observed for (*6*). Nor was the diazotised pyridinium molecule sufficiently stabilised from the thiother group for heterolytic reactions with water in which N_2 is the leaving group. Instead the highly electron deficient pyridinium system adds a hydroxyl ion similar to the observation for the nitro derivatives (*10*) discussed above. The pseudo-base then re-arranges to two main products identified as the v-thiazoles (*19*) and (*20*). The *trans*-acraldehyde (*20*) is the more stable and is readily formed from the *cis*-isomer by isomerisation about the double bond. The formyl group in IR absorbs at 1670 cm^{-1}. Both isomers have UV absorption maxima at 314 and 239 nm. High resolution mass spectrometry shows molecular ion at *m/e* 181 with the presented elemental compositions. The fragmentation is characterised by $[M-N_2]$ being the major intermediate for lower mass fragments. The coupling constant between the α-(3.8 τ) and the β-proton (2.2 τ) is $J=16$ Hz for the *trans*-isomer. Between the α-proton and the formyl proton (0.4 τ) the coupling constant is $J=8$ Hz. The vicinal vinyl coupling between the α- (4.0 τ) and the β-proton (2.7 τ) in the *cis*-isomer is $J=12$ Hz, the coupling between the α-proton and the formyl proton being as in the *trans*-isomer. The chemical shift for the formyl proton in the *cis*-isomer, however, has been moved downfield to -0.7 τ. A similar observation for *cis*-3-(v-triazolo[1,5-*a*]pyridyl)acraldehydes relative to their *trans*-isomers has been attributed to the vicinal nitrogen lone-pair in the triazole.[10] The isomer shifts in the present case are of the same order which could mean that the lone pairs on the sp^3-hybridised sulphur atom have little influence in this respect.

X-Ray analysis of the *trans*-isomer (*20*) shows that the acraldehyde side-chain has a conformational preference.[11] It lies with its substituents in the ring-plane and has the α-hydrogen atom close to the sulphur atom (*20*). The triazole ring is planar. The dihydrothiazole ring has the envelope conformation with the 1- and 3-atoms nearly coplanar with the triazole ring and the C-2 atom 0.4 Å out of plane.[11] The envelope conformation corresponds to that found in dihydrothiazolo-pyridines.[12]

The crude product after the diazotisation reaction is an almost equimolar mixture of the *cis*- and *trans*-isomers. In weak acid solution the *cis*-isomer is converted to the *trans*-isomer. Warming a solution of the 1:1 isomer mixture in deuterium oxide also led to the *trans*-isomer. No deuterium was incorporated in the molecule. Isomerisation therefore occurs without any exchange of vinyl protons.

The re-arrangement leading to the *v*-triazoles is explained by initial hydroxyl addition to the carbon next to the hetero-atom followed by re-arrangement as indicated in Scheme 3. The reaction appears general in that simple 1-alkyl- and 1-aryl-3-aminopyridinium salts are convertible into 3-(1-alkyl or aryl-4-v-triazolyl)-acraldehydes.[13,14] Similar re-arrangements to v-triazoles have also been observed from a number of 1-aminoquinolizinium salts in aqueous nitrous acid.[10]

No attempts have been made to study the intermediate diazonium salts (Scheme 3). In simple 3-aminopyridinium salts, however, a transient and quickly disappearing diazo-coupling ability was observed supporting the formulation of an initial diazonium salt.[13,14]

The cyclisation corresponds to the well established formation of benzotriazoles by diazotisation of *o*-phenylenediamine.[15]

The exocyclic double bond in the initially formed triazole would be expected to have retained the *cis*-configuration. The presence in the reaction product of almost equal amounts of the *cis*- and *trans*-isomers is presumably due to the ease of isomerisation of the *cis*-isomer under the experimental conditions used.

EXPERIMENTAL

All NMR spectra were determined on a 60 MHz Varian A-60A spectrometer.

3-Acetamidopyrid-2-thione (2a) was prepared by sodium dithionite reduction of 3-nitropyrid-2-thione [4] followed by acetylation as described for 5-acetamidopyrid-2-thione (*2b*).[3] Yield 38 %, m.p. 196–197 °C (H_2O). (Found: N 16.85; S 18.94. Calc. for $C_7H_8N_2OS$: N 16.65; S 19.06).

8-Acetamidodihydrothiazolo[3,2-a]pyridinium bromide (5a). 3-Acetamidopyrid-2-thione (0.85 g, 0.005 mol), potassium carbonate (0.35 g, 0.0025 mol) and 1,2-dibromoethane (0.94 g, 0.005 mol) were stirred together in anhydrous dimethylformamide (30 ml) in the cold. Chromatography showed the reaction to be over after 3 h. The reaction mixture was then evaporated at reduced pressure and the residue dissolved by heating in dilute methanol. The title compound was precipitated on cooling; yield 38 %, m.p. 269–270 °C (decomp.) (dilute MeOH). (Found: C 38.85; H 3.98; N 10.36. Calc. for $C_9H_{11}BrN_2OS$: C 39.28; H 4.03; N 10.18), τ (TFA) 6.0 (2 H-2), 4.6 (2 H-3), 1.3 (H-5), 2.3 (H-6), 1.3 (H-7), 7.5 ($COCH_3$); $J_{5,6}$ 6.0, $J_{6,7}$ 8.0, $J_{5,7}$ 2.0 Hz.

6-Acetamidodihydrothiazolo[3,2-a]pyridinium bromide (5b) was prepared as (*5a*) in 60 % yield, m.p. 320–323 °C (decomp.) (dil. MeOH). Reaction time 30 min. (Found: S 11.33; Br 29.24. Calc. for $C_9H_{11}BrN_2OS$: S 11.65; Br 29.04). τ (TFA) 6.1 (2 H-2), 4.7 (2 H-3), 0.5 (H-5), 1.6 (H-7), 2.2 (H-8), 7.6 ($COCH_3$); $J_{7,8}$ 9.0, $J_{5,7}$ 2.0 Hz.

8-Nitrodihydrothiazolo[3,2-a]pyridinium bromide (10a) was synthesised as (*5a*). The reaction time was 1 day. The solid residue after evaporation of the reaction mixture was extracted with hot dilute methanol (4:1) and the yellow, insoluble material crystallised from acetone. The product thus obtained in 15 % yield, m.p. 148–149 °C, has been identified as *1,2-di-(3-nitro-2-pyridylthio)ethane* (*11a*); molecular ion composition by high resolution MS: $C_{12}H_{10}N_4O_4S$; τ (TFA) 6.1 (4 H-2 CH_2), 0.8 (H-4), 2.0 (H-5), 0.8 (H-6).

The title compound was precipitated from the dilute ethanol solution on cooling; yield 38 %, m.p. 300 °C (decomp.). (Found: C 32.26; H 2.68; S 11.95. Calc. for $C_7H_7BrN_2O_2S$: C 31.95; H 2.68, S 12.19), τ (TFA) 6.1 (2 H-2), 4.5 (2 H-3), 0.8 (H-5), 2.1 (H-6), 0.8 (H-7); $J_{5,6}$ 6.0, $J_{6,7}$ 8.0, $J_{5,7} < 1$ Hz.

6-Nitrodihydrothiazolo[3,2-a]pyridinium bromide (10b) was prepared as (*10a*). The reaction time was 4 h. The yield of co-formed *1,2-di-(5-nitro-2-pyridylthio)ethane* (*11b*) was 18 %, m.p. 153–156 °C (acetone); molecular ion composition by high resolution MS: $C_{12}H_{10}N_4O_4S_2$; τ (TFA) 6.4 (4 H-2 CH_2), 1.9 (H-3), 1.0 (H-4), 0.5 (H-6).

The yield of the title compound (*10b*) was 60 %; no melting point due to gradual decomposition on heating (dil. MeOH). (Found: C 31.93; H 2.66; S 12.17. Calc. for $C_7H_7BrN_2O_2S$: C 31.95; H 2.68; S 12.19), τ (TFA) 5.8 (2 H-2), 4.4 (2 H-3), 0.3 (H-5), 1.0 (H-7), 1.9 (H-8); $J_{7,8}$ 9.0, $J_{5,7}$ 2.0 Hz.

8-Aminodihydrothiazolo[3,2-a]pyridinium bromide (6). (a) 3-Acetamidopyrid-2-thione (4.8 g, 0.04 mol) was dissolved in a solution of conc. HBr (5 ml) and ethanol (50 ml) and the resultant solution heated under reflux for 4 h. The precipitated 3-aminopyrid-2-thione (*3*) as hydrobromide was filtered off from the cold reaction mixture and reacted further with 1,2-dibromoethane in DMF as described for (*2a*) using an additional equivalent of potassium carbonate for neutralisation of the hydrobromide. The reaction time was 15 min; yield 59 %, m.p. 155–157 °C (dil. EtOH). (Found: C 33.48; H 4.43; N 11.20. Calc. for $C_7H_9BrN_2S.H_2O$: C 33.48; H 4.41; N 11.15), τ (TFA) 5.9 (2 H-2), 4.6 (2 H-3), 1.4 (H-5), 2.3 (H-6), 1.6 (H-7); $J_{5,6}$ 6.0, $J_{6,7}$ 8.0, $J_{5,7} < 1$ Hz.

(b) 8-Acetamidodihydrothiazolo[3,2-*a*]pyridinium bromide (*5a*) (9.0 g, 0.033 mol) was dissolved in water (100 ml) and Amberlite IRA-400 (OH^-) ion exchanger added. The ion exchanger was filtered off after stirring for 3 h, conc. HCl (100 ml) added to the filtrate and the solution heated under reflux for 1 h. Evaporation gave the amine (*6*) as chloride in 91 % yield (5.6 g).

6-Bromo-8-nitrodihydrothiazolo[3,2-a]pyridinium bromide (12a). Bromine (0.32 g, 0.002 mol) in methanol (2 ml) was added dropwise to an ice-cold solution of (*10a*) (0.52 g, 0.002 mol) in MeOH:H_2O (4:1) (10 ml). The bromine was decolourised at once. The precipitated bromo compound was recrystallised from methanol; yield 0.45 g (66 %), m.p. 303 °C (decomp.). (Found: C 24.61; H 2.06. Calc. for $C_7H_6Br_2N_2O_2S$: C 24.58; H 1.77), τ (TFA) 6.0 (2 H-2), 4.4 (2 H-3), 0.8 (H-5), 0.9 (H-7); $J_{5,7}$ 2.0 Hz.

8-Bromo-6-nitrodihydrothiazolo[3,2-a]pyridinium bromide (12b) was prepared as (*12b*) in 80 % yield, m.p. 300 °C (decomp.) (MeOH). (Found: C 24.72; H 1.85; N 8.31; Calc. for $C_7H_6Br_2N_2O_2S$: C 24.58; H 1.77, N 8.19), τ (TFA) 5.8 (2 H-2), 4.3 (2 H-3), 0.3 (H-5), 0.9 (H-7); $J_{5,7}$ 1.5 Hz.

trans-*3-(7-Dihydrothiazolo[2,3-*e]v-*triazolyl)-acraldehyde. (20).* 8-Aminodihydrothiazolo[3,2-*a*]pyridinium chloride (5.60 g, 0.03 mol) in water solution (125 ml) was stirred with Amberlite IRA-400 (OH^-) ion exchanger for 2 h. The ion exchanger was then removed by filtration and acetic acid (125 ml) added to the filtrate. Isoamyl nitrite (4.00 g, 0.034 mol) dissolved in acetic acid (20 ml) was added dropwise to the ice-cold solution over 3 h. At the end of this period the solution was evaporated almost to dryness at reduced pressure, a little water added, the pH adjusted to 7 with sodium carbonate and the solution extracted several times with ethyl acetate. The dried ethyl acetate extracts were evaporated and the residual material crystallised from water or chloroform; yield 1.4 g (25 %), m.p. 200 °C (Found: C 46.40; H 4.12; N 23.40. Calc. for $C_7H_7N_3SO$: C 46.41; H 3.90; N 23.20), τ (DMSO-d_6) 5.8 (2 H-2), 5.3 (2 H-3), 3.8 (H-2, quartet, $J_{2,3}$ 16 Hz, $J_{2,CHO}$ 8 Hz), 2.2 (H-3, doublet), 0.4 (H-CHO, doublet), λ_{max} (MeOH) 239, 314 nm (log *E* 4.03 and 4.11); *m/e* 181 (M^+) 58 %, [M−N_2] 22, [M−N_2H] 18, [M−N_2CO] 10, [M−$N_2C_2H_4$] 23, [M−N_2CHO] 20, and *m/e* 60 [C_2H_4S] 100.

The data refer to the *trans*-isomer. NMR of the crude reaction product showed this to contain the *cis-(19)* and *trans-(20)* isomers in the ratio 1:1. Warming the crude product for a short time in acetic acid led to complete isomerisation to the *trans*-form *(20)*.

NMR of the *cis*-isomer *(19)*, as it appears in the crude reaction mixture, shows the methylene protons as in *(20)* with the following shifts for the side-chain protons: τ (DMSO−d_6) 4.0 (H-2, quartet, $J_{2,3}$ 12 Hz, $J_{2,CHO}$ 8 Hz), 2.7 (H-3, doublet), −0.7 (H−CHO).

In an isomerisation experiment the crude mixture of the isomers (1:1) (45 mg) was heated in deuterium oxide (10 ml) for 2 ½ h. The NMR spectrum of the quantitatively recovered product showed only the *trans*-isomer present with no deuterium incorporation.

Tobacco Chemistry. 23. Structures and Syntheses of Four New Norisoprenoid Furans from Greek *Nicotiana tabacum* L.

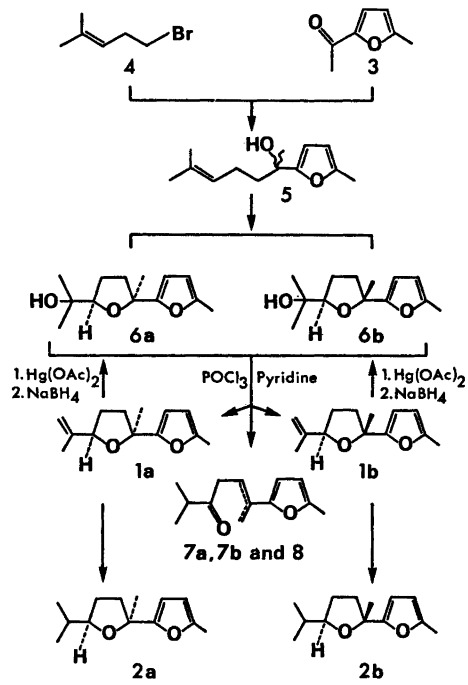
SVEN-OLOF ALMQVIST, ARNE J. AASEN, JOSEPH R. HLUBUCEK, BJARNE KIMLAND and CURT R. ENZELL*

Research Department, Swedish Tobacco Company, Box 17 007, S-104 62 Stockholm 17, Sweden

The structures of *cis* and *trans* (±)-2-methyl-5-(2-methyl-5-isopropenyltetrahydro-2-furyl)-furan, *1a* and *1b*, and their dihydro derivatives, (±)-2-methyl-5-(2-methyl-5-isopropyltetrahydro-2-furyl)furan, *2a* and *2b*, isolated from Greek tobacco were elucidated from spectral data, and subsequently confirmed by total syntheses. The *cis-trans* assignments were based upon the observation of an $Eu(DPM)_3$ induced upfield shift of the furan methyl signal in the NMR-spectrum of the *cis*-isomer of the synthetic intermediate (±)-2-[5-methyl-5-(5-methyl-2-furyl)tetrahydro-2-furyl]-2-propanol, *6a*.

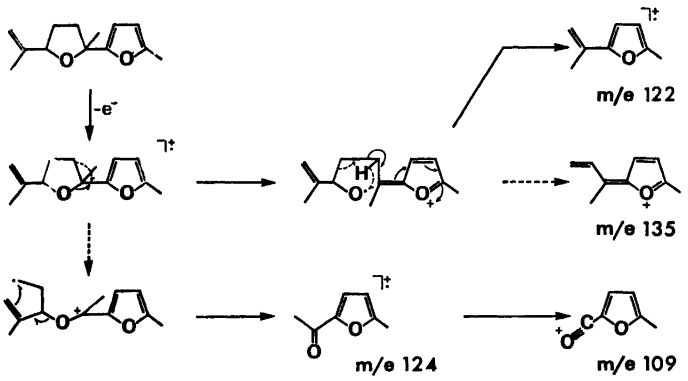
Recent research into tobacco flavour has suggested that a large number of the tobacco constituents are degradation products of terpenoid compounds.[1-3] The present communication describes the structural elucidation and syntheses of further new tobacco constituents possessing carbon skeletons derivable from those of aliphatic terpenoids.

The mass spectrum of the first isolate (from fraction C9) [4] displayed a molecular ion at *m/e* 206 corresponding to the elemental composition $C_{13}H_{18}O_2$ or $C_{14}H_{22}O$. The former alternative was favoured since signals in the NMR spectrum indicated the presence of two oxygen atoms incorporated in a furan ring and a cyclic ether. A 2-methylfur-5-yl moiety was apparent from NMR signals at δ 5.84 (1 H, doublet of quartets, J 1.0 and 3.0 Hz), δ 6.06 (1 H, doublet of quartets, J 0.4 and 3.0 Hz) and δ 2.24 (3 H, doublet of doublets, J 0.4 and 1.0 Hz).[5] The long-range spin-spin couplings between the methyl group and the furyl protons were established by spin decoupling experiments. Absence of further couplings to the proton in position 4 suggested that a fully substituted



Scheme 1.

carbon atom was attached to position 5 of the methylfuryl moiety. The second oxygen atom represented part of a cyclic ether grouping in which the two oxygenated carbon atoms carried a methyl group (δ 1.57, singlet) and an allylic proton (δ 4.45, triplet with further splittings) respectively. Double resonance experiments demonstrated that two olefinic protons (δ 4.78, 5.02) and a vinylic methyl group (δ 1.72) were weakly, mutually coupled (J *ca.* 1 Hz) and could



Scheme 2.

be ascribed to an isopropenyl group, $CH_2=C-(CH_3)-$. The remaining atoms, two methylene groups, were responsible for multiplets in the δ 1.2 – 1.8 region and were readily accomodated in the tetrahydrofuran ring of the postulated structure that could be advanced: 2-methyl-5-(2-methyl-5-isopropenyltetrahydro-2-furyl)furan. Methyl resonances of low intensity at δ 1.55 and δ 1.68 indicated that the isolate was a mixture of diastereomers (ratio 3:7). Thus both the *cis* and the *trans* tetrahydrofuran compounds (*1a* and *1b*) were present in the tobacco.

Subsequently the isomer *1a*, free of the less polar isomer (*1b*) was isolated from a more polar fraction of the tobacco by preparative gas chromatography. Its elemental composition was confirmed by accurate mass determination.

The mass spectra of the two isomers revealed prominent ions at *m/e* 109, 122, 124 and 135 for which fragments, the genesis shown in Scheme 2 may be invoked. High resolution mass spectrometry manifested the elemental compositions of the structures suggested in Scheme 2.

The mass spectrum of the second isolate, obtained by preparative gas chromatography from the same fraction [4] as *1a* and *1b*, exhibited a molecular ion at *m/e* 208, corresponding to $C_{13}H_{20}O_2$, and was similar to the mass spectra of *1a* and *1b* (abundant ions at *m/e* 109, 122, 124, and 135) indicating a structural relationship. The 2-methylfur-5-yl moiety was apparent from IR absorption at 782 cm^{-1} and signals in the NMR spectrum [5] at δ 2.26 (3 H, broad singlet), δ 5.82 (1 H, doublet with further splittings, J 3.0 Hz) and δ 6.02 (1 H, doublet, J 3.0 Hz). The methyl substituted tetrahydrofuran ring was indicated by a three-proton singlet at δ 1.54 and a one-proton multiplet at δ *ca.* 3.74. The chemical shift and multiplicity of the latter signal suggested that the proton on the oxygenated carbon was non-allylic, and that this isolate was also a diastereomeric mixture. The observed lack of clear resolution of the long-range spin couplings might be explained by small differences in chemical shifts of these protons. The diastereomeric nature (ratio 2:3) of this isolate was further supported by the presence of a seven line multiplet in the δ 0.8 – 1.0 region (6 H) which could be ascribed to two isopropyl groups. The two diastereomers could be assigned the structures *cis* and *trans* 2-methyl-5-(2-methyl-5-isopropyltetrahydro-2-furyl) furan (*2a* and *2b*).

The proposed structures of *1a*, *1b*, *2a*, and *2b* were confirmed by synthesis as outlined in Scheme 1, which also provided a means of determining their relative stereochemistry. Thus the alcohol *5*, conveniently prepared by reacting 4-methyl-3-penten-1-ylmagnesium bromide with 2-methyl-5-acetylfuran (*3*) in a Grignard reaction, was converted to a 1:1 mixture of the diastereomeric tetrahydrofuran derivatives *6a* and *6b* in one step by epoxidation followed by spontaneous cyclization.[7] Dehydration was effected by phosphorus oxychloride in pyridine to yield, after chromatography on silica, the desired pure olefins *1a* and *1b*, which exhibited spectral data and gas chromatographic behaviour (co-injection on a capillary column) indistinguishable from those of the natural mixture.

The last step also yielded three by-products evidently arising *via* rearrangement of an enol ether, namely the isomeric unsaturated ketones 2-methyl-6-(5-methyl-2-furyl)-6-hepten-3-one, (*8*), and 5*E* and 5*Z* isomers of 2-methyl-6-(5-methyl-2-furyl)-5-hepten-3-one, (*7a* and *7b*).

The pure dihydro derivatives *2a* and *2b* were prepared from *1a* and *1b*, respectively, by catalytic hydrogenation of the isopropenyl groups. Synthetic *2a* and *2b* exhibited spectral data identical to those of the natural products. The seven line multiplet in the NMR-spectrum, ascribed to the isopropyl signals, could be reconstructed by superposition of the spectra of synthetic *2a* and *2b*. Furthermore, synthetic *2a* and *2b* had different GC retention times but when coinjected separately with the natural diastereomeric mixture each, in turn, enhanced the signal for the respective natural isomer.

The relative stereochemistry of the tetrahydrofuran compounds was determined by measuring the rel. lanthanide induced chemical shifts [2,14] for the alcohols *6a* and *6b*. Attempts to separate the synthetic intermediate mixture of *6a* and *6b* were only moderately successful, even by preparative gas chromatography, and these compounds were therefore prepared by hydration [8] of the respective olefins *1a* and *1b*, which could be separated easily by liquid chromatography.

Addition of the shift reagent $Eu(DPM)_3$ to the alcohol *6* obtained from the more polar olefin *1a*, produced an upfield shift of the furan methyl signal, while for the other isomer, this signal showed the usual downfield shift. Upfield shifts are predicted for O–Eu–H angles between 54.7 and 125.3° and have been observed in a number of cases.[9] Only when the hydroxy-isopropyl group and furan ring have a *cis* relationship (*6a*) can the angle subtended by the europium atom, the hydroxyl oxygen and the furan methyl group be such as to give rise to an upfield lanthanide induced shift. Also, in a competition experiment on a 1:1 mixture, the *trans* isomer showed much stronger co-ordination to the Eu-complex.

The skeletons of these four new tobacco compounds *1a*, *1b*, *2a*, and *2b* suggest they are of terpenoid origin and pseudoionone, a known tobacco constituent,[10] could be a possible precursor. The co-occurrence of an unsaturated isoprenoid and its saturated counterpart (*e.g. 1a* and *2a*) is relatively common in tobacco isolates.[10] *1a* isolated from tobacco showed no optical activity, and it is assumed that *1a* and the related tobacco constituents described here are racemates.

EXPERIMENTAL

NMR, IR, UV, rotations, and mass spectra were recorded on Varian A60-A; HA-100D and XL-100, Digilab FTS-14, Beckmann DK-2A, Perkin-Elmer 141, and LKB 9000 (70 eV) instruments, respectively. Accurate mass determinations were carried out at the Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm. Analytical and preparative gas chromatography was performed on a Varian 1700 instrument using steel capillary columns (50 m × 0.25 mm) coated [11] with Ucon Oil HB 2000, and a 3 m × 3.2 mm glass column packed with 5 % Carbowax 20 M on Chromosorb G, respectively. The extraction of 295 kg sun-cured Greek tobacco, *Nicotiana tabacum* L., and the fractionation of the extract has been described in previous communications.[4,6] The natural compounds were isolated by preparative gas chromatography.

2-Methyl-5-(2-methyl-5-isopropenyltetrahydro-2-furyl)furan (1a+1b). Isolated as a mixture of *1a* and *1b* in ratio 3:7 (7.2 mg) from fraction C9.[4] For spectral data, see synthetic *1a* and *1b*.

(±)-cis-2-Methyl-5-(2-methyl-5-isopropenyltetrahydro-2-furyl)furan (1a): Isolated from subfraction No. 5 of fraction B2 [6] (8 mg). Spectral data are given under synthetic *1a*. Zero optical rotation was observed at λ 589, 578, 546, 436, and 365 nm.

2-Methyl-5-(2-methyl-5-isopropyltetrahydro-2-furyl)furan (2a and 2b). Isolated from fraction C9,[4] isomeric ratio 2:3. Spectral data are given under synthetic *2a* and *2b*.

Synthetic products

2-Methyl-5-acetylfuran (3) was prepared as described by Farrar and Levine.[12]

4-Methyl-3-penten-1-yl bromide (4) was obtained 95 % pure from dimethylcyclopropyl carbinol as outlined by Medina and Manjarrez [13] except for omitting the $NaHCO_3$-treatment and subsequent distillation.

(±)-6-Methyl-2-(5-methyl-2-furyl)-5-hepten-2-ol (5). 4-Methyl-3-penten-1-yl bromide (*4*, 2.6 g) in anhydrous ether (10 ml) was added dropwise to a suspension of Mg (340 mg) and ether (40 ml). Stirring was prolonged until the Mg was dissolved and the ketone (*3*, 600 mg) in ether (20 ml) was added dropwise to the cooled (0 °C) solution of the Grignard reagent. The reaction mixture was stirred for 1 h after the addition of the ketone and the temperature maintained at 0 °C. Crushed ice was added and the mixture stirred for 10 min, followed by

extraction with ether. Removal of the solvent and subsequent chromatography on silica gel furnished the furan derivative (*5*, 580 mg, 57 %) as a colourless oil. MS: *m/e* 208 (M^+, 11), 125 (100), 147 (46), 43 (33), 122 (31), 126 (18), 190 (15), 69 (15), 41 (15); $\nu_{max}^{(film)}$ 3400 (broad), 2978 (s), 2926 (s), 2860 (m), 1450 (m), 1385 (m), 1378 (m), 1221 (m), 1117 (m), 1100 (m), 1022 (s), 944 (m), 786 (s); δ ($CDCl_3$): 1.47 (3 H, s), 1.55 (3 H, m), 1.67 (3 H, m), 1.82 (2 H, m), 2.23 (3 H, d, *J* 0.8 Hz), 2.9 (OH), 5.09 (1 H, m), 5.83 (1 H, dq, *J ca.* 0.8 and 3.0 Hz), 6.03 (1 H, d, *J* 3.0 Hz).

cis *and* trans *(±)-2-[5-Methyl-5-(5-methyl-2-furyl)tetrahydro-2-furyl]-2-propanol* (6a + 6b). To a cooled (−5 °C) solution of the alcohol (*5*, 500 mg) in ether (50 ml) was added 3-chloroperbenzoic acid (600 mg) and the reaction mixture was kept at −5 °C overnight. The ether solution was extracted with diluted NaOH, washed with water, concentrated, and chromatographed on silica gel furnishing the tetrahydrofuran derivative as a colourless oil (216 mg, 40 %). The two diastereomers being present in equal amounts could only be separated by capillary GC.

cis *Isomer (6a)*. A solution of $Hg(OAc)_2.H_2O$ (171 mg) in water (0.9 ml) was diluted with tetrahydrofuran (0.9 ml) and the pure olefin *1a* (*vide infra*, the more polar of the isomers, 90 mg) added to the yellow suspension. The solution was stirred for 55 min before adding 2 M NaOH (1.5 ml) and $NaBH_4$ (15 mg). The reaction mixture was diluted with ether, washed with brine and dried (Na_2SO_4). The pale yellow residue after evaporation was chromatographed on silica (25 % ether in pentane) to yield *6a*, (39 mg). MS: *m/e* 224 (M^+, 9), 122 (100), 165 (53), 123 (43), 43 (42), 109 (21), 59 (16), 147 (13), 137 (12). IR: ν_{max}(film): 3560 (m), 3460 (broad), 3110 (w), 2980 (s), 1385 (m), 1375 (m), 1224 (m), 1092 (s), 1086 (s), 1052 (m), 1024 (s), 784 (s). NMR: The *τ* values given refer to relative induced shifts,[14] on addition of $Eu(DPM)_3$, δ ($CDCl_3$): 1.11 (3 H, s, *τ* 1.0), 1.23 (3 H, s, *τ* 0.98), 1.55 (3 H, s, *τ* 0.21), 1.7−2.3 (4 H, m), 2.25 (3 H, broad s, *τ* −0.015), 3.90 (1 H, m, *τ* 0.88), 5.85 (1 H, dq, *J* 3.0 and 1.0 Hz, *τ* 0.009), 6.04 (1 H, d, *J* 3.0 Hz, *τ* 0.13).

trans *Isomer (6b)*. It was prepared as described for the *cis* isomer but from *1b* (30 mg) to yield 11 mg. MS: *m/e* 224 (M^+, 5), 122 (100), 43 (34), 123 (28), 165 (27), 109 (16), 59 (14), 135 (9), 127 (9). IR: ν_{max}(film): 3470 (broad), 3110 (w), 2980 (s), 1386 (m), 1375 (m), 1224 (m), 1118 (s), 1056 (m), 1052 (m), 1026 (s), 1022 (s), 785 (s). NMR: For notations, see *cis* isomer. δ ($CDCl_3$): 1.15 (3 H, s, *τ* 1.0), 1.23 (3 H, s, *τ* 0.97). 1.55 (3 H, s, *τ* 0.17), 1.7−2.3 (4 H, m), 2.26 (3 H, broad s, *τ* 0.048), 3.89 (1 H, t, *J* 7.0 Hz, *τ* 0.93), 5.85 (1 H, dq, *J* 3.0 and 1.0 Hz, *τ* 0.048), 6.05 (1 H, d, *J* 3.0 Hz, *τ* 0.12).

(±)-2-Methyl-5-(2-methyl-5-isopropenyltetrahydro-2-furyl)furan (1a and 1b). To a cooled (−10 °C) solution of the diastereomeric alcohols *6a* and *6b* (500 mg) in dry pyridine (50 ml) was added $POCl_3$ (1.5 ml) dissolved in pyridine (5 ml). The mixture was kept at −10 °C for 24 h, diluted with water and extracted with ether. The extract was washed with diluted H_2SO_4, water, $NaHCO_3$, water, concentrated and chromatographed on silica gel. The two diastereomers *1a* and *1b* were separated and collected in fractions 2 and 1, respectively. Three slightly more polar products (double-spot on TLC) were found in fraction 3 (160 mg). ν_{max}(film): 1714 cm^{-1}; NMR of fraction 3 revealed the presence of the following three compounds (ratio *ca.* 5:1:4) :2-methyl-6-(5-methyl-2-furyl-5*E*-hepten-3-one, (*7a*), δ 1.91, (3 H, m), δ 3.34 (2 H, d, *J* 7 Hz); irradiation at δ 6.18, and δ 1.91 respectively simplified the multiplet at δ 1.91, and increased (6 %) the intensity of the doublet at δ 3.34, 2-methyl-6-(5-methyl-2-furyl)-5*Z*-hepten-3-one, (*7b*, δ 2.02 (*ca.* 3 H, m), δ 3.66 (*ca.* 2 H, d, *J* 7 Hz), and 2-methyl-6-(5-methyl-2-furyl)-6-hepten-3-one (*8*), δ 4.89 (1 H, m), δ 5.45 (1 H, m). Signals also occurred at δ 1.12 (6 H, dd), δ 2.30 (3 H, m), δ *ca.* 2.66 (*ca.* 4 H, m), δ 5.95 (1 H, m), δ *ca.* 6.18 (*ca.* 2 H, m). Less of the desired olefins and more of these side-products were produced when higher reaction temperatures were employed.

trans *Isomer (1b)* (70 mg, yield: 31 %, based on the weight of one of the diastereomers of *6*): MS: *m/e* 206 (M^+, 6), 109 (100), 43 (55), 124 (48), 67 (37), 122 (27), 121 (21), 125 (20), 41 (16), 82 (14); ν_{max}(film): 1373 (m), 1301 (w), 1262 (m), 1221 (m), 1181 (w), 1149 (w), 1100 (s), 1044 (m), 1020 (s), 958 (w), 943 (w), 900 (s), 873 (w,) 784 (s); δ ($CDCl_3$): 1.58 (3 H, s), 1.73 (3 H, m), 2.24 (3 H, dd, *J* 1.0 and 0.4 Hz), 4.45. (1 H, t, *J ca.* 6.5 Hz), 4.79 (1 H, broad s), 5.02 (1 H, broad s), 5.83 (1 H, dq, *J* 1.0 and 3.0 Hz), 6.05 (1 H, d, *J* 3.0 and 0.4 Hz). Irradiation at δ 1.73 simplified the peaks at δ 4.79 and 5.02, while irradiation at δ 2.24 simplified the signals at δ 5.83 and 6.05 to doublets. No separation from the natural isomer could be observed when co-injected with fraction B1 on a capillary GC column.

cis *Isomer (1a)* (75 mg, yield 33 %). MS: *m/e* 206 (M^+, 17), 109 (100), 43 (78), 67 (30), 122 (26), 148 (25), 135 (25), 41 (23), 124 (23), 121 (20).

Organic Hydroxylamine Derivatives. X.* Structural Analogues of γ-Aminobutyric Acid (GABA) of the Isoxazole Enol-betaine Type. Synthesis of 5,6,7,8-Tetrahydro-4*H*-isoxazolo[4,5-*d*]azepin-3-ol Zwitterion and 4,5,6,7-Tetrahydroisoxazolo[4,5-*c*]pyridin-3-ol Zwitterion

POVL KROGSGAARD-LARSEN and HANS HJEDS

The Royal Danish School of Pharmacy, Chemical Laboratory C, DK-2100 Copenhagen, Denmark

The syntheses of the isoxazole enol-betaines 5,6,7,8-tetrahydro-4*H*-isoxazolo[4,5-*d*]azepin-3-ol zwitterion (VIII) and 4,5,6,7-tetrahydroisoxazolo[4,5-*c*]pyridin-3-ol zwitterion (IX), both of which are new heterocyclic compounds, are described. The syntheses of (VIII) and (IX) are based on an acid catalyzed hydrolysis and subsequent cyclization of the ethylene ketals of the appropriate β-oxohydroxamic acids. The constitutions of (VIII) and (IX) are established by spectroscopic methods. The pK_A values of (VIII) and (IX) have been determined to be 4.84 ± 0.05 and 9.20 ± 0.02, and 4.33 ± 0.05 and 9.06 ± 0.04, respectively. On the basis of Dreiding stereomodels the most probable conformers of (VIII) and (IX) are postulated.

Structure-activity correlations of conformationally restricted analogues of γ-aminobutyric acid (GABA) play a decisive part in the elucidations of the structural characteristics of the GABA receptors and of the active sites of the GABA transaminase enzymes.[1-5] As part of our investigations of the active conformations of GABA, syntheses and X-ray structure determinations of GABA analogues of the isoxazole enol-betaine type have been performed.[6-9] At present we are synthesizing a series of model compounds, which are conformationally restricted bicyclic isoxazole enol-betaines in which the *intra*-molecular distance between the zwitterionic centers is systematically changed. This paper presents the syntheses of two members of this series, namely 5,6,7,8-tetrahydro-4*H*-isoxazolo[4,5-*d*]azepin-3-ol zwitterion (VIII) and 4,5,6,7-tetrahydroisoxazolo[4,5-*c*]pyridin-3-ol zwitterion (IX), which are structural analogues of GABA and β-alanine, respectively. Studies of Dreiding stereomodels seem to indicate that two conformers of (VIII) (A and B in Fig. 1) are almost equally favourable, whereas (IX) can adopt only one almost frozen conformation. The approximate *intra*-molecular distances between the charged oxygen atoms and the charged nitrogen atoms in the respective conformers of (VIII) and (IX) are shown in Fig. 1.

An X-ray diffraction analysis of (VIII) is in progress, and investigations of the biological properties of (VIII) and (IX) will be initiated in the near future.

The syntheses of the 3-hydroxyisoxazoles (VIa – c) were accomplished utilizing a reaction sequence analogous to that described by Jacquier *et al.*[10] for the preparation of 3-hydroxyisoxazoles using β-oxoesters as starting materials. The cyclic β-oxoesters (IIIb,c) were synthesized by reaction of compound (I) with ethyl and methyl chloroformate, respectively. The compounds (II) and (IIIb,c) were converted into the dioxolanes (IVa – c), which in turn were transformed into the corresponding hydroxamic acids (Va – c). Attempts to accomplish acid catalyzed hydrolyses and subsequent cyclizations of the

*Part IX. *Acta Chem. Scand. B 28* (1974) 308.

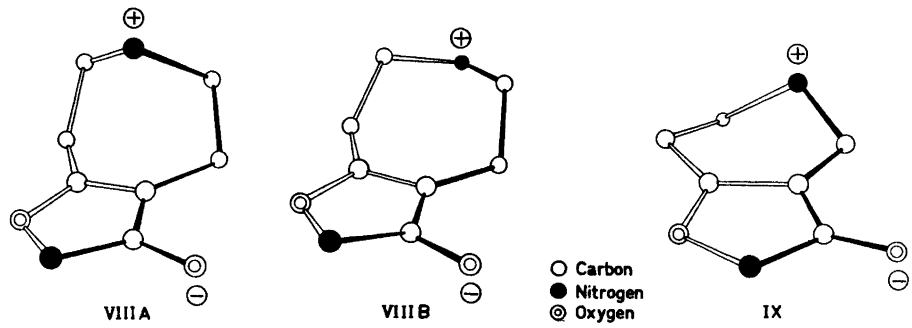

Fig. 1. Some structural characteristics of 5,6,7,8-tetrahydro-4*H*-isoxazolo[4,5-*d*]azepin-3-ol (VIII) and 4,5,6,7-tetrahydroisoxazolo[4,5-*c*]pyridin-3-ol (IX). The structural similarities of VIII and IX to GABA and β-alanine, respectively, are indicated by heavy black lines. The N^+ to O^- distances were estimated by measurements on Dreiding stereomodels: 4.5 Å (VIIIA), 5.3 Å (VIIIB), 4.4 Å (IX). pK_A-Values (H_2O): 4.84 ± 0.05, 9.20 ± 0.02 (17 °C; VIII); 4.33 ± 0.05, 9.06 ± 0.04 (20 °C; IX).

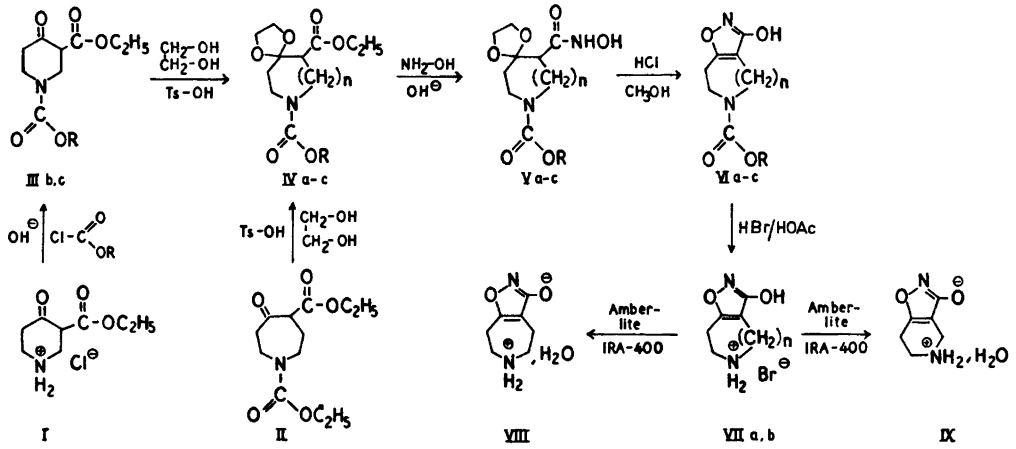
crude reaction products of the dioxolane hydroxamic acids (Va – c) to give the corresponding 3-hydroxyisoxazoles (VIa – c) according to the method described by Jacquier *et al.*[10] were rather unsuccessful. Thus in all cases complex reaction mixtures were obtained, from which no products were isolated. Isolation of the hydroxamic acids (Va – c) in a pure state using chromatography on silica gel columns and subsequent treatment of (Va – c) with hydrochloric acid, however, gave the 3-hydroxyisoxazoles (VIa – c) in moderate to good yields.

Cleavage of (VIa – c) to the corresponding hydrobromides (VIIa,b) was accomplished by treatment with 43 % solutions of hydrogen bromide in glacial acetic acid. The drastic reaction conditions including prolonged heating requisite for the cleavage of the ethoxycarbonyl group of (VIa,b) caused some decomposition of the compounds, especially of (VIb). The methoxycarbonyl group of (VIc), however, was easily cleaved by the above mentioned reagent to give (VIIb) in a pure state and in a high yield. The enol-betaines (VIII) and (IX) were



Scheme 1.

isolated from (VIIa,b), respectively, using a strongly basic ion exchange resin, and both compounds crystallized as monohydrates. The pK_A values of (VIII) and (IX) are 4.84 ± 0.05 and 9.20 ± 0.02, and 4.33 ± 0.05 and 9.06 ± 0.04, respectively.

The structure determinations of (IIIb,c), (IVa–c), and (Va–c) are based on IR and ^{1}H NMR spectroscopy and are supported by elemental analyses. Carbonyl absorption bands in the IR spectra of (IIIb,c) at 1660 cm^{-1} supported by resonance signals in the ^{1}H NMR spectra in tetrachloromethane solutions at δ *ca.* 12 and of intensities corresponding to 0.6 H and 0.8 H, respectively, reveal that the β-ketoesters (IIIb,c) are largely in the *intra*-molecular hydrogen bonded enol form. Structure elucidations of the 3-hydroxyisoxazoles (VIa–c) and (VIIa,b) were performed by IR, UV, and ^{1}H NMR spectroscopy and were supported by elemental analyses. The spectroscopic data originating in the 3-hydroxyisoxazole moieties of (VIa–c) and (VIIa,b) are in accordance with the general findings described by Jacquier *et al.*[10]

The aromatic character of the isoxazole nucleus of (VIII) and (IX) is evident from the IR absorption bands in the 1520–1460, 1630–1600, and 1680–1650 cm^{-1} regions.[11] Absorptions over the range 3600–1900 cm^{-1} and at 2140 and 2250 cm^{-1}, respectively, suggest ammonium salt character of (VIII) and (IX). The UV maxima of (VIII) and (IX) at 216 and 215 nm, respectively, are in agreement with those observed (210 and 211 nm, respectively) for 3-hydroxy-5-(2-aminoethyl)isoxazole,[8] and 3-hydroxy-5-(3-aminopropyl)isoxazole,[12] the structures of which have been established by X-ray diffraction analyses.[8,12] The above mentioned

[a] Unless otherwise stated the IR spectra were recorded in the solid state (KBr). [b] The UV spectra were recorded in ethanol solutions. [c] The IR spectra were recorded using the film technique. [d] The IR spectra were recorded in chloroform solutions.

observations combined provide conclusive evidence of the proposed constitutions of (VIII) and (IX).

Some spectroscopic data of the new compounds (IIIb,c), (IVa–c), (Va–c), (VIa–c), (VIIa,b), (VIII), and (IX) are listed in Table 1.

EXPERIMENTAL

Unless otherwise stated the determination of melting points, the recording of IR, UV, and ^{1}H NMR spectra, the designation of the patterns of the ^{1}H NMR spectra, and the performance of microanalyses were accomplished as described in a previous paper.[13] pH values were measured on a Radiometer pH meter 26, and the pK_A values were determined according to the method of Albert and Serjeant [14] as described in a previous paper.[8] Thin layer and column chromatographic procedures were accomplished using silica gel GF_{254} plates (Merck) and silica gel, 0.05–0.20 mm (Merck), respectively.

Diethyl 4-oxoperhydroazepine-1,5-dicarboxylate ethylene ketal (IVa). (IVa) was synthesized according to the general reaction for the preparation of β-oxoester ethylene ketals described by Jacquier *et al.*[10] using 11.7 g (46 mmol) of (II),[15] 14.0 g (230 mmol) of ethylene glycol, 0.6 g of 4-toluenesulfonic acid, and 400 ml of benzene. After reaction for 76 h the reaction mixture was worked up to give 12.6 g of crude product, which was subjected to column chromatography (silica gel: 200 g; eluent: methylene chloride to which increasing amounts of ethyl acetate were added). Obtained was 8.62 g of product, which after distillation gave 7.56 g (55 %) of (IVa) as a colourless oil, b.p. 152–154 °C/0.2 mmHg. (Found: C 55.75; H 7.72; N 4.59. Calc. for $C_{14}H_{23}NO_6$: C 55.80; H 7.69; N 4.65). ^{1}H NMR data (CCl_4): δ 4.05 [two coincident q (J = 7 Hz), 4 H, 2 × O–C*H*$_2$–CH$_3$]; 3.87 (s, 4 H, O–C*H*$_2$–C*H*$_2$–O); 3.8–3.1 (m, 4 H, CH$_2$–C*H*$_2$–N–C*H*$_2$–CH$_2$); 2.8–2.5 (perturbed t, 1 H, C–C*H*–CH$_2$); 2.5–1.5 (m, 4 H, CH$_2$–C*H*$_2$–C and CH$_2$–C*H*$_2$–CH); 1.25 [two coincident t (J = 7 Hz), 6 H, 2 × O–CH$_2$–C*H*$_3$].

1-Ethoxycarbonyl-4-oxoperhydroazepine-5-carbohydroxamic acid ethylene ketal (Va). To a stirred solution of 4.5 g (*ca.* 65 mmol) of potassium hydroxide in methanol (45 ml) was added 3.6 g (52 mmol) of hydroxylamine hydrochloride. The mixture was stirred for further 90 min and after cooling in an ice bath a solution of 4.02 g (13 mmol) of (IVa) in methanol (12 ml) was added, and the mixture was allowed to stand at 8 °C for 18 d. Upon addition of 5 ml of glacial acetic acid the mixture was filtered and the filtrate was evaporated *in vacuo* to give a thick mass which was worked up utilizing column chromatography [silica gel: 130 g; eluent: ethyl acetate-methanol-formic acid (90:10:1)]. Obtained was 1.76 g (46 %) of (Va) as a reddish, glassy compound. (Found: C 49.78; H 7.11; N 9.65. Calc. for $C_{12}H_{20}N_2O_6$: C 49.99; H 6.99; N 9.72). ^{1}H NMR data ($CDCl_3$): δ 9.4–7.7 (broad signal, 2 H, CO–N*H*–O*H*); 4.08 [q (J = 7 Hz), 2 H, O–C*H*$_2$–CH$_3$]; 3.92 (s, 4 H, O–C*H*$_2$–C*H*$_2$–O); 3.8–3.1 (m, 4 H, CH$_2$–C*H*$_2$–N–C*H*$_2$–CH$_2$); 2.9–2.4 (m, 1 H, C–C*H*–CH$_2$); 2.4–1.6 (m, 4 H, CH$_2$–C*H*$_2$–C and CH$_2$–C*H*$_2$–CH); 1.23 [t (J = 7 Hz), 3 H, O–CH$_2$–C*H*$_3$].

Ethyl 3-hydroxy-5,6,7,8-tetrahydro-4H-isoxazolo[4,5-d]azepine-6-carboxylate (VIa). To a solution of 1.84 g (6.4 mmol) of (Va) in methanol (5 ml) was added 3 ml of concentrated hydrochloric acid. After heating to 70 °C for 5 min the solution was evaporated *in vacuo* to give an oil which was subjected to column chromatography [silica gel: 120 g; eluent: methylene chloride-ethyl acetate-formic acid (85:15:1) to which increasing amounts of ethyl acetate were added]. Obtained was 1.36 g (94 %) of (VIa) in a crystalline state. An analytical sample was recrystallized (benzene-cyclohexane) to give colourless crystals, m.p. 95.5–97.5 °C. (Found: C 53.15; H 6.25; N 12.35. Calc. for $C_{10}H_{14}N_2O_4$: C 53.09; H 6.24; N 12.38). ^{1}H NMR data (CCl_4): δ 9.5–8.8 (broad signal, 1 H, O*H*); 4.13 [q (J = 7 Hz), 2 H, O–C*H*$_2$–CH$_3$]; 3.8–3.4 (m, 4 H, CH$_2$–C*H*$_2$–N–C*H*$_2$–CH$_2$); 3.05–2.65 [t, 2 H, CH$_2$–C*H*$_2$–C(O)=C]; 2.65–2.35 [t, 2 H, CH$_2$–C*H*$_2$–C(C)=C]; 1.25 [t (J = 7 Hz), 3 H, O–CH$_2$–C*H*$_3$].

3-Hydroxy-5,6,7,8-tetrahydro-4H-isoxazolo[4,5-d]azepinium bromide (VIIa). A solution of 1.40 g (6.2 mmol) of (VIa) in 8 ml of glacial acetic acid containing 43 % of hydrogen bromide was refluxed for a total of 2 h (bath temperature: 100 °C). After reflux for 30 and 60 min, respectively, further amounts of 8 ml of glacial acetic acid containing 43 % of hydrogen bromide were added. After cooling to 25 °C the mixture was evaporated to dryness *in vacuo*. The crystalline residue was recrystallized (methanol-ether) to give 1.13 g (78 %) of (VIIa) as colourless crystals, m.p. 253 °C (decomp.). (Found: C 35.73; H 4.68; N 11.97; Br 34.07. Calc. for $C_7H_{11}BrN_2O_2$: C 35.75; H 4.73; N 11.91; Br 34.01). ^{1}H NMR data [D_2O (sodium 3-(trimethylsilyl)propanesulfonate was used as an internal standard)]: δ 4.74 (s. *ca.* 4 H, DO*H*); 3.7–3.3 (m, 4 H, CH$_2$–C*H*$_2$–NH$_2^+$–C*H*$_2$–CH$_2$); 3.3–3.0 [m, 2 H, CH$_2$–C*H*$_2$–C(O)=C]; 3.0–2.6 [m, 2 H, CH$_2$–C*H*$_2$–C(C)=C].

5,6,7,8-Tetrahydro-4H-isoxazolo[4,5-d]azepin-3-ol zwitterion (VIII). A solution of 792 mg (3.4 mmol) of (VIIa) in water (10 ml) was passed through a column containing an ion exchange resin [Amberlite IRA 400, (OH), 100 ml] using acetic acid (1 M) as an eluent. Crude product (605 mg) was obtained. Recrystallization (water-ethanol) gave 334 mg (58 %) of (VIII) as colourless crystals, m.p. 211 °C (decomp.). (Found: C 48.75; H 7.01; N 16.37. Calc. for $C_7H_{10}N_2O_2.1H_2O$: C 48.83; H 7.03; N 16.27). [Found after drying of (VIII) over P_2O_5 (48 h;

125 °C; 0.05 mmHg): C 54.40; H 6.69; N 18.22. Calc. for $C_7H_{10}N_2O_3$: C 54.53; H 6.54; N 18.17]. ^{1}H NMR data [D_2O-CF_3COOD (19:1) (sodium 3-(trimethylsilyl)propanesulfonate was used as an internal standard)]: δ 4.95 (s, *ca.* 5 H, DO*H*); 3.6–3.3 (m, 4 H, $CH_2-CH_2-NH_2^+-CH_2-CH_2$); 3.3–2.6 (m, 4 H, $CH_2-CH_2-C=C-CH_2-CH_2$).

Diethyl 4-oxopiperidine-1,5-dicarboxylate (IIIb). To an ice-cooled solution of 12.3 g (59 mmol) of (I) (Fluka) in water (40 ml), an ice-cooled solution of 3.9 g (*ca.* 55 mmol) of potassium hydroxide and 11.0 g (80 mmol) of potassium carbonate in water (75 ml) was added with stirring, and immediately thereafter 12.9 g (118 mmol) of ethyl chloroformate was added over a period of 15 s. Stirring was continued at 0 °C for 1 h and finally at 25 °C for further 1 h. The reaction mixture was extracted with four 75 ml portions of ether and the combined ether phases were dried and evaporated to give 11.4 g of a red oil. Distillation gave 9.9 g (69 %) of (IIIb) as a colourless oil, b.p. 133–138 °C/0.7 mmHg. (Found: C 54.50; H 6.94; N 5.77. Calc. for $C_{11}H_{17}NO_5$: C 54.31; H 7.04; N 5.76). ^{1}H NMR data (CCl_4): δ 12.0 (s, 0.6 H, enol O*H*); 4.4–3.2 (m, consisting of several partially overlapping patterns of resonance signals, total 8.3 H); 2.7–2.2 [m, 2 H, $CH_2-CH_2-C=O$(oxo form) and $CH_2-CH_2-C=C$(enol form)]; 1.5–1.1 (m, consisting of several overlapping t, total 6 H, $O-CH_2-CH_3$).

Ethyl 1-methoxycarbonyl-4-oxopiperidine-5-carboxylate (IIIc). (IIIc) was prepared as described above for (IIIb) using 12.3 g (59 mmol) of (I) and 11.2 g (118 mmol) of methyl chloroformate, which gave 10.2 g of crude product as a red oil. Distillation gave 9.20 g (68 %) of (IIIc) as a colourless oil, b.p. 131–133 °C/0.3 mmHg. (Found: C 52.45; H 6.58; N 6.09. Calc. for $C_{10}H_{15}NO_5$: C 52.39; H 6.60; N 6.11). ^{1}H NMR data (CCl_4): δ 12.1 (s, 0.8 H, enol O*H*); 4.4–4.0 (two overlapping q, $O-CH_2-CH_3$) and 4.1–3.9 [m, $N-CH_2-CH$ (oxo form) and $N-CH_2-C=C$ (enol form)], total 4 H; 3.9–3.3 [m, $N-CH_2-CH_2$ (oxo and enol form)], 3.67 (s, $O-CH_3$), and 3.65 (s, $O-CH_3$), total 5 H; 2.6–2.1 [m, 2 H, $CH_2-CH_2-C=O$ (oxo form) and $CH_2-CH_2-C=C$ (enol form)]; 1.5–1.1 (two overlapping t, 3 H, $O-CH_2-CH_3$).

Diethyl 4-oxopiperidine-1,5-dicarboxylate ethylene ketal (IVb). (IVb) was synthesized as described above for (IVa) using 11.4 g (47 mmol) of (IIIb) and 14.9 g (240 mmol) of ethylene glycol. After reaction for 81 h the reaction mixture was worked up to give 12.2 g of crude product as an oil, which without previous purification by column chromatography was distilled to give 9.20 g (68 %) of (IVb) as a colourless oil, b.p. 152–156 °C/0.2 mmHg. (Found: C 54.20; H 7.21; N 4.75. Calc. for $C_{13}H_{21}NO_6$: C 54.34; H 7.37; N 4.88). ^{1}H NMR data (CCl_4): δ 4.04 [q (J=7 Hz), $O-CH_2-CH_3$], 4.00 [q (J=7 Hz), $O-CH_2-CH_3$], and 3.88 (s, $O-CH_2-CH_2-O$), total 8 H; 3.8–3.1 (m, 4 H, $CH_2-CH_2-N-CH_2-CH$); 2.6–2.3 (perturbed t, 1 H, $C-CH-CH_2$); 2.3–1.3 (m, 2 H, CH_2-CH_2-C); 1.24 [t (J=7 Hz), $O-CH_2-CH_3$] and 1.21 [t (J=7 Hz), $O-CH_2-CH_3$], total 6 H.

Ethyl 1-methoxycarbonyl-4-oxopiperidine-5-carboxylate ethylene ketal (IVc). (IVc) was synthesized as described above for (IVa) using 9.21 g (40 mmol) of (IIIc) and 12.4 g (200 mmol) of ethylene glycol. After reaction for 69 h the reaction mixture was worked up to give 9.8 g of crude product as an oil, which without previous purification by column chromatography was distilled to give 6.60 g (60 %) of (IVc) as a colourless oil, b.p. 160–162 °C/0.4 mmHg. (Found: C 52.80; H 7.08; N 5.23. Calc. for $C_{12}H_{19}NO_6$: C 52.74; H 7.01; N 5.13). ^{1}H NMR data (CCl_4): δ 4.05 [q (J=7 Hz), $O-CH_2-CH_3$] and 3.91 (s, $O-CH_2-CH_2-O$), total 6 H; 3.8–3.3 (m, $CH_2-CH_2-N-CH_2-CH$) and 3.60 (s, $O-CH_3$), total 7 H; 2.6–2.4 (perturbed t, 1 H, $C-CH-CH_2$); 2.3–1.3 (m, 2 H, CH_2-CH_2-C); 1.25 [t (J=7 Hz), 3 H, $O-CH_2-CH_3$].

1-Ethoxycarbonyl-4-oxopiperidine-5-carbohydroxamic acid ethylene ketal (Vb). (Vb) was synthesized as described above for (Va) using 4.00 (14 mmol) of (IVb), 4.9 g (*ca.* 70 mmol) of potassium hydroxide, and 3.9 g (56 mmol) of hydroxylamine hydrochloride. After standing at 8 °C for 6 d the reaction mixture was worked up as described above for (Va) to give 2.42 g (63 %) of (Vb) in a crystalline state. An analytical sample was recrystallized (ethanol-benzene) to give (Vb) as colourless crystals, m.p. 134.5–136.5 °C. (Found: C 48.40; H 6.72; N 10.32. Calc. for $C_{11}H_{18}N_2O_6$: C 48.17; H 6.62; N 10.21). ^{1}H NMR data [CCl_4-$CDCl_3$ (2:1)]: δ 9.2–8.4 (broad signal, 2 H, $CO-NH-OH$); 4.09 [q (J=7 Hz), $O-CH_2-CH_3$], 3.98 (s, $O-CH_2-CH_2-O$), and 4.4–3.0 (m, $CH_2-CH_2-N-CH_2-CH$), total 10 H; 2.8–2.3 (m, 1 H, $C-CH-CH_2$); 2.3–1.3 (m, 2 H, CH_2-CH_2-C); 1.30 [t (J=7 Hz), 3 H, $O-CH_2-CH_3$].

1-Methoxycarbonyl-4-oxopiperidine-5-carbohydroxamic acid ethylene ketal (Vc). (Vc) was synthesized as described above for (Va) using 7.72 g (28 mmol) of (IVc), 9.8 g (*ca.* 140 mmol) of potassium hydroxide, 7.8 g (112 mmol) of hydroxylamine hydrochloride, and 90 ml of methanol. After standing at 8 °C for 6 d the reaction mixture was worked up as described above for (Va) using 10 ml of glacial acetic acid and 160 g of silica gel to give 3.50 g (48 %) of (Vc) in a crystalline state. An analytical sample was recrystallized (ethanol-benzene) to give (Vc) as colourless crystals, m.p. 162–165 °C (decomp.). (Found: C 46.45; H 6.16; N 10.63. Calc. for $C_{10}H_{16}N_2O_6$: C 46.15; H 6.20; N 10.77). ^{1}H NMR data ($CDCl_3$): δ 9.5–8.5 (broad signal, 2 H, $CO-NH-OH$); 3.97 (s, $O-CH_2-CH_2-O$), 3.66 (s, $O-CH_3$), and 4.2–2.9 (m, $CH_2-CH_2-N-CH_2-CH$), total 11 H; 2.8–2.3 (m, 1 H, $C-CH-CH_2$); 2.1–1.1 (m, 3 H, CH_2-CH_2-C).

Ethyl 3-hydroxy-4,5,6,7-tetrahydroisoxazolo-[4,5-c]pyridine-5-carboxylate (VIb). (VIb) was

synthesized and isolated from the reaction mixture as described above for (VIa) using 2.30 g (8.4 mmol) of (Vb). (VIb) (1.33 g, 75 %) was obtained in a crystalline state. An analytical sample was recrystallized (benzene-cyclohexane) to give colourless crystals, m.p. 118.0 – 120.5 °C. (Found: C 50.85; H 5.67; N 13.13. Calc. for $C_9H_{12}N_2O_4$: C 50.94; H 5.70; N 13.20). ^{1}H NMR data ($CDCl_3$): δ 10.60 (s, 1 H, O*H*); 4.4 – 4.1 (m, N – C*H*$_2$ – C = C) and 4.12 [q (J = 7 Hz), O – C*H*$_2$ – CH$_3$], total 4 H; 3.9 – 3.5 (t, 2 H, N – C*H*$_2$ – CH$_2$); 2.8 – 2.5 (t, 2 H, CH$_2$ – C*H*$_2$ – C = C); 1.27 [t (J = 7 Hz), 3 H, O – CH$_2$ – C*H*$_3$].

Methyl 3-hydroxy-4,5,6,7-tetrahydroisoxazolo-[4,5-c]pyridine-5-carboxylate (VIc). (VIc) was synthesized as described above for (VIa) using 3.20 g (12.3 mmol) of (Vc), 15 ml of methanol, and 8 ml of concentrated hydrochloric acid. The reaction mixture was evaporated *in vacuo* to give an oil, which was dissolved in chloroform (30 ml). The chloroform solution was washed with a saturated solution of sodium chloride, dried, and evaporated *in vacuo* to give 2.28 g of crude (VIc). Recrystallization (benzene-cyclohexane) gave 1.16 g (48 %) of (VIc) as colourless crystals, m.p. 155.0 – 156.5 °C. (Found: C 48.50; H 5.07; N 14.08. Calc. for $C_8H_{10}N_2O_4$: C 48.48; H 5.09; N 14.14). ^{1}H NMR data ($CDCl_3$): δ 10.50 (s, 1 H, O*H*); 4.4 – 4.2 (m, 2 H, N – C*H*$_2$ – C = C); 3.9 – 3.6 (t, N – C*H*$_2$ – CH$_2$) and 3.69 (s, O – C*H*$_3$), total 5 H; 2.9 – 2.5 (t, 2 H, CH$_2$ – C*H*$_2$ – C = C).

3-Hydroxy-4,5,6,7-tetrahydroisoxazolo[4,5-c]-pyridinium bromide (VIIb). Method a. (VIIb) was synthesized as described above for (VIIa) using 1.15 g (5.4 mmol) of (VIb). The crude product was recrystallized (methanol-ether) to give 781 mg (65 %) of (VIIb) as colourless crystals, m.p. 168 – 170 °C (decomp.). (Found: C 32.46; H 4.18; N 12.67; Br 36.28. Calc. for $C_6H_9BrN_2O_2$: C 32.60; H 4.10; N 12.67; Br 36.14). ^{1}H NMR data [D_2O (sodium 3-(trimethylsilyl)propanesulfonate was used as an internal standard)]: δ 4.68 (s, *ca.* 5 H, DO*H*); 4.2 – 4.0 (m, 2 H, NH_2^+ – C*H*$_2$ – C = C); 3.7 – 3.4 (t, 2 H, NH_2^+ – C*H*$_2$ – CH$_2$); 3.2 – 2.8 (t, 2 H, CH$_2$ – C*H*$_2$ – C = C).

Method b. A solution of 1.15 g (5.8 mmol) of (VIc) in 10 ml of glacial acetic acid containing 43 % of hydrogen bromide was heated for 25 min (bath temperature: 100 °C). Evaporation of the reaction mixture to dryness *in vacuo* and recrystallization (methanol-ether) of the residue afforded 1.13 g (88 %) of (VIIb) as colourless crystals, m.p. 169 – 171 °C (decomp.). The IR spectrum was identical with that of the product of method a.

4,5,6,7-Tetrahydroisoxazolo[4,5-c]pyridin-3-ol zwitterion (IX). (IX) was prepared as described above for (VIII) using 581 mg (2.6 mmol) of (VIIb) and 65 ml of ion exchange resin. (IX) (205 mg, 49 %) was obtained as colourless crystals, m.p. 254 – 256 °C (decomp.) (water-ethanol). (Found: C 45.50; H 6.38; N 17.82. Calc. for $C_6H_8N_2O_2.1H_2O$: C 45.56; H 6.37; N 17.71). [Found after drying of (IX) over P_2O_5 (48 h; 125 °C; 0.05 mmHg): C 51.65; H 5.88; N 20.03. Calc. for $C_6H_8N_2O_2$: C 51.42; H 5.75; N 19.99]. ^{1}H NMR data [D_2O-CF_3COOD (19:1) (sodium 3-(trimethylsilyl)propanesulfonate was used as an internal standard)]: δ 4.88 (s, *ca.* 6 H, DO*H*); 4.2 – 4.0 (m, 2 H, NH_2^+ – C*H*$_2$ – C = C); 3.7 – 3.4 (t, 2 H, NH_2^+ – C*H*$_2$ – CH$_2$); 3.2 – 2.8 (t, 2 H, CH$_2$ – C*H*$_2$ – C = C).

Acknowledgement. This work has been supported by the Danish Medical Research Council. The authors express their gratitude to Professor B. Jerslev for her stimulating interest in this work and for valuable discussions and to Mrs. A. Weitze Christensen for skilful performance of experimental work.

The Chemistry of Dibenzo[*d*,*f*][1,3]diazepines. 3.[1] The Electrolytic Preparation of 2,2′-Dihydroxylaminobiphenyl and its Reaction with Aldehydes and Ketones

JAN BECHER[a] and PALLE E. IVERSEN[b]

[a] Department of Chemistry, University of Odense, DK-5000 Odense and [b] Department of Organic Chemistry, University of Aarhus, DK-8000 Aarhus C, Denmark

Preparative scale electrolytic reduction of 2,2′-dinitrobiphenyl gives 2,2′-dihydroxylaminobiphenyl which, although not isolated, combines either *in situ* or after electrolysis with various aliphatic aldehydes and ketones to give the corresponding 5,7-dihydroxy-6,7-dihydrodibenzo[*d*,*f*][1,3]diazepine derivatives. A few activated heterocyclic aldehydes and cycloalkanones underwent this reaction, but generally aromatic aldehydes and ketones and some aliphatic ketones did not react under similar conditions.

The structures of the products were established according to spectroscopic and chemical evidence. A comparison of the results of controlled potential electrolyses and *in situ* catalytic hydrogenations suggests that the former method is usually the preferred method.

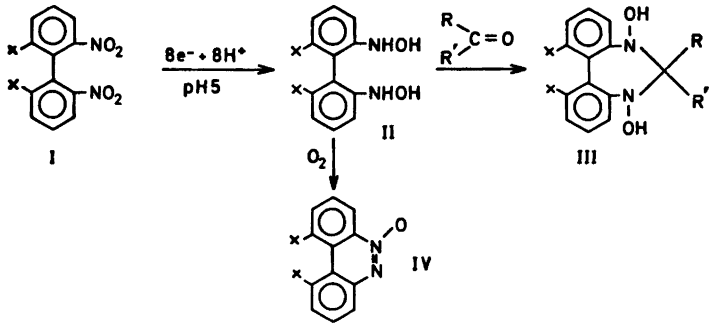
Recently Laviron and Lewandowska [2] have shown that 2,2′-dihydroxylaminobiphenyl (II) is formed by cathodic reduction of 2,2′-dinitrobiphenyl (I). Isolation of the bishydroxylamine (II) was not recorded but compelling evidence for its formation comes from the use of electroanalytical techniques and air (or anodic) oxidation to benzo[*c*]cinnoline-*N*-oxide (IV). The investigations have since been extended to 2,2′,6,6′-tetranitrobiphenyl [3,4] with similar results. The reductive cyclization of 2,2′-dinitrodiphenyl with a few aliphatic aldehydes to give 6-alkyl-5,7-dihydroxy-6,7-dihydrodibenzo[*d*,*f*][1,3]diazepines (III) has been described by Becher [5] and their mass spectra have been discussed.[1] The catalytic hydrogenation method gives low yields [5] and accordingly an electrochemical approach was adopted with the aim of exploring the scope of the cyclization reaction by using a variety of carbonyl compounds.

The trapping of hydroxylamines from electrolytic reduction of nitroalcohols by *in situ* reaction with aldehydes and ketones has been reported by Petrov and Barkhash.[6] In this case, however, the primary condensation products were not isolated but the nitrones postulated as intermediates were further reduced to the corresponding amines at the amply negative cathode potential employed. The present work thus provides new examples of a general reaction type in cathodic electrolysis, *i.e.* the reaction of an electrophile (the carbonyl compound) with an electrochemically generated nucleophile [the bishydroxylamine (II)]. The same principle has been used by Lund [7] to effect many electrochemical cyclizations leading to heterocyclic systems. In such cases the reducible group (which should be transformed into a nucleophile by cathodic reduction) and the unsaturated electrophilic function were present within the same molecule.

A related condensation with ketones was found by Volodarsky and Kutikova who prepared the 1-hydroxy-3-imidazoline-3-oxide derivatives by reaction of α-hydroxylamino oximes with acetone.[8]

RESULTS AND DISCUSSION

Electrochemical preparation. From investigations of the cathodic reduction of aromatic



nitro compounds [9] it has been concluded that weakly acidic media will favour hydroxylamine formation. Similar optimum conditions are required [10] for the reaction between carbonyl compounds and N-containing nucleophiles (which lose their nucleophilic activity by protonation). It proved convenient to conduct preparative scale electrolyses in an acetate buffer (*ca.* pH 5) and add varying amounts of organic polar solvents which by increasing the solubility of the depolarizer allowed the passage of a larger cell current with a consequent shortening of the electrolysis time.

The reductions were performed at room temperature using a mercury cathode and a conventional H-type 3-electrode cell of 250 ml volume. Potentials less cathodic than -0.8 V *vs.* Ag/AgCl were used with 1 – 2 g of the 2,2′-dinitrobiphenyl (I) and in most cases a large excess (5 ml or 5 g) of the carbonyl compound. For the more reactive carbonyl compounds the excess could be smaller. A few experiments using a 500 ml cell with 10 – 12 g of I and acetaldehyde, acetone, or cyclopentanone, gave similar results.

For aldehydes and ketones which were not reduced at ≥ -0.8 V *in situ* techniques could be used. However, an electrochemically prepared solution of II was found to be stable in the absence of oxygen and similar yields of the dihydrodibenzodiazepines (III) were obtained by adding the carbonyl compound to a freshly electrolysed solution of (I). This procedure was necessary for condensations involving the easily reducible heteroaromatic aldehydes. If oxygen is not excluded, oxidation to IV predominates. The *in situ* method is quicker and therefore preferable when the reduction potential of the carbonyl component will allow it. The products are reducible but at more negative potentials than used in this work. The further electroreduction has not yet been investigated. However, for these reasons careful control of the cathode potential is essential. For both procedures the consumption of electricity was generally very close to the theoretical value of 8 F/mol, which thus confirms the findings of Laviron.[9]

Following electrolysis the catholyte was kept under nitrogen at room temperature for 1 – 7 days to allow complete condensation. The product was isolated by filtration and/or extraction with ether after partial evaporation, and purified by recrystallization from a suitable solvent. The yields were estimated from the 60 MHz ^{1}H NMR spectra (DMSO-d_6) of the crude materials and are given in Table 1 together with the yields of recrystallized, pure substances; results from elemental analysis and melting points are to be found in Table 3 in the experimental section. The pH-conditions, methods of isolation and purification for every product were not optimised.

In the original experiments ethanol [9] was used as a co-solvent which was suitable for condensations involving the lower aliphatic aldehydes and acetone. With less reactive carbonyl reagents such as ethyl methyl ketone or cyclohexanone, NMR-analysis of the crude product revealed the presence of IIIb and IV in addition to the expected products. Compound IV was detected in all cases in amounts ranging from traces to its being the main product. It was presumably formed from unreacted II by air oxidation during the work-up, and could be isolated in high yield after purging the electrolysed solution of I with oxygen. The mechanism of formation of IIIb is not yet clear, but it is suggested that an Oppenauer-type of

Table 1. Yields of dibenzo[*d,f*][1,3]diazepine derivatives.

Compound	R	R'	X	% Crude	% Recryst.	Solvent

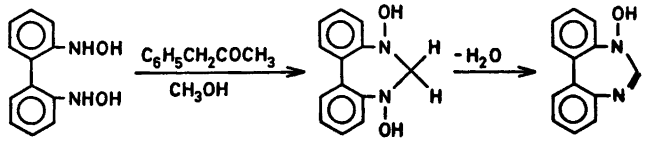
IIIl	4-pyridyl	H	H	64	32	C
IIIm	4-methyl-2-thiazolyl	H	H	55	36	C
IIIn	CH_3	H	CH_3	73	20	A
IIIo	CH_3	CH_3	CH_3	77	42	A

oxidation of the ethanol takes place with the added carbonyl reagent as an oxidant in the presence of II. The acetaldehyde formed would then react rapidly with II to give IIIb. The alcohol corresponding to the carbonyl reagent has not yet been detected but support for the suggestion comes from an experiment using benzyl methyl ketone and methanol as co-solvent which resulted in the main product (V) being derived from formaldehyde. Compound V is the dehydrated derivative 5-hydroxydibenzo[*d,f*][1,3]diazepine, a hitherto unknown and simple representative of the parent ring system (eqn. 2).

In view of this complication other solvents which would not form carbonyl compounds by oxidation were tried. Acetone-water could of course only be used for the derivative IIIf and did work satisfactorily. Acetonitrile-water mixtures were suitable solvents for the aromatic dinitro derivatives but could not be buffered satisfactorily because of the low solubility of sodium acetate. *t*-Butyl alcohol-water was also tried but proved to be too poor a solvent which led to inconveniently long electrolysis times. The most convenient mixture was 1:1 DMF-water which even so made work-up difficult in some cases because of its relatively low volatility and good dissolving power for the products. The present results show clearly that care must be exercised when alcohols and acetone (which are common co-solvents for polarographic work [2,3] in aqueous media) are considered for use in preparative electrolysis water-organic solvent mixtures.

Because of its thermal instability the formaldehyde derivative (IIIa) could not be isolated with a sufficient purity for elemental analysis. Evaporation of an ethereal solution at below 10 °C gave a solid material from which a satisfactory ^1H NMR spectrum was obtained. It was stored for several weeks at below −20 °C but deteriorated rapidly to a brownish tar at room temperature.



IIa IIIa V

From Table 1 it is seen that the condensation goes well with the lower aliphatic aldehydes, acetone, and cyclopentanone. Higher straight-chain methyl ketones, cyclohexanone and some heterocyclic aldehydes were also found to react, a longer reaction time being necessary with the ketones.

Surprisingly benzyl methyl ketone did not condense, even after 10 days, and the same was true for diethyl ketone and cycloheptanone. The sterically hindered ketone methyl isopropyl ketone did not react nor did two aromatic ketones (acetophenone and α,α,α-trifluoroacetophenone). Aromatic aldehydes, exemplified by benzaldehyde and *p*-nitrobenzaldehyde failed to condense (benzaldehyde was even tried at 70 – 80 °C for two days with negative result). It is, however, known that 2,3-dihydroxylamino-2,3-dimethylbutane needs more severe conditions to condense with aromatic aldehydes to give a 5-membered ring.[12] Despite the fact that 4-methyl-2-thiazolealdehyde and 4-pyridinealdehyde did react, no condensed product could be isolated from 2-pyridinealdehyde, *N*-benzyl-2-imidazolealdehyde and 5-nitro-2-furanaldehyde. The deuterated derivative IIIi and the dimethyl derivatives IIIn and IIIo were prepared for use in a MS-investigation,[13] but the corresponding cyclopentanone derivative could not be obtained. Cyclobutanone did react with IIa but TLC analysis showed the presence of several products and the characteristic hydroxyl proton signal did not feature in the ^{1}H NMR spectrum of the product mixture. The nature of the products has not yet been investigated. Negative results were also found with a number of α,β-unsaturated carbonyl compounds.

Catalytic reduction. A few condensations initiated by hydrogenation were performed to allow comparison with the electrochemical procedure. It has previously been found [5] that the yields of IIIb and IIIc were in the range 26 – 37 %, and that the use of larger aliphatic aldehydes to condense with the intermediate II gave poor results. However, when the hydrogenation of I was carried out in a mixture of acetone and acetate buffer, IIIf could be isolated in 76 % yield. This is similar to that obtained with much less acetone by the electrochemical method. A lower yield of 61 % was found with cyclopentanone under similar conditions, but the corresponding electrochemical yield of 90 % of IIIj is superior. These results suggested that a more general investigation of the hydrogenation method would be unrewarding.

It may well be that a catalytic hydrogenation procedure can be devised for the more reactive carbonyl compounds in which case a medium of pH 5 – 6 is probably preferable to the neutral conditions originally used.[5] For the less reactive ketones it would be necessary to use a catalyst which does not promote the further reduction of the bishydroxylamine II to the corresponding 2,2′-diaminophenyl. Apart from the simple experimental procedure the advantage of the controlled potential electrolysis lies in the fact that a stable solution of the intermediate II can be prepared thus allowing the use of carbonyl reagents with other reducible functions in the moecule.

Properties of products. The tentative assignment [5] of the *N*,*N*′-dihydroxydiazepine structure III for the condensation products is supported by the interpretation of the fragmentation pattern evident in the mass spectra of members of this family of compounds.[1,13] Further spectroscopic and chemical evidence is presented below which supports the 7-ring structure, and so far all of the information collected is consistent with this conclusion. However, the direct proof which would follow from an X-ray crystal structure determination has yet to be obtained. The symmetric acetone derivative IIIf has been selected for this purpose, and a structure determination has been undertaken in collaboration with the Inorganic Department of the University of Aarhus. Suitable single crystals could be grown from isopropanol solution, and preliminary findings show that IIIg crystallizes in the monoclinic space group $P2_1/c$ with 2 asymmetric units and the following cell constants: $a = 18.78$ Å, $b = 15.53$ Å, $c = 10.04$ Å, $\cos\alpha = \cos\gamma = 0$, $\cos\beta = -0.412$.

[13] *C NMR analysis.* The best evidence to date comes from the proton decoupled Fourier Transform (FT) ^{13}C NMR spectrum of IIIg (Fig. 1) in which the numbering of the biphenyl system has been retained for simplicity. The compound has a total of 15 C-atoms and the presence of only 8 lines clearly points to a symmetric structure. The intensity ratio for seven pairs and one single carbon would in

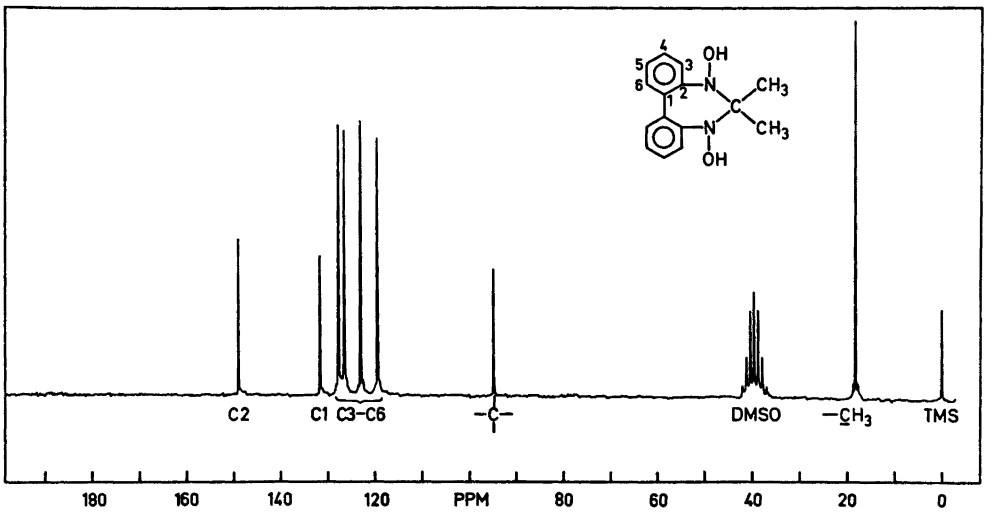


Fig. 1. ^{13}C NMR spectrum of 6,6-dimethyl-5,7-dihydroxy-6,7-dihydrodibenzo[*d,f*][1,3]diazepine IIIf in DMSO-d_6.

practice differ from 2:2:2:2:2:2:1:2 because of differences in the nuclear Overhauser effect which tend to give lines from nuclei bound to hydrogen an enhanced intensity.[14]

By considering likely substituent effects on chemical shifts[15] the interpretation of the spectrum is straightforward. The line at lowest field occurs in the region observed for C1 in aniline and is attributed to C2 bearing the hydroxylamine function. The next line upfield (C1) is due to the quaternary biphenyl carbon, and the group of 4 lines (C4-C6, C5 and C3, respectively) correspond to the remaining biphenyl carbons attached to protons and these carbon signals show an increased intensity relative to C1 and C2. The next upfield signal originates from the quaternary aliphatic carbon, showing more than half of the intensity of C1, and the last and most intense line corresponds to the methyl carbons.

Open structures and a 6-ring (with oxygen in the ring) are not symmetric and thus could not give a simple 8 line spectrum. Symmetry arguments, however, could not distinguish between a 7- and a 9-membered ring, but the 9-ring is highly improbable both because of the presence of absorption lines attributed to the NOH function in the ^1H NMR and IR spectra (see below), and because the nitrogen atom in hydroxylamines is known to be the nucleophilic centre in similar additions to carbonyl compounds. Furthermore IIIf is easily acetylated at the NOH groups (see below and experimental).

IR, ^1H NMR and UV-spectra. Cyclic and acyclic *N,N'*-dihydroxyamines have been studied by Zinner and Kliegel[16] and their spectroscopic data are similar to those found for the derivatives under study here thus confirming the presence of the NOH functions. The IR-spectra (Table 2) of nearly all the *N,N'*-dihydroxydiazepines IIId–IIIo show a strong absorption due to OH in the range 3230–3280 cm^{-1} in all cases with nearly the same intensity. An absorption with exactly the same shape and intensity was found at 3240 cm^{-1} for the known 1,3-dihydroxy-2-phenyl-4,4,5,5-tetramethylimidazoline.[17]

The ^1H NMR spectra (Table 2) of the diazepines IIId–IIIo showed the same pattern as found previously.[5] However, for the dimethylated derivative (IIIn) two NOH signals were observed at room temperature which coalesced on heating above *ca.* 80 °C.

All of the diazepines show UV absorption at 231–239 nm (Table 2) which is characteristic of benzene rings. For the aldehyde derivatives with unsubstituted benzene rings (IIId, IIIe, and IIIl and IIIm) the long wavelength absorption falls within the range 291–296 nm.

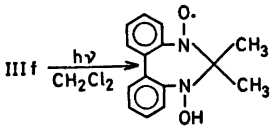
[a] sh, shoulder. [b] s, singlet; d, doublet; t, triplet; q, quartet; and m, multiplet.

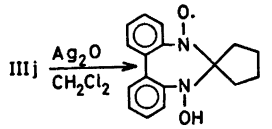
For the ketone derivatives (IIIf–IIIi) this absorption is in the range 285–290 nm, the cyclohexanone derivative being an exception. When the benzene rings are substituted (IIIn and IIIo) a hypsochromic shift to 279 nm is observed.

The spectral observations for V (Table 2) are also in good accord with the proposed structure, which is further supported by its mass spectrum (M^+: m/e 210) in which a large peak at m/e = 193 due to the $M^+ - OH$ ion is present together with the benzo[*c*]cinnoline ion (m/e 180) and the expected [1] peaks at m/e 166 and 167.

ESR-spectroscopy. It was originally reported [5] that oxidation of the bishydroxylamines IIIb and IIIc gave a mixture of relatively stable radicals. When IIIf was irradiated at room temperature with UV light in methylene chloride solution in the cavity of an ESR-spectrometer, strong signals appeared com-

prising a triplet with $a_N = 14.2$ G which compares well with $a_N = 14.0$ for the *t*-butyl-*o*-tolyl nitroxide radical.[18] The radical was quite stable and the ESR spectrum contained no hyperfine splitting, facts which are consistent with the postulation of the nitroxide:





Similarly oxidation of the spiro cyclopentane derivative IIIj either with lead dioxide in benzene on with silver oxide in methylene chloride yielded the corresponding nitroxide with a characteristic triplet in the ESR spectrum ($a_N = 13.7$ G). The use of other reagents such as alkaline DMSO [19] for oxidation of the bishydroxylamines III gave in most cases radicals or mixtures of radicals showing rather complex (often time-dependent) unsymmetrical ESR-signals. The spectra have not yet been assigned fully but the line pattern did not vary with the 6-substituent. The possibility of stabilizing the radicals by appropriate substitution in the biphenyl rings is currently under investigation.

Chemical reactions. The compounds have been formulated as cyclic secondary bishydroxylamines and their thermal and chemical stability has been found to depend strongly on the nature of substituents in the 6-position. Thus a pure sample of the unsubstituted derivative IIIa has not been obtained and the aliphatic aldehyde derivatives are relatively unstable and difficult to handle especially when impure.

The heteroaromatic aldehyde products and the ketone derivatives are relatively stable and a preliminary exploration of their chemistry has been attempted. From the ESR-work described above it is known that all of the derivatives can be easily oxidized chemically, but the products have not yet been isolated and identified. The compounds are also electroreducible (see above) although the electrode reaction has not been investigated.

The aldehyde derivatives would be expected to undergo dehydration under suitable conditions, but so far our attempts have been unsuccessful, and the parent compound V has been obtained indirectly in a side reaction as mentioned above.

Acylation of the acetone product IIIf by treatment with an excess of acetic anhydride gave the bis-acetylated derivative VI in 80 % yield. Product VI was also obtained by reaction with one equivalent of acetic anhydride, and contained none of the monoacetyl derivative. This correlates well with the findings of Zinner and Wilwing [20] who recently acylated a series of 1,3-dihydroxy-4,4,5,5-tetramethylimidazolines. Attempted acetylation of the aliphatic aldehyde products under the same conditions failed, and only black tars were obtained.

EXPERIMENTAL

Apparatus. The electrochemical and MS euipment has been described.[21,1] Microanalyses were carried out at the Microanalytical Laboratory of the University of Copenhagen by Mr. P. Hansen and by Dr. A. Bernhardt, Mülheim/Ruhr, BRD. Melting points (uncorrected) were determined on a Büchi melting point apparatus. IR-spectra were recorded using a Perkin-Elmer Model 137 or Model 457 spectrophotometer and UV-spectra were recorded using a Beckman Acta III spectrophotometer. ^{1}H NMR spectra were recorded using a JEOL C-60 HL or a Varian A-60 NMR spectrometer. The FT ^{13}C NMR spectrum of IIIg was measured at Varian Ass., Zug, Switzerland, using a Varian XL-100 NMR spectrometer. ESR-spectra were recorded using a Varian E-3 EPR spectrometer. Unit cell constants for IIIf were determined using a Picker four-circle diffractometer.

Materials. 2,2′-Dinitrobiphenyl (Ia) was obtained from Aldrich Chemical Company, Inc. and used without further purification and 6,6′-dimethyl-2,2′-dinitrobiphenyl (Ib) was prepared by Lothop's method.[22]

The aldehydes and ketones were obtained commercially and were mostly used without further purification. The preparation of the heteroaromatic aldehydes has been described [11,23] and 5-nitro-2-furanaldehyde was prepared from the diacetate.[24]

Preparative scale electro-reduction; general procedure. A conventional H-type cell of about 175 ml catholyte volume was used immersed

in a water bath and the cathode potential was controlled using a Juul Electronic potentiostat. Usually a suspension of 1.0 or 2.0 g of Ia (or Ib) in an acetate buffer mixture (A, B, or C, see below) was reduced at room temperature at potentials more positive than −0.8 V *vs.* Ag/AgCl with consumption of approximately 8 F/mol. Nitrogen was bubbled slowly through the catholyte, the middle compartment of the cell was filled with saturated aqueous potassium chloride, and the anolyte was 1:1 (approx.) ethanol (resp. methanol or DMF) – water saturated with sodium chloride. An excess (usually 5 ml or 5 g) of the carbonyl compound was added either before or after the electrolysis which was normally of 1 – 2 days duration. The catholyte was kept under nitrogen for further 1 – 7 days to allow completion of the cyclization reaction. Three different aqueous solvent mixtures were used:

A: 60 % EtOH, 0.2 M acetic acid, 0.4 M potassium acetate
B: 80 % MeOH } 15 g sodium acetate +
C: 50 % DMF } 5 ml acetic acid/200 ml

For electrolyses involving greater amounts of starting material additional acetic acid was added during the reduction. The products from the aliphatic aldehydes were usually soluble in the reaction mixture whereas those from the ketone and heteroaromatic aldehydes were partially precipitated. The catholyte was diluted with 1 – 2 volumes of water (except in the formaldehyde case) and cooled to −15 °C (except for C which was cooled to 0 °C). The precipitate was removed by filtration, washed with water, and dried under reduced pressure over silica gel. The filtrate was worked up by partial evaporation, neutralisation, and shaking with ether which led to the extraction of a small crop of usually impure product contaminated with IV. The extraction procedure (without prior dilution with water) was used in some of the early experiments but purer products (free from IV) are obtained by the precipitation method even though some material is lost with the filtrate. For the formaldehyde derivative IIIa, however, the extraction procedure is unavoidable, and in the final evaporation of the ethereal solution the temperature must be kept below 10 °C to avoid decomposition of the product which should then be kept in a refrigerator. Table 3 summarises microanalytical results, melting points and recrystallisation solvent.

Benzo[c]*cinnoline-N-oxide (IV).* Ia (1.0 g) was reduced as described above (solvent B), and after the electrolysis oxygen was bubbled through the catholyte (4 h). The methanol was

evaporated *in vacuo*, the precipitate filtered off, washed with water, and dried over silica gel giving 0.8 g of light yellow material m.p. 117–119 °C, identified as nearly pure IV by comparing its IR and ^{1}HNMR spectrum with those of an authentic specimen.

5-Hydroxydibenzo[d,f][*1,3*]*diazepine (V).* Ia (1.0 g) was reduced in the presence of benzyl methyl ketone (3.0 ml, solvent B) as described above and kept at room temperature under nitrogen for totally 4 days. The clear yellowish catholyte was partially evaporated *in vacuo*, neutralized by addition of solid sodium hydrogencarbonate, and extracted twice by ether (100 ml + 50 ml). Removal of the solvent after drying over magnesium sulphate left a semi-solid residue (1.4 g) which by recrystallisation (chloroform – petrol ether) gave 0.4 g of crude product, m.p. 153 – 5°d. TLC showed some IV to be present, and an analytically pure sample (0.12 g, bright yellow needles, m.p. 186 – 8°d) was obtained by recrystallizing 0.32 g of the crude product twice from benzene.

Catalytic reductions

6,6-Dimethyl-5,7-dihydroxy-6,7-dihydrodibenzo[d,f][*1,3*]*diazepine (IIIf).* A mixture of 2,2′-dinitrobiphenyl (Ia), (5.0 g), 50 ml of acetone, 100 ml of aqueous acetate buffer (0.5 M acetic acid, 1.0 M potassium acetate) and 0.5 g of 10 % palladium on barium sulfate were shaken for 20 h with hydrogen (1.05 atm) at room temperature. Subsequent addition of 100 ml of water to this suspension and filtration gave 4.5 g of a mixture of IIIf and the catalyst, *i.e.* the yield of IIIf was 4.0 g (76 %). Recrystallization from benzene (1.5 l) gave white needles (3.64 g), m.p. 231 – 232 °C, d.

5,7-Dihydroxy-6,7-dihydrodibenzo[d,f][*1,3*]*diazepine-6-spirocyclopentane (IIIj).* Cyclopentanone (10 ml) and ethanol (50 ml) were hydrogenated as above. Similar work-up gave grey crystals (4.05 g) corresponding to 3.55 g (61 %) of crude IIIj. Recrystallization of this material from benzene (1.4 l) yielded white crystals (0.91 g, 16 %), m.p. 178 – 180 °C, d. Concentration of the mother liquor yielded additional impure material (0.6 g). Recrystallization of the first crop gave analytically pure IIIj m.p. 202 – 204 °C, d.

Acetylation

6,6-Dimethyl-5,7-diacetoxydibenzo[d,f][*1,3*]*diazepine (VI).* IIIf (0.15 g) was stirred for 1 h at 50° with a mixture of acetic anhydride (15 ml) and one drop of pyridine. Concentration under reduced pressure and washing with pentane yielded pale grey crystals of VI (0.16 g, 80 %) m.p. 128 – 130 °C. Recrystallization of a sample from methanol gave VI as white crystals, m.p. 140 – 141 °C, d. IR (KBr): Strong absorption at 1775 cm^{-1} (ester C=O). UV (abs. ethanol): λ 288 (sh, log ε 2.26), λ 254 (sh, log ε 3.94) and λ_{max} 231 (log ε 4.37). NMR (DMSO-d_6): τ 8.51 (s, 6 H, CH_3), τ 8,00 (s, 6 H, $OCOCH_3$) and τ 2.70 – 2.45 (m, 8 H, aryl H).

Acknowledgement. Thanks are due to Dr. F. W. Wehrli, Varian AG, Zug, Switzerland, for recording the FT ^{13}C NMR spectrum of compound IIIg and mag.scient. H. J. Jakobsen, Department of Organic Chemistry, University of Aarhus, for assistance with the interpretation, Cand. polyt. R. Grønbæk Hazell and cand. scient. M. S. Lehmann, Department of Inorganic Chemistry, University of Aarhus, are thanked for assistance with X-ray analysis, and cand. scient. T. Ellebæk Petersen, Institute of Molecular Biology, University of Aarhus, for recording the ESR-spectra. The assistance of Dr. J. H. P. Utley, Queen Mary College, London, with correction of the manuscript is gratefully acknowledged.

Diels-Alder Reactions of 2,4-Cyclohexadienones.* II.** Stereoselectivity in the Dimerisation of *o*-Quinols

ERICH ADLER and KRISTER HOLMBERG

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, S-402 20 Göteborg 5, Sweden

Chemical evidence is presented for the steric arrangement at carbon atoms 5 and 9 of *o*-quinol dimers.

Formation of the phenolic compounds *9*—*11* on treatment of the diacetates of dimers *1*—*3* with ethanolic potassium hydroxide is interpreted as being due to an E2 elimination of acetic acid requiring *trans*-position of the acetoxy group at C-5 with regard to the hydrogen atom at C-4a.

Furthermore, it is shown that the C-9, C-10 ketol bridge in dimers *1*—*3* is cleaved by periodate, whereas dimers *4* and *5* are stable towards the same oxidant. Considering the accepted mechanism of ketol cleavage by periodate, these results indicate that the hydroxyl group at C-9 is oriented as shown in formulae *1*—*5*.

The structural interpretations given in this paper are in harmony with the structures of dimers *1*, *2* and *4* earlier established by X-ray crystallography.

Periodate oxidation of 2,6-,[4] 2,5-,[2] and 2,4-dimethylphenol [3] as well as of 2,4,6-trimethylphenol [4] results in the formation of the corresponding 6-hydroxy-6-methyl-2,4-cyclohexadienones ("*o*-quinols"), which rapidly dimerise by Diels-Alder reaction to give compounds *2*—*5*. The parent compound (*1*) [5] of these methyl homologous dimers has been obtained by acid hydrolysis of 6-acetoxy-6-methyl-2,4-cyclohexadienone which, in turn, was prepared by treatment of *o*-cresol with lead tetraacetate. In each case, only one of several possible isomers with different structural and steric orientation has been detected, indicating that these Diels-Alder dimerisations are regiospecific and stereospecific or at least highly selective in both respects.

As reported in the preceding paper,[2] the structure of the parent dimer (*1*) was established by the finding that it is reduced by Raney nickel to a product which is also obtained from a dibromo derivative (*1*, CH_2Br instead of CH_3),[6] the structure of which had been determined by X-ray analysis.[7] After completion of the work described in the present paper (*cf.* also preliminary communication [1]), X-ray analyses of dimers *2* and *4* were reported; they showed these dimers to be analogous to *1* with regard to both structural orientation and the steric arrangement of the *tert.* carbinol groups (C-5 and C-9).[8]

Although it seemed rather likely that the *o*-quinol dimers obtained from 2,5-dimethylphenol and 2,4,6-trimethylphenol, *i.e.* dimers *3* and *5*, would have the same structural and steric characteristics as dimers *1*, *2* and *4*, experimental confirmation was desirable. The structural orientation of the diene and dienophile moieties in dimer *5* has been clarified earlier from its NMR spectrum.[1,2] Furthermore, this orientation as well as *endo* configuration of *5* has been established by photochemically induced intramolecular cycloaddition.[9] In the present paper, chemical evidence regarding the stereochemistry of C-atoms 5 and 9 in the *o*-quinol dimers will be presented.

Steric arrangement at C-5. — In previous work [4] it was shown that the diacetates *6* and *7* of *o*-quinol dimers *1* and *2* on treatment with ethanolic potassium hydroxide give the phenolic

compounds *9* and *10* in addition to the non-acetylated dimers. Similarly, phenol *11* has now been obtained from the diacetate *8* [2] of dimer *3*.

Kende and MacGregor [10] found that the fluorine-containing analogue of dimer *2* (F instead of OH), when treated with KOH-C_2H_5OH, is converted into the fluorine analogue of phenol *10* (F instead of the *tert.* OH). Assuming this reaction to be due to E2 elimination of hydrogen fluoride from the unbridged ring, these authors concluded that the fluorine atom at C-5 is in a position *trans* to the hydrogen atom at C-4a, the favourable *anti* coplanar orientation of the leaving groups then being easily attained.

By analogy, the formation of phenols *9*–*11* from diacetates *6*–*8* suggested that OAc at C-5 is in a position *trans* to H at C-4a, favouring E2 elimination of HOAc * with concomitant aromatisation of the unbridged ring. For the *endo* forms of the corresponding non-acetylated dimers *1*–*3* the steric arrangement at C-5 then could be assumed to be as shown in the formulae given above. As mentioned earlier, this steric orientation as well as *endo* configuration has been finally established for dimers *1* [2,6,7] and *2* [8] by X-ray diffraction.

The base-catalysed elimination of acetic from the unbridged ring of diacetates *6*–*8* may be assumed to be preceded by proton abstraction from C-8a, aromatisation of the resulting enol constituting a driving force for the elimination (*cf.* also Ref. 10). The latter reaction then competes successfully with the hydrolysis of the C-5 acetoxy group.

In the diacetates of dimers *4* and *5*, however, enolisation and aromatisation of the unbridged ring are prevented by the methyl substituent at C-8a. Treatment of these diacetates with KOH-C_2H_5OH simply produces the corresponding dialcohols, no elimination of acetic acid being observed.[3,4]

Steric arrangement at C-9. In the periodate treatment of 2,6- [4] and 2,4-dimethylphenol [3] as well as of 2,4,6-trimethylphenol [4] both the formation of the *o*-quinols and their Diels-Alder dimerisation are fast reactions, consumption of the starting phenols and formation of dimers *2*, *4*, and *5* being complete after reaction times of a few minutes. These dimers contain two ketol groupings and therefore could be expected to consume further periodate undergoing ketol cleavage. In fact, prolonged treatment of 2,6-dimethylphenol with excess sodium metaperiodate or periodic acid produced a monocarboxylic acid (*13*).

Oxidation of 2,5-dimethylphenol with sodium periodate proceeds more slowly than that of the above-mentioned phenols, unchanged starting material still being detectable after reaction times of 1–2 h. From the reaction mixtures, dimer *3* as well as its cleavage product (*14*) was isolated. The latter was also obtained on oxidation of 2,5-dimethylphenol with periodic acid.

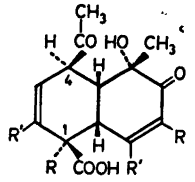
Acids *13* and *14* also formed when the isolated dimers *2* and *3*, respectively, were oxidised with periodate. Similar oxidation of dimer *1* [5] provided acid *12*.

Periodate as well as periodic acid thus cleaved only one of the two ketol groupings

* This view is supported by results discussed in a recent monograph according to which the *anti* mechanism is greatly preferred to the *syn* mechanism for E2 reactions in six-membered rings (Saunders, Jr., W. H. and Cockerill, A. F. *Mechanism of Elimination Reactions*, Wiley, New York 1973).

present in dimers *1–3*. The resulting monocarboxylic acids remained unchanged even on several hours' treatment with these oxidants.

Assignment of structures *12–14* is based on spectroscopic evidence. The UV spectra



12 R=R'=H
13 R=CH_3; R'=H
14 R'=CH_3; R=H

of *o*-quinol dimers *1–5* in ethanol exhibit a high intensity band with λ_{max} around 210 nm (ε about 10 000),[4] which can be ascribed to charge transfer within the β,γ-unsaturated carbonyl system (2,3-ethylenic bond and C-10 carbonyl group) in the photoexcited state[11] ("photodesmotic band"[12]); *cf.* also Ref. 6. They further show a comparatively strong absorption band around 310 nm (ε=150–330) involving the $n \rightarrow \pi^*$ absorption of the α,β-unsaturated carbonyl system as well as the characteristically intensified $n \rightarrow \pi^*$ absorption of the β,γ-unsaturated carbonyl system. In the spectra of acids *12–14*, however, the photodesmotic band is lacking, and the $n \rightarrow \pi^*$ bands (λ_{max} 328 nm) due to the α,β-unsaturated carbonyl grouping are of normal intensity (ε=83, 83, and 100 for *12*, *13*, and *14*, respectively). The $\pi \rightarrow \pi^*$ absorptions of the latter chromophores in acids *12–14* are very similar to those reported[4] for the corresponding dimers *1–3*, their locations being in harmony with the predicted[13] ones. Finally, the $n \rightarrow \pi^*$ absorption of the CO group at C-9 in *12–14* is partially overlapped by the $\pi \rightarrow \pi^*$ and the $n \rightarrow \pi^*$ bands of the conjugated carbonyl system and gives rise to shoulders at λ_{max} 280, 285, and 295 nm for *12*, *13*, and *14*, respectively.

The UV spectra of the methyl esters prepared from acids *12–14* were closely similar to those of the free acids.

Thus, UV spectroscopy clearly indicated that of the two ketol groupings present in dimers *1–3* the 9,10-ketol bridge was cleaved specifically. This finding is corroborated by the following IR spectroscopic data (Table 1).

Cleavage of the 9,10-ketol bridge in dimers *1–3* gives rise to a non-conjugated carboxylic acid containing an unconjugated keto group as well as the conjugated carbonyl group initially present. Cleavage of the 5,6-hydroxyketone grouping, however, would produce an α,β-unsaturated carboxylic acid containing two non-conjugated keto groups. The locations of the lowest frequency bands of the acids and their methyl esters (Table 1) agree with those expected for α,β-unsaturated keto groups (*cf.* the corresponding bands for dimers *1–3*) but are below the range typical of α,β-unsaturated COOH (1690–1715 cm^{-1})[14] and far below the range accepted for α,β-unsaturated esters (1717–1730 cm^{-1}),[14] respectively.

Contrary to dimers *1–3*, dimers *4* and *5* proved to be stable towards periodate. The presence of a methyl substituent at C-8a in

Table 1. Infrared absorption bands (cm^{-1}, KBr) of *o*-quinol dimers *1–3*, carboxylic acids *12–14* and methyl esters *12a–14a*.

Substance	CO (C-10)	CO (at C-4)	COOH	$COOCH_3$	α,β-unsaturated CO
Dimer *1*	1723				1679

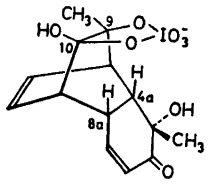
Acid *14*		1728	1710		1640
Ester *14a*		1720		1730	1663

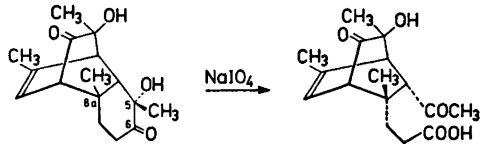
the two latter dimers suggests the following explanation for this striking difference in the behaviour of the two groups of dimers.



15

According to Bunton and Shiner,[15] periodate cleavage of α-hydroxy ketones is initiated by nucleophilic attack of periodate oxygen upon the carbonyl group, probably accompanied by co-ordination of the α-hydroxyl group to the periodate, resulting in the formation of a cyclic periodate ester intermediate.[16] Since the stereochemistry of the C-9 carbinol group is established for dimers *1* [2] and *2* [3] (see formulae), and formation of the cyclic intermediate requires approach from the side of the C-9 hydroxyl group, the structure of this intermediate will be as illustrated by formula *15*.

The resistance to periodate of dimers *4* and *5* then suggested that these dimers have the same steric arrangement at C-9 as dimer *1*, the C-9 hydroxyl group being directed towards the C-4a, C-8a linkage.[1] With this arrangement it is easily understood that the methyl group at C-8a in *4* and *5* by steric hindrance prevents the periodate to approach the ketol bridge and to form intermediates of type *15*.* As mentioned earlier, this configuration of C-9 has been confirmed in the case of dimer *4* by X-ray analysis.[8]



16 *17*

* If the configuration of C-9 would be opposite to that given in formulae *1*–*5*, periodate cleavage would be possible for all dimers. Inspection of Dreiding models indicates that, in this case, the C-10 hydroxyl group of the cyclic intermediate corresponding to *15* would not sterically interfere with the C-8a methyl group.

The fact that neither the α,β-conjugated ketol group of the *o*-quinol dimers *1*–*5* nor that present in acids *12*–*14* is cleaved by periodate may be explained by the assumption that in the conjugated system the carbonyl C-atom (C-6) is not sufficiently electropositive to be susceptible to attack by periodate oxygen. Steric hindrance could also be considered at least in the case of the rather rigid dimers but seems less probable in the acids *12*–*14*. The importance of the α,β-conjugation is strongly supported by the finding that the 7,8-dihydro derivative *16* [3] of dimer *4* on treatment with periodate suffers ketol cleavage between C-5 and C-6 to yield monocarboxylic acid *17*. Again, the methyl group at C-8a prevented the 9,10 ketol bridge from being affected.

Conclusions

The results presented above provide chemical evidence for the steric arrangement at carbon atom 5 of *o*-quinol dimers *1*–*3* as well as at carbon atom 9 of *o*-quinol dimers *4* and *5*. These assignments are in agreement with the completely established structures of dimers *1*, *2* and *4*.[2,8] It then seems justified to assume that the steric arrangements at C-9 and C-5 of dimers *3* and *5*, respectively, for which there is no direct experimental proof, are analogous to those found in dimers *1*, *2*, and *4*.

In all cases, therefore, the stereochemical orientation at C-5 and C-9 is the same and is certainly due to steric approach control in the dimerisation of the *o*-quinols, the bulky methyl groups being directed away from the reaction center. The same principle holds true for the formation of dimers from other 2,4-cyclohexadienones containing an asymmetric C-atom in the 6-position. Thus, in the Diels-Alder dimers of spiro(oxirane-2,4-cyclohexadienones)[6,3] the CH_2-O groupings of the oxirane rings at C-5 and C-9 have been shown to be oriented analogously to the CH_3,OH substituents at the same C-atoms of the *o*-quinol dimers. Furthermore, dimerisation of the parent *o*-quinol acetate, 6-acetoxy-6-methyl-2,4-cyclohexadienone, and that of its 2-methyl homologue are known to give the diacetates (*6* and *7*) of compounds *1* and *2*, the latter compounds being the dimerisation products of the corresponding non-acetylated *o*-quinols.[5,4] Finally, in the halogen containing dimers described by Kende and MacGregor [10] (*2*, F instead of OH) and by Lindgren and Ericsson [17] (*2*, Cl instead

of OH) at least the arrangement at C-5 has been shown to be analogous to that now established for the *o*-quinol dimers.

From the results discussed in the preceding [2] as well as in the present paper it can be concluded that the Diels-Alder dimerisation of the 2,4-cyclohexadienones hitherto examined proceeds in a uniform fashion with regard to both regiospecificity and stereochemical specificity.

EXPERIMENTAL

UV spectra were recorded on a Cary Model 14 Spectrophotometer; IR and NMR spectra were obtained using Beckman 9A and Varian A-60 instruments, respectively. Chemical shifts are given in δ (ppm) units, TMS being used as internal standard.

1,4-Dihydro-6,9-dihydroxy-2,5,8,9-tetramethyl-[1,4]ethanonaphthalen-10-one (11).* The diacetate *8* [2] of *o*-quinol dimer *3* [2] (765 mg) was added to a 10 % solution of KOH in ethanol (25 ml), and the mixture was kept under nitrogen for 16 h. Ethanol was removed under vacuum, water being repeatedly added during the distillation. The alkaline aqueous mixture was extracted three times with dichloromethane; the extract gave dimer *3* [2] (13 %). When the aqueous phase was neutralised with CO_2, a crystalline product deposited, m.p. 201–202° after recrystallisation from ethanol; yield, 69 %. (Found: C 74.55; H 7.08. Calc. for $C_{16}H_{18}O_3$: C 74.40; H 7.02). UV spectrum (ethanol): λ_{max}, nm (log ε) 208 (4.37) (charge transfer band of β,γ-unsaturated CO system), 280 (3.25), 288 (3.25) (aromatic ring), 314 (2.91) (intensified $n \rightarrow \pi^*$ absorption of β,γ-unsaturated CO system). IR (KBr): ν_{max}, cm^{-1} 1513, 1600, 1616 (aromatic ring), 1715 (CO), 3425, 3356 (OH).

Monoacetate 11a* was obtained with acetic anhydride-pyridine. M.p. 153–154° (ethanol-water). (Found: C 71.84; H 6.65; CH_3CO 13.96. Calc. for $C_{18}H_{20}O_4$: C 71.98; H 6.71; CH_3CO 14.33).

Diacetate 11b* was prepared using Ac_2O-$HClO_4$ in ethyl acetate.[18] M.p. 134–135° (ethanol-water). (Found: C 70.02; H 6.38. Calc. for $C_{20}H_{22}O_5$: C 69.98; H 6.39).

4-Acetyl-1,4,4a,5,6,8a-hexahydro-5-hydroxy-5-methyl-6-oxo-1-naphthalenecarboxylic acid (12).** The solution of *o*-quinol dimer *1* [5] (200 mg) in acetic acid (25 ml) was mixed with a solution of sodium metaperiodate (0.75 g) in 60 % aqueous acetic acid (25 ml). After 2 h (room temp.) a few drops of ethylene glycol were added to reduce excess periodate, the solvent was removed under vacuum and the residue extracted with dichloromethane. From the extract acid *12*, m.p. 174–175° after recrystallisation from chloroform-hexane, was obtained. (Found: C 63.95; H 6.19. Calc. for $C_{14}H_{16}O_5$: C 63.63; H 6.10). UV (ethanol): λ_{max}, nm (log ε) 224 (4.01), sh 280 (2.08), 328 (1.92). IR (KBr): ν_{max}, cm^{-1}, see Table 1, and 2400–3300 (COOH), 3510 (OH). NMR (DMSO-d_6): δ 1.30 (s, 3 H, CH_3), 2.10 (s, 3 H, CH_3CO), 2.88 (2 H, 2 CH), 3.41 (2 H, 2 CH), 5.21 (broad s, 1 H, OH), 5.51, 5.92, 5.94 and 6.73 (doublets, 1 H each, 4 olefinic H).

Methyl ester 12a. Prepared by adding an ethereal solution of diazomethane to a methanolic solution of *12*. M.p. 142–143° (benzene-hexane). (Found: C 65.0; H 6.7. Calc. for $C_{15}H_{18}O_5$: C 64.7; H 6.5). UV (ethanol): λ_{max}, nm (log ε) 224 (3.99), sh 280 (2.05), 326 (1.92). IR (KBr): ν_{max}, cm^{-1}, see Table 1, and 1622 (C=C), 3480 (OH). NMR spectrum ($CDCl_3$) resembles that of acid *12*, but shows an additional signal at δ 3.79 (s, 3 H, ester-CH_3).

4-Acetyl-1,4,4a,5,6,8a-hexahydro-5-hydroxy-1,5,7-trimethyl-6-oxo-1-naphthalenecarboxylic acid (13). An aqueous solution (100 ml) of periodic acid (H_5IO_6, 41 g, 180 mmol) was added to a solution of 2,6-dimethylphenol (9.15 g, 75 mmol) in water (2250 ml). After 2 h (25°) ethylene glycol (7 g) was added and the solution extracted with six 250 ml portions of chloroform. The combined organic phases were washed with aqueous sodium thiosulphate, dried over anhydrous sodium sulphate and evaporated to dryness. The remaining oil on addition of ethyl ether (10 ml) gave colourless crystals (yield, 54 %, m.p. 180–182°) which after recrystallisation from ethanol melted at 183–184°. (Found: C 65.51, H 6.97; equiv. wt. 294. Calc. for $C_{16}H_{20}O_5$: C 65.74; H 6.90; equiv. wt. 292). UV (ethanol): λ_{max}, nm (log ε) 240 (3.87), sh 285 (2.11), 328 (1.92). IR (KBr): ν_{max}, cm^{-1}, see Table 1, and 1630 (C=C), 2300–3300 (COOH), 3410 and 3500 (OH). NMR (DMSO-d_6): δ 1.30 and 1.46 (singlets, 3 H each, 2 CH_3), 1.76 (t, 3 H, olefinic CH_3), 2.10 (s, 3 H, CH_3CO), 2.86 (broad s, 2 H, 2 CH), 3.30 (broad s, 1 H, CH), 5.12 (s, 1 H, OH), 5.50 and 5.74 (doublets, 1 H each, 2 olefinic H), 6.73 (broad s, 1 H, olefinic CH).

Methyl ester 13a. From *13* and diazomethane. After recrystallisation from benzene-hexane, m.p. 88–89°. (Found: C 66.68; H 7.29. Calc. for $C_{17}H_{22}O_5$: C 66.64; H 7.23.) UV (ethanol): λ_{max}, nm (log ε) 238 (3.87), sh 285 (2.07), 327 (1.93). IR (KBr): ν_{max}, cm^{-1}, see Table 1, and 1630 (C=C), 3462 (OH). NMR spectrum ($CDCl_3$) resembles that of acid *13*, but shows an additional signal at δ 3.75 (s, 3 H, ester-CH_3).

4-Acetyl-1,4,4a,5,6,8a-hexahydro-5-hydroxy-2,5,8-trimethyl-6-oxo-1-naphthalenecarboxylic acid (14). The acid was obtained from 2,5-dimethylphenol and periodic acid, using the procedure described above for acid *13*. Yield, 32 %, m.p. 205–206°. (Found: C 65.65; H 7.01. Equiv. wt. 294. Calc. for $C_{16}H_{20}O_5$: C 65.74; H 6.90. Equiv. wt. 292). UV (ethanol): λ_{max},

nm (log ε) 237 (3.94), sh 295 (2.11), 328 (2.00). IR (KBr): ν_{max}, cm^{-1}, see Table 1, and 1610 (C=C), 2400–3300 (COOH), 3485 (OH). NMR (DMSO-d_6): δ 1.27 (s, 3 H, CH_3), 1.89 (s, 6 H, 2 olefinic CH_3), 2.09 (s, 3 H, CH_3CO), 2.92 and 3.37 (singlets, 2 H each, 4 CH), 5.06 (s, 1 H, OH), 5.35 and 5.84 (broad singlets, 1 H each, 2 olefinic H).

Methyl ester 14a. From *14* and diazomethane, m.p. 135–136° (benzene-hexane). (Found: C 66.44; H 7.25. Calc. for $C_{17}H_{22}O_5$: C 66.64; H 7.23). UV (ethanol): λ_{max}, nm (log ε) 236 (4.01), sh 287 (2.12), 320 (200). IR (KBr): ν_{max}, cm^{-1}, see Table 1, and 1620 (C=C), 3440 (OH). NMR spectrum ($CDCl_3$) resembles that of acid *14*, but shows an additional signal at δ 3.78 (s, 3 H, ester-CH_3).

Periodate oxidation of dimers 2 *and* 3. The dimers, dissolved in ethanol-water (2:3), were treated with a 2.5-fold excess of $NaIO_4$ for 16 h at room temperature. Chloroform extraction gave the almost pure acids *13* and *14* in yields of 66 and 62 %, respectively, identified by m.p., mixed m.p. and IR spectra.

3-Acetyl-8-hydroxy-2,5-dimethyl-7-oxo-bicyclo-[2.2.2]oct-5-ene-2-propanoic acid (17). A solution of $NaIO_4$ (1.28 g, 6 mmol) in 60 % aqueous acetic acid (35 ml) was added to a solution of dihydrodimer *16*[3] (0.83 g, 3 mmol) in the same solvent (150 ml). Extraction with dichloromethane (four 100 ml portions) after a reaction time of 18 h (25°) provided a crystalline solid, which was recrystallised from ethyl acetate to give 75 % of *17*, m.p. 193.5–194.5°. (Found: C 65.23; H 7.58. Calc. for $C_{16}H_{22}O_5$: C 65.29; H 7.53). UV (ethanol): λ_{max}, nm (log ε) sh 210 (3.58) (β,γ-unsat. CO), 308 (2.39) (CO and β,γ-unsat. CO). IR (KBr): ν_{max}, cm^{-1} 1713 (CO and COOH), 2400–3300 (COOH), 3400 (OH). NMR (DMSO-d_6): δ 1.12 and 1.22 (singlets, 3 H each, 2 CH_3), 1.94 (d, 3 H, olefinic CH_3), 2.15 (s, 3 H, CH_3CO), 1.85–3.50 (7 H, 2 CH_2 and 3 CH), 5.47 (s, 1 H, OH), 5.64 (d, further split by allylic coupling, 1 H, olefinic H).

Preparation and Purification of Fructose-1,6-diphosphate

MATTI LEISOLA and MATTI LINKO

Department of Chemistry, Helsinki University of Technology, SF-02150 Otaniemi, Finland

Some investigations have been made concerning the accumulation of fructose-1,6-diphosphate (FDP) by yeasts. The concentration of glucose-6-phosphate and fructose-6-phosphate during fermentation has been determined. Optimum conditions for the precipitation of FDP have been determined and some of the impurities of Ca_2FDP have been analyzed. A new simple purification method is introduced.

Fructose-1,6-diphosphate (FDP) is a well-known intermediate of sugar metabolism. It is accumulated in a fermentation mixture of yeast, sugar, inorganic phosphate and toluene.[1,2] FDP is recovered from the solution usually as a Ca- or Ba-salt. Complete precipitation occurs when ethanol is added to the solution.[3] Crude salts contain many impurities derived from yeast and starting materials. FDP has been purified by acid and charcoal treatment [3,4] or by ion exchange.[5] The purity achieved by these methods has been 70 – 80 %. To obtain pure FDP it is usually converted to salts with organic bases.[6,7] The main aim of this work was to find optimum conditions for the precipitation of FDP and to develop a simple purification method.

MATERIAL AND METHODS

FDP was prepared by fermentation using fresh brewer's yeast, sucrose, NaH_2PO_4 and toluene. Optimum conditions for FDP accumulation were determined earlier [8] and were as follows: pH 6.6, temperature 30 °C, the amount of yeast (25 % dry matter) 500 g in 1000 g of reaction mixture, sucrose concentration 7 – 8 % (w/w), and concentration of $NaH_2PO_4.2H_2O$ 5 – 6 % (w/w). About 45 ml toluene in 1000 g of reaction mixture were needed for maximum FDP accumulation.

After fermentation the proteins were precipitated with 100 ml of 80 % trichloroacetic acid per 1000 g of reaction mixture. The mixture was centrifuged, neutralized and filtered. The concentration of FDP in the clear solution was 50 – 55 g/l. FDP was precipitated as a Ca-salt using 50 % (w/w) $CaCl_2$ solution. Final precipitation occurred when ethanol was added to the mixture. Ca_2FDP was filtered off from the mixture and washed with 70 % ethanol and subsequently with 94 % ethanol. The product was freeze-dried.

FDP was determined enzymatically according to the method of Bergmeyer.[9] Commercial $Na_3FDP.8H_2O$ (Boehringer Mannheim, GmbH) was used as standard. Inorganic and total phosphorus was determined by Allen's [10] method. Nitrogen content of the precipitated Ca_2FDP was determined by the Kjeldahl method with an ammonia specific electrode. A thermoanalyzer was used to determine the water content of Ca_2FDP. Fermentable sugars [11] and sugar phosphates [12] were separated by ion exchange and determined by an autoanalyzer [13] using the anthrone method. The flow sheet of the reverse-osmosis system used in the purification tests is presented in Fig. 1. Cellulose acetate membranes prepared according to van Oss [14] were used. The heat treatment of the membranes was accomplished by incubating the membranes in hot water for 4 min.

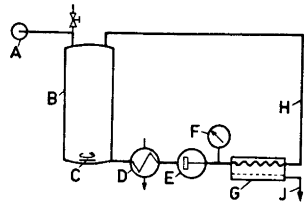

Fig. 1. The reverse osmosis system. A compressed nitrogen, B stirred tank, C magnetic stirrer, D heat exchanger, E pump, F manometer, G reverse osmosis unit, H concentrate and J permeate.

RESULTS

Only yeast that had been used in beer fermentation was able to accumulate FDP. Fresh unused brewer's yeast, fresh baker's yeast, *Rhodotorula glutinis*, and *Candida utilis* did not cause accumulation of FDP. The ability of the yeast to accumulate FDP depended on the length of time it had been used in beer fermentation. During ten days' fermentation the yeast's ability to produce FDP increased and reached its maximum level during the last few days. The conversion of sucrose to FDP was about 15 % when using yeast from the suspension in the fermentation tank and about 40 % with the yeast settled at the bottom of the tank. The yeast used in this work had passed 3 – 5 beer fermentations. When FDP was produced the end point of the fermentation was determined by measuring the concentration of inorganic phosphate in the reaction mixture (Fig. 2). The FDP-concentration of the mixture reached maximum with the lowest concentration of inorganic phosphate.

Glucose-6-phosphate (G-6-P) and fructose-6-phosphate (F-6-P) were also found in the fermentation mixture. Shortly before the end point of the fermentation their concentrations were quite high. During fermentation samples were taken from the reaction mixture as shown in Fig. 2 (black dots) for the determination of monophosphates (Fig. 3).

The precipitated Ca_2FDP was purest in the experiments with the highest initial sugar concentration (Table 1) and with an amount of

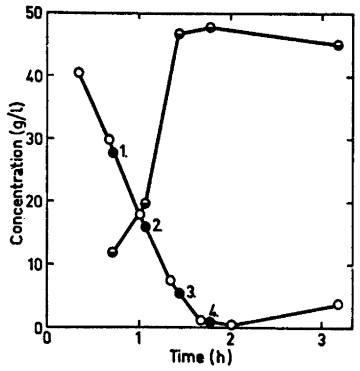

Fig. 2. The concentration of FDP (◒) and inorganic phosphate (calculated as $NaH_2PO_4 \cdot 2H_2O$) (○) in the reaction mixture during fermentation.

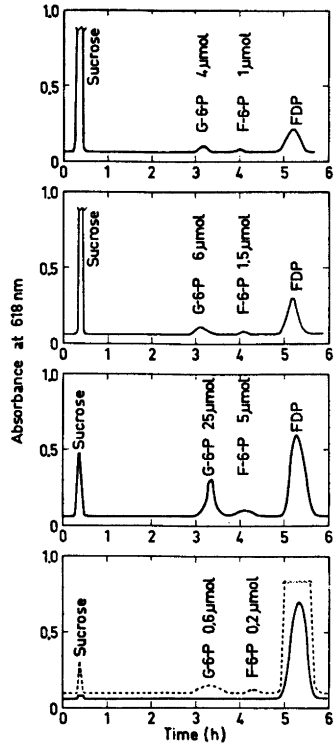

Fig. 3. The amount of G-6-P and F-6-P in the mixture during fermentation. The pictures from top to bottom refer to the sampling times 1, 2, 3, and 4 given in Fig. 2, in this order. Dilutions were 1:10 (—) and 1:1 (---).

Table 1. Dependence of purity of the precipitated Ca_2FDP on the initial sugar concentration.

Initial sugar conc. g/l	Conc. of FDP g/l	Purity of Ca_2FDP %	P_{inorg} %	N %
50	29	69	2.2	0.47
81	52	79	0.9	0.34

inorganic phosphate somewhat below the optimum. Inorganic phosphate precipitated as an impurity when FDP was recovered. Therefore it is advisable to stop the reaction when the concentration of inorganic phosphate is lowest.

FDP was recovered as a Ca-salt. Final precipitation occurred when ethanol was added. When the volume of ethanol used was equal to the volume of fermentation solution most of the

Table 2. Precipitation of FDP from 50 ml of fermentation solution with 5 ml of 50 % (w/w) $CaCl_2$ and ethanol. The concentration of FDP was 42.5 g/l.

Ethanol	Yield	Purity of Ca_2FDP	P_{inorg}	N
ml	g	%	%	%
–	2.2	65	1.19	0.41
40	4.9	58	0.41	0.45
50	4.8	63	0.48	0.46
70	4.9	64	0.60	0.44
100	4.4	64	0.78	0.47

Ca_2FDP precipitated (Table 2). Ca_2FDP precipitated instantly and could be filtered off immediately. The purity of Ca_2FDP, precipitated as mentioned above, was about 70 %. The water content of the product was 5 – 7 %, $Ca_3(PO_4)_2$ content 1 – 2 %, the amount of nitrogenous compounds (6.25N) 2 – 5 %, and the amount of monophosphates less than 1 %. The rest of the impurities were organic compounds.

The purification tests were aimed at finding a simple, preliminary method to purify the fermentation solution. Charcoal treatment, ion exchange, and ultrafiltration were tested. Best results were obtained when the solution was concentrated by reverse osmosis (Fig. 1). Because of the technical limitations of the system used the solutions were diluted with water before concentration. The results obtained with membranes heated at different temperatures are shown in Fig. 4.

The retention of FDP was at least 99 % with all these membranes. By diluting the fermentation solution before concentration a purer product was obtained. The purity was increased by washing the concentrate with water. Table 3 shows the effect of dilution of the fermentation solution and of washing of the concentrate on the purity of the precipitated Ca_2FDP.

By the above method 13 – 15 % of the impurities were removed. The purification did not affect inorganic phosphate or nitrogen content of Ca_2FDP. Most of the nitrogenous compounds and the colour of the product could be removed by treating the concentrate with charcoal. After this, there were still at least 5 % of unknown impurities in the product. Some of these could be removed by ion exchange. The composition of the purified product was as follows:

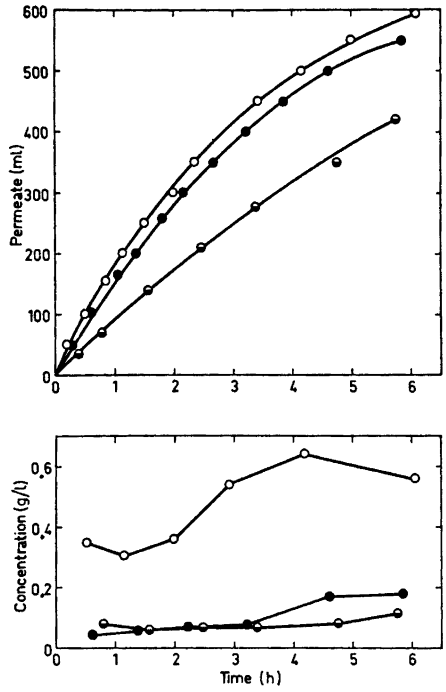

Fig. 4. Concentration of fermentation solution by reverse osmosis. Initial FDP-concentration and heat treatment of the membranes were 23 g/l, 66 °C (○); 18 g/l, 70 °C (●), and 23 g/l, 77 °C. (◒). The volume and FDP-concentration of the permeate is presented as a function of time.

Ca_2FDP	83 – 85 %
H_2O	6 – 7 %
$Ca_3(PO_4)_2$	1 – 2 %
6.25N	0.2 – 0.5 %
Monophosphates	1 %
	92 – 95 %

DISCUSSION

Obviously the membrane of the yeast has to be modified or partly destroyed to make the accumulation of FDP possible. The permeation characteristics of the membrane are changed by drying [15] or by plasmolytic agents, *e.g.* toluene. Addition of toluene is not always necessary when using dry yeast.[2] Some fresh baker's yeasts fail to cause any accumulation of FDP whilst others produce considerable amounts of this compound in the same procedure.[16] The membrane of the yeasts causing accumulation of FDP may be more sensitive to toluene or

Table 3. Purification of the fermentation solution with a cellulose acetate membrane (heat treatment 72 °C). The pressure was 2.9 MPa (30 kp/cm²) and the temperature 22 °C. Initial volume was 700 ml and final volume of the concentrate 200 ml.

Initial conc. g/l	Washing ml H_2O	Purity of Ca_2FDP %	P_{inorg} %	N %
50[a]	–	71	0.24	0.46
25	–	74	0.24	0.49
12	–	78	0.22	0.45
11	2 × 500	84	0.40	0.59

[a] Reference sample, not concentrated.

other plasmolytic agents. According to our experience even results obtained with a single yeast strain depend very much on the history of the yeast, *e.g.* its previous use in the brewing process. Many years ago Meyerhof [17] proved that the slow fermentation of FDP was caused by the destruction of the sensitive and structurally bound adenylpyrophosphatase, since adenosine triphosphate can be split only by means of this enzyme in the absence of a phosphate acceptor. However, this does not explain the considerable stimulation of the accumulation of FDP by an addition of a phosphate acceptor, *e.g.* adenosine monophosphate.[5] A similar stimulation has been found to occur with several purine compounds. Thus the detailed reasons for an efficient accumulation of FDP still seem to be somewhat unclear.

When optimum amounts of starting materials are used in the reaction mixture and the reaction is stopped at the right moment a purer product is obtained (75 %) than with earlier preparation methods. The use of maximum sugar concentration and somewhat less than an optimum amount of inorganic phosphate is important. The reaction should be stopped at the highest FDP concentration, since the amount of inorganic phosphate is lowest at this point and thus only a small amount of $Ca_3(PO_4)_2$ precipitates as an impurity with FDP. At the same time the concentration of monophosphates is also low. On the other hand, a slightly shorter reaction time might also offer a new possibility for preparation of G-6-P and F-6-P.

The purity of the product increases considerably when the fermentation solution is diluted and then concentrated by reverse osmosis before the precipitation of FDP. Washing of the concentrate with water increases the purity. Most of the unknown impurities are removed by this method. However, in some cases a considerable amount of FDP (0 – 50 %) disappeared during the concentration. The reason for this is not known; no FDP was found in the permeate.

Most of the unknown impurities of the purified Ca_2FDP were organic compounds. In X-ray diffraction analysis only phosphorus and calcium could be detected. Only traces of other elements ($\ll 1$ %) were present.

Reactions of Some *N*-Phenylcarbamates of Glycosides under Hydrolytic Conditions

LENNART KENNE, BENGT LINDBERG, ÅKE PILOTTI and SIGFRID SVENSSON

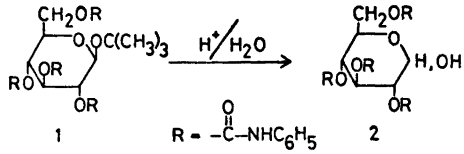
Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

Syntheses and acid hydrolysis studies of *N*-phenylcarbamates of some glycosides are reported. *tert*-Butyl 2,3,4,6-tetra-*O*-(*N*-phenylcarbamoyl)-β-D-glucopyranoside was easily hydrolysed, yielding 2,3,4,6-tetra-*O*-(*N*-phenylcarbamoyl)-D-glucose. The 2-*O*-(*N*-phenylcarbamoyl) derivatives of methyl-α-D-glucopyranoside and methyl β-D-mannopyranoside on hydrolysis reacted further, giving bicyclic oxazolidin-2-one derivatives. The glucose derivative yielded an α-furanosidic oxazolidin-2-one, the mannose derivative a mixture of β-furanosidic and β-pyranosidic oxazolidin-2-ones.

DISCUSSION

The condensation of *N*-phenylcarbamates of sugars to give oligo- and polysaccharides seemed, from the results reported by Husemann and Müller,[1] to be a promising method. Recent results by Eby and Schuerch,[2,3] however, indicate that the value of this approach is limited. We have obtained similar results and arrived at the same conclusion. We now report the syntheses of *N*-phenylcarbamates of some glycosides and their reactions under hydrolytic conditions.

Introduction of the slightly basic *N*-phenylcarbamate group into glycosides renders them more resistant to acid hydrolysis. Thus the methyl 2,3,6- and 2,3,4-tri-*O*-(*N*-phenylcarbamoyl)-α-D-glucopyranosides could not be hydrolysed.[3] Eby and Schuerch [2] prepared 2,3,4-tri-*O*-(*N*-phenylcarbamoyl)-D-glucose by hydrolysis of the corresponding 1,6-anhydro-D-glucopyranose derivative. We have now prepared 2,3,4,6-tetra-*O*-(*N*-phenylcarbamoyl)-D-glucose (*2*) by acid hydrolysis of the fully carbanilated *tert*-butyl β-D-glucopyranoside (*1*).



1 2

Methanolysis of *2* yielded a mixture of fully carbanilated methyl α- and β-D-glucopyranosides in the approximate proportion 2:3. The β-anomer predominated but the stereoselectivity of the reaction was not very high.

Although methyl tri- and tetra-*O*-(*N*-phenylcarbamoyl)-glucopyranosides are resistant to acid hydrolysis, the corresponding monoesterified products should be more labile. Methyl 2-*O*-(*N*-phenylcarbamoyl)-α-D-glucopyranoside (*3*) was therefore prepared by carbanilation of methyl 3-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside,[4] followed by mild acid hydrolysis. Under stronger hydrolytic conditions, the glucoside was hydrolysed but the product reacted further, yielding the bicyclic α-furanosidic oxazolidin-2-one derivative (*4*). A first order analysis of the NMR spectra of the acetate of *4*, using spin decoupling in order to identify the individual protons, was in agreement with the postulated structure (Table 1). The mass spectrum of the acetate also agreed with this structure. The

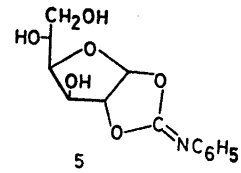
origin of the main fragment is indicated in Scheme 1.

The results of these analyses do not preclude the cyclic imidocarbonate (*5*) structure. Imidocarbonates are, however, easily hydrolysed whilst *4* is resistant to acid hydrolysis. The observed IR absorption at 1755 cm^{-1} also favours the oxazolidin-2-one structure. Substance *4* was recovered unchanged after treatment with methanolic hydrogen chloride.



5

Methyl 2-*O*-(*N*-phenylcarbamoyl)-β-D-mannopyranoside (*6*) was prepared by carbanilation of methyl 3-*O*-benzyl-4,6-*O*-benzylidene-β-D-mannopyranoside,[5] followed by catalytic hydrogenation. Acid hydrolysis of *6* yielded two products, identified by NMR, MS, and optical rotation of their acetates as the β-furanosidic (*7*) and β-pyranosidic (*8*) oxazolidin-2-one derivatives. The results of the NMR analyses are given in Table 1 and the pathways leading to the main fragments in the mass spectrum of *8* are indicated in Scheme 2. The mass spectrum of *7* was similar to that of *4*. From the spectrochemical analyses cyclic imidocarbonate structures cannot be precluded but are considered most unlikely.

On treatment of either *7* or *8* with strong acid in water or methanol, the equilibrium between them was reestablished but no other products were formed. At equilibrium, the ratio between furanoside and pyranoside was approximately 1:3.

The α-D-glucofuranosidic oxazolidin-2-one derivative (*4*) should be considerably more stable than the corresponding α-D-glucopyranosidic derivative, in agreement with the findings. In the mannose series, however, the

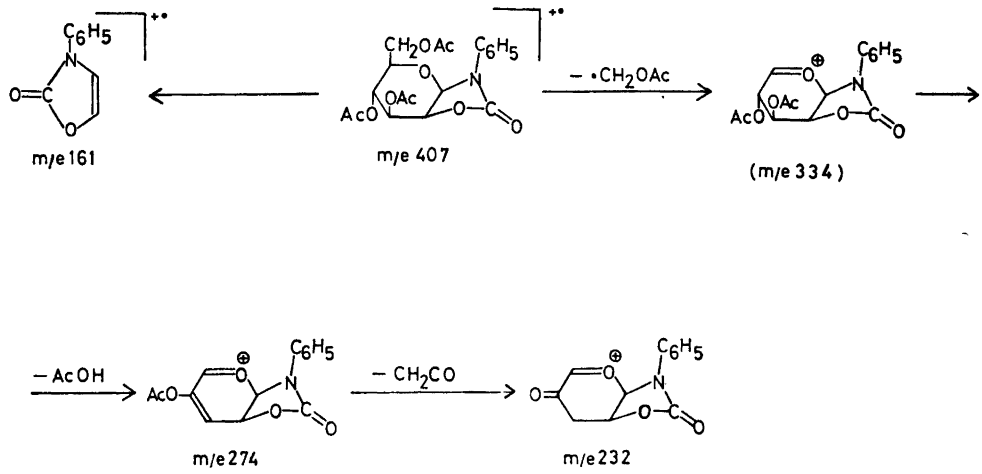
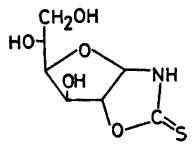


Scheme 2.

steric compression from the substituents in the β-furanoside (*7*) is much greater than that in the β-pyranoside (*8*), which may explain the somewhat greater relative stability of the latter.

