^5 = Ph$ of the benzylic proton that normally resonates most downfield suggests that this is the one located nearest R^5, namely B. The normal shielding of proton A relative to proton B is most likely due to its position in a shielding region of the triazoline ring rather than to an effect from the benzylic phenyl group.[32] The pyridine induced solvent shifts of protons A and B[2] are also consistent with this model. Thus the shift of proton A is very constant for different R^5 groups, whereas the shift of proton B is strongly dependent on R^5, being small when R^5 is large (Ph or Bu^t).

5-Amino-Δ^2-1,2,3-triazolines. In order to elucidate the conformation of 5-aminotriazolines, we have prepared series of homologous triazolines where the C-4 and C-5 substituents are varied systematically while R^1 is kept constant (*p*-nitrophenyl). In this connection triazolines with an unsubstituted amino group have been prepared for the first time.

Pertinent ^{1}H NMR data, measured by us or gathered from the literature, are presented in Tables 4 and 5. Assignments of signals are based on trends within homologous series in conjunction with considerations on equilibria positions [1] as well as on absolute δ-values.

As with the alkoxytriazolines, the small *trans* coupling constants (3.0 – 3.4 Hz, Table 4) suggest that X is preferentially axial, even though this also places R^4_{trans} axially, irrespectively of its being H, Me, or Et. This is only compatible with R^1 being equatorially oriented, as in conformation A (*cf.* the section on alkoxytriazolines).

Informations may also be obtained from aminotriazolines fused with a cyclohexane ring. For $X = NH_2$ (IIIp, Table 7 in the experimental part) $R^4_{cis} = H$ couples with the adjacent methylene protons with identical coupling constants of 6.2 Hz; for $X = NMe_2$ (IIIq) these are 5.0 and 3.1 Hz. This suggests that, compared with the corresponding hydroxytriazolines, a larger fraction of molecules with equatorial X is present.

Chemical shifts also provide information on the conformation of aminotriazolines. δ-Values for C-4 protons in triazolines where $R^4_{cis} = R^4_{trans} = H$ (R^5 is an alkyl group) are particularly informative and have been summarized in Table 6. The rule that R^4_{cis} resonates at lower field than R^4_{trans}, generally followed by the hydroxytriazolines, is not valid for the aminotriazolines (see values marked * in Table 6).

If the difference in chemical shift of the C-4 protons were due to deshielding of $R^4_{cis} = H$ by the lone-pair of the amino group, as postulated by other authors,[4] assuming a planar geometry of the triazoline ring, it is difficult to explain why the *cis* proton resonates at highest field in the starred triazolines in Table 6. Also the fact that it is $R^4_{trans} = H$, and not $R^4_{cis} = H$, that suffers the greatest change when the size of the amino group is varied, remains unexplained. Thus for

Table 6. Chemical shifts for R^4_{cis}=H and R^4_{trans}=H in 1-(*p*-nitrophenyl)-5-alkyl-5-amino-Δ^2-1,2,3-triazolines (*cf.* Table 5).* Exceptions from the rule that R^4_{cis} resonates at lower field than R^4_{trans} (*cf.* text).

R^5	R^4	X=NH_2	X=NHMe	X=NMe_2
Me	*cis*	4.40*	4.50	4.68
	trans	4.40*	4.18	3.94
Et	*cis*	4.34*	4.40	4.58
	trans	4.46*	4.25	3.96
Pr^i	*cis*	4.18*	4.27*	4.37
	trans	4.50*	4.27*	4.18

R^5=Me one observes a 0.46 ppm upfield shift for R^4_{trans}=H but only a 0.28 ppm downfield shift for R^4_{cis}=H on proceeding from X=NH_2 to X=NMe_2. The presence of lone-pairs on X is seemingly not essential for this. Quite analogous effects are observed on increasing the size of R^5, the proton *trans* to R^5 here suffering a large upfield shift and the other a smaller downfield shift.

Deshielding of the *cis* proton by the lone-pair(s) on X is clearly inadequate to explain these observations, and, also, the effect of hydroxy or amino groups on vicinal protons is not at all clearcut. Admittedly, there are examples of even very large deshieldings of this sort, but this requires either extreme steric compression [33] or that a lone-pair points directly toward the affected proton.[34] In fact, if the hetero group is freely rotating, it is more common that the *trans* oriented proton resonates at lowest field.[20,35–38]

It is more likely that the observed chemical shift variations are the result of conformational

changes. Rotational isomerism about the C-5···X bond (*cf.* Ref. 4) is one possibility, which would, however, also fail to explain, at least in a straightforward manner, the large shieldings experienced by a proton at C-4, when the C-5 group *trans* to it increases in size. We favor an explanation based on a variation in the equilibrium composition of conformations A, B, C, and D, and propose that a large C-5 substituent prefers the axial to the equatorial position, because it then avoids being *gauche* to both C-4 protons (*cf.* Ref. 7). This forces the C-4 proton situated *trans* to the C-5 group with the largest steric requirements into the axial position, where it will be shielded by the triazoline ring.

This picture explains the tendency of aminotriazolines with $R^5=H$ to adopt conformation A, and also the "*trans* shielding effect" exerted by an alkyl as well as an amino group at C-5. The anomeric effect, which seemed to determine the conformation of alkoxy- and hydroxytriazolines, would not account for these effects.

For R^5 being an alkyl group we have not been able to conclude which are the participating conformers. A and C are the most likely candidates, but the coexistence of B or D is also possible in view of the increasing steric congestion along the N-1···C-5 bond with increasing size of C-5 substituents.

EXPERIMENTAL

^1H NMR spectra were recorded on a JEOL JNM-C-60HL instrument, using TMS as internal standard. Chemical shifts (in $CDCl_3$ at magnet temperature, unless otherwise stated) are given as δ-values. AB systems were treated in a second order manner.[41] δ-Values for *p*-nitrophenyl groups are just the centers of the characteristic 'doublets'.

1-(p-Nitrophenyl)-5-ethoxy-Δ^2-1,2,3-triazoline (Ia) was prepared by dissolving 1.64 g of *p*-nitrophenyl azide in 8 ml of ethyl vinyl ether. After 11 days the product had separated in 99 % yield. After recrystallization from ethyl acetate the m.p. of the slightly yellowish crystals was 135 °C. (Found: C 50.77; H 5.23; N 23.80. Calc. for $C_{10}H_{11}N_4O_3$: C 50.86; H 5.12; N 23.72).

1-(p-Aminophenyl)-5-ethoxy-Δ^2-1,2,3-triazoline was obtained in quantitative yield by catalytic hydrogenation of Ia (0.356 g in 3 ml of methanol) for 1 h at 2.5 atm H_2 pressure, using PtO_2 (3 mg) as the catalyst. After treatment with activated carbon and crystallization from ether, yellow crystals of m.p. 71 – 76 °C were obtained. (Found: C 58.26; H 6.63; N 27.35. Calc. for $C_{10}H_{14}N_4O$: C 58.24; H 6.84; N 27.17).

1-(p-Nitrophenyl)-4,5-tetrahydropyrano-Δ^2-1,2,3-triazoline was prepared according to the literature.[23]

5-Hydroxy-Δ^2-1,2,3-triazolines have been described previously.[1,2]

5-Amino-Δ^2-1,2,3-triazolines are prepared by adding either *ca.* 0.3 g of liquid ammonia and 2 g of anhydrous sodium sulfate, 1.5 ml of 40 % aqueous methylamine, or *ca.* 0.5 g of dimethyl-

[a] Ethyl acetate-pentane was used for recrystallization. [b] Two isomeric triazolines were formed due to enamine formation in two directions;[40] only the shown triazoline was isolated in a pure state. [c] The reaction was carried out in chloroform in place of ether.

amine to a solution of 0.82 g of *p*-nitrophenyl azide and the appropriate aldehyde (*ca.* 100 % excess) or ketone (*ca.* 20 % excess) in 7 ml of diethyl ether. The mixture is allowed to stand at room temperature for the specified time (Table 7) in a stoppered flask.

If the product separates during the reaction, it is just filtered off, washed with pentane, and recrystallized from methanol; if not, the product will crystallize on removal of the solvent from the organic phase and triturating the residue with pentane. Recrystallization is performed, using methanol as solvent, until a constant melting point is obtained. Sodium sulfate used in conjunction with ammonia is first removed by dissolving the product in chloroform and filtering. Yields (referring to unrecrystallized product), melting points, and analyses are given in Table 7. The triazolines are yellow to brown. 5-Methylaminotriazolines in particular are often unstable and decompose on standing at room temperature.

The Reaction of 2-Phenyl-2-norbornene with Formaldehyde and Dimethylamine. Additional Evidence for the Occurrence of a 1,5-Hydride Shift during the Aminomethylation of a Strained Bicycloalkene Structure

KALLE MANNINEN and JUKKA HAAPALA

Department of Chemistry, University of Oulu, SF-90100 Oulu 10, Finland

Reaction of 2-phenyl-2-norbornene, with formaldehyde and dimethylamine in acetic acid, produced a mixture of compounds best explained by a 1,5-hydride shift in one intermediate step. The compounds in question were *N*-methyl-endo-3-phenyl-exo-2-norbornanemethylamine, *N*,*N*-dimethyl-endo-3-phenyl-exo-2-norbornanemethylamine, 1,1′-bis(endo-3-phenyl-exo-2-norbornyl)-dimethylamine, 1,1′-bis(endo-3-phenyl-exo-2-norbornyl)trimethylamine and endo-3-phenyl-exo-2-norbornanecarbaldehyde. *N*,*N*-Dimethyl-1-phenyl-7-nortricyclenemethylamine and *N*,*N*-dimethyl-3-phenyl-2-norbornene-2-methylamine, formed presumably by the elimination of a proton from the intermediate carbonium ion during the aminomethylation of 2-phenyl-2-norbornene were also identified. In addition, exo-3-dimethylaminomethyl-endo-2-phenyl-exo-2-norbornanol, most likely formed by the addition of water to the same carbonium ion, was found. The normal aminomethylation product of endo-3-phenyl-exo-2-norbornanecarbaldehyde, 2-dimethylaminomethyl-endo-3-phenyl-2-norbonanecarbaldehyde, was identified.

Aminomethylation of an alkene with formaldehyde and a sec. amine usually gives unsaturated amines or saturated amino alcohols.[1] The reaction leading to the unsaturated amine is explained by the assumption that carbonium-immonium-ion I, produced from an amine and formaldehyde, is first added to the double bond, followed by a transfer of a proton from the carbon atom adjacent to the double bond, to the nitrogen atom (Scheme 1).[2] The tert. amines isolated from the aminomethylation products of norbornene are, however, saturated [3,4] with the primary products being the sec. amines II and III and the aldehyde IV.[5] Furthermore, mass spectra of the reaction products of norbornene, formaldehyde and hexadeuteriodimethylamine indicate that deuterium shifts from the dimethyl group of dimethylamine to the norbornene ring.

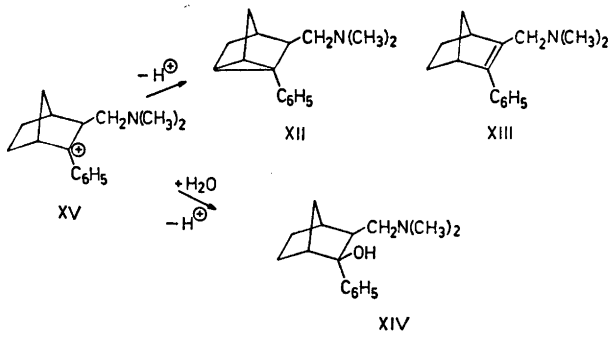
Based on this finding, the intermediate steps in the reaction of norbornene with formaldehyde and dimethylamine must involve the addition of the carbonium-immonium-ion (I) to the double bond and the shift of hydride ion to the norbornane ring (Scheme 2). The similarly derived products formed in a reaction sequence involving a 1,5-hydride shift and subsequent hydrolysis are the amine III and the aldehyde IV. This is readily seen by assuming that in Scheme 2 the ion I is replaced by the ion V. Furthermore, our recent investigation [5] revealed that the tert. amines, referred to above, which have previously isolated following aminomethylation [3,4] are Eschweiler-Clarke methylation products produced from the amines II and III.

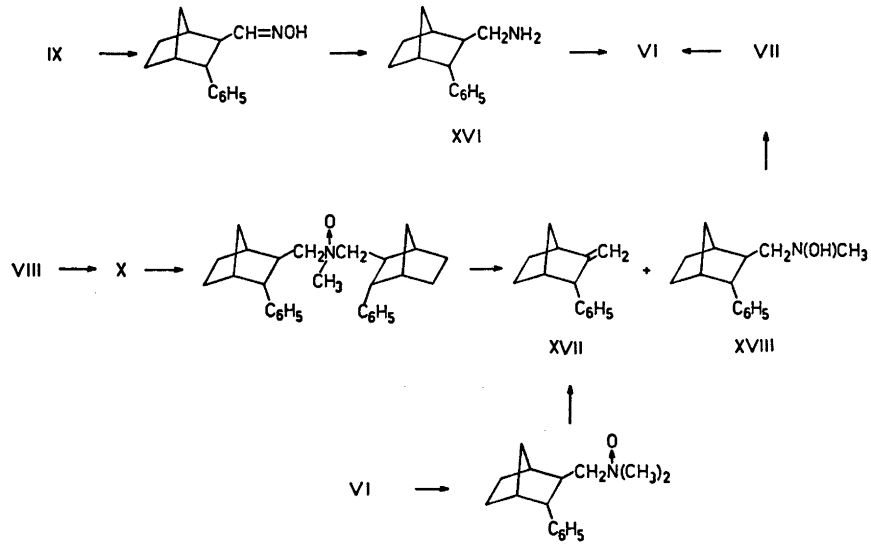
Since aminomethylation of 2-phenyl-2-norbornene yielded a saturated tert. amine as *N*,*N*-dimethyl-endo-3-phenyl-exo-2-norbornanemethylamine (VI), [6] it was of interest to determine if the phenyl substituted products VII, VIII and IX corresponding to the amines II and III and the aldehyde IV as well as X, the methylation product of VIII, are formed during the aminomethylation of 2-phenyl-2-norbornene. 2-Phenyl-2-norbornene was previously aminomethylated using a mol ratio of 1:4:1.5 (2-phenyl-2-norbornene:paraformaldehyde:dimethylamine), with dimethylamine in aqueous solution and the solvent, acetic acid, fortified by a catalytic amount of concentrated sulfuric acid. These conditions were changed so that the corresponding molar ratio was 1:1:1, dimethylamine was added as the hydrochloride, and the solvent was acetic acid without sulfuric acid. The previous reaction time of 16 h at reflux temperature, was decreased to 30 min at the same temperature. Dilution of the reaction mixture with an excess of water produced crystals which were collected by filtration and identified as the hydrochloride of VIII. The main product isolated by ether extraction of the acidic filtrate was the aldehyde IX. Neutralization of the acidic filtrate produced a mixture of six amines as indicated by gas chromatography. Three of these compounds were identified as the expected tert. amine VI, sec. amine VII and 2-dimethylaminomethyl-2-norbornanecarbaldehyde (XI). The latter is the conventional aminomethylation product of the aldehyde IX. Considering the results from the corresponding aminomethylation of norbornene,[5] the three remaining amines were unexpectedly a tricyclic amine XII, an unsaturated amine XIII, and an amino alcohol XIV. The amines XII and XIII are throught to be formed from the intermediate ion XV by the elimination of a proton and the amino alcohol XIV arises from the same ion by hydration (Scheme 3).



Scheme 3.

Since the structure of the tert. amine VI was previously verified [6] and its IR and NMR spectra were available, it appeared reasonable to identify VII, VIII and IX by converting them to VI. Therefore the aldehyde IX was converted to an oxime, which then was reduced with $LiAlH_4$ to the prim. amine XVI, and thereafter converted by methylation [7] to VI. The sec. amine VIII was methylated to X, which by Cope elimination [8] decomposed to a mixture of the known hydrocarbon XVII [9] and hydroxylamine XVIII. The reduction of XVIII with $LiAlH_4$ in ether produced the sec. amine VII, which by methylation yielded VI. The hydrocarbon XVII was prepared as a reference compound by Cope elimination. [9] The reactions which are proof for the structure of VII, VIII and XI are shown in Scheme 4. To confirm the structures of XII and XIII, the former was converted by Cope elimination to the tricyclic hydrocarbon XIX and its structure determined by mass and NMR spectra (Fig. 1). The latter (XIII) was hydrogenated to XX, which was converted by the Cope elimination to XVII (Scheme 5). The verification of the structure of XIV is based on comparison of the IR and NMR spectra of the compound prepared in another way.[10]

In another experiment with the molar ratio 1:4:2, 2-phenyl-2-norbornene, paraformaldehyde



Scheme 4.

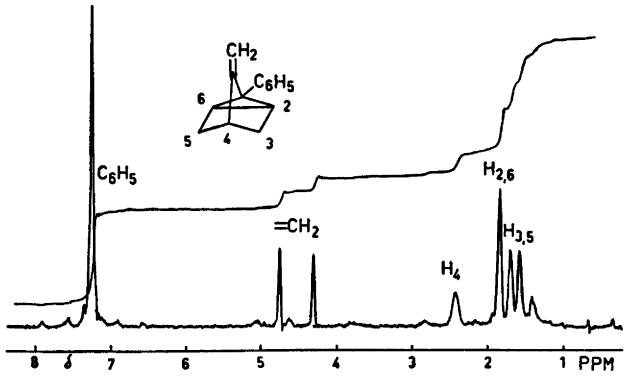


Fig. 1. NMR spectrum of 7-methylene-1-phenylnortricyclene (XIX).

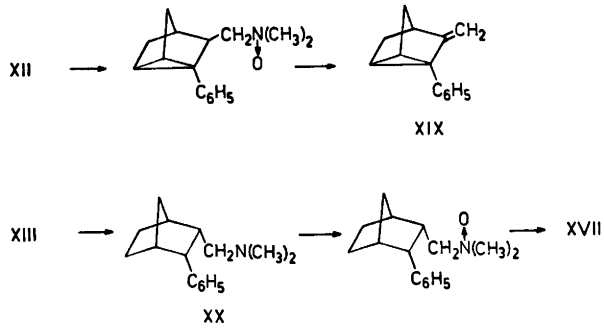

Scheme 5.

and dimethylammonium chloride were heated in acetic acid for 18 hours. Due to the excess of paraformaldehyde and long reaction time, one would expect VII and VIII to methylate to VI and X, respectively, under these conditions. Dilution of the crude reaction mixture with water yielded a compound identified as the hydrochloride of X. Analysis of the other amines indicated that the tert. amine VI was one of the major components. Among the other products were XI, XII and XIII, but gas chromatography indicated that the amino alcohol XIV was not present in the mixture. To ascertain the behavior of XIV during the aminomethylation, it was heated in acetic acid for 20 h. The mixture thus produced contained the same components as found after the aminomethylation of 2-phenyl-2-norbornene and, in addition, 2-phenyl-2-norbornene, therefore one could conclude that the formation of XIV in the aminomethylation of 2-phenyl-2-norbornene is a reversible reaction.

The results of this investigation indicate that the reaction of 2-phenyl-2-norbornene with formaldehyde and dimethylamine occurs to some extent by a similar intramolecular 1,5-hydride shift as was found to be the case with norbornene.[4,5] However, a number of other products not formed from norbornene, are produced either by the elimination of a proton from the ion XV or by the addition of water to the ion XV. The 1,5-hydride shift can explain the formation of the amines VII and VIII and the aldehyde IX. VI and VIII are most likely the Eschweiler-Clarke methylation products of the amine VII and VIII, respectively. The amino aldehyde XI seems to be formed by direct aminomethylation of the aldehyde IX. Removal of a proton from the ion XV gives either a tricyclic amine XII or an unsaturated amine

XIII, and the addition of water to XV leads to the amino alcohol XIV.

In another investigation using the deuterated compounds, we will show that the Eschweiler-Clarke methylation of amines VII and VIII under the conditions of aminomethylation gives among the tert. amines VI and X also cleavage products whose existence is explained by the 1,3-hydride shift.[11]

EXPERIMENTAL

Reaction of 2-phenyl-2-norbornene with formaldehyde and dimethylammonium chloride in acetic acid (the shorter reaction time). 2-Phenyl-2-norbornene (0.2 mol) prepared by dehydration of the alcohol obtained from 2-norbornanone and bromobenzene [6] by Grignard reaction, paraformaldehyde (6.2 g, equivalent to 0.206 mol formaldehyde) and dimethylammonium chloride (0.2 mol) were heated in acetic acid (60 ml) at 115°C for 30 min. Water (300 ml) and ethyl ether (50 ml) were added to the reaction mixture and the VII-hydrochloride which formed was collected by filtration, recrystallized from ethyl alcohol (yield 11.0 g) and characterized as shown later.

The ether layer from the filtrate was separated and the acetic acid-water layer extracted three times with small amounts of ether. The combined ether solutions containing neutral reaction products were freed of acid by washing with a dilute potassium carbonate solution and water, and then dried with calcium sulphate. The acetic acid-water layer from the filtrate was made alkaline with solid potassium carbonate, the freed amines were extracted by ether and the ether extract dried with anhydrous potassium carbonate.

Evaporation of the ether extract of the neutral solution left a residue of 11.5 g, which was distilled in a vacuum. The first fraction, b.p. 105 – 115°C/0.05 Torr, yield 8.85 g, contained 13 % biphenyl and 8 % 1-phenylnortricyclene, which were transported as impurities from the starting material, and 79 % endo-3-phenyl-exo-2-norbornanecarbaldehyde (IX) (see the structure interpretation of IX on the following pages). Fraction 2, b.p. 120 – 220°C/0.05 Torr, yield 1.2 g, was not examined closer.

The ether extract containing free amines, was evaporated until dry and the residue distilled in a vacuum. The fraction boiling at 120 – 150°C/0.05 Torr, yielded 14.5 g and contained according to gas chromatography 6 % of the tricyclic amine XII, 12 % of the unsaturated amine XIII, 11 % of the tert. amine VI, 36 % of the sec. amine VII, 7 % of the amino aldehyde XI, and 28 % of the amino alcohol XIV. The structure interpretations of these compounds are presented in a separate chapter.

Reaction of 2-phenyl-2-norbornene with an excess of formaldehyde and dimethylammonium chloride in acetic acid (the longer reaction time). 2-Phenyl-2-norbornene (0.25 mol), paraformaldehyde (33 g, equivalent to 1.1 mol formaldehyde) and dimethylammonium chloride (0.5 mol) were heated in acetic acid (170 ml) at 110 – 120°C for 18 h. Water (1500 ml) and ether (200 ml) were added to the reaction mixture and the X-hydrochloride, which formed, collected by filtration and recrystallized from ethyl alcohol (yield 6.6 g). The neutral products and amines were isolated as described earlier.

The neutral products (15.0 g), which boiled at 120 – 150°C/0.1 Torr contained endo-3-phenyl-exo-2-norbornanecarbaldehyde (IX) as a main component. Other components in this fraction (more than ten by gas chromatography) were not indentified.

The isolated free amines were distilled (b.p. 95 – 98°C/0.04 Torr, yield 20.6 g) and analyzed by gas chromatography. The distillate contained 8.5 % of the tricyclic amine XII, 15 % of the unsaturated amine XIII, 76 % of the tert. amine VI and 0.5 % of the amino aldehyde XI. *N,N*-Dimethyl-endo-3-phenyl-exo-2-norbornanemethylamine (VI) was isolated by using preparative gas chromatography, and its NMR and IR spectra were compared to the corresponding spectra of VI, which were available from the synthesis of VI by known methods.[6]

Endo-3-phenyl-exo-2-norbornanecarbaldehyde (IX) and its structure interpretation. The aldehyde obtained in the aminomethylation of 2-phenyl-2-norbornene (shorter reaction time) was purified according to Frisch [12] by its bisulphite adduct. From 6 g of the adduct was recovered 3 g of IX, b.p. 111 – 112°C/0.2 Torr, n_D^{20} 1.5547, $C_{14}H_{16}O$ (200.27). Mass spectrum: M^+ *m/e* 200 (23 %) with the base peak at *m/e* 43 (100 %). NMR spectrum (in CCl_4): δ 9.68 (1 H) doublet, $J = 1 - 2$ cps (formyl proton), 7.18 (5 H) singlet (phenyl protons), 3.60 and 3.50 (1 H) two doublets (C-3 exo-proton), 2.70 – 2.38 (3 H) a broad signal (C-2 and the bridgehead protons) and 1.77 – 1.07 ppm (6 H) a broad signal (the other protons). In the IR spectrum (in CCl_4) there was a C=O absorption at 1722 cm^{-1}. The semicarbazone of IX melted at 184 – 186°C (recrystallized from ethyl alcohol). To further confirm the structure of IX, it was converted to an oxime, which was reduced without purification with $LiAlH_4$ in ether to endo-3-phenyl-exo-2-norbornanemethylamine (XVI). XVI was distilled in a bulb tube oven at 110 – 113°C/0.02 Torr. $C_{14}H_{19}N$ (201.30). Mass spectrum: M^+ *m/e* 201 (1 %) with the base peak at *m/e* 31 (100 %). NMR spectrum (in C_6D_6): δ 7.22 (5 H) a singlet (phenyl protons), 2.60 (1 H) a broad signal having a shoulder (C-3 exo-proton), 2.47 (1 H) a doublet, $J = 7$ cps (methylene protons of the aminomethyl group), 2.30 and 2.12 (2 H) two broad signals (the bridgehead protons), 1.84 – 1.52 (1 H) three broad signals (C-2 endo proton) and 1.52 – 0.88 ppm (6 H) the other protons of

the norbornane structure. In the IR spectrum (on film) weak NH_2 absorptions at 3380 and 3470 cm^{-1} were seen. The amine XVI was methylated with formaldehyde in formic acid as described by Cope *et al.*[7] to a tert. amine, whose NMR and IR spectra were similar to those of the previously mentioned *N,N*-dimethyl-endo-3-phenyl-exo-2-norbornanemethylamine (VI).

N-Methyl-endo-3-phenyl-exo-2-norbornanemethylamine (VII) and exo-3-dimethylaminomethyl-endo-2-phenyl-exo-2-norbornanol (XIV). The previously described amine mixture (9.5 g) obtained by aminomethylation of 2-phenyl-2-norbornene (shorter reaction time) and aqueous potassium hydroxide (20 %, 60 ml) were placed in a flask and to this mixture was added gradually *p*-toluenesulphonyl chloride (2.8 g). The contents of the flask were heated for half an hour and the reaction products extracted by ether. The ether solution was extracted with dilute aqueous hydrochloric acid and water, then dried with calcium sulphate. After evaporation of the solvent, the viscous residue (3.4 g) was recrystallized from ethyl alcohol. *N*-Methyl-endo-3-phenyl-exo-2-norbornanemethylamine *p*-toluenesulphonamide, $C_{22}H_{27}NSO_2$ (369.50) mass spectrum M^+ *m/e* 369, was hydrolyzed according to Snyder *et al.*[13] by heating in 47 % hydrobromic acid in the presence of phenol. *N*-Methyl-endo-3-phenyl-exo-2-norbornanemethylamine (VII), b.p. 119 – 121°C/0.03 Torr, n_D^{20} 1.5493, $C_{15}H_{21}N$ (215.33) was obtained in 76 % yield and showed the follwing spectroscopic properties: mass spectrum *m/e* 215 (2 %) with the base peak $CH_2N^+{\cdot}H=CH_2$ at *m/e* 44 (100 %); NMR spectrum (in C_6D_6): δ 7.22 (5 H) a singlet (phenyl protons), 2.67 (1 H) a multiplet (C-3 exo-proton), 2.50 – 2.05 (7 H) (in this region the methyl protons appeared as a singlet and the bridgehead and methylene protons of the methylaminomethyl group as a complex signal) and 2.00 – 1.00 ppm (6 H) the other protons of the norbornane structure. Treatment of VII with formaldehyde in formic acid produced *N,N*-dimethyl-endo-3-phenyl-exo-2-norbornanemethylamine (VI). The unreacted amines extracted by dilute hydrochloric acid, were extracted into ether after addition of solid potassium carbonate. The ether solution was dried with anhydrous potassium carbonate, evaporated and the residue (6.4 g) distilled with collection at 110 – 150°C/0.1 Torr. The distillate was dissolved in petroleum ether at room temperature, cooled in acetone-dry ice, and the precipitated exo-3-dimethylaminomethyl-endo-2-phenyl-exo-2-norbornanol (XIV) collected. NMR and IR spectra of XIV were comparable to the spectra of the reference compound, prepared by a known method.[10] After five recrystallizations, XIV melted at 65 – 66°C (reported [10] m.p. 59.5 – 61.0°).

Endo-3-phenyl-2-dimethylaminomethyl-2-norbornanecarbaldehyde (XI). The aminoaldehyde was isolated from the mixture of amines obtained from aminomethylation of 2-phenyl-2-norbornene (shorter reaction time), by preparative gas chromatography. The reference compound was prepared by heating endo-3-phenyl-exo-2-norbornanecarbaldehyde (IX) (2g), paraformaldehyde (0.3 g) and dimethylammonium chloride (0.85 g) in 3 ml acetic acid for 10 min. The product XI was distilled in a bulb tube oven at 110°C/0.1 Torr yielding 0.15 g. $C_{17}H_{23}NO$ (257.36). Mass spectrum: M^+ *m/e* 257 with the base peak at *m/e* 58 (100 %). NMR spectrum (in C_6H_6): δ 9.57 (1 H) a singlet (formyl proton), 7.23 (5 H) a multiplet (phenyl protons), 3.20 (1 H) a doublet, $J=3$ cps (C-3 exo-proton), 2.89 and 2.27 (2 H) $J=13$ cps (the AB-system of methylene protons of the dimethylaminomethyl group), and 2.57 – 0.50 (14 H) including at 2.48, one of the bridgehead protons as a broad signal and at 2.17 ppm, the methyl protons of dimethylaminomethyl group as a singlet.

Structure evaluation of N,N-*dimethyl-1-phenyl-7-nortricyclenemethylamine (XII). 7-Methylene-1-phenylnortricyclene (XIX).* The amine mixture (7 g) obtained by aminomethylation of 2-phenyl-2-norbornene (longer reaction time) was converted with hydrogen peroxide to amine oxides, which were decomposed by heating under reduced pressure. The products were dissolved in ether and purified by removing the unreacted amines from the ether solution with aqueous hydrochloric acid. After drying and removing the ether, the residue was distilled at 124 – 126°C/8 Torr (2.0 g) yielding two components (14:86), which were isolated by preparative gas chromatography. The main component was endo-3-phenyl-2-methylenenorbornane (XVII) whose mass spectrum confirms the molecular formula of XVII and whose NMR spectrum is identical to that reported for XVII.[9] The minor component was 7-methylene-1-phenylnortricyclene (XIX), $C_{14}H_{14}$ (182.25), according to the NMR spectrum (Fig. 1). Mass spectrum: M^+ *m/e* 182 (100 %).

Structure evaluation of N,N-*dimethyl-3-phenyl-2-norbornene-2-methylamine (XIII).* N,N-*Dimethyl-endo-3-phenyl-endo-2-norbornanemethylamine (XX).* An aliquot (6.4 g) of the crude amine mixture produced in the aminomethylation (longer reaction time) of 2-phenyl-2-norbornene was hydrogenated in 100 ml methanol with Pd/C as a catalyst. During distillation the products boiled at 115 – 117°C/0.3 Torr (5.15 g). From this mixture, *N,N*-dimethyl-endo-3-phenyl-endo-2-norbornanemethylamine (XX) (19 mg) was isolated, $C_{16}H_{23}N$ (229.35), purity 98.5 %, m.p. 59 – 61°C by preparative gas chromatography. Mass spectrum: M^+ *m/e* 229 with the base peak at *m/e* 58 (100 %). NMR spectrum (in C_6D_6): δ 7.22 (5 H) a singlet (phenyl protons), 3.10 (1 H) C-3 exo-proton, 2.53 – 1.20 (17 H) including at 2.01 ppm the methyl protons of the dimethylaminomethyl group as a singlet. To confirm the structure, the sample used for NMR spectrum (17 mg) was decomposed *via* an amine oxide to a hydrocarbon (8.5 mg),

which was identified as endo-3-phenyl-2-methylenenorbornane (XVII) by its mass spectrum.

1,1'-Bis(endo-3-phenyl-exo-2-norbornyl)dimethylamine (VIII). The slightly water soluble amine hydrochloride produced by aminomethylation of 2-phenyl-2-norbornene (shorter reaction time) was heated with aqueous potassium carbonate (20 %, 150 ml) and the freed amine separated and purified *via* the sulphonamide as described earlier for VII. Hydrolysis of sulphonamide (10 g) yielded 1,1'-bis(endo-3-phenyl-exo-2-norbornyl)dimethylamine (VIII) (6.7 g, 87 %) which was distilled in a bulb tube oven at 225°C/0.02 Torr. $C_{28}H_{35}N$ (385.57), n_D^{20} 1.5773. Mass spectrum: M^+ *m/e* 385 (1 %) with the base peak at *m/e* 31 (100 %). NMR spectrum (in C_6D_6): δ 7.20 (10 H) a singlet (phenyl protons) and the other protons 2.80 – 1.00 (25 H) in this region the *N*-methylene protons show as a doublet ($J = 7$ cps) at 2.46 ppm. In the IR spectrum (as film) there is a weak absorption at 3380 cm^{-1}. Methylation of VIII with formaldehyde in formic acid produced 1,1'-bis(endo-3-phenyl-exo-2-norbornyl)trimethylamine (X), whose structure is explained below.

1,1'-Bis(endo-3-phenyl-exo-2-norbornyl)trimethylamine (X) and its structure. The slightly water soluble hydrochloride (6.0 g) obtained by aminomethylation of 2-phenyl-2-norbornene (longer reaction time) was freed from its salt with potassium carbonate as described above for VIII and the product 1,1'-bis(endo-3-phenyl-exo-2-norbornyl)trimethylamine (X) distilled in a bulb tube oven at 225°C/0.03 Torr. n_D^{20} 1.5698. $C_{29}H_{37}N$ (399.59). Mass spectrum: M^+ *m/e* 399 (1 %), M – 171 (an abstraction of endo-3-phenyl-exo-2-norbornyl radical) *m/e* 228 (5 %) and the base peak at *m/e* 58 (100 %). NMR spectrum (in C_6D_6): δ 7.21 (10 H) a singlet (phenyl protons), 2.82 – 2.48 (2 H) a multiplet (C-3 exo-protons) and 2.37 – 0.90 ppm (25 H) the other protons as two multiplets. Amine X (0.25 g) was converted with hydrogen peroxide to an amine oxide (yield 0.3 g), which decomposed by heating under reduced pressure to a neutral compound and an amine. These compounds were readily separated by solvent extraction. The neutral product (0.05 g) endo-3-phenyl-2-methylenenorbornane (XVII) was obtained in 25 % yield and its NMR spectrum agreed with that of the reference compound mentioned earlier. The isolated amine was crystallized from petroleum ether to give 0.06 g *N*-methyl-endo-3-phenyl-exo-2-norbornanemethylhydroxylamine (XVIII) in 22 % yield. M.p. 96 – 98°. $C_{15}H_{21}ON$ (231.33). Mass spectrum: M^+ *m/e* 231 (3 %), $CH_3N^{+\cdot}(OH)=CH_2$ *m/e* 231 (3 %) with the base peak at *m/e* 44 (100 %). NMR spectrum (in C_6D_6): δ 7.26 (5 H) a singlet (phenyl protons), 2.92 – 2.05 (9 H) a complex signal group, which included a distinct singlet of methyl protons at 2.52 and a broader signal at 1.84 – 1.05 ppm (7 H). The reduction of XVIII with $LiAlH_4$ in dioxane produced *N*-methyl-endo-3-phenyl-exo-2-norbornanemethylamine (VII), which was identified by gas chromatography and by its mass spectrum.

Decomposition of exo-3-dimethylaminomethyl-endo-2-phenyl-exo-2-norbornanol (XIV) in acetic acid. The amino alcohol XIV (0.545 g, 2.22 mmol) was heated in acetic acid under reflux for 20 h. To the reaction mixture dilute hydrochloric acid (10 ml) and ether (5 ml) were added, and the crystals which formed separated by filtration, then recrystallized from ethanol (yield 0.063 g). The product was identified by IR spectrum as a mixture of 1,1'-bis(endo-3-phenyl-exo-2-norbornyl)dimethylamine (VIII) and 1,1'-bis(endo-3-phenyl-exo-2-norbornyl)trimethylamine (X) hydrochlorides. From the filtrate the neutral products and amines were isolated by the conventional treatment of solvents. Gas chromatography of the neutral portion (0.17 g) yielded 2-phenyl-2-norbornene (17 %), endo-3-phenyl-exo-2-norbornanecarbaldehyde (IX) (71 %) and three unidentified compounds. 2-Phenyl-2-norbornene and IX were separated by distillation in a bulb tube oven under reduced pressure and their structures were confirmed by IR spectra. Gas chromatography revealed that the amine portion consisted of *N,N*-dimethyl-1-phenyl-7-nortricyclenemethylamine (XII) (2 %), *N,N*-dimethyl-3-phenyl-2-norbornene-2-methylamine (XIII) (7 %), *N,N*-dimethyl-endo-3-phenyl-exo-2-norbanenemethylamine (VI) (17 %), *N*-methyl-endo-3-phenyl-exo-2-norbornanemethylamine (VII) (28 %), the starting material XIV (43 %) and an unidentified amine (3 %).

Apparatus. The gas chromatographic analyses were performed with a Perkin-Elmer chromatograph model F 30 using a two meter long column (10 % Silicone Gum Rubber SE-30 on Chromosorb W) and a flame ionization detector. The analysis was programmed from 170°C to 220°C, the initial time was 5 min, and the heating rate 10 degree/min. An Autoprep model A-700 gas chromatograph manufactured by Wilkens Instrument & Research, Inc., and a 5 m long preparative column (20 % Silicone Gum Rubber SE-30 on Chromosorb W) were used for the chromatographic preparative separations at 210°C with helium as a carrier gas. The instrument was equipped with a hot wire detector. The IR spectra were carried out which a Perkin-Elmer model 457 double beam spectrophotometer, the mass spectra were recorded on a Hitachi Perkin-Elmer RMU 6 E double focusing mass spectrometer, and the NMR spectra on a Varian T 60 spectrometer with tetramethylsilane as the internal standard.

3,3-Dialkylindolin-2-ones and 3,3-Dialkylisoindolin-1-ones. 2. Hofmann and Lossen Degradation of 4,4-Dialkyl-1,3-dioxo-1,2,3,4-tetrahydroisoquinolines (4,4-Dialkylhomophthalimides). A Mechanistic Study

N. ÅKE JÖNSSON and PINCHAS MOSES

Department of Organic Chemistry, Research Department, AB Kabi, S-104 25 Stockholm, Sweden

The Hofmann rearrangement reaction of 4,4-dialkylhomophthalimides and the Lossen rearrangement of 4,4-dialkyl-*N*-tosyloxyhomophthalimides afford indolinone or isoindolinone derivatives, or mixtures of both, depending on the nature of the 4-substituents. "Bulky" substituents give rise to isoindolinones, "small" substituents afford indolinones, and "medium sized" substituents give mixtures of both, though the actual size has less significance than their spatial geometry. The mechanisms of the reactions involved are discussed.

In a previous paper [1] we reported on the formation of 3,3-disubstituted indolinones and isoindolinones from 4,4-disubstituted homophthalimides * on treatment with alkali and sodium hypochlorite solution. Two reaction methods were used: in one (A), the homophthalimide derivative was treated with 2 M sodium hydroxide solution for various times prior to treatment with hypochlorite, and in the other (B), the alkaline homophthalimide solution was treated *immediately* with the hypochlorite. The products formed consisted of indolinone or isoindolinone derivatives, or mixtures of both, depending on the nature of the starting material and on the experimental conditions employed. Working with 4,4-tetramethylenehomophthalimide, it was concluded that in reaction A, the homophthalimide slowly underwent hydrolytic ring-opening to give a mixture of the two theoretically possible "amic" acids which, upon treatment with hypochlorite, rapidly underwent rearrangement to afford the indolinone and isoindolione derivatives.

Formation of the indolinones in method B, however, seems to rule out a corresponding mechanism initiated by a hydrolytic step, as the indolinones were formed at a much more rapid rate than hydrolysis of the imide. Consequently, a different reaction mechanism seems to be operating in method B, and it is the purpose of the present paper to report on the attempts made to elucidate this mechanism.

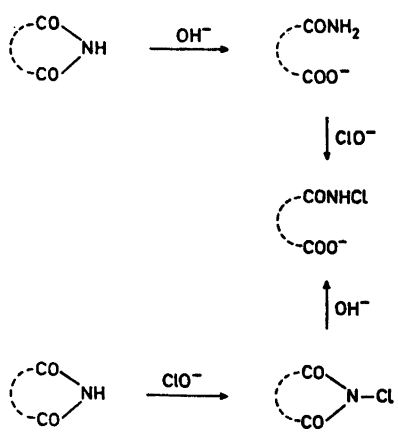
* As the correct names of these compounds are very cumbersome, they are designated as derivatives of homophthalimides in the following discussion.

DISCUSSION

The Hofmann amide degradation is generally believed to proceed through the following steps:[2]

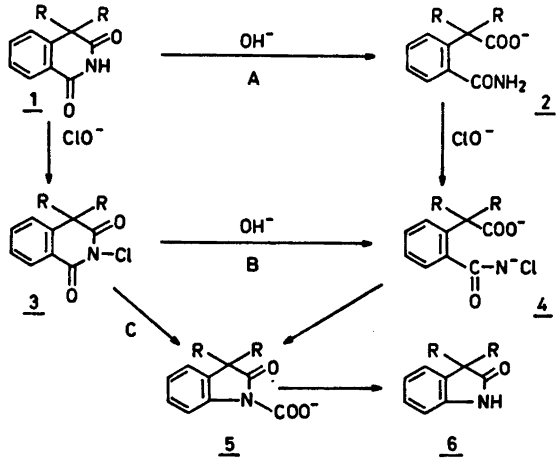
$$\mathrm{R-CONH_2} \xrightarrow{\mathrm{OHal^-}} \mathrm{R-CONHHal} \xrightarrow{\mathrm{OH^-}}$$
$$\mathrm{R-CON^-Hal} \rightarrow \mathrm{R-N=C=O} \rightarrow$$
$$\mathrm{R-NHCOOH} \rightarrow \mathrm{R-NH_2 + CO_2}$$

Obviously, the reaction requires an ionizable hydrogen atom at the amide nitrogen of the haloamide, that is, the reaction can proceed only with *primary* amides. Many imides, especially phthalimides, do however undergo this reaction which has usually been explained by an initial hydrolytic ring-opening, either of the free imide [2] or of the *N*-chloro derivative formed from this,[3] followed by rearrangement of the haloamide formed:

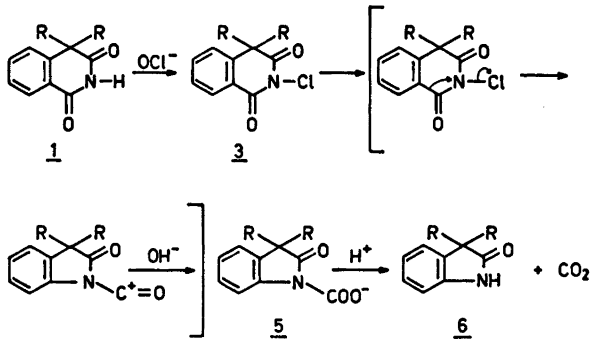


(For alternative hypotheses see Ref. 4, 5). Our results with 4,4-tetramethylenehomophthalimide, although only qualitative, clearly demonstrate that the hydrolysis of this imide is a slow reaction requiring several hours at room temperature to proceed to any considerable extent. In sharp contrast to this is the rapid formation of the indolinone derivative from this imide on reaction with alkaline sodium hypochlorite solution: almost 90 % of the indolinone derivative is obtained after a reaction time of less than 15 min. at room temperature. It can therefore be concluded that at least in this case hydrolysis of the free imide (Scheme 1, route A) is not the initial step but that the reaction is initiated by *N*-chlorination of the imide. The *N*-chloro derivative *3* might then either undergo hydrolysis to the *N*-chloro primary amide *4* (Scheme 1, route B) or rearrange directly (Scheme 1, route C). The direct rearrangement C may conceivably proceed either without participation of OH^- ions according to Scheme 2, or by the "concerted" mechanism outlined in Scheme 4. Whatever the operating mechanism may be, the carbamic acid derivative *5* is an intermediate, since its sodium salt was isolated on cooling the reaction mixture and characterised by conversion to the methyl ester with dimethyl sulphate.[1]

The Scheme 2 mechanism appeared at first sight to be a very plausible alternative, its greatest merit being the fact that it obviates the necessity for hydrolytic ring-opening of the imide. In order to test the validity of this mechanism, the reaction was carried out in the presence of $H_2{}^{18}O$: non-incorporation of ^{18}O into the indolinone formed would strongly support the proposed mechanism. MS measurements showed that formation of the indolinone *6* was accompanied by incorporation of ^{18}O. As, however, independent experiments with heavy water showed that whereas *5* did not exchange ^{18}O with the medium, the imide *1* did so very rapidly, this observation was without meaningful interpretation. Consequently, the *N*-chloro derivative *3* was prepared separately and made to react with sodium hydroxide solution. It was found that already



Scheme 1.