A number of bicyclic oxazolidin-2-ones, imidazolidin-2-ones, and corresponding 2-thione derivatives of carbohydrates have been prepared (compare Ref. 6). For several of these, in which the anomeric carbon atom is part of both rings, the ring structure (pyranoside or furanoside) has not been convincingly established. The furanosidic nature of the oxazolidin-2-thione (*9*) which is similar to the D-glucose derivative (*4*) above, has been demonstrated by Schwarz.[7] It seems probable, at least in the glucose series, that several of these derivatives are furanosidic.



9

EXPERIMENTAL

Concentrations were performed at reduced pressure at bath temperatures not exceeding 40°. Melting points are corrected. TLC was performed on Silica Gel F_{254} (Merck). Optical rotations were determined with a Perkin-Elmer 141 polarimeter. NMR spectra were recorded with a Varian XL-100 spectrometer, using tetramethylsilane as internal reference Chemical shifts (δ) are given as ppm downfield from tetramethylsilane. NMR spectra were determined for all new substances and were in agreement with the postulated structures. For GLC-MS the compounds were injected into a glass column (190 × 0.15 cm) containing 3 % UCW-98 on Gas Chrom Q fitted in a Perkin-Elmer 270 gas chromatograph-mass spectrometer.

*tert-Butyl 2,3,4,6-tetra-*O-(N-*phenylcarbamoyl*)-β-D-*glucopyranoside* (*1*). Phenyl isocyanate (1.6 ml) was added to a solution of *tert*-butyl β-D-glucopyranoside [8] (0.8 g) in anhydrous pyridine (4.0 ml). The mixture was heated 1 h at 100°, cooled, diluted with methanol (1.5 ml) to destroy excess phenyl isocyanate, and heated for another 10 min. The reaction mixture was concentrated, dissolved in acetone (20 ml) and applied to a Sephadex LH-20 column (5 × 40 cm) which was irrigated with acetone. The first fraction to be eluted (*tert*-butyl 2,3,4,6-tetra-*O*-(*N*-phenylcarbamoyl)-β-D-glucopyranoside) was concentrated, yielding crystals (2.10 g), m.p. 214–217°, $[\alpha]_D$ +2° (*c* 1.01, acetone). (Found: C 63.9; H 5.60; N 8.03. $C_{38}H_{40}N_4O_{10}$ requires: C 64.0; H 5.66; N 7.86).

*2,3,4,6-Tetra-*O-*(*N-*phenylcarbamoyl)-*D-*glucose* (*2*). *tert*-Butyl 2,3,4,6-tetra-*O*-(*N*-phenylcarbamoyl)-β-D-glucopyranoside (250 mg) was hydrolysed with 5.0 M sulphuric acid (2.0 ml) in dioxane (8.0 ml) for 2 h at 100°. The reaction mixture was neutralised with barium carbonate, filtered, and concentrated to dryness. The crude product was purified by preparative TLC (acetone-chloroform, 1:4) yielding crystals (190 mg), m.p. 244–247° (decomp.), $[\alpha]_D$ +30° (*c* 0.60, acetone). (Found: C 62.1; H 4.84;

N 8.45. $C_{34}H_{32}N_4O_{10}$ requires: C 62.2; H 4.91; N 8.53).

*Methanolysis of 2,3,4,6-tetra-*O*-(N-phenylcarbamoyl)-*D*-glucose.* 2,3,4,6-Tetra-*O*-(*N*-phenylcarbamoyl)-D-glucopyranose (20 mg) was refluxed in 3 % (w/v) methanolic hydrogen chloride (5 ml) for 16 h. The reaction mixture was neutralised with silver carbonate, filtered and concentrated to dryness. TLC of the products (acetone-chloroform, 1:4) showed the presence of two compounds in the approximate proportions 2:3, with the same mobility as fully carbanilated methyl α- and β-D-glucopyranoside,[9] respectively.

*Methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-*O*-(N-phenylcarbamoyl)-α-D-glucopyranoside.* Phenyl isocyanate (1.2 ml) was added to a solution of methyl 3-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside[4] (2.2 g) in anhydrous pyridine (3.0 ml). The mixture was heated for 1 h at 100°, cooled, diluted with methanol (1.5 ml) and heated for another 10 min. The reaction mixture was concentrated, and the product crystallised from methanol (2.4 g), m.p. 198–199°, $[\alpha]_D$ +69° (*c* 0.63, chloroform). (Found: C 62.0; H 5.60; N 3.00. $C_{23}H_{25}O_8N$ requires: C 62.3; H 5.69; N 3.15).

*Methyl 2-*O*-(N-phenylcarbamoyl)-α-D-glucopyranoside (3).* Methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-*O*-(*N*-phenylcarbamoyl)-α-D-glucopyranoside (2.3 g) was treated with 2 % hydrogen chloride in methanol (60 ml) for 36 h. The reaction mixture was neutralised with silver carbonate, filtered, and concentrated to dryness. The crude product was purified by preparative TLC (ethyl acetate) giving a chromatographically pure syrup (1.3 g), $[\alpha]_D$ +103° (*c* 0.95, ethanol).

*Acid hydrolysis of methyl 2-*O*-(N-phenylcarbamoyl)-α-D-glucopyranoside. 3* (1.0 g) was hydrolysed with 1.0 M sulphuric acid (20 ml) for 14 h at 100°. The reaction mixture was neutralised with barium carbonate, filtered, and concentrated to dryness. The product was acetylated with acetic anhydride (2.5 ml) in pyridine (2.5 ml) for 20 min at 100°. The reaction product (*4*) (1.0 g) gave one spot on TLC (ethyl acetate–light petroleum, 1:2) and crystallised from ethyl ether, m.p. 129–130°, $[\alpha]_D$ +138° (*c* 0.55, chloroform). (Found: C 56.2; H 5.20; N 3.49. $C_{19}H_{21}O_9N$ requires: C 56.0; H 5.21; N 3.44). The NMR spectrum is given in Table 1. The mass spectrum showed, *inter alia*, the following peaks (relative intensities in brackets): 43(100), 77(16), 91(6), 104(13), 119(12), 130(8), 147(12), 161(7), 162(16), 174(9), 201(10), 202(29), 203(5), 217(5), 245(3), 305(1), 347(1), and 407(14).

Methanolysis of acetylated 4. Acetylated *4* (10 mg) was refluxed in 15 % (w/v) methanolic hydrogen chloride (2.5 ml) for 16 h. The reaction mixture was neutralised with silver carbonate, filtered, and concentrated to dryness. The crude product was acetylated with acetic anhydride (1.0 ml) in pyridine (1.0 ml) for 20 min at 100°. GLC-MS gave one product identical with the starting material.

*Methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-*O*-(N-phenylcarbamoyl)-β-D-mannopyranoside.* Phenyl isocyanate (1.8 ml) was added to a solution of methyl 3-*O*-benzyl-4,6-*O*-benzylidene-β-D-mannopyranoside[5] (3.0 g) in anhydrous pyridine (5.0 ml). The mixture was heated for 1 h at 100°, cooled, diluted with methanol (2.5 ml) and heated for another 10 min. The reaction mixture was concentrated, and the product was purified on a silicic acid column (40 × 4 cm; ethyl acetate–light petroleum, 1:2), yielding a syrup (3.2 g), $[\alpha]_D$ −75° (*c* 0.96, chloroform).

*Methyl 2-*O*-(N-phenylcarbamoyl)-β-D-mannopyranoside (6).* Methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-*O*-(*N*-phenylcarbamoyl)-β-D-mannopyranoside (2.9 g) in ethanol (40 ml) was hydrogenated over palladium on carbon (10 %, 0.5 g) at room temperature and atmospheric pressure. When the hydrogen consumption had ceased, the catalyst was filtered off. Concentration yielded a syrup (1.8 g), $[\alpha]_D$ −76° (*c* 0.87, ethanol).

*Acid hydrolysis of methyl 2-*O*-(N-phenylcarbamoyl)-β-D-mannopyranoside (6).* Substance *6* (1.0 g) was hydrolysed with 1.0 M sulphuric acid (20 ml) for 14 h at 100°. The reaction mixture was neutralised with barium carbonate, filtered, and concentrated to dryness. The crude product was acetylated with acetic anhydride (2.5 ml) in pyridine (2.5 ml) for 20 min at 100°. The reaction mixture gave two spots on TLC. The mixture was separated on a silicic acid column (40 × 3 cm, acetone–chloroform, 1:19). The separation was followed by polarimetry and TLC. The first fraction to be eluted (acetylated *8*) on concentration yielded a syrup (0.82 g), $[\alpha]_D$ −117° (*c* 0.88, chloroform). The next fraction (acetylated *7*) yielded a syrup which crystallised from ethanol–light petroleum (1:2, v/v) (0.29 g), m.p. 168–170°, $[\alpha]_D$ −161° (*c* 0.56, chloroform). (Found: C 56.0; H 5.22; N 3.22. $C_{19}H_{21}O_9N$ requires: C 56.0; H 5.21; N 3.44). The NMR spectra are given in Table 1. The mass spectrum of acetylated *8* showed, *inter alia*, peaks at *m/e* 43(100), 77(12), 104(13), 119(9), 161(17), 162(6), 190(5), 203(5), 204(6), 232(27), 245(2), 305(1), 347(1) and 407(16). The mass spectrum of acetylated *7* showed peaks at *m/e* 43(100), 77(9), 104(7), 119(7), 130(11), 147(6), 162(12), 190(6), 202(41), 203(6), 217(4), 245(2), 305(1), 347(1) and 407(12).

Methanolysis and acid hydrolysis of acetylated 7 *and* 8. Methanolysis of acetylated *7* and *8* was performed in 3 % (w/v) methanolic hydrogen chloride as described above. Acid hydrolysis of acetylated *7* and *8* was performed with 1.0 M sulphuric acid as described above. The reaction mixtures were acetylated with acetic anhydride in pyridine and analysed on GLC-MS. All reactions produced the same mixture (1:3) of *7* and *8*.

The Crystal and Molecular Structure of *N*-Acetyl-5-methoxy-tryptamine (Melatonin)

ARVID MOSTAD and CHRISTIAN RØMMING

Department of Chemistry, University of Oslo, Oslo 3, Norway

The structure of melatonin has been determined by X-ray methods using 2543 observed reflections collected by counter methods. The crystals are monoclinic, space group $P2_1/c$, with unit cell dimensions $a = 7.71_4$ Å; $b = 9.27_6$ Å; $c = 17.11_8$ Å and $\beta = 96.9_1°$. The refinements yielded a conventional R-factor of 5 %; standard deviations in bond lengths and in angles not involving hydrogen atoms are 0.002 Å and 0.1°, respectively. The molecular geometry and the hydrogen bond system in the crystal is discussed. The molecule has also been studied by X-ray methods by Quarles [1] and by Wakahara, Fujiwara and Tomita.[2]

As a part of a series of structure investigations of tyrosine and tryptophan derivatives the crystal and molecular structure of *N*-acetyl-5-methoxytryptamine (melatonin) has been determined. The compound occurs naturally in mammals and its biological activity is believed to involve changes in certain neurones in the central nervous system. Bioactive monoamines, which includes melatonin, have in the recent years received increased interest and much work has been devoted to reach information useful for an explanation of the relation between structure and biological activity. We have studied the melatonin molecule in order to obtain data relevant in this discussion, for the study of the conformation of such compounds in the crystalline phase and for the comparison with several theoretical calculations made on analogous molecules. During the refinement of the structure model we became aware of studies of the same molecule by Quarles [1] and also by Wakahara *et al.*[2] However, even if the present determination yields the same general structural information it is based on more than twice of their number of data, and less than half of their standard deviations in bond lengths were obtained.

EXPERIMENTAL

Large prismatic crystals of melatonin were formed by slow evaporation of an ethanolic solution at room temperature. A preliminary study showed the crystals to be monoclinic, space group $P2_1/c$.

The intensity data were recorded on an automatic Picker diffractometer using graphite crystal monochromated MoK-radiation. The specimen was cut from a large crystal to the dimensions $0.3 \times 0.3 \times 0.3$ mm^3 and was mounted on a glass fibre with the crystallographic a-axis along the ϕ-axis. The $\omega - 2\theta$ scanning mode was employed with a 2θ scan speed of 2° min^{-1} through a scan range from 0.5° below $2\theta(\alpha_1)$ to 0.5° above $2\theta(\alpha_2)$. Background counts were taken for 10 s at each of the scan range limits. The intensities of three standard reflections measured for every 150 reflections of the data set showed slow changes of up to 10 % and the intensity data were accordingly adjusted. The estimate of the standard deviations of the measurements was based on counting statistics with an additional term of 2 % of the intensity. Out of 3306 unique reflections with $\sin\theta/\lambda$ less than 0.7, 2543 reflections were found to have intensities larger than twice their standard deviation and were regarded as observed. The remaining reflections were excluded from the refinement procedure.

The intensity data were corrected for Lorentz and polarization effects. Atomic scattering factors used during the calculations (for computer programs *cf.* Ref. 3) were those of Hansen *et al.*[4] for oxygen, nitrogen, and carbon, and of Stewart *et al.*[5] for hydrogen. Unit cell dimensions were calculated from diffractometer measurements on 17 general reflections.

Table 1. Observed and calculated structure factors. The columns are h, k, l, $10F_o$, and $10|F_c|$.

Table 1. Continued.

CRYSTAL DATA

Melatonin (*N*-acetyl-5-methoxytryptamin) $C_{13}H_{16}N_2O_2$, monoclinic. $a = 7.714(0.002)$ Å; $b = 9.276(0.002)$ Å; $c = 17.118$ (0.004) Å; $\beta = 96.91$ (0.03). $V = 1214$ Å^3; $M = 232.28$; $F(000) = 496$; $Z = 4$; $D_{calc} = 1.27$ gcm^{-3}. Absent reflections: $(h0l)$ for l odd, $(0k0)$ for k odd; space group $P2_1/c$.

STRUCTURE DETERMINATION

The structure was determined by the application of the symbolic addition procedure and

Sayre's equation and refined by Fourier- and full-matrix least-squares methods. Final refinements included individual isotropic thermal parameters for hydrogen atoms and anisotropic temperature factors expressed by $\exp-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)$ for the other atoms in addition to all positional parameters. The final conventional R-factor is 0.052.

The observed and calculated structure factors are listed in Table 1; positional and thermal parameters of non-hydrogen atoms are listed in Table 2 and those of hydrogen atoms in Table 3. Bond lengths and angles are tabulated in Table 4; estimated standard deviations were calculated from the correlation matrix. An analysis of the rigid body vibrations of the indol nucleus was carried out and the bond lengths corrected for thermal librations are given in Table 4.

DESCRIPTION OF THE STRUCTURE

The structure of the melatonine molecule as found in the present determination is shown in Fig. 1. The bond lengths and angles in the indole-ethylamine part of the molecule is in very good agreement with those given by Falkenberg [6] as the averaged structure based on several precise structure analyses of compounds containing this group. In the indole nucleus there are consistent and systematic variations in the bond lengths and angles indicating a reduced aromatic character; the same variations are also found in the theoretically calculated structure.[7] The C11−N12 bond length of 1.445 Å may be considered normal for a C(sp^3)−N(sp^2) distance and the N-acetyl group shows dimensions typical for a peptide.

The methoxy group is close to the plane of the indole moiety and the conformation about the O5−C15 bond is strictly staggered. It is

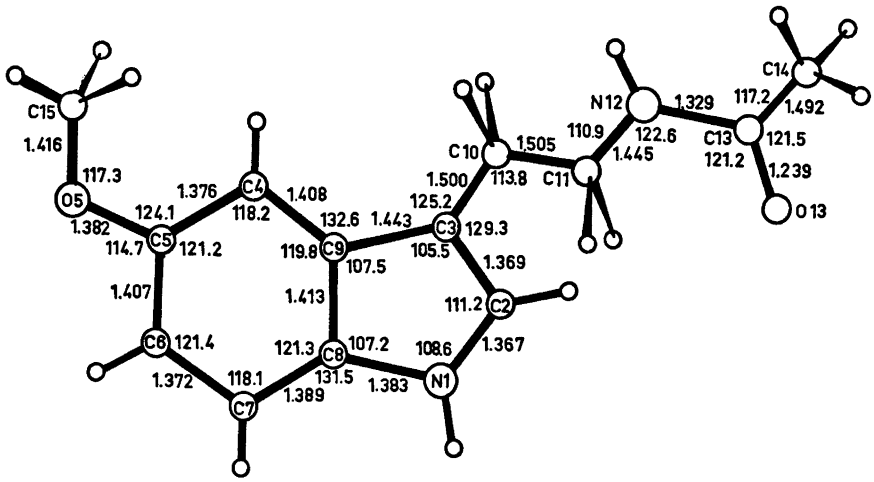

Fig. 1. Conformation of the melatonin molecule. Corrected bond lengths (Å) and angles (°) are indicated.

interesting to note that the external angles at C5 differ in a way (C4 – C5 – O5 = 124.1°, ∠C6 – C5 – O5 = 114.7) corresponding to that found at the OH group in phenols in which the H-atom is situated in the plane of the aromatic ring. The opening of the angles C15 – O5 – C5, O5 – C5 – C4 and also of C5 – C4 – HC4 relative to their standard values indicate a steric strain; nevertheless the arrangement of the atoms involved is planar, the dihedral angle C4 – C5 – O5 – C15 is 0° within the accuracy of determination.

The six- and five-membered rings are each strictly planar, the deviations from the corre-

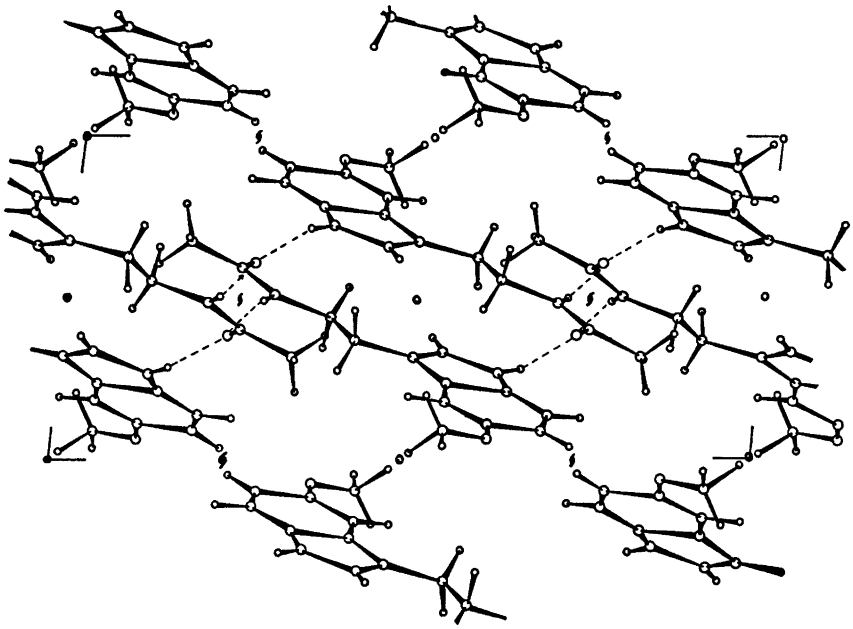

Fig. 2. The crystal structure of melatonin as viewed along the *b* axis.

Table 4. Interatomic distances (Å) and bond angles (°) with estimated standard deviations. For the indole part bond lengths corrected for rigid-body librations are given in parentheses. Standard deviations are 0.002 Å in bonds and 0.1° in angles between heavy atoms, 0.02 Å and 1.0°, respectively, if one hydrogen atom is involved.

sponding least-squares planes being less than 0.01 Å; the angle between the two planes is 1.4°. The non-hydrogen atoms of the longer side-chain are also roughly co-planar; a plane through these atoms does not quite coincide with the pyrrole-plane, however, the dihedral angle C2 – C3 – C10 – C11 being 5.5°.

The molecular arrangement in the crystal and the hydrogen bond system is illustrated in Fig. 2. Two hydrogen donors, N1 and N12, each with one hydrogen atom are available for hydrogen bond formation. There are also two potential acceptor atoms, but O13 is the acceptor for two hydrogen bonds and O5 for none. Each molecule is hydrogen bonded to three neighbouring molecules. The structure may be described as centrosymmetric hydrogen bonded dimers which are again hydrogen bonded to four neighbouring dimers forming helices along a set of screw axes. In this way the crystal consists of layers of hydrogen bonded molecules parallel to the $b-c$ plane. Between these layers there are only weak van der Waals interactions.

Conformational Analysis of 2,5-Substituted 1,3-Dioxa-2-silacyclohexanes

P. ALBRIKTSEN* and S. HEGGELUND

Chemical Institute, University of Bergen, N-5000 Bergen, Norway

Results of the NMR analysis indicate that the free-energy difference between chair and boat conformations of the *cis*-2-*tert*-butyl-2,5-dimethyl-1,3-dioxa-2-silacyclohexane ring system is unusually low. The free energy difference between axial and equatorial substituents in position 5 of the 1,3-dioxa-2-silacyclohexanes is larger as compared to the pertinent cyclohexanes. Isomers with an axial substituent in the ring position 5 have not been detected.

Conformational studies on 1,3-dioxa-2-silacyclohexanes are scanty. Krieble and Buckhard [1] published the synthesis of 2,2-dimethyl-1,3-dioxa-2-silacyclohexane and later several substituted compounds have been prepared.[2–9] NMR studies on substituted 1,3-dioxa-2-silacyclohexanes have been reported twice.[6,8] Hellier [8] reported the NMR spectra of 2,2,5,5-tetra-substituted compounds, but only chemical shift data have been reported for the 5,5-dimethyl substituted compound.

This work was undertaken, partly because no relevant data on silicon analogues to 1,3-dioxanes or trimethylene sulfites were available in literature, and partly to obtain information on the conformational dependence of elongated bonds in cyclic sixmembered ring systems. Moreover, it was of interest to compare the effect of substituents in sixmembered ring systems containing silicon in the ring position 2, with analogous compounds containing sulphur or phosphorus. Only compounds with substituents in positions 2 and 5 have been studied by NMR.

* Present address: Rafinor A/S & Co., N-5140 Mongstad, Norway.

EXPERIMENTAL

The 1,3-dioxa-2-silacyclohexanes were synthesized from the appropriate diols by the following procedures:

Method A. The 1,3-diol together with two mol of *N,N*-dimethyl amine were dissolved in a suitable solvent (ether, chloroform or benzene). An equimolar amount of the appropriate dichlorosilane was added dropwise and the mixture was refluxed for 4 h, filtered and the pure compound was obtained, after removal of solvent by distillation.

Method B. The 1,3-diol and a small amount of sodium methanolate were dissolved in benzene or mesitylene. The equivalent amount of the appropriate dimethoxysilane was added dropwise and the methanol formed was removed by azeotropic distillation with the solvent. The pure compound was obtained by distillation.

All non-commercial available 1,3-diols were synthesized from the appropriate malonates [10] by reduction with $LiAlH_4$.

2,2-Dimethyl-1,3-dioxa-2-silacyclohexane (I).[7] $B.p._{760}$ 122 °C ($b.p._{22}$ 35 °C), n_D^{20} 1.4132, GC purity 99 %. Yield method A, 74 %, and method B, 85 %.

2,2,5-Trimethyl-1,3-dioxa-2-silacyclohexane (II). $B.p._8$ 29 °C, n_D^{20} 1.458, GC purity 98 %. Yield method A, 55 %, and method B, 72 %.

5-tert-*Butyl-2,2-dimethyl-1,3-dioxa-2-silacyclohexane (III).* Method A: $B.p._{9.5}$ 69 – 71 °C, n_D^{20} 1.4373, GC purity 98 %, yield 68 %. Method B: $B.p._7$ 67 – 68 °C, n_D^{20} 1.434, GC purity 98 %, yield 60 %.

2-tert-*Butyl-2-methyl-1,3-dioxa-2-silacyclohexane (IV).* $B.p._{30}$ 38 °C, GC purity 98 %.

2-tert-*Butyl-2,5-dimethyl-1,3-dioxa-2-silacyclohexane* [cis (V) and trans (VI)]. $B.p._{16}$ 60 – 61 °C, azeotropic distillation with mesitylene. (The mesitylene was used as solvent during the preparation of the chlorosilane.)

GC specifications: The compounds were analysed and purified on a preparative gas chromatographic column, 2.1 m × 6 mm, containing either 15 % Apiezon L on Chromosorb W HMDS

or 10 % Apiezon L on Fluoropack HMDS.

NMR specifications: The materials were introduced into 5 mm o.d. NMR sample tubes, directly from the gaschromatograph. A suitable solvent as well as a small amount of TMS were added to serve as locking and reference substance. The samples were degassed by the freeze-pump-thaw technique. The spectra were recorded on a 60 MHz JEOL-C-60-H instrument. All spectra were recorded in internal lock mode with frequency sweep at *ca.* 50 Hz sweep width and calibrated every 5 Hz using a frequency counter. The counter was accurate to 0.1 Hz and the line positions were taken as the average of several spectra. The computations were carried out on an IBM 360/50 computer and the graphical output was obtained using a Calcomp plotter.

SPECTRAL ANALYSIS

The spectrum of 2,2-dimethyl-1,3-dioxa-2-silacyclohexane (I) can be divided into three regions; a triplet at δ 3.9, a multiplet at δ 1.7, and a singlet at δ 0.1. The triplet at high frequency is assigned to the protons in positions 4 and 6, and the multiplet to protons at carbon 5. The singlet is due to the methyl groups attached to the silicon. The spectrum was analysed as an $[ABC]_2$ spin-system (Table 1). The RMS value obtained was 0.1 when 67 theoretical lines were correlated to observed transitions and 14 parameters were allowed to vary.

The spectrum of 2,2,5-trimethyl-1,3-dioxa-2-silacyclohexane (II) contained four bands at δ 0.05, δ 0.7, δ 2.0, and δ 4.0 – 3.7. The two low frequency bands are assigned to the methyl-groups. The high frequency band is assigned to protons at carbond 4 and 6 and the band at δ 2.0 to the protons in the ring position 5. The spectrum was analysed as an $[AB]_2CD_3$ spin-system. Spectra obtained at 27 °C and 50 °C were analysed (Table 1). The RMS value obtained in both cases was 0.06 when 18 parameters were allowed to vary and 185 lines were correlated to observed transitions.

The spectrum of 5-*tert*-butyl-2,2-dimethyl-1,3-dioxa-2-silacyclohexane (III) consists of four bands at δ 0.08, δ 0.82, δ 1.74, and δ 4.1 – 3.7. The two low frequency bands are due to the two methyl groups and the *tert*-butyl group. The bands at δ 4.1 – 3.7 and δ 1.7, assigned to protons at $C_4(C_6)$ and C_5 (Fig. 1), respectively, were analysed as an $[AB]_2C$ spin system. The

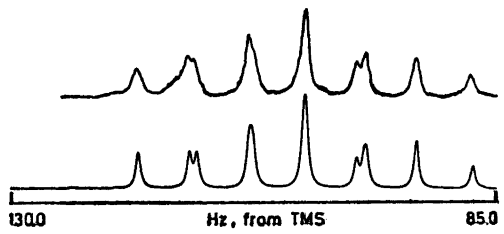

Fig. 1. The observed spectrum (upper) and the calculated spectrum of proton 5 of 5-*tert*-butyl-2,2-dimethyl-1,3-dioxa-2-silacyclohexane (III).

RMS value obtained was 0.12 when 40 theoretical lines were correlated to observed transitions and 15 parameters were allowed to vary.

The NMR spectrum of 2-*tert*-butyl-2-methyl-1,3-dioxa-2-silacyclohexane(IV) appeared to be deceptively simple, with a triplet at δ 3.93, a complex band at δ 1.63 and singlets at δ 0.97 and δ 0.08 integrating to 4:2:9:3, respectively. The spectrum could be reproduced by assuming an $[A]_4CD$ spin system, but iterative calculations were not feasible, as the experimental spectrum had too little fine structure. Parameters used in the non-iterative calculation are listed in Table 1. The errors in the parameters are *ca.* 0.3 Hz. The GC analysis of 2-*tert*-butyl-2,5-dimethyl-1,3-dioxa-2-silacyclohexane (V and VI) dissolved in mesitylene showed only one peak for this compound. The NMR spectrum, however, gave a complex pattern with singlets at δ 0.95 and δ 0.08, two doublets at δ 0.67 and δ 0.57, a broad unresolved band centered at *ca.* δ 2.0, and a region at δ 4.0 – 3.4 containing eleven complex peaks (Fig. 2). The signals at δ 4.0 – 3.4, assigned to the protons at carbons 4 and 6, were analysed as two overlapping $[AB]_2$ parts of $[AB]_2CD_3$ spin systems. Only non-iterative calculations were performed. The calculated spectrum of parameters of Table 1 is shown in Fig. 2. The errors in the coupling constants are *ca.* 0.3 Hz.

RESULTS AND DISCUSSIONS

2,2-Dimethyl-1,3-dioxa-2-silacyclohexane (I). The observed chemical shifts (Table 1) are close to those reported by Hellier [3] and Voronkow *et al.*[4] The reported [3] vicinal coupling constant 5.4 Hz is, however, the mean value

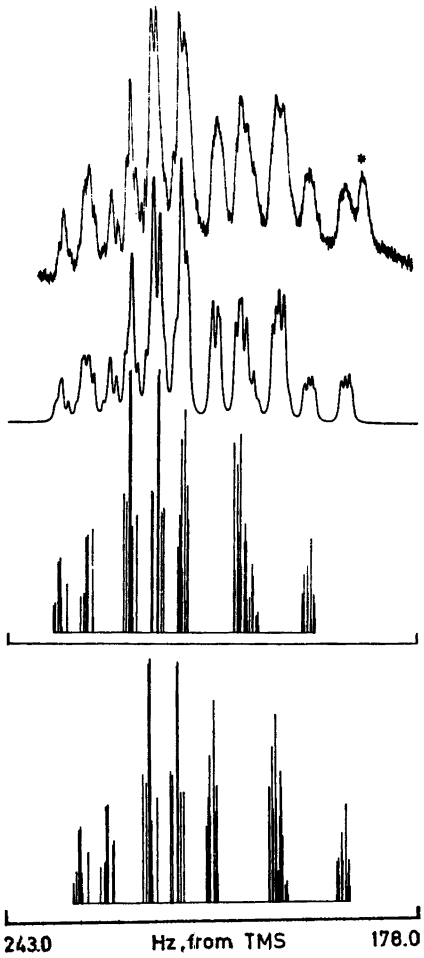

Fig. 2. The observed spectrum (upper) of protons at carbons 4 and 6 of *cis-* and *trans*-2-*tert*-butyl-2,5-dimethyl-1,3-dioxa-2-silacyclohexane (V and VI). The theoretical spectrum is shown below. The stickplots show the individual spectra of the *cis-* (upper) and *trans-* (lower) isomer (see the text). * = impurity.

of the coupling constant obtained by us, 7.09 Hz and 3.46 Hz (Table 1). The chemical shift data and the lack of any observable geminal coupling constants suggest a rapid equilibrium between two equivalent chair conformations. The 1,3-dioxane has been reported [11,12] to exist in a 1:1 equilibrium between two chair conformations. The observed vicinal couplings of compound I are of the same magnitude as observed in dioxanes. Moreover, considering the symmetry of I, it is reasonable to assume a 1:1 equilibrium between two chair conformations for compound I too. The NMR spectrum of compound I in CS_2 was examined in the temperature range +27 °C to −88 °C,* but the coalescence temperature was not reached and no noticeable changes of the spectra were observed. A coalescence temperature below −88 °C indicates a lower inversion barrier as compared to 1,3-dioxane. This is a reasonable assumption because coupling constants and chemical shift differences of the siloxanes examined (Table 1) are close to pertinent values obtained for dioxanes.[13] Regardless of the transition states, inversion between chairforms involves rotations about single bonds. To the authors knowledge, no values of the rotation barrier about Si−O bonds have been reported. The Si−O bond length, 1.63 Å,[14] as compared to C−O, 1.43 Å, causes a "flattening" of O−Si−O ring moiety as compared to the O−C−O part of the dioxane ring. The effect of longer bonds on the rotation barrier can be seen from CH_3-SiH_3, where the barrier is estimated to *ca.* 1.9 kcal/mol [14] as compared to the ethane barrier of *ca.* 3.0 kcal/mol. Introduction of a single bond, into a cyclic system, with lower rotation barrier should lower the inversion barrier of the ring-system. Geminal methyl groups at carbon 2 in dioxane lowers the barrier from 9 kcal/mol to about 7.8 kcal/mol,[15] and the methyl groups attached to the silicon atom might cause a similar lowering of the barrier in compound I.

Assuming an equilibrium between two equally populated chair forms, the two observed vicinal coupling constants can be expressed by ${}^3J_{obs} = \frac{1}{2}(J_{aa} + J_{ee})$ and ${}^3J_{obs} = \frac{1}{2}J_{ae} + J_{ea})$. This enables us to calculate dihedral angles for the chair conformation by the *R*-value method,[16] giving $R = 2.05$, corresponding to a dihedral angle about 57° of the $-CH_2-CH_2-CH_2-$ moiety. The *R*-value is essentially the same as those obtained from NMR measurements on various six-membered ring compounds,[16-18] which are shown to exist in chair conformations.

2,2,5-Trimethyl-1,3-dioxa-2-silacyclohexane (II). The NMR data obtained for this compound clearly indicates that it exists in a chair

* The temperature ranges for compounds I and II (*vide infra*) are decided from solubility restrictions.

conformation or an equilibrium between two chair forms. The silicon methyl groups appear to be a broad but split signal, indicating two different methyl groups. The couplings 9.5 Hz and 3.97 Hz (Table 1), assigned to $^3J_{4a5a}$ and $^3J_{4e5a}$, indicate that the methyl group at carbon 5 is predominantly in the equatorial position. The coupling constants suggest that compound II exists almost entirely in a conformation with an equatorial methyl group at carbon 5. The NMR data obtained at 58 °C are not sufficiently different from those obtained at 27 °C, to make any calculations of conformational energies feasible. There was, however, no significant changes in the spectrum between −70 and +58 °C. The latter observation might indicate a chair-twist rather than a chair-chair equilibrium where an equatorial methyl group at carbon atom 5 is expected to be at least 0.8 kcal/mol [19] more stable as compared to the axial position. The large value of $^4J_{ee}$, 1.85 Hz, suggests a chair-twist equilibrium or that II exists in a rigid chair form.

5-tert-*Butyl-2,2-dimethyl-1,3-dioxa-2-silacyclohexane (III).* The coupling constants obtained are close to values of compound II, except for $^3J_{aa}$, which is substantially larger, 10.6 Hz. The coupling constants (Table 1) indicate that compound III exists predominantly in a chair conformation with the tertiary butyl group in the equatorial position. No significant changes of the spectrum was observed between −107 and +197 °C, and it is therefore reasonable to assume that III constitutes an anancomeric system.

2-tert-*Butyl-2-methyl-1,3-dioxa-2-silacyclohexane (IV).* The spectrum of compound IV appeared to be deceptively simple. The protons at C_5 are, however, not equivalent with chemical shift difference about 0.1 ppm. The coupling constants obtained, 6.5 Hz and 4.3 Hz, are substantially different from the values of I and this suggests an equilibrium different from that assumed for compound I. An equilibrium between two twist conformations can explain a chemical equivalence of protons at carbons 4 and 6 and a non-equivalence of protons at carbon 5. An estimate of the vicinal coupling constants of an equally populated twist-twist equilibrium, *ca.* 6.5 Hz and *ca.* 4.3 Hz, can be calculated from coupling values suggested by Wücherpfennig.[20] Recently Pihlaja *et al.*[21] reported the existance of twist forms in 1,3-dioxanes. The longer Si−O bond as compared to the C−O bond could reduce the equatorial preference of a 2-*tert*-butyl group, but it might also make twist conformations more probable.

cis- *and* trans-*2*-tert-*Butyl-2,5-dimethyl-1,3-dioxa-2-silacyclohexane (V and VI).* The NMR spectrum of this sample clearly indicated, in spite the appearence of only one peak in GC, the existance of more than one compound. The complexity of the spectrum made it feasible only to analyse the region δ 3.4−4.0 (Fig. 2), assigned to protons in ring-positions 4 and 6. The region assigned to the proton at C_5 did not show any resolved fine-structure, and hence it was not possible to obtain any information from this band.

The band at $\delta \sim 3.5$ can only be reproduced upon the following assumptions (see Fig. 2): (a) The spectrum consists of two superimposed spectra due to closely related spin-systems and (b) The methylgroup at carbon 5 occupies the equatorial position in both compounds. The two superimposed spectra are both of the $[AB]_2CD_3$ type. From the magnitude of relevant coupling constants and chemical shifts (Table 1) and the symmetry of the spin system, it is reasonable to assume that both isomers exist in a chair conformation. Entry VI is tentatively assigned to the *trans* isomer with the methyl group at carbon 5 and the *tert*-butyl group in the equatorial position. The existence of a large coupling constant in both isomers indicates equatorial methyl groups. This implies that the *tert*-butyl group in the *cis* isomerV is situated axial or V exists in a boat conformation or in a chair-boat equilibrium. The Si−O bond (1.63 Å) is considerably longer compared to the C−O (1.43 Å) and the P−O bond (1.54 Å). The equatorial preference of a *tert*-butyl group on silicon might be less as compared to pertinent carbon and phosphorus analogues. The large coupling $^3J_{aa}$ excludes any equilibrium between twist conformations.

Boat forms of six-membered saturated ring compounds are normally 5−6 kcal/mol higher in free energy (ΔG°_{25}) than the corresponding chair conformations. ΔH° (chair-boat) for cyclohexane and 1,3-dioxane are roughly those estimated from the rotational barriers in propane [27] and dimethyl ether.[23] It is expected that for other heterocycles the ΔG°_{25} (chair-

boat) may be less than 6 kcal/mol depending primarily on rotational barriers, as yet unknown. It is assumed that the rotational barrier of $CH_3-CH_2-Si-CH_3$[24] is less than the value of the carbon analogue. The longer Si–X bond as compared to the C–X bond may be the reason for this. A lower rotational barrier about the Si–X bond,[24] as compared to the C–X bond, together with a more favourable equatorial *tert*-butyl group suggest the existence of a boat conformation or a chair-boat equilibrium for compound V. The existence of a boat conformation for *cis*-2,5-di-*tert*-butyl-1,3,2-dioxaphosphorinan-2-one [25] is shown, based on the magnitude of the coupling between the phosphorus atom and the protons at carbons 4 and 6. Certain 1,3-dioxanes, substituted at carbons 2 and 5, have been reported to exist in boat conformations.[26–29]

CONCLUSION

The barrier to ring inversion in siloxanes is probably less than the barrier observed for analogous 1,3-dioxanes. Twist and boat conformations must be considered when discussing conformational equilibria of 1,3-siloxanes. Contribution from non-chair forms is assumed to be due to a lower rotational barrier together with a substantial longer Si–X bond as compared to carbon analogues. There is no evidence for the existence of isomers with an axial substituent at carbon 5. The free energy difference between axial and equatorial substituents in position 5 is apparently larger for 1,3-siloxanes as compared to cyclohexanes and 1,3-dioxanes.

Short Communications

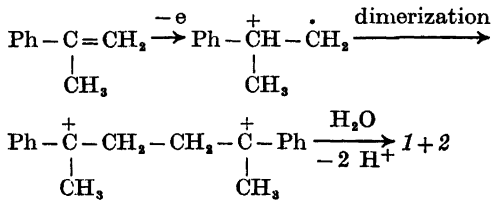
An Anodic Synthesis of 2,5-Dimethyl-2,5-diphenyltetrahydrofuran

HANS STERNERUP

Division of Organic Chemistry, University of Lund, Chemical Center, P.O.B. 740, S-220 07 Lund 7, Sweden

The anodic oxidation of aromatic hydrocarbons with at least one benzylic hydrogen partly results in the formation of the corresponding olefin *via* proton loss from an intermediate benzylic cation. Since the olefin formed is oxidized at a lower potential than the starting material, further oxidation takes place – possibly in the adsorbed state – with formation of the two-electron oxidation product from the olefin, as has been shown in the case of indan.[1] If cumene is oxidized according to the same mechanism it should under suitable conditions give α-methylstyrene as the primary product. This might then be oxidized further to phenylacetone by analogy with the known behaviour of α-methylstyrene upon lead tetraacetate oxidation.[2,3] Hence, it might be possible to realize a direct route from cumene to this important intermediate.

The oxidation of cumene in acetonitrile/water (volume ratio 98:2) with sodium perchlorate or tetrabutylammonium tetrafluoroborate as supporting electrolyte gives, however, 2-phenylpropanol-2 as the main product. To see if it was possible to obtain phenylacetone from α-methylstyrene itself, this compound was oxidized under identical conditions, but no trace of phenylacetone was detectable. GLC analysis of the reaction product showed, besides starting material, only two well-resolved peaks (retention times 5.1 and 5.8 min on a 5 % neopentylglycol succinate column (2 m × 0.3 mm) at 170 °C, ratio 52:48), with identical mass spectra. After distillation, the product partly crystallized on standing. Recrystallization from ethanol gave crystals which on GLC analysis were found to correspond to one of the peaks in the gas chromatogram (with retention time 5.8 min). From the mother liquor, the second compound could be isolated as an oil. NMR and elemental analysis led to the identification of the two compounds as the *cis* (*1*) and *trans* (*2*) isomers of 2,5-dimethyl-2,5-diphenyltetrahydrofuran. The formation of these compounds is in accordance with earlier mechanistic work on the additive dimerization of arylolefins.[4]



The NMR spectra of *1* and *2* have been reported [5] and agree well with those given in the experimental section.

Experimental The concentric capillary gap cell used has been described in a recent paper.[6] Analytical procedures were as described earlier.[7]

Oxidation of cumene. Cumene (120 g, 1 mol), $NaClO_4.H_2O$ (2.8 g, 0.01 mol) and water (18 ml, 1 mol) were dissolved in acetonitrile (1000 ml). At the beginning of the electrolysis the applied voltage was 13 V. The current was kept at 25 A throughout the experiment. The voltage increased slowly and as soon as it reached 30 V, 4.5 ml of a solution of $NaClO_4$. H_2O (2.8 g) in water (36 ml) was added. After passing a charge of 2.70 F the electrolysis was interrupted and the solvent removed by evaporation *in vacuo*. Ether was added to the residue and the solution washed with water and dried over $MgSO_4$. After removing the ether, the residue (57.7 g) was distilled to give the following fractions: 1, b.p. 87 °C/11 mmHg (11.0 g); 2, b.p. 87 – 92 °C/11 mmHg (28.1 g); 3, residue (13.4 g). Fraction 2 was found to be pure 2-phenylpropanol-1 by comparison with an authentic sample.

Oxidation of α-methylstyrene. α-Methylstyrene (118 g, 1 mol), $NaClO_4.H_2O$ (2.8 g, 0.02 mol) and water (18 ml, 1 mol) were dissolved in acetonitrile (1000 ml). The electrolysis was run at 50 A until 1 F had passed. The applied voltage rose from 12 to 26 V during the run. The reaction solution was worked up as above. The residue after evaporation of the ether (100.5 g) was distilled to give the following fractions: 1, 103 °C/0.4 mmHg (8.7 g); 2, 103 – 128 °C/0.4 mmHg (4.8 g); 3, 128 – 143 °C (30.6 g); 4, residue (43.3 g). GLC of fraction 3 showed two well-resolved peaks with an integral ratio of 52:48. On standing this fraction partly crystallized. A sample of the solid compound was recrystallized from ethanol giving colourless

crystals, m.p. 74 – 75 °C (lit.[5] 75 °C). By suction of fraction 3 the oily isomer was obtained contaminated with 20 % of the solid isomer. NMR of the crystalline isomer:[5] δ 1.53 ppm (s, 6, methyl protons), 2.15 (an AA'BB' spectrum centered at 2.15 ppm, 4, methylene protons), 7.12 – 7.63 (m, 10, aromatic protons). NMR of the liquid isomer:[5] δ 1.60 ppm (s, 6, methyl protons), 2.20 (s, 4, methylene protons), 7.00 – 7.58 ppm (m, 10, aromatic protons). The two isomers showed identical mass spectra, *m/e* (% of base peak): 238(15), 237(100), 219(7), 117(21), 105(95), 91(11), 77(16), 43(15). (Found: C 85.3; H 7.97; O 6.49. Calc. for $C_{18}H_{20}O$: C 85.7; H 8.00; O 6.34).

4-Chlorobuten-3-yne: a Spectrochemical Characterization

MATS GRANBERG, FRED KARLSSON and RAGNAR VESTIN

Department of Physical Chemistry, University of Stockholm, Arrhenius Laboratory, Fack, S-104 05 Stockholm, Sweden

True acetylenic hydrogens are generally replaced by halogen by action of alkaline hypohalites. This reaction has been applied to vinylacetylene with different halogen atoms by Carothers and Jacobson.[1] We prepared 4-chlorobuten-3-yne by adding monovinylacetylene to a potassium hypochlorite solution.

The substance was isolated and purified with gas liquid chromatography at a temperature of 100 °C. The column was packed with diethylhexyl sebacate (15 %) absorbed on Chromosorb.

The identification is primarily based on the mass spectrum obtained by using a combined GLC – MS. After correction for background, the largest peaks are: *m/e*(rel. intensity), 49(19.5), 50(46.5), 51(100.0), 52(4.5), 60(10.5), 62(3.5), 84(10.5), 85(12.0), 86(98.5), 87(8.5), 88(30.5) and 89(1.5).

The occurrence of chlorine is demonstrated by the intensity relation 3:1 of the mass numbers 86:88 corresponding to the molecular ions with ^{35}Cl and ^{37}Cl and the mass numbers 60:62 probably corresponding to the ions $CHC^{35}Cl^+$ and $CHC^{37}Cl^+$. The molecular weight is consequently 86.5. The relation $^{13}C:^{12}C$ in the substance appears most evident from the intensity relation 4.5:100.0 between the mass numbers 52:51, corresponding to the ions $^{13}CC_3H_3^+$ and $C_4H_3^+$. Hence the assumption of four carbon atoms is confirmed.

A UV-spectrum of the substance was run between 340 and 200 nm. An absorption at 277 – 278 nm was observed.

For monovinylacetylene, absorption at 221 nm and 227.5 nm has been reported by Georgieff *et al.*[2]

The IR-spectrum of gaseous 4-chlorobuten-3-yne is given in Fig. 1. A theoretical calculation of the frequencies, from a normal coordinate analysis using a simple diagonal valence force field, shows good agreement with the obtained spectrum for some of the peaks.[3,4]

At 3120 cm^{-1} we observed the asymmetric hydrogen stretch for the vinyl group. The peak at 3035 cm^{-1} belongs either to the symmetric hydrogen stretch for the vinyl group or a stretch of the remaining hydrogen. At 2220 cm^{-1} the characteristic stretching of $-C\equiv C-$ was observed and at 1600 cm^{-1} the $-C=C-$ stretch. There is no strong absorption around 3300 cm^{-1} which shows the purity of the substance and eliminates the isomeric chlorobutenyne structures.[5,6]

crystals, m.p. 74 – 75 °C (lit.[5] 75 °C). By suction of fraction 3 the oily isomer was obtained contaminated with 20 % of the solid isomer. NMR of the crystalline isomer:[5] δ 1.53 ppm (s, 6, methyl protons), 2.15 (an AA'BB' spectrum centered at 2.15 ppm, 4, methylene protons), 7.12 – 7.63 (m, 10, aromatic protons). NMR of the liquid isomer:[5] δ 1.60 ppm (s, 6, methyl protons), 2.20 (s, 4, methylene protons), 7.00 – 7.58 ppm (m, 10, aromatic protons). The two isomers showed identical mass spectra, *m/e* (% of base peak): 238(15), 237(100), 219(7), 117(21), 105(95), 91(11), 77(16), 43(15). (Found: C 85.3; H 7.97; O 6.49. Calc. for $C_{18}H_{20}O$: C 85.7; H 8.00; O 6.34).

4-Chlorobuten-3-yne: a Spectrochemical Characterization

MATS GRANBERG, FRED KARLSSON and RAGNAR VESTIN

Department of Physical Chemistry, University of Stockholm, Arrhenius Laboratory, Fack, S-104 05 Stockholm, Sweden

True acetylenic hydrogens are generally replaced by halogen by action of alkaline hypohalites. This reaction has been applied to vinylacetylene with different halogen atoms by Carothers and Jacobson.[1] We prepared 4-chlorobuten-3-yne by adding monovinylacetylene to a potassium hypochlorite solution.

The substance was isolated and purified with gas liquid chromatography at a temperature of 100 °C. The column was packed with diethylhexyl sebacate (15 %) absorbed on Chromosorb.

The identification is primarily based on the mass spectrum obtained by using a combined GLC – MS. After correction for background, the largest peaks are: *m/e*(rel. intensity), 49(19.5), 50(46.5), 51(100.0), 52(4.5), 60(10.5), 62(3.5), 84(10.5), 85(12.0), 86(98.5), 87(8.5), 88(30.5) and 89(1.5).

The occurrence of chlorine is demonstrated by the intensity relation 3:1 of the mass numbers 86:88 corresponding to the molecular ions with ^{35}Cl and ^{37}Cl and the mass numbers 60:62 probably corresponding to the ions $CHC^{35}Cl^+$ and $CHC^{37}Cl^+$. The molecular weight is consequently 86.5. The relation $^{13}C:^{12}C$ in the substance appears most evident from the intensity relation 4.5:100.0 between the mass numbers 52:51, corresponding to the ions $^{13}CC_3H_3^+$ and $C_4H_3^+$. Hence the assumption of four carbon atoms is confirmed.

A UV-spectrum of the substance was run between 340 and 200 nm. An absorption at 277 – 278 nm was observed.

For monovinylacetylene, absorption at 221 nm and 227.5 nm has been reported by Georgieff *et al.*[2]

The IR-spectrum of gaseous 4-chlorobuten-3-yne is given in Fig. 1. A theoretical calculation of the frequencies, from a normal coordinate analysis using a simple diagonal valence force field, shows good agreement with the obtained spectrum for some of the peaks.[3,4]

At 3120 cm^{-1} we observed the asymmetric hydrogen stretch for the vinyl group. The peak at 3035 cm^{-1} belongs either to the symmetric hydrogen stretch for the vinyl group or a stretch of the remaining hydrogen. At 2220 cm^{-1} the characteristic stretching of $-C\equiv C-$ was observed and at 1600 cm^{-1} the $-C=C-$ stretch. There is no strong absorption around 3300 cm^{-1} which shows the purity of the substance and eliminates the isomeric chlorobutenyne structures.[5,6]

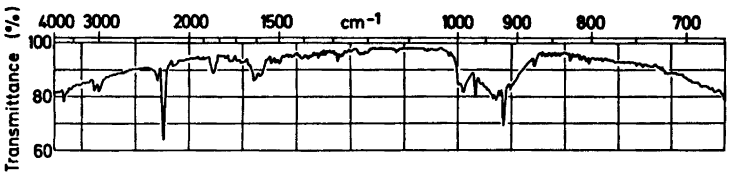

Fig. 1. IR spectrum of 4-chlorobuten-3-yne. Vapour mixed with He, 1 m cell, KBr optics. The curved background line depends on multiple reflections in the 1 m cell; no reference cell could be used.

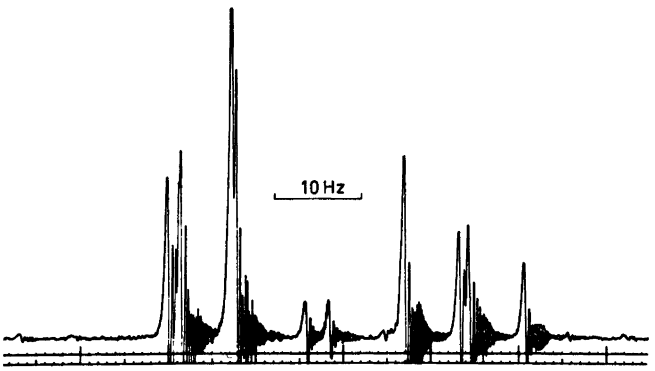

Fig. 2. High resolution NMR spectrum of 4-chlorobuten-3-yne at 98 MHz with C_6D_6 as solvent.

The NMR-spectra of 4-chlorobuten-3-yne were recorded at 60 MHz with carbon tetrachloride as solvent and at 98 MHz with deuteriochloroform and deuteriobenzene as solvents. The spectra run with CCl_4 and $CDCl_3$ as solvents showed a surprising resemblance to an A_2B spin system spectrum. With C_6D_6 as solvent a spectrum was obtained with quite a different appearance (see Fig. 2) as expected from the molecular structure. The observed thirteen lines were used in a least squares fitting procedure, LAOCN 3 [7] and the following chemical shifts and spin-spin coupling constants were obtained.

The three vinyl protons are labelled C *trans* to A and *cis* to B; $\nu_A = 534.6$ cps [$\delta_A = 5.45(5)$ ppm], $\nu_B = 507.3$ cps [$\delta_B = 5.18$ ppm], $\nu_C = 535.0$ cps [$\delta_C = 5.45(9)$ ppm], $J_{AB} = 0.9$ cps, $J_{AC} = 17.7$ cps, and $J_{BC} = 11.9$ cps.

The values of the chemical shifts are measured from TMS used as internal standard. The obtained values of the coupling constants are in good agreement with those obtained from other vinyl compounds.[8] The chemical shift values are somewhat low, probably due to the solvent, C_6D_6, but their relative positions are in agreement with other vinyl compounds.[8,9]

Acknowledgements. We thank Prof. Bjørn Pedersen for his kind co-operation in assigning the NMR-spectrum. We also thank Mr. Allan Linnarson and Mr. Benkt Sandgärde for determining the mass spectrum and Mr. Jozef Kowalewski for helpful discussions.

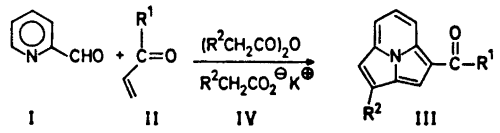
Indolizine Derivatives. I. A Novel One-step Synthesis of Pyrrolo[2,1,5-*cd*]-indolizines. The Mechanism of the Acylative Cyclization of 2-Pyridine-carbaldehyde and Unsaturated Carbonyl Compounds

ESKO POHJALA

Department of Chemistry, Helsinki University of Technology, SF-02150 Otaniemi, Finland

Some fifteen years ago practical syntheses of many pyrrolo[2,1,5-*cd*]indolizine derivatives starting from indolizines [1] were developed. Later, the preparation of pyrrolo[2,1,5-*cd*]-indolizines from pyrrolizines,[2] alkylpyridines,[3] and pyridineacrylates [4] have been reported. The overall yields based on commercial starting materials were seldom better than moderate.

As shown in this paper, the acylative cyclization between the readily available 2-pyridine-carbaldehyde (I) and an α,β-unsaturated carbonyl compounds such as II seems to provide a new, convenient route to 1-acyl-substituted pyrrolo[2,1,5-*cd*]indolizines (III).



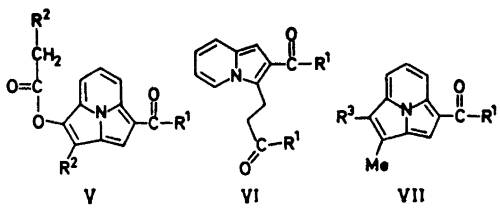
I II IV III

R^1 = Me, Ph, MeO
R^2 = H, Me

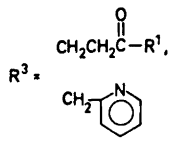
In a typical procedure I and IIa, Ac_2O and KOAc (rather arbitrary mol ratios 2:3:20:10, respectively) are refluxed for 15 min. After a standard work-up* the product IIIa is freed of coloured by-products, best by benzene elution over alumina or silica. The yield is 60 – 70 %.

In order to study the scope and mechanism of this peculiar cyclization reaction, other unsaturated carbonyl compounds were used in place of IIa. Similar cyclizations in a propionate system were examined. The results are shown in Table 1.

The structures of the cyclization products are in accord with analyses and spectral data. The nature and sites of the substituents in pyrrolo[2,1,5-*cd*]indolizines are easily determined by NMR-spectroscopy.[4] The substitution



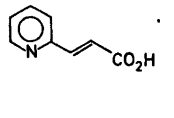
V VI VII



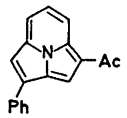
pattern in the resulting pyrrolo[2,1,5-*cd*]indolizines, that is, the acyl group at C-1 and the methyl group (when R^2 = Me) at C-3, verifies that C-1 and C-2 must originate from the α- and β-carbons of II, respectively, and C-2a and C-3 from the 1- and 2-carbons of IV, respectively.

The reaction may be visualized (Scheme 1) as beginning with a Perkin reaction to give the bicyclic intermediate VIII, followed by nucleophilic addition of the anion IX to furnish the intermediate X, which then rearranges into the tricyclic intermediate XI. The aromatization completes the reaction. In the propionate case, besides III, V is also formed, probably owing to steric factors. The propionyloxy group at C-4 originates from the aldol intermediate VIII'. A molecule of hydrogen is then lost from the subsequent intermediate XI'.

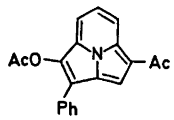
The mechanism is supported by the following findings: Pyridineacrylic acid XII, prepared by the Doebner reaction, reacts as well, yielding with IIa only IIIa in any acylate system. The



XII



XIII



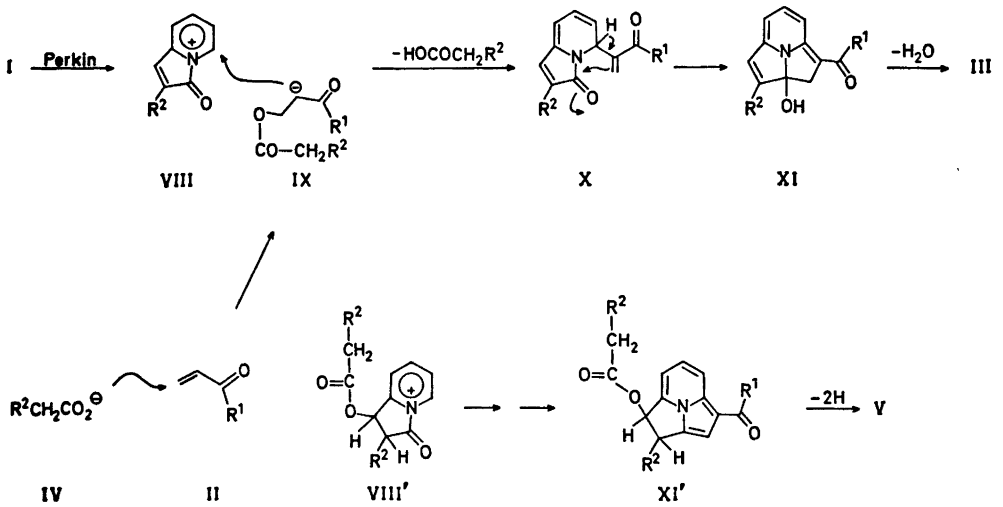
XIV

reaction between I, IIa, and phenylacetic acid gives the compounds XIII and XIV (the phenyl group at C-3). If $KOCOCH_2R^2$ is omitted, neither II nor XII gives rise to pyrrolo[2,1,5-*cd*]indolizines. In mere $(R^2CH_2CO)_2O$ I and the

* The cooled acylating mixture is stirred with water untill acetic anhydride has disappeared. The product is extracted into ether, washed and dried.

Table 1.

	R^1	R^2	Products	(%) of III	Ref.
a	Me	H	IIIa	60–70	(1)
b	Me	Me	IIIb, Vb VIIb	~50	
c	Ph	H	IIIc, VIc	~40	
d	Ph	Me	IIId, Vd, VId, VIId	~20	
e	OMe	H	IIIe	~15	(1)
f	Benzalacetone		None		



Scheme 1.

unsaturated ketones II yield the indolizine VI as the sole product, whereas I and the unsaturated ester IIe do not react at all. Irrespective of the amount of added $KOCOCH_2R^2$, I and IIc always form some indolizine VIc, presumably because the enolate anion IXc is able to compete with an anhydride anion in the first condensation step. Owing to electronic effects, benzalacetone (IIf) does not give sufficiently of the corresponding anion IXf, hence no Xf, which could lead to IIIf.

This mechanism explains the decreasing cyclization tendency IIa > IIc > IIe > IIf; the more II is inclined to form IX, the higher is the reactivity, and makes allowance for the need of a salt catalyst also after the Perkin step.

The author thanks Prof. J. Gripenberg and Dr. T. Hase for their critical comments, and The Finnish Academy for a research grant.

Improved *O*-Methylation of Carotenoids

GERD NYBRAATEN and SYNNØVE LIAAEN-JENSEN

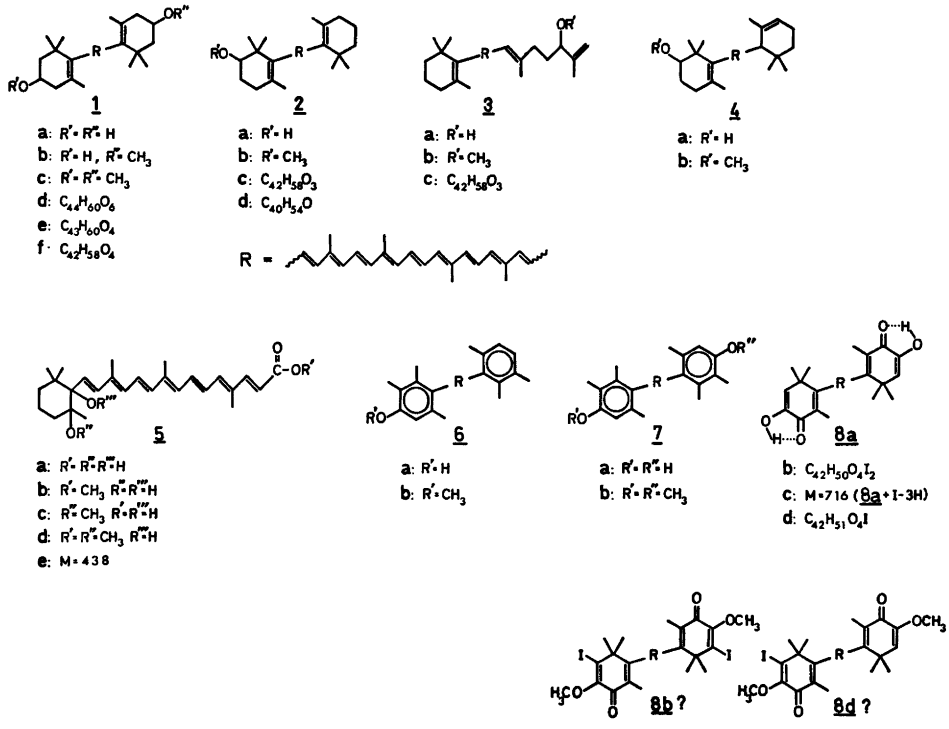
Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034-Trondheim, Norway

Methods available for *O*-methylation of carotenoids have recently been reviewed.[1] These include selective methylation of allylic, secondary hydroxy groups by hydrogen chloride in methanol [2–4] and methylation of non-allylic secondary hydroxy groups with methyl iodide and potassium *t*-amyloxide [5] or better by the Kuhn procedure [6–10] with methyl iodide and silver oxide or barium oxide in dimethylformamide or dimethylformamide/dimethyl sulfoxide. By the latter procedure tertiary hydroxy group may also be methylated.[11] Methylation of enolic and phenolic hydroxy groups in the carotenoid series is not achieved with diazomethane.[12–13]

In the present work, the original Kuhn procedure with silver oxide [6] was shown to result in abnormal products for zeaxanthin (*1a*) and *β,β*-caroten-2-ol (*2a*), Scheme 1. Zeaxanthin (*1a*) gave three products *1d, e, f* more polar than zeaxanthin dimethyl ether (*1c*) with unchanged electronic spectrum and molecular ion *m/e* 684.4392 (684.4390 calc. for $C_{44}H_{60}O_6$), 640 and 626 respectively, and with fragment ions M − 14, M − 30, M − 44, and M − 60 in addition to M − 92 and M − 106 ascribed to eliminations from the polyene chain.[14] Product *1d* has formally added $2 \times C_2H_2O_2$, and the molecular ions of *1e* and *1f* are compatible with the addition of ($C_2H_2O_2 + CH_2$) and $C_2H_2O_2$, respectively. *β,β*-Caroten-2-ol (*2a*) gave a product *2c* (20 % of recovered carotenoid; 45 % total recovery), more polar than the methyl ether *2b*, with molecular ion *m/e* 610, again compatible with a formal addition of $C_2H_2O_2$. The same type of abnormal product has recently been observed for aleuriaxanthin (*3a*).[15]

The BaO/DMF modification [7] gave for *β,β*-caroten-2-ol (*2a*) 49 % pigment recovery, 25 % thereof was a didehydro-*2a* = *2d* (4 nm hypsochromic shift in methanol, *m/e* 550.4170 = M = $C_{40}H_{54}O$).

The BaO-DMF/DMSO procedure,[8] tested for zeaxanthin (*1a*), *β,β*-caroten-2-ol (*2a*),[10] and *β,ε*-caroten-2-ol (*4a*) gave the desired methyl ethers. Thus zeaxanthin (*1a*) gave the dimethyl ether (*1c*, 30 % of recovered carotenoid), the mono-



Scheme 1.

methyl ether (*1b*, 20 %), and unreacted *1a* (50 %); total pigment recovery 50 % after 40 h. β,ε-Caroten-2-ol (*4a*) gave the methyl ether *4b* (35 % of recovered carotenoid) and unreacted *4a*; total pigment recovery 48 %.

These results demonstrate that the Kuhn procedures[6,7] may give abnormal products in the carotenoid series. Yields of methylated products are variable, *cf.* Refs. 9 and 4, and particularly unsatisfactory for secondary, sterically hindered alcohols (*2a*[10] and *4a*) and tertiary alcohols.[11]

Recently Stoochnoff and Benoiton[16] reported that methyl iodide and sodium hydride in tetrahydrofuran effect methylation of weakly acidic or sterically hindered hydroxy groups. The potentiality of this method in the carotenoid series has now been studied:

Secondary, allylic hydroxyl. Aleuriaxanthin (*3a*) gave the methyl ether *3b* (60 % of recovered carotenoid) besides unreacted *3a*; total pigment recovery 66 %.

The methyl ether *3b* had *m/e* 566 (M), 550.4176 (M−CH_4; calc. for $C_{40}H_{54}O$ 550.4175), M−28, M−79, M−92, M−106, M−158.

Secondary, non-allylic hydroxyl. Zeaxanthin (*1a*) gave the monomethyl ether *1b* (15 % of recovered carotenoid) and the dimethyl ether *1c* (85 %); total recovery 92 %. Both methyl ethers exhibited the predicted molecular ions and M−31, M−92, M−106, and M−158 fragment ions; *1b* also an M−18 ion.

Sterically, hindered hydroxyl. β,ε-Caroten-2-ol (*4a*) gave the methyl ether *4b* (60 % of recovered carotenoid) and unreacted *4a*; total recovery 72 %.

Azafrin (*5a*) gave (24 h, room temperature) the methyl ester *5b* (50 % of recovered pigment), *5e* (20 %) and unreacted *5a*; total recovery 85 %. Modified conditions (45 °C, 5 h, 20 °C, 12 h) gave small amounts of the presumed monomethyl ether *5c* and the presumed methyl ester monomethyl ether *5d*; total recovery 75 %.

The methyl ester *5b* had electronic spectrum like azafrin (*5a*), *m/e* 440 (M), M−18, M−31 *etc.*; inseparable from authentic *5b* on cochromatography. Silylation afforded the mono(trimethylsilyl) ether, *m/e* 512 (M); *cf.* Ref. 17.

Phenolic hydroxyl. 3-Hydroxyisorenieratene (*6a*) gave the methyl ether *6b* (100 % of recovered carotenoids) and unreacted *6a*; pigment recovery 80 %. 3,3′-Dihydroxyisorenieratene (*7a*) provided the dimethyl ether *7b* (100 % of recovered carotenoid); pigment recovery 30 %.

Enolic hydroxyl. Astacene (*8a*), see Scheme 1, gave products *8b* (60 % of recovered carotenoid), *8c* (15 %) and *8d* (25 %); pigment recovery 25 %. All products had electronic spectra (round) like canthaxanthin (β,β-caroten-4,4′-dione).

Product *8b* had *m/e* 872.1762 (calc. 872.1799 for $C_{42}H_{50}O_4I_2$), M−78, M−92, M−106, and M−158 ascribed to elimination from the polyene chain,[14] M−126 (?) and double peaks at both *m/e* 127 and *m/e* 128 partly ascribed to I^+ and HI^+. No phenazine derivative[1] was obtained with *o*-phenylenediamine under conditions where astacene (*8a*) gave such derivatives.

Product *8c* had *m/e* 716 (M), M−15, M−92, M−106, M−126 and double peaks at both *m/e* 127 and *m/e* 128.

Product *8d* had *m/e* 746 (M, compatible with $C_{42}H_{51}O_4I$), M−92, M−126 (?) and double peaks at both *m/e* 127 and *m/e* 128.

Data for products *8b* and *8c* are consistent with the structures suggested in Scheme 1. The assumed mechanism for their formation involves abstraction of a proton by the hydride to a resonance stabilized enolate/carbanion, followed by *O*-methylation by methyl iodide and a synchronous or subsequent Michaeltype addition of iodide to C-2. That hydride, rather than iodide, serves as leaving group on reforming the keto group in 4-position, is unexpected. Alternative *C*-methylation should lead to products capable of forming a phenazine derivative.

Only one other iodine derivative of carotenoids is previously described, namely "isocarotintetraiodid",[18] now considered to be a π-complex.[19]

Conclusion. *O*-Methylation with methyl iodide and sodium hydride seems to represent a rather universal method in the carotenoid series.

Thus methylation of phenolic carotenoids was achieved for the first time. Enolic hydroxy groups like in astacene (*8a*) also appear to undergo *O*-methylation, but complications in form of iodinated products arose.

The results obtained indicate that the CH_3I/NaH procedure is superior to previous methods for methylation of non-allylic and allylic (to one double bond) secondary hydroxy groups, including sterically hindered ones.

Judged by the results for azafrin (*5a*) tertiary hydroxy groups appear to be rather unreactive and carboxylic acids provide methyl esters.

Experimental details are reported elsewhere.[20] General conditions used for *O*-methylation with CH_3I/NaH were: To the carotenoid (0.1−1.0 mg) in dry tetrahydrofuran (2 ml) was added freshly distilled CH_3I (1 ml) and NaH (40 mg). The reaction mixture was kept at room temperature in darkness in inert atmosphere for 16−24 h, and worked up in the usual manner. The products were purified by TLC. R_F-values on kieselguhr paper (Schleicher and Schüll No. 287) of the compounds studied are given below with the percentage acetone in petroleum ether used for development given in parenthesis: *1a* 0.40 (10), *1b* 0.39 (2), *1c* 0.89 (2), *1d* 0.58 (2), *1e* 0.65 (2), *1f* 0.31 (2), *2a* 0.85 (5), *2b* 0.55 (0), *2c* 0.93 (2), *2d* 0.40 (0), *3a* 0.45 (2), *3b* 0.54 (0), *4a* 0.54 (1), *4b* 0.86 (1), *5a* 0.0 (100), *5b* 0.72 (5), *6a* 0.52 (5), *6b* 0.68 (2), *7a* 0.27 (10), *7b* 0.85 (5), *8a* 0.40 (10), *8b* 0.72 (10), *8c* 0.69 (10) and *8d* 0.42 (10 %).

The Reaction between Phosphonium Ylides and Isocyanates, a Convenient Route to Ketenimines

PAUL FRØYEN

Chemical Institute, University of Bergen, N-5014 Bergen, Norway

Reactions of phosphonium ylides with isocyanates have been reported in a few papers. In 1919 Staudinger and Meyer [1] found that triphenyl ketenimine (II) could be prepared from phenyl isocyanate by reaction with diphenylmethylene triphenylphosphorane (I; $R^1 = R^2 =$ Ph)

$$Ph_3P{=}CR^1R^2 + Ph{-}N{=}C{=}O \rightarrow$$

(I)

$$Ph{-}N{=}C{=}C\begin{matrix}R^2\\ \diagup\\ \\ \diagdown\\ R^1\end{matrix} + Ph_3P{=}O$$

(II)

Although this was the first preparation of a ketenimine, no yield was reported and no attempt was made to extend the synthesis to other ketenimines. Later, however, Trippett and Walker [2] studied the reactions of phenyl isocyanate with a series of ylides, but no ketenimine was formed during these reactions. It was reported that the reaction between the "non-stabilized" ylide dimethylmethylene triphenylphosphorane (I; $R^1 = R^2 = CH_3$) and phenyl isocyanate stops at the betaine stage. In other cases, when the ylide under investigation contained an α-hydrogen atom, migration of that hydrogen occurred, a new ylide being formed:

$$Ph_3P{=}CHR + Ph{-}N{=}C{=}O \rightarrow$$

$$Ph_3\overset{+}{P}{-}CHR \quad \overset{-}{O}{-}\overset{|}{C}{=}NPh \rightarrow Ph_3P{=}CR{-}C(O)NHPh$$

Finally, Ratts and Partos [3] attempted the following reaction:

$$Ph_3P{=}C{=}C{=}CPh_2 + CH_3N{=}C{=}O \rightarrow$$

$$Ph_2C{=}C{=}C{=}C{=}NCH_3$$

(III)

and were able to isolate the amide of the cumulene imine (III). As far as the present author knows, there have been no other attempt to make ketenimines along this route. Thus, no ordinary ketenimine, except the one synthesized by Staudinger and Meyer has been prepared by

the ylide-isocyanate reaction. The lack of interest in the Staudinger-Meyer synthesis of ketenimines is remarkable, particularly in view of the cumbersome methods currently used for the preparation of these compounds. No single reaction for the preparation of ketenimines has the character of a general reaction. The method most widely used is perhaps the dehydration of *N*-monosubstituted amides,[4] but this preparation gives good yields only in the case of triarylsubstituted compounds.

In order to test the synthetic potential of the ylide-isocyanate method, the present author has undertaken a study of the formation of ketenimines from the reaction of isocyanates with a series of phosphonium ylides $Ph_3P=CR^1R^2$, representing both non-stabilized ylides, *i.e.* pK of the carbon acid $CH_2R^1R^2 > 37$, and stabilized ylides *i.e.* pK of $CH_2R^1R^2 < 35$. The ylide used in the reactions 8, 9, 10, and 11 (Table 1) is of borderline stability (pK of $CH_3Ph_2 \simeq 35$ on the McEwen scale.) The expected ketenimine was isolated in all cases except one. A summary of the results is given in Table 1. The reaction appears in most cases to proceed quantitatively as judged by the amount of triphenylphosphine oxide isolated and by the characteristic infrared absorption at approximately 2000 cm^{-1}. In several cases, however, some material is lost by polymerization during the work-up.

As can be seen from Table 1, the reaction works equally well with aliphatic and aromatic isocyanates, although the latter react under milder conditions. Non-stabilized ylides do undergo the reaction, but not as readily as moderately stabilized ylides. Thus in the case of 12 and 13 (Table 1) comparatively stable intermediates were formed and the reactions could not be completed at 80 °C (boiling benzene). When the ylide was present in a pure state the second step of the reaction could be performed at 130 – 150 °C in mesitylene. However, non-stabilized ylides are most conveniently prepared *in situ* from the corresponding phosphonium salt and alkyl or aryl lithium. When this procedure is applied, lithium halides will be present in the reaction mixture and seriously affect the reactivity of the ylides. In the case of 13 an attempt was made to perform the reaction along this route. The first step of the reaction went smoothly, but the subsequent decomposition of the intermediate to triphenylphosphine oxide and *N*-α-naphthyl dimethylketenimine could not be performed under the abovementioned conditions. Heating for one hour at 170 °C (boiling mesitylene) gave only a trace of the expected products. This result was not unexpected, however, since it is well known from studies of the Wittig reaction that Lewis acids, particularly lithium salts, co-ordinate with the ylides and with the forming intermediates, and the olefin forming step may only be performed under forcing conditions.

In the case of (14), $R^1=CN$, $R^2=COOC_2H_5$) no reaction was observed in boiling benzene. This negative result may be attributed to the extraordinary strong electron-withdrawing groups linked to the carbanion portion of the ylide. The interaction between the ylide carbon and the cyano and ester groups is reflected in a considerable decrease in the nucleophilicity of the ylide, and thereby in its reactivity towards isocyanates. Disubstituted phosphonium ylides were applied in all cases because monosubstituted ylides ($Ph_3P=CHR$) undergo a prototropic shift at the intermediate stage of the reaction forming a new ylide.[2]

Experimental. Materials. The phosphonium ylides were prepared by the "salt method" on treatment of a solution of the appropriate phosphonium salt with a suitable base. The stabilized ylides were generated with sodium ethoxide in anhydrous ethanol and recrystallized from benzene. Dimethyl- and diphenylmethylene triphenylphosphorane were prepared in liquid ammonia, using sodium amide as a base.

Synthesis of ketenimines (Table 1). In a dry 150 ml, two necked, roundbottomed flask equipped with a magnetic stirrer, a nitrogen inlet, and a reflux condenser with drying tube was placed 50 ml of dry benzene, and 0.01 mol of ylide. Thereafter 0.01 mol of isocyanate was slowly added. The reaction mixture was vigorously stirred during the addition. In the case of 4, 5, 9, 10, and 11 (Table 1) the reaction mixture was refluxed for several hours in a slow current of dry nitrogen. 8 was heated at 100 °C in an autoclave for 24 h. In the case of 12 and 13 the reactions were completed after about 5 min at 140 °C in mesitylene. In the other cases, however, the reaction went to completion in a few minutes at ambient temperature. The ketenimine formation was always recognized on the strong infrared absorption at approximately 2000 cm^{-1}. The product was worked up without further heating if no sign of the infrared isocyanate band at 2150 cm^{-1} was observed. The benzene was evaporated *in vacuo* whereafter the ketenimine was extracted with petroleum ether. After evaporation of this solvent, the ketenimines were purified by distillation or by recrystallization. In two cases (6 and 7, Table 1) the product was unstable and could not be purified by distillation.

An Inulin-like Fructan Produced by *Streptococcus mutans*, Strain JC2

KARL-GUNNAR ROSELL[a] and DOWEN BIRKHED[b]

[a] Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden and [b] Department of Oral Microbiology, University of Lund, School of Dentistry, S-214 21 Malmö, Sweden

In studies of polysaccharides elaborated by bacteria, isolated from human dental plaque, *Streptococcus mutans*, strain JC2,[1] was one of the organisms investigated. An enzyme preparation with hexosyltransferase activity was isolated from the supernatant fluid of a glucose broth culture by chromatography on hydroxylapatite.[2] When the enzyme preparation was incubated with sucrose, alcohol-precipitable polysaccharide material was formed. This, on acid hydrolysis, yielded comparable amounts of D-glucose and D-fructose. Judging from previous results,[3,4] the mixture most probably contained a glucan and a fructan. Indeed, a fructan, $[\alpha]_D^{22} -33°$ (*c* 0.3, 0.1 M NaOH), was isolated by precipitation with barium hydroxide as was a glucan, $[\alpha]_D +192°$ (*c* 0.3, 0.1 M NaOH) by precipitation with ethanol. Gel filtration chromatography on Sepharose 2B, as devised by Arturson and Granath,[5] showed that both polysaccharides had high molecular weights, $\overline{M}_w \simeq 2 \times 10^7$.

The two polysaccharides were subjected to methylation analyses as previously described for dextrans [6] and fructans [7] and the methylated sugars obtained were analysed by GLC-MS.[8] The results, given in Table 1, show that the glucan is of the type generally elaborated by *Streptococcus* species, *e.g.* an α-glucan with 3-, 6-, and 3,6-linked residues. The fructan, however, was not of the levan type with (2→6)-linkages, known to be produced by several bacteria, but of the inulin type, with (2→1)-linked β-fructofuranose residues. Some branching through the 6-position was observed. The sugars obtained in the methylation analysis were reduced with sodium borodeuteride. The deuterium labelling observed on MS showed that the tri-*O*-methyl-hexitol came from 3,4,6-tri-*O*-methyl-D-fructose and not from 1,3,4-tri-*O*-methyl-D-fructose. The alditol acetate derivatives of these sugars cannot be separated by GLC; however, the corresponding acetylated sugars are readily separated,[7] and not even traces of the 1,3,4-tri-*O*-methyl derivative were observed.

Until recently, only fructans of the levan type were known to be formed by bacterial fructosyltransferases. After the completion of the present work, another report [9] on a bacterial (2→1)-linked fructan, from *Streptococcus mutans*, strain Ingbritt, has come to our knowledge.

Table 1. Methyl ethers from the hydrolysate of the methylated fructan (A) and the methylated glucan (B).

Trimethyloxosulphonium Chloride from the Iodide through Ion Pair Extraction

ARNE BRÄNDSTRÖM[a] and BO LAMM[b]

[a]Chemical Research Laboratory, AB Hässle, Fack, S-431 20 Mölndal 1, Sweden and [b]Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

Trimethyloxosulphonium halides are important reagents as precursors of dimethyloxosulphonium methylid.[1] Whereas the synthetic procedure yields the iodide,[2] the trimethyloxosulphonium chloride has the advantage of being more soluble in tetrahydrofuran. The preparation of the ylid is thus made possible in this solvent.

The conversion of the iodide to the chloride has been carried out with elemental chlorine.[1] The same change of anion can be more simply and rapidly achieved using ion pair extraction. If trimethyloxosulphonium iodide and an equimolar amount of a suitable quaternary ammonium chloride, *e.g.*, the benzyltributylammonium salt, are distributed between dichloromethane and water, the latter will contain trimethyloxosulphonium chloride, whereas the organic phase will contain benzyltributylammonium iodide. Since iodides are extracted into dichloromethane and similar solvents a thousandfold better than the corresponding chlorides,[3] the ion exchange is practically complete.

The reason for choosing benzyltributylammonium chloride in the present work was that this salt could be simply prepared from inexpensive starting materials, tributylamine and benzyl chloride, in acetonitrile. Kantor and Hauser have reported [4] that this quaternization fails in refluxing benzene or in the absence of solvent. An early report [5] of a successful preparation of the salt in benzene solution could not be reproduced by us and is probably erroneous. The melting point, 185 °C, given in Ref. 5 disagrees with the one found in the present work, 162 – 164 °C. To obtain a good yield in acetonitrile, one week's refluxing was necessary.

Experimental. Benzyltributylammonium chloride. A mixture of 185.4 g (1 mol) of freshly distilled tributylamine, 139.0 g (1.1 mol) of benzyl chloride, and 300 ml of acetonitrile, purified according to O'Donnell and his coworkers,[6] was kept at gentle reflux for one week. Most of the acetonitrile was removed at aspirator vacuum, and 500 ml of dry ether was added, which caused the quaternary salt to precipitate. This was filtered off and washed with dry ether until colourless (*ca.* 500 ml). Drying *in vacuo* yielded 268.2 g (86 %) of crude product. Recrystallization from ethyl acetate containing some ethanol gave an odourless product, m.p. 162 – 164 °C (unchanged on further recrystallization). The recovery was only 60 %. Argentometric titration showed the purified salt to contain 11.3 % of chloride; calc. for $C_{19}H_{34}NCl$, 11.4 %.

Trimethyloxosulphonium chloride. A solution of 15.6 g (0.05 mol) of benzyltributylammonium chloride in 100 ml of water was shaken with 10.2 g (0.05 mol) of trimethyloxosulphonium iodide [2] and 75 ml of dichloromethane until a clean two-phase liquid system was obtained. The aqueous phase was washed with 50 ml of dichloromethane and evaporated, first at aspirator vacuum and then for several hours at an oil pump until constant weight. A quantitative yield of trimethyloxosulphonium chloride was obtained (5.6 g), m.p. 222 – 223 °C, lit.[1] 220 – 222 °C. Iodide was absent as indicated by a spot test with 30 % hydrogen peroxide. From the 60 MHz ^{1}H NMR spectrum, recorded in deuterium oxide solution, it could be concluded that a trace (less than 0.2 mol %) of benzyltributylammonium ion was present which can be disregarded in synthetic use.

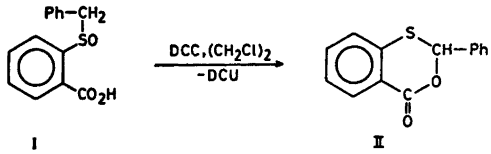
We have found that *o*-benzylsulfinylbenzoic acid (I) is readily converted to 2-phenyl-3,1-benzoxathian-4-one (II) by dicyclohexylcarbodiimide (DCC) in over 90 % yield. The reaction product is obviously the result of a Pummerer-type of rearrangement.[1] It was also found, as expected, that the transformation I→II could be performed using the classical Pummerer reagent acetic anhydride. The latter reaction was reported recently by Numata and Oae [2] after the initiation of our investigation. The lactone II was first described in 1961 as the product from a condensation of thiosalicylic acid with benzaldehyde.[3]



I II

Starting with optically active I we found that product II, after repeated chromatography on silica gel, possesses optical activity. A remarkable difference in the stereochemical course of the reaction, depending upon the nature of the Pummerer reagent and the solvent used, was observed, however. While the DCC-method gave II with an opposite sign of rotation to I, the situation with the use of acetic anhydride (AA) was found to be more complex. While a small excess of AA in benzene similarly gave II with opposite sign of rotation, the reverse was found with AA as both reagent and solvent. The results are given in Table 1.

These data imply that the DCC-reaction in 1,2-dichloroethane proceeds with the highest degree of stereoselectivity, while the reaction in acetic anhydride is associated with much more of racemization. This is not surprising, however, in view of the higher temperature needed in the latter case and the known.[4,5] ability of this medium to cause racemization of sulfoxides due to an acetoxy-interchange at the sulfur atom. Unfortunately, the optical yield of the DCC-reaction remains unestimated because the rotation of optically pure II is not yet known.

To the best of our knowledge, the only stereoselective Pummerer rearrangement so far reported is the reaction of 2,2-dialkyl-1,3-oxathiolan-5-one *S*-oxides with acetic anhydride in dichloromethane to give 4-acetoxy-2,2-dialkyl-1,3-oxathiolan-5-ones, where the 85–90 % stereoselectivity observed was interpreted in terms of an intramolecular migration of the acetoxy-group on one side of the ring.[6]

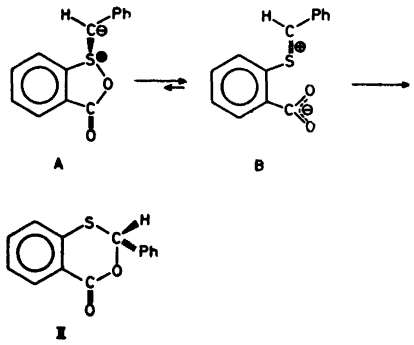
However, the presently described conversion of I to II appears to be the only reported Pummerer type of reaction in which an intramolecular transfer of chirality has occurred with the formation of an optically active product. Although a more detailed investigation of the mechanism is needed, some remarks and conclusions may nevertheless be made.

From Moffatt's investigations on the reactions of DMSO-DCC with carboxylic acids,[7] it was established that the necessary intermediate for the formation of an α-acyloxysulfide in this reaction is an acyloxysulfonium ylide. We feel that the key step responsible for the chirality-transfer is the opening of the cyclic ylide (A) and recombination to the ring-expanded product II, most probably *via* an ion pair (B) with restricted rotation around the partially double C–S-bond.

Stereoselectivity is thus induced with the formation of A as a consequence of the different reactivities of the diastereotopic protons [8] at the prochiral benzylic carbon atom. The ylide A should be a common intermediate in the DCC as well as the AA reaction, although with loss

Table 1.

I, $[\alpha]_D^{25}$	Pummerer reagent	Solvent	Temp. °C	II, $[\alpha]_D^{25}$	Yield %	Reaction time h
+451	DCC	$(CH_2Cl)_2$	25	−46.3	91	15
+451	DCC/H_3PO_4	THF	25	−7.9	89	2
+451	AA	C_6H_6	80	−30.2	91	5
+451	AA	AA	100	+17.3	95	2
+451	AA	AA NaOAc added	100	+8.2	98	2



of stereochemical integrity in more acidic media. The steps preceding A should follow the normal Pummerer mechanism, the difference from the normal route being due to internal nucleophilic participation by the carboxyl group present in the molecule.

Experimental. o-*Benzylthiobenzoic acid*, prepared by benzylation of thiosalicylic acid, was obtained in 85 % yield. M.p. 183 – 185 °C (lit.[9] m.p. 189 °C).

o-*Benzylsulfinylbenzoic acid (I).* o-Benzylthiobenzoic acid (15 g, 0.0615 mol) was dissolved in 600 ml of acetone-acetic acid (2:1) and oxidized with 5 % excess of a 15 % solution of peracetic acid in acetic acid. The reaction mixture was kept at 5 °C for 5 h and then at 25 °C for 20 h. After evaporation of the solvent, the product was recrystallized from acetone-petroleum ether. The yield was 13.2 g (82 %) of pure I, m.p. 164 – 165 °C (dec.).

Resolution of I. Racemic I (8.5 g, 0.0327 mol) was dissolved, together with brucine (dihydrate; 14.1 g, 0.0327 mol), in 350 ml of boiling acetone-ethyl acetate (6:1). The solution was left at 25 °C for 24 h, and the salt (11.1 g), which had crystallized, was isolated. The acid, liberated from a small amount of this salt, showed $[\alpha]_D^{25} = -373°$ (EtOH). The salt was treated with 300 ml of boiling acetone and, after cooling to room temperature, filtered by suction and dried. An amount of 8.6 g was obtained. A small crop of liberated acid showed an increased negative rotation, $[\alpha]_D^{25} = -444°$ (EtOH). This procedure was repeated, using 100 ml of acetone, which yielded 8.4 g of salt from which the acid, $[\alpha]_D^{25} = -443°$ (EtOH), was liberated. One recrystallization of the acid from acetone-ethanol gave 2.5 g of optically pure (–)-I, $[\alpha]_D^{25} = -449°$ (EtOH, $c = 0.5$). M.p. 165 – 166 °C (dec.).

The other enantiomer was liberated from the mother liquor from the first crystallization, $[\alpha]_D^{25} = +332°$ (EtOH). The optical purity was increased by two recrystallizations of the acid from acetone-ethanol. In this way (+)-I (2.5 g, m.p. 165 – 166 °C (dec.) with maximum rotation, $[\alpha]_D^{25} = +451°$, was obtained.

2-Phenyl-3,1-benzoxathian-4-one (II). A. I + DCC. DCC (0.103 g, 0.5 mmol) was dissolved in 5 ml of dry 1,2-dichloroethane, the solution cooled to 0 °C and finely powdered (racemic) I (0.130 g, 0.5 mmol) was added. The reaction mixture was kept for 1 h at 0 °C and for 14 h at 25 °C. Acetic acid (0.075 g, 1.25 mmol) was added and after stirring for 30 min the precipitated *N,N'*-dicyclohexylurea (DCU) was removed by filtration and the remaining filtrate evaporated to dryness. The product was then chromatographed on silica gel 60 (120 – 230 mesh) with chloroform as the eluent. Pure (racemic) II (0.110 g, 91 %) of m.p. 85.5 – 87.5 °C, (lit.[3] 83 – 84 °C, lit.[2] 90 – 91 °C) was obtained.

Starting with (+)-I this procedure yielded (–)-II, $[\alpha]_D^{25} = -46.3°$ (EtOH, $c = 1$), m.p. 88 – 90 °C, of unknown optical purity. The optical activity remained unchanged when (–)-I was rechromatographed with benzene as the eluent.

DCC (0.309 g, 1.5 mmol) in THF (3 ml) was added at 0 °C to a stirred solution of (+)-I (0.130 g, 0.5 mmol) and anhydrous orthophosphoric acid (0.025 g, 0.25 mmol) in THF (4 ml). Almost immediately crystalline DCU separated. After 30 min at 0 °C the mixture was kept at room temperature for 1.5 h. Oxalic acid (0.19 g, 1.5 mmol) was added and after 30 min the DCU was removed by filtration and the filtrate was evaporated. The residue was dissolved in benzene (10 ml), filtered to remove a small amount of DCU, and evaporated. The product was chromatographed as described above with chloroform as the eluent. 0.108 g (89 %) of II with m.p. 87 – 89 °C and $[\alpha]_D^{25} = -7.9°$ (EtOH, $c = 1$) was obtained.

B. I + AA. Treatment of I (0.130 g, 0.5 mmol) with an excess of acetic anhydride[2] (5 ml), evaporation and chromatographic purification of the product as described above, gave II in more than 90 % yields. By this method, however, (+)-I was converted to a product with $[\alpha]_D^{25} = +17.3°$ (EtOH, $c = 1$), m.p. 89 – 90 °C. The optical rotation was retained when the product was rechromatographed with benzene or ether as the eluents.

Addition of sodium acetate (0.1 g, 1.22 mmol) gave II with $[\alpha]_D^{25} = +8.2°$ (EtOH, $c = 1$), m.p. 89 – 90 °C.

When the reaction was performed in benzene (10 ml) with a 3:1 molar ratio of acetic anhydride (0.153 g, 1.5 mmol), the rotatory power of the chromatographed product was $[\alpha]_D^{25} = -30.2°$ (EtOH, $c = 1$) and m.p. 88 – 89.5 °C.

The optical rotations were determined at 589 nm with a Perkin-Elmer model 141 photoelectric polarimeter with the use of 1 ml microcells of 10 cm length.

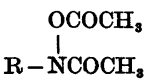
Electrolytic Generation of Nucleophiles. III.[1] Reductive Acetylation of Nitro and Nitroso Compunds

LeROY H. KLEMM,[a] PALLE E. IVERSEN[b] and HENNING LUND[b,*]

[a] Department of Chemistry, University of Oregon, Eugene, Oregon 97403, USA and [b] Department of Organic Chemistry, University of Aarhus, DK-8000 Aarhus C, Denmark

During the current investigations [2] of the reaction between electrophiles and electrolytically generated nucleophiles reductive acetylation of *N*-heterocyclic compounds was found useful.[3] Below is reported the analogous electrolysis of nitro and nitroso compounds in the presence of acetic anhydride to *N*,*O*-diacetyl-*N*-substituted hydroxylamines (I).



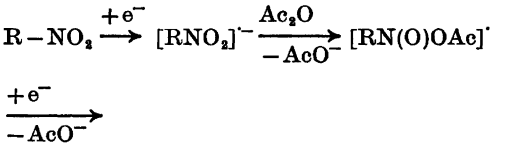
I

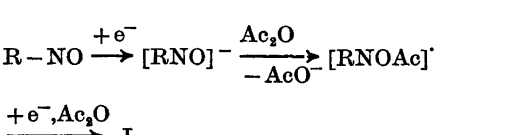
N,*O*-Diacetylhydroxylamines, which are of interest in chemical carcinogenesis,[4,5] mutagenesis,[6] and nucleic acid transformations,[7] have been obtained by acetylation of the corresponding hydroxylamines [8] or monoacetylated derivatives;[9] direct catalytic reduction of nitroarenes in the presence of acetic anhydride to I has only very limited success.[10]

Electrolytic reduction at a suitable potential of nitro or nitroso compounds in an aprotic medium, such as acetonitrile, containing an excess of acetic anhydride gives the desired compounds in one step in fair to good yield (47 – 87 % isolated yield). In Table 1 are given the yields from some electrolytic reductions and some of the properties of the isolated products.

The mechanism of the reaction has not been established; besides the scheme given below, where anion radicals or anions act as nucleophiles towards the electrophile acetic anhydride, there might be the possibility that the anion radicals acts as an electron donor towards acetic anhydride. Acetic anhydride could then cleave into an acetate ion and an acetyl radical, which then could couple with a substrate anion radical. The nucleophilic reaction mechanism is at present thought more likely than the radical coupling, mainly for the following two reasons: (a) *n*-values for the nitro and nitroso compounds are found close to 4 and 2, respectively, which is less likely for a radical process where acetyl radicals may react with other substrates than the nitro anion radicals, and (b) no "catalytic" increase [11] in the polarographic waveheight of *t*-nitrosobutane was obtained in the presence of acetic anhydride.

Nitroso compounds seem to be intermediates during the reductive acetylation of nitro compounds as judged from the fact that a slight blue colour, presumably due to the monomer *t*-nitrosobutane,[12] is observed during the electrolysis of *t*-nitrobutane. The same products have been isolated from the reductive acetylation of either nitro or nitroso compounds, and the following reaction scheme is thus suggested:





The same experimental procedure, which here has been applied to nitro and nitroso compounds and previously to heteroaromatic compounds,[3] has also been applied to the reductive acetyla-

tion of anthraquinone, benzoquinone, and 2,3,5,6-tetramethoxybenzoquinone in yields of 70–85 %. The simplicity in controlling the degree of the reduction probably makes the procedure the method of choice where a reductive acylation to a partly reduced substrate is sought.

Experimental. Apparatus. An H-type 3-electrode cell of conventional design[13] has been used in combination with a Juul Electronic 100V/3A or 100V/10A potentiostat. Spectra were recorded on a Varian A60 NMR-spectrometer and a Perkin-Elmer Infracord IR-spectrophotometer. Analytical VPC was performed on a FM810 gas chromatograph and preparative VPC on a Perkin-Elmer F21. Melting and boiling points are uncorrected.

Materials. The nitro and nitroso compounds were either commercially available or prepared according to published procedures.[12,14]

General procedure. Electroreductions were mostly performed at room temperature (water bath surrounding the cell) at a stirred mercury cathode maintained at controlled potential, usually −0.9 to −1.3 V *vs* an Ag/AgI or Ag/Ag *p*-toluenesulfonate reference electrode. The solvent/electrolyte was anhydrous acetonitrile (dried over type A4 molecular sieves) containing 0.8 M sodium perchlorate and 10 % (by volume) of redistilled acetic anhydride throughout the cell. The anode was made of platinum gauze, because a graphite rod rapidly breaks down when used as an anode in aprotic perchlorate medium. The substrate (usually 1–2.3 g) was dissolved in the catholyte (180 ml) and current was passed through at the chosen potential until it ceased, usually after uptake of 5–10 % more than the theoretical consumption. Especially for the aliphatic compounds it was found advantageous to work up immediately and use short electrolysis times to minimize the formation of by-products. During the electrolysis a white precipitate was formed and the catholyte turned more or less yellowish. The precipitate could be filtered off, washed with acetonitrile, and identified as sodium acetate by its IR-spectrum; it was formed in an amount closely corresponding to the amount of electricity consumed.

Typically the resulting catholyte was concentrated *in vacuo*, diluted with methylene chloride or chloroform, filtered to remove the inorganic salts and evaporated *in vacuo*. The residue was analyzed by NMR or VPC (2 m 15 % SE30 on Chromosorb W, isothermal at 50 °C for 5 min, then programmed to 200 °C with 10 °C/min, biphenyl as internal standard). The products were isolated and purified by means of distillation, recrystallization, preparative VPC (2.7 m 15 % SE30, conditions similar to the analytical VPC) or column chromatography (chloroformsilica gel), and identifiel by means of IR (*N*-Ac, 1670–1690; *O*-Ac, 1780–1800 cm^{-1}), NMR and comparison with authentic samples and/or literature data (Table 1).

N,O-Diacetyl-*p*-tolylhydroxylamine, amber

liquid; IR-spectrum (film, cm^{-1}): 1780(s), 1670(s) 1170(br, s), 850(br, m), 820(br, m). NMR-spectrum (CCl_4): δ 1.94 (s, 3 H); δ 2.10 (s, 3 H); δ 2.36 (s, 3 H); δ 7.0 – 7.5 (multiplet, 4 H). The IR- and NMR-spectra correspond to those previously published.[6]

N,N′,O,O′-*Tetraacetyl*-m-*dihydroxylaminobenzene* (IV). *m*-Dinitrobenzene (1.0 g) was reduced at 5 °C in acetonitrile containing $NaClO_4$ in the presence of 10 ml acetic anhydride at -0.2 V *vs* Ag/AgI-electrode, $n = 8$. The solvent was evaporated and the residue extracted with methylene chloride. Evaporation of CH_2Cl_2 left 5.55 g of a residue; from NMR-analysis of the residue a yield of 88 % of tetraacetyl-1,3-dihydroxylaminobenzene was found. The residue was dissolved in 5 ml CH_2Cl_2 and 5 ml ether and then petroleum ether (b.p. < 50 °C) were added to beginning turbidity. A small amount of coloured material was filtered off and the filtrate cooled to -20 °C. The crystals, 1.60 g, m.p. 113 °C was recrystallized from methanol yielding a compound m.p. 119 °C (1 °C/min). NMR δ 2.11 (s, 6 H); δ 2.22 (s, 6 H); δ 7.3 – 7.7 (multiplet, 4 H). (Found: C 54.76; H 5.44; N 9.10. Calc. for $C_{14}H_{16}N_2O_6$: C 54.54; H 5.23; N 9.09).

Palladium(II) Catalyzed Aromatic Acetoxylation. IV. Nuclear Acetoxylation in the Gas Phase: Reversal of the Usual Isomer Distribution Pattern in Aromatic Substitution

LENNART EBERSON* and LENNART JÖNSSON

Division of Organic Chemistry 1, Chemical Center, University of Lund, P.O. Box 740, S-220 07 Lund 7, Sweden

The acetoxylation of aromatic compounds in the gas phase using different palladium based catalysts has been studied. Low yields (of the order of 1 % per pass) of acetoxylated products were obtained on catalysts in which promotors, such as bismuth or silver-bismuth, had been added to the palladium. For monofunctional benzenes the isomer distributions observed were close to the statistically expected ones. However, when a cooxidant (*e.g.* potassium dichromate) was incorporated in the catalyst, the *meta* isomer became predominant, as has earlier been observed in homogeneous palladium acetate catalyzed acetoxylation reactions. ESCA studies on two of the catalysts indicated that the catalyst favoring *meta* orientation has a relatively high surface concentration of Pd(II) species.

Previous work from this laboratory[1-4] has shown that the homogeneous palladium(II) acetate catalyzed acetoxylation of monofunctional benzene derivatives that takes place in acetic acid in the presence of oxygen (eqn. 1) shows a reversal of the normal substituent effect, *i.e.*,

$$2Ar-H + 2HOAc + 1/2O_2 \xrightarrow[HOAc]{Pd(II)} 2Ar-OAc + H_2O \quad (1)$$

ortho,para-directing substituents give predominantly *meta* acetoxylation and *meta*-directing ones *ortho,para* acetoxylation. Similar findings have been reported by other investigators.[5,6]

Under the conditions referred to above, the reaction is, however, very slow, the degree of conversion being typically of the order of 100 % per 24 h, based on the amount of palladium used. We have therefore initiated a study of the factors influencing the rate and selectivity of this acetoxylation process with the goal of attaining practically useful reaction rates while retaining the selectivity for *meta* substitution. Since it was known that aromatic acetoxylation is also feasible in the gas phase over solid palladium based catalyst,[7-9] we decided to investigate this type of reaction first. This paper shows that it is indeed possible to achieve a modest degree of *meta* selectivity in the gas phase process too, and that possibly the presence of Pd(II) species on the catalyst surface is necessary for the *meta* selectivity.

RESULTS AND DISCUSSION

Product studies. A number of palladium catalysts for the gas phase acetoxylation of benzene have already been described by Arpe and Hörnig.[9] It was shown that gold is an efficient promotor for the formation of phenyl acetate, and that impregnation with activators like potassium and cadmium acetate—alone or in combination—was necessary to suppress the formation of phenol and concomitant resinification of the catalyst. The catalyst carrier in all these cases was silica (Davison, grade 62).

We have repeated these experiments with benzene as the substrate using the apparatus and conditions described in the experimental section with essentially the same results as those

* To whom inquiries should be addressed.

Table 1. Catalysts used for gas phase acetoxylation of aromatic compounds; palladium content = 1.0 %; impregnated with KOAc and $Cd(OAc)_2$[a].

Designation	Promotor(s) atom-% of Pd	Carrier[b]
A	Bi 30	Alumina pellets
B	Bi 30	Alumina granules
C	Bi 30	Glass wool
D	Au 55, Bi 20	Alumina pellets
E	Ag 40, Bi 10	Alumina pellets
F	Ag 20, Bi 10, $K_2Cr_2O_7$ 36[c]	Alumina pellets
G	Bi 30, $K_2Cr_2O_7$ 36[c]	Alumina pellets

[a] Without these activators the yield of acetoxy compounds was considerably lower. [b] With activated carbon or silica as carrier, no acetoxy compounds were formed. [c] Before reduction.

obtained by Arpe and Hörnig [9] (see Tables 1 and 2). We found, however, alumina in the form of pellets or granules to be superior to silica as a catalyst support and have therefore consistently used this material in this investigation. The yield of phenol and resulting resinification was especially less pronounced with this carrier. Also, it was found advantageous to use lower concentrations of palladium on the catalyst (1 % instead of 2 – 3 %). The optimum temperature was found to be in the range of 180 – 190 °C; at lower temperatures vaporization was not sufficiently fast and at higher temperatures side-reactions often occurred, sometimes with almost complete combustion of acetic acid and substrate and a spontaneous increase of reactor temperature to above 300 °C.

Next anisole was used as a substrate with a number of catalyst compositions modelled after those used by Arpe and Hörnig (Table 1, catalyst A – E). In this case bismuth or the combination silver-bismuth were found to be better promotors than gold, at least with respect to the yield of nuclear acetate obtained per pass (see Table 3). Alumina as pellets or granules and glass wool could be used as carriers, whereas silica or activated carbon did not support the acetoxylation process. As seen from the results given in Table 3, none of the catalysts A – E show any selectivity toward *meta* substitution. The isomer distribution in all five cases is close to the statistically expected one, 40:40:20.

It has been shown that the presence of co-oxidants, such as potassium dichromate [5] or nitric acid and derivatives thereof,[5,6,10,11] has a favorable effect on the homogeneous acetoxylation process and that *meta* selectivity is obtainable under such conditions.[6,12] We have suggested [1,2,4] that the *meta* selectivity of the homogeneous Pd(II) catalyzed reaction can be explained by electrophilic attack of a Pd(II) species on the aromatic substrate with formation of an oxypalladation adduct. The role of the cooxidant would then be to assist in the decomposition of the oxypalladation intermediate. Another possible role of the cooxidant in the homogeneous process would be to reoxidize Pd(0) to Pd(II) species.

Translating these ideas to the heterogeneous system, it was expected that impregnation of the catalyst with potassium dichromate would increase the *meta* selectivity. Firstly, the redox system Cr(III)/Cr(VI) would act as a mediator between O_2 and Pd(0) (it is known [13] that O_2 oxidizes Cr(III) to Cr(VI) on alumina) and hence possibly increase the concentration of Pd(II) on the catalyst surface. Secondly, Cr(VI) would assist in decomposing any oxypalladation adduct formed. As can be seen from Table 3, catalyst F, designed along these lines, does increase the *meta* selectivity for anisole acetoxylation compared to the others, even though the effect is fairly small. The possible correctness of the idea behind the incorporation of the

Table 4. Gas phase acetoxylation of aromatic compounds at 185 ± 5 °C over catalyst F (see Table 1).

[a] Fluoro-, bromo-, and iodobenzene did not react under the reaction conditions employed. [b] At 245 ± 5 °C.

Cr(III)/Cr(VI) redox system in the catalyst was, however, further substantiated by the following experiment: The catalyst (F) bed was first oxidized by air at 300 °C (10 l/h for 10 h), and then the acetic acid/anisole solution introduced at 185 °C using a slow stream of *nitrogen*. The product from this run consisted of methoxymethyl phenyl ether (19 %) and nuclear acetates (81 %) in the *o:m:p* ratio of 17:62:21. Since the preoxidized catalyst is expected to contain a relatively high concentration of Pd(II) and Cr(VI) sites, it is obvious that the presence of these oxidation states favors *meta* orientation. Further evidence in this direction is provided by the ESCA results discussed below.

Catalyst F was then used for the acetoxylation of a number of aromatic substrates. It can be seen by inspection of Table 4 that nuclear acetoxylation is by no means a general reaction under these conditions, but that four monosubstituted benzenes (anisole, chlorobenzene, *t*-butylbenzene, and isopropylbenzene) do undergo acetoxylation with predominant *meta* orientation. For *p*-xylene, a substrate that previously has been shown [7] to undergo only side-chain acetoxylation in the gas phase, we were able to secure a 25 % relative yield of the nuclear acetate on catalyst F. Mesitylene gave side-chain acetate only.

While it has been shown above that it is possible to achieve *meta* selectivity in the gas phase process, it is not as high as in the homogeneous $Pd(OAc)_2/CH_3COOH/O_2$ reaction described by us earlier. On the other hand, later experience by us [13] and others [6] has revealed that attempts to increase the reaction rate, *e.g.*, by addition of nitrate ion, result in a decrease in *meta* selectivity. What appears to be a greater disadvantage of the gas phase reaction is the low space-time yield and the relatively fast inactivation of the catalyst due to resin formation. In spite of a great deal of experimentation with the catalyst composition, we have not been able to overcome these difficulties.

ESCA studies. Since the ESCA technique [14] is a sensitive method for the analysis of surface species, an ESCA investigation of two of the catalysts used in this investigation was performed in the hope that it would be possible to decide if the palladium metal of the reduced catalyst – the final step in the preparation of the catalyst is reduction by methanol – is transformed to Pd(II) during the reaction.

ESCA spectra of catalysts A and F, recorded before and after the catalytic reaction, revealed that charging of the samples made the exact external energy calibration impossible. It was, however, established from a reference spectrum [15] of a mixture of Pd(II) acetate and Pd metal that there is a shift between Pd(0) and $Pd(OAc)_2$ of 2.7 ± 0.5 eV (Fig. 1). A spectrum of the same mixture, applied on the carrier used in the catalysts, showed a shift of 2.9 ± 0.5 eV. In this experiment, it was noticed that Pd(II) acetate was partially transformed into Pd metal under the conditions prevailing during the recording of the spectrum.

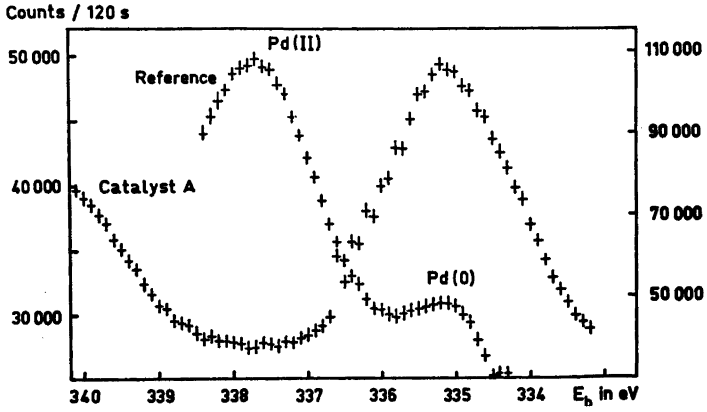

Fig. 1. ESCA spectra of (1) a reference mixture of Pd(II) acetate and Pd metal ($3d_{5/2}$ level) and (2) catalyst A.

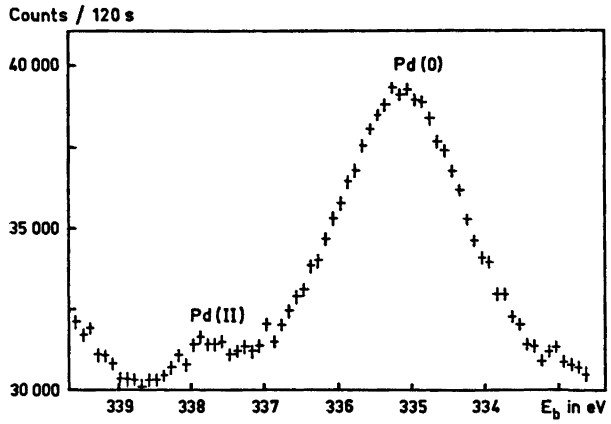

Fig. 2. ESCA spectrum of catalyst F.

Fig. 1 and 2 show printout spectra of catalysts A and F, respectively, after the reaction. In both cases the catalysts have been prepared in a way which excludes the presence of any Pd(II) on the catalyst before the reaction. Yet the spectrum of catalyst F, one which has been shown to give predominantly *meta* substitution and designed to do so by incorporation of a feature favoring formation of Pd(II), shows a signal shifted 2.8 eV from that of Pd(0). This signal must originate from Pd(II) generated in the course of the reaction. We thus conclude that the presence of Pd(II) species is a necessary requirement for the oxypalladation mechanism leading to anomalous substitution patterns both in the homogeneous and heterogeneous process. It also appears probable that there is another, more efficient acetoxylation mechanism possible in these systems, mediated *via* Pd(0) and leading to a statistical isomer distribution in nuclear acetoxylation or, if possible, to side-chain substitution. We have previously noticed [2] and commented [4] upon the fact that the appearance of Pd metal in the homogeneous process seems to be connected with the commencement of side-chain acetoxylation and would like to suggest that some type of dehydrogenation mechanism catalyzed by Pd(0) does occur both in side-chain and nuclear acetoxylation.

In a recent paper,[16] Evnin, Rabo, and Kasai have shown that it is possible to effect the vapor-phase oxidation of ethylene to acetaldehyde over a heterogeneous catalyst system. In the design of this catalyst, the same principle as that described above was used, *i.e.*, palladium metal was combined with an oxidizing agent, capable of reoxidizing Pd(0) to Pd(II) with high efficiency. In this particular case, vanadium pentoxide was used as the oxidizing agent.

EXPERIMENTAL PART

Materials. All chemicals used in this investigation were either purchased in the highest commercial quality available or prepared according to known procedures (see Parts I – III of this series). Carriers for catalysts were alumina pellets (1/8 in γ-Al_2O_3, activated), alumina granules (from Kebo, Stockholm, Sweden), silica (activated, 0 – 1 mm), carbon (activated 3 – 5 mm) and glass wool.

Preparation of catalysts. Catalysts A – G were prepared as follows: Alumina in the form of pellets or any of the other carriers used (100 g) was impregnated with *ca.* 100 ml of an HNO_3/H_2O (50:50) solution containing palladium acetate (2.1 g, corresponding to a Pd content of 1 % in the final catalyst) and the different compounds added as promotors. These were for A – C, $Bi(NO_3)_3.5H_2O$ (1.4 g); D, $Au(NO_3)_3$ (1.9 g) + $Bi(NO_3)_3.5H_2O$ (0.9 g); E, $AgNO_3$ (0.6 g) + $Bi(NO_3)_3.5H_2O$ (0.5 g); F, $AgNO_3$ (0.3 g) + $Bi(NO_3)_3.5H_2O$ (0.5 g) + $K_2Cr_2O_7$ (1.0 g); G, $Bi(NO_3)_3.5H_2O$ (1.4 g) + $K_2Cr_2O_7$ (1.0 g). The catalyst was first dried in a rotating film evaporator and then in the reactor tube at 200 °C for 30 min. Reduction of the catalyst was achieved by passing nitrogen, saturated with methanol at 25 °C, through the reactor for 2 h at 200 °C and 2 h at 400 °C at a flow rate of 5 l/h. The reduced catalyst was allowed to cool under nitrogen. Finally, the catalyst was impregnated with 50 ml of a water solution of

potassium acetate (1.5 g) and cadmium acetate (2.0 g) and dried in an oven at 150 °C.

Acetoxylation reactions. The catalytical reactions were carried out in a conventional flow reactor, consisting of a Pyrex tube (700 × 25 mm) which contained catalyst (100 g) and carrier (*ca.* 25 g) in the part (150 mm) adjacent to the inlet tube. This part of the reactor served to vaporize the liquid reactants before entering the catalyst zone. The tube was heated in an electrical oven, the temperature of which was controlled to within ± 5 °C.

The reaction was carried out in the following way: A solution of the substrate (0.05 mol) and a small amount of acetic anhydride (2 g) in acetic acid (20 g; molar ratio substrate/acetic acid = 1:6) was introduced into the reactor during 3 h *via* a fine dosage dropping funnel. Air (7 – 7.5 l/h) or oxygen (3 – 3.5 l/h) was flowing through the reactor at the same time. The product was condensed at – 20 °C and worked up by treatment with sodium bicarbonate solution and subsequent ether extraction (three times). The combined ether extracts were washed with water and dried with anhydrous magnesium sulfate and analyzed by GLC (Varian 1400 gas chromatograph, equipped with a disc integrator; column 2 m × 3 mm 5 % neopentylglycol succinate on Chromosorb W or 2 m × 3 mm 10 % Apiezon L on Chromosorb P). Internal standard was *m-t*-butylphenyl acetate, pentamethylbenzene, durene, or benzal diacetate. Products were identified by comparison with authentic specimens (GLC or GLC/MS).

ESCA studies. The ESCA measurements were carried out with an ES 100 electron spectrometer from AEI Scientific Apparatus Ltd., England. The pressure of the sample compartment was $10^{-6} - 10^{-7}$ Torr and the temperature 25 °C. The energy of the X-ray radiation was 1486.6 eV ($AlK_{\alpha 1,2}$) and the apparatus constant of the spectrometer 9.5 eV. The samples were deposited on nonconducting tape.

The spectra were recorded using both recorder and printer. The printout spectra (Fig. 1 and 2) were plotted from a printout giving the number of counts per 120 s in intervals of 0.1 eV.

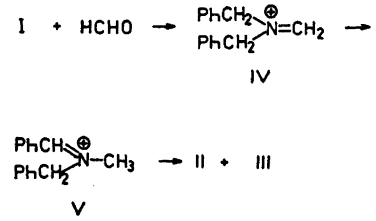
The Interpretation of an Abnormal Reaction Path Occurring during the Methylation of Certain Secondary Norbornanemethylamines with Formaldehyde in Acetic Acid

KALLE MANNINEN

Department of Chemistry, University of Oulu, SF-90100 Oulu 10, Finland

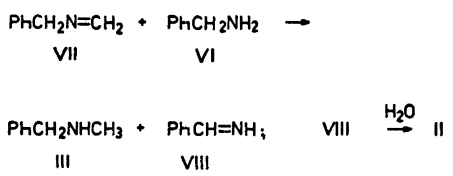
The carbon-nitrogen bond cleavage which occurs as a side reaction during the methylation of certain norbornanemethylamines with formaldehyde in acetic acid was investigated by employing deuterated and undeuterated reactants and by interpreting the NMR and mass spectra of the reaction products. It was shown that the pathway of the side reaction involves an intramolecular 1,3-hydride shift.

In the methylation of primary and secondary amines with formaldehyde, known as the Eschweiler-Clarke procedure,[1] the yields are best when the reaction is carried out in formic acid, although the reaction also proceeds in acetic acid.[2] In some cases carbonyl compounds [2-9] and secondary amines [2] are found among the by-products. Clarke *et al.*[2] suggest for the formation of the by-products benzaldehyde (II) and *N*-methylbenzylamine (III) by the methylation of dibenzylamine (I) a mechanism which proceeds *via* subsequent intermediate cations IV and V and the hydrolysis of V to the compounds II and III. These intermediate steps would include an intramolecular hydrogen shift (Scheme 1). On the other hand, Pine and



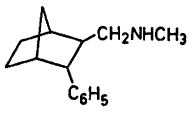
Scheme 1.

Sanchez [10] suggest that the reaction leading to aldehyde II during the methylation of benzylamine (VI) with formaldehyde in formic acid involves an intermolecular hydrogen shift between the Schiff base VII (from VI and formaldehyde) and VI. The hydrolysis of the subsequent benzylidene amine (VIII) leads to aldehyde II (Scheme 2).

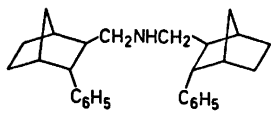


Scheme 2.

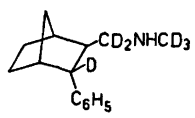
When studying the reaction of 2-norbornene with formaldehyde and secondary amines in acetic acid, it has been observed that the primary reaction products, secondary norbornanemethylamines, whose formation involves a 1,5-hydride shift, are methylated during the course of the reaction to the corresponding tertiary amines, and that these methylations include a side reaction which leads to carbonyl compounds and secondary amines.[11] Furthermore, when comparing the reaction products obtained from the reaction of 2-phenyl-2-norbornene, formaldehyde, and dimethylamine with those obtained from the corresponding reaction of 2-norbornene, the conclusion has been drawn that the formation of the main components found in the product mixture of the reaction follows a similar mechanism.[12] It



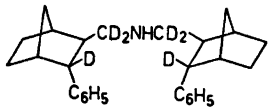
IX



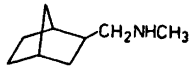
X



XI



XII

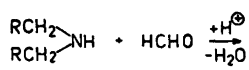


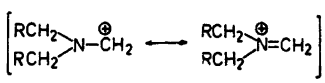
XIII

has not been investigated, however, if in the side reaction of the methylation the transfer of a hydrogen atom from the carbon atom adjacent to nitrogen is an intramolecular or an intermolecular process. To clarify this question, in the present study secondary amines IX and X (from 2-phenyl-2-norbornene, formaldehyde, and dimethylamine [12]), deuterated amines XI and XII (from 2-phenyl-2-norbornene, perdeuterioformaldehyde, and hexadeuteriodimethylamine), and secondary amine XIII (from 2-norbornene, formaldehyde, and dimethylamine [11]) were allowed to react with formaldehyde and perdeuterioformaldehyde in acetic acid, and the products were analysed by mass and NMR spectra.

RESULTS AND DISCUSSION

It is known that the reaction of a secondary amine with formaldehyde under acidic conditions leads to carbonium-immonium ion XIV (Scheme 3). This ion is considered to function as an intermediate species not only in the Mannich reaction [13] but also in the Leuckart-Wallach reaction, which includes the Eschweiler-Clarke methylation.[14] The reduction of ion XIV leads to the methylated product, the source of the hydride ion being formic acid, which is

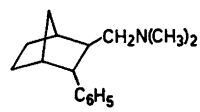




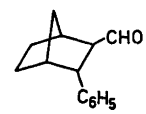
XIV

Scheme 3.

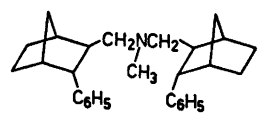
either added to the reaction mixture or is produced from formaldehyde by oxidation during the reaction. The reaction leading from ion XIV to a carbonyl compound and a secondary amine could possibly require either an isomerization suggested by Clarke *et al.*[2] (Scheme 1) or an intermolecular hydride shift analogous to that in the Sommelet reaction [3,15] as suggested by Pine and Sanchez [10] (Scheme 2).



XV



XVI

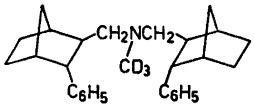


XVII

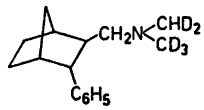
Earlier [12] the secondary amines IX and X have been methylated with formaldehyde in formic acid to the corresponding tertiary amines and the side reactions were not studied; now, the same reactions were performed in acetic acid and a more detailed characterization of the reaction products followed. After heating amine IX and formaldehyde (mol ratio 1:2) for 4 h, the reaction mixture contained tertiary amine XV, aldehyde XVI, and the starting compound IX. In the same way amine X gave, besides the normal methylation product XVII, also the cleavage products XVI and IX and the methylation product XV. These results distinctly show that during the reaction of secondary

amines IX and X with formaldehyde in acetic acid a cleavage of the carbon-nitrogen bond takes place besides methylation. Quite evidently hydrogen is released from the methylene carbon, adjacent to nitrogen, as hydride ion in the same fashion as in the Sommelet reaction of benzylamine.[16]

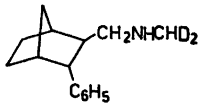
Since, according to Angyal,[3,15] methyleneimine produced from ammonia and formaldehyde or methylenebenzylamine (VII) (a Schiff base generated from benzylamine and formaldehyde) is likely to act as a hydride acceptor in the Sommelet reaction, which occurs when heating benzylamine with hexamethylenetetramine and yields benzaldehyde, also the carbonium-immonium ions of type XIV (generated from IX or X and formaldehyde) could function as hydride acceptors. To investigate this possibility amine X hydrochloride was heated with an excess of perdeuterioformaldehyde in acetic acid for 60 h so that both X and its cleavage product, a secondary amine, would be completely methylated. Upon diluting the reaction mixture with water, the methylated amine X precipitated as hydrochloride, was filtered off and liberated from its salt with potassium carbonate. The amine was identified by NMR and mass spectra to be compound XVIII. An amine containing five deuterium atoms and an aldehyde containing no deuterium were isolated from the filtrate. These compounds were assigned the structures XIX and XVI, respectively, by the aid of NMR and mass spectra. In order to identify the precursor of XIX, amine X and perdeuterioformaldehyde (mol ratio 1:2) were heated in acetic acid for only 4 h. The secondary amine isolated from the filtrate now contained only two deuterium atoms and was assigned the



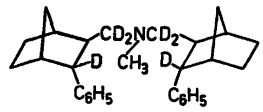
XVIII



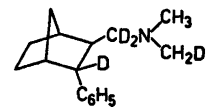
XIX



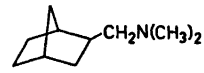
XX



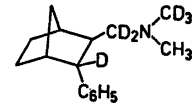
XXI



XXII



XXIII

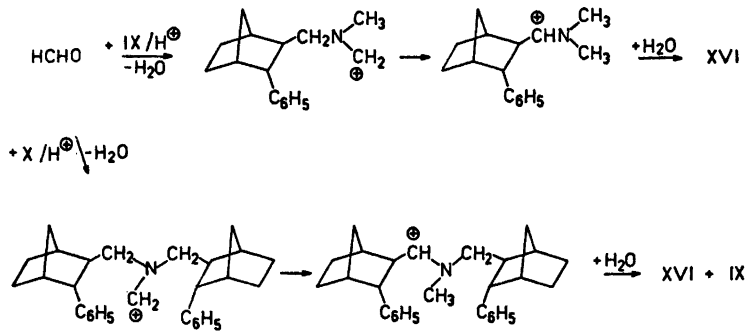


XXIV

structure XX. When the deuterated secondary amine XII (corresponding to X) was heated with an excess of formaldehyde in acetic acid for 60 h, the methylation product was, as expected, amine XXI and the methylated cleavage product was amine XXII.

The formation of XVIII from X and correspondingly XXI from XII indicates that the hydrogens of the methyl group in the actual methylation product originate from formaldehyde or its oxidation product, formic acid. The formation of amine XIX from X and perdeuterioformaldehyde, occurring by cleavage yielding XX and by subsequent methylation of XX with perdeuterioformaldehyde, and the corresponding formation of amine XXII from XII and formaldehyde are in accordance with the assumption that cations such as XIV function as acceptors of the hydride and the deuteride during the cleavage of the carbon-nitrogen bonds. In order to find out if the hydride transfer takes place intermolecularly, a mixture of amines XI and XIII was heated with formaldehyde in acetic acid. Amine XXIII, which is the methylation product of XIII, did not, according to the mass spectrum, contain any deuterium whereas compound XXIV is the methylation product of XI. This crossover experiment shows that the intermolecular hydrogen transfer from the carbon, adjacent to nitrogen, to the carbonium-immonium ion in the other molecule is out of question.

An intramolecular 1,3-hydride shift followed by a hydrolysis according to Scheme 4 seems to be the best explanation for the cleavage of the carbon-nitrogen bond which occurs as a side reaction during the methylation of secondary amines IX and X with formaldehyde in



Scheme 4.

acetic acid. This mechanism is analogous to that presented by Clarke *et al.*[3] who used the pathway in Scheme 1 to explain the side reaction taking place in the methylation of dibenzylamine with formaldehyde in formic acid.

EXPERIMENTAL

Preparation of the reactants. *N*-Methyl-exo-2-norbornanemethylamine (XIII), *N*-methyl-endo-3-phenyl-exo-2-norbornanemethylamine (IX), and 1,1′-bis(endo-3-phenyl-exo-2-norbornyl)dimethylamine (X) were prepared as described earlier.[11,12] To prepare the deuterated secondary amines XI and XII, 15.95 g (0.094 mol) of 2-phenyl-2-norbornene, 0.205 g of perdeuterioparaformaldehyde (equivalent to 0.064 mol of perdeuterioformaldehyde), and 10 g (0.114 mol) of hexadeuteriodimethylammonium chloride were allowed to react in acetic acid (30 ml) at 85 – 105 °C for 15 min. Addition of water and ether to the reaction mixture precipitated 1,1′-bis(endo-3-phenyl-exo-2-norbornyl-3*d*)di-(methyl-d_2)amine (XII) as hydrochloride, which was then liberated from its salt by potassium carbonate in a hot water-ethanol mixture. $C_{28}H_{29}D_6N$ (391.62). Mass spectrum: M^+ *m/e* 391. NMR spectrum (in C_6D_6): δ 7.21 (10 H, a singlet, the phenyl protons), 2.33 – 2.00 (4 H, the bridgehead protons), 1.80 (2 H, the endo-protons at C-2), and 1.65 – 0.87 ppm (12 H, the other norbornanering protons). *N*-Methyl-d_3-endo-3-phenyl-exo-2-norbornane-3*d*-methyl-d_2-amine (XI) was isolated from aqueous acetic acid and purified by the Hinsberg method. $C_{15}H_{18}D_5N$ (221.38). Mass spectrum: M^+ *m/e* 221 (9 %) and the base peak at *m/e* 49 (100 %) belonging to the fragment $CD_2NH^+\cdot=CD_2$. NMR spectrum (in C_6H_6): δ 7.21 (5 H, a singlet, the phenyl protons), 2.37 – 2.02 (2 H, the bridgehead protons), 1.78 (1 H, the endoprotons at C-2), and 1.70 – 1.00 ppm (6 H, the other norbornanering protons).

Reaction of N-methyl-endo-3-phenyl-exo-2-norbornanemethylamine (IX) with formaldehyde in acetic acid. Amine IX (0.173 g, 0.805 mmol) and 0.049 g of paraformaldehyde (equivalent to 1.63 mmol of formaldehyde) were heated in 1 ml of acetic acid in a boiling water bath for 4 h. Five ml of water and solid potassium carbonate were added to the reaction mixture until it was alkaline. The product was taken up in ether, the ether solution dried with potassium carbonate and the solvent evaporated. The residue (0.162 g) consisted of three components, which were identified by gas chromatography: endo-3-phenyl-exo-2-norbornanecarbaldehyde (XVI), *N*,*N*-dimethyl-endo-3-phenyl-exo-2-norbornanemethylamine (XV) and amine IX in the proportion 24:29:47. Aldehyde XVI was separated from the amines by extraction and amines IX and XV were isolated by preparative gas chromatography. The structures were confirmed by NMR and IR spectra and by the reference spectra.[12]

Reaction of 1,1′-bis(endo-3-phenyl-exo-2-norbornyl)dimethylamine (X) with formaldehyde in acetic acid. A mixture of 0.15 g (0.39 mmol) of amine X and 0.021 g of paraformaldehyde (equivalent to 0.7 mmol of formaldehyde) was heated in acetic acid (1 ml) for 4 h. The treatment of the reaction mixture as described above yielded 0.145 g of crude product, which in the gas chromatogram showed peaks for aldehyde XVI, tertiary amine XV, and secondary amine IX in the proportion 60:8:32. The unreacted starting material (X) and its methylation product, 1,1′-bis(endo-3-phenyl-exo-2-norbornyl)trimethylamine (XVII) did not elute from the column. After the bis-amines X and XVII were precipitated from the solution with hydrochloric acid, compounds XVI, XV, and IX were isolated and identified as described above.

Reaction of 1,1′-bis(endo-3-phenyl-exo-2-norbornyl)dimethylamine (X) with perdeuterioformaldehyde in acetic acid. A mixture of 4.5 g (10.7 mmol) of amine X hydrochloride and 2.5 g of perdeuterioparaformaldehyde (equivalent to 73.5 mmol of perdeuterioformaldehyde) in 40 ml acetic acid was heated under reflux for 60 h. The methylated X, liberated from its hydrochloride (sparingly soluble in water and ether) with potassium carbonate (the yield of hydrochloride 0.67 g) was identified by mass

and NMR spectra as 1,1′-bis(endo-3-phenyl-exo-2-norbornyl)trimethyl-1″,1″,1″-d_3-amine (XVIII), $C_{29}H_{34}D_3N$ (402.61). Mass spectrum: M^+ *m/e* 402 (1 %), M−171 (an abstraction of the endo-3-phenyl-exo-2-norbornyl radical) at *m/e* 231 (4 %) with the base peak at *m/e* 61 (100 %). NMR spectrum (in C_6D_6): δ 7.21 (10 H, a singlet, the phenyl protons), 2.84−2.60 (2 H, a multiplet, the exo-protons at C-3), 2.40−1.80 (8 H, a multiplet, the *N*-methylene and bridgehead protons), and 1.65−1.00 ppm (14 H, a multiplet, the other protons).

The neutral products and the amines were isolated by extraction from aqueous acetic acid. The main neutral component, endo-3-phenyl-exo-2-norbornanecarbaldehyde (XVI) (yield 1.5 g) did not contain any deuterium according to its mass spectrum. The amine portion (yield 0.8 g) contained *N,N*-dimethyl-d_5-endo-3-phenyl-exo-2-norbornanemethylamine (XIX) as the main component, $C_{16}H_{18}D_5N$ (234.39). Mass spectrum: M^+ *m/e* 234 (1 %) and the base peak $CD_3N^+\cdot(CHD_2)=CH_2$ at *m/e* 63 (100 %). NMR spectrum (in C_6D_6): δ 7.20 (5 H, a singlet, the phenyl protons), 2.71 (1 H, an approximate triplet, the exo-proton at C-3), 2.47−2.23 (2 H, a broad signal, the bridgehead protons), 2.15−1.87 (3 H, a multiplet, the protons of the *N,N*-dimethyl-d_5-aminomethyl group), and 1.75−1.09 ppm (7 H, the other protons).

Amine X hydrochloride (3.66 g, 9.51 mmol) and 0.65 g of perdeuterioparaformaldehyde (equivalent to 19.1 mmol of perdeuterioformaldehyde) were allowed to react in acetic acid (30 ml) for 4 h as described above. After precipitating the unreacted starting material X and the methylated amine as a hydrochloride, a secondary amine was recovered from the diluted aqueous acetic acid solution (yield 10 mg, 5 % of amine XIX as impurity). The amine was identified by mass spectroscopy as *N*-methyl-d_2-endo-3-phenyl-exo-2-norbornanemethylamine (XX), $C_{15}H_{19}D_2N$ (217.35). Mass spectrum: M^+ *m/e* 217 (2 %) and the base peak $CHD_2NH^+\cdot=CH_2$ at *m/e* 46 (100 %).

*Reaction of 1,1′-bis(endo-3-phenyl-exo-2-norbornyl-3*d*)di(methyl-*d_2*)amine (XII) with formaldehyde in acetic acid.* Amine XII hydrochloride (0.42 g, 1 mmol) and paraformaldehyde (0.15 g, equivalent to 5 mmol of formaldehyde) were heated in 7 ml of acetic acid for 60 h. The reaction mixture was treated as described above yielding the methylated XII, 1,1′-bis(endo-3-phenyl-exo-2-norbornyl-3*d*)trimethyl-1,1,1′,1′-d_4-amine (XXI), $C_{29}H_{31}D_6N$ (405.64). Mass spectrum: M^+ *m/e* 405 (1 %), M-172 (an abstraction of endo-3-phenyl-exo-2-norbornyl-3*d*) *m/e* 233 (7 %) and the base peak at *m/e* 63 (100 %). NMR spectrum (in C_6D_6): δ 7.23 (10 H, a singlet, the phenyl protons), 2.37−1.80 (9 H, the bridgehead protons, the C-2 endo-protons and the *N*-methyl protons at 2.09 as a singlet), and 1.70−0.83 ppm (12 H, the other protons). In the gas chromatogram the retention time of the main neutral component, which was isolated from aqueous acetic acid solution, is the same as that of endo-3-phenyl-exo-2-norbornanecarbaldehyde (XVI). The main amine component was identified by mass and NMR spectra as *N,N*-dimethyl-*d*-endo-3-phenyl-exo-2-norbornane-3*d*-methyl-d_2-amine (XXII), $C_{16}H_{19}D_4N$ (233.38). Mass spectrum: M^+ *m/e* 233 (3 %) and the base peak $CH_3(CH_2D)N^+\cdot=CD_2$ at *m/e* 61 (100 %). NMR spectrum (in C_6D_6): δ 7.22 (5 H, a singlet, the phenyl protons), 2.33 (2 H, a multiplet, the bridgehead protons), 2.08 (5 H, a singlet, the protons of *N,N*-dimethyl-*d* group), 1.89 (1 H, the endo-proton at C-2), and 1.55−1.07 ppm (6 H, the other protons).

Treatment of a mixture of N*-methyl-exo-2-norbornanemethylamine (XIII) and* N*-methyl-*d_3*-endo-3-phenyl-exo-2-norbornane-3*d*-methyl-*d_2*-amine (XI) with formaldehyde in acetic acid.* A mixture of 0.13 g (0.9 mmol) of amine XIII, 0.205 g (0.95 mmol) of amine XI, and 0.16 g of paraformaldehyde (equivalent to 5.09 mmol of formaldehyde) was heated in 1.6 ml of acetic acid for 9 h. The neutral products and the amines were separated by extraction. *N,N*-Dimethyl-exo-2-norbornanemethylamine (XXIII), the methylation product of amine XIII, distilled at 70 °C/10 Torr in a bulb tube oven and contained no deuterium according to the mass spectrum. The mass spectrum was the same as that of XXIII formed from XIII and formaldehyde.[11] The methylation product of amine XI distilled in a bulb tube oven at 120 °C/0.2 Torr and was identified by its mass spectrum as *N,N*-dimethyl-1,1,1-d_3-endo-3-phenyl-exo-2-norbornane-3*d*-methyl-d_2-amine (XXIV). $C_{16}H_{17}D_6N$ (235.40). Mass spectrum: M^+ *m/e* 235 and the base peak $CH_3(CD_3)N^+\cdot=CD_2$ at *m/e* 63 (100 %).

Apparatus. The apparatus employed is the same as used in the previous investigation.[12]

Base-induced Conversion of Dichloromethanesulfonyl Chloride to Trichloromethanesulfinate

TOMAS KEMPE and TORBJÖRN NORIN

Department of Organic Chemistry, Royal Institute of Technology, S-100 44 Stockholm 70, Sweden

Dichloromethanesulfonyl chloride (*1*) is converted to trichloromethanesulfinate (*3*) when treated with triethylamine or pyridine. The reaction is suggested to proceed *via* an intermediate sulfene *2*.

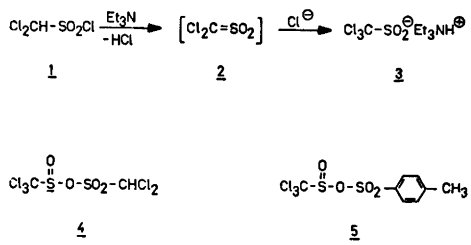
When trichloromethanesulfinate (*3*) is treated with triethylammonium bromide a halogen exchange is observed, as shown by a mass spectrometric investigation. This exchange reaction may also proceed *via* dichlorosulfene (*2*).

Mass spectra of trichloromethanesulfonyl chloride and trichloromethanesulfonyl bromide are discussed.

The conversion of sulfonyl chlorides to halosulfinates have not previously been observed. Intermediate halosulfinates have, however, been postulated [1] in the formation of sulfines from sulfonyl chlorides when treated with a base. This paper describes the reaction of dichloromethanesulfonyl chloride (*1*) when treated with triethylamine or pyridine. This reaction is shown to yield trichloromethanesulfinate (*3*).

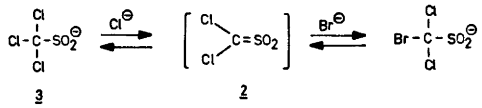
Dichloromethanesulfonyl chloride (*1*) was treated with an equivalent amount of triethylamine or pyridine in ethyl ether or benzene at room temperature to yield a product which separated during the reaction. This product was shown to be trichloromethanesulfinate (*3*), and was characterized by transforming it into the trichloromethanesulfinyl chloride [2] or into the crystalline morpholide.[3] The crystalline trichloromethanesulfonyl chloride [4] and the corresponding bromide [5] were also prepared by oxidation with chlorine or bromine in water.

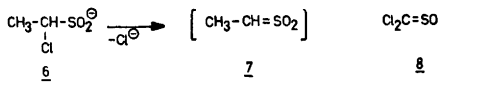
Chloromethanesulfonyl chloride is not converted to dichloromethanesulfinate when treated with triethylamine. This was shown by the fact that the corresponding dichloromethanesulfonyl chloride could not be detected in the reaction mixture after oxidation with chlorine in water. Consequently, the reaction of dichloromethanesulfonyl chloride seems to be a special case due to the effect of the two halogen atoms of the dichloromethyl grouping.



The conversion of dichloromethanesulfonyl chloride (*1*) to trichloromethanesulfinate (*3*) may proceed *via* an intermediate sulfene *2* [6] which, when attacked by a chloride ion, yields the sulfinate *3*. A second mechanism for the reaction should also be considered. This mechanism involves an intermediate sulfinyl sulfonate *4*, formed in a reaction of the intermediate sulfene *2* and dichloromethanesulfonyl chloride (*1*).[7] The sulfinylsulfonate *4* then decomposes in the presence of a base to the sulfinate *3* and the sulfene *2*. The sulfene *2* can react further in a chain reaction. Intermediate sulfinyl sulfonates, *e.g.* *5*, which lack α-protons, should not react further. However, in the presence of toluenesulfonyl chloride the conversion of dichloromethanesulfonyl chloride proceeds in the normal way, and the toluenesulfonyl chloride is recovered quantitatively. This experiment shows that a sulfinyl sulfonate does not seem to be an intermediate in the reaction.

It is of interest to note that there is a halogen exchange in trichloromethanesulfinate (*3*) when this compound is treated with triethylammonium bromide. This halogen exchange was demonstrated by a mass spectrometric investigation (see experimental), and may proceed *via* dichlorosulfene (*2*), which is in rapid equilibrium with trichloromethanesulfinate (*3*).





The formation of dichlorosulfene (*2*) from trichloromethanesulfinate (*3*) is analogous to the decomposition of 1-chloroethanesulfinate (*6*) to yield the intermediate methylsulfene (*7*).[8] Dichlorosulfine (*8*) has recently been prepared,[9,10] and was found to be a rather stable compound. It is therefore reasonable to predict that dichlorosulfene (*2*) is also stable. It is of interest to note that theoretical calculations predict that electron-donating substituents stabilize sulfenes.[11]

The Fourier transform ^{13}C NMR spectrum of the triethylammonium salt of trichloromethanesulfinic acid in a chloroform solution exhibits a signal at 115.6 ppm (downfield from TMS; benzene external standard $\delta_{(benzene)}$ 127.6 ppm) due to the carbon atom of the trichloromethyl group. This chemical shift is comparable with those of trichloromethanesulfinyl chloride (109.6 ppm) and trichloromethanesulfonyl chloride (106.8 ppm). The sp^2-hybridized carbon of dichlorosulfene (*2*) is expected to exhibit a chemical shift further downfield. If there is a rapid equilibrium between dichlorosulfene (*2*) and trichloromethanesulfinate (*3*), there seems to be very little contribution from the carbon species of dichlorosulfene and the equilibrium must be strongly shifted towards the sulfinate *3*.

It is known [12] that 2-chlorothiirane 1,1-dioxide is formed, when chloromethanesulfonyl chloride is treated with triethylamine in the presence of diazomethane, thus trapping the intermediate sulfene. However, when the base-induced conversion of dichloromethanesulfonyl chloride (*1*) was carried out in the presence of diazomethane no reaction with the suggested intermediate dichlorosulfene (*2*) and diazomethane could be observed.

Trichloromethanesulfonyl chloride and the corresponding bromide have been used for the halogenation of hydrocarbons.[5] The $Cl_3C-SO_2\cdot$ radical has been suggested as being the hydrogen abstractor in the halogenation reaction with trichloromethanesulfonyl chloride, whereas in the reaction with the corresponding bromide, the $Cl_3C\cdot$ radical is suggested as being the hydrogen abstractor.[5]

This difference between the sulfonyl chloride and the corresponding bromide is also reflected in the mass spectrometric fragmentation pattern of the two compounds. No molecular ion peaks are observed in the spectra. The mass spectrum of the sulfonyl chloride exhibits peaks at *m/e* 181 and 117 due to the $(Cl_3C-SO_2)\cdot^+$ and $(Cl_3C)\cdot^+$, respectively. A peak at *m/e* 298 must be an artefact due to radical dimerization to the bis(trichloromethyl) sulphone. The mass spectrum of the sulfonyl bromide, on the other hand, did not exhibit any trichloromethanesulfonyl fragment, $(Cl_3C-SO_2)\cdot^+$, at *m/e* 181. The parent peak was the trichloromethyl radical ion, $(Cl_3C)\cdot^+$, at *m/e* 117.

EXPERIMENTAL

All melting points are uncorrected. IR spectra were measured on a Perkin Elmer Model 421 infrared spectrophotometer. ^1H NMR spectra (TMS internal standard) were recorded on a Varian Model A-60 A instrument. ^{13}C NMR spectra were recorded on a Varian HA-100-D spectrometer. Mass spectra were obtained when using an LKB Model 9000 mass spectrometer (direct inlet).

Pyridinium and triethylammonium salts of trichloromethanesulfinic acid. A solution of pyridine (7.9 g, 0.1 mol) or triethylamine (10.1 g, 0.1 mol) in ethyl ether (25 ml) was added during 15 min to dichloromethanesulfonyl chloride [13] (18.3 g, 0.1 mol) in ethyl ether (100 ml). The mixture was stirred for 1 h at room temperature. The pyridinium salt thus formed was filtered off, washed with ethyl ether and dried *in vacuo*. Yield: 25 g (95 %); m.p. 115–117 °C. IR ($CHCl_3$) 1200 cm^{-1} (S=O); ^1H NMR ($CHCl_3$) δ 10.4–9.2 ppm (m, pyridinium protons).

The triethylammonium salt, prepared as described above for the pyridinium salt, was a

heavy oil. This oil was separated from the ether phase, and traces of ethyl ether dissolved in the oil were removed *in vacuo*. Yield: 27 g (95 %); IR (film) 1220 cm^{-1} (S=O); ^1H NMR ($CHCl_3$) δ 1.2 (t, 9, CH_3) and 2.8–3.2 ppm (two overlapping quartets, 6, CH_2, coupling with the CH_3 and N–H).

Trichloromethanesulfinyl chloride. Thionyl chloride (23.8 g, 0.2 mol) was added to the pyridinium salt of trichloromethanesulfinic acid (26.2 g, 0.1 mol) or its triethylammonium salt (28.4 g, 0.1 mol) in benzene (100 ml). The mixture was heated under reflux for 30 min and then cooled to room temperature. Insoluble salts were removed by filtration, and the solution evaporated *in vacuo*. The residue was distilled under reduced pressure to give trichloromethanesulfinyl chloride. Yield: from the pyridinium salt, 14 g (69 %), and from the triethylammonium salt, 13 g (64 %); b.p. 53–54 °C/9 mmHg (lit.[2] b.p. 36–38 °C/1 mmHg); m.p. 18 °C; n_D^{24} 1.5455; IR (film) 1200 cm^{-1} (lit.[2] 1190 cm^{-1}, S=O).

The trichloromethanesulfinyl chloride was further characterized as the corresponding morpholide: m.p. 88–89 °C (lit.[3] m.p. 85–87 °C). (Found: C 24.20; H 3.30; Cl 41.86; N 5.38; S 12.50. Calc. for $C_5H_8Cl_3NO_2S$: C 23.78; H 3.19; Cl 42.11; N 5.54; S 12.69).

Trichloromethanesulfonyl bromide. Triethylamine (10.1 g, 0.1 mol) was added to dichloromethanesulfonyl chloride (18.3 g, 0.1 mol) in benzene (100 ml), and the mixture was stirred at room temperature for 30 min. A solution of bromine (19.2 g, 0.12 mol) in water (200 ml) and benzene (100 ml) was then added in one portion to the trichloromethanesulfinate under vigorous stirring. The organic layer was allowed to separate after 15 min, washed with aqueous sodium bisulfite solution (10 %) to remove excess bromine, and then with water. The benzene solution was dried and evaporated *in vacuo* to give a crystalline residue. The crystals were dissolved in a minimum amount of ethanol. The product (trichloromethanesulfonyl bromide) was precipitated with water, filtered and dried *in vacuo*. Yield: 14.5 g (55 %); m.p. 138–140 °C (lit.[5] m.p. 138–139 °C); IR (CCl_4) 1400 and 1180 cm^{-1} (lit.[5] 1398 and 1177 cm^{-1}, $-SO_2Br$); mass spectrum (20 eV, direct inlet) *m/e* (rel. intensity) CCl_3^+· 117 (100), 119 (94.5) and 121 (27.9).

Trichloromethanesulfonyl chloride. The pyridinium salt (5.2 g, 0.02 mol) or the triethylammonium salt (28.4 g, 0.1 mol) of trichloromethanesulfinic acid, was added to a water solution which was continuously saturated with chlorine. The reaction was stopped when no more chlorine was consumed. The product, trichloromethanesulfonyl chloride, which separated as white crystals during the oxidation, was filtered off and washed with water. For further purification, the crystals were dissolved in a minimum amount of ethanol and precipitated with water, then filtered and dried *in vacuo*. Yield: from the pyridinium salt, 3 g (68 %), and from the triethylammonium salt, 14 g (64 %); m.p. 140–141 °C (lit.[4] 140–140.5 °C); mass spectrum (20 eV, direct inlet) *m/e* (rel. intensity) CCl_3^+· 117 (100), 119 (95.11), 121 (32.1); 149 (0.26), 151 (0.27), 153 (0.09); $Cl_3C-SO_2^+$· 181 (1.58), 183 (1.53), 185 (0.53); $Cl_3C-SO_2-CCl_2^+$· 263 (0.24), 265 (0.40), 267 (0.27), 269 (0.10); $Cl_3C-SO_2-CCl_3^+$· 298 (0.074), 300 (0.14), 302 (0.12), 304 (0.05).

Treatment of dichloromethanesulfonyl chloride with diazomethane in the presence of triethylamine. Dichloromethanesulfonyl chloride (16.5 g, 0.09 mol) in ethyl ether (100 ml) and triethylamine (9.1 g, 0.09 mol) in ethyl ether (100 ml) were simultaneously added dropwise, to a stirred and cold solution (–40 to 50 °C) of diazomethane [14] (0.09 mol) in ethyl ether (200 ml). The addition requires about 30 min. The reaction mixture was stirred for an additional 30 min. Diazomethane was not consumed, as shown by its characteristic colour. Acetic acid was added dropwise in order to react with the diazomethane. The ether solution was separated from an insoluble residue. The residue (18 g) was oxidized with chlorine in water to give trichloromethanesulfonyl chloride. The sulfonyl chloride was dissolved in a minimum amount of ethanol, and then precipitated with water, filtered off and dried *in vacuo*. Yield 9 g, m.p. 140–141 °C. The ether solution was washed with water and dried. Evaporation *in vacuo* gave a liquid residue (5 g).

Infrared spectrum (film) of this residue did not exhibit absorption typical of a sulfone (1300–1320 and 1140–1170 cm^{-1}). Distillation of the oily residue at reduced pressure gave a compound which was characterized as methyltrichloromethanesulfinate. B.p. 74–75 °C/9 mmHg (lit.[2] b.p. 38–40 °C/1 mmHg); n_D^{25} 1.5022; IR (film) 1190, 970, 795 and 820 cm^{-1} (lit.[2] IR 1190, S=O; 970, S–O–C; 795 and 822 cm^{-1}, C–Cl of Cl_3C-); ^1H NMR, δ 4.0 ppm (s, CH_3-).

The reaction of dichloromethanesulfonyl chloride in the presence of toluenesulfonyl chloride. Toluenesulfonyl chloride (5.2 g, 0.02 mol) in ethyl ether (25 ml) was mixed with triethylamine (2.75 g, 0.02 mol), and dichloromethanesulfonyl chloride (5 g, 0.02 mol) was slowly added. After 1 h at room temperature the ether phase was separated from the oily residue and evaporated *in vacuo* to yield 5.2 g unreacted toluenesulfonyl chloride. The recovered toluenesulfonyl chloride was identified with an authentic sample.

The reaction of dichloromethanesulfonyl chloride with half an equivalent triethylamine. Triethylamine (5.0 g, 0.05 mol) was slowly added to a solution of dichloromethanesulfonyl chloride (18.3 g, 0.1 mol) in ethyl ether (100 ml). The mixture was stirred at room temperature for 1 h. The heavy oil was allowed to separate from the ether solution. Evaporation of the ether solution *in vacuo* yielded half an equivalent unreacted dichloromethanesulfonyl chloride (9 g) which was identified with an authentic sample.

The reaction of dichloromethanesulfonyl chloride in the presence of triethylammonium bromide. Triethylamine (5 g, 0.05 mol) was added for 3 min to a solution of dichloromethanesulfonyl chloride (9.1 g, 0.05 mol) and triethylammonium bromide (0.1 g, 0.05 mol) in chloroform (100 ml). The mixture was stirred for 1 h at 25 °C. A solution of bromine (8.8 g, 0.055 mol) in chloroform (25 ml) and water (75 ml) was then added in one portion with vigorous stirring. The organic layer was allowed to separate after 10 min, and washed with aqueous sodium bisulfite (10 %) to remove excess bromine and then with water. The organic layer was dried and evaporated *in vacuo* to give a semicrystalline residue. Mass spectrum (20 eV, direct inlet) of the crude residue shows the presence of different halomethyl fragments at *m/e* (rel. intensity): $CCl_3^{+\cdot}$ 117 (100), 119 (96.4), 121 (30.7); $BrCl_2C^{+\cdot}$ 161 (48.9), 163 (78.1), 165 (35.0), 167 (5.1); $Br_2ClC^{+\cdot}$ 205 (5.8), 207 (11.7), 209 (9.5), 301 (2.9).

Treatment of trichloromethanesulfinate with triethylammonium bromide. Triethylamine (5.0 g, 0.05 mol) was added to a solution of dichloromethanesulfonyl chloride (9.1 g, 0.05 mol) in chloroform (100 ml). The solution was stirred for 15 min at 25 °C. Triethylammonium bromide (9.1 g, 0.05 mol) was added and the mixture was stirred for an additional hour. A solution of bromine (8.8 g, 0.055 mol) in chloroform (25 ml) and water (75 ml) was then added in one portion with vigorous stirring. The organic layer was allowed to separate after 10 min, and washed with aqueous sodium bisulfite (10 %) to remove excess bromine and then with water. The organic layer was dried and evaporated *in vacuo* to give a semicrystalline residue. Mass spectrum (20 eV, direct inlet) of the crude residue shows the presence of halomethyl fragments at *m/e* (rel. intensity): $CCl_3^{+\cdot}$ 117 (100), 119 (95.2), 121 (30.6); $BrCl_2C^{+\cdot}$ 161 (4.5), 163 (6.9), 165 (3.2), 167 (0.5).

Reaction of chloromethanesulfonyl chloride and triethylamine. Triethylamine (3.3 g, 0.033 mol) was slowly added to a cooled solution of chloromethanesulfonyl chloride (5 g, 0.033 mol) in ethyl ether (50 ml). The reaction mixture was stirred for 30 min at room temperature and then extracted with water (100 ml). The aqueous solution was saturated with chlorine and extracted with carbon tetrachloride. Dichloromethanesulfonyl chloride is not obtained in this experiment as shown by NMR analysis. A yield of less than 1 % is detectable which was determined by a reference solution of dichloromethanesulfonyl chloride in CCl_4.

A *trans*-Coplanar Elimination of Sulfur Dioxide and Chloride Ion in 2-Chloroalkanesulfinates*

TOMAS KEMPE and TORBJÖRN NORIN

Department of Organic Chemistry, Royal Institute of Technology, S-100 44 Stockholm 70, Sweden

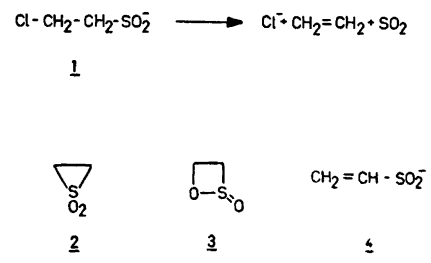
2-Chloroalkanesulfinates are shown to decompose into alkenes, sulfur dioxide, and chloride ions. The mechanism of the reaction is discussed. The reaction is shown to proceed *via* a *trans*-coplanar elimination. The possible implication of a 2-substituted alkanesulfinate in the base-promoted rearrangement of α-halosulfones (Ramberg-Bäcklund rearrangement) is discussed.

The decomposition of a 2-haloalkanesulfinate has not previously been studied. However, it is known [1] that the barium salt of 2-hydroxyethanesulfinic acid decomposes to yield ethylene and barium sulfite. During the course of this work the decomposition of perfluoroalkanesulfinates to yield perfluoroalkenes has been reported.[2] It is also of interest to note that a 2-halosulfinate has been discussed [3] as an intermediate in the base-induced rearrangement of α-halosulfones to alkenes (Ramberg-Bäcklund rearrangement).

In connection with a study of sulfur dioxide elimination reactions, 2-chloroethanesulfinic acid was treated with base. The sulfinate was found to decompose spontaneously to ethylene, chloride ion, and sulfur dioxide in good yield (Scheme I). In this paper the decomposition of 2-chloroalkanesulfinates will be discussed and evidence for a *trans*-coplanar elimination will be presented.

2-Chloroethanesulfinate (*1*) is readily available and has been used as a model compound for kinetic and mechanistic studies. This compound was prepared from the corresponding sulfinyl chloride which may be prepared by addition of thionyl chloride to ethylene according to a previous method.[4] A more convenient method for the preparation of 2-chloroethanesulfinyl chloride has now been developed. Treatment of ethylene sulfide and acetic anhydride in equivalent amounts with chlorine afforded 2-chloroethanesulfinyl chloride in good yield. The corresponding sulfinic acid was prepared by a careful hydrolysis with aqueous sodium hydrogen carbonate followed by acidification with sulfuric acid. The 2-chloroethanesulfinic acid was extracted with ethyl ether. The crude sulfinic acid, obtained after evaporation of the solvent, was found to be pure and was characterized by IR and NMR.

The decomposition of 2-chloroethanesulfinate (*1*) can be performed in water or in organic solvents. The rate of the decomposition in water with excess sodium hydroxide has been determined. The formation of ethylene was found to follow first order kinetics and the activation energy of the reaction was 127.8 ± 8.4 kJ mol^{-1}.



Scheme 1.

* Kempe, T. and Norin, T., presented in part at the "14de Nordiska Kemistmötet", Umeå, June 1971; "Vth Symposium on Organic Sulphur Chemistry", Lund, June 1972.

Different reaction mechanisms for the decomposition reaction can be formulated. Ethylene sulfone (*2*) can be ruled out as an intermediate since this compound was found to be stable under the reaction conditions used. A less probable intermediate is 1,2-oxathietane 2-oxide (*3*, β-sultine). β-Sultines are known [5] to decompose to alkanes and sulfur dioxide. However, they also react with alcohols to give 2-hydroxyalkanesulfinic acid esters.[5]

When the decomposition of 2-chloroethanesulfinate was carried out in methanol in the presence of triethylamine, no methyl 2-hydroxyethanesulfinate could be detected in the reaction product.

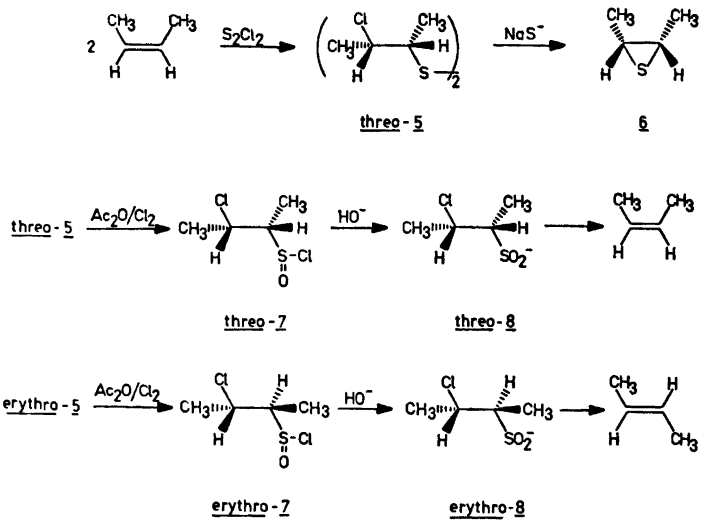
When the decomposition of 2-chloroethanesulfinate was performed in a deuterium oxide solution, no deuterium incorporation could be detected in the ethylene as shown by the mass spectrum of the 1,2-dibromoethane formed by bromination of the ethylene. Thus ethylenesulfinate (*4*) derived from the 2-chloroethanesulfinate by hydrogen chloride elimination, cannot be an intermediate in the reaction.

The most likely mechanism for the 2-halosulfinate decomposition is a *trans*-coplanar elimination of sulfur dioxide and chloride ion. In order to obtain additional information regarding this reaction its stereochemistry was investigated as follows.

The addition of sulfur monochloride to alkenes is known to proceed *via* a *trans*-addition yielding the corresponding 2-haloalkyl disulfides [6] (Scheme 2). Lautenschlaeger and Schwartz have recently shown [6] that the addition to *cis*-2-butene yields bis(*threo*-2-chloro-1-methylpropyl)disulfide (*threo-5*) which upon treatment with sodium sulfide gives the *cis*-2,3-dimethylthiirane (*6*). The corresponding *trans*-2-butene yields the *trans*-2,3-dimethylthiirane under similar conditions.

We have reacted *cis*-2-butene with sulfur monochloride. The disulfide (*threo-5*) thus obtained was oxidized with chlorine in acetic anhydride to yield the corresponding *threo*-2-chloro-1-methylpropanesulfinyl chloride (*threo-7*) by a known reaction.[7] This compound was hydrolysed with aqueous sodium hydroxide. The intermediate *threo*-2-chloro-1-methylpropanesulfinate (*threo-8*) rapidly decomposed to yield *cis*-2-butene. Less than 1 % *trans*-2-butene was present in the product as shown by gas chromatography.

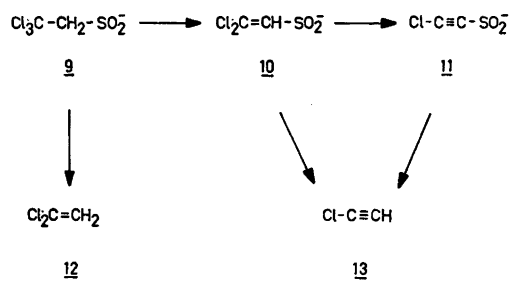
Similarly *trans*-2-butene yielded *erythro*-2-chloro-1-methylpropanesulfinyl chloride (*erythro-7*) which, without isolation, was treated with aqueous sodium hydroxide to yield *trans*-2-butene *via* the intermediate *erythro*-2-chloro-1-methylpropanesulfinate (*erythro-8*). Less than 1 % *cis*-2-butene was present in the product.



Scheme 2.

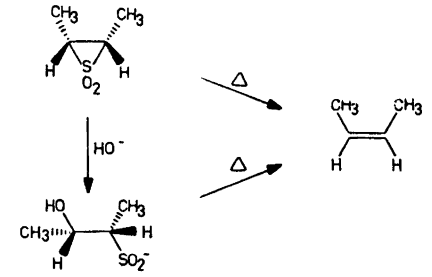
The 2-halosulfinate decomposition is thus a stereospecific reaction and the results presented above support a mechanism involving a *trans*-coplanar elimination.

A 2-chloroalkanesulfinate decomposition also occurs with 2,2,2-trichloroethanesulfinate (*9*, Scheme 3). When the sulfinyl chloride of *9* was hydrolysed with an equivalent amount of aqueous sodium hydroxide, 1,1-dichloroethylene (*12*) was formed. With an excess of sodium hydroxide, chloroacetylene (*13*) was isolated in addition to dichloroethylene (*12*). Two possible routes for the formation of chloroacetylene may be considered. In one the 2,2-dichloroethylenesulfinate intermediate (*10*) decomposes *via* a reaction mechanism similar to that for the 2-halosulfinate and in the other, further dehydrohalogenation of the 2,2-dichloroethylenesulfinate (*10*) gives 2-chloroacetylenesulfinate (*11*) which decomposes into chloroacetylene (*13*) and sulfur dioxide.[8]



Scheme 3.

There is strong evidence for the presence of intermediate thiirane 1,1-dioxides in the base-induced rearrangement of α-halosulfones (Ramberg-Bäcklund rearrangement).[9] The decomposition of this intermediate thiirane 1,1-dioxide to alkene and sulphur dioxide is a stereospecific reaction [9] (Scheme 4). Although this decomposition is known to be a thermal reaction it is not clear whether the base, in some cases, may take part in the decomposition. It has been established that ethylene sulfone upon treatment with alkali yields 2-hydroxyethanesulfinate.[1] Hence nucleophilic attack of the base on the intermediate thiirane 1,1-dioxide in the Ramberg-Bäcklund rearrangement should yield 2-substituted alkanesulfinates. This reaction has been discussed by Bordwell *et al.*[10] They propose that an intermediate 2-methoxyalkanesulfinate would appear to be stable under conditions whereby thiirane 1,1-dioxides are converted to alkenes. Therefore, they conclude that this mechanism does not operate in the decomposition of thiirane 1,1-dioxides in the presence of methoxide ions. However, there are no indications that alkanesulfinates with a leaving group in 2-position are stable under the conditions for a Ramberg-Bäcklund rearrangement and the formation of an intermediate 2-substituted alkanesulfinate cannot be excluded. This intermediate would then decompose by a reaction analogous to the stereospecific decomposition of 2-chloroalkanesulfinates (Scheme 4).



Scheme 4.

EXPERIMENTAL

All boiling points are uncorrected. IR spectra were measured on a Perkin Elmer Model 421 infrared spectrophotometer. NMR spectra (TMS internal standard) were recorded on a Varian Model A-60A instrument. Mass spectra were obtained using an LKB Model 9000 mass spectrometer.

2-Chloroethanesulfinyl chloride. A solution of ethylene sulfide (23.5 g, 0.39 mol) and acetic anhydride (40 g, 0.39 mol) was cooled to 5 °C. Chlorine was then passed into the solution at such a rate that the temperature remained between 10 and 15 °C. When no more chlorine was consumed excess chlorine and acetyl chloride was removed by evaporation *in vacuo* at room temperature. The residue was distilled at reduced pressure to give 2-chloroethanesulfinyl chloride; b.p. 42 °C/0.7 mmHg (lit.[4] b.p. 81 °C/9 mmHg); yield 46 g (80 %); IR (film) 1150 cm^{-1} (S=O); NMR ($CDCl_3$) δ 3.95 ppm (m, CH_2).

2-Chloroethanesulfinic acid. 2-Chloroethanesulfinyl chloride (14.7 g, 0.1 mol) was slowly added to an aqueous solution (100 ml) of sodium hydrogen carbonate (16.8 g, 0.2 mol) cooled to 5 °C. The mixture was stirred for 10 min and

then acidified with conc. sulfuric acid (10 g). The 2-chloroethanesulfinic acid thus formed was extracted with ethyl ether (200 ml). The solution was dried and the solvent evaporated *in vacuo* to give the oily 2-chloroethanesulfinic acid; yield 9 g (70 %); IR (film) 1080 (broad) cm^{-1} (SO_2H); NMR ($CDCl_3$) δ 3.2 (t, 2, CH_2) and 3.9 ppm (t, 2, CH_2).

Decomposition of 2-chloroethanesulfinic acid in the presence of sodium hydroxide. 2-Chloroethanesulfinic acid (8 g, 0.062 mol) was added to an aqueous sodium hydroxide solution (2 M, 100 ml). The reaction mixture was slowly heated to 60 °C and was then kept at that temperature for 10 min. The ethylene thus formed was passed through a chloroform solution (100 ml) containing bromine (16 g, 0.1 mol). The chloroform solution was treated with an aqueous sodium bisulfite solution (10 %) in order to remove unreacted bromine, washed with water and dried. Evaporation of the solvent afforded crude 1,2-dibromoethane; b.p. 131–132 °C/760 mmHg; yield 4 g (34 %); n_D^{22} 1.5360. The 1,2-dibromoethane was analysed by GLC-MS (column, 150 cm × 3 mm, packed with 5 % SE 30 on Chromosorb W 60/80 mesh, column temperature 70 °C), *m/e* (rel. intensity); $C_2H_4Br^+$ 107(100), 109(100); $C_2H_4Br_2^{+\cdot}$ 186(1.3), 188(2.6), 190(1.3).

Decomposition of 2-chloroethanesulfinyl chloride in the presence of D_2O/NaOD. 2-Chloroethanesulfinyl chloride (1 g, 6.8 mmol) was added to a sodium deuterium oxide solution (1 M, 15 ml) in deuterium oxide. The mixture was heated to ensure decomposition of 2-chloroethanesulfinate. The ethylene gas was passed through a chloroform solution containing bromine to give 1,2-dibromoethane. The excess of bromine was removed in the usual way. The 1,2-dibromoethane was analysed by GLC-MS as has been described above. No deuterated 1,2-dibromoethane could be detected in the reaction mixture. The mass spectrum of the product was identical with that of an authentic sample of 1,2-dibromoethane.

Decomposition of 2-chloroethanesulfinic acid in the presence of ethylene sulfone. The NMR spectrum of 2-chloroethanesulfinic acid in chloroform solution exhibits peaks at δ 3.2 (t, 2, CH_2), 3.9 (t, 2, CH_2) and 7.4 ppm (s, SO_2H). When excess pyridine is added to the sulfinic acid, gas is evolved. The peaks at δ 2.93 and 3.85 ppm of 2-chloroethanesulfinate decrease. 2-Chloroethanesulfinate disappeared after 18 min and no other peaks except that of ethylene (δ 5.22 ppm) could be detected in this region. Ethylene sulfone[11] (δ 3.12 ppm) was found to be stable in pyridine/chloroform solution under the condition used. No appreciable decrease of the peak at δ 3.12 ppm was observed after 1 h. 2-Chloroethanesulfinic acid and ethylene sulfone were mixed in a chloroform solution. Excess pyridine is then added and the decomposition of 2-chloroethanesulfinate is followed by NMR. When the 2-chloroethanesulfinate is completely consumed (*ca.* 20 min) the intensity of the peak from the ethylene sulfone (δ 3.12 ppm) is still undiminished.

Decomposition of 2-chloroethanesulfinate in the presence of methanol. Triethylamine (2 g, 0.02 mol) was added to a solution of 2-chloroethanesulfinic acid (2.5 g, 0.02 mol) in methanol (40 ml) at room temperature. The reaction mixture was then boiled for 30 min. The presence of sulfur dioxide could be detected by the characteristic smell of the gas. The volatile constituents in the solution were then evaporated *in vacuo* to give a crystalline residue which was washed several times with ethyl ether. The combined ether solutions were washed with water and dried. Evaporation of the solvent under reduced pressure did not afford any residue. The insoluble crystals which did not dissolve in ethyl ether was characterized as triethylammonium chloride which upon treatment with alkali gave triethylamine. This experiment shows that methanol does not react with any intermediate (*e.g.* β-sultine) during the decomposition of 2-chloroethanesulfinate and it is thus unlikely that any such intermediate is involved in the decomposition reaction.

Bis(2,2,2-trichloroethyl)disulfide was prepared essentially according to the method of Aichenegg.[12] Sulfur monochloride (81 g, 0.6 mol) was added dropwise over 2 h to a mixture of 1,1-dichloroethylene (250 g, 2.58 mol) and $FeCl_3$ (8 g). The reaction mixture was kept at room temperature overnight and was then diluted with 1 vol of acetone, followed by addition of sufficient water to give 2 layers. The organic phase was recovered and washed with water. The procedure was repeated until no more acetone was present in the organic phase, which was then dried and evaporated *in vacuo* to give a residue. Distillation at reduced pressure afforded bis(2,2,2-trichloroethyl)disulfide; b.p. 122 °C/0.5 mmHg (lit.[12] b.p. 145–150 °C/0.36–0.46 mmHg); yield 90 g (46 %); n_D^{25} 1.5750 (lit.[12] n_D^{20} 1.5780).

2,2,2-Trichloroethanesulfinyl chloride. A solution of bis(2,2,2-trichloroethyl)disulfide (32.8 g, 0.1 mol) and acetic anhydride (20.4 g, 0. 2 mol) was cooled to 5 °C. Chlorine was then passed into the solution at such a rate that the temperature remained between 10 and 15 °C. When no more chlorine was consumed, chlorine and acetyl chloride were removed by evaporation *in vacuo* at room temperature. The residue was distilled at reduced pressure to give 2,2,2-trichloroethanesulfinyl chloride; b.p. 56 °C/1.5 mmHg; yield 32 g (74 %); n_D^{25} 1.5446; IR (film) 1160 cm^{-1} (S=O); NMR (neat) δ_A 4.68 and δ_B 4.85 ppm (J_{AB} 14 Hz).

Decomposition of 2,2,2-trichloroethanesulfinyl chloride with an equivalent amount of base. An aqueous sodium hydroxide solution (1.6 M, 50 ml) was slowly added to a cooled mixture (5 °C) of 2,2,2-trichloroethanesulfinyl chloride (8.6 g, 0.04 mol) and water (150 ml). Carbon tetrachloride (50 ml) was then added to dissolve

the 1,1-dichloroethylene formed. The reaction mixture was then kept at room temperature for 2 h. The NMR spectrum of the carbon tetrachloride solution shows that 1,1-dichloroethylene was formed in 53 % of the theoretical yield (determined by using a reference solution of 1,1-dichloroethylene in CCl_4). 1,1-Dichloroethylene; IR (CCl_4) 1610 cm^{-1} (C=C); NMR (CCl_4) δ 5.5 ppm (s, $H_2C=$).

Decomposition of 2,2,2-trichloroethanesulfinyl chloride in excess base. To an aqueous sodium hydroxide solution (1 M, 200 ml) and carbon tetrachloride (5 ml) was slowly added 2,2,2-trichloroethanesulphinyl chloride (4.3 g, 0.02 mol). The reaction mixture was kept during 2 h at room temperature under nitrogen. Air must be excluded owing to the explosive nature of chloroacetylene in the presence of oxygen. The IR and NMR spectra of the carbon tetrachloride solution showed that chloroacetylene was formed together with 1,1-dichloroethylene. The yield of chloroacetylene was not determined. Chloroacetylene; IR (CCl_4) 3300 (CH) and 2100 cm^{-1} (C≡C); NMR (CCl_4) δ 1.78 ppm (s, CH). 1,1-Dichloroethylene was treated with a sodium hydroxide solution under the conditions described above. Chloroacetylene could not be detected in this experiment.

*Bis(*threo*-2-chloro-1-methylpropyl)disulfide from* cis*-2-butene and sulfur monochloride.*[6] *cis*-2-Butene (35 g) was added to a solution of $FeCl_3$ (1 g) in ethyl ether (150 ml). Sulfur monochloride (27 g, 0.2 mol) was then slowly added to the stirred solution over 30 min. *cis*-2-Butene was passed continuously through the reaction mixture to maintain an excess. The reaction mixture was stirred at room temperature for 3 h after addition of sulfur monochloride and then washed with water. The organic phase was dried and the solvent removed *in vacuo*. The residue was distilled under reduced pressure and a fraction was collected at b.p. 80–83 °C/0.2 mmHg; yield 19 g. Without further purification this fraction was used in the preparation of *threo*-2-chloro-1-methylpropanesulfinyl chloride (see below).

threo*-2-Chloro-1-methylpropanesulfinyl chloride.* A solution of bis(*threo*-2-chloro-1-methylpropyl)disulfide (18.5 g, 0.075 mol, a mixture of *meso* and *racemic* forms) and acetic anhydride (15.3 g, 0.15 mol) was cooled to 5 °C. Chlorine was passed into the solution at such a rate that the temperature remained between 10 and 15 °C. When no more chlorine was consumed, chlorine and acetyl chloride were removed by evaporation *in vacuo* at room temperature. The residue was distilled at reduced pressure to give *threo*-2-chloro-1-methylpropanesulfinyl chloride; b.p. 64–66 °C/2 mmHg; yield 15 g (57 %); n_D^{25} 1.5140; IR (film) 1150 cm^{-1} (S=O).

Decomposition of threo*-2-chloro-1-methylpropanesulfinyl chloride in the presence of sodium hydroxide.* *threo*-2-Chloro-1-methylpropanesulfinyl chloride (7 g, 0.04 mol) was added at room temperature to an aqueous sodium hydroxide solution (2 M, 100 ml). The butene gas thus formed was passed through a sodium hydroxide solution to remove sulfur dioxide and then collected over water in a measuring cylinder. No more gas evolution could be observed after 2 h at room temperature. The gas (820 ml) was analysed at GLC (column, 4.5 m × 3 mm, packed with 15 % dimethylsulfolane on GasChrom RZ 60/80 mesh, relative retention times *trans*- and *cis*-2-butene 1.00:1.08, column temperature 30 °C). *cis*-2-Butene was present in more than 99 % purity.

*Bis(*erythro*-2-chloro-1-methylpropyl)disulfide from* trans*-2-butene and sulfur monochloride.*[6] This compound was first prepared according to the procedure described for the corresponding *threo*-isomer. However, because of the slow reaction of *trans*-2-butene and sulfur monochloride under these conditions a modified procedure was used. *trans*-2-butene (*ca.* 35 g) was added to a solution of chloroform (130 ml) and pyridine (0.2 ml). Sulfur monochloride (20.5 g, 0.152 mol) was then added slowly to the chloroform solution which was cooled with water. The reaction temperature was not allowed to rise above 25 °C. An excess of *trans*-2-butene was passed continuously through the reaction mixture. After the addition, the reaction mixture was kept at room temperature for 2 h. The chloroform and excess *trans*-2-butene were removed *in vacuo*. It was not possible to distil the residue at reduced pressure (0.2 mm) owing to decomposition. The crude residue was therefore used for the preparation of *erythro*-2-chloro-1-methylpropanesulfinyl chloride (see below).

erythro*-2-Chloro-1-methylpropanesulfinyl chloride.* A solution of crude bis(2-chloro-1-methylpropyl)disulfide (37.5 g, 0.152 mol), prepared as described above from *trans*-2-butene and sulfur monochloride, and acetic anhydride (31 g, 0.304 mol) was cooled to 5 °C. Chlorine was then passed into the solution at such a rate that the temperature remained between 10 and 15 °C. When no more chlorine was consumed the excess chlorine and acetyl chloride was evaporated *in vacuo* at room temperature. The residue could not be distilled owing to decomposition. Therefore, the crude *erythro*-2-chloro-1-methylpropanesulfinyl chloride was used for the decomposition experiment (see below) without further purification.

Decomposition of crude erythro*-2-chloro-1-methylpropanesulfinyl chloride in the presence of sodium hydroxide.* Crude *erythro*-2-chloro-1-methylpropanesulfinyl chloride (7 g) was decomposed as described above for the corresponding *threo*-isomer to yield *trans*-2-butene (280 ml) of more than 99 % purity.

Kinetic procedures. The rates of the decomposition of 2-chloroethanesulfinate have been measured at 21 °C and 34 °C in excess 0.5 M aqueous sodium hydroxide solution. The rates for the appearance of ethylene was followed

by collecting the gas in a measuring cylinder over water (21 °C).

Run a at 21 °C. 2-Chloroethanesulfinyl chloride (1.1178 g, 7.6 mmol) was added to a sodium hydroxide solution (0.5 M, 120 ml) to give 2-chloroethanesulfinate. The solution was kept at 21 °C and the gas was collected. Totally, 161 ml ethylene was evolved over 1396 min, which corresponds to an 85 % yield (correction was made for water pressure and atmosphere pressure). The rate of the decomposition was calculated from the slope of a plot of $\log [a/(a-x)]$ *versus* time. (a = theoretical yield of ethylene; x = the ethylene gas evolved). The decomposition gave good first order kinetics up to 63 % reaction. The rate at 21 °C was $(16.1 \pm 1.5) \times 10^{-4}$ min^{-1}.

Run b at 34 °C. 2-Chloroethanesulfinyl chloride (1.1025 g, 7.5 mmol) was added to a sodium hydroxide solution (0.5 M, 120 ml). The solution was kept at 34 °C and the ethylene gas was collected. Totally, 171 ml ethylene was evolved over 225 min which corresponds to 90 % yield. The rate of the decomposition was derived as described in *run a*. The decomposition gave good first order kinetics up to 75 % reaction. The rate at 34 °C was $(14.7 \pm 0.7) \times 10^{-3}$ min^{-1}.

The activation energy 127.8 ± 8.4 kJ. mol^{-1} was obtained using the Arrhenius equation:

$$\log k_2/k_1 = (\Delta H_a/2.303R)[(T_2 - T_1)/T_2T_1]$$

where k is the rate constant, ΔH_a the activation energy, $R = 8.314$ J deg.$^{-1}$ mol^{-1} and T = absolute temperature.

Non-equivalence of Methylene Protons in Some Nitroxide Radicals of the Type XYZC—CH_2—N(O·)-*tert*-Butyl and XYN—CH_2—N(O·)-*tert*-Butyl

CARL LAGERCRANTZ and MORIO SETAKA*

Dep artment of Medical Physics, University of Göteborg, S-400 33 Göteborg 33, Sweden

A number of nitroxide radicals of the type XYZC—CH_2—N(O·)-*tert*-butyl and one of the type XYN—CH_2—N(O·)-*tert*-butyl were found to exhibit ESR spectra with unequal splittings of the methylene protons together with temperature-dependent line width alternations. The origin of the non-equivalence and the line width alternations was shown to be connected with the presence of unsymmetrically related conformers produced by a steric hindrance combined with an unsymmetric center in position β to the nitrogen atom of the nitroxide group.

In connection with ESR studies on the trapping of short-lived free radicals by the nitroxide method,[1] it was observed that some acyclic nitroxides of the type XYZC—CH_2—N(O·)-*tert*-butyl and one of the type XYN—CH_2—N(O·)-*tert*-butyl gave rise to spectra exhibiting unequal splittings of the methylene protons.

In this paper it is shown that the non-equivalence of the methylene protons originates from the presence of unsymmetrically related conformers produced by a steric hindrance combined with an unsymmetric center in position β to the nitrogen atom of the nitroxide group. Non-equivalence of β-methylene** protons connected with the presence of a chiral atom has been observed for nitronyl nitroxide radicals,[3] nitroxide radicals,[4] and some nitro radicals.[5]

RESULTS

Primary short-lived radicals R—CH_2· (I) were produced in water or a slightly alkaline aqueous solution by the abstraction of a hydrogen atom from methyl groups of the parent compounds R—CH_3 (II) by photochemically generated OH radicals. The nitroxides (III) were subsequently formed in the reaction of the primary radicals with *tert*-nitrosobutane, eqn. 1.

$$\underset{\text{II}}{\text{R}-\text{CH}_3} \xrightarrow{\cdot\text{OH}} \underset{\text{I}}{\text{R}-\text{CH}_2\cdot}$$

$$\underset{\text{I}}{\text{R}-\text{CH}_2\cdot} + \textit{tert}\text{-nitrosobutane} \longrightarrow \underset{\text{III}}{\text{R}-\text{CH}_2-\text{N}(\text{O}\cdot)\text{-}\textit{tert}\text{-butyl}} \qquad (1)$$

The experimental details have been described elsewhere.[1]

5,5-Dimethylhydantoin, 5-methylhydantoin, isopropyl alcohol, 2-hydroxy-2-methylpropanoic acid, and *N*,*N*-dimethylformamide were found to give rise to the nitroxides *1*—*5*, which exhibit unequal β-methylene proton splittings, whereas *tert*-butyl alcohol and 2,2-dimethylpropanoic acid gave rise to the structurally similar nitroxides *6* and *7* which exhibited equivalent β-methylene proton splittings above room temperature.

The ESR spectra of the nitroxides *1*—*5* consisted of 3 × 4 lines indicating an interaction with the ^{14}N nucleus and two non-equivalent

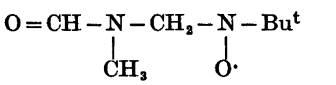
3 X = CH_3, Y = OH, Z = H; 4 X = CH_3, Y = OH, Z = COO^-; 6 X = CH_3, Y = CH_3, Z = OH; 7 X = CH_3, Y = CH_3, Z = COO^-.



5

protons, evidently those of the methylene group. The nitroxides *3* and *5* gave rise to further splittings, nitroxide *3* to a doublet caused by the hydrogen atom on the β-carbon atom, nitroxide *5* to a triplet by interaction with the ^{14}N nucleus of the amide group. The proton splittings of the nitroxides *1*, *3*, and *4* varied somewhat with the temperature in an inversed way, so that the large one decreased and the small one increased when the temperature was raised (Table 1). The spectra obtained with nitroxides *3*, *4* and *5* are shown in Figs. 1, 2, and *3*, respectively.

Line width alternations were observed with the nitroxides with the unequal β-proton splittings. The two inner lines of the 1:1:1:1 quartet caused by the two non-equivalent methylene

protons broadened upon decreasing the temperature, but sharpened when the temperature was increased, so that all 12 lines became of equal height, as seen from the spectra in Fig. 2 obtained at different temperatures with nitroxide *4*, derived from 2-hydroxy-2-methylpropanoic acid. However, the spectra obtained with nitroxide *5* (Fig. 3) exhibited still very pronounced line width alternations, with broadening of the inner lines of the methylene quartets, even at the highest accessible temperature (+50 °C). The basic 12-line structure of the spectra was preserved for the nitroxides *1*–*5* in the entire experimentally accessible range of temperature, *i.e.* from −20 °C to about +90 °C.

Nitroxide *6* gave rise to 3×3 (1:2:1)-line spectra, indicating equivalence of the methylene protons. The center line of the 1:2:1 triplet became broadened already below +50 °C. Nitroxide *7* exhibited 3×3 (1:2:1)-line spectra above room temperature. Below room temperature, the center line of the 1:2:1 triplets broadened and below −10 °C there was a change into a 3×4 (1:1:1:1)-line spectrum, indicating nonequivalence of the methylene protons.

DISCUSSION

Most acyclic nitroxides of the type $R-CH_2-N(O\cdot)-R'$ hitherto described in the literature give rise to ESR spectra with equivalent methylene protons at room temperature. Many such nitroxides show line width alternations at lower

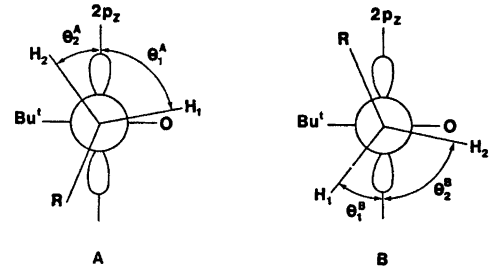

Fig. 4. Steric arrangement around the bond axis between the nitrogen atom of the nitroxide group and the α-carbon atom. The conformers A and B are symmetrically related, so that $\theta_1^A = \theta_2^B$ and $\theta_2^A = \theta_1^B$. The arrangement on the nitrogen atom was made planar.

temperatures due to the presence of a steric hindrance which introduces two symmetrically related conformers (A and B in Fig. 4).[6,7] This case was actually observed with nitroxide *6* below +50 °C. At even lower temperatures the rate of jumping between the conformers A and B became slow enough to allow the spectrometer to record a superposition spectrum of the individual conformers, the spectra of which are identical. The center line of the methylene triplets is now resolved into two separate lines, and the spectrum consists of 12 lines of equal intensity. Such an interpretation is evidently valid also for the spectra obtained with nitroxide *7* below −10 °C.

The results obtained with the nitroxides *1*–*5* cannot be explained by the mechanism outlined.

If this mechanism had been valid, the 12-line spectra would have exhibited a broadening of the inner lines of the methylene 1:1:1:1 quartet upon increasing the temperature, not a broadening upon decreasing the temperature which was actually observed. Furthermore, the 12-line spectra would have been changed into 9-line spectra with 1:2:1 methylene triplets in the high temperature range, a finding which was not observed for any of the nitroxides *1*–*5*.

The nitroxides *1*–*4* with unequal β-proton splittings all have a center of chirality in position β to the nitrogen atom of the nitroxide group, whereas no such center is present in the nitroxides *6* and *7* which show equivalent β-protons at high temperature. A hindered rotation around the bond axis between the α-carbon atom and the chiral β-atom introduces two conformers which are mutually unsymmetrical due to a steric interaction between the oxygen atom or the *tert*-butyl group on the nitrogen atom and the non-identical substituent groups XYZ on the chiral β-atom. The origin of the unsymmetrically related conformers in the case of radical *5* is less easily explained. The nitrogen atom of the amide group is evidently involved but it is not clear if the unsymmetry originates from the nitrogen atom as a chiral center, or indirectly from the steric behaviour of one of the substituent groups, possibly the COH group.

The mutually unsymmetrical conformers, A and B in Fig. 5, infer that the dihedral angles are related by the inequalities $\theta_1^A \neq \theta_2^B$ and $\theta_2^A \neq \theta_1^B$. Considering the splitting constant of a β-proton of nitroxides to be proportional to the cosine square of the dihedral angle concerned,[8] the non-equivalence of the β-protons is produced as follows. As a result of the unsymmetry conformers A and B will be represented by individual ESR spectra with non-identical splitting constants, as shown for one of the three methylene splittings in Fig. 6a and b. At low temperature, when the rate of jumping between conformations A and B is slow, the spectrometer will resolve all eight lines of the actual superposition spectrum of the two conformers (Fig. 6c). When the temperature is raised and the rate of interconversion increases past the limit of slow exchange, the lines coalescence in pairs into a 4-line spectrum, which gradually sharpens towards the situation shown in Fig. 6d.

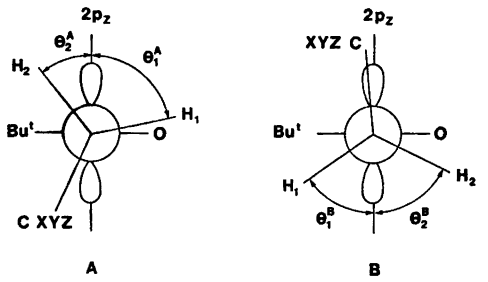

Fig. 5. Steric arrangement around the bond axis between the nitrogen atom of the nitroxide group and the α-carbon atom. The conformers A and B are unsymmetrically related, so that $\theta_1^A \neq \theta_2^B$ and $\theta_2^A \neq \theta_1^B$. The arrangement on the nitrogen atom was made planar.

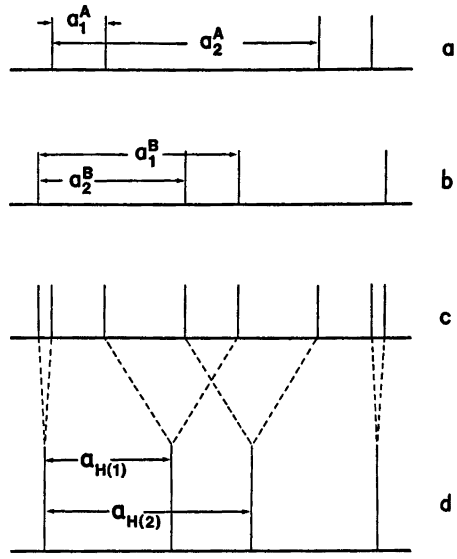

Fig. 6. Schematic ESR spectra of one of the three methylene splittings for nitroxides with the unsymmetrically related conformers A and B.
a and *b*: individual spectra corresponding to conformers A and B. *c*: actual spectrum at low jumping rate, *d*: at high rate.

This mechanism explains the origin of the four-line splittings produced by the methylene protons as observed with nitroxides *1*–*5*. Evidently the rate of interconversion between different conformations exceeds the limit of slow exchange in the whole range of the experimentally accessible temperatures. The broadening of the inner lines as compared with the

outer ones of the methylene quartet observed at low temperatures originates from the coalescence of pairs of lines in conformations A and B far more widely separated than the corresponding pairs of the wings. The continuous variation of $a_{(H1)}$ and $a_{(H2)}$ so that the sum $a_{H(1)} + a_{H(2)}$ remains constant as seen from Table 1, is believed to be connected with an unequal population of the two conformations A and B. The position of the inner lines of the methylene quartets formed by coalescence (see Fig. 6d) is a weighted mean of the positions of the parent lines in conformations A and B. An increase in the temperature will therefore move the inner lines towards the line position of the conformation, whose population was increased by the rise in temperature.

The interpretation made for the origin of the unequal β-methylene splittings of the nitroxides *1–5* is in some details similar to that proposed by Gilbert *et al.*[5] for the nitro radicals mentioned above, and seem to satisfactorily explain our findings.

Organic Hydroxylamine Derivatives. XI.* Structural Analogues of γ-Aminobutyric Acid (GABA) of the Isoxazole Enol-betaine Type. Synthesis and the Crystal Structure of 3-Hydroxy-5-(3-aminopropyl)isoxazole Zwitterion

LOTTE BREHM and POVL KROGSGAARD-LARSEN

The Royal Danish School of Pharmacy, Chemical Laboratory C, DK-2100 Copenhagen Ø, Denmark

The synthesis and the crystal structure determination of 3-hydroxy-5-(3-aminopropyl)isoxazole zwitterion (V), which is a structural analogue of ε-aminocaproic acid, are described. The synthesis is based on methyl 3-(3-methoxyisoxazol-5-yl)propionate (I), which by conventional methods is converted into (V). The pK_A values of 3-hydroxy-5-(3-aminopropyl)isoxazole zwitterion have been determined to 5.37 ± 0.04 and 10.36 ± 0.04.

Crystals of 3-hydroxy-5-(3-aminopropyl)isoxazole monohydrate, $C_6H_{10}N_2O_2.H_2O$, are monoclinic, space group $C2/c$, $a = 23.45(1)$, $b = 5.768(1)$, $c = 13.483(4)$ Å, $\beta = 120.33(3)°$, $Z = 8$. The structure has been solved by a direct phasing technique using X-ray diffraction data, and has been refined by full-matrix least-squares methods. The final R value is 0.039 for 1218 independent observations. The molecule is a zwitterion, and the crystal structure is stabilized by a system of hydrogen bonds.

As part of our investigations of isoxazole enol-betaines, which are structural analogues of γ-aminobutyric acid (GABA) or closely related amino acids with GABA-like activity in the mammalian central nervous system, the crystal structure determinations of muscimol (3-hydroxy-5-aminomethylisoxazole zwitterion) [1,2] and homomuscimol (3-hydroxy-5-(2-aminoethyl)isoxazole zwitterion) [3] have been performed. The present paper describes the synthesis and the crystal structure determination of 3-hydroxy-5-(3-aminopropyl)isoxazole zwitterion (V), which is a structural analogue of ε-aminocaproic acid.[4] This synthetic amino acid exhibits a weak, GABA-like depressant activity when applied to feline spinal interneurones.[5] The biological properties of ε-aminocaproic acid are, however, multifarious, and rather conflicting results have been obtained after administration of this compound to different structures of the mammalian central nervous system (see Ref. 6). Investigations of the biological properties of 3-hydroxy-5-(3-aminopropyl)isoxazole will be initiated in the near future.

RESULTS AND DISCUSSION

The synthesis of 3-hydroxy-5-(3-aminopropyl)isoxazole zwitterion (V) is based on methyl 3-(3-methoxyisoxazol-5-yl)propionate (I), which is converted into 3-(3-methoxyisoxazol-5-yl)-propionamide (II). Subsequent reduction of (II) with diborane gives the corresponding primary amine, isolated from the reaction mixture as its hydrochloride (III). (III) is cleaved by hydrogen bromide in glacial acetic acid to 3-(3-hydroxyisoxazol-5-yl)propylammonium bromide (IV), from which the isoxazole enol-betaine (V) is isolated using a strongly basic ion exchange resin.

The structure determinations of (II – V) are based on IR, UV, and ^{1}H NMR spectroscopy and supported by elemental analyses. The spectroscopic data arising from the 3-methoxy- and 3-hydroxyisoxazole moieties of (II, III) and (IV), respectively, are in accordance with the general findings described by Jacquier *et al.*[7] The aromatic character of the isoxazole nucleus of (V) is evident from IR absorption bands at 1610 and 1520 – 1450 cm^{-1},[8] and absorptions over the range 3600 – 2000 and at 2170 cm^{-1} suggest ammonium salt character of (V). The UV maximum of (V) at 211 nm is in agreement with that observed (210 nm) for homomuscimol.[8] Some spectroscopic data of the compounds (II – V), which are all new, and the pK_A values of (V) are listed in Table 1.

The molecular structure of (V) is unambiguously confirmed by the results of the X-ray diffraction analysis. The dimensions and the conformation of the molecule are shown in Figs. 2a and 2b.

The isoxazole ring is planar within the limits of experimental error; Table 2 lists the displacements of some atoms from the least-squares plane through this ring. The least-squares plane through the planar *trans-zigzag* aminopropyl side chain makes an angle of 11.3° with the isoxazole ring plane (Table 2). The three hydrogen atoms are tetrahedrally arranged about the nitrogen atom. Their positions correspond to a 5 – 15° rotation about the C – N bond relative to that for a strictly staggered conformation.

Tables 3 and 4 and Figs. 2a and 2b show some

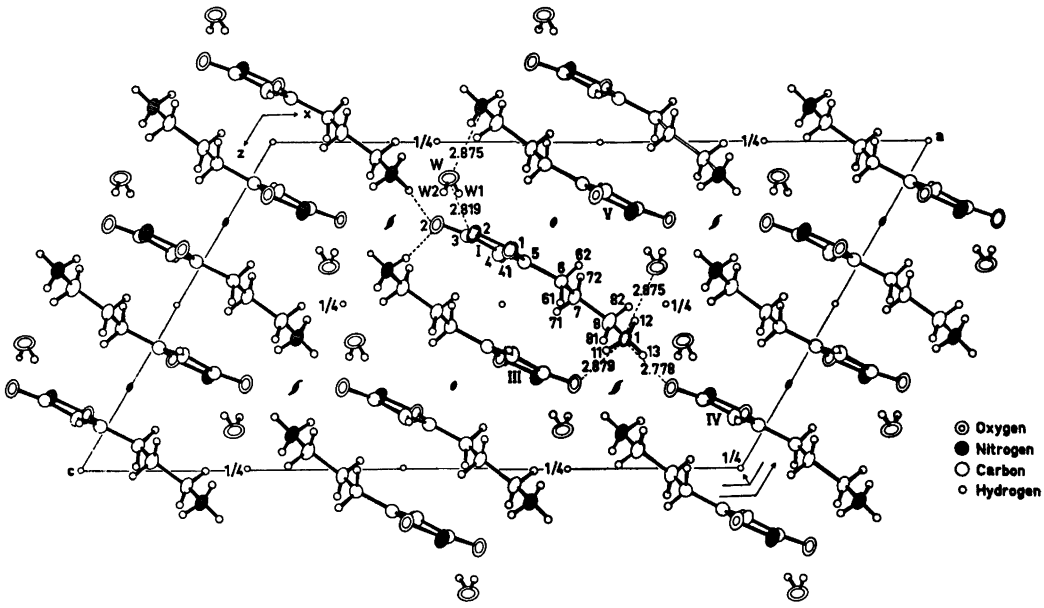

Fig. 3. Projection of the structure down the *b* axis. Some of the shorter *inter*molecular contacts are indicated.

calculated *intra*molecular distances and angles. The bond lengths and angles appear consistent with the general pattern of 3-hydroxy-5-(ω-aminoalkyl)isoxazole zwitterions.[2,3] The *intra*molecular distance $N(1)^+ \cdots O(2)^-$ is 7.925 Å.

The anisotropic thermal parameters of the non-hydrogen atoms are given in Table 6 and are drawn schematically in Fig. 2a.

The packing of the molecules in the crystal structure is determined by a system of hydrogen bonds. All hydrogen atoms that are covalently bonded to nitrogen or oxygen atoms are utilized

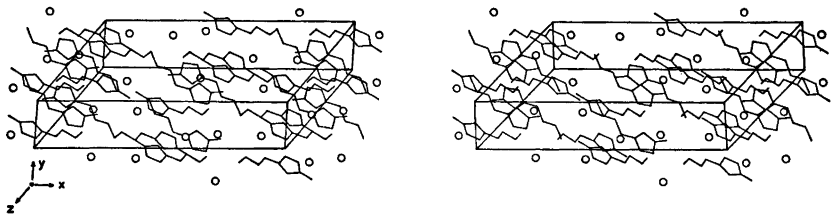

Fig. 4. Stereo diagram illustrating the molecular packing.

in the formation of hydrogen bonds. The zwitterions are inclined at about 13° to the ($\bar{1}01$) planes and, since they are approximately planar, form layers as shown in Figs. 3 and 4. Those zwitterions related by the *n*-glide plane are bound head to tail by the hydrogen bond $N(1)-H(13)\cdots O(2)_{IV}$, thereby leading to infinite chains in the [101] direction. These chains are interlinked on one side by double hydrogen bonds [$N(1)-H(11)\cdots O(2)_{III}$; $O(2)\cdots H(11)_{III}-N(1)_{III}$], formed between pairs of molecules related by a centre of symmetry. The spaces between these pairs of layers are filled with water molecules, each of which is linked by hydrogen bonds in directions almost parallel to the *b* [$O(W)-H(W1)\cdots N(2)_I$; $O(W)-H(W2)\cdots O(2)_{II}$] and *c* [$O(W)\cdots H(12)_V-N(1)_V$] axes to three different 3-hydroxy-5-(3-aminopropyl)-isoxazole molecules. In addition the $N(1)\cdots O(W)_{IV}$ distance is short, presumably because of the strong attractive interactions between the molecules. All other *inter*molecular contacts are greater than 3.2 Å. A summary of the geometry of the close contacts is shown in Table 5.

EXPERIMENTAL

The determination of melting points, the recording of IR, UV, and ^1H NMR spectra, and the performance of microanalyses were accomplished as described in a previous paper.[9]

The pH values were measured on a Radiometer pH meter 26, and the pK_A values were determined according to the method of Albert and Serjeant [10] as described previously.[3]

The computations were performed on a GIER computer and an IBM 360/75 computer using *INDIFF*,[11] a local version of *The N. R. C. 2A Picker Data Reduction Program*,[12] *The X-Ray System*,[13] and *ORTEP*.[14] The X-ray atomic scattering factors used were those of Cromer and Mann [15] for oxygen, nitrogen, and carbon, and of Stewart, Davidson, and Simpson [16] for hydrogen.

Synthesis

3-(3-Methoxyisoxazol-5-yl)propionamide (II). A mixture of 3.20 g (17 mmol) of methyl 3-(3-methoxyisoxazol-5-yl)propionate (I) [17] and aqueous ammonia (170 ml; ϱ 0.88) was stirred until a clear solution was obtained. This was allowed to stand at 25 °C for 18 h. Evaporation *in vacuo* afforded 3.0 g of crystalline product, which was recrystallized (acetone) to give 2.21 g (75 %) of (II) as colourless crystals, m.p. 142.0–143.0 °C. (Found: C 49.60; H 6.03; N 16.42. Calc. for $C_7H_{10}N_2O_3$: C 49.40; H 5.92; N 16.46). ^1H NMR data [$CDCl_3$-DMSO-d_6 (1:1)]: δ 7.5–7.1 and 6.8–6.5 (two broad signals, total 2 H, $CONH_2$); 5.75 (s, 1 H, $C=CH-C$); 3.84 (s, 3 H, $O-CH_3$); 3.1–2.7 (m, 2 H, $CH_2-CH_2-C=$); 2.6–2.2 (m, 2 H, $CO-CH_2-CH_2$).

3-(3-Methoxyisoxazol-5-yl)propylammonium chloride (III). To 100 ml of ice-cooled tetra-

hydrofuran containing diborane, externally generated[18] from 4.75 g (125 mmol) of sodium borohydride in diglyme (125 ml) and 25.5 g (180 mmol) of boron trifluoride etherate in diglyme (50 ml), was added during a period of 15 min a solution of 5.95 g (35 mmol) of (II) in tetrahydrofuran (125 ml). The mixture was refluxed for 19 h, and after cooling to 25 °C followed by careful addition of 6 M hydrochloric acid (50 ml) the solution was evaporated to dryness *in vacuo*. Upon addition of water (10 ml) and a 50 % aqueous solution of potassium hydroxide (40 ml) the mixture was extracted with two 50 ml portions of ether. The combined ether phases were dried and evaporated *in vacuo* to give 3.3 g of an oil. The oily product was dissolved in ethanol (13 ml) and upon addition of an ethanolic solution of hydrogen chloride, prepared from ethanol (100 ml) and acetyl chloride (12 ml), followed by addition of ether (18 ml) (III) was allowed to crystallize at 5 °C for 18 h to give 2.88 g (43 %) as colourless crystals, m.p. 129 – 131 °C (decomp.). (Found: C 43.40; H 6.80; N 14.65; Cl 18.43. Calc. for $C_7H_{13}ClN_2O_2$: C 43.65; H 6.80; N 14.54; Cl 18.41). ^{1}H NMR data [DMSO-d_6-$CDCl_3$ (3:2)]: δ 8.7 – 8.0 (broad, 3 H, NH_3^+); 5.93 (s, 1 H, C=C*H*–C); 3.87 (s, 3 H, O–CH_3); 3.1 – 2.5 (m, 4 H, NH_3^+–CH_2–CH_2–CH_2–C=); 2.3 – 1.7 (m, 2 H, CH_2–CH_2–CH_2).

3-(3-Hydroxyisoxazol-5-yl)propylammonium bromide (IV). 1.40 g (7.3 mmol) of (III) were dissolved in 11 ml of glacial acetic acid containing 43 % of hydrogen bromide. The solution was heated in an oil bath for 30 min, during which time the temperature rose to 90 °C. A further amount of 11 ml of the above mentioned reagent was carefully added, and the solution was refluxed (bath temperature: 90 – 100 °C) for 40 min. After cooling to 25 °C the reaction mixture was evaporated to dryness *in vacuo*. Recrystallization (methanol-ether) gave 1.10 g (68 %) of (IV) as colourless crystals, m.p. 193 °C (decomp.). (Found: C 32.30; H 5.02; N 12.60; Br 35.74. Calc. for $C_6H_{11}BrN_2O_2$: C 32.30; H 4.97; N 12.55; Br 35.82). ^{1}H NMR data (DMSO-d_6): δ 11.5 – 10.8 (broad, 1 H, O*H*); 8.5 – 7.4 (broad, 3 H, NH_3^+); 5.82 (s, 1 H, C=C*H*–C); 3.0 – 2.4 (m, 4 H, NH_3^+–CH_2–CH_2–CH_2–C=); 2.2 – 1.5 (m, 2 H, CH_2–CH_2–CH_2).

3-Hydroxy-5-(3-aminopropyl)isoxazole zwitterion (V). A solution of 900 mg (4.0 mmol) of (IV) in water (10 ml) was passed through a column containing an ion exchange resin [Amberlite IRA 400, (OH), 90 ml] using acetic acid (1 M) as an eluent. The fractions containing (V) were collected and evaporated *in vacuo* to give an oil. The oily residue was dissolved in water (15 ml), and upon addition of ethanol (35 ml) (V) was allowed to crystallize at 5 °C for 18 h to give 280 mg (43 %) as colourless crystals, m.p. 136 – 137 °C (decomp.). (Found: C 44.80; H 7.58; N 17.39. Calc. for $C_6H_{10}N_2O_2.H_2O$: C 44.99; H 7.55; N 17.49). [Found after drying of (V) over P_2O_5 (16 h; 75 °C; 0.05 mmHg): C 50.55; H 6.96; N 19.69. Calc. for $C_6H_{10}N_2O_2$: C 50.69; H 7.09; N 19.71]. ^{1}H NMR data [D_2O (sodium 3-(trimethylsilyl)propanesulfonate was used as an internal standard)]: δ 5.52 (s, 1 H, C=C*H*–C); 4.69 (s, 5 H, DO*H*); 3.2 – 2.8 and 2.8 – 2.4 (two t, total 4 H, NH_3^+–CH_2–CH_2–CH_2–C=); 2.2 – 1.5 (quintet, 2 H, CH_2–CH_2–CH_2).

X-Ray analysis

Colourless prismatic crystals of 3-hydroxy-5-(3-aminopropyl)isoxazole monohydrate were grown at room temperature by diffusion of absolute ethanol into an aqueous solution of the compound.

Crystal data. 3-Hydroxy-5-(3-aminopropyl)-isoxazole monohydrate, $C_6H_{10}N_2O_2.H_2O$, M = 160.18. Monoclinic, $a = 23.45(1)$, $b = 5.768(1)$, $c = 13.483(4)$ Å, $\beta = 120.33(3)°$, $U = 1574.0$ Å^3, $D_m = 1.35$ g cm^{-3}, $Z = 8$, $D_c = 1.352$ g cm^{-3}. Linear absorption coefficient for X-rays [λ (Mo$K\alpha$) = 0.7107 Å], $\mu = 1.17$ cm^{-1}. Number of electrons per unit cell, $F(000) = 688$. Space group $C2/c$ from systematically absent reflections: hkl when $h+k$ odd, $h0l$ when l odd, and from intensity statistics.

The unit-cell parameters were refined by least-squares techniques from the diffractometer-measured θ angles observed for 40 reflections well distributed in reciprocal space. The crystal density was measured by flotation in a chlorobenzene/bromobenzene mixture.

Data collection. Three-dimensional diffraction data were measured at room temperature on a Nonius three-circle automatic diffractometer using graphite monochromated Mo$K\alpha$ radiation. The ω scan technique with a scan speed of 1.2° min^{-1} was employed. Background counts were taken for half the scanning time at each of the scan range limits. One standard reflection was measured after every 25 reflections.

All the data were measured from a single crystal with approximate dimensions 0.25 × 0.32 × 0.30 mm. The crystal was mounted with [010] along the ϕ axis of the goniostat.

Out of the 1725 independent reflections measured in the range $2.5° \leq \theta \leq 27°$, 1231 had $I_{net} \geq 3.0\sigma(I)$, where $\sigma(I)$ is the standard deviation from counting statistics. These were regarded as observed reflections, whereas the remaining reflections were regarded as unobserved and excluded from the refinement procedure. Lorentz and polarization corrections were applied, but no absorption corrections were made owing to the low absorption coefficient.

Structure determination. The observed structure amplitudes were brought to an absolute scale by Wilson statistics and normalized structure amplitudes, $|E(hkl)|$, were calculated.

The phase problem was solved by direct methods using the programs of the X-Ray 72 System.[18] Of the highest thirteen peaks in an E-map based on 92 $E(hkl)$'s with $|E(hkl)| \geq 1.5$, eleven corresponded to all the "heavy" (nitro-

gen, oxygen, and carbon) atoms in the asymmetric unit. Individual atomic parameters of this model were refined, first with isotropic and then anisotropic thermal parameters using the full-matrix least-squares method. On convergence the R value was 0.093. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, where weights were initially taken as unity.

After having omitted from the data set the strongest observation, *i.e.* $\bar{4}04$, which was considered to be severely affected by extinction, a three-dimensional difference synthesis was computed. The subsequent map showed maxima with peak heights of $0.4-0.7$ e Å^{-3} in positions expected for all the hydrogen atoms, and there were no extraneous peaks greater than the lowest hydrogen atom. Introduction of the hydrogen atoms in the refinement, with the isotropic temperature factors of the connected non-hydrogen atoms as constant parameters reduced the R value to 0.050 for 1231 independent observations. Among the strongest reflections twelve were considered to be affected by extinction, and were omitted from the data set.

The least-squares refinement was completed with the introduction of a weighting scheme of the form: $w=1/(1+[(|F_o|-b)/a]^2)$, where $a=17.50$ e and $b=18.75$ e. On the last cycle of least-squares refinement shifts of all parameters were less than one tenth of their estimated standard deviations and the final R value is 0.039 for 1218 independent observations. Tables 6 and 7 list the final positional and thermal parameters for the non-hydrogen and hydrogen atoms, respectively. From these parameters the terminal set of structure factors, listed with the observed data in Table 8, was computed. Comparison of the 92 signs determined by direct methods with the corresponding phases computed from the refined structure shows that all had been correctly assigned.

Table 6. Final positional and thermal ($\times 10^4$ Å^2) parameters for non-hydrogen atoms. The estimated standard deviations of positional and thermal parameters ($\times 10^4$) are given in parentheses. The temperature expression is of the form:
$\exp[-2\pi^2(h^2a^{*2}U_{11}+k^2b^{*2}U_{22}+l^2c^{*2}U_{33}+2hka^*b^*U_{12}+2hla^*c^*U_{13}+2klb^*c^*U_{23})]$

Organic Hydroxylamine Derivatives. XII.* Structural Analogues of γ-Aminobutyric Acid (GABA) of the Isoxazole Enol-betaine Type. Synthesis of Some 3-Hydroxy-5-(1-aminoalkyl)isoxazole Zwitterions

POVL KROGSGAARD-LARSEN and SØREN BRØGGER CHRISTENSEN

The Royal Danish School of Pharmacy, Chemical Laboratory C, DK-2100 Copenhagen Ø, Denmark

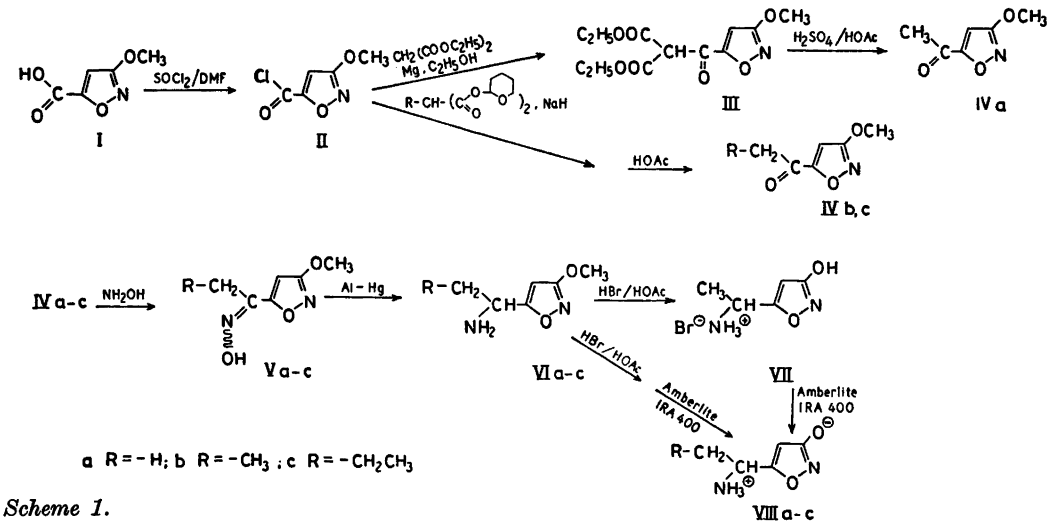
The syntheses of three 3-hydroxy-5-(1-aminoalkyl)isoxazole zwitterions (VIIIa–c), which are conformationally restricted analogues of γ-aminobutyric acid (GABA), are described. The syntheses are based on 3-methoxy-5-isoxazolecarboxylic acid (I), which is transformed into the final products (VIIIa–c) *via* the ketones and oximes (IVa–c) and (Va–c), respectively. The pK_A values of (VIIIa–c) have been determined.

Muscimol (3-hydroxy-5-aminomethylisoxazole zwitterion), which is a conformationally restricted analogue of the inhibitory synaptic transmitter γ-aminobutyric acid (GABA),[1,2] is a valuable model compound in the investigations of structure-activity correlations for GABA agonists.[3–6] The present paper describes the synthesis of three 3-hydroxy-5-(1-aminoalkyl)isoxazole zwitterions (VIIIa–c), which are structurally related to muscimol. The aim of this work is to make available some structurally closely related GABA analogues in which the geometry of the preferred conformations is systematically changed. The increasing size of the alkyl groups of the compounds through the series (VIIIa–c) may increase the energy barriers separating the accessible conformations of the respective molecules.

Biological investigations of the racemates (VIIIa–c) are in progress. When the results of these investigations are available, efforts will be made to obtain the optical isomers of pertinent compounds of the series (VIIIa–c) for an investigation of the stereospecificity of the GABA receptor(s).

The acid chloride (II) is a key compound in the syntheses of the products (VIIIa–c). An unpurified product of (II) has previously been prepared in an apparently rather low yield as an intermediate in a synthesis of muscimol.[7] Reaction of the carboxylic acid (I) with a dimethylformamide-thionyl chloride reagent, however, gave (II) in good yields and in a pure state. Attempts to synthesize the methyl ketone (IVa) by reaction of the acid chloride (II) with lithium dimethylcuprate according to the method of Posner and Whitten [8] gave (IVa) in rather low yields. Reaction of (II) with diethyl ethoxymagnesiummalonate gives compound (III), which is converted into (IVa). The ketones (IVb, c) are synthesized *via* the appropriately substituted bistetrahydropyranyl malonates, using a method analogous to that described by Bowman and Fordham.[9] The oximes (Va–c), prepared by a conventional method, are reduced by aluminium amalgam to give the corresponding primary amines (VIa–c) as described by Bowden *et al.* for an analogous reaction.[7] Cleavage of (VIa) with hydrogen bromide in glacial acetic acid gives the hydrobromide (VII), which is subsequently converted into the enol-betaine (VIIIa) using a strongly basic ion exchange resin. Likewise the amines (VIb, c) are transformed into the final products (VIIIb, c), respectively, without isolation of the intermediately formed hydrobromides.

* Part XI. *Acta Chem. Scand. B 28* (1974) 625.



Scheme 1.

The structure determinations of (II)–(IVa–c), (VIa–c), (VII), and (VIIIa–c) are based on IR, UV, and ^{1}H NMR spectroscopy and supported by elemental analyses. The IR and ^{1}H NMR spectroscopic data originating in the 3-methoxy- and 3-hydroxyisoxazole moieties of (II)–(IVa–c), (VIa–c), and (VII), are in accordance with the general findings described by Jacquier *et al.*[10] The UV spectra of the compounds (II)–(IVa–c) are consistent with the presence of carbonyl groups in conjugation with the isoxazole nucleus. As revealed by IR, UV, and ^{1}H NMR spectroscopy compound (III) is largely in the enol form. The oximes (Va–c) are shown by ^{1}H NMR spectroscopy to consist of mixtures of the *Z*- and *E*-forms. Separation of the oximes (Va–c) in the isomeric forms and the determination of

Table 1. Some IR and UV data of the compounds (II)–(IVa–c), (VIa–c), (VII), and (VIIIa–c) and the pK_A values of (VIIIa–c).

[a] Unless otherwise stated the UV spectra were recorded in 99.9 % ethanol solutions. [b] The pK_A values were determined by titration in aqueous solutions at 17 °C. [c] The IR spectra were recorded using the film technique. [d] The IR spectra were recorded in the solid state (KBr). [e] The UV spectrum was recorded in cyclohexane solution.

their configuration have been performed and will be published in the near future. The spectroscopic properties of the zwitterions (VIIIa–c) are in accordance with those published for muscimol,[11] 3-hydroxy-5-(2-aminoethyl)-isoxazole zwitterion,[7,12] and 3-hydroxy-5-(3-aminopropyl)isoxazole zwitterion,[13] the structures of which have been established by X-ray diffraction analyses.[2,12,13] The pK_A values of muscimol (4.78 and 8.43)[11] and those determined for the enol-betaines (VIIIa–c) (*cf.* Table 1) are almost alike. This is an important fact since the compounds (VIIIa–c) together with muscimol are model compounds in the conformation-biological activity investigations.

Some spectroscopic data of the compounds (II–IVa–c), (VIa–c), (VII), and (VIIIa–c), which are all new, and the pK_A values of (VIIIa–c) are listed in Table 1.

EXPERIMENTAL

Unless otherwise stated the determination of melting points, the recording of IR, UV, and ^{1}H NMR spectra, and the performance of microanalyses were accomplished as described in a previous paper.[14] pH Values were measured on a Radiometer pH meter 26. Thin layer and column chromatographic procedures were accomplished using silica gel GF_{254} plates (Merck) and silica gel, 0.05–0.20 mm (Merck), respectively. The pK_A values were determined according to the method of Albert and Serjeant[15] as described in a previous paper.[12]

3-Methoxy-5-chloroformylisoxazole (II). To a mixture of 14.3 g (100 mmol) of 3-methoxy-5-isoxazolecarboxylic acid (I)[16] and thionyl chloride (160 ml) was added 5.1 g (70 mmol) of dimethylformamide. After reflux for 5 min the excess of thionyl chloride was removed *in vacuo* and the residue was extracted with six 30 ml portions of ether. The combined ether phases were concentrated *in vacuo* and the residue was distilled to give 11.1 g (69 %) of (II) as a pale yellow oil, b.p. 80–85 °C/14 mmHg. (Found: C 37.15; H 2.60; Cl 22.13; N 8.68. Calc. for $C_5H_4ClNO_3$: C 37.18; H 2.50; Cl 21.95; N 8.67). ^{1}H NMR data (CCl_4): δ 6.73 (s, 1 H, C=C*H*–C); 4.03 (s, 3 H, O–C*H*$_3$).

Ethyl 2-ethoxycarbonyl-3-oxo-3-(3-methoxyisoxazol-5-yl)propanoate (III). To a solution of 5.28 g (33 mmol) of diethyl malonate, 2.4 g (50 mmol) of ethanol and 150 μl of tetrachloromethane in ether (30 ml) was added 0.84 g (35 mmol) of magnesium. The mixture was refluxed for 2 h and filtered, and to the refluxing filtrate was added slowly and with stirring a solution of 4.83 g (30 mmol) of (II) in ether (20 ml). Reflux was continued for further 30 min, and after cooling to room temperature 60 ml of sulfuric acid (2 M) were added and the ether phase was isolated, dried, and concentrated *in vacuo* to give 7.8 g (91 %) of (III) as a yellow oil. An analytical sample was distilled at 0.01 mmHg to give (III) as a very viscous oil. (Found: C 50.32; H 5.32; N 5.19. Calc. for $C_{12}H_{15}NO_7$: C 50.52; H 5.30; N 4.91). ^{1}H NMR data (CCl_4): δ 12.7–12.3 (broad s, 0.4 H, enol-O*H*); 6.50 and 6.29 (two s, 0.4 H and 0.6 H, respectively, C=C*H*–C); 4.94 (s, 0.3 H, C*H*–C=O); 4.5–4.0 (m, 4 H, 2 × CH$_3$–C*H*$_2$–O); 3.96 and 3.93 (two s, total 3 H, C*H*$_3$–O); 1.5–1.1 (m, 6 H, 2 × C*H*$_3$–CH$_2$).

3-Methoxy-5-acetylisoxazole (IVa). A mixture of 7.8 g (27 mmol) of (III), glacial acetic acid (15 ml), concentrated sulfuric acid (2 ml), and water (10 ml) was refluxed for 3 h. After cooling to room temperature and after addition of water (60 ml) the solution was adjusted to pH 6 by addition of an aqueous solution of potassium hydroxide (10 M) and extracted with three 50 ml portions of ether. The combined ether extracts were dried, and evaporated *in vacuo*. Distillation of the residue afforded 3.0 g (78 %) of compound (IVa) as a colourless oil, b.p. 92–98 °C/15 mmHg. (Found: C 50.95; H 5.11; N 9.92. Calc. for $C_6H_7NO_3$: C 51.06; H 5.00; N 9.93). ^{1}H NMR data (CCl_4): δ 6.34 (s, 1 H, C=C*H*–C); 3.95 (s, 3 H, O–C*H*$_3$); 2.47 (s, 3 H, CO–C*H*$_3$).

3-Methoxy-5-(1-hydroxyiminoethyl)isoxazole (Va). A solution of 5.0 g (35 mmol) of (IVa), 5.3 g (39 mmol) of sodium acetate trihydrate, and 2.7 g (39 mmol) of hydroxylammonium chloride in aqueous ethanol (35 ml; 50 %) was refluxed for 30 min. Evaporation of the solution to *ca.* 15 ml followed by filtration afforded 5.0 g (90 %) of a colourless crystalline product. An analytical sample was recrystallized (water) to give (Va) as colourless crystals. The product was by thin layer chromatography shown to consist of two compounds with $R_F = 0.38$ and $R_F = 0.33$ (eluent: methylene chloride). (Found: C 45.95; H 5.19; N 18.02. Calc. for $C_6H_8N_2O_3$: C 46.15; H 5.16; N 17.94). ^{1}H NMR data of (Va) [$CDCl_3$-DMSO-d_6 (6:1)], which are consistent with a mixture (*ca.* 1:4) of the isomeric oximes: δ 11.37 (s, 1 H, N–O*H*); 6.73 and 6.04 (two s, 0.2 H and 0.8 H, respectively, C=C*H*–C); 2.91 (two coincident s, 3 H, O–C*H*$_3$); 2.10 (two coincident s, 3 H, C–C*H*$_3$).

3-Methoxy-5-(1-aminoethyl)isoxazole (VIa). To a solution of 5.0 g (32 mmol) of (Va) in aqueous methanol (150 ml; 50 %) aluminium amalgam was added. [The latter was prepared by treatment of 10.5 g (388 mmol) of aluminium strips with an aqueous mercuric chloride solution (300 ml; 5 %) for 30 s followed by washing with ethanol]. After stirring for 90 min at room temperature the mixture was filtered and concentrated *in vacuo* to give a colourless oil, which was distilled to give 3.1 g (67 %) of (VIa) as a colourless oil, b.p. 106–110 °C/16 mmHg. (Found: C 50.75; H 7.19; N 19.88. Calc. for $C_6H_{10}N_2O_2$: C 50.69; H 7.09; N 19.71).

^{1}H NMR data (CCl_4): δ 5.58 (s, 1 H, C=C*H*−C); 4.1−3.7 (partly overlapped q, $CH_3-CH-NH_2$), and 3.75 (s, CH_3-O) total 4 H; 1.52 (s, 2 H, NH_2); 1.35 [d(J=6 cps), 3 H, CH_3-CH].

3-Hydroxy-5-(1-aminoethyl)isoxazole hydrobromide (VII). A solution of 1.47 g (10.3 mmol) of (VIa) in glacial acetic acid (10 ml) containing 43 % of hydrogen bromide was heated to reflux for a total of 20 min. After reflux for 10 min an additional 10 ml of glacial acetic acid containing hydrogen bromide was added. After cooling to 25 °C the solution was evaporated to dryness *in vacuo*. The residue was dissolved in methanol (15 ml) and concentrated *in vacuo* to give an oil, which slowly crystallized. The product was recrystallized (ether−propan-2-ol) to give 1.57 g (72 %) of (VII) as slightly coloured crystals, m.p. 150 °C (decomp.). (Found: C 28.66; H 4.59; Br 38.15; N 13.47. Calc. for $C_5H_9BrN_2O_2$: C 28.73; H 4.34; Br 38.23; N 13.40). ^{1}H NMR data (DMSO-d_6): δ 9.0−8.2 (broadened s, 4 H, O*H* and NH_3^+); 6.17 (s, 1 H, C=C*H*−C); 4.54 [q (J=7 cps), 1 H, $CH_3-CH-NH_3^+$]; 1.51 [d (J=7 cps), 3 H, CH_3-CH].

3-Hydroxy-5-(1-aminoethyl)isoxazole zwitterion (VIIIa). A solution of 756 mg (36.0 mmol) of (VII) in water (10 ml) was passed through a column containing an ion exchange resin [Amberlite IRA 400, (OH), 110 ml] using acetic acid (1 M) as an eluent. Recrystallization of the crude product (water-ethanol) gave 290 mg (63 %) of (VIIIa) as colourless crystals, m.p. 213−215 °C (decomp.). (Found: C 46.70; H 6.26; N 21.67. Calc. for $C_5H_8N_2O_2$: C 46.87; H 6.29; N 21.87). ^{1}H NMR data [D_2O (sodium 3-(trimethylsilyl)propanesulfonate was used as an internal standard)]: δ 5.75 (s, 1 H, C=C*H*−C); 4.76 (s, 4 H, DO*H*); 4.48 [q (J=7 cps), 1 H, $CH_3-CH-NH_3^+$]; 1.59 [d (J=7 cps), 3 H, CH_3-CH].

3-Methoxy-5-propionylisoxazole (IVb). To a stirred solution of 18.9 g (225 mmol) of 3,4-dihydro-2*H*-pyrane and 75 µl for concentrated sulfuric acid in benzene (75 ml) 8.85 g (75 mmol) of methylmalonic acid was added in portions with cooling to < 30 °C. After stirring for 30 min potassium hydroxide (6.0 g) was added and stirring was continued for 30 min. The solution was decanted from inorganic material and concentrated to 30 ml *in vacuo* (bath temperature < 30 °C). This solution was dropwise added to a stirred suspension of sodium hydride (*ca.* 75 mmol, prepared from 3.6 g of a 50 % dispersion of sodium hydride in oil) in benzene (75 ml) with cooling to < 30 °C. To the clear solution 10.9 g (67.5 mmol) of compound (II) dissolved in benzene (40 ml) was slowly added. After stirring for 2 h acetic acid (7.5 ml) was added and the solution was refluxed for 45 min. Upon addition of ether (150 ml) the mixture was extracted with water (200 ml). The organic phase was dried and concentrated *in vacuo* to give 30 g of a yellow oil, which was subjected to column chromatography (silica gel: 570 g; eluent: methylene chloride). Sublimation of the product at 0.2 mmHg (bath temperature 50 °C) yielded 6.4 g (61 %) of (IVb) as pale yellow crystals. An analytical sample was recrystallized (ethanol-water) to give (IVb) as colourless crystals, m.p. 64.5−65.5 °C. (Found: C 54.30; H 5.91; N 9.05. Calc. for $C_7H_9NO_3$: C 54.19; H 5.85; N 9.03). ^{1}H NMR data (CCl_4): δ 6.30 (s, 1 H, C=C*H*−C); 3.91 (s, 3 H, CH_3-O); 2.85 [q (J=7 cps), 2 H, CH_3-CH_2-CO]; 1.17 [t (J=7 cps), 3 H, CH_3-CH_2].

3-Methoxy-5-(1-hydroxyiminopropyl)isoxazole (Vb). (Vb) was synthesized as described above for (Va) using 4.65 g (30 mmol) of (IVb), 4.5 g (33 mmol) of sodium acetate trihydrate, and 2.41 g (33 mmol) of hydroxylammonium chloride as starting materials. (Vb) (5.2 g; 97 %) was isolated as colourless crystals. An analytical sample was recrystallized (water-ethanol) to give (Vb) as colourless crystals. The product was by thin layer chromatography shown to consist of two compounds with R_F=0.47 and R_F=0.33 [eluent: methylene chloride-ethyl acetate (9:1)]. (Found: C 49.65; H 6.02; N 16.57. Calc. for $C_7H_{10}N_2O_3$: C 49.40; H 5.92; N 16.46). ^{1}H NMR data of (Vb) ($CDCl_3$) which are consistent with a mixture (*ca.* 1:2) of the isomeric oximes: δ 9.2−8.8 (broad s, 1 H, N−O*H*); 6.77 and 6.05 (two s, 0.3 H and 0.6 H, respectively, C=C*H*−C); 3.96 (two coincident s, 3 H, CH_3-O); 2.9−2.4 (m, 2 H, CH_3-CH_2-C); 1.4−0.9 (m, 3 H, CH_3-CH_2).

3-Methoxy-5-(1-aminopropyl)isoxazole (VIb). (VIb) was synthesized as described above for (VIa) using 3.6 g (21 mmol) of compound (Vb) and aluminium amalgam prepared from 6.86 g (254 mmol) of aluminium. The filtered reaction mixture was concentrated *in vacuo* to *ca.* 10 ml. Upon addition of concentrated hydrochloric acid (3 ml) the mixture was extracted with ether (10 ml). Upon addition of an aqueous solution of potassium hydroxide (3 ml; 10 M) the aqueous phase was extracted with two 5 ml portions of ether, which were combined, dried, and concentrated *in vacuo*. The residue was distilled to give 1.85 g (56 %) of compound (VIb) as a colourless oil, b.p. 120−124 °C/17 mmHg. (Found: C 54.10; H 7.91; N 17.89. Calc. for $C_7H_{12}N_2O_2$: C 53.83; H 7.74; N 17.94). ^{1}H NMR data (CCl_4): δ 5.53 (s, 1 H, C=C*H*−C); 4.0−3.5 (partially overlapped t, $CH_2-CH-NH_2$), 3.83 (s, CH_3-O), total 4 H; 1.9−1.3 (m, 2 H, CH_3-CH_2-CH); 1.36 (s, 2 H, NH_2); 0.90 (t, 3 H, CH_3-CH_2).

3-Hydroxy-5-(1-aminopropyl)isoxazole zwitterion (VIIIb). A solution of 416 mg (2.64 mmol) of compound (VIb) in glacial acetic acid (6 ml) containing 43 % hydrogen bromide was refluxed for a total of 10 min. After reflux for 5 min an additional amount of 6 ml of glacial acetic acid containing hydrogen bromide was added. The solution was concentrated *in vacuo* to give an oily residue, which was dissolved in water (10 ml). The solution was treated with activated charcoal and passed through a

column containing ion exchange resin [Amberlite IRA 400, (OH), 14 ml) using acetic acid (1 M) as an eluent. The fractions containing (VIIIb) were treated with activated charcoal and concentrated *in vacuo* to give 478 mg of an oily product. Crystallization from ethanol-methanol (1:1) afforded 96 mg (26 %) of (VIIIb) as colourless crystals, m.p. 167-168 °C (decomp.). (Found: C 50.60; H 7.17; N 19.66. Calc. for $C_6H_{10}N_2O_2$: C 50.69; H 7.09; N 19.71). ^{1}H NMR data [D_2O (sodium 3-(trimethylsilyl)propanesulfonate was used as an internal standard)]: δ 5.77 (s, 1 H, C=C*H*−C); 4.77 (s, 3 H, DO*H*); 4.30 [t (J=8 cps), 1 H, CH_2−C*H*−NH_3^+]; 2.1−1.7 (m, 2 H, CH_3−CH_2−CH); 0.95 (t, 3 H, CH_3−CH_2).

3-Methoxy-5-butyrylisoxazole (IVc). (IVc) was synthesized as described above for compound (IVb). As starting materials were used 6.6 g (50 mmol) of ethylmalonic acid, 12.6 g (150 mmol) of 3,4-dihydro-2*H*-pyrane, sodium hydride (*ca.* 50 mmol), and 7.3 g (45 mmol) of compound (II). The resulting mixture was subjected to column chromatography (silica gel: 400 g; eluent: methylene chloride to which increasing amounts of ethyl acetate were added). Distillation of the product gave 4.75 g (63 %) of (IVc) as a slightly coloured oil, b.p. 132−137 °C/8 mmHg. (Found: C 56.95; H 6.67; N 8.25. Calc. for $C_8H_{11}NO_3$: C 56.79; H 6.55; N 8.28). ^{1}H NMR data (CCl_4): δ 6.43 (s, 1 H, C=C*H*−C); 4.03 (s, 3 H, CH_3−O); 2.88 (t, 2 H, CH_2−CH_2−CO); 2.1−1.4 (m, 2 H, CH_3−CH_2−CH_2); 1.02 (t, 3 H, CH_3−CH_2).

3-Methoxy-5-(1-hydroxyiminobutyl)isoxazole (Vc). (Vc) was synthesized as described above for (Va) using 1.54 g (22 mmol) of hydroxylammonium chloride, 3.00 g (22 mmol) of sodium acetate trihydrate, and 3.38 g (20 mmol) of compound (IVc) as starting materials. (Vc) (3.5 g; 95 %) was isolated as colourless crystals. The product was by thin layer chromatography shown to consist of two compounds with R_F=0.65 and R_F=0.55 [eluent: methylene chloride-ethyl acetate (4:1)]. ^{1}H NMR data of (Vc) ($CDCl_3$), which are consistent with a mixture (*ca.* 4:7) of the isomeric oximes: δ 9.3−8.6 (broad s, 1 H, N−O*H*); 6.80 and 6.06 (two s, 0.4 H and 0.7 H, respectively, C=C*H*−C); 3.97 (two coincident s, 3 H, CH_3−O); 2.8−2.4 (m, 2 H, CH_2−CH_2−C); 1.9−1.2 (m, 2 H, CH_3−CH_2−CH_2); 0.98 (t, 3 H, CH_3−CH_2).

3-Methoxy-5-(1-aminobutyl)isoxazole (VIc). (VIc) was synthesized as described above for compound (VIb). As starting materials were used 2.7 g (15 mmol) of (Vc), and aluminium amalgam from 4.75 g (176 mmol) of aluminium. (VIc) (1.6 g; 64 %) was obtained as a colourless oil, b.p. 87−89 °C/0.5 mmHg. (Found: C 56.70; H 8.25; N 16.62. Calc. for $C_8H_{14}N_2O_2$: C 56.45; H 8.29; N 16.46). ^{1}H NMR data (CCl_4): δ 5.58 (s, 1 H, C=C*H*−C); 3.9−3.6 (partially overlapped t, CH_2−C*H*−NH_2), 3.86 (s, CH_3−O), total 4 H; 1.9−0.7 (m, 7 H, CH_3−CH_2−CH_2−CH); 1.40 (s, 2 H, NH_2).

3-Hydroxy-5-(1-aminobutyl)isoxazole zwitterion (VIIIc). (VIIIc) was synthesized as described above for compound (VIIIb) using 1.02 g (6.0 mmol) of (VIc). Crystallization from methanol gave 262 mg (28 %) of (VIIIc) as colourless crystals, m.p. 172.5−173 °C (decomp.). (Found: C 53.90; H 7.65; N 18.04. Calc. for $C_7H_{12}N_2O_2$: C 53.83; H 7.74; N 17.94). ^{1}H NMR data [D_2O (sodium 3-(trimethylsilyl)-propanesulfonate was used as an internal standard)]: δ 5.75 (s, 1 H, C=C*H*−C); 4.75 (s, 6 H, DO*H*); 4.35 (t, 1 H, CH_2−C*H*−NH_3^+); 2.1−1.6 (m, 2 H, CH_2−CH_2−CH); 1.6−1.1 (m, 2 H, CH_3−CH_2−CH_2); 1.1−0.7 (m, 3 H, CH_3−CH_2).

The Role of Cyclic Adenosine 3′,5′-Monophosphate in the Synthesis of the Enzymes of γ-Aminobutyrate Breakdown in *Escherichia coli* K-12

HEIKKI ROSENQVIST,* VESA TOIVONEN and VEIKKO NURMIKKO

Department of Biochemistry, University of Turku, SF-20500 Turku 50, Finland

When *Escherichia coli* K-12 (W 3001) is grown on glucose the synthesis of the enzymes of the pathway of γ-aminobutyrate breakdown is repressed. The specific activity of the NADP-specific succinate semialdehyde dehydrogenase is greater than that of the NAD-specific enzyme.

The synthesis of the enzymes of γ-aminobutyrate breakdown is induced when *E. coli* K-12 is grown on γ-aminobutyrate. In this case, however, the NAD-specific succinate semialdehyde dehydrogenase has more activity than the NADP-specific enzyme. This may indicate the existence of two different enzymes.

When *E. coli* K-12 is grown on γ-aminobutyrate, each of glucose, 2-oxoglutarate, glutamate, and succinate repress both γ-aminobutyrate oxoglutarate transaminase and succinate semialdehyde dehydrogenase. Cyclic AMP does not prevent the repression caused by glucose, which does not therefore operate simply by depletion of endogenous cyclic AMP.

In 1968, cyclic adenosine 3′,5′-monophosphate (cyclic AMP) was found to prevent glucose induced "catabolite repression" [1] of β-galactosidase in *E. coli*.[2,3] The ability of cyclic AMP to prevent the glucose repression of enzyme synthesis is not restricted to β-galactosidase. Cyclic AMP has now been shown to stimulate the synthesis of many enzymes in various bacteria.[3,4,5] It is supposed that catabolite repression is a consequence of the depletion of intracellular cyclic AMP by glucose.[6–11]

The activities of the enzymes of γ-aminobutyrate breakdown are low when *E. coli* is grown on glucose; the enzymes are repressed by glucose.[12–15] However, Dover and Halpern [13] have shown for *E. coli* K-12 that these enzymes specifically can escape from this catabolite repression when γ-aminobutyrate, glutamate, or aspartate are used as nitrogen source instead of ammonium salts.

In this work the effect of exogenous cyclic AMP on the repression by glucose of the enzymes of γ-aminobutyrate breakdown in *E. coli* K-12 (W 3001) was studied.

MATERIAL AND METHODS

Cultivation of E. coli. A wild strain of *E. coli* K-12 (*E. coli* K-12, W 3001) was transferred with a platinum wire from an agar slant to an inoculum medium (10 ml) containing 1 % Difco yeast extract. 1 % Difco tryptone, and 0.5 % dipotassium monohydrogen phosphate, that had been autoclaved at 115 °C for 7 min. After 4 h incubation at 37 °C, the whole medium was poured aseptically into 250 ml of sterilized inoculum medium. After 16 h incubation at 37 °C without shaking, the cells were centrifuged (4 000 *g*, 10 min) at room temperature, washed twice with cold 0.9 % sodium chloride and suspended in a minimal medium containing 0.1 % ammonium chloride, 0.7 % disodium hydrogen phosphate, 0.3 % potassium dihydrogen phosphate, 0.5 % sodium chloride, 0.01 % magnesium sulfate heptahydrate, and 0.2 % D(+)-glucose. The suspension was shaken (250 rpm) in a rotatory shaker (New Brunswick G-10) at 37 °C, and the turbidity was measured with a Klett-Summerson colorimeter using filter No. 62 (590 – 660 nm). When the turbidity of the culture was about 150 colorimeter scale units, the washing and centrifugation were performed as described above. The cells were suspended in a minimal medium together with ammonium chloride as the nitrogen source and

* Present address: Metsäliiton Teollisuus Oy, SF-44100 Äänekoski, Finland.

γ-aminobutyrate as the only carbon source. Additions to the culture (divided into three) were made as indicated on the figure legends. Cultivation and washing were performed as described above. The cells for the enzyme assays were harvested by centrifugation (5 ml, 7 000 *g*, 5 min) and washed twice with 0.9 % sodium chloride (+10 °C). The cell pellets were stored at 3 °C until subjected to ultrasonic vibration.

Ultrasonication. The samples were suspended in 2 ml of 20 mM sodium phosphate buffer (pH 7.0) containing 0.1 % (v/v) 2-mercaptoethanol, and ultrasonicated (MSE Ultrasonic Disintegrator, 60 W) for 6 min (2 microns peak to peak) at 0 °C. The suspensions were then centrifuged at 7 000 *g* for 10 min.

Enzyme and protein assays. γ-Aminobutyrate oxoglutarate transaminase and succinate semialdehyde dehydrogenase were measured by the methods described before.[16]

β-Galactosidase was determined by the method published earlier,[17] except that the cells were disrupted by ultrasonication and not by toluene treatment. The two methods were compared and shown to give similar results.

The protein contents of the extracts were estimated by the Folin-Ciocalteau method.[18]

Table 1. The specific activities of the enzymes of the pathway of γ-aminobutyrate breakdown [(μmol NADH or NADPH formed) min^{-1} (mg protein) $^{-1}$]. in *E. coli* K-12 (W 3001) cells grown on glucose and γ-aminobutyrate. The cells for the assays were harvested in the middle of the exponential growth phase.

Enzyme	Carbon source: Glucose	Carbon source: γ-Aminobutyrate
γ-Aminobutyrate oxoglutarate transaminase (NADPH)	0.009	0.789
Succinate semialdehyde dehydrogenase (NADPH)	0.025	0.250
Succinate semialdehyde dehydrogenase (NADH)	0.003	0.602

RESULTS AND DISCUSSION

When *E. coli* K-12 (W 3001) is grown on glucose the specific activities of the enzymes of γ-aminobutyrate breakdown are low (Table 1). The NADP-specific succinate semialdehyde dehydrogenase is clearly much more active than the NAD-specific enzyme. On the other hand, when γ-aminobutyrate acts as carbon source, the activities of both these enzymes and that of γ-aminobutyrate oxoglutarate transaminase are high. It appears that the synthesis of these three enzymes is induced. In this cultivation, however, the specific

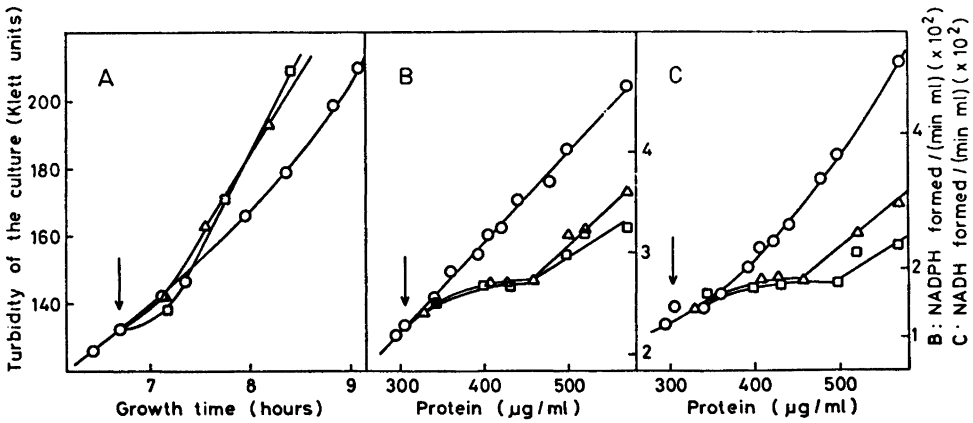

Fig. 1. Effect of glucose and cyclic AMP on the synthesis of γ-aminobutyrate oxoglutarate transaminase (B) and NAD-specific succinate semialdehyde dehydrogenase (C). The activities are expressed in (μmol NAD(P)H formed) ml^{-1} min^{-1}. *E. coli* K-12 (W 3001) culture growing on γ-aminobutyrate (0.25 %, ○) was divided into three. The following additions were made at the arrow: none (○); glucose (10 mM, △); and glucose (10 mM) plus cyclic AMP (5 mM) (□). In A, growth curves are marked by corresponding symbols.

activity of the NAD-specific succinate semialdehyde dehydrogenase is higher than that of the NADP-specific enzyme.

As mentioned above, several examples of catabolite repression caused by glucose are prevented by cyclic AMP. In the classic case of β-galactosidase,[2] glucose represses the synthesis of induced β-galactosidase, whereas exogenous cyclic AMP eliminates this repression. It is of interest whether a similar situation exists for the control of γ-aminobutyrate oxoglutarate transaminase and succinate semialdehyde dehydrogenase. Glucose causes the repression of these enzymes in *E. coli* K-12 (W 3001) grown on γ-aminobutyrate (Fig. 1). Cyclic AMP added together with glucose might prevent the repression if it were caused by depletion of endogenous cyclic AMP. When cyclic AMP is added with glucose, however, the differential rates of synthesis of the enzymes of γ-aminobutyrate breakdown, do not exceed the repressed values. Accordingly, the repression is not similar to the repression of β-galactosidase: it is unaffected by exogenous cyclic AMP, although exogenous cyclic AMP does prevent the repression by glucose of β-galactosidase in *E. coli* K-12 W 3001 grown on γ-aminobutyrate (Fig 2). As shown in Fig. 3, 2-oxoglutarate, glutamate, and succinate each repress γ-aminobutyrate oxoglutarate transaminase and succinate semialdehyde dehydrogenase.

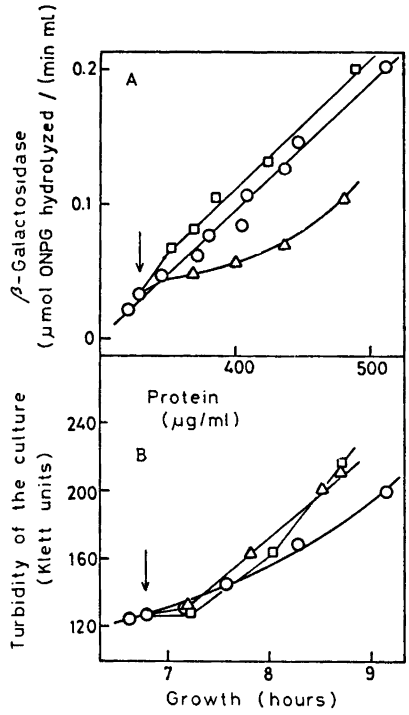

Fig. 2. Effect of glucose and cyclic AMP on the differential rate of β-galactosidase synthesis (A) in the culture growing on γ-aminobutyrate as the only carbon source (0.25 %, O) and corresponding growth curves (B). To induce β-galactosidase isopropyl-β-D-thiogalactoside (IPIG) (1.25 mM) was added to the growth medium 15 min before the arrow. At the arrow the culture was divided into three and the following additions were made: none (O); glucose (10 mM, △); and glucose (10 mM) plus cyclic AMP (5 mM) (□). In B, growth curves are marked by corresponding symbols.

The metabolism of γ-aminobutyrate is associated with nitrogen metabolism *via* the transamination of 2-oxoglutarate, and also provides succinate, whose role in the citric acid cycle is both energetic and biosynthetic. The control of this metabolism is therefore likely to be complex. We have shown here that repression of γ-aminobutyrate-oxoglutarate transminase and succinate semialdehyde dehydrogenase is caused by glucose and several Krebs cycle intermediates. It is particularly interesting that the repression by glucose appears not to be mediated merely by lowering the level of endogenous cyclic AMP. Dover and Halpern have previously shown that glucose repression of these enzymes is unusual in that the enzymes can escape from this control when γ-aminobutyrate is the sole nitrogen source.[18]

It has long been known that some enzymes of the citric acid cycle in bacteria are repressed when the culture is grown on glucose. It has also been reported that glutamate is an efficient corepressor.[19-20] In this case catabolite repression requires some other metabolite. This could explain why the enzymes of the citric acid cycle, like the enzymes of γ-aminobutyrate breakdown are not found to be under the control of cyclic AMP. Glutamate, however, is not necessarily the metabolite responsible for control of the enzymes in the metabolism of γ-aminobutyrates, although it is the dominant free amino acid in *E. coli*.[22]

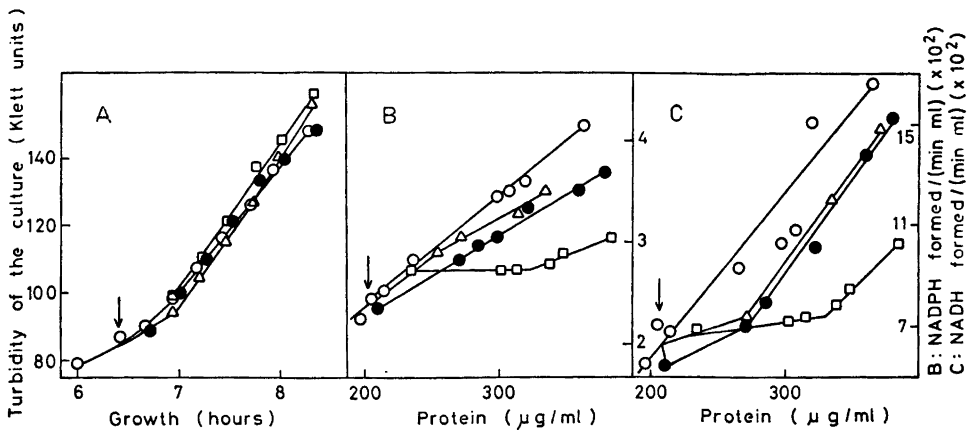

Fig. 3. Differential rate of synthesis of γ-aminobutyrate oxoglutarate transaminase (B) and NAD-specific succinate semialdehyde dehydrogenase (C). The activities are expressed in [μmol NAD(P)H formed] ml^{-1} min^{-1}. The growth curves are presented in A. *E. coli* K-12 (W-3001) culture growing on γ-aminobutyrate (0.25 %, ○) was divided into four. The following additions were made at the arrow: none (○); 2-oxoglutarate (10 mM, △); glutamate (10 mM, □); and succinate (10 mM, ○).

Reactions of Nitrobenzyl Alcohol under Acidic Conditions. Possibilities of Intramolecular Nucleophilic Participation by the Nitro Group

JAN BAKKE

Chemistry Department, College of Arts and Science, The University of Trondheim, N-7000 Trondheim, Norway

o-Nitrobenzyl alcohol was refluxed in toluene under acidic conditions. Three products were obtained: di-(*o*-nitrobenzyl) azoxybenzene-*o*,*o*'-dicarboxylate (*2*), 6*H*,12*H*-indazolo[2,1-*a*]indazole-6,12-dione (*3*), and benzidine-*m*,*m*'-dicarboxylic acid (*5*). *p*-Nitrobenzyl alcohol scarcely reacted under these reaction conditions. Possible reaction paths are discussed.

The study of the reactions of *ortho*-substituted nitrobenzene derivatives has revealed interesting interactions between the nitro group and the *ortho*-substituent.[1] These interactions often result in a reduction of the nitro group and an oxidation of the *ortho*-substituent.

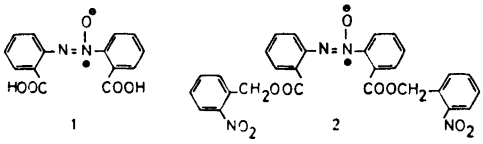
We have earlier studied the reactions between the nitro and methyl group in *o*-nitrotoluene under a variety of conditions,[2,3] and also the photochemical interaction between the nitro and hydroxyl group in 2-(*o*-nitrophenyl)ethanol.[4]

In continuation of our work on nitro group chemistry, some reactions of *o*-nitrobenzyl alcohol have been studied. Reactions under acidic conditions were believed to be particularly interesting. In the presence of strong acid, protonation of the hydroxyl group could be expected. However, the leaving of the water molecule would probably be assisted by the *o*-nitro group, thus providing interesting opportunities for reactions between the nitro group and the benzylic carbon atom.

The assistance by the nitro group was anticipated from the work of Noyce, Hartter and Miles [5] on acidic dehydration of 1,2-diarylethanols. They showed the reaction of 1-(*p*-nitrophenyl)-2-phenylethanol to be very slow, and indicated that this compound existed in solution as the protonated species. Further, the work of Spence and Tennant [6] and Sword [7] indicated that an *o*-nitro group assisted the ring opening of protonated epoxides.

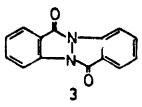
o-Nitrobenzyl alcohol was accordingly treated with *p*-toluenesulfonic acid in refluxing toluene. After a few hours, the *o*-nitrobenzyl alcohol was consumed and three main products were obtained. Two of these were neutral and the third was slightly acidic. The structures of these substances were elucidated, mainly by spectroscopic methods.

One of the neutral compounds had an IR spectrum indicating ester groups (1725 and 1740 cm^{-1} together with a band at 1260 cm^{-1}) and nitro groups (1525 and 1340 cm^{-1}) to be present, but no NH or OH groups. The NMR spectrum suggested the compound to contain benzylic protons. The mass spectrum indicated an elemental formula of $C_{28}H_{24}N_4O_9$. The high molecular weight, the two ester carbonyls, and the benzylic protons would be explained by a dicarboxylic acid esterified with *o*-nitrobenzyl alcohol. The elemental formula of such an acid would be $(C_{12}H_8N_2O)(COOH)_2$. One possible structure would be azoxybenzene-*o*,*o*'-dicarboxylic acid (*1*). Saponification of the isolated compound gave an dicarboxylic acid identical to *1*, [10] together with *o*-nitrobenzyl alcohol as the neutral product. The structure of the isolated compound was thus the di-*o*-nitrobenzyl ester of azoxybenzene-*o*,*o*'-dicarboxylic acid (*2*).



1 2

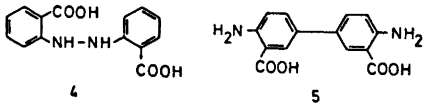
The other neutral compound gave an IR spectrum indicating carbonyl groups (1690 cm^{-1}) but no NH, OH, or NO_2 groups to be present in the molecule. The mass spectrum indicated an elemental formula of $C_{14}H_8N_2O_2$. The structure *3* (6*H*,12*H*-indazolo[2,1-*a*]indazole-6,12-dione) was in accordance with these data, and the isolated compound was identical to an authentic sample of *3*.[8]



3

The isolated acidic product was almost insoluble in neutral solvents, and gave a rather indistinct melting point. The IR spectrum suggested the product to contain primary amino groups together with carboxylic acid groups.

The structure of *2* showed the formation of a compound with a nitrogen-nitrogen bridge between the aromatic rings. One could thus imagine that compounds with more reduced nitrogen-nitrogen bridges could have been formed, for instance of the hydrazobenzene type. Under the acidic reaction conditions, a hydrazobenzene would probably undergo a benzidine rearrangement to give products with primary amino groups. From these considerations and from the IR spectrum, a possible structure for the acidic product would be benzidine-*m*,*m*′-dicarboxylic acid (*5*). Reaction of hydrazobenzene-*o*,*o*′-dicarboxylic acid (*4*) with *p*-toluenesulfonic acid gave a product identical to the one isolated from *o*-nitrobenzyl alcohol. This path of formation, the IR spectrum and m.p. properties [9] identified the compound as *5*, and also indicated that *4* was the primary product in the reaction of *o*-nitrobenzyl alcohol.

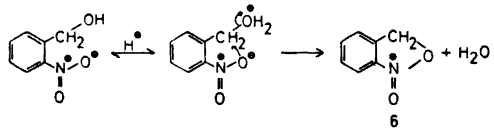


4 5

The structures of the isolated compounds (*2*, *3*, *5*) from the reaction of *o*-nitrobenzyl alcohol show a variety of reductions and oxidations to have taken place. From the products, it is obvious that intermolecular reactions have taken place, as neither *2*, *3* nor *5* are at the same oxidation stage as *o*-nitrobenzyl alcohol.

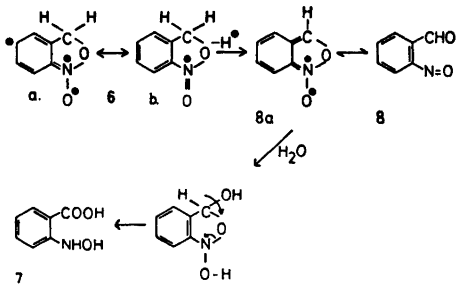
However, the reactions have probably not taken place solely by intermolecular processes, as *p*-nitrobenzyl alcohol was shown to react only with difficulty under the conditions used in the reaction of *o*-nitrobenzyl alcohol. The initial reaction of *o*-nitrobenzyl alcohol is therefore probably of intramolecular nature.

An intramolecular reaction might have started with a protonation of the hydroxyl group, followed by internal substitution reaction to give the cyclic intermediate *6*. Similar



6

intermediates have been postulated both in the ring opening of *o*-nitrophenylethylene oxides,[6,7] in the reactions of *o*-nitrobenzhydrol,[11] and in the solvolysis of *o*-nitrobenzhydryl bromide.[12] The intermediate *6* may then undergo internal electron shifts, for instance by the reactions postulated in Scheme 1, to produce *o*-hydroxylaminobenzoic acid (*7*) and *o*-nitrosobenzaldehyde (*8*) or the cyclic form *8a*. Compounds *7*



Scheme 1.

and *8* would probably be rather unstable under the reaction conditions, both towards oxidations and reductions, and towards condensation reactions. From the resonance formula *a* of

compound *6*, a nucleophilic attack on the aromatic ring seemed possible. Such attacks have indeed been observed with analogous structures when nucleophiles like chloride ions have been present in the reaction.[6,7,11,12] In the present reaction, with *p*-tosylate ions as the predominant nucleophile, such attack was neither expected nor found.

It should also be noticed that bimolecular formulas analogous to *6* can be written, and that the reaction of *o*-nitrobenzyl alcohol is not proven to be intramolecular.

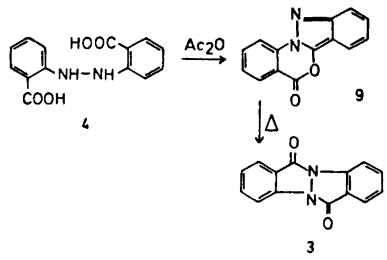
By further oxidation-reductions of compounds *7* and *8*, molecules with different combinations of oxidized benzylic carbon and reduced nitrogen atoms would be obtained, and by condensations of these molecules compounds *2*, *3*, and *5* could arise.

Benzidine-*m*,*m*′-dicarboxylic acid (*5*) is believed to originate from hydrazobenzene-*o*,*o*′-dicarboxylic acid (*4*). Both compounds *2* and *4* have been produced by condensation reactions between two nitrogen atoms. Azoxy- and hydrazobenzenes are interconvertible by various reduction and oxidation reactions.[13] If such interconversions have been important in their formation in the present reactions, or if they have been partly or solely formed by condensation reactions is not known at present.

Condensation products from the reduction of nitro compounds are usually formed under basic and not under acidic conditions.[13] However, the non-polar solvent used in the present reaction may explain the observed condensation reactions. In toluene, the protonation of the amines and hydroxylamines formed would be slow as compared to the reaction in more polar (*e.g.* aqueous) solvents, and the amines and hydroxylamines would therefore be more accessible to condensation reactions.

Of the two dicarboxylic acids formed by the reaction (*1*,*5*), only azoxybenzene-*o*,*o*′-dicarboxylic acid (*1*) was esterified by *o*-nitrobenzyl alcohol. Benzidine-*m*,*m*′-dicarboxylic acid (*5*) is hardly soluble in toluene and was therefore probably removed from the reaction before esterification could take place.

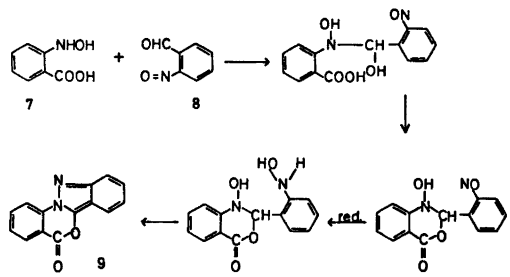
Several formation paths for compound *3* may be envisaged. Formally, the substance could be formed by condensation of *o*-hydroxylaminobenzoic acid (*7*) with *o*-aminobenzoic acid. However, not suprisingly, an experiment showed *o*-aminobenzoic acid to be precipitated as the *p*-toluenesulfonate under the reaction conditions, and substances *2* and *3* to be formed in the same ratio as when *o*-aminobenzoic acid was not added to the reaction. Compound *3* has earlier been made by heating of hydrazobenzene-*o*,*o*′-dicarboxylic acid (*4*) in acetic anhydride, followed by heating of the initially formed lactone (*9*).[8,14]



Under the present reaction conditions, hydrazobenzene-*o*,*o*′-dicarboxylic acid (*4*) gave benzidine-*m*,*m*′-dicarboxylic acid (*5*) as the major reaction product, with only traces of a substance which could have been *3*. The major part of *3* is therefore not formed from *4*.

However, lactone *9* was transformed to compound *3* when refluxed with *p*-toluenesulfonic acid in toluene, and the IR spectrum of a reaction mixture from *o*-nitrobenzyl alcohol indicated traces of lactone *9* to be present. The results thus indicate that compound *3* may have been formed from lactone *9*, but that hydrazobenzene *o*,*o*′-dicarboxylic acid (*4*) was not a precursor for *9*.

One possibility for the formation of *9* would be the reaction between one molecule of *o*-hydroxylaminobenzoic acid (*7*) and one of *o*-nitrosobenzaldehyde (*8*) (or the cyclic form *8*a).



Further investigations are necessary to determine the exact path of formation of the products *2*, *3* and *5*. Two points seem nevertheless to be clear from the present investigation. First, as *p*-nitrobenzyl alcohol reacted only slightly under the applied conditions, the *ortho* position of the nitro and hydroxymethyl groups is necessary for the reaction. Second, intermolecular reactions take place as the products are at different oxidation stages from *o*-nitrobenzyl alcohol.

One hypothesis fitting these two points is the one presented above: The reaction starts as an intramolecular reaction resulting in products with oxidized carbon atom and reduced nitrogen atom. Further intermolecular red-ox and condensation reactions then give the isolated products.

EXPERIMENTAL

The IR spectra were recorded on a Perkin-Elmer infrared spectrophotometer, Model 457. NMR spectra were recorded on a Varian A 60 spectrometer with TMS as in internal standard. The chemical shifts are given in δ-units. Mass spectra were recorded on an A.E.I. M.S. 902 mass spectrometer. The elemental formulas were obtained by peak matchings which gave *m/e* within ± 0.0006 mass units from the calculated values. Melting points are uncorrected.

Reaction of o-nitrobenzyl alcohol with p-toluenesulfonic acid. *p*-Toluenesulfonic acid (0.6 g) and toluene (*p.a.*) (35 ml) were refluxed with a water separator at the condenser. A toluene/water mixture (5 ml) was separated. *o*-Nitrobenzyl alcohol (0.3 g) was added to the solution and the mixture refluxed for 5 h. TLC indicated *o*-nitrobenzyl alcohol to diminish and two new compounds with $R_F > R_F$-nitrobenzyl alcohol and one with $R_F = 0$ (eluted with 10 % ether/chloroform) to be formed. After 5 h all of the nitrobenzyl alcohol had reacted. The mixture was left at 25 °C overnight and then filtered. The toluene solution contained 0.2 g which TLC indicated to consist of the two compounds with $R_F > R_F$-nitrobenzyl alcohol. Compound *3* (15 mg) crystallized from a chloroform solution of this mixture.

Attempts to separate the two compounds by dry column chromatography on silica gel or alumina were unsuccessful, and compound *2* was finally obtained pure by crystallization from chloroform/light petroleum. The 200 mg obtained from the toluene solution was estimated by TLC chromatography to contain *ca.* 150 mg of di-(*o*-nitrobenzyl)*o,o'*-azoxybenzene dicarboxylate (*2*) and *ca.* 50 mg of 6*H*,12*H*-indazolo[2,1-*a*]indazole-6,12-dione (*3*). More accurate estimations have not yet been possible.

Di-(*o*-nitrobenzyl)*o,o'*-azoxybenzenedicarboxylate (*2*) had m.p. 177 – 178 °C, IR (KBr): 1740, 1725, 1525, 1480, 1340, 1260, 1140, 1090, 1080, 865, 795, 770, 760, 740, 730, 720 cm^{-1}. NMR ($CDCl_3$): 16 protons with signals 7.15 – 8.20 (complex), 4 protons at 5.7 (singlet). Mass spectrum; *m/e* 556.1233 (2 %, $C_{28}H_{20}N_4O_9$), 540.1278 (2 %, $C_{28}H_{20}N_4O_8$), 420.0833 (2 %, $C_{21}H_{14}N_3O_7$), 404.0877 (2 %, $C_{21}H_{14}N_3O_6$), 376.0931 (50 %, $C_{20}H_{14}N_3O_5$), 136 (55 %), 78 (100 %).

Compound *3* had m.p. 296 – 297 °C (lit.[8] 300 – 300.8 °C), IR (KBr): 1690, 1620, 1480, 1470, 1365, 1320, 1210, 1150, 1130, 755, 670 cm^{-1}. Mass spectrum, *m/e* 236.0587 (100 %, $C_{14}H_8N_2O_2$), 208.0635 (21 %, $C_{13}H_8N_2O$, loss of CO from *m/e* 236 verified by *m** 183.32), 179.0612 (9 %, $C_{12}H_7N_2$), 118.0295 (11 %, C_7H_4NO).

In a new experiment, *o*-nitrobenzyl alcohol (8 g) and *p*-toluenesulfonic acid (16 g) in toluene (800 ml) were refluxed for 5 h. Substances *2* and *3* were obtained by crystallization of the toluene dissolved material (8.6 g).

The black material not dissolved in toluene was washed with water to remove *p*-toluenesulfonic acid. The undissolved material (1.3 g) had IR almost identical to benzidine-*m,m*-dicarboxylic acid (see below) and m.p. at 265 °C when the m.p. tube was put into the preheated (250 °C) m.p. apparatus. 1.1 g of the solid was dissolved on extraction with ethanol (2×100 ml) and 0.13 g of black powder remained. The undissolved black powder had an undistinguished IR and gave no indications of melting below 320 °C. This material is believed to be a polymer. The substance dissolved in ethanol (1.1 g) was refluxed with chloroform (25 ml), 0.25 g of it was dissolved. The undissolved material (0.8 g, 11 %) had IR and m.p. behaviour identical with benzidine-*m,m'*-dicarboxylic acid (see below). The chloroform-dissolved material consisted of at least seven compounds as judged by TLC. Two of these were compounds *2* and *3*, and one may have been azobenzene carboxylic acid. The chloroform fraction was not investigated further.

Saponification of di-(o-nitrobenzyl) o,o'*-azoxybenzenedicarboxylate (2).* *2* (50 mg) from the reaction of *o*-nitrobenzyl alcohol was dispersed in ethanol (10 ml) and sodium hydroxide (1 M, 1 ml) added. After stirring overnight at 25 °C, the reaction was complete. The neutral product (15 mg) was identical with *o*-nitrobenzyl alcohol and the acidic product (15 mg) with *o,o'*-azoxybenzenedicarboxylic acid m.p. 250 °C (decomp.) and IR (KBr): 3500 – 2000, 1690, 1610, 1490, 1420, 1310, 1290, 1280, 1090, 940, 800, 770, 755, 660, cm^{-1}. Mass spectrum *m/e*: 286.0584 (1 %, $C_{14}H_{10}N_2O_5$), 270.0636 (2 %, $C_{14}H_{10}N_2O_4$), 241.0616 (100 %, $C_{13}H_9N_2O_3$), 197.0709 (13 %, $C_{12}H_9N_2O$), 165 (13 %), 159 (13 %), 121 (68 %), 115 (29 %), 93 (58 %), 77 (32 %), 65 (65 %).

Reaction of o-nitrobenzyl alcohol in the presence of o-aminobenzoic acid. o-Nitrobenzyl alcohol (0.3 g), o-aminobenzoic acid (0.3 g), and *p*-toluenesulfonic acid (0.6 g) were refluxed in toluene (30 ml) for 5 h. A precipitate formed at once, and TLC indicated the reaction to be slower than the one without o-aminobenzoic acid; the ratio between products *2* and *3* was the same as before.

Reaction of hydrazobenzene-o,o'-dicarboxylic acid (4). *4* (1 g) and *p*-toluenesulfonic acid (2 g) were refluxed in toluene (100 ml) for 3 h. The toluene phase contained 15 mg which TLC indicated to consist partly of compound *3*. The crystalline part of the reaction mixture was washed with water to remove *p*-toluenesulfonic acid, and the residue dried. This compound had IR (KBr): 3510, 3400, 3400 – 2700, 1680, 1630, 1590, 1560, 1240, 815, 690 cm^{-1} and m.p. 275 °C when the m.p. tube was put into a preheated (250 °C) m.p. apparatus.

The result from the reaction was the same when *4* (0.1 g) was dissolved in refluxing toluene (100 ml) and added to a refluxing solution of *p*-toluenesulfonic acid (100 mg) in toluene (100 ml) and then refluxed for 3½ h.

Reaction of p-nitrobenzyl alcohol with p-toluenesulfonic acid. *p*-Toluenesulfonic acid (2 g) in toluene (100 ml) was refluxed with a water separator at the condenser. A toluene/water mixture (5 ml) was removed, and *p*-nitrobenzyl alcohol (1 g) added. The mixture was refluxed for 5 h. TLC of the product indicated only a slight reaction with trace of one product with $R_F > R_F$-nitrobenzyl alcohol to have been formed.

Reaction of the lactone 9. *p*-Toluenesulfonic acid (140 mg) and *9* [8] (25 mg) were refluxed in toluene (7 ml) for 5 h. IR and TLC showed *9* to have been transformed almost completely to *3*.

Intramolecular Hydrogen Bonding in Aryl Substituted Aliphatic Alcohols

JAN M. BAKKE and GEIR B. LORENTZEN

Chemistry Department, College of Arts and Science, The University of Trondheim, N-7000 Trondheim, Norway

The internal hydrogen bonding in *ortho* substituted benzyl alcohols and in *ortho* and *para* substituted 1,2-diarylethanols (1-X-phenyl-2-Y-phenylethanol) (*1*) has been studied by IR spectroscopy and with chloro, methoxy, and nitro groups as substituents. The hydrogen bonds to these *ortho* groups in benzyl alcohols or in 1-(*o*-X-phenyl)-2-phenylethanols are non-existent or very weak, with the strongest bond to the nitro group. With the Y groups in *ortho* position in 1,2-diarylethanols (*1*), relatively strong hydrogen bonds to the *ortho* substituents (Y) are indicated. The results may be explained by steric relations in the molecule.

Intramolecular hydrogen bonding in *ortho* substituted phenols is well documented.[1,2] Many of these internal hydrogen bonds are particularly strong, *e.g.* in *o*-nitrophenol, and broad and strong absorptions are recorded in the OH region of the infrared spectra; a large frequency shift occurs as compared to the absorption found with nonbonded phenols.

In contrast to the *ortho* substituted phenols, no systematic study seems to have been carried out on *ortho* substituted benzylic alcohols or 2-arylethanols with the *ortho* substituent as hydrogen bond acceptor. Both these classes of substances have, however, been thoroughly studied from the point of view of internal hydrogen bonding to the π-bond system.[3–5]

It was thus considered of interest to study some *ortho* substituted benzyl alcohols and arylethanols where the *ortho* group might serve as hydrogen bond acceptor. The aim of the study was to see if the *ortho* substituents would serve as acceptors and whether there existed a preference in acceptor site for the hydrogen bond, *i.e.* if the π-bond system or the *ortho* substituent would dominate as acceptor site.