Scheme 2.

after about ten minutes, an 80 % yield of the indolinone *6* could be isolated after acidification of the reaction mixture, and that it contained incorporated ^{18}O to the extent required by 100 % participation of OH^- ions from the medium. Although a rapid exchange of oxygen in the chloroimide followed by rearrangement according to Scheme 2 is not entirely ruled out by these experiments this apparently means that the *N*-chloro derivative *3* rearranges either *via* a conventional hydrolysis reaction (Scheme 1 route B) or by way of the "concerted" reaction (Scheme 4) as all efforts to effect the rearrangement with for example silver salts in an inert solvent have failed so far. That rapid hydrolysis of *3* is not inconceivable may be deduced from the fact that *N*-methoxy-4,4-tetrahydrohomophthalimide, which both sterically and electronically closely resembles the *N*-chloro analogue *3*, is virtually completely hydrolysed by 1 M sodium hydroxide in 50 % aqueous dioxane at room temperature in less than 5 min. (The resistance offered by the imide *1* to alkaline hydrolysis must apparently by ascribed to the effect exerted by its anion, which would tend to repel the approach of OH^- ions from the medium). Since no experiments could be devised to distinguish between these two mechanisms (Scheme 1, route B and Scheme 4), the choice was finally made on the basis of indirect evidence derived from the Lossen reaction, as discussed further on.

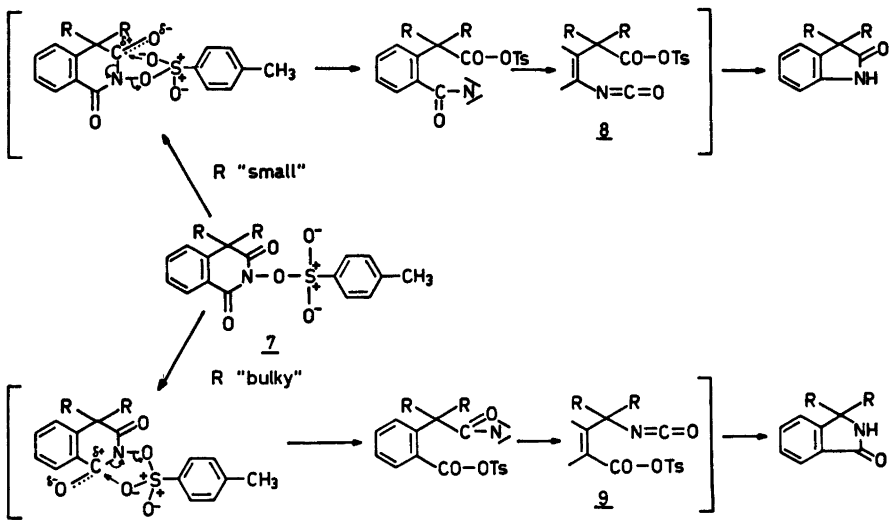
Both of the above rearrangement mechanisms would also explain the role played by the 4-substituent in governing the course of the reaction: increasing "bulkiness" of the substituent would shift attack from the more electrophilic but more hindered aliphatic carbonyl group to the less electrophilic but less hindered aromatic one, thus favouring transition from indolinone to isoindolinone formation. This is in complete alignment with the finding that the 4,4-dimethyl-, 4,4-tetramethylene-, and 4,4-pentamethylenehomophthalimides gave high yields of the corresponding indolinones, 4,4-diallylhomophthalimide gave moderate yields of both indolinone and isoindolinone derivatives, and 4,4-diethylhomophthalimide afforded solely the isoindolinone derivative in moderate yield. The 4,4-dipropyl- and 4,4-dibutylhomophthalimides did not react at all, indicating that here the steric effect extends to block reaction even at the imide nitrogen or aromatic carbonyl group.

A semi-quantitative indication of the relative degrees of reactivity of the carbonyl groups in the various 4,4-dialkylhomophthalimides could be obtained by determining the rate of ^{18}O incorporation. It can be seen from Table 4 that the velocity of exchange decreases in the series

$$R = -(CH_2)_4- \gg C_2H_5-;$$
$$CH_2=CHCH_2- > n\text{-}C_3H_7-$$

This is in agreement with the found reactivities of the homophthalimides with respect to the Hofmann rearrangement reaction.

In order to obtain further insight into the mechanism of the Hofmann reaction, the Lossen rearrangement of the corresponding *N*-tosyloxyhomophthalimide derivatives *7* was studied, as it is known that these two reactions

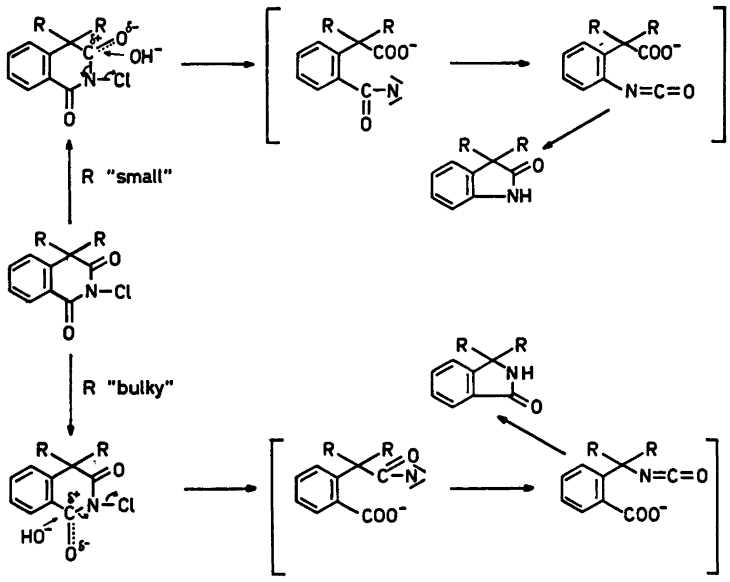


Scheme 3.

proceed according to the same mechanism. It was found that when the *N*-tosyloxy derivatives of homophthalimide substituted with the 4,4-dimethyl-, 4,4-tetramethylene-, 4,4-diallyl-, 4,4-diethyl-, and 4,4-dibutyl groups were warmed in aqueous dioxane containing potassium carbonate, the first two members of the series afforded the corresponding indolinone derivatives, the allyl derivative gave a mixture of indolinone and isoindolinone, the ethyl derivative gave only isoindolinone, and the butyl derivative also afforded small amounts of the isoindolinone. It is obvious that the substituent in the 4-position has a profound directive influence on the course of the reaction. Also, since the electronic effects of the methyl group must be very similar to that of the ethyl group, this influence must be steric rather than electronic in nature. Furthermore, experiments in heavy water revealed that *incorporation of ^{18}O occurred neither in the indolinones nor in the isoindolinones formed* which means that in this case the attacking species is not an OH^- ion and the reaction does not involve hydrolytic opening of the imide ring. An attractive mechanism reconcilable with this finding would be the one outlined in Scheme 3, since this would explain in a satisfactory manner the directive influence of the 4-substituent. This mechanism is entirely analogous to the one proposed for the Hofmann reaction, with the difference that the leaving group here is a toluene sulphonate instead of a chloride ion and the attacking species is an intramolecular sulphonyl oxygen instead of an external hydroxyl ion. The increasing steric hindrance exerted by the 4-substituent with increasing bulk would progressively shift the attack from the aliphatic to the aromatic carbonyl group, resulting in formation of indolinone or isoindolinone as the case may be.

As was mentioned above in the discussion of the Hofmann rearrangement, the experiments devised cannot distinguish between a reaction involving normal hydrolysis of the *N*-chlorohomophthalimide (Scheme 1, route B) and a "concerted" reaction not involving a distinct hydrolytic step (Scheme 4). However, if we accept the Lossen mechanism as a justifiable model for the closely related Hofmann reaction, we would favour the entirely analogous "concerted" mechanism as outlined below (Scheme 4) in preference to the stepwise hydrolysis and subsequent rearrangement.

It was a fortuitous circumstance for the elucidation of the mechanism of the Lossen rearrangement that in these compounds the unique structural constellation of the postulated mixed anhydride derivatives *8* and *9* imparted to these intermediates a much greater tendency to ring-closure than to reaction with the



Scheme 4.

environmental water, for otherwise correct interpretation of the heavy water experiments would not have been possible.

EXPERIMENTAL

All melting points were taken with a Heræus Fus-O-Mat apparatus. Mass spectra were determined on an LKB 9000 instrument. Microanalyses were carried out by Prof. K. J. Karrman, University of Lund, Lund, Sweden.

N-Chloro-4,4-tetramethylenehomophthalimide and its Hofmann rearrangement. A mixture of 4,4-tetramethylenehomophthalimide (16 g; 0.147 mol) and *tert*-butyl hypochlorite (16 g; 0.147 mol) was stirred in a waterbath at 60°C for 3 h, by when a clear orange solution had formed. Excess hypochlorite was removed in vacuum and the residual oil was recrystallized from 175 ml of diisopropyl ether, giving 15.3 g (83 %) of white crystals, m.p. 85 – 94°C. An analytically pure sample melted at 90 – 94°C. (Found: C 62.8; H 4.86; N 5.60; O 12.8; Cl 13.9. $C_{13}H_{12}ClNO_2$ requires: C 62.5; H 4.85; N 5.61; O 12.8, Cl 14.2).

The above chloro derivative (1.25 g; 0.005 mol) was treated with ice-cold 2 M sodium hydroxide solution (10 ml; 0.02 mol) and stirred at room temperature for 10 min. Acidification with acetic acid afforded 730 mg (78 %) of 3,3-tetramethyleneindolin-2-one, m.p. 113°C.

When the rearrangement reaction was carried out in a medium containing 20 atom-% of $H_2{}^{18}O$, the indolinone isolated contained about 9 % of the labelled isomer of M.W. 189.

N-Chloro-4,4-diethylhomophthalimide and its Hofmann rearrangement. A mixture of 4,4-diethylhomophthalimide (10.9 g; 0.05 mol) and *tert*-butyl hypochlorite (10 ml; 0.092 mol) in dry benzene (50 ml) was stirred at room temperature overnight. Removal of volatile material in vacuum afforded 12.4 g (99 %) of a thick oil which slowly crystallized on standing. An analytical sample recrystallized from petroleum ether melted at 51 – 56°C. (Found: C 61.6; H 5.5; Cl 14.8; N 5.5; O 12.9. $C_{13}H_{14}ClNO_2$ requires: C 62.0; H 5.6; Cl 14.1; N 5.6; O 12.7).

The above chloro derivative (2.5 g; 0.01 mol) was warmed and stirred with 2 M sodium hydroxide solution (20 ml; 0.04 mol) for 45 min, the reaction mixture was cooled, acidified with acetic acid and the product collected, giving 1.4 g (74 %) of 3,3-diethylisoindolin-1-one, m.p. 166 – 169 °C.

General method for the preparation of 4,4-dialkyl-N-hydroxy-homophthalimides. Sodium (2.5 g; 0.11 mol) was added to dry methanol (50 ml) and when reaction was complete the solution was cooled and treated with a hot solution of hydroxylamine hydrochloride (7.7 g; 0.11 mol) in water (5 ml). To the stirred solution was added the appropriate substituted homophtalic acid (or, preferably, the anhydride, obtained by heating the acid) and the mixture was refluxed for 4 to 6 h, then stirred at ambient temperature overnight. Dilute hydrochloric acid was added, the solution taken to dryness

under vacuum, the residue taken up in hot acetone, the sodium chloride filtered off and the filtrate taken to dryness, giving an oil which became crystalline on cooling. The data of the derivatives thus prepared are presented in Table 1.

General method for the preparation of 4,4-dialkyl-N-tosyloxyhomophthalimides. A solution made up from the appropriate 4,4-dialkyl-*N*-hydroxyhomophthalimide (0.05 mol), DMF (200 ml) and 1 M sodium hydroxide solution (50 ml; 0.05 mol) was added dropwise at room temperature to a solution of tosyl chloride (10 g; 0.052 mol) in chloroform (150 ml). The mixture was stirred at room temperature for 2 to 20 h, the layers were separated and the aqueous phase was extracted with chloroform. The combined chloroform phase was washed with water, with dilute hydrochloric acid and finally with sodium carbonate solution. After drying, the solvent was removed, giving an oil which generally crystallized on standing. The data of the derivatives thus prepared are presented in Table 2.

General procedure for the Lossen rearrangement reaction. A mixture made up from the 4,4-dialkyl-*N*-tosyloxyhomophthalimide (0.01 mol), dioxane (10 ml), potassium carbonate (1.5 g; 0.011 mol) and water (5 ml) was stirred in an oil-bath (80 °C) overnight. Volatile material was removed under vacuum, the residue was treated with water, extracted with chloroform, the organic extract was washed with water, dried (K_2CO_3), the solvent was removed and the residual product was recrystallized. Pertinent data of the products obtained are presented in Table 3. In the experiments with isotope labelling, water containing 20 atom-% of $H_2{}^{18}O$ was used.

In the reaction with the dibutyl derivative, the product was characterised as isoindolinone by the NMR spectrum, in which the aromatic H-atoms appear at τ 2.0 – 2.6 in contrast to their appearance at τ 2.8 – 3.0 in the indolinones. In addition, the UV-spectrum in methanol exhibits a peak at 225 nm, as did also other isoindolinones, in contrast to the peak appearing at 247 nm in the indolinones (*cf.* Ref. 1).

N-Methoxy-4,4-tetramethylenehomophthalimide. A mixture of *N*-hydroxy-4,4-tetramethylenehomophthalimide (23.1 g; 0.1 mol), potassium carbonate (13.8 g; 0.1 mol) and water (100 ml) was warmed until a clear solution had been obtained when dimethyl sulphate (10.3 ml; 0.11 mol) in acetone (50 ml) was added dropwise. After stirring in the water-bath for 2.5 h, an additional 10 ml of dimethyl sulphate was added, whereafter the mixture was stirred in the water-bath for a further 4 h. After standing at room temperature overnight, most of the acetone was removed by distillation, causing a heavy oil to separate out. This was washed with water by decantation whereupon it solidified, giving 22.4 g (91.5 %) of white crystals, m.p. 75 – 80 °C. Recrystallization from methanol gave white crystals m.p. 77 – 81°C. (Found: C 68.6; H 6.1; N 5.7; O 19.7. $C_{14}H_{15}NO_3$ requires: C 68.6; H 6.1; N 5.7; O 19.6).

α,α-Diallylhomophthalic acid. Ethyl *o*-carbethoxyphenyl acetate (59 g; 0.25 mol) in DMF (100 ml) was added dropwise at room temperature under vigorous stirring to a mixture of allyl bromide (72 ml; 0.8 mol) and sodium hydride (50 % in oil; 30 g; *ca.* 0.7 mol) in DMF (400 ml). The stirred mixture was warmed on the water bath (*ca.* 70 °C) for 5 h, then stood at room temperature overnight. The inorganic salt was filtered off, the filtrate was taken to dryness under vacuum, the residual oil was treated with 5.5 M sodium hydroxide solution (100 ml) and the mixture refluxed overnight. After dilution with water, the solution was extracted with chloroform, the aqueous phase was treated with dilute hydrochloric acid to incipient turbidity (pH *ca.* 5), the solution was stirred with decolourising carbon, filtered through a Celite pad, and the filtrate strongly acidified with hydrochloric acid. The resulting viscous oil was extracted into chloroform, the extract was washed with brine, dried (Na_2SO_4) and taken to dryness under vacuum, giving a crystalline residue weighing 51 g (78.5 %), m.p. *ca.* 140 °C. Fractional crystallization from a mixture of chloroform-ether-petroleum ether 1:1:1 afforded 27.7 g (42 %) of the diacid, m.p. 139 °C dec., and 20.0 g (30.3 %) of a colourless oil which was identified by NMR as practically pure anhydride. (Found: C 69.0; H 6.2; O 24.5.

$C_{16}H_{16}O_4$ requires: C 69.2; H 6.2; O 24.6 %).

Experiments with ^{18}O-labelling. ^{18}O-Labelling of 4,4-dialkylhomophthalimides. The homophthalimide derivative (0.1 mmol) and sodium hydroxide (0.25 mmol) in 0.1 ml of water containing 20 atom-% of $H_2{}^{18}O$ was allowed to stand at room temperature for various times, then acidified with acetic acid and the precipitated imide isolated. The amount of incorporated ^{18}O was determined by MS. The results are presented in Table 4.

Table 4. ^{18}O-Exchange of 4,4-dialkylhomophthalimide (*1*).

R	Reaction time	Content of labelled isomer %
$-(CH_2)_4-$	12 min	11
	25 min	20
	4 h	20
	96 h[a]	30
C_2H_5	24 h	10
$CH_2=CHCH_2$	24 h	10
C_3H_7	24 h	4–5

[a] Also contains 5 % of isomer M. W. 219.

^{18}O-Exchange of N-carboxy-4,4-tetramethyleneindolin-2-one. The sodium salt of the carbamic acid derivative *5*[1] (26 mg; 0.1 mmol) was dissolved in a solution of sodium hydroxide (9.1 mg; 0.23 mmol) in 0.2 ml of water containing 10 atom-% of $H_2{}^{18}O$. After 3 h at room temperature the solution was warmed on a water bath for 10 min, cooled, acidified with dilute acetic acid and the resulting 4,4-tetramethyleneindolin-2-one was isolated. MS measurements showed that it contained practically no incorporated heavy oxygen.

Acknowledgements. The authors are indebted to Dr. C. G. Hammar for mass spectra determinations and expert interpretation of the results.

Algal Carotenoids. IX.* Absolute Configuration of β,ε-Caroten-2-ol, β,β-Caroten-2-ol, and β,β-Carotene-2,2′-diol

RICHARD BUCHECKER,[a] CONRAD HANS EUGSTER,[a] HELGE KJØSEN [b] and SYNNØVE LIAAEN-JENSEN [b]

[a] Organisch-Chemisches Institut der Universität Zürich, Rämistrasse 76, CH-8001 Zürich, Switzerland and [b] Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim, Norway

The previous tentative stereochemical assignments 2*R*,6′*R* for β,ε-caroten-2-ol (*1a*), 2*R* for β,β-caroten-2-ol (*2a*), and 2*R*,2′*R* for β,β-carotene-2,2′-diol (*3*) have been confirmed.

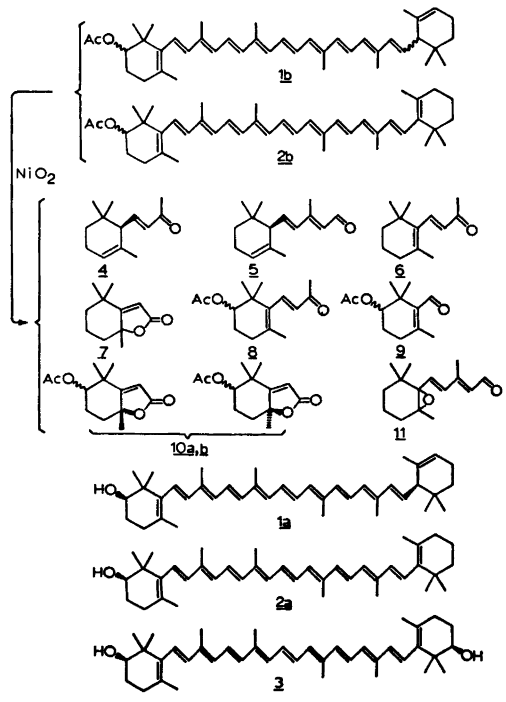
Oxidative (NiO_2) degradation of a mixture of β,ε-caroten-2-yl acetate (*1b*) and β,β-caroten-2-yl acetate (*2b*) gave *ca.* 50 components (GLC), among which (+)-α-ionone (*4*), the ε-apo-carotenal *5*, β-ionone (*6*), dihydroactinidiolide (*7*), 2-acetoxy-β-ionone (*8*), 2-acetoxy-β-cyclocitral (*9*), the *cis-trans* isomeric acetylated lactones *10a,b* and presumably the artefact epoxide *11* were identified from GLC, UV, MS, and CD data.

Whereas isolation of (+)-α-ionone (*4*) defined the 6′*R* configuration of *1a*, the 2*R* configuration followed from application of the modified Horeau method to *2a* and previous CD correlations.

For convenience carotenoid numeration has been used.

Recently we have isolated the first carotenoids possessing 2-hydroxylated β-rings, namely β,ε-caroten-2-ol (*1a*), β,β-caroten-2-ol (*2a*) and β,β-carotene-2,2′-diol(*3*) from the green alga *Trentepohlia iolithus* (L.) Wallroth.[1] Whereas complete spectral characterization defined the constitutions involved, the chemical reactions of these carotenoids have subsequently been studied.[2]

As to their absolute configurations the fact that β,β-carotene-2,2′-diol (*3*) and zeaxanthin [= (3*R*,3′*R*)-β,β-carotene-3,3′-diol] exhibited very similar CD curves of opposite sign was rationalized employing Mills' rule.[3] Regarding both *3* and zeaxanthin as 4-hydroxylated cyclohexene derivatives with preferred pseudo-equatorial hydroxy groups, 2*R* and 3*R* configuration, respectively, represent opposite half-chair conformations with opposite optical rotation. 2*R*-Stereochemistry for the mono-ol *2a* then followed from CD correlation. Moreover, by using the additivity hypothesis of Klyne and co-



Scheme 1.

* Part VIII. *Phytochemistry. In press.*

workers [4] 2*R*,6′*R* stereochemistry was inferred for *1a*; see Scheme 1.

Since the application of Mills' rule may lead to erroneous results,[5] it was necessary to check the validity of Mills' rule in this case. Furthermore, independent confirmation of the 6′*R* stereochemistry of *1a* was desirable.

RESULTS AND DISCUSSION

Since β,ε-caroten-2-ol (*1a*) and β,β-caroten-2-ol (*2a*) can only be separated with difficulty,[1] oxidative degradation of a mixture of *1a* and *2a* was effected in the Swiss laboratory by the procedure worked out for lutein (= β,ε-carotene-3,3′-diol).[6]

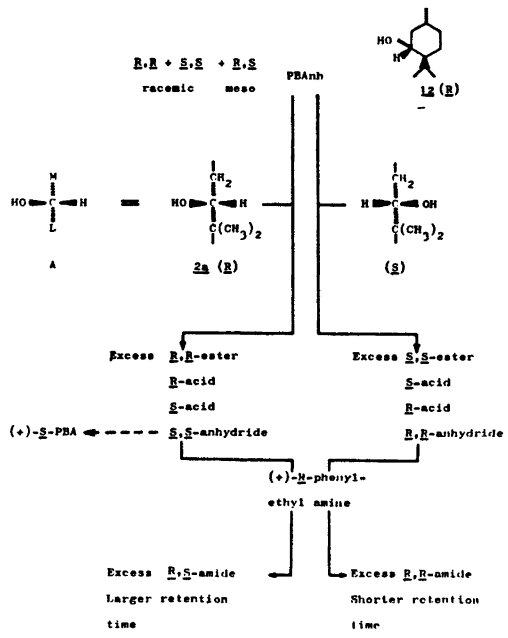
The hydroxy groups were protected by acetylation and a *ca.* 1:1 mixture of semicrystalline *1b* and *2b*, Scheme 1, was oxidized with NiO_2 to give approximately 50 components by GLC. By preparative GLC and subsequent UV, MS, and CD characterization, the following compounds were identified:

(+)-(6*R*)-α-Ionone (*4*) with predicted GLC, UV, and MS properties had opposite Cotton effect to that of (−)-α-ionone (6*S*).[6,7] The ε-apo-11-carotenal (*5*) had GLC, UV,[8] and MS properties consistent with structure *5*. 6*R*-Stereochemistry followed from positive CD 298 nm (curve conform to but bathochromically shifted relative to that of *4*).

β-Ionone (*6*), inseparable from authentic β-ionone, had MS properties as predicted. Dihydroactinidiolide (*7*) [9] with GLC, UV, and MS data consistent with this assignment, was according to the CD data, a racemic mixture. Both *6* and *7* are considered derived from the unsubstituted β-rings and offer no stereochemical information. The same is true for a minor component, from MS alone tentatively identified as the epoxide *11* and considered to be an artefact caused by the oxidation reagent.

Three compounds derived from the 2-acetylated β-end groups were isolated, namely 2-acetoxy-β-ionone (*8*), 2-acetoxy-β-cyclocitral (*9*), and a presumed *cis-trans* isomeric mixture of the acetylated lactones *10a,b*. Again the identifications were based on GLC, UV, and MS data. The CD spectrum of 2-acetoxy-β-cyclocitral (*9*) was analogous to and hypsochromically displaced by *ca.* 20 nm relative to that of the analogue *8* (both resembling that of *2a* itself). Were comparison of the CD spectra of *8* and of 2-acetoxy-β-ionone of known configuration possible, stereochemical conclusions could be made on this basis.

However, evidence for the 2*R* configuration for *2a* was obtained independently using the modified Horeau method.[10] Briefly the Horeau method [11–14] is based on the partial resolution of racemic and meso α-phenylbutyric anhydride (PBAnh) by means of an optically active alcohol, which reacts preferentially with one diastereomer, followed by hydrolysis and optical rotation measurement of the unreacted α-phenylbutyric acid (PBA), Scheme 2.



Scheme 2.

When the isolated PBA is dextrorotatory the alcohol in concern has configuration A; L(arge) and M(edium) refer to the space requirements of the substituents. In the modified version,[10] Scheme 2, the excess enantiomer of the PBAnh is reacted with an optically active primary amine [(+)-*R*-α-phenylethyl amine] followed by quantitative separation of the diastereomeric amides by GLC. Since the chiral amine does not react equally fast with the two enantiomeric PBAnh, parallel experiments with an achiral secondary alcohol like cyclohexanol must be performed.

In the original modification Brooks and Gilbert [10] used a different column for the GLC separation. The relative retention time for the two diastereomeric amides were therefore checked with (−)-*R*-menthol (*12*), corresponding to configuration A, Scheme 2, and consequently providing excess *R,S*-amide.

Three separate experiments with *β,β*-caroten-2-ol (*2a*) each resulted in excess formation of the *R,S*-amide using achiral cyclohexanol in the reference reaction. Lower optical yields in the experiments with *β,β*-caroten-2-ol (*2a*) than for (−)-*R*-menthol (*12*) are explained by the lower solubility of *2a*.

Configuration A, corresponding to *β,β*-caroten-2*R*-ol (*2a*) is thus proved in agreement with the previous tentative assignment.[1] 2*R*-Configuration for *3a* and *1a* follows from the CD correlations already made.[1]

Furthermore it follows from this independent determination of the absolute configuration of *β,β*-caroten-2-ol (*2a*) that 2-acetoxy-*β*-ionone (*8*), 2-acetoxy-*β*-cyclocitral (*9*), and the diastereomeric lactones *10a,b* (Scheme 1) all have the 2*R* configuration.

The fact that the 6′*R* configuration of *1a* corresponds to that of *ε*-rings in related carotenoids isolated from higher plants, suggests a common enzymatic cyclization mechanism.

The implications of the 2*R* stereochemistry here established for the 2-hydroxy-*β*-type carotenoids for the stereochemistry of 2-isopentenyl substituted carotenoids (C_{50}) will be treated elsewhere.[15]

EXPERIMENTAL PART

Materials. Mixed crystalline mono-ols (*1a* and *2a*) were obtained from *Trentepohlia iolithus* after chromatography of the saponified mono-ester fraction as described previously.[1]

Crystalline *β,β*-caroten-2-ol (*2a*) was obtained after chromatography of the mixed mono-ols on magnesia.[1]

Solvents used were of analytical grade.

Instruments. UV spectra (ethanol, if not stated otherwise) were recorded on a Beckman Acta III spectrometer and CD spectra (ethanol, if not stated otherwise) on a Roussel-Jouan Dichrographe model 185 with a xenon high pressure lamp. Due to the small samples these spectra are qualitative only.

Mass spectra were obtained on a GLC/MS Varian MAT CH5 instrument.

Preparative GLC was effected on a Perkin Elmer 900 gas chromatograph with packed glass column 2.5 m/3 mm type SP 1000 (4 % Carbowax 20 M, treated with *p*-nitroterephthalic acid on Chromosorb 100 − 120 mesh) programmed at 160 − 240°C, 5°/min, He-flow 65 ml/min.

Retention times cited below were for an analytical glass capillary column Ucon HB 5100 + H_3PO_4 20 m/0.32 mm, programmed from 80 to 180°C, 2°/min, 0.4 atm. pressure.

For the Horeau experiments a glass capillary column OV 101 + FFAP 23 m/0.3 mm, isotherm, 160°C, 0.5 atm. pressure was employed.

Oxidative degradation

Acetylation. 1a and *2a* (140 mg, 43:57) in pyridine (25 ml) was acetylated quantitatively with acetic anhydride (5 ml) for 24 h at room temperature; yield 139 mg (90 %) *1b* and *2b*.

Degradation. The mixed acetates (*1b* and *2b*, 139 mg) dissolved in ether-benzene (1:1, 100 ml) and NiO_2[16] (8 g) were stirred mechanically at room temperature until decolouration occurred (36 h). The filtrate was concentrated to dryness; yield 28 mg comprising *ca.* 50 components by analytical GLC.

Retention times by analytical GLC were: *α*-ionone (*4*) 10.9 min, *β*-ionone (*6*) 14.3 min, 2-acetoxy-*β*-cyclocitral (*9*) 23.1 min, dihydroactinidiolide (*7*) 25.3 min, *ε*-apo-11-carotenal (*5*) 29.3 min, 2-acetoxy-*β*-ionone (*8*) 37.6 min, and the isomeric lactones *10a,b* 46.8 and 47.1 min.

(+)-(6R)-α-Ionone (4), yield *ca.* 0.3 mg, inseparable from authentic *α*-ionone by co-chromatography, had *m/e* 192 (M), 177 (M − CH_3), 43 (CH_3CO); UV λ_{max} 227 nm; CD (hexane, nm, relative intensities) 368 (−1.0), 352 (−3.5), 337 (−5.0), 324 (−5.3), 315 (−4.0), 244 (+43.5).

(−)-*α*-Ionone (6*S*) for comparison had CD (methylcyclohexane: isopentane 1:3, nm, $\Delta\varepsilon$) 372 (+0.19), 353 (+0.61), 338 (+0.92), 325 (+0.93), 312 (+0.71), in alcohol also 243 (−17.33).

ε-Apo-11-carotenal (*5*) had *m/e* 218 (M); UV λ_{max} 286 nm, reported [8] 286 nm in ethanol: CD (nm, strong) 298 (+), 273 (+), 205 (end absorption +).

β-Ionone (*6*), inseparable from authentic *β*-ionone, had *m/e* 192 (M), 177 (M − CH_3), 43 (CH_3CO).

Dihydroactinidiolide (*7*) had *m/e* 180 (M), 165 (M − CH_3); UV λ_{max} 225 nm, reported [9] 241 nm, solvent unknown; no CD (racemic).

2-Acetoxy-β-ionone (*8*) had *m/e* 250 (M), 235 (M − CH_3), 190 (M − AcOH), 175 (M − CH_3 − AcOH), 43 (CH_3CO); UV λ_{max} 286 nm, reported [17] for *β*-ionone (*6*) 295 nm in ethanol; CD (nm, weak) 370 − 320 (+), 290 − 260 (−), 250 (0), 240 − 200 (end absorption +).

2-Acetoxy-β-cyclocitral (*9*) had *m/e* 210 (M), 195 (M − CH_3), 150 (M − AcOH); UV λ_{max} 243 nm, reported [18] for *β*-cyclocitral 247.5 nm in ethanol; CD (nm) *ca.* 363 (−), 342 (0), *ca.* 315

(+), 282 (0), 250–240 (–), 233 (0), 200 (end absorption +).

Isomeric lactones 10a,b had *m/e* 238 (M), 178 (M–AcOH), 43 (CH_3CO); UV λ_{max} 218 nm, *cf. 7*.

Epoxidic aldehyde 11 had *m/e* 234 (M), 219 (M–CH_3), 191 (M–CH_3–CO→oxepinium ion, $m^*=156$).

Modified Horeau experiments

Procedure by Brooks and Gilbert [10] was used directly for (–)-menthol (*12*) and the first experiment with β,β-caroten-2-ol (*2a*); in the latter case in a heterogeneous system due to low solubility.

α-Phenylbutyric anhydride was prepared as described by others.[19,20]

(–)-R-*Menthol* [10] (*12*). The retention time found for *R*-α-phenylethyl- *R*-α-phenylbutyramide was 7.0 min and for *R*-α-phenylethyl-*S*-α-phenylbutyramide 8.1 min. Standard reaction with cyclohexanol gave the ratio *R,S*-amide:*R,R*-amide = 1:(1.115 ± 0.007). Reaction with *12* gave ratio *R,S*-amide:*R,R*-amide = 1:(0.866 ± 0.015); corrected value by comparison with standard reaction 1:0.866/1.115 = 1:0.775.

β,β-Caroten-2-ol (*2a*). (i) *2a* (4.8 mg) in pyridine (14 μl) and PBAnh (6 μl) was heated in a sealed Pyrex tube at 40–45°C for 1 3/4 h. (+)-*R*-α-phenylethyl amine (6 μl) was added at room temperature, the mixture shaken for 15 min and transferred to ethyl acetate (3–4 ml) for GLC.

Found for standard reaction with cyclohexanol (1 μl = 1 mg) ratio *R,S*-amide:*R,R*-amide 1:(1.115 ± 0.007).

Found for *2a* ratio *R,S*-amide:*R,R*-amide 1:(0.95 ± 0.02); corrected ratio 1:0.85.

(ii) Procedure as for (i) but using *2a* (2.9 mg), pyridine (21 μl, all carotenoid dissolved) PBAnh (3.6 μl) and (+)-*R*-α-phenylethyl amine (3.6 μl).

Found for standard reaction with cyclohexanol (0.6 μl) ratio *R,S*-amide:*R,R*-amide 1:(1.085 ± 0.01).

Found for *2a* ratio *R,S*-amide:*R,R*-amide 1:(0.945 ± 0.007); corrected ratio 1:0.87.

(iii) Procedure as for (i) but using *2a* (2.4 mg), pyridine (14 μl, all carotenoid dissolved), PBAnh (3 μl) and (+)-*R*-α-phenylethyl amine (3 μl).

Found for standard reaction with cyclohexanol (0.5 μl) ratio *R,S*-amide:*R,R*-amide = 1:(1.120 ± 0.011).

Found for *2a* ratio *R,S*-amide:*R,R*-amide = 1:(0.928 ± 0.008); corrected ratio 1:0.83.

Acknowledgements. We thank Dr. G. Ohloff, Firmenich & Co., for help with the preparative GLC separations, Professor K. Grob, Universität Zurich, for advise and help with the GLC-MS measurements and the Swiss National Foundation (grant No. 2.434.71) and The Norwegian Research Council for Science and Humanities (grant No. D. 32.22–1) for financial support.

The Reduction of Lignin Model Compounds and Spruce Dioxane Lignin by the Birch Reaction

P.-Å. PERNEMALM * and C. W. DENCE

Empire State Paper Research Institute, State University of New York, College of Environmental Science and Forestry, Syracuse, N.Y. 13210, U.S.A.

Several phenyl methyl ethers and spruce dioxane lignin were reduced by treatment with sodium in liquid ammonia in the presence of ethanol (Birch reduction). The product mixtures were resolved by vapor phase chromatographic techniques and the reduction products identified using combinations of NMR, IR, UV and mass spectrometric methods.

The aromatic moiety in 3,4-dimethoxyphenyl (veratryl) structures was reduced to a mixture of the corresponding unconjugated dihydro and tetrahydro derivatives. In addition, a methoxyl substituent was replaced by hydrogen, giving rise to 4-substituted di- and tetrahydroanisoles. In this instance both conjugated and unconjugated dienes were present with the latter greatly predominating. By contrast, reduction of a syringyl derivative, 3,4,5-trimethoxytoluene, resulted in the formation of the 1,4-dihydro derivative in 80 % yield as the only major product. With phenyl ethers containing a benzyl alcohol, α-keto or an α- or β-aryl ether substituent, reduction of these groups to the corresponding hydrocarbon took place and generally preceded reduction of the aromatic ring.

Reduction of spruce dioxane lignin with sodium in liquid ammonia under similar conditions resulted in the isolation of a material whose spectral properties were consistent with those of 2,5-dihydro-4-propylanisole.

Metal–liquid ammonia treatment of isolated lignins and softwood and hardwood meal has been used by Freudenberg,[1,2] Shorygina,[3–6] and Yamaguchi [7,8] and their co-workers, primarily as a means of studying lignin structure. As a consequence of this type of treatment, interunitary ether linkages were found to undergo hydrogenolysis yielding a variety of guaiacyl and syringylpropane monomeric fragments in which the propyl substituent exhibited varying degrees of reduction. The commonly observed net effect of the overall reaction is an increase in the hydroxyl content and a decrease in the methoxyl content of the lignin.

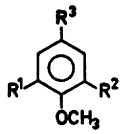
The discovery of Wooster, [9] subsequently exploited by Birch, [10–12] that the presence of a suitable proton source in the liquid ammonia solution promotes the reduction of benzenoid and other aromatic ring systems was particularly significant in the development of dissolving metal chemistry. In the application of dissolving metal reductions to lignin reported to date, no external proton source appears to have been added. There is, however, the strong possibility that lignin (in particular the phenolic hydroxyl and terminal methylol groups) may function as its own proton source in such reductions.

The extensive changes occurring when lignin is subjected to a dissolving metal reduction makes such a process theoretically attractive from a chemical modification viewpoint.[13] An examination of the literature indicates, however, a lack of systematic studies designed to describe the complete scope of possible transformations occurring when lignin is reacted under Birch reduction conditions. In attempting to fill this void, studies utilizing lignin model compounds appear to offer the best approach for isolating and subsequently cataloging the various reaction types in view of the complexity of the overall process.

Accordingly, the present investigation consisted mainly of an examination of the reactions of comparatively simple lignin model com-

* Present address: Department of Analytical Chemistry, University of Uppsala, Sweden.

Table 1. Model compounds reacted with sodium in liquid ammonia.



Compound	R^1	R^2	R^3
I	H	H	H
V	H	OCH_3	H
VIII	H	OCH_3	CH_3
XV	OCH_3	OCH_3	CH_3

XXVII	H	H	$O-$(*p*-methoxyphenyl)

pounds with sodium-liquid ammonia solutions in the presence of an external proton source, ethanol; *i.e.*, with a Birch reduction system. The models selected for study (see Table 1) consisted solely of compounds whose phenolic rings were completely etherified. This arbitrary structural restriction was made on the basis of results from a previous study [10] where it was shown that with few exceptions [10,14,15] unetherified phenolic units were not reduced by metals in liquid ammonia.

The model compound study was augmented by a brief examination of the behavior of Norway spruce dioxane lignin in the same reduction system.

RESULTS AND DISCUSSION

Products formed from the reactions of the various models with sodium in liquid ammonia in the presence of ethanol are summarized in Table 2. Spectrometric data essential to the identification of the various products are compiled in Table 3.

Anisole (I). The reduction of anisole with Na/NH_3 in the presence of ethanol was previously reported by Birch [10] to yield 2,5-dihydroanisole (II) as the principal product. In a subsequent investigation, Benkeser *et al.* [16] presented evidence indicating the probable formation of two additional compounds, 2,3-dihydroanisole (III) and 3,4,5,6-tetrahydroanisole (IV). The yields of reaction products recorded in Table 2 agree closely with those reported by Benkeser [16] using either sodium or lithium as the

Table 2. Reaction products and product yields.

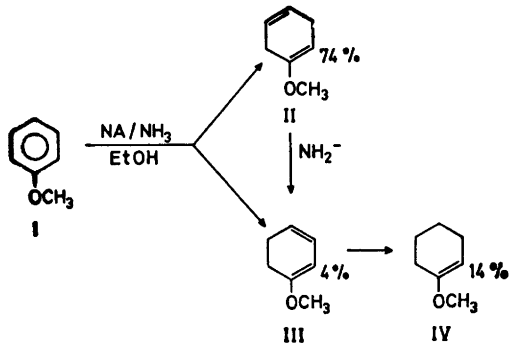
[a] Identified by comparison of gas chromatographic retention time with that of authentic material (anisole, phenol, or guaiacol) and estimated by comparison with peak areas corresponding to known amounts of the corresponding authentic substance. [b] Not measured. [c] Yield based on weight of neutral fraction which was almost pure XXVIII.

metallic component. The principal steps in the overall reaction are outlined below.



The comparatively low yield of 2,3-dihydroanisole (III) undoubtedly reflects the facile reduction of the conjugated diene system to the tetrahydro derivative.

As indicated by the data in Table 2, reductive cleavage resulting in the formation of phenol occurred to less than 0.1 %. In the absence of ethanol under otherwise identical conditions, the yield of phenol was 27 %. Partial conversion (isomerization) of II to III probably from the action of the amido ion formed in the equilibrium reaction

$$^{-}OC_2H_5 + NH_3 \rightleftharpoons NH_2^{-} + C_2H_5OH$$

on the former structure.[17,18]

Veratrole (V). Veratrole was previously reported by Birch [12] to yield a mixture of 2,5-dihydroanisole (II) and 3,6-dihydroveratrole (VI) with the former predominating. In the present study, the same two products were obtained together with other compounds listed in Table 2. The total yield of products (~99 %) accounts essentially for all of the starting material.