It was considered of particular interest to study the 1,2-diaryl substituted ethanols of type *1* where competition between four acceptor sites for the hydrogen bonds is possible (*i.e.* the conformers I – IV) in addition to conformer V which has the hydroxyl group non-bonded.

[a] Private communication from v. R. Schleyer, P. [b] This work.

The substituents used in the study of the alcohols of type *1* may be classified according to their electronic properties. Two of the substituents utilized, the nitro and methoxy groups, would be expected to have opposite electronic effects on the aryl rings, but to function as good hydrogen bond acceptors.[6,7] The chloro substituent would be expected to give rise to only weak hydrogen bonds and to have electronic properties intermediate between those of the nitro and methoxy group.[1,2]

By using these substituents it was hoped to obtain some information concerning the preferred conformer or conformers I – V, both as the acceptor sites and the electron density in the π-bond systems varied. The study was carried out by IR spectroscopy.

RESULTS

The IR absorptions in the OH-region (*i.e.* 3300 – 3700 cm^{-1}) of benzyl alcohols are given in Table 1 and those of 1,2-diarylethanols in Tables 2a – 2c.

All spectra were recorded in dilute CCl_4 solution with concentrations below 10^{-2} M and for compounds *1h*, *1i*, and *1k* below 10^{-4} M. Continued dilution did not change the ratio between the various absorption bands. These concentrations are so low that intermolecular hydrogen bonds are usually broken.[7]

Some of the bands given in Tables 1 and 2 were only partly resolved. In such cases the exact frequencies of the absorptions making up

Table 2. Hydroxyl stretching frequencies in 1,2-diarylethanols (*1*), in cm^{-1}. Absorbance (A) as log I_0/I.

Substance	X	Y	ν_1	ν_2	A_1/A_2

the registered band, and furthermore the absorbance (A) of each absorption, is uncertain [8] and must be used with caution. No "Curve Resolver" was available.

DISCUSSION

The IR absorption in the O–H stretching region of benzyl alcohol in dilute solution is usually interpreted as being contributed to by two conformers of the alcohol: one with a free hydroxyl group and one with a hydrogen bond to the π-bond system.[3-5] The spectrum (Table 1) shows the OH band of the hydrogen bonded conformer to be 20 cm^{-1} below that of the free conformer. This is a shift of the same magnitude as that between the two rotamers A and B of ethanol [8-9] (9 – 17 cm^{-1}) and it has been questioned if the band at 3615 cm^{-1} in benzyl alcohol is really due to a hydrogen bonded species.[10]

A B

From Table 1 it is evident that there are no strong internal hydrogen bonds in any of the studied benzyl alcohols. Of the three *ortho* substituted benzyl alcohols, *o*-methoxy-, *o*-nitro-, and *o*-chlorobenzyl alcohol; the methoxy and chloro compounds have ν_2 in the same position as in the corresponding *m*- or *p*-compounds. The *o*-nitrobenzyl alcohol has a rather strong band at 3600 cm^{-1}, 15 cm^{-1} lower than that of *m*-nitrobenzyl alcohol. From these frequencies, it seems probable that there is no or only a very weak hydrogen bond to the *ortho* substituents in *o*-methoxybenzyl alcohol and *o*-chlorobenzyl alcohol. For *o*-nitrobenzyl alcohol there appears to be a possibility of a hydrogen bond to the *o*-nitro group as judged from ν_2.

Judging from the spectral shifts of phenol or methanol in CCl_4 solutions containing nitrobenzene or anisole, the ether oxygen seems to give rise to stronger hydrogen bonds than the nitro group.[6] Further, a six membered ring would be formed by internal hydrogen bonding in *o*-methoxybenzyl alcohol and a seven membered ring in the *o*-nitrobenzyl alcohol. A six membered ring is usually favoured over a seven membered one both from enthalpy and entropy points of view. Both these circumstances would be expected to favour the formation of an internal hydrogen bond in *o*-methoxybenzyl alcohol as compared to *o*-nitrobenzyl alcohol.

There are, however, two other factors which would favour formation of the internal hydrogen bond in *o*-nitrobenzyl alcohol. One is the electron withdrawing property of the nitro group as opposed to the electron donating ability of the methoxy group. This would make the hydroxyl proton in *o*-nitrobenzyl alcohol more acidic than that in *o*-methoxybenzyl alcohol, and thus the nitrobenzyl alcohol a better hydrogen donor than the methoxybenzyl alcohol.

The other factor is of steric nature. The strength of some types of hydrogen bond is dependent on the angle O–H···O with maximum strength for an angle of 180°.[7] The angle O–H···O may be larger in the seven membered ring of *o*-nitrobenzyl alcohol than in the six membered one of *o*-methoxybenzyl alcohol, thus favouring the internal hydrogen bond in *o*-nitrobenzyl alcohol over the one in *o*-methoxybenzyl alcohol. These points will be further discussed in the following section on 1,2-diarylethanols.

The studied 1,2-diarylethanols (*1a – 1n*) can be divided into two groups, according to whether the *ortho* substituent is present in the 1-aryl or in the 2-aryl ring. The OH stretch absorptions of 1,2-diphenylethanol (*1a*) and of 1,2-di-*o*-substituted arylethanols (*i.e. 1e* and *1j*) are also reported in Table 2.

The substances with *o*-X-substituents (*i.e. 1b, f, h, l*) have IR absorption in the OH region (Table 2) similar to the corresponding *ortho* substituted benzyl alcohols (Table 1); *i.e.* *o*-methoxy-, *o*-nitro-, and *o*-chlorobenzyl alcohol, respectively. Some points are nevertheless worth of discussion.

No band at 3640 cm^{-1} could be detected for 1-(*o*-methoxy)-2-phenylethanol (*1b*), thus indicating a larger proportion of hydrogen bonded conformer than for *o*-methoxybenzyl alcohol. Replacing a hydrogen of *o*-methoxybenzyl alcohol with a benzyl group would slightly decrease the proton donor ability of the hydroxyl group. This electronic effect can therefore not be the reason for the decrease of the contribution of the free conformer.

In *1b* there is a possibility of hydrogen bonding to the 2-phenyl ring (*i.e.* IV) in addition to the 1-aryl ring (III). This may explain the apparent absence of the free conformer (V). However, the larger CH_2-Ph group placed on the hydroxyl bearing carbon may have severe consequences for the population of the various conformers, and may give increased importance to the one with hydrogen bonding to the 1-aryl ring (III) as compared to *o*-methoxybenzyl alcohol. This substitution at the hydroxyl bearing carbon may also result in a large portion of conformer I with a hydrogen bond to the *o*-methoxy group. The shoulder at 3590 cm^{-1} may be interpreted as a band of this species.

The result from the 2-aryl-1-(*o*-nitrophenyl)-ethanols (*1f*, *h*) have some bearing on these problems. 1-(*o*-Nitrophenyl)-2-phenylethanol (*1f*) has a relatively broad absorption centered at 3610 cm^{-1}, and no observable band at 3640 cm^{-1}. The IR absorption thus gives no indication of a free hydroxyl group (*i.e.* no V). The same possibilities exist for hydrogen bonding in *1f* as in *1b: i.e.*, to the aryl rings and to the *ortho* substituent. From the discussion above on the methoxy case and from the results from substances *1f* and *1h*, some indications of the preferred acceptor site of the hydrogen bond may be obtained. Both in *1f* and *1h* there may exist a hydrogen bond to the *o*-nitro group. However, the IR spectra (Table 2b) indicate that such bonds are not stronger and do not account for a larger proportion of the conformers than in *o*-nitrobenzyl alcohol. This type of hydrogen bond therefore seems not to be predominant in substances with *o*-X-substituents, at least not with $X=NO_2$. Further, the frequency of the main peak in *1f* is at 3610 cm^{-1} and that of *1h*, where a *p*-nitro group has been substituted in the 2-phenyl ring, is at 3625 cm^{-1}. This is the expected direction of the frequency shift if an important conformer of *1f* was one with hydrogen bonding to the 2-phenyl ring (*i.e.* IV). By substituting a *p*-nitro group into the 2-ring, a weaker bond to this ring may be expected,[6] resulting in an IR absorption at a higher frequency. The proportion of this conformer is probably determined largely by steric effects, as a hydrogen bond giving rise to an absorption near 3600 cm^{-1} in any case is rather weak. The results from the substances with *o*-X-substituents thus indicate the conformer IV with hydrogen bonding to the 2-aryl ring to be of importance in this group. This conclusion is in accordance with the one of v. R. Schleyer *et al.* on the hydrogen bonding in 2-arylethanols,[5] and is confirmed by the spectrum of 1,2-di(*p*-nitrophenyl)ethanol (*1k*) (Table 2b) which shows a single band at 3620 cm^{-1}. The band at 3635 cm^{-1} in the spectrum of *p*-nitrobenzyl alcohol indicates a large fraction of non-bonded conformer. The absence of such a band in the spectrum of 1,2-di(*p*-nitrophenyl)ethanol shows the importance of hydrogen bonding to the 2-aryl ring.

The substances with *o*-Y-substituents (*1c*, *d*, *g*, *i*) give a different IR absorption pattern from the ones discussed above, as all four substances have a rather broad band in the region 3550–3560 cm^{-1}.

This is a larger frequency shift than those discussed above and indicates stronger hydrogen bonds than those found with the compounds with *o*-X-substituents and for the benzyl alcohols in Table 1.

The only possible reason for these relatively strong hydrogen bonds must be that the *ortho* substituent (Y) in the 2-aryl ring is acting as a hydrogen bond acceptor (conformer II). From the discussions above on benzyl alcohols and diarylethanols with *o*-X-substituents no such strong hydrogen bonds could be expected to the 1-or 2-aryl rings (*i.e.* conformers III and IV).

The reason for the stronger hydrogen bond to the *o*-Y-substituents as compared with the *o*-X-substituents must be a more favourable geometry for the hydrogen bond in conformer II than in I. For 1-aryl-2-(*o*-methoxyphenyl)ethanols (*1c*, *d*) this conformer results in a seven-membered ring, and for 1-aryl-2-(*o*-nitrophenyl)-ethanols (*1g*, *i*,) in an eight-membered ring. In both cases one would expect a larger $O-H\cdots O$ angle (closer to 180°) than for the corresponding 1-*o*-substituted arylethanols or *o*-substituted benzyl alcohols, where six- and seven-membered rings, respectively, results from hydrogen bonding to the *o*-substituents.

These results may thus explain in part, why *o*-nitrobenzyl alcohol and not *o*-methoxybenzyl alcohol has a hydrogen bond to the *ortho* substituent (see above). When the methoxy group is part of a seven membered ring system (*e.g. 1c*) it becomes part of an even stronger hydrogen bond than the nitro group in *o*-nitrobenzyl

alcohol does. When the nitro group is involved in an eight-membered ring system, (*e.g. 1g*) a stronger hydrogen bond results than for the seven-membered ring system. The results thus stress the importance of the ability of the angle O – H···O to approach 180°.

From the intensity ratios A_1/A_2 it is nevertheless indicated that the conformer II may not be of great percentage for the species discussed so far.

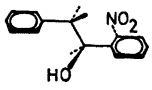
A different picture emerges when one inspects the spectra of 1,2-di(*o*-methoxyphenyl)-and 1,2-di(*o*-nitrophenyl)ethanol (*1e* and *1j*). These two compounds provide a relatively broad band in the region 3540 – 3560 cm^{-1} of the spectra, indicating a hydrogen bond to the *ortho* substituent in the 2-aryl ring. However, for these two compounds, the band in this region has a larger intensity than those discussed above, indicating a relatively larger proportion of the conformer II.

The reason for this might be the changed electron density in the 1-aryl ring as compared to the substances discussed above. In *1j* with a nitro substituent in the 1-aryl ring, this might give conformer III diminished importance, thus increasing the relative importance of conformer II. However, in substance *1i*, there is a *p*-nitro group in the *1*-phenyl ring which would give approximately the same electron density in this ring as in substance *1j* with two *o*-nitro groups. Nevertheless, the spectrum of *1i* indicates a far smaller proportion of conformer II than that of compound *1j*.

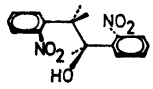
Changes in the electron density of the 1-ring can thus not be invoked to explain the increase of conformer II in compound *1j* as compared to *1g* and *1i*. For 1,2-di-(*o*-methoxyphenyl)ethanol the change in electron density in the 1-aryl ring cannot be the explanation for the increase in importance of conformer II. In this case, the 1-aryl ring was made a better hydrogen acceptor by the introduction of the *o*-methoxy group, and should thus have decreased the importance of conformer II as compared to *1c* and *1e*.

An explanation of the apparently increased importance of conformer II for the di-*o*-substituted compounds *1e* and *1j* therefore has to be sought in the changed steric conditions.

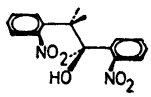
In the solid state, X-ray studies by Sivertsen [12] showed that for compounds *1f* and *1j* the hydroxyl group is placed *transoid* to the *o*-nitro group at the 1-aryl ring.



1f



1j



1j

Further, in *1j*, the nitro-group in the 2-aryl ring is placed *cisoid* to the hydroxyl group.

Inspection of models suggests that these conformations are important even in dilute solution. Except for a small hydrogen bonded portion, the *o*-nitro group of the 1-aryl ring in both *1f* and *1j* will probably be *transoid* to the hydroxyl group. For *1j*, this has consequences for the conformation of the 2-aryl group as there will be repulsion between the two nitro groups if these are in the *cisoid* conformation. The conformation with the nitro groups *transoid* to each other will therefore probably be preferred in solution as well as in the solid state. This means that the hydroxyl group and the nitro group in the 2-aryl ring will be *cisoid* to each other, favourable for hydrogen bonding, and resulting in an increase in conformation II for substance *1j* as compared to compound *1g*. The same type of argument may be used to explain the increased portion of conformer II in 1,2-di(*o*-methoxyphenyl)ethanol (*1e*) as compared to 1-phenyl-2-(*o*-methoxyphenyl)ethanol (*1c*).

This reasoning is based on the assumption that the proportion of various conformers is determined by the steric relations in the molecule and not by the presence of the hydrogen bond. This assumption is not unreasonable when one remembers that a hydroxyl group stretch frequency of 3540 cm^{-1} probably corresponds to an enthalpy of the hydrogen bond of only a few kcal/mol.[7]

The chlorosubstituted 1,2-diarylethanols did not give any indications of hydrogen bonding to the chlorine atoms as shown by the IR data (Table 2c), although a hydrogen bond to the

2-aryl group probably is as important for these alcohols as for those discussed above.

In conclusion, the hydrogen bonds to the *ortho* substituent in *o*-chlorobenzylalcohol and *o*-methoxybenzylalcohol are either non-existent, or of the same strength as those to the π-bond system. In *o*-nitrobenzyl alcohol on the other hand such a hydrogen bond is not excluded. The same is the case with the corresponding 1-(*o*-X-phenyl)-2-arylethanols (*1*). With 1-aryl-2-(*o*-Y-phenyl)ethanols, there exists a relatively strong hydrogen bond to the *o* substituent (Y) in the 2-aryl ring when the substituent is nitro or methoxy. The populations of the various conformers seem to be mainly determined by steric effects and not by the presence or absence of a hydrogen bond.

EXPERIMENTAL

The infrared spectra were recorded in dilute CCl_4 solution. The CCl_4 was dried by refluxing over P_2O_5 and pipetted on to the sample. The spectra were run in 1 cm quartz cells or a 10 cm cell equipped with NaCl windows. The spectra were recorded on a Perkin-Elmer infrared spectrophotometer, Model 457. The resolution of the instrument is 4 cm^{-1} in the OH stretch region. The spectra were recorded in the slow scanning mode, with a minimum slit opening. The various benzyl alcohols studied were all available commercially. The synthesis of the substances *1g*, *1j*, and *1k* have been reported earlier.[13,14]

1-(o-Nitrophenyl)-2-phenylethanol (1f). This substance was made from *o*-nitrostilbeneoxide by refluxing with *p*-toluenesulfonic acid followed by $NaBH_4$ reduction of the resulting ketone. This procedure is analogous to the one used for the synthesis of 1-(*p*-nitrophenyl)-2-phenylethanol.[15] *1h* had m.p. 76–77 °C, IR (KBr): 3350 (broad), 1525, 1340, 1040, 750, 700, 545 cm^{-1}. NMR ($CDCl_3$): δ 7.2–8.2 (9 H, m, aromatic H), 5.3–5.6 (1 H, X part of ABX pattern, $-CHOH-CH_2-$), 2.5–3.4 (2 H, AB part of ABX pattern, $-CHOH-CH_2$), 2.3 (1 H, s, $-OH$).

The synthesis of 1-(*o*-nitrophenyl)-2-(*p*-nitrophenyl)ethanol (*1h*) and 1-(*p*-nitrophenyl)-2-(*o*-nitrophenyl)ethanol, (*1i*) will be described elsewhere.[16]

General procedure for the preparation of chloro and methoxy substituted 1,2-diarylethanols. All the chloro and methoxy derivatives of 1,2-diphenylethanol were prepared by Grignard reactions. The reaction mixture was poured onto a mixture of ice and acetic acid. The ether layer was separated and washed with 10 % sodium bicarbonate solution and water and dried over potassium carbonate. The solvent was removed under reduced pressure and the product was purified by various methods.

1,2-Di(o-methoxyphenyl)ethanol (1e) was synthesised by Grignard reaction of *o*-methoxybenzyl chloride and *o*-methoxybenzaldehyde. *1e* had m.p. 80–82 °C, IR (KBr): 3400, 1605, 1590, 1500, 1470, 1440, 1250, 1190, 1110, 1055, 1040, 755, 740 cm^{-1}. NMR ($CDCl_3$): δ 6.8–7.5 (8 H, m, aromatic H), 5.23 (1 H, t, J=6Hz, $-CHOH-CH_2-$), 3.84 (3 H, s, $-OCH_3$), 3.80 (3 H, s, $-OCH_3$), 3.14 (2 H, d, J=6Hz, $-CHOH-CH_2-$), 2.9 (1 H, s, $-OH$).

2-(o-Methoxyphenyl)-1-phenylethanol (1c) was made by Grignard reaction from *o*-methoxybenzyl chloride and benzaldehyde and gave colourless prisms, m.p. 66–68 °C, on crystallization from ligroin/diethyl ether. NMR ($CDCl_3$): δ 2.53 (1 H, s, $-OH$, exchanged by D_2O), 2.9–3.15 (2 H, deformed d, $-CHOH-CH_2-$), 3.76 (3 H, s, $-OCH_3$), 4.75–5.1 (1 H, deformed t, $-CHOH-CH_2-$), 6.65–7.45 (9 H, broad m, aromatic H). Mass spectrum *m/e:* 228 (M^+), 122, 102, 91, 79.

1-(p-Methoxyphenyl)-2-(o-methoxyphenyl)-ethanol (1d) was made by Grignard reaction from *o*-methoxybenzyl chloride and *p*-methoxybenzaldehyde. 1-(*p*-Methoxyphenyl)-2-(*o*-methoxyphenyl)ethanol crystallized from ligroin/chloroform as tiny, white needles, m.p. 61–62 °C. NMR ($CDCl_3$): δ 2.45 (1 H, s, $-OH$, exchanged with D_2O), 2.9–3.1 (2 H, deformed d, $-CHOH-CH_2-$), 3.73 (3 H, s, $-OCH_3$, 3.76 (3 H, s, $-OCH_3$), 4.7–5.05 (1 H, deformed t, $-CHOH-CH_2-$), 6.7–7.35 (8 H, broad m, aromatic H).

1-(o-Chlorophenyl)-2-phenylethanol (1l) was prepared by Grignard reaction from benzyl chloride and *o*-chlorobenzaldehyde. Recrystallization from ligroin/chloroform gave 1-(*o*-chlorophenyl)-2-phenylethanol as colourless short prisms, m.p. 70–72 °C. NMR ($CDCl_3$): δ 2.62 (1 H, broad s, $-OH$, exchanged with D_2O), 2.8–3.0 (2 H, deformed d, $-CH(OH)-CH_2-$), 5.05–5.35 (1 H, m, $-CH(OH)-CH_2-$), 6.4–7.35 (9 H, m, aromatic H), IR (KBr): 3150–3500 (broad), 3015, 2950, 1600, 1590, 1500, 1040, 700–780 cm^{-1} (several bands).

2-(o-Chlorophenyl)-1-phenylethanol (1m) was prepared from *o*-chlorobenzyl chloride and benzaldehyde. Recrystallization of the product from ligroin/chloroform yielded 1-phenyl-2-(*o*-chlorophenyl)ethanol, m.p. 68–70 °C. NMR ($CDCl_3$): δ 2.48 (1 H, broad s, $-OH$, exchanged with D_2O), 2.9–3.15 (2 H, deformed d, $-CH(OH)-CH_2-$), 4.7–4.95 (1 H, deformed t, $-CH(OH)-CH_2-$), 6.95–7.35 (9 H, m, aromatic H). IR (KBr): 3200–3500 (broad, $-OH$), 3015, 2945, 1600, 1580, 1480 1030, 680–780 cm^{-1} (several bands).

1,2-Di-(o-chlorophenyl)ethanol (1n) was prepared from *o*-chlorobenzyl chloride and *o*-chlorobenzaldehyde. This yielded a pale yellow crystalline mass, which on recrystallization from ligroin/chloroform gave 1,2-di-(*o*-chlorophenyl)-ethanol as colourless cubes, m.p. 82–84 °C.

NMR ($CDCl_3$): δ 2.22 (1 H, broad s, $-OH$, exchanged with D_2O), 2.8–3.45 (2 H, AB-part of an ABX-system, $-CH(OH)-CH_2-$), 5.25–5.55 (1 H, X-part of an ABX-system, $-CH(OH)-CH_2-$), 7.05–7.6 (8 H, m, aromatic H). IR (KBr): 3500–3100 (broad), 3050, 2940, 1695, 1675, 1480, 1035, 765 cm^{-1}.

Mass Spectra of *N*-Phosphorylated Imino Compounds

SVEND TREPPENDAHL, PALLE JAKOBSEN AND JAN WIECZORKOWSKI

Medicinsk-Kemisk Institut, University of Copenhagen, Rådmansgade 71, DK-2200 Copenhagen N, Denmark

The mass spectra of diethyl phosphor(isocyanatidate) (I), diethyl phosphor(isothiocyanatidate) (II), diethyl phosphoro(thionylamidate) (III), diethyl *N*,*N*-dichlorophosphoramidate (IV), and diethyl phosphorazidate (V) have been recorded and interpreted with the aid of high resolution measurements and the metastable defocusing technique.

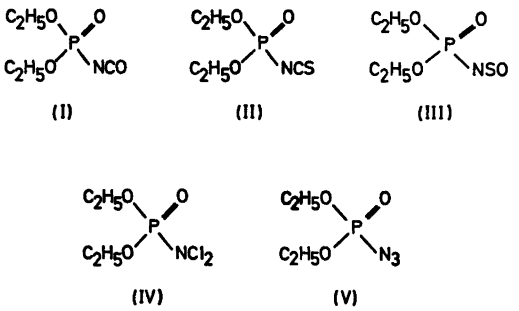
Characteristic for the fragmentations are P—N bond cleavage and degradation in the ethoxy groups. A general fragmentation scheme for the compounds is given.

Recently we have described the general fragmentation pattern of various esters of phosphoramidic acid $(RO)_2P(O)NH_2$.[1]

Continuing our mass spectrometric investigations of phosphorus compounds containing a P—N bond, we have studied some compounds in which the phosphinylimino system  is present. The purpose of this investigation is to examine to what extent mass spectrometry can be used for identification of these types of compounds, and to compare the degradation patterns of *N*-phosphorylated imino compounds with nitrogen connected to different groups.

We shall discuss here the mass spectra of the following compounds: Diethyl phosphor(isocyanatidate) (I), diethyl phosphor(isothiocyanatidate) (II), diethyl phosphoro(thionylamidate) (III), diethyl *N*,*N*-dichlorophosphoramidate (IV), and diethyl phosphorazidate (V).

The mass spectra of the *N*-phosphorylated imino compounds investigated are characterised by fragmentation in the ethoxy groups in agreement with the findings for phosphoramidic acid esters.[1] In addition to these fragmentations,



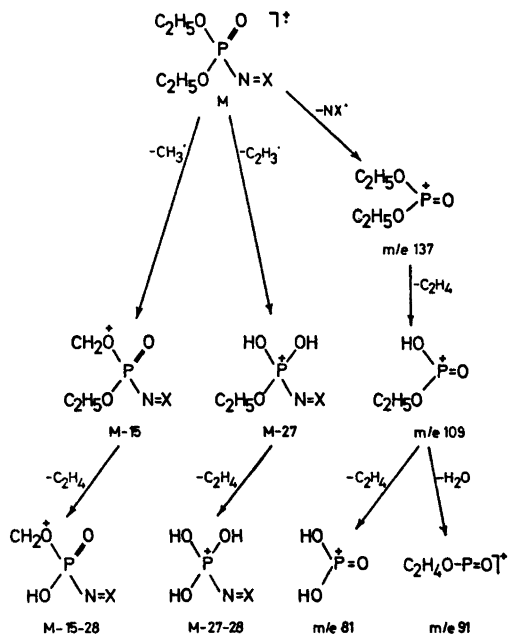
P—N bond cleavage is of importance for the degradation of the molecular ion for all the compounds investigated.

P—O bond breaking from the molecular ion is seen for all compounds except diethyl *N*,*N*-dichlorophosphoramidate, but in all cases the fragments formed are of lower intensity than for the corresponding fragments in diethyl phosphoramidic acid ester.

A generalized fragmentation scheme is given as Scheme 1 (X: C=O, C=S, S=O, Cl_2, or N_2). The P—O bond breaking (loss of C_2H_5O and C_2H_4O) is omitted from the scheme. Variations from the scheme will be mentioned in the discussion.

DISCUSSION

Diethyl phosphor(isocyanatidate) (I) fragments in accordance with the general scheme with the only exception that it splits off HNCO instead of NCO from the molecular ion. No fragmentations take place in the NCO part of the molecule which is in accordance with findings for aliphatic isocyanates.[2]



Scheme 1.

Diethyl phosphor(isothiocyanatidate) (II) fragments similarly to the isocyanate (I), but the ion M − HNCS is of low intensity whereas M − NCS is abundant. The formation of $HNCS^{+\cdot}$ (*m/e* 59) which is general for aliphatic isothiocyanates [8] is also of importance for this phosphor(isothiocyanatidate).

Diethyl phosphoro(thionylamidate) (III) shows no peak at *m/e* 137 corresponding to loss of NSO from the molecular ion, but a metastable peak at *m/e* 94.3 indicates that the P − N bond is cleaved. Furthermore *m/e* 137 is shown by the defocusing technique to be precursor for *m/e* 109 [$C_2H_5OP(O)OH$], so the fragmentation of this thionyl compound is in accordance with the general scheme. No cleavage in the NSO group like loss of SO, as reported for the aromatic thionylamines [4] or loss of SO or HSO as reported for the aliphatic thionylamines [5] is observed. Another degradation involving complex rearrangements results in the formation of the base peak *m/e* 73 with the composition C_2H_3NS.

Diethyl *N,N*-dichlorophosphoramidate (IV) follows only one of the three degradation routes given in scheme 1, namely P − N bond cleavage followed by degradation in the ethoxy groups. It is remarkable that no fragmentation in the ethoxy groups is observed from the molecular ion as this degradation is of importance for both the imino compounds investigated and for diethyl phosphoramidate.[1]

Diethyl phosphorazidate (V) fragments according to the general scheme following all the three routes. No loss of N_3 from the molecular ion like the "normal" azide degradation [6] is observed. This is in accordance with results found for sulphonylazides [7] where loss of N_3 is shown to be of minor importance.

Loss of N_3 is observed from *m/e* 124 and *m/e* 106.

Table 1. Exact mass measurements.

CONCLUSION

As is evident from the discussion above electron impact induced fragmentations of the phosphinylimines investigated are dominated by degradations in the ethoxy groups, namely loss of C_2H_4, C_2H_3· and CH_3·. In addition P – N bond cleavage in the molecular ion is of importance. The phosphinylimines follow, with minor exceptions, three main degradation routes (Scheme 1), a fact which might be useful for characterisation of similar compounds.

EXPERIMENTAL

The mass spectra were recorded on an AEI MS-902 mass spectrometer. The samples were introduced through the heated glass inlet system below 100 °C. All the decompositions given are, unless otherwise noted, supported by accompanying metastable peaks or verified by metastable defocusing (indicated by two asterisks in the figures). The elemental compositions of all characteristic ions have, when necessary, been determined by high resolution mass measurements (Table 1).

The measurements were performed on analytically pure compounds.

Diethyl phosphor(isocyanatidate) (I) was prepared by the action of oxalyl chloride on diethyl phosphoramidate.[8] B.p. 95 °C/15 mmHg, n_D^{20} 1.4170, yield 62 %.

Diethyl phosphor(isothiocyanatidate) (II) was synthesized from the corresponding phosphorochloridate and potassium thiocyanate in acetone solution.[9] B.p. 58 °C/0.12 mmHg, n_D^{20} 1.4795, yield 60 %.

Diethyl phosphoro(thionylamidate) (III) was obtained by the action of thionyl chloride on diethyl phosphoramidate.[10] B.p. 76 °C/0.1 mmHg, n_D^{20} 1.4578, yield 72 %.

Diethyl *N,N*-dichlorophosphoramidate (IV) was prepared by chlorination of the acetate-buffered aqueous solution of diethyl phosphoramidate.[11] B.p. 59 °C/0.03 mmHg, n_D^{20} 1.4622, yield 83 %.

Diethyl phosphorazidate (V) was prepared from diethyl phosphorochloridate and sodium azide in acetone solution according to Scott *et al.*[12] B.p. 70 °C/4 mmHg, n_D^{20} 1.4268, yield 85 %.

Acknowledgement. The authors acknowledge the help of Dr. Jørgen Møller, Physical Laboratory II, University of Copenhagen, the H. C. Ørsted Institute, in obtaining the mass spectral data.

The assistance of Mrs. E. Wolff-Jensen in recording the spectra and performing the measurements is also acknowledged.

Production of Carbohydrate by the Marine Diatom *Chaetoceros affinis* var. *Willei* (Gran) Hustedt. III. Structural Studies of the Extracellular Polysaccharide

BERIT SMESTAD,[a] ARNE HAUG[b] and SVERRE MYKLESTAD[b]

[a] Institute of Pharmacy, University of Oslo, Oslo 3 and [b] Institute of Marine Biochemistry, University of Trondheim, N-7034 Trondheim, Norway

Methylation and periodate oxidation studies have been carried out on the extracellular polysaccharide from cultures of *Chaetoceros affinis* var. *Willei* (Gran) Hustedt. It is apparent from the results obtained that the polysaccharide is highly branched. The results from periodate oxidation concomitant with the methylation studies indicate that the main part of the rhamnose is located in the outer part of the molecule, whereas the fucose and galactose are present both in the outer and inner parts. Apart from being present as end groups the rhamnose is 1,2-linked, galactose 1,4- and 1,3- (major) and some of the fucose 1,3-linked while the main part is present at branch points.

It is well known that many planktonic algae excrete considerable amounts of organic material into the surrounding medium, and that this material in many cases at least partly consists of carbohydrates. Very little is known about the nature of these carbohydrates. Recently, the production of soluble, extracellular polysaccharides has been reported from several diatom species. Allan *et al.*[1] studied eight species, and found significant amounts of soluble polysaccharide in the medium in all cases. The amounts were very small (less than 5 mg/l or 0.2 mg per 10^8 cells), with the exception of one species, *Nitzschia frustulum*, which in standard one-liter culture in enriched seawater produced 15.6 mg/l (1.3 mg per 10^8 cells) in 7 days, and in mass cultures over two weeks were reported to give as much as 150 mg/l (9 mg per 10^8 cells), depending upon conditions like salinity and nutrient levels. Hydrolysis of the polysaccharide gave rhamnose (24 %), mannose (34 %), galactose (8 %), and two unidentified components (14 and 20 %). The composition of the polysaccharide depended upon salinity.

In a study of *Chaetoceros affinis* (clone CH 1), Myklestad and Haug [2] reported the production of an extracellular polysaccharide in amounts of 16 – 40 mg/l (10 – 20 mg per 10^8 cells). The production took place in the stationary growth phase, after the main production of glucan was finished. Later studies [3] have shown that two other *Chaetoceros* species, *C. curvisetus* (CH 24) and *C. decipiens* (CH 40), also produce substantial amounts of extracellular polysaccharides, while in a number of other species, only very small amounts of extracellular polysaccharide can be detected. Both the amounts and the composition of the extracellular polysaccharide strongly suggest that in the case of the three *Chaetoceros* species mentioned above, the polysaccharide is excreted into the medium, and that it is not a case of leakage from dead or dying cells. The function of the polysaccharide in the life of the diatom is unknown. These extracellular polysaccharides all gave fucose, rhamnose, galactose, and sulfate on hydrolysis.

The present paper describes structural studies of the extracellular polysaccharide produced by *Chaetoceros affinis*.

RESULTS AND DISCUSSION

The cultivation of the diatom and isolation of the extracellular polysaccharide has been de-

Table 1. Composition of polysaccharide before and after periodate oxidation.

	Carbohydr. content [a] mg	Wt. ratio rha:fuc:gal	Am. of each sugar; mg (calculated)

Prod. after 2nd. periodate oxidation	8.5	4:75:21	0.3:6.4:1.8

[a] Determined by the phenol-sulfuric acid method.[5]

scribed previously.[2,4] The polysaccharide had $[\alpha]_D = -74°$, a carbohydrate content [5] of 80 %, $-SO_3Na$ was 8.9 % [6] corresponding to an equivalent weight of 1157. Potentiometric titration of the polysaccharide gave an equivalent weight of 850–900, which, if the only anion present is sulfate, was calculated to correspond to 11.4–12.1 % sulfate. The polysaccharide moved as a single, anionic compound in free-boundary electrophoreses both at pH 2 and pH 7, with approximately the same mobility at both pH values.[4]

Analysis for phosphate gave negative results, but small amounts of protein (1.5 % of the sample) were present.[4]

Complete acid hydrolysis of the polysaccharide and analysis by GLC of the derived alditol acetates [7] showed the presence of rhamnose, fucose, and galactose in the proportions 35:39:26 (Table 1). No other sugars were detected. The presence of small amounts of arabinose and traces of other sugars reported previously [4] was most probably due to contamination.

Periodate oxidation [8] was carried out as described under "Experimental". The polysaccharide reduced 0.59 mol of periodate per C_6-anhydro-unit (Table 2). Complete acid hydrolysis of the derived polyalcohol and analysis of the derived alditol acetates by GLC showed that the sugars rhamnose, fucose, and galactose were present in the polyalcohol in the proportions 12:64:24. From Table 1 it can be seen that the periodate cleaved 87.5 % rhamnose, 25.7 % fucose and 58.3 % galactose of the total of the respective sugars in the starting material.

After weak acid hydrolysis followed by dialysis and another periodate oxidation, the polymer reduced 0.36 mol of periodate per C_6-anhydro-unit (Table 2).

Table 1 shows that of the original carbohydrate content of the polysaccharide, 24 % carbohydrate still remains after the second periodate oxidation. This polyalcohol contains the sugars rhamnose, fucose, and galactose in the proportions 4:75:21, which is equivalent to 2.5, 47, and 19.8 % left of the respective sugars present in the starting material.

These results show that most of the rhamnose is vulnerable to periodate oxidation, and must be present mainly in the outer part of the

Table 2. Periodate consumption.

polysaccharide molecule. Had it been present in the interior part, smaller fragments containing considerable amounts of carbohydrate would have passed through the dialysis bag during dialysis; this did not take place.

Methylation studies. Both the original polysaccharide and the product after the second periodate oxidation were methylated, [9] hydrolysed and converted into the partially methylated alditol acetates.[7] The mixtures were analysed on GLC (columns 1 and 2), and the identification of the products, confirmed by mass-spectrometry, is presented in Tables 3 and 4. The retention times obtained correspond quite well with those obtained by Lönngren and Pilotti.[10] For the derivatives of the original polysaccharide, the areas under the peaks are given in Table 3, allowing a semiquantitative estimation of the relative amounts of the methylated derivatives.

The methylation results show that all three sugars are present as end groups, rhamnose being responsible for the main part, followed by galactose and fucose as the minor part.

The rhamnose residues which are not present as end groups are mainly 1,2-linked as shown by the large proportion of 3,4-di-*O*-methylrhamnose and were accordingly vulnerable to periodate attack, in good agreement with the periodate results described above. A small proportion of rhamnose appears to be 1,3-linked and the possibility of this sugar occurring as branch points is indicated by the presence of small amounts of 2-*O*-methylrhamnose.

The galactose residues in the chain are mainly 1,3-linked, giving rise to 2,4,6-tri-*O*-methylgalactose. A smaller amount is 1,4-linked, and these residues, together with the end groups were oxidised in the first periodate treatment. The possibility of galactose forming a few branch points in the molecule is indicated by traces of di-*O*-methylgalactose.

Fucose, however, forms the main part (> 90 %) of the branch points in this poly-

Table 4. GLC analysis of the methylated alditol acetates from the product obtained after 2nd. periodate oxidation.

2,4,6-Tri-*O*-methylgalactose	1.89	L

[a] See Table 3. [b] Relative size of peaks: L = large, M = medium, S = small.

saccharides, being to a large extent recovered as free fucose and 2- and 4-*O*-methylfucose. A small proportion of the fucose was recovered as 2,4-di-*O*-methylfucose, showing the presence of 1,3-linked fucose residues in the molecule.

The methylation of the polyalcohol obtained after the reduction of the product remaining after the second periodate oxidation gave 2,4,6-tri-*O*-methylgalactose and 2,4-di-*O*-methylfucose as the main products, indicating that the Smith degradation had removed some of the side chains attached to the fucose residues. The polymer was, however, still branched, indicated by the presence of mono-*O*-methylfucose.

The polysaccharide was not desulfated before methylation. No systematic investigation of the Hakomori methylation procedure on sulfated polysaccharides has been carried out, but complete methylation by this procedure of highly sulfated polysaccharides has proved impossible,[18] indicating that the methylation procedure does not lead to desulfation. The presence of free fucose and some of the methylderivatives indicating three substituents may, thus, originate from sulfated sugar residues and not from branch points. This is indicated by the results given in Table 3; the area under the peaks corresponding to free fucose and to mono-*O*-methylfucose and rhamnose and di-*O*-methylgalactose is considerably larger than the area under the peaks corresponding to end groups. The possibility of incomplete methylation should, however, also be considered. The position of sulfate is not known, but a band at 850 cm^{-1} in the IR spectrum indicates that it is present on an axial, secondary hydroxyl group.[11,12] This can be C-4 on D-galactose in $^4C_1$ conformation, C-2 on L-rhamnose in $^1C_4$, or C-4 on L-fucose in $^1C_4$ conformation. A small band at 820 cm^{-1} was also present. This indicates sulfate on a primary hydroxyl group, which, in this polysaccharide, would be C-6 on D-galactose.

The results described above show the extracellular polysaccharide produced by the diatom *C. affinis* to be a highly branched polymer of a complex structure. The rhamnose residues occur mainly in the outer part of the molecule, and the major part of the end groups of the molecule are rhamnose, although fucose and galactose also occur as end groups. The branch points in the molecule are fucose residues.

EXPERIMENTAL

Hydrolysis. The sample was dissolved in 90 % formic acid [13] and heated in a sealed tube for 6 h at 100 °C. After dilution with 5 volumes of water, the mixture was heated for another 2 h. The formic acid was removed by several evaporations to dryness after addition of methanol.

Preparation of alditol acetates (7). After hydrolysis the sugars were reduced to the corresponding alditols using $NaBH_4$. A mixture of acetic anhydride and pyridine (1 + 1) was added, followed by heating at 100 °C in sealed tubes for 1 h. 2 ml water was added and heating continued in a boiling waterbath for another 15 min. The derived alditol acetates were extracted with chloroform and analysed by GLC.

Gas liquid chromatography (GLC) of the partially methylated alditol acetates was performed on 0.3 × 200 cm stainless steel column in a Varian 1400 gas chromatograph, using 3 % ECNSS-M on Varaport-30 (column 1) at 165 °C and 0.3 × 400 cm glass column using 3.5 % OV-225 on Varaport-30 (column 2) at 185 °C.

Alditol acetates of the sugars were analysed as described by Myklestad *et al.* [4]

Carbohydrate contents were measured by the phenol-sulfuric acid method [5] using a mixture of rhamnose, fucose, and galactose in the proportions 35:39:26 as standard.

The proportions of sugars present in the hydrolysates were determined by GLC.

Sulfate content was estimated by potentiometric titration and after Antonopoulos method. [6]

IR-spectra were recorded in a Perkin-Elmer 257-spectrometer.

Dialysis was always carried out against distilled water.

The *polysaccharide* was prepared as described elsewhere.[2,4]

Periodate oxidation was performed in acetate buffer at pH 4.0, using excess periodate. The reaction was followed by withdrawing aliquots of 50 µl, which were diluted to 50 ml and OD read at 223 nm.[6] The reaction was complete after 4 h and excess periodate destroyed by adding ethylene glycol. The polyaldehyde was reduced to the corresponding polyalcohol with $NaBH_4$. Excess $NaBH_4$ was destroyed and the solution neutralized with acetic acid. The product was dialysed and freeze-dried.

Weak acid hydrolysis (1 N H_2SO_4 for 4 h at room temperature) was carried out in order to cleave acetal-linkages. The hydrolysate was neutralised with Na_2CO_3 and the final products freeze-dried after dialysis.

This polysaccharide was subjected to another periodate oxidation like the one mentioned above. The reaction was followed by withdrawing samples of 100 µl which were diluted to 25 ml. Carbohydrate contents and sugar-ratios were measured after all the above-mentioned steps.

Methylation.[14] The polysaccharide (10 mg) was freeze-dried, dried *in vacuo* over P_2O_5 overnight and dissolved in 1 ml dimethyl sulfoxide (DMSO) in a McCarthey-bottle.[9] Methylsulfinyl sodium in DMSO (1.5 ml, 2 M)[15] was added and the reaction mixture was stirred vigorously for 4 h. Methyl iodide (0.5 ml) was added while cooling, and stirring continued for another 2 h. The reaction mixture was then poured into water and dialysed against distilled water several times. The methylated product was hydrolysed, the partially methylated sugars converted into the corresponding partially methylated alditol acetates, and analysed by GLC on columns 1 and 2. The identity of the peaks were confirmed by GLC (column 2) combined with mass-spectrometry,[16] carried out on a combined GLC-MS instrument, type Varian CH7. Instrumental details are published elsewhere.[17]

Methylation of the product obtained after *the second periodate oxidation.* The polymer was methylated, converted to the partially methylated alditol acetates as described above, and analysed by GLC on column 2.

Acknowledgement. We are indebted to Dr. E. Percival, Royal Holloway College, for the gift of a sample of 3-*O*-methyl-fucose and to Institute of Clinical Biochemistry, Rikshospitalet, Oslo, for carrying out the combined GLC-MS experiment.

N-Quaternary Compounds. XXXVII.[1] Syntheses and Reactions of Pyrid-2-thiones with α-Bromoacrylic Acid

KJELL RAGNAR REISTAD, GUNNAR ARNFIN ULSAKER and KJELL UNDHEIM

Department of Chemistry, University of Oslo, Oslo 3, Norway

Syntheses of 6-ethyl- and 6-isopropyl-3-hydroxypyrid-2-thiones are described. The syntheses involve a series of reaction steps from a common α-picolinic acid precursor. The relative reactivities of some pyrid-2-thiones towards α-bromoacrylic acid have been investigated.

Further studies of the reaction between pyrid-2-thiones and α,β-unsaturated carbonyl compounds (Scheme 1) required for comparative purposes preparation of pyrid-2-thiones substituted in the 6-position. In previous studies the pyridine has carried a methyl group or a hydrogen atom in the 6-position.[2,3] Syntheses of the ethyl (*1c*) and isopropyl (*1d*) pyrid-2-thiones are herein described. These have been used for investigation of the relative reaction rate as Michael addends to α-bromoacrylic acid.

3-Hydroxypyridines are key intermediates in the syntheses of pyrid-2-thiones. Electrophilic substitution such as halogenation goes preferentially into the 2-position.[4] The halogen thus introduced is in an activated pyridine position and is replaceable by nucleophilic sulfur. In the present work 3-hydroxy-6-methylpyridine was brominated almost quantitatively in the 2-position (*4*) in aqueous HBr on addition of hydrogen peroxide. Thiation to (*1b*) was carried out by means of potassium hydrogen sulfide [4] or phosphorus pentasulfide.[5,6] In the case of the 3-alkoxy derivatives (5), choice of experimental conditions can be made such that thiation alone or thiation with concurrent cleavage of the alkoxy group occur.[6] The latter has been made use of in the below syntheses (Schemes 2 and 3).

In the syntheses of 6-substituted 3-hydroxypyridines substituted furfurals or furoic acids are convenient starting points [7] provided the desired 5-substituted furans are readily accessible. As several steps are involved in the syntheses of the desired compounds from these sources, we have instead looked at readily available pyridines. The synthesis of 3-hydroxy-6-ethylpyridine (*16*) from 3-nitro-6-chloropyridine was first repeated.[8] The chlorine was nucleophilically displaced by means of the sodium salt of diethyl methylmalonate followed by decarboxylations to 3-nitro-6-ethylpyridine. After reduction, the amino group was diazotised and the diazonium salt hydrolysed to (*16*). In our hands the diazotisation and hydrolysis proved preparatively unsatisfactory. Instead another synthetic route was worked out in which the bromo acid (*6*) (Scheme 2) is a common starting material for both the ethyl and

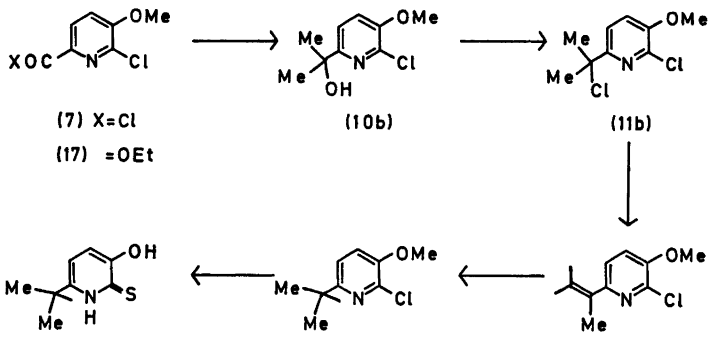
sopropyl series. For oxidation of the 6-methyl group by potassium permanganate the phenolic OH-group was protected by *O*-methylation. The choice of methyl as the *O*-protecting group was directed by the findings mentioned above that alkyl-aryl ethers are readily cleaved by the thiating agent and that the methoxy group is not affected by the reagents used in the intermediate steps. It was noticed during the preparation of the acid chloride from the acid (*6*) by means of thionyl chloride that partial halogen interchange took place in the pyridine ring. The halogen interchange was reduced but not overcome by heating the acid for a short time in thionyl chloride. The further reactions for the syntheses of the pyrid-2-thiones according to Schemes 2 and 3, may be run on products with partially interchanged halogens. For analytical purposes, however, the reactions herein described (Scheme 2) were run on the chloro compounds. Complete chlorine-bromine interchange was achieved (*7*) by heating the acid chloride of (*6*) in thionyl chloride for 4 d. Amination followed by the Grignard reaction on the amide (*8*) furnished the methyl ketone (*9*). The reaction with methylmagnesium iodide in ether was carried out at ice-bath temperature. The crude product contained about 10 % of the isopropyl alcohol (*10b*) which was removed on crystallisation. Clemmensen reduction of the ketone (*9*) resulted in hydrogenolysis of the chlorine (*15*). HBr was used to cleave the ether (*15*) and the hydroxy derivative (*16*) was brominated and thiated as described above. In a preferential alternative method the ketone (*9*) was reduced to the hydroxy derivative (*10a*) by means of sodium borohydride. Acid catalysed water elimination from (*10a*) was found difficult to effect. Instead (*10a*) was chlorinated by means of thionyl chloride. HCl elimination from (*11a*) to the vinyl pyridine (*12a*) was achieved by means of potassium *tert*-butoxide. The double bond was saturated by hydrogenation at atmospheric pressure over platinum oxide without significant hydrogenolysis of the chlorine. The thiation of the ethyl derivative (*13a*) was carried out by means of phosphorus pentasulfide under conditions which gave concurrent cleavage of the alkyl-oxygen ether linkage and formation of (*1c*).

A very similar approach to the synthesis of the isopropylpyrid-2-thione (*1d*) was used (Scheme 3) starting from the 6-carboxylic acid (*6*). The latter was initially converted to the ethyl ester (*17*) which was subjected to the Grignard reaction. This reaction required heating in ether which led to extensive dehalogenation in the pyridine ring. With the reactive acid chloride (*7*), however, the reaction proceeded smoothly at ice-bath temperature to the tertiary hydroxy compound (*10b*). As for the ethyl analogue (*10a*) acid catalysed water elimination



Scheme 3.

from (*10b*) was unsatisfactory and (*10b*) was chlorinated by means of thionyl chloride. In aqueous potassium hydroxide (*11b*) was converted to the propene (*12b*) which was selectively reduced to the isopropyl derivative (*13b*) on catalytic hydrogenation. Thiation by means of phosphorus pentasulfide finally furnished the hydroxy-thione (*1d*).

In the Michael addition of pyrid-2-thiones to α-bromoacrylic acids a methyl group in the pyridine 6-position causes a rate enhancement relative to the desmethyl analogues.[2] The overall reaction rates for the thiones (*1*) were investigated by competitive reactions in ethyl acetate with α-bromoacrylic acid in the cold. The precipitated HBr-salts of the dihydrothiazolo[3,2-*a*]pyridium products (*3*) were collected when the total yield corresponded to about 15 % and analysed by NMR (100 MHz). Slight solubility differences and partially overlapping of NMR signals made the figures obtained no more than qualitative. With reference to the standard (*1b*) the relative reaction rate for the desmethyl analogue (*1a*) was 0.3 and the rates for the other 6-substituted pyridines (*1c*, *1d*) approximately as for the standard (*1b*).

The overall reaction (Scheme 1) involves firstly adduct formation (*2*) and then cyclisation (*3*). The intermediate adduct (*2*) was not seen. In the cyclisation of (*2*) increasing steric interaction in the series (*1b*) to (*1d*) would be expected between the 6-substituent and the substituents on the side-chain carbon atom involved in the cyclisation reaction. In the adduct formation steric interaction from the 6-substituents is presumably not very different within the series and the alkyl groups exert similar inductive activation. The closely related overall reaction rates for the alkyl derivatives therefore suggest that the intramolecular cyclisation reaction is considerably faster than the intermolecular adduct formation. The rate differences for the two steps are such that the steric decrease in the cyclisation rate with increasing bulkiness of the substituents does not decrease the rate of cyclisation below that of adduct formation.

EXPERIMENTAL

All NMR spectra were determined on a Varian 60 MHz A-60 A spectrometer.

2-Bromo-3-hydroxy-6-methylpyridine (4). 3-Hydroxy-6-methylpyridine (21.8 g, 0.2 mol) was dissolved in 48 % HBr (100 ml, 0.88 mol) and the solution cooled to 0 – 5 °C and kept at this temperature during the ensuing reaction. Hydrogen peroxide (15 %, 50 ml, 0.22 mol) was added slowly with stirring to the cooled solution. The stirring was continued for another 2 h at 0 – 5 °C after the addition was complete. The precipitated product was then filtered off, the filtrate concentrated and the new precipitate collected. The combined product was dissolved in water and the solution neutralised with ammonia. The title compound was precipitated and obtained in more than 90 % yield; and having properties as previously described.[4]

2-Bromo-3-methoxy-6-methylpyridine (5). 2-Bromo-3-hydroxy-6-methylpyridine (188 g, 1 mol) and methyl iodide (200 g, 1.4 mol) were added to 1 M sodium methoxide in methanol (1 l). The mixture was heated under reflux overnight, more of the 1 M sodium methoxide solution (250 ml) and methyl iodide (50 g, 0.35 mol) added and the reaction mixture heated under reflux for another 3 h. The precipitated salt was filtered off from the cold reaction mixture, the filtrate evporated, the residue suspended in 0.1 M NaOH (300 ml) and the title compound extracted into ether. The etheral solution was washed and dried and yielded the title compound in 74 % yield (149 g) on evaporation; properties as previously described.[9]

2-Bromo-3-methoxypyridine-6-carboxylic acid (6). Potassium permanganate (47.4 g, 0.3 mol) was added gradually over 4 h to a suspension of 2-bromo-3-methoxy-6-methylpyridine (20.2 g, 0.1 mol) in water (1 l) at 70 °C. Towards the end of the reaction the temperature was raised to 85 – 90 °C. Methanol (20 ml) was then added to decompose any excess potassium permanganate and the reaction mixture filtered warm. The manganese dioxide filtered off was washed 3 – 4 times with boiling, dilute methanol (1:1) and the combined washings and filtrate concentrated to about half its volume before acidification with HCl. The white carboxylic acid precipitated was recrystallised from dilute ethanol (1:5); yield 16.5 g (71 %), m.p. 245 – 247 °C. (Found: C 36.31; H 2.61; N 6.01. Calc. for $C_7H_6BrNO_3$: C 36.24; H 2.61; N 6.04), τ(TFA) 5.6 (OMe), 1.1 and 1.6 (H-4, H-5).

2-Chloro-3-methoxypyridine-6-carbonyl chloride (7). A solution of 2-bromo-3-methoxypyridine-6-carboxylic acid (11.6 g, 0.05 mol) in thionyl chloride (300 ml) was heated under reflux for 4 d. The solution was then evaporated and the residue triturated with acetonitrile. There remained 6.0 g (58 %) of the title compound sufficiently pure for further reaction. For elemental analysis part of the product was recrystallised from acetonitrile, m.p. 126°C. (Found: C 40.82; H 2.45. Calc. for $C_7H_6ClNO_2$ C 40.81; H 2.45), τ($CDCl_3$) 6.0 (OMe), 1.9 and 2.7 (H-4, H-5).

*2-Chloro-3-methoxypyridine-6-*N,N*-diethylcarboxamide (8).* Diethylamine (5.5 g, 0.075 mol) was added dropwise with stirring to an ice-cold solution of 2-chloro-3-methoxypyridine-6-carbonyl chloride (5.1 g, 0.025 mol) in toluene (250 ml). The reaction mixture was left overnight, the precipitated salt removed by filtration and the filtrate evaporated. Recrystallisation of the residue from diisopropyl ether gave the amide m.p. 60 – 62 °C, yield 5.5 g (90 %). (Found: C 54.40; H 6.15. Calc. for $C_{11}H_{15}ClN_2O_2$: C 54.44; H 6.23), τ($CDCl_3$), 6.1 (OMe), 6.5 and 8.8 (*N*-Et_2), 2.4 and 2.8 (H-4, H-5).

2-Chloro-3-methoxy-6-acetylpyridine (9). A Grignard solution in anhydrous ether (50 ml), prepared from magnesium turnings (0.5 g, 0.022 mol) and methyl iodide (3.1 g, 0.022 mol), was added dropwise to an ice-cold, stirred solution of 2-chloro-3-methoxypyridine-6-*N*,*N*-diethylcarboxamide (4.8 g, 0.02 mol) in anhydrous ether (200 ml). The reaction was run under nitrogen. The reaction was stirred for 1 h after the addition had been completed and the reaction mixture then poured onto ice with some acetic acid. The ether layer was separated, the aqueous layer extracted with ether and the etheral solutions dried and evaporated. The product thus obtained contained about 10 % of the corresponding tertiary alcohol (*10b*). The latter was readily removed by crystallisation from ethanol in which the ketone is very little soluble in the cold; yield 2.3 g (62 %), m.p. 103 – 104 °C. (Found: C 51.98; H 4.42. Calc. for $C_8H_8ClNO_2$: C 51.77; H 4.34), τ($CDCl_3$) 7.3; τ(CH_3CO) 6.0 (OMe), 2.0 and 2.7 (H-4 and H-5).

2-Chloro-3-methoxy-6-(1-hydroxyethyl)pyridine (10a). Sodium borohydride (0.6 g, 0.015 mol) was added gradually to a methanolic solution (50 ml) of 2-chloro-3-methoxy-6-acetylpyridine (0.9 g, 0.005 mol). The solution was evaporated after 1 h, the residue triturated with water and the pH adjusted to about 7 before chloroform extractions. Evaporation of the dried chloroform extracts gave the title compound 0.8 g, 90 %), m.p. 35 – 37 °C. The product was sufficiently pure for elemental analysis. (Found: C 51.25; H 5.42. Calc. for $C_8H_{10}ClNO_2$: C 51.21; H 5.37), τ($CDCl_3$) 8.5 (3 H, d, CH_3C), 6.1 (OMe), 5.2 (H, q, CH-Me), 2.8 (2 H, broad singlet, H-4 and H-5).

2-Chloro-3-methoxy-6-(1-chloroethyl)pyridine (11a). 2-Chloro-3-methoxy-6-(1-hydroxyethyl)-pyridine (0.8 g, 0.004 mol) was kept in thionyl chloride (30 ml) overnight. Evaporation left the title compound. The chlorination is quantitative and the product can be used directly in the next step. For analysis part of the product was dissolved in chloroform, this solution washed well with water and dried before evaporation. The residual material, after recrystallisation from diisopropyl ether, had m.p. 51 – 53 °C. (Found: C 46.48; H 4.36. Calc. for $C_8H_9Cl_2NO$: C 46.63; H 4.40), τ($CDCl_3$) 8.2 (3 H, d, CH_3C), 6.1 (OMe), 4.9 (H, q, CH – Me), 2.6 and 2.8 (H-4 and H-5).

2-Chloro-3-methoxy-6-methylpyridine (13a). A solution of 2-chloro-3-methoxy-6-(1-chloroethyl)pyridine (0.8 g, 0.004 mol) in 0.5 M potassium *tert*-butoxide in *tert*-butanol (16 ml) was heated at 80 °C for 90 min. Acetic acid (4 ml) was added to the cold reaction mixture until acid pH. The *2-chloro-3-methoxy-6-vinylpyridine (12a)* thus obtained was not isolated but the solution subjected to hydrogenation over platinum oxide at room temperature and atmospheric pressure for 3 h. The catalyst was then removed and the solution evaporated to dryness at reduced pressure. Water was added to the residual material, pH adjusted to about 7 and the title compound extracted into chloroform. Evaporation of the washed and dried chloroform extracts left an oily material, 0.4 g (58 %). For elemental analysis a portion of this material was dissolved in anhydrous ether, and HBF_4 in ether added dropwise. The white, semicrystalline tetrafluoroborate was fully solidified on trituration with acetone; m.p. 166 – 168 °C. (Found: C 36.80; H. 4.30. Calc. for $C_8H_{10}ClNO.HBF_4$: C 37.05; H 4.25), τ(NMR of oily material in $CDCl_3$) 8.7 and 7.3 (Et), 6.1 (OMe), 2.8 and 2.9 (H-4, H-5).

3-Hydroxy-6-ethylpyridine (16). Zinc amalgam was prepared from granulated zinc (5 g) and mercuric chloride (0.6 g) in water (20 ml) and conc. HCl (1 ml). The water solution was decanted after 5 min and dilute HCl (1:1) solution (60 ml) added. 2-Chloro-3-methoxy-6-acetylpyridine (2.4 g, 0.013 mol) was next added and the reaction mixture heated under reflux

for 3 h. The reaction mixture was then neutralised and the compound extracted into ether. The ether was evaporated leaving 3-methoxy-6-ethylpyridine. The latter was dissolved in 48 % HBr in acetic acid (25 ml) and the solution heated for 5 h. Evaporation left the HBr salt which was dissolved in a minimum amount of water and the solution neutralised when the title compound was slowly precipitated in 20 % yield; properties as described.[5]

2-Chloro-3-methoxy-(2-hydroxy-2-propyl)pyridine (10b). A solution of methylmagnesium iodide was prepared from magnesium turnings (2.0 g, 0.08 mol) and methyl iodide (11.4 g, 0.08 mol) in anhydrous ether (100 ml) under nitrogen. The acid chloride (*7*) (4.1 g, 0.02 mol) was then added dropwise with stirring to the Grignard solution cooled by ice-water. After completion of the addition the reaction was heated under reflux for 2 h before being poured onto ice containing a little acetic acid. The ether layer was separated, the aqueous layer was extracted with ether and the combined etheral solutions were dried and evaporated. The residual oily material was distilled; yield 3.3 g (82 %), b.p. 116–118 °C/0.15 mmHg. For elemental analysis a portion was crystallised from diisopropyl ether, the crystalline material being collected at −20 °C; m.p. 30–32 °C. (Found: C 53.25; H 5.96. Calc. for $C_9H_{12}ClNO_2$: C 53.61; H 6.00), τ($CDCl_3$) 8.5 (CMe_2, s), 6.1 (OMe), 2.6 and 2.8 (H-4, H-5).

2-Chloro-3-methoxy-6-isopropenylpyridine (12b). A solution of 2-Chloro-3-methoxy-6-(2-hydroxy-2-propyl)pyridine (4.0 g, 0.02 mol) and thionyl chloride (3.5 g, 0.03 mol) in benzene (50 ml) was heated under reflux for 30 min before the benzene was evaporated. The residual halide was added to aqueous 0.5 M potassium hydroxide (80 ml) and the suspension heated under reflux for 2 h. The cold reaction mixture was extracted with ether, the dried ether extracts evaporated and the residual oil distilled; yield 2.6 g (71 %), b.p. 88–90 °C/0.05 mmHg. (Found: C 58.66; H 5.43. Calc for $C_9H_{10}ClNO$: C 58.87; H 5.49), τ(CCl_4) 7.9 (CH_3–C), 6.2 (OMe), 4.3 and 4.9 (=CH_2), 2.8 and 3.0 (H-4, H-5).

2-Chloro-3-methoxy-6-isopropylpyridine (13b). A solution of 2-chloro-3-methoxy-6-isopropenylpyridine (2.2 g, 0.012 mol) in methanol (25 ml) was hydrogenated over 5 % palladium on charcoal (1/2 teaspoon) at 0.38 MPa* and room temperature. The catalyst was filtered off after 4 h, the solvent evaporated and the residual oil distilled; yield 1.6 g (72 %), b.p. 78–84 °C/0.1 mmHg. (Found: C 57.88; H 6.66. Calc. for $C_9H_{12}ClNO$: C 58.20; H 6.47), τ($CDCl_3$) 8.7 (6H, d, CMe_2) and 7.1 (H, m, CH–CMe_2), 6.1 (OMe), 2.8 and 2.9 (H-4, H-5).

3-Hydroxy-6-isopropylpyrid-2-thione (1d). 2-Chloro-3-methoxy-6-isopropylpyridine (5.6 g, 0.03 mol) and phosphorus pentasulfide (6.7 g, 0.03 mol) were ground well together and the mixture heated at 140 °C for 10 h. The reaction mixture was then decomposed on warming with water and the resultant suspension neutralised with conc. ammonia and extracted several times with chloroform. The residue, after evaporation of the dried chloroform extracts, was dissolved in boiling carbon tetrachloride and some hexane added. The yellow title compound crystallised out from this solution on standing; yield 3.5 g (68 %), m.p. 110–112 °C. (Found: C 56.45; H 6.57; S 19.08. Calc. for $C_8H_{11}NOS$: C 56.77; H 6.55; S 18.95), τ(TFA) 8.6 (6H, d, CMe_2) and 6.9 (H, m, CH–CMe_2), 2.1 and 2.6 (H-4, H-5).

3-Hydroxy-6-ethylpyrid-2-thione (1c) was prepared from (*13a*) and phosphorus pentasulfide as the isopropyl analogue (*1d*) above. The crude thione in chloroform was filtered through a short silica gel column before evaporation. Recrystallisation from toluene gave m.p. 150–151 °C; yield 43 %. (Found: C 53.94; H 6.13. Calc. for C_7H_9NOS: C 54.19; H 5.85), τ($CDCl_3$) 8.7 and 7.3 (Et), 3.0 and 3.5 (H-4, H-5).

In another experiment 3-hydroxy-6-ethylpyridine (*16*) was brominated as described for the 6-methyl analogue (*4*) above and the crude bromo compound (*14*) subjected to thiation as above using phosphorus pentasulfide. The yield in the thiation was 60 %.

8-Hydroxy-5-isopropyldihydrothiazolo[3,2-a]pyridinium-3-carboxylate (3d). 3-Hydroxy-6-isopropylpyrid-2-thione (1.7 g, 0.01 mol) and α-bromoacrylic acid (3.0 g, 0.02 mol) in ethyl acetate (66 ml) were stirred at room temperature for 24 h. The precipitated title compound as HBr salt was then filtered off (1.9 g, 59 %). Due to the case of decarboxylation the salt was not attempted recrystallised but washed well with ethyl acetate before elemental analysis; m.p. 195–197 °C (decomp.) (Found: C 41.00, H 4.40. Calc. for $C_{11}H_{14}NO_3S.HBr$: C 41.20; H 4.38, τ(TFA) 8.5 (6H, d, CMe_2) and 6.7 (H, m, CH–CMe_2), 5.7 (2 H-2), 3.5 (H-3), 2.0 and 2.5 (H-7, H-6).

8-Hydroxy-5-ethyldihydrothiazolo[3,2-a]pyridinium-3-carboxylate (3c) *as HBr salt* was formed from 3-hydroxy-6-ethylpyrid-2-thione and α-bromoacrylic acid in 65 % yield under the above reaction conditions in ethyl acetate. Due to the ease of decarboxylation the crude product after being washed well with ethyl acetate was subjected directly for elemental analysis; m.p. 179 °C (decomp.). (Found: C 38.98, H 4.26. Calc. for $C_{10}H_{11}NO_3S.HBr$: C 39.23; H 3.95), τ(TFA) 8.5 and 7.0 (Et), 5.7 (2 H-2), 3.5 (H-3), 2.0 and 2.5 (H-7, H-6).

* 1 MPa ≈ 10.2 kg cm^{-2}.

An X-Ray and Vapour Pressure Study on Lecithin—Cholesterol—Water Interactions

BO LUNDBERG

Department of Biochemistry and Pharmacy, Åbo Akademi, SF-20500 Åbo, Finland

The molecular interactions in the lamellar mesomorphous phase of the lecithin-cholesterol-water system have been examined by X-ray diffraction and vapour pressure measurements. Cholesterol is found to have a condensing effect on the molecules of egg lecithin. This effect is accompanied by an increase in the thickness of the lipid layer and a decrease in the thickness of the water layer. The water binding capacity of egg lecithin is only slightly affected by cholesterol. The effect of cholesterol on hydrated egg lecithin seems mainly to be restricted to the hydrocarbon region.

Cholesterol is a prominent constituent in biological structures, *e.g.*, membranes and may also play a part in the development of pathological structures as atherosclerotic lesions and gall-stones. Cholesterol by itself insoluble in water can be solubilised in the mesomorphous phase of the lecithin-water system.[1]

A significant feature of the molecular interactions between cholesterol and lecithins is the condensing effect of cholesterol in mixed monolayers with most lecithins above their chain melting temperature.[2] This reduction in the mean molecular area was also found to be valid for bulk systems from calculations of X-ray data.[1]

Cholesterol has on the contrary been shown to cause a considerable increase in the surface area of lecithin in sonicated vesicles.[3]

Ladbrooke *et al.* applied differential scanning colorimetry (DSC) to cholesterol-lecithin suspensions and found that cholesterol inhibits the chain motion of lecithin above the gel-liquid crystal transition temperature and concluded that the transition vanishes at a 1:1 mol ratio.[4] The deuteron NMR [5] and ESR spin label method [6] have provided more details of the molecular interaction. It has been found that the restriction of the lecithin chain motion is smaller at the free nonpolar ends of the chains than in the region near the glycerol backbone. The lecithin phosphate group and cholesterol hydroxyl appear to be juxtaposed and may be hydrogen bonded.[7]

Regarding the interaction between mixtures of lecithin-cholesterol and water, DSC measurements indicate that the bound water is a maximum at 50 mol % cholesterol.[8] Other authors, on the contrary, have found decreasing affinity for water with increasing cholesterol concentration.[9] No vapour pressure measurements on lecithin-cholesterol mixtures seem to have been reported.

MATERIALS AND METHODS

The cholesterol used (Merck *p.a.*) was recrystallized three times from 1,2-dichlorethane. It was found to be chromatographically pure by TLC and GLC. The egg lecithin was isolated in this laboratory.[10] It was proved to be chromatographically and spectroscopically pure by TLC and IR-spectroscopy. The water was distilled twice in an apparatus of silica.

The lipid mixtures were prepared by dissolving cholesterol and lecithin in ampouls and the solvent was then removed in a stream of nitrogen. The last traces of solvent were removed *in vacuo* and then an appropriate amount of water was added. The ampouls were sealed under nitrogen and placed in a thermostated water bath to equilibrate over a period of ten days. After the X-ray diffraction measurements the water contents were checked with a Karl Fisher titration.

The X-ray diffraction measurements were conducted with an apparatus previously de-

scribed.[11] The Cu$K\alpha$ radiation used was Ni-filtered and the incident X-ray beam was collimated by a slit system. The scattering angle was measured with a Rigaku-Denki low-angle goniometer. No slit corrections were done.

The adsorption of water vapour by egg lecithin-cholesterol mixtures was measured by keeping the lipid mixtures in weighing bottles over standard saturated salt solutions in vacuum. All measurements were performed at a temperature of (25 ± 1) °C.

RESULTS

The X-ray diffraction measurements were limited to the region of the lamellar mesophase in the egg lecithin-cholesterol-water system. To make sure that the samples belonged to this phase they were examined by a polarizing microscope after the X-ray measurements. In order to make the results as surveyable as possible the cholesterol concentration at three constant lecithin/water ratios (9:1, 7.5:2.5, 6:4) was varied. The variations in long spacings, D, with cholesterol for the three different lecithin to water ratios are shown in Fig. 1. For the lecithin/water ratio of 9:1 the maximum solubilising capacity is reached at about 20 % cholesterol concentration then the curve stops.

Starting with the D values and the corresponding lecithin, cholesterol, and water percentages one can calculate a number of parameters in the system studied. In the calculations the following considerations were accounted for. From the molecular volumes and volume fractions of this egg lecithin [10] and cholesterol the mean molecular volumes for

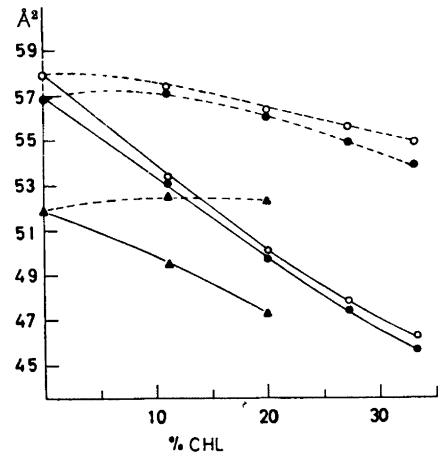

Fig. 2. The mean molecular surface area (S_M), continuous lines, and partial molecular area of lecithin (S_L), broken lines, as a function of the dry weight percentage of cholesterol. Each curve is relative to a fixed lecithin to water ratio of 9:1 (▲), 7.5:2.5 (●), and 6:4 (○), respectively.

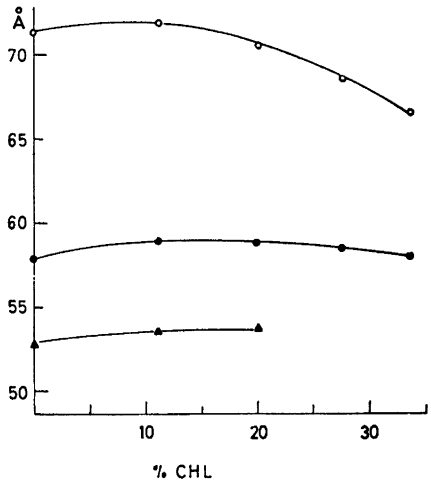

Fig. 1. The long spacings (D) as a function of a dry weight percentage of cholesterol. Each curve is relative to a fixed lecithin to water ratio of 9:1 (▲), 7.5:2.5 (●), and 6:4 (○), respectively.

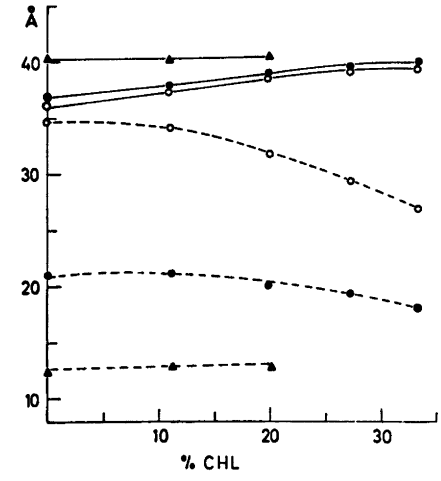

Fig. 3. The thickness of the lipid layer (d_L), continuous lines, and the thickness of the water layer (d_w), broken lines, as a function of the dry weight percentage of cholesterol. The curves represent lecithin to water ratios of 9:1 (▲), 7.5:2.5 (●), and 6:4 (○), respectively.

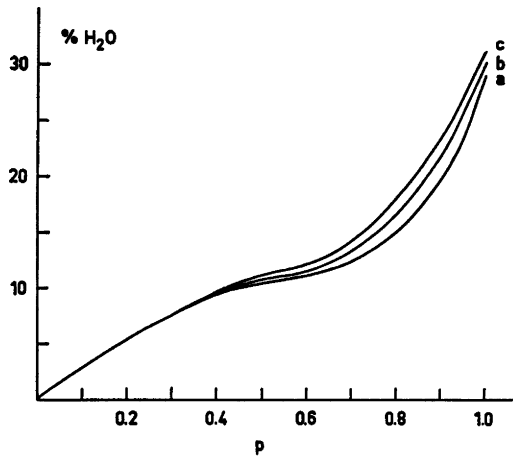

Fig. 4. Adsorption of water vapour by egg lecithin in mixtures with cholesterol. The weight percentage of adsorbed water based on water and lecithin weight only is plotted against the relative vapour pressure (p). Curve a 0 % cholesterol; b 15 % cholesterol, and c 30 % cholesterol.

mixtures of them (V_{LC}) are calculated. The mean molecular volume (V_L) of the lipidic layer exclusive the phosphoryl choline group is calculated from the molecular volumes of the glycerohydrocarbon part [10] and cholesterol and the volume fractions of them. The cholesterol molecules are assumed to occupy a practically constant area in the mixed layers of the lamellar phase whatever the molar fraction is. From monolayer measurements the surface area of cholesterol has been calculated to 37.5 Å² per molecule.[14] Starting with the related values, the following parameters can be estimated.

1. The mean molecular surface area, S_M, in Å² per molecule. $S_M = V_{LC}/(D/2 \times \phi_{LC})$, where $D/2$ is one half of the long spacing and ϕ_{LC} equals volume fraction of lecithin and cholesterol.

2. The surface area, S_L, per lecithin molecule in Å² per molecule. $S_L = S_M - (X_c \times 37.5)/X_L$, where X_C and X_L are mol fractions of cholesterol and lecithin, respectively.

3. The thickness, d_L, in Å of the lipid layer: $d_L = 2V_L/S$.

4. The thickness in Å of the water layer, d_w, including the phosphoryl choline group: $d_w = D - d_L$.

The experimental D values and the calculated parameters are summarized in Figs. 1, 2, and 3.

The results from the vapour pressure measurements are presented in Fig. 4. To make the curves more commensurable the water percentages are calculated on water and lecithin weight only. A slight increase in water adsorption with increasing cholesterol concentration is noted.

DISCUSSION

The most striking changes when cholesterol is incorporated into the hydrated lecithin bilayers are the reduction in the surface area of lecithin (see Fig. 2) and the corresponding increase in lipid layer thickness (see Fig. 3). It is still under discussion whether these cholesterol effects are caused by inhibition of chain motions or by orientation of their long axes more nearly perpendicular to the plane of the bilayer or by both these effects. NMR studies have shown that cholesterol severely restricts the lecithin chain motions.[5] Spin label studies indicate that lecithin which makes an angle of about 30°, with the normal to the lamellar phase, is made more nearly perpendicular by the addition of cholesterol.[15] It may be that the reduction in surface area and increase in lipid layer thickness is due to both the effects mentioned.

Although the reduction in surface area of lecithin by cholesterol is significant it is not of the same order of magnitude as in mixed films. For a 1:1 mixed monolayer the surface area of lecithin is at the collapse point *ca.* 44 Å²/molecule compared with *ca.* 55 for the same molar proportions at 6:4 hydration (see Fig. 2) in the bulk system. This discrepancy may be explained by the fact that the conditions are not identical. In a monolayer the paraffinic ends are in contact with air, whereas in a bulk system they face other paraffinic ends.

The vapour pressure measurements show that the water binding capacity of lecithin is not much altered by the incorporation of cholesterol. This indicates that the configuration of the lecithin phosphoryl choline group is not much altered by the interaction with the cholesterol hydroxyl. NMR studies have indicated a reduction in the $N(CH_3)_3$ mobility. The proportion of bulky hydrophilic end groups

decreases, however, when cholesterol is incorporated and therefore there is more space for water and greater freedom for hydrogen bondings.

The results from the vapour pressure measurements favour the opinion that the lecithin-cholesterol interaction is mainly hydrophobic. The most noticeable apolar effect is the reduction in the molecular area. In the light of the present study this condensing effect mainly found in membrane model studies with monolayers may have been overstressed. The situation with paraffinic ends facing each other is the same for both lamellar bulk systems and biomembranes. Therefore the much smaller condensing effect calculated from X-ray measurements may be relevant for membranes too. The main effect of cholesterol in natural structures seems more likely to be the chain melting effect thus regulating the physical state of the hydrocarbon region.

A Calorimetric Study of *peri* Strain in 1,8-Dimethylnaphthalene and 1,4,5,8-Tetramethylnaphthalene

MARGRET MÅNSSON

Thermochemistry Laboratory, Chemical Center, University of Lund, S-220 07 Lund, Sweden

Enthalpies of combustion, utilizing a micro combustion calorimetric technique, and enthalpies of sublimation have been determined for 1,8-dimethylnaphthalene and 1,4,5,8-tetramethylnaphthalene. Standard enthalpies of formation for the compounds in the gaseous state, $\Delta H_f°(g)$, have been derived and are (26.0 ± 0.7) and (19.5 ± 0.9) kcal mol^{-1}, respectively. The calculated strain energies caused by *peri* interactions in the two compounds are 6 and 15 kcal mol^{-1}, respectively.

Substitution in the 1,8-positions in naphthalene is generally referred to as *peri* substitution. Due to the structure of the naphthalene molecule such substituents come closer together than if they were *ortho*. As was pointed out in the review by Balasubramaniyan [1] *peri* interactions in naphthalene early aroused considerable interest among chemists, an interest that seems to be increasing rather than decreasing.

Thermochemical methods have not been utilized in the study of *peri* interactions in true naphthalene derivatives until quite recently. In two independent investigations [2,3] the energy of combustion was determined for crystalline 1,8-dimethylnaphthalene. In Ref. 2 energies of combustion were also reported for the 2,3-, 2,6-, and 2,7-isomers. From these measurements enthalpies of formation for the compounds in the crystalline state are derived. However, in studies of intramolecular interactions gas phase enthalpies of formation generally are those that contain the pertinent information. Enthalpy of vaporization (sublimation) determinations therefore are an essential part of such investigations. The development of a micro-bomb (4.5 cm^3) combustion calorimeter [3] now makes it possible to perform a full series of combustion measurements on 50 mg or less of pure material, yet with adequate accuracy. Calorimetric enthalpy of vaporization measurements for compounds with vapour pressures at 298 K extending down into the 10^{-5} Torr* region [4] in most cases have become a routine procedure in our laboratory.

In this paper enthalpy of combustion and sublimation measurements are reported for 1,8-dimethylnaphthalene (1,8-DMN) and 1,4,5,8-tetramethylnaphthalene (1,4,5,8-TMN). One of the questions asked was whether the first pair of *peri* methyl groups in the 1,8-DMN molecule would make it more "costly", or perhaps less so, to introduce the second *peri* pair in the 4,5-positions. Or, would the stepwise *peri* dimethyl substitutions in naphthalene cause constant increments in the energy?

The so called *ortho*-effect for a pair of methyl groups in benzene has been investigated previously by combustion calorimetry,[5,6] in combination with calorimetric measurements of enthalpies of vaporization.[7] The calculated mean value for the strain energy introduced by two *ortho* methyl groups is of the order of 0.6 – 0.7 kcal mol^{-1}.** The magnitude of the expected increased strain due to the much closer proximity of *peri* methyl groups should be an interesting piece of information derivable from the calorimetric measurements.

EXPERIMENTAL

Compounds. The benzoic acid used in the calibration experiments was National Bureau of Standards SRM 39i.

* 1 Torr = (101.325/760) kPa.

** 1 cal = 4.184 J.

The 1,8-dimethylnaphthalene (DMN) sample has been accounted for earlier.[3] 1,4,5,8-Tetramethylnaphthalene (TMN) was synthesized by Dr. Hans Sternerup (Department of Organic Chemistry, Chemical Center, Lund) from *p*-xylene and γ-valerolactone as described in Ref. 8. About 2.5 % of impurities remained after two recrystallizations from methanol. Running the material through a neutral aluminium oxide column, with pentane as eluent, did not markedly improve the purity. Subsequent recrystallization (twice) from hexane reduced the total amount of GLC detectable impurity to 0.13 mol %. Carbowax and silicone (SE-30) columns were used in the GLC studies. Mass spectrometric analysis, coupled with GLC, identified the impurities as an isomeric tetramethyl- and a trimethyl-naphthalene, present in approximately equal amounts. The NMR spectrum was fully consistent with the assumed 1,4,5,8-arrangement of the four methyl groups. The purified material was pressed into a pellet, which was then broken up and ground in an agate mortar to ascertain the escape of traces of solvent (hexane) that might be trapped in the crystalline material.[9] The melting temperature, determined on a Perkin-Elmer DSC-2 differential scanning calorimeter was 405.$_7$ K. For the combustion measurements 3.5 mm diameter pellets were made. The mass loss from such a pellet was less than 1 μg h^{-1}.

A Perkin-Elmer DSC-2 differential scanning calorimeter was used to determine enthalpies of fusion. High purity indium was used as calibration standard and naphthalene was included in the series for comparison. The enthalpies of fusion obtained for naphthalene, DMN, and TMN were 18.8$_5$, 15.8, and 23.9 kJ mol^{-1}, respectively. McCullough *et al.*[10] obtained 18.98 kJ mol^{-1} for naphthalene.

Combustion calorimetry. The micro combustion calorimeter as well as the calorimetric procedure were identical to those described in Ref. 3. Details of the combustion measurements on DMN have already been given together with the resulting standard energy of combustion for the crystalline material.[3] In the combustion experiments on TMN the initial pressure of oxygen, $p^i(O_2)$, varied around 35 atm;* for DMN it was 31 atm. Five experiments were performed on TMN; in one a small correction for unburned carbon had to be applied. The energy equivalent of the calorimetric system was determined by combustion of benzoic acid; series III in Ref. 3. The constancy of the calibration was checked by performing electrical calibrations in three of the runs on TMN; (for an account of the agreement between benzoic acid and electrical calibrations *cf.* Ref. 3).

All weighings of sample were made on a Mettler M5 micro balance, which had been carefully calibrated against standard weights,[3] calibrated at the National Bureau of Standards. The weighings have been reduced to masses and molar masses computed from the 1969 table of atomic weights.[11] The corrections to standard states, ΔU_Σ, were calculated using a computer program based on the procedure by Hubbard *et al.*[12] The estimated values for c_p and $(\partial v/\partial T)_p$ were the same as those in Ref. 3. The final overall precision of the ΔU_c° mean values was estimated as recommended by Rossini.[13] The reference temperature of the combustion experiments is 298.15 K.

Vaporization calorimetry. The enthalpies of sublimation at 298.15 K were measured using the Morawetz calorimeter.[4] Five determinations were made on DMN following the procedure described in Ref. 4, with around 13 mg evaporated per experiment.

Heating the vaporization calorimeter to temperatures above ~335 K was not considered "safe" and TMN therefore could not be melted directly into the evaporation pan. Furthermore, the compound could only be sublimed into the calorimeter at a very slow rate. Instead TMN was melted into a thin-walled gold cup that was then "soldered" to the evaporation chamber with gallium. Four test experiments on octadecane yielded (153.6 ± 1.1) kJ mol^{-1} (mean and standard deviation of the mean); literature values are 153.1 [14] and 152.7 [15] kJ mol^{-1}. When three successful vaporization experiments had been performed on TMN the calorimeter as such failed and further measurements had to be postponed. The sublimation enthalpy reported here is the mean value from these three determinations. Around 2.5 mg of TMN had evaporated per experiment. In the evaluation of the overall uncertainty of the enthalpy of sublimation for TMN, the standard deviation of the measured mean value, 0.40 kJ mol^{-1}, was raised to 0.60 kJ mol^{-1} to allow for a possible systematic error in this particular series of measurements.

RESULTS AND DISCUSSION

The results from the combustion experiments on TMN are given in Table 1, with Δu_c° referring to unit mass of sample. For DMN the corresponding mean value and standard deviation of the mean is Δu_c°(DMN) = −(41323 ± 5) J g^{-1}.[3] The Δu_c° values refer to the idealized combustion reaction in which all reactants and products are in their thermodynamic standard states at 298.15 K. Table 2 gives the standard molar energies, ΔU_c°, and enthalpies, ΔH_c°, of combustion for the compounds in the crystalline state at 298.15 K. Also listed in Table 2 are the molar enthalpies of sublimation, ΔH_{subl}, and derived enthalpies of formation, ΔH_f°, for the compounds in the crystalline and gaseous states (298.15 K). The enthalpies of formation at

* 1 atm = 101.325 kPa.

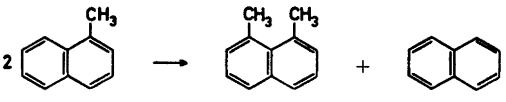
ΔH_f°(g)/kcal mol^{-1}	$26.0_1 \pm 0.7_2$	$19.5_0 \pm 0.8_7$

298.15 K for gaseous carbon dioxide and liquid water used in the calculations are from Ref. 16.

The selected standard enthalpy of formation for gaseous naphthalene [17] becomes $35.9_9 \pm 0.2_5$ kcal mol^{-1} * when two recent determinations of its enthalpy of sublimation [18,19] are taken into account. In the series naphthalene, 1,8-DMN, 1,4,5,8-TMN the increments in the gaseous enthalpies of formation are −(10.0 ± 0.7) and −(6.5 ± 1.0) kcal mol^{-1}, respectively.** This means that the di-*peri* substitution causes a strain that is $3._5$ kcal mol^{-1} larger than what might have been predicted on the basis of results for the mono-*peri* compound alone. Since the structures of these particular compounds are not yet known this result cannot be rationalized in terms of, *e.g.*, molecular deformations.

The absolute values of the strain introduced by the methyl-methyl *peri* interactions can be evaluated in a number of more or less equivalent ways. For instance, the average increment in the gas phase standard enthalpy of formation for methyl substitution in the series benzene, toluene, *m*-xylene, 1,3,5-trimethylbenzene [5–7] is equal to −7.87 kcal mol^{-1}. This increment, combined with the enthalpy of formation of naphthalene, can be used to calculate enthalpies of formation for unstrained di- and tetramethylnaphthalenes. The values obtained are $20._3$ and $4._5$ kcal mol^{-1}, respectively, implying that the *peri* strain in 1,8-DMN is $5._7$ kcal mol^{-1}, whereas it amounts to as much as $15._0$ kcal mol^{-1} in 1,4,5,8-TMN.

The enthalpy change for the isomerization reaction



is a direct measure of the strain in 1,8-DMN, since 1-methylnaphthalene as well as naphthalene in this context are to be considered as

* To facilitate comparisons with other results in the literature the discussion of the final results will be in terms of *calories* rather than the SI unit *Joule*.

** Unless otherwise stated the uncertainties are twice the final overall standard deviation of the mean. The enthalpy of formation differences can be calculated almost directly from the differences in combustion and vaporization enthalpies and therefore the overall uncertainties in these quantities were used in such calculations.

unstrained.* The *peri* strain energy calculated in this way is ($6._2 \pm 1._4$) kcal mol^{-1}. The similarly calculated *peri* strain in 1,4,5,8-TMN is ($15._8 \pm 2._8$) kcal mol^{-1}.

Added in proof. A recent study of the crystal structure of 1,8-DMN by D. Bright, I. E. Maxwell and J. de Boer (*J. Chem. Soc. Perkin Trans. 2* (1973) 2101), in connection with strain energy minimization calculations, shows that the repulsive interaction between the *peri* methyl groups is reduced mainly by bond-angle distortion at the junction between the methyl groups and the naphthalene nucleus. The inner angles are increased from the ideal 120° to almost 125°. The naphthalene skeleton, however, remains planar and there is no detectable out-of-plane displacement of the methyl groups. These are found to be in the fixed orientation, where four of the methyl hydrogens face each other in pairs, and the remaining two practically lie in the plane of the aromatic rings. The *peri* 4,5-hydrogens are found to be bent towards one another, such that the distance between them is reduced to 2.17 Å (from 2.43 Å). The results from the strain energy minimization calculations are in good agreement with the observed molecular geometry, except that they do not reproduce the "bending" of the *peri* 4,5-hydrogens.

Considering the general features of the 1,8-DMN structure, it seems reasonable that the second *peri* dimethyl substitution should be more costly than the first, in agreement with the calorimetric studies. A comparison between the numerical values of the minimization-calculated and the thermochemically derived strain energies is not meaningful, since the reference systems are not directly comparable.

Acknowledgements. The excellent assistance of Miss Monica Andersson, who performed many of the combustion measurements, and of Mrs. Stina Bergström and Mrs. Gunilla Gräntz, who made the vaporization experiments, is gratefully acknowledged.

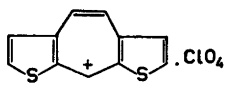
X-Ray Crystallographic Studies on Cycloheptadithiophene Compounds and Similar Systems I. The Crystal Structure of Dithieno[2,1-*b*;4,5-*b*′]tropylium Perchlorate

BENGT AURIVILLIUS

Division of Inorganic Chemistry 2, Chemical Center, University of Lund, Box 740, S-220 07 Lund 7, Sweden

The crystal structure of a dithienotropylium perchlorate



has been investigated by X-ray diffraction methods. The substance is monoclinic, space group $P2_1/n$ with four formula units $C_{11}H_7S_2 \cdot ClO_4$ in a unit cell of dimensions $a = 6.819$, $b = 12.032$, $c = 14.677$ Å and $\beta = 93.60°$. The intensity data were collected by means of an integrating Weissenberg camera and the intensities were estimated visually. The structure was refined to a final R factor of 0.08 for 882 observed reflections. The crystal structure is built up from layers of dithienotropylium cations interleaved by perchlorate ions. As for many other organic salts the oxygen atoms of the perchlorate ion are disordered. The dithienotropylium cation is essentially planar; the largest deviations from the best plane are 0.05 Å and occur for the two sulfur atoms. A few short intermolecular distances exist, one of them being a sulfur–perchlorate oxygen distance of 3.03(3) Å.

The aromaticity of a number of cycloheptadithiophene compounds and also corresponding dithioborepines has been investigated by Gronowitz and co-workers.[1,2] They found that the dithieno[2,1-*b*;4,5-*b*′]tropylium ion was unusually stable, having a pK_{R^+} value of 6.65, while the dibenzotropylium ion has a pK_{R^+} value of only −1.5. They suggested that one of the factors contributing to the higher stability of the thiophene derivative was the absence of *peri* effects between the sulfur atoms and the 9-hydrogen, allowing the three rings to be almost coplanar. Ring strain effects were also assumed to be smaller in the thiophene case. It was therefore of great interest to obtain a detailed knowledge of the bonding distances within the various molecules and ions. One way to obtain the information wanted is to study the solid state of the compounds by means of X-ray diffraction methods. The present and a few following papers will report the results as obtained from studies on single crystals of the various substances.

The present paper deals with the crystal structure of dithieno[2,1-*b*;4,5-*b*′]tropylium perchlorate. For the sake of brevity the actual substance will be called dithienotropylium perchlorate in the following.

X-RAY DIFFRACTION WORK

A small single crystal, kindly supplied by Dr. B. Yom-Tov, was mounted with [001] as rotation axis and the layers 0–10 were registered by means of an integrating Weissenberg camera using Cu$K\alpha$ radiation. The symmetry was found to be monoclinic. The following conditions limiting possible reflections were found:
hkl, no conditions; $h0l$, $h+l=2n$; $0k0$, $k=2n$.
These conditions are characteristic of the space group $P2_1/n$ (No. 14).*

* Orientation different from that given in the International Tables. General point position 4(*e*): x,y,z; $\frac{1}{2}-x, \frac{1}{2}+y, \frac{1}{2}-z$; $\bar{x},\bar{y},\bar{z}$; $\frac{1}{2}+x, \frac{1}{2}-y, \frac{1}{2}+z$.

Table 1. Crystal data for dithienotropylium perchlorate.

Dithienotropylium perchlorate $C_{11}H_7S_2.ClO_4$.
F.W. = 302.7

Monoclinic, $P2_1/n$, $a = 6.819(2)$, $b = 12.032(4)$, $c = 14.667(6)$ Å, $\beta = 93.60(3)°$, $V = 1201(1)$ Å^3.
$Z = 4$.

$D_m = 1.79$, $D_x = 1.68$ g cm^{-3}, $\mu(\mathrm{Cu}K\alpha) = 64.0$

The multiple film technique was used and the intensities were estimated visually using a calibrated scale. The number of observed independent reflections were 882. As the crystal was small and as the value of the linear absorption coefficients was 64.0 cm^{-1}, no absorption correction was performed.

X-Ray powder diffraction photographs were recorded in a Guinier-Hägg focusing camera with $\mathrm{Cu}K\alpha_1$ radiation and potassium chloride ($a = 6.2909$ Å) added as an internal standard. The lattice parameters were obtained with the aid of least-squares calculations. The density of the crystals was determined by flotation. Some crystal data of the compound are given in Table 1.

DETERMINATION AND REFINEMENT OF THE STRUCTURE

The positions of the eight sulfur and four chlorine atoms of the unit cell were deduced from a three-dimensional Patterson function. Using conventional procedures the positions of all non-hydrogen atoms of the cation $C_{11}H_7S_2^+$ and of one of the oxygen atoms (O1) of the perchlorate group were immediately found from difference Fourier maps. As the rest of the perchlorate oxygen atoms did not turn up it was concluded that the perchlorate ion is disordered. The disorder may either be such that the perchlorate ion "rotates" with Cl – O1 as an axis or such that the remaining three oxygen atoms occupy sets of preferred orientations.

Successive least-squares refinements followed by difference Fourier calculations revealed the positions of five more oxygen atoms, *viz.* O2 – O6. The atoms O1, O2, O3, and O4 form one tetrahedron and the atoms O1, O5, and O6 form part of another tetrahedron of oxygens around chlorine. The position of the missing oxygen atom (O7) of the last tetrahedron was deduced by geometrical considerations and was afterwards found to correspond to a peak of moderate height in the last difference Fourier maps.

In a least-squares refinement the isotropic temperature factors found for the oxygen atoms O2 – O7 indicated the occupancy numbers to be 0.6 for O2 – O4 and 0.4 for O5 – O7. No further refinement of the occupancy numbers was made.

A refinement of the positional and thermal parameters of all atoms, using anisotropic temperature factors resulted in a conventional R factor of 0.088. A stereo picture of the perchlorate ion as obtained from the calculations is given in Fig. 1.

Difference Fourier maps based on positional and thermal parameters obtained above revealed the positions of the seven hydrogens of the organic molecule. A least-squares refinement of all atoms using fixed isotropic temperature factors ($B = 4.0$ Å^2) for the hydrogen atoms gave an R factor of 0.080. Thus a small improvement in the discrepancy factor was attained when introducing the positions of the hydrogen atoms in the calculations. However, not all atoms converged at this calculation. Therefore a new refinement was performed where the positions of the hydrogens were fixed at the values obtained above. All parameters of the non-hydrogen atoms now converged. Only small shifts in the parameters were obtained and the R factor did not change.

Fig. 1. Ortep stereoscopic view of the two preferred orientations of the perchlorate ion in dithienotropylium perchlorate.

Table 2. Analysis of the weighting scheme used in the last cycle of least-squares refinement. The averages $w(|F_o|-|F_c|)^2=\overline{w\Delta^2}$ are normalized. $w=(8.0+|F_o|+0.03|F_o|^2)^{-1}$.

The atomic scattering factors used were those suggested by Hanson, Herman, Lea and Skillman.[3] In the last refinement the expression $w=(8.0+|F_o|+0.03|F_o|^2)^{-1}$ was used for the calculation of the weights. The final weighting scheme is given in Table 2 and the final positional and thermal parameters in Table 3. On request to the author lists of observed and calculated structure factors are available from the Division of Inorganic Chemistry 2.

DESCRIPTION AND DISCUSSION OF THE STRUCTURE

The crystal structure of dithienotropylium perchlorate is built up from layers of dithienotropylium cations interleaved by perchlorate ions. The cation layers extend in each unit cell in the planes $z = 0$ and $z = \frac{1}{2}$. The chlorine atoms of the perchlorate ions are situated close to the planes $z = \frac{1}{4}$ and $z = \frac{3}{4}$. The perchlorate oxygen atoms are disordered probably in such a way that two orientations are preferred (*cf.* Fig. 1). Pertinent distances and angles for the perchlorate ion are summarized in Table 4.

As has been stated previously [4] the dithienotropylium cations are nearly planar, the largest deviations from the best plane being about 0.05 Å. A detailed analysis of the planarity of the cation is given in Table 5. Fig. 2 shows the

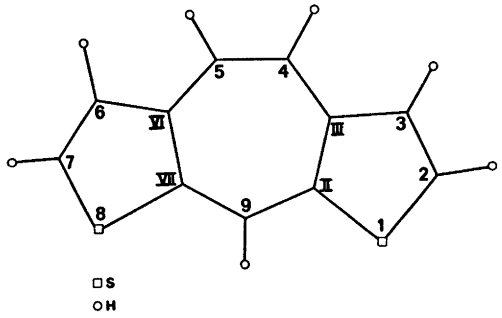

Fig. 2. Applied numbering of the atoms of the dithienotropylium cation.

applied numbering of the atoms of the dithienotropylium cation. The *e.s.d.*'s of the positions of the sulfur atoms are ~0.004 Å and of the carbon atoms ~0.013 Å. It is seen from Table 5 that for each of the separate rings, the thiophene rings and the tropylium ring, respectively, no deviation exceeds 2.0σ for the respective atom. Thus each of the rings now discussed may be considered to be planar. Taking the ring system of the cation as a whole, the carbon atoms deviate at most 3σ from the best plane whereas the sulfur atoms deviate about 10σ. Nearly the same result is obtained if the two sulfur atoms are included in the least-squares calculations of the best planes.

To sum up, each separate ring in the dithienotropylium cation may be considered to be planar but the ring as a whole shows a small deviation from planarity.

Fig. 3 shows the dithienotropylium cation projected perpendicularly on its best plane.

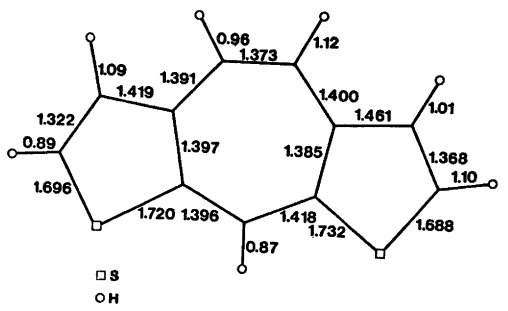

Fig. 3a. Pertinent distances within the dithienotropylium cation. Mean values of the *e.s.d.*'s are 0.012 Å for C–S distances, 0.016 Å for C–C distances and 0.14 Å for C–H distances.

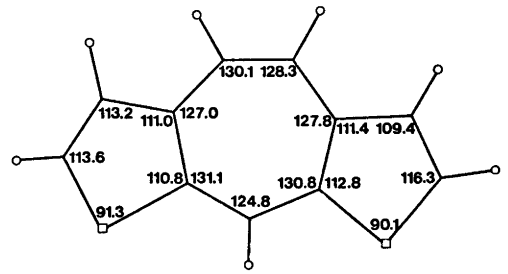

Fig. 3b. Pertinent angles for the non-hydrogen atoms of the dithienotropylium cation. Mean values of *e.s.d.*'s are 0.6° for angles with S at the centre and 1.0° for other angles formed between nonhydrogen atoms.

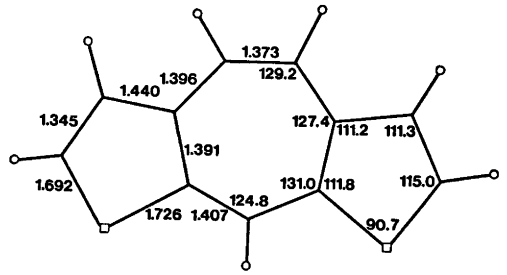

Fig. 3c. Mean values of distances and angles for the two halves of the dithienotropylium cation. For *e.s.d.*'s, *cf.* Table 6.

Table 5. Best least-squares planes through the S1 thiophene ring, the S8 thiophene ring, the tropylium ring and the complete dithienotropylium cation (*cf.* Fig. 2). Distances (Å) of all non-hydrogen atoms to the best plane of the respective ring are given. All non-hydrogen atoms are used to determine the best planes, except for the complete ion where the sulfur atoms are excluded from the calculations. The best planes are calculated according to Blow [10] and the result is given in the form: $lx'+my'+nz'+p=0$. All atoms used for the computations are ascribed unit weights.

Interatomic distances and angles are given in the drawings (Figs. 3a – c)

It is seen from Figs. 3a and 3b that the cation, besides being nearly planar, also has an approximate mirror plane passing through the atom C9 and the midpoint of the line C4 – C5 (*cf.* Fig. 2). Whereas the differences between equivalent distances are at most possibly significant, the angles show one significant difference $\Delta/\sigma=2.5$. The author has, however, chosen to neglect this difference. Mean values and their *e.s.d.*'s have been calculated for the two halves of the cation, which implies an overestimation of the *e.s.d.*'s hitherto used by a factor of about 1.2 (Table 6, Fig. 3c).

Though the precision of the present investigation is not so high, a few conclusions may be drawn from Table 6. The annealed formal double bonds of the thiophene rings (CIII – CII, CVI – CVII) are on the average slightly longer than the other formal double bonds of the ring (C2 – C3, C6 – C7) (*cf.* Fig. 2). The sulfur-tropylium carbon distances (S1 – CII, S8 – CVII) are on the average slightly longer than the thiophenic ones (S1 – C2, S8 – C7). It might be mentioned that the same situation is met with in the crystal structure of the related compound bis-9-(diethieno[2,3-*b*;3′,2′-*f*]borepinyl)ether. (The structure will soon be published by the present author.) Similar disparities of the C – S bonds in thiophene derivatives have, among others, been discussed by Goldberg and Shmueli.[5] They state that the longer of the C – S bonds is that connecting sulphur to the

Table 6. Mean values of distances and angles for the two nearly identical halves of the dithienotropylium cation. *E.s.d.*'s are given within parentheses. A comparison is also made between the distances of the averaged thiophene rings in the present compound and of the thiophene ring in α-thiophenecarboxylic acid.[6] The latter molecule is oriented so that the carbon atom outside the thiophenic ring corresponds to the atom C9 in the present compound.

Atoms	Distance (Å) Mean value	Corresponding value in α-thiophene-carboxylic acid
S1 – C2 S8 – C7	1.692(11)	1.701(10)

CIII – C4 – C5 CVI – C5 – C4	129.2(9)	
CII – C9 – CVII	124.8(11)	

carbon atom that seems to be more actively engaged in the π-delocalization (*viz.* the tropylium carbon atoms in the present compound).

The mean values of the distances and angles in the thiophene groups of the present compound are also compared to the corresponding values published for α-thiophene-carboxylic acid [6] in Table 6. It is seen that the averages of the sulfur-tropylium carbon distances are slightly longer than the sulfur – carbon distances in the carboxylic acid. No explanation can at the moment be given for the difference found in the angle at the non-fused thiophenic α-position in the present compound and in the carboxylic acid.

The positive charge of the C9 atom of the present compound is supposed to be delocalized over the whole cation, the β-thiophenic positions (C3, C6) being less positive than the other atoms.[4] More or less ionic interactions would therefore be expected between the perchlorate oxygen atoms and all of the non-hydrogen atoms of the dithienotropylium cation. Fig. 4 shows C – O contacts less than 3.2 Å and S – O contacts less than 3.3 Å for one cation. As seen, the C – O contacts fall in the range 3.06 – 3.11 Å. They are thus slightly shorter than or equal to the sum of the van der Waals radii, 3.1 Å. A somewhat similar situation arises in the crystal structure of succinylcholine perchlorate.[7] Here the positive charges of the quaternary ammonium groups are delocalized from the nitrogen atoms and weak ionic interactions occur between the carbonyl carbon atoms and the oxygen atoms of the perchlorate group. The corresponding C – O distances are 3.05 Å.

One of the distances between sulfur and a perchlorate oxygen atom in the present compound is quite short, 3.03 Å. However, S – O distances of the same magnitude, 3.02 and 3.04 Å, are found in the crystal structure of 5*H*,8*H*-dibenzo[*d*,*f*][1,2]-dithiocin-1,1-dioxide.[8] Likewise, a short S – O distance, 3.04 Å, exists in the crystal structure of phenylamino-2-phenyl-5-thiazolinone-4.[9] In the compounds just discussed the interactions do not seem to be of an ionic character.

Thus if there are ionic interactions between the atoms of the dithienotropylium cation and the perchlorate oxygen atoms, these interactions are weak.

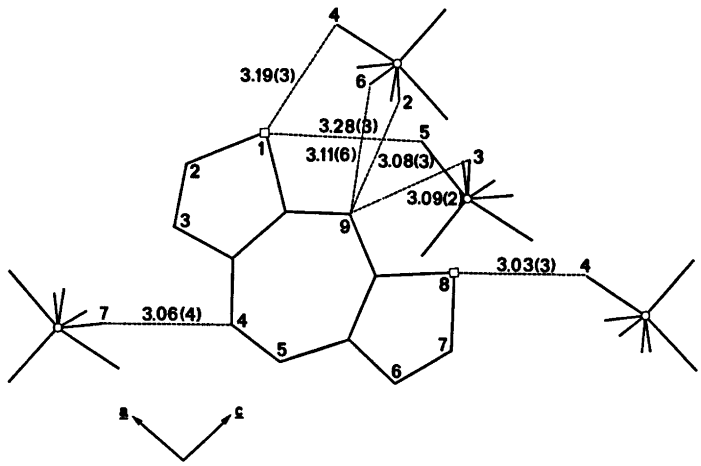

Fig. 4. The atoms of dithienotropylium perchlorate are projected on the *ac* plane along the *b* axis. Short contacts (Å) between the atoms of one dithienotropylium cation and the oxygen atoms of neighbouring perchlorate groups are indicated by dashed lines. The perchlorate oxygen atoms at the ends of the dashed lines are numbered according to Table 3a. *E.s.d.*'s in the distances are given within parentheses.

Short Communications

A Study of the Ca—Na Salt of α-D-Galacturonic Acid by X-Ray Diffraction

JOHAN HJORTÅS,[a] BJØRN LARSEN[b] and SRINUAN THANOMKUL[a*]

[a] Institutt for røntgenteknikk and [b] Institutt for marin biokjemi, Universitetet i Trondheim-NTH, N-7034 Trondheim-NTH, Norway

The studies of α-D-galacturonic acid derivatives, previously initiated with a structure determination of the methyl α-D-galacturonic acid methyl ester,[1] have been continued with an investigation of the Ca—Na salt, some preliminary results of which are given here.

Ca—Na-α-D-galacturonate was prepared by careful neutralization of an aqueous solution of α-D-galacturonic acid with $Ca(OH)_2$ to pH 6. The solution was then evaporated to crystallization and the product recrystallized from water at approximately 40 °C.**

Crystal data are: $2Ca^{2+}+2Na^{+}(C_6H_9O_7)_6^{-}.12H_2O$, hexagonal space group $P6_3$, cell dimension (with estimated standard deviations in parentheses) $a = 13.493(2)$ Å, $c = 9.655(2)$ Å, measured density 1.665 g cm^{-3}, calculated density 1.636 g cm^{-3}.

1077 reflexions with intensity greater than twice the background were observed on an automatic Picker FACS-1 diffractometer, using Mo$K\alpha$ radiation and the $\omega/2\theta$ scanning mode with max. $2\theta = 50°$. The Ca and Na positions were obtained from a 3-dimensional Patterson map. The C and O atoms were found by successive Fourier calculations. Full matrix least squares refinement,[2] with isotropic temperature factors for the Ca, O, and C atoms, has yielded the conventional R index of 0.091. A projection of the molecule along the c axis is shown in Fig. 1.

The Ca atoms occupy positions on the 3-fold axes and are caged by O(5) and O(7) from the galacturonate molecule and O(w1) from a water molecule, with Ca—O distances of 2.83, 2.39, and 2.43 Å, respectively. Due to the multiplicity of the axis the coordination around Ca is 9-fold. The Na atom on the 6_3 axis has O(2) and O(3) from the ring as nearest neighbours at distances of 2.36 and 2.50 Å, respectively. The coordination of Na is six-fold. Further refinement is in progress.

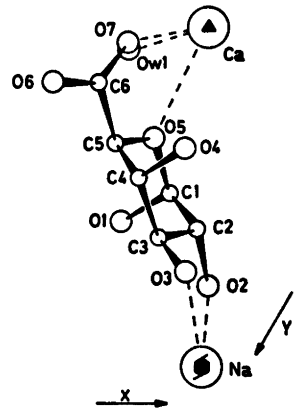

Fig. 1. Projection of the molecule along the c axis.

** We originally planned to make the Ca salt but the product turned out to be the Ca—Na salt in low yield, the Na atoms probably coming from contamination. We later crystallized the Ca—Na salt from equal amounts of $Ca(OH)_2$ and NaOH and the crystals are identical to those previously obtained.

The Mutarotation of D-Glucose and Its Dependence on Solvent. III. The Existence of α- and β-D-Glucofuranose in *N,N*-Dimethylformamide

ANDREAS REINE,[a] JOHAN A. HVEDING,[a] OVE KJØLBERG [a] and OLA WESTBYE [b]

[a] Department of Chemistry, University of Oslo, Oslo 3, Norway and [b] Department of Pharmacology and Toxicology, The Veterinary College of Norway, Oslo Dep., Norway

Few authors have hitherto been concerned with the behaviour of D-glucose in *N,N*-dimethylformamide (DMF). Kuhn and Grassner [1] assume that the mutarotation almost exclusively is due to a pyranose-furanose conversion, while Jacin *et al.*[2] from their GLC investigations conclude that no anomerization had occurred during their experimental time. Our polarimetric observations are not compatible with any of the above statements. The plot of ln $([\gamma_t]-[\gamma\infty])$ against time always showed a significant deviation from a straight line at the experimental temperatures 20, 30, and 40 °C.[3] The rate of rotational change in thoroughly purified DMF (see Experimental) is extremely low, but was found to be very sensitive to the degree of purity. The shape of the mutarotation curves for both α- and β-D-glucose in DMF is similar to that described for the corresponding anomers of D-galactose in water.[4] Also the "thermal" mutarotation was found to be complex in analogy with that found for D-galactose in water.[5,6]

The observed deviation from a simple logarithmic law can be explained by the formation of the furanose anomers. In a preliminary communication [7] we have described the presence of D-glucofuranose, detected as trimethylsilyl

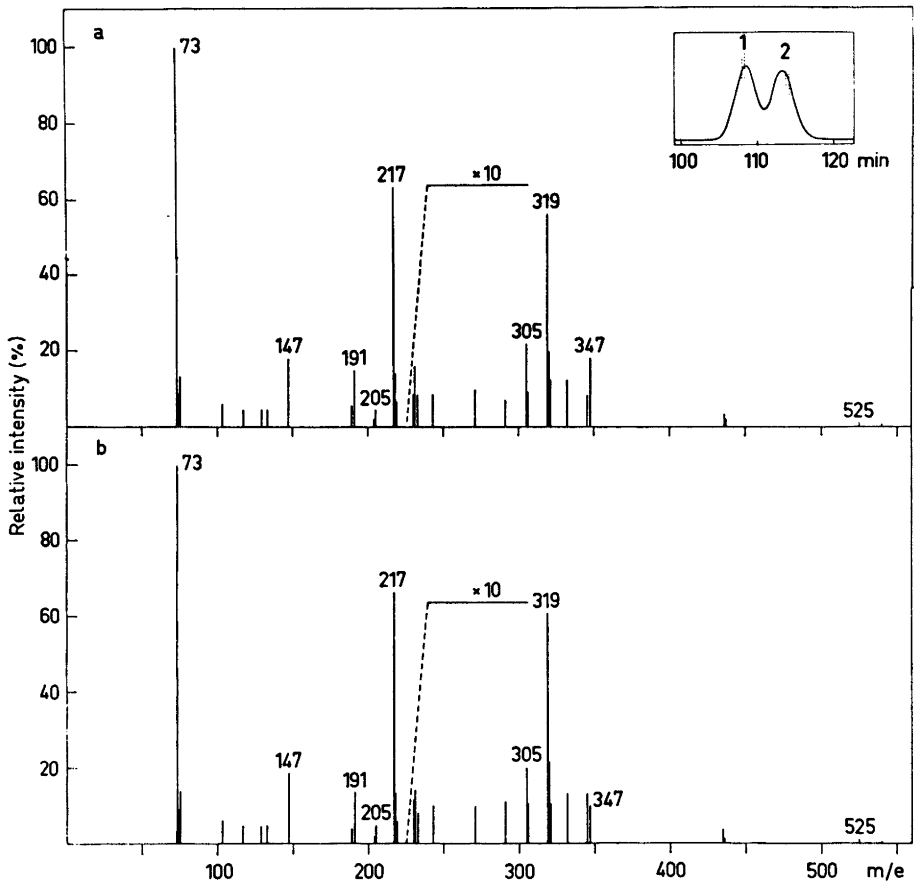

Fig. 1. Gas chromatographic separation and mass spectra of the two fastest moving persilylated tautomers of D-glucose. The partial mass spectra a and b are taken from peaks 1 and 2, respectively. The scan periods are indicated by broken lines in the chromatogram.

(TMS) derivative, in the equilibrium mixture (70 °C). We now report the existence of both α- and β-D-glucofuranose in this mixture. Using OV-17 as the stationary phase the previously described mixture of TMS derivatives was resolved into two minor peaks (1 and 2) and two major peaks (3 and 4). The relative retention times of these peaks were 0.76, 0.79, 1.00, and 1.65, respectively. The peaks 3 and 4 were, by the same methods as described earlier,[7] found to represent the α- and β-pyranosides, respectively. The gas chromatographic separation of peaks 1 and 2 in the GCMS analysis is shown in Fig. 1 along with partial mass spectra of these components. The two spectra (M^+ 540, 0.1 %) are nearly identical and show the characteristic differences from those of the pyranoses.[8,9] To establish which of peaks 1 and 2 represents the α- and which the β-anomer a separation was made by GLC on a preparative scale. To avoid a large α-pyranoid peak a mixture obtained by tautomerization of β-D-glucose at 70 °C for 1.5 min was used for this purpose. As the retention times of the two furanoid forms differ very little, they appeared as one broad peak under the preparative conditions. An NMR spectrum of a fraction collected from the first half of this peak showed a strong singlet at δ 5.04 and a weak doublet at δ 5.34, both being in the region ascribed to the anomeric protons. A fraction collected from the last half of the peak showed the same singlet and doublet, but both had approximately the same intensity. With the possible dihedral angles between neighbouring *cis*-hydrogens and between neighbouring *trans*-hydrogens in furanoid rings [10] the Karplus equation leads to the conclusion that the singlet only can be attributed to a β-furanoside. The α-furanoside should give a doublet. We judge our observations to indicate that peaks 1 and 2 represent the β- and α-furanoid form of TMS-glucose, respectively.

The total amount of furanose at 70 °C is calculated to be about 4.5 % of the total sugar content. This furanose proportion was found to develope in the first minutes of the mutarotation. This is in agreement with the many observations that in the ring formation of a sugar a five-membered ring is kinetically favourable while normally the six-membered ring is thermodynamically most stable. The mutarotation of D-glucose may have a complex character also in other organic solvents. It is of interest in this connection to note that the behaviour of D-glucose in ethylene glycol has been found to be "anormal".[11]

Experimental. The D-glucose products and *N*,*N*-dimethylformamide were those described earlier.[3] Purification of the DMF was obtained by filtration through Molecular Sieves (Union Carbide, 4A and 5A).

The polarimeter and the thermostats were as described in part I.[3] For the analytical studies a Hewlett Packard 5700A gas chromatograph equipped with a flame-ionization detector was used, while a Varian Aerograph 200 with a thermal conductivity detector was used for the preparative separation. The GLC-mass spectrometry was carried out on an LKB 9000 mass spectrometer. The column packing material was 10 % OV-17 on Chromosorb W (60 – 80 mesh, HMDS-treated for GLC and AW-DMCS for GCMS). For the analytical GLC an aluminium column (3 m × 3 mm) was maintained at 145 °C. The preparative GLC was carried out on a stainless steel column (1.5 m × 6 mm) at 150 °C and the separation for the mass spectrometer on a glass column (4 m × 6 mm) at 150 °C. The ion source block was maintained at 250 °C, the molecular separator at 190 °C, and the ionizing energy was 70 eV.

The NMR spectra ($CDCl_3$) were recorded on a Varian HA-100-15-D spectrometer operating at 98 MHz. Tetramethylsilane (TMS) was used as internal standard.

The mutarotation experiments were carried out as described previously.[3] For the preparation of the TMS derivatives the solutions (1 g/100 ml), still kept at the mutarotation temperature, were treated with trimethylchlorosilane and hexamethyldisilazane in the proportions described by Sweeley *et al.*[12] The reaction mixtures were stored for 8 h at room temperature in order to obtain full silylation, as short silylation time gave extra peaks in the chromatogram. The precipitated salts were removed by decantation, and the solutions were concentrated *in vacuo*. The sugar derivatives were extracted with hexane prior to injections into the gas chromatograph.

Some Benzylseleno- and β-Phenylethylseleno-substituted Alkanoic Acids

ARNE FREDGA

Department of Organic Chemistry, University of Uppsala, Box 531, S-751 21 Uppsala 1, Sweden

The title compounds have been prepared for two reasons. The original purpose was to test their activity in preventing dietary liver necrosis in rats (factor-3-effect) [1-4] and to study the influence of structural factors, *e.g.* the distance between the selenium atom and the carboxyl group, and the presence of substituents in the benzene nucleus. This part of the work has been carried out in collaboration with Professor Klaus Schwarz * and the results have in part been published.[5,6]

The compounds have also found use for studying the NMR-effects of the isotope ^{77}Se.

* Laboratory of Experimental Metabolic Diseases, Veterans Administration Hospital, Long Beach, California, and Department of Biological Chemistry, School of Medicine, University of California in Los Angeles.

These investigations were carried out in collaboration with Professor Salo Gronowitz and his group * and the results will be published elsewhere.

The present paper describes 38 acids (compounds I – IV and higher homologues). Three of these acids have been mentioned in earlier publications.[7,8] Since compounds of the types II and IV were found to be of minor interest regarding the factor-3-effect, only a limited number of these acids were prepared. The data are summarized in Tables 1 – 4.

$C_6H_5-CH_2-Se-CH_2-COOH$ (I)
$4\text{-}CH_3-C_6H_4-CH_2-Se-CH_2-COOH$ (II)
$4\text{-}Br-C_6H_4-CH_2-Se-CH_2-COOH$ (III)
$C_6H_5-CH_2-CH_2-Se-CH_2-COOH$ (IV)

In earlier papers, a number of naphthylmethylseleno acids [9] and nitro-substituted acids [10] have been reported.

Experimental. Diseleno-dicarboxylic acids were reduced in alkaline solution to selenol-substituted acids. These were not isolated but directly reacted with the appropriate chlorides or bromides. For the reduction, four methods have been used:

(1) Reduction with formaldehyde-sulphoxylate (rongalite) in aqueous ammonia.[9]

(2) Reduction with zinc powder in aqueous ammonia.[9]

(3) Reduction with sodium amalgam: the solution of the diselenide acid is stirred with the amalgam and the halogen compound is gradually added.[8]

(4) The diselenide acid is converted to mercury selenolate by shaking with metallic mercury in a suitable solvent.[11,12] The mercury selenolate acid is dissolved in slightly alkaline

Table 4. (β-Phenylethylseleno)-alkanoic acids.

Acid	m.p. °C	Calculated C	H	Se	Found C	H	Se

					59.76	7.64	23.09

solution and the mercury is precipitated by adding an equivalent quantity of sodium sulphide ($Na_2S.12H_2O$) and shaking for some hours.[7]

Method 1 is generally most convenient and has been used for the majority of the compounds. Methods 3 and 4 can be used when foreign ions (zinc, sulphite) are not desirable. The procedure has been described in more detail in earlier papers.[7–9] A further example is given below.

11-(Benzylseleno)-undecanoic acid. Diseleno-11,11′-diundecanoic acid (6.7 g, 0.0125 mol) is placed in a strong flask or bottle of about 300 ml. Concentrated aqueous ammonia (75 ml) and water (25 ml) is added; since the ammonium salt of the acid is sparingly soluble in water, ethanol must be added with shaking to obtain a clear solution. Rongalite in slight excess is then added; if the solution is still yellow after 15 – 20 min, additional small amounts are added until the solution is quite colourless. The calculated amount of benzyl chloride (3.2 g, 0.025 mol), dissolved in 50 ml ethanol is finally added and the mixture is shaken until the milky suspension is practically clear. If the solution is yellow (due to partial oxidation to diselenide by the halogen compound), it is decolourised by adding some rongalite, after which a little benzyl chloride is added. Sometimes this operation must be repeated. A moderate excess of benzyl chloride is not harmful since it is converted to benzylamine by the ammonia. The solution is left to stand overnight.

The ethanol is then evaporated by a fan or a current of air, ammonia is added to strongly alkaline reaction and the solution is diluted to about 300 ml and finally shaken with ether to remove non-acidic impurities. The dissolved ether is removed by a current of air and the acid is precipitated by excess hydrochloric acid. The acid is obtained as a rapidly crystallising oil and recrystallised, first from formic acid (diluted with a little water) and then from ligroin or carbon tetrachloride. M.p. 67 – 68 °C. The yield of crude product is practically 100 %. Analyses see Table 1.

Acknowledgements. The analyses were carried out by the Analytical Department of the Institute. The author is greatly indebted to Mr. Ragnar Öhberg for preparing starting materials. Thanks are also due to Boliden AB for generous gifts of selenium. Comparisons of Circular Dichroism in Liquid Solution and in the Crystal State with Reference to Conformations of 3,3′-Bithienyls

R. HÅKANSSON,[a] B. NORDÉN[b] and E. WIKLUND[a]

[a]Department of Organic Chemistry and [b]Department of Inorganic Chemistry, University of Lund, Chemical Center, P. O. Box 740, S-220 07 Lund 7, Sweden

The electronic structures as well as the nuclear arrangements in bithienyls have been the subject of recent studies by several workers, in the gas, liquid, and solid states.[1–7] However, in contrast to the corresponding biaryls,[8–10] which have a higher *quasi*-symmetry, no complete theory has been developed for the origin of the optical activity of the resolvable 3,3′-bithienyls. Consequently, the use of circular dichroism (CD) has been in general restricted to decisions between the two possible absolute configurations, on an empirical basis.[7] A correlation of the CD with a more precise structural assignment requires either a bridged compound [11,12] in which the conformation can be estimated from molecular models, or an independent structure determination.

In this paper we wish to report that the CD spectrum of 4,4′-dibromo-2,2′-dicarbomethoxy-3,3′-bithienyl (I) and that of 2,2′-dibromo-4,4′-dicarbomethoxy-3,3′-bithienyl (II), as obtained by the randomised crystal powder technique [13] on crystal fractions previously used in an X-ray structure determination,[4] closely resemble the corresponding solution CD spectra (Figs. 1 – 2).

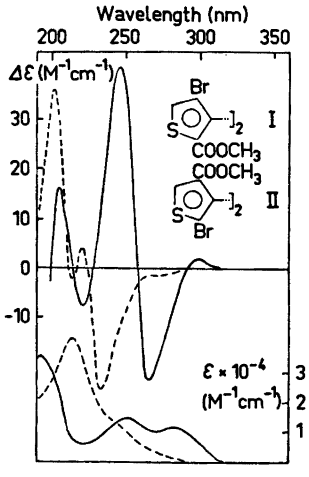

Fig. 1. Liquid solution (acetonitrile) CD and UV spectra of $R(+)$I ——— and $R(-)$ II – – –.

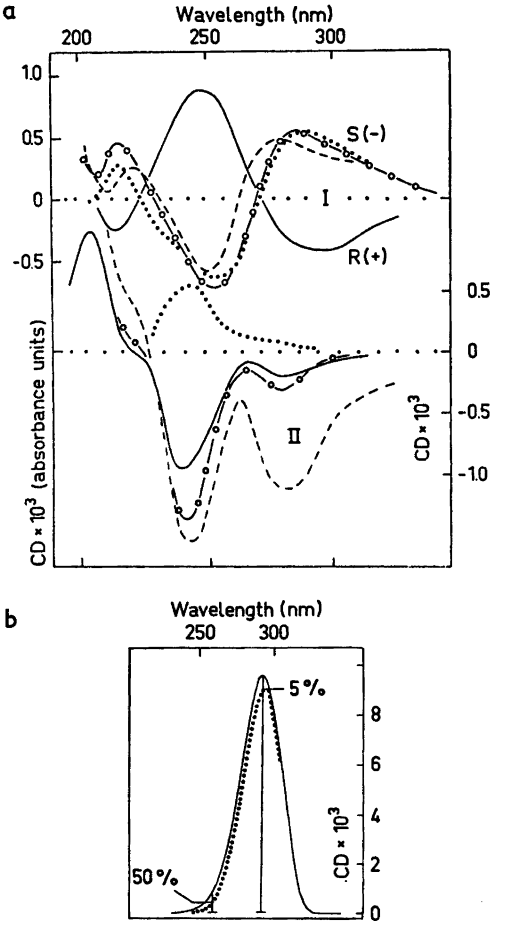

Fig. 2. a. CD spectra (selected from some 50) representative of cases of varying confidence: *Above:* $R(+)$ I ——— (3.0×10^{-3} %, KCl), S(−) I · · · (2.0×10^{-3} %, KCl), − O − (1.5×10^{-3} %, KCl), – – – (0.5×10^{-3} %, KCl). *Below:* $R(-)$ II – – – (3.7×10^{-3} %, KBr), − O − (0.7×10^{-3} %, KBr), ——— (0.5×10^{-3} %, KCl), S(+) · · · (0.3×10^{-3} %, KBr). b. Depolarisation test: A camphersulphonic acid/PVA standard [17] following the specimen in the light path · · · only standard ———. The decrease (50 % at 260 nm) is a measure of the percentage of the light intensity which is not acting as in a circularly polarized mode.

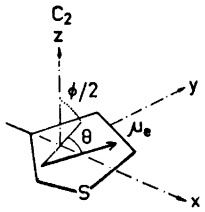
Before we may have confidence in an ordinary "pressed KBr disc" CD spectrum, it is necessary to minimize the influence of two principal errors, *viz.* the optical artifacts due to anisotropic CD or refraction (birefringence) of the crystallites, and those due to a stress birefringence induced by pressing the disc. The

first error is minimized by the randomisation procedure, while the second is detected by measuring the depolarisation.[13] An additional effect seems to be the scattering due to different refractive indices in substance and matrix. Preliminary experiments indicate that more reliable results are obtained by extrapolation to a zero substance concentration (*cf.* Fig. 2). On this basis Fig. 2 yields the following CD features for the *R*-configurations of I and II, in absorbance units (wavelengths, nm, in parentheses); I: −0.2 (225), +0.6 (250), −0.5 (275); II: +0.7 (200), ±? (230), −0.9 (240), −0.3 (275).



By analogy with, *e.g.*, biphenyls, a tentative conclusion which may be drawn from the great similarity between these features and the spectra in Fig. 1a, is that on the average the same structures of I as well as of II exist in both the solution and the crystal, *viz. cisoid* conformations with a dihedral angle $\phi = 75 - 90°$ in I and $60 - 70°$ in II.[4]

This conclusion is correct as long as any of the CD bands considered is due to a transition polarised at an angle θ (in the present notation) fairly close to zero, and if the CD is governed by a dipole-dipole coupling [14] ("exciton") mechanism. Such an origin of the CD may be of predominant importance considering the high oscillator strengths of the transitions involved and the probably small electronic exhcange between the thiophene nuclei.

The dipole coupling between the two equivalent transition moments μ_{e1}, μ_{e2}, directed as denoted above, gives rise to two components A and B (point group C_2) with rotational strengths given by eqn. (1) and at relative energies determined by (2).[15] It is thus obvious that CD bands due to transitions with $|\theta| > 35.3°$ will not depend in sign or energy on a conformational change ($0 < \phi < 180°$). However, it is most improbable that this is the trivial explanation for the

$$R_A = -R_B = \frac{\pi\nu}{2c} r_{12}\, \mu_e^2 \cos^2\theta \sin\phi \qquad (1)$$

$$\nu_A - \nu_B = \frac{2\mu_e^2}{hcr_{12}^3}(1 - 2\cos^2\theta\cos^2(\varphi/2) - 3\sin^2\theta) \qquad (2)$$

similarities between Fig. 1 and Fig. 2. Firstly, there is evidence for an intensive low-energy transition with $a = +30°$,[15] implying a "conformational" CD sign change due to eqn. (2) when ϕ exceeds 131.8°. Secondly, with a low $\nu_A - \nu_B$ the A and B components mutually cancel to a great extent, leading to an apparent CD spectrum whose features are very sensitive to changes in R, and consequently also to conformational changes.

Experimental details are to be described elsewhere.[13,16] KBr was found more suitable than KCl giving birefringence free discs with high transmission down to 230 nm. Close to 200 nm KCl was superior to KBr with respect to transparency. Discs with depolarisations (defined in Fig. 2) exceeding 5 % were discarded.

Acknowledgements. Our thanks are due to Professor BengtAurivillius and his collaborators for structural discussions and for undertaking the X-ray determinations. For measuring and sampling procedures we thank Mr. Jan Glans, Mrs. Siw Olsson and Mrs. Karin Trankéll. A grant (to B. N.) from the Royal Physiographic Society in Lund is also acknowledged.

The Conformation of Aliphatic Ethers

JOHANNES DALE and DAVID G. T. GREIG

Kjemisk Institutt, Universitetet i Oslo,
Oslo 3, Norway

The observation that the unique conformation of 1,5,9,13-tetraoxacyclohexadecane [1] and the stable crystal conformation of poly(trimethylene oxide) [2] are such that in each $-O-CH_2CH_2-CH_2-O-$ unit both CO-bonds are *anti* and both CC-bonds *gauche* of the same sign ($ag\pm g\pm a$) suggests that the 1,4-CH···O interaction may be attractive, whereas the the 1,4-CH···CH interaction must be even more repulsive than in hydrocarbons.[3]

It was of interest to verify this in simpler molecules and to check whether the relatively acidic character of the α-CH is a necessary condition for such an attractive interaction. We have therefore examined a series of dialkyl ethers and dimethoxypropanes where such interactions are possible between ether oxygen and either a non-acidic γ-hydrogen or an acidic α-hydrogen (Table 1). It was expected that any interaction would be reflected in an abnormal averaged chemical shift of the protons involved, in a relatively small vicinal α,β coupling constant, and in a relatively low dipole moment of the 1,3-dimethoxypropanes.

Chemical shift. The measured chemical shift values are shown in Table 1. For the methyl groups in propyl- and isobutyl ethers no significant chemical shift change due to interaction with or closeness to ether oxygen is noticeable, if the more distant methyl group in the butyl ether is taken as the reference. Of course, any interaction would be weak and averaged over three (or six) protons, so at most one can only conclude that such interaction is not demonstrated in the chemical shift.

In dimethoxypropane the α-methylene groups, which are those that would be involved in the interaction, appear about 0.10 ppm lower than α-methylene in the mono-ethers. This is a significantly larger effect than the 0.02 ppm that would be expected [4] merely by introducing an ether function in the γ-position.

For 1,3-dimethoxy-2,2-dimethylpropane no conclusion can be drawn, since the relatively large upfield shift of the α-methylene groups, due to the branching at the β-carbon,[5] dominates the picture. Similar upfield shifts are observed for methyl isobutyl ether (Table 1) and for methyl neopentyl ether.[5]

Vicinal coupling constants. Since the α-methylene protons give rise to a simple triplet* (or doublet) in a region well separated from the other resonances, except the single line of the methoxy group, the average α,β-vicinal coupling constant can be observed directly. For each conformer as well as for any mixture of conformers, an averaged coupling constant can be estimated, provided reliable values of *gauche* and *anti* H – H coupling constants are known. These have been shown [6,7] to depend additively on substituent electronegativities. Thus for "freely rotating" systems, with three identical conformers, the averaged vicinal coupling constant (representing *anti* and *gauche* couplings in the ratio of 1:2) has the values 8, 7.26, and 7 Hz for CH_3CH_3, $CH_3CH_2CH_3$, and CH_3CH_2OR, respectively.[6] Assuming additivity, we therefore expect the averaged α,β-coupling constant for $CH_3CH_2CH_2OR$ to be 6.26 Hz. From studies with rigid systems, such as *t*-butylcyclohexanols [8] and substituted 1,3-dioxans,[9] the best values for the corresponding individual coupling constants are $J_{anti} = 11$ Hz and $J_{gauche} = 4$ Hz, which gives 6.33 Hz as the average value for equally populated conformers, in excellent agreement with the value derived above. For the unbranched aliphatic mono-ethers, the calculated α,β-vicinal coupling constant is then 7.5 Hz if only the *anti*-conformer is populated, and 5.75 Hz for averaging between only two enantiomeric *gauche*-conformers. For methyl isobutyl ether the "double *gauche*" conformer, if it were populated exclusively, should have $J = 4$ Hz and the two "*gauche-anti*" conformers alone an averaged $J = 7.5$, but again the average value for equally populated conformers is 6.33 Hz. For each of four pure conformers of 1,3-dimethoxypropane (Fig. 1) the vicinal coupling constant can also be simply calculated (7.5, 6.63, 5.75, and 5.75 for *aa*, $ag^{\pm}$, $g^{\pm}g^{\pm}$, and $g^{\pm}g^{\mp}$) but since the $g^{\pm}g^{\mp}$ conformer is sterically forbidden, we get the average value 6.5 Hz for a statistical 1:4:2 population of the other three conformers, taking symmetry number and chirality into account.[10]

Before comparing these calculated values, summarized in Table 1, with the experimentally observed coupling constants, the expected influence of solvent and temperature on conformer population must be considered. Hydrogen bonding of chloroform to ethers has been demonstrated,[11] and this could influence the values of the coupling constants by altering the electronegativity of ether oxygen and/or the conformer populations. Since diethyl ether has the same coupling constant in $CDCl_3$ and CCl_4, any observed increase of the α,β-vicinal coupling constant in going from CCl_4 can be simply taken as the result of a decreased *gauche* conformer population.

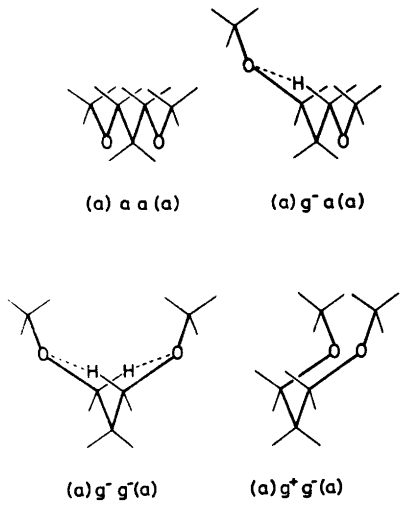

Fig. 1. Conformers of 1,3-dimethoxypropane.

When the observed coupling constant is close to the value expected for the statistical population of equi-enthalpic conformers, the direction of change observed on cooling may still reveal whether *gauche* or *anti* is enthalpy-preferred. All spectra were therefore recorded also at temperatures higher and lower than the usual probe temperature (Table 1).