The nature of the products indicates that two main competing reactions occur: (1) replacement of one methoxyl group with a hydrogen resulting ultimately in the formation of anisole reduction products and (2) reduction to di- and tetrahydroveratrole. The fact that the ratios of the three anisole derivatives parallel those of the corresponding products resulting from direct treatment of anisole indicates that the methoxyl group is replaced by a hydrogen before the aromatic nucleus is reduced.

The detection of a significant amount (7 %) of guaiacol indicates the occurrence of a competing ether cleavage reaction. The high yield of guaiacol compared to that of phenol is consistent with the substituent effect noted by Birch.[12]

4-Methylveratrole (VIII). The two principal products detected in the reaction mixture, 2,5-dihydro-4-methylanisole (IX) and 3,6-dihydro-4-methylveratrole (XI), together account for 82 % of the starting material (Table 2).

The position of the methoxyl group relative to the methyl group in the anisole derivatives was established by comparison of the IR and NMR spectra of 2,3,4,5-tetrahydro-4-methylanisole with those of the isolated products. The NMR spectrum of the conjugated compound 2,3-dihydro-4-methylanisole (X), which shows two vinyl protons as two doublets (*cf.* Table 3), further reinforces the validity of the structure assignment.

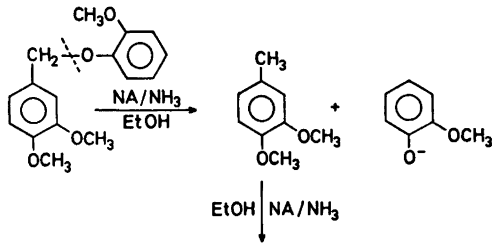
Spectra of the phenolic compound (XIV) suggested the presence of a methylguaiacol. Comparison of the IR and NMR spectra of this compound with those of authentic 4- and 5-methylguaiacol (XIV) clearly indicated that it was the latter isomer.

3,4,5-Trimethoxytoluene (XV). The reaction mixture consisted of only one major product, 1,4-dihydro-3,5-dimethoxytoluene (XVI), formed in 80 % yield and of trace amounts of di- and tetrahydroanisoles and veratroles. Failure of the 1,4-dihydro derivative to undergo further reduction is attributed to the difficulty in conjugating double bonds which involves displacement of one double bond from a position in which it is conjugated with the unshared electron pair of the oxygen of a methoxyl group. Benzoic acid derivatives typically give rise to 1,4-dihydro compounds under Birch conditions, and the previously reported [19] conversion of 3,4,5-trimethoxybenzoic acid to 1,4-dihydro-3,5-dimethoxybenzoic acid by such treatment is particularly relevant to the case at hand.

In an attempt to form a bromo derivative, 1,4-dihydro-3,5-dimethoxytoluene was reacted with bromine in CCl_4. The isolated product, 2,6-dibromo-3,5-dimethoxytoluene, ostensibly arose from a series of bromine additions and hydrogen bromide eliminations.

3,4-Dimethoxy-α-(o-methoxyphenoxy)toluene (XVII). Because of the small amount of material available for reaction, none of the products were isolated but were identified and estimated

by comparing retention times and peak areas with those of authentic materials isolated from the reduction of 4-methylveratrole (VIII). The yields of the various products obtained in the reduction of this ether are very nearly identical to those of the corresponding compounds resulting from the reduction of 4-methylveratrole (see Table 2). This suggests that the benzyl aryl ether linkage undergoes rapid hydrogenolysis generating guaiacol and 4-methylveratrole, which subsequently undergoes reduction to di- and tetrahydro anisoles and veratroles.



di- and tetrahydroanisoles and veratroles

That the hydrogenation of the benzyl aryl ether linkage is complete is indicated by the essentially quantitative recovery of guaiacol. The results in Table 2 also reveal that the overall reaction is virtually complete in 30 min or less and that the products thereafter undergo little additional change.

1-(3,4-Dimethoxyphenyl)ethanol (XVIII). Inspection of Table 2 indicates that the two dihydro products, XIX and XX, account for nearly 90 % of the starting material. While these two products were recovered from the product mixture, the tetrahydro compounds XXI and XXII were identified solely on the basis of similarities in the gas chromatographic patterns of the product mixture with those of veratrole and 4-methylveratrole. Quantitative analysis of XXI and XXII was accomplished by comparing their peak areas with that corresponding to a specified quantity of 3,6-dihydro-4-ethylanisole.

The general similarity of the product distribution to that noted above for veratrole and 4-methylveratrole leads to the conclusion that the starting material undergoes a stepwise reaction involving first hydrogenolysis of the benzyl alcohol group followed by reduction of the product, 4-ethylveratrole, by the usual pattern. The total absence of hydroxyl group characteristics in the various product fractions supports the conclusion that reduction of this alcohol to the corresponding hydrocarbon is essentially quantitative.

1-(3,4-Dimethoxyphenyl)-2-(o-methoxyphenoxy)ethanol (XXIII). The distribution of reaction products replicates in general the now familiar pattern observed for other veratryl derivatives in which the dihydroanisole and dihydroveratrole derivatives account for the bulk of the starting material. The observed reductive cleavage of the β-aryl ether group is especially significant since linkages of this type comprise a major portion of the interunitary linkages in lignin. In this regard, treatment of lignin with sodium in liquid ammonia has, in fact, resulted in the formation of monomeric fragments in which the β-carbon of the side chain was completely reduced as would be expected if hydrogenolysis of the β-aryl ether linkage had occurred.

The less-than-theoretical recovery of guaiacol (50 %) probably has no fundamental significance since the other cleavage product can be fully accounted for in terms of the partially reduced 4-ethylanisoles and 4-ethylveratroles. Failure to achieve the expected near-quantitative recovery of guaiacol is ascribed to mechanical losses (*e.g.*, volatilization) in the workup.

As in the previous instance, the reduction products were identified by their relative positions in the gas chromatogram of the product mixture and were estimated by comparing their areas with the peak area produced by injection of a known amount of 3,6-dihydro-4-ethylveratrole (XX).

Acetoveratrone (XXIV). Acetoveratrone reacted more vigorously and was converted to products which collectively had sustained a greater loss of methoxyl groups than the models discussed heretofore. These observations can be logically rationalized on the basis of the electron-withdrawing property of the aceto group which would have the effect of activating the ring toward attack by a solvated electron.

Chromatography of the product mixture on an OV-1 column (maintained at 90 °C) resulted in the collection of a fraction whose NMR spectrum indicated the presence of a nonconjugated dihydroanisole with the methoxyl group situated either *meta* or *para* to the side chain.

When the chromatographic separation was repeated on a preparative size Carbowax column maintained at a considerably higher temperature (160 °C), the NMR spectrum (vinyl proton region) of the fraction corresponding to the same peak suggested the presence of a mixture consisting of 2,5- and 2,3-dihydro-4-ethylanisole. Evidently isomerization of the unconjugated to the conjugated compound had occurred as a result either of the higher column temperature or as the result of reaction with the column itself.

Additional peaks in the NMR spectrum of the material isolated from the Carbowax column, and in particular a signal at δ 1.65 (doublet), suggest the presence of 2,3-dihydro-3-ethylanisole. If this compound was indeed present in the product mixture, it most probably can be considered as an artifact resulting from isomerization of 2,5-dihydro-3-ethylanisole on the chromatographic column. If 2,5-dihydro-3-ethylanisole is a product in the Birch reduction of acetoveratrone, the increased tendency for replacement of methoxyl at the *para* position would accord with the activating effect of the aceto group on this position. This would further imply that some replacement of the *para* methoxyl group occurred prior to reduction of the α-carbonyl group.

The foregoing observations cannot be taken as providing incontrovertible evidence for the presence of 2,5-dihydro-3-ethylanisole in the product mixture. Nevertheless. if present, this compound was not separated from the corresponding 4-ethyl isomer under the imposed chromatographic conditions. Accordingly, the value reported in Table 2 is the combined yield of both isomers.

3,4-Dimethoxyphenyl-2-(o-methoxyphenoxy)-acetophenone (XXVI). The reductive pattern of this compound was similar to that of acetoveratrone in that more than 50 % of the starting material was accounted for by the dihydroanisole derivatives (Table 2). The yield of 3,6-dihydro-4-ethylveratrole was, however, nearly double the value obtained for acetoveratrone. The reduction of the veratryl (3,4-dimethoxyphenyl) moiety was accompanied by the near quantitative cleavage of the β-aryl ether linkage as indicated by an 89 % recovery of guaiacol (Table 2). It is also noteworthy that, whereas reduction of acetoveratrone was accompanied by the formation of what appeared to be polymeric substances, material of this type was absent in the case at hand. This observation probably accounts for the difference in the total yield of recovered products in each instance.

4,4'-Dimethoxydiphenyl ether (XXVII). The diaryl ether linkage represented by the title compound was not extensively cleaved under Birch reduction conditions, and the sole cleavage product detected was 2,5-dihydroanisole in 0.9 % yield. The only other product identified was the tetrahydrodiphenyl ether (XXVIII) which accounted for nearly 90 % of the starting material.

The effect of para substituents on the cleavage of diaryl ether linkage in Na/NH_3 solutions has been studied by Sartoretto and Sowa.[30] These authors found that methoxyl groups situated *para* to the ether linkage retarded the cleavage reaction. Further reduction of partially reduced diaryl ether XXVIII in all likelihood is retarded since both double bonds in each ring contain oxygen-bearing (electron-releasing) substituents.

Dioxane lignin. In order to enhance the probability of obtaining monomeric fragments with partially reduced phenolic rings, the dioxane lignin was pretreated with borohydride to remove carbonyl groups followed by methylation with diazomethane to convert the phenolic hydroxyl groups to methyl ethers. The modified lignin was dissolved in liquid ammonia and reacted with sodium (Na/phenylpropane, ~20/1) in the presence of ethanol. The reaction mixture was fractionated into neutral, acidic and dioxane-soluble components as described in the Experimental section.

The neutral fraction was separated by vapor phase chromatography into two components which were collected and subjected to spectroscopic analysis. The NMR and mass spectra of the component with the longer retention time were consistent with the patterns expected for 2,5-dihydro-4-propylanisole (see XXIX in Table 3). The assignment of the methoxyl *para* to the propyl group is arbitrary but considered justifiable in the light of the results of the model studies and since the influence of the α-carbonyl groups on cleavage of the *para*-situated methoxyl had been eliminated by prior reduction.

The amount of 2,5-dihydro-4-propylanisole (XXIX) was estimated from peak area measure-

ment to be ~1 % using 2-methoxy-4-propylphenol as a standard. This low yield is consistent with the expectation that the dihydro compound would arise only from those lignin monomer units which originally possessed free phenolic hydroxyl groups and which had no carbon-carbon bonds linking either the aromatic ring or the side chain to the adjoining unit. Based on the lignin structural scheme proposed by Freudenberg,[21] approximately only 5 % of the units in the polymer network meet these requirements.

The NMR spectrum of the neutral component with the lower retention time did not correspond to any of the spectra of the products identified in the model compound reductions.

The acidic fraction was several fold larger than the neutral fraction and may be accounted for by the hydrogenolytic conversion of phenolic ether groups to phenols which are stable to reduction under Birch conditions. Gas chromatographic analysis of the acidic fraction revealed the presence of only one peak. The material corresponding to this peak was collected (200 mg or 1.6 %) and subjected to IR, NMR, and mass spectroscopic analysis. Collectively, these spectra suggested that the material was a phenol with methoxyl and propyl groups attached to the ring. Since the IR spectrum did not correspond to that of authentic 4-propylguaiacol, the compound has been tentatively identified as 2-methoxy-5-propylphenol (XXX, Table 3). If this assignment is correct, the formation of this compound would be analogous to and consistent with the previously noted detection of 2-methoxy-5-methylphenol in the reduction of 4-methylveratrole.

Lignin-derived structures, such as the above, which contain a methoxyl substituent *para* to side chain, would necessarily have as their origin phenolic units which subsequently were converted to methyl ethers in the methylation pretreatment. This structural restriction accounts in part for the low recovery of XXX.

An NMR spectrum of the dioxane-soluble fraction displayed a broad band in the aromatic proton region but no pronounced signal in the vinyl proton region. This fraction appeared therefore to consist mainly of phenolic oligomers and was not investigated further.

Summary

1. Veratrole and its derivatives were reduced under Birch conditions to mixtures of di- and tetrahydroanisoles and veratroles. The dihydro-derivatives consisted mainly of the unconjugated type (1,4-addition) with much smaller amounts of conjugated cyclohexadiene derivatives being formed, either by 1,2-addition or from isomerization of unconjugated diene systems.

2. The relative proportion of the products varied somewhat from reaction mixture to reaction mixture in a manner which appeared to reflect differences in the electron-donating or electron-withdrawing characteristics of the sub-

stituent at the 1-position (*i.e.*, the side chain). The side chain substituent gave evidence of influencing not only the sites and degree of ring reduction but also the relative extents of replacement of the *meta*- and *para*-situated methoxyl groups as well.

3. Unlike the veratryl derivatives whose reduction gave rise to complex mixtures of partially reduced anisoles and veratroles, Birch reduction of 3,4,5-trimethoxytoluene afforded a comparatively simple product mixture consisting essentially of one product hydrogenated at the 1- and 4- positions with concomitant loss of the 4-methoxyl group.

4. Model compounds having α- and β-aryl ether substituents on the side chain were reduced in a stepwise fashion with cleavage of ether linkage preceding ring reduction. Hydrogenolysis in such cases was rapid and produced essentially quantitative yields of the phenol corresponding to the aryl substituent. Under the same conditions, methyl aryl ether groups were hydrogenolyzed to the corresponding phenols only to a slight extent, and the diphenyl ether linkage in 4,4′-dimethoxydiphenyl ether appeared entirely resistant to cleavage. In this latter case, the individual rings were each reduced to the dihydro stage in high yield.

5. Birch reduction of spruce dioxane lignin led to the formation of a neutral material in approximately 1 % yield which the available evidence strongly indicated to be 2,5-dihydro-4-propylanisole. Other evidence suggested that phenolic fragments in the monomer to oligomer range were produced as a consequence of hydrogenolysis of alkyl aryl ether linkages.

Conclusion

The present model compound study has shown that phenol ethers are extensively converted to cyclohexene and cyclohexadiene derivatives by reduction with sodium in liquid ammonia in the presence of a proton donor. Reduction of the aromatic ring is largely preceded by reduction of α-carbonyl groups and hydrogenolysis of benzyl alcohol and α- and β-aryl ether groups.

With respect to lignin itself, results of the current study lead to the conclusion that Birch reduction of phenolic ether moieties will occur only to a very limited extent since phenolic structures, preferentially formed through hydrogenolysis of phenyl alkyl ether units, generally are not reduced under Birch conditions. Some Birch reduction can be expected to take place, however, on those units having ether units more resistant to hydrogenolysis (*e.g.*, diphenyl ether units) and on phenolic units converted to methyl ethers prior to reduction as demonstrated by the present study.

EXPERIMENTAL

Synthesis of reactants. 3,4-Dimethoxy-α-(*o*-methoxyphenoxy)toluene (XVII) was prepared as described by Mikawa,[22] m.p. 77 – 78 °C [lit.[22] 78 – 79 °C]. 3,4,5-Trimethoxytoluene (XV) was obtained by a Clemmensen reduction [23] of syringaldehyde [24] followed by methylation with dimethyl sulfate and alkali, [25] b.p. 95 – 98 °C at 2 – 3 mmHg. NMR (neat): δ 6.43 (s, 2 H), 3.78 (s, 3 H), 3.73 (s, 6 H), 2.26 (s, 3 H).

Acetoguaiacone was methylated with dimethyl sulfate and alkali to produce acetoveratrone (XXIV), b.p. 135 – 136 °C at 2 – 3 mmHg. NMR ($CDCl_3$): δ 7.37 – 7.70 (m, 2 H), 6.76 – 7.00 (m, 1 H), 3.90 (s, 3 H), 2.55 (s, 3 H). Reduction of XXIV with sodium borohydride afforded 1-(3,4-dimethoxyphenyl)ethanol (XVIII), b.p. 105 – 110 °C at 2 – 3 mmHg. NMR (CCl_4): δ 6.82 (bs, 1 H), 6.70 (s, 2 H), 4.64 (q, 1 H, $J = 5.5$ Hz), 3.67 (s, 6 H), 3.59 (s, 1 H), 1.32 (d, 3 H, $J = 5.5$ Hz).

1-(3,4-Dimethoxyphenyl)-2-(*o*-methoxyphenoxy)ethanol (XXIII) was prepared by reduction of the corresponding ketone, [26] m.p. 133.5 – 134.0 °C [lit.[34] 133 – 134 °C]. 4,4′-Dihydroxydiphenyl ether was converted to the corresponding dimethyl ether (XXVII) by methylation with dimethyl sulfate and alkali, m.p. 100 – 102 °C [lit. [28] 102 °C].

Anisole, veratrole, and 4-methylveratrole were obtained commercially and used without further purification.

Synthesis of products. 2,3,4,5-Tetrahydroanisole (IV) was prepared by reaction of cyclohexanone with trimethyl orthoformate in the presence of mesitylene sulfonic acid as described by Lindsay and Reese.[29] Distillation of the product mixture through a Vigreux column yielded a fraction boiling at 139 – 142 °C [lit. [29] 138 – 142 °C] whose NMR and IR spectral characteristics (Table 2) were consistent with those expected for the compound. The same procedure was used to prepare 2,3,4,5-tetrahydro-4-methylanisole (XII) from 4-methylcyclohexanone; b.p. range of XII, 159 – 161.5 °C.

2,3-Dihydroanisole was obtained by two methods. The first consisted of treatment of 2-cyclohexen-1-one with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid as outlined by Nussbaum *et al.* [30] The product mixture was distilled through a Vigreux column

and the fraction boiling at 146 – 147 °C collected. Gas chromatographic analysis indicated that the product was approximately 80 % pure.

2,3-Dihydroanisole was also obtained by reacting a fraction comprised of a mixture of 2,3-dihydroanisole and 2,5-dihydroanisole with potassium *t*-butoxide [31] to isomerize the non-conjugated component. The fraction boiling at 142 – 145 °C was approximately 70 % pure as indicated by gas chromatographic analysis. This fraction was further purified by preparative gas chromatography (see Table 3 for NMR and IR characteristics).

3-Hydroxy-4-methoxytoluene (5-methylguaiacol) was prepared by subjecting isovanillin (3-hydroxy-4-methoxybenzaldehyde) to a Clemmensen reduction. The product was distilled under reduced pressure yielding an oil which solidified on cooling, m.p. 32 – 33 °C [lit. [12] 33 °C]. NMR ($CDCl_3$): δ 6.56 – 6.80 (bd, 3 H), 5.60 (s, 1 H), 3.67 (s, 3 H), 2.18 (s, 3 H).

4-Propylanisole was prepared by the catalytic hydrogenation of isoeugenol methyl ether.

Other products were obtained by preparative gas chromatography of the product mixtures and subsequently purified.

Bromination of 1,4-dihydro-3,5-dimethoxytoluene. 1,4-Dihydro-3,5-dimethoxytoluene (200 mg) was dissolved in CCl_4 and reacted at room temperature with a solution of bromine in the same solvent. After removal of solvent, a solid was obtained which after recrystallization from methanol/water melted at 170 °C. Yield, 88 mg, mass spectrum (70 eV): parent ion (p) and base peak at *m/e* 312, p + 2 and p – 2 peaks are 54 % of parent peak; NMR ($CDCl_3$): 6.46 (s, 1 H), 3.89 (s, 6 H), 2.62 (s, 3 H).

Reduction of model compounds. Approximately 400 ml of liquid NH_3 was distilled from a cylinder through a glass filter and condensed in a 1 l, three-necked, round-bottomed flask by means of a dry ice/acetone-cooled cold finger. The flask was immersed in a dry ice/acetone bath and fitted with a dropping funnel to which was attached a $CaCl_2$ drying tube.

The aromatic compound (0.2 mol) in ethanol* (1.0 mol) was added to the ammonia through the dropping funnel and the mixture heated to its reflux temperature by removal of the dry ice/acetone bath. Sodium (1.0 mol) was then added carefully in 0.5 – 1.0 g amounts; and when the addition was completed, the mixture was allowed to reflux for 4 h. Some additional ammonia was distilled into the flask during this period to maintain the level constant. Under these conditions, the starting compound was for all practical considerations completely consumed in all instances.

The reaction was quenched after replacing the cold finger with a stopper, by the slow addition of 100 ml of methanol through the dropping funnel. After most of the excess sodium had reacted (~ 30 min), 100 ml of water was added and the mixture was extracted with 5 × 50 ml of ether (neutral fraction); the water phase was acidified with concentrated HCl and extracted with 5 × 50 ml ether (acidic fraction).

Small samples of the neutral and acidic fractions were set aside for quantitative VPC analysis. The remaining portions of the two fractions were concentrated by distilling off the solvent through a Vigreux column at atmospheric pressure.

Preparation and modification of dioxane lignin. Dioxane lignin was prepared from 150 g of ethanol-benzene (1:1) extracted Norway spruce wood meal by treatment with a solution of 1,4-dioxane/water (9:1) containing 0.2 N HCl as described by Browning.[32] Yield, 22.8 g. Anal.: C 59.45; H 5.67; OCH_3 14.27.

To maximize the possibility of obtaining Birch reaction products, the dioxane lignin was first modified by reducing the carbonyl groups with $NaBH_4$ and etherifying the phenolic hydroxyl groups with diazomethane. Dioxane lignin (10.5 g) in 440 ml of $EtOH/H_2O$ (1:1) and 120 ml of 0.1 M NaOH was reacted with 6.4 g of $NaBH_4$ overnight.[33] The reaction mixture was acidified to pH 4 with hydrochloric acid and concentrated. Water was added and the resulting precipitate was centrifuged off and washed twice with water. Yield, 9.3 g. An IR spectrum of the product indicated that all but a trace of carbonyl had been removed.

The borohydride-reduced lignin (9.1 g) was partially dissolved in 200 ml of 1,4-dioxane and reacted twice with diazomethane over a 2 h period. The solution was concentrated to 200 ml and after removal of a small portion for IR and elemental analysis, was reacted directly with Na/NH_3 in the presence of ethanol. Anal.: C 62.08; H 5.90; OCH_3 16.51.

Birch reduction of modified dioxane lignin. Modified dioxane lignin dissolved in 1,4-dioxane (see previous section) was reacted for 4 h in the standard way using 400 ml of liquid ammonia, 23.0 g of sodium, and 46.0 g of ethanol. After the addition of methanol and water and evaporation of the ammonia, a brownish-yellow liquid remained which contained no undissolved material.

The reaction mixture was extracted with 5 × 50 ml of ether (neutral fraction) following which the water phase was acidified with concentrated hydrochloric acid. A brown precipitate formed upon acidification which did not dissolve when the mixture was extracted with 5 × 50 ml of $CHCl_3$ (acidic fraction). The polymer-like precipitate was filtered off and dissolved in 1,4-dioxane (dioxane-soluble fraction).

The amount of material in each fraction in solution was obtained by evaporating an aliquot of each solution to dryness and weighing the residue: neutral fraction, 0.35 g; acidic fraction, 1.85 g; and dioxane-soluble fraction, 3.45 g.

Separation of reaction products. Preliminary

* Dioxane (50 ml) was employed as a co-solvent to dissolve compounds XVII, XXIII, XXVI, and XXVII.

attempts to separate the product mixtures into their individual components by distillation through Vigreux and spinning band columns were generally unsuccessful. Chromatography on a silver nitrate-silica gel column [34] was similarly unproductive, seemingly as a result of reaction between the products and the column.

Satisfactory separation of the product mixtures was ultimately obtained using preparative-scale gas chromatography. The retention time data in these analyses were diagnostically useful for classifying peaks as corresponding to dihydro unconjugated, dihydro conjugated, and tetrahydro cyclohexyl ring systems.

Preparative-scale gas chromatography was performed on an F & M Model 776 gas chromatograph. A 220 × 1.8 cm stainless steel column was filled with 3 % Carbowax 20M-TPA on Chromosorb G (30/60). Column conditions: oven, 90 – 150 °C (isothermal): detector, 190 °C; injector, 170 °C; manifold, 180 °C; flow rate, 200 ml N_2/min. A 300 – 400 µl amount of 50 % (by volume) ether solution was injected.

The collected samples were injected on an analytical column to confirm purity and, if necessary, reinjected on the preparative column to effect greater purification. After separation and purification, the components in the product mixture were subsequently characterized by various combinations of IR, UV, NMR and mass spectrometry. In other instances (compounds XVII, XXIII, XXIV, and XXVI), identification and estimation were based solely on comparison of the retention time and peak area of the component with the corresponding parameters of a known standard.

The analytical instrumentation consisted of Varian Aerograph models 1520 and 1700 fitted with a 180 × 0.3 cm stainless steel column filled with 3 % Carbowax 20M-TPA on Chromosorb G (45/60). Column conditions: oven, 90 – 130 °C (isothermal); detector. 195 – 250 °C; injector, 150 – 200 °C; flow rate, 25 ml N_2/min. Products in the acetoveratrone and dioxane lignin reaction mixtures were separated and collected using an F & M Model 720 (thermal conductivity) instrument fitted with a 180 × 0.6 cm stainless steel column filled with 3 % OV-1 on Chromosorb G (45/60). Column conditions: oven, 90 – 160 °C (isothermal); detector, 120 – 200 °C; 110 – 180 °C; flow rate, 40 ml He/min.

For quantitative gas chromatographic analysis, standards were prepared from the collected or synthesized samples whenever possible and peak heights were compared to those of the corresponding peaks in the reaction mixture. Otherwise, peak areas were compared to those of a closely related compound with a similar structure. The column support in these cases was coated with Carbowax 20M-TPA (3 %).

Spectrometric analysis. Infrared spectra were recorded on a Perkin-Elmer grating infrared spectrophotometer. Liquid samples were measured as films; solids were either mixed with KBr and made into pellets or dissolved in chloroform or carbon tetrachloride. Mass spectra were obtained using a Perkin-Elmer Hitachi Model RMU-6E single-focusing spectrophotometer. Ultraviolet spectra were obtained on samples dissolved in 95 % ethanol using a Unicam Model SP-800A recording spectrophotometer.

NMR spectra were recorded on a Varian A-60 spectrometer using trimethylsilane as an internal standard. The spectra were obtained with the samples in the neat condition whenever possible, but usually the amount of collected sample was too small and the sample was dissolved in a solvent. The instability of some of the products in $CDCl_3$ resulted in the use of CCl_4 which, after first being washed with base, obviated this problem.

Diels-Alder Reactions of 2,4-Cyclohexadienones. I. Structural and Steric Orientation in the Dimerisation of 2,4-Cyclohexadienones*

ERICH ADLER and KRISTER HOLMBERG

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

Salicyl alcohol (*3a*) and its methyl homologues *3b*—*3e* on treatment with periodate give the Diels-Alder dimers *5a*—*e* of the initially formed spiro(oxirane-2,4-cyclohexadienones) *4a*—*e*. Similarly, dimers *2a*—*e* are formed from 2,4-cyclohexadienones *1a*—*e* ("*o*-quinols").

Cleavage of the oxirane rings in *5a*—*e* by hydrogen bromide gave the bis(bromohydrins) *6a*—*e*, which on treatment with Raney nickel were converted to the corresponding *o*-quinol dimers *2c* and *2e* or to the further hydrogenated compounds *8*, *10*, and *11*, the three latter products also being obtained on Raney nickel reduction of *o*-quinol dimers *2a*, *2b* and *2d*, respectively.

Since the complete structure of dimer *5a* has been determined by X-ray crystallographic analysis of its bis(bromohydrin) *6a*, the final structure of *o*-quinol dimer *2a* now is established as well. Furthermore, the results of the Raney nickel reductions show that the Diels-Alder dimerisations of the spiro(oxirane-2,4-cyclohexadienones) *4b*—*e* and those of *o*-quinols *1b*—*e* are analogous with regard to regiospecificity and stereochemical specificity.

Recent X-ray analysis [16] elucidated the structures of *2b* and *2d* and showed these to be analogous to the structure of *2a* and, furthermore, photochemical work [14] proved that dimer *2e* is analogous to *2a* with regard to *endo* configuration and structural orientation. From the structural correlations revealed by the Raney nickel reductions it can be concluded that the orientation and the stereochemistry thus established for *o*-quinol dimers *2b*, *2d*, and *2e* are characteristic for the spirooxirane dimers *5b*, *5d*, and *5e* as well.

The steric arrangements of the *tert*-carbinol and oxirane groups in the two types of dimers can be ascribed to steric approach control in the dimerisation. Reasons for the regiospecificity in the dimerisation of 2,4-cyclohexadienones are briefly discussed.

In earlier communications [1-4] it has been shown that periodate oxidation of methyl homologues of *o*-cresol gives 6-hydroxy-6-methyl-2,4-cyclohexadienones ("*o*-quinols", *1b*—*1e*) which undergo rapid Diels-Alder reaction to give the *o*-quinol dimers *2b*—*2e*. The corresponding dimer (*2a*) of unsubstituted *o*-quinol (*1a*) has been obtained on acid hydrolysis of the acetate of *1a*.[5] Contrary to the free *o*-quinols, the acetates are comparatively stable at room temperature.

The aim of the present study was primarily to elucidate the structures of *o*-quinol dimers *2a*—*2e*.

Dimerisation of *o*-quinols *1a*—*e* formally offers several possibilities with regard to the structure of the products. Firstly, in the molecule acting as dienophile either the α,β or the γ,δ double bond of its conjugated carbonyl system may participate in the reaction. As observed earlier in similar cases,[6] the γ,δ double bond reacts specifically (see for instance, Refs. 2 and 3 and the review article, Ref. 7). Furthermore, there are the following alternative possibilities:

(*a*) The dimers may have *endo* or *exo* configuration.

(*b*) Due to the presence of an asymmetric C-atom in the monomers four isomeric dimers with different steric arrangements at C-atoms 5 and 9 are conceivable.

(*c*) There are two possible structural orientations of the diene and dienophile moieties, as illustrated by formulae *2a* and *2a'*.

Although the alternatives involved in items *a*—*c* make the formation of sixteen isomeric dimers (D,L pairs) possible, in each case only one dimeric product has been obtained. The

dimerisation of the *o*-quinols (*1a-e*) thus proceeds with a very high degree of stereochemical selectivity (items *a* and *b*) and regioselectivity (item *c*). No further isomers could be detected by NMR analysis and thin layer chromatography of the crude reaction products. For simplicity, it will therefore be assumed in the following that the dimerisations are stereospecific and regiospecific.

By degrading the dimer of *o*-quinol *1a* to 1,7-dimethyl-2-naphthol, Metlesics and Wessely [5] proved the structural orientation in this dimer to be that given in formula *2a* rather than *2a'*. Experimental evidence for the *endo* configuration and the steric arrangements at C-5 and C-9, however, was still lacking.

Periodate oxidation of salicyl alcohol (*3a*) was found [8] to result in the formation of spiro(oxirane-2,4-cyclohexadienone) *4a* which rapidly dimerised to give the bis(spirooxirane) *5a*. Treatment of this dimer with hydrogen bromide afforded a bis(bromohydrin), for which structure *6a* was established by X-ray crystallography.[9] This also proved structure *5a* for the parent dimer.[8]

Reductive opening of the oxirane rings in *5a* or reductive debromination of *6a* could be expected to give the *o*-quinol dimer *2a*, provided that the latter had the same structural and steric arrangements as established for *5a* and *6a*. Attempts to perform these conversions by treating *5a* with $LiAlH_4$ or $NaBH_4$ or by treating *6a* or the corresponding bis(iodohydrin) with hydrogen in the presence of Pt and Pd catalysts as well as with various other reductants remained without success. Raney nickel in boiling ethanol, however, effected the conversion of the bromomethyl groups in *6a* into methyl groups with simultaneous hydrogenation of the C=C and C=O double bonds present to give the tetrahydroxy compound *8*. The same reduction product was obtained on similar treatment of *o*-quinol dimer *2a*. This constitutes unambiguous proof of structure *2a* and shows that the Diels-Alder dimerisation of *o*-quinol *1a* is completely analogous to that of spirooxirane *4a* with regard to both regiospecificity and stereospecificity.

Treatment of *8* with chromic acid in the presence of manganese(II) nitrate [10] resulted in rapid cleavage of the 1,2-diol groups to give the dicarboxylic acid *9*. The ease with which this cleavage takes place tends to indicate *cis* configuration for both 1,2-diol groups (*cf.* Ref. 11).

It was further of interest to examine whether the similarity in structural and steric characteristics thus established for the pair *5a* and *2a* is true also for other pairs of the two kinds

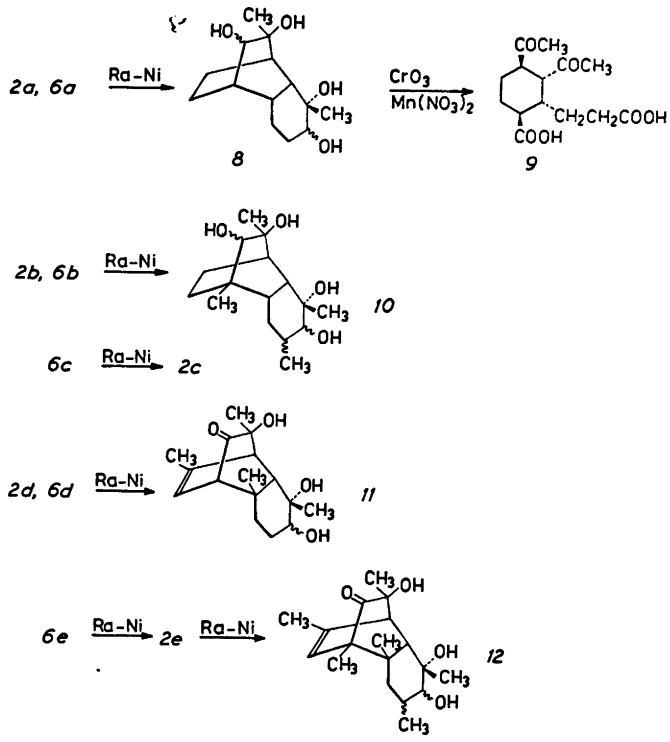

Chart 3.

of dimers. The bis(bromohydrins) (*6b – 6e*) obtained from the methyl-substituted dimers *5b – 5e* as well as the corresponding *o*-quinol dimers (*2b – 2e*) were therefore treated with Raney nickel (Chart 3).

The bis(spirooxiranes) *5b – 5d* were prepared by periodate oxidation of the *o*-hydroxybenzyl alcohols *3b – 3d*, again only one isomer being obtained from each of the alcohols. Treatment of the dimers *5b – 5d* with hydrogen bromide provided the bis(bromohydrins) *6b – 6d*, which, when treated with methanolic potassium hydroxide, regenerated the bis(spirooxiranes) *5b – 5d*. Dimer *5e* and its bis(bromohydrin) *6e* have been described earlier.[8] The *o*-quinol dimers *2b*, *2d*, and *2e*, which are formed on periodate oxidation of 2,6-dimethyl-, 2,4-dimethyl-, and 2,4,6-trimethylphenol *via* the short-lived *o*-quinols *1b*, *1d*, and *1e*, respectively, have also been reported.[2,3] Dimer *2c* has now been prepared similarly from 2,5-dimethylphenol.

Whereas the periodate oxidation of 2,6- and 2,4-dimethylphenol as well as of 2,4,6-trimethylphenol is rapid, the phenols being consumed within a few minutes and the corresponding dimers being obtained in fair yields, 2,5-dimethylphenol reacts sluggishly, unconsumed phenol still being found after 1 h. In addition to the expected dimer *2c* (see Exptl.), the reaction mixture contained substantial amounts of 2,5-dimethyl-1,4-benzoquinone as well as a monocarboxylic acid formed from *2c* by ketol cleavage, as will be further described in a following paper.

Since periodate consumption by *o*-cresol is still slower than by 2,5-dimethylphenol, periodate oxidation of the former phenol cannot be used for the preparation of dimer *2a*, which, however, is available *via* the *o*-quinol acetate (*1a*, OAc instead of OH).[5]

Raney nickel reduction of bis(bromohydrins) *6b – 6e* revealed that these compounds and, consequently, the bis(spirooxiranes) *5b – 5e* as well have the same structural and steric arrangements as the corresponding *o*-quinol dimers *2b – 2e*. Thus, bis(bromohydrin) *6b* as well as *o*-quinol dimer *2b* gave the octahydro derivative *10* of dimer *2b*. Product *10* was obtained in fair yields, indicating high stereoselectivity of the Raney nickel reduction.

From the reaction mixture obtained on Raney

nickel reduction of *6c*, the corresponding *o*-quinol dimer *2c* could be isolated and, similarly, *6e* was reduced to *2e*. In the last-mentioned case, prolonged reduction converted both *6e* and *2e* into the partially hydrogenated *o*-quinol dimer *12*. Finally, a similarly hydrogenated *o*-quinol dimer (*11*) was obtained from both bis(bromohydrin) *6d* and *o*-quinol dimer *2d*.

It is noteworthy that hydrogenation of *o*-quinol dimer *2e* in acetic acid, using PtO_2 as catalyst (3 atm, 48 h), yielded a tetrahydro compound, m.p. 213 – 214°,[13] not identical with *12*, m.p. 240 – 242°, obtained with Raney nickel. The UV spectra (ethanol) of these compounds indicate that the homoconjugated carbonyl system is intact in both cases. The spectra exhibit the expected transannular charge transfer bands at 205 nm (log $\varepsilon = 3.61$) and 208 nm (log $\varepsilon = 3.65$), respectively, and enhanced $n \rightarrow \pi^*$ absorptions at 310 nm (log $\varepsilon = 2.25$) and 308 nm (log $\varepsilon = 2.35$), respectively. Apparently, the two compounds are stereoisomers arising by hydrogenation of the α,β-conjugated carbonyl system of *2e*. This indicates different stereochemical selectivity of the two hydrogenation systems used.

From the results of reduction summarized in Chart 3 it can be concluded that the dimerisation of *o*-quinols *1a – 1e* involves the same structural and steric orientation as the dimerisation of the correspondingly substituted spiro(oxirane-2,4-cyclohexadienones) *4a – 4e*. However, since only the structure of dimer *5a* was completely known,[8,9] the reduction experiments only established the complete structure of *o*-quinol dimer *2a* (structural orientation as in formula *2a* rather than *2a'*, *endo* configuration and steric arrangements at C-5 and C-9 as shown by formula *2a*).

Further experimental data are now available which indicate that the structures of *o*-quinol dimers *2b – 2e* as well as those of the bis(spirooxiranes) *5b – 5e* are analogous to those of *2a* and *5a*, respectively.

NMR spectra of dimers *2d* and *2e* clearly show the presence of the vicinal hydrogen atoms at positions 4 and 4a. In the NMR spectrum (DMSO-d_6) of *2d* H-4 gives rise to a triplet at δ 2.96, whereas the signal for H-4a is a doublet at δ 2.72 ($J_{4,4a} = J_{4,2} = 2.2$ Hz). Similarly, the NMR spectrum ($CDCl_3 + D_2O$) of *2e* shows H-4 as a triplet at δ 3.15 and H-4a as a doublet at δ 2.84 ($J_{4,4a} = J_{4,2} = 2.0$ Hz). This proves the structural orientation of dimers *2d* and *2e* to be of type *2a* rather than *2a'*. The same orientation then must be true for the bis(spirooxiranes) *5d* and *5e*, and has already been proven for the last-mentioned dimer by similar NMR analysis.[8] Furthermore, Becker [14] concluded from the photochemically induced intramolecular cycloaddition of *o*-quinol dimers *2b*, *2d*, and *2e* (*cf.* also Ref. 15) that these dimers had *endo* configuration and a structural orientation analogous to *2a*. Finally, recent X-ray crystallographic analysis completely established the structures of *o*-quinol dimers *2b* and *2d*,[16] revealing that the steric orientations at C-5 and C-9 in these two dimers are the same as found for dimers *2a* (Ref. 1 and present paper) and *5a*.[9] The correlations between the *o*-quinol dimers and the bis(spirooxiranes) reported above then imply that the complete structures of bis(spirooxiranes) *5b* and *5d* are as depicted in Chart 2.

Experimental proof is still lacking for the structures of *o*-quinol dimer *2c* and its bis(spirooxirane) counterpart *5c* as well as for the steric arrangements at carbon atoms 5 and 9 of the dimer pair *2e* and *5e*. It seems justified, however, to assume that the structural features of these dimers are analogous to those discussed above. Chemical evidence for the stereochemistry at C-5 and C-9 of the *o*-quinol dimers will be given in a forthcoming paper.

It is likely that the structural and steric specificity found in the dimerisation of *o*-quinols and spiro(oxirane-2,4-cyclohexadienones) is valid for the dimerisation of other 2,4-cyclohexadienones as well. On the basis of dipole moment measurements, the dimer of 2,6,6-trimethyl-2,4-cyclohexadienone [17] has been assigned the *endo* form as well as a structural orientation corresponding to that of the dimers discussed in the present paper. Furthermore, chemical and spectroscopic data indicated that the steric arrangement at C-5 of the dimers *2f* and *2g* of the fluorinated [18] and chlorinated [19] 2,4-cyclohexadienones *1f* and *1g* is analogous to that found in dimers *2a* and *5a* as well as in the pairs *2b*, *5b* and *2d*, *5d*.

To summarize, it can be concluded that the rapid Diels-Alder dimerisation of *o*-quinols *1a – e* as well as that of the spiro(oxirane-2,4-cyclohexadienones) *4a – e:*

(*a*) follows the *endo* rule,

(*b*) is stereospecific, the CH_3 groups at C-5 and C-9 of dimers *2a – e* as well as the CH_3

groups of the oxirane rings in dimers *5a–e* being oriented away from the reaction center, which indicates steric approach control,[20] and

(c) is regiospecific, the diene and the dienophile moieties being oriented to each other as illustrated by formula *2a* rather than *2a'*.

The factors responsible for the regiospecificity of Diels-Alder reactions involving unsymmetrical dienes and dienophiles so far are not well understood (for reviews, see Refs. 21–25). Neither steric interactions nor polar factors have been found to be of decisive importance. Although Diels-Alder reactions now are generally considered to be concerted $4\pi+2\pi$ cycloadditions, it has been pointed out that the preferred structural orientation is "consistent with reaction through the transition state in which build up of diradical character is best accomodated".[25] It is easily seen that diradicals which, in a formal sense, could be regarded as intermediates in the formation of 2,4-cyclohexadienone dimers of type *2a* are favoured, by greater resonance stabilisation, over those which would lead to the isomers of type *2a'*.

The view that Diels-Alder reactions may involve a diradical-like transition state has found support in a very recent theoretical study on the regioselectivity of concerted cycloadditions.[26]

EXPERIMENTAL

Ultraviolet spectra were recorded on a Cary Model 14 spectrophotometer; IR and NMR spectra were obtained using Beckman 9A and Varian A-60 instruments, respectively. Chemical shifts are given in δ(ppm) units, TMS being used as internal standard. Melting points are uncorrected.

o-*Quinol dimers 2a, 2b, 2d,* and *2e* were prepared according to Refs. 5, 3, 2, and 3, respectively, and *bis(bromohydrins) 6a* and *6e* were obtained according to Ref. 8.