Conclusions. For the normal unbranched mono-ethers, the numerical values of the averaged α,β-vicinal coupling constants show that there can be no important enthalpy difference between *gauche* and *anti* in CCl_4 solution, but the clear decrease observed as equal population is approached at higher temperature suggests that *anti* is slightly preferred. In $CDCl_3$ solution, the interaction of $CDCl_3$ with ether oxygen clearly favours the *anti*-conformers, as shown both by the numerical values and the temperature variation of the coupling constant. One can therefore conclude that the 1,4-*gauche* CH···O interaction is not attractive, but slightly repulsive when CH has no acidic character.

For the branched methyl isobutyl ether the same conclusions can be drawn.

1,3-Dimethoxypropane on the other hand has a significantly low coupling constant in CCl_4 solution and must consist at room temperature of roughly equal quantities of the *ag* and $g^{\pm}g^{\pm}$ forms. Since the *ag* form is statistically favoured, this means that the $g^{\pm}g^{\pm}$ conformer is lowest in enthalpy. The temperature variation of the

* Such a "deceptivelty simple" AA'XX' spectrum (Abraham, R. J. *The Analysis of High Resolution NMR Spectra*, Elsevier 1971) is a perfect triplet only when the *anti* and *gauche* conformers are equally populated, but even when a sligt broadening of the middle line betrays some enthalpy difference, the average vicinal coupling constant can still be extracted (=half the separation of the two outer lines).

coupling constant supports this conclusion. In $CDCl_3$ solution the situation is qualitatively similar, but the preference for *gauche* is much less pronounced. We thus conclude that the 1,4-*gauche* CH···O interaction is attractive, and competitive with the chloroform-ether interaction, when CH is made sufficiently acidic by the adjacent ether oxygen. Also the chemical shift data led to this conclusion. The dipole moment measured in benzene solution is 1.57 D (and 1.35 D for 1,3-dimethoxy-2,2-dimethylpropane) and this is significantly lower than calculated for randomly oriented ether groups ($1.3\ D \times \sqrt{2} = 1.8$ D) or for the *aa*-conformer (2.6 D), and so supports a general *gauche* preference. The even lower dipole moment of the 2,2-dimethyl derivative shows that there is no competition for the ether oxygen from the non-acidic methyl protons.

Experimental. Dipropyl ether was bought from Fluka and was used without purification. The methyl alkyl ethers were prepared [12] by gently heating the corresponding alcohol with dimethyl sulfate and distilling until the vapour temperature reached 100 °C. The distillate was passed through an alumina column and redistilled from sodium metal. Methyl propyl ether, b.p. 39–40 °C; methyl butyl ether, b.p. 70–71 °C; methyl isobutyl ether, b.p. 59–60 °C.

1,3-Dimethoxy-2,2-dimethylpropane was prepared [13] from neopentyl glycol by reaction with sodium hydride and methyl iodide in dry tetrahydrofuran and the product purified on an alumina column.

Dimethoxypropane [14] was prepared by the action of dimethyl sulfate on the dry disodium salt of trimethylene glycol (from sodium methoxide and trimethylene glycol in methanol). The distillate was twice redistilled from solid sodium hydroxide, passed through an alumina column and finally distilled from sodium hydride; b.p. 106–107 °C.

No impurity signals were apparent in the NMR spectra of the ethers so prepared.

The NMR spectra were recorded on a Varian HA 100 instrument for solutions containing about 7 % of the ether and TMS as internal reference. The dipole moments were determined as described previously.[15]

The Use of Tetrabutylammonium Azide in the Curtius Rearrangement

ARNE BRÄNDSTRÖM,[a] BO LAMM[b] and INGELA PALMERTZ[b]

handling of hydrazoic acid with its concomitant hazards.

The present paper describes a method of azide synthesis, in which the azide ion is readily extracted as an ion-pair with tetrabutylammonium ion from an aqueous solution into an organic phase.

Tetrabutylammonium azide has been obtained in pure, crystalline form after extraction into methylene chloride, followed by evaporation of the solvent. This azide has earlier been prepared from hydrazoic acid and tetrabutylammonium hydroxide.[4–6] The azide, which apparently can be safely handled in dry form, is soluble in a number of organic solvents. Metathesis with carboxylic acid chlorides can thus be carried out in a one-phase system. The resulting acyl azides can be directly used in subsequent reactions.

In the present work, a number of acyl azides have been prepared and made to rearrange to isocyanates by heating. The reactions were followed by the nitrogen evolution. The isocyanates formed were characterized by conversion to substituted ureas with aniline.

It is possible to perform reactions with the isocyanates in the same solution that was used in the Curtius rearrangement. Final separation from the tetrabutylammonium chloride should ordinarily cause no problems, since the salt is readily removed from organic solvents by water.

Results obtained with different acyl chlorides are summarized in Table 1.

Experimental. Tetrabutylammonium azide. A solution containing 0.2 mol of tetrabutylammonium hydroxide was prepared by addition of 50 ml of 10 M sodium hydroxide solution (an excess) to 67.9 g (0.2 mol) of tetrabutylammonium hydrogen sulphate in 100 ml of water. A solution of 26 g (0.4 mol) of sodium azide in 50 ml of water was added and tetrabutylammonium azide extracted with 100 ml of dichloromethane. It is important to have an excess of sodium hydroxide in order to avoid extraction of free hydrazoic acid, which might make the subsequent operations very dangerous. The organic layer (upper phase), 170 ml, was separated off and the aqueous phase again extracted with 100 ml of dichloromethane (lower phase). The combined organic phases were evaporated *in vacuo* at 40 °C to yield 59.8 g (theor. 56.9 g) of crude tetrabutylammonium azide as a colourless oil. Residual water was removed by azeotropic distillation with benzene or toluene. The solutions thus obtained were used directly in the following step. If so desired, the dry tetrabutylammonium azide can be obtained in quantitative yield as a crystalline, hygroscopic solid by evaporation of the solvent *in vacuo*. Recrystallization from toluene gives colourless crystals, m.p. 80 °C, lit.[6] 80 °C (decomp.).

Curtius rearrangement. A dry solution of 0.2 mol of tetrabutylammonium azide (the above batch) in 150 ml of benzene or toluene (see Table 1) was placed in a round-bottomed flask equipped with a reflux condenser, a thermometer, a stirrer and a dropping funnel. To this solution the equivalent amount (0.2 mol) of freshly distilled acyl chloride in 150 ml

of benzene or toluene was added in portions. The temperature was kept below 25 °C by cooling in ice water. The mixture was left for 3 – 4 h and then heated, a gas burette being attached to the top of the reflux condenser. Nitrogen evolution started at 50 – 90 °C. The gas evolution was allowed to proceed at a brisk rate by gradual heating, giving a total reaction time of less than 4 h. The isocyanate was separated from the solvent by distillation through a 30 cm stainless steel spiral column having 5 mm internal diameter. Because of the instability of isocyanates, yields were variable but usually better than 50 %.

To obtain a better determination of the yields, the Curtius rearrangement was repeated (on a 7 mmol scale). After the nitrogen evolution had ceased, a slight excess of aniline was added to the reaction mixture. The resulting *N*-alkyl-*N'*-phenyl urea was freed from tetrabutylammonium chloride by washing the solution with water. The organic solvent was evaporated and the resulting product recrystallized from aqueous ethanol. The yields of the urea derivatives obtained are given in Table 1. The reaction with aniline is assumed to be quantitative,[7] and the recrystallization losses are small. The identity was further verified by ^{1}H NMR.

Reinvestigation of the Synthesis of Thiete 1,1-Dioxide

BO LAMM and KENNETH GUSTAFSSON

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

The four-membered cyclic unsaturated title compound was needed as a synthetic intermediate in our work. Dittmer and Christy [1,2] first prepared it as indicated in Fig. 1. Since

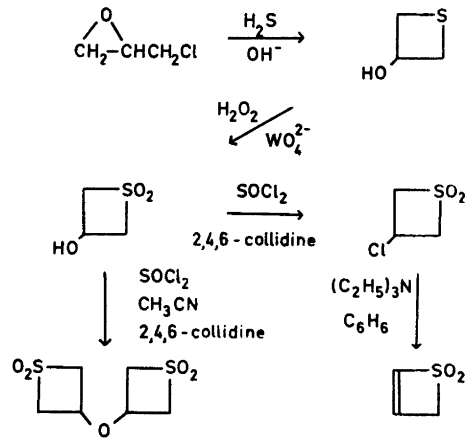

Fig. 1. Synthetic route to thiete 1,1-dioxide and bis-(3-thietanyl 1,1-dioxide) ether.

the yield in the first step was only 39 %, and since the second step involved a reportedly [8] hazardous evaporation of peracetic acid, an alternative synthetic route was later described.[3] This starts with a 2 + 2 cycloaddition of sulfene to *N*,*N*-dimethylvinylamine. The latter compound is very unstable, requiring low temperature and oxygen-free conditions, and we did not deem a large-scale preparation attractive.

Upon reinvestigation of the original procedure, we found that the first step is much more conveniently carried out in potassium hydroxide solution than with barium hydroxide.[1] The reaction of epichlorohydrin with hydrogen sulfide in basic solution was first described by Sjöberg.[4] He obtained 30 % yield with potassium hydroxide, but a much higher yield, 65 %, is actually secured by continuous extraction of the aqueous phase with ether.

The second step, oxidation of 3-thietanol to the sulfone, can advantageously be carried out with 30 % aqueous hydrogen peroxide and a catalytic amount of sodium tungstate [5] instead of the usual mixture of aqueous hydrogen peroxide and acetic acid.[1]

of benzene or toluene was added in portions. The temperature was kept below 25 °C by cooling in ice water. The mixture was left for 3 – 4 h and then heated, a gas burette being attached to the top of the reflux condenser. Nitrogen evolution started at 50 – 90 °C. The gas evolution was allowed to proceed at a brisk rate by gradual heating, giving a total reaction time of less than 4 h. The isocyanate was separated from the solvent by distillation through a 30 cm stainless steel spiral column having 5 mm internal diameter. Because of the instability of isocyanates, yields were variable but usually better than 50 %.

To obtain a better determination of the yields, the Curtius rearrangement was repeated (on a 7 mmol scale). After the nitrogen evolution had ceased, a slight excess of aniline was added to the reaction mixture. The resulting *N*-alkyl-*N'*-phenyl urea was freed from tetrabutylammonium chloride by washing the solution with water. The organic solvent was evaporated and the resulting product recrystallized from aqueous ethanol. The yields of the urea derivatives obtained are given in Table 1. The reaction with aniline is assumed to be quantitative,[7] and the recrystallization losses are small. The identity was further verified by ^{1}H NMR.

Acknowledgement. We thank Professors Lars Melander and Martin Nilsson for their constructive criticism.

Reinvestigation of the Synthesis of Thiete 1,1-Dioxide

BO LAMM and KENNETH GUSTAFSSON

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

The four-membered cyclic unsaturated title compound was needed as a synthetic intermediate in our work. Dittmer and Christy [1,2] first prepared it as indicated in Fig. 1. Since

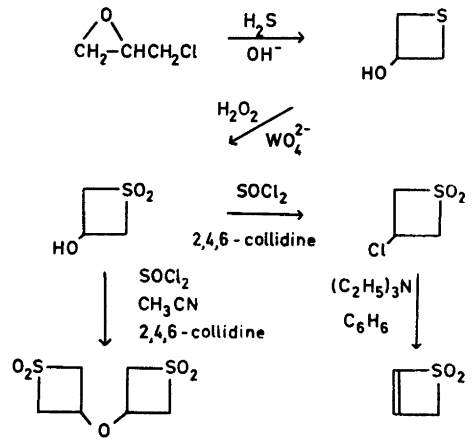

Fig. 1. Synthetic route to thiete 1,1-dioxide and bis-(3-thietanyl 1,1-dioxide) ether.

the yield in the first step was only 39 %, and since the second step involved a reportedly [8] hazardous evaporation of peracetic acid, an alternative synthetic route was later described.[3] This starts with a 2 + 2 cycloaddition of sulfene to *N*,*N*-dimethylvinylamine. The latter compound is very unstable, requiring low temperature and oxygen-free conditions, and we did not deem a large-scale preparation attractive.

Upon reinvestigation of the original procedure, we found that the first step is much more conveniently carried out in potassium hydroxide solution than with barium hydroxide.[1] The reaction of epichlorohydrin with hydrogen sulfide in basic solution was first described by Sjöberg.[4] He obtained 30 % yield with potassium hydroxide, but a much higher yield, 65 %, is actually secured by continuous extraction of the aqueous phase with ether.

The second step, oxidation of 3-thietanol to the sulfone, can advantageously be carried out with 30 % aqueous hydrogen peroxide and a catalytic amount of sodium tungstate [5] instead of the usual mixture of aqueous hydrogen peroxide and acetic acid.[1]

Upon an attempted preparation of 3-chlorothietane 1,1-dioxide in acetonitrile as solvent, the hitherto unreported bis-(3-thietanyl 1,1-dioxide) ether was obtained instead of the chloro compound. This ether was characterized through its spectral data (IR, 60 MHz ^{1}H NMR, and high-resolution MS). The analogous sulfide is known.[6]

It is possible that in acetonitrile, the 3-thietanol 1,1-dioxide anion can compete with chloride ion in the decomposition of the chlorosulfite ester initially formed from 3-thietanol 1,1-dioxide and thionyl chloride, since the alcohol is soluble in acetonitrile. The desired chloro compound is formed only under "dry" conditions.

Experimental. 3-Thietanol. A solution of 200 g of potassium hydroxide (3 mol, assuming 15 % moisture content) in 900 ml of water was saturated with hydrogen sulfide. Epichlorohydrin, 143 g (1.54 mol), was added dropwise during 2 h with good stirring and simultaneous introduction of hydrogen sulfide. The temperature gradually rose to 60 °C in this process. A slow stream of hydrogen sulfide was introduced for 1 h, and the mixture left overnight. It was then exhaustively extracted with ether, a continuously working apparatus being used. The ether was removed *in vacuo* and the remainder distilled to yield 91 g of 3-thietanol (65 % yield), b.p. 95 – 97 °C at 3.3 kPa (25 mmHg).

3-Thietanol 1,1-dioxide. Of the preceding compound, 90 g (1 mol) was dissolved in 500 ml of water containing 2 g of sodium tungstate and about 0.5 ml of glacial acetic acid; pH 4 – 5. While stirring well and maintaining the temperature at 20 °C with a glass cooling coil, 250 ml of 30 % hydrogen peroxide (appr. 2.5 mol) was added during 1 h. The reaction mixture was watched for 5 h and cooled as required to maintain the temperature at 20 °C. It was then left overnight. After decantation from a small amount of a sticky, white by-product, excess peroxide was destroyed with a pinch of palladium on carbon. After a negative peroxide test, the colourless solution was evaporated *in vacuo* at a temperature not exceeding 40 °C. *Since explosions have been reported to occur in the similar preparation using acetic acid-hydrogen peroxide,[2] we earnestly urge the reader to take necessary precautions.* The evaporation of 1 mol batches has been carried out four times without incidents.

The remainder after evaporation consisted of a colourless crystalline material and a small amount of a likewise colourless oil. The crystals were brought into solution with boiling ethyl acetate and decanted from the oil. Upon cooling, large crystals were obtained, m.p. 100 °C, lit.[1] 99.5 – 102 °C, yield 75 g (61 %).

3-Chlorothietane 1,1-dioxide. The directions in Ref. 1 were closely followed. With 20 g batches, the yield was typically 77 %, lit.[1] 86 %, m.p. 135 – 137 °, lit.[1] 136.5 – 137.5 °C.

Thiete 1,1-dioxide. Also this compound was prepared according to Ref. 1. Recrystallization from ether containing a few per cent ethanol gave a fraction m.p. 49 – 50 °C, lit.[1] 48 – 50 °C, representing 63 % yield, lit.[1] 81 %. From the mother liquor, a second crop was secured, m.p. 45 – 50 °C, 27 % yield.

Bis-(3-thietanyl 1,1-dioxide) ether. 3-Thietanol, 5 g (0.041 mol) and redistilled 2,4,6-collidine, 5 g (0.041 mol) were dissolved in 50 ml of dry acetonitrile. A solution of 9.8 g (0.082 mol) of thionyl chloride in 25 ml of acetonitrile was added dropwise during 30 min with stirring and cooling in ice. A crystalline precipitate was formed during the addition but disappeared when the mixture was heated in a boiling water bath for 30 min. The resulting clear solution was evaporated at aspirator vacuum, and the solid remainder triturated with cold water. A greyish, insoluble material was filtered off and recrystallized from boiling water with charcoal decolourization. White needles were obtained, yield 0.6 g (13 %), m.p. 165 – 165.5 °C (Kofler Hot Stage). One further recrystallization did not change the m.p. The 60 MHz ^{1}H NMR spectrum in deuterated dimethyl sulfoxide consisted of a complex pattern at δ 4.1 – 5.0 and another one at δ 5.2 – 5.6, the integrals of which were in the ratio 4:1. The IR spectrum (KBr disc) had two broad bands, characteristic of sulfones, at 1 120 – 1 160 and 1 300 – 1 340 cm^{-1}, and a band with peaks at 1 210 and 1 230 cm^{-1} which can be ascribed to an ether structure. In the region above 1 450 cm^{-1}, only two bands at 2 970 and 3 040 cm^{-1}, typical of C – H stretching, were apparent but no hydroxyl band. The high-resolution mass spectrum was obtained with an AEI MS 902 instrument, using 50 eV electrons for ionization and a heated direct insertion probe. The fragmentation pattern was found to be very dependent on the probe temperature. A very low intensity M + 1 peak appeared at 150 °C (not visible at lower temperatures), measured mass 227.008, rel. height 0.03 % ($C_6H_{11}S_2O_5$ = 227.005). No parent peak was visible. Fragment peaks were apparent at 168.9634 mass units, 4.12 % ($C_3H_5S_2O_4$ = 168.9629); 148.0202, 0.59 % ($C_5H_8SO_3$ = 148.0194); 123.0119, 1.03 % ($C_3H_7SO_3$ = 123.0116); 104.9983, 14.0 % ($C_3H_5SO_2$ = 105.0010); 94.0085, 8.1 % ($C_2H_6SO_2$ = 94.0088); 78.9854, 6.3 % (CH_3SO_2 = 78.9853); 75.9986, 10.7 % (C_2H_4SO = 75.9989); and 63.9623, 100 % (SO_2 = 63.9619). The $C_3H_5S_2O_4$ peak is thought to result from a rearrangement procedure.

Acknowledgements. Financial support from the Swedish Natural Science Research Council is gratefully acknowledged. The mass spectrum determination was carried out by Mr. W. Pimlott at the Department of Medical Membrane Chemistry, University of Göteborg. His help in interpreting the data is much ap-

preciated. Mr. P. Bergmark assisted in the preparative work and is also thanked.

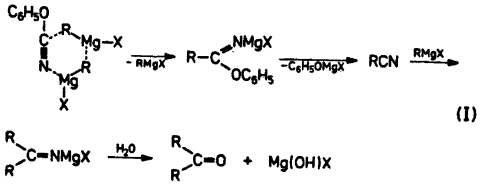
Alkyl Cyanates. XV. Reaction of Alkyl and Aryl Cyanates with Grignard Reagents. Product Formation

ARNE HOLM and ERIK HUGE-JENSEN

Chemical Laboratory II (General and Organic Chemistry), The H. C. Ørsted Institute, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark

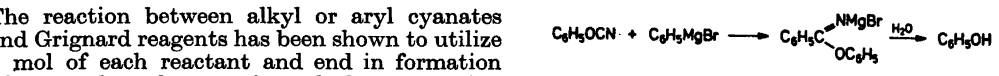
The reaction between alkyl or aryl cyanates and Grignard reagents has been shown to utilize 1 mol of each reactant and end in formation of a complex of magnesium alcoholate or phenolate, nitrile, and diethyl ether. The same complex is obtained directly by mixing the components. Evidence for imido ester salts as intermediates in the reaction between alkyl or aryl cyanates and Grignard reagents has not been obtained.

The reaction between Grignard reagents and aryl cyanates has been described by Martin and Rackow[1] and by Grigat, Pütter and Mühlbauer.[2,3] Martin and Rackow found that nitrile was formed and that 2 mol of Grignard reagent to 1 mol of phenyl cyanate were necessary for the reaction to go to completion. The second mol or molecule of Grignard reagent was assumed to act as a Lewis acid facilitating the nucleophilic attack on the cyanate. However, the nitrile formed partly reacts with the excess Grignard reagent yielding a ketone after hydrolysis, according to Martin and Rackow (eqn. I).[1] The experiments were carried out at −20 °C.



(I)

Grigat *et al.* investigated the reaction at −50 °C and isolated benzonitrile in 61 % yield using 1 mol of phenylmagnesium bromide to 1 mol of phenyl cyanate. The reaction was formulated as eqn. II.



(II)

The magnesium salt of phenyl imidobenzoate was assumed to be an intermediate although no evidence for this was presented. The reaction between phenylmagnesium bromide and 4-methylphenyl cyanate proceeded similarly.

The reaction between ethyl cyanate and Grignard reagents is briefly mentioned by Martin *et al.*[4] With cyclohexylmagnesium bromide and benzylmagnesium chloride nitrile was formed as described above with the aromatic cyanates. However, ethylcyclohexane and propylbenzene, respectively, were also found to be reaction products. With phenylmagnesium bromide only benzonitrile was identified.

At the time that these results were published we had some unpublished data and now wish to report on a more detailed investigation.

Addition of pentylmagnesium bromide in ether to an equimolar amount of isobutyl cyanate at −80 °C gave a white precipitate (*vide infra*). After warming to room temperature the supernatant ether solution was analysed by gas chromatography and found to contain approximately 20 % of the theoretical amount of capronitrile. Only traces of isobutyl alcohol were present. After hydrolysis of the reaction mixture the total yields of capronitrile and isobutyl alcohol were 72 % and 73 %, respectively.

The addition of phenylmagnesium bromide to an equimolar amount of isobutyl cyanate at −80 °C proceeded similarly, and benzonitrile

and isobutyl alcohol were isolated in 87 % and 89 % yields, respectively, after hydrolysis. Furthermore, the gas-chromatrographic analysis showed that some benzene (8 %) was also formed.

When 2 mol of phenylmagnesium bromide were added to 1 mol of isobutyl cyanate at −80 °C and the mixture was warmed to room temperature a further reaction with the benzonitrile formed took place. After hydrolysis diphenylketimine, $(C_6H_5)_2C=NH$, could be isolated in 70 % yield besides an 84 % yield of isobutyl alcohol, even though diphenylketimine is liable to form benzophenone on further hydrolysis. Benzophenone was the only product isolated by Martin and Rackow and by Grigat *et al.*

To test the generality of these reactions a number of experiments were carried out in which the organic moieties of the cyanate and the Grignard reagent were varied. As shown in Table 1 the yields in most cases were high. The low yields of ethanol isolated in the reactions between ethyl cyanate and Grignard reagents are assumed to be due to the high solubility of ethanol in water from which ethanol is extracted. Secondary cyanates are known to undergo elimination reactions with basic reagents [5] and this may explain the low yields of alcohol and nitrile isolated from the reactions of isopropyl cyanate with aliphatic Grignard reagents. In no cases were alkylation products detected in the reaction mixture as found in the investigation of Martin *et al.*[4]

We have most carefully tried to obtain evidence for the intermediacy of the halomagnesium imidate proposed by Martin and Rackow and by Grigat *et al.* (eqns. I and II). On hydrolysis the imidate salt should yield an imido ester or eventually a further hydrolysis product (eqn. III).

(III)

However, despite careful scrutiny we have not observed any of these products, either in the final reaction mixture or when the reaction was interrupted before completion. We have furthermore not observed reaction products of the possible imidate salt and a second mol of cyanate, which would be similar to those

Table 1. Yields of reaction products in the reaction between alkyl and aryl cyanates and Grignard reagents.

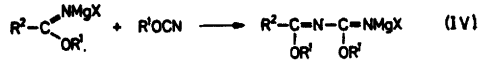
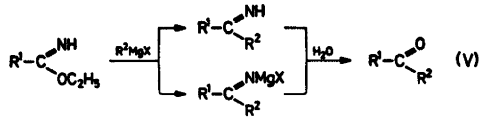
[a] The yields are calculated from the amount of cyanate employed and were obtained from gas chromatograms by electronic integration unless another means is indicated. [b] Yields determined by conventional work-up.

obtained in reactions between some nitriles and Grignard reagents (eqn. IV).[6,7]



(IV)

It seems evident that the halomagnesium imidate should be formed in a reaction between an alkyl imido ester and a Grignard reagent. This reaction has been commented on only briefly, but general reaction schemes (eqn. V) were proposed.[8,9]



(V)

In a reinvestigation we have found, however, that nitrile is the isolable reaction product (eqn. VI).[10]

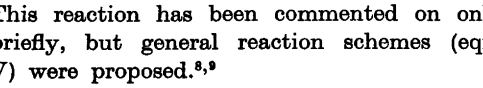
(VI)

Obviously combination of the nitrile with excess Grignard reagent followed by hydrolysis will lead to the observed ketone.

Thus the reaction between alkyl imido ester and Grignard reagent in fact yields the same products as are obtained from cyanates and Grignard reagents. It is also important to note that we have not been able to isolate the halomagnesium salt that obviously should be first formed, which again parallels the reaction between cyanate and Grignard reagent.

The white precipitate formed on mixing cyanate with Grignard reagent (*vide supra*) appears to be a complex with the composition $R^1OMgX.R^2CN.\frac{1}{2}(C_2H_5)_2O$. This composition was obtained from the integrals of the nuclear magnetic resonance spectrum of the complex ($R^1=R^2=C_6H_5$) dissolved in $(CD_3)_2SO$. In the infrared spectrum obtained in paraffin oil an absorption is observed at 2263 cm^{-1} which is assigned to benzonitrile coordinated to the magnesium atom. In infrared spectra of the complexes $C_6H_5CN \rightarrow AlCl_3$ and $C_6H_5CN \rightarrow SnCl_4$ the absorptions are observed at 2280 cm^{-1} and 2258 cm^{-1}, respectively.[11,12] Uncoordinated benzonitrile absorbs at 2235 cm^{-1} in paraffin oil. The product obtained on mixing phenoxymagnesium bromide and benzonitrile in diethyl ether had the same characteristics as those described for the complex formed from phenyl cyanate and phenylmagnesium bromide.

Further evidence for the composition of the complex was obtained by adding a different nitrile to the reaction mixture before hydrolysis. It could be shown by means of GLC that an exchange of nitrile in the complex with the nitrile added had taken place (eqn. VII).



(VII)

It has not been possible to obtain a satisfactory elemental analysis of the white complex owing to its hygroscopic nature.

In conclusion, the reaction between alkyl or aryl cyanates and Grignard reagents has been shown to proceed with 1 mol of each reactant despite the statement of Martin and Rackow.[1] The presence of a halomagnesium imidate on the route to the final products has not been shown, but on the other hand the data obtained do not exclude this intermediate. The final reaction product is in all cases a complex between magnesium alcoholate or phenolate, nitrile, and diethyl ether, which can also be made directly by mixing the components.

The further details of these reactions can be ascertained only from kinetic experiments, the results of which are presented in following papers.[13,14]

EXPERIMENTAL

All Grignard reagents were prepared in diethyl ether distilled from lithium aluminum hydride directly into the glass apparatus. This solvent was used in all reactions. The glass apparatus had been flamed and filled with argon. The magnesium used (monosublimed, Dow Chemical Corp.) was washed with anhydrous diethyl ether. Every precaution was taken against oxygen and moisture. The halides used in the preparations of the Grignard reagents were distilled and their purity checked gas-chromatographically. The molarity of the Grignard reagents was determined by titration with standard acid and the content of halogen by titration with standard silver nitrate. The content of halogen was never more than 4 % higher than the content of Grignard reagent. The different concentrations were obtained by dilution of *ca.* 2 M standard solution.

Alkyl cyanates were prepared from 5-alkoxy-1,2,3,4-thiatriazoles [5,15] and aryl cyanates from

phenols and cyanogen chloride in the presence of triethylamine.[16] The purity of the cyanates was checked by infrared and nuclear magnetic resonance spectroscopy and elemental analysis.

Infrared spectra were obtained on a Perkin-Elmer 337 grating spectrometer and nuclear magnetic resonance spectra on a Varian A-60 A instrument.

A. The reaction between isobutyl cyanate and pentylmagnesium bromide. To 50 ml of 2 M isobutyl cyanate cooled in an acetone/dry ice bath was added 50 ml of 2 M pentylmagnesium bromide with stirring over a 30 min period. After approximately 10 % of the Grignard solution had been added a white precipitate was formed. After the addition was finished the reaction mixture was allowed slowly to reach room temperature (30 min), which caused transformation of the solid into a very viscous liquid. A sample of the supernatant ether solution was analysed by means of gas chromatography and found to contain capronitrile corresponding to approximately 20 % of the theoretical amount, but only traces of isobutyl alcohol. After hydrolysis with 50 ml of 4 M hydrochloric acid saturated with sodium chloride a sample of the ether phase was again analysed gas-chromatographically and now found to contain capronitrile and isobutyl alcohol, both in approximately 75 % yield based on isobutyl cyanate. The water phase was extracted twice with 20 ml of ether, the combined extracts dried over magnesium sulfate and the ether partially removed by evaporation *in vacuo* at 10 °C. Distillation at atmospheric pressure yielded 3 fractions: *1.* 80 – 103 °C, 0.7 g; *2.* 103 – 108 °C, 5.0 g (68 %); *3.* 160 – 163 °C, 6.5 g (73 %); residue 1.0 g. The first fraction was found on gas chromatography to contain ether and isobutyl alcohol; the second was almost pure isobutyl alcohol and the third almost pure capronitrile. The products were identified by comparison of their infrared spectra with those of authentic samples. The residue was a tar of unknown composition.

The gas-chromatographic analyses were performed on a Perkin-Elmer 116 E gas chromatograph; column SE 30; column temperature 117 °C; injection temperature 200 °C; detector temperature 100 °C; carrier gas helium; flow rate approximately 100 ml/min.

B. The reaction between isobutyl cyanate and phenylmagnesium bromide (molar ratio 1:1). This experiment was carried out analogously to the reaction between isobutyl cyanate and pentylmagnesium bromide. After drying the combined ether extracts and evaporation of the ether, the remaining liquid was shown by gas chromatography to contain benzene in an amount corresponding to 8 % of the phenylmagnesium bromide used. The following fractions were obtained by distillation: *1.* 10 mmHg, bath temperature 40 °C, 6.6 g (89 %); *2.* 1 mmHg, bath temperature 80 °C, 9.0 g (87 %); residue 0.2 g (black tar). Fractions 1 and 2 were found to consist, of isobutyl alcohol and benzonitrile, respectively, by gas chromatography and infrared spectroscopy.

C. The reaction between isobutyl cyanate and phenylmagnesium bromide (molar ratio 1:2). To 50 ml of 2 M isobutyl cyanate cooled in an acetone/dry ice bath was added 100 ml of 2 M phenylmagnesium bromide with stirring during 30 min. The reaction mixture was then warmed to room temperature and stirred for additional 24 h. Water (100 ml) was added, the phases separated and the water phase extracted twice with 30 ml of ether. After drying ether was removed *in vacuo* and the residue distilled: *1.* 1 mmHg, bath temperature 30

Table 2. Conditions for the gas-chromatographic analysis for determining yields of the reaction between cyanates and Grignard reagents.

[a] Temperature programming (5 min at 50 °C and increase of the temperature to 120 °C at 10 °C per min).

°C, 6.2 g (84 %); *2.* 1 mmHg, bath temperature 125 °C, 12.6 g (70 %); residue 0.5 g (black tar). Fraction 1 was identified as isobutyl alcohol by infrared spectroscopy and fraction 2 as diphenylketimine by infrared spectroscopy and elemental analysis (Found: C 85.91; H 6.22; N 7.29. Calc. for $(C_6H_5)_2C=NH$: C 86.20; H 6.08; N 7.74).

D. Determination of yields by electronic integration of gas chromatograms in reactions of cyanates with Grignard reagents. 40 ml of 1 M cyanate was mixed with 40 ml of 1 M Grignard reagent by flowing the two solutions together in a stainless steel T-tube of diameter 0.6 mm. After mixing the reaction mixture was sprayed into a glass bulb cooled in ice/water. The reagents were cooled to −50 °C before mixing. The reaction mixture was hydrolysed with 20 ml of 4 M hydrochloric acid saturated with sodium chloride and the ether and water phases separated. The water was extracted 3 times with 30 ml of ether and the combined ether phases were dried over magnesium sulfate. A known amount of *o*-xylene (internal standard) was added to the filtered ether solution and the mixture diluted to 200 ml in a graduated flask. The gas chromatograms (conditions are given in Table 2) of these solutions were integrated electronically and yields of alcohol, phenol, and nitrile determined from standard curves (g_x plotted against $g_s A_x/A_s$*). Gaschromatographic analyses were performed on a Pye Unicam 104 chromatograph in connection with a Varian aerograph 477 integrator and a Victor digitmatic digital recorder. The flow rate was 45 ml/min.

E. The reaction of phenyl cyanate with phenylmagnesium bromide. To 20 ml of 0.2 M phenyl cyanate was added slowly 2.4 ml of 1.67 M phenylmagnesium bromide with stirring at room temperature. The ether solvent was evaporated and the residue washed 3 times with 5 ml of anhydrous ether and kept at 1 mmHg and 35 °C for 1 h.

The nuclear magnetic resonance spectrum of the white product dissolved in $(CD_3)_2SO$ indicated a content of phenolate, benzonitrile, and diethyl ether in the ratio 2:2:1.

The infrared spectrum of the product in paraffin oil had a characteristic band at 2263 cm^{-1}. Benzonitrile dissolved in paraffin oil absorbs at 2235 cm^{-1}.

F. The reaction of phenoxymagnesium bromide with benzonitrile. 0.02 mol (1.88 g) of phenol and 0.02 mol (2.06 g) of benzonitrile were dissolved in 50 ml of diethyl ether. To this solution was added at room temperature 9.72 ml of 2.057 M methylmagnesium bromide. A white precipitate was formed at once. The ether was evaporated *in vacuo* and the residue washed 3 times with 5 ml of anhydrous ether and kept at 1 mmHg and 35 °C for 1 h.

The nuclear magnetic resonance spectrum of the product in $(CD_3)_2SO$ showed a content of phenolate, benzonitrile and diethyl ether in ratio 2:2:1.

The infrared spectrum of the product dissolved in paraffin oil had an absorption band at 2263 cm^{-1}.

G. Exchange of nitrile formed in the reaction of a cyanate with a Grignard reagent with a different nitrile. 50 ml of 2 M isobutyl cyanate and 50 ml of 2 M pentylmagnesium bromide were allowed to react as described above. After warming to room temperature 20 % of the theoretical amount of capronitrile was shown to be present in the supernatant ether by means of GLC. Valeronitrile (0.1 mol, 8.3 g) was added to the reaction mixture, and after 10 min with stirring the contents of caponitrile and valeronitrile in the ether phase were 36 % and 76 %, respectively, of the theoretical. After hydrolysis with 4 M hydrochloric acid saturated with sodium chloride the contents of capronitrile, valeronitrile and isobutyl alcohol in the ether phase were 75 %, 100 %, and 75 %, respectively, of the theoretical. The conditions for the gas-chromatographic analysis are described in *A*.

A similar experiment was carried out on the mixture from the reaction between phenyl cyanate and phenylmagnesium bromide. The benzonitrile formed was exchanged with *p*-tolunitrile.

Acknowledgement. The authors are very grateful to Professor Martin Ettlinger for his interest in and valuable discussions of this work.

Studies on a Soluble Dipeptidase from Pig Intestinal Mucosa. Enzymatic Properties

OVE NORÉN

Department of Biochemistry C, University of Copenhagen, DK-2200 Copenhagen N, Denmark

The kinetics of a soluble dipeptidase (glycyl-L-leucine dipeptidase, EC 3.4.13.2) purified from pig intestinal mucosa were studied under stable assay conditions. The pH-optima for the reaction of L-alanyl-L-alanine and glycyl-L-leucine with the enzyme were settled to 8.4 and 8.0, respectively. In the reaction with these two substrates the enzyme followed Michaelis-Menten kinetics and the K_m-values found were 0.74 mM and 2.1 mM for L-alanyl-L-alanine and glycyl-L-leucine. Several L-amino acids inhibited the enzyme and a kinetic study on the L-leucine inhibition showed it to be competitive in nature. The soluble dipeptidase was also inhibited by SH-compounds, EDTA, and SH-reagents while glycerol and divalent metal ions only slightly influenced the activity of the enzyme. DFP had no inhibitory effect.

Only a few intestinal exopeptidases have hereto been purified.[1-4] We have in a preceding report described a preparative purification procedure of a soluble dipeptidase from pig intestinal mucosa (glycyl-L-leucine dipeptidase, EC 3.4.13.2) together with its specificity.[5] Earlier studied proteolytic enzymes of the gastrointestinal tract followed the Michaelis-Menten kinectics and showed a distinct dependence of common enzyme inhibitors.[6] The objective of this investigation was to put the purified soluble dipeptidase in relation to these well-characterized proteolytic enzymes by studying these parameters.

MATERIALS AND METHODS

Enzyme. The soluble dipeptidase was prepared as described earlier.[5] The enzyme had a specific activity of 1400 units of activity per mg protein. In order to avoid repeated freezing and thawing the enzyme was stored in small samples at −20 °C in 0.07 M sodium phosphate buffer (pH 7.0) containing 0.2 M NaCl, 4 mM 2-mercaptoethanol, and 12.5 % (w/v) glycerol. The concentration of the enzyme was about 600 units of activity per ml. Under these conditions the enzyme was found to be stable for several months. One of the stored samples was used for each experiments.

Chemicals. Glycyl-L-leucine was purchased from Sigma Chem. Co., St. Louis, U.S.A., and L-alanyl-L-alanine was obtained from Cyclo Chem. Corp., Los Angeles, U.S.A. The purity of the two dipeptides was tested by thin layer chromatography (precoated cellulose plates, 0.1 mm, Merck, Darmstadt, Germany; butanol-acetic acid-water, 4:1:1 by vol.; ninhydrin-visualization). Amino acids were obtained from Mann Res. Labs., New York, U.S.A. DFP and sodium *p*-hydroxymercuribenzoate (PHMB) were purchased from Sigma Chem. Co., St. Louis, U.S.A. All other chemicals used were of analytical grade and de-ionized and glass destilled water was used throughout.

Assays. Dipeptidase activity was assayed according to one of the following procedures. *Fixed time procedure* followed in general the assay method of Josefsson and Lindberg [7] with the modifications of Sjöström.[8]

The dipeptides and amino acid solutions were prepared in 0.05 M Tris-HCl buffer solution at proper pH (pH-meter 28, Radiometer, Copenhagen, Denmark) in their suitable concentrations (12.3 mM and 8.5 mM for glycyl-L-leucine and L-alanyl-L-alanine, respectively, unless otherwise stated). The incubation mixtures, containing an enzyme concentration of about 0.2 units of activity per ml, were incubated at 25 °C for 10 min unless otherwise stated. In experiments where compounds with disturbing UV-absorbance were present the dipeptidase activity was assayed by using the 2,4,6-trinitrobenzenesulfonic acid (TNBS-) reagent as described earlier.[5] *Continuously recording procedure*, as described by Sjöström [8] was used for the determination of the kinetic coefficients of the enzyme. The molar extinction

coefficient of the peptide bond of the substrates was determined at each wavelength used.

Unit of dipeptidase activity. One unit of soluble dipeptidase activity is defined as the amount of enzyme hydrolyzing 1 μmol glycyl-L-leucine (12.3 mM) per min in 0.05 M Tris-HCl buffer (pH 8.0) at 25 °C.

RESULTS AND DISCUSSION

Stability of the enzyme. Stability studies were performed, using glycyl-L-leucine as substrate and the fixed time procedure, to assure stable assay conditions for the soluble dipeptidase. Solutions of varying enzyme concentrations (2 – 20 units of activity per ml) were prepared in two different buffers (0.05 M Tris-HCl, pH 8.0, and 0.1 M sodium phosphate, pH 7.8) and stored at 0 °C. Samples were withdrawn at once after the preparation of the solutions and then for each 30 min interval during a 2 h period and assayed for the dipeptidase activity. No decrease of enzyme activity was observed. Likewise, an enzyme solution (0.5 units of activity per ml) in 0.05 M Tris-HCl buffer (pH 8.0) stored at 25 °C and assayed for its activity at 6 min interval during a 36 min period showed no loss of activity. The stability of the soluble dipeptidase was also studied at different pH-values (0.05 M Tris-HCl buffer, pH 7.0, 8.0, and 9.0). At each pH a series of incubation mixtures with varying enzyme concentrations (0.82 – 0.13 units of activity per ml) were prepared and assayed for their activity, using incubation times for the separate mixtures inversely proportional to their enzyme concentrations (5 – 30 min). At each pH the various solutions showed the same percentage of glycyl-L-leucine hydrolysis, indicating no loss of activity during the time of incubation.

pH-Optima of the enzyme. The influence of pH on the reaction rate was studied in the pH range 6.9 – 8.9 (0.05 M Tris-HCl buffer) with glycyl-L-leucine and L-alanyl-L-alanine as substrate and using the fixed time procedure. pH-Measurements of the different reaction mixtures at the start and at the end of the incubation period made in parallel experiments showed a change of less than 0.03 pH-units. The pH-activity curves for the enzyme are presented in Fig. 1. The pH-optimum, 8.0, for the dipeptidase reaction with glycyl-L-leucine is in good accordance with the values earlier reported for pig intestinal

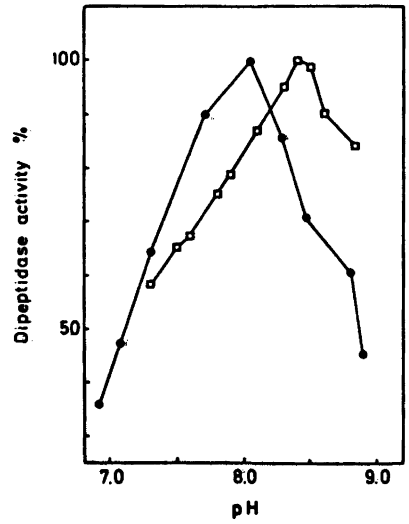

Fig. 1. pH-Activity curves for the soluble dipeptidase. Substrate: □ L-Alanyl-L-alanine; ● glycyl-L-leucine.

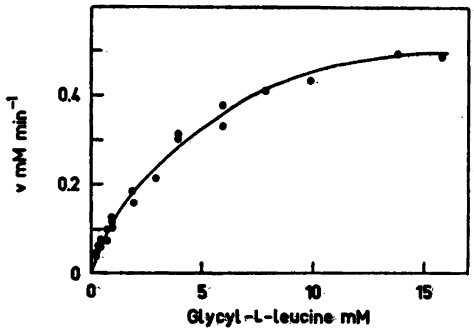

Fig. 2. Dipeptidase activity as a function of glycyl-L-leucine concentration.

mucosa homogenate[7] and for the purified monkey intestinal dipeptidase.[8] The pH-optimum for L-alanyl-L-alanine was found to be 8.4.

Kinetics of the enzyme. Experiments using the fixed time procedure were performed to determine the type of kinetic behaviour of the enzyme. The rate of hydrolysis of glycyl-L-leucine was measured in 0.05 M Tris-HCl buffer (pH 8.0) at different substrate concentrations (0.25 mM to 16 mM). The reactions were not allowed to proceed to more than 15 % of hydrolysis. The velocities calculated from these experiments were plotted *versus* the corresponding

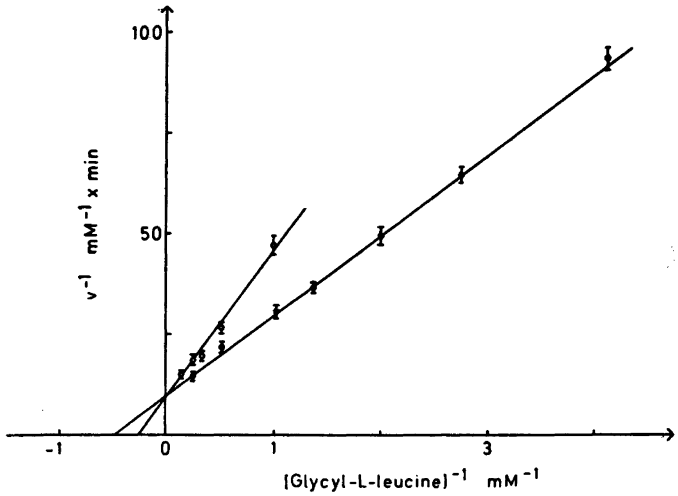

Fig. 3. Experimental data for the determination of the kinetic coefficients for the soluble dipeptidase without (●) and with (○) L-leucine (4 mM) using glycyl-L-leucine as substrate. ⊥ indicates 2 S. D. of the velocity measurements.

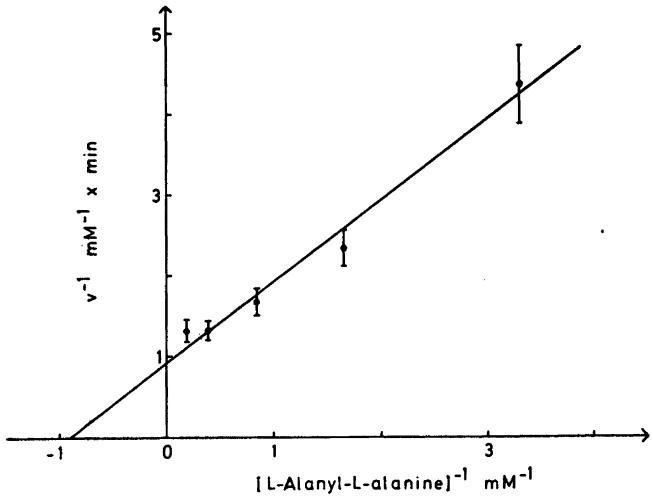

Fig. 4. Experimental data for the determination of the kinetic coefficients for the soluble dipeptidase using L-alanyl-L-alanine as substrate. A vertical bar indicates 2 S.D. of the velocity measurements.

substrate concentrations (Fig. 2). They were found to be located along a hyperbola and even at low substrate concentrations no sigmoid shape was observed. At high substrate concentrations the curve approached asymptotically a maximum value of velocity and substrate inhibition was not observed within the concentration range studied.

The determination of K_m- and V-values for the soluble dipeptidase were performed using the continuously recording procedure. To get a rapid and objective method for the calculation of the kinetic coefficients, with their standard errors, the statistical estimation method of Wilkinson [9] was used. The calculation procedure was translated into Univac-Algol and the ex-

perimental data were processed in a computer (Univac 1106, Recku, Copenhagen, Denmark). The experiments were performed in 0.05 M Tris-HCl buffer at pH 8.0 with glycyl-L-leucine and at pH 8.4 with L-alanyl-L-alanine, varying the peptide concentrations between 0.24 – 3.87 mM and 0.30 – 4.84 mM, respectively. The results obtained are presented in Fig. 3 and 4. Six different velocity measurements were made at each substrate concentration in the experiments with glycyl-L-leucine and the calculations resulted in a K_m of 2.1 (S.E. 0.13) mM and a V of 0.11 (S.E. 0.0034) mM per min. In the experiments with L-alanyl-L-alanine five separate velocity measurements were made at each substrate concentration and the calculations gave a K_m of 0.74 (S. E. 0.10) mM and a V of 0.94 (S. E. 0.039) mM per min.

Previous studies on soluble intestinal dipeptidase activities [10,11] have shown kinetic in accordance with the theory of Michaelis and Menten. This finding is also valid for studies performed on membrane bound intestinal peptidase activities using L-phenylalanyl-glycine and glycyl-L-phenylalanine as substrates [11] and for the renal dipeptidase.[12] K_m values have also been reported for the purified soluble monkey intestinal dipeptidase [8] without details on its kinetic behaviour. In the present study it has been found that for the two substrates studied the Michaelis-Menten kinetics may be applied. The found K_m values are of the same magnitude as those reported for the dipeptides with the enzymes mentioned above.

Using these kinetic data the molecular activity can be calculated to 2.4×10^5 min^{-1} and 6.4×10^5 min^{-1} for glycyl-L-leucine and L-alanyl-L-alanine, respectively, by using a molar extinction coefficient of 14.6×10^4 M^{-1} cm^{-1} for the soluble dipeptidase.[13]

Inhibitors of the enzyme

Amino acids. In the study of possible product inhibition of the dipeptidase reaction with glycyl-L-leucine it was observed, that L-leucine inhibited the reaction markedly, while glycine was only slightly inhibitory. Keeping the wide specificity of the soluble dipeptidase in mind [5] these observations prompted a more general study on the inhibitory effect of the amino acids.

Table 1. Influence of amino acids on the activity of the soluble dipeptidase.

Val	73	A

[a] A. Spectrophotometric method.[7] B. TNBS-method.[5]

Each amino acid (Table 1) was mixed separately with glycyl-L-leucine and incubated with a solution of the dipeptidase. The activity was measured using the fixed time procedure. The results (Table 1) showed that L-histidine inhibited the reaction most strongly but also L-isoleucine, L-leucine, and L-tryptophan showed a marked inhibitory effect. L-Arginine, L-methionine, L-serine, and L-valine moderately slowed down the reaction rate, while the other amino acids tested had no or only a slight inhibitory effect on the dipeptidase reaction. This variation in the inhibitory effect of the amino acids, is, however, not parallel to our knowledge about the specificity of the dipeptidase,[5] and requires therefore a more detailed study to elucidate the inhibitory mechanism of the amino acids.

The type of amino acid inhibition was studied using L-leucine as inhibitor. L-Leucine (4 mM) was added separately to a series of glycyl-L-leucine solutions (0.99 – 5.94 mM). The reaction velocity of a dipeptidase solution was then assayed with the various substrate concentrations using the continuously recording procedure (0.05 M Tris-HCl buffer, pH 8.0). Five different velocity measurements were made at each substrate concentration. The experimental data

are presented in the double reciprocal form in Fig. 3. The apparent K_m and V were calculated to be 3.8 (S.E. 0.35) mM and 0.11 (S. E. 0.0054) mM per min, respectively, using the statistical estimation method described above. The K_m-values obtained for glycyl-L-leucine in the absence and presence of L-leucine were compared using the t-test [14] and were found to be significantly different (degrees of freedom 63, P = 99.9. As the V-values obtained showed no difference L-leucine can be regarded as a competitive inhibitor. From the determined kinetic coefficients K_i for L-leucine was calculated to be 5.0 mM.

Glycyl-D-leucine. Glycyl-D-leucine, not hydrolyzed by the enzyme,[5] was mixed with the L-form of the dipeptide in equal concentrations (12.3 mM) and incubated with an enzyme solution, using the fixed time procedure (0.1 M sodium phosphate buffer, pH 7.8). No change of the rate of hydrolysis was observed in this mixture when compared with a parallel incubation mixture containing the same amount of enzyme but glycyl-L-leucine only. Thus glycyl-D-leucine does not interfere with the substrate binding site on the enzyme.

SH-compounds. To ascertain stability of the dipeptidase during its purification, all solutions had to contain 2-mercaptoethanol (4 mM),[5] although this compound strongly inhibited the dipeptidase activity (Table 2). Other SH-compounds, when present in the same concentration, also inhibited the dipeptidase reaction with glycyl-L-leucine (Table 2). As a consequence of its presence in the enzyme stock solutions, the influence of 2-mercaptoethanol on the dipeptidase reaction was further investigated in concentrations valid for the assay mixtures. An enzyme stock solution was passed through a column of Sephadex G-25 Fine (0.07 M sodium phosphate buffer, pH 7.0, added 0.2 M NaCl) to remove the 2-mercaptoethanol and glycerol present. This enzyme solution was assayed according to the fixed time procedure against two series of glycyl-L-leucine solutions (0.25 mM and 12.3 mM), each series added 2-mercaptoethanol in concentration varying from 0 to 12 μM. No influence on the dipeptidase reaction was observed in the series with 12.3 mM substrate concentration, while a 2-mercaptoethanol concentration above 6 μM showed a slight inhibition of the activity in the series with 0.25 mM substrate concentration. To avoid inhibition in the kinetic experiments (see above), precautions were therefore taken not to allow the 2-mercaptoethanol concentration in the incubation mixtures to rise above 6 μM.

EDTA. The influence of EDTA (1 mM) on the dipeptidase reaction was measured using the fixed time procedure with glycyl-L-leucine as a substrate. EDTA was added to the substrate-buffer solution and no preincubation of the dipeptidase was undertaken. The inhibition observed (Table 3), suggests that the enzyme is dependent of a metal ion for its proper function.

SH-reagents. The influence of Hg^{2+} and PHMB on the dipeptidase reaction was studied. The reagents were added to the substrate-buffer solution and the dipeptidase activity was measured using the fixed time procedure with glycyl-L-leucine as substrate. In the concentrations used both reagents had strong inhibitory effect on the

[a] A. Spectrophotometric method.[7] B. TNBS-method.[5]

dipeptidase reaction (Table 3), suggesting that thiol group(s) of the soluble dipeptidase are necessary for its function.

Glycerol. During the purification procedure glycerol was used to achieve stable conditions for the dipeptidase.[5] Its influence on the dipeptidase reaction was therefore studied using the fixed time procedure with glycyl-L-leucine as substrate and with glycerol present in the substrate-buffer solution. In the concentration used only a slight inhibitory effect was recognized (Table 3).

DFP. The inhibitory effect of DFP was studied by preincubating a dipeptidase solution (0.8 units of activity per ml) for 20 min at 25 °C in an 0.1 M sodium phosphate buffer (pH 7.7), made 0.15 mM in respect to DFP. Parallel samples, pre-incubated as above, but without DFP added, served as a control. The dipeptidase activity was measured against glycyl-L-leucine using the fixed time procedure. No effect on the dipeptidase activity was observed under these conditions (Table 3). Chymotrypsin, included in the study and assayed against casein, showed a total inactivation under the same experimental conditions.[15]

Divalent metal ions. Co^{2+}, Mn^{2+}, Mg^{2+}, and Zn^{2+} were added directly to the glycyl-L-leucine solution. The activity of the soluble dipeptidase measured using the fixed time procedure, was only slightly influenced (Table 3), which is in accordance with observations earlier reported on the glycyl-L-leucine dipeptidase activity in crude extracts of pig intestinal mucosa.[7]

Acknowledgement. For valuable discussions during the preparation of this work the author is grateful to Professor Lars Josefsson. Thanks are also directed to Mrs. D. Anthonsen who has performed skilful technical assistance. The investigation was aided by grants from the Danish Natural Science Research Council (Project No. 511).

Lignin Chromophores. Part I. Synthesis of Chromophores of the 2,4′- and 4,4′-Dihydroxystilbene Types

JOSEF GIERER, JOŽE LENIC,* ISA NORÉN and ILONA SZABO-LIN**

Swedish Forest Products Research Laboratory, Chemistry Department, Box 5604, S-114 86 Stockholm, Sweden

Convenient syntheses of 2,4′- and 4,4′-dihydroxystilbenes (types C and E) and their hydroxymethyl derivatives (types D and F) are described.

The key step of the syntheses is a Knoevenagel condensation of appropriate aromatic aldehydes with suitably substituted arylacetic acids to give stilbenecarboxylic acids and/or their lactones. This step is followed by decarboxylation of the stilbenecarboxylic acids and removal of protecting (acetyl) groups (preparation of types C and E), or by esterification of the stilbenecarboxylic acids or lactones and reduction of the resulting esters with lithium aluminium hydride (preparation of types D and F).

The versatility of the method is shown. The analytical and spectral data for the various products and intermediates are summarised in tables.

During pulping, certain phenolic units in lignins are converted to hydroxystilbene structures. These may represent intermediates during the various pulping processes [1-3] or constitute potential chromophoric systems in the resulting pulps [1,4,5] and spent liquors.[6-8] Thus, phenolic units of the phenylcoumaran type (A, see Fig. 1) give 2,4′-dihydroxystilbene structures (C [9,10] and D [2]), and phenolic units of the 1,2-diarylpropane-1,3-diol type (B) yield 4,4′-dihydroxystilbene structures (E [11,12] and F). It has been suggested that these reactions in alkaline media proceed *via* intermediate methylene quinones (G and H)[1,4,9] and in acidic media *via* intermediate carbonium ions (I and J).[1,2,13] Elimination of the terminal hydroxymethyl group from these two types of intermediates gives stilbene structures which are unsubstituted at the olefinic carbon atoms (C and E).[1,4-13] Loss of their β-proton affords intermediate stilbene structures, substituted at one of the olefinic carbon atoms by a hydroxymethyl group (D and F).[2,13]

For studies of the reactions of the 2,4′- and 4,4′-dihydroxystilbene type structures (C–F) during pulping, bleaching and ageing representative models were needed.

Previously,[6,14] hydroxystilbenes have been synthesised by heating tris-hydroxyaryl-trithianes in the presence of heavy metals (Fe, Cu). The trithianes required can be prepared by treating the appropriate aromatic hydroxyaldehyde with an excess of hydrogen sulfide in acidic solution.[15] However, owing to various side reactions, in particular polymerisations, during the heat treatment of the trithianes, the yields obtainable by this desulfurisation method are usually low. Moreover, the desulfurisation method can only be used for the preparation of symmetrically substituted stilbenes.

The synthesis of asymmetrically substituted stilbenes entails the coupling of two different moieties by some type of condensation after protection of the phenolic hydroxyl groups. Grignard syntheses [16] and Wittig syntheses [16-22] have been used to achieve condensation between free,[18] benzylated,[16,21] acetylated,[16,22] methylated,[20] methoxymethylated,[21] or trimethylsilylated,[19] phenolic benzylhalogenides and aromatic aldehydes. These methods afford low overall yields of hydroxystilbenes, unsubstituted at the olefinic carbon atoms.

(1) Knoevenagel condensation of appropriate aromatic aldehydes with suitably substituted arylacetic acids to give stilbenecarboxylic acids or their lactones.[23–25]

(2) Decarboxylation of the stilbenecarboxylic acids [26,27] followed by

(3) Removal of protecting (acetyl) groups (preparation of types C and E)

(4) Alternative to (2): Esterification of the stilbenecarboxylic acids and conversion of lactones into methyl esters, followed by

(5) Lithium aluminium hydride reduction (preparation of types D and F).

By choosing appropriate reactants for the condensations and using the above reaction sequences, a wide variety of symmetrical and asymmetrical phenolic and non-phenolic stilbenes and hydroxymethyl-substituted stilbenes, differing in their patterns of aromatic substitution, could be synthesised. The various steps (1 – 5) in the preparation of some typical representatives (4,4'- and 2,4'-dihydroxystilbenes of types C – F) are described in the experimental section.

Yields, m.p. and elemental analyses of the intermediates and final products are given in Tables 1 – 6; the NMR-data are summarised in Tables 7 – 12. The final products were also characterised by mass spectra. Molecular ions

[a] Prepared by cleavage of the corresponding lactone with methanolic hydrogen chloride and subsequent acetylation.

and fragmentation patterns were in accordance with the expected data.

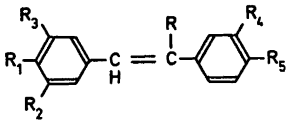
No attempts were made to increase the yields by systematic variation of the reaction conditions.

Some of the syntheses were not completed. Nevertheless, the data for the intermediates prepared are included in the tables.

In view of the versatility of this method, the small number of steps involved, the accessibility of the appropriate starting materials and the yields obtainable, the synthetic routes outlined above appear to compete well with those mentioned in the introduction.

The various compounds are assigned roman numerals according to their aromatic substitu-

tion pattern as follows:



I R_1 = OAc , R_2 = OCH_3 , R_3 = R_4 = R_5 = H

II R_1 = R_2 = OCH_3 , R_3 = R_4 = R_5 = H

III R_1 = R_5 = OAc , R_2 = R_4 = OCH_3 , R_3 = H

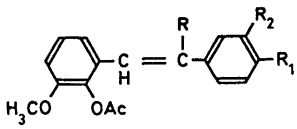
IV R_1 = OAc , R_2 = R_4 = R_5 = OCH_3 , R_3 = H

V R_1 = R_2 = R_4 = R_5 = OCH_3 , R_3 = H

VI R_1 = OAc , R_2 = OCH_3 , R_3 = H , R_4–R_5 = O–CH_2–O

VII R_1 = OAc , R_2 = R_3 = OCH_3 , R_4 = R_5 = H

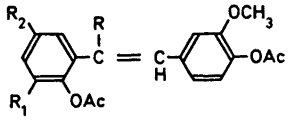
VIII R_1 = OAc , R_2 = R_3 = R_4 = R_5 = OCH_3



IX R_1 = R_2 = H

X R_1 = OAc , R_2 = OCH_3

XI R_1 = R_2 = OCH_3



XII R_1 = R_2 = H

XIII R_1 = OCH_3 , R_2 = CH_3

The indices used refer to:

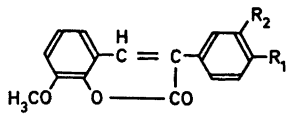
a, stilbenecarboxylic acids (R = COOH);

b, stilbenes unsubstituted at the olefinic carbon atoms (R = H);

c, deacetylation products of b (R = H, OH instead of OAc);

d, stilbenecarboxylic acid methyl esters (R = $COOCH_3$);

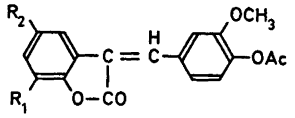
e, hydroxymethyl-substituted stilbenes (R = CH_2OH, OH instead of OAc).



XIV R_1 = R_2 = H

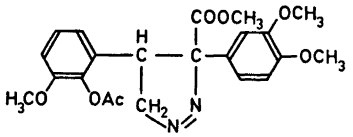
XV R_1 = OAc, R_2 = OCH_3

XVI R_1 = R_2 = OCH_3



XVII R_1 = R_2 = H

XVIII R_1 = OCH_3, R_2 = CH_3



XIX

EXPERIMENTAL

Melting points are corrected. Evaporations were carried out under reduced pressure.

Thin-layer chromatography (TLC) was performed using plates coated with a 0.25 mm thick layer of silica gel (Merck HF_{254}, type 60). The following solvent systems were used: chloroform, chloroform containing 5 % ethanol, chloroform containing 5 % ethyl acetate, toluene containing 5 % ethyl acetate, and diisopropyl ether:formic acid:water 90:7:3. Spots were visualised by exposure to iodine vapour or by spraying with a 3 % solution of vanillin in conc. sulfuric acid followed by heating at 110 °C for 5 – 10 min.

Column chromatography was accomplished using silica gel (Merck 0.05 – 0.5 mm, 70 – 325 mesh, ASTM) or silicic acid (Mallinckrodt, 100 mesh); solvent systems: chloroform containing 5 % ethyl acetate or toluene containing 5 % ethyl acetate. The separations were followed by TLC.

NMR-spectrometry. The NMR-spectra were run on a Perkin-Elmer R-12 spectrometer using $CDCl_3$, CD_3OD or $(CD_3)_2SO$ as solvents. Chemical shifts are given in δ (ppm downfield from tetramethylsilane, internal standard).

The mass spectra were recorded on a Perkin-Elmer 270 instrument at 70 eV using the direct inlet system. The temperature of the probe heater was 60 °C.

Preparation of condensation reactants

o-*Vanillin acetate* by acetylation of *o*-vanillin (20 g) with acetic anhydride (30 ml) in pyridine (30 ml); yield 20 g, 78 %. Recrystallisation from isopropanol gave a product melting at 74 – 75 °C (lit.[28] 76 °C).

Syringaldehyde acetate from syringaldehyde (5 g) by acetylation with acetic anhydride (5 ml) in pyridine (5 ml); yield 5.9 g, 96 %. Recrystallisation from chloroform/hexane yielded the pure acetate, m.p. 115 – 117 °C (lit.[28] 114 °C).

4-Acetoxy-3-methoxyphenylacetic acid (homovanillic acid acetate) was prepared by oxidation of eugenol acetate (m.p. 23 – 28 °C, lit. [29] 27 °C) with potassium permanganate according to Ref. 30 with slight modifications. Total yield: 3.28 g, 94 %. After recrystallisation from glacial acetic acid, the acid melted at 137 – 138.5 °C, lit.[31] 139 – 140 °C.

3,4-Methylenedioxyphenylacetic acid (homopiperonalic acid) was analogously prepared from safrole. Yield 46 %, m.p. 125 – 127 °C (lit.[32] 127 – 128 °C).

6-Hydroxymethyl-4-methylguaiacol was obtained by reacting 4-methylguaiacol (creosol) with formaldehyde (300 ml, 3.7 mol) in a 5 % aqueous solution of sodium hydroxide according to Ref. 33. The colourless prisms (m.p. 50 – 51.5 °C) were recrystallised from ligroin; yield 24 %. Starting material (44 %) was recovered and *bis*-(2-hydroxy-3-methoxy-5-methylphenyl)-methane, m.p. 128 – 129 °C, was obtained in a low yield (4 %) from the fraction distilling at about 200 °C/5 mmHg.

2-Hydroxy-3-methoxy-5-methylphenylacetonitrile. 6-Hydroxymethyl-4-methylguaiacol (9.2 g, 0.055 mol) and sodium cyanide (5.5 g, 0.112 mol) were dissolved in anhydrous methanol and refluxed for 7 h (*cf.* Ref. 34). After removal of methanol the residue was dissolved in water and the solution neutralised with carbon dioxide. The nitrile precipitated in the form of brownish crystals (yield 7.45 g, 77 %) which were contaminated with a small amount of the above-mentioned diphenylmethane derivative and of a cyclic trimeric condensation product.[35] Recrystallisation from benzene-petroleum ether gave the pure nitrile; m.p. 62.5 – 63.5 °C). (Found: C 67.51; H 6.18; O 18.27; N 8.02. $C_{10}H_{11}O_2N$ (177.11) requires: C 67.80; H 6.21; O 18.08; N 7.91.) δ 6.80 – 6.53 (d, 2 H, arom. H); 6.58 (s, 1 H, phenol. H); 3.83 (s, 3 H, arom. OCH_3); 3.67 (s, 2 H, methylene H); 2.27 (s, 3 H, arom. CH_3).

[a] Acetates prepared from the hydroxymethylstilbenes, listed in this table, exhibit signals for the aliphatic acetyl H at δ 2.05 and for the aromatic acetyl H between δ 2.22 and 2.31. [b] The signal of the methylene H appears at δ 5.90. [c] Mixture of *cis*- and *trans*-forms. [d] Methyl H: 2.18 (s, 3 H). [e] The signals of the methylene protons were relatively broad indicating weak allylic coupling to the olefinic proton.

2-Hydroxy-3-methoxy-5-methylphenylacetic acid. The acetonitrile described above (4.6 g, 0.027 mol) was dissolved in conc. hydrochloric acid (1 l) and kept at room temperature for 2 days. The solution was extracted with chloroform and the combined chloroform extracts were extracted with water and dried. Evaporation gave colourless needles which were recrystallised from chloroform/hexane, m.p. 120 – 123 °C; yield 2.73 g, 56 %. [Found: C 61.66; H 5.80; O 32.62. $C_{10}H_{12}O_4$ (196.10) requires: C 61.22; H 6.12; O 32.65.] δ 8.05 (b, 1 H); 6.60 (s, 2 H); 3.85 (s, 3 H); 3.64 (s, 2 H); 2.25 (s, 3 H).

Heating the 2-hydroxyphenylacetic acid in glacial acetic acid afforded the corresponding lactone; m.p. 98 – 99 °C. [Found: C 67.33; H 5.52; O 27.03. $C_{10}H_{10}O_3$ (178.10) requires: C 67.44; H 5.61; O 26.96.] δ 6.66 (s, 2 H); 3.86 (s, 3 H); 3.62 (s, 2 H); 2.30 (s, 3 H).

Condensation (1)

trans-*4,4'-Diacetoxy-3,3'-dimethoxystilbene-α-carboxylic acid* (IIIa). A mixture of homovanillic acid acetate (6.82 g, 0.0304 mol), vanillin acetate (7.65 g, 0.0395 mol) and triethylamine (7.8 ml) in acetic anhydride (76 ml) was refluxed for 45 min. The bulk of acetic anhydride and of triethylamine was then removed by distillation under reduced pressure. The residue was repeatedly washed with water and brought to crystallisation by addition of ethanol. From the combined aqueous washing liquors an additional amount of stilbenecarboxylic acid crystallised and was added to the bulk of the material. Recrystallisation from ethanol gave the pure compound IIIa as yellowish crystals.

trans-*2,4'-Diacetoxy-3,3'-dimethoxystilbene-α'-carboxylic acid* (Xa) was prepared analogously by heating homovanillic acid acetate (6.82 g, 0.0395 mol) and *o*-vanillin acetate (7.65 g, 0.0395 mol) in acetic anhydride (76 ml) and triethylamine (7.8 ml) under reflux for 30 min. After removal of acetic anhydride and triethylamine by distillation under reduced pressure, the residue was dissolved in chloroform and the chloroform solution was extracted several times first with water and then with a saturated solution of sodium bicarbonate. From the combined bicarbonate extracts the stilbenecarboxylic acid (Xa) was obtained in the usual way. Recrystallisation from isopropanol gave the pure compound (6.25 g, 51.3 %, yellowish crystals).

3-(4-Acetoxy-3-methoxyphenyl)-8-methoxycoumarin (XV), formed by lactonisation from compound Xa, was isolated from the remaining chloroform solution. After extraction with sodium bisulfite (removal of the excess of *o*-vanillin acetate), extraction with water, drying (Na_2SO_4) and evaporation, a dark oil was obtained which crystallised on addition of isopropanol. Yield 1.0 g (8.2 %). Recrystallisation from isopropanol gave the pure lactone XV; colourless needles.

Prolongation of the reaction time to 2 h increased the yield of lactone to 22 %.

When 2-acetoxyphenylacetic acids and aromatic aldehydes were refluxed under similar conditions (preparation of type D stilbenes), lactonisation of the starting acids prevented condensation. Conversion of the 2-hydroxyphenylacetic acids into their piperidinium salts enabled condensation but the resulting 2-hydroxystilbene-α-carboxylic acid piperidides underwent extensive lactonisation yielding the corresponding five-membered stilbene lactones (*cf.* Ref. 36).

3-(4-Acetoxy-3-methoxy-benzylidene)-coumaran-2-one (XVII). *o*-Hydroxyphenylacetic acid (3.8 g, 0.025 mol) was dissolved in piperidine (30 ml) and the solvent was removed by distillation under reduced pressure. Large prisms of the *piperidinium salt of o-hydroxyphenylacetic acid* were obtained which after recrystallisation from benzene melted at 104–105 °C; yield 5.2 g (90.5 %) (Found: C 66.1; H 8.3; O 20.1; N 5.7. Calc. for $C_{13}H_{19}O_3N$: C 65.82; H 8.17; O 20.25; N 5.91).

The piperidinium salt (10.85 g, 0.457 mol) and vanillin acetate (11.45 g, 0.590 mol) were refluxed in acetic anhydride (50 ml) containing piperidine (1.6 ml) for 3 h. After removal of acetic anhydride by distillation, ice-water was added to the residue and the resulting oil was separated from the aqueous layer. Addition of ethanol brought about crystallisation. Repeated recrystallisation from the same solvent gave the pure coumaranone XVII; yield 8.3 g (58.5 %), yellowish crystals.

The reaction is likely to proceed as follows: piperidinium salt → piperidide → stilbenecarboxylic acid piperidide → coumaranone. This view is supported by the following results: Refluxing the piperidinium salt (0.5 g) in acetic anhydride (5 ml) for 1 h gave the piperidide; yield 0.4 g, m.p. 114–115 °C. Addition of vanillin acetate to a solution of the piperidide in acetic anhydride containing piperidine and refluxing the mixture for 2 h afforded coumaranone XVII. Finally, the piperidide of XIIa in the deacetylated form (Found: C 70.9; H 6.5; O 18.1; N 4.0. $C_{21}H_{23}O_4N$ requires: C 71.40; H 6.51; O 18.12; N 3.96) (250 mg) was converted into the coumaranone XVII by heating in acetic anhydride (3 ml) under reflux for 4 h. After removal of acetic anhydride and addition of ice to the residue, XVII was obtained as an oil which crystallised on standing; yield 216 mg (98.5 %); m.p. 148–150 °C (see Table 2).

The preparation of the piperidinium salt, its conversion into the piperidide and the condensation to the coumaranone XVII could be conveniently performed in one step with essentially the same result. Thus, addition of vanillin acetate to a solution of *o*-hydroxyphenylacetic acid and piperidine in acetic anhydride and refluxing the mixture for 2 h afforded XVII. The working-up was carried out as described above; yield 58 %.

3-(4-Acetoxy-3-methoxybenzylidene)-5-methyl-7-methoxycoumaran-2-one (XVIII) was similarly prepared from 2-hydroxy-3-methoxy-5-methylphenylacetic acid (see above) (0.795 g, 0.004 mol), piperidine (6.5 ml), vanillin acetate (0.84 g, 0.0043 mol) and acetic anhydride (9 ml). The product crystallised on addition of ethanol and was purified by recrystallisation from isopropanol; yellowish plates.

Decarboxylation (2)

trans-*4,4'-Diacetoxy-3,3'-dimethoxystilbene* (IIIb).[6] Stilbenecarboxylic acid IIIa (13.5 g, 0.034 mol) and hydroquinone (250 mg) were dissolved in freshly distilled quinoline (140 ml). Copper chromite [37] (250 mg) was added and the mixture was heated under reflux for 30 min in a steady stream of nitrogen passing through. After the decarboxylation, the quinoline solution was concentrated to about 25 ml by evaporation under reduced nitrogen pressure. The partially deacetylated product was reacetylated by addition of acetic anhydride (30 ml) and keeping the mixture overnight. After the usual working-up, an oil was obtained which crystallised on addition of isopropanol. The stilbene was purified by recrystallisation from toluene (yield 55.8 %). About the same yield of the *trans*-stilbene (58.3 %) and a minor amount of the amorphous *cis*-isomer (10.0 %) were obtained (see Table 3), when the acetylation mixture was separated on a silicic acid column.

trans-*2,4'-Diacetoxy-3,3'-dimethoxystilbene* (Xb)[22] was similarly prepared from stilbenecarboxylic acid Xa (6.0 g, 0.015 mol), hydroquinone (120 mg) and copper chromite (120 mg). After reacetylation and the usual working-up, an oil was obtained which was fractionated by chromatography on a silicic acid column. *trans*-Stilbene Xb (2.93 g, 54.9 %), the amorphous *cis*-isomer (about 100 mg, ~2 %), and lactone XV (0.6 g, 12 %) were isolated. *trans*-Stilbene Xb and lactone XV were further purified by recrystallisation from isopropanol.

Deacetylation (3)

trans-*4,4'-Dihydroxy-3,3'-dimethoxystilbene* (IIIc).[6,14] The *trans*-form of IIIb (0.59 g, 0.0015 mol) was dissolved in tetrahydrofuran in an atmosphere of nitrogen and the solution was

dropped to a cooled suspension of lithium aluminium hydride (0.47 g, 0.012 mol) in the same solvent (100 ml). After 15 min, the excess of lithium aluminium hydride was decomposed by addition of ethyl acetate saturated with water. Hydrochloric acid (2 M) was added until all the precipitate was dissolved and the solution was extracted repeatedly with ethyl acetate. The combined extracts were washed with water until neutral, dried and evaporated. The stilbene was recrystallised from ethanol.

trans-*2,4'-Dihydroxy-3,3'-dimethoxystilbene* (Xc)[21,22] was prepared from the corresponding diacetate (Xb, 182 mg) by addition of sodium (30 mg) to a solution in ethanol (10 ml). Neutralisation (CO_2) and evaporation of the solvent gave a residue which was dissolved in chloroform. The chloroform solution was extracted with water, dried (Na_2SO_4) and evaporated. The product was recrystallised from ethanol.

On exposure to air, the phenolic stilbenes undergo slow autoxidation with discoloration. The impurities can be removed by recrystallisation from ethanol containing small amounts of sodium borohydride.

In the preparation of phenolic hydroxymethyl-substituted stilbenes (types D and F), the reduction of the stilbenecarboxylic acid methyl ester group by lithium aluminium hydride (see below) is, of course, accompanied by the removal of acetyl groups. Thus, no extra deacetylation step is needed.

Esterification (4):

(a) starting from stilbenecarboxylic acids

4,4'-Diacetoxy-3,3'-dimethoxystilbene-α-carboxylic acid methyl ester (IIId). To a saturated solution of the stilbenecarboxylic acid IIIa (5.6 g, 0.014 mol) in dioxane (100 ml) an ethereal solution of diazomethane (about 0.02 mol) was dropped slowly. The mixture was kept at room temperature for 16 h. After removal of the solvents by distillation under reduced pressure, a yellowish oil was obtained which crystallised on standing. Recrystallisation from toluene gave the pure compound IIId.

The use of a larger excess of diazomethane lowered the yield owing to addition of the methylating reagent across the olefinic double bond. In one instance (esterification of XIa) the resulting 3,4-diarylpyrazoline derivative (XIX) was isolated, purified and identified by elemental analyses and NMR; m.p. 105–107 °C. (Found: C 61.7; H 5.6; O 25.8; N 6.6. $C_{22}H_{24}O_7N_2$ requires: C 61.68; H 5.60; O 26.16; N 6.54.) δ 6.97–6.55 (m, 6 H); 6.00–5.82 (1 q, 1 H); 5.05–4.57 (1 q, 1 H); 4.65–4.45 (1 q, 1 H (AMX spectrum) 3.75 (s, 3 H); 3.68 (s, 3 H); 3.62 (s, 6 H); 2.42 (s, 3 H).

2,4'-Diacetoxy-3,3'-dimethoxystilbene-α'-carboxylic acid methyl ester (Xd) was similarly prepared by treatment of stilbenecarboxylic acid Xa with diazomethane. The ester crystallised from the oily reaction product on prolonged standing in the refrigerator. Recrystallisation from toluene gave the pure compound. In addition to the ester, the oily reaction product contained the corresponding lactone (XV) and some other by-products not further characterised (TLC).

(b) starting from stilbene lactones

The yields of methyl esters were high except those of 2-acetoxystilbene-α-carboxylic acid methyl esters (XIId and XIIId) which had to be prepared be refluxing the corresponding stilbene lactones in an excess of methanolic hydrogen chloride.

2,4'-Diacetoxy-3'-methoxystilbene-α-carboxylic acid methyl ester (XIId). 3-(4-Acetoxy-3-methoxybenzylidene)-coumaran-2-one (XVII) (1.6 g) was dissolved in a 0.5 % solution of hydrogen chloride in anhydrous methanol (150 ml) and the solution was refluxed for 90 min.

After removal of the solvent and hydrogen chloride by evaporation, the residual oil was separated by preparative TLC and the fraction containing the deacetylated methyl ester was acetylated with acetic anhydride in pyridine. The resulting diacetyl compound XIId was purified by recrystallisation from ethanol.

2,4'-Diacetoxy-3,3'-dimethoxy-5-methylstilbene-α-carboxylic acid methyl ester (XIIId) was prepared analogously by refluxing a solution of 3-(4-acetoxy-3-methoxybenzylidene)-5-methyl-7-methoxycoumaran-2-one (XVIII, 0.818 g) in 1 % methanolic hydrogen chloride (75 ml) for 2.5 h. The product was worked up and purified as described for the preceding compound. Starting material (315 mg, 38.5 %) was also isolated.

Lithium aluminium hydride reduction (5)

The conversion of stilbenecarboxylic acid methyl esters into hydroxymethyl stilbenes was performed following the procedure described for the reduction of ferulic acid ethyl ester [38] and of acetylferulic acid methyl ester [39] to coniferyl alcohol with some modifications.

4,4'-Dihydroxy-3,3'-dimethoxy-α-hydroxymethylstilbene (*IIIe*). To a cooled suspension of lithium aluminium hydride (2.66 g, 0.07 mol) in anhydrous tetrahydrofurane (200 ml) a solution of 4,4'-diacetoxy-3,3'-dimethoxystilbene-α-carboxylic acid methyl ester (IIId, 4.1 g, 0.01 mol) in tetrahydrofurane (100 ml) was added at 0 °C in a nitrogen atmosphere during 20 min. The reduction was allowed to continue for 4 h at 0 °C with vigorous stirring and was followed by TLC.

Excess of lithium aluminium hydride was decomposed by addition of ethyl acetate satu-

rated with water. After dissolution of the precipitate by acidification with 2 M hydrochloric acid, the solution was extracted with ethyl acetate. Evaporation of the combined and dried (Na_2SO_4) extracts gave a colourless viscous oil which crystallised on standing. Recrystallisation from toluene yielded pure compound IIIe.

2,4'-Dihydroxy-3'-methoxy-α-hydroxymethyl stilbene (XIIe) was prepared similarly from 2,4'-diacetoxy-3'-methoxystilbene-α-carboxylic acid methyl ester (XIId). Recrystallisation from ether–petroleum ether gave the pure compound. An additional amount was isolated from the combined mother liquors by preparative column chromatography.

2,4'-Dihydroxy-3,3'-dimethoxy-5-methyl-α-hydroxymethylstilbene (XIIIe) was prepared in a similar manner from 2,4'-diacetoxy-3,3'-dimethoxy-5-methylstilbene-α-carboxylic acid methyl ester (XIIId).

The phenolic hydroxymethylstilbenes were stable, provided air (oxygen) and moisture were excluded.

Direct reductions of stilbene lactones with lithium aluminium hydride [40] (*cf.*, however, Ref. 41), aluminium hydride [42] and borohydride [43] resulted in complex mixtures consisting mainly of products formed by alkaline or reductive cleavage of the lactone ring with concomitant or subsequent reduction of the stilbene double bond (NMR).

Thus, compound XVII, when treated with sodium borohydride in ethanol-chloroform-water (7:4:1) at room temperature, afforded a mixture of products which was separated by chromatography on a column of silica gel yielding a main component, melting at 118–119 °C. This compound was acetylated with acetic anhydride in pyridine and identified as 2,4'-diacetoxy-3'-methoxy-α-acetoxymethylbibenzyl (XIIe, OAc instead of OH, $-CH_2-CH_2-$ instead of $-CH=CH-$). δ 7.43–6.43 (m, 7 H); 4.20 (d, 2 H); 3.60 (s, 3 H); 3.75–3.40 (m, 1 H); 2.89 (d, 2 H); 2.20 (s, 6 H); 1.89 (s, 3 H).

Acknowledgements. This work was supported by grants to one of us (Ilona Szabo-Lin) from "1959 års fond", which is gratefully acknowledged.

Our thanks are due to Mrs. Ingegerd Östlund for skilful assistance in the preliminary experiments.

Animal Carotenoids. 9.* On the Absolute Configuration of Astaxanthin and Actinioerythrin

A. G. ANDREWES,[a,**] G. BORCH,[b] S. LIAAEN-JENSEN[a] and G. SNATZKE[c]

[a] Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway, [b] Chemistry Department A, The Technical University of Denmark, DK-2800 Lyngby, Denmark and [c] Lehrstuhl für Strukturchemie, Ruhr-Universität Bochum, D-463 Bochum, West Germany

Dedicated to Professor Dr. techn. Nils Andreas Sørensen at the occasion of his 65th birthday December 8, 1974

The use of chiroptical methods for determination of the absolute configuration of astaxanthin (*1*) is discussed.

Chemical conversion of astaxanthin (*1*) diester into zeaxanthin (*7*) failed.

Consideration of the CD-spectrum of the tetrol *10*, obtained by $LiAlH_4$-reduction of astaxanthin (*1*) diester, led to the (3*S*,3′*S*)-assignment for astaxanthin (*1a*).

Chiroptical properties of actinioerythrin (*13*) are reported.

The constitution of astaxanthin (*1*) was elucidated by Kuhn and Sørensen [1] in 1938. Astaxanthin (*1*) is converted to astacene (*2*) under alkaline conditions in the presence of oxygen,[1] Scheme 1. The structure *1* of astaxanthin has subsequently been confirmed by Davis and Weedon [2] by partial synthesis of astacene (*2*) from canthaxanthin (*3*). However, the absolute configuration at 3,3′-positions has not yet been determined.

From feeding experiments with (^{14}C)-lutein it has been claimed that astaxanthin (*1*) in goldfish (*Carassius auratius*) is formed biogenetically from lutein.[3] Lutein, first considered to have (3*R*,3′*S*,6′*R*)-configuration,[4] was later demonstrated to possess (3*R*,3′*R*,6′*R*)-configuration (*4*).[5–7] If astaxanthin (*1*) were synthesized *in vivo* from lutein (*4*) without epimerization on the enzyme, astaxanthin should have 3*S*,3′*R*-configuration and be achiral. However, astaxanthin *ex Hommarus gammarus* (from crustacyanin) is optically active.[8a] Its biosynthesis in goldfish, therefore, calls for further attention.

From its chiroptical properties astaxanthin cannot be bound to positive centers of proteins

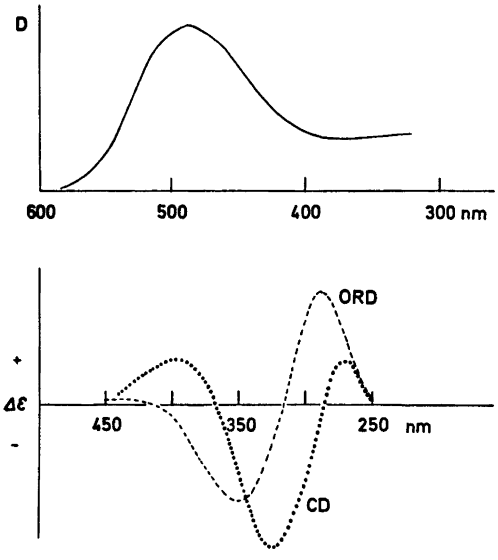

Fig. 1. Electronic absorption spectrum (—— top), CD-spectrum (· · ·, bottom) and ORD-spectrum (– – –, bottom; calculated from the CD-spectrum) of astaxanthin (*1*) *ex Hommarus gammarus* in chloroform solution.

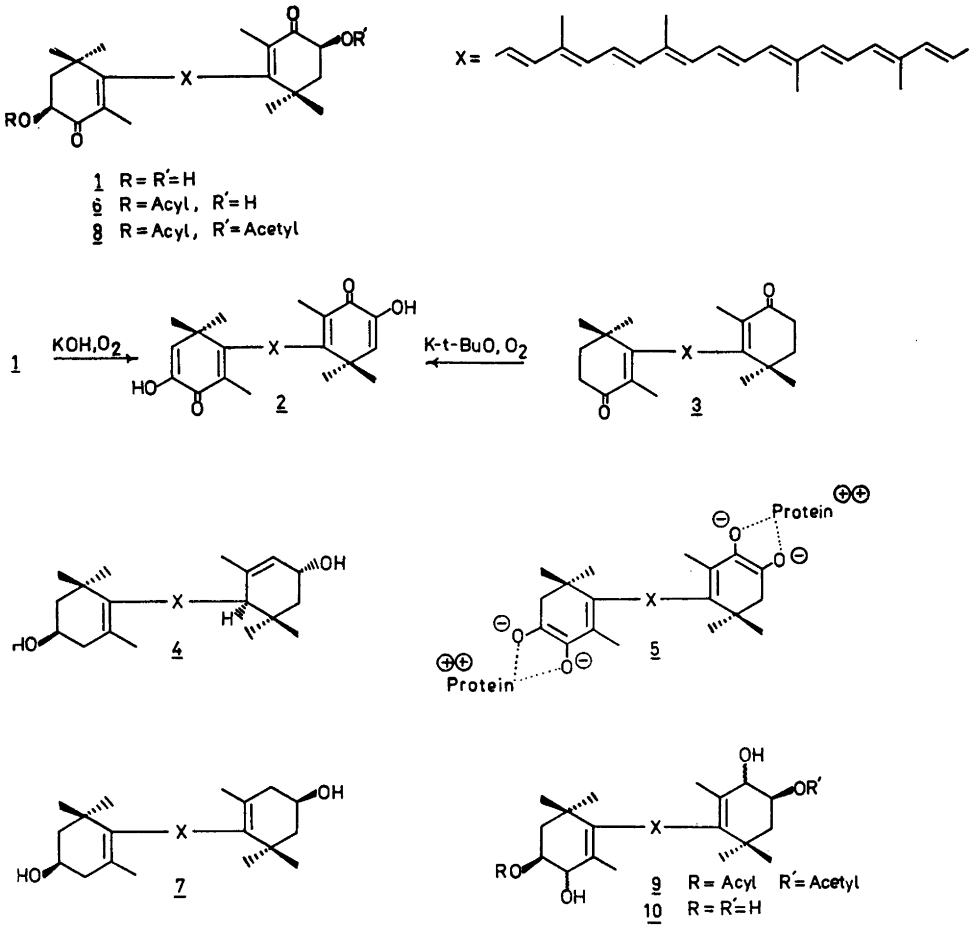

Scheme 1.

in lobster eggs as a bis-dianion (*5*),[1] because mere extraction with organic solvents cannot produce chirality of the carotenoid. The optical activity of astaxanthin *ex* ovoverdin is recently confirmed.[8b]

In order to establish the absolute configuration at the two chiral centers of astaxanthin (*1*) the use of chiroptical properties was considered. CD and ORD spectra of carotenoids have been investigated by several groups (*cf.*, *e.g.*, Refs. 8 – 10) but are theoretically not well understood.

Klyne and his colleagues [8a] have, quite successfully, developed an empirical rule which states that the two chiral end groups of a carotenoid contribute independently to the optical activity, so that contributions for these end groups are additive. This procedure is probably justified only for absorption bands connected with excitations of "partial chromophores" but not for the CD within the main band of all-*trans* carotenoids. However, due to the intense absorption of carotenoids in the latter region only few ORD/CD measurements are available for the visible region.[9,11]

Mills' rule [12,13] has also successfully been applied for determining the stereochemistry of 2- and 3-hydroxy-β-cyclogeranyl rings in carotenoids.[14,15] Recent work in our laboratories has further indicated that the preferred conformation of a chiral β-cyclogeneranyl ring is indeed of decisive importance for the CD spectra of carotenoids regardless of the type of substituents on the cyclohexene ring when dealing with half-chair conformations.[7]

RESULTS AND DISCUSSION

The ORD curve of a concentrated solution of astaxanthin (*1*) *ex* lobster has been reported by Buchwald and Jencks [16] for the 600 – 400 nm region and of astaxanthin *ex Hommarus gammarus* and of astaxanthin diacetate *ex Hommarus gammarus* and *ex Halocynthia papillosa* by Bartlett *et al.*[8a] in the 400 – 213 nm region. No stereochemical conclusions have been drawn from these data.

Fig. 1 shows the CD-spectrum of astaxanthin (*1*) *ex Hommarus gammarus* recorded in the 420 – 250 nm region. The ORD spectrum (450 – 250 nm) calculated [17] from this CD spectrum is consistent with data reported previously by Bartlett *et al.*[8a] In the 450 – 400 nm region their ORD curve deviates somewhat from that reported by Buchwald and Jencks.[16] In concentrated solution in the 600 – 400 nm region Buchwald and Jencks [16] probably measured some artefacts. The CD spectrum of astaxanthin monoester (*6*) *ex Haematococcus pluvialis*.[18] is shown in Fig. 2. In spite of the different solvents used, the CD spectra of *1* and *6* are very similar, thus supporting earlier reports [19] that individual chiral carotenoids have the same absolute configuration regardless of the biological source.

In general, the absolute configuration of a cyclohexenone can be derived from its CD spectrum in the range of the $n\rightarrow\pi^*$ band under the restrictions that this band can be unequivocally identified in the CD spectrum, and that a safe prediction can be made for the preferred conformation of the cyclohexenone ring.[20] Unfortunately, at least the first problem cannot be solved, because for astaxanthin (*1*) the CD band corresponding to the $n\rightarrow\pi^*$ transition cannot be identified. For simple conjugated oligo-enones, the $n\rightarrow\pi^*$ band appears at longest wavelengths corresponding to the transition of lowest energy. Calculations by Moore [21] have shown, however, that commencing with a polyene aldehyde of five carbon-carbon double bonds, the first $\pi\rightarrow\pi^*$ band should appear at longer wavelengths than the corresponding $n\rightarrow\pi^*$ band. In this connection recent work on a steriodal trienone has revealed that the $n\rightarrow\pi^*$ band occurs at *ca.* 360 – 380 nm and the $\pi\rightarrow\pi^*$ band at 345 nm.[22] With this short chromophore the separation of the two bands is rather small and distinctly visible only in unpolar solvents. In the case of astaxanthin (*1*), one would expect the $n\rightarrow\pi^*$ band to appear in the visible range where the anisotropy factor $g' = \Delta\varepsilon/\varepsilon$ is too small to give reliable CD data. Below 400 nm the CD spectrum of astaxanthin (*1*) resembles somewhat that of zeaxanthin (*7*), Scheme 1, which contains no carbonyl groups. A hypsochromic shift of the CD spectrum of *7* compared to that of *1*, is parallelled by a similar shift of the $\pi\rightarrow\pi^*$ band in the visible region of the corresponding isotropic electron absorption spectra. Such resemblance can, however, not be taken as proof for the same absolute configuration at the chiral centers C-3 and C-3′ without sufficient reference data.

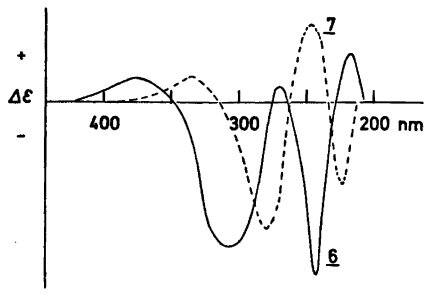

Fig. 2. CD-spectra of astaxanthin monoester (*6*, ——) and zeaxanthin (*7*, - - -) in EPA 5:5:2 solution.

For further work astaxanthin monoester (*6*) *ex Haematococcus pluvialis* [18] was used. All attempts to convert *6 via* its monoacetate *8* into zeaxanthin diester (or its enantiomer) failed.

These included the reduction of the two carbonyl groups of *8* to the tetrol-diester *9* with $NaBH_4$ followed by (i) SO_3 pyridine complex treatment and $LiAlH_4$-reduction,[23] (ii) formation of the *p*-toluene sulfonate [24] or methane sulfonate [25] derivative and subsequent $LiAlH_4$-reduction, (iii) replacement of hydroxyl by bromide followed by $LiAlH_4$-reduction.[26]

A second approach directed towards reduction of the keto groups of *6 via* N-derivatives, studied with canthaxanthin (*3*) as a model compound, was also unsuccessful. Thus, canthaxanthin (*3*) provided no hydrazone, phenylhydrazone or tosylhydrazone, but gave an oxime and a semicarbazone. Reduction of the semicarbazone under strongly alkaline conditions [24] failed. Previous attempts along the same lines have also been unsuccessful.[27]

Since a direct correlation with natural zea-

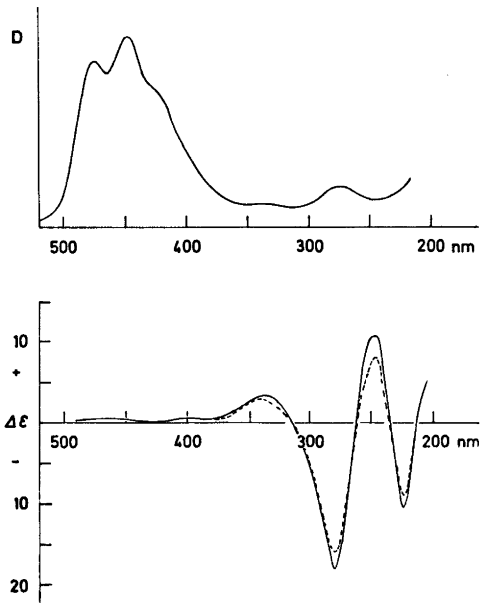

Fig. 3. Electronic absorption spectrum of the tetrol *10* (——, top), and CD-spectra of tetrol *10* (——, bottom) and zeaxanthin (*7*, – – –, bottom) *ex Flexithrix* strain QQ [30] in EPA 5:5:2 solution.

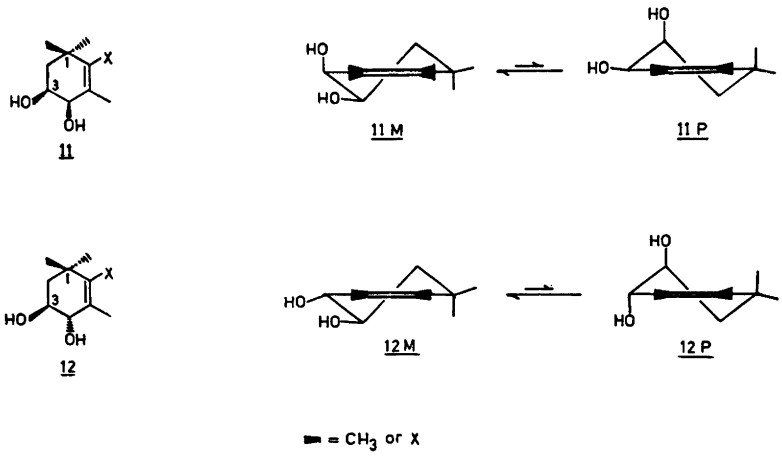
xanthin (*7*), known to have 3*R*,3′*R*-configuration [28,29] could not be achieved, chiroptical data of the tetrol *10* (obtained by $LiAlH_4$-reduction of *8*) was used to solve the stereochemistry of astaxanthin (*1*). The CD spectrum of the tetrol *10* together with that of zeaxanthin (*7*) *ex Flexithrix* sp.[30] with corrected [7] Δε-value is given in Fig. 3. The CD curves of *10* and *7* are very similar in shapes and signs of the individual Cotton effects; rotational strengths of the tetrol *10* being slightly higher than those reported for zeaxanthin (*7*).[7,8,31] By the following arguments this result is taken to prove the 3*S*,3′*S*-configuration of astaxanthin (*1*).

It is well known [32] that reduction by $LiAlH_4$ or $NaBH_4$ of a cyclohexanone preferentially leads to the equatorial alcohol if the ketone is unhindered, whereas, in the contrary case, the axial alcohol prevails. In the case of a cyclohexenone usually a mixture of epimers is formed,[33] especially if the ring is not rigid. Reduction of *8* was therefore expected to yield a mixture of three diastereomeric tetrols.

A series of attempts to isolate individual diastereomers of the tetrol *10* failed, thus also precluding the possible use of hydrogen bonding studies by IR. The systems investigated included that in which the diastereomeric tetrols derived from actinioerythrin (*13*) could be separated [34] and the one where Bodea and coworkers [35] claimed successful separation of $NaBH_4$-reduced astaxanthin.

However, separation of the tetrol *10* into individual diastereomers is not essential for our argumentation.

Assuming 3*S*,3′*S*-configuration for astaxanthin (*1*), the *cis* diol end group *11* will have 3*S*,4*R*-configuration and the *trans* diol end group *12* the 3*S*,4*S*-configuration, Scheme 2. Of the two half-chair conformations *12M* and *12P* associated with the *trans* diol *12*, *12M* will be



Scheme 2.

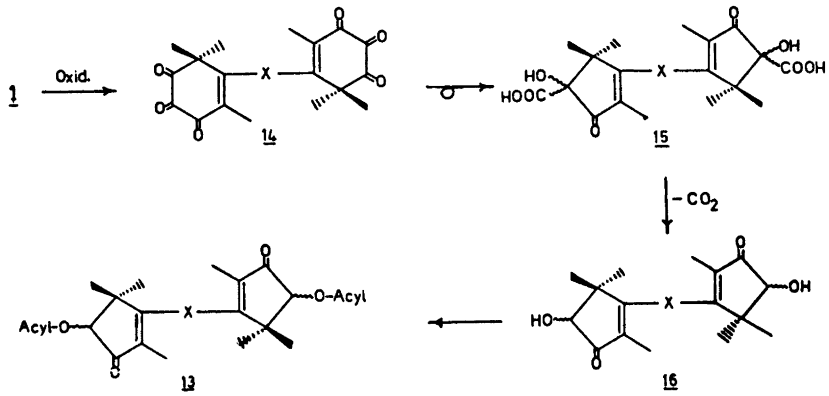
preferred because there is only one (1:3-Me:H) interaction as opposed to one (1:3-OH:Me) and one (1:3-OH:H) interaction present in the *12P*-conformation. In the case of the *cis* diol *11*, the *M*-helical conformation *11M* will also be preferred because the *P*-conformation contains a (1:3-OH:Me) interaction which is thought to be more severe than the sum of a (1:3-OH:H) and a (1:3-Me:H) interaction, *cf.* Ref. 36, especially in EPA solution where solvation will take place. Zeaxanthin (*7*), whose end group has the same configuration for the 3-OH-group, is also expected to have the ring predominantly in the *M*-conformation to avoid such a (1:3-OH:Me) interaction; this is consistent with ^{1}H NMR evidence.[37,38] The preponderance for the *M*-conformation of the cyclohexene half-chair of these end groups (*viz.* monohydroxylated end group of *7*, and *cis* and *trans* dihydroxylated *11* and *12* of *10*) will be greatest for the trans diol *12* end group and smallest for the *cis* diol end group *11*.

As already mentioned, there is reason to assume [10] that the signs of the CD bands are determined solely by the helicity of the (half-chair) conformation of the cyclohexene ring. This is consistent with another rule proposed [39] for the CD of conjugated dienes and enones, which states that the axial substituents (including hydrogen) in allylic position to the diene or α-position to the conjugated ketone determine the sign of the Cotton effects, *cf.* Ref. 40. On the basis of this hypothesis and the conformational analysis given above, the CD of *7*, *11*, and *12* should thus be mainly determined by the configuration at C-3 (or C-3′). As the signs and positions of the Cotton effects of *7* and the tetrol *10* are exactly the same, we conclude, therefore, that the configuration at C-3 and C-3′ of *10* and thus also of astaxanthin (*1*) is *S*.

Considering now the rotational strength observed for zeaxanthin (*7*) and the tetrol *10*, Fig. 3. From the arguments advanced above, complex hydride reduction resulting in a preponderance of products with the *cis* diol end group *11* would be expected to result in a $\Delta\varepsilon$-value for the tetrol *10* lower than for zeaxanthin (*7*). Preponderance of products with the *trans* diol end group *12* would, on the other hand, result in higher $\Delta\varepsilon$-values relative to zeaxanthin (*7*). The actual values observed ($\Delta\varepsilon = -14.8$ for *7*, *versus* $\Delta\varepsilon = -18.0$ for *10*) only allows the tentative conclusion that more of the *trans* diol end group *12* was formed than of the *cis* diol end group *11*.

Independent support for the stereochemical assignment of astaxanthin (*1*) may be possible through partial synthesis of the 3,3′-dimethyl ether of the tetrol *10* from optically active zeaxanthin (*7*) dimethyl ether for CD comparison with *10*. The route utilized by Surmatis and Thommen [41] for the synthesis of astaxanthin (*1*) dimethyl ether is one possible approach.

Another carotenoid with unknown stereochemistry is actinioerythrin (*13*, Scheme 3), which is a naturally occurring diester of a bis-cyclopentenone-α-ketol [34] with the unique 2,2′-bis-nor-carotenoid structure. It has been suggested that *13* is formed *in vivo* from astaxanthin (*1*) [42] by oxidation to *14* (Scheme 3), benzilic acid rearrangement to *15*, decarboxylation to the bis-α-ketol *16*, and finally esterification. As the



Scheme 3.

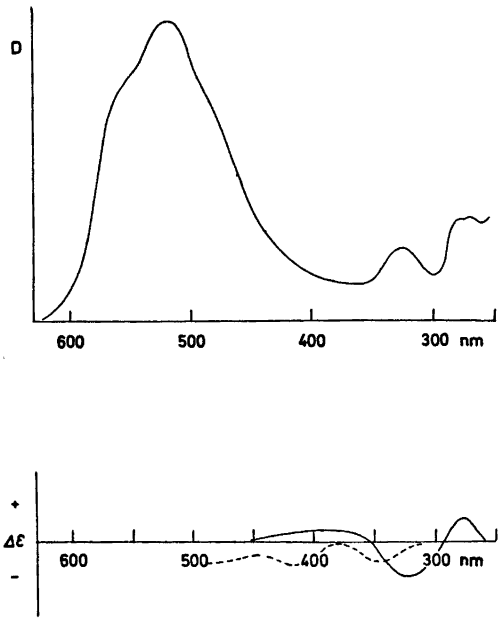


Fig. 4. Electronic absorption spectrum (——, top) of actinioerythrin (*13*), CD-spectrum (——, bottom) and ORD-spectrum (- - -, bottom; calculated from the CD-spectrum) of actinioerythrin (*13*) in chloroform solution.

prochiral intermediate *14* may be involved, the absolute configuration of the OR-group of *13* must not necessarily, from biosynthetic considerations, have the same streochemistry as that of astaxanthin (*1*). On the other hand, optical activity of *13* does not contradict such a biogenetic pathway since a chiral enzyme can stereospecifically react either with the *re*- or the *si*-side of the ring of *14*. Actinioerythrin *13* is indeed chiral as evidenced by its CD spectrum, Fig. 4. The ORD spectrum calculated [17] therefrom is also given in Fig. 4. In the case of *13*, a negative CD within the main absorption band in the visible region was observed. Because of high noise and a small anisotropy factor no quantitative values can be given, however. Due to the difficulties encountered in the interpretation of the CD of cyclopentenones [20] no conclusions about the absolute streochemistry of actinioerythrin (*13*) can be drawn at present, except that the two chiral centers of this molecule must have the same chirality.

EXPERIMENTAL

Materials. Astaxanthin *ex Hommarus gammarus* and astaxanthin monoester *ex Haematococcus pluvialis* were obtained from the collection of Professor N. A. Sørensen, and astaxanthin *ex* lobster eggs provided by Hoffmann-La Roche, Basel. Actinioerythrin was left from a previous investigation.[24]

Methods. Methods used were those commonly employed in the Trondheim laboratory.[24] CD spectra were recorded in Copenhagen in EPA (ether:isopentane:ethanol, 5:5:2) solution with a Roussel-Jouan Dichrographe II.

Acetylation of astaxanthin monoester (6). *6* (0.5 mg) in dry pyridine (2 ml) was treated with acetic anhydride (0.2 ml) for 6 h at 25 °C to yield quantitatively *8*; λ_{max} 485 nm ($CHCl_3$), 474 nm (MeOH); $R_F = 0.5$, silica gel G plate developed with 20 % APE (acetone in petroleum ether).

$LiAlH_4$ reduction of 8. *8* (0.5 mg) in dry ether (10 ml) was treated with $LiAlH_4$ at 25 °C for 3 min (representative experiment). After extractive isolation with $CHCl_3$, *10* was isolated and purified by TLC on silica gel G plates developed with APE. The tetrol *10* had the following properties: λ_{max} (430), 453, 480 nm (acetone), 451 nm (MeOH); *m/e* 600 (M), 582 (M − 18), 564 (M − 36), 546 (M − 54), 508 (M − 92) and 494 (M − 106); $R_F = 0.35$, silica gel G plates developed with 40 % APE.

Attempted separation of diastereomeric tetrols 10. Attempted separation of the diastereomeric tetrols *10* on kieselguhr paper, cellulose plates, cellulose columns, acetylated polyamide columns and MgO columns failed. On the latter column *10* failed to move with 10 % acetone in benzene; Nicoara *et al.*[25] reported successful separation of *10* in this system.

$NaBH_4$ reduction of 8. *8* (0.5 mg) in wet MeOH (10 ml) was treated with $NaBH_4$ at 0 °C for 5 min. After extractive isolation *9* was obtained in quantitative yield; λ_{max} (430), 453, 480 nm (acetone); 451 nm (MeOH); $R_F = 0.4$, silica gel G plates developed with 25 % APE.

Reactions of 9. *9* (0.1 mg) was treated for 20 h at 25 °C with SO_3-pyridine (10 mg) in dry THF (2 ml);[23] no sulfate ester was detected upon TLC analysis. Treatment of *9* (0.1 mg) with excess *p*-toluene sulfonyl chloride in ether or pyridine gave no ester. Treatment of *9* in dry pyridine with methane sulfonyl chloride resulted in degradation of the pigment. Attempted formation of the 4,4′-dibromo derivative of *9* by treatment with NBS-$(CH_3)_2S$ in CH_2Cl_2 [26] failed.

Reactions with canthaxanthin (3). *3* when treated with hydrazine hydrochloride, phenylhydrazine hydrochloride, or tosylhydrazine in MeOH or pyridine solvents failed to yield the corresponding hydrazones even at elevated temperatures. *3* smoothly formed the oxime and semicarbazone under standard conditions. The latter when treated with KOMe in dimethyl

sulfoxide [24] failed to yield the reduced product when treated at 100 °C in a sealed tube under N_2 for 30 min.

Acknowledgements. We thank Professor N. A. Sørensen for samples of astaxanthin and astaxanthin ester and for his interest and advice. A gift of astaxanthin was also obtained from Hoffmann-La Roche, Basel. A. G. A. was supported by a research grant from the same firm to S. L.-J. G. S. thanks the Deutsche Forschungsgemeinschaft for financial support.

Bacterial Carotenoids. XLIII.* C_{50}-Carotenoids. 13.** Synthesis of (2*R*,2′*R*)-2,2′-Dimethyl-β,β-carotene and Absolute Configuration of (2*R*,2′*R*)-2-(4-Hydroxy-3-hydroxymethyl-2-butenyl)-2′-(3-methyl-2-butenyl)-β,β-carotene

ARTHUR G. ANDREWES,[a] SYNNØVE LIAAEN-JENSEN[a] and GUNNER BORCH[b]

[a] Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway and [b] Chemistry Department A, The Technical University of Denmark, DK-2800 Lyngby, Denmark

This first assignment of absolute stereochemistry to a C_{50}-carotenoid, *C.p.* 450 = (2*R*,2′*R*)-2-(4-hydroxy-3-hydroxymethyl-2-butenyl)-2′-(3-methyl-2-butenyl)-β,β-carotene (*5*), followed from CD-correlation with natural (2*R*,2′*R*)-β,β-carotene-2,2′-diol (*4*) and (2*R*, 2′*R*)-2,2′-dimethyl-β,β-carotene (*12*) synthesized here.

All fourteen [1–4] known naturally occurring C_{45}- and C_{50}-carotenoids are distinguished by having additional C_5-isopentenyl units formally added to the 2- or 2,2′-positions on a C_{40}-skeleton; exemplified by bacterioruberin (*1*), bisanhydrobacterioruberin (*2*), and decaprenoxanthin (*3*), Scheme 1. Provided enzymatic control, this addition induces optical activity at C-2 (2′), indicated by asterisks in Scheme 1. From CD correlation bacterioruberin (*1*) and bisanhydrobacterioruberin (*2*) are known to possess the same absolute configurations.[5] Chiroptical properties of decaprenoxanthin (*3*) have also been reported.[5,6] However, despite rapid advances in the stereochemistry of C_{40}-carotenoids, no absolute configurations of C_{45}- or C_{50}-carotenoids have hitherto been reported.

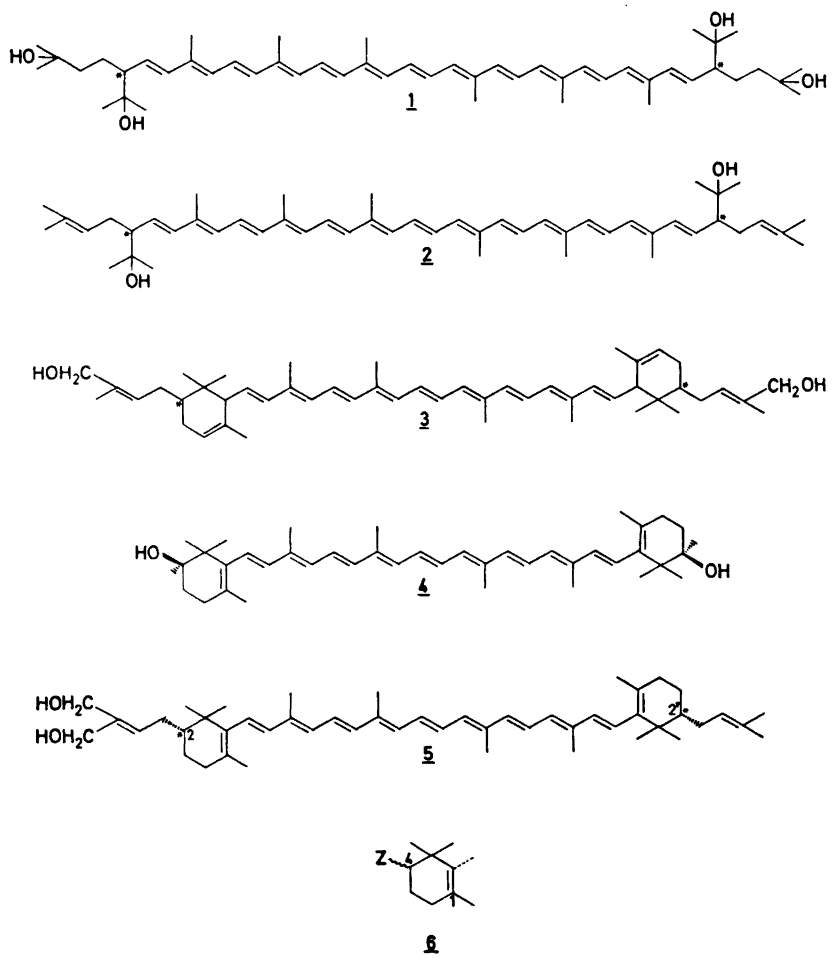
Recent reports on the absolute stereochemistry of (+)-(*R*)-β-irone (*7*, Scheme 2) [7] and tentative stereochemical assignment to (2*R*,2′*R*)-β,β-carotene-2,2′-diol (*4*) [8] prompted us to investigate the stereochemistry of some C_{50}-carotenoids; in particular that of 2-(4-hydroxy-3-hydroxymethyl-2-butenyl)-2′-(3-methyl-2-butenyl)-β,β-carotene (*5*; *C.p.* 450 [3]), Scheme 1.

(2*R*,2′*R*)-β,β-Carotene-2,2′-diol (*4*) and *C.p.* 450 (*5*, stereochemistry hitherto unknown) have common chromophores and differ only in the nature of the 2-substituent. Each have termini which may be regarded as 4-substituted cyclohexenes (see structure *6*, Scheme 1). From Mills' rule,[9,10] the optical rotation of cyclohexene systems with an asymmetric carbon at position 4 is caused by a preferred conformation of the cyclohexene ring itself and the nature of the substituent is not relevant. Application of Mills' rule may lead to erroneous results,[11] although its validity in the carotenoid series for the stereochemical correlation of (2*R*,2′*R*)-β,β-carotene-2,2′-diol (*4*) and zeaxanthin (3*R*,3′*R*)-β,β-carotene-3,3′-diol) has recently been confirmed.[12a] As a further model for CD-correlation (2*R*,2′*R*)-2,2′-dimethyl-β,β-carotene (12) was synthesized from (+)-(*R*)-β-irone (*7*). Optically inactive *12* has previously been synthesized by Eugster *et al.*[12b] by a different route.

RESULTS AND DISCUSSION

(+)-(6*R*)-β-Irone (*7*) was isolated by preparative GLC from a base-isomerized mixture of natural irones.[7] The synthesis of (2*R*,2′*R*)-2,2′-dimethyl-β,β-carotene (*12*) followed the route

* No. XLII. *Acta Chem. Scand. 27* (1973) 3040.
** No. 12. *Acta Chem. Scand. B 28* (1974) 244.



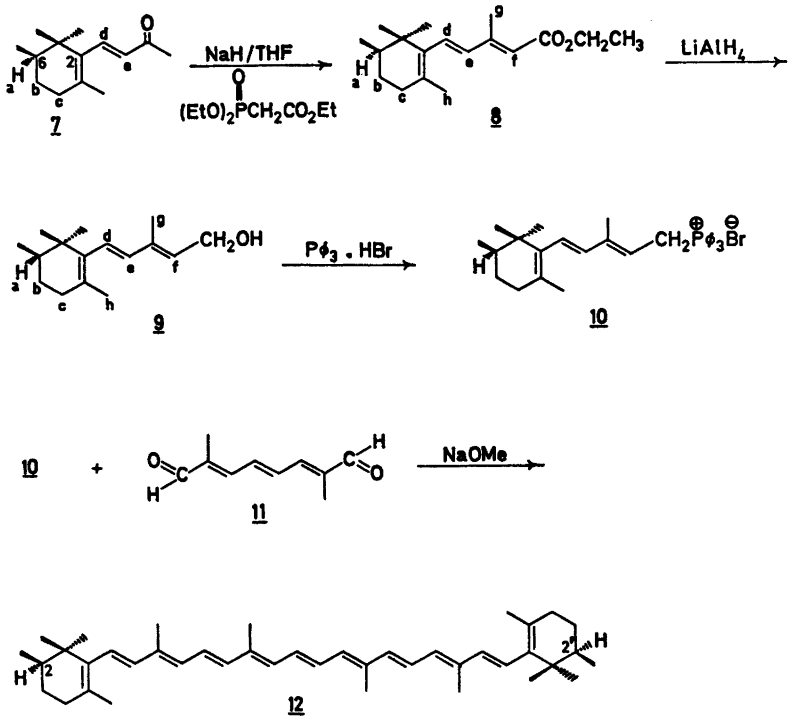
Scheme 1.

shown in Scheme 2. Treatment of *7* with ethyl diethylphosphonoacetate gave (*R*)-β-ironylidene acetate (*8*). Reduction with $LiAlH_4$ provided the allylic alcohol *9* which was converted to the corresponding phosphonium bromide *10*. Condensation of *10* with the trienedial *11* gave (2*R*,2′*R*)-2,2′-dimethyl-β,β-carotene (*12*).

The electronic absorption spectrum of *12* corresponded to that of β-carotene. The ^1H NMR spectrum, including signal assignments, is reproduced in Fig. 1. The upper mass region of the mass spectrum is shown in Fig. 2.

The CD spectra of *trans* (2*R*,2′*R*)-2,2′-dimethyl-β,β-carotene (*12*), (2*R*,2′*R*)-β,β-carotene-2,2′-diol (*4*) and *C.p.* 450 (*5*, available from a previous investigation [3]) are shown in Fig. 3. Immediately apparent is the similarity between the curves of *4* and *12*, possessing the same absolute stereochemistry, and differing only in the nature of the 2-substituent, hydroxyl *versus* methyl. This compatibility further confirms that the principle of Mills' rule is applicable to these carotenoid systems.

The CD spectrum of *C.p.* 450 (*5*) is virtually exactly opposite to those of *4* and *12*, revealing opposite absolute configuration in 2,2′-positions. *C.p.* 450 has therefore configuration *5*. Formally, *C.p.* 450 is (2*R*,2′*R*)-2-(4-hydroxy-3-hydroxymethyl-2-butenyl)-2′-(3-methyl-2-butenyl)-β,β-carotene.[13]



Scheme 2.

Fig. 2. Mass spectrum of (2*R*,2′*R*)-2,2′-dimethyl-β,β-carotene (*12*).

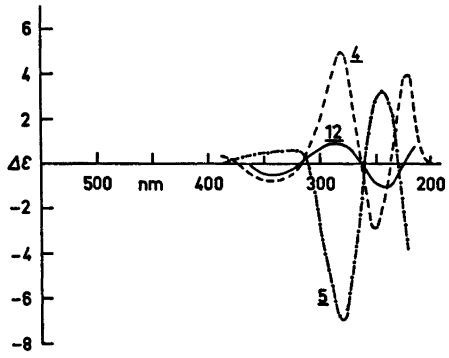

Fig. 3. CD-spectra of (2*R*,2′*R*)-2,2′-dimethyl-β,β-carotene (*12*, ———), (2*R*,2′*R*)-β,β-carotene-2,2′-diol (4, – – –) and *C.p.* 450 (*5*, - · - ·) in EPA.

Further studies on the absolute configurations of other C_{50}-carotenoids are in progress.

EXPERIMENTAL

Material and methods. All solvents were of analytical grade or distilled before use. Comparative TLC of carotenoid intermediates was on silica gel HF_{254} plates developed with petroleum ether-acetone solutions. Separation and purification of synthetic carotenoids were accomplished with alumina plates (1 mm) developed with petroleum ether-ethyl ether (97:3). Comparative chromatography of carotenoids was on Merck alumina HF_{254} Type E pre-coated plates (0.2 mm).

Instruments used were as specified elsewhere.[14] Specific rotations of carotenoid intermediates were obtained on a Perkin-Elmer 141 polarimeter and CD spectra recorded in EPA (ether-isopentane-ethanol, 5:5:2) on a Roussel-Jouane Dicrographe.

(+)-(*R*)-β-Irone (*7*) was isolated with an Aerograph Autoprep A-700 chromatograph using a 4.5 m × 12 mm metal column packed with Carbowax 20M (15 %) on Chromosorb W (60 – 80 mesh) at 190°C and 190 ml/min (helium). Carotenoid intermediates (*7*, *8*, *9* were examined for purity with a Perkin-Elmer F-11 gas chromatograph fitted with a 1.8 m glass column packed with OV-17 (5 %) on Chromosorb W;

temperature programmed from 110 °C at 2°/min.

C.p. 450 (5). 5 was available from an earlier reported study.[3] The CD spectrum is given in Fig. 3.

Composition of natural Iris oil. GLC analysis of natural Iris oil (Absolute Iris Essence) showed the following irone composition: (−)-(2*R*,6*R*)-*trans*-α-irone (numbering and nomenclature of irones follow that used by Rautenstrauch and Ohloff,[7] *cf.* *7*, Scheme 2), 20.7 % (of total irones); (+)-(2*S*,6*R*)-*cis*-α-irone (*cis* refers to the 2,6-substituents), 41.8 %; (+)-(2*S*,6*R*)-*cis*-γ-irone, 37.4 %.

Alkali-catalyzed isomerization of Iris oil. Iris oil (3 g) in a MeOH-H_2O (20 ml, 85:15) solution containing 10 % KOH was heated at 40 °C under N_2 for 24 h.[7] The ether extractable fraction was concentrated under vacuum and distilled at 0.3 Torr. A yellow oil (2 g) which distilled at 110 − 130 °C was collected and (+)-(6*R*)-β-irone (*7*, 0.85 g) isolated by preparative GLC. Irone composition of oil after isomerization: (+)-(6*R*)-β-irone (*7*), 61.6 %; (+)-(2*S*,6*R*)-*cis*-α-irone, 8.2 %; (−)-(2*R*,6*R*)-*trans*-α-irone, 30.2 %. Analytical GLC showed the β-irone (*7*) collected exceeded 98 % purity. The following physical properties for *7* were recorded: $[\alpha]^{20}$ (EtOH) 589 nm = 16°, 578 nm = 17°, 546 nm = 20° and 436 nm = 36°; λ_{max} 296 nm in MeOH; IR (liq.) 2980, 2920, 2860 (s, C−H), 1690, 1670 (s, C=O), 1605 (s, C=C), 1360 (s), 1250 (s, C=O), 980 cm^{-1} (m, *trans* −HC=CH−); τ($CDCl_3$; signal assignments with reference to *7*, Scheme 2) 9.083 d(3 H, *J* = 5 Hz, CH−CH_3), 9.080, 8.95 (6 H, *gem.* dimethyl), 8.8 − 8.4 (3 H, H-*a*,*b*), 8.27 (3 H, =C-CH_3), 8.1 − 7.8 (2 H, H-*c*), 7.75 (3 H, O=C−CH_3), 3.94 d(1 H, *J* = 16 Hz, H-*e*), 2.77 d(1 H, *J* = 16 Hz, H-*d*); *m/e* 206 (M), 191 (M − 15), 149 (M − 57), 135 (M − 71) and 122 (M − 84).

Ethyl (+)-(6R)-β-ironylideneacetate (8). Ethyl diethylphosphonoacetate [15a] (1.7 g) was added to a suspension of NaH (200 mg) in tetrahydrofuran (THF, 6 ml) and stirred at 20 °C for 1 h. The mixture was cooled to 0 °C and *7* (0.85 g) in THF (1 ml) added. The reaction was stirred for 3 h at 0 − 5 °C, then at 20 °C for an additional 15 h. Water was added and the mixture extracted with ether. The organic layer was dried with Na_2SO_4, concentrated under vacuum and chromatographed on a kieselgel column developed with benzene from which *8* was isolated (1.016 g, 89 %). GLC and ^1H NMR analysis showed *8* to consist of 85 % *trans*- and 15 % *cis*-isomers (around the new double bond). The product *8* had: $[\alpha]^{20}$ (EPA) 589 nm = 33°, 578 nm = 35°, 546 nm = 41°, and 436 nm = 81°; λ_{max} (MeOH) 260, 295 nm; ν_{max} (liq.) 2960, 2920, 2840 (s, C−H), 1715 (s, C=O), 1610 (s, C=C), 1450 (m), 1235 (s, C−O), 1153 (s, C−O), 1050 (s), 970 cm^{-1} (m, *trans* −CH=CH−); τ($CDCl_3$; signal assignments with reference to *8*, Scheme 2) 9.12, 8.97 (6 *H*, *gem.* dimethyl), 9.06 d(3 H, *J* = 2.5 Hz, −CH−CH_3), 8.72 t(3 H, *J* = 7 Hz, CH_2−CH_3), 8.7 − 8.3 (3 H, H-*a*,*b*), 8.32 (3 H, H-*h*) 8.1 − 7.8 (2 H, CH_3-*c*), 7.66 (3 H, CH_3-*g*), 5.77 q (2 H, *J* = 7 Hz, C$H_2$$CH_3$), 4.35 (1 H, *cis*-H-*f*, *cf.* Ref. 15b), 4.25 (1 H, *trans*-H-*f*), 3.97 d(1 H, *J* = 16 Hz, H-*e*), 3.40 d(1 H, *J* = 16 Hz, H-*d*); *m/e* 276 (M) 263 (M − 15), 231 (M − 45) and 203 (M − 73).

(+)-(6R)-β-Ironylidene-ethanol (9). *8*, (0.94 g) in THF (10 ml) was added to a stirred solution of $LiAlH_4$ (0.2 g) in THF (20 ml) at 0 °C during 30 min. Stirring was continued for 1 h and the reaction monitored by TLC (disappearance of starting material). The complex was decomposed by cautious addition of MeOH followed by a saturated solution of NH_4Cl. After ether extraction *9* (0.84 g, quantitative yield) was isolated; $[\alpha]^{20}$ (EPA) 589 nm = 30°, 578 nm = 31°, 546 nm = 37°, 436 nm = 68° and 365 nm = 327°; λ_{max} (MeOH) 237, 265 nm; ν_{max} (liq.) 3320 (s, OH), 2960, 2920, 2860 (s, C−H), 1000 (m, OH), 920 cm^{-1} (s, *trans* −CH=CH− τ($CDCl_3$; signal assignments with reference to *9*, Scheme 2) 9.13, 8.99 (6 H, *gem.* dimethyl), 9.09 d(3 H, *J* = *ca.* 5 Hz, −CH−CH_3), 8.7 − 8.3 (3 H, H-*a*,*b*), 8.32 (3 H, CH_3-*h*), 8.14 (3 H, CH_3-*g*), 8.25 − 7.85 (2 H, H-*c*), 5.17 d(2 H, *J* = 7 Hz, CH_2−OH), 4.38 broad t(1 H, *J* = 6.5 Hz, H-*f*), 3.95 (2 H, H-*d*,*e*; *m/e* 234 (M) and 219 (M − 15).

(6R)-β-Ironylidene-ethyltriphenylphosphonium bromide (10). A solution of *9* (0.8 g) and triphenylphosphonium bromide (1.5 g) in $CHCl_3$ (5 ml) was stirred at 20 °C for 48 h under N_2. The solvent was removed under vacuum and the oily residue dissolved in a minimum amount of acetone (5 ml) and chromatographed on a kieselgel column. Elution with acetone removed unreacted *9* and triphenylphosphine. *10* was eluted with MeOH and obtained as an amorphous powder after removal of solvent. Yield of *10* was 1.74 g (84 %).

(2R,2'R)-2,2'-Dimethyl-β,β-carotene (12). NaOMe (0.6 M) was slowly added to a stirred solution of *10* (200 mg) in dry MeOH (5 ml) until the phosphonium salt was completely converted to the deep red phosphorane. A solution of 2,7-dimethylocta-2,4,6-trienedial (*11*, 200 mg, prepared from the acetylenic analogue [16]) in CH_2Cl_2 (0.5 ml) was added and the mixture stirred. Progress of the reaction was monitored by TLC and additional phosphorane, generated externally, was added until *11* was completely converted to *12*. Water was added, the crude product extracted into ether, concentrated under vacuum and chromatographed on a kieselgel column developed with benzene. Yield of *12* (*cis-trans* mixture) was 42 mg (34 % based on dial *11*). *12* was purified on alumina plates from which the all *trans*-isomer was collected. Crystallized from MeOH-acetone solution *12* melted at 179 °C. Comparative TLC on precoated alumina plates developed with petroleum ether-ethyl ether (97:3) showed *12* to have R_F = 0.42; β,β-carotene in this system had R_F = 0.38. On Schleicher & Schüll paper No. 288 (Al_2O_3) developed with petroleum ether + ethyl ether (99 + 1) *12* had R_F = 0.33; β,β-carotene in the

same system had $R_F = 0.20$. *12* had λ_{max} (hexane) 265, (423), 449 [E (1 %, 1 cm) = 2428; $\varepsilon = 137\,000$ compared with $\varepsilon = 134\,000$ for β,β-carotene [17]], 476 nm [E(1 %, 1 cm) = 2072; $\varepsilon = 117\,000$], (acetone) (427), 451, 479 nm; $\tau(CDCl_3)$ see Fig. 1 with signal assignments; CD (EPA), see Fig. 3; *m/e* 564 (M), 549 (M − 15), 472 (M − 92), 458 (M − 106), 415 (M − 149), 406 (M − 158), 420 (M − 162), 373 (M − 191), 360 (M − 204), 347 (M − 217) and 282, see Fig. *2*.

Acknowledgements. Natural Iris oil was kindly supplied by Dr. V. Rautenstrauch through Dr. G. Ohloff, Research Department, Firmenich & Cie, Geneva. 2,7-Dimethylocta-2,6-dien-4-yne-1,8-dial was a gift from Dr. J. Surmatis, Hoffmann-La Roche, Nutley, N. J. *C.p.* 450 was isolated by lic.techn. Sissel Norgård, this laboratory. A. G. A. acknowledges the Royal Norwegian Council for Industrial and Scientific Research for a post-doctoral fellowship.

Mass Spectrometry of Onium Compounds. XXVI.[1] Ionisation Potentials in Structure Analysis of Gaseous Aminopyridine 1-Oxides

KJELL UNDHEIM, MAHMOUD A. F. EL-GENDY and TORGEIR HURUM

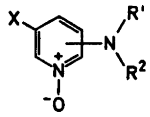
Department of Chemistry, University of Oslo, Oslo 3, Norway

The isomeric aminopyridine 1-oxides, their methylamino and acetylamino analogues exist predominantly in the amine form in the gas phase in the mass spectrometer. The conclusion is based on ionisation potential data, and fragmentation characteristics, which have been compared with such data for *N*,*N*-dimethylamino and *N*,*N*-acetylmethylaminopyridine 1-oxides and 1-methoxypyridin-onimines.

From ionisation potential measurements by electron impact in the mass spectrometer we have in recent reports [2,3] shown that the potentially tautomeric hydroxy-, mercapto-, and amino-pyridines in the gas phase exist predominantly in the enol and amine forms, respectively. The preference for the amino form in the gas phase has very recently been conclusively shown by a structural study of 2-aminopyridine by means of its microwave spectrum.[4] In this report we deal with the 1-oxides of the isomeric aminopyridines and their acylamino analogues. For comparative purposes in the interpretation of ionisation potential (IP) data corresponding *N*-methylamino analogues are included in the study. The IP data obtained are given in Table 1. The ionisation efficiency curves were recorded as previously described [5] and are interpreted by the semilog plot method.[6]

The influence of a substituent on the ease of ionisation depends on the nature of other substituents as well as on the ring system and relative position.[7] Generally an electron releasing substituent decreases the IP.[8] Thus the IP value for pyridine 1-oxide,[9] measured to 8.78

Table 1. Ionisation potentials for aminopyridine 1-oxides.



Comp.	Isomer	X	R^1	R^2	IP ± 0.05 eV
1	2	H	H	H	8.04

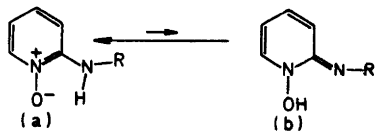
(19) X = Cl, IP = 7.40 eV



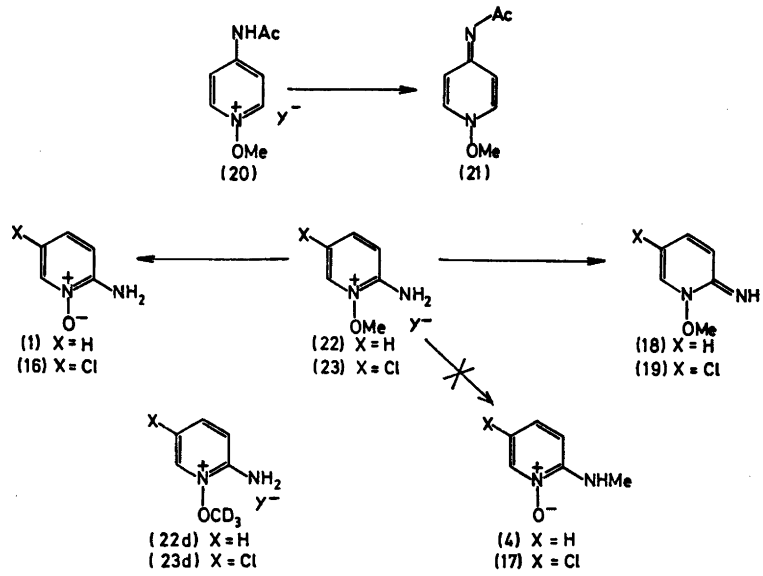
Scheme 1.

eV in the present work, is lowered on amine substitution (Table 1). Methylation of the amino group in aniline decreases the IP.[10] This effect was found to be very similar in all three aminopyridine isomers.[3]

The primary and secondary 2- and 4-aminopyridine 1-oxides can partially exist as the tautomeric 1-hydroxypyridin-2- and -4-onimines (Scheme 1). The *N*,*N*-dimethylaminopyridine 1-oxides, however, cannot tautomerise and must evaporate as such. The IP values (*7*–*9*) are increased by 0.2 eV from the 2- to the 3-isomer but decreased by 0.5 eV from the 3- to the 4-isomer. The same changes are seen for the primary amines (*1*–*3*) and for the secondary amines (*4*–*6*). The same pattern is evident also by comparison of the data for the 2-analogue series (*1*,*4*,*7*) with the 3- and 4-series; monomethylation has decreased IP with 0.2–0.3 eV relative to the parent amine and dimethylation has further reduced this value by 0.1 eV.

On prototropic shifts the 3-amines (*2*, *5*) can form the corresponding zwitterionic 1-hydroxy derivatives. The charge separation introduced will reduce the volatility compared to that of the non-charged amine form. On energetic grounds structures with charge separation should be disfavoured in the gas phase because at 10^{-6} Torr the charges cannot be dispersed by solvation or other intermolecular interactions. The 3-amines (*2*, *5*) must therefore be assumed present in the gas phase in the amine form. Consequently it follows from the systematic IP differences discussed above that the 2- and 4-isomers exist in the amine form in the gas phase. Furthermore the same IP pattern is seen for the acetyl derivatives (*10*–*12*) on comparison with the *N*-methyl analogues (*13*–*15*), and hence the same conclusion is reached. The amino form has also been found to be preferred by 2- and 4-aminopyridine 1-oxides and acylamino analogues in solid state and solution.[11,12]

Support for the above conclusion was to be sought in IP measurements of analogues locked in the onimine form by *O*-methylation. The 1-methoxy analogues, however, were only available as pyridinium salts with weak nucleophilic anions as *p*-toluenesulfonate or perchlorate anion. In the mass spectrometer these reactive molecules were largely decomposed, transmethylated on the nitrogen or demethylated. The cation from 4-acetamido-1-methoxypyridinium perchlorate (*20*, Scheme 2), however, appeared



Scheme 2.

to evaporate after proton loss as 1-methoxypyridin-4-*N*-acetylonimine (*21*). Unfortunately the relative molecular ion peak intensity was only of the order 1 % which with our present technique is too weak for obtaining reproducible IP data.