1,4a,5,8a-Tetrahydro-5,9-dihydroxy-2,5,8,9-tetramethyl-1,4-ethanonaphthalene-6,10(4H)-dione (2c).*,** A solution of sodium metaperiodate (54 g, 0.25 mol) in water (1.1 l) was added to a solution of 2,5-dimethylphenol (13.2 g, 0.10 mol) in water (3.3 l). After 1 h, unconsumed periodate was destroyed by addition of ethylene glycol (10 g), a small amount of amorphous material was filtered off and the solution was extracted with six 250 ml portions of methylene chloride. The dried extract on evaporation under vacuum left a deep red semi-solid residue. The solution of the latter in ethanol was treated with sulphur dioxide, and, after addition of sodium bisulfite, was concentrated under vacuum, water being added repeatedly. The aqueous mixture containing a crystalline deposit was made alkaline by addition of sodium bicarbonate and extracted with methylene chloride. Undissolved crystalline material was collected and identified as *2,5-dimethylhydroquinone*, m.p. 210°; yield, 13 %. The extract, after washing with aqueous bicarbonate and water, drying and evaporation, gave an oil, from which on treatment with ether (5 ml) almost colourless crystals of *2c* deposited (yield, 12 %). After recrystallisation from ethanol, m.p. 200–201°. (Found C 69.39; H 7.53. Calc. for $C_{16}H_{20}O_4$: C 69.54; H 7.30.) IR (KBr): ν_{max} (cm^{-1}) 1660 (conj. CO), 1725 (CO), 3450 (OH). UV (abs. ethanol), λ_{max} (nm) and log ε values: 210, 3.93 (charge transfer band, homoconjugated CO system); 233, 3.98 (conj. CO); 305, 2.45 (homoconj. and conj. CO). NMR (DMSO-d_6): δ 1.10 and 1.18 (singlets, 3 H each, 2 CH_3), 1.53 and 1.95 (doublets, 3 H each, 2 olefinic CH_3); 2.80–3.35 (4 H, 4 CH), 4.76 and 5.45 (singlets, 1 H each, 2 OH), 5.60–6.00 (2 H, 2 olefinic H).

If the deep red semi-solid residue obtained above before the SO_2 treatment was extracted with hot benzene, the extract gave *2,5-dimethyl-1,4-benzoquinone*, m.p. 122°.

Diacetate of 2c. From *2c* by treatment with the $Ac_2O/HClO_4$ reagent according to Ref. 28. M.p. 190–191° after recrystallisation from ethanol. (Found: C 66.84; H 6.58; CH_3CO 23.10. Calc. for $C_{20}H_{24}O_6$: C 66.65; H 6.71; CH_3CO 23.89.)

o-*Hydroxybenzyl alcohols* 3b, 3c, *and* 3d. 2-Hydroxy-3-methylbenzyl alcohol (*3b*) and 2-hydroxy-5-methylbenzyl alcohol (*3d*) were prepared from the corresponding methylphenol, trioxane and boric oxide (B_2O_3) according to Ref. 12, whereas a slight modification of the method described there was used for 2-hydroxy-4-methylbenzyl alcohol (*3c*). The orthoborate obtained in 50 % yield from *m*-cresol (27 g), boric oxide (8.75 g) and trioxane (7.5 g) was collected and added to a stirred mixture of toluene (50 ml) and ice water (50 ml), and the mixture was made alkaline by addition of 18 g of a 30 % aqueous sodium hydroxide solution. The aqueous phase was washed with diisopropyl ether, then was made slightly acidic with aqueous H_2SO_4 and extracted with ether. The extract yielded a crystalline product (yield, 30 %), which was recrystallised from chloroform and from benzene. M.p. 107–108° (Lit.[27] m.p. 111°).

Dimeric spiro(oxirane-2,4-cyclohexadienones) 5b, 5c, *and* 5d. A solution of sodium metaperiodate (11.75 g, 0.055 mol) in water (250 ml)

* Nomenclature according to *Chem. Abstr. 76* (1972) 1445 CS.

** Preparation based on experiments carried out by Dr. Britt Berggren and tekn.lic. Ingrid Jansson.

was added to a solution of the *o*-hydroxybenzyl alcohol (*3b*, *3c*, and *3d*, respectively, 6.90 g, 0.050 mol) in water (700 ml). The mixture was kept in the refrigerator for 24 h. The almost colourless precipitate formed was recrystallised from chloroform.

1',4',4'a,8'a-Tetrahydro-1',7'-dimethyl-dispiro-[oxirane-2,5'(6'H)-[1,4]ethanonaphthalene-9',2''-oxirane]-6',10'-dione (5b).* From *3b* and periodate. Yield of crude product, 74 %. M.p. 206 – 207°. (Found: C 70.61; H 5.92. Calc. for $C_{16}H_{16}O_4$: C 70.57; H 5.92.) IR (KBr): ν_{max} (cm^{-1}) 1696 (conj. CO), 1731 (CO), 3076 (oxirane-CH_2). NMR (DMSO-d_6): δ 1.35 (s, 3 H, CH_3), 1.76 (t, 3 H, olefinic CH_3), 2.40 – 3.20 (7 H, 2 CH_2 and 3 CH), 5.80 and 6.48 (doublets, 1 H each, 2 olefinic H), 6.66 (m, 1 H, olefinic H).

1',4',4'a,8'a-Tetrahydro-2',8'-dimethyl-dispiro-[oxirane-2,5'(6'H)-[1,4]ethanonaphthalene-9',2''-oxirane]-6',10'-dione (5c). From *3c* and periodate. Yield of crude product, 71 %. M.p. 222.5 – 223.5°. (Found: C 70.42; H 5.99. Calc. for $C_{16}H_{16}O_4$: C 70.57; H 5.92.) IR (KBr): ν_{max} (cm^{-1}) 1698 (conj. CO), 1731 (CO), 3048 (oxirane-CH_2). NMR (DMSO-d_6): δ 1.71 and 2.09 (doublets, 3 H each, 2 olefinic CH_3), 2.71 and 2.93 (doublets, 1 H each, AB system with $J = 6.8$ Hz, oxirane-CH_2), 3.02 (broadened singlet, 2 H, oxirane-CH_2), 3.52 (broad, 2 H, 2 CH), 6.01 – 6.27 (2 H, olefinic H). Signals arising from 2 H are partially hidden by the signal due to incompletely deuterated DMSO.

1',4',4'a,8'a-Tetrahydro-3',8'a-dimethyl-dispiro[oxirane-2,5'(6'H)-[1,4] ethanonaphthalene-9',2''-oxirane]-6',10'-dione (5d). From *3d* and periodate. Yield of crude product, 87 %. M.p. 217.5 – 218.5°. (Found: C 70.44; H 5.98. Calc. for $C_{16}H_{16}O_4$: C 70.57; H 5.92.) IR (KBr): ν_{max} (cm^{-1}) 1698 (conj. CO), 1727 (CO), 3056 (oxirane-CH_2). NMR (DMSO-d_6): δ 1.34 (s, 3 H, CH_3), 1.80 (d, 3 H, olefinic CH_3), 2.23 (d, 1 H, CH), 2.74 and 3.00 (doublets, 1 H each, AB system with $J = 6.5$ Hz, oxirane-CH_2), 2.99 and 3.18 (doublets, 1 H each, AB system with $J = 6.2$ Hz, oxirane-CH_2), 5.78 (m, 1 H, H-2'), 6.09 and 6.60 (doublets, 1 H each, H-7' and H-8', $J = 10$ Hz). Signals from 2 H are hidden by the signal for incompletely deuterated DMSO.

Bis(bromohydrins) 6b, 6c *and* 6d. Aqueous hydrobromic acid (7.40 g of 66 % HBr solution, 0.060 mol HBr) was added dropwise to a solution of bis(spirooxirane) (*5b*, *5c*, and *5d*, respectively, 6.80 g, 0.025 mol) in dioxane (750 ml). After 8 h at room temperature the solution was brought to dryness under vacuum.

5,9-Bis(bromomethyl)-1,4a,5,8a-tetrahydro-5,9-dihydroxy-1,7-dimethyl-1,4-ethanonaphthalene-6,10(4H)-dione (6b). From *5b* and HBr. The solid residue obtained gave colourless crystals (64 %) from ethanol, m.p. 185.5 – 186.5°. (Found: C 44.47; H 4.11; Br 36.43. Calc. for $C_{16}H_{16}O_4Br_2$: C 44.27; H 4.18; Br 36.81.) IR (KBr): ν_{max} (cm^{-1}) 1688 (conj. CO), 1713 (CO), 3439 and 3483 (OH). NMR (DMSO-d_6): δ 1.26 (s, 3 H, CH_3), 1.78 (broadened singlet, 3 H, olefinic CH_3), 2.70 – 3.80 (7 H, 2 CH_2 and 3 CH), 5.37 and 6.20 (singlets, 1 H each, 2 OH), 5.62 (dd, 1 H, olefinic H), 6.14 (d, 1 H, olefinic H), 6.40 (m, 1 H, olefinic H).

5,9-Bis(bromomethyl)-1,4a,5,8a-tetrahydro-5,9-dihydroxy-2,8-dimethyl-1,4-ethanonaphthalene-6,10(4H)-dione (6c). From *5c* and HBr. The acetone solution of the light yellow oily residue was concentrated to a volume of 15 ml. The crystalline product deposited (63 %), after recrystallisation from benzene and from acetone, had m.p. 174 – 175° and contained 1 mol of acetone per mol. (Found: C 46.01; H 4.79; Br 32.71. Calc. for $C_{16}H_{16}O_4Br_2.C_3H_6O$: C 46.36; H 4.97; Br 32.47.) IR (KBr): ν_{max} (cm^{-1}) 1698 (conj. CO), 1719 (CO), 3440 (OH). NMR (DMSO-d_6): δ 1.58 (d, 3 H, olefinic CH_3), 1.98 (broadened singlet, 3 H, olefinic CH_3), 2.09 (s, 6 H, acetone), 2.87 – 3.70 (8 H, 2 CH_2 and 4 CH), 5.18 and 6.17 (singlets, 1 H each, 2 OH), 5.80 (broadened doublet, 1 H, olefinic H), 5.98 (broadened singlet, 1 H, olefinic H).

5,9-Bis(bromomethyl)-1,4a,5,8a-tetrahydro-5,9-dihydroxy-3,8a-dimethyl-1,4-ethanonaphthalene-6,10(4H)-dione (6d). From *5d* and HBr. The solid residue was recrystallised from ethanol to give *6d* (88 %), m.p. 211 – 212°. (Found: C 44.56; H 4.25; Br 36.54. Calc. for $C_{16}H_{16}O_4Br_2$: C 44.27; H 4.18; Br 36.81.) IR (KBr): ν_{max} (cm^{-1}) 1673 (conj. CO), 1730 (CO), 3394 and 3482 (OH). NMR (DMSO-d_6): δ 1.37 (s, 3 H, CH_3), 1.73 (d, 3 H, olefinic CH_3), 2.84 and 2.92 (doublets, 1 H each, 2 CH), 3.33 (t, 1 H, CH), 3.34 and 3.57 (doublets, 1 H each, AB system with $J = 11$ Hz, CH_2), 3.65 (s, 2 H, CH_2), 5.36 and 6.24 (singlets, 1 H each, 2 OH), 5.55 (d, further split by allylic coupling, 1 H, H-2), 6.05 and 6.40 (doublets, 1 H each, H-7 and H-8, $J = 10$ Hz).

The bis(bromohydrins) *6b* – *6d* on treatment with a 2.4-fold excess of 0.1 M methanolic KOH during 10 min regenerated the corresponding bis(spirooxiranes) *5b* – *5d* (yields, 70 – 90 %), identified by m.p., mixed m.p. and IR spectra.

Diacetates 7b, *7c* and *7d* were obtained by dissolving the bis(bromohydrins) (*6b*, *6c*, and *6d*, respectively, in the EtOAc-Ac_2O-$HClO_4$ reagent [28] and working up the reaction mixture after 15 min. Recrystallisation from ethanol gave colourless products.

Diacetate 7b. From *6b* (68 %), m.p. 165 – 166°. (Found: C 46.34; H 4.36; Br 31.41. Calc. for $C_{20}H_{22}O_6Br_2$: C 46.35; H 4.28; Br 30.84.) IR (KBr): ν_{max} (cm^{-1}) 1653 (C=C), 1709 (conj. CO), 1741 – 1750 (CO and ester-CO).

Diacetate 7 c. From *6c* (70 %), m.p. 156 – 157°. (Found: C 46.53; H 4.33; Br 30.05. Calc. for $C_{20}H_{22}O_6Br_2$: C 46.35; H 4.28; Br 30.84.) IR (KBr): ν_{max} (cm^{-1}) 1623 (C=C), 1700 (conj. CO), 1740 and 1756 (CO and ester-CO).

Diacetate 7 d. From *6d* (65 %), m.p. 147.5 –

* Nomenclature according to *Chem. Abstr. 76* (1972) 1319 CS.

148.5°. (Found: C 46.44; H 4.35; Br 30.89. Calc. for $C_{20}H_{22}O_6Br_2$: C 46.35; H 4.28; Br 30.84.) IR (KBr): ν_{max} (cm^{-1}) 1630 (C=C), 1718 (conj. CO), 1738 and 1759 (CO and ester-CO).

Reductions with Raney nickel

Perhydro-2,3,5,6-tetrahydroxy-3,5-dimethyl-1,4-ethanonaphthalene (8). *(a) From bis(bromohydrin)* 6a. The stirred solution of *6a* containing 0.5 mol of dioxane per mol (1.015 g) in 95 % ethanol (125 ml) was refluxed for 5 h with Ra-Ni "W-6"[29] (10 g) and then filtered through celite and evaporated to dryness under vacuum. The solid residue was treated with boiling acetone (30 ml), which dissolved the major part of the product. The hot solution was filtered and, on cooling, gave colourless crystals (yield, 6 %), m.p. 251 – 252°, which rose to 253 – 254° on recrystallisation from methanol-acetone. (Found: *M*, by mass spectrometry, 256.1689. Calc. for $C_{14}H_{24}O_4$: *M*, 256.1674.) IR (KBr) ν_{max} (cm^{-1}) 3400 and 3450 (broad, OH), The NMR spectrum (CD_3OD) shows two singlets at δ 1.26 and 1.33 (3 H each, 2 CH_3) and signals between δ 1.40 and 3.67 (14 H, 6 CH and 4 CH_2). There were no signals due to olefinic protons.

(b) From o-*quinol dimer* 2a. The procedure was similar to that described under (a). From the cooled acetone solution a crude crystalline product of m.p. 210 – 215° (15 %) was obtained. Two recrystallisations from methanol-acetone gave pure *8*, m.p. 252 – 253°, identical with the product obtained according to (a) by mixed m.p., IR, NMR, and mass spectra.

2,3-Diacetyl-6-carboxycyclohexanepropanoic acid (9). To the solution of compound *8* (484 mg) in a mixture of acetic acid (7 ml), water (0.75 ml) and 1.5 ml of an aqueous solution of manganese(II) nitrate (500 g $Mn(NO_3)_2$/l), after cooling to 10°, a solution of chromic acid (0.8 g of CrO_3 in 2.3 ml of water) was added in portions during a period of 3 min. The solution was again cooled to 10° and conc. H_2SO_4 (0.45 ml) was added during 1 min. The reaction mixture was kept at 30° for 8 min and after addition of water (30 ml in portions) neutralised with aqueous bicarbonate and finally extracted with ethyl acetate. The extract gave a yellow oil which on treatment with a small amount of ether provided crystals, m.p. 179 – 180° (yield, 54 %) after recrystallisation from acetone. (Found: *M*, by mass spectrometry, 284.1274. Calc. for $C_{14}H_{20}O_6$: *M*, 284.1260.) IR (KBr): ν_{max} (cm^{-1}) 1702 and 1742 (CO and COOH), 2400 – 3600 (COOH). The NMR spectrum (DMSO-d_6) shows 2 singlets at δ 2.10 and 2.12, due to 2 CH_3CO.

Perhydro-2,3,5,6-tetrahydroxy-1,3,5,7-tetramethyl-1,4-ethanonaphthalene (10). *(a) From bis(bromohydrin)* 6b. The stirred solution of *6b* (1.085 g) in 95 % ethanol (110 ml) was refluxed for 7 h with Ra-Ni (19 g). Removal of the solvent from the filtered solution gave a semi-solid product, which was extracted with boiling acetone (30 ml). After cooling to 0° the mixture was filtered and the filtrate concentrated to a volume of 10 ml. Addition of hexane until beginning precipitation, followed by cooling in the refrigerator, provided *10* (25 %), m.p. 199 – 200° after recrystallisation from acetone. (Found: C 67.33; H 9.91. Calc. for $C_{16}H_{28}O_4$: C 67.57; H 9.92.) IR (KBr): ν_{max} (cm^{-1}) 3275, 3370, 3412, 3494 and 3519 (OH). The NMR spectrum (DMSO-d_6) indicates the presence of 4 OH (δ 3.51, 3.92, 4.14 and 4.22) and shows no absorption due to olefinic H.

(b) From o-*quinol dimer* 2b. Treatment of *2b* (1.90 g) with Ra-Ni (15 g) in ethanol (2.5 h reflux) and work-up as above. The semi-solid residue after treatment with 25 ml of a chloroform-hexane mixture (2:1) gave crystals of *10* (48 %), m.p. 200 – 201° after recrystallisation from ethyl acetate and from acetone. Identical with the product obtained according to (a) by mixed m.p., IR and NMR spectra.

o-*Quinol dimer* 2c *from bis(bromohydrin)* 6c. The stirred solution of *6c* (2.17 g) in 95 % ethanol (130 ml) was refluxed with Ra-Ni (6 g) for 1.5 h. The filtered solution on evaporation gave a light yellow oil which was chromatographed on a silica gel column using acetone-hexane (2:1) as solvent. Dimer *2c* (R_F = 0.65), m.p. 199 – 200° (from ethanol), was obtained in 15 % yield and shown to be identical with the product prepared by periodate oxidation of 2,5-dimethylphenol (p. 469) by mixed m.p., IR and NMR spectra.

1,4,4a,5,6,7,8,8a-Octahydro-5,6,9-trihydroxy-3,5,8a,9-tetramethyl-1,4-ethanonaphthalen-10-one (11). *(a) From bis(bromohydrin)* 6d. The stirred solution of *6d* (2.17 g) in 95 % ethanol (130 ml) was refluxed for 2 h with Ra-Ni (20 g), then filtered and evaporated giving a semi-crystalline residue which on treatment with a mixture of chloroform (10 ml) and acetone (10 ml) left crystals of *11* (22 %), m.p. 240 – 241° after recrystallisation from acetone. (Found: *M*, by mass spectrometry, 280.1676. Calc. for $C_{16}H_{24}O_4$: *M*, 280.1674.) IR (KBr): ν_{max} (cm^{-1}) 1718 (CO), 3272, 3480, and 3536 (OH). NMR (DMSO-d_6): δ 1.11 (s, 6 H, 2 CH_3), 1.18 (s, 3 H, CH_3), 1.30 – 2.10 (4 H, 2 CH_2), 1.87 (d, 3 H, olefinic CH_3), 2.27, 2.32, and 3.36 (doublets, 1 H each, 3 CH), 3.62 and 5.08 (singlets, 1 H each, 2 OH), 4.52 (d, 1 H, sec. OH), 5.44 (d, further split by allylic coupling, 1 H, olefinic H). The signal for 1 CH is hidden by the signal for incompletely deuterated DMSO.

(b) From o-*quinol dimer* 2d. The stirred solution of *2d* (1.90 g) in 95 % ethanol (125 ml) was refluxed for 3 h with Ra-Ni (15 g), then filtered and evaporated to dryness. The solid residue on recrystallisation from chloroform gave *11* (39 %), m.p. 239 – 240° after further recrystallisation from acetone. The product was identical by mixed m.p., IR and NMR spectra with *11* obtained according to (a).

o-Quinol dimer 2e *from bis(bromohydrin)* 6e. Compound *6e* (1.386 g) was treated for 4 h with Ra-Ni (9 g) in refluxing 95 % ethanol (140 ml). The filtered solution was brought to dryness, leaving crude crystalline *2e*, m.p. 170 – 175° (67 %). After recrystallisation from acetone and from benzene, the product had m.p. 181 – 182° and was identical by mixed m.p., IR and NMR spectra with *2e* prepared by periodate oxidation of mesitol.

1,4,4a,5,6,7,8,8a-Octahydro-5,6,9-trihydroxy-1,3,5,7,8a,9-hexamethyl-1,4-ethanonaphthalen-10-one (12). *o*-Quinol dimer *2e* (912 mg) was treated for 5 h with Ra-Ni (18 g) in refluxing 95 % ethanol. The filtered solution was concentrated under vacuum to a volume of 10 ml. After 2 h at 0° the crystalline product deposited was collected and recrystallised from 95 % ethanol, m.p. 240 – 242° (35 %). (Found: *M*, by mass spectrometry, 308.1996. Calc. for $C_{18}H_{28}O_4$: *M*, 308.1987) IR (KBr): ν_{max} (cm^{-1}) 1710 (CO), 3270, 3530 (OH). NMR (DMSO-d_6): δ 0.92 (s, 6 H, 2 CH_3), 1.05, 1.13, and 1.26 (singlets, 3 H each, 3 CH_3), 1.89 (d, 3 H, olefinic CH_3), 1.60 – 3.52 (partly overlapped by H_2O signal, 6 H, CH_2 and 4 CH), 3.60 (s, 1 H, OH), 4.58 (d, 1 H, *sec.* OH), 5.09 (broad singlet, 2 H, OH and olefinic H). UV data, see p. 468.

Mercuric Mercury and Methylmercury Complexes of Glutathione

GEORG A. NEVILLE* and TORBJÖRN DRAKENBERG

The Institute of Hygiene, University of Lund, Magle Stora Kyrkogata 12, S-223 50 Lund, Sweden and Organic Chemistry 2 and Physical Chemistry 2, Chemical Center, University of Lund, Box 740, S-220 07 Lund, Sweden

The preparation, isolation and characterization of mercury(II) complexes of glutathione from alcoholic aqueous media is described. With mercury(II) chloride, a complex having the composition of a double salt in the solid state, $(C_{10}H_{16}O_6N_3S)_2Hg_3Cl(OH)(HCl)_2$, was obtained which on dissolution in water showed similar ^{13}C NMR spectral features as the complex, $(C_{10}H_{15}O_6N_3S)Hg.H_2O$, obtained with mercury(II) acetate. By comparison with the complex, $C_{10}H_{16}O_6N_3SHgCH_3$, obtained with methylmercury chloride, these complexes appear to have 1:1 inner salt (or chelate) structures in solution. Evidence from ^{13}C NMR Fourier transform spectroscopy suggests that the co-ordination requirements of (mercuric) mercury bonded to sulphur are satisfied by chelation of the glycyl peptide nitrogen of glutathione. The results are discussed in relation to earlier polarographic and alkalimetric investigations and recent NMR studies of metal complexation by glutathione.

Glutathione, a true peptide, is found in the erythrocytes of whole blood and has a number of functions including protection of hemoglobin against oxidation by hydrogen peroxide. It acts as a prosthetic group of glyceraldehyde-phosphate dehydrogenase and as a coenzyme of glyoxalase. It is also believed that glutathione functions as a "sulfhydryl-preserver" in maintaining certain proteins (as sulfhydryl-containing enzymes) in the reduced state which is essential for their activity.[1] Although the binding of mercury to human erythrocytes has been subjected to considerable investigation,[2] little is known concerning the detailed molecular nature of binding. The binding is generally attributed to sulfhydryl groups of hemoglobin, glutathione and of stromal groups.[3]

In a polarographic study of the reaction of mercuric mercury (acetate and chloride) with glutathione (RS), Stricks and Kolthoff[4] obtained indirect evidence for the formation of three compounds with mercury: $Hg(RS)_2$, $Hg_2(RS)_2$, and $Hg_3(RS)_2$ in the absence of chloride and in the pH range between 3 and 9. In the presence of much chloride ion, the formation of the complexes $Hg_2(RS)_2$ and $Hg_3(RS)_2$ is suppressed by formation of the complex $HgCl_4^{2-}$. Similar conclusions were reached by Kapoor, Doughty and Gorin[5] in their alkalimetric titration study of the reaction of $HgCl_2$ with glutathione, however, with one exception, no precipitates were isolated and characterized. Kapoor *et al.*[5] obtained a precipitate whose mercury content was found to be 49 % by bringing a 3:2 $HgCl_2$/glutathione mixture to pH 5. No other analyses were obtained on this substance and no structural features were proposed for it.

Recently Fuhr and Rabenstein[6] reported on the nature of mercurial binding to glutathione in mercury(II) nitrate solutions using ^{13}C NMR spectroscopy, and Simpson, Hopkins and Haque[7] reported on binding of methylmercury chloride to the model peptide, *N*-acetyl-L-cysteine, by means of a ^1H NMR study. In this paper, the isolation of mercury complexes of glutathione with mercury(II) acetate, mercury(II) chloride, and methylmercury chloride is reported together with the use of Fourier Transform ^{13}C NMR spectroscopy for their characterization.

RESULTS AND DISCUSSION

In contrast to the dilute aqueous conditions employed in polarographic and titrimetric investigations,[4,5] mercury complexes were pre-

* 1972 Centennial Fellow of the Medical Research Council of Canada. Present address: Health Protection Branch, Dept. National Health & Welfare, Tunney's Pasture, Ottawa, Canada.

pared and isolated in this study from alcoholic aqueous media moderately concentrated with reactants. Complete elemental analyses were obtained to establish empirical formulae. Recent work [8] in the characterization of hydrated mercury complexes of cysteine methyl ester serves to emphasize the value of complete elemental analysis including analysis for oxygen. FT ^{13}C NMR spectroscopy has been valuable for elucidating mercurial binding and configuration in isolated mercury complexes of methionine [9] and of cysteine, *S*-methyl cysteine and cysteine methyl ester.[10]

The mercury(II) glutathionate complex prepared from mercury(II) acetate is devoid of acetate groups as shown by infrared spectra, microanalysis, and ^{13}C NMR spectra. Microanalysis provided elemental ratios in excellent agreement with the composition $C_{10}H_{17}O_7N_3SHg$ (M. W. 524.14) which could be formulated in terms of either a hydroxy complex, $(C_{10}H_{16}O_6N_3S)Hg(OH)$, or as a hydrated inner salt (or chelate), $(C_{10}H_{15}O_6N_3S)Hg.H_2O$. The consideration of a hydroxy complex is not unreasonable in view of crystallographic work by Johansson [11] demonstrating a basic salt structure for mercury(II) perchlorate. Similarly, Björnlund [12] has established that the compound previously formulated as $HgO.Hg(BrO_3)_2.H_2O$ is, in reality, $Hg(OH)BrO_3$. Unfortunately, the three complexes reported here were shown to be amorphous by X-ray diffraction. Attempts to grow crystals at moderate temperature (120 °C) from mercury-sulphur containing complexes in the presence of their mother liquors resulted in complete degradation,[8] and attempts to obtain crystals by solute diffusion [13] were unpromising and thwarted by oxidation of glutathione.

Microanalysis and infrared spectra showed the methylmercury(II) glutathionate complex, obtained using methylmercury chloride, to be anhydrous and to have the composition $C_{11}H_{19}O_6N_3SHg$ and not be in the form of a hydrochloride salt. In this complex, the methylmercury group is bonded only to the sulphur of glutathione and is free of any other intramolecular interaction in solution. This conclusion is consistent with the nature of the 1:1 complex formed by CH_3Hg^+ and *N*-acetyl-L-cysteine [7].

In the case of the complex obtained using a 1:1 molar ratio of glutathione and mercury(II) chloride, complexation was found to be more complicated. Examination of the elementary stoichiometric ratios revealed a chlorine to mercury ratio of 1.5 to 1.0 and provided the basis for consideration of the mixed complex, $[(C_{10}H_{16}O_6N_3S)HgCl.HCl][(C_{10}H_{16}O_6N_3S)Hg(OH).HCl].H_2O$. From the calculated composition: C 20.75; H 3.22; O 19.36; N 7.26; S 5.54; Hg 34.67; Cl 9.19 %, monohydration was rejected on the basis of the unacceptable deviation from the oxygen analyses. The hydrogen analysis is not a sufficiently sensitive indicator for hydration in complexes of high formula weight. The % drying loss is not reliable by itself as an indicator of hydration and is best supported by oxygen analysis. The best fit of the analytical data for the complex of glutathione obtained with $HgCl_2$ was provided by a basic chloride, dihydrochloride formulation: $(C_{10}H_{16}O_6N_3S)_2Hg_2Cl(OH)(HCl)_2$.

For the complex obtained with glutathione and mercury(II) chloride, it would appear that precipitation of this complex in ethanolic media occurs as a double salt as suggested by elemental analysis. Upon dissolution in water, the double complex must dissociate and behave as a simple 1:1 mercury glutathionate species like that obtained using mercury(II) acetate because its solutions provide similar ^{13}C NMR spectra.

The complexes described above cannot simply be monomeric forms of the $Hg_2(SR)_2^{2-}$ complexes proposed by Kapoor *et al.* [5] The latter were indicated at pH 7 after the consumption of one mol of base per mol of glutathione. Kapoor *et al.* consider that the second equivalent of mercury in the bis complexes co-ordinates with two amino groups made available by neutralization of the ammonium ions. The complexes reported here were isolated under more acidic conditions and would not be expected to show co-ordination by free amino groups. Infrared spectra support this interpretation by the similarity of their broad N–H stretching regions with that of glutathione.

STRUCTURAL EVIDENCE BY ^{13}C NMR

The ^{13}C NMR chemical shift evidence (Table 1) shows that in aqueous solution the glutathione complexes obtained with mercury(II) acetate and mercury(II) chloride are very similar in their structural and electronic features. As it was necessary to examine the mercury(II)

Table 1. ^{13}C NMR chemical shifts (ppm rel. TMS) for D_2O solutions of glutathione and its complexes obtained with mercury(II) acetate, methylmercury chloride, and mercury(II) chloride.

[a] Relative to glutathione; [b] $\delta_{CH_3Hg} = 10.8$ ppm; [c] Measured at 90 °C, all other samples at 37 °C.

glutathionate hydrochloride complex at 90 °C in order to have all the sample in solution, the chemical shifts for this complex may change by approximately 1.0 ppm due to the temperature effect.* Both mercuric complexes show a pronounced downfield shift (~8 ppm) of the methylene carbon bearing the sulphur indicating mercurial bonding to sulphur as generally surmised. A downfield shift of 4.4 ppm (based on noncomplexed glutathione at pD 7.0) was reported by Fuhr and Rabenstein [6] for the cysteinyl methylene carbon of glutathione complexing with mercury(II) nitrate. Jung *et al.* [14] reported a downfield shift of 13 ppm for the same methylene carbon when glutathione was converted to its oxidized (S – S) form.

It is proposed that the co-ordination requirements of mercury(II) ion in our solvated mercuric complexes are satisfied by chelation to a deprotonated peptide nitrogen analogous to that reported by Rabenstein [15] for bis(glycylglycinato)cobaltate (III). Crystal structures of metal-peptide complexes [16] would appear to rule out consideration of chelation to oxygen following lactam-lactim enolization. Two possibilities exist for such peptide nitrogen coordination with either of the amide linkages flanking the methine carbon (C – 3) (see Table 1). Chelation involving the C-9 linkage would result in a 5-membered ring but should produce practically the same perturbation of C-3 as would be expected in the 6-membered ring involving chelation by the C-8 linkage. The fact that C-4 shows essentially the same frequency in the mercuric complexes both at 37 and 90 °C relative to glutathione together with the fact that C-2 for the $Hg(OAc)_2$ complex shows a downfield shift at 37 °C relative to both glutathione and its methylmercury derivative provide evidence for chelation by the C-8 peptide nitrogen. The distinction between perturbations to C-2 and C-4 appears to disappear at 90 °C but the nature of complexation could also be altering. Additional evidence in support of this chelated structure is provided by reference to the methylmercury derivative whose C-2 and C-4 chemical shifts at 37 °C are essentially the same as those for glutathione.

The chemical shifts for C-8 and C-9 of the complexes are assigned on a provisional basis because the differences are relatively small and because the parent frequencies are identical. The small downfield shifts for C-8 and C-9 of the methylmercury derivative of glutathione appear consistent with CH_3Hg bonding to

* The temperature effect was verified by examining solutions of glutathione and of the complex prepared from mercury(II) acetate at 90 °C. The ^{13}C frequencies observed for carbons numbered 2 – 6 in these two samples were essentially the same at those observed for the $HgCl_2$ complex of glutathione at 90 °C. The C-1 frequency of glutathione was shifted downfield by approximately 0.5 ppm at 90 °C confirming that the larger downfield shift occurring with complexation is due to mercurial bonding to sulphur. The carbonyl frequencies were not observed at 90 °C due to increased relaxation times. Prolonged examination at 90 °C was found to be detrimental to these samples, glutathione undergoing oxidation and the complex prepared from mercury(II) acetate discolouring intensely.

sulphur with no other mercurial interaction in solution with other parts of the substrate molecule. The ^{13}C chemical shifts and assignments are consistent with those reported by Jung *et al.* [14] for glutathione and its oxidized form. Some variation in frequency is to be expected between corresponding carbon nuclei of the different complexes due to differences in dipolar and ionic interactions, hydrogen bonding and pH; however, these effects for the carbonyl ^{13}C frequency have been estimated by Maciel and Natterstad [17] to be of the order of 1 ppm.

In their study of the complexation of glutathione by Cd^{2+} and Zn^{2+}, Fuhr and Rabenstein [6] concluded from changes in the Cys-CONH carbon frequency that some binding by these ions might be occurring to the glycyl peptide linkage in addition to the sulphur atom. With mercury(II) nitrate, it was concluded that binding is exclusively to the sulphydryl group at mercury to glutathione ratios up to 0.5 with formation of a 1:2 complex. By comparison with our data (Table 1) which shows deshielding of the cysteinyl methylene carbon of glutathione by 7.8 and 2.8 ppm for complexation with mercury(II) acetate and methylmercury chloride, respectively, it is noteworthy that the deshielding produced by complexation with mercury(II) nitrate (4.4 ppm) is more similar to that obtained with methylmercury chloride. It is not clear from the mercury(II) nitrate study whether nitrate is completely dissociated from mercury or if complexation involves $^{+}HgNO_3$ and 1:1 complex formation. Complexation of glutathione by mercury(II) acetate unquestionably involves loss of the acetate groups.

EXPERIMENTAL

A Varian XL-100-NMR spectrometer was used to obtain ^1H noise decoupled 25.2 MHz Fourier transform ^{13}C NMR spectra of approximately 0.2 M deuterium oxide solutions of glutathione and of its mercury complexes. Frequencies were measured relative to dioxane and converted to the TMS scale ($\delta_{TMS} = \delta_{dioxane} + 67.4$ ppm).[18] An accumulation time of approximately one hour was required to accumulate 1000 free induction decays (FID) each of 0.4 s with a pulse delay of 3.6 s. A pulse width of 80 μs was used. Off-resonance decoupling was employed to verify the chemical shifts and assignments reported by Jung *et al.* [14] for glutathione.

Microanalyses were performed by Alfred Bernhardt, Mikroanalytisches Laboratorium, 5251 Elbach über Engelkirchen, Fritz-Pregle-Strasse 14 – 16, W. Germany. Appropriate separatory processes were employed to eliminate interference of mercury with the C, H, and Cl determination. Sulphur was analyzed by a reductive process.

Mercury(II) chloride complex of glutathione, $(C_{10}H_{16}O_6N_3S)_2Hg_2Cl(OH)(HCl)_2$. Glutathione (0.768 g, 0.0025 mol, Sigma, reduced form) was dissolved in warm (50 °C) 95 % ethanol (10 ml) with magnetic stirring by adding just sufficient water (8 ml) for dissolution. A solution of mercury(II) chloride (0.679 g, 0.0025 mol, BDH Analar) in 95 % ethanol (10 ml) was added dropwise to the stirred glutathione solution. Precipitation occurred immediately, but the solid readily dissolved with stirring except near the end of the addition when a flocculent precipitate persisted. When the last few drops of $HgCl_2$ solution were added, the mixture formed a white slurry. When a white gum appeared after 5 min of stirring and cooling, the mixture was treated with water. Immediate clarification of the supernatant occurred, and the mixture was treated periodically with water (total 20 ml) until all gum had dissolved with stirring at room temperature. Finely divided solid was obtained from the mixture after refrigeration for 4 h. The solid was collected, washed with 95 % ethanol and dried over NaOH *in vacuo*. The yield of product was 1.03 g or 73 %. The product was found to be appreciably soluble in water. IR spectra (4000 – 600 cm^{-1}) appeared to be little different from glutathione, and X-ray diffraction patterns showed the product to be amorphous. (Found: C 21.25; H 3.41; O 18.47, 18.66, 18.62; N 7.20; S 5.58; Hg 34.84, 34.04; Cl 9.09, 9.07, 9.12; and drying loss (50 °C/HV), 3.11 %. $(C_{10}H_{16}O_6N_3S)_2Hg_2Cl(OH)(HCl)_2$ (M.W. 1139.26) requires C 21.08; H 3.10; O 18.26; N 7.38; S 5.63; Hg 35.22; Cl 9.34.)

Mercury(II) glutathionate monohydrate, $(C_{10}H_{15}O_6N_3S)Hg.H_2O$. Glutathione (0.768 g, 0.0025 mol, Sigma, reduced form) was dissolved at room temperature in water (20 ml) and 95 % ethanol (10 ml), then the solution was warmed to 40 °C. To this solution, a warm (40 °C) solution of mercury(II) acetate (0.797 g, 0.0025 mol, Merck) in methanol (10 ml) was added dropwise with magnetic stirring. Precipitation occurred immediately and persisted gradually producing coagulated spherical masses. Towards the end of the addition a milky suspension was obtained. On cooling to room temperature, the mixture lost its stickiness and the solid could be easily pulverized in the presence of the supernatant liquid. When the solid was found to be extremely difficult to filter with suction due to clogging of the paper, it was collected by slow filtration using a fluted paper. The very finely divided, powdery solid was washed with acetone and dried over NaOH *in vacuo*. The yield was 0.97 g or 75 %. The solid is insoluble in water at room temperature, but it dissolves readily on

addition of a drop of 12 M HCl or trifluoroacetic acid. Infrared spectra showed the absence of acetyl C=O stretching, otherwise, the spectral features (4000 – 600 cm^{-1}) are very similar to those of glutathione. X-Ray diffraction patterns showed the solid to be amorphous. (Found: C 23.05; H 3.48; O 21.36; N 7.96; S 6.14; Hg 38.23; drying loss (50 °C/HV), 3.23. ($C_{10}H_{16}O_6N_3S$); $Hg.H_2O$ (M.W. 524.14) requires C 22.90; H 3.27; O 21.37; N 8.02; S 6.12; Hg 38.27, and drying loss, 3.44 %).

Methylmercury glutathionate, ($C_{10}H_{16}O_6N_3S$)-$HgCH_3$. CAUTION: Use well-ventilated hood and exercise precautions with alkyl mercury.[19]

A solution of glutathione (0.768 g, 0.0025 mol, Sigma reduced form) was prepared in water (10 ml) with slight warming and then diluted with 95 % ethanol (10 ml). A saturated solution of methylmercuric chloride (0.627 g, 0.0025 mol, Alfa Inorganics) was prepared in 95 % ethanol (40 ml). The mercurial solution was added quickly since no precipitation or "tail-effect" formed during addition. The small portion of undissolved CH_3HgCl was transferred to the reaction mixture during washing with ethanol. No precipitation occurred following the addition nor on standing of the mixture.

After treating the mixture with acetone until turbid and refrigerating it, a flocculent white solid was collected, washed with acetone and dried over NaOH *in vacuo* (Fr. A, 0.212 g). The mother liquor was reduced to about 10 ml by rotary evaporation, then it was treated with diethyl ether to obtain turbidity – some acetone had to be added to maintain miscibility – however, an oil formed. Slight warming and addition of ethanol produced no beneficial effect. On standing overnight, the syrupy residue hardened to a gum. The mixture was then heated until the gum dissolved. When the solution had cooled to room temperature ether was added slowly and periodically over a 4 h period to maintain a light turbidity. Solid (Fr. B, 0.445 g) was then obtained following refrigeration. The mother liquor, on evaporation in a petri dish in a fume hood, gave a hard, glassy residue (Fr. C, 0.358 g). Fractions A and B contracted in volume appreciably during drying *in vacuo* (20 mmHg) at room temperature, but there appeared to be no evidence for sublimation. Each fraction was found to be amorphous by X-ray diffraction, and infrared spectra were rather similar to spectra of glutathione. (Found: C 25.40; H 3.98; O 18.33; N 7.88; S 6.05; Hg 38.47. $C_{11}H_{19}O_6N_3SHg$ (M.W. 521.96) requires C 25.31; H 3.69; O 18.39; N 8.05; S 6.14; Hg 38.45.)

Acknowledgement. The interest of Prof. Maths Berlin, Institute of Hygiene, University of Lund, Sweden in encouraging structural studies related to mercurial toxicology and biotransformation is gratefully acknowledged. Special appreciation is extended of Prof. Börje Wickberg, Organic Chemistry 2, Chemical Center, University of Lund, Sweden, for provision of laboratory space and resources. The interest and help of Dr. Lars Haraldson, Analytical Chemistry, University of Lund, Sweden, in discussing various aspects of microanalytical data is warmly acknowledged. The Medical Research Council of Canada is generously thanked for the provision of a Centennial Fellowship and research grant in support of this work. The Swedish Natural Science Research Council is also thanked for continuing financial support for instrumental resources at the Chemical Centre.

Short Communications

The Relevance of Base Catalysis in Aromatic Nucleophilic Substitution to C—X Bond Cleavage

ZVI RAPPOPORT[a]
and JOSEPH F. BUNNETT[b]

[a]Department of Organic Chemistry, The Hebrew University, Jerusalem, Israel and [b]University of California, Santa Cruz, California, 95064, U.S.A.

Lamm and Lammert [1] have recently criticized the "absence of element effect" criterion for assessing whether or not bond-breaking occurs during the rate-determining step of nucleophilic substitution reactions. According to this criterion, originated by Bunnett, Garbisch and Pruitt [2] and initially applied to S_NAr reactions, if several substrates whose leaving group first atoms represent different elements react with a common nucleophilic reagent at nearly the same rate, scission of the bond to the leaving group does not occur during the rate-determining step. (A proviso, however, is that if rate-determining scission of the C–X bond had made little progress at the transition state, a sameness of rate might nevertheless result.)

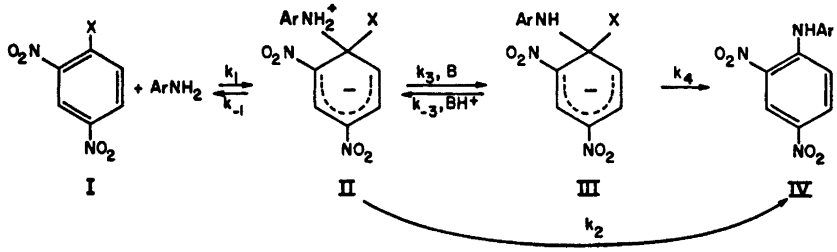
Bernasconi and Zollinger [3] reported in 1966 that the reaction of 1-chloro-2,4-dinitrobenzene with *p*-anisidine in benzene solution is strongly catalyzed by DABCO (1,4-diaza[2.2.2]bicyclooctane). The rate law has a prominent third-order term, first order in substrate, first order in anisidine and first order in DABCO. Lamm and Lammert extended study of that process to embrace also the leaving groups Br, $PhSO_2$, and $MeSO_2$. Among these four, whose first atoms represent three elements, the maximum difference in the third-order rate constants was 9-fold, rather greater than the maximum difference of 1.3-fold for reactions of the same substrates (excepting the methylsulfonyl compound) with piperidine in methanol,[2] but nevertheless a small difference.