Similar studies for the *ortho* isomers also proved difficult. Thus the spectra from 1-methoxy-2-aminopyridinium toluene-*p*-sulfonate contain a signal for the mass number (*m/e* 124) of 1-methoxypyridin-2-onimine (*18*). Demethylation, however, is a competitive reaction to proton abstraction and evaporation of the onimine. Pyrolytic demethylation (*m/e* 110) was suggested by variable signal intensities. This deduction was confirmed by the appearance potential (AP) (8.02 eV) which was the same as IP for (*1*). The relative intensities for the signals corresponding to deprotonation and demethylation were increased from 1:8 to 1:2 on changing the anion from toluene-*p*-sulfonate to perchlorate. AP for the *m/e* 124 species was determined to 7.46 eV as compared to 7.67 eV for the isomeric *N*-methylpyridine 1-oxide (*4*). The experimental difficulties encountered and the closeness of these values made any conclusion uncertain. Support was sought in other derivatives. For this purpose the 5-chloro analogues (*17*) and (*23*) were prepared. A chlorine atom has little effect on the IP of an aromatic system.[8,9] This is also seen in the present work by comparison of the data (Table 1) for (*1*) and the 5-chloro analogue (*16*). IP for the *N*-oxide (*17*) was 7.61 eV as compared to 7.40 eV for the gaseous species from the 1-methoxy analogue (*23*). The difference is the same as between (*4*) and (*22*).

Any pyrolytic transmethylation in the salt (*22*) before evaporation (*22*→*4*) would affect AP for the *m/e* 124 species. Formation of (*4*) could occur by intra- or intermolecular reactions from (*22*). The latter possibility was investigated by deuteriation. The methyl group in (*22*) was perdeuteriated (*22d*) and mixed with equimolar quantities of the non-deuteriated 5-chloro analogue (*23*). The chlorine atom in (*23*) serves to mark the pyridine nucleus in the non-deuterated compound for identification after any transmethylation reaction. The chlorine atom is assumed not to significantly affect the activity. This assumption is supported by the very similar nature of the spectra from (*22*) and (*23*). A homogeneous mixture was strived at by evaporation in the instrument of a common methanol solution. In the case of intermolecular transmethylation four isotopically different molecular ion signals should be obtained.[18] The spectra, however, contained two such signals which exclude an intermolecular process. The conclusion was experimentally confirmed by mixing the deuteriated 5-chloro compound (*23d*) with (*22*). Comparative examination of the fragmentation spectra from the isomeric 2-methylaminopyridine 1-oxide (*4*) and 1-methoxypyrid-2-onimine (*18*) also excludes any significant intramolecular transmethylation. Thus $[M-OH]^+$ is the base peak in the spectrum of (*4*), other characteristic peaks being $[M-O]^+$ 18 % and $[M]^{+\cdot}$ 23 %. In the spectrum from (*22*) the molecular ion $[M]^{+\cdot}$ is the most intense peak, the relative intensities of the $[M-O]^+$ and $[M-OH]^+$ being 10 – 15 %. Similar differences were found in the spectra of the chlorine analogues (*16*, *23*). The gaseous molecules from (*22*) and (*23*) after proton loss are therefore assigned the respective onimine structures (*18*, *19*).

The IP effect of a methyl group relative to that of a hydrogen atom on a phenolic oxygen in simple systems is of the order 0.2 – 0.3 eV.[2,8] Using this value in conjunction with the IP's for (*18*) and (*19*) the IP's for the onimine forms of (*1*) and (*16*) are estimated to about 7.7 eV. The observed values are about 8.0 eV. The results are thus in agreement with the above concluded amino formulation.

From the larger dipole moments it is known that pyridine *N*-oxides are much more strongly polarised than corresponding pyridines.[14,15] High polarisation in the ground state and mesomeric stabilisation from the *N*-oxide group after electron removal are expected to be important factors in the observed decrease in IP for *N*-oxides relative to the corresponding pyridines.[3]

Characteristic primary fragments for the *N*-oxides and base peaks are recorded in Table 3. The mass spectra of heteroaromatic *N*-oxides are characterised by either the $[M-O]^+$ or $[M-OH]^+$ fragment, the latter being the more important when a hydrogen is readily extractable from an α-substituent.[16,17] All *N*-oxides show the $[M-O]^+$ fragment. The 2-isomers are of special interest for the study of the $[M-OH]^+$ fragment. In the 2-amino (*1*) the molecular ion is the base peak. The 2-

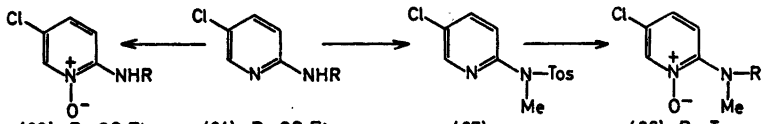

Scheme 3.

methylamino and 2-dimethylamino derivatives (*4,7*), however, have $[M-OH]^+$ as base peak, and the molecular ion has relatively low intensity. This suggests that $[M-OH]^+$ is preferentially formed by hydrogen abstraction from the carbon of the *N*-methyl group rather than from the electronegative amino nitrogen atom.

The primary fragmentation of the acetyl derivatives are characterised by the ready cleavage of the acetyl group as such or by expulsion as ketene preceeded or followed by *N*-oxide fragmentations.

The new compounds used in these studies were synthesised by modifications of established routes. The flow sheet for the 5-chloro derivatives is shown in Scheme 3. Amino groups must be deactivated by an acyl group for selective peroxide oxidation of the pyridine nitrogen atom such as in the carbamate (*24*). The acyl group is hydrolytically removed after oxidation. Methylation of the amino group in the carbamate (*24*) was unsatisfactory but proceeded readily in the sulfonamide (*25*) to form (*27*) which was oxidised and hydrolysed to (*17*).

EXPERIMENTAL

The mass spectra were recorded on an AEI MS902 mass spectrometer attached to an AEI DS30 data system. The electron energy was 70 eV and the ionising current 100 μA. During recording of the ionisation efficiency curves, repeller was at cage potential and the ionising current was 20 μA. Xenon was the reference compound. The IE-curves were interpreted by the semilog-plot method. The recorded IP values are the average of three determinations, the deviation being ± 0.05 eV. The compounds were introduced by the heated direct insertion probe at a source temperature of 220 °C.

Syntheses

2-Amino- (1) [18] and *3-aminopyridine 1-oxide (2)* [12,19] were synthesised according to literature.

4-Aminopyridine 1-oxide (3). 4-Nitropyridine 1-oxide (7.0 g, 0.05 mol) in ethanol (150 ml) was hydrogenated at 0.38 MPa* over 10 % palladium on charcoal for 1 – 2 h (until the uptake of hydrogen had almost ceased). The catalyst was then removed, the solution evaporated and the residual amine acetylated by refluxing for 1 h in a solution of acetic anhydride (3 ml) and ethyl methyl ketone (15 ml). The solid which crystallised from the cold solution was recrystallised from ethyl acetate-ethanol (1:1). 4-Acetamidopyridine 1-oxide (*12*) was thus obtained as needles, m.p. 264 – 265 °C (Lit. 260 – 261 °C).[12]

(*12*) thus obtained (1.5 g, 0.01 mol) was heated in 3 M HCl (12 ml) for 3 h, the reaction mixture evaporated and the residual title compound as HCl-salt crystallised from ethanol; yield 0.9 g (84 %), m.p. 181 – 183 °C.[20]

2-Methylamino- (4) [18] and *4-methylamino-pyridine 1-oxide (6)* [11] were synthesised according to literature.

3-Methylaminopyridine 1-oxides (5). 3-Acetylmethylaminopyridine 1-oxide (1.7 g, 0.01 mol) was dissolved in 3 M HCl (15 ml) and the solution refluxed for 4 h. Evaporation left the title compound as HCl-salt which was recrystallised twice from ethanol/ether; yield 1.2 g (74 %), m.p. 165 °C (Found: C 44.92; H 5.68. Calc. for $C_8H_{10}N_2O_2$: C 45.00; H 5.62).

2-Dimethylamino- (7) [18] and *4-dimethylaminopyridine 1-oxide (9)* [11] were prepared according to literature.

3-Dimethylaminopyridine 1-oxide (8). 3-Bromopyridine 1-oxide[21] (1.8 g, 0.01 mol) and 30 % aqueous dimethylamine (15 ml) were heated together at 155 °C for 48 h in a sealed glass tube. Potassium carbonate (1 g) was added to the solution before evaporation; the dried residue was extracted with ethanol, the ethanol solution heated with charcoal before evaporation of the filtrate. The residual material (1.1 g, 80 %) was crystallised from ethanol/ether in needles, m.p. 41 °C. (Found: C 60.85; H 7.51. Calc. for $C_7H_{10}N_2O$; C 60.86; H 7.24).

2-Acetamido- (10) [12] *3-acetamidopyridine 1-oxide (11)* [4,19] were prepared according to literature; the synthesis of *4-acetamidopyridine 1-oxide (12)* is described under (*3*) above.

2-Acetylmethylamino- (13) [18] and *4-acetylmethylaminopyridine 1-oxide (15)* [12] were prepared according to literature.

3-Acetylmethylaminopyridine 1-oxide (14). 3-Acetylmethylaminopyridine[22] (1.5 g, 0.01 mol) and 35 % hydrogen peroxide (1.8 ml) in acetic acid (6 ml) were heated at 70 – 80 °C for 24 h. The solution was then evaporated at reduced pressure, the residue dissolved in chloroform (20 ml) and treated with anhydrous potassium carbonate. After filtration and evaporation the

* 1 MPa ≈ 10.2 kg/cm².

residual material (1.5 g, 90 %) was recrystallised from ethanol/ethyl acetate, m.p. 163 – 165 °C. (Found: C 58.15; H 5.85. Calc for $C_8H_{10}N_2O_2$: C 57.83; H 6.02).

2-Amino-1-methoxypyridinium perchlorate (22) was prepared from its toluene-*p*-sulfonate.[18]

2-Amino-5-chloro-1-methoxypyridinium perchlorate (23). 2-Amino-5-chloropyridine 1-oxide (7.2 g, 0.05 mol) and methyl toluene-*p*-sulfonate (9.3 g, 0.05 mol) were heated together at 100 °C overnight to produce 1-methoxy-pyridinium toluene-*p*-sulfonate which after crystallisation from ethanol/ethyl acetate or ethanol/ether had m.p. 137 °C; yield 14.2 g (86 %).

The tosylate thus prepared (1.7 g, 0.005 mol) in ethanol (3 ml) was mixed with 60 % perchloric acid (0.8 ml) when the desired perchlorate was precipitated (1.1 g, 85 %); needles from ethanol, m.p. 100 °C (Found: C 28.12; H 3.10. Calc. for $C_6H_8Cl_2N_2O_6$: C 27.80; H 3.12). The 1-trideuteriomethoxypyridinium analogues (*22d*) and (*23d*) were prepared as above by *O*-methylation of the respective *N*-oxides using trideuteriomethyl toluene-*p*-sulfonate as the alkylating agent. Exchange of anion was again carried out in ethanolic solution by addition of perchloric acid.

4-Acetylamino-1-methoxypyridinium perchlorate (20) [12] was prepared by the above procedures.

2-Ethoxycarbonylamino-5-chloropyridine 1-oxide (24). Ethyl chloroformate (14 ml) was added dropwise to a stirred and cooled (0 °C) solution of 2-amino-5-chloropyridine (15.5 g) in pyridine (60 ml) and the solution left at room temperature. Water was added after 18 h and the precipitated material (68 %) crystallised from ethanol, m.p. 178 °C.

A solution of 2-ethoxycarbonylamino-5-chloropyridine thus obtained (20.1 g, 0.1 mol) and 30 % hydrogen peroxide (15 ml) in acetic acid (32 ml) was heated at 70 – 80 °C for 24 h. The solution was then evaporated at reduced pressure, the residue dissolved in chloroform (150 ml) and the solution heated and shaken with anhydrous potassium carbonate (10 g) for 10 min. Filtration and evaporation of the filtrate left the crude 1-oxide which crystallised in needles from ethanol; yield 21 g (97 %). (Found: C 44.48; H 4.18. Calc. for $C_8H_9ClN_2O_3$: C 44.34; H 4.15).

2-Amino-5-chloropyridine 1-oxide (16). 2-Ethoxycarbonylamino-5-chloropyridine 1-oxide (10.0 g, 0.05 mol) was heated under reflux in conc. HCl (20 ml) for 24 h. Evaporation and crystallisation of the residual material from ethanol furnished the title compound as HCl salt; yield 5.7 g (71 %), m.p. 163 °C. (Found: C 33.15; H 3.31. Calc. for $C_5H_5ClN_2O.HCl$: C 33.21; H 3.63).

The title compound was generated from its salt by addition of one equivalent of sodium ethoxide solution to a solution of the HCl-salt as above prepared. Removal of the salt, evaporation of the ethanol solution and recrystallisation of the residue from ethyl acetate/ethanol furnished the title compound, m.p. 193 °C. (Found: C 41.68; H 3.67. Calc. for $C_5H_5ClN_2O$: C 41.52; H 3.46).

5-Chloro-2-p-toluenesulfonamidopyridine (25). A solution of 2-amino-5-chloropyridine (12.9 g, 0.1 mol) and *p*-toluenesulfonyl chloride (22.5 g, 0.15 mol) in pyridine (25 ml) was heated on a steam-bath for 5 h. The precipitate formed on pouring the solution into water was recrystallised from benzene; m.p. 174 – 175 °C, yield 28.1 g (quantitative). (Found: C 51.07; H 4.29. Calc. for $C_{12}H_{11}ClN_2O_2S$: C 50.95; H 3.89).

5-Chloro-2-N-methyl-p-toluenesulfonamidopyridine (27). A solution of dimethyl sulfate (12.6 g, 0.1 mol) in acetone (50 ml) was added dropwise over 30 min to a refluxing mixture of 5-chloro-2-*p*-toluenesulfonamidopyridine (28.2 g, 0.1 mol) and anhydrous potassium carbonate (28.0 g, 0.2 mol) in acetone (500 ml). The heating was continued for another 3 h. The cold reaction mixture was then filtered and the filtrate evaporated. The oily product was next dissolved in chloroform (150 ml), the solution extracted with 10 % NaOH solution to remove any material not alkylated, and the organic solution washed and dried. Evaporation and recrystallisation from ethanol gave colourless prisms; m.p. 68 – 70 °C, yield 26.0 g (88 %). (Found: C 52.82; H 4.84. Calc. for $C_{13}H_{13}ClN_2O_2S$: C 52.61; H 4.38).

5-Chloro-2-methylaminopyridine 1-oxide (17). 5-Chloro-2-*N*-methyl-*p*-sulfonamidopyridine (14.8 g, 0.05 mol) and 30 % hydrogen peroxide (8 ml) in acetic acid (30 ml) were heated at 70 – 80 °C for 24 h. The solution was then evaporated and the residual oxide (*28*) subjected to hydrolysis by heating on a steam bath for 3 h in 80 % sulfuric acid (25 ml). The cold solution was diluted with water (20 ml) and made alkaline with 0.91 M ammonia before extraction with chloroform. The chloroform solution was washed, dried and evaporated and the residue crystallised from ethanol/ether; yield 6.4 g (81 %), m.p. 153 °C. (Found: C 45.64; H 4.47. Calc. for $C_6H_7ClN_2O$: C 45.42; H 4.41).

The Crystal and Molecular Structure of 3-Hydroxyphenylalanine (*m*-Tyrosine)

ARNE BYRKJEDAL, ARVID MOSTAD and CHRISTIAN RØMMING

Department of Chemistry, University of Oslo, Oslo 3, Norway

The crystal structure of 3-hydroxyphenylalanine has been determined by X-ray diffraction methods using 1690 observed reflections collected on a counter diffractometer. The crystals are monoclinic, space group $P2_1$, with cell dimensions $a = 5.95_6$ Å; $b = 5.29_9$ Å; $c = 13.86_6$ Å; $\beta = 104.3_6°$. The structure was refined to a conventional R-factor of 0.041, the standard deviations for bond lengths and angles involving non-hydrogen atoms are 0.002 Å and 0.1°, respectively.

The compound forms crystals each containing one enantiomer from solutions of the racemate. Both regarding molecular geometry and crystal packing of *m*-tyrosine the similarity to L-DOPA is pronounced.

3-Hydroxyphenylalanine (*m*-tyrosine) is a natural product occurring in certain plants [1] and also in mammals where the metabolic pathway from phenylalanine to L-DOPA partly may proceed through L-*m*-tyrosine.[2,3] The shift of the hydroxyl group from the 4-position in tyrosine to the 3-position in *m*-tyrosine gives rise to altered chemical as well as biological properties. L-*m*-Tyrosine behaves thus in some cases more like phenylalanine than like L-tyrosine [4] and it has been reported to act as a growth inhibitor.[5] Several of the biological activities of L-*m*-tyrosine have been shown to be analogous to those of L-DOPA [6,7] and the compound or its metabolically formed amines seem to interfere with the normal action of the neurotransmitters dopamine and noradrenaline.[8–10]

We have examined the crystal structure of 3-hydroxyphenylalanine as a part of a series of hydroxyphenyl- and pyridonalanines in order to study the variation in molecular conformation with varying crystal environment and to collect information useful for studies of relationships between structure and biological activity.

EXPERIMENTAL

A concentrated solution of oxalic acid in cold water was heated with an excess of 3-hydroxyphenylalanine and filtered. The solution was cooled down to room temperature and after a couple of weeks crystals of the pure compound appeared.

Oscillation and Weissenberg photographs showed the crystals to be monoclinic. The only condition for the presence of reflections was k even for ($0k0$). The number of molecules per unit cell being *two*, the only space group possible is $P2_1$ since $P2_1/m$ would require the molecule to exhibit mirror- or centrosymmetry.

Unit cell dimensions were calculated from diffractometer measurements of 28 reflections using CuKβ-radiation ($\lambda = 1.3922$ Å). The intensity data were recorded on an automatic Picker diffractometer using MoK-radiation monochromated by means of a graphite crystal. The specimen had approximate dimensions $0.2 \times 0.2 \times 0.5$ mm. Reflections with $\sin\theta/\lambda < 0.8$ were scanned in the $\theta - 2\theta$ mode at a rate of 1° min^{-1} in 2θ; the scan range was from 0.8° below $2\theta(\alpha_1)$ to 0.8° above $2\theta(\alpha_2)$. The background was measured for 30 s at each of the scan range limits. Three standard reflections were measured after every 100 reflections; they showed no significant change in intensity.

A total of 2010 independent reflections were measured of which 1690 were considered observed with intensities greater than 2.0 standard deviations. The standard deviations for the intensities were taken as $\sigma(I) = (c_T + (0.02\ c_N)^2)^{\frac{1}{2}}$ where c_T is the total number of counts and c_N the scan count minus background count. The data were corrected with Lorentz and polarization factors, but not for absorption ($\mu = 0.12$ mm^{-1}).

Atomic form factors used were those of Hanson *et al.*[11] for oxygen, nitrogen and carbon and of Stewart *et al.*[12] for hydrogen. Calculations during the structure investigation were performed by means of computer programs described in Ref. 13. The full-matrix least-squares refinement program minimizes $\sum w(\Delta F)^2$ where $w = \sigma^{-2}(F_o)$.

Table 1. Observed and calculated structure factors. The columns are h, k, l, $10 \times F_o$ and $10 \times F_c$.

CRYSTAL DATA

3-Hydroxyphenylalanine (*m*-tyrosine), $C_9H_{11}NO_3$, monoclinic, $a=5.956(0.002)$ Å; $b=5.2992(0.0004)$ Å; $c=13.866(0.002)$ Å; $\beta=104.36(0.02)°$, ($t=18$ °C). $V=424.0$ Å^3; $M=181.19$; $F(000)=192$; $Z=2$; $D_{obs}=1.42$ g cm^{-3} (flotation); $D_{calc}=1.419$ g cm^{-3}. Absent reflections: ($0k0$) for k odd; space group $P2_1$.

STRUCTURE DETERMINATION

The positions of the phenyl ring atoms and the carbon and oxygen atoms directly attached to it were deduced from a sharpened Patterson map. The remaining non-hydrogen atoms were located from subsequent Fourier syntheses. Two cycles of full-matrix least-squares refinement with isotropic temperature factors reduced R to 0.15; further refinement with anisotropic temperature factors brought R down to 0.07. The hydrogen atoms could all be located from a difference Fourier map at this stage. The refinement of all positional parameters (except for one origin defining y-parameter), anisotropic

thermal parameters for the non-hydrogen atoms and isotropic parameters for the hydrogen atoms was carried on until the shifts were negligible compared to the standard deviations. The final R-factor is 0.041 for 1690 reflections and R_w is 0.042. A difference Fourier synthesis showed electron densities between -0.2 eÅ^{-3} and $+0.3$ eÅ^{-3}.

The anisotropic thermal parameters were analysed in terms of rigid-body motion both for the whole molecule and for the hydroxyphenyl and alanine parts separately. The results indicated that the whole molecule does not behave as a rigid body whereas splitting the molecule into the two parts gave much better results. The latter description was adapted when correcting bond lengths for libration effects.

A comparison of observed and calculated structure factors is given in Table 1; final parameters for non-hydrogen atoms are listed in Table 2 and for hydrogen atoms in Table 3. Interatomic distances and bond angles are given in Table 4. Standard deviations were calculated from the correlation matrix; standard deviations in distances were found to be 0.002 Å and in angles 0.1° when hydrogen atoms were not involved.

DISCUSSION

Bond lengths and angles are shown in Fig. 1 in which the numbering of the atoms is indicated.

The molecular geometry is remarkably similar to that of 3,4-dihydroxyphenylalanine (DOPA).[14] Neglecting the extra hydroxyl group in DOPA, none of the bond lengths differs by more than 0.01 Å, nor the bond angles by more than 0.7° except for the external angles at C3. In the present structure the external angles are found to be 118.5° and 121.8° with the greater angle

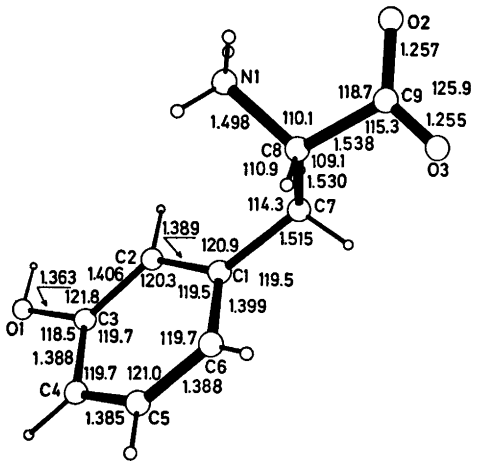

Fig. 1. Bond lengths (Å, corrected) and angles (°) in *m*-tyrosine.

cis to the phenol hydrogen atom which is situated in the phenyl ring plane. This feature is common for many phenol structures; the difference between the external angles in the present structure, 3,3° may be compared to that in L-tyrosine of 4.6°,[15] in DL-tyrosine of 4.4°,[16] and those in L-DOPA of 6.3 and 6.6°.

The similarity between *m*-tyrosine and DOPA applies also to the conformation of the molecules in the crystal. The following dihedral angles (°) were found:

	m-tyrosine	L-DOPA
C2 – C1 – C7 – C8	– 71.6	– 71.2
C1 – C7 – C8 – C9	171.6	175.2
N1 – C8 – C9 – O (*cis* to N)	– 16.0	– 14.4

The conformational angles are given as positive when progress along the atoms describes a clock-wise rotation.

All hydrogen atoms bonded to hetero atoms are involved in hydrogen bonds. Thus N1 and O1 act as hydrogen donors; the two carboxyl oxygen atoms are acceptors in four hydrogen bonds. In this way each molecule is connected to six neighbouring molecules through eight hydrogen bonds. The situation is illustrated in Fig. 2 which shows the crystal structure as seen along the *c*-axis. The pronounced similarity of the structures of *m*-tyrosine and L-DOPA may be seen from Fig. 3 where details of corresponding projections along *b* are visualized. Except for the *para* hydroxyl group in L-DOPA forming hydrogen bonds to corresponding groups in

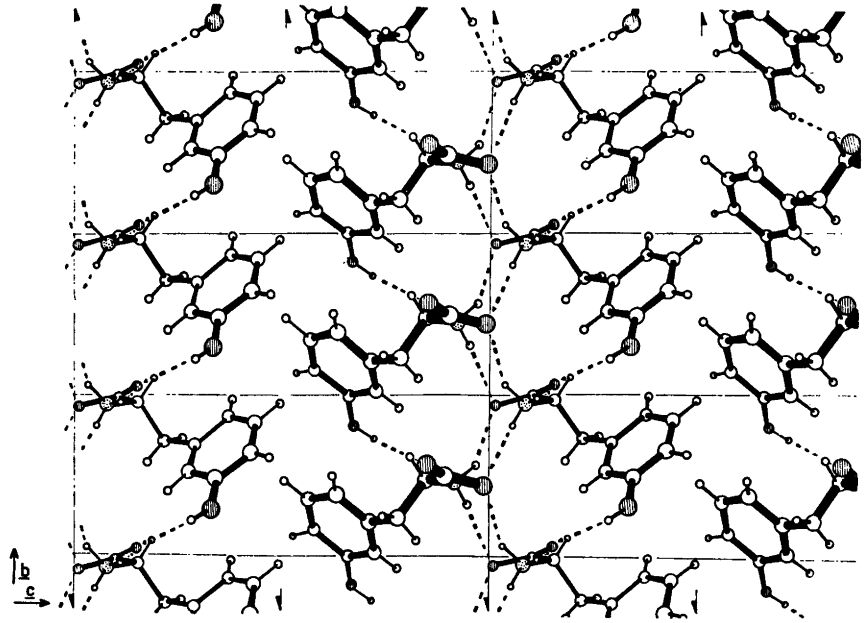

Fig. 2. The crystal structure as seen along the *a*-axis.

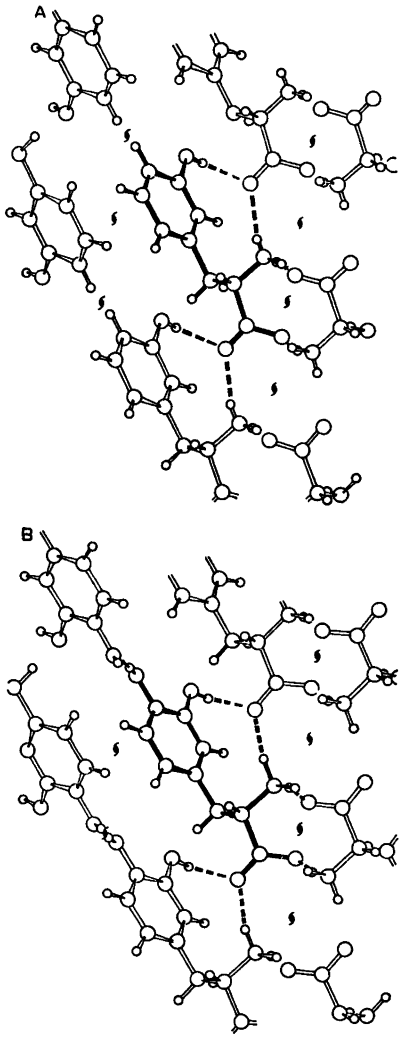

Fig. 3. The structure of *m*-tyrosine (A) and L-DOPA (B) as viewed along *b*.

molecules along a two-fold screw axis, the hydrogen system in the two structures is nearly identical. The N1–H···O3 bond of 2.78 Å (2.82 Å in L-DOPA) establishes chains of molecules along the *a*-axis. These chains are tied together through O1–H···O3 bonds of 2.79 Å (2.74 Å in L-DOPA) and through two N1–H···O2 bonds of 2.89 Å and 3.00 Å (2.87 Å and 3.02 Å in L-DOPA) to form double molecular layers normal to the (001) plane. Between the layers there are only weak van der Waals interactions.

Aryl Cyanates. Reaction of Aryl Cyanates with Grignard Reagents. Kinetic Studies

ERIK HUGE-JENSEN and ARNE HOLM

Chemical Laboratory II (General and Organic Chemistry), The H. C. Ørsted Institute, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark

A kinetic investigation of the reactions of aryl cyanates with Grignard reagents and dibutylmagnesium in diethyl ether has been carried out. The reaction is best described as involving a concerted four-center mechanism in the rate-determining step, first order both in aryl cyanate and in the organomagnesium species: alkyl- or arylmagnesium halide and dialkyl- or diarylmagnesium, present in the Grignard reagents.*

For reactions of *m*-substituted phenyl cyanates with "butylmagnesium bromide" a linear correlation is obtained between the logarithm of the rate constants and the Hammett *sigma* values with a ϱ-value of $+0.97$. For reactions of *p*-substituted phenyl cyanates with "butylmagnesium bromide" it has not been possible to obtain a smooth curve when plotting the logarithm of the rate constants *versus* the Hammett *sigma* values.

The reaction constant for the reaction of phenyl cyanate with *p*-substituted "phenylmagnesium bromides" is calculated to be *ca.* -0.80.

"Arylmagnesium bromides" are found to be more reactive than dibutylmagnesium, which again is more reactive than "butylmagnesium bromide".

In another paper[1] we have described the product formation in the reaction between alkyl or aryl cyanates and Grignard reagents, and we now wish to report a kinetic investigation of the reaction between aryl cyanates and Grignard reagents.

The present work has been carried out in order to obtain information about the mechanism of the reaction (I) between aryl cyanates and Grignard reagents, which leads to the formation of aryloxymagnesium halides and nitriles:

$$\mathrm{ArOCN} + \mathrm{RMgX} \longrightarrow \mathrm{ArOMgX} + \mathrm{RCN} \qquad (\mathrm{I})$$

A thermographic method[2a,b] was used for the kinetic measurements, and this technique allowed rate measurements reproducible within ± 5 % by use of a concentration of 0.01 M of the reagent present in lesser amount. All measurements were carried out with one of the reagents in excess.

Fig. 1 shows three examples of plots of $\ln (\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T)$ * *versus* the reaction time, t, for the reaction of phenyl cyanate with "butylmagnesium bromide". From all kinetic measurements linear plots were obtained for at least 70 % transformation of the limiting reagent. The linearity of the plots means that the reaction order in phenyl cyanate is one. The pseudo first order rate constants (k_{obs}) are obtained from the slopes of the lines and found to be linearly dependent on the initial concentration of Grignard reagent (Fig. 2), and therefore the reaction order in "butylmagnesium bromide" is assumed to be one. Because of the association of most Grignard reagents at concentrations above 0.1 M[3] it is surprising that

* The Grignard reagents are in the following symbolized as "RMgX".

* $\mathrm{Ln}\, a/(a-x) = \ln (\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T) = k_{obs} \times t$, where ΔT_∞ is the total rise in temperature, ΔT_1 is the rise in temperature after 2 ms and ΔT is the rise in temperature at the time t. ΔT_1 is a correction for heat evolved from reaction between traces of impurities (water) and the Grignard reagent and from mixing.

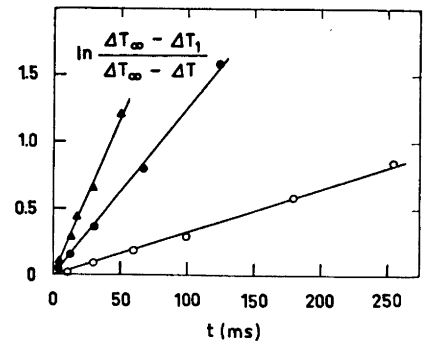

Fig. 1. Plot of $\ln (\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T)$ *versus* the reaction time, t, for the reaction of phenyl cyanate with excess "butylmagnesium bromide" in diethyl ether at 25 °C ($c^0_{C_6H_5OCN} = 0.010$ M; $c^0_{\text{"}C_4H_9MgBr\text{"}} = 0.103$ M (○), 0.413 M (●) and 0.750 M (▲)).

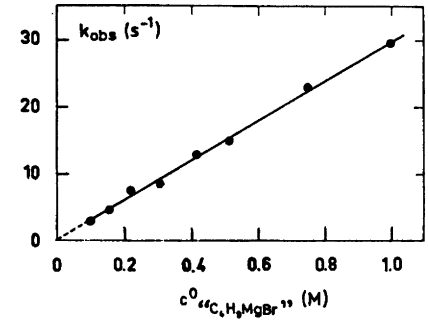

Fig. 2. Plot of the pseudo first order rate constant (k_{obs}) *versus* the initial concentration of the Grignard reagent for the reaction of phenyl cyanate with excess "butylmagnesium bromide" in diethyl ether at 25 °C ($c^0_{C_6H_5OCN} = 0.010$ M).

the pseudo first order rate constant is linearly dependent on the initial concentration of "butylmagnesium bromide". However, the degree of association of "butylmagnesium bromide" has not been measured. This reagent could be associated to a lesser extent than the lower homologues because the degree of association decreases as the hydrocarbon chain is lengthened.[3] Another possibility is of course that the cyanate also reacts with the dimers (polymers) besides the organomagnesium species (butylmagnesium bromide and dibutylmagnesium) involved in the Schlenk equilibrium (reaction (II)).[4]

$$2\ C_4H_9MgBr \overset{K_s}{\rightleftharpoons} (C_4H_9)_2Mg + MgBr_2 \qquad \text{(II)}$$

In kinetic measurements with a constant excess of "butylmagnesium bromide" the pseudo first order rate constant was found to be increased by 9 % when the initial concentration of phenyl cyanate was doubled (Table 1). An increase is expected due to the temperature dependence of the rate constant. The doubling of the concentration of phenyl cyanate doubles the total rise in temperature. On this

Table 1. Pseudo first order rate constants for the reaction of phenyl cyanate with a constant excess of "butylmagnesium bromide" in diethyl ether at 25 °C.

$c^0_{C_6H_5OCN}$ (M)	$c^0_{\text{"}C_4H_9MgBr\text{"}}$ (M)[a]	k_{obs} (s^{-1})
0.010	0.220	7.6
0.020	0.220	8.3

[a] Sublimed magnesium ("Specpure", Johnson, Matthey Chemicals Ltd.) was used for preparation of the "butylmagnesium bromide" used in these experiments.

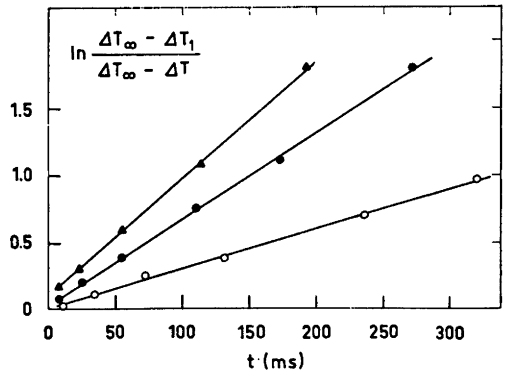

Fig. 3. Plot of $\ln (\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T)$ *versus* the reaction time, t, for the reaction of excess phenyl cyanate with "butylmagnesium bromide" in diethyl ether at 25 °C ($c^0_{\text{"}C_4H_9MgBr\text{"}} = 0.010$ M; $c^0_{C_6H_5OCN} = 0.100$ M (○), 0.200 M (●) and 0.300 M (▲)).

basis it is difficult to say anything about catalysis by traces of transition metals present in the magnesium used for the preparation of the Grignard reagent.

Kinetic measurements with excess phenyl cyanate and 0.010 M "butylmagnesium bromide" likewise give linear pseudo first order plots (Fig. 3), and the pseudo first order rate constants obtained from the slopes of the curves are again linearly dependent on the initial concentration of the reagent in excess (phenyl cyanate). The k_{obs}-values found with excess phenyl cyanate are almost equal to the k_{obs}-values found in measurements with excess "butylmagnesium bromide" (Table 2).

Table 2. Pseudo first order rate constants for the reaction of phenyl cyanate with "butylmagnesium bromide" in diethyl ether at 25 °C.

$c^0_{C_6H_5OCN}$ (M)	c^0"C_4H_9MgBr" (M)	k_{obs} (s^{-1})
0.010	0.100	2.9
0.100	0.010	2.9
0.010	0.200	6.2
0.200	0.010	6.2
0.010	0.300	9.2
0.300	0.010	8.6

Because of the results reported above the rate of the reaction between phenyl cyanate and "butylmagnesium bromide" can be described by eqn. (1):

$$-d[C_6H_5OCN]/dt = k[C_6H_5OCN]\ ["C_4H_9MgBr"] \quad (1)$$

We have made kinetic measurements on the reaction of phenyl cyanate with excess dibutylmagnesium and found that the k_{obs}-value is a factor of 22 higher than the k_{obs}-value for the reaction between phenyl cyanate and "butylmagnesium bromide" (Tables 2 and 3). The pseudo first order plots are linear for up to 80 % transformation of phenyl cyanate (Fig. 4), and the pseudo first order rate constants are linearly dependent on the initial concentration of dibutylmagnesium (Table 3).

If only the dibutylmagnesium present in "butylmagnesium bromide" reacts with phenyl cyanate the k_{obs}-value for the reaction of 0.010 M phenyl cyanate with 0.100 M "butylmagnesium bromide" can be calculated to be 2.1 s^{-1},* which is 0.8 s^{-1} smaller than the observed value (Table 2). Therefore it seems reasonable to assume that both butylmagnesium bromide and dibutylmagnesium react when "butylmagnesium bromide" is reacting with phenyl cyanate.

Table 3. Pseudo first order rate constants for the reaction of phenyl cyanate with excess dibutylmagnesium in diethyl ether at 25 °C.

$c^0_{C_6H_5OCN}$ (M)	$c^0_{(C_4H_9)_2Mg}$ (M)	k_{obs} (s^{-1})
0.010	0.097	63
0.010	0.194	134

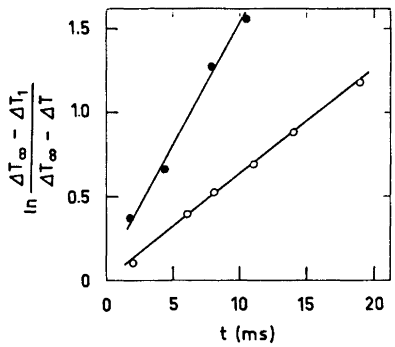

Fig. 4. Plot of $\ln (\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T)$ *versus* the reaction time, t, for the reaction of phenyl cyanate with excess dibutylmagnesium in diethyl ether at 25 °C ($c^0_{C_6H_5OCN} = 0.010$ M; $c^0_{(C_4H_9)_2Mg} = 0.097$ M (○) and 0.194 M (●)).

When magnesium bromide etherate is added to "butylmagnesium bromide" the k_{obs}-value becomes smaller (Table 4). The concentration of dibutylmagnesium decreases according to the Schlenk equilibrium when magnesium bromide is added, and therefore it is reasonable that the pseudo first order rate constant becomes smaller. However, the value is still high, which we suppose is due to the reactivity of butylmagnesium bromide.

* The concentration of dibutylmagnesium in 0.100 M "butylmagnesium bromide" is *ca.* 0.0032 M for $K_s = 1 \times 10^{-3}$ (Ref. 5). The calculation of k_{obs} is made with the assumption that k_{obs} is linearly dependent on the initial concentration of dibutylmagnesium in the interval 0–0.1 M, thus $k_{obs} = 63 \times 0.0032/0.097 = 2.1$ s^{-1}.

Table 4. Pseudo first order rate constants for the reaction of phenyl cyanate with excess "butylmagnesium bromide" in diethyl ether at 25 °C.

$c^0_{C_6H_5OCN}$ (M)	c^0"C_4H_9MgBr" (M)	$c^0_{MgBr_2}$ (M)	k_{obs} (s^{-1})
0.010	0.138	0.003	5.7
0.010	0.138	0.069	4.4

On basis of the results described above the rate expression (eqn. (1)) should consequently be:

$$-d[C_6H_5OCN]/dt = (k_2[C_4H_9MgBr] + k_2'[(C_4H_9)_2Mg])[C_6H_5OCN] \quad (2)$$

where k_2 and k_2' are the second order rate constants for the reaction of phenyl cyanate with butylmagnesium bromide and dibutylmagnesium, respectively. k_2' is calculated from the pseudo first order rate constant and the corresponding concentration of dibutylmagnesium (Table 3), $k_{obs} = k_2' \times c^0_{(C_4H_9)_2Mg}$, $k_2' = 650\ M^{-1}s^{-1}$. The second order rate constant (k_2) for the reaction of phenyl cyanate with butylmagnesium bromide can be calculated from the following equation:

$$k_{obs} = k_2 \times c^0_{C_4H_9MgBr} + k_2' \times c^0_{(C_4H_9)_2Mg} \quad (3)$$

For c^0"C_4H_9MgBr" = 0.100 M, $c^0_{C_4H_9MgBr} = 0.0936$ M, $c^0_{(C_4H_9)_2Mg} = 0.0032$ M, and $k_{obs} = 2.9\ s^{-1}$, which gives $k_2 = 8.6\ M^{-1}\ s^{-1}$.

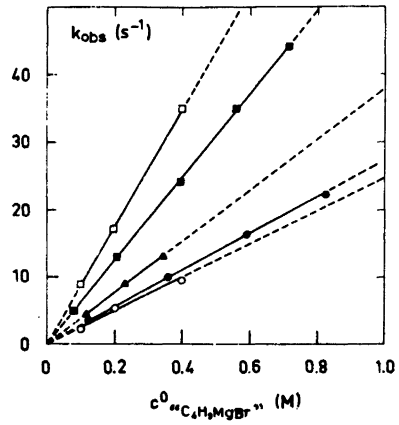

Fig. 5. Plot of pseudo first order rate constants *versus* the initial concentrations of the Grignard reagent for the reactions of *m*-substituted phenyl cyanates with excess "butylmagnesium bromide" in diethyl ether at 25 °C ($c^0_{m\text{-}XC_6H_4OCN} = 0.010$ M; *m*-$(CH_3)_2NC_6H_4OCN$ (○); *m*-$CH_3C_6H_4OCN$ (●); *m*-$CH_3OC_6H_4OCN$ (▲); *m*-ClC_6H_4OCN (■); *m*-$CF_3C_6H_4OCN$ (□)).

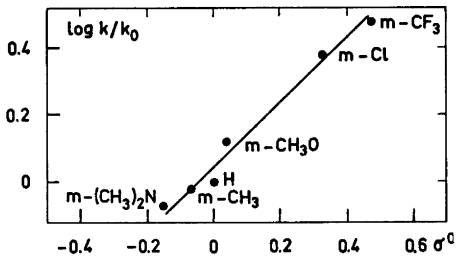

Fig. 7. Plot of log k/k_0 *versus* σ^0 for the reaction between *m*-substituted phenyl cyanates and "butylmagnesium bromide" in diethyl ether at 25 °C ($c^0_{m\text{-}XC_6H_4OCN}$ = 0.010 M and c^0"C_4H_9MgBr" = 0.100 M).

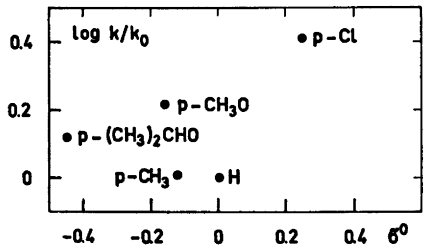

Fig. 8. Plot of log k/k_0 *versus* σ^0 for the reaction between *p*-substituted phenyl cyanates and "butylmagnesium bromide" in diethyl ether at 25 °C ($c^0_{p\text{-}XC_6H_4OCN}$ = 0.010 M and c^0"C_4H_9MgBr" = 0.100 M).

Kinetic measurements have been carried out on reactions between *m*- and *p*-substituted phenyl cyanates and excess "butylmagnesium bromide". Pseudo first order plots were in all cases linear until 70 % transformation of the substituted cyanates, and the pseudo first order rate constants obtained from these plots were linearly dependent on the initial concentration of "butylmagnesium bromide" (Figs. 5 and 6).

The logarithm of the pseudo first order rate constants for the reactions of *m*-substituted phenyl cyanates with "butylmagnesium bromide" could be linearly correlated with the Hammett *sigma* values (Table 5 and Fig. 7). The slope of the line is positive (ϱ = +0.97). The logarithm of the pseudo first order rate constants found in reactions of *p*-substituted phenyl cyanates with "butylmagnesium bromide" could not be linearly correlated with the Hammett *sigma* values (Table 5 and Fig. 8). The rate constants are increased both when the substituent is electron-attracting (Cl) and when the substituent is electron-donating (CH_3, $(CH_3)_2CHO$ and CH_3O), and the points could not be connected by a smooth curve. It thus seems hazardous on this basis to draw any detailed mechanistic conclusions. However, the increased rate observed in reactions with *p*-substituted phenyl cyanates is in itself an indication of a change either in reaction mechanism or in the transition state.

The most reactive of the aromatic cyanates we have investigated is 2,6-dimethylphenyl cyanate (Table 5). The pseudo first order plots obtained in kinetic measurements with excess "butylmagnesium bromide" are linear up to 70 % transformation of 2,6-dimethylphenyl cyanate, and the pseudo first order rate constant is linearly dependent on the initial concentration of "butylmagnesium bromide" (Fig. 9). The apparent steric acceleration may be due to restricted rotation of the cyanate group with resulting decrease of conjugation with the phenyl group. Thus the inductive effect of the phenyl group becomes more pronounced, causing a reaction rate acceleration in accord with the observed positive sign of the reaction constant.

Aromatic Grignard reagents were found to be much more reactive towards phenyl cyanate than "butylmagnesium bromide" and more

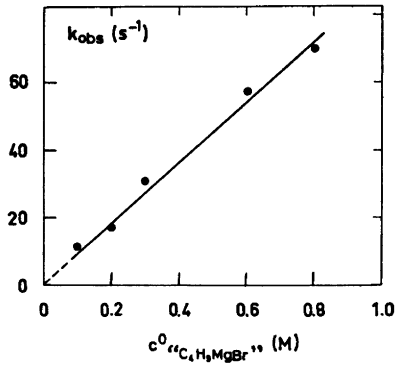

Fig. 9. Plot of pseudo first order rate constants *versus* the initial concentrations of the Grignard reagent for the reaction of 2,6-dimethylphenyl cyanate with "butylmagnesium bromide" in diethyl ether at 25 °C ($c^0_{2,6\text{-}(CH_3)_2C_6H_3OCN} = 0.010$ M).

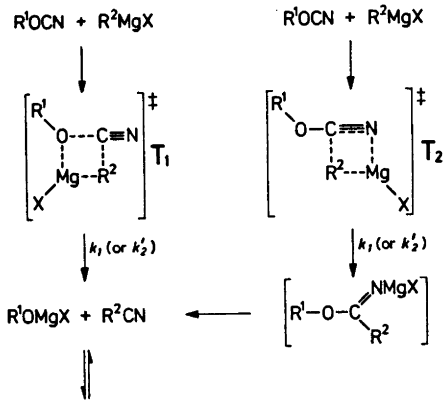
reactive even than dibutylmagnesium (Table 6). When the aromatic Grignard reagent is substituted in the *para*-position an electron-donating substituent (CH_3) makes the Grignard reagent more reactive towards phenyl cyanate and an electron-attracting substituent (Cl) reduces the reactivity of the Grignard reagent. From the k_{obs}-values and the Hammett *sigma* values a reaction constant (ϱ) of -0.8 can be calculated.



Scheme 1.

Table 6. Pseudo first order rate constants for the reaction of 0.010 M phenyl cyanate with different Grignard reagents (c^0"$_{RMgX}$" = 0.100 M) and dibutylmagnesium ($c^0_{R_2Mg} = 0.100$ M) in diethyl ether at 25 °C.

"RMgX" or R_2Mg	k_{obs} (s^{-1})
"*p*-$CH_3C_6H_4MgBr$"	248
"C_6H_5MgBr"	192
"*p*-ClC_6H_4MgBr"	85
$(C_4H_9)_2Mg$	65
"C_4H_9MgBr"	2.9
"*t*-C_4H_9MgCl"	<2.9

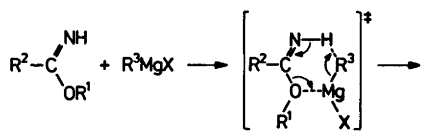
A radical mechanism for the reaction between aryl cyanates and Grignard reagents can probably be excluded. First of all the formation of only a few products in high yields does not indicate the presence of free radicals. In reactions of Grignard reagents where free radicals are formed several products are observed, as for example in the case of the reaction of "*t*-butylmagnesium chloride" with benzophenones.[9] In the reactions of benzophenone with different Grignard reagents "*t*-butylmagnesium chloride" also exhibited the highest measured reaction rate.[10] In the present case "*t*-butylmagnesium chloride" on the contrary has the smallest reaction rate. Furthermore, despite a number of experiments using flow technique we have not observed radicals in ESR measurements.

As shown above the reaction order for the reaction between aryl cyanates and Grignard reagents is two, first order in both reactants. For *m*-substituted aryl cyanates k_{obs}-values are linearly dependent on the initial concentration of the reagent in excess, signifying lack of complex formation prior to the rate-determining step. In the rate-determining step two alternative pathways have to be considered. *1.* Attachment of magnesium directly to the oxygen atom synchronously with nitrile formation. *2.* Attachment of magnesium to nitrogen followed by a further reaction, to give products (Scheme 1).

In case *1* the positive sign of the reaction constant, $\varrho_{ArOCN} = +0.97$, is in agreement with development of a negative charge on oxygen, as will be the case if phenolate is formed. Similarly the negative sign of the reaction

constant $\varrho_{ArMgX} = -0.80$ fulfills the electronic requirements for the formation of the bond between the nitrile group and the Grignard reagent. The size of the constants here observed will, however, normally be associated with a transition state of low polarity. Comparison with reaction constants for reactions of Grignard reagents where the mechanism is known has not been possible. The low polarity of the transition state seems to be evidence against reaction path *1*, but it is, however, hardly conclusive since a bond is formed to magnesium concurrently with breaking of the oxygen-carbon bond. This reduces the polarity of the transition state since the bond between oxygen and magnesium has some covalent character (27 %),[11] but the extent of this effect is uncertain.

The second pathway implies formation of an imido ester salt, for which no evidence has been brought to light despite carefull scrutiny.[1] Still this intermediate cannot be excluded on these grounds since it can be interpreted to mean that the rate constant for the decomposition of the imido ester salt is much bigger than the rate constant for the formation of the imido ester salt. Magnesium salts of simple imido esters are unknown in general, but a few examples of isolation of imido esters, where apparently the salts are intermediates, are reported when a strongly electron-attracting group is present in the molecule. Thus an imido ester can be obtained from the reaction between sodium malonodinitrile and phenyl cyanate,[12] and the reaction of ethyl cyanate with hydrogen cyanide in pyridine yields the corresponding imido ester.[13] The reaction of nitriles with an alcohol in the presence of alcoholate likewise yields imido esters.[14–16] These observations may be considered as an indication of the intermediacy of an imido ester also in the case of the reaction with Grignard reagents. On first consideration this gains support from the fact that in the reaction between imido esters and Grignard reagents, which similarly leads to alcoholates and nitriles, imido esters cannot be regenerated after mixing of the reactants even when using the flow technique.[17] Some caution, however, is necessary in the evaluation of this result, since it may well be that the abstraction of the proton from the imido ester by the Grignard reagent proceeds by a cyclic concerted reaction not leading to salt formation (III).



$$R^2CN + R^1OMgX + R^3H \qquad \text{(III)}$$

It is also in the case of pathway *2* difficult to evaluate what is to be expected with regard to the reaction constant. The aryl group in the cyanate is removed to a greater distance from the reaction center, and the screening effect of the oxygen atom could explain the low value of the reaction constant.

No conclusive evidence can be produced for either of the two alternatives, and evidently these reactions need more attention.

EXPERIMENTAL

All Grignard reagents were prepared in diethyl ether distilled from lithium aluminum hydride directly into the glass apparatus. This solvent was used in all experiments. The magnesium used (monosublimed, Dow Chemical Corp.) was washed with anhydrous diethyl ether. Every precaution was taken against oxygen and moisture. The halides used in the preparations of the Grignard reagents were distilled or recrystallized and their purity checked gas-chromatographically. In preparations of Grignard reagents an excess of magnesium was always used. The molarity of the Grignard reagents was determined by titration with standard acid and the content of halogen by titration with standard silver nitrate. The content of halogen was never more than 4 % higher than the content of Grignard reagent. The different concentrations were obtained by dilution of *ca.* 2 M standard solutions.

The aryl cyanates were prepared from phenols and cyanogen chloride in the presence of triethylamine.[18] The purity of the cyanates was checked by infrared and proton magnetic resonance spectroscopy and elemental analysis.

Dibutylmagnesium was prepared from "butylmagnesium chloride" and butyllithium.[19]

Magnesium bromide etherate was prepared from 1,2-dibromoethane.[20]

A detailed description of the apparatus used for the kinetic measurements is given in Ref. 2.

Acknowledgements. The authors are very grateful to Professor Martin Ettlinger for his interest in and valuable discussions of this work.

Formation of β-Allenic Alcohols in Reactions of Acetylenes with Lithium Aluminium Hydride*

LARS-INGE OLSSON, ALF CLAESSON and CONNY BOGENTOFT**

Department of Organic Chemistry, Faculty of Pharmacy, University of Uppsala, Box 574, S-751 23 Uppsala, Sweden

β-Allenic alcohols can be prepared in low to good yields upon treatment of 5-alkoxy-, 5-tetrahydro-2-pyranyloxy-, and 5-trialkylamino-4-pentyn-1-ols (*1*—*10*) with $LiAlH_4$. The reactions proceed in some cases *via* detectable carbanionic intermediates (*21*).

The most convenient way to obtain β-allenic alcohols seems to be the $LiAlH_4$ reduction of alkenynols.[1-3] This reaction has also been applied to stereoselective synthesis.[4] Less used are the following methods: (*i*) the reaction of dihalocyclopropanes with alkyllithium, which was used for preparation of cyclic derivatives,[5] (*ii*) $LiAlH_4$ reduction of β-allenic aldehydes [4] and ketones,[6] (*iii*) addition of propadienyllithium derivatives to oxiranes,[7] and (*iv*) reduction of hydroxy propargylchlorides with a zinc-copper couple.[8]

α-Allenic alcohols are readily prepared by the reaction of 2-butyn-1-ol derivatives with $LiAlH_4$ (Scheme 1).[9-12] The reaction proceeds through an S_N2' mechanism, where X serves as a leaving group (Thp-oxy = tetrahydro-2-pyranyloxy).

Scheme 1.

In this paper we report on an extension of this reaction, in which β-allenic alcohols are formed from the homologous acetylenic derivatives *1*—*10* (Table 1) upon treatment with $LiAlH_4$ under suitable conditions.

RESULTS

The starting acetylenes *1*—*4*, *6*, and *7* were prepared using standard procedures, *i.e.* addition of lithiumalkynides to oxiranes in NH_3.[14] HMPA was used as co-solvent to increase nucleophilicity of the alkynides. *5* was made in analogy to similar compounds [13] and the ammonium salts *8* and *9* were prepared *via* the Mannich reaction [15] of the corresponding β-acetylenic alcohols followed by quaternization. Compound *10* originates from the addition of 3-piperidino-1-butyne to ethylene oxide.

Upon treatment of the acetylenic derivatives *1*—*7* with an excess of $LiAlH_4$ in tetrahydrofuran (THF) at 65 °C and the ammonium salts *8*—*10* at 35 °C the corresponding β-allenic alcohols *10*—*17* were formed in the indicated yields (*cf.* Table 1). No reaction occurs with compounds *1*—*7* when ether is used as a solvent. THF is used for compounds *8*—*10* because of its ability to dissolve the quaternary ammonium salts.[9] In all the reactions except that of *10* reduced allenes are formed as by-products (called "alkenols" in Table 1). In refluxing dioxane these alcohols are main products but so far they have not been further examined.

In some of the reactions one of the major products was the semi-reduced form of the starting acetylene, a fact that made possible a mechanistic interpretation of the formation

* Allenes and Acetylenes VI. Part V: Bogentoft, C., Olsson, L.-I. and Claesson, A. *Acta Chem. Scand. B 28* (1974) 163.

of amino alcohol. Quaternization is quantitative. [d] Rel. areas of peaks. Not corrected for detector response.

of the β-allenic alcohols (*cf.* Discussion). Three of these compounds (*18*–*20*) were isolated by GLC and characterized (*cf.* Table 2).

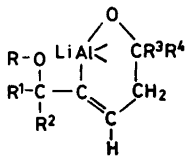
By use of GLC+MS it was easy to indicate a similar product, 5-Thp-oxy-3-octen-1-ol, from the reduction of *3* with $LiAlH_4$. In the mass spectrum of this compound there was no M^+ ion but the $M^+ - Thp\text{-}oxy$ peak was as predicted shifted two mass units compared with the corresponding peak in the spectrum of *3*.

In the reactions of *6* and *7*, where the Thp-oxy groups leave tertiary carbons, no products of this type were encountered.

5-*t*-Butoxy-3-octen-1-ol (*19*) obtained from the acetylenic derivative *4* has the *trans* configuration as indicated by GLC using the corresponding *cis*-alkenol for comparison. The latter originated from partial hydrogenation of *4* over a Lindlar catalyst. Compound *19* also shows strong absorption at 970 cm^{-1} in the IR spectrum. The finding is in accordance with the well known reduction of propargylic alcohols with $LiAlH_4$ to form *trans* allylic alcohols.[13]

DISCUSSION

After the initial alcoholate formation the reductions of *1*–*5* with $LiAlH_4$ proceed in two distinct steps (i) attack by $LiAlH_4$ on the triple bond to form *21* or a similar carbanion intermediate (*ii*) elimination of an alkoxy or Thp-oxy group.



21

Using D_2O to hydrolyze the $LiAlH_4$ reaction mixture from the acetylene *4* confirmed the presence of an intermediate like *21*. NMR analysis of the labeled *19* thus obtained proved that the deuterium occupied exclusively the 4-position; the proton at C-5 became a triplet and spin decoupling of the C-1 protons made the allylic protons at C-2 appear as a doublet ($J = 6$ Hz).

Some of the intermediates are surprisingly stable as can be seen in the reaction of *2*, where the intermediate constitutes 84 % after 22 h. It is interesting to note that the Grignard reagent from *t*-butyl-2-bromoallyl ether also shows remarkable stability, only giving rise to small amounts of allene through elimination of bromomagnesium *t*-butoxide.[17]

It has not been possible to determine whether the quaternary ammonium compounds *8*–*10* give β-allenic alcohols *via* similar long-lived intermediates.

The Thp-oxy group seems to be a better leaving group than *t*-butoxide (*cf.* the reactions of 1 and 2). This is in some contrast to two analogous reactions that we have examined. We have used the *t*-butoxy and Thp-oxy groups with approximately equal success in a modification[12] of Landor's preparation of α-allenic alcohols (*cf.* Scheme 1) and also in a S_N2' type reaction which gives *trans* homoallylic alcohols from $LiAlH_4$ reduction of 4-alkoxy-2-buten-1-ols.[15]

The β-allenic alcohols are susceptible to attack by hydride on the allenic group and further reduction to a mixture of unsaturated alcohols ("alkenols" in Table 1) occurs in most cases. The reaction temperature, which will minimize this reaction and yet get an acceptable reaction rate for compounds similar to *1*–*7*, seems to be 55–60 °C. The quaternary ammonium compounds react at a lower temperature(~35 °C) and only small amounts of alkenols (≤3 %) are formed as by-products.

Though β-allenic alcohols in a few cases are obtained in acceptable yields and purity by reaction of acetylenic Thp-oxy derivatives with $LiAlH_4$ (Table 1) it can be concluded that quaternary ammonium compounds like *8*–*10* seem to be the most suitable substrates for their preparation by this method.

EXPERIMENTAL

General. IR spectra were run on a Perkin-Elmer Infracord 157 G spectrophotometer using liquid films between NaCl discs. NMR spectra were obtained in $CDCl_3$ with tetramethylsilane as internal standard, using a Perkin-Elmer R-12 B spectrometer. These spectra were routinely recorded and are in full agreement with the proposed structures. Mass spectra were obtained at 70 eV with an AEI MS-30 mass spectrometer connected to a Pye 104 gas chromatograph. Columns; 1.5 m glass columns packed with 5 % Carbowax 20 M or 3 % OV-17 on Gas-Chrom Q. Correct mass spectral data were obtained for all products in Table 1.

Table 2. Spectral data of compounds *11*–*20*.

[a] Only bands of diagnostic value are listed.

For GLC analyses a 2.7 m glass column containing 3 % OV-25 was used. Individual compounds were isolated on a 300 × 0.94 cm aluminium column packed with 20 % Carbowax 20 M on Chromosorb W (60–80).

All reactions with $LiAlH_4$ and Grignard reagents were performed under nitrogen.

Propargylic ethers used in the subsequent preparations were 3-(tetrahydro-2-pyranyloxy)-propyne,[18] *t*-butyl propargyl ether,[19] 3-(tetrahydro-2-pyranyloxy)-1-hexyne,[10,11] 3-*t*-butoxy-1-hexyne,[15] 3-methyl-3-(tetrahydro-2-pyranyloxy)-1-butyne,[20] and 3-methyl-3-(tetrahydro-2-pyranyloxy)-1-pentyne.[20]

Preparation of 1–4, 6, and 7. To 1.14 mol of lithium amide in 1000 ml of liquid ammonia the appropriate propargylic ether (1 mol, see below) dissolved in 100 ml of THF was added during 30 min. 2.4 mol of ethylene oxide or propylene oxide was added and then 100 ml of HMPA. The mixture was stirred overnight and the ammonia allowed to evaporate. Water was added and the products taken up in ether, which was washed with saturated NH_4Cl and several times with 0.01 M hydrochloric acid to remove all traces of HMPA, dried over Na_2SO_4–K_2CO_3 and distilled. For boiling points and yields see Table 1.

2-Methyl-6-methoxy-4-octyne-2-ol (5). Addition[20] of dihydropyran to 2-methyl-4-pentyne-2-ol[21] gave the tetrahydropyranyl protected alcohol (b.p. 96 °C/14 mmHg) in 85 % yield. This (25.0 g; 0.137 mol) in 50 ml of THF was added dropwise during 0.5 h at room temperature to ethylmagnesium bromide [prepared in ether-THF (1:4) from ethyl bromide (19.0 g; 0.174 mol) and magnesium (4.25 g; 0.174 mol)] and stirring was continued for 1 h to give the corresponding acetylenic Grignard derivative. To this reagent propionaldehyde (7.25 g; 0.25 mol) in 25 ml of THF was added dropwise during 0.5 h and the mixture was stirred at room temperature for 2 h. Dimethyl sulfate (23.6 g; 0.187 mol) was added during 0.5 h and then 50 ml of HMPA. The mixture was refluxed for 10 h. After cooling, water was added and the product was taken up in light petroleum, which was then evaporated. The residue was methanolyzed by stirring with 0.5 g of *p*-toluenesulfonic acid in 400 ml of methanol at room temperature for 1 h. 10 g of K_2CO_3 was added and the mixture diluted with 400 ml of ether. Filtering and distillation yielded *5*.

Reactions of 1–7 with $LiAlH_4$. 0.02 mol of the acetylenes 1–7 in 20 ml of THF was slowly dropped to an ice-cooled, stirred suspension of $LiAlH_4$ (0.03 mol for Thp-oxy derivatives and 0.022 for the others). The mixture was then kept at an oil bath temperature of 70 °C and the reactions were followed by GLC (*cf.* Table 1). Work-up using NaOH-water[22] yielded the products in Table 1.

3,4-Pentadien-1-ol[2] *(11) from 8.* Dibenzylamin (11.8 g; 0.06 mol), 3-butyn-1-ol (4.0 g; 0.057 mol), paraformaldehyde (3 g; 0.1 mol)

and 0.2 g of Cu(I)Br were mixed in 25 ml of dry dioxane and refluxed for 1.5 h. The mixture was poured into 100 ml of water, acidified to pH ~ 2 and extracted twice with ether. The aqueous phase was made alkaline with conc. ammonia and extracted three times with ether (3 × 100 ml). Drying over K_2CO_3 and evaporation of solvents yielded 5-dibenzylamino-3-pentyn-1-ol (14 g; 88 %). This crude amino alcohol was treated with an 100 % excess of methyl iodide in refluxing acetone for 1 h. Evaporation yielded the ammonium iodide *8* to which 75 ml of THF was added. $LiAlH_4$ (3.02 g; 0.08 mol) was added in small portions with ice-cooling and swirling. The mixture was then kept in an oil bath of 35 °C during 2 h. Work-up using the NaOH method [22] and distillation yielded the title compound.

1-(2,3-Butadienyl)cyclohexanol (16) was similarly prepared from 1-(2-propynyl)cyclohexanol [21] and piperidine.

3,4-Hexadien-1-ol [4] *(17)*. 3-Piperidino-1-butyne [23] (from the propargylic tosylate and piperidine) was added to ethylene oxide *via* its lithium derivative as described for *1–4*. HMPA was omitted. 5-Piperidino-3-hexyn-1-ol was obtained in 45 % yield. (B.p. 110 °C/0.1 mmHg). This alcohol was treated as described in the preparation of *11* to give the title compound.

Acknowledgement. We are indebted to Prof. Bengt Danielsson for valuable discussions and to Miss Inger Tämnefors for preparing some of the starting acetylenes. The work has been supported financially by the Swedish Natural Science Research Council.

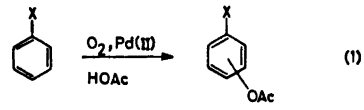
Palladium(II) Catalyzed Aromatic Acetoxylation. V. Mixed Amine Acetatonitratopalladium(II) Complexes as Catalysts in the Acetoxylation of Chlorobenzene

LENNART EBERSON* and ERNST JONSSON**

Division of Organic Chemistry 1, Chemical Center, University of Lund, P. O. Box 740, S-220 07 Lund 7, Sweden

The palladium(II) acetate catalyzed acetoxylation of aromatic compounds has been further investigated, using chlorobenzene as the substrate. Addition of cooxidants, such as dichromate or nitrate, speeds up the reaction by a factor of about 50 but decreases the *meta* selectivity somewhat. In the presence of nitrate (or nitric acid or nitrogen dioxide) Pd metal never precipitates during the reaction. The nitrate catalyzed reaction could be run with a high degree of *meta* selectivity (up to 65 % of the product mixture) if an amine was added in an amount equivalent to the formation of a bisaminepalladium(II) complex. When 2,2′-bipyridine was used for complexation, the compound acetato(2,2′-bipyridine)nitratopalladium(II) monohydrate could be isolated from the reaction mixture. This complex, synthesized separately, possessed good catalytic activity for acetoxylation of chlorobenzene.

Previous work in this series [1,2] and by others [3–14] has established that direct acetoxylation of aromatics — in the ring and/or in the α position of an alkylsubstituted aromatic compound — can be achieved *via* a palladium acetate catalyzed process in boiling acetic acid in an oxygen atmosphere, as shown for nuclear acetoxylation of a monosubstituted benzene derivative in eqn. 1. The isomer distribution turned out to be anomalous under these or similar conditions,[2,10,14] the *meta* acetoxy derivative being the predominant isomer from a number of monosubstituted benzenes with otherwise *ortho*, *para*-directing substituents (*i.e.* in electrophilic substitution). These findings were rationalized in terms of an addition-elimination mechanism, in which electrophilic attack by a palladium(II) species is the initial step.[15]



(1)

Under the conditions described above, the reaction is, however, too slow to be of any practical value,[1] and we have therefore continued our studies of Pd(II) catalyzed aromatic acetoxylation with the aim of finding ways of speeding up the process while retaining the *meta* selectivity. This latter feature is of obvious interest from the synthetic point of view, since it gives a one-step route to phenol derivatives that are otherwise only accessible by multi-step procedures.

Some clues — apart from the well known effect of adding strong acid [3,6] — as to which directions one should look for additional catalytic effects in aromatic acetoxylation were to be found in the literature. Thus, Henry [10] had shown that the addition of a co-oxidant, such as potassium dichromate, to the $Pd(OAc)_2$/HOAc system favors nuclear acetoxylation in a substrate (toluene) that otherwise would give predominantly α acetoxylation.[7–9] Also here a selectivity for *meta* substitution was noticeable (*ortho*:*meta*:*para* equal to 19:62:19 in the presence of methanesulfonic acid). In the analogous vapor phase reaction, acetoxylation over a palladium based catalyst,[16] a similar facilitation of nuclear acetoxylation, coupled to a certain degree of *meta* selectivity, was

* To whom inquiries should be addressed.

** Present address: Gambro AB, P.O. Box 10015, S-220 10 Lund, Sweden.

noticed when the catalyst contained a co-oxidant. Moreover, Henry [10] as well as other investigators [6,12,14] has found that the addition of nitrate ion, nitric acid, or oxides of nitrogen has an accelerating effect upon aromatic acetoxylation, yet that nitration then becomes a significant side reaction.

We have applied these and similar ideas to the Pd(II) catalyzed nuclear acetoxylation of chlorobenzene, a substrate that after some preliminary experimentation was found to be a good model compound, since both nitration and biaryl coupling were only minor side reactions. The results indicate that it is indeed possible to speed up the reaction by a factor of about 50 while still retaining the *meta* selectivity to a high degree. Mixed amine acetatonitratopalladium(II) complexes were found to be best in this respect. The 2,2′-bipyridine-acetatonitratopalladium complex was isolated and characterized and found to possess good catalytic activity.

RESULT

A first approach to increase the rate of a reaction is to change the solvent. Since DMF has turned out to be a superior solvent for the palladium acetate catalyzed oxidation of terminal alkenes to ketones,[17] we first tried a mixture of acetic acid and DMF (1:1 v/v) as a solvent for the acetoxylation of chlorobenzene under oxygen. However, DMF acted as a reductant for Pd(II) acetate at the temperature employed and hence this solvent cannot be used. The main product from this reaction was, somewhat curiously, *N*,*N*-dimethylacetamide.

N,*N*-Dimethylacetamide in a mixture with acetic acid was then tried but with similar negative results; at 90 °C Pd(II) is reduced by the solvent mixture and acetoxylation runs with chlorobenzene at 65 and 85 °C did not yield any acetoxylation products. Dimethyl sulfoxide as a co-solvent also underwent oxidation by Pd(II), giving the corresponding sulfone. Thus, none of the dipolar aprotic solvents tried is inert towards Pd(II).

Next we added a strong acid to the reaction mixture (Table 1, experiments 2 and 3). As expected, this changed the reaction path from acetoxylation to predominant biaryl coupling, a mixture of dichlorobiphenyls (at least five of the six possible ones) being obtained. With methanesulfonic acid this process was essentially instantaneous and should be of pre-

[a] All experiments were performed with 1.0 mmol of $Pd(OAc)_2$ and 9.9 mmol of chlorobenzene. The total amount of acetic acid and added liquid component was 50 ml. [b] Based on $Pd(OAc)_2$. [c] Reported [2] *o*:*m*:*p* = 3:88:9. [d] Difficult to analyze due to the small amount formed. [e] The main product was a mixture of isomeric dichlorobiphenyls. [f] Traces of phenyl acetate were detected. [g] H_2O_2 decomposed as soon as Pd(0) precipitated.

parative interest if the isomer distribution can be controlled. Trifluoroacetic acid also caused the formation of predominantly biaryl products, although a low yield of acetoxychlorobenzenes was secured.

Following Henry's observations,[10] we performed experiments in which potassium dichromate was added as a co-oxidant (Table 1, experiments 4 and 5). Both reactions, which differed from each other by being run under oxygen and nitrogen, respectively, gave acetoxylation products in a reasonably fast process (about 20 times faster than in the absence of potassium dichromate), showing that the finding that toluene is predominantly acetoxylated in the ring under these conditions is due to a rate increase of the nuclear substitution reaction. The reaction became even faster when trifluoroacetic acid was present together with potassium dichromate (146 % yield after 4 h), whereas under otherwise identical conditions methanesulfonic acid and trichloroacetic acid decreased the rate (Table 1, experiments 6 – 8). However, these rate increases are accompanied by changes in the isomer distribution, so that the desired *meta* selectivity has disappeared. Instead, the *ortho* isomer is slightly favored. No coupling was noticed in the experiments with dichromate present.

Some other oxidants were tried (experiments 9 – 13 in Table 1) but with no apparent success with respect to the aims of this investigation. In these cases acetoxylation did occur, but the reactions were either too slow or complicated by side reactions. Moreover, these reactions as well as all mentioned above suffered from the disadvantage of Pd metal precipitation with a concomitant sluggishness of the reoxidation of Pd(0) to Pd(II). Apart from this practical drawback, Pd(0) can catalyze unwanted reactions.

However, the last experiment (No. 14 in Table 1) gave very promising results from several points of view. Addition of NO_2 to the reaction solution caused a fairly rapid acetoxylation process to occur while at the same time the solution remained homogeneous during the run. Only a trace of chloronitrobenzenes was formed as a by-product, and the isomer distribution, although not directly in favor of the *meta* isomer, was only little affected.

A number of runs (Table 2) in which NO_2 was used as a co-oxidant were performed. Since water is formed during the reaction it was

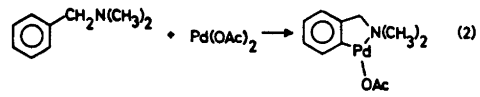
[a] All experiments were performed with 1.0 mmol of $Pd(OAc)_2$, 10.0 mmol of NO_2, and 9.9 mmol of chlorobenzene in an oxygen atmosphere. The total amount of acetic acid and added liquid component was 50 ml. [b] Based on $Pd(OAc)_2$. [c] Yield after 1 h 52 %.

first established that small amounts of water had no effect on the yield and product distribution (nor had acetic anhydride), and that additives like trifluoroacetic acid, sodium acetate, or nitric acid did not have any deleterious effect upon the yield but on the other hand did not increase the *meta* selectivity to the desired level. Complexing bases of the pyridine type (Tables 2 and 3) were better in this respect and did not decrease the rate if not added in excessive amounts (*cf.* Table 2, experiments 23 and 24). All factors considered, isoquinoline appears to be the best complexing base hitherto found (experiment 26), the percentage of the *meta* isomer being 61 %, the yield 88 % after 4 h, and the occurrence of nitration almost negligible.

In the experiment (No. 15) with water present, the reaction was run for 27 h, after which time the yield was 250 %, based on the Pd(II) acetate used. The reaction mixture was still catalytically active and no Pd metal had precipitated. The isomer distribution changed slightly with time, being 17:37:46 at the discontinuation of the experiment, presumably due to different reactivity of the three isomers toward further acetoxylation. A second acetoxylation process does take place, as shown by the detection of at least three isomers of diacetoxychlorobenzene (22 % yield). Bisacetoxylation was noticed in two other cases as well (experiments 19 and 20).

Ethylenediamine was the most strongly rate accelerating base tried, the yield after 1 h being 52 % and after 4 h 71 %. A similar high initial rate was noticed with benzyldimethylamine (34 % after 1 h) but this reaction later slowed down appreciably (7 % during the second hour). In both cases the reaction mixture turned dark, probably due to oxidative degradation of the amine; it is also possible that benzyldimethylamine is removed in a palladation reaction, such as that depicted in eqn. 2:



(2)

This type of compound is known from the literature.[18]

When NO_2 in excess was added to a solution of palladium acetate and 2,2′-bipyridine in acetic acid, a yellow precipitate was formed. The same precipitate was also produced when the reaction mixture from experiment No. 25 was allowed to cool. A solution of the filtered and dried complex in acetic acid has the same catalytical effect as the initial solution, without any extra NO_2 being added. Elemental analyses and spectral data (IR, NMR) showed that the salt must be acetato(2,2′-bipyridine)nitratopalladium(II) monohydrate. This complex reacted

37	Methyl benzoate	4	(Isoquin)$_2$Pd(OAc)$_2$+NO_2[e]	0			

[a] All experiments were performed with 1 mmol of the complex, 9.9 mmol of the substrate, and 50 ml of HOAc in an O_2 atmosphere. [b] Based on the amount of complex. [c] A mixture of nitroanisoles was the main product. [d] Yield of nitrobenzene, 305 %. [e] 5.5 mmol.

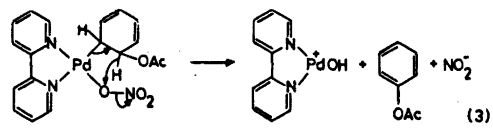
with excess nitric acid in HOAc and gave a solution of (2,2′-bipyridine)dinitratopalladium(II), which was catalytically inactive.

The mixed acetatonitrate complex was then used as a catalyst for the acetoxylation of a number of substrates (Table 4). Chlorobenzene (experiment 35) gave a higher *meta* selectivity than and almost the same yield of acetoxychlorobenzenes as in experiment 25 (Table 3) in which the complex was generated in solution. Compounds with activating groups gave acetoxylation products but in low yield; as expected, nitration is the major process in the case of anisole (experiment 33) and, in spite of much experimentation, it has not yet been possible to suppress this reaction. Even benzene is nitrated to a fairly high degree (experiment 36) under similar conditions. Methyl benzoate did not react at all. Phenyl acetate gave a mixture of diacetoxybenzenes as the main product but at a surprisingly low rate, which might explain why earlier attempts to acetoxylate phenyl acetate under slightly different conditions have failed.[10]

DISCUSSION

The primary aim of this investigation has been to increase the rate of the Pd(II) catalyzed nuclear acetoxylation of aromatic compounds while retaining the anomalous *meta* selectivity noticed earlier. At the same time it was desirable to find a better method of reoxidizing the Pd(0) state, so that no Pd metal would precipitate. Otherwise, there is a risk that the heterogeneous reoxidation reaction will be rate-limiting and/or that Pd metal might cause unwanted reactions.

The system palladium(II) acetate/NO_2 or HNO_3 in combination with oxygen represents a first step toward the realization of these goals, even if the *meta* selectivity is not so pronounced in these cases and in some cases published in the patent literature[14] (toluene, *o*:*m*:*p* = 16:41:43; isopropylbenzene, *o*:*m*:*p* = 0:59:41, *t*-butylbenzene, *o*:*m*:*p* = 0:43:57). However, modification of the acetatonitrato catalyst by adding a pyridine base increases the *meta* selectivity, 2,2′-bipyridine and isoquinoline being the best ligands so far studied. The isolation of a defined complex with good catalytic activity indicates that it is essential that palladium has both nitrate and acetate as a ligand (the corresponding complexes with two nitrate or acetate groups, respectively, were catalytically inactive). This is in accordance with the mechanism discussed earlier,[15] in which the first step is the reversible formation of a π complex between the palladium species, PdL_4, and the aromatic compound which then undergoes attack by a nucleophile (in acetoxylation, acetate ion) to form an adduct. Loss of $PdHL_3$ completes the reaction sequence.



(3)

It is the last step that is affected favorably by the addition of a co-oxidant, nitrate ion being especially effective since it can be present within

the coordination sphere of the adduct (eqn. 3) and regenerate a Pd(II) species directly.

The improvements of the acetoxylation process described in this paper have made the reaction feasible from the practical point of view, at least for laboratory use. A remaining drawback is the nitration reaction which becomes especially pronounced in compounds with activating substituents. Attempts to find other oxidants with properties similar to those of nitrate ion have so far failed.

EXPERIMENTAL

Materials. All chemicals used were purchased in the highest commercial quality available or prepared according to literature methods (see also Parts I and II of this series [1,2]). Solutions of nitrogen dioxide were prepared by heating a known amount of lead nitrate and dissolving it in glacial acetic acid. Identification of compounds was based on mass spectral/gas chromatographic (LKB 9000 system) comparison with authentic samples. Analyses [1,2] were performed with a Varian 1700 gas chromatograph in conjunction with a disc integrator. Biphenyl was used as an internal standard.

Analytical oxidation experiments. These were performed according to method B in Part I [1] with the modifications described in the tables.

Preparation of acetato(2,2'-bipyridine)nitratopalladium(II) monohydrate. 2,2'-Bipyridinepalladium(II) acetate [19] was dissolved in acetic acid and an excess of nitrogen dioxide was dissolved in the solution. The yellow-red precipitate was collected and recrystallized from acetic acid or DMF, m.p. 202 °C (dec.). IR (KBr): 3600 – 2950 (broad); 1600(w); 1385(s) cm^{-1}. NMR (DMSO-d_6): δ 2.10(s, 3); 3.35(s, 2); 7.7 – 8.6(m,8). (Found: C 35.8; H 3.24; N 10.2. Calc. for $C_{12}H_{13}N_3O_6Pd$: C 35.8; H 3.24; N 10.5).

Diacetoxychlorobenzenes. The retention times of the three isomers were 12, 13, and 14 min, respectively, on a 2 m × 0.3 cm 5 % neopentylglycol succinate on Chromosorb W column (120 – 200 °C at 10 °C/min). The mass spectra of the three isomers were very similar with a small parent peak at *m/e* 228 (2 – 3 %) and major peaks at *m/e* 186 (15 – 17), 146 (20 – 30), and 144 (100).

Acknowledgements. We gratefully acknowledge the generous financial support we have obtained from the Swedish Board for Technical Development. Part of the instrument costs was defrayed by the Knut and Alice Wallenberg Foundation.

Radiation Induced Effects on Exchangeable Hydrogens in Crystalline Carbohydrates

GÖRAN LÖFROTH and TORBJÖRN GEJVALL

Radiobiology Department, University of Stockholm, Wallenberg Laboratory, Lilla Frescati, S-104 05 Stockholm 50, Sweden

Crystalline mono- and disaccharides, unlabeled and labeled with deuterium or tritium in the exchangeable positions, were irradiated with ^{60}Co γ-rays. Hydrogen gas, H_2, is formed with G-values of 3.0 – 3.8 in unlabeled carbohydrates. Mass spectrometry of the hydrogen gas formed in the deuterium labeled carbohydrates showed that only 2 – 4 % is in the form of HD and that no D_2 is detectable. Irradiation of the tritium labeled carbohydrates transfers tritium to non-exchangeable positions and a large part of this tritium is present in the original carbohydrate. G-Values of 1 – 2 can be calculated for the transfer process assuming that no isotope effect is present. The results indicate that the radiation induced transfer from exchangeable positions to non-exchangeable positions in crystalline carbohydrates occurs at an early stage following the absorption of the radiation.

Radiation induced hydrogen transfer from exchangeable sites to non-exchangeable sites has been detected in several types of compounds in the solid state.[1,2] In amino acids, labeled with deuterium in the exchangeable positions, transfer of exchangeable hydrogen to carbon-bound hydrogen in the radiation induced free radicals has been investigated by ESR (Ref. 1 and quoted refs.). Smitherman *et al.*[2] have studied transfer from exchangeable to non-exchangeable sites in lyophilized samples of proteins, nucleic acid and D-glucose by means of tritiated compounds and have suggested that destruction of secondary radicals may be responsible for the radiation induced hydrogen transfer.

In the present investigation the extent of the radiation induced hydrogen transfer to positions at carbon atoms has been determined in some crystalline carbohydrates labeled with tritium in the exchangeable positions. In parallel studies with non-labeled samples and samples labeled with deuterium in the exchangeable positions quantitative determinations of the radiation induced formation of hydrogen gas, H_2, HD, and D_2, have been performed in order to evaluate the involvement of the exchangeable hydrogens in the formation of hydrogen gas.

EXPERIMENTAL

The ^{60}Co γ-irradiation source and the non-labeled carbohydrates have previously been described.[3]

Labeling of the exchangeable hydrogens in the carbohydrates was made by crystallization in aqueous solvents containing tritiated or deuterated water. The specific activities of the tritiated samples were in the range 22 – 76 mCi/mol. The theoretical exchange of deuterium for hydrogen, as calculated from the ratio of the number of exchangeable deuterium atoms to the number of exchangeable hydrogen plus deuterium atoms in the crystallization solution, ranged from 55 % (in sucrose) to 87 % (in α-D-glucose).

The tritiated carbohydrates were irradiated in the presence of air and then dissolved in water bubbled with nitrogen. The water was distilled off at reduced pressure and temperatures not exceeding 35 °C. Dissolution of the residue in water and distillation were repeated until all exchangeable tritium had been removed and the solid residue had a constant specific activity. This took about eight cycles. Syntheses of di-*O*-isopropylidene-D-fructose and di-*O*-isopropylidene-D-glucose were made directly on the unirradiated and irradiated samples whereas syntheses of the octa-*O*-acetyl derivatives of sucrose and trehalose were made on

samples from which the exchangeable tritium had been removed. Di-*O*-isopropylidene-D-glucose was prepared according to Glen *et al.*[4] and the other derivatives were synthesized and purified as described earlier.[3] The determination of radioactivity was mainly done with aqueous scintillation with Instagel (Packard Inc.).

For the determination of hydrogen gas the samples were irradiated in sealed glass ampoules. After irradiation the ampoule was opened when attached to a small flask having a second side arm closed with a rubber membrane through which water was added for dissolution of the sample and head space gas withdrawn for analysis. Hydrogen gas was determined by gas chromatography with a 2.5 m × 2.1 mm Molecular Sieve 5A 60 – 80 mesh column at 50 °C and with hot wire detection at 100 °C. The determination of HD and D_2 relative to H_2 was made on a CH-4 Atlas M-A-T mass spectrometer at the Mass Spectrometry Laboratory, Karolinska Institute, Stockholm, on the head space gas of samples irradiated *in vacuo* and on the head space gas of samples irradiated in the presence of air and then dissolved in water *in vacuo*.

RESULTS

Labeling of the carbohydrates with tritium in the exchangeable positions occurred to the extent expected from the amount of added tritium and the number of exchangeable positions in the carbohydrates and the crystallization solvent. This indicates that no measureable isotope effect is present in the recrystallization labeling procedure.

Upon irradiation, followed by removal of the exchangeable tritium by repeated distillation, a dose related increase of non-exchangeable tritium was present in the samples (*cf.* Figs. 1 and 2). Except for trehalose dihydrate the tritium incorporation is linearly dependent on the dose up to at least about 10^{21} eV/g. With the assumption that no isotope effect is operating in the transfer process the following

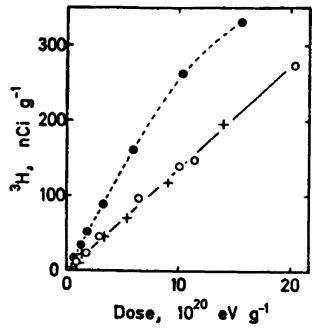

Fig. 1. The radiation induced transfer of ^3H from exchangeable to non-exchangeable positions in crystalline carbohydrates labeled with ^3H in the exchangeable positions (mCi/mol carbohydrate); dose *vs.* amount of non-exchangeable ^3H per g irradiated carbohydrate; ● D-fructose 35 mCi/mol, O α-D-glucose 22 mCi/mol, and + α-lactose.H_2O 66 mCi/mol.

Table 1. Radiation induced transfer of tritium in crystalline carbohydrates from exchangeable positions to non-exchangeable positions determined after (a) repeated evaporation of water and (b) derivatization and purification with respect to the original carbohydrate.

Compound and sp. activity	Dose 10^{20} eV/g	nCi non-exchangeable ^3H per g[a] (a) of irradiated sample	(b) of original carbohydrate
D-Fructose 35 mCi/mol	5.9	160	110
	10.4	264	165
	16.0	331	249
α-D-Glucose 22 mCi/mol	10.1	139	108
Sucrose 61 mCi/mol	11.4	113	63
Trehalose·$2H_2O$ 76 mCi/mol	15.8	214	72

[a] After correction for tritium incorporation in non-exchangeable positions in unirradiated samples.

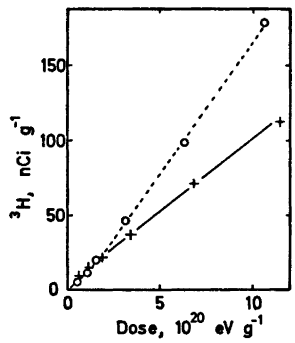

Fig. 2. As for Fig. 1 with O trehalose.$2H_2O$ 76 mCi/mol and + sucrose 61 mCi/mol.

G-values are obtained: D-Fructose 2.3, α-D-glucose 1.8, α-lactose monohydrate 1.2, and sucrose 0.8. In the case of trehalose dihydrate there is an exponentially increasing dose response up to about 10^{21} eV/g (Fig. 2) with an initial G-value of about 0.9 and a slope in the dose region $0.5 \times 10^{21} - 10^{21}$ eV/g corresponding to a G-value of about 1.7. A G-value of 0.95 for transfer of exchangeable hydrogens to non-exchangeable positions has been reported for lyophilized D-glucose samples, the modification of which was not reported.[2] Tritium is also present in non-exchangeable positions in unirradiated samples; these incorporations were generally small (*i.e.* 0.3 – 5 nCi/g) compared with the radiation induced incorporations and they have been corrected for in the calculations.

By preparation of the di-*O*-isopropylidene derivative directly from unirradiated and irradiated D-fructose it was found that most of the radiation induced tritium incorporation (about 70 %) is present in D-fructose itself (Table 1). A similar investigation on the other carbohydrates by means of the suitable acetyl derivatives resulted in a high tritium incorporation into the acetoxy methyl group. Derivatization after removal of the exchangeable tritium was, however, feasible and analyses of sucrose and trehalose dihydrate showed that a large part of the radiation induced incorporation is in the original carbohydrate (Table 1). The same seems to hold also for α-D-glucose as determined by analyses of its di-*O*-isopropylidene derivative prepared directly from the crystalline samples; in this case, in contrast to D-fructose, an appreciable tritium incorporation (178 nCi/g) occurred in the unirradiated sample. The difference may be that the D-fructose derivative is prepared with only anhydrous acetone and zinc chloride whereas also the presence of another acid, *e.g.* phosphoric acid, is necessary for D-glucose.

Analyses of hydrogen gas formation in the dose range $10^{19} - 4 \times 10^{20}$ eV/g showed that the total yield, obtained after dissolution of the samples, is linearly dependent on the dose; $G(H_2)$ was found to be 3.8 for α-D-glucose, lactose monohydrate, and maltose monohydrate 3.1 for sucrose and 3.0 for D-fructose and trehalose dihydrate. Depending on the type of carbohydrate, various portions of the hydrogen gas are released from the crystals in the solid state; the per cent released was 15 – 25 for α-D-glucose, D-fructose and sucrose, 50 – 60 for lactose monohydrate, and 70 – 80 for maltose monohydrate and trehalose dihydrate. The present result on hydrogen gas formation in α-D-glucose is the same as that reported by Phillips and Baugh.[5]

Mass spectrometric analyses of the relative amount of HD to H_2 performed on α-D-glucose, D-fructose, sucrose, and trehalose dihydrate deuterated in the exchangeable positions and irradiated with doses of about 1.5×10^{20} eV/g showed that only 2 – 4 % of the hydrogen gas was in the form of HD. Analyses of D_2 was usually not possible, probably due to contamination from helium, except for one analysis of each of α-D-glucose, sucrose, and trehalose dihydrate; in these analyses no peak was detected at mass number 4 while the HD was detected; this result indicates that D_2 at most is only one fifth to one tenth of HD. Control experiments with non-labeled samples dissolved in D_2O after irradiation showed that no or negligible amounts of HD were formed.

DISCUSSION

Several mechanisms have been discussed for the radiation induced hydrogen transfer from exchangeable to non-exchangeable sites.[2] Among these are reactions involving hydrogen atoms and molecular hydrogen. The present data show that no more than a very small part of the radiation induced hydrogen gas is derived from the exchangeable hydrogens in the carbohydrates studied. This infers that neither

hydrogen gas nor such hydrogen atoms which are precursors to hydrogen gas play a significant role in the radiation induced hydrogen transfer from exchangeable to non-exchangeable positions.

Exchange reactions of secondary radicals, as observed in amino acids,[1] are not likely mechanisms, as irradiated polycrystalline carbohydrates,[6] and single crystals of sucrose [7] and trehalose [8] deuterated in exchangeable positions show the same ESR spectra as non-labeled samples.

The radiation induced transfer of hydrogen to non-exchangeable sites, as measured by tritium incorporation, is, except for trehalose dihydrate, linearly dependent on the dose over a very large dose range. In the same dose range, formation of stable, secondary free radicals occurs with decreasing efficiency with increasing doses; this also occurs at doses below 2×10^{19} eV/g for sucrose.[9] It is thus unlikely that removal of secondary radicals is related to the tritium incorporation. The fact that a large part of the tritium incorporated into non-exchangeable positions is present in the original carbohydrate favours an interpretation that the transfer occurs at an early stage following the absorption of the radiation.

Further studies, particularly to investigate into which position(s) the exchangeable hydrogens are incorporated, may give additional insight into the transfer mechanism and may also lead to methods to synthesize labeled carbohydrates.

Acknowledgement. This investigation has been supported by grants from the Swedish Atomic Research Council.

Alkyl Cyanates. XVI. Reaction of Alkyl Cyanates with Grignard Reagents. Kinetic Studies

ARNE HOLM,[a] TORKIL HOLM[b] and ERIK HUGE-JENSEN[a]

[a]Chemical Laboratory II (General and Organic Chemistry), The H. C. Ørsted Institute, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark and [b]Department of Organic Chemistry, The Technical University, DK-2800 Lyngby, Denmark

A kinetic investigation of the reactions of alkyl cyanates with Grignard reagents* and dibutylmagnesium in diethyl ether has been carried out by means of thermographic measurements. In the presence of excess organomagnesium reagent first order plots are obtained for reaction of the cyanate, but the kinetic order in organomagnesium reagent is less than one and decreasing at high concentrations. In the presence of excess cyanate the same kinetics are observed, the order in organomagnesium reagent being one and the order in cyanate decreasing at high concentrations, which corresponds to a mechanism involving complex formation between the reactants. Addition of $MgBr_2$ to the organomagnesium reagent depresses the observed first-order rate constants. The depression is consistent with both R_2Mg and RMgX contributing to the reactions.

The reactivity of aromatic Grignard reagents in reactions with alkyl cyanates is higher than the reactivity of dibutylmagnesium, which again is higher than the reactivities of aliphatic Grignard reagents. The Hammett ϱ-value for the reactions of isobutyl cyanate with *p*-substituted "phenylmagnesium bromides" is found to be *ca.* -1.5. On the basis of the kinetic data and the ϱ-value the reactions are best described as involving a concerted four-center mechanism in the rate-determining step.

In another paper we have reported on the product formation in the reaction between alkyl or aryl cyanates and Grignard reagents,[1] and now we wish to report on a kinetic investigation of the reaction between alkyl cyanates and Grignard reagents.

The present work has been carried out with the aim of obtaining deeper insight into the reactions between alkyl cyanates and Grignard reagents which lead to the formation of alkoxymagnesium halides and nitriles (I):

$$R^1OCN + R^2MgX \longrightarrow R^1OMgX + R^2CN \qquad (I)$$

A thermographic method was used for the kinetic measurements.[2] This technique allowed reproducible rate measurements within ± 5 % when the limiting reagent was present in a concentration of 0.01 M. At lower concentrations the accuracy of measurements becomes unsatisfactory. At higher concentrations the error of the k_{obs}-values becomes too high due to the temperature dependence. All measurements were carried out with one of the reactants in excess.

Fig. 1 shows three examples of plots of $\ln (\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T)$* *versus* the reaction time, *t*, for the reaction of ethyl cyanate with „butylmagnesium bromide". From all kinetic experiments linear plots were obtained up to at least 70 % reaction of the limiting reagent. The linearity of the plots means that the reaction order in ethyl cyanate is one. The pseudo first order rate constants (k_{obs}) are obtained from the slopes of the lines. In Fig. 2 is shown how the pseudo first order rate constants vary with the initial concentrations of "butylmagnesium

* The Grignard reagents are in the following symbolized as "RMgX".

* $\text{Ln}\, a/(a-x) = \ln (\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T) = k_{obs} \times t$, where ΔT_∞ is the total rise in temperature, ΔT_1 is the rise in temperature after 2 ms and ΔT is the rise in temperature at the time *t*. ΔT_1 is a correction for heat evolved from reaction between traces of impurities (water) and the Grignard reagent and for heat of mixing.

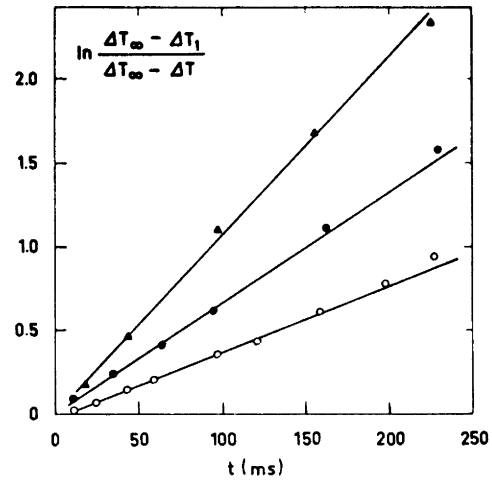

Fig. 1. Plots of ln $(\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T)$ *versus* the reaction time, t, for the reaction of ethyl cyanate with excess "butylmagnesium bromide" in diethyl ether at 25 °C ($c^0_{C_2H_5OCN}$ = 0.010 M; c^0"C_4H_9MgBr" = 0.100 M (○), 0.200 M (●) and 0.600 M (▲)).

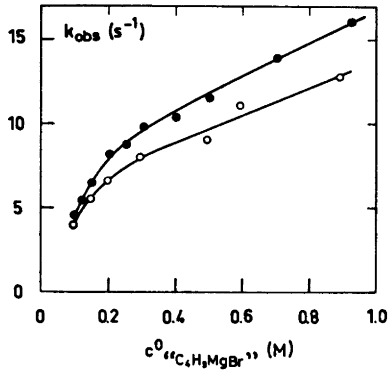

Fig. 2. Plots of the pseudo first order rate constants *versus* the initial concentrations of "butylmagnesium bromide" for reactions of this Grignard reagent with ethyl cyanate (○) and isobutyl cyanate (●) in diethyl ether at 25 °C (c^0_{ROCN} = 0.010 M).

bromide" for the reactions of this Grignard reagent with ethyl and isobutyl cyanate. Because of the curvature of the plots shown it is concluded that the reaction order in Grignard reagent is less than one.

Kinetic experiments with excess isobutyl cyanate and 0.010 M "butylmagnesium bromide" likewise give linear pseudo first order

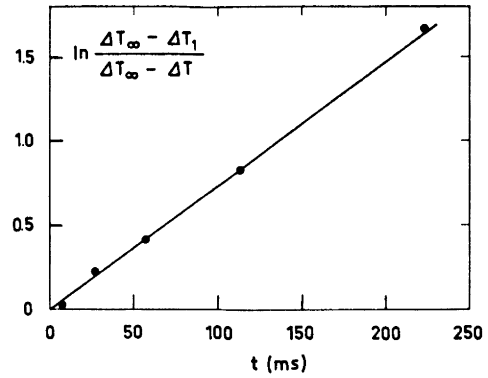

Fig. 3. Plot of ln $(\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T)$ *versus* the reaction time, t, for the reaction of 0.138 M isobutyl cyanate with 0.010 M "butylmagnesium bromide" in diethyl ether at 25 °C.

plots (Fig. 3), and a plot of the pseudo first order rate constant *versus* the initial concentration of isobutyl cyanate is very similar to the plot obtained with excess "butylmagnesium bromide" (Fig. 4). The deviation appears roughly to be within the limits of the accuracy of measurements of this method.

Kinetic measurements on the reaction of isobutyl cyanate with dibutylmagnesium in diethyl ether have been carried out. The pseudo first order plot is linear up to 80 % reaction of isobutyl cyanate (Fig. 5). From the slope of the

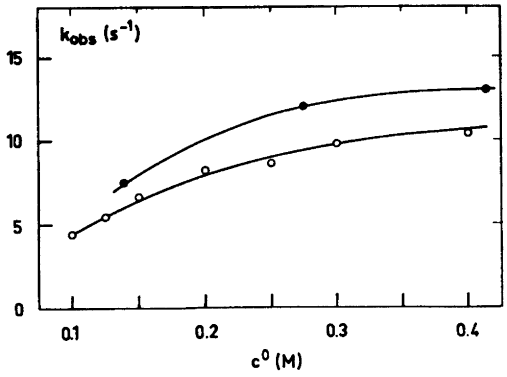

Fig. 4. Plots of the pseudo first order rate constant *versus* the initial concentrations of the reactant in excess for the reaction of isobutyl cyanate with "butylmagnesium bromide" in diethyl ether at 25 °C (○: 0.010 M i-C_4H_9OCN and excess "C_4H_9MgBr"; ●: 0.010 M "C_4H_9MgBr" and excess i-C_4H_9OCN).

Table 1. The influence of the magnesium bromide concentration on the pseudo first order rate constant for the reaction of isobutyl cyanate with "butylmagnesium bromide" in diethyl ether at 25 °C.

$c^0_{i\text{-}C_4H_9OCN}$ M	$c^0_{"C_4H_9MgBr"}$ M	$c^0_{MgBr_2}$ M	k_{obs} (s^{-1})
0.010	0.138	0.003	6.8
0.010	0.138	0.069	4.0
0.010	0.138	0.138	1.5

line a pseudo first order rate constant of 47 s^{-1} is obtained for $c^0_{i\text{-}C_4H_9OCN} = 0.010$ M and $c^0_{(C_4H_9)_2Mg} = 0.100$ M.

When a large amount of magnesium bromide etherate is added to "butylmagnesium bromide" the pseudo first order rate constant is decreased, but the value of the rate constant is still considerable (Table 1). Therefore it is concluded that both butylmagnesium bromide and dibutylmagnesium present according to the Schlenk equilibrium [3] (II) react with the cyanate

$$2\ C_4H_9MgBr \overset{K_s}{\rightleftharpoons} (C_4H_9)_2Mg + MgBr_2 \qquad (II)$$

when "butylmagnesium bromide" reacts with isobutyl cyanate. A decrease of k_{obs} on addition of magnesium bromide is expected because of a lowered content of the most reactive species, dibutylmagnesium. However, it cannot be excluded that magnesium bromide also forms a complex with the cyanate because the pseudo first order rate constant is decreased more than expected.* However, we have not been able to show the presence of a complex between a cyanate and magnesium bromide. The only products obtained when the reactants are mixed are magnesium cyanate and alkyl bromide. This result is due to nucleophilic attack of the halide ion on the cyanate, a wellknown process,[5,6] but of course primary complex formation is still possible.

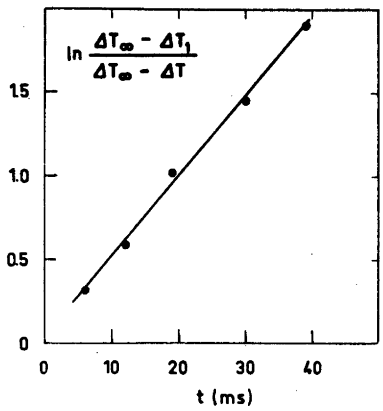

Fig. 5. Plot of ln $(\Delta T_\infty - \Delta T_1)/(\Delta T_\infty - \Delta T)$ *versus* the reaction time, t, for the reaction of isobutyl cyanate with excess dibutylmagnesium in diethyl ether at 25 °C ($c^0_{i\text{-}C_4H_9OCN} = 0.010$ M and $c^0_{(C_4H_9)_2Mg} = 0.100$ M).

As shown above (Figs. 2 and 4) the pseudo first order rate constant is not linearly dependent on the initial concentration of the reactant in excess, regardless of whether it is the Grignard reagent or the alkyl cyanate. We therefore conclude that complexes between the cyanate

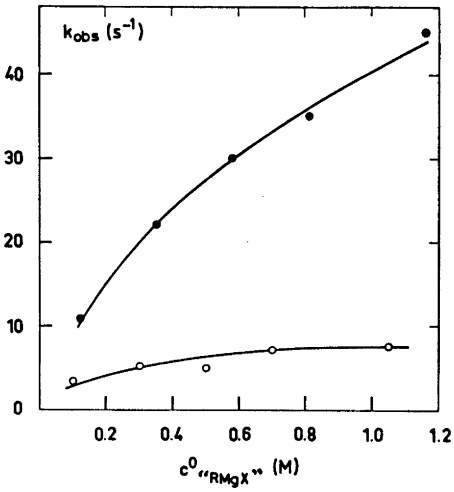

Fig. 6. Plot of the pseudo 1st order rate constant *versus* the initial concentration of the Grignard reagent for the reactions of isobutyl cyanate with "methylmagnesium bromide" (○) and "ethylmagnesium bromide" (●) in diethyl ether at 25 °C ($c^0_{i\text{-}C_4H_9OCN} = 0.010$ M).

* The contribution to the k_{obs}-value from the reaction between isobutyl cyanate and dibutylmagnesium present in 0.100 M "butylmagnesium bromide" can be calculated to be *ca.* 1.5 s^{-1}. The concentration of dibutylmagnesium in 0.100 M "butylmagnesium bromide" is *ca.* 0.0032 M for $K_s = 1 \times 10^{-3}$ (Ref. 4). The calculation of the contribution to the k_{obs}-value is made with the assumption that $k_{obs}(R_2Mg)$ is linearly dependent on the initial concentration of dibutylmagnesium in the interval 0–0.1 M; thus $k_{obs} = 47 \times 0.0032/0.100 = 1.5$ s^{-1}.

Table 2. Pseudo first order rate constants for the reaction of 0.010 M isobutyl cyanate with Grignard reagents and dibutylmagnesium in diethyl ether at 25°C ($c^0_{\text{"RMgX"}} = c^0_{R_2Mg} = 0.100$ M).

"RMgX" or R_2Mg	k_{obs} (s^{-1})
"*p*-$CH_3C_6H_4MgBr$"	619
"C_6H_5MgBr"	244
"*p*-ClC_6H_4MgBr"	85
$(C_4H_9)_2Mg$	47
"C_2H_5MgBr"	10
"C_4H_9MgBr"	4.4
"CH_3MgBr"	3.5
"*t*-C_4H_9MgCl"	< 3.5

and the magnesium species in the Grignard reagent have been formed.

In Fig. 6 are shown plots of the pseudo first order rate constant *versus* the initial concentration of the Grignard reagent for the reactions of isobutyl cyanate with "methylmagnesium bromide" and "ethylmagnesium bromide". The pseudo first order rate constant is not linearly dependent on the initial concentration of the Grignard reagent in these cases either. Therefore the mechanism of the reactions of isobutyl cyanate with these Grignard reagents is assumed to be the same as for the reaction with "butylmagnesium bromide".

Alkyl cyanates are found to react faster with aromatic Grignard reagents than with dibutylmagnesium and with aliphatic Grignard reagents (Table 2). An electron-donating substituent (CH_3) in the *p*-position of a "phenylmagnesium bromide" increases the reactivity, and on *p*-substitution with an electron-attracting group (Cl) the reactivity decreases (Table 2). From the k_{obs}-values and the Hammett *sigma* values a reaction constant of *ca.* −1.5 is calculated signifying electron deficiency at the magnesium carbon atom in the transition state. This effect of substitution is only slightly more pronounced than what we have found in reactions of phenyl cyanate with *p*-substituted "phenylmagnesium bromides". In this case the constant is *ca.* −0.8.[7]

A free radical mechanism for the reaction between alkyl cyanates and Grignard reagents can be excluded for the same reasons discussed in another paper [7] concerning the reaction between aryl cyanates and Grignard reagents.

Since complex formation takes place in these reactions two alternatives are possible which are kinetically indistinguishable. *1.* A complex is formed in equilibrium with the starting materials. Rate-determining decomposition of the complex leads to products. *2.* The complex formed is in equilibrium with the reactants but it does not lead to products but represents a "blind alley".

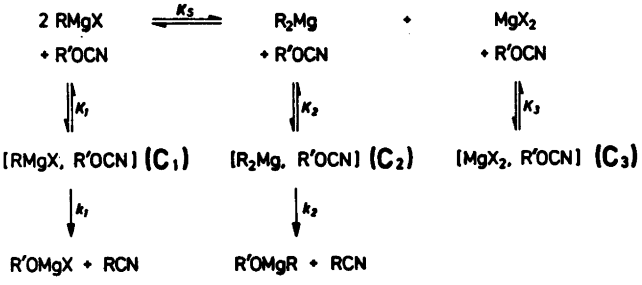
From the rate expression $v_{obs} = k_{obs} \times [R'OCN]_{total} = k_{obs}([R'OCN] + [C_1] + [C_2] + [C_3])$ together with $v = k_1[C_1] + k_2[C_2]$ and $v = k_1 \times [RMgX][R'OCN] + k_2[R_2Mg][R'OCN]$, respectively, for Scheme 1 and 2 the following equation is derived:

$$\frac{1}{k_{obs}} = \frac{1}{k'} \times \frac{1}{[RMgX]} + \frac{k''}{k'} \qquad (1)$$

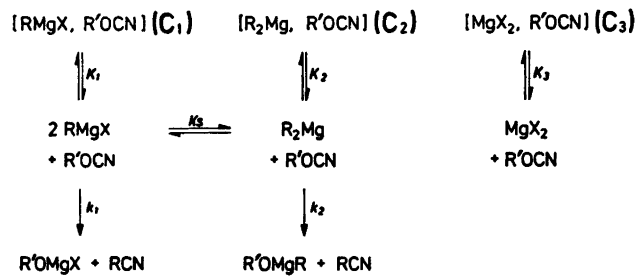
In case *1*, $k' = k_1K_1 + k_2K_2K_s^{\frac{1}{2}}$ and $k'' = K_1 + (K_2 + K_3)K_s^{\frac{1}{2}}$. In case *2*, $k' = k_1 + k_2K_s^{\frac{1}{2}}$ and $k'' = K_1 + (K_2 + K_3)K_s^{\frac{1}{2}}$.

As seen from Fig. 7 good agreement with eqn. (1) is obtained when $1/k_{obs}$ is plotted against 1/[RMgX], supporting the assumption of reversible complex formation.

The reactions between alkyl cyanates and Grignard reagents leading to nitriles and alco-



Scheme 1.



Scheme 2.

holates are strongly exothermic whereas complex formation between MgX_2 and cyanate does not give rise to any noticeable evolution of heat. According to the Hammond principle [8] the transition states leading to products should therefore be more similar to the reactants than to the products and likewise more similar to the complexes. Two transition states T_1 and T_2 in accordance with this formulation leading to the observed products have been visualized in Scheme 3. It is clearly not possible to distinguish between those two alternatives from the kinetics or from the final products. However, the presence of an intermediate such as the imido-ester salt shown in Scheme 3 certainly would point to the likelihood of T_2. Despite numerous

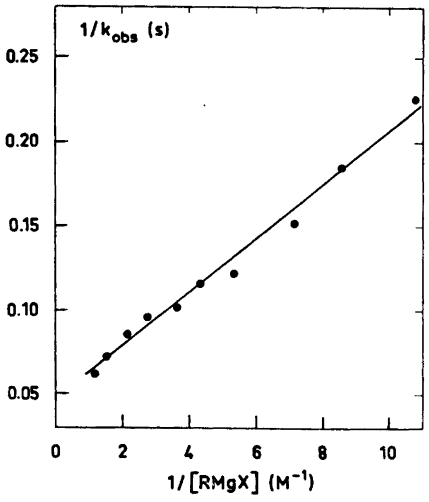

Fig. 7. Plot of $1/k_{obs}$ *versus* 1/[RMgX] for the reaction of isobutyl cyanate with excess "butylmagnesium bromide" in diethyl ether at 25 °C ($c^0_{i\text{-}C_4H_9OCN} = 0.010$ M).

attempts [1] it has, however, not been possible to obtain any evidence for this substance and no distinction between T_1 and T_2 can thus be made.

EXPERIMENTAL

All Grignard reagents were prepared in diethyl ether distilled from lithium aluminium hydride directly into the glass apparatus. This solvent was used in all experiments. The magnesium used (monosublimed, Dow Chemical Corp.) was washed with anhydrous diethyl ether. Every precaution was taken against oxygen and moisture. The halides used in the preparation of the Grignard reagents were distilled or recrystallized and their purity checked gas-chromatographically. Grignard reagents were always prepared with an excess of magnesium. The molarity of the Grignard reagents was determined by titration with standard acid and the content of halogen by titration with standard silver nitrate. The content of halogen was never more than 4 % higher than the content of Grignard reagent.

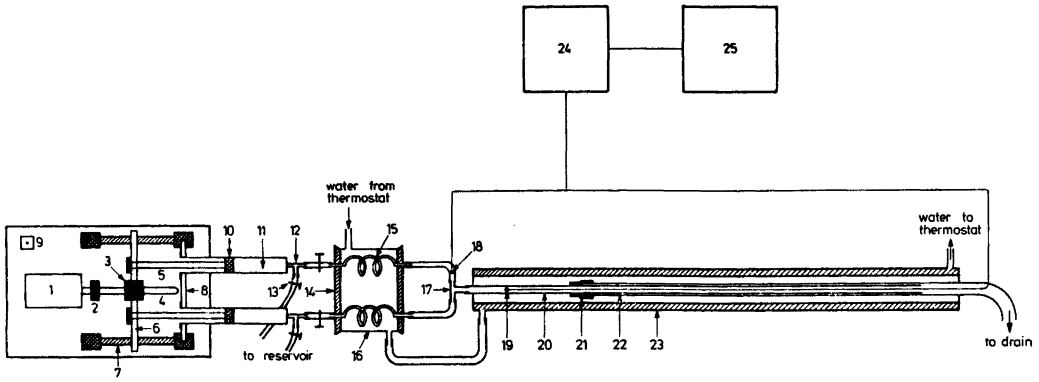

Fig. 8. Schematic drawing of the apparatus used for the kinetic measurements.

The different concentrations were obtained by dilution of *ca.* 2 M standard solutions.

The alkyl cyanates were prepared from 5-alkoxy-1,2,3,4-thiatriazoles.[9,10] The purity of the cyanates was checked by infrared and nuclear magnetic resonance spectroscopy and elemental analysis.

Dibutylmagnesium was prepared from "butylmagnesium chloride" and butyllithium.[11]

Magnesium bromide etherate was prepared from 1,2-dibromoethane and magnesium.[12]

Studies on a Soluble Dipeptidase from Pig Intestinal Mucosa. Structural Properties

OVE NORÉN and HANS SJÖSTRÖM

Department of Biochemistry C, University of Copenhagen, DK-2200 Copenhagen N, Denmark

A soluble dipeptidase (glycyl-L-leucine dipeptidase, EC 3.4.13.2) purified from pig intestinal mucosa was investigated for some of its structural properties. A molecular weight of 104 000 was determined under native conditions by gelfiltration but under denaturing conditions the molecular weight was 52 000 as determined by gelfiltration and polyacrylamide gel electrophoresis. These findings might suggest the native dipeptidase to be composed of two polypeptide chains of uniform molecular weight. The two polypeptide chains may be identical as only one N-terminal amino acid, proline, was found. The amino acid composition and the molar extinction coefficient (14.6×10^4 M^{-1} cm^{-1}) were determined. The soluble dipeptidase contained carbohydrate (about 0.3 %). The number of free SH-groups of the soluble dipeptidase was found to be about 5 when determined with *p*-hydroxymercuribenzoate but was higher (8 – 17) when determined with Ellman's reagent.

Little is known about the characteristics of the exopeptidases of the small intestine, a fact which is in contrast to the information available for the proteolytic enzymes of pancreas and ventricle. The purification and the specificity of a soluble dipeptidase (glycyl-L-leucine dipeptidase, EC 3.4.13.2) from the pig intestinal mucosa have earlier been reported.[1] The kinetics of the enzyme and the influence of some common enzyme inhibitors on its activity have been described.[2] In this paper the molecular weight and the amino acid composition are reported together with some other data on its structural properties.

MATERIALS AND METHODS

Enzyme. The soluble dipeptidase was prepared and tested for homogeneity as described earlier.[1] The enzyme preparation used had a specific activity of 1400 units [2] of activity per mg protein. It was stored (– 20°C) in 0.07 M sodium phosphate buffer containing 0.2 M NaCl, 4 mM 2-mercaptoethanol, and 12.5 % (w/v) glycerol and had a concentration of 0.4 mg per ml.

Chemicals. Bovine serum albumin was bought from Armour Pharmaceuphtical Co., Ltd., Eastbourne, England. Dansyl chloride, dansyl amino acids, acrylamide and *N,N'*-methylenebisacrylamide were purchased from BDH Chemicals Ltd., Poole, England. ε-Dansyl-lysine was a gift from Dr. Johan Stenflo, Malmö General Hospital, Malmö, Sweden. Yeast alcohol dehydrogenase was obtained from Calbiochem, San Diego, U.S.A. and bovine chymotrypsinogen from Mann Res. Labs., New York, U.S.A. HCl (suprapure), HBr (suprapure), 5,5'-dithiobis(2-nitrobenzoic acid) (Ellman's reagent) and Schiff's reagent were manufactured by Merck, Darmstadt, Germany. Blue Dextran 2000, Sephadex G-200, Sephadex G-25 Fine, and Sepharose 6B were bought from Pharmacia, Uppsala, Sweden, and sodium dodecyl sulfate (sequanal grade) from Pierce Chemical Co., Illinois, U.S.A. *E. coli* alkaline phosphatase (type III), sperm whale myoglobin, egg albumin, sodium *p*-hydroxymercuribenzoate (PHMB), milk xanthine oxidase (grade II), human transferrin, *nor*-leucine, cysteic acid, and methionine sulfone were bought from Sigma Chem. Co., St. Louis, U.S.A. Nitrogen (oxygen free) was a product of Norsk Hydro A/S Oslo, Norway. Other chemicals used were of analytical grade and the water used was distilled and de-ionized.

Determination of molecular weight

Native conditions. For the estimation of the molecular weight of the soluble dipeptidase under native conditions the method of Andrews [3] was used. A Sephadex G-200 column was loaded with a sample containing xanthine oxidase, alcohol dehydrogenase, alkaline phos-

phatase, egg albumin, and the soluble dipeptidase. The sample applied was 12.5 % (w/v) in respect to glycerol and was then applied to the column underneath the eluent. Fractions of about 2.5 ml were collected and their precise volumes determined by weight. The concentrations of alcohol dehydrogenase and egg albumin in the fractions were analyzed by measuring the absorbance at 230 nm (PMQ II Spectrophotometer, Zeiss, Oberkochen, Germany). The concentration of dipeptidase (substrate: glycyl-L-leucine), alkaline phosphatase (substrate: *p*-nitrophenyl phosphate) and xanthine oxidase (substrate: hypoxanthine) in the fractions were measured using established methods.[4-6]

Denaturing conditions. The molecular weight of the soluble dipeptidase was also estimated under denaturing conditions using polyacrylamide gel electrophoresis and gelfiltration in dodecyl sulfate. Before the experiments the soluble dipeptidase and the molecular weight standards (serum albumin, egg albumin, chymotrypsinogen, myoglobin) were treated in 1 % (w/v) dodecyl sulfate and 1 % (v/v) 2-mercaptoethanol for 2 min at 100 °C.[7] In some experiments the soluble dipeptidase was pretreated with dodecyl sulfate only under the same conditions.

The polyacrylamide gel electrophoresis in dodecyl sulfate was performed essentially as described by Weber *et al.*[7] using a total monomer concentration in the gel of 10 % (w/v). The *N,N'*-methylenebisacrylamide was 1 % (w/v) of the total monomer concentration. About 20 μg of each protein were applied and the gels were stained with Coomassie Brilliant Blue. Three parallel gels were run in each experiment, one containing the molecular weight standards, a second the soluble dipeptidase, and a third the molecular weight standards and the soluble dipeptidase together.

Gelfiltration in dodecyl sulfate [8] was performed using Sepharose 6B. The column was eluted using a peristaltic pump (Varioperpex, LKB Produkter AB, Bromma, Sweden). Fractions of equal volume were collected each 15 min and their absorbance measured at 230 nm. The void volume in every experiment was determined by Blue Dextran. Before and after the experiments with the enzyme the column was calibrated with the molecular weight standards (100 μg of each applied).

Determination of amino acid composition and E(1 %, 1 cm) value

A solution of the dipeptidase (1 ml) was thoroughly dialyzed, (dialysis tubes, Visking Co., Chicago, U.S.A.) against 3 × 500 ml 0.05 M *N*-ethylmorpholine-acetate buffer (pH 8.5). The absorbance at 280 nm of the dialyzed sample was measured with the used dialysis buffer as a reference and the sample was then transferred to three different ampoules (300 μl in each). After lyophilization of the samples, 1 ml 6 M HCl and a crystal of phenol were added.[9] The ampoules were flushed with nitrogen and after a thorough evacuation [10] they were closed and hydrolyzed for different times (24, 48, 72 h) at 110 °C. After performed hydrolysis the HCl was removed, using a rotoevaporator (40 °C). The amino acid analysis was performed on an amino acid analyzer (Multichrom, Model 4255, Beckman, Munich, Germany) using the dual column system.[10]

The E(1 %, 1 cm) value was calculated from the absorbance and the amino acid analysis data using the finally calculated amino acid composition.

The amount of the sulfur containing amino acids of the soluble dipeptidase was determined using the oxidation with performic acid.[11] A solution of dipeptidase solution (300 μl) was dialyzed as described above. The sample was lyophilized, dissolved in 100 μl formic acid and 2 ml performic acid was added. As no precipitates were observed during the oxidation the process was interrupted after 4 h by 300 μl HBr (47 %) and then 15 ml of water was added and the sample was lyophilized. The hydrolysis (24 h) was performed as described above. The amount of cysteic acid and methionine sulfone formed was determined using the amino acid analyzer and their content was related to the leucine content. The yield of cystine (20 nmol) in the procedure was determined in separate experiments.

The tryptophan content was determined spectrophotometrically using the method of Edelhoch.[12] A dipeptidase solution (300 μl) was first dialyzed against 2 l 0.02 M sodium phosphate buffer (pH 6.5) and then against 200 ml 6 M guanidine chloride (Norit treated) in the same buffer. The absorbance of the sample was measured using the last dialysis buffer as a reference and afterwards given norleucine (50 nmol). It was then hydrolyzed (24 h) and analyzed for its amino acid content. The protein content was calculated both from the absorbance data and from the amino acid analysis.

Determination of N-terminal amino acid

The end-group analysis of the soluble dipeptidase was performed using the dansyl chloride method.[13] Prior to the reaction with dansyl chloride, the dipeptidase solution (300 μl) was made 1 % (w/v) in respect to dodecyl sulfate and 2-mercaptoethanol according to Weiner *et al.*[14] The dipeptidase solution was then dialyzed overnight against a 0.2 M *N*-ethylmorpholine-acetate buffer (pH 8.5) containing 0.16 % dodecyl sulfate and lyophilized. The lyophilized sample was dissolved in water and *N*-ethylmorpholine (50 μl of each) and then 75 μl of a dansyl chloride solution (25 mg/ml dimethylformamide) was added. The reaction

was interrupted after 3 h by 500 μl ice-cold trichloroacetic acid (20 % w/v) added drop by drop. The formed precipitate was spun down and washed four times with 500 μl 1 M HCl each time to get rid of the dansylic acid. To the dried precipitate 50 μl 6 M HCl was added and the sample was hydrolyzed for 16 h. After performed hydrolysis the HCl was removed in a rotoevaporator. The sample was then dissolved in 10 μl acetone-acetic acid (3:2, by vol.) and subjected to chromatography on polyamide sheets (Cheng Chin Trading Co., Taipei, Taiwan). The chromatographic systems used were water-90 % formic acid (200:3, by vol.) and benzene-acetic acid (9:1, by vol.).[15] In order to separate dansyl-arginine, dansyl-histidine, and ε-dansyl-lysine the additional solvent systems ethyl acetate-methanol-acetic acid (20:1:1, by vol.) and 0.05 M trisodium phosphate-ethanol (3:1, by vol.)[16] were run.

Determination of number of free SH-groups

The number of free SH-groups of the soluble dipeptidase was determined using Ellman's reagent [17] and PHMB.[18]

Prior to the reaction with Ellman's reagent 2-mercaptoethanol was removed from the dipeptidase solution using either dialysis against 3 × 1 l 0.05 M Tris-HCl buffer (pH 8.1), containing 10 mM EDTA or gelfiltration on a Sephadex G-25 column (0.9 cm × 11.7 cm) equilibrated in the same buffer. The absorbance of the sample at 280 nm was measured (0.15–0.30). To 300 μl of the sample were then added 10 % (w/v) dodecyl sulphate solution (15 μl) and Ellman's reagent (25 μl, 5 mg/ml methanol). The course of the reaction was followed by measuring the absorbance at 412 nm during a 30 min period and the concentration of free SH-groups was calculated using a molar extinction coefficient of 13 600 M^{-1} cm^{-1} for the 3-carboxylato-4-nitro-thiophenolate ion.[17]

Before the reaction with PHMB the dipeptidase solution (150 μl) was dialyzed overnight against 0.1 M sodium phosphate buffer (pH 7.5). The solution was measured for its absorbance at 280 nm, made 0.5 % (w/v) in respect to dodecyl sulfate and then added 75 nmol PHMB. The reaction was allowed to proceed overnight at room temperature. The mercury content of the dipeptidase was measured by a method developed in our laboratory using an atomic absorption spectrophotometer (Model 103, Perkin-Elmer, Norwalk, Connecticut, U.S.A.), equipped with a flameless mercury analysis system (Carlsen, J. B. *Anal. Biochem. In press*).

Determination of carbohydrate content

The carbohydrate content of the soluble dipeptidase was analyzed by polyacrylamide gel electrophoresis in combination with Schiff's reagent.[19] About 75 μg of the soluble dipeptidase was run on two parallel gels each. After completion of the electrophoresis, one gel was stained with Coomassie Brilliant Blue and the other one with Schiff's reagent. A dilution series of transferrin was run in parallel in order to get a semiquantitative estimation of the carbohydrate content of the dipeptidase.

RESULTS AND DISCUSSION

The molecular weight of the soluble dipeptidase was estimated to be 104 000 under native conditions (Fig. 1), assuming it to be globular and of the same grade of hydration as the molecular weight standards. In comparison to earlier reported molecular weight data on dipeptidases this value is close to that found for the purified intestinal monkey dipeptidase [20] but somewhat higher than observed for the mouse ascites tumor dipeptidase [21] and much higher than that reported for the renal dipeptidase.[22]

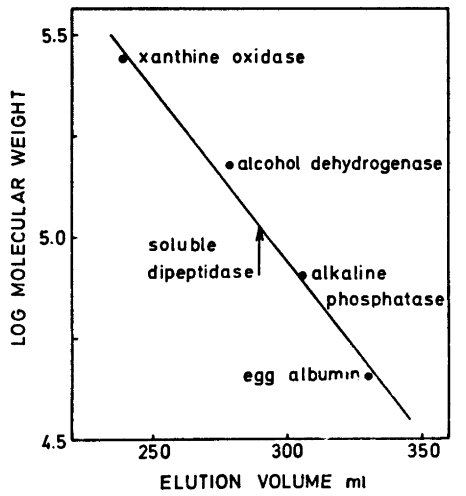

Fig. 1. Determination of the molecular weight of the soluble dipeptidase on Sephadex G-200. The column (2.5 cm × 93 cm) was equilibrated in and eluted with 0.1 M sodium phosphate buffer (pH 7.0), containing 4 mM 2-mercaptoethanol, at a constant flow rate of 5 ml/h. The sample (2.7 ml) applied contained 150 μg soluble dipeptidase.

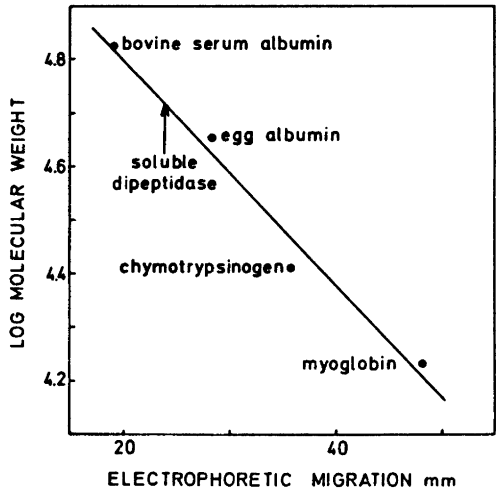

Fig. 2. Determination of the molecular weight of the soluble dipeptidase under denaturing conditions using polyacrylamide gel electrophoresis. The experiment was performed applying 8 mA per gel for 4 h.

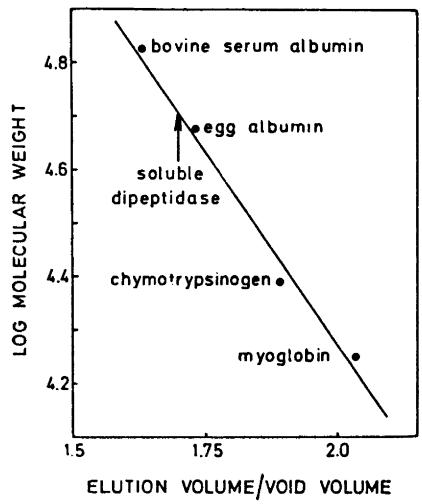

Fig. 3. Determination of the molecular weight of the soluble dipeptidase under denaturing conditions using gelfiltration on Sepharose 6B (room temperature). The column (0.9 cm × 57 cm) was equilibrated in and eluted with 0.07 M sodium phosphate buffer (pH 7.2), containing 1 % dodecyl sulfate, at a constant flow rate of 1.75 ml/h.

The molecular weight estimated for the reduced and dodecyl sulfate treated enzyme when determined by gel electrophoresis was 52 000 (Fig. 2). Irrespective of the enzyme being reduced and dodecyl sulfate treated or only dodecyl sulfate treated, the gel electrophoresis resulted in only one dominating band with a constant position, when the soluble dipeptidase was run alone. Likewise one peak corresponding to a molecular weight of 51 000 (Fig. 3) was obtained in the experiments on Sepharose 6B, irrespective of which of the two pre-treatments that had been used.

These molecular weight data may suggest the soluble dipeptidase to be composed of two polypeptide chains with a uniform molecular weight and associated with non-covalent bonds. Since N-terminal amino acid analysis revealed proline only, the two polypeptide chains might be identical.

The amino acid composition of the soluble dipeptidase is given in Table 1. Figures are given for mol % and for the number of amino acids per molecule of enzyme using a molecular weight of 104 000. The yield of cystine in the oxidation experiments with performic acid was determined to 83 % and this figure was used in the calculations. The cysteic acid and methionine sulfone content obtained in the amino acid analysis was related to the other amino acids by means of the leucine content. The figure for the tryptophan content was obtained by relating it to the leucine content and to the absorbance at 280 nm. In both cases a value of 18.4 mol of tryptophan per mol of dipeptidase was obtained.

A value of 14.0 for E(1 %, 1 cm) was found. Using a molecular weight of 104 000 the molar extinction coefficient was calculated to be 14.6×10^4 M^{-1} cm^{-1}.

The Ellman reaction with the soluble dipeptidase was rapid and complete within 10 min but the results obtained varied. When the 2-mercaptoethanol was removed by gelfiltration the reaction gave 12 – 17 mol SH-groups per mol dipeptidase while removal of the 2-mercaptoethanol by dialysis resulted in 8 – 11 mol SH-groups per mol dipeptidase. When the dipeptidase was analyzed with the PHMB-reagent only 4.8 – 5.1 mol SH-groups per mol enzyme were found showing that this reagent is less reactive to the soluble dipeptidase than Ellman's reagent. The number of free SH-groups obtained indicates that the soluble dipeptidase contains only few disulfide bonds, if any.

Table 1. Amino acid composition of the soluble dipeptidase. The values of the stable and quantitatively liberated amino acids are given as the mean of the results from the three different hydrolysis times with the coefficient of variation. The number of residues per molecule dipeptidase is calculated on the basis of a molecular weight of 104 000.

Amino acid	Mol %	Coefficient of variation (%)	Number of residues per molecule dipeptidase
Lys	7.05	3.9	66
His	2.56	5.3	24
Arg	3.76	3.5	35
Asx	10.11	0.77	94
Thr [a]	4.32	–	40
Ser [a]	6.06	–	57
Glx	11.03	1.3	103
Pro	4.84	2.2	45

Ile [c]	5.47	–	51
Leu	9.40	1.4	88
Tyr [a]	3.60	–	34
Phe	3.55	5.6	33
Trp [d]	1.97	–	18
Total number of residues			934

[a] Extrapolated to zero time by assuming destruction according to a first order reaction.[10] [b] Values obtained after performic acid oxidation.[11] [c] Values obtained from 72 h hydrolysis. [d] Determined spectrophotometrically.[12]

By comparing the intensity of the color obtained with the Schiff reagent on the band of the soluble dipeptidase with the intensity of the bands obtained for transferrin, the carbohydrate content of the enzyme was estimated to be 0.3 %. Recently, the carbohydrate content of another pig intestinal peptidase has also been reported.[23]

A comparison with the prolidase recently reported purified from pig intestinal mucosa [24] and now investigated for its structural properties [25] shows the same molecular weight and subunit structure. It has a similar carbohydrate content. There are, however, some differences in the amino acid composition of the two enzymes. The content of tyrosine and tryptophan of the soluble dipeptidase is higher than that found for the prolidase. This finding is consistent with the differences found in the $E(1\ \%, 1\ \text{cm})$ values for the two enzymes. The two enzymes also display differences in their covalent structure, which may explain the differences in stability of the enzymes and in their reactivity to Ellman's reagent.

Acknowledgements. We thank Professor Lars Josefsson for his valuable criticism during the performance of this work. We are also indebted to Mrs. D. Anthonsen, Mr. M. Kjaer-Andersen and Miss A. Mørch for their skilful technical assistance.

The work was supported by grants from the Danish Natural Science Research Council (Project No. 511).

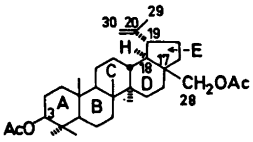
Triterpenes. The Synthesis of Novel 18βH,19β-Substituted Lupane Derivatives

ELIAS SUOKAS and TAPIO HASE

Department of Chemistry, Helsinki University of Technology, SF-02150 Otaniemi, Finland

Catalytic hydrogenation of the conjugated diene (II), obtained from betulin diacetate (I) by mercuric acetate dehydrogenation, has been shown to proceed *via* 1,2- and 1,4-addition to compounds (IVb) and (VIIa). The latter is capable of further hydrogenation to (VIb). Acid catalysed isomerisation of (VIIIa) gives a novel isomer (XII) of betulin diacetate (I).

Betulin diacetate (I) gives on dehydrogenation with mercuric acetate the conjugated diene (II).[1,2] Analogously [3] to the corresponding lupane derivative (III), the hydrogenation of (II) with PtO_2-catalyst gives a mixture of the dihydro diacetate (IVb) with an endo double bond in ring E, and a tetrahydro diacetate of unknown stereochemistry at C-18 and C-19, differing from dihydrobetulin diacetate (V). For this compound we now present formula (VIb), which follows from the results outlined below.



I

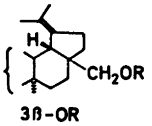
XVII R^1 = -Ac, R^2 = $-CH_3$



3ß-OR

VIIa R = -Ac

VIIb R = -H

The hydrogenation of diene (II) in the presence of Pd/$BaSO_4$-catalyst gives quantitatively the 1,4-addition product with the double bond exo to ring E. The stereochemistry at C-18 is determined from the reactions presented below and is found to be 18β H as in formula (VIIa). Ozonisation of the exo double bond in compound (VIIa) and reduction of the ozonide with $(MeO)_3P$ under neutral conditions gives a five membered ring ketone, which has a large positive value of molecular ellipticity $[\theta]_{313}$ +6270° indicating [4] a 18βH-structure for the ketone (VIIIa). The m.p., $[\theta]$, and $[\alpha]_D$ are in agreement with values reported for the compound (VIIIa).[5-7]

Acid catalysed isomerisation of the exo double bond in the diacetate (VIIa) gives another diacetate having an isopropenyl side chain and being different from betulin diacetate (I). Ozonolysis of the terminal methylene group gives a 19-acetyl derivative, which does not epimerise even under alkaline hydrolysis. It is known [5] that the 18αH,19αAc-isomer (IX) [5,8] is stable as such and this side chain will be base epimerised into the unknown 18αH,19βAc-isomer only under special circumstances involving further reaction with the 17β-CH_2OH group to give the hemiacetal (X).[5] As the new 19-acetyl compound is different from the stable

18αH,19αAc-isomer and *tert*-BuO⊖ only hydrolyses it, and does not give the hemiacetal (X), which should be formed from the 18αH,19βAc-isomer, the stereochemistry at C-18 must be 18βH. This stereochemistry also applies to the preceding isopropenyl compound. The CD curve of the new 19-acetyl derivative ($[\theta]_{281} - 3990°$) gives the 19β-acetyl stereochemistry for the compound, when the octant rule projection is drawn with the least hindered conformation as in Fig. 1.[4] The large [θ] value indicates hindered rotation about the C-19/C-20 axis and is caused mainly by the hydrogens at C-12. According to Dreiding models the corresponding 18βH,19αAc-derivative would be highly crowded and hardly

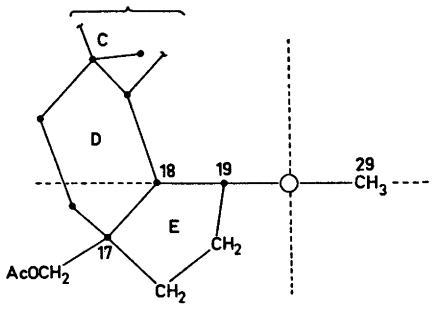

Fig. 1.

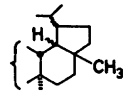
capable of resisting epimerisation. For the reasons given above we present the 18βH,19βAc-structure (XIa) for the new acetyl compound and correspondingly the 19β-isopropenyl side chain structure (XII) for its precursor, an isomer of betulin diacetate (I).

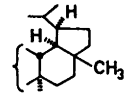
The treatment of the 19β-acetyl compound (XIa) with methyllithium gave the triol (XIII), which on reacetylation lost a molecule of water and gave mainly the terminal methylene compound (XII) and a small amount of the tetrasubstituted exo double bond compound (VIIa). This reaction and the ozonolysis of (VIIa) to the ketone (VIIIa) indicates that C-18 does not become involved in the acid catalysed isomerisation of the tetrasubstituted exo double bond compound (VIIa) and thus the 18βH-structure is correct for the compound (VIIa).

Hydrogenation of the terminal methylene in the 19β-isopropenyl compound (XII) gave a dihydro derivative, identical with the tetrahydro compound from the hydrogenation of the diene (II) (IR, ^{1}H NMR, mixed m.p., $[\alpha]_D$, mass spectra, TLC). These hydrogenation products therefore have the 18βH,19β-isopropyl structure (VIb). Hydrogenation of the lupane derivative (III) with PtO_2-catalyst has been reported [3] to give a mixture of the dihydro compound (XIV) and tetrahydro compound (XV). Because the amount of the tetrahydro compound (XV) does not increase with a prolonged reaction time, it was assumed [3] that (XIV) and (XV) must be



3ß-OAc

XV



3ß-OAc

XVI

formed *via* different routes. However, it has been suggested [3] that the tetrahydro compound (XV) is formed by addition of hydrogen from the α-face to the dihydro compound (XIV), a mechanism which leads to 18αH,19β-isopropyl structure (XVI). The hydrogenation of the betulin derived diene diacetate (II) under the same reaction conditions with PtO_2-catalyst gives similary two compounds (IVb) and (VIb) and the amount of the tetrahydro derivative (VIb) does not increase during extended reaction time. Because the tetrahydro compound (VIb) has *trans*-hydrogens at C-18 and C-19 it

cannot be formed *via cis*-addition of hydrogen to dihydro compound (IVb). Instead its formation by the addition of hydrogen from α-face to the 1,4-addition product (VIIa) is possible, and, indeed, the hydrogenation of the exo double bond compound (VIIa) with PtO_2-catalyst gave the same tetrahydro compound (VIb) as obtained from the diene (II) under the same conditions. Thus the hydrogenation of diene (II) with PtO_2-catalyst in EtOAc-AcOH solution gives first both the dihydro compound (IVb) and dihydro compound (VIIa). The former resists further hydrogenation while the latter gives the tetrahydro compound (VIb).

Finally, we note that the *cis*-structure (XVI) assigned,[2] without proof, to the tetrahydro derivative from the diene (III), should probably be replaced by the *trans*-structure (XVII), in view of our results in the betulin series (*i.e.*, II→VIb).

EXPERIMENTAL

Melting points are uncorrected. ^{1}H NMR spectra were recorded on a Varian A-60 spectrometer in $CDCl_3$ (unless stated otherwise) and related to internal TMS, the IR spectra on a Perkin-Elmer 125 spectrometer using KBr pellets, mass spectra on a Perkin-Elmer 270 B mass spectrometer, CD curves in dioxane solution on a Cary 61 spectrorotameter, specific rotations in $CHCl_3$ solution (unless stated otherwise) on a Perkin-Elmer 141 polarimeter, and elemental analyses with a F&M 185 CHN-analyser.

The typical values for the hydroxy- or acetoxy-, 3αH, and 17β-CH_2-groups, present in all the synthetised compounds, are omitted from the spectral data.

Hydrogenation of 3β,28-diacetoxy-lupa-18,20-(30)-diene (II).(a) *With PtO_2-catalyst.* 3β,28-Diacetoxy-lupa-18,20(30)-diene (II) [1,2] (3 g) and PtO_2-catalyst (0.6 g) in EtOAc-AcOH (1:1, 170 ml) were shaken for 20 h under hydrogen at room temperature and normal pressure. After that, the reaction mixture contained, according to TLC, two compounds at ratio of about 3:7, which does not change on prolonged reaction time. The catalyst was filtered off and the solvent removed. For better resolution of the two compounds the reaction mixture was hydrolysed by refluxing in KOH/EtOH for 1 h, worked up, and chromatographed on silica plates impregnated with 10 % $AgNO_3$.

The less polar 3β,28-dihydroxy-18β(H),19α-(H)-lupane (VIa) (0.4 g), recrystallised from EtOH, had m.p. 255 °C, $[\alpha]_D$ +11° (*c* 1.45), ^{1}H NMR ($CDCl_3$-CS_2) δ 0.68 – 0.95 (7 Me groups), (Found: C 81.29; H 11.87. Calc. for $C_{30}H_{52}O_2$: C 81.02; H 11.79). Diacetate (VIb), from (VIa) by refluxing 10 min in Ac_2O, had m.p. 210 °C (Ac_2O), $[\alpha]_D$ +20° (*c* 1.5), M+ 528.

The more polar 3β,28-dihydroxy-lup-18-ene (IVa) (1.6 g), recrystallised from EtOH, had m.p. 220 °C, $[\alpha]_D$ −24° (*c* 1.1), δ 0.75 – 1.05 (7 Me groups), 2.05 – 2.5 (3H, m), 3.0 – 3.8 (4H, m). (Found: C 81.33; H 11.60. Calc. for $C_{30}H_{50}O_2$: C 81.39; H 11.38). Diacetate (IVb) m.p. 211 °C, $[\alpha]_D$ +15° (c 1.5), δ 0.82 – 1.05 (7 Me groups).

(b) *With Pd/$BaSO_4$-catalyst.* 3β,28-Diacetoxy-lupa-18,20(30)-diene (II) [1,2] (2 g) and 10 % Pd/$BaSO_4$-catalyst (0.4 g) in EtOAc (140 ml) were shaken for 17 h under hydrogen at room temperature and normal pressure. Only one compound resulted according to TLC. Catalyst was filtered off and the solvent evaporated. Crystallisation from EtOH yielded 3β,28-diacetoxy-18β(H)-lup-19(20)-ene (VIIa), (1.8 g), m.p. 197 °C, $[\alpha]_D$ −19° (*c* 1.15), M+ 526, δ 0.83 – 0.95 (5 Me groups), 1.68 (2 Me, s), 2.2 – 2.6 (3H, m). (Found: C 77.69; H 10.58. Calc. for $C_{34}H_{54}O_4$: C 77.52; H 10.33). Hydrolysis with KOH/EtOH gave the diol (VIIb), m.p. 177 °C, $[\alpha]_D$ −36° (*c* 1.21), δ 0.75 – 0.95 (5 Me groups), 1.70 (2 Me, s), 2.15 – 2.6 (3 H, m).

Ozonolysis of 3β,28-diacetoxy-18β(H)-lup-19-(20)-ene (VIIa). 3β,28-Diacetoxy-18β(H)-lup-19(20)-ene (VIIa) (1 g) in EtOAc-CH_2Cl_2 (1:1, 75 ml) was ozonised at −75 °C until the solution remained slightly blue. Excess ozone was driven off with a nitrogen stream and the ozonide reduced with $(MeO)_3P$. The mixture contained (TLC) one major and several minor components. The major component was separated by chromatography on silica plates with $CHCl_3$ eluent. Recrystallisation from EtOH gave 3β,28-diacetoxy-20,29,30-trisnor-18β(H)-lupan-19-one (VIIIa) (0.35 g), m.p. 250 °C, $[\alpha]_D$ +31° (*c* 1.12) (Ref. 5, m.p. 250 – 253 °C, $[\alpha]_D$ +35.5°), $[\theta]_{313}$ +6270°. ν_{max} 1730, δ 0.70 – 0.98 (5 Me groups), 4.05 – 4.35 (2 H, m). Hydrolysis in KOH/EtOH gave the diol (VIIIb) m.p. 263 °C (EtOH), $[\alpha]_D$ +31° (THF, *c* 1.13) (Ref. 7, m.p. 254 – 6 °C, $[\alpha]_D$ +40.5° $[\theta]_{313}$ +7260°), ν_{max} 1730. Reacetylation of VIIIb) with Ac_2O gave (VIIIa).

Isomerisation of 3β,28-diacetoxy-18β(H)-lup-19(20)-ene (VIIa). 3β,28-Diacetoxy-18β(H)-lup-19(20)-ene (VIIa) (1.5 g) and *p*-toluenesulfonic acid (0.2 g) in AcOH (150 ml) were refluxed for 1.5 h. Reaction mixture contained, according to TLC, starting material and a less polar compound. Chromatography on silica impregnated with 10 % $AgNO_3$ with light petroleum (b.p. 60 – 80 °C)-benzene (3:1) eluent gave 3β,28-diacetoxy-18β(H),19α(H)-lup-20(30)-ene (XII). Recrystallisation from EtOH gave (0.6 g) m.p. 174 °C, $[\alpha]_D$ +6° (*c* 1.04), ν_{max} 3080, 1640, 885, δ 0.85 (5 Me groups), 0.99, 1.07, 1.70 (à 1 Me, s), 2.9 (1 H, m), 4.7 (2 H, br.d. 6 Hz). (Found: C 77.96; H 10.33. Calc. for $C_{34}H_{54}O_4$: C 77.52; H 10.33).

Ozonolysis of 3β,28-diacetoxy-18β(H),19α(H)-lup-20(30)-ene (XII). 3β,28-Diacetoxy-18β-(H),19α(H)-lup-20(30)-ene (XII) (0.35 g) in

$CHCl_3$-CH_2Cl_2 solution (1:1, 50 ml) was ozonised at −75 °C until slightly blue. Unreacted ozone was driven off with nitrogen and the ozonide reduced with $(MeO)_3P$. Chromatography and recrystallisation from EtOH gave 3β,28-diacetoxy-30-nor-18β(H),19α(H)-lupan-20-one (XIa) (0.15 g), m.p. 207 °C, $[\alpha]_D$ +27° (*c* 1.25), $[\theta]_{281}$ −3990°, ν_{max} 1725, δ 0.83 (3 Me groups), 0.79 (2 Me groups), 2.17 (1 Me, s), 3.1 (1 H, m). (Found: C 74.95; H 9.94. Calc. for $C_{33}H_{52}O_6$: C 74.96; H 9.91). Hydrolysis with KOH/EtOH gave the diol (XIb) m.p. 234 °C (EtOH), $[\alpha]_D$ +22° (*c* 1.0), ν_{max} 1695, 1355, δ 0.75−0.97 (5 Me groups), 2.17 (1 Me, s). Compound (XIa) does not react on standing for 3 h in AcOH-TsOH solution, and refluxing (XIa) in *tert*-BuOH with *tert*-BuO^-K^+ only hydrolyses (XIa) to (XIb).

Methylation of 3β,28-diacetoxy-30-nor-18β-(H),19α(H)-lupan-20-one (XIa). 3β,28-Diacetoxy-30-nor-18β(H), 19α(H)-lupan-20-one (XIa) (0.25 g) in abs. ether (50 ml) was purged with a nitrogen stream, cooled to −75 °C and 1 ml of methyllithium (2 M-solution in ether) was added. The reaction mixture was allowed to warm slowly to room temperature, washed with water, dil. H_2SO_4, $NaHCO_3$, and dried. Chromatography on silica plates gave two compounds. The less polar compound was found to be hydrolysed starting material, 3β,28-dihydroxy-30-nor-18β(H), 19α(H)-lupan-20-one (XIb), and the major component was 3β,20,28-trihydroxy-18β(H), 19α(H)-lupane (XIII), crystallised from EtOH (0.13 g), m.p. 220 °C, $[\alpha]_D$ −4° (*c* 0.87), δ 0.75−1.20 (7 Me groups). Acetylation of (XIII) by refluxing in Ac_2O for 10 min gave approximately 1:9 mixture of diacetates (VIIa) and (XII) resulting from dehydration and acetylation reactions, respectively.

Hydrogenation of 3β,28-diacetoxy-18β(H), 19α-(H)-lup-20(30)-ene (XII) and 3β,28-diacetoxy-18β(H)-lup-19(20)-ene (VIIa). Both diacetates (XII) and (VIIa) were hydrogenated as the diene diacetate (II) above with PtO_2-catalyst. Both reactions gave only one compound on TLC and both were identical (m.p., mixed m.p., [α]d, IR, ^1H NMR, TLC, mass spectra) with the tetrahydro compound (VIb) from the hydrogenation of the diene (II).

A Comparison of Three Phenol Methods for Extraction of Rat Liver RNA

POVEL N. PAUS*

Department of Microbiology, University of Oslo, Blindern, Oslo 3, Norway

Three commonly used phenol methods for extraction of rat liver total RNA, requiring the use of 4-aminosalicylate, naphthalene-1,5-disulfonate, and heat, respectively, have been compared.

Different amounts of giant heterogeneous nucleoplasmic RNA were isolated by the three methods. The amounts isolated, being dependent upon the ionic strength of the extraction liquid, were inversely related to the amounts of rapidly labeled RNA present in the 4 – 28 S region. No method was able to extract additional rapidly labeled RNA after extraction by any of the other methods, suggesting that the differences observed in the patterns were caused by aggregation/disaggregation during extraction.

A previously undescribed, extremely rapidly labeled, small molecular fraction was isolated, more abundantly by the 4-aminosalicylate method than by the others. It was tentatively identified as growing polynucleotide chains. The amounts isolated were partly dependent upon the ionic strength of the aqueous phase used for extraction.

Isolated rat liver total RNA may give different sedimentation and electrophoretic patterns according to the method of extraction (*e.g.*, the methods of Parish and Kirby,[1] Attardi *et al.*,[2] Warner *et al.*[3]). The differences are found both for rapidly labeled RNA (rlRNA) including giant heterogeneous nucleoplasmic RNA (giant hnRNA), and for ribosomal RNA (rRNA). This may be explained by differential extraction, configurational changes, aggregation/disaggregation phenomenons, or by splitting of covalent bonds during the extraction.

The present comparison of the above-mentioned methods was performed as part of an attempt to determine which of the isolated RNA structures represented *in vivo* existing molecules, and which were caused by the extraction procedures.

MATERIALS AND METHODS

Animals. Male 250-g CD*F inbred rats (Charles River Breeding Laboratories, Wilmington, Mass.), fed *ad libitum*, were killed at intervals varying from 1 min to 48 h after intraperitoneal injection of radioactive precursors.

Chemicals. Orotic acid-5-^{3}H (22.3 Ci/mmol) and orotic acid-6-^{14}C (60.8 mCi/mmol), The Radiochemical Centre, Amersham, United Kingdom. Pronase (B-grade), Calbiochem. Ribonuclease II-A and Deoxyribonuclease (DN-C), Sigma Chemical Company. The latter was freed of RNAase by isoelectric focusing in a 4 – 6 pH-gradient, and stored frozen. (Both Worthington RNAase-free DNAase and Sigma electrophoretically purified DNAase were found to contain traces of RNAase.) Purified human salivary α-amylase, gift from Dr. A. Hensten Pettersen, Department of Microbiology, Dental Faculty, University of Oslo.

Extraction procedures. The extraction procedures require the use of 4-aminosalicylate, naphthalene-1,5-disulfonate, and heat (60 °C), respectively, for the release of rlRNA. To minimize the possibility of degradation by RNAase, of aggregation due to salting-out procedures [4] or to high temperature,[5] DNA and glycogen were removed by specially purified enzymes, and heat extraction was performed at 55 °C. Bentonite (treated according to Fraenkel-Conrat *et al.*[6]), 1 mg/ml, and dextran sulfate, 0.1 mg/ml, were added to all aqueous solutions except to the TKM-buffer (Tris 0.05 M, KCl 0.025 M, $MgCl_2$ 2.5 mM; pH 7.0) used for incubation with DNAase and amylase, where

* Present address: Department of Pediatrics, School of Medicine, P. O. Box 109, La Jolla, California 92037, U.S.A.

bentonite was omitted. All glassware was cleaned with chromic-sulfuric acid, 0.1 M sodium hydroxide, or 2 % w/v SDS prior to rinsing in doubly distilled water. To avoid selective loss of low-molecular-weight RNA, all collections of precipitates were performed by centrifugation of ethanolic solutions at not less than 10 000 *g* for 1½ h. Phenol and *m*-cresol were distilled under reduced pressure before use.

Method 1 was based upon the 4-aminosalicylate method of Parish and Kirby.[1] However, the extraction was performed at 4 °C, and DNA and glycogen were removed by exposure to 250 μg DNAase and 500 μg amylase in 25 ml TKM-buffer at 25 °C for 1 h. The enzymic treatment was terminated by shaking with 2 % w/v SDS and ½ volume phenol reagent at 4 °C for 15 min, and the nucleic acids recovered from the aqueous phase by ethanol precipitation.

Method 2 (modified from Attardi *et al.*[2]). The aqueous phase, used for homogenization and extraction, consisted of 2 % w/v SDS and 0.5 % w/v sodium naphthalene-1,5-disulfonate in TKM-buffer. Otherwise, the procedure was identical to Method 1.

Method 3 (from Warner *et al.*[3]). This method was also identical to Method 1, except for the

following: The aqueous phase consisted of 1 % w/v SDS and 10 mM EDTA in 0.05 M sodium acetate pH 5.1. Extraction was performed by heating at 55 °C (true temperature of the solution) for 3 min before chilling. After re-extraction at 55 °C, the combined aqueous phases were treated with ½ volume phenol at 4 °C.

In the exhaustive extractions, temperatures gradually increasing up to 100 °C were used for all methods.

Ultracentrifugation. Routinely 1 mg RNA, dissolved in 1 ml gradient buffer, was applied on top of linear 30 ml 10–40 % w/w sucrose gradients containing 0.1 M sodium acetate pH 6.0, and run at 5 °C and 24 000 rpm for 14 h in a Spinco SW 25.1 rotor. Fractions of 0.8 ml were collected, diluted to 2 ml, and read spectrophotometrically. Liquid scintillation counting was performed as described previously.[7] *s* values were approximated by the method of Martin and Ames.[8]

Gel electrophoresis. Homogeneous 2.6 % acrylamide gels with a diameter of 10 mm and a length of 8 cm were run and scanned as described.[9] As the electrophoretic conditions were found to be disaggregating, electrophoresis was performed both with magnesium in the buffer for stabilization, and in EDTA-buffer. The migration of the individual fractions was affected to a slightly different degree. The buffers consisted of 2 % v/v glycerol in 0.05 M sodium phosphate with 1 mM EDTA (EDTA-buffer) or with 5 mM magnesium acetate (magnesium-buffer) pH 6.25. After scanning, the gels were frozen, and cut into 1.5 mm slices. These were weighed, hydrolyzed,[10] and counted.

RESULTS AND DISCUSSION

*Characteristics of RNA_1, RNA_2 and RNA_3.** By all methods 40 – 50 mg RNA was extracted per liver. The specific activity of RNA_1 was some 50 % higher than that of the others (Fig. 1a – c).

UV-patterns. All materials had UV-absorbing peaks in the region > 28 S, representing aggregates of rRNA (Fig. 2a – c). The aggregates of RNA_1 and RNA_2 were to a large extent dissociated by electrophoresis in EDTA-buffer at room temperature (Fig. 2d,e), while the more abundant aggregates of the hot-phenol-extracted RNA_3 were harder to disaggregate (Fig. 2f).

When run in magnesium-buffer, more peaks were visible between the ribosomal peaks and in the 4 – 18 S region in RNA_3 than in the cold-extracted RNAs (Fig. 2a – c). These extra peaks were quite reproducible on careful electrophoretic examination. Traces of several of them could be seen when RNA_1 and RNA_2 were run under more dissociating conditions (Fig. 2d,e). Ultracentrifugation demonstrated the same differences between the materials as gel electrophoresis, although the resolution was less (Fig. 1a – c). Furthermore, the 28 S RNA_3 peak then appeared lower and broader than the other 28 S peaks, and it often sedimented more slowly.

Dissociation of 5 S RNA from nuclear 28 S RNA,[11] and formation of rRNA aggregates during heating are probably responsible for part of the reduction of the 28 S RNA_3 peak. Its broadening and reduction in sedimentation rate indicate that conformational changes may be caused by the heating. The increased amount of UV-absorbing material between the ribosomal peaks and in the 4 – 18 S region might partly be derived from ribosomal RNA. This is supported by the release of corresponding material in RNA_1 and RNA_2 upon heating.[12]

The 3 S peak was not labeled using orotic acid as radioactive precursor, and probably represents DNA breakdown products from the DNAase treatment.

Radioactivity patterns. Varying amounts of rapid label remained confined to the top slices of the gels (> 60 – 70 S) (Fig. 2a – c). After labeling for 20 min, only about 50 % of $rlRNA_1$ entered the gels. Almost all $rlRNA_2$ entered, while 10 – 15 % of $rlRNA_3$ was excluded. Except for the material in the 1 – 3 S rlRNA peak (see below), the excluded material was the most rapidly labeled. Upon ultracentrifugation, all RNA sedimenting faster than 65 S had the same labeling kinetics, suggesting that these molecules all belong to the same group. $rlRNA_1$ tended to adhere to the nitro-cellulose tube walls when centrifuged. Because of the great differences in the patterns, at least two – if not all three methods – must give distorted pictures of the *in vivo* state of rlRNA.

The radioactivity in the 4 – 28 S region was quantitatively inversely related to the amount of the appearent giant rlRNA. In doubly labeled RNA, the short label: long label ratio in the 4 – 28 S region was slightly lower than in the rapidly sedimenting RNA. This could indicate that the label in the 4 – 28 S region represents the same molecular groups as the giant structures, in addition to some other, more slowly labeled molecules.

In RNA_1 an additional peak of radioactivity, 25 – 30 % of the total, migrated in the 6 – 8 S region or in the 1 – 3 S region, depending on the electrophoresis being performed in magnesium- or EDTA-buffer. It always sedimented as a 1 – 3 S peak. It was inconstantly present in RNA_2 and RNA_3. Only traces were regained after ethanol precipitation from EDTA-buffer. After thorough DNAase degradation during extraction, so that no 3 S UV-absorbing material was left, it was absent. It was the first fraction to become labeled, with significant amounts of label already after 2 min, and with maximal labeling after 10 min. For all labeling times it retained a strikingly solitary character, never merging with the RNA of higher molecular weight.

Chromatin associated 3 S RNA has been described.[13–16] The existence of this RNA as a separate entity has recently been questioned.[17–19] The smaller size of our 1 – 3 S rlRNA and its extremely rapid labeling do not indicate similarity between these fractions. According to these parameters our fraction may represent growing polynucleotide chains. During the isolation, it is possibly precipitated bound to DNA or to other macromolecular structures. The electrophoretic migration at 6 – 8 S in

* Subscript 1, 2, or 3: That which pertains to Extraction method 1, 2, or 3.

magnesium-buffer could be caused by charge differences, as it sedimented at 1 – 3 S, irrespective of EDTA or magnesium being present in the buffer.

Exhaustive extraction. To investigate whether the differences in the rapid label patterns were caused by selective extraction of rlRNAs, the extraction according to each of the methods was repeated until no more radioactivity was released into the aqueous phase. No additional radioactivity could then be extracted by any of the methods, even if the temperatures were gradually increased to 100 °C. Any residual interphase contained only negligible amounts of radioactivity when solubilized and counted directly. These studies, as well as the labeling kinetics, and the conversion studies performed by heating RNA,[12] indicate that the extra amount of label obtained with Method 1 is due to 1 – 3 S rlRNA not being precipitated by the other methods. The other major differences in the radioactivity patterns could be due to different aggregational or conformational states of the isolated RNAs.

Effects of the composition of the aqueous phase. The presence of the large amounts of rapidly sedimenting $rlRNA_1$ and the rapidly labeled 1 – 3 S peak was investigated based on the difference in composition between the aqueous solutions of Methods 1 and 2. The patterns were unaffected by an exchange of SDS for tri-isopropylnaphthalene sulfonate, by addition of 6 % v/v butan-2-ol to extraction $buffer_2$, by addition of EDTA to the extraction buffers, or by omission of *m*-cresol from the phenol reagent. Addition of potassium chloride to increase the ionic strength of extraction $buffer_2$ up to that of aqueous $phase_1$ resulted in a radioactive recovery of about 80 % of the usual. A strong increase in radioactivity was seen in the 1 – 3 S region, while the distribution in the rest of the gradient was intermediate between RNA_1 and RNA_2 (Fig. 3). The ionic strength of the extraction liquid therefore seems to be essential. A specific effect of the extracting agents on the droplet size in the water-phenol emulsion could possibly also influence the patterns.

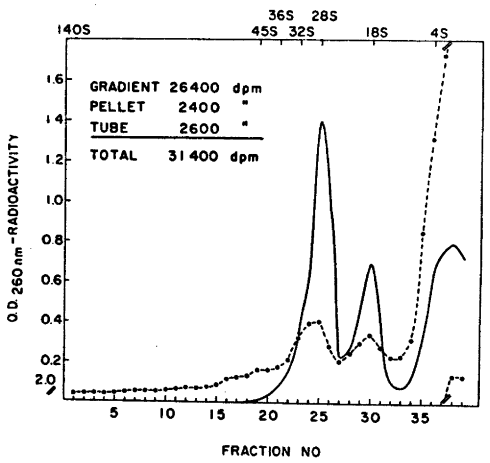

Fig. 3. Ultracentrifugation of 1 mg rat liver total RNA, isolated by Method 2 with 0.1 M KCl added to the extraction buffer, 30 min after administration of 50 μCi ^{14}C-orotic acid. Legend otherwise as in Fig. 1.

Enzymatic Properties of Pig Intestinal Proline Dipeptidase

HANS SJÖSTRÖM

Department of Biochemistry C, University of Copenhagen, DK-2200 Copenhagen, Denmark

The basic enzymatic properties of pig intestinal proline dipeptidase (aminoacyl-L-proline hydrolase, EC 3.4.13.9) were studied. The enzyme was inhibited both by substrate and product. pH-optima and K_m of the reactions with L-alanyl-L-proline (6.8 and 0.29 mM) and glycyl-L-proline (7.4 and 0.13 mM) as also K_i of the proline inhibition (0.21 mM at pH 7.4 and 0.49 mM at pH 6.8) were determined. The values were used for the calculation of theoretical progression curves, which were in good accordance with the experimental ones. 2-Mercaptoethanol, used as a stabilizer of the enzyme preparation showed inhibitory properties. The prolidase activity was not affected by DFP whereas thiol-reagents inhibited the enzyme. Bivalent metal ions showed no influence on the activity. Inhibition by 1,10-phenantroline, partially reversible by Zn^{2+}, suggested this metal to be involved in the catalysis.

Proline dipeptidase (also known as prolidase, aminoacyl-L-proline hydrolase, EC 3.4.13.9) is a dipeptide hydrolase which almost exclusively cleaves dipeptides of the aminoacyl-L-proline or aminoacyl-L-hydroxyproline type. It was first recognized by Bergmann and Fruton [1] and since then several reports on the enzyme from various animal sources have appeared.[2-8] The basal enzymatic characteristics of the pure enzyme, necessary for further enzyme kinetic work, have now been investigated on the pig intestinal prolidase, recently obtained as a homogeneous preparation.[9]

The present report settles the optimal assay conditions for the enzyme and investigates the possibility of product inhibition. A theoretical progression curve, based on the experimental data, is calculated and compared to the one obtained experimentally. In addition, the prolidase is characterized in respect to some common enzyme inhibitors and activators.

EXPERIMENTAL PROCEDURES

Enzyme preparation. The enzyme was prepared according to final purification Procedure II as described elsewhere.[9] It was stored frozen at −20 °C in small samples in 0.05 M Tris-HCl buffer (pH 7.5), made 4 mM in respect to 2-mercaptoethanol. The concentration of the enzyme was about 50 units of activity per ml. Under these conditions the enzyme was found to be stable for several months. 2-Mercaptoethanol was present to prevent aggregation of the enzyme. For each experiment one of the stored samples was used. After thawing it was generally diluted with 0.1 M potassium phosphate buffer (pH 6.8) at 4 °C to give a concentration of about 0.5 units of activity per ml, a concentration suitable for adequate substrate hydrolysis during a 10 min time period using the ordinary substrate concentration. Although the inhibitory effect observed for 2-mercaptoethanol at higher concentrations became negligible by this dilution, samples used for experiments involving low substrate concentrations were dialyzed (dialysis tubes, Visking Co., Chicago, U.S.A.) over-night against the buffer to further dilute the 2-mercaptoethanol.

Chemicals. L-Alanyl-L-proline was purchased from Fluka AG Chem. Fabrik, Buchs, Switzerland, and glycyl-L-proline was obtained from Sigma Chem. Comp., St. Louis, U.S.A. They were found chromatographically pure (thin layer chromatography, Merck DC Alufolien Cellulose 0.1 mm; butanol – acetic acid – water 4:1:1 by vol., ninhydrin reagent). In all experiments involving the continuously recording procedure the substrate concentration was calculated on the basis of the determined molar extinction coefficient of the peptide bond. Both substrates were dried as described by Bergmann *et al.*[10] until constant weight was obtained. Di-isopropylfluorophosphate (DFP) and *p*-hydroxymercuribenzoate (crystalline sodium salt, PHMB) were products of Sigma, St. Louis, U.S.A. 1,10-phenantroline was obtained from Merck, Darmstadt, Germany. De-ionized and glass distilled water was used

throughout. All other reagents used were of analytical grade.

Enzyme assay. Prolidase activity was assayed according to the method of Josefsson and Lindberg[11] with the following modifications. The dipeptide and amino acid solutions were prepared in their suitable concentrations using 0.1 M KH_2PO_4 buffer solution adjusted to proper pH with 0.1 M KOH (pH-meter 28, Radiometer, Copenhagen, Denmark). To get a higher precision of the method, 100 µl of the enzyme solution were mixed with 750 µl of the buffered substrate (2 mM) solution. Two samples were used for each digestion time. They were incubated at 25 °C for a suitable time period (5 – 60 min). Because of the small amounts of protein in the samples the ethanol precipitation procedure was omitted and instead the hydrolysis was interrupted by the addition of 750 µl 0.5 M H_3PO_4. The samples were directly read in a Zeiss spectrophotometer PMQ II at 226 nm (L-alanyl-L-proline) and 224 nm (glycyl-L-proline). In certain experiments the sensitivity of the method was increased by mixing a greater volume of enzyme solution into a smaller volume of substrate solution. The total volume of the incubation solution was always the same as in ordinary assays, as was the final substrate concentration.

In experiments where the substrate concentration was varied, alternative wavelengths from 205 nm and upwards were used to compensate for the absorbance differences. To get an approximation of the initial velocity a continuously recording procedure was chosen. The spectrophotometer was provided with a logarithm recorder (Servoger R. E. 514.9) and a thermostated cuvetteholder for cuvettes with 1 cm light path. The enzyme solution (20 µl) was mixed with pre-temperated, buffered substrate solution (1000 µl), and subsequently transferred to the cuvette. The mixing and transfer process took about 15 s. The enzyme concentration was chosen to allow approximation of the initial velocity and the reading wavelength was chosen to give a starting absorbance between 0.7 and 0.8. The spectrophotometer was set to zero before each experiment using a mixture of the enzyme solution and a buffered solution of the corresponding amino acids at appropriate concentrations.

Unit of prolidase activity. One unit of prolidase activity was defined as the amount of enzyme hydrolyzing 1 µmol L-alanyl-L-proline (1.8 mM) per min at 25 °C and pH 6.8.

RESULTS

Factors affecting stable assay conditions

Stability as a function of pH. The buffer prepared for these studies was made from a stock solution containing equimolar concentrations of H_3PO_4, citric acid, and H_3BO_3. After adjusting the solution to appropriate pH with 0.1 M KOH, water was added to give a final concentration of 0.1 M for each of the constituents. Samples of the enzyme stock solution were diluted ten times with the described buffer solution, preadjusted to pH-values varying from 2.9 to 10.3. The samples, containing 3 units of activity per ml, were stored for 30 min at 25 °C and subsequently diluted another ten times with 0.1 M potassium phosphate buffer (pH 7.0) to accomplish a nearly neutral solution before the samples were assayed for their activity. All pH-values were controlled during the experiments in parallel experiments, where the enzyme stock solution was substituted with 0.05 M Tris-HCl buffer (pH 7.5). As shown in Fig. 1 there is no difference in enzyme stability in the pH-range between 5.5. and 8.5.

Stability as a function of time, temperature, and enzyme concentration. The stability of the prolidase at 0 °C (melting ice) was studied in 0.1 M potassium phosphate buffer (pH 6.8), using an enzyme concentration of 0.5 units of activity per ml. Assays (1.8 mM L-alanyl-L-proline) were performed at suitable time intervals during a time period of 3 h from the time of preparing the diluted enzyme solutions. The results showed a small decrease of the activity during the first hour and then a more stable activity. Thus practically constant assay values were obtained during a 2 h period if the enzyme solution first was left for 1 h at 0 °C.

The stability of the prolidase after being preincubated as above was also studied at 25 °C at the enzyme concentrations 0.03, 0.06,

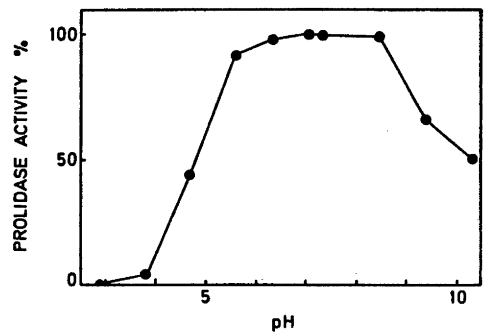

Fig. 1. Stability of prolidase as a function of pH. Substrate: L-alanyl-L-proline.

and 0.15 units of activity per ml. The same experimental procedure as above was used and the time period was 1 h. A continuously proceeding slow loss of activity was observed in all incubations, although the loss was most pronounced during the first 20 min period.

This slow loss of the enzyme activity was, however, without influence in the assay procedure, as it was found that progression curves (1.8 mM L-alanyl-L-proline) when followed to 80 % hydrolysis at the three different enzyme concentrations showed identical profiles, *i.e.* the enzyme concentrations of 0.03 units of activity per ml resulted in the same hydrolysis figure, when incubated for 100 min as did the one containing 0.15 units of activity per ml, when incubated for 20 min. This finding thus suggests a substrate stabilisation of prolidase.

Factors affecting optimal assay conditions

Reaction velocity as a function of pH. The influence of pH on the reaction velocity was investigated in the pH-range from 6.0 to 7.9 using 0.1 M potassium phosphate buffer. Measurements of the pH at the start and at the end of the incubation period, made in parallel experiments, showed a change of less than 0.04 pH-units. The results, shown in Fig. 2, gave a velocity maximum for the enzyme reaction at pH 6.8 when L-alanyl-L-proline was the substrate. A similar experiment displayed a pH-optimum of 7.4 for the enzyme reaction when glycyl-L-proline was the substrate.

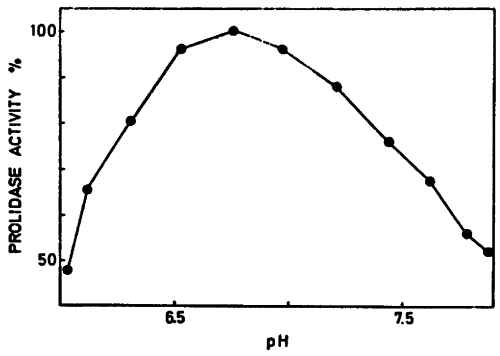

Fig. 2. Prolidase activity as a function of pH. Substrate: L-alanyl-L-proline.

Reaction velocity as a function of substrate concentration. The dependence of reaction velocity on substrate concentration was studied at five different substrate concentrations using L-alanyl-L-proline and glycyl-L-proline as substrates. Each experiment consisted of a double analysis at each substrate concentration and was run at the pH-optima proper to each of the reactions. The enzyme solution, dialyzed against 4000 vol. of 0.05 M Tris-HCl buffer (pH 7.5) over-night and subsequently frozen in portions suitable for each experiment, was appropriately diluted and kept at 0 °C for 1 h before the start of each experiment. Five experiments of this type were run for each substrate. A reference assay made at the beginning and end of each experiment showed neither an alteration of the activity during the test period nor a difference between the five separate experiments. Therefore the data could be statistically analyzed as one experiment with ten measurements at each substrate concentration. Assuming a classical Michaelis-Menten kinetics, the method of Wilkinson [12] could be used. The calculation including 4 of the 5 concentrations was performed on a Univac 1106 computer and resulted in a K_m of 0.29 (S.E. 0.025) mM and a V of 0.077 (S.E. 0.0033) mM/min for the reaction with L-alanyl-L-proline and a K_m of 0.13 (S.E. 0.015) mM and a V of 0.062 (S.E. 0.0011) mM/min for the reaction with glycyl-L-proline. Fig. 3a – b gives the data plotted as suggested by Lineweaver and Burk.

Product inhibition

Most of the naturally occurring amino acids were separately added to the buffered L-alanyl-L-proline solution in a concentration of 2 mM to investigate their possible role as inhibitors for the prolidase reaction. L-Tyrosine, L-phenylalanine and L-tryptophan were excluded because they disturbed the assay method. Of the various amino acids L-proline in consistency with earlier findings [3] was found to be a rather strong inhibitor, whereas the other amino acids besides cysteine, caused no or only slight inhibition. The inhibition induced by cysteine is probably explained by its thiol-group (*cf.* influence on the activity with 2-mercaptoethanol).

The extent and kind of inhibition with L-proline were further investigated by adding

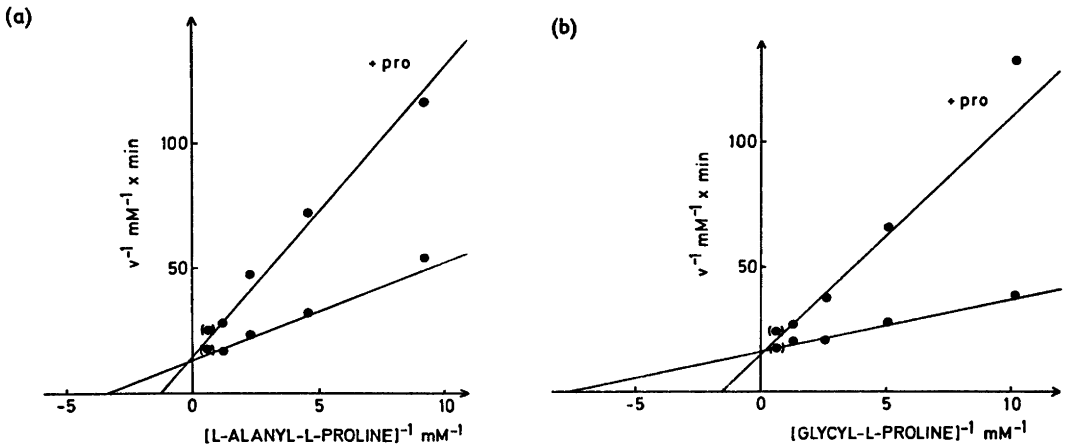

Fig. 3. Lineweaver-Burk plots of prolidase hydrolysis of (a) L-alanyl-L-proline and (b) glycyl-L-proline and the effect of L-proline (0.8 mM) on the reactions. ● Mean value of 10 measurements. Enzyme concentration during incubation (a) 0.03 units of activity per ml; (b) 0.1 units of activity per ml.

the amino acid (0.8 mM) to incubations with varying substrate concentrations. The experiment was run in the same way as described for the determination of the kinetic coefficients. In fact, the experiments described above and the inhibitor experiments were mixed with each other for making comparisons of the V-values more justified. Using the same statistical analysis procedure as above the apparent K_m was found to be 0.76 (S.E. 0.10) mM in the experiments with L-alanyl-L-proline and 0.62 (S.E. 0.039) mM in the experiments with glycyl-L-proline. The corresponding values for V were 0.069 (S.E. 0.0063) mM/min and 0.068 (S.E. 0.0038) mM/min, respectively. Fig. 3a – b gives the experimental data plotted as suggested by Lineweaver and Burk.

Other inhibitors

Influence of DFP on the activity. 150 µl of an 0.2 mM solution of DFP in 0.1 M potassium phosphate buffer (pH 7.7) were added to 50 µl of the enzyme solution, corresponding to a thousand-fold excess of the reagent. The samples in parallel with controls, in which the DFP solution was replaced by the buffer, were incubated at 25 °C for 20 min and then assayed (1.8 mM L-alanyl-L-proline) for their enzyme activity. No decrease of activity was observed in the DFP-containing samples when compared to the controls. Using the same experimental conditions the DFP solution was found to cause a complete inactivation of chymotrypsin,[13] when assayed against casein.

Influence of thiol-reagents on the activity. The essentiality of free SH-groups for the activity of prolidase was demonstrated in experiments with PHMB, Ag^+, Cu^{2+}, and Hg^{2+}, all known to react with thiol-groups of proteins. The enzyme was incubated at 25 °C for 10 min with the compounds added separately to a buffered L-alanyl-L-proline solution (pH 6.8) at concentrations of 1, 10, and 100 µM (Table 1). Preincubations of prolidase with a hundred-fold excess of PHMB (molar basis) for 16 h in 0.05 M Tris-HCl buffer (pH 7.5, 4 °C) resulted in a complete inactivation, which remained also after the excess of PHMB had been removed by dialysis.

Table 1. Effect of thiol-reagents on the prolidase activity.

Concentration µM	Activity % Ag^+	Cu^{2+}	Hg^{2+}	PHMB
0	100	100	100	100
1	0	100	100	50
10	0	60	10	40
100	0	30	0	20

Influence of 2-mercaptoethanol on the activity. An enzyme solution, free from 2-mercaptoethanol by dialysis, was assayed according to the general procedure but using a series of buffered L-alanyl-L-proline solutions, containing varying concentrations (0 – 4 mM) of 2-mercaptoethanol. The results revealed a 50 % inhibition at a 2-mercaptoethanol concentration of 0.7 mM, while very low 2-mercaptoethanol concentrations (10 μM) did not affect the prolidase activity.

Influence of certain metal ions on the activity. $CoCl_2$, $MgCl_2$, $MnCl_2$ and $ZnCl_2$ from aqueous stock solutions (0.02 M) were separately added to buffered L-alanyl-L-proline and glycyl-L-proline solutions at concentrations of 10 and 100 μM. The activity of a prolidase solution was assayed according to the general assay procedure using the various substrate solutions. No obvious effect on the enzyme activity was observed with any of the metal ions when compared to an incubation with no metal added. The influence of the metal ions on the prolidase activity was also investigated after the enzyme was treated with 1,10-phenantroline. An enzyme solution (0.05 M Tris-HCl buffer pH 7.5) was stored during a fortnight at 4 °C with and without 1,10-phenantroline (1 mM) and then assayed against L-alanyl-L-proline. The results showed a 90 % decrease of the activity in the 1,10-phenantroline containing solution compared to only a 20 % decrease in the control solution. 1,10-phenantroline was then removed by dialysis and the enzyme solution was given the four metal ions separately at concentrations as above. Repeated assays of the prolidase activity then showed partial reactivation in the samples containing Zn^{2+}, while no effect was observed in the other samples.

DISCUSSION

The omission of the centrifugation step in the original assay procedure [22] increased the precision of the method as did the increase of the volumes, thereby making it more suitable for these studies. At a substrate concentration of 1.8 mM the coefficient of variation of the assay was found to be 4.5 % ($n = 20$). The sensitivity of the method can be increased by decreasing the substrate concentration, as the inadequacy caused by not measuring the reaction at maximal velocity can be compensated for by the use of the general formula given in this report. Systematic errors due to the hygroscopic nature of the substrates, *i.e.* varying water content, can be overcome by using the molar extinction coefficient of the peptide bond. The applicability of Lambert-Beers law was verified within the whole wavelength region used.

The pH-optima for the prolidase reaction with L-alanyl-L-proline and glycyl-L-proline agree well with the values earlier reported for crude intestinal extracts of various species.[5–7,14] Peters,[15] however, reported a pH-optimum of 8.0 for the glycyl-L-proline hydrolysis by a quinea-pig intestinal extract. This pH-optimum for the glycyl-L-proline reaction was also given for the purified pig kidney prolidase.[4]

As separate experiments with substrate concentrations higher than 2 mM demonstrated substrate inhibition, the data for obtaining the kinetic coefficients were processed both with and without the values of 1.6 mM substrate concentration (Fig. 3). The kinetic coefficients obtained with a four point analysis fitted best in the progression curve (see below) thus making these values more probable in spite of the lower statistical precision.

Using the t-test according to Cleeland,[16] it was found that the two values of K_m and the two apparent K_m values obtained from the inhibition experiments with proline differed ($P = 99.9$ %). No differences between the corresponding V values could be demonstrated (L-alanyl-L-proline, $P = 90$ %, glycyl-L-proline, $P = 90$ %). These findings suggest L-proline as a competitive inhibitor and result in a K_i for the inhibition of 0.49 mM at pH 6.8 and 0.21 mM at pH 7.4.

Since variation of buffer (0.1 M Tris-HCl, pH 7.5, and 0.1 M potassium phosphate, pH 7.5) did not affect the prolidase activity and the enzyme activity was stable during the incubation period, the experimental progression curve could be completely explained by product inhibition and by the decrease of enzyme saturation with substrate.

Jennings and Niemann [17] have described an integrated rate equation (1) for a product inhibited enzyme model. This equation, using a K_m of 0.29 mM and a K_i of 0.49 mM for the

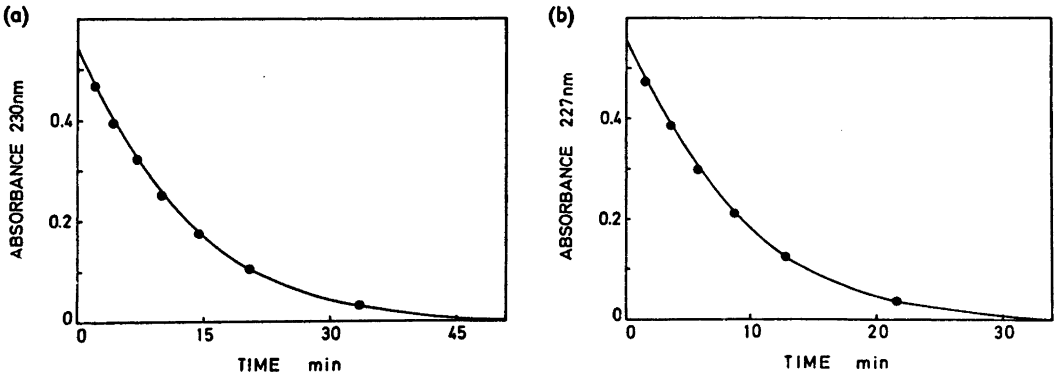

Fig. 4. Progression curves of prolidase with (a) 0.71 mM L-alanyl-L-proline and (b) 0.64 mM glycyl-L-proline as substrates. The theoretical values were calculated according to eqn. (1) at a constant interval of substrate concentration. The fitting of the equation to the enzymatic activity of the experiments were made as described in the text. ——— Experimental curve; ● calculated values.

prolidase reaction with L-alanyl-L-proline and a K_m of 0.13 mM and a K_i of 0.21 mM for the reaction with glycyl-L-proline is plotted in Fig. 4. In each of the curves, one point (substrate concentration, S_t; time, t) around 50 % hydrolysis was first taken from the experimental data to obtain $k_3 \times E$, and thereby fit the equation to the experimental curves.

$$k_3 E t = K_m(1 + S_0/K_i) \ln S_0/S_t + (1 - K_m/K_i)(S_0 - S_t) \quad (1)$$

E enzyme concentration
S_0 substrate concentration to time zero
S_t substrate concentration to time t
k_3 rate constant of the enzyme-substrate complex dissociation

This equation permits evaluation of the kinetic coefficients from a few progression curves instead of their estimation from many separate determinations of initial velocities.

The equation was also used to calculate the molecular activity (k_3) for the enzyme at 25 °C, using a molar extinction coefficient of 11.2×10^4 M^{-1} cm^{-1} for prolidase (280 nm)[18]. The molecular activity was found to be 3×10^4 and 8×10^3 min^{-1} for L-alanyl-L-proline and glycyl-L-proline, respectively. The value of the glycyl-L-proline hydrolysis is low as compared to that reported by Davis and Smith.[4] The discrepance is, however, partlyexplained by the higher experimental temperature used by them.

The experiments with DFP and thiol-reagents suggest prolidase as an enzyme dependent on free SH-group(s) for its activity, which is in agreement with earlier observations on pig kidney prolidase.[4]

The inhibition observed in this study with the thiol-compounds, earlier also reported with glutathione,[4] could be explained by the binding of the sulfur to an essential metal of the enzyme. This metal may be zinc, as suggested from the experiments including 1,10-phenantroline. As the enzyme activity in our studies, in contrast to earlier findings with higher metal concentrations,[2-4,6,7,15] was found to be unaffected with Co^{2+}, Mg^{2+}, Mn^{2+} and Zn^{2+} and also stable in the presence of 1 mM EDTA,[9] the metal is proposed to be strongly bound to the enzyme.

Acknowledgements. I wish to thank my teacher, Prof. L. Josefsson, for encouragement and valuable criticism throughout the work. Miss A. Mørch is thanked for her skilful technical assistance.

The investigation was aided by grants from the Danish Natural Science Research Council (Project No. 511).

Mechanism of the Grignard Addition Reaction. XI. Electrode Kinetics and Chemical Reactivity of Grignard Reagents

TORKIL HOLM

Department of Organic Chemistry, Technical University of Denmark, DK-2800 Lyngby, Denmark

Electrolysis of alkylmagnesium bromides using platinum electrodes lead to Tafel plots of slope 0.13 for allyl-, benzyl-, and *t*-butylmagnesium bromide, but 0.32 for methylmagnesium bromide. Two different mechanisms for the discharge process are therefore indicated. Ethyl-, butyl-, and isopropylmagnesium bromide behave like methyl at low current densities, but change over toward the *t*-butyl slope at high current densities. Values of the anodic polarisation at high current densities are correlated to the reactivity of the reagent toward benzophenone.

By electrolysis of alkylmagnesium bromides in ether solution using platinum electrodes a polarization is observed which varies with the nature of the alkyl group. These "decomposition potentials" were measured by Evans *et al.* in 1935.[1] Since magnesium is produced at the cathode and hydrocarbons attributable to the free radical form at the anode, the difference in decomposition potentials was assumed by Evans to reflect a characteristic difference in the anodic discharge potential of each alkyl anion.

In the study of the reactivity of the Grignard reagent toward benzophenone an initial transfer of a single electron from Grignard reagent to ketone has been assumed to be rate determining[2,3] and since this SET process might be related to the electrode process it was found of interest to try to correlate the chemical reactivity of the Grignard reagents with the electrochemical reactivity.

No experimental details were given by Evans concerning electrodes or current densities and serious objections may be raised against the oversimplified interpretation. More recently Psarras and Dessy[4] made an investigation of the polarographic behaviour of Grignard reagents, but failed to determine characteristic anodic potentials. Martinot made an electrokinetic investigation of several Grignard reagents[5] and found decreasing electrochemical reactivity in the order *t*-butyl > i-butyl > ethyl > butyl. Martinot found identical Tafel slopes of 0.20 for the four reagents in the anodic process, while the cathodic process for the four reagents had a Tafel slope of -0.008.

During the present work a simple procedure was used which usually gave reproducible values for the polarisation of the anode and allowed the determination of Tafel slopes as well as relative values of the electrochemical reactivity for several alkylmagnesium bromides.

A cell with two platinum electrodes was charged with *ca.* 0.8 M alkylmagnesium bromide in ether. A potential was set up by means of a constant current generator. The equilibrium value of the potential was measured exactly by means of a digital voltmeter for values of the current density I_D varying from 10^{-5} to 10^{-1} A/cm^2. For each reading of the potential E, a correction was made by increasing the current to two times the original value and noting the following increase in electrode potential E_{inc}. The apparent back electromotoric force was then taken as:

$$\text{bEMF} = E - E_{inc} \qquad (1)$$

The values of bEMF were plotted against the logarithm of the current density; Fig. 1.

The potential between the electrodes is considered the sum of ohmic resistance potentials, concentration potentials, and overvoltage for both electrode processes. It was assumed that

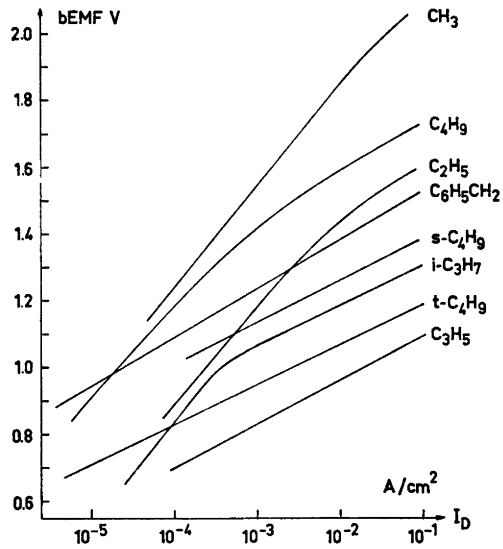

Fig. 1. Back electromotoric force (see text) *versus* log current density during electrolysis of alkylmagnesium bromides between platinum electrodes in diethyl ether at 20 °C.

the current densities applied were so small that the concentration polarisation was proportional to I_D just like the ohmic potential drop. Variations in the calculated values of bEMF was therefore considered representative for variations in overvoltage, and since for reasons which will be explained later the cathodic potential could be considered almost constant, the variations were ascribed specifically to anodic overvoltage.

Overvoltage usually follows the Tafel equation

$$\eta = a + b \log I_D \qquad (2)$$

From the Tafel plots obtained with the various Grignard reagents it seems that the values of the slope b in eqn. (2) may vary between two extremes. A low value, *ca.* 0.13, is observed with allyl, benzyl, and *t*-butylmagnesium bromide, while a high value, *ca.* 0.32, is obtained for methylmagnesium bromide. With reagents like isopropyl-, ethyl-, butylmagnesium bromide, *etc.* a change in slope is observed from the high value, 0.32, at low current densities to the low value 0.13, at high current densities. A simple interpretation would be the operation of two mechanisms for discharge of alkylmagnesium species at the anode: (1) reaction at platinum, and (2) reaction at "radical saturated" platinum. The simple discharge of alkylmagnesium species at the platinum surface to form alkyl radical and magnesium ion would be in operation at low current densities or with extremely shortlived radicals like methyl. A more complex discharge mechanism would apply if a sufficient concentration of surface bound radicals are present on the anode. The electron transfer may in this case occur with a lower activation than necessary with pure platinum, as if the surface bound radicals served as a catalyst for the electron transfer. With reagents forming stable radicals like allyl, benzyl, and *t*-butyl, the saturation is obtained even with the lowest current densities and with methyl it is not obtained even with the highest, but with isopropyl and ethyl saturation may be obtained of the current density is high enough.

For identical values of b the value of a in (2) would represent a measure of the electrochemical reactivity of the reagent. Since at the highest I_D values the slopes of the plots tended toward a common value (0.13), bEMF for the various Grignard reagents are given in Table 1 for a current density of 0.06 A/cm^2. The Tafel slope problems of course make the values for especially methyl and ethyl rather dubious.

It has been implicated in the interpretation that the overvoltage may be ascribed to the anode process. This conclusion seemed permissible from experiments in which a $Mg/MgBr_2$ reference electrode was included in the system. At low current densities the potential between the reference electrode and the cathode was near zero and at increasing I_D the potential increased linearly with I_D indicating that overvoltage is of much less importance at the magnesium cathode than at the anode. In the work of Martinot the cathodic overvoltage for six alkylmagnesium bromides varied ±5 mV for 0.6 M solutions, and the Tafel slope for the cathodic processes was smaller than 0.01.

In order to see if the electrode process is related to the rate determining step in the reaction of Grignard reagents with benzophenone, pseudo first order rate constants were obtained by means of the thermographic method [6] for the reaction of 0.02 M Grignard reagent with 0.25 M benzophenone in ether as shown in Table 1.

Table 1. Pseudo first order constants, k_{obs}, in s^{-1} for the reaction of 0.02 M alkylmagnesium bromide with 0.25 M benzophenone in diethyl ether at 20 °C. Excess bromide relative to the base titration is given as % Br^-. Anodic overvoltage $\eta_{0.06}$ (see text) is given in Volts, molarity of electrolysed solution given as [RMgBr].

R	% Br^-	k_{obs}	$\eta_{0.06}$	[RMgBr]
CH_3	0.8	0.3	1.98	1.00
C_3H_5	2.8	5.0	1.57	0.87
i-C_3H_7	13.0	133	1.28	0.99
C_4H_9	4.4	2.6	1.70	1.09
i-C_4H_9	9.6	0.90	1.60	0.98
s-C_4H_9	19.5	64	1.36	1.00
t-C_4H_9	30.0	400	1.16	0.69
C_3H_5	19.7	16 000	1.07	0.68
$C_6H_5CH_2$	15.0	21	1.50	1.02
c-C_5H_{10}	9.9	214	1.35	0.98

The logarithm of the rate constants was plotted against the anodic overvoltage for $I_D = 0.06$ A/cm² relative to the magnesium cathode; see Fig. 2. An approximate linear correlation is obtained for methyl-, ethyl-, isopropyl-, *t*-butyl, and benzylmagnesium bromide, which might indicate that the SET mechanism which was suggested for *t*-butylmagnesium bromide [3] may be a relevant model for many simply alkylmagnesium bromides. This would not mean that free radicals are actual intermediates, but only that the alkyl assumes a significant amount of radical character in the transition state. The stability of the radical type transition state may be increased by pairing between benzophenone ketyl radical and the alkyl radical.

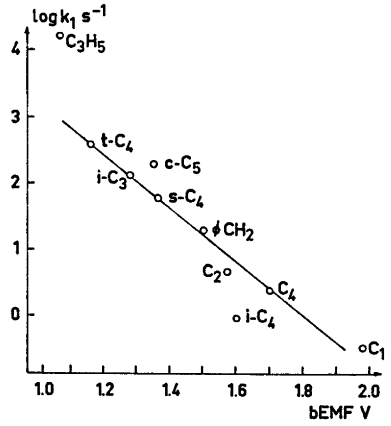

Fig. 2. Pseudo first order rate constants for the reaction at 20 °C of alkylmagnesium bromide (0.02 M) in diethyl ether with 0.25 M benzophenone. C_1, C_2, C_3, C_4, *etc.* means methyl-, ethyl-, propyl-, butylmagnesium bromide, *etc.*

The reactivity of some Grignard reagents is not very well correlated with the discharge potential. It seems that β-branching as in isobutyl represents more steric hindrance for the chemical reaction than for the electrode process. For allyl- and cyclopentylmagnesium bromide the reaction is faster than would be predicted from the discharge potentials. The mechanism of reaction for these reagents may be different or it may be a hybrid between the stepwise SET mechanism and appropriate polar or concerted mechanisms.

A certain amount of radical character or at least electron deficiency at the α-carbon in the transition state is always indicated in reactions in which the ethyl reagent is more reactive that the methyl reagent which applies to most of the reactions of Grignard reagents which have been investigated kinetically. A correlation of rate data for the metalation of 1-hexyne with Grignard reagents with Evans decomposition potentials was attempted by Dessy in 1955.[7] If this correlation is established it would suggest the operation of a SET mechanism even in this type of reaction.*

EXPERIMENTAL

The Grignard reagents were prepared from sublimed magnesium ("Specpure", Johnson, Matthiey & Co.) as reported.[8] The electrolysis cell consisted of a 10 × 75 mm Pyrex test tube. The electrodes were smooth platinum wires (0.6 mm) which were placed 6 mm apart in a rubber stopper with 65 mm extending into the tube. The electrodes were cleaned before each experiment by washing with dilute acid and with acetone. They were then heated in a bunsen burner. The cell was assembled and copper leads were connected to a Fluke 382 A current calibrator and to a Takeda-Riken digital volt-

* *Note added in proof.* A recent report [9] demonstrates a linear correlation of log rate for reaction of RMgBr with di-*t*-butyl peroxide in ether with Evans decomposition potentials. The correlation is improved if $\eta_{0.06}$ is used. Reaction of Grignard reagents are shown to have a rate determining SET step. The reactivity of benzophenone is 3.3×10^5 times greater than the reactivity of di-*t*-butyl peroxide toward the same Grignard reagent.

meter. The cell was evacuated to 0.1 mmHg through a hypodermic needle and 3 ml of the Grignard reagent were injected through the rubber stopper. The tube was placed in water at 20 °C and the current calibrator was adjusted to 1.000 mA. After 10 min the potential between the electrodes was read with two decimals and the current was increased to 2.000 mA. The new value of the potential was read exactly and from the measurements obtained the back electromotoric force was calculated according to eqn. (1). The procedure described was repeated every 10 min until a constant value for the bEMF was obtained, which usually occurred within 30 min. With methyl- and ethylmagnesium bromide up to 1 – 2 h were required to obtain a constant value. After the measurement at 1.000 mA the bEMF was measured according to the same principle at 0.4, 0.2, 0.1, 0.04, 0.02, 0.01, 0.004, 0.002, 0.001, 0.0004, 0.0002, and 0.0001 mA. The results are shown as plots of bEMF *versus* log I_D in Fig. 1.

For measurements using an external reference electrode two cells were connected through a Pyrex G 4 fritte. The reference electrode was a piece of sublimed magnesium connected to a platinum wire and suspended in a saturated solution of magnesium bromide in diethyl ether (2.5 M). During measurements using isopropyl- and allylmagnesium bromide the reference electrode was only 35 – 40 mV anodic to the cathode of the electrolysis cell at low current densities. Based on this observation and on the observation of Martinot [5] the magnesium-coated platinum cathode was considered useful as an intrinsic reference for comparison of anodic potentials.

The values of the back electromotoric force at a current density of 60 mA/cm² was taken as representative for the anodic discharge potential of the specific Grignard reagent relative to the $Mg/MgBr_2$ reference and are tabulated in Table 1.

The kinetic measurements were performed using a thermographic method.[6] The standard concentrations were 0.02 M Grignard reagent and 0.25 M benzophenone. The liquid speed in the reaction tube was usually 3 000 mm/s, but for measurement of allylmagnesium bromide the speed was 13 800 mm/s in a glass capillary of 0.24 mm inside diameter. The high speed allowed temperature measurement *ca.* 0.15 ms after mixing. From the time/temperature readings pseudo first order plots were prepared according to the expression

$$\ln [(T_\infty - T_0)/(T_\infty - T_t)] = kt$$

The plots were linear usually for more than 50 % of the reaction and values of k_1 were obtained from this linear part of the plot.

The logarithm of the rate constants were plotted *versus* the anodic discharge potentials of the respective reagents as shown in Fig. 2.

Short Communications

Partial Purification of Cysteine Synthase (*O*-Acetylserine Sulfhydrylase) from Onion (*Allium cepa*)

BENGT GRANROTH

Department of Biochemistry, University of Helsinki, SF-00170 Helsinki 17, Finland

In a previous investigation on the sulfur metabolism of *Allium* plant tissues it was found that cysteine derivatives can be formed enzymatically by condensation of various thiols with serine.[1] It was proposed that this reaction is mediated by the second member in a two-enzyme system which forms cysteine from serine. Most workers in this field now agree that cysteine is formed by the following reactions:
Acetyl-CoA + serine ⟶ *O*-acetylserine + CoA
O-Acetylserine + sulfide ⟶ L-cysteine + acetate.

The first step is catalyzed by serine acetyl transferase (EN 1972 2.3.1.30). The enzyme of the second step is known in the literature as *O*-acetylserine sulfhydrylase. However, according to the 1972 Enzyme Nomenclature it should be named cysteine synthase (EN 1972 4.2.99.8), not to be confused with cysteine synthase (EN 1964 4.2.1.22). In this paper the 1972 Nomenclature will be followed. The enzyme reacts not only with sulfide but also with methyl mercaptan and ethyl mercaptan, forming *S*-methylcysteine and *S*-ethylcysteine, respectively (for literature, see Ref. 1). In order to study further the mechanism of the biosynthesis of cysteine derivatives in onion, an attempt has now been made to purify the cysteine synthase of onion. Becker and coworkers have purified the cysteine synthase of *Salmonella typhimurium*,[2] and their procedure has been applied to the onion enzyme. However, the much lower enzyme content in onion and the presence of large amounts of polysaccharides necessitated the design of other initial purification steps. Also, it was found beneficial to raise the pH throughout the purification procedure.

Experimental. Materials. The onions used were different batches of freshly harvested or stored bulbs obtained from the local market. *O*-Acetyl-L-serine was synthesized by acetylation of L-serine in perchloric acid/acetic anhydride/acetic acid solution.[3] Other reagents were of commercial origin.

Enzyme assay. Cysteine formation was measured by the assay of Becker *et al.*[2]

Purification of cysteine synthase. The initial purification steps were performed at temperatures between 0 and +4 °C. The peeled and sliced onion (3 kg) was homogenized for 30 s at medium speed in a 5 l Waring Blendor with 1500 ml extraction buffer (0.1 M Tris-HCl, pH 8.2, containing 0.01 M 2-mercaptoethanol). A certain amount of solid Tris (about 14.5 g) was added immediately before the homogenization to establish a pH of 8.2 when the homogenization process was finished. The required amount of Tris varied from batch to batch of onion and was estimated from a small scale experiment. The slurry was strained through cheesecloth and centrifuged in a refrigerated centrifuge for 20 min at 10 400 *g*. One gram activated charcoal (BDH, for decolorizing purposes) was added per 100 ml supernatant, and the mixture was stirred for 5 min in an ice-bath and immediately centrifuged as above. Two grams moist Ca-phosphate gel was added per 100 ml supernatant, and the mixture was stirred for 10 min and centrifuged as above.[4] After this step all operations were carried out at room temperature. The pH of the supernatant was re-adjusted to 8.2 with 1 M ammonia, and solid ammonium sulfate was added to 40 % saturation. After stirring for 45 min and centrifugation, the precipitate was discarded and the supernatant was made 60 % saturated with ammonium sulfate. The solution was stirred for one hour and allowed to stand for another hour and centrifuged. The precipitate was dissolved in water and dialyzed overnight against 0.1 M Tris-HCl containing 0.01 M 2-mercaptoethanol.

First Sephadex filtration. The dialyzed enzyme was applied to a Sephadex G-100 column (52 cm × 2.7 cm ⌀), equilibrated with 0.1 M Tris-HCl – 0.01 M 2-mercaptoethanol, and eluted with the same buffer. Fractions of 5 ml were collected and the active fractions were pooled.

DEAE-Cellulose chromatography. The pooled enzyme was applied to a DEAE-cellulose column (14 × 1 cm ⌀), equilibrated with 0.1 M Tris-HCl – 0.01 M 2-mercaptoethanol, and was eluted with a 1 liter linear gradient of 0 to 0.35 M NaCl in the same buffer. Fractions of 5 ml were collected, and the fractions with the highest activities were pooled.

Second Sephadex filtration. The pooled enzyme from the previous step was dialyzed against polyethylene glycol 6000 (Shell) until the volume was reduced to about 2 ml, and then applied to

a Sephadex G-100 column (55 × 1.7 cm ⌀), equilibrated with 0.1 M Tris-HCl, pH 7.4. The column was eluted with the same buffer. The enzyme peak was pooled and stored at −18 °C.

Results and discussion. The initial adsorption steps clear the enzyme extract from many interfering substances, and gel filtration is a powerful means of further purification. In a Sephadex separation the shape of the UV profile varied with the batch of onion, but the enzyme activity always was eluted between two major UV peaks. In further purification on DEAE-cellulose the enzyme was eluted approximately in the same way as the *Salmonella* enzyme when purified on a DEAE-Sephadex column.[2] Chromatography on Sephadex G-100 also indicates similarity of enzyme from both sources. Like the *Salmonella* enzyme the purified onion enzyme is fairly stable at room temperature.

The enzyme activity varied much between different batches of onion, investigated at different times of the year, the reason for this remaining unknown. In a favourable case *ca.* 900 enzyme units were obtained from 3 kg onion (measured from the pooled enzyme after the first Sephadex fractionation). The result of the purification could not be presented in terms of specific activity since protein determination was unreliable in the crude extract and too low after the chromatographic steps. Protein determination as well as further characterization of the enzyme would have required a considerable scale-up of the whole isolation procedure. Onion is a poor source of the enzyme compared with microorganisms such as *Salmonella* in which the synthesis of this enzyme can be derepressed by growth in a medium containing L-djenkolic acid as the sole sulfur source.[5]

Synthesis of *S*-Substituted Cysteine Derivatives by the Cysteine Synthase (*O*-Acetylserine Sulfhydrylase) of Onion (*Allium cepa*) and *Escherichia coli*

BENGT GRANROTH and ANNIKKI SARNESTO

Department of Biochemistry, University of Helsinki, SF-00170 Helsinki 17, Finland

Previous investigations showed that *Allium* plants can form a wide variety of cysteine derivatives from externally supplied thiols and serine.[1] It was proposed that this reaction is mediated by the non-specific action of cysteine synthase (EN 1972 4.2.99.8). This enzyme was previously known as *O*-acetylserine sulfhydrylase. It is the second member of the two-enzyme system which normally forms cysteine from serine. The cysteine synthase of onion has now been partially purified.[2] In this investigation we have found that cysteine synthase is non-specific with regard to a wide range of thiols, and there is no difference in this respect between enzyme of plant and bacterial origin.

Materials and methods. Substrate. O-Acetyl-L-serine was synthesized by acetylation of L-serine in perchloric acid/acetic anhydride/acetic acid solution.[3] Labeled substrate was prepared on a micro scale from L-serine-C14(U) by the same method. The labeled substrate (specific activity 10 μCi/μmol) was divided in aliquots, vacuum dried and stored dry at −18 °C until use.

Enzyme. The partial purification of onion cysteine synthase is described elsewhere.[2] The enzyme was partially purified from *E. coli* using essentially a small-scale modification of the procedure of Becker *et al.*[4] The starting material was 1 g frozen cells of *E. coli* ATCC 4157, grown in a glucose/inorganic salt medium, and kindly provided by Mr. Seppo Vilkki, Phil. Lic. The cells were mixed with 9 ml buffer (0.05 M Tris-HCl pH 7.8 and 0.01 M 2-mercaptoethanol) and 13 ml ballotini glass beads and disintegrated by continuous circulation for 2 min at 0 °C in a silicone tube agitated by a fast peristaltic pump. The enzyme was purified by streptomycin precipitation and ammonium sulfate fractionation as described by Becker *et al.*[4] After this step the enzyme was dialyzed against 0.05 M Tris-HCl buffer pH 7.6. The specific activity was 1.46 units per mg protein.

Reaction. O-Acetyl-L-serine labeled with L-serine-C14(U) was incubated with the enzyme for 30 min in small, conical, stoppered test tubes under conditions similar to those described in the assay for cysteine synthase activity,[4] with the sulfide ion replaced by one of the following thiols: methyl, ethyl, propyl, allyl, butyl, or benzyl mercaptan. One μl of each thiol was

a Sephadex G-100 column (55 × 1.7 cm ⌀), equilibrated with 0.1 M Tris-HCl, pH 7.4. The column was eluted with the same buffer. The enzyme peak was pooled and stored at −18 °C.

Results and discussion. The initial adsorption steps clear the enzyme extract from many interfering substances, and gel filtration is a powerful means of further purification. In a Sephadex separation the shape of the UV profile varied with the batch of onion, but the enzyme activity always was eluted between two major UV peaks. In further purification on DEAE-cellulose the enzyme was eluted approximately in the same way as the *Salmonella* enzyme when purified on a DEAE-Sephadex column.[2] Chromatography on Sephadex G-100 also indicates similarity of enzyme from both sources. Like the *Salmonella* enzyme the purified onion enzyme is fairly stable at room temperature.

The enzyme activity varied much between different batches of onion, investigated at different times of the year, the reason for this remaining unknown. In a favourable case *ca.* 900 enzyme units were obtained from 3 kg onion (measured from the pooled enzyme after the first Sephadex fractionation). Synthesis of *S*-Substituted Cysteine Derivatives by the Cysteine Synthase (*O*-Acetylserine Sulfhydrylase) of Onion (*Allium cepa*) and *Escherichia coli*

BENGT GRANROTH and ANNIKKI SARNESTO

Department of Biochemistry, University of Helsinki, SF-00170 Helsinki 17, Finland

Previous investigations showed that *Allium* plants can form a wide variety of cysteine derivatives from externally supplied thiols and serine.[1] It was proposed that this reaction is mediated by the non-specific action of cysteine synthase (EN 1972 4.2.99.8). This enzyme was previously known as *O*-acetylserine sulfhydrylase. It is the second member of the two-enzyme system which normally forms cysteine from serine. The cysteine synthase of onion has now been partially purified.[2] In this investigation we have found that cysteine synthase is non-specific with regard to a wide range of thiols, and there is no difference in this respect between enzyme of plant and bacterial origin.

Materials and methods. Substrate. O-Acetyl-L-serine was synthesized by acetylation of L-serine in perchloric acid/acetic anhydride/acetic acid solution.[3] Labeled substrate was prepared on a micro scale from L-serine-C14(U) by the same method. The labeled substrate (specific activity 10 μCi/μmol) was divided in aliquots, vacuum dried and stored dry at −18 °C until use.

Enzyme. The partial purification of onion cysteine synthase is described elsewhere.[2] The enzyme was partially purified from *E. coli* using essentially a small-scale modification of the procedure of Becker *et al.*[4] The starting material was 1 g frozen cells of *E. coli* ATCC 4157, grown in a glucose/inorganic salt medium, and kindly provided by Mr. Seppo Vilkki, Phil. Lic. The cells were mixed with 9 ml buffer (0.05 M Tris-HCl pH 7.8 and 0.01 M 2-mercaptoethanol) and 13 ml ballotini glass beads and disintegrated by continuous circulation for 2 min at 0 °C in a silicone tube agitated by a fast peristaltic pump. The enzyme was purified by streptomycin precipitation and ammonium sulfate fractionation as described by Becker *et al.*[4] After this step the enzyme was dialyzed against 0.05 M Tris-HCl buffer pH 7.6. The specific activity was 1.46 units per mg protein.

Reaction. O-Acetyl-L-serine labeled with L-serine-C14(U) was incubated with the enzyme for 30 min in small, conical, stoppered test tubes under conditions similar to those described in the assay for cysteine synthase activity,[4] with the sulfide ion replaced by one of the following thiols: methyl, ethyl, propyl, allyl, butyl, or benzyl mercaptan. One μl of each thiol was

supplied giving an unknown actual concentration in the aqueous phase because of the wide variation in water solubility and volatility of the thiols used. After 30 min acetic acid was added to stop the reaction, and the mixture was dried in a vacuum desiccator. The reaction products were dissolved in water and subjected to thin layer chromatography with methyl ethyl ketone/pyridine/water/acetic acid (70 + 15 + 15 + 2 v/v) followed by autoradiography.[1,5]

Results. When the enzymes from onion and *E. coli* were incubated with labeled *O*-acetylserine and one of the thiols methyl, ethyl, propyl, allyl, or benzyl mercaptan, distinct spots of *S*-methylcysteine, *S*-ethylcysteine, *S*-propylcysteine, *S*-allylcysteine, and *S*-benzylcysteine, respectively, appeared on the autoradiograms. When butyl mercaptan was tested the reaction was only weak, which may reflect the low water solubility of this compound.

Discussion. Although the biosynthesis of *trans*-(+)-*S*-(propen-1-yl)cysteine sulfoxide from *S*-(2-carboxypropyl)cysteine in onion has been elucidated the origin of the side chain in other *S*-substituted cysteine derivatives has remained unknown.[1] At present, there is no evidence about the origin of the allyl side chain in *S*-allylcysteine sulfoxide in garlic. The side chain of *S*-propylcysteine sulfoxide, a minor component in onion, may be formed by hydrogenation of propenylcysteine sulfoxide, although this has not yet been experimentally proved. The metabolism of *S*-methylcysteine and its sulfoxide has been studied in several higher plants (for literature, see the reviews of Thompson [6] and Granroth [1] and some more recent publications [7–11]). This compound can be formed either by methylation of cysteine or by thiomethylation of serine, but the former reaction seems to be the normal one.

The demonstration in this investigation of the non-specific action of cysteine synthase from two different sources suggests that the ability to form cysteine derivatives from thiols and serine is wide-spread and may be an important detoxification mechanism. In onion sulfur metabolism it explains the side-chain recycling mechanism previously observed.[1] This is a reaction in which the thioalkyl moiety of an *S*-substituted cysteine derivative is combined with serine to form a new molecule with the same structure as the original. This reaction is sometimes confusing and makes the investigation of onion sulfur metabolism more intricate.

The N-Terminal Amino Acid Sequence of *Bacillus subtilis* α-Amylase

FELIX FRIEDBERG* and JOHANNES THOMSEN

The Danish Institute of Protein Chemistry, 4, Venlighedsvej, DK-2970 Hørsholm, Denmark

While it has been reported that native α-amylase isolated from *Bacillus subtilis* has a weight of 48 000 daltons, this weight is reduced to approximately 24 000 in the presence of 6 M guanidine.HCl, *i.e.* two subunits of equal weight are obtained.[1] Unequivocal proof that the primary structure of these two subunits is identical will have to come from sequence studies. Preliminary results, which are reported here, suggest that the enzyme molecule contains only one kind of polypeptide chain.

Two commercial preparations of the α-amylase, one manufactured by Novo Industries,** the other procured from Sigma Chemical Company and labeled Type II-A were examined. Both products exhibited identical elution volumes upon chromatography on Sephadex G-100. (Employing 0.025 M sodium acetate buffer, pH 6.0, as elution medium, a major fraction and a minor-slower migrating one were obtained. Utilizing 0.025 M ethylenediaminetetraacetate buf-

fer, pH 9.0, only one peak was seen. The latter occupied the position allotted to the minor peak at pH 6.0). The amino acid composition of both samples agreed closely with that reported in the literature.[2]

In our studies with the sequencer, the two preparations yielded identical results.

For the automatic Edman degradation the Beckman sequencer (Model 890B) and the slow protein-Quadrol program was utilized.[3] Phenylthiohydantoins were identified by gas chromatography.[4]

When the intact enzyme was analyzed, the sole sequence at the amino end was found to be:

1 2 3 4 5 6 7 8
Val – Asn – Gly – Thr – Leu – Met – Gln – Tyr –
9 10 11 12
Phe – Glu – Trp – Tyr

As expected, after exposure of the enzyme to CNBr a component (A) was isolated that began as follows:

Gln – Tyr – Phe – Glu – Trp – Tyr

(The treatment with CNBr was performed by allowing a solution of 100 mg enzyme in 25 ml 70 % formic acid to stand for 17 h at room temperature followed by dilution with water and lyophilization. Chromatography on Sephadex G-100 utilizing 0.2 M ammonium hydroxide and monitored at 280 nm yielded two peaks. The first one to emerge was the fraction designated above as component A. This material seemed homogeneous upon polyacrylamide gel electrophoresis while the second fraction appeared heterogeneous).

Further studies of the primary structure of the α-amylase are in progress.

The Effect of *gem*-Dimethyl Groups in the Cyclization of Diynes

GERD BORGEN and GUDMUND GAUPSET

Kjemisk Institutt, Universitetet i Oslo, Blindern, Oslo 3, Norway

Since the smallest ring obtainable by oxidative coupling of a *gem*-dimethyl substituted diyne has been shown [1] to be the 18-membered, and the possibility of making cyclic compounds with *gem*-dimethyl groups in different positions is also limited in this method, other cyclization methods had to be considered in order to prepare certain *gem*-dimethyl-substituted rings required for conformational studies.

Cyclization of terminal diynes with dibromides in liquid ammonia to give unsubstituted cyclic diynes has been described earlier [2,3] and this method has now been tried on *gem*-dimethyl substituted diynes.

The cyclization reactions are specified in Table 1 where the corresponding yields and melting points of the cyclic acetylenes formed are also given.

No cyclization to the corresponding 16-membered ring was obtained using 5,5-dimethylnona-1,8-diyne and dibromoheptane. With the same diyne and dibromononane the yield was only 6 %. The longer diyne chain, 6,6-dimethylundeca-1,10-diyne, however, reacted with the shorter dibromide, dibromopentane, to give 15 % yield of cyclic product, and with the *gem*-dimethyl substituted dibromoheptane to give a cyclic, crystalline reaction product in 59 % yield.

The results can be explained by considering the possible conformations of the reactants. Bends on the carbon chain, caused by *gauche* bonds, will most easily occur at the carbon alpha to the acetylene bond or at the *gem*-dimethyl substituted carbon.[3,4] As pointed out earlier,[1] this effect and the additional effect of the steric requirements of the *gem*-dimethyl groups, reduces the number of probable conformers for 5,5-dimethylnona-1,8-diyne to only one, shown in Fig. 1A, having the *gem*-dimethyl group at the "corner" of the chain. The terminal acetylene groups are, however, quite distant in this conformer, and they point in directions unfavourable for cyclization. This explains why no cyclization was obtained with 5,5-dimethylnona-1,8-diyne in its reaction with 1,7-dibromoheptane, as well as the low yield obtained with the same diyne and 1,9-dibromononane. With a *gem*-dimethyl group in the 4-position of dibromoheptane the dibromide chain should more easily become bent and the chances for cyclization should increase; in another work [5] the corresponding 16-membered ring was indeed obtained.

The conformational situation after extension of the diyne chain with one methylene on each

fer, pH 9.0, only one peak was seen. The latter occupied the position allotted to the minor peak at pH 6.0). The amino acid composition of both samples agreed closely with that reported in the literature.[2]

In our studies with the sequencer, the two preparations yielded identical results.

For the automatic Edman degradation the Beckman sequencer (Model 890B) and the slow protein-Quadrol program was utilized.[3] Phenylthiohydantoins were identified by gas chromatography.[4]

When the intact enzyme was analyzed, the sole sequence at the amino end was found to be:

1 2 3 4 5 6 7 8
Val – Asn – Gly – Thr – Leu – Met – Gln – Tyr –
9 10 11 12
Phe – Glu – Trp – Tyr

As expected, after exposure of the enzyme to CNBr a component (A) was isolated that began as follows:

Gln – Tyr – Phe – Glu – Trp – Tyr

(The treatment with CNBr was performed by allowing a solution of 100 mg enzyme in 25 ml 70 % formic acid to stand for 17 h at room temperature followed by dilution with water and lyophilization. The Effect of *gem*-Dimethyl Groups in the Cyclization of Diynes

GERD BORGEN and GUDMUND GAUPSET

Kjemisk Institutt, Universitetet i Oslo, Blindern, Oslo 3, Norway

Since the smallest ring obtainable by oxidative coupling of a *gem*-dimethyl substituted diyne has been shown [1] to be the 18-membered, and the possibility of making cyclic compounds with *gem*-dimethyl groups in different positions is also limited in this method, other cyclization methods had to be considered in order to prepare certain *gem*-dimethyl-substituted rings required for conformational studies.

Cyclization of terminal diynes with dibromides in liquid ammonia to give unsubstituted cyclic diynes has been described earlier [2,3] and this method has now been tried on *gem*-dimethyl substituted diynes.

The cyclization reactions are specified in Table 1 where the corresponding yields and melting points of the cyclic acetylenes formed are also given.

No cyclization to the corresponding 16-membered ring was obtained using 5,5-dimethylnona-1,8-diyne and dibromoheptane. With the same diyne and dibromononane the yield was only 6 %. The longer diyne chain, 6,6-dimethylundeca-1,10-diyne, however, reacted with the shorter dibromide, dibromopentane, to give 15 % yield of cyclic product, and with the *gem*-dimethyl substituted dibromoheptane to give a cyclic, crystalline reaction product in 59 % yield.

The results can be explained by considering the possible conformations of the reactants. Bends on the carbon chain, caused by *gauche* bonds, will most easily occur at the carbon alpha to the acetylene bond or at the *gem*-dimethyl substituted carbon.[3,4] As pointed out earlier,[1] this effect and the additional effect of the steric requirements of the *gem*-dimethyl groups, reduces the number of probable conformers for 5,5-dimethylnona-1,8-diyne to only one, shown in Fig. 1A, having the *gem*-dimethyl group at the "corner" of the chain. The terminal acetylene groups are, however, quite distant in this conformer, and they point in directions unfavourable for cyclization. This explains why no cyclization was obtained with 5,5-dimethylnona-1,8-diyne in its reaction with 1,7-dibromoheptane, as well as the low yield obtained with the same diyne and 1,9-dibromononane. With a *gem*-dimethyl group in the 4-position of dibromoheptane the dibromide chain should more easily become bent and the chances for cyclization should increase; in another work [5] the corresponding 16-membered ring was indeed obtained.

The conformational situation after extension of the diyne chain with one methylene on each

Table 1. Yields and melting points in cyclization of *gem*-dimethyl substituted diynes and dibromides.

Reactants		Cyclic product	Yield	M.p.
Diyne	Dibromide		%	Cyclic diyne °C
5,5-Dimethylnona-1,8-diyne	1,7-dibromo heptane	[5,5-dimethylcyclohexadeca-1,8-diyne]	0	
»	1,9-dibromo-nonane	5,5-dimethylcyclo-octadeca-1,8-diyne	6	Liquid
6,6-Dimethylundeca-1,10-diyne	1,5-dibromo-pentane	6,6-dimethylcyclo-hexadeca-1,10-diyne	15	26
»	4,4-dimethyl-1,7-dibromo-heptane	6,6,15,15-tetramethyl-cyclo-octadeca-1,10-diyne	21 – 59	91

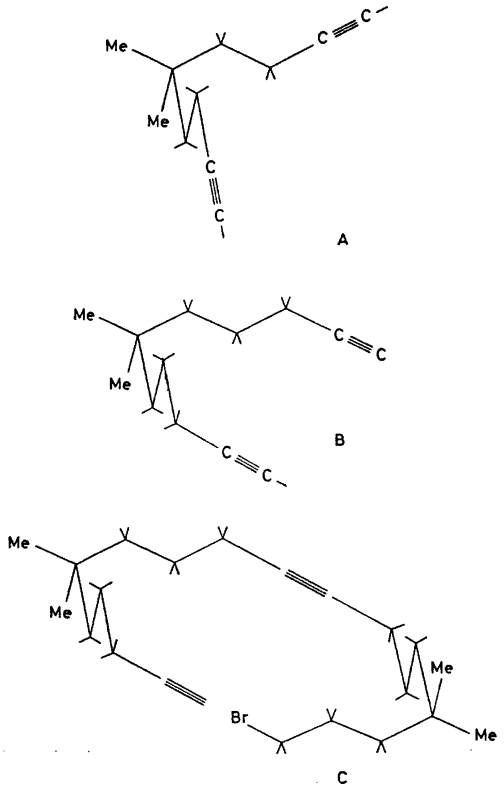

Fig. 1. Conformations before cyclization of:
A, 5,5-dimethylnona-1,8-diyne.

C, 6,6-dimethylundeca-1,10-diyne in reaction with 4,4-dimethyl-1,7-dibromoheptane.

side is shown in Fig. 1B. A conformation with the *gem*-dimethyl groups on a "corner" and with parallel terminal acetylene bonds well fitted for cyclization is then possible. This explains why this diyne gave with 1,5-dibromopentane a cyclic product in 15 % yield. In Fig. 1C the same diyne is shown to fit perfectly together with a conformationally more favourable dibromide. Here the two reactants can take similar conformations and their reacting end groups thereby come in very close positions before the final cyclization. This explains the good yield of cyclic diacetylene obtained in the reaction, as well as the stability of the conformation of the crystalline cyclic compound. It melts as high as 91 °C and shows the same infrared absorptions in the solid phase as in carbon disulfide solution.

Experimental. 5,5-Dimethylcyclo-octadeca-1,8-diyne. To a solution of sodamide, made by dissolving sodium (2.2 g = 0.094 mol) in liquid ammonia (600 ml) was added 5,5-dimethylnona-1,8-diyne [1] (7.0 g = 0.047 mol). After 1 h of stirring 1,9-dibromononane (13.5 g = 0.047 mol) was added. Stirring was continued under refluxing ammonia for 5 d. A condenser with solid carbon dioxide was used. Dry diethyl ether was added (400 ml) and stirring continued for 2 d. Thereafter water was added (500 ml), the ether phase thoroughly washed with water and dried with magnesium sulfate. After filtration and evaporation of ether the residue (9.0 g) was purified on an alumina column, eluted with a solution of benzene/pentane 1/3 whereby *5,5-dimethylcyclo-octadeca-1,8-diyne* (0.8 g = 6 %) was isolated. The compound did not crystallize above – 100 °C. Mol. w. 272 by mass spectrometry. Calc. M = 272. Further identified by the hydrogenated product.[8]

6,6-Dimethylundeca-1,10-diyne. Monosodium acetylide was prepared [6] by passing acetylene into a solution of sodium amide, prepared from sodium (5 g) in liquid ammonia (300 ml). 1,7-Dibromo-4,4-dimethylheptane, prepared in 8 steps from β,β-dimethylglutaric acid [7] was added during 20 min and the reaction mixture stirred for 40 h. The ammonia was allowed to evaporate,

water and diethyl ether added, the ether extract washed with water and dried over magnesium sulfate. Evaporation of the ether gave the crude *6,6-dimethylundeca-1,10-diyne* (7.6 g = 65 %) which was found by IR spectroscopy to contain no dibromide and was used in the next step without further purification.

13,13-Dimethylcyclohexadeca-1,8-diyne. To a stirred solution of sodamide, made from sodium (2.02 g = 0.088 mol) in liquid ammonia (600 ml), was added 6,6-dimethylundeca-1,10-diyne (7.5 g = 0.044 mol). After 1 h 1,5-dibromopentane (12 g) was added and the stirring continued for 8 d under refluxing ammonia. The ammonia was slowly evaporated, the residue dissolved in water and the water solution extracted with ether. The ether extracts were dried with magnesium sulfate, and the ether evaporated. The crude reaction product (7.3 g) was purified on an alumina column, and by elution with a benzene/pentane 1/3 solution was obtained the 13,13-dimethylcyclohexadeca-1,8-diyne (1.5 g = 15 %), m.p. 26 °C. (Found: C 88.33; H 11.45. Mol. w. 244 (by mass spectrometry). Calc. for $C_{18}H_{28}$: C 88.45; H 11.55. Mol. w. 244).

6,6,15,15-Tetramethylcyclo-octadeca-1,10-diyne. 6,6-Dimethylundeca-1,10-diyne (8.5 g = 0.05 mol) was added to a solution of sodamide, made from sodium (2.3 g = 0.1 mol) in liquid ammonia (600 ml) and stirred for 1.5 h.

4,4-Dimethyl-1,7-dibromoheptane [7] (14.3 g = 0.05 mol) was added and the reaction mixture was stirred and refluxed for 5 d. Dry diethyl ether (500 ml) was added, the ammonia evaporated and the ether solution stirred at room temperature for 2 d. Water was added, the ether solution washed with more water, dried with magnesium sulfate. After evaporation of ether the crystalline residue (8.5 g) was dissolved in petane and purified through a short alumina column. After recrystallization with ethanol was obtained: *6,6,15,15-tetramethylcyclo-octadeca-1,10-diyne* (3.0 g = 21 %, 8.5 g = 59 % yield as crystalline reaction product), m.p. 91 °C. (Found: C 87.79; H 12.04. Mol. w. 300 (by mass spectrometry. Calc. for $C_{22}H_{36}$: C 87.92; H 12.08. Mol. w. 300).

Base-promoted Non-stereospecific 1,2-and 1,4-Elimination Reactions

ALF THIBBLIN and PER AHLBERG

Institute of Chemistry, University of Uppsala, Box 531, S-751 21 Uppsala, Sweden

The stereochemistry of elimination reactions from the two diastereomeric 1-(1-acetoxyethyl)-indenes (A_1 and A_2) and from 3-(1-acetoxyethyl)indene (B) have been studied in MeO^-/MeOH. The mechanisms of the elimination reactions are discussed.

When a methanol solution 0.03 M in substrate was reacted with KOMe or NaOMe (0.06 M) at 30 °C, *trans-* and *cis-*1-ethylideneindene (C_1 and C_2) were obtained (Scheme 1). The proportions varied considerably with the substrate structure (A_1, A_2, and B). The thermodynamic equilibria exclusively favour C_1 and C_2, no trace of A_1, A_2, or B being observed after long reaction times. Neither any epimerization of A_1 or A_2 nor any 1,3-proton transfer to B could be observed when a deficiency of base was used. The reactions were studied using a quench – – extraction – NMR procedure. The results are given in Table 1.

Table 1. Product compositions obtained with A_1, A_2, and B in MeO^-/MeOH at 29.96 ± 0.07 °C.

Initial substrate conc. 0.03 M	Initial [NaOMe] M	Initial [KOMe] M	$\frac{100\ C_2}{C_1+C_2}$
A_1	0.06		37.1 ± 2.0
A_1		0.06	37.0 ± 2.0
A_2	0.06		8.1 ± 2.0
A_2		0.06	8.2 ± 2.0
B	0.06		22.6 ± 2.0
B		0.06	22.5 ± 2.0
A_1[a]	0.02		38 ± 3
A_2		0.01	7.4 ± 2.0

[a] 0.05 M.

A preliminary correlation between diastereomers and structures (A_1 and A_2) has been made assuming *anti* elimination from substrate A_2 to be favoured over *syn* elimination. The same structure assignments were obtained using Cram's rule. In NMR-spectra of mixtures of C_1 and C_2 the methyl group of C_2 appears at 0.18 ppm lower field. The proximity of the methyl group of C_2 to the deshielding region of the benzene ring is assumed to yield proton resonance at lower field than the methyl protons of C_1.

water and diethyl ether added, the ether extract washed with water and dried over magnesium sulfate. Evaporation of the ether gave the crude *6,6-dimethylundeca-1,10-diyne* (7.6 g = 65 %) which was found by IR spectroscopy to contain no dibromide and was used in the next step without further purification.

13,13-Dimethylcyclohexadeca-1,8-diyne. To a stirred solution of sodamide, made from sodium (2.02 g = 0.088 mol) in liquid ammonia (600 ml), was added 6,6-dimethylundeca-1,10-diyne (7.5 g = 0.044 mol). [a] 0.05 M.

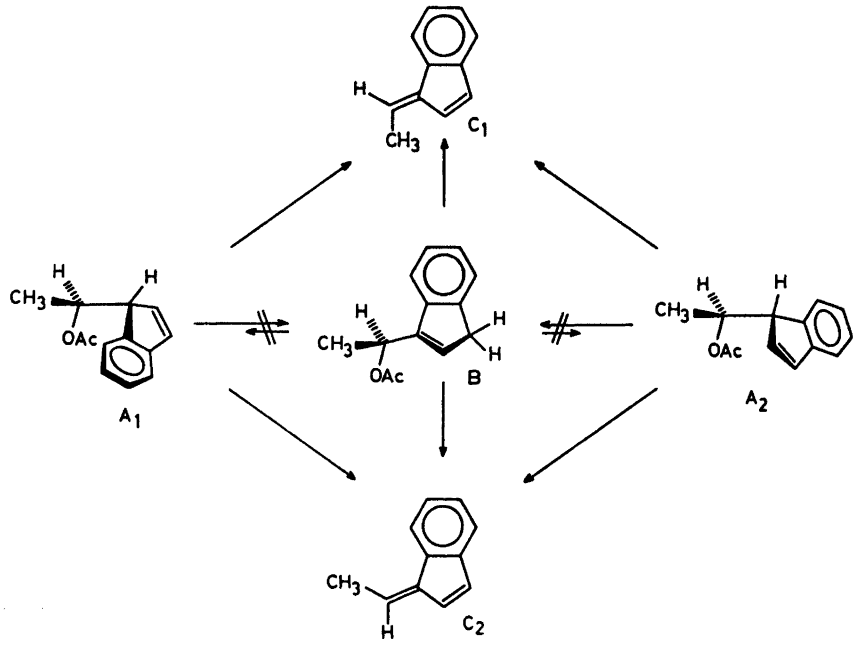
A preliminary correlation between diastereomers and structures (A_1 and A_2) has been made assuming *anti* elimination from substrate A_2 to be favoured over *syn* elimination. The same structure assignments were obtained using Cram's rule. In NMR-spectra of mixtures of C_1 and C_2 the methyl group of C_2 appears at 0.18 ppm lower field. The proximity of the methyl group of C_2 to the deshielding region of the benzene ring is assumed to yield proton resonance at lower field than the methyl protons of C_1.



Scheme 1.

The equilibrium constants for interconversion of the substrates were determined in an experiment using pyridine as catalyst. Pyridine was used because its catalytic efficiency in the 1,3-proton transfer reactions is much larger than the rate with which it effects elimination. Only trace amounts of elimination products were obtained. The equilibrium constants were $[B]_{eq}/[A_1]_{eq} \approx 22$, $[B]_{eq}/[A_2]_{eq} \approx 26$, and $[A_1]_{eq}/[A_2]_{eq} \approx 1.2$.

As shown in Table 1 the olefin C_1 is the predominant product in the reactions with all substrates. The same product compositions were obtained with KOMe and NaOMe as bases. Our analytical method did not allow accurate determinations of the absolute second order rate constants because the reactions were too fast ($k_{A1} \approx 0.07$ $M^{-1}s^{-1}$). However, it has been possible to measure relative rates of elimination reactions from the three substrates. Thus, mixtures of A_1 and A_2 or A_1 and B have been reacted in competion experiments with a deficiency of base. The ratios of elimination rates $k_{A1}:k_{A2}:k_B$ were found to be 1:5.2:1.6.

The results show that A_1 and A_2 exclusively give 1,2-elimination reactions and B exclusively 1,4-elimination reactions.

The studied reactions are expected to proceed by mechanisms in the E1cB–E2 part of the mechanistic spectrum. The results give indications of the operation of irreversible carbanion mechanisms, but they do not exclude concerted mechanisms. Carbanion mechanisms are supported by the fact that the elimination reactions from the three substrates converge towards olefin C_1. If the reactions are non-concerted, they all could have a common carbanion as intermediate. Rotation around the $C_\alpha - C_\beta$ bond interconverts different conformations of the carbanion. Thus, the substrates either could give fixed compositions of carbanion conformers, or the intermediate(s) formed have time to interconvert. The experimental results clearly show that an equilibrium mixture of the carbanion conformers is not formed.

The absence of competing epimerization and 1,3-proton transfer reactions is evidence against pre-equilibrium E1cB-mechanisms. In a similar reaction system Ahlberg and Bengtsson[1,2] have found that ion-pairs are intermediates in elimination reactions from 1-(2-acetoxy-2-propyl)indene and 3-(2-acetoxy-2-propyl)indene in methanol with tertiary amines as bases.

The stereochemistry of elimination reactions near the borderline E1cB-E2 has been studied by Cristol and Pappas,[3] who have reported stereoconvergent elimination reactions from *erythro-* and *threo*-2-*p*-toluenesulfonyl-1,2-diphenyl-1-chloroethane in NaOH/EtOH and explained the convergency with a duality of mechanism (E2/E1cB). Cram, Greene and

Depuy [4] have made an extensive study of elimination reactions from diastereomeric substrates. 1,2-Diphenyl-1-propyl-X (X = Br, Cl or NMe_3^+) was reacted in primary, secondary, and tertiary alkoxide/alcohol media. Furthermore the chloride was studied in potassium 2-octyloxide/benzene. All the elimination reactions were *anti* eliminations with one exception, the *erythro* isomer with NMe_3^+ as leaving group gave in *t*-BuOK/BuOH *syn* elimination. Later studies [5] have shown that no exchange is involved, *i.e.* a pre-equilibrium E1cB-mechanism is excluded. Alunni and Baciocchi [6] have also examined the stereochemistry of elimination reactions. They found that 1-phenyl-2-X-propanes (X = halogen) in EtONa/EtOH eliminate with a *trans/cis* ratio ranging from about 25 for the bromo and chloro compounds to 112 for the flouro compound. Sufficient activation of a substrate destroys the stereospecificity and presumably changes the mechanism from E2 to E1cB.[5]

Examples of 1,4-elimination reactions, promoted by base are not common in the literature. Cristol and coworkers [7,8] have studied 1,4-elimination reactions from *cis*- and *trans*-9,10-di-X-dihydroanthracene derivatives (X = halogen, OH, OAc, and OCOPh) with sodium hydroxide in ethanolic dioxane. *syn*-1,4-Elimination was found to be preferred. The diols react presumably with carbanion mechanisms, but the mechanisms of the other reactions are not settled. Naphthalene tetrachlorides with sodium methoxide in methanol/acetone gave 1,2- and 1,4-elimination reactions.[9] Other substrates which have been found to give 1,4-elimination reactions are 1-chloro-2-alkylperfluorocyclobutene and -pentene in KOH/EtOH or MeOH. Contrary to other studies of 1,4-eliminations these two substrates have free rotation around the $C_\gamma - C_\delta$ bond. Mixtures of *cis*- and *trans*-olefins were obtained as products.[10]

Ahlberg and Bengtsson [1,3] have recently reported the first true 1,4-elimination reactions, *i.e.* it was demonstrated that the reactions were not mixtures of 1,3-proton transfer and 1,2-elimination. The substrate, 3-(2-acetoxy-2-propyl) indene, was reacted with tertiary amines as bases in methanol.

The mechanisms of the above reported elimination reactions are under further study in these laboratories.

Experimental. The substrates were prepared by addition of acetaldehyde to indenylmagnesium bromide.[11,12] Chromatographic separation of the alcohols formed followed by zinc dichloride catalysed esterification with acetic anhydride gave diastereomerically pure *threo*- and *erythro*-1-(1-acetoxyethyl)indenes. Rearrangement of the diastereomeric acetate mixture in pyridine produced 3-(1-acetoxyethyl)indene.

Stock solutions of NaOMe and KOMe were prepared by dissolving pure-cut pieces of the metals in methanol (Fluka spectrograde quality dried over molecular sieves) under nitrogen atmosphere. The reactions were carried out in a V-formed flask; 5 ml substrate solution was placed in one of the shanks and 5 ml base solution in the other. The flask was placed in a thermostat at a temperature of 29.96 ± 0.07 °C. After 10 min in the thermostat the reaction was started by shaking the flask. 90 min later the reaction mixture was quenched according to a method previously described by Ahlberg,[1] who has also reported the procedure for determining the equilibrium constants. The analysis were made with NMR-technique.

Syntheses and Conformations of *gem*-Dimethyl Substituted Cyclo-octadecanes. The 1,1-Dimethyl and the 1,1,4,4-Tetramethyl Derivatives

S. L. BJÖRNSTAD, G. BORGEN and G. GAUPSET

Kjemisk Institutt, Universitetet i Oslo, Blindern, Oslo 3, Norway

Two *gem*-dimethyl substituted cyclo-octadecanes have earlier been synthesized; a tetramethyl derivative diametrically substituted in positions 1 and 10 and an octamethyl derivative symmetrically substituted in the four positions 1, 4, 10, and 13.[1-3] Increased substitution in cyclo-octadecane was shown to raise the melting point, to lower the melting entropy and to increase the conformational stability. The octa-methyl substituted derivative was found to be conformationally homogeneous and to take the same compact conformation in solution as in the crystal.

We have now extended this investigation to cyclo-octadecanes substituted with *gem*-dimethyl groups in only one position and in positions 1 and 4, giving molecules with lower constitutional symmetry than those studied earlier.

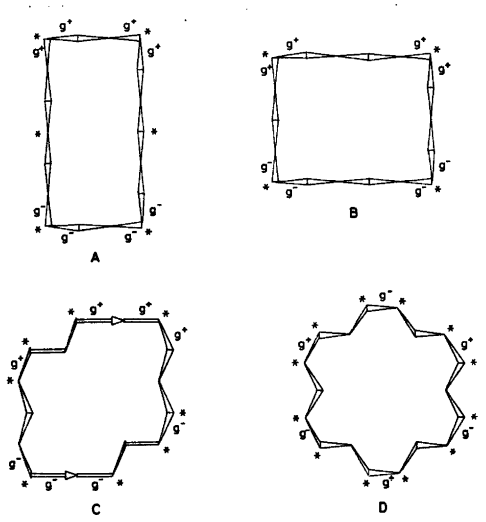

Fig. 1. Possible diamond-lattice conformations of cyclo-octadecane. g = gauche bonds. * = allowed positions for *gem*-dimethyl groups.

1,1-Dimethylcyclo-octadecane and 1,1,4,4-tetramethylcyclo-octadecane were synthesized by hydrogenation of the corresponding cyclic diynes.[4,5] In Table 1 are shown the melting points and the enthalpies and entropies of melting of these compounds together with the results of those earlier determined.

The infrared spectra were taken of the compounds as crystals in potassium bromide and dissolved in carbon disulphide. The spectra of the two phases were not identical.

In Fig. 1 are shown[6] the four possible diamond lattice conformations of cyclo-octadecane and the "allowed" positions for the space-demanding *gem*-dimethyl group. Conformations of lowest energy will, however, be obtained when those of the allowed ring positions which are situated between two *gauche* bonds carry the *gem*-dimethyl groups because thereby a minimum of new gauche-butane interactions are introduced. Dimethyl substitution in the relative positions 1, 4, 10, and 13 between two gauche bonds is only possible in conformation A and this is in accordance with the observation that 1,1,4,4,10,10,13,13-octamethylcyclo-octadecane is conformationally homogeneous. A similar rectangular 3-bond bridge conformation as Fig. 1A is also found by X-ray analyses in an unsubstituted cyclic hydrocarbon, cyclotetratriacontane.[7]

For dimethyl substitution in the relative positions 1 and 10 low-energy and, at the same time, sterically allowed positions exist both in conformation A and C, also in accordance with the observation that more conformers than the crystal conformer exist in solution.

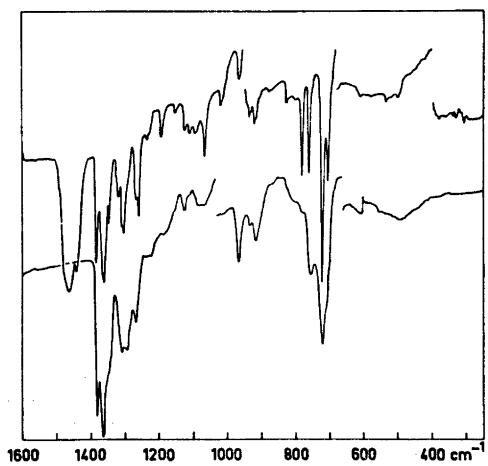

Fig. 2. Infrared spectra of 1,1,4,4-tetramethylcyclo-octadecane as KBr-disc at −50 °C. (upper curve) and in CS_2-solution (lower curve).

Conformational inhomogeneity in 1,1-dimethylcyclo-octadecane is as expected. For the 1,1,4,4-tetramethylcyclo-octadecane the above reasoning should lead to conformational homogeneity. The IR-spectrum in Fig. 2 shows, however, that although the crystal conforma-

	M.p. °C	ΔH kcal/mol	ΔS e.u.	Conformational homogeneity in solution
Cyclo-octadecane	73	9.4[a]	30.1[a]	Inhomogeneous
1,1-Dimethylcyclo-octadecane	10	5.7	20.1	»
1,1,4,4-Tetramethylcyclo-octadecane	37	7.8	25.1	»
1,1,10,10-Tetramethylcyclo-octadecane	86	9.5	26.1	»
1,1,4,4,10,10,13,13-Octamethyl-cyclo-octadecane	165	6.4[a]	14.9[a]	Homogeneous

[a] The compounds have transition points [1] and the values represent the total of transition and melting.

tion is obviously present in solution, the broadening of the bands seems too pronounced to be due to vibrational scattering and could be caused by the existence of other conformers in solution.

In our earlier investigation of *gem*-dimethyl substituted cyclo-octadecanes a raise in melting point and a drop in melting entropy was found with increased degree of substitution.[1] The two new *gem*-dimethyl substituted derivatives of cyclo-octadecane did not follow this regularity. Although the changes in entropies when going from the crystal to the melt are of the expected magnitude, the melting points and melting enthalpies for both compounds are surprisingly much lower than for cyclo-octadecane itself. We think that this is explained by the fact that the first two *gem*-dimethyl substituted cyclo-octadecanes investigated both had a centre of symmetry while the two new compounds, 1,1-dimethyl- and 1,1,4,4-tetramethylcyclo-octadecane both lack this high degree of symmetry. As the crystal packing of the molecules may not be so tight in unsymmetrical molecules as in symmetrical and the melting enthalpy thereby lowered [2] the result is a low melting point in unsymmetrical molecules that is not necessarily due to lower conformational stability.

Experimental. 1,1-Dimethylcyclo-octadecane. To 5,5-dimethylcyclo-octadeca-1,8-diyne [4] (0.2 g) dissolved in cyclohexane (50 ml) was added palladium on charcoal (0.1 g) and the solution fully hydrogenated at 344 kPa (40 h). The catalyst was filtered off, the solvent evaporated, the residue dissolved in pentane and filtered through alumina. Evaporation of pentane gave: *1,1-dimethylcyclo-octadecane.* M.p. 10 °C. Mol.w. 280. (Mass spectrometry). (Found: C 85.72; H 14.35. Calc. for $C_{20}H_{40}$: C 85.63; H 14.37).

1,1,4,4-Tetramethylcyclo-octadecane. 12,12,15-15-Tetramethylcyclo-octadeca-1,7-diyne [5] (0.47 g) was hydrogenated as described above. Recrystallization from ethanol gave: *1,1,4,4-tetramethylcyclo-octadecane.* Mol.w. 308 (Mass spectrometry). (Found: C 85.69; H 14.39. Calc. for $C_{22}H_{44}$: C 85.63; H 14.37).

The infrared spectra were recorded in a Perkin-Elmer Grating Infrared Spectrophotometer 457. For the calorimetric measurements a Perkin-Elmer Differential Scanning Calorimeter IB was used.

Frontal Gel Chromatography of a Humic Acid

INGVAR LINDQVIST

Department of Chemistry, College of Agriculture, S-750 07 Uppsala 7, Sweden

Gel chromatography has been widely applied in the study of humic acids to obtain discrete fractions or at least reduce their polydispersity. The inherent difficulties of the method, when applied to humic acids, have unfortunately not been considered in detail in most cases. Swift and Posner have recently given the first careful treatment of the subject.[1] They point out that a meaningsful separation requires that "(A) the elution volume of a substance is largely independent of sample concentration and flow rate and (B) the whole of the applied sample (*i.e.* the final peak) is eluted within the total column volume". The last point has been completely neglected by most investigators although the adsorption effects were strongly emphasized already in 1967.[2] Swift and Posner showed that only elution with alkaline buffers (pH of the order of 9) can possible fulfil the condition of negligible adsorption. Tentative molecular weight calibrations were later made using appropriate buffers[3] (one calibration necessary for each buffer).

In the study of humic acids one often has large amounts of samples of low concentrations. Therefore, frontal analysis will give a clearer insight of the complications of the fractionation procedure than zonal analysis. An example of such a frontal analysis will be given in this paper. It partly confirms the conclusions of Swift and Posner and gives at the same time some additional information about the system studied.

Experimental. The humic acid was obtained from a peat soil by pyrophosphate extraction at pH 7. The acid was precipitated with hydrochloric acid, dissolved to pH 7, dialysed and lyophilized. A 0.2 % solution in boric acid-borax buffer (0.033 M − 0.0082 M + 0.02 % NaN_3) was prepared at pH 8.5.

80 ml of this acid was fractionated by gel chromatography on Sephadex G-100 (Pharmacia Fine Chemicals, Uppsala, Sweden). Two columns (2.54 cm × 33 cm), equilibrated with buffer, were used (void volume 70 ml, total volume 150 ml); in each run 4 ml humic acid were eluted with the buffer. 10 ml fractions were collected at an elution speed of 25 ml/h. A typical elution pattern is shown in Fig. 1. Four fractions were taken out, roughly where indicated, and collected from all the twenty runs. These collected fractions are numbered 1 − 4 in the following. Small but measurable amounts of humic acid are obtained after the total volume, indicating some adsorption even at pH 8.5.

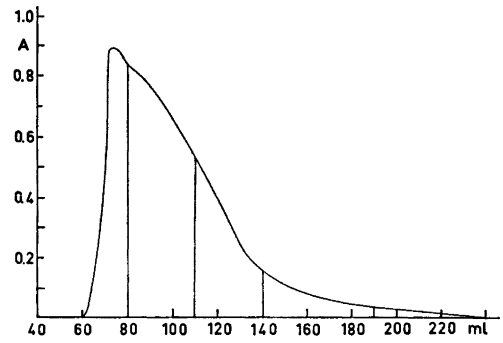

Fig. 1. Example of a zonal gel chromatographic analysis on G-100 of the humic acid. The collection of four main fractions 1 − 4 is indicated. Absorbances at 400 nm as function of elution volume.

Frontal analysis was made of each fraction on the same Sephadex G-100 column. The samples applied were large enough to give rise to a plateau level in each experiment (165 ml of fraction 1 was used, 207 ml of fraction 2, 275 ml of fraction 3 and 273 ml of fraction 4). 15 ml fractions were collected and the absorbance values at 400 nm and 500 nm measured in a 10 mm cuvette on a Zeiss PMQ II Spectrophotometer. In Fig. 2 the results obtained at 400 nm are given as histograms with tentatively drawn elution profiles. The shifts from sample to buffer are indicated by vertical lines.

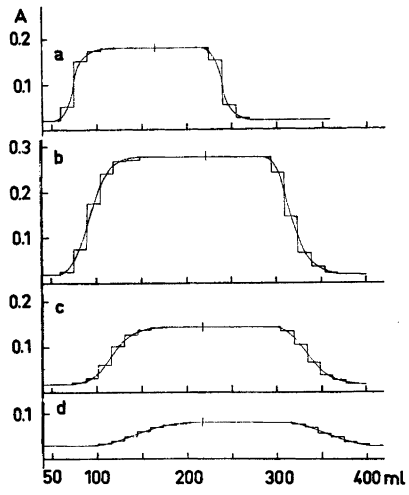

Fig. 2. Frontal gel chromatographic analysis on G-100 of the humic acid at pH 8.5. Absorbances at 400 nm as function of elution volumes. (a) Fraction 1, (b) Fraction 2, (c) Fraction 3, (d) Fraction 4.

The fractions were then recollected and dialysed against a phosphate buffer (Radiometer Type S1001) so that fractions 1–4 at pH 6.5 were obtained with the same concentrations as at pH 8.5. Frontal analyses were made in the same way as above (using 259 ml of fraction 1, 350 ml of fraction 2, 380 ml of fraction 3 and 395 ml of fraction 4). The results are given in Figure. 3.

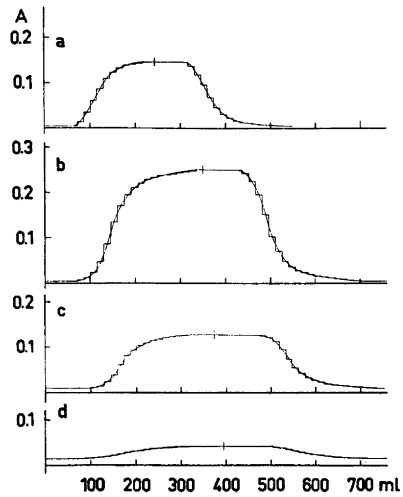

Fig. 3. Frontal gel chromatographic analysis on G-100 of the humic acid at pH 6.5. Absorbances at 400 nm as function of elution volumes. (a) Fraction 1, (b) Fraction 2, (c) Fraction 3, (d) Fraction 4.

Discussion. 1. The histograms at pH 8.5 are enantiographic within the accuracy of the experiment; the front and the back elutions do not differ appreciably. The situations of the half-values of the front and back also agree reasonably well. This means that no complicating equilibria exist in the system and that any existing adsorption must be linear. (The fact that no humic acid appears after the total volume does not itself prove the absence of adsorption; the last fractions still can be retarded.) The skewness of every histogram is in agreement with the shape of the corresponding fraction in the zonal analysis. Some of the fractions were rerun after dilution and similar patterns obtained, further confirming that a true fractionation existed.

2. At pH 6.5 the results of the frontal analyses are quite different. All fractions are appreciably retarded. The histograms are, however, still enantiographic within the limits of experimental accurary. Only two main explanations seem to be possible: the molecules have decreased in size or the adsorption (admittedly linear adsorption) is greater at the lower pH. The mere existence of a retardation cannot definitely distinguish between the two possibilities. The results show the correctness and importance of the statement by Swift and Posner that size calibrations must be made for each type of buffer.

3. The resolution achieved can easily be evaluated from the frontal analyses. When fraction 1 at pH 8.5 has passed to 90 %, fraction 2 has already passed to 37 %; and for 90 % of fraction 2, 50 % of fraction 3 has been obtained. At pH 6.5 the situation is slightly better for the resolution between fraction 1 (containing the excluded part) and fraction 2 (90 % of fraction 1 corresponds to 30 % of fraction 2), while the following resolution is much worse (90 % of fraction 2 corresponds to 80 % of fraction 3). It seems natural to explain these effects as due to a larger adsorption at pH 6.5 than at pH 8.5. Even at the higher pH the resolution is not as good as would be expected for only size separation. Some adsorption would lead to a trailing of the high-molecular fractions to overlap with the subsequent less high-molecular fractions, and would be increasingly disturbing for the last fractions as is observed. As long as the adsorption is linear it does not affect the size calibration for a given buffer but it makes the resolution of the fractionation worse.

4. The ratios A_{400}/A_{500} found for the three first fractions (the low concentrations of the fourth made the determinations very uncertain) are 2.60, 2.54, and 2.36 at pH 8.5 and 2.75, 2.62, and 2.36 at pH 6.5. The fractionation is thus reflected in the absorption spectra indicating larger similarity with the "core structure" (*cf.* Ref. 4) for the low-molecular fractions.

Friedel-Crafts Reactions. II.* Amidoalkylation by *N*-Acetoxymethyl-*N*-methylformamide in the Presence of Trifluoroacetic Acid

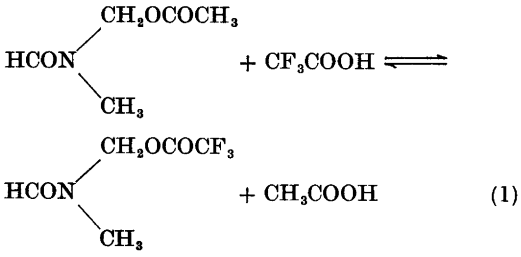
KLAS NYBERG

Division of Organic Chemistry, University of Lund, Chemical Center, P.O.B. 740, S-220 07 Lund 7, Sweden

Amidoalkylation of aromatic compounds has received considerable attention, since it represents a convenient method for the synthesis of derivatives of benzylamines.[2] The reaction is generally carried out using *N*-hydroxymethylamides or *N*-hydroxymethylimides in the presence of a catalyst (proton or Lewis acids). The major limitation of the reaction often is the preparation of the *N*-hydroxymethylamide and its instability towards isolation, and it would therefore be an advantage to use the corresponding esters as starting materials.[2]

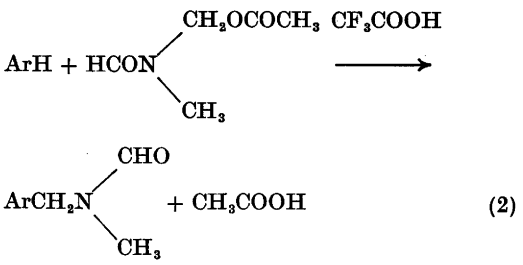
A direct synthesis of *N*-acetoxymethyl-*N*-methylformamide and *N*-formyloxymethyl-*N*-methylformamide has been achieved by anodic oxidation of *N*,*N*-dimethylformamide in acetic acid and formic acid, respectively.[3] The formyloxy derivative is capable of amidomethylating aromatic compounds in the presence of hydrochloric or sulfuric acid.[4]

When *N*-acetoxymethyl-*N*-methylformamide is dissolved in trifluoroacetic acid, an equilibrium is established, as can be shown by NMR, according to eqn. 1.



(1)

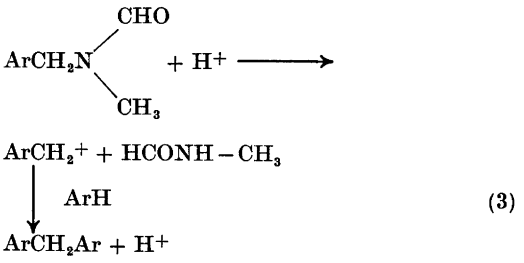
Upon addition of an aromatic compound a reaction takes place, leading to the formation of an *N*-benzyl-*N*-methylformamide derivative. The overall reaction is represented by eqn. 2. The rate of the reaction is determined by the concentration of trifluoroacetic acid as well as the nucleophilicity of the aromatic compound. Some examples of the synthetic scope of the reaction is shown in Table 1. The reactions with mesitylene, pentamethylbenzene and 1,3,5-trimethoxybenzene are very efficient under mild reaction conditions. Benzene, however, is a



(2)

weak nucleophile in this reaction and requires a considerable reaction period to give a reasonable yield of the product even in the presence of an additional catalyst (CF_3SO_3H).

The only side-reaction of any importance is the formation of diphenylmethanes. This probably takes place in an acid-catalyzed reaction according to eqn. 3.[1] However, the formation of



(3)

diphenylmethanes can be almost totally suppressed by selecting the reaction conditions properly (using equivalent amounts of acetate and aromatic compound, minimum amounts of catalyst).

Experimental. *N*-Acetoxymethyl-*N*-methylformamide was prepared in the following way using a concentric capillary gap cell.[5] A solution of *N*,*N*-dimethylformamide (5.0 mol), acetic acid (1.5 l) and Bu_4NBF_4 (0.023 mol) was electrolyzed at a current of 50 A and an applied voltage of 40 – 60 V with a temperature of 60 °C. When 2 F/mol of *N*,*N*-dimethylformamide had been passed, the electrolysis was interrupted. Acetic acid and *N*,*N*-dimethylformamide were removed by distillation up to 70 °C/20 mmHg. The product was then collected at 70 – 75 °C/1.5 mmHg (601 g; 92 % yield). The acetate has also been prepared on a 50 mol scale using a large electrolysis cell operating at 350 A.[6]

General procedure. Equivalent amounts of *N*-acetoxymethyl-*N*-methylformamide and the aromatic compound were dissolved in 25 ml of the solvent. Trifluoroacetic acid was added and the mixture was stirred (see Table 1 for details of the reaction conditions). When the reaction was over, trifluoroacetic acid and the solvent were removed by evaporation *in vacuo*. The residue was dissolved in ether, washed with sodium bicarbonate solution until neutral, washed with

* Part I, *cf.* Ref. 1.

Table 1. Yields of *N*-benzyl-*N*-methylformamides in the reaction between aromatic compounds (0.1 mol) and *N*-acetoxymethyl-*N*-methylformamide (0.1 mol) in the presence of trifluoroacetic acid.

ArH	CF_3COOH (mol)	Solvent	Reaction time (h)	Yield (%)
Benzene	0.5[a]	$CHCl_3$[b]	96	40
Mesitylene	0.25	CH_2Cl_2[c]	16	93
Pentamethyl benzene	0.25	$CHCl_3$[b]	5	85
1,3,5-Trimethoxy-benzene	0.1	CH_2Cl_2[c]	20	81

[a] CF_3SO_3H (0.01 mol) was used as an additional catalyst. [b] At reflux temperature. [c] At room temperature.

water, and finally dried over anhydrous sodium sulfate. After filtration and removal of the ether by evaporation *in vacuo* the product was isolated as shown below. The mixture from the reaction with 1,3,5-trimethoxybenzene was diluted with methylene chloride and worked up as above (the product was poorly soluble in ether).

N-*Benzyl-N-methylformamide.* The product was isolated by distillation, b.p. 148–150 °C/20 mmHg (6.0 g; 40 % yield). The NMR spectrum was in agreement with published data,[7] MS: *m/e* 149 (100 % abundance), 148 (18), 134 (11), 120 (7), 106 (18), 92 (10), 91 (73), 79 (15), 65 (14), 42 (18).

N-*(2,4,6-Trimethylbenzyl)*-N-*methylformamide.* The residue was dissolved in 50 ml of hexane. Crystallization took place at −20 °C giving the product, m.p. 59–61 °C (17.8 g; 93 % yield). NMR (in $CDCl_3$): δ 2.27 and 2.28 (9 H, $ArCH_3$), 2.72 and 2.80 (3 H, $N-CH_3$), 4.50 and 4.67 (2 H, $N-CH_2$), 6.90 (2 H, ArH), 8.20 (1 H, CHO). MS: *m/e* 191 (15), 133 (20), 132 (100), 117 (11).

N-*(2,3,4,5,6-Pentamethylbenzyl)*-N-*methylformamide.* The residue was dissolved in 50 ml of boiling hexane. After cooling, the precipitate was filtered off, giving the product, m.p. 87–89 °C (18.7 g; 85 % yield). NMR (in $CDCl_3$): δ 2.22 (15 H, $ArCH_3$), 2.58 and 2.75 (3 H, $N-CH_3$), 4.45 and 4.67 (2 H, $N-CH_2$), 8.00 and 8.08 (1 H, CHO). MS: *m/e* 219 (10), 161 (11), 160 (100), 145 (9).

N-*(2,4,6-Trimethoxybenzyl)*-N-*methylformamide.* The residue was dissolved in a mixture of 100 ml of cyclohexane and 25 ml of benzene at boiling. After cooling, the precipitate was filtered off, giving the product, m.p. 103–105 °C (19.3 g; 81 % yield). NMR (in $CDCl_3$): δ 2.72 (3 H, $N-CH_3$), 3.80 (9 H, CH_3O), 4.35 (2 H, $N-CH_2$), 6.12 (2 H, ArH), 8.25 (1 H, CHO). MS: *m/e* 239 (47), 210 (17), 182 (10), 181 (100), 180 (13), 168 (17), 136 (16), 121 (22).

Electrolytic Generation of Nucleophiles. IV.* Reductive Alkylation and Acylation of Disulfides

PALLE E. IVERSEN and HENNING LUND

Department of Organic Chemistry, University of Aarhus, DK-8000 Aarhus C, Denmark

Mayer and coworkers [3] have briefly reported on the electrolytic reductive methylation of various disulfides with dimethyl sulfate in aqueous isopropanol on a rather small scale. We have extended the reaction to aprotic medium with a variety of electrophiles to present a general alternative way of preparing sulfide derivatives and demonstrate another example of *in situ* reaction of electrochemically generated nucleophilic species.

The electrolytic reduction of a disulfide bond leads to a thiolate anion which could either be protonated to give the corresponding mercapto derivative [3] or react with an appropriate electrophile present, thus creating a new C–S linkage:

$$R-S-S-R \xrightarrow{2e^-} 2RS^- \xrightarrow{H^+} RSH$$
$$\qquad\qquad\qquad\qquad\quad \xrightarrow{R'X} R-S-R'+X^-$$

In the present investigation have been employed readily available (mostly symmetric) disulfides which yielded products of relatively low volatility (Tables 1 and 2). One advantage of the electrochemical method was already pointed out by Mayer and coworkers:[3] Derivatives can be made from disulfide precursors where the corresponding thiols are unstable or not known as in the case of 3*H*-1,2-benzodithiol-3-one and -3-thione. Another feature is that controlled potential electrolysis can work selectively on substrates which contain other reducible functions as exemplified by bis(2-nitrophenyl)disulfide. This is of course also possible by normal chemical procedures, if a suitable reducing agent can be found.

For a given disulfide the choice of the electrophile is restricted by the fact that the S–S bond must be easier reducible than the electrophile itself. Methyl chloride in an aprotic polar solvent, such as *N*,*N*-dimethylformamide (DMF), was found to be a convenient and efficient methylating reagent for the reductive methylation of most disulfides in DMF (Table 1). This has also recently been used by Simonet and coworkers [4] in electrolytic reductive alkylation of sulfonyl chlorides. Results from experiments with some other alkylating and acylating agents are given in Table 2 showing that the alkylations mostly give better yields than the acylations. In the experiment with *N*,*N*-dimethylcarbamoyl chloride, the electrophile was reduced at the potential applied, so that a good yield was not to be expected. However, the fact that our attempts to prepare the wanted dimethylthiocarbamoyl dimethylcarbamoyl sulfide by conventional methods [5] were unsuccessful, makes the relatively low yield (44 % crude) more acceptable. The addition of pyridine did not affect the product yield significantly

[a] 5 ml of pyridine added. [b] Solvent acetonitrile/0.8 M $NaClO_4$, sat. LiCl in the reference electrode. [c] 2 ml of pyridine added. [d] The product was di-*S*-thiobenzoylmethane.

in this particular case, but it proved to be advantageous for the reductions with acetic anhydride.

In most experiments DMF has been employed as the solvent, but acetonitrile may also be useful for reductive alkylations and acylations. In some cases, *e.g.* dibenzyldisulfide, the yield of methylated product was considerably lower in acetonitrile (82 %) than in DMF (95 %), whereas with *N*,*N*-dimethylcarbamoyl chloride as the electrophile the yield was higher in acetonitrile than in DMF. Ethanol and presumably other protic solvents are inferior to the aprotic solvents and a considerable amount of thiol was found as a side product in methylations with methyl chloride, but possibly dimethyl sulfate may be used instead.

Experimental. The electrolytic equipment has been described earlier.[1] The disulfides were either commercial products or prepared by literature methods. The DMF was dried over A4 molecular sieves. Boiling and melting points are uncorrected.

General procedure for electrolytic reductive alkylation and acylation. The disulfides (5.0 ml or 5.0 g) were reduced overnight at room temperature (cell surrounded by a water bath) in DMF (approx. 175 ml) containing 0.5 M lithium chloride. The reference electrode was Ag/AgCl/0.5 M LiCl in DMF, and working potentials and amounts of added electrophile are indicated in Tables 1 and 2. For some of the very easily reducible compounds the mercury cathode was polarized negatively before addition of the disulfide to avoid the formation of a black precipitate by reaction with the metal. The electricity consumption was usually very close to 2 F/mol of disulfide. After reduction an equal volume of benzene was added to the catholyte which was then washed 3 times with 1.5 l of water to remove the DMF. For experiments in acetonitrile the solvent was evaporated *in vacuo* before the extraction with benzene. The organic layer was dried over anh. magnesium sulfate, the solvent removed *in vacuo*, and the residue either fractionated *in vacuo* or recrystallized from ethanol. In a few experiments with diphenyl- and dibenzyldisulfide about 600 ml of water were added to the catholyte which was then extracted continuously with petroleum ether (16–20 h) and worked up as above. The extraction procedure was checked with benzyl methyl sulfide giving 95 % recovery. The prepared sulfide derivatives were known from the literature and identified by comparison with authentic specimens or literature data. Optimization of yields has not been attempted.

S-*Methyl(2-thiomethyl)thiobenzoate.* For this compound our m.p. (53–54 °C) did not agree with the reported[3] one (121–122 °C). NMR-spectrum (60 MHz, CCl_4, TMS): δ 2.35 (s, 3 H); δ 2.40 (s, 3 H); δ 6.9–7.9 (multiplet, 4 H). Strong IR-absorptions (KBr, cm^{-1}): 1660, 1205, 905. (Found: C 54.47; H 5.13; S 32.07. Calc. for $C_9H_9OS_2$: C 54.54; H 5.09; S 32.30). For comparison the NMR (CCl_4) *S*-methyl signals are given for S-*methylthiobenzoate:* δ 2.40 (s, 3 H) and S-*methyl(2-methylthio)dithiobenzoate*: δ 2.32 (s, 3 H) and δ 2.69 (s, 3 H).

Radiation Effects on the Glycosidic Bond in Some Crystalline Disaccharides

GÖRAN LÖFROTH and TORBJÖRN GEJVALL

Radiobiology Department, University of Stockholm, Wallenberg Laboratory, Lilla Frescati, S-104 05 Stockholm 50, Sweden

Irradiated crystalline disaccharides have been analyzed by gas chromatography of the trimethylsilyl derivatives for the presence of constituent monosaccharides after dissolving in pyridine or water. Sucrose yields D-fructose and α-D-glucose in equal amounts, with initial G-values of 0.8. Maltose monohydrate yields equal amounts of α- and β-D-glucose with $G \approx 0.15$, and trehalose dihydrate yields α-D-glucose with $G = 0.8$. By means of these results and previously reported degradation yields, it is demonstrated that the major part of the radiation damaged molecules in sucrose, maltose monohydrate, and trehalose dihydrate has intact glycosidic bonds. No detectable amounts of D-glucose or D-galactose were found in irradiated lactose monohydrate.

The susceptibility of the glycosidic bond in crystalline disaccharides to ionizing radiations has been mentioned in the early literature,[1–4] but no conclusive data have yet been reported.

The total degradation yields for four crystalline disaccharides have been reported in a previous communication [5] together with degradation yields, measured as degradation of their constituent monosaccharides, for three of these disaccharides (sucrose, maltose monohydrate, and trehalose dihydrate). The results showed that the damage to these disaccharides is mainly associated with only one of the monosaccharide moieties of any degraded disaccharide molecule. These results give rise to two possible interpretations. The glycosidic bond may be either intact, joining the damaged monosaccharide moiety (or part of it) with the undamaged one, or broken, in which case a constituent monosaccharide is released. We have now measured the radiation induced release of constituent monosaccharides for sucrose, maltose monohydrate, trehalose dihydrate, and lactose monohydrate, and the present results give information about the radiation sensitivity of the glycosidic bonds.

EXPERIMENTAL

The ^{60}Co γ-irradiation and the disaccharides, sucrose, β-maltose monohydrate, α,α-trehalose dihydrate, and α-lactose monohydrate, have previously been described.[5]

For the determination of released constituent monosaccharides in the irradiated crystalline disaccharides, a known amount of anhydrous pyridine was added to a weighed amount of the irradiated or unirradiated sample to give a concentration of approximately 10 mg carbohydrate/ml pyridine. The samples were either directly dissolved in pyridine or first dissolved in water and subsequently freeze-dried.

The trimethylsilyl derivatives were prepared by addition of hexamethyldisilazane and trimethylchlorosilane to the pyridine solution, as described by Sweeley *et al.*[6] As reference samples unirradiated disaccharides, and occasionally irradiated disaccharides, were used to which were added known small amounts of the appropriate monosaccharides dissolved in pyridine or water.

The pyridine solutions of the derivatives were analyzed by gas chromatography on a Perkin Elmer F11 with FID detection.[7] Columns were: 1.4 m × 2.2 mm of 2 % SE 30 on Chromsorb W 60 – 80 mesh at 160 °C and 1.2 m × 2.2 mm of a 2:1 mixture of 8 % QF 1 and 4 % SF 96 on Gas Chrom P 100 – 120 mesh at 140 °C.

RESULTS

For the investigated disaccharides, with the exception of lactose monohydrate, irradiation gave rise to small amounts of the constituent

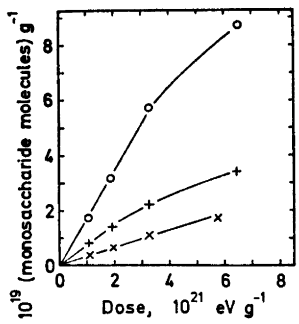

Fig. 1. γ-Radiation induced release of monosaccharides from crystalline disaccharides *vs.* dose: O, D-fructose + α-D-glucose from sucrose; +, α-D-glucose from trehalose dihydrate; ×, α- + β-D-glucose from maltose monohydrate.

monosaccharides which did not appear in unirradiated samples. Sucrose yielded D-fructose and α-D-glucose in equal amounts. Maltose monohydrate yielded α- and β-D-glucose in equal amounts, whereas trehalose dihydrate only gave rise to α-D-glucose. The yield-dose curves for the formation of these free constituent monosaccharides are given in Fig. 1 and the initial G-values are given in Table 1. Neither α- and β-D-glucose nor α- and β-D-galactose were present in detectable amounts in irradiated lactose monohydrate (Table 1).

There were no detectable differences in the gas chromatograms or yields of monosaccharides between samples analyzed directly after irradiation, and samples analyzed after dissolving in water and subsequent freeeze-drying, with the exception that mutarotation occurred for D-glucose when the aqueous solutions were not frozen immediately after dissolving the sample.

Table 1. Initial G-values for the release of constituent monosaccharides from crystalline disaccharides.

	G-value			
	D-Fructose	α-D-Glucose	β-D-Glucose	β-D-Galactose
Sucrose	0.8	0.8		
Maltose.H_2O		≈0.15	≈0.15	
Trehalose.$2H_2O$		0.8		
Lactose.H_2O		<0.1		<0.1

DISCUSSION

The fact that D-glucose released from sucrose, maltose monohydrate, and trehalose dihydrate are the anomers which would be expected from the spatial configuration of the disaccharide, shows that the breakage of the glycosidic bond is concomitant with retention of the geometry of the carbon atom involved in the bond. An inversion, *e.g.* from α- to β-D-glucose in sucrose, of a detectable magnitude ($G \approx 0.1$) would have been noticed. The monosaccharides are probably already present as such in the solid state, as their formation is independent of the method used to dissolve the irradiated sample. The pyranoside and furanoside forms of D-fructose have been resolved by GLC of their trimethylsilyl derivatives.[8] They are, however, not separated by the experimental conditions used in the present investigation (*cf.* Ref. 6) which were employed to separate and quantitate the small amounts of released constituent monosaccharides.