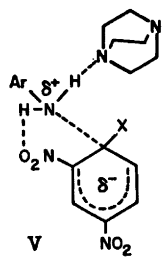
After Bernasconi and Zollinger, Lamm and Lammert took the third-order term to represent base catalysis. They accepted base catalysis as evidence that the rate-determining step is, in their words, "the second reaction step, involving cleavage of the C–X bond." From their results they drew the inference that a small element effect is of limited validity as a criterion of mechanism in the sense mentioned.

The reservations of Lamm and Lammert, if well grounded, would have important implications regarding the question of whether nucleophilic aromatic substitution and the analogous nucleophilic vinylic substitution [4] are one- or multi-step processes. Thus, in vinylic substitutions [4] retention of stereochemistry argues for a concerted process [5] while the near absence of a leaving group element effect indicates a multi-step mechanism. It is important to know whether the element effect criterion has general validity.

The work of Lamm and Lammert unfortunately does not constitute a definitive test of the criterion. The crucial point is that although a valid third-order term in the rate law, as described, does indicate the presence of a DABCO molecule in the rate-determining transition state, it does not indicate the structure of the transition state or the function of the DABCO molecule in it. There are at least two reasonable structures for the transition state which do not involve scission of the C–X bond.

First, it is conceivable that the initial (k_1) step is rate-limiting, with DABCO present in the transition state interacting by hydrogen-bonding with a rather acidic hydrogen of the anisidine amino moiety. In the transition state (V), one of the amino hydrogens would hydrogen-bond intramolecularly to the *o*-nitro





V

group [6] and the other to a DABCO molecule. The feasibility of this model depends on the relative magnitudes of the decreases in $T\Delta S^{\ddagger}$ and in $\Delta H^{\ddagger}$ implied by incorporation of a DABCO molecule. The loss in $T\Delta S^{\ddagger}$ is likely to be about 5 kcal [7] and the strength of the hydrogen bond might well be of similar or greater magnitude; DABCO is quite basic, the amino hydrogens are likely to be quite acidic (because the transition state is probably attained late in the attachment of anisidine nitrogen to aromatic carbon) and the hydrogen bond is expected to be a strong one. (The fact that the reaction of I (X = Cl) with butylamine in benzene is merely second order,[8] which might seem to contradict this model, could be rationalized by postulating for a primary amine of high nucleophilicity an early transition state, in which the amine hydrogens would not be very acidic.)

A second alternative takes account of good evidence [9] that S_NAr reactions of amine nucleophiles may involve three steps: Initial formation of zwitterionic σ-complex II, deprotonation of II by a base to form anionic σ-complex III, and finally leaving group expulsion. Lamm and Lammert discussed it, however, as a two-step process. It is possible that formation of II is a mobile equilibrium and that the deprotonation (k_3) step is rate-limiting. The DABCO molecule would be present in the rate-determining transition state, taking the proton, but there would be no scission of the C–X bond. This model would require that expulsion of the leaving group from III be much faster than reprotonation to II.

There are now known several examples of relatively slow reactions, in water solution, that have rate-determining proton transfer steps.[10] Rate-determining proton transfer steps are even more likely in benzene because hydrogen-bonded networks of solvent to acidic or basic sites, which expedite proton transfer,[11] are not possible.

Because there are plausible alternative interpretations of the results of Lamm and Lammert, they do not constitute a serious challenge to the validity of the element effect as a criterion of mechanism.

[a] After recrystallization from ethanol or aqueous ethanol. [b] This compound has been described earlier.[1,2]

group in position 2, giving rise to the base peak. In the spectrum of one of these compounds, 3-(2-hydroxy-6-methylphenyl)-2-methyl-4-oxo-3,4-dihydroquinazoline (1), an unexpected and prominent peak at $M^+ - 42$ was observed. High resolution measurement and a metastable peak verified that the corresponding transition was due to the expulsion of a ketene moiety from the molecular ion. However, according to the literature no reasonable explanation for this unusual fragmentation seems to be available. In order to elucidate the mechanism the shift technique was used. Thus a number of suitably substituted 4-oxo-3,4-dihydroquinazolines were synthesized and their mass spectra evaluated. The data are collected in Table 1. In analogy to the behaviour of the monohydroxy derivatives of methaqualone, important peaks corresponding to loss of the 2-substituent appear, *i.e.* $M^+ - C_2H_5$ in the spectra of 4, 5, 10, and 11 and $M^+ - CH_3$ in the spectra of 8, 9, and 12.

All compounds having R^2 = OH (Table 1) also fragment through another important route, related to the loss of ketene from compound 1. Thus the spectra of compounds 2 and 6 exhibit a prominent peak at $M^+ - CO$, compounds 8 and 12 at $M^+ - CH_2CO$ and compounds 4 and 10 at $M^+ - CH_3CHCO$.

These data indicate the origin of the atoms involved. The fragmentation implies interaction between the group at C-2 in the quinazoline ring and the phenolic group R^2. For the case when ketene is lost, the reaction may tentatively be formulated as outlined in Fig. 1.

The mechanism of the fragmentation can be concerted or involve a skeletal rearrangement.

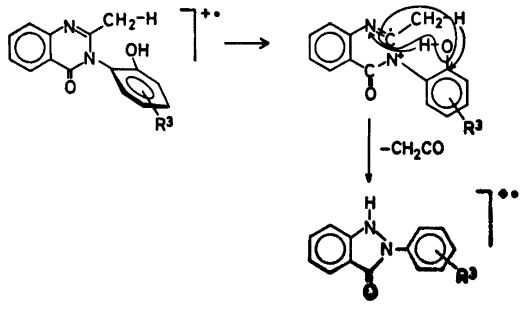

Fig. 1.

In compounds having a 2,6-disubstituted aromatic ring at N-3 this ring and the oxoquinazoline nucleus obviously are not coplanar. This implies that an initial cleavage of the quinazoline ring must occur in order for the interaction to take place (*cf.* Fig. 1). However, on the basis of the present evidence it is not feasible to speculate further on the details of the fragmentation. The driving force can be assumed to originate in the liberation of a neutral fragment. Besides, an energetically favourable steric arrangement must take place in order to make the reaction possible. This assumption is supported by the fact that only compounds having a hydroxyl group in *ortho*-position (R^2 = OH) are exposed to the fragmentation.[1]

Experimental. Melting points were determined in open capillary tubes in an electrically heated

metal block, using calibrated Anschütz thermometers. Infrared spectra were run in KBr discs using a Perkin-Elmer Infracord Model 157G with a grating monochromator. Infrared spectra were routinely recorded and are in agreement with the expected structures. Mass spectra were recorded on an AEI MS-30 mass spectrometer. The ionizing energy was maintained at 70 eV and the temperature of the source at 200°C.

Synthesis. Compounds having a methoxy group (*i.e.* compounds No. 3, 5, 7, 9, and 11) were prepared as follows. *N*-Formylanthranilic acid, *N*-acetylanthranilic acid, or *N*-propionylanthranilic acid (0.01 mol) was condensed with 2-methoxy-6-methylaniline [3] or 2,6-dimethoxyaniline [3] (0.01 mol) in the presence of phosphorus trichloride (0.005 mol) as earlier described.[2] Compounds 2, 4, 6, 8, 10, and 12 were prepared from the corresponding methoxy derivatives by boiling with an excess of 48 % hydrobromic acid for 1.5 h.

On the Stereochemistry of the Interaction between Nucleic Acids and Basic Protein Side Chains

S. FURBERG and J. SOLBAKK

Institute of Chemistry, University of Oslo, Oslo 3, Norway

Interactions between nucleic acids and basic proteins play an important role in cell chemistry and it would appear to be of interest to establish the stereochemistry of these interactions at the atomic level. We thought that some information might be obtained by X-ray analysis of single crystals of salts between phosphate diesters and various organic bases simulating arginine and lysine side chains. Such complexes may serve as models for the contacts occurring in nucleoproteins between phosphate groups and basic amino acids. The compounds studied are the diethyl phosphates of propylguanidine (I), arginine (II) and putrescine (III). A good model should preferably contain no hydrogen bond forming groups other than those present at the contacts, and compound (II) is therefore less satisfactory than the others. The crystal structures of the three compounds have been reported elsewhere.[1-3] In the present note the patterns of hydrogen bonding will be discussed and related to the structure of complexes between DNA and polyarginine, protamine, and polylysine.

The bonding between arginine and phosphate diesters. Arginine forms salts with phosphate diesters and bonding occurs between $(RO)_2PO_2^-$ and the guanidinium cationic group $-(NH)C(NH_2)_2^+$. In Fig. 1 the surroundings of the guanidinium group in model compounds (I) and (II) are shown. Extensive hydrogen bonding occurs, the stereochemistry of which may be described as follows:

(1) The guanidinium group forms five N−H···O hydrogen bonds to oxygen atoms in neighbouring molecules. These bonds are not far from linear and lie roughly in the plane of the guanidinium group, as is to be expected. The tendency for this general pattern of hydrogen bonding is also evident in crystal structures of inorganic salts of arginine.[4] In the present structures, especially (I), in which the guanidinium group is bonded only to diester phosphate groups, some additional characteristic stereochemical features are observed:

(2) One of the five hydrogen bonds both in (I) and (II) involves an ester oxygen atom and is much weaker (length 3.08 Å and 3.09 Å, respectively) than the others, which lie within the normal range for N−H···O bonds (mean length about 2.85 Å). The direction of this bond is roughly that of the bisecting line of the P−O−C angle. Such a hydrogen bond has apparently not been observed previously.

(3) Four of the hydrogen bonds occur in two pairs of nearly parallel bonds to oxygen atoms in the same anionic group. The N···N distances in the guanidinium group (*ca.* 2.3 Å) are not far from the O···O distances in phosphates (*ca.* 2.5 Å) and carboxylates (*ca.* 2.25 Å), making it stereochemically favourable for pairs of nearly parallel bonds to be formed. The pairs are of two types, a "strong" pair involving two normal bonds to the two *oxo* oxygen atoms in the same phosphate group, and a "weak" pair of one normal and one weak bond to one *oxo* and one ester oxygen atom, respectively. The pairs are at an angle of about 120° with one another. In compound (II) the "strong" pair is formed to the carboxyl group rather than to the phosphate, but the "weak" pair exists in both structures. It may be concluded that a guanidinium group may form a strong link between two phosphate diester groups by pairs of hydrogen bonds, and that

On the Stereochemistry of the Interaction between Nucleic Acids and Basic Protein Side Chains

S. FURBERG and J. SOLBAKK

Institute of Chemistry, University of Oslo, Oslo 3, Norway

Interactions between nucleic acids and basic proteins play an important role in cell chemistry and it would appear to be of interest to establish the stereochemistry of these interactions at the atomic level. We thought that some information might be obtained by X-ray analysis of single crystals of salts between phosphate diesters and various organic bases simulating arginine and lysine side chains. Such complexes may serve as models for the contacts occurring in nucleoproteins between phosphate groups and basic amino acids. The compounds studied are the diethyl phosphates of propylguanidine (I), arginine (II) and putrescine (III). A good model should preferably contain no hydrogen bond forming groups other than those present at the contacts, and compound (II) is therefore less satisfactory than the others. The crystal structures of the three compounds have been reported elsewhere.[1-3] In the present note the patterns of hydrogen bonding will be discussed and related to the structure of complexes between DNA and polyarginine, protamine, and polylysine.

The bonding between arginine and phosphate diesters. Arginine forms salts with phosphate diesters and bonding occurs between $(RO)_2PO_2^-$ and the guanidinium cationic group $-(NH)C(NH_2)_2^+$. In Fig. 1 the surroundings of the guanidinium group in model compounds (I) and (II) are shown. Extensive hydrogen bonding occurs, the stereochemistry of which may be described as follows:

(1) The guanidinium group forms five N−H···O hydrogen bonds to oxygen atoms in neighbouring molecules. These bonds are not far from linear and lie roughly in the plane of the guanidinium group, as is to be expected. The tendency for this general pattern of hydrogen bonding is also evident in crystal structures of inorganic salts of arginine.[4] In the present structures, especially (I), in which the guanidinium group is bonded only to diester phosphate groups, some additional characteristic stereochemical features are observed:

(2) One of the five hydrogen bonds both in (I) and (II) involves an ester oxygen atom and is much weaker (length 3.08 Å and 3.09 Å, respectively) than the others, which lie within the normal range for N−H···O bonds (mean length about 2.85 Å). The direction of this bond is roughly that of the bisecting line of the P−O−C angle. Such a hydrogen bond has apparently not been observed previously.

(3) Four of the hydrogen bonds occur in two pairs of nearly parallel bonds to oxygen atoms in the same anionic group. The N···N distances in the guanidinium group (*ca.* 2.3 Å) are not far from the O···O distances in phosphates (*ca.* 2.5 Å) and carboxylates (*ca.* 2.25 Å), making it stereochemically favourable for pairs of nearly parallel bonds to be formed. The pairs are of two types, a "strong" pair involving two normal bonds to the two *oxo* oxygen atoms in the same phosphate group, and a "weak" pair of one normal and one weak bond to one *oxo* and one ester oxygen atom, respectively. The pairs are at an angle of about 120° with one another. In compound (II) the "strong" pair is formed to the carboxyl group rather than to the phosphate, but the "weak" pair exists in both structures. It may be concluded that a guanidinium group may form a strong link between two phosphate diester groups by pairs of hydrogen bonds, and that

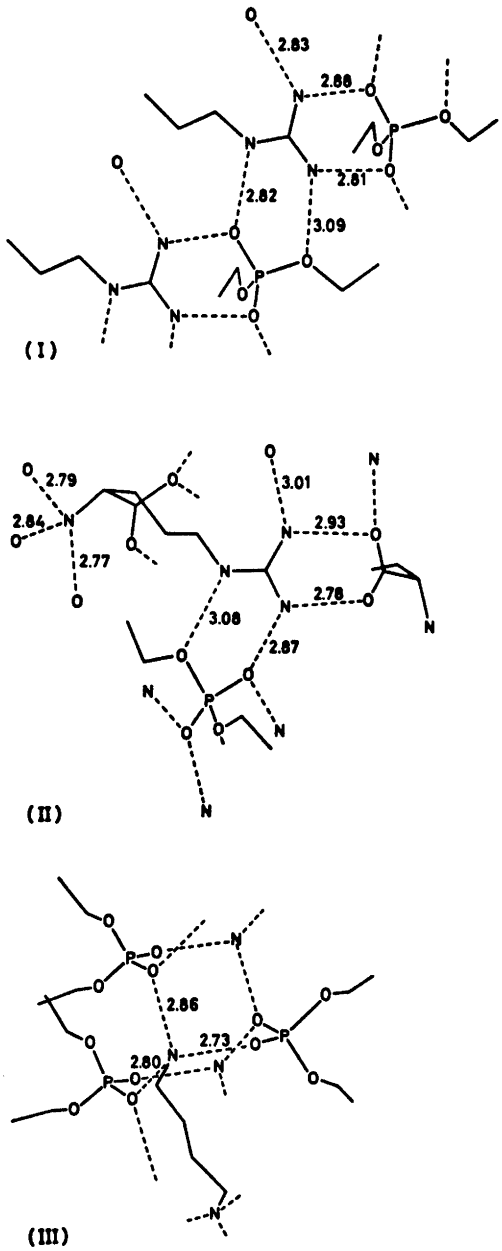

Fig. 1. Hydrogen bonds (broken lines) in diethyl phosphates of propylguanidine (I), arginine (II), and putrescine (III). Hydrogen atoms are not shown.

a phosphate diester group may be linked to two arginines, as shown by structure (I).

(4) The angles between the N–H···O bonds and the adjacent P–O (*oxo*) bonds lie in the range 108°–137°, the mean value being 123°. The hydrogen bonds of the "weak" pairs nearly lie in the O–P–O plane of the acceptor oxygen atoms, whereas the bonds of the "strong" pair form an angle of about 25° with it. In other structures this angle may be greater, but it seems likely that the general direction of any pair will be so as to point away from the oxygen atoms to which they are not bonded.

The stereochemical features described above in (1)–(4) are likely to persist at contacts between phosphate diesters and arginines in general and should be taken into account when formulating structural models of nucleoproteins and related complexes at the atomic level.

As an example, the hydrogen bonding in DNA-polyarginine and DNA-protamine complexes will be discussed on this basis. A general model of the structure of these complexes has been proposed, in which the polypeptide chain winds helically around the DNA molecule in the small groove.[6] The stereochemistry of the phosphate/guanidinium interactions was, however, not described. We have studied the stereochemical fit between DNA and polyarginine by wire models (scale 1 Å = 4 cm) using the coordinates of Arnott and Hukins [5] for B-DNA. We assume that the ten-fold symmetry is maintained in a general way on complex formation, as indicated by the X-ray fibre diagrams,[6,7] and that only minor modifications in the position and orientation of the phosphate groups occur. The different stable arginine conformations [4] were considered, and also the fact that the Cα carbon atoms have to lie less than about 10 Å from the ten-fold axis because of the symmetry (dipeptide length < 7.2 Å).

There are several feasible ways of linking the arginines to the phosphates in B-DNA by hydrogen bonds. In view of the bonding observed in the model compounds it appears, however, likely that both *oxo* oxygen atoms of the phosphates are engaged in the formation of a "strong" pair of hydrogen bonds to a guanidinium group, and satisfactory models can be built on this basis. The other pair from the guanidinium groups points away from the complex and may form cross-links to phosphates in the complementary helix in neighbouring complexes. This bonding pattern is similar to the one observed in compound (I). The distances between complexes in fibres of DNA-polyarginine and DNA-protamine [6,7] are consistent with the existence of such guanidinium bridges.

This bonding scheme is stereochemically compatible with placing the polypeptide chain in either of the DNA grooves, although the large groove appears to be the more favourable one. X-Ray evidence indicates, however, that the small groove is the site of binding in the DNA-protamine complex.[6,7]

It is also possible from a stereochemical point of view that the guanidinium groups link together consecutive phosphates along the DNA helices, as has been proposed.[7] The "strong" pair of hydrogen bonds can, however, in this case not be formed without strain, and we consider this possibility less likely than the one described above.

The bonding between lysine and phosphate diester. The $-NH_3^+$ group of protonated lysine would be expected to form, if possible, three hydrogen bonds in roughly tetrahedral arrangement, as observed in compound (III) (Fig. 1) and also in crystals of amino acids. The P–O···N angles in (III) lie in the range 110–135° and the mean length of the three bonds is 2.80 Å.

The oxygen atoms receiving hydrogen bonds from an NH_3^+ group are at distances of about 5 Å. The most favorable hydrogen bonding scheme in B-DNA-polylysine complexes would appear to be that the lysine NH_3^+ groups are linked to an *oxo* oxygen atom (O3) in one phosphate and, by a weak bond, to an *ester* oxygen atom (O4) in the next phosphate along the helix, these atoms being at a distance of 5.0 Å. *Oxo* oxygen atoms of consecutive phosphates seem to be too far apart. The third bond would then be formed to an *oxo* oxygen atom in the complementary helix in a neighbouring complex. The distance between complexes in fibres is consistent with this view.

Algal Carotenoids. XI.* New Carotenoid Epoxides from *Trentepohlia iolithus*

GERD NYBRAATEN and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034-Trondheim, Norway

A recent re-examination of the carotenoids of the green alga *Trentepohlia iolithus*[1] demonstrated the natural occurrence of carotenoids containing 2-hydroxylated β-rings. Structures *1*, *2*, and *3* (Scheme 1) were established from full spectroscopic characterization. The absolute stereochemistry has subsequently been confirmed.[2]

We now report the natural occurrence of the epoxides *4a* and *7* (probably *7a*) of β,ε-caroten-2-ol (*1*) and of β,β-caroten-2-ol (*2*), comprising 0.2 % (0.4 mg) and 0.3 % (0.6 mg), respectively, of the total carotenoids of *T. iolithus*.

In order to include stereochemical considerations the partial synthesis of the 5,6-epoxides *4a* and *4b* from β,ε-caroten-2-ol (*1*, 3.6 mg) by *m*-chloroperbenzoic acid,[3] Scheme 2, will be discussed first. Reported data for relevant cyclohexene model substances reveal a directive effect of a hydroxy substituent, resulting in preferential epoxidation *cis* to the hydroxy substituent, explained by hydrogen bonding between the hydroxy group and the peracid.[4] Similar results are observed with an acetoxy substituent.[5] Thus zeaxanthin (β,β-caroten-3,3′-diol) diacetate gives preferentially *cis* products (*cis* relationship between the epoxy and acetoxy groups) on epoxidation.[5]

On epoxidation of β,ε-caroten-2-ol (*1*) two diastereomeric products *4a* (60 % of total) and *4b* (40 % of total) were obtained. Both *4a* and *4b* exhibited λ_{max} (acetone) 419, 441.5, and 470 nm and *m/e* 568 (M), fragment ions M–16, M–80, 181, and 221 consistent with carotenoid epoxides, as well as common fragment ions M–92, M–106, M–16–92, M–16–106, M–80–92 ascribed to eliminations from the polyene chain, combined with losses of 16 and 80 mass units.[6a] Relative yields and adsorptive properties support the stereochemistry assigned to the epoxidic products *4a* and *4b*, see Scheme 2. Thus *4a* was chromatographically less strongly retained than *4b*, compatible with intramolecular hydrogen bonding, and *4a* indeed showed the predicted hydrogen bonding in IR (predominantly associated hydroxyl at 3509 cm^{-1} as expected for conformation A Scheme 2, *cf.* Ref. 6b).

On furanoid rearrangement with hydrogen chloride in ether the epoxide *4a*, referred to

Algal Carotenoids. XI.* New Carotenoid Epoxides from *Trentepohlia iolithus*

GERD NYBRAATEN and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034-Trondheim, Norway

A recent re-examination of the carotenoids of the green alga *Trentepohlia iolithus*[1] demonstrated the natural occurrence of carotenoids containing 2-hydroxylated β-rings. Structures *1*, *2*, and *3* (Scheme 1) were established from full spectroscopic characterization. The absolute stereochemistry has subsequently been confirmed.[2]

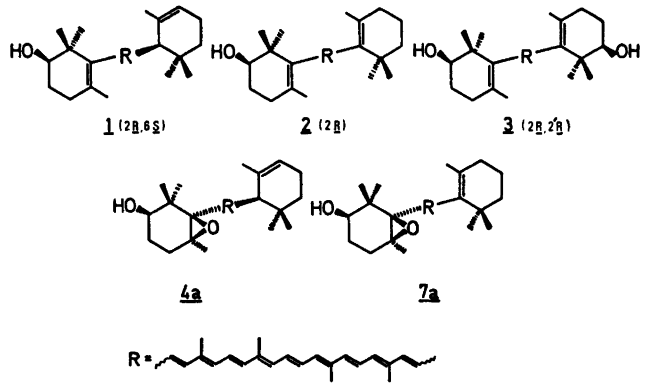
We now report the natural occurrence of the epoxides *4a* and *7* (probably *7a*) of β,ε-caroten-2-ol (*1*) and of β,β-caroten-2-ol (*2*), comprising 0.2 % (0.4 mg) and 0.3 % (0.6 mg), respectively, of the total carotenoids of *T. iolithus*.

In order to include stereochemical considerations the partial synthesis of the 5,6-epoxides *4a* and *4b* from β,ε-caroten-2-ol (*1*, 3.6 mg) by *m*-chloroperbenzoic acid,[3] Scheme 2, will be discussed first. Reported data for relevant cyclohexene model substances reveal a directive effect of a hydroxy substituent, resulting in preferential epoxidation *cis* to the hydroxy substituent, explained by hydrogen bonding between the hydroxy group and the peracid.[4] Similar results are observed with an acetoxy substituent.[5] Thus zeaxanthin (β,β-caroten-3,3′-diol) diacetate gives preferentially *cis* products (*cis* relationship between the epoxy and acetoxy groups) on epoxidation.[5]

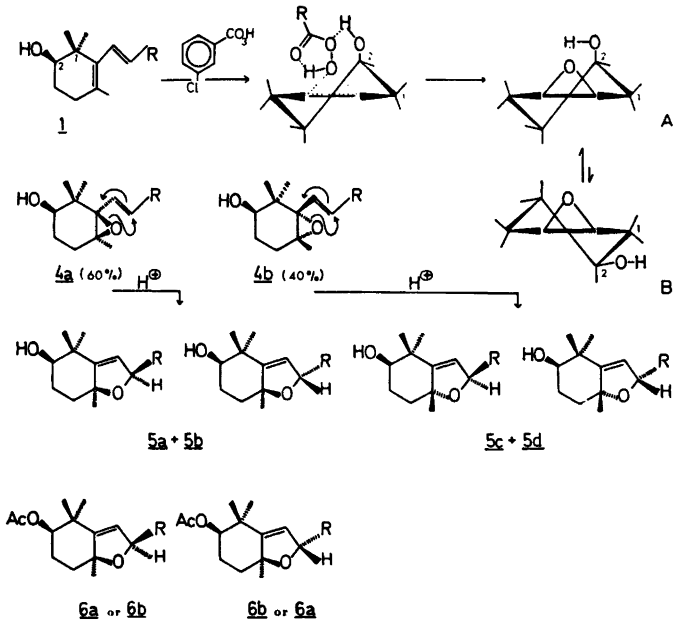
On epoxidation of β,ε-caroten-2-ol (*1*) two diastereomeric products *4a* (60 % of total) and *4b* (40 % of total) were obtained. Both *4a* and *4b* exhibited λ_{max} (acetone) 419, 441.5, and 470 nm and *m/e* 568 (M), fragment ions M–16, M–80, 181, and 221 consistent with carotenoid epoxides, as well as common fragment ions M–92, M–106, M–16–92, M–16–106, M–80–92 ascribed to eliminations from the polyene chain, combined with losses of 16 and 80 mass units.[6a] Relative yields and adsorptive properties support the stereochemistry assigned to the epoxidic products *4a* and *4b*, see Scheme 2. Thus *4a* was chromatographically less strongly retained than *4b*, compatible with intramolecular hydrogen bonding, and *4a* indeed showed the predicted hydrogen bonding in IR (predominantly associated hydroxyl at 3509 cm^{-1} as expected for conformation A Scheme 2, *cf.* Ref. 6b).

On furanoid rearrangement with hydrogen chloride in ether the epoxide *4a*, referred to

* No. X. *Phytochemistry. In press.*



Scheme 1.



Scheme 2.

as *cis* epoxide, gave two products *5a* and *5b*, assumed to be C-8 epimers on the basis of the favoured mechanism for furanoid rearrangement, not altering the stereochemistry at C – 5,[7] Scheme 2. The epoxide *4b*, referred to as *trans* epoxide, likewise gave two furanoid products *5c* and *5d*. Relative R_F-values were *5a* > *5c* > *5b* = *5d*. However, in spite of identical R_F-values *5b* and *5d* are considered to be diastereomers. The furanoid products *5a*, *b*, *c*, *d* all had λ_{max} (methanol) at 396, 420, and 446 nm.

Separate acetylation of the furanoxides *5a* and *5b* was slow (17 h, 55 % conversion, typical of 2-hydroxy substitution [8]) and gave the monoacetates *6a* and *6b*, not separable in the systems tested. In general separation of the stereoisomeric epoxides and furanoxides was more difficult when acetylated.

Turning now to the naturally occurring epoxide *4a*, the natural epoxide had electronic spectrum, mass spectrum and R_F-value (co-chromatography) consistent with semisynthetic *4a* described above, and provided on standard acetylation slowly (*cf.* Ref. 8) a monoacetate (80 % conversion after 8 h) with unchanged electronic spectrum and *m/e* 610 (M), M – 16,

M−60, M−80. Furanoid rearrangement of *4a* gave two products with electronic spectra, mass spectra, and R_F-values (co-chromatography) as *5a* and *5b* described above. Separate acetylation of the furanoid products *5a* and *5b* gave 60 % conversion to the corresponding acetates, inseparable in our chromatographic systems and from *5a,b* derived from *1* in a special reaction discussed in the following paper.[8] On this basis it is concluded that the natural epoxide has structure *4a* (*cis*). It deserves comment that natural violaxanthin (5,6,5′,6′-diepoxy-5,6,5′,6′-tetrahydro-β,β-carotene-3,3′-diol), has a *trans* relationship between the 5,6-epoxy bridge and the 3-hydroxy substituent.[4,7] However, the present epoxide *4a* and violaxanthin both have the same axial/equatorial relationship between the hydroxy substituent and the polyene chain, see Scheme 2 for alternative conformations A and B of *4a*.

The second naturally occurring epoxide *7* exhibited λ_{max} (ether) 423, 443, and 472 nm consistent with data reported for the mono-epoxide of β,β-carotene [9] and mass spectrum like *4a* except an (M−56−18) peak. Acetylation of *7* provided a monoacetate with unchanged electronic spectrum and mass spectrum as for *4a*-monoacetate with no significant RDA-fragmentation. Furanoid rearrangement of *7* gave two products both with λ_{max} (methanol) 404, 423, and 445 nm and *m/e* 568 (M), M−16, M−80, 221, inseparable from two furanoid products obtained from β,β-caroten-2-ol (*2*) in the reaction discussed in the following paper.[8] From the stereochemistry observed for the corresponding reaction of β,ε-caroten-2-ol (*1*) [8] and by analogy with the natural epoxide *4a*, the stereochemistry of *7a* (*cis*) is considered likely for the second epoxide *7* isolated from *T. iolithius*.

Methods commonly employed in this laboratory were used. Experimental details are given elsewhere.[10] The epoxides *4a* and *7* were readily separated from *1*, *2*, and *3* on magnesium oxide columns (benzene). R_F-values (Schleicher & Schüll No. 287 circular, kieselguhr paper, 1 % acetone in petroleum ether) were: *4a* (0.56), *4b* (0.35), *4a*-acetate (0.88), *5a* and *5b* (0.48 and 0.18), *5c* and *5d* (0.33 and 0.18), *6a* and *6b* (0.72), *7* (0.53), *7*-acetate (0.84), furanoid *7* (0.22 and 0.55), and furanoid *7*-acetates (0.74). Purification for mass spectrometry was achieved by TLC on kieselgel, 20 % acetone in petroleum ether).

Algal Carotenoids. XII.* Chemical Reactions of Carotenoids with 2-Hydroxylated β-Rings

GERD NYBRAATEN and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034-Trondheim, Norway

Spectroscopic evidence alone was sufficient for the structural elucidation of the first carotenoids with 2-hydroxylated β-rings, namely β,ε-caroten-2-ol (*1a*), β,β-caroten-2-ol (*2a*), and β,β-carotene-2,2′-diol (*3*), Scheme 1, from the green alga *Trentepohlia iolithus*.[1,2] We now report a chemical characterization of carotenoids possessing this end group (*1a* and *2a*).

Models reveal steric hindrance of the 2-hydroxy-substituent of a β-ring. Lower reactivity than for analogous 3-hydroxy carotenoids was therefore predicted.

Standard acetylation [3] of β,β-caroten-2-ol (*2a*) was slower than for β,β-caroten-3-ol (*4a*): 50 % and 100 % conversion, respectively, to the corresponding acetates *2b* and *4b* after 3.5 h, see Fig. 1. The 2-hydroxy compound

* No. XI. *Acta Chem. Scand. B 28* (1974) 483.

M−60, M−80. Furanoid rearrangement of *4a* gave two products with electronic spectra, mass spectra, and R_F-values (co-chromatography) as *5a* and *5b* described above. Separate acetylation of the furanoid products *5a* and *5b* gave 60 % conversion to the corresponding acetates, inseparable in our chromatographic systems and from *5a,b* derived from *1* in a special reaction discussed in the following paper.[8] On this basis it is concluded that the natural epoxide has structure *4a* (*cis*). It deserves comment that natural violaxanthin (5,6,5′,6′-diepoxy-5,6,5′,6′-tetrahydro-β,β-carotene-3,3′-diol), has a *trans* relationship between the 5,6-epoxy bridge and the 3-hydroxy substituent.[4,7] However, the present epoxide *4a* and violaxanthin both have the same axial/equatorial relationship between the hydroxy substituent and the polyene chain, see Scheme 2 for alternative conformations A and B of *4a*.

The second naturally occurring epoxide *7* exhibited λ_{max} (ether) 423, 443, and 472 nm consistent with data reported for the mono-epoxide of β,β-carotene [9] and mass spectrum like *4a* except an (M−56−18) peak. Acetylation of *7* provided a monoacetate with unchanged electronic spectrum and mass spectrum as for *4a*-monoacetate with no significant RDA-fragmentation. Algal Carotenoids. XII.* Chemical Reactions of Carotenoids with 2-Hydroxylated β-Rings

GERD NYBRAATEN and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034-Trondheim, Norway

Spectroscopic evidence alone was sufficient for the structural elucidation of the first carotenoids with 2-hydroxylated β-rings, namely β,ε-caroten-2-ol (*1a*), β,β-caroten-2-ol (*2a*), and β,β-carotene-2,2′-diol (*3*), Scheme 1, from the green alga *Trentepohlia iolithus*.[1,2] We now report a chemical characterization of carotenoids possessing this end group (*1a* and *2a*).

Models reveal steric hindrance of the 2-hydroxy-substituent of a β-ring. Lower reactivity than for analogous 3-hydroxy carotenoids was therefore predicted.

Standard acetylation [3] of β,β-caroten-2-ol (*2a*) was slower than for β,β-caroten-3-ol (*4a*): 50 % and 100 % conversion, respectively, to the corresponding acetates *2b* and *4b* after 3.5 h, see Fig. 1. The 2-hydroxy compound

* No. XI. *Acta Chem. Scand. B 28* (1974) 483.

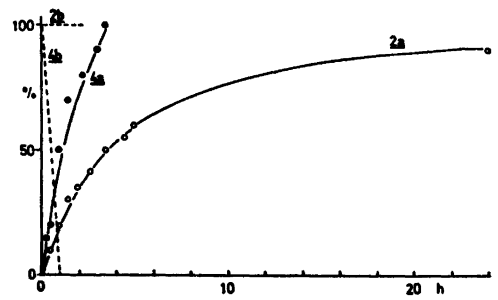

Fig. 1. Relative rates of acetylation of β,β-caroten-2-ol (*2a*), β,β-caroten-3-ol (*4a*), and relative rates of hydrolysis of β,β-carotenyl-2-acetate (*2b*) and β,β-carotenyl-3-acetate (*4a*).[17]

(*2a*) was chromatographically less strongly adsorbed than the 3-hydroxy analogue *3a* in agreement with the larger shielding of the hydroxy group in *2a*. However, no separation of the acetates *2b* and *4b* was achieved.

β,β-Caroten-2-yl acetate (*2b*) crystallized as red prisms, m.p. 81–83 °C, with predicted spectral properties (visible, IR, ^{1}H NMR). Alkali treatment of the acetates *2b* and *4b* (5 % KOH, −25 °C) resulted in complete hydrolysis of *4b* after 50 min when *2b* was not effected, see Fig. 1. However, *2b* was completely hydrolyzed after 60 min at 20 °C.

The low rate of acetylation was also observed for *1a*, which provided the acetate *1b* in 85 % yield after 16 h.

No difference in the rate of silylation of the 2-hydroxy compound *2a* and the 3-hydroxy compound *4a* was observed under standard conditions[3] at −30 °C. The trimethylsilyl ether *2c* (Scheme 1) was less polar than *4c*.

Comparative methylation of the 2-hydroxy compounds *1a* and *2a* and the 3,3′-dihydroxy compound *5a* (=zeaxanthin) was attempted by various modifications of Kuhn's method.[4–7] Abnormal products[8] were obtained using silver oxide;[4] *2a* also gave an abnormal product[8] with barium oxide.[5] By the CH_3I/BaO/DMF/DMSO modification[6,7] *1a* gave the methyl ether *1d*[8] and *2a* provided the methyl ether *2d*.[8] More satisfactory was methylation with methyl iodide and sodium hydride.[9,8] The 2-hydroxy compound *1a* gave the methyl ether *1d* (60 % of recovered carotenoid; 72 % total recovery) under conditions where the 3,3′-diol (*5a*) was quantitatively converted to the dimethyl ether *5d* (85 %) and monomethyl ether *5e* (15 %).[8] The methyl ether *1d* had *m/e* 566=M, M−15, M−56 (RDA-fragmentation of ε-ring[10]), M−92, M−106, M−158. All methyl ethers exhibited the same visible absorption as the parent alcohols.

The results discussed demonstrate the lower reactivity of the sterically hindered 2-hydroxy group in *1a* and *2a* than of the corresponding 3-hydroxy group in *4a* and *5a* as to acetylation, hydrolysis of the acetates and methylation. Differences in the rate of silylation, fast for both categories, were not established. Together with the higher R_F-values for the 2-hydroxy compounds their low rate of reaction may serve to distinguish carotenoids with 2-hydroxylated and 3-hydroxylated β-rings on the micro scale.

The green/blue colour reaction of the 2-hydroxy compounds *1a*, *2a*, and *3a* with hydrochloric acid,[10,1] rationalized by the isolation of a furanoid product of *1a* on treatment with 0.01 M HCl in chloroform-methanol,[11] prompted further investigation on the reaction leading to the partly characterized furanoxides.

The structures of the furanoid products obtained from the mono-ols *1a* and *2a* will first be discussed, Scheme 2. Under conditions to be described below two furanoxides *6a* and *6b* were obtained from *1a* and two furanoxides *7a* and *7b* from *2a*.

The furanoxides *6a* and *6b* were found identical (R_F-values, electronic and mass spectra as well as slow acetylation to the same acetates) with the furanoxides obtained from the so-called *cis* 5,6-epoxide (*cis* relationship between the epoxy and hydroxy substituent) *8* of *1a*. The location of the hydroxy group and the stereochemistry, including the C-8 epimeric nature of the two furanoxides follow therefrom. It is pointed out that the reaction X (Scheme 2) leading from *1a* to the furanoxides *6a*+*6b* must be stereospecific at C-5.

The furanoxides *7a* and *7b* from *2a* were found identical by the criteria mentioned above with the C-8 epimeric furanoid rearrangement products of natural 5,6-epoxy-5,6-dihydro-β,β-caroten-2-ol (*9*), tentatively considered to be a *cis* epoxide.[11] This would imply the same stereospecificity at C-5 in the reaction X leading from *2a* to *7a*+*7b*.

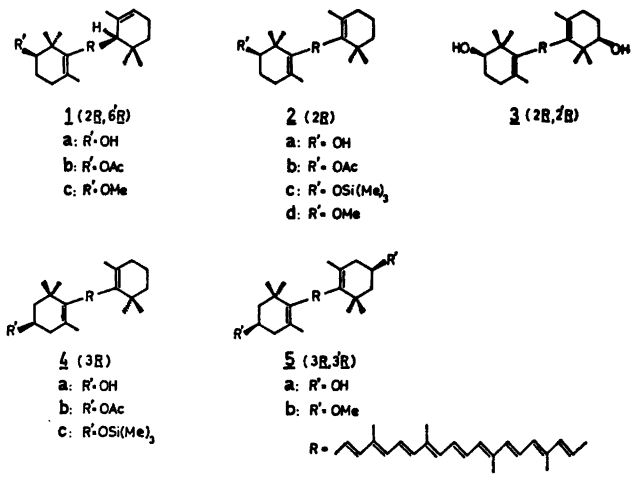
The nature of reaction X will now be considered. The presence of minor epoxides[11] as contaminants would offer an easy explanation. However, this possibility is ruled out from the ready separation of *1a* and *2a* from their 5,6-epoxides,[11] and from the yields obtained in reaction X (pigment recovery 15–30 %; furanoid products comprising 20–60 % of the recovered carotenoids).

A series of experiments designed to define the reaction are summarized:

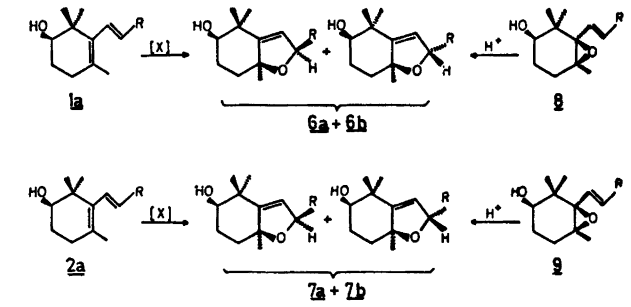
(a) Contrary to the previous assumption[1] hydrogen chloride is not the essential factor X, which is present in certain qualities of chloroform (Baker *p.a.* and a technical quality DAB 7, but not Merck *p.a.*) when chromatographed on alumina and stored at least 20 h before use.

(b) The reaction, formally requiring addition of an oxygen atom, was not prevented under presumed anaerobic conditions.

(c) No evidence for dichlorocarbene being involved was obtained. Thus treatment of *2a* with dichlorocarbene[12] gave no furanoid products, but two other products, one corre-



Scheme 1.



Scheme 2.

sponding to $C_{41}H_{56}Cl_2O$ (formal addition of dichlorocarbene) from mass spectral data.

(d) A free hydroxy group in 2-position is essential for the reaction. Thus no furanoid products were obtained from the acetate *1b* or the methyl ether *1d* with the 2-hydroxy function blocked. Moreover, no furanoid products were obtained from the 3,3'-dihydroxy compound *5a* or from β,β-carotene.

A free radical reaction of a phosgene peroxide complex,[13–16] formed on storage of chloroform after removal of the stabilizer, with participation of the 2-hydroxy group, providing the *cis* epoxide, subsequently rearranging to the furanoxides by traces of acids, or directly to the C_8-epimeric furanoxides, is considered.

Experimental details are given elsewhere.[17] R_F-Values (Schleicher & Schüll No. 287 circular, kieselguhr paper, percentage figure indicates acetone in petroleum ether) were: *1a* (2 %, 0.71), *1b* (1 %, 0.87), *1c* (1 %, 0.86), *2a* (2 %, 0.63), *2b* (1 %, 0.90), *2c* (0 %, 0.83), *2d* (2 %, 0.93), *4a* (1 %, 0.51), *4b* (1 %, 0.90), *4c* (0 %, 0.78), *5a* (10 %, 0.40), *5b*,[8] *6a*+*6b* (1 %, 0.48+0.18), *7a*-acetate = *7b*-acetate (1 %, 0.74), *7a*+*7b* (1 %, 0.55+0.22), *8* (1 %, 0.56), and *9* (1 %, 0.53).

Recommended procedure for preparation of furanoxides: To the 2-hydroxy carotenoid (0.05 – 1 mg) dissolved in *p.a.* chloroform (5 ml) is added Baker *p.a.* chloroform, chromatographed on Merck neutral alumina, activity grade 1, and stored under ordinary atmosphere for at least 20 h, (0.1 – 0.2 ml). A green colour spontaneously develops, turning yellow on ordinary work-up after a few minutes with ether and water.

Derivatives of Hydrazine. X. The Reaction between Thiophosgene and Semicarbazide or Thiosemicarbazide

UFFE ANTHONI and PER HALFDAN NIELSEN

Chemical Laboratory II (General and Organic Chemistry), University of Copenhagen, The H. C. Ørsted Institute, DK-2100 Copenhagen, Denmark

The reaction between thiophosgene and semicarbazide previously reported to give an *N*-isothiocyanatoamine has been shown by combined physical and chemical evidence to give instead bis(2-amino-1,3,4-oxadiazol-5-yl) trithiocarbonate. In the same way, the corresponding reaction between thiophosgene and thiosemicarbazide has been shown to give bis(2-amino-1,3,4-thiadiazol-5-yl) trithiocarbonate. A logical scheme to encompass the formation and reactions of these compounds is suggested.

The reaction between thiophosgene and hydrazine derivatives generally affords thiocarbonohydrazides. However, if carried out in aqueous hydrochloric acid other compounds, claimed by Beckett and Dyson [1] to be *N*-isothiocyanatoamines, are sometimes the main products. In the aromatic series it has previously been shown [2] that the product formed by the action of thiophosgene on 1,1-diphenylhydrazine is, in fact, 2-thiocyanatodiphenylamine formed by rearrangement of the very unstable *N*-isothiocyanatodiphenylamine. The reaction between thiophosgene and 1-methyl-1-phenylhydrazine proceeds in a similar way.[3] Aliphatic *N*-isothiocyanatoamines are also very unstable,[4] undergoing dimerisation [5] except when sterically hindered.[6] These results indicate that the products obtained by Beckett and Dyson, reported to be stable at room temperature, very probably do not contain the N—NCS grouping.

The present paper summarises the results obtained by reinvestigating the products from thiophosgene and semicarbazide (*1a*) or thiosemicarbazide (*1b*) in aqueous hydrochloric acid. They were formulated by Beckett and Dyson as *N*,*N*′-bisisothiocyanato-*N*,*N*′-biscarbamoyl-

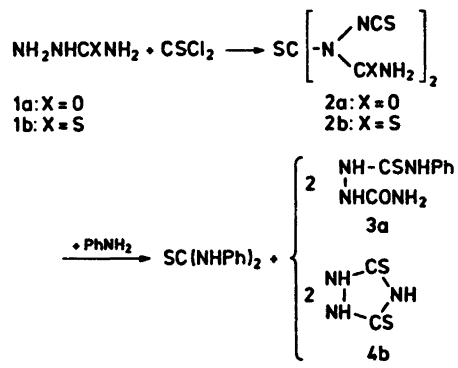

Fig. 1.

thiourea (*2a*) and the corresponding thiocarbamoyl derivative (*2b*) as shown in Fig. 1.

The structural proof for *2a* and *2b* was based on the reaction with aniline, which gave 1,3-diphenylthiourea and 1-(phenylthiocarbamoyl)semicarbazide (*3a*) or dithiourazole (*4b*), respectively. Since 4,4-diphenylsemicarbazide reacted analogously to *1a*, isomeric forms of *2a* and *2b* were not considered likely.

Using techniques not available at the time of the earlier work, we have reformulated the reaction between *1b* and thiophosgene as shown in Fig. 2. The reaction affords a compound $C_5H_4N_6S_5$ compatible with both structures *2b* and *6b*. The IR spectrum in KBr discs, however, is devoid of absorption in the region between 1700 cm^{-1} and 2700 cm^{-1}, excluding the presence of both the —NCS and the —SCN grouping.[3,4] Accordingly, formula *2b* cannot be correct for this compound. The reaction with aniline gave, in addition to 1,3-diphenylthiourea, a

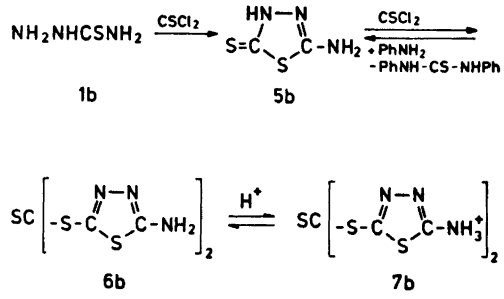

Fig. 2.

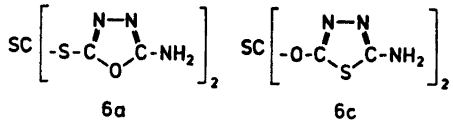
compound $C_2H_3N_3S_2$. This was formulated by Beckett and Dyson as dithiourazole (*4b*), but is now known to be, in fact, the isomeric 2-amino-1,3,4-thiadiazoline-5-thione (*5b*),[7,8] which can be prepared from thiosemicarbazide and carbon disulfide. Since identical products were obtained from the reaction between thiophosgene and *1b* or *5b*, these can be formulated as *6b*. The possibility that thiophosgene instead reacts with the amino group of *5b* giving a thiourea seems to be excluded by the observation that *1b* and thiophosgene in acetone give the dihydrochloride of *6b*, *7b*, with an IR spectrum showing only the expected changes from protonation of the amino groups. Furthermore, *6b* is a trithiocarbonate which is expected to react with aniline to give *5b* and 1,3-diphenylthiourea [9] whilst a thiourea is not expected to show this reaction.

The formation of *6b* from *1b* very probably proceeds *via* formation of *5b* as indicated in Fig. 2. The formation of *2b* or any other *N*-isothiocyanatoamine as an intermediate is considered very unlikely. First, if *2b* acts as an intermediate, a rearrangement to *6b* would involve simultaneous rearrangement of the thiocarbonyl group to the sulfur atoms of both NCS groups. Second, it is well known that the attack of N—NCS on thioamides affords nitriles,[10] and therefore a mechanism proceeding *via*, *e.g.*, $NH_2CSNHNCS$ is not expected.

Next the constitution of the reaction product from *1a* and thiophosgene was considered. A comparison of the physical and chemical properties with those of *6b* pointed to a similar structure. Thus, the IR spectra in KBr were almost identical in the range from 1000 – 4000 cm^{-1}, expect that the two strong bands at 1135 and 1500 cm^{-1} in *6b* were displaced to two doublets at 1170 + 1180 cm^{-1} and 1595 + 1608 cm^{-1}. Mass spectrometry established that pyrolysis of *6b* afforded substantial amounts of CS_2, while the product in question gave mixtures of CS_2 and COS with a percentage of COS ranging from 10 to 100, depending on the temperature and duration of the pyrolysis. Since elemental analysis established the formula $C_5H_4N_6O_5$ either structure *6a* or *6c* was possible.



The changes in the IR spectrum undoubtedly arise from the shift of two skeletal stretching frequencies, but both formulas are consistent with this result. However, the reaction with aniline gave 1,3-diphenylthiourea and 1-(phenylthiocarbamoyl)semicarbazide in confirmation of the results stated by Beckett and Dyson, while 1-(phenylcarbamoyl)thiosemicarbazide was not formed. This was definitely proved by comparison with authentic samples of both compounds, prepared from PhNCS and semicarbazide and from PhNCO and thiosemicarbazide, respectively. This leaves no doubt that the correct structure of the reaction product from thiophosgene and la is *6a*. (Of course, a "mixed" product, containing both the oxadiazolyl moiety of *6a* and the thiadiazolyl moiety of *6c*, is excluded by the same observation).

Further discussion of the structure of *6a* and *6b*, based on ^{13}C NMR spectroscopic investigations, will be presented in a forthcoming paper.

EXPERIMENTAL

Analyses were carried out at the Microanalysis Department of this laboratory. The melting points were determined in capillary tubes on a Büchi melting point apparatus and are not corrected. The infrared spectra were recorded on a Perkin Elmer Model 337 Grating Infrared Spectrophotometer. Mass spectra of the pyrolysis products from *6b* were obtained on a Finnigan 1015 S/L combined gas chromatograph-mass spectrometer.

1-(Phenylthiocarbamoyl)semicarbazide (3a). This compound was prepared following the directions given by Arndt *et al.*[11] The yield was 75 %, m.p. 201 – 202 °C. (Found: C 45.95; H 4.83; N 26.75; S 15.43. Calc. for $C_8H_{10}N_4OS$: C 45.71; H 4.80; N 26.66; S 15.86).

2-Amino-1,3,4-thiadiazoline-5-thione (5b). An authentic sample of this compound was prepared by Sandström's method.[8] The yield was 65 %, m.p. 234–235 °C. (Found: C 18.06; H 2.47; N 30.98. Calc. for $C_2H_3N_3S_2$: C 18.05; H 2.47; N 31.58).

Bis(2-amino-1,3,4-thiadiazol-5-yl) trithiocarbonate (6b). Method A. 2-Amino-1,3,4-thiadiazoline-5-thione (0.1 mol) was suspended in water (50 ml) and shaken with thiophosgene (0.05 mol) for 2 h. The precipitate was collected and dried. The compound was dissolved in dimethyl sulfoxide and reprecipitated with water. The yield was almost quantitative. M.p. 240–250 °C. (Found: C 19.80; H 1.37; N 26.91; S 52.10. Calc. for $C_5H_4N_6S_5$: C 19.47; H 1.31; N 27.28; S 51.95).

Method B. The directions given by Beckett and Dyson [1] were followed. The compound decomposed on attempted recrystallisation and was therefore purified by dissolution in dimethyl sulfoxide and reprecipitation with cold acetone. The analyses given below refer to the crude product. M.p. 240–250 °C decomp. The yield was 60 %. (Found: C 20.21; H 1.60; N 26.39; S 51.06). This compound was proved to be identical with the sample prepared as described under A by their IR and mass spectra and by mixture melting points.

*Bis(2-amino-1,3,4-thiadiazol-5-yl) trithiocarbonate dihydrochloride (*7b*).* 2-Amino-1,3,4-thiadiazoline-5-thione (0.1 mol) was dissolved in acetone (50 ml) and thiophosgene (0.05 mol) was added in one portion. The crystalline yellow precipitate was filtered off and dried. (Found: C 15.91; H 1.52; N 21.88. Calc. for $C_5H_6N_6S_5Cl_2$: C 15.73; H 1.59; N 22.04). On treatment with aqueous base, *6b* was liberated.

Bis(2-amino-1,3,4-oxadiazol-5-yl) trithiocarbonate (6a). The directions given by Beckett and Dyson [1] were followed. The compound could not be recrystallized, but it was reprecipitated from dimethyl sulfoxide and water. M.p. 185–194 °C decomp. The yield was 25 %. (Found: C 21.56; H 1.53; N 29.95; S 34.23. Calc. for $C_5H_4O_2S_3$: C 21.73; H 1.46; N 30.42; S 34.81).

1-(Phenylcarbamoyl)thiosemicarbazide. This compound was prepared following the directions given by Freund and Schander.[12] The yield was 70 %, m.p. 216–217 °C. (Found: C 45.66; H 4.85; N 26.81. Calc. for $C_8H_{10}N_4OS$: C 45.71; H 4.80; N 26.66).

Syntheses in the Camphor Series. Alkylation of Quinones with Cycloalkyl Radicals. Attempted Syntheses of Lagopodin A and Desoxyhelicobasidin

J. GOLDMAN,* N. JACOBSEN and K. TORSSELL

Department of Organic Chemistry, University of Aarhus, DK-8000 Aarhus C, Denmark

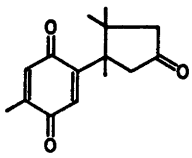
In an attempt to synthesize lagopodin A and desoxyhelicobasidin, a new synthesis of (3*R*)-3-carboxy-3,4,4-trimethylcyclopentanone and (1*R*)-1,2,2-trimethylcyclopentanecarboxylic acid was worked out together with several other reactions in the camphor series. For the same purpose alkylation of quinones with cycloalkyl radicals derived from cycloalkane carboxylic acids by decarboxylation with silver ion sand peroxydisulphate was investigated and several cycloalkyl derivatives were prepared. It was not possible to add the sterically hindered trimethyl cyclopentyl radicals to quinones. The structure *22* is suggested for a camphorlactone claimed to be *21*.[8]

In previous papers [1,2] we have described the alkylation of quinones with radicals from the decarboxylation of carboxylic acids with silver ions and peroxydisulphate (Eqns. 1 and 2)

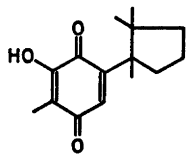
$$Ag^+ + S_2O_8^{2-} \rightarrow Ag^{2+} + SO_4^{\cdot -} + SO_4^{2-} \quad (1)$$

$$Ag^{2+} + RCOOH \rightarrow R^{\cdot} + CO_2 + H^+ + Ag^+ \quad (2)$$

In the present work the alkylation of quinones with cycloalkylradicals was investigated in order to examine the possibility of synthesizing the naturally occurring terpenoid quinones lagopodin A [3] *1* and desoxyhelicobasidin [4] *2* by this method.



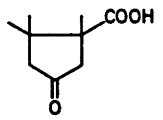
1



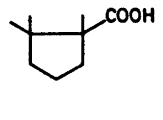
2

* Present address: A/S Grindstedværket, DK-8200 Aarhus N, Denmark

During the search for a convenient synthesis of the carboxylic acids *3* and *4*, required for this purpose, some other useful reactions in the



3



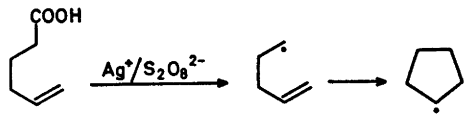
4

camphor series were discovered. These are discussed in the section containing the syntheses of *3* and *4*.

RESULTS

Alkylation of 1,4-naphthoquinones 5. The alkylation of 1,4-naphthoquinone *5* and 2-methyl-1,4-naphthoquinone *6* with cycloalkylradicals (C_3-C_6) gave the corresponding cycloalkylquinones in fair yields (Table 1).

The possibility of generating cyclopentylradicals indirectly by the cyclisation of an open chain unsaturated radical (Eqn. 3) was also examined.



(3)

When 5-hexenoic acid was decarboxylated in the presence of 2-methyl-1,4-naphthoquinone, 2-methyl-3-(4-pentenyl)-1,4-naphthoquinone *12* was isolated. Only traces of the cyclopentylquinone *9* could be detected.

Table 1. Alkylation of quinones with cycloalkyl radicals.

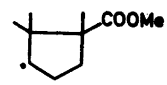
Quinone	Carboxylic acid	Product	Yield %	m.p.
6	Cyclopropane-	7 	37	82-83°
6	Cyclobutane-	8 	56	59-60°
6	Cyclopentane-	9 	42	96-97°
6	Cyclohexane-	10 	46	78-79°
5	Cyclohexane-	11 	55	87-88° (lit.[5] 87-88)

Synthesis of 3 and 4. Since the published syntheses of the optically active [3] or the racemic[6] *3* are rather complicated, a new route to *3* and *4* in their optically active forms was investigated.

Oxidative decarboxylation of (1*R*)-*cis*-camphoric acid-1-methylester *13* with lead tetraacetate in the presence of cupric ions by the method of Kochi [7] gave (1*R*)-1,2,2-trimethylcyclopent-3-ene-carboxylic acid methylester *14*.

Alkaline hydrolysis of *14* gave the corresponding carboxylic acid *15* which was hydrogenated catalytically to *4* (1*R*-configuration).

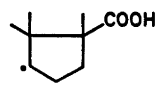
The oxidative decarboxylation of *13* was also performed by the use of silver ion-peroxydisulphate-cupric ions in water-acetonitrile in the same yield but with higher conversion of *13*. In this reaction the presence of pyridine proved essential for the oxidation of the intermediate radical *16* to *14* by the cupric ions. When the reaction was carried out in the absence of pyridine, a mixture of *14* and the saturated ester *17* (Scheme 1) was formed.



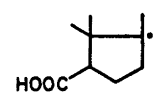
16

To investigate the selectivity of the oxidative decarboxylation between secondary and tertiary carboxyl groups with both lead tetraacetate and silver ion-peroxydisulphate, camphoric acid was decarboxylated by both oxidants under conditions similar to those in the syntheses of *14*.

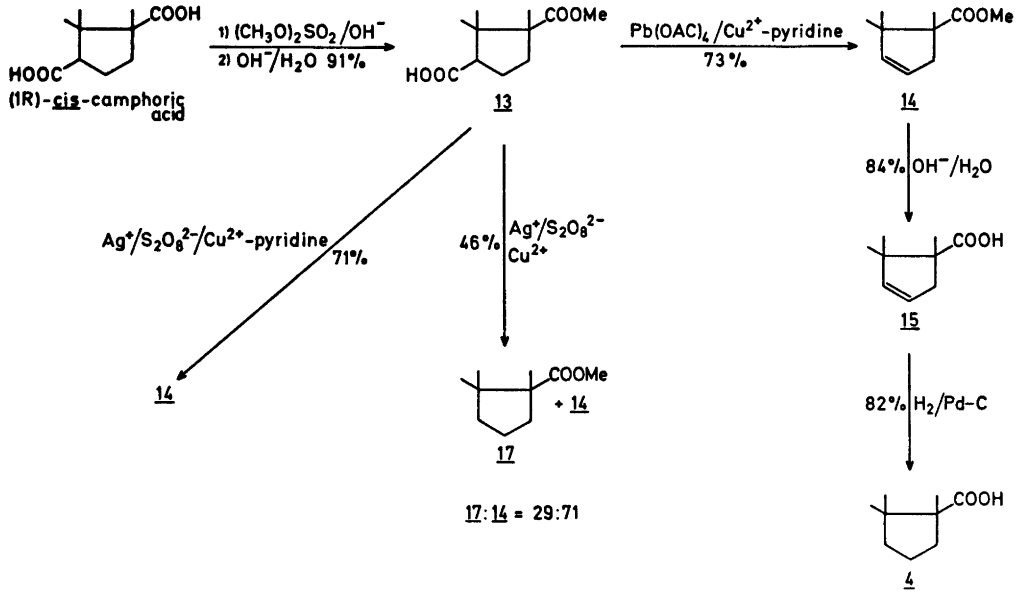
Two radicals, *18* and *19*, result from the decarboxylation of the secondary and the tertiary carboxylic group, respectively.



18

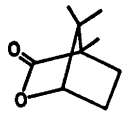


19

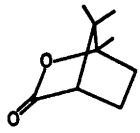


Scheme 1.

The main products in both reactions were the lactones *20* and *21* formed from *18* and *19*, respectively, probably by internal ligand-transfer,

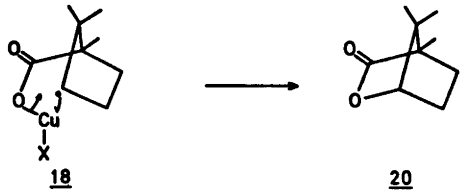


20



21

and analogously *19*→*21*.



18 20

The expected products, cyclopentenoic acids (formed analogously to *14*) were only present in small amounts.

These results show that the tertiary carboxylic group is decarboxylated much faster than the secondary by both reagents.

The spectra and physical data of *21* were very different from those published by Hayashi *et al.*[8] for a compound claimed to be *21*. Their data

Table 2. Ratio[a] of products from decarboxylation of camphoric acid.

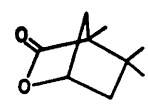
ammonium salt with disiamylborane, followed by oxidation with hydrogen peroxide by the method of Brown,[9] were unsuccessful.

Bromination of *15* gave a dibromoderivative *24* which, when treated *in situ* with aqueous sodium carbonate, gave a bromolactone *25*. Catalytical hydrogenation of *25* gave *20* which on hydrolysis and oxidation would lead to an isomer of the desired keto acid *3*.

The *endo*-configuration of *25* was deduced as follows: The carboxylate ion in the dibromacid *24* substitutes the bromine atom in *trans* position, and since the addition of bromine to the double bond proceeds in a *trans* fashion, the bromine of *25* is located *cis* to the lactone bridge (Scheme 2).

Treatment of *15* with *p*-toluenesulphonic acid in refluxing toluene gave the desired lactone *26*, together with a minor amount (13 %) of *20*. It proved impossible to separate *20* from *26*

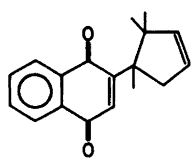


26

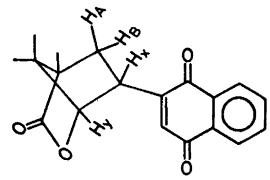
by other means than preparative GLC so the mixture was hydrolyzed and the (1*R*)-*cis*-4-hydroxy-1,2,3-trimethylcyclopentanecarboxylic acid *23* was purified by crystallization from water.

Oxidation of *23* by chromic acid in a 2-phase system gave *3* in good yield.

Attempted syntheses of lagopodin A and desoxyhelicobasidin 2. As a model of the synthesis of desoxyhelicobasidin we used naphthoquinone with *4* but without success, partly because of the low solubility of *4* in water and aqueous acetonitrile which caused formation of a 2-phase system on addition of peroxydisulphate



27



28

and thereby ineffective decarboxylation of *4*. The same reaction using *4* as its silver- or tetrabutylammonium salt or *4* together with a weak base like 2,6-lutidine, gave no alkylated naphthoquinone, although *4* was consumed in these reactions.

To overcome the solubility problem, we tried to carry out the alkylation with *15* instead of *4* but in this reaction the simple alkylated naphthoquinone *27* was not obtained.

Instead *28* was formed as the only isolable quinone product in a yield of 41 % (apparently only the *endo*-isomer).

The *endo* structure was preferred for the following reason: The NMR coupling constants, of the H_A, H_B, and H_x protons, of *28* are in reasonably good agreement (Table 4) with those of the bromolactone *25* which for reasons already mentioned should be the *endo*-isomer.

We are not, however, able to find sufficient NMR data of related structures in the literature to justify a definite assignment.

Table 4. ^1H Coupling constants (Hz) of *25* and *28*.

Compounds	J_{AB}	J_{AX}	J_{BX}	J_{XY}
25	−15.2	10.1	4.0	2.0
28	−13.9	10.7	5.1	1.7

Two mechanisms, 5A and 5B, for the formation of *28* can be formulated, see below.

In view of the small gain in energy by cyclization of *29* compared with the greater amount of energy liberated by a decarboxylation, *30* is preferred to *29* as intermediate.

The mechanism B has also been proposed by Moriarty [10] for the oxidation of various alkenecarboxylic acids by lead tetraacetate.

Attempts to alkylate toluquinone with *3* to give lagopodin A and isomers also failed, indicating that the steric hindrance of the tertiary cycloalkyl radicals in the alkylation step is of such a magnitude that the fast oxidation of these radicals by Ag^{2+} or $SO_4^{\cdot-}$ prevails.

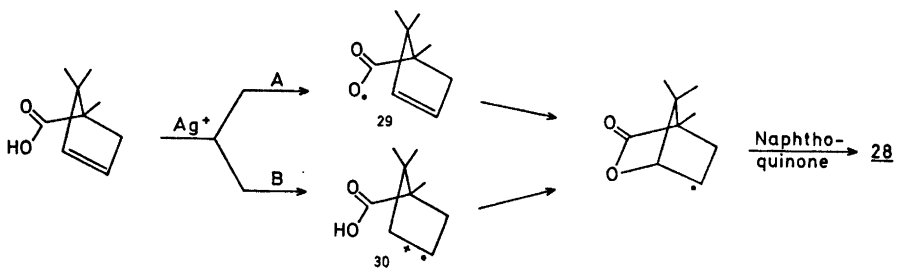
In agreement with this alkylation with 1-methylcyclohexanecarboxylic acid also gave very poor yields.

EXPERIMENTAL

Melting points are uncorrected. *NMR* spectra were recorded on a Varian A-60, *IR* spectra on a Perkin-Elmer Infracord, and *UV* spectra on a Perkin-Elmer 402 spectrometer. Analytical GLC was performed with a Perkin-Elmer F11 chromatograph. Optical rotations were measured on a Perkin-Elmer 141 polarimeter. Calculation of *NMR* shifts and coupling constants was made by means of the LAOCN-3 programme.

Alkylation of quinones. Details of the reaction have been described earlier.[1]

General procedure. To a vigorously stirred water-acetonitrile solution of the quinone, the



carboxylic acid, and silver nitrate at 60 – 65 °C an aqueous solution of ammonium peroxydisulphate was added during 45 min. After a further 10 min stirring at 60 – 65 °C, the mixture was cooled to room temperature and extracted with ether. The ether phase was washed with aqueous $NaHCO_3$ until neutral, dried, and evaporated. The crude products were chromatographed, either on TLC plates (silica gel Merck); procedure A: eluent 20 % ether in petrol ether; procedure B: eluent CH_2Cl_2 or on a column of neutral aluminia; procedure C: eluent CH_2Cl_2.

2-Cyclopropyl-3-methyl-1,4-naphthoquinone, 7. To 2-methyl-1,4-naphthoquinone (1.72 g, 0.01 mol), cyclopropanecarboxylic acid (1.29 g, 0.015 mol), and silver nitrate, 0.5 g, in acetonitrile (25 ml) and water (60 ml) was added ammonium peroxydisulphate (3.42 g, 0.015 mol) in water (15 ml). Chromatography (procedure B) of the crude product gave *7*, 780 mg (37 % based on the quinone), m.p. 82 – 83 °C (from CH_3OH). (Found: C 78.6; H 5.82. Calc. for $C_{14}H_{12}O_2$: C 79.2; H 5.70). UV (EtOH) λ_{max} nm (log ε): 246 (4.21), 251 (4.21), 274 (4.10), 333 (3.5). IR (CCl_4): cm^{-1} 1660(s), 1595 (m). NMR (CCl_4): δ 0.8 – 1.3 (4 H, m), 1.3 – 2.0 (1 H, m), 2.20 (3 H, s), 7.4 – 8.1 (4 H, m).

2-Cyclobutyl-3-methyl-1,4-naphthoquinone, 8. To 2-methyl-1,4-naphthoquinone (0.86 g, 0.005 mol), cyclobutanecarboxylic acid (0.75 g, 0.0075 mol), and silver nitrate (0.5 g) in acetonitrile (20 ml) and water (20 ml) was added ammonium peroxydisulphate (1.71 g, 0.0075 mol) in water (10 ml). Chromatography (procedure B) of the crude product gave *8*, 630 mg (56 % calculated on the quinone), m.p. 59 – 60 °C (from methanol). (Found: C 79.7; H 6.46. Calc. for $C_{15}H_{14}O_2$: C 79.6; H 6.24). UV (EtOH): λ_{max} nm (log ε) 245 (4.23), 251 (4.22), 274 (4.17), 332 (3.4). IR (CCl_4): cm^{-1} 1660(s), 1595(m). NMR (CCl_4): δ 1.7 – 2.8 (6 H, m), 2.07 (3 H, d, $J = 1$), 3.2 – 4.0 (1 H, m), 7.5 – 8.1 (4 H, m). On irradiation of the multiplet at 3.2 – 4.0 ppm, the doublet at 2.07 ppm collapsed into a singlet.

2-Cyclopentyl-3-methyl-1,4-naphthoquinone, 9. To 2-methyl-1,4-naphthoquinone (0.86 g, 0.005 mol), cyclopentanecarboxylic acid (0.86 g, 0.0075 mol), and silver nitrate (0.5 g) in acetonitrile (70 ml) and water (20 ml) was added ammonium peroxydisulphate (1.71 g, 0.0075 mol) in water (10 ml). Chromatography (procedure B) of the crude product gave *9*, 510 mg (43 % based on the quinone), m.p. 96 – 97 °C (from CH_3OH). (Found: C 79.6; H 6.77. Calc. for $C_{16}H_{16}O_2$: C (79.6; H 6.71). UV (EtOH): λ_{max} nm (log ε) 246 (4.24), 250 (4.24), 269 (4.16), 276 (4.18), 332 (3.5). IR (CCl_4): cm^{-1} 1660(s), 1595(m). NMR (CCl_4): δ 1.3 – 2.2 (8 H, m), 2.17 (3 H, s), 2.9 – 3.5 (1 H, m), 7.5 – 8.1 (4 H, m).

2-Cyclohexyl-3-methyl-1,4-naphthoquinone, 10. The general procedure was followed. To 2-methyl-1,4-naphthoquinone (1.72 g, 0.01 mol), cyclohexanecarboxylic acid (1.92 g, 0.015 mol) and silver nitrate (0.5 g) in acetonitrile (40 ml) and water (40 ml) was added ammonium peroxydisulphate (3.42 g, 0.015 mol) in water (20 ml). Chromatography (procedure A) gave *10*, 1.16 g (46 % calculated on the quinone), m.p. 78 – 79 °C. (Found: C 80.0; H 7.24. Calc. for $C_{17}H_{18}O_2$: C 80.3; H 7.15). UV (EtOH): λ_{max} nm (log ε) 246 (4.28), 250, sh, 269, sh, 275 (4.11), 331 (3.5). IR (CCl_4): 1660(s), 1595(m). NMR (CCl_4): δ 1.0 – 2.2 (10 H, m), 2.17 (3 H, s), 2.4 – 3.1 (1 H, m), 7.5 – 8.1 (4 H, m).

2-Cyclohexyl-1,4-naphthoquinone, 11. To 1,4-naphthoquinone (1.58 g, 0.01 mol), cyclohexanecarboxylic acid (1.92 g, 0.015 mol), and silver nitrate (0.5 g) in acetonitrile (22 ml) and water (20 ml) was added ammonium peroxydisulphate (3.42 g, 0.015 mol) in water (15 ml). Chromatography (procedure A) of the crude product gave *11*, 1.32 g (55 % based on the quinone), m.p. 87 – 88 °C (lit.[5] 87 – 88 °C). UV (EtOH): λ_{max} nm (log ε) 248 (4.25), 253 (4.24), 267 (4.17), 334 (3.5). IR (CCl_4): cm^{-1} 1665(s), 1615(m), 1595(m). NMR (CCl_4): δ 0.9 – 2.4 (10 H, m), 2.4 – 3.2 (1 H, m), 6.61 (1 H, d, $J = 1$), 7.5 – 8.2 (4 H, m).

3-Methyl-2-(4-pentenyl)-1,4-naphthoquinone, 12. To 1-methyl-1,4-naphthoquinone (1.72 g, 0.01 mol), 5-hexenoic acid (1.71 g, 0.015 mol), and silver nitrate (0.5 g) in acetonitrile (25 ml) and water (25 ml) was added ammonium peroxydisulphate (3.42 g, 0.015 mol) in water (15 ml). Chromatography (procedure B) of the crude product gave *12*, 920 mg (38 % based on the quinone), m.p. 46 – 47 °C. (Found: C 79.6; H 6.75. Calc. for $C_{16}H_{16}O_2$: C 80.0; H 6.71). UV (EtOH): λ_{max} nm (log ε) 249 (4.19), 267 (4.15), 273 (4.15), 333 (3.4). IR (CCl_4): cm^{-1} 1660(s), 1620(m), 1595(m). NMR (CCl_4): δ ~1.5 (2 H, distorted quintet, $J = 7$), 2.1 (2 H, b, t, $J = 7$), 2.10 (3 H, s), 2.5 (2 H, d, t, $J_1 = 8$, $J_2 = 7$), 4.8 – 5.3 (2 H, m), 5.5 – 6.2 (1 H, m), 7.5 – 8.1 (4 H, m). Only traces of *9* could be detected by TLC.

2-(endo-5-(1,7,7-Trimethyl-2-oxo-3-oxa)-bicyclo[2.2.1]heptyl)-1,4-naphthoquinone, 28. To 1,4-naphthoquinone (0.79 g, 0.005 mol), *15* (0.93 g, 0.006 mol), and silver nitrate (0.5 g) in acetonitrile (15 ml) and water (20 ml) was added ammonium peroxydisulphate (1.30 g, 0.0057 mol) in water (8 ml). Chromatography (procedure C) gave *28*, 640 mg (41 % calculated on the quinone), m.p. 132 – 133 °C (after recrystallization from methanol and from cyclohexane). $[\alpha]_D^{25} = -158°$ (ethanol, $c = 0.5$) (Found: C 72.9; H 5.79. Calc. for $C_{19}H_{18}O_4$: C 73.5; H 5.84). UV (EtOH): λ_{max} nm (log ε) 248 (4.21), 254 (4.21), 264 (4.09), 339 (3.4). IR (CCl_4): cm^{-1} 1795(s), 1665(s), 1625(m), 1600(m). NMR ($CDCl_3$): δ 1.09 (3 H, s), 1.15 (3 H, s), 1.17 (3 H, s), 1.71* (1 H, A part of ABXYZ system), 2.32* (1 H, B part), 3.84* (1 H, X part), 4.50 (1 H, d, Y part, $J_{XY} = 1.7$), 6.82 (1 H, d, Z part, $J_{XZ} = 1.5$), 7.6 – 8.2 (4 H, m) $J_{AB}^* = -13.9$, $J_{AX}^* = 10.7$, $J_{BX}^* = 5.1$. The signal at δ 3.84, which appeared as four triplets, was changed

* Calculated values.

into four doublets, $J = 1.7$, by irradiation of the doublet at 6.82.

Dimethyl-(1R)-cis-camphorate was prepared by the method of Riedel [11] in a yield of 97 %. NMR (CCl_4): δ 0.72 (3 H, s), 1.18 (3 H, s), 1.21 (3 H, s), 1.3 – 2.9 (5 H, m), 3.65 (6 H, s).

(1R)-cis-Camphoric acid-1-methylester, 13. 123 g (0.54 mol) of dimethyl-(1*R*)-*cis*-camphorate and potassium hydroxide (0.54 mol) were dissolved in methanol (800 ml) and water (400 ml) and left at room temperature for 3 days. The solution was refluxed for 30 min and the methanol was distilled off. The aqueous phase was washed with ether, acidified with conc. HCl and extracted with CH_2Cl_2. Drying and evaporation of the CH_2Cl_2 phase gave 108 g (94 %) of almost pure *13*, m.p. 85 – 86 °C (from petrol ether) (lit.[12] 86 – 87 °C) $[\alpha]_D^{25} = +43°$ (ethanol $c = 2$). IR (CCl_4): cm^{-1} 2500 – 3200(s), 1735(s), 1705(s). NMR (CCl_4): δ 0.83 (3 H, s), 1.20 (3 H, s), 1.28 (3 H, s), 1.3 – 3.0 (5 H, s), 3.67 (3 H, s), 11.7 (1 H, s).

Decarboxylation of (1R)-cis camphoric acid-1-methylester, 13 *with lead tetraacetate. Preparation of 15.* A mixture of 47 g (0.22 mol) of *13*, lead tetraacetate (111 g, 90 % pure, 0.22 mol), neutral cupric acetate (7.2 g), and pyridine (11 g) in benzene (450 ml) was refluxed with stirring for 2 h. The reaction mixture was filtered, washed with dilute nitric acid to remove pyridine and copper salts and extracted with aqueous potassium carbonate until neutral. On acidification of the alkaline washings, 13 g of *13* were recovered. The benzene phase was dried and distilled. The fraction boiling at 180 – 186 °C was (1*R*)-1,2,2-trimethylcyclopent-3-ene-1-carboxylic acid methylester, *14*, 19.5 g (73 % based on converted *13*). (For use in the hydrolysis it is only necessary to distil off the benzene). $n_D^{22} = 1.4501$, $[\alpha]_D^{25} = +113°$ (ethanol, $c = 1$). IR (CCl_4): cm^{-1} 1735(s), 1620(w). NMR (CCl_4): δ 0.88 (3 H, s), 1.13 (3 H, s), 1.18 (3 H, s), 2.0 (1 H, distorted d, $J \sim 17$), 3.2 (1 H, distorted d, $J \sim 17$), 3.66 (3 H, s), 5.3 (1 H, m), 5.5 (1 H, m).

Decarboxylation of 13 *with* $Ag^+/S_2O_8^{2-}$. To a stirred mixture of *13* (21.4 g, 0.1 mol) cupric sulphate (6 g), silver sulphate (4 g), and pyridine (6 ml) in water (150 ml) and acetonitrile (100 ml) at 60 – 70 °C was added ammonium peroxydisulphate (30.6 g, 0.13 mol) in water (50 ml) during 1 h while the pH was kept at 6 – 7 by addition of 4 M sodium hydroxide. After a further 10 min stirring, 4 M sulphuric acid (100 ml) was added and the mixture was cooled and extracted three times with petrol ether. The organic phase was dried and the petrol ether was distilled off together with some acetonitrile leaving almost pure *14* (11.8 g, 70 %) containing less than 1 % of *17* (GLC, 5 % SE-30, using authentic samples as references). In the absence of pyridine it was necessary to use more acetonitrile (140 ml) and less water (90 ml) to bring *13* in solution, and the crude product was very impure and had to be distilled before GLC analysis. The fraction, boiling at 106 – 130 °C/45 mm, (7.8 g, 46 %) was collected and found to contain *14* (71 %) and *17* (29 %) by GLC.

1,2,2-Trimethylcyclopent-3-ene-1-carboxylic acid, 15. A solution of *14* (7.7 g, 0.046 mol) and potassium hydroxide (35 g, 0.63 mol) in methanol (170 ml) and water (15 ml) was refluxed for 20 h. The methanol was distilled off, the residue was dissolved in water and washed with ether. The aqueous phase was cooled to 0 °C, acidified with conc. HCl, and the precipitated (1*R*)-1,2,2-trimethylcyclopent-3-ene-1-carboxylic acid *15* filtered, washed with cold water, and dried. Yield: 5.9 g (84 %), m.p. 157 – 158 °C (from formic acid or aqueous formamide or after sublimation at 120 °C/10 mm, lit.[13] 157 – 159.5 °C). $[\alpha]_D^{25} = +122°$ (ethanol, $c = 1$). IR ($CHCl_3$): cm^{-1} 2500 – 3500(s), 1705(s), 1625(w). NMR (CCl_4): δ 1.02 (3 H, s), 1.17 (3 H, s), 1.27 (3 H, s), 2.0 (1 H, distorted d, $J = 17$), 3.2 (1 H, distorted d, $J = 17$), 5.3 (1 H, m), 5.5 (1 H, m), 11.9 (1 H, s).

Decarboxylation of (1R)-cis-camphoric acid by lead tetraacetate. Preparation of 20 and 21. Camphoric acid (10 g, 0.05 mol), lead tetraacetate (27.8 g, 90 % pure, 0.055 mol), neutral cupric acetate (2 g), and pyridine (3 ml) were refluxed in benzene (200 ml) for 3 h. The mixture was washed with 30 % nitric acid, water, and aqueous sodium carbonate, successively, dried, and evaporated *in vacuo* at room temperature leaving 4.9 g (64 %) of a mixture of *20*, 17 % and *21*, 83 % (GLC). On acidification of the sodium carbonate phase, *ca.* 1.5 g of acidic material – mainly camphoric acid – was obtained.

Decarboxylation of (1R)-cis-camphoric acid with Ag^+*/persulphate.* Camphoric acid (10, g, 0.05 mol), cupric sulphate (2 g), silver sulphate (2 g), pyridine (3 ml), water (200 ml), and acetonitrile (20 ml) were stirred at 60 – 65 °C while 13.68 g (0.06 mol) of ammonium peroxydisulphate in water (50 ml) were added during 70 min. During the addition, the pH was kept at 5 – 7 by addition of diluted NaOH. After a further 10 min stirring at 60°C, 2 M H_2SO_4 (50 ml) was added and the mixture was extracted with ether. The ether extract was washed with aqueous sodium carbonate, dried, and evaporated to give 4.4 g (57 %) of a mixture of *20* and *21* (5:95, GLC). Small amounts of acidic material could be obtained on acidification of the carbonate phase. Preparative GLC 10 % PEG) of the mixture gave *21*, m.p. 113 – 115 °C $[\alpha]_D^{25} = +12.6°$ (ethanol, $c = 0.5$). (Found: C 70.0; H 9.10. Calc. for $C_9H_{14}O_2$: C 70.1; H 9.15). IR (KBr): cm^{-1} 1775(s). NMR (CCl_4): δ 0.95 (3 H, s), 1.06 (3 H, s), 1.29 (3 H, s), 1.5 – 2.1 (4 H, m), 2.28 (1 H, distorted dd). MS Mass % of base peak): 154 (5) M^+, 139 (5), 126 (31), 111 (27), 108 (26), 95 (100).

Lactonisation of 1,2,2-trimethylcyclopent-3-ene-carboxylic acid, 15. Preparation of 26 and 20. 15 (8.55 g, 0.056 mol) and *p*-toluenesulfonic acid (4.3 g, 0,0027 mol) were refluxed for 20 h in

toluene (70 ml). The mixture was extracted with aqueous sodium carbonate. On acidification of the carbonate washing, *15* (1.35 g) was recovered by extraction with CH_2Cl_2. The toluene phase was dried and evaporated *in vacuo* at room temperature. The residue was sublimated at 115 °C/10 mm to give 4.08 g (57 %) of a mixture of (1*R*)-*cis*-4-hydroxy-1,2,2-trimethylcyclopentane carboxylic acid lactone, *26*, and the isomeric 3-hydroxy carboxylic acid lactone, *20*, ratio 87:13 (GLC, 10 % PEG). This mixture could not be separated by crystallization. The *IR* spectrum of the mixture was almost identical with the spectrum of *26*, published by Faigle and Karrer.[14] NMR (CCl_4) of *26*: (after substraction of the signals from 20) δ 0.97 (3 H, s), 1.07 (3 H, s), 1.10 (3 H, s), 1.7 (2 H, m), 1.9 (2 H, m), 4.6 (1 H, m).

(1R)-cis-4-Hydroxy-1,2,2-trimethylcyclopentanecarboxylic acid, 23. The lactone mixture of *20* and *26* (4 g) was refluxed for 20 h with 40 g KOH in 160 ml of methanol and 80 ml of water. The methanol was evaporated and the aqueous phase washed with ether, acidified with conc. HCl and extracted with several portions of CH_2Cl_2. The CH_2Cl_2 phase was dried and evaporated and the residue recrystallized from water giving pure *23* (2.95 g, 66 %), m.p. 199 – 200 °C (lit.[15] 200 °C). $[\alpha]_D^{25} = +14°$ (ethanol, $c = 4$). IR (KBr): cm^{-1} 3400(s), 2500 – 3100(s), 1700(s). NMR (D_2O, K_2CO_3): δ 0.93 (3 H, s), 0.98 (3H, s), 1.01 (3 H, s), 1.38 – 2.37 (4 H, m), 4.07 – 4.50 (1 H, m).

(3R)-3-Carboxy-3,4,4-trimethylcyclopentanone, 3. To *23* (1.5 g, 0.087 mol) dissolved in a 2-phase system consisting of ether (20 ml), water (10 ml), and dimethoxyethane (3.5 ml) was added at 25 °C a mixture of $Na_2Cr_2O_7.2H_2O$ (1.6 g, 0.054 mol), and conc. H_2SO_4 (1 g) in water (15 ml) with vigorous stirring during 15 min. After further 4 h of stirring, the organic layer was separated and the aqueous phase extracted several times with ether. The combined organic phases were dried and evaporated to give *3* (1.20 g, 81 %), m.p. 220 – 221 °C (from H_2O (lit.[3] 221 °C). $[\alpha]_D^{25} = +23°$ (ethanol, $c = 2$). IR ($CHCl_3$): cm^{-1} 2500 – 3500(s), 1745(s), 1700(s). NMR ($CDCl_3$): δ 1.14 (3 H, s), 1.21 (3 H, s), 1.35 (3 H, s), 2.20 and 3.01 (2 H, AB system, $J_{AB} = 19$), 2.36 (1H, b , s), ~11 (1 H, b, s).

(1R)-1,2,2-Trimethylcyclopentanecarboxylic acid, 4. 15 (10.0 g, 0.065 mol) in 100 ml alcohol was hydrogenated over 5 % Pd/C (0.6 g) for 20 h at room temperature and 1 atm. The solution was filtered and evaporated and the residue recrystallized from acetonitrile to give *4* (8.3 g, 82 %), m.p. 191 – 192 °C (lit.[16] 192 – 193 °C). $[\alpha]_D^{25} = +20°$ (ethanol, $c = 1$). IR (CCl_4): cm^{-1} 2500 – 3300(s), 1700(s). NMR (CCl_4): δ 0.98 (3 H, s), 1.07 (3 H, s), 1.18 (3 H, s), ~1.6 (5 H, m), 2.0 – 2.7 (1 H, m), 11.77 (1 H, s).

Methyl-(1R)-1,2,2-trimethylcyclopentanecarboxylate, 17. To *4* (4.68 g, 0.03 mol) and sodium hydroxide (1.6 g, 0.039 mol) in 20 ml of water at 40 °C was added dimethyl sulphate (3.4 ml, ~0.036 mol). The temperature was kept at 60 °C for 1 h and excess of NaOH was added. The product *17* was extracted with ether and distilled (3.6 g, 71 %), b.p.$_{760}$ 176 – 180 °C. $n_D^{24} = 1.4448$. $[\alpha]_D^{25} = +8.4°$ (ethanol, $c = 3$). IR (film): cm^{-1} 1740(s). NMR (CCl_4): δ 0.81 (3 H, s), 1.01 (3 H, s), 1.10 (3 H, s), 1.6 (5 H, m), 2.0 – 2.7 (1 H, m), 3.59 (3 H, s).

(1R,3S)-3-Bromo-cis-4-hydroxy-1,2,2-trimethylcyclopentanecarboxylic acid lactone, 25. To *15* (10.0 g, 0.065 mol) in chloroform (30 ml) kept below 5 °C was added bromine (11.5 ml, 0.072 mol) during 1 h. After the addition, the mixture was stirred at 5 °C for 30 min. The $CHCl_3$ was evaporated and the residue was stirred vigorously with 10 % Na_2CO_3 (120 ml) for 1 h. Extraction of the mixture with methylene chloride, drying, and evaporation gave 13.8 g of a crystalline product which was recrystallized from petrol ether (b.p. 60 °C) to give pure bromolactone *25* (11.9 g, 72 %), m.p. 90.5 – 91.5 °C. (Found: C 46.5; H 5.75; Br 34.2. Calc. for $C_9H_{13}O_2Br$: C 46.4; H 5.62; Br 34.3). $[\alpha]_D^{25} = -71°$ (ethanol, $c = 1$). IR (CCl_4): cm^{-1} 1795(s). NMR (CCl_4): δ 1.01 (3 H, s), 1.04 (3 H, s), 1.09 (3 H, s), 1.82* (1 H, A part of ABXY system), 2.60* (1 H, B part), 4.26* (1 H, X part), 4.53* (4 H, Y part). $J_{AB}^* = -15.2$. $J_{AX}^* = 4.0$. $J_{BX}^* = 10.1$. $J_{XY}^* = 2.0$.

Catalytic hydrogenation of bromolactone, 25. 25 (2.34 g, 0.01 mol) in methanol (20 ml) was hydrogenated over 1 g of 5 % Pd/C and 4 g of MgO (1 atm. 25 °C) until slightly more than 0.01 mol of hydrogen was consumed (28 h). The solution was filtered, diluted with water (100 ml) and extracted 5 times with methylene chloride. The organic phase was washed with aqueous K_2CO_3, dried, and evaporated and the residue sublimated at 100 °C/10 mm to give *20*, 910 mg (59 %), m.p. (from ether) 162 – 164 °C (lit.[17] 165 – 167 °C). The IR spectrum was identical with that published by Faigle and Karrer,[14] $[\alpha]_D^{25} = -19°$ (ethanol, $c = 2$). NMR (CCl_4): δ 0.92 (3 H, s), 0.98 (3 H, s), 1.01 (3 H, s), 1.4 – 2.1 (4 H, m), 4.23 (1 H, m). MS: Mass (intensity – % of base peak): 154 (2) M^+, 140 (2), 126 (10), 111 (10), 108 (15), 97 (18), 95 (100).

Derivatives of Hydrazine. XI. Rotational Isomerism of Methyl Diselenocarbamates and Diselenocarbazates

BRITTA MYNSTER DAHL and PER HALFDAN NIELSEN

Chemical Laboratory II (General and Organic Chemistry), University of Copenhagen, The H. C. Ørsted Institute, DK-2100 Copenhagen, Denmark

The preparation of methyl diselenocarbamates and diselenocarbazates carrying one or more *N*-alkyl substituents is described. The ^{1}H NMR spectra of these compounds are reported and signals assigned to *Z* and *E* isomers arising from rotational isomerism about the central C–N bond. The assignments are primarily based on multiplicity, position, and solvent shifts of the signals compared with results obtained from analogous compounds with known configuration. The *Z*–*E* isomer ratios are briefly discussed.

During work on derivatives of dithio- and diselenocarbazic acids,[1–4] we became interested in the conformational properties of diselenocarbazic esters. These compounds, in analogy with, *e.g.*, amides [5] and hydrazides,[6,7] may exhibit *Z*–*E* isomerism arising from hindered rotation around the central N^2–C bond. Dipolar structures and selenol forms are also possible in analogy with observations reported for related sulfur compounds.[2,8]

This paper describes a study, primarily by means of ^{1}H NMR spectroscopy, on the rotational isomerism of methyl N^2-methyldiselenocarbazate (*1*), methyl N^2,N^3-dimethyldiselenocarbazate (*2*), and methyl N^2,N^3,N^3-trimethyldiselenocarbazate (*3*) in CCl_4, $CDCl_3$, and nitrobenzene. The compounds prepared for this study, including the three *N*-alkyl-*N*-methyldiselenocarbamates (*4*–*6*) used as reference substances, are listed in Table 1.

The ^{1}H NMR spectra of the compounds *1*–*6* are given in Table 2. The signals arising from the methyl groups (N^2–CH_3, N^3–CH_3, and Se–CH_3) as well as the N^3–H protons can generally be identified by their integrated intensities, multiplicities and relative positions. Furthermore, the signals from the Se–CH_3 groups were characterized by ^{77}Se satellites (J_{Se-C-H} = *ca.* 14 Hz), and in many cases the identity was also established by recording the spectra of the corresponding Se–CD_3 compounds. This procedure was necessary in cases where the chemical shifts of the Se–CH_3 groups were close to those of N^3–CH_3 groups. In the case of *2* the signals from the N^3–CH_3 group collapsed into sharp peaks on addition of D_2O.

With the sole exception of *3* each *N*-methyl group gave rise to two NMR signals when the spectra were recorded at room temperature. Since none of the compounds *1*–*6* carry hydrogen at the N^2 atom, dipolar and selenol forms are not possible. Accordingly the occurrence of two signals from each group must be due to the presence of anisochronous CH_3 groups arising from hindered rotation about the central N^2–C bond. The NMR spectrum of *3* was recorded in a range of solvents and in a temperature range from −55 °C to +140 °C, but it was impossible to detect more than one signal from each group. Since the rotational barrier around the N^2–C bond cannot be much different in the compounds *1*–*3* this is taken as evidence for *3* existing exclusively in one isomeric form.

In order to decide which signals arise from the *Z* form and which from the *E* form, two methods have been used. (1) The chemical shifts of the N^2–CH_3 groups were compared to those of the N^3–CH_3 groups of 3-methyl-1,3,4-selenadiazolidine-2-selones [9] which are necessarily situated in *Z* position. (2) The solvent-induced shifts of the same signals in CCl_4, $CDCl_3$, and $C_6H_5NO_2$ were

[a] Melted during drying at 0 °C.

compared. The previously obtained data for 3-methyl-1,3,4-selenadiazolidine-2-selones [9] were supplemented as shown in Table 3. It is seen, that (1) the $CH_3-N-CSe$ signal of the *Z* form shows a chemical shift in $CDCl_3$ between 3.50 and 3.64 ppm, and (2) it is displaced towards lower δ-values when the compounds are recorded in CCl_4 solution, but towards higher δ-values in $C_6H_5NO_2$.

From the results listed in Table 2 it is seen, that the low-field N^2-CH_3 signals have chemical shift values in $CDCl_3$ in the range 3.48–3.88 ppm while the high-field signals are located in the range from 3.17 to 3.55 ppm. Though this indicates that it is the former signals which should be assigned to the *Z* CH_3 group there is a certain overlap of the regions and a confirmation is clearly needed for this assignment.

Considering next the solvent shifts, it is seen that the low-field N^2-CH_3 signals behave uniformly and differently from the high-field N^2-CH_3 signals. Thus, the low-field N^2-CH_3 signals ($CDCl_3$) are shifted to lower field in nitrobenzene and to higher field in CCl_4. The high-field N^2-CH_3 signals are found at almost identical positions in CCl_4 and $CDCl_3$, but are shifted to higher field in nitrobenzene solution. This result is only compatible with an assignment of the low-field N^2-CH_3 signals to the CH_3 group in *Z* position.

The *Z*–*E* isomer ratios for the diselenocarbamates *5* and *6* are both close to 1:1. This indicates that the steric requirements of =Se and $-SeCH_3$ are not significantly different for the compounds studied, that is provided the size of a substituent on the N^2-atom does not exceed that of an isopropyl group. In the case of the diselenocarbazates *1*–*3* there seems to be a definite tendency for predominance of the *Z* form. Walter and Reubke [7] has explained the predominance of the *E*-form in hydrazides (corresponding to the present *Z*-forms) with substituents exerting no steric influence to the tendency towards intramolecular compensation of existing dipoles. Since the diselenocarbazates *1*–*3* undoubtedly exhibit significant bond moments along the C=Se and N–N bonds, the predominance of the *Z* forms can be explained in an analogous way by the mutual repulsion of these dipoles.

Table 2. ^{1}H NMR chemical shifts (δ, ppm) at *ca.* 40 °C of *N*-alkylsubstituted methyl diselenocarbazates and diselenocarbamates. Abbreviations: s = singlet, d = doublet, q = quartet, and sep = septet. Centers of multiplets are given.

EXPERIMENTAL

The analyses were carried out in the microanalysis department of this laboratory. Melting points were determined in capillary tubes and were not corrected. Infrared spectra were obtained on a Perkin-Elmer model 337 grating infrared spectrophotometer and the proton magnetic resonance spectra on a Varian A-60 A instrument with tetramethylsilane as an internal standard.

The directions given below for the preparations of the methyl esters refer to the entry "Method" in Table 1.

Salts used as starting materials for the preparation of esters:

Dialkylammonium 2,2-dialkyldiselenocarbamates. One ml of 10 M aqueous sodium hydroxide was added to a suspension of the amine hydrochloride (10^{-2} mol) in pentane (100 ml) cooled in an ice bath. The mixture was shaken

vigorously and dried (KOH). Into the stirred solution of the liberated amine at 0°C a solution of carbon diselenide (5×10^{-3} mol) in pentane (40 ml) was added dropwise over a period of 2 h in a nitrogen atmosphere. The yellow solid that separated was collected on a glass filter, washed with pentane and dried *in vacuo*.

Hydrazinium diselenocarbazates. Generally, these salts were prepared analogously to the diselenocarbamates described above, starting with the free hydrazines and using dry ether as the solvent.[10]

Method A. Methyl iodide (10^{-3} mol) was added to a filtered, aqueous solution (4 ml) of the appropriate hydrazinium salt (10^{-3} mol). The reaction mixture was stirred vigorously at room temperature until it was (nearly) colourless. The crystals that precipitated were collected by centrifugation, washed with a small amount of cold water and dried *in vacuo*.

Method B. An ethanolic solution (4 ml) of methyl iodide (10^{-3} mol) was added to a filtered aqueous solution (5 ml) of the appropriate hydrazinium salt (10^{-3} mol). The reaction mixture was stirred for 5 – 10 min at room temperature and the solvent was evaporated *in vacuo* with gentle heating until a volume of ½ – 1 ml was reached. This residue was extracted with pentane and the pentane solution dried ($MgSO_4$) and taken to dryness. The residue (R) of yellow to colourless crystals was washed with a small amount of cold pentane.

Method C. An aqueous solution (5 ml) of dimethylammonium 2,2-dimethyldiselenocarbamate (2×10^{-3} mol) was added to an ethanolic solution (3 ml) of methyl iodide (2×10^{-3} mol) with stirring. More water (10 ml) was added to ensure complete precipitation. The light yellow crystalline compound was washed with water and dried *in vacuo*.

Method D. As Method B. The residue (R) consisted of an oil, which was purified by dissolution in the minimum amount of pentane and cooling to *ca.* −80 °C with scratching. The solid that separated, which in all cases melted below room temperature, was quickly collected by centrifugration, washed with a small amount of cold pentane and dried *in vacuo*.

Fungus Pigments. XXIV*. Peniolactol Obtained from Wood Attacked by the Fungus *Peniophora sanguinea* Bres.

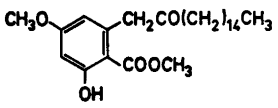
JARL GRIPENBERG

Department of Chemistry, Helsinki University of Technology, SF-02150 Otaniemi, Finland

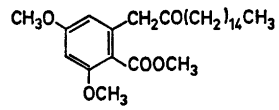
On the basis of spectral analysis, the structure 3,4-dihydro-3,6,8-trihydroxy-3-pentadecyl-1*H*-2-benzopyran-1-one (*1b*) is assigned to peniolactol.

In a paper describing the isolation of the pigment peniosanguin methyl ether from the extract of wood attacked by the fungus *Peniophora sanguinea* Bres.[1], it was noted that the pigment was accompanied by a colourless compound.

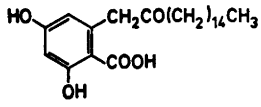
The structure *1*, which can exist in the two tautomeric forms *a* and *b*, is now proposed for this colourless compound which has been termed peniolactol. This structure proposal is based on the spectral properties of the compound and its derivatives, as outlined below.



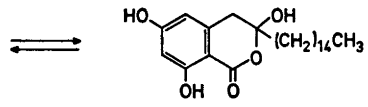
2



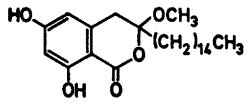
3



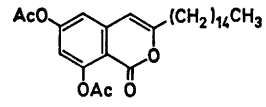
1a



1b



4



5

Peniolactol has the composition $C_{24}H_{38}O_5$. In the mass spectrum only a very weak peak is found at *m/e* 406, corresponding to this molecular formula. There are instead two strong peaks at *m/e* 388 and 362, formed by loss of water and carbon dioxide, respectively. The base peak of the spectrum is at *m/e* 239, corresponding to $C_{15}H_{31}CO$.

Methylation of peniolactol with diazomethane gives a dimethyl derivative (*2*), and methylation with dimethyl sulphate and potassium carbonate of either peniolactol or its dimethyl derivative gives a trimethyl derivative (*3*).

IR-absorptions at 1654 and 1712 cm^{-1} in *2*

* Part XXIII, *Tetrahedron Lett.* (1974) 619.

and at 1712 and 1720 cm^{-1} in *3* show the presence of two carbonyl groups, one of which is an unconjugated aliphatic keto group and the other an aromatic methyl ester which is strongly chelated in *2*. Peniolactol shows only one carbonyl absorption at 1640 cm^{-1}, the aliphatic keto group being masked by lactol formation as indicated in *1b*. This requires that the aliphatic keto group is situated in a side chain *ortho* to the carboxyl group and the latter therefore lies between the aliphatic side chain and one phenolic hydroxyl. The position of the second phenolic hydroxyl in the *para*-position to the carboxyl group may be deduced from the NMR spectra of *2* and *3*, which show the presence of two *meta*-coupled aromatic protons. These NMR spectra also contain the expected two proton singlet for a methylene group between an aromatic ring and a carbonyl group.[2-4]

The structures of *2* and *3* are also supported by their UV spectra. Thus the spectrum of *2* is almost identical with that of ethyl 2-acetonyl-4-benzyloxy-6-hydroxybenzoate [2] and the mono- and diethyl esters of α-carboxy-6-hydroxy-4-methoxy-*o*-toluic acid.[5] Similarly that of *3* is almost identical with the spectrum of α-carboxy-4,6-dimethoxy-*o*-toluic acid.[6]

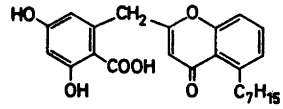
Esterification of peniolactol with methanol and sulphuric acid gives a monomethyl derivative, which must be the pseudo-ester *4*, because there is no absorption due to the aliphatic carbonyl group in its IR spectrum.

Acetylation of peniolactol gives an anhydrodiacetate (*5*). This structure is supported by the absence of the NMR signal due to the methylene group and the appearance of a one proton singlet at δ 6.09.

The NMR spectra of all the derivatives of peniolactol contain, in addition to the signals from the groups directly attached to the aromatic ring (discussed above), a very strong and somewhat broadend singlet at $\delta \sim 1.27$ which is accompanied by a three proton distorted triplet on the high field side and a two proton ill defined triplet on the low field side. This part of the spectrum is very similar to that of straight chain aliphatic acids and ketones, indicating that the group $-(CH_2)_{14}CH_3$ in the structures above is indeed the normal one.

As mentioned above, the IR spectrum indicates that, at least in the crystalline state, peniolactol exists in the lactol form *1b*. The position of this equilibrium in *o*-(2-oxoalkyl)-benzoic acids appears to depend to some extent on the substitution of the aromatic ring, although there seems also to be some confusion in the literature in this respect. Thus Buckley, Ritchie and Taylor [7] have made an extensive study of the unsubstituted 2-acetonylbenzoic acid and they conclude, on the basis of the IR spectrum in different media, that the equilibrium lies far towards the open chain form. In derivatives with a hydroxy or methoxy group in the 6-position,[2,8-10] there is no IR absorption that can be ascribed to the unconjugated carbonyl group as in peniolactol. They should therefore be regarded as existing in the lactol form, although some workers [2,10] still depict them as the open chain tautomers.

Peniolactol is evidently acetate derived and a number of compounds of analogous structure, but with a shorter aliphatic sidechain, have been isolated from fungi.[3,10,11-18] They are sometimes in a different state of oxidation or are ring closed to an isocoumarin or to a macrocyclic lactone. A number of depsides and depsidones [19] also belong to the same type of structure and a particularly interesting compound in this connection is siphulin (*6*),



6

which has been isolated from the lichen *Siphula ceratites* [6] and has the same number of carbon atoms as peniolactol.

Since the extract from which peniolactol was isolated was obtained from decaying wood coloured red by the mycel of *Peniophora sanguinea* the question arises whether or not peniolactol is produced by *Peniophora sanguinea* or by some other fungus present in the decaying wood. The possibility that peniolactol is not a fungus product at all but a constituent of the wood, appears to be very improbable. In view of the very large amount of work which has been carried out on wood extracts it seems very unlikely that peniolactol, which is a nicely crystalline compound, should have been overlooked.

The presence of peniolactol in an extract can

easily be detected on TLC plates by spraying the plate with bis-diazotised benzidine. Examination of extracts obtained from different parts of the same piece of decaying wood revealed that peniolactol was never detected in those extracts obtained from non-coloured parts of the wood, whereas its presence could always be demonstrated in extracts which also contained the pigments. Furthermore, in a few fortunate cases it was possible to isolate the mycel of *Peniophora sanguinea*, seemingly free from contaminants, and in these cases the extract always contained peniolactol. It may therefore be concluded that peniolactol is indeed produced by *Peniophora sanguinea*.

EXPERIMENTAL

Melting points were determined by means of a Kofler melting point microscope and are uncorrected. Spectra were obtained using the following instruments: UV spectra on a Beckman DK-2, IR spectra on a PE 125, NMR spectra on a Varian A 60 and mass spectra on a PE 270B. Elemental analyses were carried out by Ilse Beetz, Mikroanalytisches Laboratorium, Kronach, German Federal Republic.

Isolation of peniolactol. The crude peniosanguin methyl ether [1] was dissolved in pyridine to which solution water was added until precipitation occurred. The peniosanguin methyl ether thus obtained was separated and more water was added to the mother liquor causing the precipitation of peniolactol. Further reprecipitation from pyridine gave peniolactol as slightly grey crystals. It melts at about 150 °C with decomposition. (Found: C 71.45; H 8.75, $C_{24}H_{38}O_5$ requires C 70.90; H 9.42) Mass spectrum: *m/e* 388, 362, 239, 205, 192, 150, 123. IR maxima: 3480, 2920, 2850, 1640, 1615 cm^{-1}. UV spectrum (EtOH): λ_{max} 214(4.44), 246(3.92), 264(4.02), 299(3.76); λ_{min} 240(3.82), 250(3.89), 286(3.68) nm (log ε).

Methyl 2-hydroxy-4-methoxy-6-(2-oxoheptadecyl)benzoate (2). Peniolactol (50 mg) dissolved in ether was treated with an excess of diazomethane. After standing over night the ether was evaporated and the residue purified by preparative TLC. Yield 35 mg, m.p. 96 – 97 °C (Found: C 71.54, H 9.42; $C_{26}H_{42}O_5$ requires C 71.85, H 9.74), Mass spectrum: *m/e* 434(M^+), 402, 239, 219, 206, 196, 164. IR maxima: 2920, 2850, 1712, 1654, 1620 cm^{-1}. UV spectrum (EtOH): λ_{max} 214(4.40), 263(4.13), 302(3.79); λ_{min} 239(3.60), 282 (3.55) nm (log ε). NMR spectrum ($CDCl_3$): δ 0.89 (3 H, br tr), 1,28(26 H, s), 2.41(2 H, br tr), 3.81(3 H, s), 3.82(3 H, s), 3.90(2 H, s), 6.23 (1 H, d; $J = 2.5$ Hz), 6.43 (1 H, d; $J = 2.5$ Hz), 11.62(1H, s).

Methyl 2,4-dimethoxy-6-(2-oxoheptadecyl)benzoate (3). Peniolactol (30 mg) dissolved in acetone was stirred for 8 h at room temperature with potassium carbonate (0.5 g) and dimethyl sulphate (0.2 ml). After filtration, addition of water and removal of the acetone under vacuum, a white precipitate was obtained which was purified by preparative TLC and recrystallisation from methanol. M.p. 71 – 72 °C. The same compound was also obtained when (*2*) was treated in the same way. (Found: C 72.30, H 9.22. $C_{27}H_{44}O_5$ requires C 72.28;, H 9.89). Mass spectrum: *m/e* 448(M^+), 416, 233, 220, 210, 196, 179, 178. IR maxima: 2920, 2850, 1720, 1712 1604 cm^{-1}. UV spectrum(EtOH): λ_{max} 250(3.81), 286(3.56); λ_{min} 239(3.77), 271 (3.41) nm (log ε). NMR spectrum ($CDCl_3$): δ 0.90(3 H, br tr), 1.27(26 H, s), 2.45(2 H, br tr), 3.67(2 H, s), 3.80(6 H, s), 3.82 (3H, s), 6.32(1 H, d; $J = 2$ Hz), 6.42(1 H, d; $J = 2$ Hz).

3,4-Dihydro-6,8-dihydroxy-3-methoxy-3-pentadecyl-1H-2-benzopyran-1-one (4). Peniolactol (40 mg) was refluxed for 8 h in methanol containing two drops of conc. sulphuric acid. Water was then added and the methanol removed under vacuum. Extraction with ether and recrystallisation from light petroleum gave (*4*). M.p. 92 – 93 °C (Found: C 71.35, H 9.74. $C_{25}H_{40}O_5$ requires C 71.39, H 9.59). IR maxima: 3250, 2910, 2850, 1660, 1615 cm^{-1}. UV spectrum (EtOH): λ_{max} 214(4.35), 230(infl.; 4.16), 246 (3.86), 270(4.15), 302(3.87); λ_{min} 242(3.80), 249(3.83), 291(3.84) nm (log ε). NMR spectrum ($CDCl_3$): δ 0.90(3 H, br tr), 1.28(26 H, s), 2.00(2 H, br tr), 3.08(2 H, br s), 3.38(3 H, s), 6.22(1 H, d; $J = 2.5$ Hz), 6.34(1 H, d; $J = 2,5$ Hz), 11.12(1 H, br s; exch. with D_2O).

6,8-Diacetoxy-3-pentadecyl-1H-2-benzopyran-1-one (5). Peniolactol dissolved in acetic anhydride containing a drop of pyridine was kept over night at room temperature. The anhydroacetate was precipitated with water and purified by preparative TLC. M.p. 86 – 87 °C. (Found: 70.96, H 8.38. $C_{28}H_{40}O_6$ requires C 71.16, H 8.53). Mass spectrum: *m/e* 472(M^+), 430, 388, 205, 192, 177, 163. IR maxima: 2950, 2880, 1770, 1730, 1660 cm^{-1}. UV spectrum(dioxan): λ_{max} 237(4.56), 243(infl.; 4.47), 262(3.95), 270 (4.00), 280(3.91), 323(3.67); λ_{min} 257(3.91), 264(3.94), 276(3.86), 292(3.13) nm (log ε). NMR spectrum(CCl_4): δ 0.89(3 H, br tr), 1.24(26 H, s), 2.27(3 H, s), 2.33(3 H, s), 2.20 – 2.30(2 H, m), 6.09(1 H, s), 6.77(1 H, d; $J = 3$ Hz), 6.95(1 H, d; $J = 3$ Hz).

Studies on Intermediates Involved in the Syntheses of Pentaerythritol and Related Alcohols. VI.* Base-catalyzed Retro Condensation Reactions of Some α-Hydroxymethyl Carbonyl and Nitro Compounds

JAN-ERIK VIK**

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

The base-catalyzed retro aldol condensation reactions of some aldehydic intermediates in the syntheses of pentaerythritol and related alcohols have been investigated kinetically. Rate constants for these reactions, involving the splitting off of formaldehyde, have been obtained for the compounds 2,2-bis(hydroxymethyl)-3-hydroxypropanal, 3-hydroxy-2-hydroxymethyl-2-methylpropanal, 2-ethyl-3-hydroxy-2-hydroxymethylpropanal, and 2,2-dimethyl-3-hydroxypropanal. These aldehydes were all found to undergo retro aldol reaction in aqueous solution at rather low concentration of sodium hydroxide. Under the conditions used, the reactions did not proceed beyond the liberation of one molecule of formaldehyde per molecule of starting material. 2,3-Dihydroxypropanal, having one α-hydrogen, released almost no formaldehyde at 20 °C in 0.010 M NaOH. 3-Hydroxy-2-hydroxymethylpropanal, also containing one α-hydrogen, gave rise to formaldehyde formation slowly, but, as will be shown in a subsequent paper, probably in an indirect way *via* another reaction.

For comparison, the corresponding reactions of some other activated, hydroxymethyl-substituted compounds have been investigated also. The ketones 4-hydroxy-3-hydroxymethyl-3-methyl-2-butanone, 3-hydroxy-2-hydroxymethyl-2-methyl-1-phenyl-1-propanone, 2,2-bis(hydroxymethyl)-1-tetralone, 2,2-bis(hydroxymethyl)-1-indanone, and 2,3-dihydroxy-1,2-diphenyl-1-propanone also released formaldehyde, the second and the fourth of these compounds giving rise to more than one mol of formaldehyde per mol of ketone.

Of the nitro compounds examined, 2-hydroxymethyl-2-nitro-1,3-propanediol, 2-methyl-2-nitro-1,3-propanediol, 2-ethyl-2-nitro-1,3-propanediol, and 2-methyl-2-nitro-1-propanol reacted with consumption of hydroxide ion under formation of nitronate ions and one mol of formaldehyde. 2-Nitroethanol and 2-nitro-1-butanol slowly released formaldehyde, but these reactions were not investigated kinetically.

9,9-Bis(hydroxymethyl)fluorene was almost stable in 0.2 M NaOH at 55 °C.

The reactions were followed by spectrophotometric determination of free formaldehyde according to the method reported by Nash, based on the Hantzsch reaction.

This investigation is part of a series of studies undertaken with the purpose of clarifying, as to rates and mechanisms, the reaction steps involved in the syntheses of polyalcohols by condensation reactions between formaldehyde and low molecular weight aliphatic aldehydes. It is believed that a better knowledge of these reactions will help to indicate which types of side reactions are important under different reaction conditions and how these conditions should be chosen in order to improve the quality and yield of the polyalcohols produced. More specifically, if formaldehyde is used in nearly stoichiometric amounts, retro aldol condensation reactions presumably can be important during the last stages of the syntheses when the concentration of formaldehyde is low. The amounts of intermediate aldehydes still present at this stage and those of their possible

** Present address: Perstorp AB, S-284 00 Perstorp, Sweden.

conversion products formed in side reactions may thus be determined by retro aldol reactions.

Aldol condensation reaction are believed to be generally reversible [1] and the reversibility has been proven in many cases.[2,3] In order to examine the rates of those retro aldol condensation reactions which are possible under the conditions of synthesis of pentaerythritol and related alcohols, a suitable method was needed, by means of which the progress of these reactions could be followed. The formaldehyde determination method reported by Nash,[4] based on the Hantzsch reaction, is almost ideal for the purpose. It allows accurate and relatively rapid determinations of formaldehyde in very dilute aqueous solutions, undisturbed by the presence of most other carbonyl compounds. The procedure utilizes the reaction of formaldehyde with acetylacetone and an ammonium salt with the formation of diacetyldihydrolutidine, which is yellow and has an absorptivity of 8000 at 412 nm. The lutidine derivative is formed rapidly and quantitatively in neutral aqueous solution. Since the preferable reaction conditions are very mild, the starting materials, as was proven for all the compounds examined, neither react to form coloured products nor release additional formaldehyde during the determinations.

The fully α-hydroxymethyl-substituted aldehydes, 2,2-bis(hydroxymethyl)-3-hydroxypropanal (I, trimethylolacetaldehyde), 3-hydroxy-2-hydroxymethyl-2-methylpropanal (II, dimethylolpropionaldehyde), 2-ethyl-3-hydroxy-2-hydroxymethylpropanal (III, dimethylolbutyraldehyde), and 2,2-dimethyl-3-hydroxypropanal (IV, pentaldol), are the immediate precursors of pentaerythritol, trimethylolethane, trimethylolpropane, and neopentylglycol, respectively (Fig. 1).

For both statistical and sterical reasons, these aldehydes were expected to be most susceptible to base-catalyzed retro aldol con-

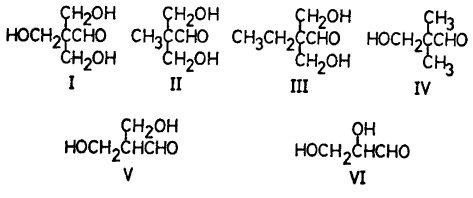

Fig. 1.

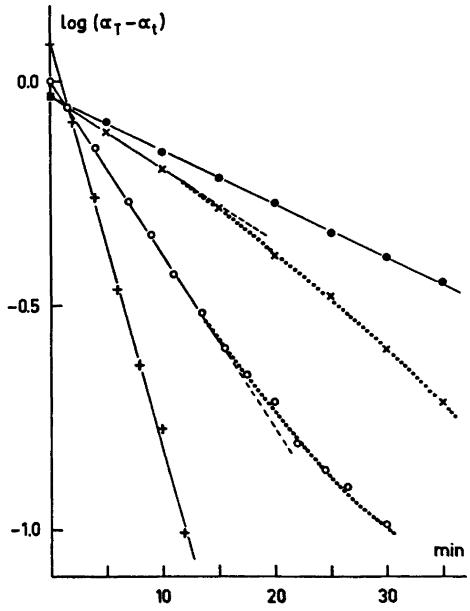

Fig. 2. Pseudo first-order plots for disappearance at 40 °C of starting materials in terms of absorbance units (α_T = theoretical maximum absorbance of the equimolar amount of formaldehyde derivative and α_t = absorbance at time t actually found for the formaldehyde derivative). +: I in 0.0020 M NaOH; ○: III in 0.0050 M NaOH; ×: IX in 0.0020 M NaOH, and ●: XI in 0.010 M NaOH.

densation with resultant loss of formaldehyde and were first examined. When treated in about 5×10^{-4} M solutions with NaOH they responded somewhat differently. Aldehyde I, within experimental errors, lost an equimolar amount of formaldehyde and gave linear pseudo first-order plots. Similar plots for compounds II and III were curved in a way which indicated that an equilibrium was reached when slightly less than an equimolar amount of formaldehyde had been formed. In Fig. 2, plots from runs with some different compounds are shown. For compound IV the pseudo first-order plots were still more curved, equilibrium being reached at an earlier stage of the reaction.

For compounds I – III rate constants could thus be evaluated graphically from pseudo first-order plots of log ($[A]_0 - [CH_2O]$) against time. Here $[A]_0$ is the initial concentration of the starting material and $[CH_2O]$ the concentration of formaldehyde at time t. Compound IV,

on the other hand, was found to obey the rate expression:

$$-\frac{d[IV]}{dt} = \frac{d[CH_2O]}{dt} = k_1'[IV] - k_{-1}'[CH_2O] \times$$
$$\times [(CH_3)_2CHCHO] = k_1'([IV]_0 - [CH_2O]) -$$
$$- k_{-1}'[CH_2O]^2$$

This leads to the integrated expression:

$$\psi = \frac{1}{\sqrt{1+4\tau[IV]_0}}$$

$$\ln \frac{1+2\tau[CH_2O]/(1+\sqrt{1+4\tau[IV]_0})}{1+2\tau[CH_2O]/(1-\sqrt{1+4\tau[IV]_0})} = k_1't$$

$$\text{where } \tau = \lim_{t\to\infty} \frac{[IV]_0 - [CH_2O]}{[CH_2O]^2}$$

The pseudo first-order rate constant k_1' was evaluated from plots of the function ψ against time (Fig. 3). The same type of expression could be used also for aldehydes II and III, but since the experimental value found for τ was rather uncertain in these cases, the use of pseudo first-order plots was considered more reliable. The difficulty in determining τ-values accurately is due to the fact that the final concentration of formaldehyde reached was not quite stable with time. On prolonged exposure to the alkaline reaction mixture it showed a tendency to decrease with a few percent, possibly due to oxidation. This was much more critical in the runs with II or III than in those with IV, since, in the former runs, the value of $([A]_0 - [CH_2O])_\infty$ was comparatively small.

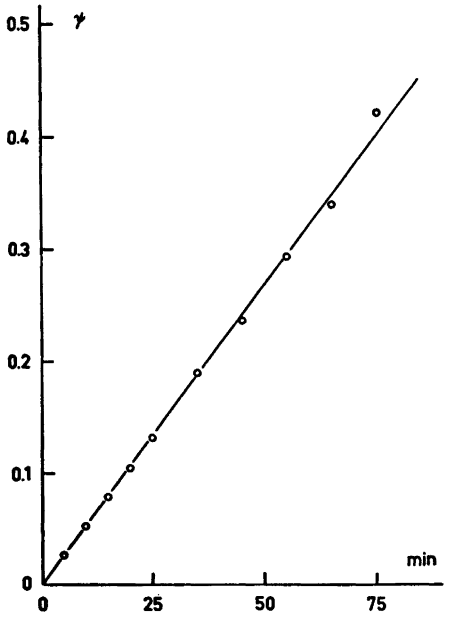

Fig. 3. Experiment with aldehyde IV at 40 °C in 0.0040 M NaOH showing function ψ against time.

That equilibria with significant amounts of starting material left were indeed established even in the rather dilute solutions examined, was proven indirectly for compound IV and its products, formaldehyde and isobutyraldehyde. The latter two aldehydes, both 2×10^{-3} M, were found to condense rather rapidly at 20 °C. For this reaction a pseudo second-order rate constant, k_{-1}'', referring to the rate expression:

$$-\frac{d[(CH_3)_2CHCHO]}{dt} = -\frac{d[CH_2O]}{dt} =$$
$$= k_{-1}''[(CH_3)_2CHCHO][OH^-] = k_{-1}''[CH_2O][OH^-]$$

was obtained from the decrease in formaldehyde concentration. The value calculated from the experimental data was $(5 \pm 2) \times 10^{-2}$ M^{-1} s^{-1}. Comparison of this value with the value 5.48×10^{-2} M^{-1} s^{-1}, obtained earlier for the same reaction in 0.1 M CH_2O by another method,[5] shows that, even at the low formaldehyde concentration of 0.002 M, the rate of formation of enolate ion from isobutyraldehyde is still probably at least partly rate determining. This was also apparent from plots of the experimental data. The reaction was neither strictly first-order nor second-order in formaldehyde concentration (equal to the concentration of isobutyraldehyde) but something in between. For this reason, the value given above was evaluated graphically from pseudo first-order plots.

If one tries to calculate a third-order rate constant from the value of k_{-1}'' given above, by dividing with the formaldehyde concentration in the run, the value obtained is 25 ± 10 M^{-2} s^{-1}. This could be used in conjunction with the value 0.00248 M^{-1} s^{-1} for the retro aldol condensation of IV (see Table 2) to calculate the equilibrium constant for the opposed reactions at 20 °C,

$$K_{IV} = \frac{[CH_2O][(CH_3)_2CHCHO]}{[HOCH_2C(CH_3)_2CHO]} = \frac{k_1'}{k_{-1}'''} = \frac{1}{\tau}$$

a value of about 10^{-4} M then being obtained. This value is not in agreement with the values of τ obtained directly from the runs with IV, as these latter values for runs at 20 °C give K_{IV}-values around 2×10^{-5} M. The reason for this discrepancy is obviously that the third-order constant calculated above is not a true third-order constant, but was obtained from runs at concentrations of formaldehyde exceeding the concentration at which the reaction is still of first-order with respect to formaldehyde. The K_{IV}-value of 10^{-4} M therefore is too high and values calculated from the τ-values, even though these are rather uncertain, probably are more correct.

From the data in Table 1 a ΔH-value of about 10 kcal mol^{-1} is obtained for the retro aldol condensation of IV. The difference in activation energies for the retro aldol reaction of IV (see Table 2) and the aldol condensation of isobutyraldehyde with formaldehyde,[5] on the other hand, amounts to only $19.2 - 15.1 = 4.1$ kcal mol^{-1}. If the large uncertainties in the τ-values and also those in the activation energies for the forward and the reverse reactions are taken into account, this discrepancy is still too large and cannot be explained as arising from experimental errors alone. Instead, it must be borne in mind that the activation energies refer to different reaction conditions with respect to formaldehyde concentration and thereby to different rate determining steps for the condensation reaction, as well as to different alkalinities, also at the same nominal concentration of NaOH.

Table 1. Equilibrium constant, K_{IV}, for the retro aldol condensation of 2,2-dimethyl-3-hydroxypropanal at different temperatures.

°C	20	30	40	50
$K_{IV} \times 10^5$ M	1.7	2.8	4.7	10

In any case, as apparent from the experimental results, the third-order rate constant for the condensation of isobutyraldehyde with formaldehyde is remarkably large when compared with the corresponding constants for the other aldehydes examined. Under comparable conditions the reaction with isobutyraldehyde goes much more nearly to completion. This confirms the conclusion drawn in an earlier paper [5] concerning the order of reactivity for isobutyraldehyde and some other aldehydes at low formaldehyde concentrations.

The observation that apparently not more than one hydroxymethyl group was split off from aldehydes I – III gave rise to the question as to whether only aldehydes with quaternary substituted α-carbons undergo retro aldol condensations of this type with ease. To examine this, the aldehydes, 3-hydroxy-2-hydroxymethylpropanal (V, dimethylolacetaldehyde) and 2,3-dihydroxypropanal (VI, D,L-glyceraldehyde), were subjected to similar treatment. Compound VI, on 5 h treatment with 0.05 M NaOH at 20 °C, lost only about 3 % of the

theoretical amount of formaldehyde. Compound V released formaldehyde slowly, about 0.5 equiv. after 2 h and about 0.8 after 24 h at 40 °C in 0.01 M NaOH. Some observations in connection with this latter reaction indicated, however, that formaldehyde here was produced as the result of a different reaction sequence. This motivates a separate discussion in a forthcoming paper. Although the number of aldehydes examined is rather small, the experimental data indicate that, of the aldehydes of the type investigated, those with a tertiary α-carbon atom lose formaldehyde much more slowly than those with a quaternary α-carbon atom.

In order to further investigate the scope of this retro aldol condensation type, some representatives of other classes of compounds were also examined. Of the ketones investigated, 4-hydroxy-3-methyl-2-butanone (VII, monomethylol methyl ethyl ketone) and 4-hydroxy-3-hydroxymethyl-3-methyl-2-butanone (VIII, dimethylol methyl ethyl ketone) are examples of simple aliphatic ketones and 3-hydroxy-2-hydroxymethyl-2-methyl-1-phenyl-1-propanone (IX, dimethylol propiophenone), 2,2-bis(hydroxymethyl)-1-indanone (X), and 2,2-bis(hydroxymethyl)-1-tetralone (XI) represent mixed aliphatic-aromatic types. 2,3-Dihydroxy-1,2-diphenyl-1-propanone (XII, hydroxymethylbenzoin) is structurally similar to aldehyde VI.

Again, the aliphatic compound with tertiary α-carbon, VII, was found to resist degradation and remained unchanged after 3 h in 0.01 M NaOH at 40 °C. The other five ketones, by contrast, all underwent retro aldol condensation. Three of them, namely compounds VIII, XI, and XII, gave linear pseudo first-order plots of log ($[A]_0 - [CH_2O]$) against time. For compounds IX and X, however, such plots were curved in a way indicating that more than one equivalent of formaldehyde was formed from the starting material. This was also evident from the total amount of formaldehyde determined after prolonged exposure to the alkaline reaction conditions. It is thus no general rule that the loss of the first and of the second of two α-hydroxymethyl groups occurs with so widely differing rates, that the reactions always can be well-distinguished kinetically (example in Fig. 2).

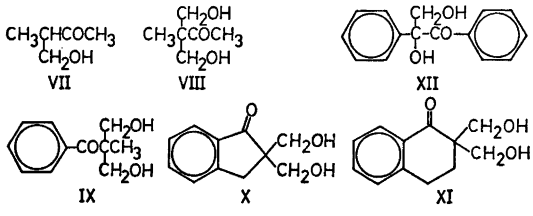

Fig. 4.

Compound XII was found to dissolve only with great difficulty in water and was therefore first dissolved in a small amount of methanol, the stock solution then being made up by dilution with water. This caused the presence of about 0.5 % of methanol as solvent in the reaction mixtures. The values obtained from these runs are therefore not strictly comparable with those from runs with the other compounds, since the methoxide ion present in equilibrium with hydroxide ion is possibly a more potent catalyst. General base catalysis should only be observed, however, if the first reaction step, that is the formation of an alkoxide ion, is rate determining, and that is probably not the case.

It is interesting to note that of the two closely similar compounds X and XI, the retro aldol condensation product from the latter seemed stable under conditions where that of the former lost more formaldehyde. Ketone IX, with a more flexible carbon side chain, also lost more than an equimolar amount of formaldehyde. It is tempting to assume that this has something to do with the spatial arrangements in compounds IX–XI. Thus, in both compounds IX and X, there is a greater possibility for the unsaturated system of the enolate ion arising by loss of formaldehyde from the initially formed alkoxide ion to be coplanar than in the corresponding ion from compound XI. One may object, that this does not hinder compound XI from first losing a molecule of formaldehyde. The rate of this reaction, however, is lower for compound XI than for the others, and the activation energy is higher. Relatively small differences may be sufficient to slow down the rate of the second retro aldol reaction in the case of XI to a level where this reaction is no longer detectable under the experimental conditions used.

For all the aldehydes and ketones for which rates of reaction were determined (see Table 2),

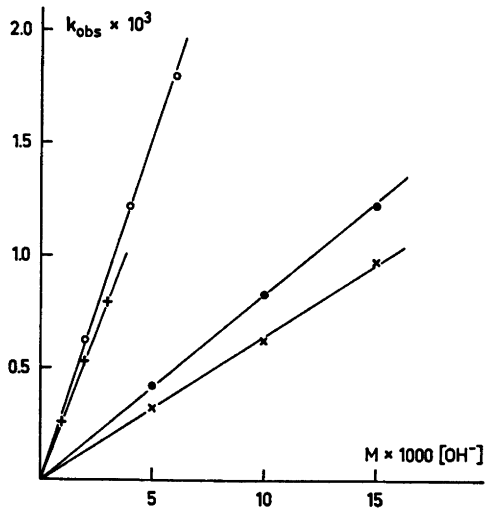

Fig. 5. Pseudo first-order rate constant observed for aldehydes I (○) and II (×) at 20 °C and ketones IX (●) and XII (+) at 25 °C.

these rates were found to be directly proportional to the hydroxide ion concentration, as illustrated in Fig. 5.

Hydroxymethyl-substituted nitro compounds, available by the Henry reaction, are also known to undergo retro aldol type reactions.[6] The rates of these reactions for the nitro analogs of compounds I–IV, 2-hydroxymethyl-2-nitro-1,3-propanediol (XIII, tris(hydroxymethyl)-nitromethane), 2-methyl-2-nitro-1,3-propanediol (XIV, bis(hydroxymethyl)nitroethane), 2-ethyl-2-nitro-1,3-propanediol (XV, bis(hydroxymethyl)nitropropane), and 2-methyl-2-nitro-1-propanol (XVI), have now been determined (compounds in Fig. 6).

The reactions proceeded rapidly to begin with, but then slowed down as seen from pseudo first-order plots. In these cases this could not be explained by equilibria being attained between starting material and product.

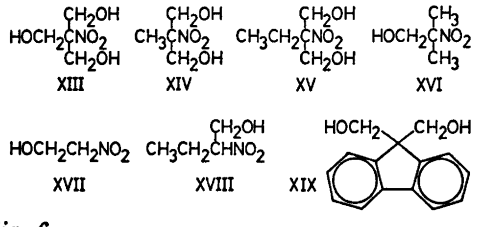

Fig. 6.

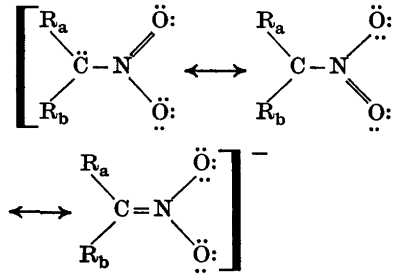
This was evident from the results of runs with varying concentrations of the catalyst, NaOH, more formaldehyde being formed if more NaOH was added. When equimolar amounts of nitro compound and NaOH were used, the reactions were found to follow the second-order rate expression (C denoting the nitro compound):

$$-\frac{d[C]}{dt} = \frac{d[CH_2O]}{dt} = k[C][OH^-] =$$
$$= k([C]_0 - [CH_2O])^2$$

These findings indicated that hydroxide ion actually was consumed during the reaction. The carbanion formed after loss of the formaldehyde molecule apparently was relatively stable under the reaction conditions, due to resonance involving the nitro group, and therefore did not react with water with regeneration of the catalyst:

$$HO^- + HOCH_2CR_aR_bNO_2 \rightleftharpoons H_2O + {}^-OCH_2CR_aR_bNO_2$$

$${}^-OCH_2CR_aR_bNO_2 \longrightarrow CH_2O +$$



Second-order plots from experimental runs with compound XV are shown in Fig. 7.

Two compounds with nitro groups on less substituted carbons, 2-nitroethanol (XVII) and 2-nitro-1-butanol (XVIII), were also examined. They lost only relatively small amounts of formaldehyde during one hour at 45 °C in 3×10^{-4} M NaOH, conditions under which the others reacted rather fast. No further determinations were made.

Finally, one hydroxymethyl-substituted hydrocarbon, 9,9-bis(hydroxymethyl)fluorene (XIX), was studied, but was found to be almost stable in 0.2 M NaOH at 55 °C for some hours.

The experimental results, in the form of rate constants and Arrhenius activation energies, are summarized in Table 2.

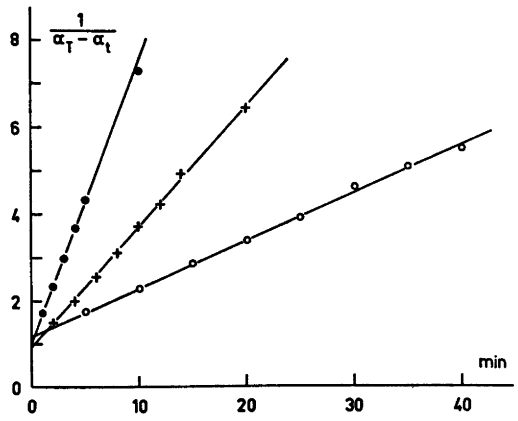


Fig. 7. Second-order plots from runs with nitro compound XV in 3×10^{-4} M NaOH at 25 °C (○), 35 °C (+), and 45 °C (●), respectively (α_T and α_t as in Fig. 2).

As seen from this table, of the compounds investigated, those activated by a nitro group react much faster than those activated by a carbonyl group. Of the latter compounds, the aliphatic aldehydes apparently react considerably faster than their ketonic analogs, as confirmed by the rate constants for the couple II and VIII. The electron attracting aromatic rings in the ketones IX and X activate these compounds to rates on a level with those of aldehydes II and III, whereas ketone XI is comparable in reactivity with aldehyde IV. As mentioned previously, the values for compound XII may not be strictly comparable with those for the other compounds, but it is evident that the second aromatic ring has a further activating effect.

The Arrhenius activation energies vary from 15.6 kcal mol^{-1} for compound XIII to 20.4 kcal mol^{-1} for compound VIII. Of the structurally related compounds II, VIII, and XIV, the aldehyde and the nitro compound have comparable activation energies, while the ketone has a distinctly higher one. The difference in rate constants between II and VIII roughly corresponds to their difference in activation energies. Nitro compound XIV, on the other hand, reacts considerably faster, which shows, that for this and the other nitro compounds, other factors contribute to facilitate their reactions.

While the limits of error for the activation energies of all the compounds appearing in Table 2, with the exception of compound X, are thought to be reliable within about ±0.5 kcal mol^{-1}, the value for this latter compound has an uncertainty of at least twice this value. Rate constants given are normally based on mean values from at least two runs and in several cases from as many as six to ten runs. They were most often reproducible within ±5 %, but for compound X they were more scattered.

EXPERIMENTAL

Materials. Aldehydes I, II, and III were prepared as described in an earlier paper.[7] A stock solution of aldehyde V was prepared by hydrolysis of its diethyl acetal on an acid ion exchanger.[8] Aldehyde IV was prepared by the method of Späth and v. Szilágyi [9] (m.p. 87–88 °C; lit.[9] 88–89 °C). Aldehyde VI (m.p. 130–132 °C; lit.[10] 131–132 °C) and nitro compounds XIII (m.p. 175 °C; lit.[11] 174 °C), XIV (m.p. 154–156 °C; lit.[12] 149–150 °C), XV (m.p. 55–57 °C; lit.[12] 56 °C), XVI (m.p. 90–91 °C; lit.[13] 90–91 °C), XVII (b.p.$_{0.5}$ 60 °C; lit.[14] b.p.$_{0.5}$ 63 °C), and XVIII (b.p.$_{10}$ 105 °C; lit.[12] b.p.$_{10}$ 105 °C) were commercial chemicals. Of these compounds, XIII–XVI were recrystallized from water to reach the melting points listed, while the others were used as received. All ketones and the substituted fluorene were kindly put to the author's disposal by Dr. B. Wesslén. They had the following physical constants: VII (b.p.$_{15}$ 93–95 °C; lit.[15] b.p.$_{11}$ 89–90 °C), VIII (m.p. 62–63 °C; lit.[16] 63 °C), IX (m.p. 95–97 °C), lit.[17] 96–97 °C), X (m.p. 92–93 °C; lit.[18] 92–93 °C), XI (m.p. 93–94 °C; lit.[18] 93–94 °C), XII (m.p. 85–86 °C; lit.[19] 85–86 °C), and XIX (m.p. 144–145 °C; lit.[20] 145.5–146.5 °C). Acetylacetone of commercial grade was redistilled before use. NaOH stock solutions were prepared from Merck Titrisol ampoules by dilution with CO_2-free, distilled water and were never used for more than a week.

Apparatus. Vis-spectra and absorption measurements were made partly with a Beckman DK 2A istrument and partly with an Unicam SP 800 instrument. Quartz cells of 1.000 cm length were used throughout the investigation.

General procedure. Normally about 0.25 mmol of the compound to be examined was weighed, introduced into a 100 ml volumetric flask, and dissolved by addition of boiled, distilled water to the mark. Compound XII was first dissolved in 5 ml of methanol before dilution to the mark with water. For each run, 10 ml of the stock solution was taken, introduced into a 100 ml volumetric flask, diluted as much as possible, allowing for later addition of the catalyst, and thermostatted in a water bath to the desired temperature ±0.05 °C. From a

NaOH stock solution, kept in the same thermostatted bath, the proper amount of catalyst was taken and the reactions were started by introduction of the latter into the reaction mixture followed by dilution to the mark with thermostatted, distilled water. At regular time intervals, often every fifth minute but sometimes as frequently as every 60 seconds, 4.0 ml samples were taken. They were immediately neutralized by introduction into 10 ml volumetric flasks containing about 0.25 to 0.5 ml of H_2SO_4 of the molarity required. To the samples, now slightly acid, were added 5 ml of the aqueous reagent described by Nash,[4] containing 150 g of NH_4OAc, 3 ml of glacial acetic acid and 2 ml of redistilled acetylacetone per l. After dilution to 10.0 ml with water, the solutions were heated 5 to 8 min at 58 °C. The absorbances of the resulting yellow solutions were then measured at 412 nm. To ensure that the absorbances were not changed due to other Vis-absorbing species in the reaction mixtures, spectra were always run between 360 and 450 nm.

Catalyst concentration ranges. With compound I: 0.002 – 0.006 M; II: 0.005 – 0.015 M; III: 0.005 – 0.015 M; IV: 0.004 – 0.040 M; V: 0.010 M; VI: 0.050 M; VII: 0.010 M; VIII: 0.050 – 0.400 M; IX: 0.001 – 0.010 M; X: 0.0025 – 0.020 M; XI: 0.003 – 0.030 M; XII: 0.0002 – 0.0030 M; XIII – XVIII: 0.0003 M; XIX: 0.20 M.

Temperature ranges used are evident from Table 2.

Acknowledgements. Generous financial support from The Swedish Board for Technical Development and from Perstorp AB, Perstorp, Sweden, is gratefully acknowledged. The author is indebted to Professor Erich Adler for his kind help and to Dr. Per Flodin for his encouraging support. Mrs. Marianne Frantsi, Mrs. Ulla-Britt Persson, and Mr. Kurt Johnsson are thanked for their skilled and careful laboratory assistance.

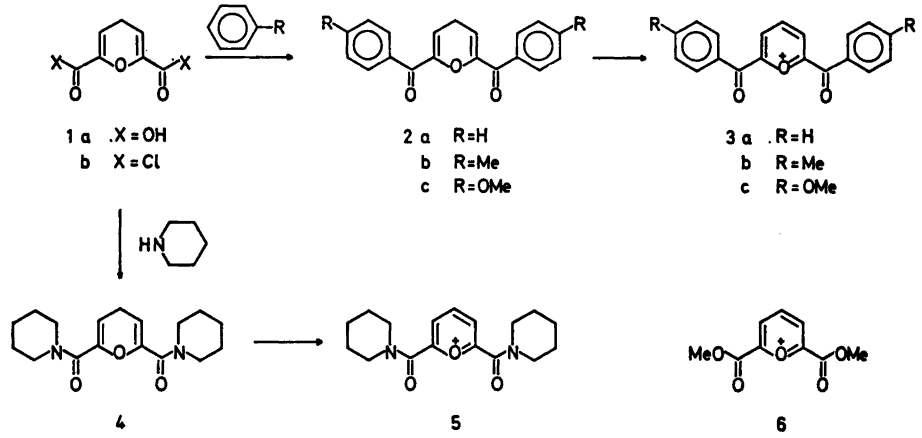
Pyrylium Salts. III. Properties and Reactions of 2,6-Dicarbonyl Derivatives

KJELL UNDHEIM and CARL ERIK CARLBERG

Department of Chemistry, University of Oslo, Oslo 3, Norway

Some 2,6-dicarbonylpyrylium perchlorates have been prepared. These pyrylium ions are highly reactive and readily form 4*H*-adducts with enolisable carbonyl compounds and olefins. The adduct formation is reversible. Activated benzene derivatives are attacked. Alcohols can be dehydrogenated to the corresponding carbonyl derivatives. The equilibrium constant for pyrylium ion/4*H*-pyran pairs is related to the electron releasing properties of the substituents.

The pyrylium ion is less aromatic stabilized than the tropylium ion and without stabilising substituents the pyrylium ion is highly reactive. The initial products from reactions with nucleophiles or bases may readily be reacted further which makes pyrylium salts versatile synthetic intermediates.[2,3] We have recently reported a synthesis of the reactive 2,6-dimethoxycarbonylpyrylium perchlorate (*6*) and discussed some of its reactions.[1,4] The present work describes additional carbonyl derivatives (Scheme 1) which differ from the ester (*6*) in electronic activation. Self-condensation of the pyrylium ions is avoided by having carbonyl substituents without any activated hydrogen atom. Thus the amide (*5*) is formed from a secondary amine (*4*), and the α-carbon is part of an aromatic ring in (*3*).

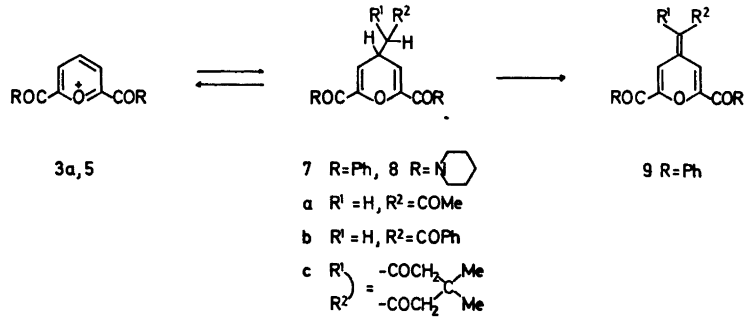


Scheme 1.

2,6-Dicarboxy-4*H*-pyran is readily available as synthetic starting material.[1,5] The amide (*4*) was prepared from its acid chloride. The latter reacted with benzene or benzene analogues under Friedel-Crafts conditions. Substituted benzenes gave exclusively (NMR) the *para*-acylated isomers (*2b,c*). The 4*H*-pyrans were then converted to the respective pyrylium salts

by reaction with triphenylmethyl perchlorate [6] in liquid SO_2. The NMR spectra in trifluoroacetic acid (TFA) have three low-field aromatic protons (AB_2) as expected for the pyrylium nucleus.[4] The shifts (Hγ 0.15 τ and Hβ 0.75 τ) for the benzoyl derivative (*3a*) are as found for the ester (*6*). The shifts are slightly affected in the expected manner by the phenyl *para*-substituents (*3b,c*). The corresponding protons in the amide (*5*) are at higher fields (0.4 and 1.25 τ), but at lower fields (1.0 and 1.5 τ), than in 2,6-diphenylpyrylium perchlorate which was prepared [2] for comparative reasons.

Variable anisotropy effects of the 2,6-substituents will affect the chemical shifts of the pyrylium protons. This may partly explain why these protons in the ester (*6*) and the benzoyl derivative (*3a*) have similar chemical shifts although the latter is the more reactive. Generally, however, the relative chemical shifts are indicative of the electron density in the pyrylium system and thereby informative about the relative reactivity as increased electron release will stabilize the pyrylium system.



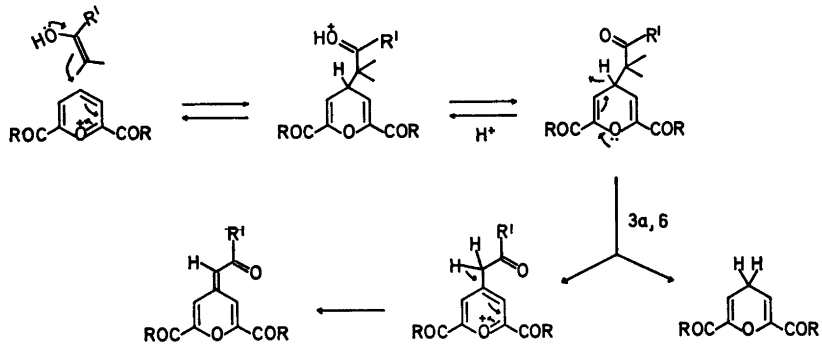
Scheme 2.

The 2,6-disubstituted pyrylium ions are attacked by a nucleophile at C-4 with formation of a 4*H*-pyran adduct. The NMR discussion above indicates that the 2,6-diphenylpyrylium ion should be the least reactive of the substances under consideration. For its reactions with activated methylene groups such as in acetonylacetone and benzoylacetone it requires the presence of a strong base.[7,8] The ester (*6*) however, attacks much less activated groups such as the methyl group in acetone or acetophenone in the cold without base addition.[1] A further comparison is available with the tropylium ion which reacts slowly with acetone on heating but readily attacks activated methylene groups in such compounds as malonic and acetoacetic ester.[9] The benzoyl derivatives (*3*) in preliminary experiments showed similar reactions and were no less reactive than the ester (*6*). Studies of the benzoyl series were therefore limited to the simplest derivative (*3a*). Both the pyrylium salts (*3a*) and (*5*) can be dissolved in acetone cooled below -10 °C without reaction. On allowing a solution of the benzoyl derivative (*3a*) in deuterioacetone (15 % concentration) to slowly warm up it was shown by NMR that a rapid reaction (1 – 2 min) ensued at about -10 °C. The amide (*5*) started to react at about -8 °C requiring about 10 min for completion of the reaction. The reaction appears autocatalytic through the perchloric acid liberated in the process. Acid catalysis was confirmed by an immediate reaction on dissolution of the pyrylium salt (*3a*) in deuterioacetone at -20 °C into which had been passed dry HCl. The function of the acid is presumably to promote enolisation of the ketonic reagent.[10]

Preparatively 4*H*-pyrans (*8a,b*) are available from the amide (*5*) by dissolution of the latter in excess acetone or acetophenone. Difficulties were experienced in preparative isolation of the benzoyl derivatives (*7a,b*) due to ease of oxidation to (*9*) and subsequent polymerisations. Such difficulties were not encountered in the reactions of the ester (*6*).[1] With equimolar quantities of the benzoyl derivative (*3a*) and the ketonic reagents in liquid SO_2 at -20 °C NMR showed only the presence of the 4-anhydro products (*9a,b*) and the parent 4*H*-pyran (*2a*). Similar hydride exchange processes have been

observed for the ester (*6*)[1] and in reactions of (*3a*) with anisole as discussed below. The carbamoyl group in (*5*), on the other hand, stabilizes the pyrylium nucleus sufficiently to prevent hydride transfer from the adducts (*8a,b*). With equimolar amounts of dimedone in SO_2 both (*3a*) and (*5*) form the 4*H*-adducts (*7c,8c*). The reduced tendency for dehydrogenation in this case may be associated with the increase in steric hindrance to the transfer of the hydride ion from C-4.

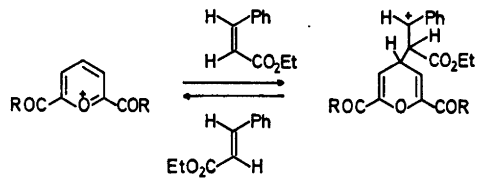
Adduct formation between the pyrylium ion



Scheme 3.

and the ketonic reagent is reversible (Scheme 3). Heating a solution of the phenacyl-4H-pyran (*8b*) in TFA at 70 °C produced some of the parent pyrylium ion (*5*). After perchloric acid addition only the pyrylium ion (*5*) was present.

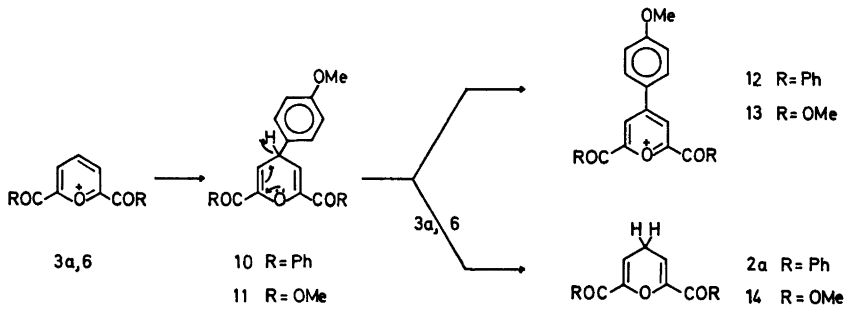
In the discussion of the reaction between the pyrylium ion and the ketonic reagents, it was postulated that the reaction proceeds *via* enolised ketone. As a consequence the pyrylium ion would also be expected to react with other suitably substituted double bonds. Thus with styrene an almost explosive, exothermic polymerisation occurred on addition of the benzoyl pyrylium salt (*3a*). The less reactive amide (*5*) required about 15 min in the cold before being consumed, while 2,6-diphenylpyrylium perchlorate had not caused any significant polymerisation after heating at 70 °C for 1 h. Ethyl cinnamate was polymerised by (*3a*) on heating. A carbonium type intermediate for this process is indicated in Scheme 4. Depending on reaction conditions the ionic intermediate can polymerise the olefin by a cationic mechanism, expel a proton to form an olefin, add the anion or any other nucleophile present, or reverse the process back to the precursor pyrylium ion. The ionic intermediate corresponds to the carbonium ion intermediate in E_1-elimination and should preferentially give the thermodynamically more stabilized olefin. Rapid and reversible formation of an ionic intermediate was strongly indicated by addition of (*3a*) or (*5*) to solutions of ethyl *cis*-cinnamate and its *p*-methoxy homologue in deuterioacetonitrile in the cold. The NMR spectra of the solutions showed only *trans*-cinnamic acid immediately after mixing the reagents.



Scheme 4.

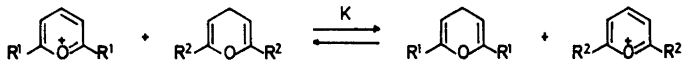
The behaviour towards aromatic nucleophiles was subsequently studied. 2,6-Diphenylpyrylium perchlorate is unreactive to simple phenyl derivatives but forms adducts at C-4 with the nucleophilic Grignard reagents.[7] Activated benzene such as phenol is attacked by the tropylium ion on heating.[11] Both the benzoyl derivative (*3a*) and the ester analogue (*6*), but not the amide (*5*), were found to react with anisole in liquid SO_2. None of the pyrylium salts would attack toluene. The 4*H*-adducts (*10*) and (*11*)[12] initially formed by *para*-substitution of anisole (NMR) reacted further to form the correspond-

ing 4-anisylpyrylium salts (*12,13*). The hydride abstraction by unsubstituted pyrylium ion from the 4*H*-adduct is a rapid process compared to anisole addition since the anisylpyrylium salts (*12,13*) and the respective 4*H*-pyrans are formed in almost equimolar amounts. Presumably the driving force for the redox process is the great increase in resonance stabilisation of the pyrylium nucleus brought about by the anisole radical.



Scheme 5.

A guide to relative redox potentials for the various cations investigated is available by equilibration studies. The triphenylmethyl cation is used both to generate the tropylium ion from cycloheptatriene and the pyrylium ions from the respective 4*H*-pyrans. Mixing equimolar amounts of cycloheptatriene and 2,6-dimethoxycarbonylpyrylium perchlorate in acetonitrile results in complete (NMR) hydride transfer from cycloheptatriene to the pyrylium nucleus.[1] Both the benzoyl derivative (*3a*) and the amide (*5*) were found to react with cycloheptatriene in the same manner. Within the pyrylium series equilibration studies between redox pairs were attempted in several solvents (15 % concentration) at 20 °C by the use of NMR. The hydride exchange reactions (Scheme 6) under these conditions required days (5 – 7) to reach equilibrium and reproducible quantitative measurements were difficult to achieve because of competing side reactions. The best results were obtainable in TFA.



Scheme 6.

By these crude measurements the equilibrium constants were of the order: $K_{3a/6} = 0.9$; $K_{5/3a} = 1.3$ and $K_{5/6} = 1.2$. The values show that the pyrylium ion with the more electron releasing substituents is thermodynamically the more stable. It is also evident that increase in the electron releasing properties of the substituents stabilizes the pyrylium nucleus to a greater extent than it stabilizes the 4*H*-pyran. As a consequence pyrylium ions without electron releasing substituents are most effective for hydride abstractions and can be used for dehydrogenation of other kinds of molecules. Thus the pyrylium salts (*3a,5,6*) on heating with molar amounts of diphenylcarbinol in nitromethane for half an hour fully converted the carbinol (chromatography) to benzophenone.

EXPERIMENTAL

All NMR spectra were determined on a 60 MHz Varian A-60A spectrometer.

Synthesis of 2,6-dibenzoyl-4H-pyrans (2). Anhydrous aluminium chloride (0.048 mol) was added gradually (15 – 30 min) at 10 – 25 °C to 2,6-dichlorocarbonyl-4*H*-pyran (0.024 mol) in benzene or its analogues (0.144 mol). Reaction temperature and time were varied individually as follows: (*2a*)(50 °C, 4 h); (*2b*)(25 °C, 6 h); (*2c*)(10 °C, 4 h). The reaction mixture was next

poured onto ice (100 g) and conc. HCl (5 ml), and the precipitated ketone collected by filtration.

2,6-Dibenzoyl-4H-pyran (2a). Yield 82 %, m.p. 189–190 °C (benzene). (Found: C 78.42; H 4.90. Calc. for $C_{19}H_{14}O_3$: C 78.61; H 4.86), τ (TFA) 3.85 (2 H, t, $H^{3,5}$), 6.65 (2 H, t, H^4, $J_{3,4}$ 4 Hz), 2.0–2.7 (10 H, m, 2 × Ph), ν_{max} (KBr) 1645 cm^{-1} (CO).

2,6-Di-p-methylbenzoyl-4H-pyran (2b). Yield 69 %, m.p. 162 °C (EtOH). (Found: C 78.97; H 5.69. Calc. for $C_{21}H_{18}O_3$: C 79.19; H 5.70), τ (TFA) 3.85 (2 H, t, $H^{3,5}$), 6.65 (2 H, t, H^4 $J_{3,4}$ 4 Hz), 2.1–2.9 (8 H, A_2B_2, 2 × Ph), 7.5 (6 H, 2 × Me) ν_{max} (KBr) 1645 cm^{-1} (CO).

2,6-Di-p-methoxybenzoyl-4H-pyran (2c). Yield 60 %, m.p. 160 °C (EtOH). (Found: C 71.88; H 5.26. Calc. for $C_{21}H_{18}O_5$: C 71.99; H 5.18), τ (TFA) 3.85 (2 H, t, $H^{3,5}$), 6.65 (2 H, t, H^4, $J_{3,4}$ 4 Hz), 1.8–2.9 (8 H, A_2B_2, 2 × Ph), 5.95 (6 H, 2 × OMe), ν_{max} (KBr) 1640, 1650 cm^{-1} (CO).

Synthesis of 2,6-di-N-piperidylcarbonyl-4H-pyran (4). A solution of piperidine (13.30 g, 0.14 mol) in dioxane (40 ml) was added over 1 h to a solution of 2,6-dichlorocarbonyl-4*H*-pyran (4.94 g, 0.024 mol) in dioxane (150 ml) and benzene (20 ml) in the cold. The solution was poured into water (200 ml) after 3 h, the solution acidified with HCl and the amide isolated by ether extraction. The combined ether extracts were evaporated and the residual yellow material crystallised from ethanol; m.p. 146–148 °C, yield 3.80 g (52 %). (Found: C 67.30; H 8.14. Calc. for $C_{17}H_{24}N_2O_3$: C 67.08; H 7.95). τ (TFA) 4.25 (2 H, t, $H^{3,5}$), 6.85 (2 H, t, H^4, $J_{3,4}$ 4 Hz), 5.9–6.4, 8.0–8.4, (20 H, m, 2 × piperidine ν_{max} (KBr) 1630 cm^{-1} (CO).

Synthesis of 2,6-dibenzoylpyrylium perchlorate (3). The 2,6-dibenzoyl-4*H*-pyran (0.015 mol) was added to liquid SO_2 (100 ml) at −30 °C and the mixture stirred while triphenylmethyl perchlorate (0.015 mol) was added gradually under anhydrous conditions. The reaction mixture was left at room temperature after completion of the addition until all the SO_2 had evaporated. The residue was treated with anhydrous ether (150 ml) and stirred vigorously for 10 min. If the oily residue after SO_2 evaporation did not crystallise, it was solidified at about −40 °C and the solid pulverised under ether. The treatment with anhydrous ether was generally repeated three times. The insoluble pyrylium salt thus obtained was pure enough for elemental analysis. It is highly hygroscopic and must be stored in dry atmosphere in an air-tight flask.

2,6-Dibenzoylpyrylium perchlorate (3a). Yield 87 %, m.p. 164–166 °C (decomp). (Found: C 58.74; H 3.60. Calc. for $C_{19}H_{13}O_3.ClO_4$: C 58.70; H 3.37). τ (TFA) 0.75 (2 H, AB_2, $H^{3,5}$), 0.15 (H, H^4, $J_{3,4}$ 8 Hz), 1.8–2.8 (10 H, 2 × Ph).

2,6-Di-p-methylbenzoylpyrylium perchlorate (3b). Yield 82 %, m.p. 150–152 °C (decomp.). (Found: C 60.25; H 4.35. Calc. for $C_{21}H_{17}O_3.ClO_4$: C 60.51; H 4.11). τ (TFA) 0.95 (2H, AB_2, $H^{3,5}$), 0.25 (H, H^4, $J_{3,4}$ 8 Hz), 1.8–2.8 (8 H, A_2B_2, 2 × Ph), 7.5 (6 H, 2 × Me).

2,6-Di-p-methoxybenzoylpyrylium perchlorate (3c). Yield 79 %, m.p. 156–158 °C (decomp.). (Found: C 55.98; H 4.01. Calc. for $C_{21}H_{17}O_5.ClO_4$: C 56.20; H 3.82). τ (TFA) 0.85 (2 H, AB_2, $H^{3,5}$), 0.20 (H, H^4, $J_{3,4}$ 8Hz), 1.6–3.0 (8 H, A_2B_2, 2 × Ph), 5.95 (6 H, 2 × OMe).

2,6-Di-N-piperidylcarbonylpyrylium perchlorate (5). The pyrylium salt was prepared from 2,6-di-*N*-piperidylcarbonyl-4*H*-pyran in the same way as the ketones above. The yield was 85 %, m.p. 150–152 °C (decomp.). (Found: C 50.43; H 5.74. Calc. for $C_{17}H_{23}N_2O_3.ClO_4$: C 50.69; H 5.76) τ (TFA) 1.25 (2 H, AB_2, $H^{3,5}$), 0.4 (H, H^4, $J_{3,4}$ 8 Hz), 5.6–6.5, 7.9–8.4 (20 H, 2 × piperidine).

4-Acetylmethyl-2,6-di-N-piperidylcarbonyl-4H-pyran (8a). 2,6-Di-*N*-piperidylcarbonylpyrylium perchlorate (2.01 g, 0.005 mol) was added to acetone (25 ml) with stirring and the solution left in the cold for 1 h. Evaporation left an oily material which on trituration with ether gave a crystalline solid, m.p. 100–102 °C; yield 1.30 g (72 %). (Found: C 66.49; H 7.80. Calc. for $C_{20}H_{28}N_2O_4$: C 66.64; H 7.83) τ ($CDCl_3$) 4.45 (2 H, d, $H^{3,5}$, $J_{3,4}$ 3.5 Hz), 7.1 (2 H, d, CH_2CO, $J_{CH_2,4}$ 6 Hz), 7.85 (3 H, CH_3CO), 6.0–6.6, 8.0–8.5 (20 H, 2 × piperidine); H^4 is superimposed on the piperidine protons in the 6.0–6.6 region; ν_{max} (KBr) 1630 (CO–N), 1710 cm^{-1} (–CO–C).

4-Benzoylmethyl-2,6-di-N-piperidylcarbonyl-4H-pyran (8b) was prepared as above from acetophenone in 78 % yield, m.p. 154–156 °C. (Found: C 70.80; H 7.02. Calc. for $C_{25}H_{30}N_2O_4$: C 71.07; H 7.16), τ (TFA) 4.5 (2 H, d, $H^{3,5}$, *J* 3.5 Hz), 6.85 (2 H, d, CH_2CO, $J_{CH_2,4}$ 6 Hz), 2.2–3.0 (5 H, Ph), 6.2–6.8, 8.3–8.6 (20 H, 2 × piperidine); H^4 is superimposed on the piperidine protons in the 6.2–6.8 region; ν_{max} (KBr) 1630 (CO–N), 1680 cm^{-1} (CO–C).

4-(5,5-Dimethyl-1,3-dione-2-cyclohexyl)-2,6-di-N-piperidylcarbonyl-4H-pyran (8c). 2,6-Di-*N*-piperidylcarbonylpyrylium perchlorate (2.01 g, 0.005 mol) was dissolved in liquid SO_2 (25 ml) at −30 °C and dimedone (0.70 g, 0.005 mol) added with stirring. The SO_2 was then allowed to evaporate and the residual oily material crystallised by trituration with ether; yield 1.57 g (71 %), m.p. 140–142 °C. (Found: C 67.92; H 7.92. Calc. for $C_{35}H_{34}N_2O_5$: C 67.85; H 7.74), τ (CD_3CN) 4.75 (2 H, d, $H^{3,5}$, $J_{3,4}$ 4 Hz), 5.5 (H, t, H^4), 7.4–7.6 (4 H, CH_2CO), 8.9–9.0 (6 H, 2 × Me), 6.2–6.8, 8.2–8.6 (20 H, 2 × piperidine). These values are for the enolic tautomer (75 %); non-enolised molecules differ in that the H^4 proton and the COCHCO proton seem to be in the 6.2–6.6 region; ν_{max} (KBr) 1630 (CO–N), 1600 cm^{-1} (CO–C=).

2,6-Dibenzoyl-4-(5,5-dimethyl-1,3-dione-2-cyclohexyl)-4H-pyran (7c) was prepared as above from 2,6-dibenzoylpyrylium perchlorate and

dimedone in 78 % yield, m.p. 122–124 °C. (Found: C 75.51; H 5.42. Calc. for $C_{27}H_{24}O_5$: C 75.68; H 5.65), τ (CD_3CN) 4.2 (2 H, d, $H^{3,5}$, $J_{3,4}$ 4 Hz), 5.2 (H, t, H^4), 7.2–7.4 (4 H, 2 CH_2CO), 8.8–9.0 (6 H, 2 Me), 2.0–2.7 (10 H, 2 × Ph); these values are for the enolic tautomer (85 %); ν_{max} (KBr) 1645 (CO-aryl), 1590 cm^{-1} (CO–C=).

*2,6-Dibenzoyl-4-*p*-methoxyphenylpyrylium perchlorate (12).* 2,6-Dibenzoylpyrylium perchlorate (1.94 g, 0.005 mol) was dissolved in liquid SO_2 (25 ml) at −30 °C and anisole (0.66 g, 0.006 mol) added gradually with stirring under anhydrous conditions. The solution was then left at room temperature until all the SO_2 had evaporated. The residual oily material was solidified on treatment with anhydrous ether and the ether decanted. The ether treatment was repeated three times before the residue was extracted twice with anhydrous dioxane to remove 2,6-dibenzoyl-4*H*-pyran. The remaining pyrylium salt (1.05 g) corresponds to 82 % of theoretical yield of the pyrylium salt; m.p. 155–156 °C (decomp.). (Found: C 62.93; H 4.01. Calc. for $C_{26}H_{19}O_4.ClO_4$: C 63.10; H 3.87), τ (TFA) 0.95 (2 H, $H^{3,5}$), 5.8 (3 H, OMe), 1.3–2.8 (4 H, A_2B_2, subst. Ph), 1.3–2.8 (10 H, 2 × Ph).

N-Quaternary Compounds. XXXVI.[1] Nitro- and Diazonium-group Activation in Reactions of Pyridinium Derivatives

SIGURD HAGEN, GUNNAR ARNFINN ULSAKER and KJELL UNDHEIM

Department of Chemistry, University of Oslo, Oslo 3, Norway

6-(8)-Nitrodihydrothiazolo[3,2-*a*]pyridinium salts as pseudo-bases are readily brominated. Diazotisation of the 8-amino derivative is followed by re-arrangement of the diazonium salt into dihydrothiazolo[2,3-*e*]*v*-triazoles.

Simple pyridinium derivatives are electron deficient and therefore not reactive towards electrophiles. The pyridinium ring in dihydro thiazolo[3,2-*a*]pyridinium-8-oxide, however, is readily substituted by electrophiles because of the activation from the oxide function.[2] In the present work we have investigated effects of other substituents on the reactivity of the pyridinium ring. Syntheses of amino derivatives are shown in Scheme 1. The acetamides (*2a*) and (*2b*) required for the syntheses were prepared by dithionite reduction [3] of the corresponding nitropyrid-2-thiones [4] and the amides isolated after acetylation. The 3-amine (*3*) was prepared from the amide (*2a*) by acid hydrolysis.

Pyrid-2-thiones are initially attacked on the sulphur atom by electrophilic carbon.[5,6] A 3-ethoxy group increases the reaction rate by virtue of its electron releasing properties while a 3-hydroxy group has the opposite effect. The latter has been attributed to intramolecular hydrogen bonding (*7*).[6] In the present work it was noticeable that the 3-acetamide was less reactive than the 5-isomer as expected on the basis of steric interference and hydrogen bonding (*8*).

Generally, in aminopyridines it is the pyridine nitrogen atom which is the more basic and nucleophilic. Accordingly, cyclisation of the *S*-alkylated intermediate (*4*) should occur over the pyridine nitrogen atom to the dihydrothiazolo[3,2-*a*]pyridinium derivatives (*5a-6*) even in the case of the 3-amine (*3*). This was confirmed by acid hydrolysis of the bicyclic product from (*2a*) which gave the condensation product from (*3*). The latter product contains a diazotisable amino group as discussed below.

S-Alkylation is the overall rate determining step in the reaction sequence with very rapid cyclisation of the *S*-alkylated intermediate

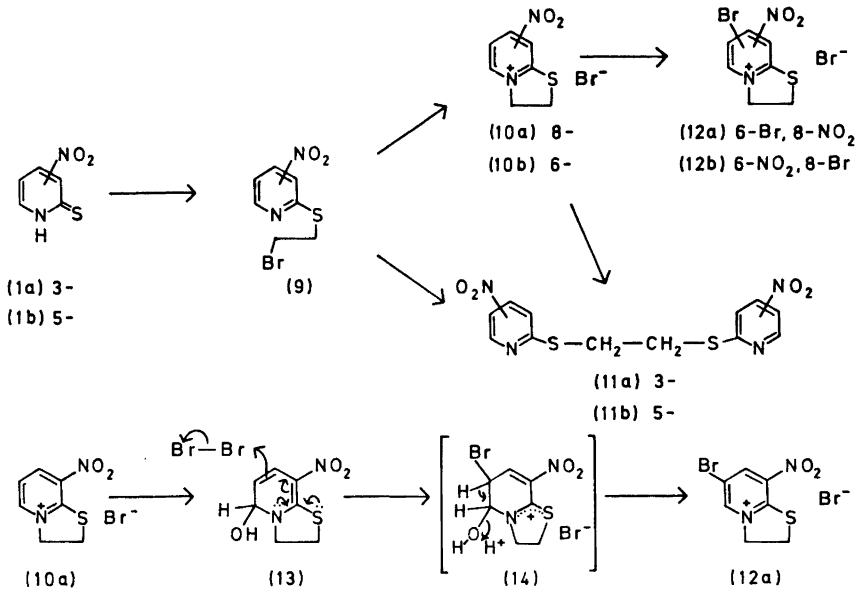
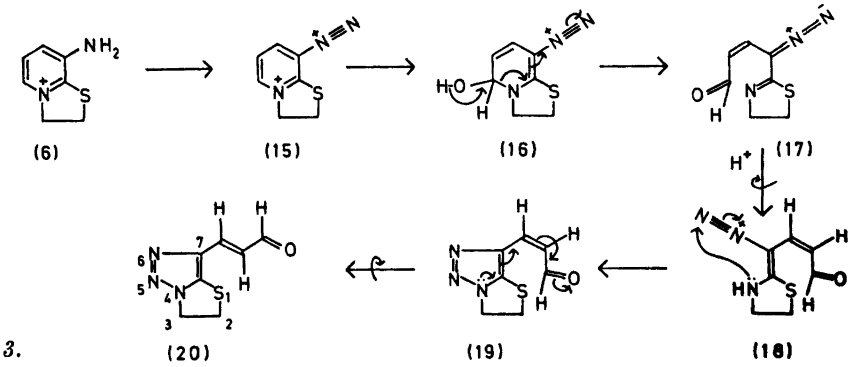


Scheme 2.

since the latter was not observed in the reaction. In the reaction of the nitro analogues (*1*), however, a dipyridyl thioether (*11*) was isolated. The nitro group serves to decrease the nucleophilicities of both the sulphur and the pyridine nitrogen atoms. The reduced cyclisation rate could account for formation of (*11*). The bicyclic product (*10*), however, is reactive towards nucleophiles and (*11*) could equally well have been formed by a nucleophilic ring-opening of (*10*). The latter path was demonstrated by addition of the parent thione (*1*) as sodium salt to the pyridinium salt (*10*) which resulted in formation of (*11*).

Dihydrothiazolo[3,2-*a*]pyridinium derivatives with a hydroxy group in 8-position are very readily substituted by electrophiles and even undergo diazo-coupling reactions.[2] The electron releasing properties of the amino group and the acetamido group, however, were not sufficient to effect direct bromination in (*5*) and (*6*) under mild conditions.[2] Contrary to deductive expectations, however, the nitro-substituted pyridinium derivatives (*10*) are readily brominated in aqueous methanol. This observation is understandable in terms of pseudo-base formation as illustrated in Scheme 2 for the 8-nitro derivative (*13*). As distinct from the amino salts (*5,6*) the electron withdrawing effect by the nitro group increases the electron deficiency of the pyridinium ring to the extent that hydroxyl addition occurs. Pseudo-base formation in pyridinium systems has been found to occur preferentially in an α-position to the heteroatom.[7] The pseudo-base thus formed can be regarded both as an *N*-vinyl and *S*-vinyl derivative activated for electrophilic substitution in 6- or 8-position, respectively (Scheme 2). The mechanistically postulated substitution pattern is further supported by the NMR spectra which show two pyridinium protons with chemical shifts less than 1 τ and coupling constants $J = 1.5 - 2.0$ Hz as expected for 1,3-coupling.

In order to prove the dihydrothiazolo[3,2-*a*]-pyridinium structure with a primary amino group, after the reaction of 3-amino-pyrid-2-thione (*3*), the condensation product was diazotised using isoamyl nitrite in aqueous acetic acid. The diazonium group is interesting since it is by far the most strongly electron-attracting group known.[8] It is an electrophilic reagent which can attack a vicinal thioether group with 1,2,3-thiadiazole formation.[9] Any appreciable product formation with opening of the dihydrothiazole ring, however, was not



Scheme 3.