Lactose monohydrate behaves differently from the three other investigated disaccharides. The initial total degradation yield for lactose monohydrate with $G \approx 50$ is also exceptionally high compared with the G-values of 6 – 8 for the other disaccharides.[5] The absence of released glucose and galactose in irradiated lactose monohydrate is in agreement with data given by von Sonntag and Dizdaroglu.[9]

The G-values for the radiation induced degradation of sucrose, trehalose dihydrate, and maltose monohydrate have been determined to be 6, 7, and 8, respectively and the G-values for the degradation of their constituent monosaccharides have been determined to be the same or slightly higher,[5] *i.e.* for sucrose: G(−glucose) + G(−fructose) = 6, for trehalose dihydrate: G(−glucose) = 7, and for maltose monohydrate: G(−glucose) = 10.

From these data and the present results on the release of constituent monosaccharides (Table 1), it can be calculated that radiation damaged molecules of the type S−O−S*, in which one monosscharide moiety (S) is damaged but has an intact glycosidic bond, account for more than 70 % of the degradation in sucrose and maltose monohydrate and for about 90 % in trehalose dihydrate. It can also be calculated that processes leading to breakage

of the glycosidic bond have $G \leq 1.6$ in sucrose, $G \leq 2.3$ in maltose monohydrate, and $G \leq 0.8$ in trehalose dihydrate. This result makes it difficult to assign the glycosidic bond as origin and/or trapping site of the free radicals as these are formed with G-values of $3-5$.[10,11]

Transformation of Steroids by Cell-free Preparations of *Penicillium lilacinum* NRRL 895. V. Properties of 20-Oxopregnane Side Chain Cleavage and 20(α+β)-Oxidoreductase Activities

KJELL CARLSTRÖM

Department of Pure and Applied Biochemistry, Royal Institute of Technology, and the Department of Obstetrics and Gynaecology, Sabbatsberg Hospital, Karolinska Institutet, S-113 82 Stockholm,* Sweden

Assay conditions for the 20-oxopregnane side chain cleavage and the 20(α + β)-oxidoreduction in cell-free preparations from *P. lilacinum* have been determined. Progesterone and 17α-hydroxyprogesterone but not 17α-acetoxyprogesterone were substrates for the two types of enzymes. Side chain cleavage showed an absolute requirement for NADPH and may involve participation of flavins and iron-sulphur protein. The reaction was intensitive to cyanide, azide, fluoride, and carbon monoxide, indicating that no cytochromes take part in the oxygenation of the substrate. Reduction at C-20 required NADH or NADPH with a preference for NADH. NADPH favoured formation of the 20α-alcohol while NADH favoured formation of the 20β-epimer. Clomiphene citrate selectively inhibited the 20α-reduction.

Oxidation of ketones to esters (Baeyer-Villiger oxidations) are well known in microbial metabolism. Long chain aliphatic ketones, simple cyclic ketones, monoterpenes and steroids serve as substrates for this reaction.[1] While the electron transport system in the monoterpene biooxidation has been thoroughly studied,[2-6] little is known about the corresponding systems utilized in steroid oxidations. Prairie and Talalay studied the lactonization of ring D in 17-oxosteroids by a partially purified enzyme from *P. lilacinum*.[7] They found that atmospheric oxygen was incorporated in the testololactone formed from 4-androstene-3,17-dione. The reaction showed an absolute requirement for NADPH and was insensitive towards cyanide, chelating agents and several metal ions. The C_{17-20}-lyase and steroid esterase activities in purified enzyme preparations from *Cylindrocarpon radicicola* have been studied by Rahim and Sih.[8] Esterase-free lyase preparations transformed progesterone into testosterone acetate in good yield and Nakano and co-workers demonstrated that atmospheric oxygen was incorporated in the 17β-position.[9] The reaction required NADPH and the effects of metal ions and inhibitors were similar to those observed for the ring D lactonization.

The 20-oxopregnane side chain cleavage in cell-free extracts from *P. lilacinum* has recently been shown to proceed *via* the same pathway as in *C. radicicola* and other microorganisms.[8,10-15] This reaction is accompanied by reduction of the 20-oxo group, and it has been suggested that the 20-reductase(s) compete with the side chain cleaving enzyme for the C_{21} steroid substrate.[16,17] The present paper describes assay conditions for the 20-oxopregnane side chain cleavage as well as 20(α + β)-reduction. Effects of metal ions, inhibitors, and substrate structure have also been studied.

violet. Clomiphene citrate: 1(*p*-2-diethylaminoethoxyphenyl)-1,2-diphenyl-2-chloroethylene dihydrogen citrate; progesterone: 4-pregnene-3,20-dione; 17α-acetoxyprogesterone: 17α-acetoxy-4-pregnene-3,20-dione; 17α-hydroxyprogesterone: 17α-hydroxy-4-pregnene-3,20-dione; testololactone: 17α-oxa-4-androstene-3,17-dione; testosterone: 17β-hydroxy-4-androsten-3-one.

Radioactive steroids. [7-^{3}H]Progesterone (specific activity 16 Ci/mmol) and [21-^{14}C] progesterone (specific activity 0.050 Ci/mmol) were obtained from New England Nuclear Corp., Boston, Mass, They were purified by TLC before use.

[7-^{3}H,21-^{14}C]17α-Hydroxyprogesterone was prepared by enzymatic 17α-hydroxylation of labelled progesterone.[18] The following procedure was used: Five male Sprague-Dawley rats (200 – 230 g) were killed by a blow to the head. The testes were removed, decapsulated and washed with ice cold 0.06 M Tris-HCl pH 7.2, containing 5 g of NaCl, 0.3 g of KCl, 0.3 g of $CaCl_2$, 0.3 g of $MgSO_4.7H_2O$, and 2 g of glucose per litre. The testes were homogenized with one volume of the medium in a Turmix household mixer for 60 s at +4 °C. Twenty ml of the homogenate were transferred into a beaker and 50 μCi of [7-^{3}H]progesterone + 20 μCi of [21-^{14}C]-progesterone in 30 μl of ethanol and 20 mg of NADPH were added. The mixture was stirred in air at 37° for 45 min. The reaction was terminated by the addition of 1 ml acetic acid. After addition of 50 μg each of unlabelled progesterone, 4-androsten-3,17-dione, 17α-hydroxyprogesterone, 20α-hydroxy-4-pregnen-3-one, and testosterone, the mixture was extracted three times with one volume of ethyl acetate. The ethyl acetate extract was washed with 1 M NaOH, 8 % $NaHCO_3$ and water and was evaporated to dryness.

The extract was defatted by partition between 70 % methanol and hexane and subjected to TLC on Silica gel GF_{254} (system I). The zone containing 17α-hydroxyprogesterone + 20α-hydroxy-4-pregnen-3-one was isolated, acetylated with acetic anhydride in pyridine and subjected to a second TLC in the same system. The ^{3}H radioactivity in the 17α-hydroxyprogesterone zone corresponded to a yield of 25 %. The 17α-hydroxyprogesterone was rechromatographed on Al_2O_3 GF_{254} 0.5 % ethanol in benzene as solvent. It moved as a single homogenous band. Its radiochemical homogeneity was established by crystallization to constant specific activity.

In the substrate solutions the radioactive compounds were diluted with unlabelled steroids dissolved in ethanol. For progesterone the final radioactivity corresponded to 18 000 – 100 000 cpm ^{3}H per 0.319 μmol steroid in 10 μl of ethanol. The corresponding figure for 17α-hydroxyprogesterone was 2 500 cpm ^{3}H 0.319 μmol steroid in 10 μl of ethanol.

Other reagents. Progesterone, 20α-hydroxy-4-pregnen-3-one, and 20β-hydroxy-4-pregnen-3-one were purchased from Ikapharm Ltd, Ramat-Gan, Israel; 5α-cholestane, 17α-hydroxyprogesterone, testosterone, and 4-androstene-3,17-dione from Sigma Chemical Co, St Louis, Mo, and 17α-acetoxyprogesterone, 17α,20α-dihydroxy-4-pregnen-3-one, and 17α,20β-dihydroxy-4-pregnen-3-one from Steraloids Inc., Pawling, N. Y. All steroids were checked for purity by TLC and/or GLC.

Clomiphene citrate was kindly donated by Draco, AB, Lund, Sweden. It contained 60 % of the *cis* and 40 % of the *trans* epimer.

Other chemicals were of reagent grade and were treated as described previously.[19]

Chromatographic systems. TLC on Silica gel GF_{254} (system I) and on Al_2O_3 GF_{254} (0.5 % ethanol in benzene as solvent); GLC on OV-17 and GC-MS were carried out as previously described.[19] Steroid silyl ether mixtures were quantitatively analyzed by GLC using 2.5 % XE-60 as stationary phase.

Growth of organism and preparation of cell-free extracts. P. lilacinum NRRL 895 was grown on Czapek-Dox medium, induced with progesterone, washed and frozen as described previously.[19] Cell-free extracts were prepared by high speed grinding with glass beads followed by centrifugation at 100 000 *g*.[20,21] The crude 100 000 *g* supernatant contained endogenous cofactors sufficient for a limited degree of C_{17-20}-lyase activity and minor amounts of testosterone. Extracts free from cofactors and steroids were prepared by gel filtration through a 300 mm × 15 mm i.d. Sephadex G-25 column connected to a LKB Uvicord II UV recorder and a fraction collector. Extracts free from steroids were prepared by passing the sample through an Amberlite XAD-2 column.

Incubations of steroids with cell-free extracts. The procedures for incubation and extraction of the reaction mixture have been described previously.[10] The steroid substrates were added in 10 µl of ethanol per ml of enzyme preparation. Inhibitors and metal salts were added as solutions in 0.06 M Tris-HCl adjusted to pH 7.2. If not otherwise stated, the transformations were carried out using crude 100 000 *g* supernatants with [7-^{3}H,21-^{14}C]progesterone as substrate for 60 min at 26 – 28 °C.

Steroid analysis. Quantitative analysis was made by TLC and liquid scintillation counting as previously described.[10] The variation between individual samples in duplicate incubations is given in Table 1. When [7-^{3}H,21-^{14}C] progesterone was the substrate, blank values due to tailing or non-enzymatic reactions were rather small. Thus, after incubation with boiled extracts + NADPH, 98.0 % of the total ^{3}H radioactivity on the TLC plate was found in the progesterone fraction, 0.9 % in the 4-androstene-3,17-dione fraction, 0.3 % in the 20($\alpha+\beta$)-hydroxy-4-pregnen-3-one fraction, 0.2 % in the testosterone fraction, and 0.6 % in the "testololactone" fraction. However, with [7-^{3}H,21-^{14}C]17α-hydroxyprogesterone as substrate there were considerable blank values, especially in the zone more polar than 17α-hydroxyprogesterone. When unacetylated blank samples were chromatographed, 0.9 % of the ^{3}H radioactivity was found in the 4-androstene-3,17-dione fraction, 88.4 % in the 17α-hydroxyprogesterone fraction, 6.6 % in the testosterone fraction, 3.4 % in the 17α,20($\alpha+\beta$)-dihydroxy-4-pregnen-3-one fraction and 0.6 % in the most polar fraction. Due to contamination of the testosterone fraction with substrate, samples from incubations with [7-^{3}H,21-^{14}C]17α-hydroxyprogesterone were analyzed before and after acetylation. Blank corrections were made in all assays.

The reactions were terminated at a stage when still large amounts of C_{21} steroids remained in the mixture. This will explain the low or insignificant amounts of testololactone detected.[15]

Protein assays were made by the biuret method.[22]

Identifications. The steroid metabolites were identified by their chromatographic and mass spectrometric properties as free steroids, acetates, and silyl ethers and by their ^{3}H/^{14}C ratios.[10,19] In the GC-MS, 17α,20α-dihydroxy-4-pregnen-3-one and its 20β-epimer were analyzed as 20-acetates and as *O*-methyloxime silyl ether derivatives.

RESULTS

Assay conditions. The C_{17-20}-lyase activity had its optimum between pH 7.2 and 7.6. 20-Reduction was maximal at pH 6.4 (Fig. 1). The time-course of the transformation of progesterone is shown in Fig. 2. The concentration of 20($\alpha+\beta$)-hydroxy-4-pregnen-3-one was maximal at about 60 min and then decreased. The formation of C_{19} steroids still continued after 180 min.

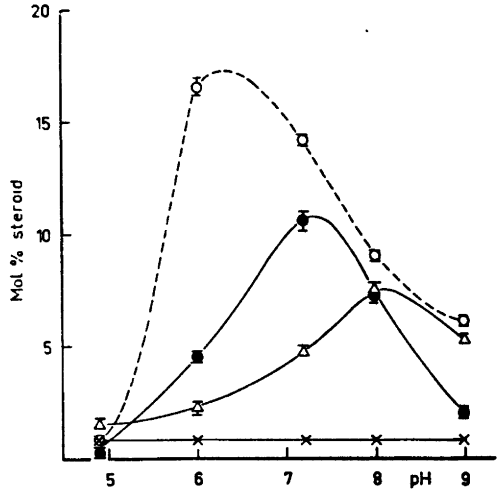

Fig. 1. pH/activity relationship for the side chain cleavage and the 20($\alpha+\beta$)-reduction of progesterone by cell-free preparations from *P. lilacinum*. Crude 100 000 *g* supernatants. Initial concentration of progesterone 2.90×10^{-4} M and of exogenous NADPH 1.21×10^{-3} M. 20($\alpha+\beta$)-Hydroxy-4-pregnen-3-one ○; testosterone ●; 4-androstene-3,17-dione△; "Compound T" (tentatively identified as testololactone) ×.

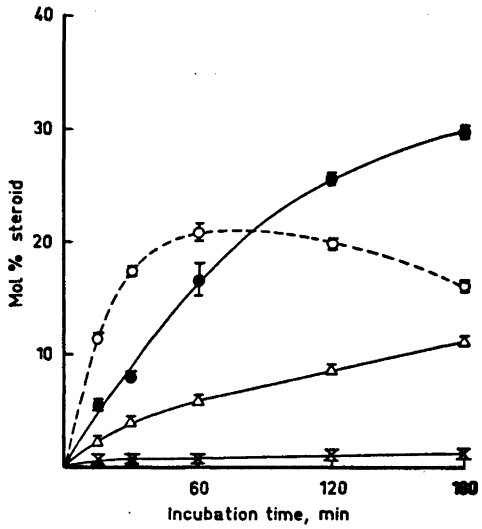

Fig. 2. Time-course of the side chain cleavage and the 20(α+β)-reduction of progesterone by cell-free preparations from *P. lilacinum*. Crude 100 000 *g* supernatant. Initial concentration of progesterone 2.90×10^{-4} M and of exogenous NADPH 1.34×10^{-3} M. 20(α+β)-Hydroxy-4-pregnen-3-one ○; testosterone ●; 4-androstene-3,17-dione △; "Compound T" (tentatively identified as testololactone) ×.

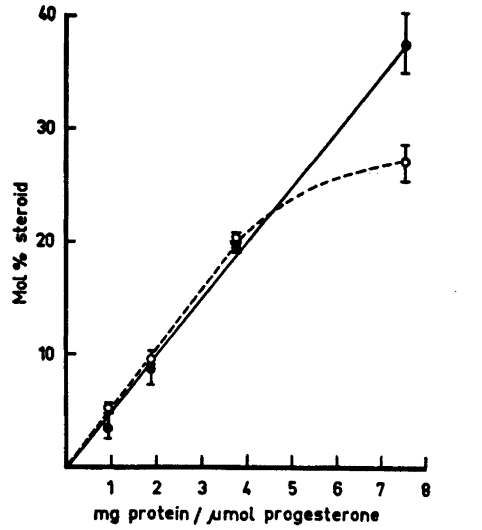

Fig. 3. Effect of the enzyme/substrate ratio on the side chain cleavage and the 20(α+β)-reduction of progesterone by cell-free preparations from *P. lilacinum*. Crude 100 000 *g* supernatant. Initial concentration of exogenous NADPH 1.10×10^{-3} M and of progesterone 2.66×10^{-4} M in the first three points and 1.33×10^{-4} M in the last point (7.52 mg protein/μmol progesterone). Total side chain cleavage ●; total 20-reduction ○.

The side chain cleavage as well as the 20-reduction was linear with the enzyme/substrate ratio up to about 4 mg/μmol (Fig. 3).

Substrate specificity. Progesterone and 17α-hydroxyprogesterone were substrates for the C_{17-20}-lyase and the 20(α+β)-oxidoreductase activities (Table 2). 17α-Acetoxyprogesterone yielded no detectable metabolites (by GLC and TLC).

The metabolites of 17α-hydroxyprogesterone were identified after isolation by TLC in system I (triple run). One half of the 17α,20-dihydroxy-

Table 2. Transformation of progesterone and 17α-hydroxyprogesterone by cell-free preparations from *P. lilacinum*.

[a] Crude 100 000 *g* supernatant. [b] Crude 100 000 *g* supernatant after passing Amberlite XAD-2. P indicates progesterone as substrate, 17 17α-hydroxyprogesterone. Initial concentrations of progesterone and 17α-hydroxyprogesterone 2.90×10^{-4} M and of exogenous NADPH 1.33×10^{-3} M.

Table 3. R_F- and t_R values for the 20-epimeric 17α,20-dihydroxy-4-pregnen-3-ones as free alcohols, 20-acetates and O-methyloxime silyl ether derivatives.

	R_F-value, system I		t_R-value (5α-cholestane = 1.00)
	Double run	Triple run	1.5 % SE-30, column temp. 240 °C, carrier gas flow 32 ml/min
17α,20α-Dihydroxy-4-pregnen-3-one	0.12	0.20	
17α-Hydroxy,20α-acetoxy-4-pregnen-3-one	0.37		1.47
O-Methyloxime silyl ether derivative of 17α,20α-dihydroxy-4-pregnen-3-one			1.49
17α,20β-Dihydroxy-4-pregnen-3-one	0.16	0.28	
17α-Hydroxy,-20β-acetoxy-4-pregnen-3-one	0.29		1.39
O-Methyloxime silyl ether derivative of 17α,20β-dihydroxy-4-pregnen-3-one			1.41

4-pregnen-3-one fraction was acetylated and rechromatographed in the same system (double run). R_F-Values and t_R-values are given in Table 3. The "atypical" behaviour of the 20α-acetate with greater chromatographic mobility than the 20β-epimer is noteworthy. TLC and GLC behaviour and mass spectra of the metabolites were in close agreement with those of authentic reference compounds.

Cofactor requirements. The crude 100 000 *g* supernatant contained endogenous cofactors sufficient for a certain degree of C_{17-20}-lyase activity. In such extracts this activity was stimulated by NADPH as well as by NADH (Table 4). Extracts purified by gel filtration were inactive without cofactors. In such extracts the C_{17-20}-lyase activity showed an absolute requirement for NADPH. Addition of FMN

caused a slight increase in the stimulatory effect of NADPH (Table 4).

The 20-reduction in crude 100 000 *g* supernatants and in purified extracts required NADPH or NADH (Tables 4 and 5). NADH was more effective in stimulating the 20-reduction than was NADPH. NADH favoured formation of the 20β-epimer in all types of extracts. Clomiphene citrate selectivity inhibited the 20α-reduction.

Effects of metal ions. The C_{17-20}-lyase activity was strongly suppressed by Hg^{2+}, Cu^{2+} and

10^{-3}M concentrations of KCN, NaN_3, NaF, EDTA, and 8-hydroxyquinoline had no significant effects on side chain cleavage or 20-reduction. Crude 100 000 *g* supernatants were used. Initial concentration of progesterone was 2.66×10^{-4}M and of exogenous NADPH 1.10×10^{-3} M. The incubations in experiment 13 were performed in darkness.

Zn^{2+} and to a lesser degree also by Ni^{2+} (Table 6). Fe^{2+} slightly stimulated the activity in extracts purified by gel filtration.

The 20($\alpha+\beta$)-reduction was strongly inhibited by Hg^{2+}, Cu^{2+} and Zn^{2+}. A slight suppression of the activity was achieved by Ni^{2+}, Co^{2+} and Mn^{2+} ions.

Effects of inhibitors. The enzyme preparation was preincubated with inhibitors 15 min before the addition of steroid and NADPH. The effects of inhibitors are shown in Table 7. The C_{17-20}-lyase activity was insensitive towards CO and 10^{-3} M concentrations of CN^-, N_3^-, and F^-. Methylene blue, phenazine metosulphate, and *p*-hydroxymercuri benzoate were strong inhibitors. Ferron and 1,10-phenantroline had a significant inhibitory effect whereas EDTA and 8-hydroxyquinoline were inactive.

The reduction at C-20 was inhibited by 10^{-3} M CN^- and by ferron, phenazine metosulphate, methylene blue, and *p*-hydroxymercuri benzoate, whereas the other inhibitors tested were without effects.

DISCUSSION

Progesterone and 17α-hydroxyprogesterone but not 17α-acetoxyprogesterone were substrates for the side chain cleavage in *P. lilacinum*. Side chain splitting enzymes from microorganisms in general have a very broad substrate specificity. It has previously been reported that whole cells of *P. lilacinum* split the side chain from different 20-oxosteroids in the 5α-pregnane, 5β-pregnane, 4-pregnene, 5-pregnene and 1,4-pregnadiene series.[11,23]

Crude 100 000 *g* supernatants contained endogenous cofactors sufficient for a limited degree of side chain cleavage, and addition of exogenous NADPH or NADH further increased the activity. In contrast to crude extracts, extracts purified by gel filtration showed an absolute requirement for NADPH. The stimulatory effect of NADH in crude extracts (see also paper I in this series [19]) might be explained by hydrogen transfer to endogenous $NADP^+$, thereby increasing the NADPH levels. The occurrence of transhydrogenases in microorganisms is well known.[24] It should be mentioned that stimulation by NADH due to transhydrogenation has been reported for the side chain cleavage of cholesterol by adrenal mitochondria.[25]

From a wealth of information on microbial and mammalian oxygenases it might be assumed that flavin participates in the side chain cleavage in *P. lilacinum*, at least in the oxidation of NADPH. In accordance with this assumption FMN caused a slight increase in the stimulatory effect of NADPH. It should be mentioned that participation of FMN in the oxidation of NADH as well as in the oxygenation of the substrate has also been established in the NADH-de-

pendent lactonization of camphor by highly purified enzymes from *Pseudomonas putida*.[6]

An iron-sulphur protein might also participate in the side chain cleavage studied. Thus heavy metals known to combine with the sulphur moiety as well as substances reacting with Fe^{2+} inhibited the reaction. Ni^{2+} was also inhibitory, which might be due to a similarity in the ionic radii of Ni^{2+} and Fe^{2+}.[26] A similar effect can be expected from Co^{2+} and in fact inhibition by Co^{2+} was observed in one experiment. Addition of Fe^{2+} slightly stimulated the side chain cleavage in purified extracts but was ineffective in crude 100 000 *g* supernatants. It is noteworthy that the effects of Fe^{2+} and Fe-reacting agents differ from those presented for the ring D lactonization in *P. lilacinum* enzyme preparations and the side chain cleavage in *C. radicicola*.[7,8] In those studies Fe^{2+} and 1,10-phenantroline were inactive. An explanation for the discrepancy might be found in the higher degree of purity of the enzymes used in those studies. Early studies by Gunsalus and co-workers indicated the participation of a non-heme iron protein in the camphor lactonization.[3] Thus addition of Fe^{2+} generally stimulated and bipyridine inhibited the reaction. The effect of Fe^{2+} was, however, less reproducible. In a later study using a reconstituted, extensively purified system devoid of iron, added Fe^{2+} and bipyridine were without effect.[6] The lack of effect of Fe^{2+} in the purified system could be due to the "ferredoxin-flavodoxin replacement phenomenon", *i.e.* replacement of the non-heme iron protein in the electron transport chain by an iron-free flavoprotein such as flavodoxin.[6,27]

Cytochrome P-450 has been shown to be the terminal oxidase protein in the mammalian 20-oxopregnane side chain cleavage as well as in a large number of mammalian and microbial hydroxylations.[28–30] However, the insensitivity to heme-reacting inhibitors excludes participation of cytochromes in the side chain cleavage of *P. lilacinum*. In the camphor lactonizing system no heme-proteins have been found and the reaction catalyzed by this system was insensitive to CO, CN^- and N_3^-.[3] Insensitivity to CN^- and N_3^- has also been demonstrated for 20-oxopregnane side chain cleavage by whole cells of *Nocardia restrictus*[31] and by enzyme preparations from *C. radicicola*.[8] D-Ring lactonization in enzyme preparations from *P. lilacinum*[7] and lactonization of cyclohexanone in cell-free extracts from *Nocardia opaca*[32] are also known to be insensitive towards CN^- and N_3^-. Obviously the "biochemical Baeyer-Villiger oxidations" belong to a class of oxygenases which do not utilize cytochromes as terminal oxidase.

The side chain cleavage occurred with a concomitant and efficient reduction in the C-20 position. Crude 100 000 *g* supernatants contained endogenous cofactors sufficient for a limited degree of side chain cleavage but not for a simultaneous 20-reduction (Table 4, see also paper I in this series[19]). Addition of exogenous NADH of NADPH increased the side chain cleavage and simultaneously 20-reduced metabolites appeared. Initial exogenous cofactor levels higher than those necessary for a maximal side chain cleavage did not affect that reaction but further stimulated the 20-reduction. In the early stages of incubations excess of NADPH was present and the amounts of 20-alcohols and C_{19} steroids increased simultaneously (Fig. 2). When a larger part of the NADPH was oxidized, the concentration of 20-alcohols levelled off and later even decreased while the C_{19} steroid concentration still increased. El-Tayeb and co-workers suggested a competition between C_{17-20}-lyase and 20-oxidoreductase enzymes for the 20-oxo-C_{21} steroids.[16,17] The results given above show that the level of reduced pyridine nucleotide is an important limiting factor for the 20-reduction. With an excess of NADPH or NADH also "good" lyase substrates such as progesterone yield considerable amounts of 20-alcohols together with the side chain cleavage products.

Purified microbial 20-oxidoreductases are known to possess a pronounced pyridine nucleotide specificity. NADPH is the specific cofactor for the 20α-oxidoreductase in *Actinomyces roseochromogenus* and the 20β-oxidoreductase in *Curvularia lunata*, while the crystallized 20β-oxidoreductase from *Streptomyces hydrogenans* is NADH-specific.[33–35] The 20(α + β)-reduction in *P. lilacinum* was more effeciently stimulated by NADH than NADPH. NADH favoured formation of the 20β-epimer. Interestingly clomiphene citrate selectively inhibited the 20α-reduction.

Acknowledgement. The GC-MS analysis was carried out at the Department of Chemistry I, Karolinska Institutet, Stockholm, Sweden.

Fungal Extractives. VIII.* Two Sesquiterpene Furans from *Lactarius*

GÖRAN MAGNUSSON,[a] SVANTE THORÉN,[a] JAN DAHMÉN[b] and KURT LEANDER[b]

[a] Organic Chemistry 2, The Lund Institute of Technology, Chemical Center, Box 740, S-220 07 Lund 7, Sweden and [b] Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

The structures and relative configurations of two sesquiterpene furans (*8* and *9*) isolated from *Lactarius vellereus*, *L. pergamenus*, and *L. helvus* have been determined with the help of standard spectroscopic methods and computer analysis of lanthanide-induced chemical shifts. Evidence that *8* and *9* are artifacts formed during the isolation procedure is presented.

Hydroazulenic sesquiterpenes with a *gem*-substituted cyclopentane ring were reported (without stereochemical details) for the first time by Nozoe *et al.*[2] (compounds *1* and *2*). Five more compounds with this carbon skeleton have since been reported: Velleral[3] (*3*) and two lactones[4,5] (*4* and *5*) from *Lactarius vellereus* and *L. pergamenus*; lactarorufins A[6] (*6*) and B[7] (*7*) from *L. rufus*. The hydroazulene *2* has also been found in *L. necator* and its relative configuration determined (Fig. 1).[8]

* Part VII, see Ref. 1.

We now report the structures and relative configurations of two sesquiterpene furans (*8* and *9*) from *L. vellereus*, *L. pergamenus*, and *L. helvus* (Russulaceae).

Compound *8* was shown by ^{13}C NMR (15 C and 19 H) and mass spectrometry (M^+ at *m/e* 232) to have the molecular formula $C_{15}H_{20}O_2$. Its IR spectrum revealed the presence of a hydroxyl group, a *gem*-dimethyl group (ν_{max} 1390 and 1385 cm^{-1}) and a furan ring (ν_{max} 1540 and 880 cm^{-1}). The ^1H NMR spectrum showed that the furan ring is disubstituted with substituents in the 3 and 4 positions (signals at δ 7.37 and 7.10 ppm)[9,10] and that the hydroxyl group is attached to a tertiary carbon atom next to the furan ring (two doublets centered at δ 4.34 ppm with $J_1 = 11.0$ and $J_2 = 1.4$ Hz). In addition to the signals from the *gem*-dimethyl group there was a broadened three-proton signal (δ 1.71 ppm), which was assigned to a methyl

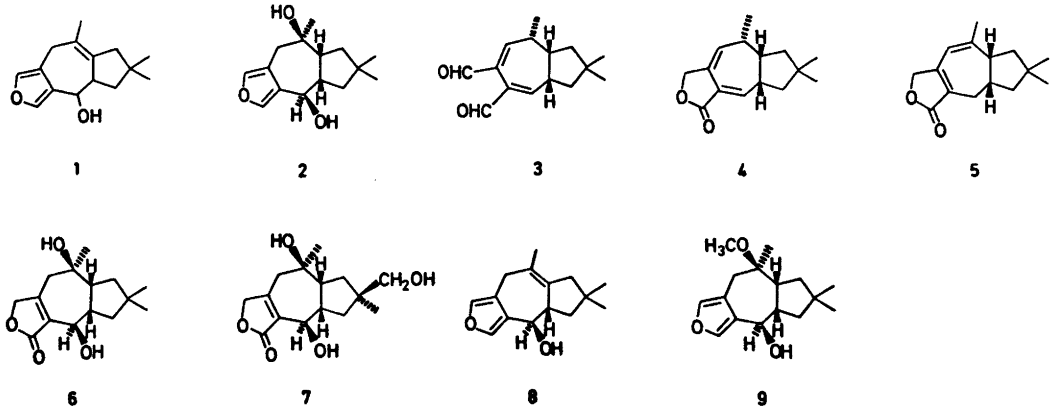

Fig. 1.

group situated on a double bond. From the ^{13}C NMR data (Table 1) it was established that *8* is a tricyclic compound with a tetrasubstituted double bond, with three primary, three secondary, two tertiary and one quaternary carbon atoms and, in addition, with furan ring carbon atoms. Extensive ^{1}H NMR decoupling experiments established the structure and relative configuration of *8* (Fig. 2). The ^{1}H NMR shifts

reported here for *8* are in close agreement with those reported for *1*[2], except for the furan protons which appear at δ 7.37 and 7.10 ppm (in $CDCl_3$) instead of at 7.72 and 7.04 ppm (solvent not reported). The specific rotation for *8* is +123° (in methanol) instead of +69.5° (solvent not reported) for *1*.[2] In spite of these differences it seems probable that the compounds *1* and *8* are identical.

Compound *9* was shown by the same techniques as used for *8* to be a tricyclic molecule with a 3,4-disubstituted furan ring and a secondary alcohol group next to this ring. The molecular formula ($C_{16}H_{24}O_3$) implied a formal addition of one molecule of methanol to *8*. Compound *9* is devoid of sp^2 carbon atoms other than those constituting the furan ring (^{13}C NMR data in Table 1) and possesses four primary, three secondary, three tertiary, and two quaternary carbon atoms. From these data, including ^1H NMR chemical shifts and integrals, a probable structure could be constructed. There are eight configurational isomers I–VIII (Fig. 3) of this structure to be considered.

Extensive decoupling experiments did not solve the stereostructure of *9*, but revealed two important facts: The protons H_3 and H_4 (see formula I in Table 2) showed *vicinal* coupling of $J = 4.0$ Hz reflecting an approximate dihedral angle of either 50° or 135° as judged from the Karplus curves;[11] the protons H_3 and H_2 were coupled with $J < 0.5$ Hz. The dihedral angle in this *cis*-allylic coupling system should then be close to 0°.[12,13] (The decoupling experiments were run in $CDCl_3$ with D_2O added. The coupling constants were unchanged in CCl_4 solution). The IR spectrum of *9* (0.0027 M solution in CCl_4) showed only one band (3430 cm^{-1}) in the hydroxyl stretching region. This indicates an intramolecular $OH\cdots OCH_3$ bond and thus that the hydroxy and methoxy groups are on the same side (*cis*) of the seven-membered ring. The intramolecular hydrogen bond in combination with the two possible dihedral angles between H_3 and H_4 requires the bridgehead hydrogens to be *cis*. This still, however, leaves two possible isomers, compounds I and IV.

Another approach to the stereochemical problem was tried. A ^1H NMR spectrum of *9* in CCl_4 containing Yb(fod)$_3$, (fod = 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedionate), showed induced chemical shifts but these did not establish the relative configuration of *9*. A newly developed computer program [14] (*cf.* also Ref. *15*) was used to calculate the expected lanthanide-induced chemical shifts for isomers I–VIII. Since conformational changes may occur in *9* in the presence of the Yb(fod)$_3$ complex, no assumptions regarding hydrogen bonding or dihedral angles were made. From Dreiding models the Cartesian coordinates in an arbitrary coordinate system of the hydrogens $H_1 - H_{23}$ were determined. Twenty-eight cases were included (four conformers of each of the *cis*-ring junction isomers I–IV, and three of each *trans*-ring junction isomer V–VIII). These sets of figures together with the experimental lanthanide-induced chemical shift values

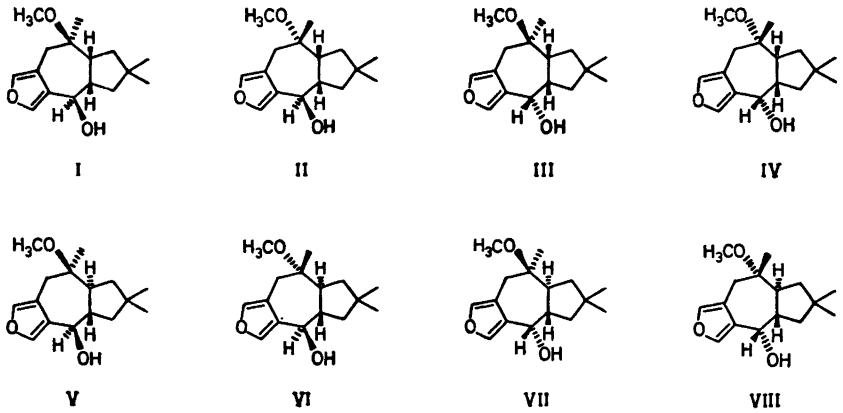

Fig. 3.

were used as input parameters in the program. Association of the shift reagent with the furan oxygen was neglected [16] and an association with the methoxy oxygen could be ruled out by the relatively small observed shift difference for the methyl group ($H_{12}-H_{14}$). The shifts of the methyls and the methoxy group were calculated as mean values of their proton shifts and a single position was chosen for the freely rotating methoxy group. Unequivocal assignments of the protons H_4 and H_9, H_{10} and H_{11}, and of the methyl group protons $H_{15}-H_{17}$ and $H_{18}-H_{20}$ were not possible and permutations of these three assignment pairs were therefore made. Only approximate values for the experimentally-induced chemical shifts of the four methylene protons (H_5-H_8) of the cyclopentane ring could be estimated and these were used with reduced weight in the computer program. A threefold potential barrier for oxygen–carbon rotation was assumed (in analogy with the calculations in Ref. 15) and the relative populations of the three rotamers of the hydroxy group were adjusted to best fit.

Four isomers (III, IV, VII, VIII) could be excluded in the initial calculations. Cases which gave agreement factors (R) [17] higher than 25 %, and cases with R-values between 20 % and 25 % and ytterbium–oxygen distances (d) far outside ($d > 5.77 \ldots . 1.87 > d$ Å) reasonable limits (*ca.* 3.2–2.2 Å)[18] were rejected. There remained eight cases, two conformers of each isomer I, II, V, and VI, with R-values in the interval 13.6–19.5 % and with acceptable Yb–O distances. It was realised that there need not necessarily be only a single conformer present even though this was the case in the absence of the Yb complex (^{1}H NMR, ^{13}C NMR, IR). Mixed conformer populations of the four isomers were therefore used in the second calculation. One isomer (I) gave a very low agreement factor (R = 6.0 %; d = 2.22 Å) for a mixture of the boat and chair conformations in a ratio of *ca.* 55:45 (Fig. 4). Agreement factors for the three other isomers (II, V, VI) did not improve in this second calculation and could be rejected with high statistical significance (> 99.5 %).[17,19] Experimental and calculated shifts for I are presented in Table 2. Isomer I is one of the two derived by the independent reasoning above. In view of the complexity of the twentythree proton system some uncertainty in the calculation results cannot be excluded. However, in combination with the spectroscopic evidence the calculations firmly establish the relative configuration of the furan alcohol *9*.

[a] Only roughly estimated shifts (± 50 Hz).

Interestingly the stereostructure found for *9*, with the *cis*-fused hydroazulene ring system and

the methyl group [$-CH_{3(12-14)}$] *trans* to the bridgehead hydrogens is the same as in other basidiomycete sesquiterpenes (see, *e.g.*, Fig. 1) and has the same relative configuration of the hydroxyl bearing carbon as in compounds *2*, *6*, *7*, and *8*.

It should be pointed out that compounds *8* and *9* may not be native to the *Lactarius* species investigated. The procedure used for the isolation of *8* and *9* was different from that used for the dialdehydes velleral (*3*), isovelleral,[10] and the two lactones *4* and *5*. *Methanol* was used instead of hexane [3] for extraction. Carbon tetrachloride extraction of the methanolic phase gave *8* and *9*, but neither the two dialdehydes (*cf.* Ref. 20) nor the two lactones were detected (TLC). On the other hand *8* and *9* were not obtained when hexane was used for extraction. It thus seems probable that *8* and *9* were formed during the work-up process. In order to test this possibility the mushrooms were ground with *ethanol* instead of methanol. From this extract there were isolated *8* and an *ethyl* ether (*10*), homologous to *9*. The methyl ether *9* was not detected. This finding is a strong indication that compound *9* at least, and probably also *8* are artifacts. Their formation by an enzymatically-assisted reaction sequence would seem more plausible than a pure chemical one since no stereoisomers of *8* and *9* were detected. The nature of the precursors of these compounds is of course important but, at this stage it is premature to consider this topic.

EXPERIMENTAL

The ^1H NMR spectra were recorded on a Varian XL-100 instrument with ^{13}C NMR capability and Fourier transform equipment. Mass spectra were recorded on an LKB 1100 instrument.

Isolation procedure. Fresh fungi (*Lactarius vellereus, L. pergamenus, L. helvus*) were ground with methanol and the mixture was pressed with Celite in a fruit press (Hafico). The aqueous filtrate was evaporated at room temperature to half its volume, diluted with water to the original volume and then extracted with three portions of carbon tetrachloride. The residue obtained on evaporation of the solvent was chromatographed on a silica gel column. Elution with benzene – ether (9:1) and then light petroleum – ether (2:1) gave the furan compounds *8* and *9*.

Furan alcohol 8. Recrystallisation from hexane at −20 °C gave *8*, m.p. 34 – 44 °C; $[\alpha]_D^{22}$ +123° (*c* 0.6, methanol), $[\alpha]_D^{22}$ +123° (*c*. 0.6, chloroform); IR: ν_{max} ($CHCl_3$) 3600, 1535 (furan), 1385 and 1368 (*gem*-CH_3), 1049 and 875 (furan) cm^{-1}; UV, nm (ε): λ_{max} (ethanol) 208.5 (ε 8200); ^1H NMR: δ_{TMS} ($CDCl_3/D_2O$) 7.37 (1H, d of d $J_1 = 1.7$ and $J_2 = 1.4$ Hz; $-CHOD-fur-H$), 7.10 (1 H, m; $-CH_2-fur-H$), 4.34 (1 H, d of d $J = 11.0$ and 1.4 Hz; $fur-CHOD-CH-$), 3.35 (1 H, d broad $J = 17.0$ Hz; $fur-HCH-C=C-$), 2.91 (1 H, d $J = 17.0$ Hz; $fur-HCH-C=C-$), 2.86 (1 H, m; $-CHOD-CH-$), 2.19 2.01)1 H each, d of d broad $J = 16.0$ Hz; $=C-HCH-C-$), 1.88 (1 H, m $J = 13.0$, 8.0 and 1.5 Hz; $-CH-HCH-C-$), 1.51 (1 H, d of d $J = 13.0$ and 9.0 Hz; $-CH-HCH-C-$), 1.71 (3 H, s broad; $CH_3-C=C-$), 1.11 0.87 (3 H each, s; *gem*-CH_3-CH_3) ppm. ^{13}C NMR data see Table 1. MS (70 eV): *m/e* 232 (M^+ 1 %; $C_{15}H_{20}O_2$), 214 (100), 199 (80), 197 (28), 158 (57), 129 (29), 128 (30).

Furan alcohol 9. Recrystallisation from ether at −20 °C gave *9*, m.p. 65 – 66 °C; $[\alpha]_D^{22}$ +6.0° (*c* 0.6, methanol); IR: ν_{max} ($CHCl_3$) 3360, 1538 (furan), 1390 and 1375 (*gem*-CH_3), 1110, 1060, 880 (furan) cm^{-1}; UV, nm (ε): λ_{max} (ethanol) 216 (4400); ^1H NMR: δ_{TMS} ($CDCl_3/D_2O$) 7.38 (1 H, d $J = 1.6$ Hz; $-CHOD-fur-H$), 7.17 (1 H, m $-CH_2-fur-H$), 4.61 (1 H, d $J = 4.0$ Hz; $fur-CHOD-CH-$), 3.21 (3 H, s; $-OCH_3$), 2.97 (1 H, m t $J = 18.0$, 1.2 and 1.0 Hz; $fur-HCH-C-$), 2.78 (1 H, d of d $J = 18.0$ and 1.4 Hz; $fur-HCH-C-$), 2.80 2.68 (1 H each, m; bridgehead protons), 1.70 (1 H, d of d $J = 10.5$ and 8.0; $-CH-HCH-C-$), 1.10 – 1.55 (3 H, m), 1.19 (3 H, s; $CH_3-C(OCH_3)-$), 1.06 (6 H, s; *gem*-CH_3-CH_3) ppm. ^{13}C NMR data, see Table 1. MS (70 eV): *m/e* 246 ($C_{16}H_{24}O_3$, $M^+ - H_2O$ 63 %), 231 (36), 215 (63), 214 (100), 199 (100), 158 (72).

Furan alcohol 10. Fresh fungi (*L. vellereus*) were ground with ethanol and the mixture was treated as described under *Isolation procedure*. Compound *10* was isolated by chromatography on a silica gel column with light petroleum – ether (3:1) as eluent. *10* was obtained as a viscous oil, $[\alpha]_D^{22}$ +5.6° (*c* 0.7, ethanol) with physical properties similar to those described for *9*, except for changes due to the ethoxy group.

Acknowledgements. We cordially thank Dr. P. Stilbs, Physical Chemistry 2, LTH, for invaluable guidance in computer techniques. Thanks are also due to Prof. B. Wickberg for stimulating discussions, Dr. T. Drakenberg for recording numerous NMR spectra and Dr. B. Thomas for linguistic criticism. This work was supported by a grant from the Swedish Natural Science Research Council. The XL-100 NMR instrument was provided by a grant from the Knut and Alice Wallenberg Foundation.

Oxidation of Lignin Model Compounds with Chlorine Dioxide and Chlorite. Reactions with Stilbenes

BENGT O. LINDGREN and TORSTEN NILSSON *

Swedish Forest Products Research Laboratory, Box 5604, S-114 86 Stockholm, Sweden

The reaction products from the oxidation of several different types of stilbenes with chlorine dioxide have been isolated and characterised. *trans*-Stilbene was oxidised to α,α'-epoxy-bibenzyl which then underwent rearrangement or was attacked by nucleophiles present in the reaction mixture. 4-Hydroxy-3,3',4'-trimethoxy-*trans*-stilbene was attacked mainly on its phenolic hydroxyl group, resulting in formation of polymers. Some veratraldehyde and veratric acid, as well as vanillin and vanillic acid was also formed by attack at the double bond. *cis*-2,3-Diphenyl-prop-2-en-1-ol gave mainly allylic oxidation products, whereas *cis*-2,3-di-(3,4-dimethoxyphenyl)-prop-2-en-1-ol mainly underwent oxidative cleavage into veratraldehyde and 3,4-dimethoxyphenacyl alcohol. The reaction paths are discussed.

Most of the model studies [1-4] of the reaction between lignin and chlorine dioxide have been performed with lignin model compounds which contain free phenolic groups, *e.g.* vanillin and guaiacol. Such studies are informative for the reactions of chlorine dioxide when used in the first bleaching stage of sulfate pulp. However, for the final stages of bleaching, where the main part of the chlorine dioxide reacts, these model compounds are of less relevance, since most of the phenolic groups in lignin evidently are oxidised during the earlier stages.

Final bleaching with chlorine dioxide gives pulps with high brightness. Chlorine dioxide thus reacts with the colour-giving elements of lignin. The chlorine dioxide oxidation of model compounds of such elements are therefore of greater interest than the reaction of phenols for the understanding of how the lignin residues react during the final bleaching. They may also be of interest for understanding the reactions of a first bleaching stage with chlorine dioxide.

The structure of these colour-giving elements are, however, unknown. They may include conjugated systems composed of carbonyl groups, double bonds, or aromatic as well as quinoid structures.

On this basis we have studied how chlorine dioxide reacts with models containing one type of these elements, *viz.* double bonds conjugated with benzene nuclei. Four different stilbene derivatives were chosen as models.

The action of chlorine dioxide on organic compounds is generally a complex process as the chlorine dioxide is primarily reduced to chlorine and chlorite [5,6] which may both react with the starting material, the intermediates, or the reaction products. Complicated reaction products are therefore expected from the chlorine dioxide oxidation of stilbenes.

RESULTS AND DISCUSSION

The stilbene derivatives chosen were *trans*-stilbene, *cis*-2,3-diphenyl-prop-2-en-1-ol, *cis*-2,3-di-(3,4-dimethoxyphenyl)-prop-2-en-1-ol, and 4-hydroxy-3,3',4'-trimethoxy-*trans*-stilbene.

Treatments with chlorine dioxide were carried out in aqueous *t*-butanol or dioxane solutions and in non-aqueous solutions (chloroform or carbon tetrachloride).

In a typical experiment chlorine dioxide solution was added in darkness at room temperature to the stilbene solution. The reaction products obtained were first separated into two fractions containing acidic and neutral compounds, respectively. The neutral part was fractionated

* Present address: Svenska Mejeriernas Riksförening u.p.a., Box 205, S-201 22 Malmö 1, Sweden.

further by column chromatography. If a subfraction contained two or more compounds, their respective yields were determined from the peak areas of the gas chromatograms ("GLC:s") or of the NMR spectra. The acid fractions were analysed by spectral methods and by GLC/MS after methylation.

trans-*Stilbene*. The chlorine dioxide treatment of *trans*-stilbene in carbon tetrachloride solution yielded the following main products: α-chlorobenzyl phenyl ketone (yield 43 %), *trans*-α,α'-epoxy-bibenzyl (yield 36 %), and α,α'-dichlorobibenzyl (yield 7 %). The presence of small amounts of benzil in the reaction mixture was also observed. The yields were estimated from the peak areas of the NMR spectrum and were substantiated by the isolation of the chloro ketone and the dichloro compound in amounts corresponding to those mentioned above. The isolated dichloro compound consisted mainly of the *racem.* form like the product obtained after chlorination of *trans*-stilbene.[7] The epoxide had mostly decomposed during the working-up procedure.

The first step in the oxidation of *trans*-stilbene in carbon tetrachloride is most likely an addition of chlorine dioxide to the aliphatic double bond, but subsequent steps are less obvious. The chloro ketone was evidently not formed *via* the epoxide since no chloro ketone was found after treatment of the epoxide with chlorine dioxide, chlorine, or a mixture of them.

When *trans*-stilbene was treated with chlorine dioxide in aqueous dioxane solution the formation of α-chloro-α'-hydroxybibenzyl (yield 44 %), diphenylacetic acid (15 %), α,α'-dihydroxybibenzyl (12 %, the *erythro* and *threo* isomers in about equal amounts), benzoic acid (5 %), benzoin (3 %), benzil (3 %), α,α'-dichloro-bibenzyl (3 %), and α-chloro-benzyl phenyl ketone (2 %) was detected.

The presence of *trans*-α,α'-epoxy-bibenzyl was not observed. However, this does not exclude the possibility that it was formed as an intermediate since it was found to be unstable in the reaction mixture. The α-chloro-α'-hydroxybibenzyl and α,α'-dihydroxybibenzyl may have been formed partly *via* the epoxide. Parts of the epoxide may also have rearranged into the diphenyl acetaldehyde which was then oxidised (probably by chlorite [10]) to the diphenylacetic acid.

cis-*2,3-Diphenyl-prop-2-en-1-ol*. When this stilbenol was treated with chlorine dioxide in carbon tetrachloride solution the main products were two allylic oxidation products *viz.* *cis*-2,3-diphenyl acrolein (yield 25 %) and *cis*-2,3-diphenyl-acrylic acid (yield 19 %). The other products found were benzaldehyde (11 %), 2,3-diphenyl-2-chloro-propan-1-ol-3-one (5 %), α-chloro-benzyl phenyl ketone (4 %), and *trans*-stilbene (0.5 %). *cis*-2,3-Diphenyl-acrylic acid might well have been formed by chlorite oxidation [10] of *cis*-2,3-diphenyl-acrolein. An addition of formaldehyde, which reacts rapidly with chlorite, but only slowly with chlorine dioxide [6] would then suppress the formation of the acid in favour of the aldehyde. We therefore investigated the possibility that chlorine dioxide in the presence of formaldehyde could be used for oxidation of allylic carbinol groups to aldehyde groups. In agreement with the assumption above, the yield of *cis*-2,3-diphenyl acrolein increased to 38 % in the presence of formaldehyde if the oxidation was carried out as described above in carbon tetrachloride solution. If the oxidation was performed in aqueous solution its yield was 27 % in the presence of formaldehyde and only 8 % in the absence of formaldehyde. Chlorine dioxide plus formaldehyde may then in special cases be a cheap reagent for oxidation of allyl alcohols to acroleins.

Chlorine dioxide oxidised *cis*-2,3-di-(3,4-dimethoxyphenyl)-prop-2-en-1-ol in aqueous *t*-butanol solution to 3,4-dimethoxy-phenacyl alcohol (yield 42 %), veratraldehyde (24 %), veratric acid (25 %), and 2,3-dichloro-2,3-di-(3,4-dimethoxyphenyl)-propan-1-ol (20 %). The same products were predominant when the oxidation was carried out in chloroform solution.

Thus, this oxidation involved mainly a cleavage of the aliphatic double bond. No evidence for an allylic oxidation was observed, which clearly distinguished the oxidation of this stilbene derivative from the oxidation of that containing no methoxyl group, *viz.* *cis*-2,3-diphenyl-prop-2-en-1-ol. The methoxylated model compound reacted faster with chlorine dioxide than the one without methoxyl groups. The methoxyl groups evidently promote chlorine dioxide addition to the double bond, rather than oxidation in the allylic position.

4-Hydroxy-3,3',4'-trimethoxy-trans-*stilbene.* The chlorine dioxide oxidation of this stilbene in chloroform solution gave only a low yield of identifiable products. These products were vanillic and veratric acid (total acid yield 10 %), veratraldehyde, monochlorinated veratraldehyde, and vanillin (each aldehyde in a yield less than 1 %). The main part of the reaction product consisted of a dark, probably polymeric material. The possibility that chlorine dioxide induced vinylic polymerization involving free radicals was excluded since only one mol of stilbene was consumed per mol chlorine dioxide (determined by UV-absorption spectrometry). This polymerisation was probably caused by oxidation of the phenolic hydroxyl group (*cf.* the polymerisation caused by chlorine dioxide oxidation of other phenols).[1-5]

No general pattern was found in the reactions of the four stilbenes with chlorine dioxide. Epoxidation, allylic oxidation, splitting of the aliphatic double bond, α-chloro ketone formation *etc.* were observed. The phenolic stilbene seemed to be attacked mainly at the free phenolic group.

The products from the oxidation of the methoxylated stilbenes with chlorine dioxide, however, suggest that the conjugated double bonds which possibly are present in the residual lignin, may be cleaved by the dioxide, forming carbonyl groups.

EXPERIMENTAL

General. Unless otherwise stated, the following methods were used. The chlorine dioxide treatment of the stilbenes were carried out at room temperature in darkness. NMR-spectra (in deuterio chloroform) were obtained on a Perkin-Elmer R12 (60 MHz); IR-spectra (in chloroform) on a Perkin-Elmer 237; and UV-spectra, on a Beckman DK-2; GLC on a Perkin-Elmer 800, 900 or F 30; and GLC/MS on a Perkin-Elmer 270. TLC:s were run on silica gel plates with chloroform, chloroform/methanol or toluene as solvents.

trans-Stilbene and chlorine dioxide

Oxidation by chlorine dioxide in carbon tetrachloride. Chlorine dioxide (9 mmol) in carbon tetrachloride (158 ml) was added to *trans*-stilbene (5 mmol, 900 mg) in carbon tetrachloride (10 ml). After 20 h, the reaction mixture gave the following NMR signals (in carbon tetrachloride solution) (their assignments are given in brackets): δ 3.83 s (*trans*-α,α'-epoxy-bibenzyl) relative peak area 10; δ 5.21 s (α,α'-dichloro-bibenzyl) area 2; δ 6.28 s (α-chloro-benzyl phenyl ketone) area 6; δ 7.0 – 7.6 m (aromatic protons of the products and of unreacted stilbene) area 125; δ 7.8 – 8.0 m (α-chloro-benzyl phenyl ketone) area 14. Calculations from the peak areas showed that the mixture consisted of about 46 mol % α-chloro-benzyl phenyl ketone, 36 % *trans*-α,α'-epoxy-bibenzyl and 7 % α,α'-dichloro-bibenzyl.

The mixture was chromatographed on a silica gel column with toluene as eluent. (The reaction mixture was found to contain only negligible amounts of acids). Five fractions were collected.

The following NMR signals of fraction 1 (evaporation residue 109 mg) were observed: δ 5.20 s (assigned to both the *racem.* and the *meso* form of α,α'-dichloro-bibenzyl) relative peak height 3; δ 6.88 s (unassigned) height 0.7; δ 7.14 s (assigned to the *racem.* form of α,α'-dichloro-bibenzyl) height 12.4; δ 7.20 – 7.45 m (assigned to *trans*-stilbene); δ 7.35 s (assigned to the *meso* form of α,α'-dichloro-bibenzyl), height 4; and δ 7.7 s (assigned to *trans*-stilbene) height 3. TLC of the fraction showed two spots which were indistinguishable from those of *trans*-stilbene and α,α'-dichloro-bibenzyl (the D,L and the *meso* forms of the latter were not separated).

The TLC and the NMR signals of fraction 2 (33 mg) were indistinguishable from those of an authentic sample of *trans*-stilbene epoxide and in accordance with those given by Ceccarelli *et al.*[11]

Fraction 3 (42 mg) was a mixture of the components in fractions 2 and 4.

Fraction 4 (422 mg) showed NMR and IR spectra indistinguishable from those of an authentic sample of α-chloro-benzyl phenyl ketone, and had a m.p. 65 – 67.5 °C (lit.[12] 68.5 °C).

Fraction 5 (122 mg) consisted of about two thirds diphenylacetaldehyde as shown by comparing its IR and NMR spectra with those of an authentic sample. The presence of NMR signals at δ 7.7 – 8.0, together with a GLC analysis of the crude product of another run, indicated the presence of small amounts of benzil.

Oxidation by chlorine dioxide in aqueous dioxane solution. A dioxane (350 ml)/water (265 ml) solution of *trans*-stilbene (10 mmol, 1.80 g) and chlorine dioxide (19 mmol) was kept for 2.5 days and was then partly evaporated to remove chlorine dioxide and most of the dioxane. The resulting solution was divided by extraction with a sodium hydrogen carbonate solution into an acid (0.31 g) and a neutral fraction (1.71 g).

The NMR spectrum of the acid fraction was run both before and after methylation with

diazomethane in absolute methanol. The methylated fraction was also analysed by GLC (3 % OV-17). By comparing the retention times and NMR signals obtained with those from benzoic and diphenyl- acetic acid the fraction was found to consist almost exclusively of these acids. Their yields were estimated from the NMR signals.

1.40 g of the neutral fraction was fractionated on a silica gel column with chloroform as eluent. The following fractions were taken:

Fraction 1 (74 mg) consisted of α,α′-dichlorobibenzyl (mainly the D,L form) as shown by NMR (*cf.* the experiment in carbon tetrachloride solution).

Fraction 2 (155 mg) was a mixture of α-chloro-benzyl phenyl ketone, benzil and an unidentified compound. Benzil and the chloro ketone were identified from GLC (OV-17, 145 °C, $R_T = 23$ and 31 min, respectively) and by comparing the NMR and IR spectra cf these fractions with those of authentic compounds. The yields of the two compounds were estimated by GLC and their NMR integral signals.

Fraction 3 (772 mg) gave NMR signals at δ 7.20, 7.18, 7.09, 7.05 (four s, 10 H); δ 4.95 (s, 1 H); δ 4.88 (s, 1 H) and δ 3.21 (broad s, 1 H). Its IR spectrum showed strong absorption at 3550 cm^{-1} and 3400 cm^{-1} due to the presence of hydroxyl groups. The spectral and chromatographic properties of this fraction were equal to those of the mixture of the *erythro* and *threo* forms of α-chloro-α′-hydroxy-bibenzyl obtained by chlorination of *trans*-stilbene in a dioxane/water system.

Fraction 4 (60 mg). Its TLC and spectra (NMR and IR) were indistinguishable from those of an authentic sample of benzoin. Its m.p. was 131.4 – 132.5 °C (lit.[13] 137 °C).

Fraction 5 (103 mg). Two of its TLC spots were coloured red when sprayed with lead tetraacetate solution followed by Schiff's reagent (suggesting the presence of α-diols). Its IR spectrum showed absorption (3590 cm^{-1}) indicating hydroxyl groups. Its NMR spectrum showed the following main peaks: δ 7.21 (s, 10 H); δ 4.76 (s, 2 H); and 2.7 (broad s, 2 H), which correspond to the reported[14] data for *meso*-α,α′-dihydroxy-bibenzyl. An NMR signal at δ 4.61 was assigned to D,L-α,α′dihydroxy-bibenzyl (see fraction *6*).

Fraction 6 (104 mg). Its IR spectrum showed absorption at 3590 cm^{-1} and its TLC spots showed positive reaction with lead tetraacetate followed by Schiff's reagent. Its NMR spectrum showed signals at δ 7.20 – 7.05 (4 s, 10 H); 4.62 (s, 2 H) and 3.0 (broad s, 2 H) and was assigned to D,L-α,α′-dihydroxy-bibenzyl.

cis-2,3-Diphenyl-2-propen-1-ol and chlorine dioxide

A carbon tetrachloride solution of *cis*-2,3-diphenyl-2-propen-1-ol (6.2 mmol) and chlorine dioxide (6.6 mmol) was reacted for 18 h and was then washed with ice water and evaporated to dryness. The residue (1.6 g) was separated into neutral and acid components as usual by partition between sodium hydrogen carbonate solution and ether.

The acidic part consisted of *cis*-2,3-diphenyl-acrylic acid (yield 19 %, m.p. 174 – 175 °C, lit.[15] 172 – 173 °C, NMR indistinguishable from that of an authentic sample) contaminated with small amounts of benzoic acid which was observed by GLC/MS analyses of the fraction after diazomethane methylation.

An aliquot (90 %, *i.e.* 1.2 g) of the neutral fraction was eluted with chloroform from a silica gel column; five fractions (together 1.03 g) were collected.

Fraction 1 (400 mg) was rechromatographed on a silica gel column with hexane/toluene 1:1 as eluent. The separation was still incomplete, but *trans*-stilbene (0.5 %), α-chloro-benzyl phenyl ketone (4 %) and benzaldehyde (11 %) and small amounts of *cis*-2,3-diphenyl-acrolein were identified by NMR signals and TLC. The yields were estimated from the NMR integrals.

Fraction 2 (309 g) consisted of *cis*-2,3-diphenyl-acrolein (yield 25 %) m.p. 93.5 – 94.5 °C, lit.[16] 95 °C. NMR: δ 9.67 (s, 1 H); δ 7.4 – 7.1. (m, 11 H). TLC and GLC (OV-17, 3 %, 170 °C) showed that the fraction was practically pure. MS: *m/e* 208 (molecular ion, base peak), 207 (50 % of the base peak height), 192 (20), 179 (70), 178 (75), 165 (30), 152 (20), 105 (30) and 103 (45).

Fraction 3 (89 mg) contained according to NMR and TLC mainly *cis*-2,3-diphenyl-acrolein (see fraction *2*) and 2,3-diphenyl-2-chloro-propan-1-ol-3-one (see fraction *4*) but also an unidentified compound.

Fraction 4 (88 mg). Its IR absorption (3580 and 3450 cm^{-1} for hydroxyl group and 1675 cm^{-1} for keto group conjugated with double bond) and its NMR spectrum [δ 7.8 – 7.0 (m, 12 H); δ 4.1 (m, 2 H) and δ 2.95 (broad s, 1 H)] indicated that it consisted of 2,3-diphenyl-2-chloro-propan-1-ol-3-one (5 %).

Fraction 5 (144 mg) was a complicated mixture which contained, besides unidentified material, the chloro ketone from fraction 4 and small amounts of the starting material.

In other runs, *cis*-2,3-diphenyl-prop-2-en-1-ol (5.2 mmol) was reacted with chlorine dioxide (5.2 mmol) in the presence and in the absence of formaldehyde (6 mmol). The reaction was carried out in carbon tetrachloride (as above) and in a mixture of *t*-butanol/water (7:10). The reaction product was analysed by GLC. For results, see text.

cis-2,3-Di-(3,4-dimethoxyphenyl)-prop-2-en-1-ol.[17]

Oxidation by chlorine dioxide in aqueous t-butanol solution. Chlorine dioxide (1 mmol) in

water (18.5 ml) was added to *cis*-2,3-di-(3,4-dimethoxyphenyl)-prop-2-en-1-ol (1 mmol) in *t*-butanol (18.5 ml). After one hour the reaction mixture was partly evaporated to remove most of the *t*-butanol, diluted with water and extracted with methylene chloride.

The acidic part (44 mg, yield 25 % calc. as veratric acid) of the extract was methylated with diazomethane and analysed with GLC/MS (OV-1). It consisted of methyl veratrate contaminated with a small amount of veratraldehyde.

The neutral part (280 mg) was fractionated with chloroform on a silica gel column. The yields were estimated from the NMR integral signal of the raw product and were in agreement with the fraction weights. The following fractions were collected:

Fraction 1 (40 mg). Its NMR, GLC, MS, and TLC properties were indistinguishable from those of an authentic sample of veratraldehyde.

Fraction 2 (23 mg) was a mixture of veratraldehyde, an unknown compound and 3,4-dimethoxy-phenacyl alcohol (see fraction *3*).

Fraction 3 (82 mg) consisted according to TLC mainly of one substance which from its NMR and IR spectra appeared to be 3,4-dimethoxy-phenacyl alcohol [NMR: δ_a 7.42 (d, 1 H); δ_b 7.40 (q, 1 H); δ_c 6.85 (d, 1 H); δ_d 4.80 (broad s, 2 H); δ_e 3.90 (s, 6 H); δ_f 3.55 (broad s, 1 H, disappeared upon addition of D_2O). $J_{ab}=1.5$ Hz, $J_{bc}=8.5$ Hz. IR: a broad absorption at 3450 cm^{-1}, a sharp absorption at 1670 cm^{-1} and doublets at 1590 cm^{-1} and 1510 cm^{-1}]. The NMR and TLC of the acetylated fraction were indistinguishable from those of an authentic sample of 3,4-dimethoxyphenacyl acetate.[18]

Fraction 4 (27 mg) consisted of a mixture of 3,4-dimethoxy-phenacyl alcohol and the dichloro-compound from fraction *5* below.

Fraction 5 (30 mg) had the same NMR spectrum [δ 6.75 (m, 3 H); δ 4.95 (s, 1 H); δ 4.35 (s, 2 H) and δ 3.80 (s, 6 H)] as 2,3-dichloro-2,3-di-(3,4-dimethoxyphenyl)-propanol, which was obtained by chlorination of *cis*-2,3-di-(3,4-dimethoxyphenyl)-prop-2-en-1-ol in carbon tetrachloride solution (see below).

Fraction 6 (37 mg) was a mixture of constituents which were not identified, except for a small amount of the dichloro compound of fraction 5.

Oxidation by chlorine dioxide in chloroform solution. An experiment similar to that above was carried out in chloroform. The reaction products were veratric acid (22 %) and a neutral part which did not differ significantly (as shown by TLC and NMR) from the reaction products obtained when the experiment was done in *t*-butanol/water.

Chlorination. cis-2,3-Di-(3,4-dimethoxyphenyl)-prop-2-en-1-ol was also reacted with chlorine. When the reaction was performed in carbon tetrachloride, the residue gave after chromatography on silica gel with chloroform, a fraction (56 %) which was identical with the dichloro compound from fraction 5 above, according to NMR signals and TLC.

When performed in *t*-butanol/water, the chlorination gave the chlorohydrine as the main product.

4-Hydroxy-3,3',4'-trimethoxy-stilbene[19] and chlorine dioxide

To the stilbene (2 mmol) in chloroform (20 ml) was added chlorine dioxide (2.6 mmol) in chloroform (40 ml). The reaction mixture immediately turned reddish, and subsequently yellow. After 20 min the mixture was evaporated to dryness and a viscous oil (727 mg) was obtained which was analysed by GLC (5 % OV-1, 100→200 °C, +4 °C/min) and MS. Veratraldehyde, vanillin, monochlorinated veratraldehyde, and veratric acid were identified. All yields were less than 1 %. The acidic part (34 mg, 9 % if calculated as veratric acid) was methylated with diazomethane and analysed with GLC (5 % OV-1, 180 °C) and MS. Methyl veratrate was by far the predominant compound. IR analysis gave the same result. The ester was contaminated with small amounts of veratraldehyde, monochlorinated veratraldehyde, and monochlorinated methyl veratrate (GLC/MS). The neutral fraction consisted of dark polymeric material.

In other experiments, chloroform solutions of the stilbene (10 mM) and chlorine dioxide (5 mM) were mixed in different proportions (10/1, 10/2, 9/4 and 1/1 ml/ml) and were diluted to 25 ml. After 10 min and after 24 h, samples of the solutions were diluted 100 fold and UV-spectra were taken. For results, see text.

α,α'-Epoxy-bibenzyl[20] and chlorine dioxide, chlorine, or a mixture of chlorine dioxide and chlorine

A carbon tetrachloride solution (50 ml) of α,α'-epoxy-bibenzyl (1 mmol) and chlorine dioxide (1 mmol) was reacted for 20 h at room temperature in darkness. Two similar experiments were performed with chlorine (1 mmol) and a mixture of chlorine dioxide (1 mmol) and chlorine (0.5 mmol), respectively.

The reaction mixtures were partly evaporated and analysed by NMR.

Only negligible alternations seemed to have occurred, and no α-chloro-benzyl phenyl ketone was detected.

Conversion of Penta-*O*-acetyl-1,2-*O*-isopropylidene-*aldehydo*-D-glucose into Tri-*O*-acetyl-2,3-dideoxy-*aldehydo*-D-*erythro*-hex-2-enose

KLAUS BOCK AND CHRISTIAN PEDERSEN

Department of Organic Chemistry, Technical University of Denmark, DK-2800 Lyngby, Denmark

Acetolysis of 3,5,6-tri-*O*-acetyl-1,2-*O*-isopropylidene-α-D-glucofuranose gave 1-*R*-1,3,4,5,6-penta-*O*-acetyl-1,2-*O*-isopropylidene-*aldehydo*-D-glucose (*2*) and a small amount of the 1-*S*-isomer (*3*). Treatment of (*2*) with hydrogen bromide in acetic acid yielded mainly *trans*-4,5,6-tri-*O*-acetyl-2,3-dideoxy-*aldehydo*-D-*erythro*-hex-2-enose (*4*). Besides, a small amount of 2,3,5,6-tetra-*O*-acetyl-D-glucofuranose was formed. The mechanism of the formation of (*4*) is discussed.

Both Brigl and Zerrweck [1] and Schlubach *et al.*[2] have shown that acetolysis of tri-*O*-acetyl-1,2-*O*-isopropylidene-α-D-glucofuranose (*1*) gives a crystalline product in good yield, and several structures were proposed for this product. In a recent paper Magnani and Mikuriya [3] have shown by NMR spectroscopy that the product is an *aldehydo*-D-glucose derivative, (*2*) or (*3*).

We have also studied the acetolysis of (*1*) and obtained the same product as that described by the above mentioned authors. In addition, we isolated a minor amount of an isomeric material. Proton NMR spectra of the two products (Table 1) show that they both contain an isopropylidene group and five *O*-acetyl groups in agreement with structures (*2*) and (*3*), as found by Magnani and Mikuriya [3] for the major product. The low field position of H4 in both products rule out the furanose structure proposed by Schlubach *et al.*[2] The main product (*2*) has $J_{12}=2.2$ Hz whereas J_{12} of the minor product (*3*) is 3.8 Hz. This indicates a *trans* orientation of H1 and H2 in (*2*) and a *cis* orientation in (*3*). On this basis the configuration of C1 in (*2*) is assumed to be *R* and that of (*3*) is *S*. ^{13}C NMR data (Table 2) further confirm the structures.

In connection with other work (*2*) was treated with hydrogen bromide in acetic acid for 24 h. This gave an unstable mixture which was hydrolysed with water and silver carbonate. From the product thus obtained was isolated 45 % of the unsaturated aldehyde (*4*). Besides, small amounts of the 6-bromo-aldehyde (*5*) and of tetra-*O*-acetyl-D-glucofuranose (*6*) were obtained. The structure of (*4*) was proved through ^{1}H and ^{13}C NMR spectra (Tables 1 and 2) and

Table 2. ^{13}C NMR spectra in deuteriochloroform. Chemical shifts are in ppm relative to internal tetramethylsilane.

[a] Assignment may be reversed.

by comparison with an authentic sample prepared according to Fraser-Reid and Radatus.[4]

The first step in the reaction of (*2*) with hydrogen bromide in acetic acid is probably a protonation followed by loss of acetic acid to give (*8*) which could rearrange to (*9*). The latter type of ion has been described by Barton *et al.*[5] Since (*9*) contains a good leaving group it could react with bromide ions to give (*11*) which, in the presence of HBr, would be in equilibrium with (*12*). NMR spectra directly on the reaction mixture show no aldehydic protons, indicating that (*12*) is favoured; this also applies to the equilibrium between (*9*) and (*10*) (see below). Reaction of the latter with bromide ions could result in elimination of bromine and formation of (*13*). Alternatively, (*9*) would be in equilibrium with (*10*) which, by a similar reaction with bromide ions, could give (*13*), bromine, and acetone. It is also possible that (*10*) could yield (*11*) by migration of bromine from C1 to C2 with simultaneous displacement of acetone. Bromoacetone was found in the reaction product, and it is probably formed in a secondary reaction between the bromine eliminated from (*10*) or (*12*) and acetone.

The 2-deoxy-aldehyde (*13*) is probably the final product from the reaction of (*2*) with hydrogen bromide in acetic acid. It loses acetic acid to some extent when the reaction mixture is worked up, and the elimination is completed by the subsequent treatment with water and silver carbonate.

When (*2*) was allowed to react with hydrogen bromide in acetic acid for only 1 h the 2-bromo-aldehyde (*7*) could be isolated together with a rather large amount of (*6*). The latter is probably formed by hydrolysis of the ions (*9*) or (*10*) during work up, followed by acyl-migration and ring-closure. After 24 h reaction (*7*) could not be found. Since it must arise from (*11*) by elimination of acetic acid during work up the latter would appear to be present in the initial stage of the reaction, as proposed above, but disappears later as it is converted into (*13*) *via* (*12*).

When pure (*7*) was treated with HBr in acetic acid for 24 h in the presence of acetone it gave (*4*) after work up. In the absence of acetone the main product was unreacted (*7*) and only small amounts of (*4*) were formed. The first step must be addition of HBr to (*7*) followed by elimination of bromine which then reacts with acetone.

The conclusion is that (*13*) is formed from (*9*) or (*10*) *via* the 2-bromo-compound (*11*), or to some extent, directly from (*10*) by elimination of bromine and acetone.

Pure (*7*) was prepared in good yield by reaction of (*4*) with bromine followed by elimination of HBr by treatment with silver carbonate and water.

EXPERIMENTAL

Melting points are uncorrected. Proton NMR spectra were obtained on Varian A-60 and HA-100 instruments, ^{13}C spectra on a Bruker WH-90 instrument. Thin layer chromatography (TLC) was performed on silica gel PF_{254} (Merck); for preparative work 1 mm layers on 20 × 40 cm plates were used. Spots were visualized with UV light or by charring with a hot wire.

*Acetolysis of tri-*O*-acetyl-1,2-*O*-isopropylidene-α-*D*-glucofuranose.* A mixture of (*1*) (40.0 g) and powdered, anhydrous $ZnCl_2$ (11.0 g) was dissolved in acetic anhydride (80 ml) by stirring at 0 °C. The solution was kept at +5° for 24 h. Ice and water was then added and the mixture was stirred until the oily precipitate had crystallized. The product was then filtered off, washed with water and dried. The crude material (40 g) was shown by NMR spectroscopy to be a mixture of (*2*) and (*3*) in a *ca.* 12:1 ratio. Two recrystallizations from ethanol gave 29.0 g (56 %) of 1-*R*-1,3,4,5,6-penta-*O*-acetyl-1,2-*O*-isopropylidene-*aldehydo*-D-glucose (*2*), m.p. 136–138 °C. Further recrystallizations from ethanol and from ether-pentane did not change the m.p., $[\alpha]_D^{22}$ +58.3° (*c* 3.0, $CHCl_3$). (Reported[1] m.p. 141 °C, $[\alpha]_D$ +60.5°).

In two experiments fractional crystallization of the material in the mother liquor gave a small amount of the 1-*S*-isomer (*3*), m.p. 139–140 °C, $[\alpha]_D^{20}$ −19.0° (*c* 1.4, $CHCl_3$). (Found: C 50.94; H 6.22. Calc. for $C_{19}H_{28}O_{12}$; C 50.88; H 6.29). Attempts to repeat the isolation of (*3*) from the mother liquors of other preparations of (*2*) were unsuccessful.

Preparation of (*2*) from (*1*) by treatment with acetic anhydride and sulfuric acid, as described by Schlubach *et al.*,[2] gave lower yields than those obtained when zinc chloride was used.

Reaction of (*2*) with hydrogen bromide in acetic acid

For 24 h. The isopropylidene-derivative (*2*) (820 mg) was dissolved in 8 ml of glacial acetic acid containing 30 % HBr and the solution was kept at room temp. for 24 h. It was then diluted with dichloromethane and washed with water and aqueous sodium hydrogencarbonate, dried ($MgSO_4$) and evaporated. The residue in acetone

(6 ml) was stirred over night with water (0.5 ml) and silver carbonate (1.0 g). Filtration through activated carbon and evaporation gave a crude product which was separated into 3 fractions by preparative TLC using ether-pentane (3:1) as eluent. The fastest moving fraction gave 35 mg (6.5 %) of the 6-bromo-compound (*5*) as a *cis-trans* mixture in a 2/5 ratio. The product was a syrup and the two isomers could not be separated, λ_{max} 217 nm (ethanol). Proton and ^{13}C NMR data are given for the *trans* isomer in Tables 1 and 2.

The next fraction gave 220 mg (45 %) of 4,5,6-tri-*O*-acetyl-2,3-dideoxy-*aldehydo*-D-*erythro-trans*-hex-2-enose (*4*) as a syrup, $[\alpha]_D^{20}$ +25.3° (*c* 4.3, $CHCl_3$), λ_{max} 217 nm (ethanol) (reported [4] $[\alpha]_D$ +12.0°, λ_{max} 217 nm). A 2,4-dinitrophenylhydrazone had m.p. 111–112 °C (reported [4] m.p. 108–109 °C). Proton and ^{13}C NMR data were identical with those of an authentic sample prepared according to Ref. 4.

The slowest moving fraction gave 53 mg (9 %) of tetra-*O*-acetyl-D-glucofuranose (*6*) which was acetylated to give the pentaacetate as a 1:2 mixture of the α- and β-anomers. Proton NMR spectra were identical with those of previously described compounds.[6]

Isolation of bromoacetone. A solution of (*2*) (5.0 g) in HBr–HOAc (8 ml) was kept for 24 h at room temp. Dichloromethane (75 ml) was then added and the solution was washed twice with water and once with aqueous $NaHCO_3$ and dried ($MgSO_4$). The dichloromethane was distilled off through a Vigreux column and the residue was distilled at 50 mmHg pressure. A fraction of 1.0 g was collected, b.p. 40 °C. This lachrymatory product consisted of a mixture of bromoacetone and acetic acid. A proton NMR spectrum gave signals at δ 2.4 and 4.0 and a ^{13}C spectrum at 27.1, 35.7, and 199.5 ppm. Both spectra were identical with those of an authentic sample.

B. For 1 h. A solution of (*2*) (1.0 g) in HBr-HOAc (10 ml) was kept for 1 h at room temp. and then worked up. The product was treated with water and silver carbonate as described above. The crude product (737 mg) was purified by preparative TLC (ether-pentane 3:1). The main fraction (332 mg) was a mixture of (*4*) and the 2-bromo-compound (*7*) as seen from an NMR spectrum. The ratio between (*4*) and (*7*) varied from 1:2 to 1:5 in different experiments. It was not possible to separate the two compounds and (*7*) was therefore only identified by comparing proton NMR spectra of the mixture with those of pure (*7*) and (*4*).

Another fraction gave 170 mg (22 %) of (*6*), characterized through its NMR spectrum.

4,5,6-Tri-O-*acetyl-2-bromo-2,3-dideoxy*-aldehydo-D-erythro-*hex-2-enose* (*7*). To a solution of (*4*) (350 mg) in tetrachloromethane (5 ml) was added a solution of bromine (0.08 ml) in tetrachloromethane (1.4 ml) and the solution was kept for 10 min at room temp. Silver carbonate (2.0 g) and acetonitrile (15 ml) were then added and the mixture was stirred for 1 h. The silver salts were filtered off, the solvent was removed and the residue was dissolved in dichloromethane and washed with aqueous $NaHCO_3$, dried and evaporated. Preparative TLC (ether-pentane 3:1) gave 195 mg (43 %) of (*7*) as a syrup, $[\alpha]_D^{20}$ +24.5° (*c* 0.84, $CHCl_3$), λ_{max} 235 nm (ethanol). The compound was unstable and a satisfactory analysis could therefore not be obtained. NMR spectral data (Tables 1 and 2) were in agreement with the structure. A mass spectrum showed no molecular peak, but two peaks at *m/e* 290 and 292, resulting from loss of acetic acid and showing that bromine was present.

Conversion of (*7*) *to* (*4*). A mixture of (*7*) (260 mg), HBr in acetic acid (3 ml), and acetone (0.2 ml) was kept for 24 h at room temp. It was then worked up and treated with silver carbonate and water as described above. The product was separated into two fractions by preparative TLC. The fast moving fraction gave 20 mg (8 %) of the 6-bromo-aldehyde (*5*). The slow moving fraction gave 107 mg (49 %) of (*4*). Both products were characterized through their NMR spectra.

Microanalyses were performed by Novo Microanalytical Laboratory.

Diels-Alder Reactions of 2,4-Cyclohexadienones.* III.** Formation of Stereoisomers in the Dimerization of an *o*-Quinol Acetate

KRISTER HOLMBERG

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

o-Quinol acetate *4*, which at 120 °C gives the *endo* Diels-Alder dimer *8*, at temperatures of 160 – 180 °C gives the C-5 stereoisomeric dimer *9* in addition to *8*. On heating at 160 – 180 °C *8* is also converted to *9*. When treated with ethanolic KOH, the diacetates *8* and *9* are hydrolyzed to give the stereoisomers *10* and *12*, respectively, the phenol *11* being formed as an additional product in both cases. The non-acetylated dimer *12* isomerizes at 160 – 180 °C to give dimer *10*. These results indicate that of the two acetylated dimers isomer *9* is thermodynamically more stable than isomer *8*, whereas the reverse seems to be the case for the corresponding non-acetylated dimers *12* and *10*, respectively. This behaviour can be understood by considering the bulkiness of the substituents at C-5 of the two types of dimers.

Acid hydrolysis of dimer diacetate *8* initially gives dimer *10*, which subsequently undergoes proton-catalyzed opening of the bicyclooctenone ring system to give phenol *13*. Similar treatment of the dimer diacetate *9* with acid effects, in addition to ester hydrolysis, aromatization of the unbridged ring followed by rearrangement of the bicyclooctenone system with the formation of phenol *16*.

In a number of papers the spontaneous Diels-Alder dimerization of 2,4-cyclohexadienones has been reported.[1–7] The reactions were found to proceed with a high degree of selectivity, only one of several conceivable dimerization products being obtained in each case. By using chemical, photochemical, and spectrometric methods,[4–8] as well as X-ray diffraction analysis,[9,10] all dimers so far investigated were shown to be *endo* forms with the same stereochemical and structural orientation.

The stereochemical orientation at C-5 and C-9 was interpreted as being due to steric approach control [11] in the dimerization, the most bulky substituent being directed away from the reaction center. This is illustrated by formula *5* for the dimer of the parent *o*-quinol (*1*) (6-hydroxy-6-methyl-2,4-cyclohexadienone) and by formula *7* for the dimer of the corresponding spirooxirane (*6*). Analogous configurations have been proposed for dimers of 2,4-cyclohexadienones carrying halogen atoms instead of hydroxyl groups in the 6-position.[12,13]

Contrary to *o*-quinols (type *1*) and spiro-epoxydienones (type *6*), *o*-quinol acetates such as *2* and *4* are comparatively stable at room temperature, but dimerize when heated at

* Part XIII in the series "Periodate Oxidation of Phenols".

** Part II, see Ref. 7.

120 °C.[14,3] Hydrolysis of the dimeric *o*-quinol acetates gave the free dimers which were identical with those obtained by spontaneous dimerization of the corresponding *o*-quinols (*1* and *3*), and, *vice versa*, acetylation of the latter dimers gave the dimerization products of the corresponding *o*-quinol acetates *2* and *4*. Since the structures of the non-acetylated dimers (*5* and *10*) were known,[6,10] these interconversions also established the structures of the dimeric diacetates, the dimer of *o*-quinol acetate *4*, for instance, possessing structure *8*.

FORMATION OF STEREOISOMERS IN THE DIMERIZATION OF *o*-QUINOL ACETATE *4*

In earlier work [3] it has been observed that in the dimerization of *o*-quinol acetate *4* at 120 °C which mainly yields the *endo* dimer *8*, m.p. 159 – 160 °C, small amounts of an isomeric by-product of m.p. 182 – 184 °C are also formed. It has now been found that the yield of the higher-melting compound increases if the heating temperature is raised above 120 °C (see below). According to a recent X-ray investigation [15] the product of m.p. 182 – 184 °C is the C-5 stereoisomer *9* of dimer *8*. Dimer *8* is a Diels-Alder adduct of two sterically identical molecules of monomer *4* ($S+S$ and $R+R$ enantiomers, respectively). The structure of *9* indicates that it is formed by Diels-Adler addition of $S+R$ enantiomers and of $R+S$ enantiomers of the monomer.

Fig. 1 shows the influence of temperature and heating time on the weight proportions of monomer *4*, dimer *8* and dimer *9* in the reaction mixtures. The proportions of the latter isomer increases with increasing temperature, optimum yields being obtained within the range of 160 – 180 °C. In a preparative experiment *9* was obtained in a yield of 60 % after heating of monomer *4* for 2.5 h at 165 °C.

At higher temperatures dimer *9* undergoes retro Diels-Alder reaction, cleavage being nearly complete; heating of *9* for 30 min at 205 °C thus gave 84 % of monomer *4*. Under the same conditions, the earlier reported [3] thermal cleavage of dimer *8* similarly produced the monomer in a yield of 79 %.

As indicated in Fig. 1, the reaction mixtures obtained on heating of monomer *4* further contained an "unidentified product", which predominated after 6 hours' heating at 185 °C (Fig. 1 c). The dark viscous oil obtained under the last-mentioned conditions probably was a mixture and was not further investigated. It may be noted that brief heating of *o*-quinol acetates at 450 °C has been reported [16] to produce monoacetates of substituted hydroquinones and catechols.

Dimer *9* was also formed when dimer *8* was heated just above its melting point (2.5 h at 165 °C); this isomerization can be interpreted to be due to retro Diels-Alder reaction of *8*, followed by recombination of the enantiomers of the monomer.

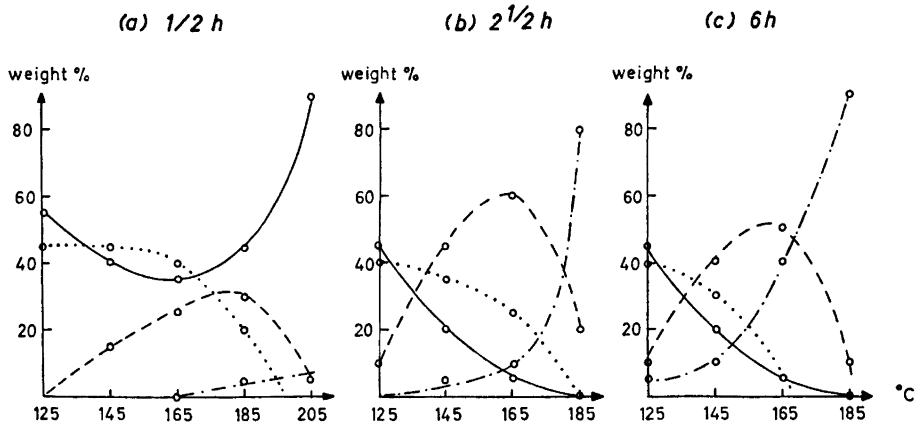

Fig. 1. Yields of products formed on heating of *o*-quinol acetate *4 vs.* temperature (*cf.* also Experimental). Compounds *4* (——), *8* (...), *9* (– – –) and unidentified product (–.–.–.).

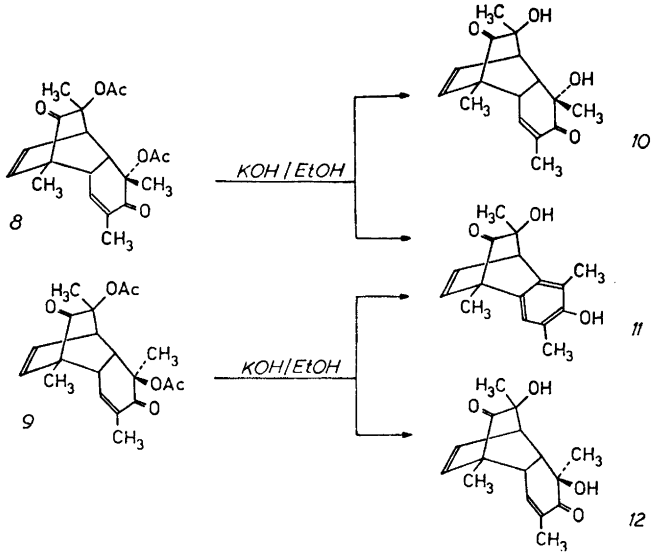
These findings indicate that the sterically favoured configuration at C-5 is that present in compound *9*, this isomer being thermodynamically more stable than *8*. Evidently, the methyl group at C-5 is less bulky than the acetoxy group, although in the latter substituent free rotation around the C-5 – O linkage is possible.

The formation of isomer *8* from the monomeric *o*-quinol acetate (*4*) obviously is kinetically controlled; this may be connected with the *endo* oriented acetoxy group of the dienophile providing additional π-electrons to the reacting double bond system.

Contrary to the configuration of C-5 that of C-9 is retained in the heat isomerization of *8*. In the formation of both isomers the C-9 acetoxy group is oriented towards the reaction center and the C-9 methyl group away from it. This may possibly be understood on the basis of a proposal made by Williamson *et al.*,[17] according to which *syn-anti* isomerism of Diels-Alder reactions is governed not only by steric factors but also by electronic factors: if the dienophile is a dipole, electrostatic forces will direct the most polarizable bridge substituent into a position *anti* to the ethylene bridge. The configurations at C-9 of dimers *8* and *9* are in accord with this view, the methyl groups, which are the less polarizable substituents, heading towards the C-1, C-4 ethylene bridge.

The behaviour of dimer *9* on alkaline hydrolysis is noteworthy (Scheme 1). As reported earlier, treatment of isomer *8* with ethanolic potassium hydroxide gives the phenolic compound *11*, in addition to the expected hydrolysis product, *i.e.* the non-acetylated dimer *10*.[3] The two compounds were formed in about equal yields. The ease of the base-catalyzed elimination of acetic acid in compound *8* has been interpreted to be due to a favourable *trans* relationship of H-4a and AcO-5 with *anti* elimination taking place.[7] In the C-5 stereoisomer (dimer *9*) H-4a and AcO-5 are in *cis* position and elimination must consequently proceed by a *syn* mechanism. According to a recent monograph on elimination reactions,[18] *syn* elimination in 6-membered rings takes place much less readily than *anti* elimination. Alkaline hydrolysis of dimer *9* was therefore expected to give the non-acetylated dimer *12* in high yield. Surprisingly, however, phenol *11* was formed as the major reaction product (68 %) on treatment with ethanolic potassium hydroxide and only minor amounts (9 %) of dimer *12* were obtained. The ease of elimination in both *8* and *9* may be due to initial abstraction of a proton from C-8a to give enolates which readily aromatize by loosing HOAc.



Scheme 1.

THERMAL BEHAVIOUR OF DIMERS *10* AND *12*

For comparison with the thermal behaviour of the acetylated dimers *8* and *9*, that of the corresponding free dimers *10* and *12* was also investigated. Dimer *12* (m.p. 147 – 149 °C), when heated at temperatures between 160 and 180 °C, readily isomerized to compound *10*. For instance, after 1 h at 160 °C 83 % of isomer *10* were obtained and no starting material was detected in the reaction product. This result indicates that in the case of the non-acetylated dimers isomer *10* is thermodynamically more stable than isomer *12*, while the reverse is true for the corresponding diacetates (*8* and *9*, respectively), as shown by the experiments discussed above.

Apparently, the greater stability of dimer *10* as compared to dimer *12* is due to the fact that in the former isomer the smallest C-5 substituent, *i.e.* the OH group, is *endo* oriented. This, of course, indicates that steric approach control is essential in the dimerization of the monomeric *o*-quinol (*3*) which arises when dimer *12* is heated as described above.

It may also be mentioned that no formation of an *exo* form of a 2,4-cyclohexadienone dimer has hitherto been reported.

Dimer *10* proved to be unstable when heated at 210 °C, *i.e.* 15 °C above its melting point, an isomeric compound of m.p. 163 – 165 °C being formed as a major product. Dimer *12* on similar heat treatment gave the same compound, the reaction obviously passing via isomer *10*. Wessely *et al.*[19,20] reported that at 280 °C dimer *10* gives small amounts of 6-hydroxy-5,6-dimethyl-2,4-cyclohexadienone as the product of an acyloin rearrangement of the primarily formed isomer *3*. It was recently found in this laboratory that a major product of the thermolysis at 280 °C is the above-mentioned compound of m.p. 163 – 165 °C.[21] Its structure is still unknown.

ACID-CATALYZED FORMATION OF PHENOLS *13* AND *16* FROM DIMER ACETATES *8* AND *9*, RESPECTIVELY

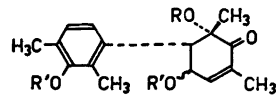
As mentioned earlier, dimer *12* is obtained in a very poor yield (9 %) by alkaline hydrolysis of its diacetate *9*, the phenolic compound *11* being formed predominantly. In an attempt to find a better method for the preparation of *12*, diacetate *9* was subjected to acid hydrolysis (7 h reflux with aqueous-ethanolic sulfuric acid) as previously used[14] for the preparation of dimer *5* from its diacetate. Under these conditions, *9* gave the desired *o*-quinol dimer *12* in a yield of 45 %. In addition, a phenolic compound (26 %, m.p. 205 – 206 °C) was obtained; it was not identical with phenol *11*.

Similar acid treatment of diacetate *8* produced, in addition to *o*-quinol dimer *10* (28 %), a phenolic product (46 %, m.p. 139 – 140 °C) which, unexpectedly, differed from both the aforementioned phenols.

The structures of the two new phenols are discussed in the following sections.

Phenol, m.p. 139 – 140 °C, from dimer diacetate 8. The compound, $C_{16}H_{20}O_4$, is isomeric with the dimeric *o*-quinols (*10*, *12*). Its UV and IR spectra indicated the presence of an aromatic ring, an α,β-conjugated keto group and hydroxyl groups. Treatment with Ac_2O/pyridine gave a diacetate showing the IR characteristics of both an aryl ester and an alkyl ester group, as well as remaining hydroxyl absorption. Acid-catalyzed acetylation[22] produced a triacetate, indicating that the last-mentioned hydroxyl group was a tertiary one. From the shift of the IR absorption peak due to the conjugated CO group from 1680 cm^{-1} (untreated phenol) and 1675 cm^{-1} (diacetate) to 1704 cm^{-1} (triacetate) it could be concluded that the tertiary hydroxyl group is located adjacent to the CO group (*cf.* Ref. 4, p. 2056).

These findings, as well as NMR data (see Exptl.), suggested structures *13*, *13a*, and *13b*



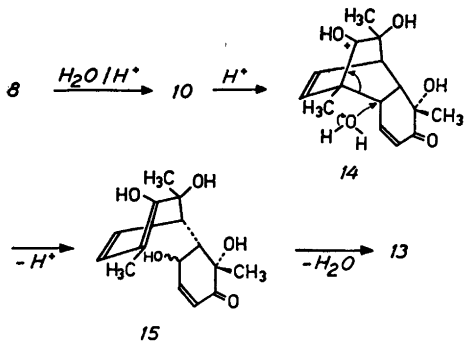
13 R=R'=H
13a R=H; R'=Ac
13b R=R'=Ac

for the phenol, its diacetate, and its triacetate, respectively.

It was found that the yield of dimer *10*, obtained in addition to the phenol *13*, decreased with increasing heating time, the yield of *13* simultaneously increasing. Furthermore, 7 h treatment of *10* under the hydrolysis conditions produced phenol *13* in a yield of 66 %, 15 % of unreacted *10* being recovered. These findings

indicated that dimer *10* is an intermediate in the formation of phenol *13*, the initial ester hydrolysis (*8*→*10*) being faster than the subsequent consumption of *10*.

The mechanism shown in Scheme 2 is proposed for the conversion of dimer *8 via 10* to phenol *13*. It is believed that protonation

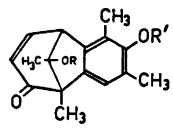


Scheme 2.

of the keto group at C-10 initiates ring opening at C-8a, a hydroxyl group being introduced at the latter carbon atom, as indicated in formula *14*. Acid-catalyzed elimination of water from the cyclohexadienol ring of the resulting intermediate *15* leads to the phenolic end-product *13*.

For the suggested conversion *14*→*15*, a few analogies have been found in the literature, *viz.* the acid-catalyzed formation of isocamphorquinone from camphorquinone [23] and the conversion of *endo* bornylamine into α-terpineol.[24]

Phenol, m.p. 205–206 °C, from dimer diacetate 9. This compound had the composition $C_{16}H_{18}O_3$ and was thus isomeric with phenol *11*. The strong red-shift of the UV maxima of its ethanolic solution which took place on addition of alkali indicated the presence of a phenolic group. The IR spectrum of the compound revealed a conjugated carbonyl group in addition to hydroxyl groups and an aromatic ring. Treatment with Ac_2O/pyridine gave a monoacetate, exhibiting IR absorptions at 1752 cm^{-1} (aryl ester) and at 3480 cm^{-1} (OH). Acetylation with $Ac_2O/HClO_4$ [22] esterified also the last-mentioned hydroxyl group, which must be tertiary. On the basis of these results, as well as of NMR data, structures *16*, *16a*, and *16b* are proposed for the phenol of m.p. 205–206 °C, its monoacetate, and its diacetate, respectively.



16 R=R'=H
16a R=H; R'=Ac
16b R=R'=Ac

Phenol *16* was also obtained by acid hydrolysis of the diacetate *17* of phenol *11*. However, the non-acetylated *o*-quinol dimer *12*, as well as phenol *11*, proved to be stable under the conditions of the acid hydrolysis. These findings suggest the following pathway for the formation of phenol *16* (Scheme 3).

Elimination of acetic acid from *9* accompanied by aromatization gives monoacetate *18*, the latter also being formed by partial hydrolysis of diacetate *17*. Protonation of the keto group of *18* induces two consecutive 1,2-shifts resulting in the formation of monoacetate *21* which is finally hydrolyzed to give phenol *16*.

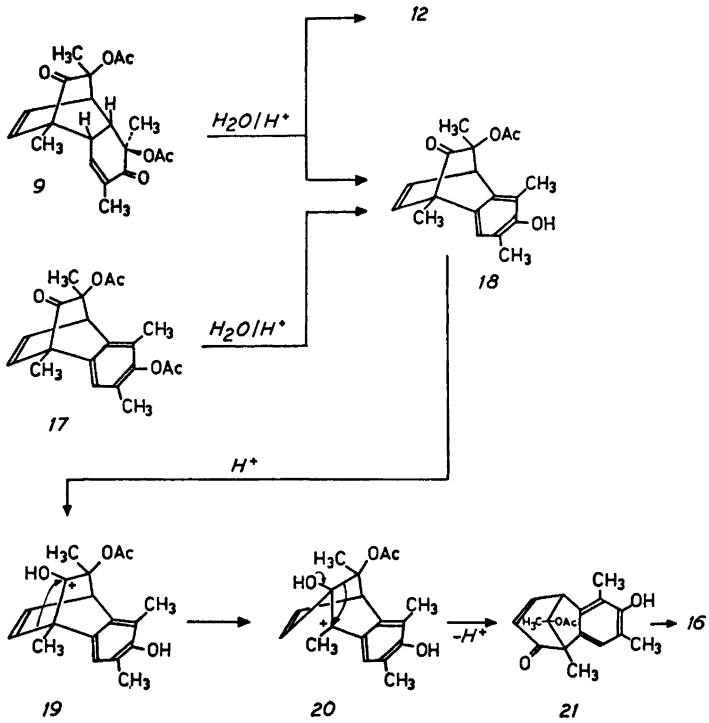
The assumption that the rearrangement takes place before the tertiary acetoxyl group is hydrolyzed, is based on the fact that neither the non-acetylated dimer *12*, which is the major product of the acid hydrolysis of *9*, nor the non-acetylated phenol *11* is affected under the conditions used. The role of the tertiary acetoxyl group is not clear; it might be considered that its $-I$ effect causes the electron density at C-10 in *19* to become sufficiently low for the Wagner-Meerwein type rearrangement *19*→*20* to occur. The intermediate *20* is a well-stabilized tertiary *p*-hydroxybenzylium ion.

It seems remarkable that diacetate *8*, contrary to its isomer *9*, under the acidic conditions used does not undergo elimination of acetic acid with aromatization of the unbridged ring, in competition with ester hydrolysis (*cf.* p. 859). Similar to the base-catalyzed eliminations, acid-catalyzed *syn* elimination of acetic acid seems to proceed more readily than the corresponding *anti* elimination.

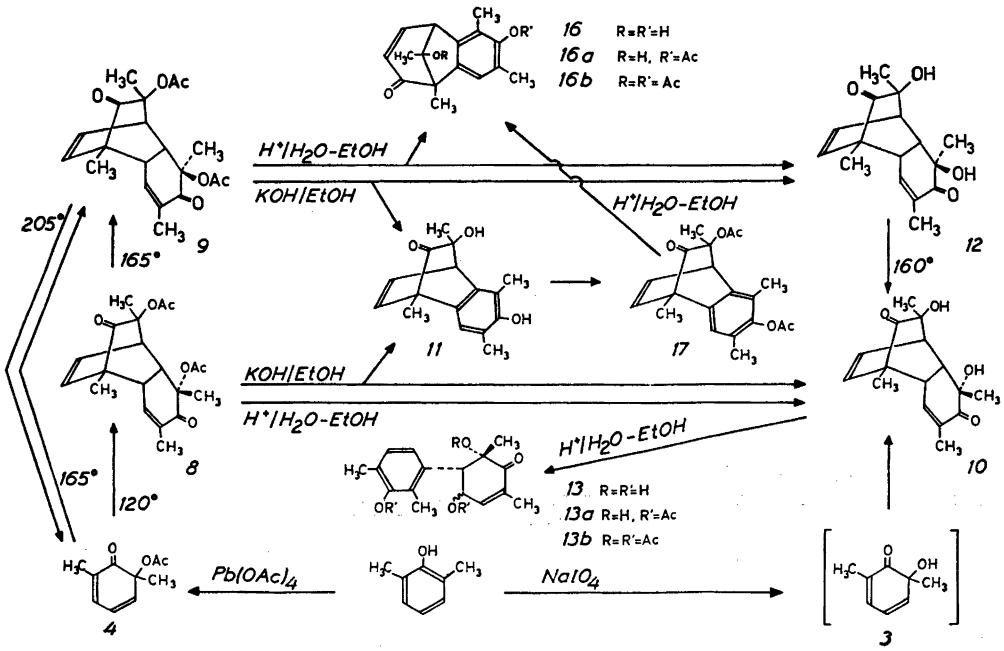
The reactions discussed in this paper are summarized in Scheme 4.

EXPERIMENTAL

Ultraviolet spectra were recorded on a Cary Model 14 spectrophotometer; IR and NMR spectra were obtained using Beckman 9A and Varian A-60 instruments, respectively. Chemical shifts are given in δ (ppm) units with TMS being used as internal standard.



Scheme 3.



Scheme 4.

6-Acetyloxy-2,6-dimethyl-2,4-cyclohexadienone (4) was prepared using the method reported by Wessely *et al.*[19] with slight modifications. Lead tetraacetate (57.5 g, 0.13 mol), which had been freed from acetic acid by washing with ether, was added to a solution of 2,6-dimethylphenol (13.6 g, 0.11 mol) in chloroform which was cooled with ice-water. After 16 h at room temperature the mixture was filtered and the filtrate brought to dryness. The residue was treated with ether (40 ml) and, after cooling the solution in the refrigerator for 4 h, undissolved material was filtered off. The solvent was evaporated, leaving an oil which crystallized when kept in the refrigerator for 24 h. Recrystallization from ether-light petroleum (b.p. 60–80 °C) gave yellow crystals of *4*, m.p. 35–36 °C (lit.[19,25] 36 °C) in a yield of 76 %. NMR ($CDCl_3$): δ 1.38 (s, 3 H, CH_3), 1.93 (d, 3 H, olefinic CH_3), 2.08 (s, 3 H, CH_3CO), 6.11 and 6.19 (broad singlets, 1 H each, H-4 and H-5), 6.69 (m, 1 H, H-3).

Dimer diacetate 8. *o*-Quinol acetate *4* (10 g) was heated under N_2 for 1 h at 120 °C. The resulting oil was dissolved in ether (50 ml) and, after 24 h at room temperature, the crystalline product deposited was recrystallized from ethanol to give 48 % of *8*, m.p. 159–160 °C (lit.[3] 159–160 °C). NMR ($CDCl_3$): δ 1.42, 1.50 and 1.73 (singlets, 3 H each, 3 CH_3), 1.83 (t, 3 H, olefinic CH_3), 2.10 and 2.17 (singlets, 3 H each, 2 CH_3CO), 3.00 (broad d, 1 H, H-8a. Coupling with H-4a gives rise to the doublet, which is further split by coupling with H-8 and by homoallylic coupling with CH_3-7), 3.48 (dd, 1 H, H-4a), 3.77 (td, 1 H, H-4), 5.64 (dd, 1 H, H-2), 6.23 (broad signal, 1 H, H-8), 6.29 (dd, 1 H, H-3). $J_{2,3}=7.8$ Hz, $J_{2,4}=1.5$ Hz, $J_{3,4}=7.0$ Hz, $J_{4,4a}=1.5$ Hz, $J_{4a,8a}=8.1$ Hz.

Dimer diacetate 9. *o*-Quinol acetate *4* was heated under N_2 for 2.5 h at 165 °C and the resulting oily product purified as described for isomer *8*. M.p. 182–184 °C; yield, 60 %. Elemental analysis, see Ref. 3, p. 1595. UV (ethanol): λ_{max}, nm (log ε) 209 (3.82) (β,γ-enone), 238 (3.80) (α,β-enone), 310 (2.18) (α,β- and β,γ-enones). IR (KBr), see Ref. 3. NMR ($CDCl_3$): δ 1.36 (s, 3 H, CH_3), 1.50 (s, 6 H, 2 CH_3), 1.80 (broad s, 3 H, olefinic CH_3), 1.95 and 2.12 (singlets, 3 H each, 2 CH_3CO), 2.90 (broad s, 2 H, H-4a and H-8a), 3.84 (td, 1 H, H-4), 5.60 (dd, 1 H, H-2), 6.14 (dd, 1 H, H-3), 6.17 (broad s, 1 H, H-8). $J_{2,3}=8.2$ Hz, $J_{2,4}=1.6$ Hz, $J_{3,4}=6.9$ Hz.

Estimation of yields of products formed by heat treatment of o-quinol acetate 4 (see Fig. 1). Monomer *4* was heated under N_2 for 0.5, 2.5, and 6 h, in each instance at temperatures of 125, 165, and 185 °C; an experiment with a heating time of 0.5 h at 205 °C was also carried out. After rapid cooling the reaction mixtures were dissolved in $CDCl_3$ and NMR spectra were recorded. The proportions of *4*, *8*, and *9* were estimated from the integrals of the signals of the various CH_3 and CH_3CO groups of the compounds present. The "unidentified product", increasing in amount with increasing temperature and heating time, is characterized by broad signals between δ 2.10 and 2.35, as shown for a product obtained on 6 h heating of *4* at 185 °C. It was assumed to have the same empirical formula as the three known products.

Isomerization of diacetate 8 *to diacetate* 9. Compound *8* (5.0 g) was heated under N_2 at 165 °C for 2.5 h. Ether (50 ml) was added, and *9* (3.0 g, 60 %) was collected after 24 h. The product was identical with that obtained from *4* (see above) by m.p., mixed m.p. and spectral properties.

Thermal degradation of dimer diacetates 8 *and* 9. Heating of the compounds under N_2 at 205 °C for 30 min, followed by rapid cooling, gave *o*-quinol acetate *4* in yields of 79 and 84 %, respectively.

Alkaline hydrolysis of dimer diacetate 8 with ethanolic KOH was carried out as described in Ref. 3. The reaction products *10* and *11* gave the following NMR spectra. *o-Quinol dimer* 10. NMR ($CDCl_3$): δ 1.25, 1.31 and 1.33 (singlets, 3 H each, 3 CH_3), 1.85 (t, 3 H, olefinic CH_3), 2.86 (s, 1 H, OH, exchangeable with D_2O), 2.90 (m, 1 H, H-8a. The signal is split by vicinal coupling to H-4a and H-8 and homoallylic coupling to CH_3-7), 3.30 (dd, 1 H, H-4a), 3.41 (td, 1 H, H-4), 4.06 (s, 1 H, OH, exchangeable with D_2O), 5.51 (dd, 1 H, H-2), 6.27 (dd, 1 H, H-3), 6.31 (broad signal, H-8). $J_{2,3}=7.0$ Hz, $J_{2,4}=1.5$ Hz, $J_{3,4}=6.0$ Hz, $J_{4,4a}=2.0$ Hz, $J_{4a,8a}=7.0$ Hz.

Phenol 11. NMR ($CDCl_3$): δ 1.47 and 1.70 (singlets, 3 H each, 2 CH_3), 2.02 (s, 1 H, OH), 2.21 and 2.32 (singlets, 3 H each, 2 aromatic CH_3), 4.30 (dd, 1 H, H-4), 4.98 (s, 1 H, OH), 6.22 (dd, 1 H, H-2), 6.66 (t, 1 H, H-3), 6.89 (s, 1 H, H-8).

Alkaline hydrolysis of dimer diacetate 9. A solution of *9* (5.0 g) in 10 % ethanolic KOH (200 ml) was kept under N_2 for 16 h at room temperature. Ethanol was removed under vacuum, water being added during the evaporation, and the aqueous solution (about 100 ml) was extracted with three 50 ml portions of chloroform. The dried extract on evaporation gave an oil which was purified on a silica gel column using acetone-hexane (2:1) as eluent. *o-Quinol dimer* 12, $R_F=0.50$, m.p. 147–149 °C (from ethanol), was obtained in a yield of 9 %. (Found: C 69.50; H 7.32. Calc. for $C_{16}H_{20}O_4$: C 69.54; H 7.30.) UV (ethanol): λ_{max}, nm (log ε) 211 (3.91), 238 (3.87), 310 (2.13). IR (KBr): ν_{max}, cm^{-1} 1672 (conj. CO), 1722 (CO), 3480 and 3500 (OH). NMR ($CDCl_3$): δ 1.31 (s, 6 H, 2 CH_3), 1.38 (s, 3 H, CH_3), 1.86 (t, 3 H, olefinic CH_3), 2.75 (broad signal, 2 H, H-4a and H-8a), 3.27 (s, 2 H, 2 OH, exchangeable with D_2O), 3.35 (broad d, 1 H, H-4), 5.50 (dd, 1 H, H-2), 6.30 (broad signal, 2 H, H-3 and H-8).

The alkaline aqueous phase was neutralized with acetic acid and extracted with chloroform.

Evaporation of the chloroform phase and treatment of the residue with ether gave 68 % of a product of m.p. 172 – 173 °C, identical by m.p., mixed m.p. and spectral properties with phenol *11*.[3]

Thermal isomerization of o-*quinol dimer* 12 *to* o-*quinol dimer* 10. A sample of compound *12* (3.0 g) was heated under N_2 for 1 h at 160°C. After cooling, ether (40 ml) was added. The crystalline product obtained after recrystallization from ethanol had m.p. 194 – 196 °C. Yield, 83 %. The product was identical by m.p., mixed m.p. and spectral properties with dimer *10*.[3]

Acid hydrolysis of dimer diacetate 8. A solution of *8* (2.0 g) in a mixture of ethanol (75 ml) and 10 % aqueous sulfuric acid (75 ml) was heated under reflux for 7 h in an atmosphere of nitrogen. The reaction mixture was extracted with three 75 ml portions of chloroform, the combined organic phases were concentrated to half their volume and then extracted with 3 × 50 ml of 2.5 M aqueous NaOH. The chloroform phase was dried and evaporated. Addition of ethanol (5 ml) to the semi-solid residue gave 28 % of crude *o*-quinol dimer *10*, m.p. 191 – 193 °C. Recrystallization from ethanol raised the m.p. to 195 – 196 °C (lit.[3] 194 – 196 °C).

The combined aqueous alkaline phases were neutralized with aqueous HCl and extracted twice with 100 ml portions of chloroform. The residue obtained after removal of the chloroform, when treated with ether gave a crystalline product which was recrystallized from benzene yielding 46 % of *4,6-dihydroxy-2,6-dimethyl-5-(3-hydroxy-2,4-dimethylphenyl)-2-cyclohexenone* (13), m.p. 139 – 140 °C. (Found: C 69.57; H 7.31. Molecular ion, M = 276. Calc. for $C_{16}H_{20}O_4$: C 69.54; H 7.30. Molecular ion, M = 276.). UV (ethanol): λ_{max}, nm (log ε) sh 239 (3.81), 276 (3.22). IR (KBr): ν_{max}, cm^{-1} 1492 and 1580 (arom. ring), 1680 (conj. CO), 3420 and 3520 (OH). NMR ($CDCl_3$): δ 1.48 (s, 3 H, CH_3-6), 1.95 (t, 3 H, CH_3-2), 2.15 and 2.22 (singlets, 3 H each, 2 aromatic CH_3), 2.10, 3.52 and 4.98 (broad singlets, 1 H each, 3 OH, exchangeable with D_2O), 4.11 (d, 1 H, H-5), 4.76 (broad signal, 1 H, H-4), 6.66 (broad signal, 1 H, H-3), 6.57 and 6.71 (doublets, 1 H each, 2 aromatic H, J = 8.0 Hz). $J_{CH_3\text{-}2,H\text{-}3}$ and $J_{CH_3\text{-}2,H\text{-}4}$ = 1.5 Hz; $J_{4,5}$ = 6.0 Hz.

Acid treatment of o-*quinol dimer* 10. The same procedure as described above for the acid hydrolysis of dimer acetate *8* gave unreacted *10* (15 %) and phenol *13* (66 %).

Diacetate 13a. From phenol *13* with Ac_2O/pyridine. Yield, 81 %; m.p. 136 – 137 °C (ethanol). (Found: C 66.62; H 6.73. Calc. for $C_{20}H_{24}O_6$: C 66.65; H 6.71), IR (KBr): ν_{max}, cm^{-1} 1675 (conj. CO), 1739 and 1752 (alkyl and aryl ester), 3480 (OH). The NMR signals of the CH_3CO groups are located at δ 1.78 and 2.29 ($CDCl_3$).

Triacetate 13b. From phenol *13* with Ac_2O/$HClO_4$.[22] Yield, 84 %; m.p. 157 – 158 °C (ethanol). (Found: C 65.66; H 6.49. Calc. for $C_{22}H_{26}O_7$: C 65.66; H 6.51). IR (KBr): ν_{max}, cm^{-1} 1704 (conj. CO), 1738 (2 alkyl ester CO) and 1755 (aryl ester CO). The NMR signals of the CH_3CO groups are located at δ 1.92, 1.94 and 2.31 ($CDCl_3$).

Acid hydrolysis of dimer diacetate 9. A 2 g sample of diacetate *9* was treated as described above for isomer *8*. The neutral fraction gave *o*-quinol dimer *12*, m.p. 147 – 149 °C, identical with the product of the same melting point obtained on alkaline hydrolysis of *9* by mixed m.p. and spectral properties.

The aqueous alkaline phase after neutralization was extracted with chloroform, and the dried extract concentrated to a volume of 30 ml. From the solution colourless crystals of *2,3-dihydro-2,5-dihydroxy-1,2,4,6-tetramethyl-1,3-propeno-1H-inden-10-one* (16) deposited. After recrystallization from acetone-chloroform, m.p. 205 – 206 °C; yield, 26 %. (Found: C 74.42; H 7.03. Molecular ion, M = 258. Calc. for $C_{16}H_{18}O_3$: C 74.40; H 7.02. Molecular ion, M = 258). UV (ethanol): λ_{max}, nm (log ε) 241 (4.03), 301 (3.71). UV (0.1 M NaOH in 80 % aqueous ethanol): λ_{max}, nm (log ε) 268 (4.03), 332 (3.83), 373 (4.24). IR (KBr): ν_{max}, cm^{-1} 1470, 1582, 1593 (aromatic ring), 1655 (conj. CO), 3320 (broad, OH). NMR (DMSO-d_6): δ 1.12 and 1.43 (singlets, 3 H each, 2 CH_3), 2.17 (s, 6 H, 2 aromatic CH_3), 3.61 (d, 1 H, H-3), 4.84 (broad signal, 1 H, OH, exchangeable with D_2O), 5.56 (d, 1 H, H-9), 6.56 (dd, 1 H, H-8), 7.37 (s, 1 H, H-7), 8.67 (broad signal, 1 H, OH). $J_{3,8}$ = 3.5 Hz, $J_{8,9}$ = 6.0 Hz.

Monoacetate 16a. From phenol *16* with Ac_2O/pyridine. Yield, 73 %; m.p. 175 – 176 °C (benzene). (Found: C 71.83; H 6.67. Calc. for $C_{18}H_{20}O_4$: C 71.88; H 6.71). UV (ethanol): λ_{max}, nm (log ε) 232 (4.09), 237 (3.72), 303 (3.16). IR (KBr): ν_{max}, cm^{-1} 1670 (conj. CO), 1752 (arylester), 3480 (OH). The NMR signal of the CH_3CO group is located at δ 2.32 ($CDCl_3$).

Diacetate 16b. From *16* with Ac_2O/$HClO_4$.[22] Yield, 80 %; m.p. 143 – 144 °C (ethanol). (Found: C 70.01; H 6.50. Calc. for $C_{20}H_{22}O_5$: C 69.98; H 6.39). IR (KBr): ν_{max}, cm^{-1} 1685 (conj. CO), 1735 and 1750 (alkyl and aryl ester). NMR signals of the CH_3CO groups: δ 1.66 and 2.36 (DMSO-d_6).

Acid hydrolysis of diacetate 17. A solution of diacetate *17*[3] (0.5 g) in a mixture of ethanol (20 ml) and 10 % aqueous sulfuric acid (20 ml) was refluxed under N_2 for 7 h and then worked up as described above for the similar hydrolysis of *8*. The neutral fraction consisted of unreacted diacetate *17* (65 %). The phenolic fraction gave compound *16*, m.p. 205 – 206 °C. in a yield of 22 %.

Dioxolanylium Ions Derived from Carbohydrates. I. Reactions with Water and with Bromide Ions

STEFFEN JACOBSEN and CHRISTIAN PEDERSEN

Department of Organic Chemistry, Technical University of Denmark, DK-2800 Lyngby, Denmark

Treatment of 3,4-*O*-benzylidene derivatives of methyl β-D-arabinopyranoside with triphenylmethyl fluoroborate gave benzoxonium ions which were stable in acetonitrile solution. Reaction of the benzoxonium ions with water gave hydroxy-benzoates with *cis*-opening of the dioxolanylium ring. Treatment with bromide ions lead to *trans*-opening and formation of bromodeoxypentopyranosides. Similar results were obtained with methyl 4-*O*-benzoyl-2,3-*O*-benzylidene-α-D-lyxopyranoside and with methyl 5-*O*-benzoyl-2,3-*O*-benzylidene-β-D-ribofuranoside.

The preparation of dioxolanylium ions from aldehydic acetals by hydride abstraction with triphenylmethyl fluoroborate or similar reagents is well known.[1–3] Dioxolanylium ions derived from carbohydrates have been obtained in a few cases using this method.[3–5]

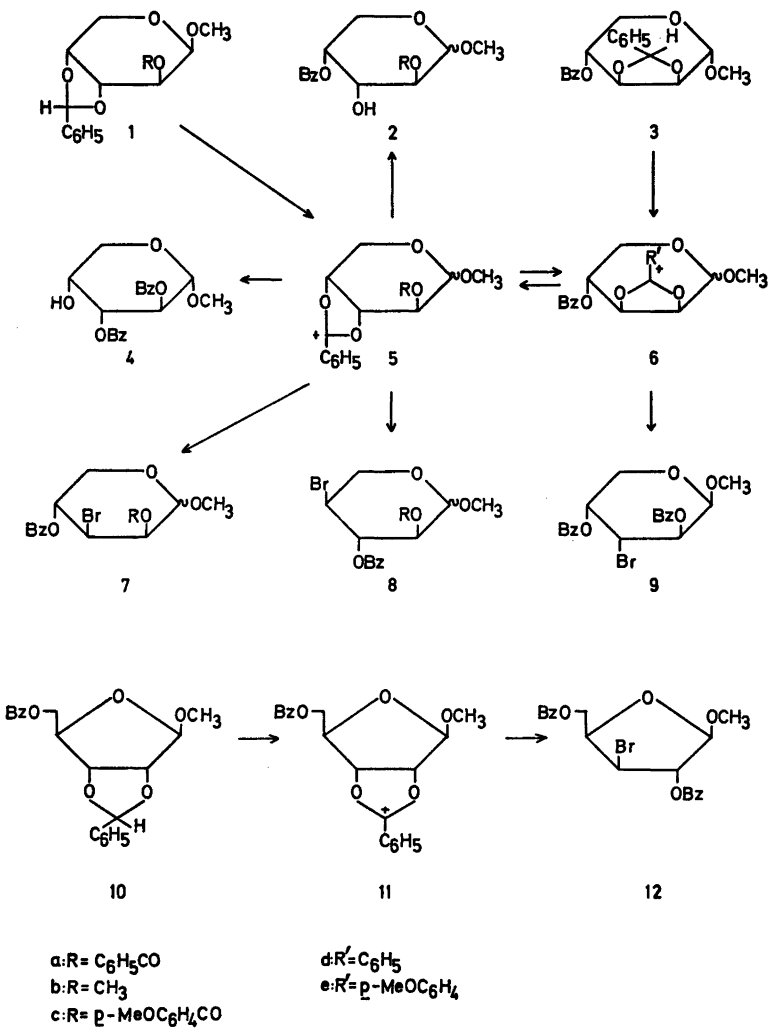
We have now investigated the reaction of a variety of carbohydrate benzylidene acetals with triphenylmethyl fluoroborate with the purpose of preparing 2-phenyl-dioxolanylium (benzoxonium) ions and studying their reactions with nucleophilic reagents. In the present paper the reactions of some pentose derivatives are described. A following paper will describe the behaviour of some hexose derivatives. When this work was almost completed a communication by Hanessian and Staub appeared in which closely related work is described.[6]

When methyl 2-*O*-benzoyl-3,4-*O*-benzylidene-β-D-arabinopyranoside (*1a*) was treated with triphenylmethyl fluoroborate in acetonitrile solution it was completely converted to a benzoxonium ion within a few hours and NMR spectra (Table 1) showed that it was the 3,4-benzoxonium ion (*β5a*) which was the main product. When moisture was excluded the ion was stable in acetonitrile solution for several days except that anomerization took place to some extent. The ion *β5a* is in equilibrium with the 2,3-benzoxonium ion (*β6d*),[3,4,7] derived from methyl lyxoside. However, the spectra indicated that the equilibrium was almost completely shifted towards *β5a*. This was confirmed by the reaction of methyl 3,4-*O*-benzylidene-2-*O*-methyl-β-D-arabinopyranoside (*1b*) with triphenylmethyl fluoroborate. This can of course only give the 3,4-benzoxonium ion (*β5b*) and the NMR spectrum (Table 1) of the ion formed was very similar to that of *β5a*.

A similar treatment of the lyxose derivative (*3*) would be expected to give initially the 2,3-benzoxonium ion (*α6d*), however, the product observed through NMR spectra was the 3,4-benzoxonium ion (*α5a*). Thus, the equilibrium between *5* and *6* is apparently largely shifted towards *5* in both anomers.

In order to get an NMR spectrum of a 2,3-benzoxonium ion methyl 3,4-*O*-benzylidene-2-*O*-*p*-methoxybenzoyl-β-D-arabinopyranoside (*1c*) was treated with triphenylmethyl fluoroborate. This gave a *p*-methoxybenzoxonium ion (*β6e*) in equilibrium with the 3,4-benzoxonium ion (*β5c*). Since a *p*-methoxy group stabilizes a benzoxonium ion [4] this equilibrium was shifted strongly towards *6* and only *ca.* 10 % of *5* was present. NMR data of both ions could be obtained from a spectrum of the mixture (Table 1) and the spectrum of *β6e* is quite different from that of *β5c* and from the spectra of the other 3,4-benzoxonium ions.

Treatment of the ribofuranose derivative *10* with triphenylmethyl fluoroborate gave the



benzoxonium ion *11* as already described by Hanessian and Staub;[6] its NMR data are presented in Table 1.

It is well known that dioxolanylium ions react rapidly with water to give *cis*-hydroxy esters [2] and this reaction has been described for the benzoxonium ion (*11*).[6] Addition of water to a solution of *β5a* in acetonitrile gave methyl 2,4-di-*O*-benzoyl-*β*-D-arabinopyranoside (*β2a*) as the only detectable product. This is in agreement with the results of King and Allbutt [8] who found that hydrolysis of a benzoxonium ion gives predominantly the product which has the *O*-benzoyl group axially oriented. In *β2a*, which preferentially adopts the $^1C_4$ conformation, the *O*-benzoyl group at C4 is axial. When *α5a* was hydrolysed, the main product was the 2,4-di-*O*-benzoate (*α2a*); but in this case a small amount of the 2,3-di-*O*-benzoate (*4*) was also isolated, possibly arising from acyl-migration. No products resulting from hydrolysis of *6* were found, indicating that the equilibrium between *5* and *6* is shifted strongly towards *5*, as also found from the NMR spectra. Hydrolysis of the 2-*O*-methylated ion (*β5b*) gave the 4-*O*-benzoate (*β2b*) as the only detectable product.

Reaction of benzoxonium ions with halide ions leads to *trans*-opening with formation of

Table 1. Proton NMR spectra of benzoxonium ions in deuterioacetonitrile. Chemical shifts are in ppm relative to TMS; coupling constants are in Hz.

Compound	H1	H2	H3	H4	H5	H5′	J_{12}	J_{23}	J_{34}	J_{45}	$J_{45'}$	$J_{55'}$	OCH_3	Conformation

A ^{13}C NMR spectrum of *β5a* in deuterioacetonitrile gave the following chemical shifts (relative to TMS): C1, 94.7; C2, 67.6; C3 and C4, 87.1 and 84.3; C5, 55.6; $C_6H_5C^+$, 181.5; $-OCH_3$, 55.2.

bromo-benzoates.[2,3] Treatment of the ions described above with tetraethylammonium bromide in acetonitrile proceeded in accordance herewith. The benzoxonium ions disappear within a few minutes when bromide is added, but the formation of the bromo-deoxy compounds requires *ca.* 2 h. This may indicate that intermediate orthoester bromides are formed rapidly and that they rearrange more slowly to the bromo-deoxy compounds.

Reaction of *β5a* with bromide ions gave two products in equal amounts. One was the 4-bromo-L-xylose derivative (*α8a*), resulting from attack of a bromide ion on C4 of *β5a*. The other product was the 3-bromo-arabinoside (*9*) which is probably formed by attack of bromide on C3 of *β6d*. The latter ion is only present to a small extent, as discussed above, but if its reaction with bromide is more rapid than that of *5* formation of rather large amounts of *9* would be possible.

Reaction of the 2-*O*-methylated ion (*β5b*) with bromide gave *α8b* as the main product and a small amount of the 3-bromo-lyxose derivative (*β7b*). Both can arise from *β5b* by substitution with bromide ions at C4 and C3, respectively. The same two bromo-compounds were obtained when *1b* was treated with *N*-bromosuccinimide according to Hanessian and Plessas.[7] Reaction of *3* with triphenylmethyl fluoroborate followed by treatment with bromide ions gave *α7a* as the main product together with a small amount of *β8a*. Thus, in this case the ion *α6d* does not seem to be reactive enough, probably because the α-methoxy group at C1 exerts steric hindrance towards attack at C3 of *α6*. Similarly, the low reactivity of C3 of the *β*-anomer (*β5a*) may be explained through steric hindrance by the methoxy group at C1.

Treatment of the benzoxonium ion (*11*) with bromide ions gave a good yield of the 3-bromo-3-deoxy-D-xylofuranose derivative (*12*). Since anomerisation took place during the reaction with bromide a mixture of the two anomers of *12* was obtained. These were treated with hydrogen bromide and the furanosyl bromide thus obtained was reacted with methanol. This gave the pure *β*-anomer of *12*.

The reactions of the benzoxonium ions described above with other nucleophiles will be discussed in a forthcoming paper.

EXPERIMENTAL

Thin layer chromatography (TLC) was performed on silica gel PF_{254} (Merck); for preparative work 1 mm layers were used on 20 × 40 cm plates. NMR spectra were obtained on Varian A-60 or HA-100 instruments and on a Bruker WH-90 instrument.

BENZYLIDENE COMPOUNDS

Methyl 2-O-benzoyl-3,4-O-benzylidene-β-D-arabinopyranoside (1a). Finely powdered methyl *β*-D-arabinopyranoside (4.92 g), benzaldehyde (3.30 g), *p*-toluenesulfonic acid (100 mg), and chloroform (150 ml) were refluxed for 10 h with a Soxhlet extractor containing 30 g of 4 Å molecular sieves. The solution was then washed with aqueous sodium hydrogencarbonate and water and dried ($MgSO_4$). The solvent was evaporated and the residue was benzoylated with benzoyl chloride (4.2 ml) in pyridine (50 ml) to give a product which was crystallized from ether at −20 °C. Decantation of the ether and recrystallization from ethyl acetate–pentane gave 5–7 g (47–65 %) of *1a* as a mixture of diastereomers, m.p. 95–105 °C.[7,8]

Methyl 4-O-benzoyl-2,3-O-benzylidene-α-D-lyxopyranoside (3) was prepared in the same way from methyl α-D-lyxopyranoside (3.3 g) which gave 2.5 g (35 %) of a mixture of the diastereomeric benzylidene acetals. Fractional crystallization from ethyl acetate-cyclohexane yielded small amounts of pure *exo* and *endo* isomers of (3). The H-*endo* isomer had m.p. 101–103 °C, $[\alpha]_D^{22}$ −22.5° (*c* 1.0, $CHCl_3$). (Found: C 67.38; H 5.84. Calc. for $C_{20}H_{20}O_6$: C 67.40; H 5.66). The H-*exo* isomer had m.p. 93–94 °C, $[\alpha]_D^{22}$ −44.8° (*c* 1.5, $CHCl_3$). (Found: C 67.51; H 5.72).

Methyl-3,4-O-benzylidene-2-O-p-methoxybenzoyl-β-D-arabinopyranoside (1c). Crude methyl 3,4-*O*-benzylidene-*β*-D-arabinopyranoside (1.15 g) was treated with *p*-methoxybenzoyl chloride (1.27 g) in pyridine to give 1.7 g of a mixture of *endo*- and *exo*-H product. Preparative TLC (ether–pentane 1:1) gave two fractions. The fast moving component was the *endo*-H product (*1c*) (645 mg) which was crystallized from ethyl acetate–pentane to give 290 mg of pure material, m.p. 97–99 °C, $[\alpha]_D^{21}$ −161.7° (*c* 1.1, $CHCl_3$). (Found: C 65.28; H 5.70. Calc. for $C_{21}H_{22}O_7$: C 65.27; H 5.74). The slow moving fraction, obtained as a syrup, was the *exo*-H product contaminated with some of the *endo*-compound.

Methyl 5-O-benzoyl-2,3-O-benzylidene-β-D-ribofuranoside (10). A similar treatment of methyl *β*-D-ribofuranoside[10] (1.64 g) gave 3.3 g of crude *10* which was crystallized from ether (10 ml)–pentane (35 ml) to give 2.5 g (70 %) of the H-*exo* product, m.p. 70–72 °C. Further recrystallization from ether–pentane gave the

pure product, m.p. 73 – 75 °C, $[\alpha]_D^{27}$ –27.4° (*c* 2.4, $CHCl_3$). (Found: C 67.55; H 5.71. Calc. for $C_{20}H_{20}O_6$: C 67.40; H 5.66).

Conversion of benzylidene derivatives to hydroxy-benzoates

General procedure. The appropriate benzylidene derivative (1 part) was treated with a 10 – 25 % molar excess of triphenylmethyl fluoroborate in dry acetonitrile (10 parts) at room temp. for the time specified below. The solution was then poured into aqueous sodium hydrogencarbonate, the mixture was extracted with chloroform, and the chloroform solution was dried and evaporated. Preparative TLC with ether – pentane (2:1) as eluent gave triphenylmethane moving with the solvent front, closely followed by triphenylcarbinol and the product(s).

Methyl 2-O-benzoyl-3,4-O-benzylidene-β-D-arabinopyranoside (*1a*) (809 mg) was treated with triphenylmethyl fluoroborate for 5 h after which time it was completely converted to the ion *β5a* as seen from an NMR spectrum. Hydrolysis and chromatography as described above gave 569 mg (67 %) of methyl 2,4-di-*O*-benzoyl-β-D-arabinopyranoside (*β2a*), m.p. 143 – 146 °C. Recrystallization from ethyl acetate – pentane gave the pure product, m.p. 147 – 149 °C, $[\alpha]_D^{25}$ –240.4° (*c* 2.3, $CHCl_3$). (Found: C 64.36; H 5.23. Calc. for $C_{20}H_{20}O_7$: C 64.51; H 5.41). Acetylation with acetic anhydride in pyridine gave the known methyl 3-*O*-acetyl-2,4-di-*O*-benzoyl-β-D-arabinopyranoside, m.p. 86 – 88 °C (reported [11] m.p. 86 – 87 °C). A mixed melting point with an authentic sample gave no depression.

Direct crystallization of *β2a* from ethyl acetate-pentane without previous chromatographic separation gave a 40 % yield of a product with m.p. 140 – 146 °C.

Methyl 4-O-benzoyl-2,3-O-benzylidene-α-D-lyxopyranoside (3) (474 mg) was treated with triphenylmethyl fluoroborate for 7 h. Hydrolysis and chromatography gave two products. The fast moving compound was methyl 2,4-di-*O*-benzoyl-α-D-arabinopyranoside (*α2a*) (206 mg, 42 %). The slow moving fraction gave 41 mg (8 %) of methyl 2,3-di-*O*-benzoyl-α-D-arabinopyranoside (*4*). The products were identified through their NMR spectra (Table 2). On benzoylation they gave identical products as seen from NMR spectra. The two benzoylated products were mixed and recrystallized from methanol to give 191 mg of methyl tri-*O*-benzoyl-α-D-arabinopyranoside, m.p. 144 – 145 °C (reported [12] m.p. 146 °C). A mixed m.p. with an authentic sample gave no depression.

Methyl 3,4-O-benzylidene-2-O-methyl-β-D-arabinopyranoside (1b) [13] (560 mg) was treated with triphenylmethyl fluoroborate for 2 h. Hydrolysis and chromatography gave 274 mg (46 %) of methyl 4-*O*-benzoyl-2-*O*-methyl-β-D-arabinopyranoside (*β2b*) which slowly crystallized from pentane. Recrystallization from ethyl acetate – pentane gave the pure product, m.p. 107 – 108 °C, $[\alpha]_D^{21}$ –204.0° (*c* 0.9, $CHCl_3$). Benzoylation gave the known methyl 3,4-di-*O*-benzoyl-2-*O*-methyl-β-D-arabinopyranoside, m.p. 72 – 74 °C (reported [14] m.p. 75 – 77 °C). A mixed m.p. with an authentic sample gave no depression.

Conversion of benzylidene derivatives to bromo-deoxy compounds

General procedure. The benzoxonium ion was prepared as described above in acetonitrile solution. To this solution was added dry tetraethylammonium bromide (3 molar equiv.) and the mixture was stirred until it was homogeneous and then kept for 2 h at room temp. The solution was then stirred for 5 min with aqueous sodium hydrogencarbonate and extracted with chloroform. The chloroform solution was washed with water, dried and evaporated. Preparative TLC (ether – pentane 1:2) gave triphenylmethane, moving with the solvent front, and triphenylcarbinol, usually followed closely by the product(s).

Methyl 2-O-benzoyl-3,4-O-benzylidene-β-D-arabinopyranoside (1b) (935 mg) by this treatment gave two products. The fast moving fraction (380 mg, 33 %) was methyl 2,3-di-*O*-benzoyl-4-bromo-4-deoxy-α-L-xylopyranoside (*α8a*). Crystallization from cyclohexane gave the pure product, m.p. 109 – 110 °C, $[\alpha]_D^{25}$ –129.7° (*c* 1.1, $CHCl_3$). (Found: C 55.32; H 4.31; Br 18.50. Calc. for $C_{20}H_{19}BrO_6$: C 55.18; H 4.40; Br 18.36).

The slower moving product (351 mg, 31 %) was methyl 2,4-di-*O*-benzoyl-3-bromo-3-deoxy-β-D-arabinopyranoside (*9*) which crystallized slowly. Three recrystallizations from cyclohexane gave a product with m.p. 82 – 86 °C, $[\alpha]_D^{25}$ –267.8° (*c* 1.0, $CHCl_3$). (Found: C 55.34; H 4.37; Br 18.54). The structures of the two bromides were established from their NMR spectra (Table 2). Separation of the mixture of bromides described by Hanessian and Plessas [7] gave products identical with those described above.

In addition to *α8a* and *9* 135 mg (14 %) of *4* was also isolated.

Methyl 3,4-O-benzylidene-2-O-methyl-β-D-arabinopyranoside (1b) (925 mg) gave by the same treatment two products. The fast moving fraction (63 mg, 5 %) was methyl 4-*O*-benzoyl-3-bromo-3-deoxy-2-*O*-methyl-β-D-lyxopyranoside (*β7b*) as a syrup, $[\alpha]_D^{21}$ –33.7° (*c* 1.3, $CHCl_3$). (Found: C 48.78; H 4.97; Br 23.37. Calc. for $C_{14}H_{17}BrO_5$: C 48.71; H 4.97; Br 23.15). The slower moving fraction (494 mg, 41 %) was methyl 3-*O*-benzoyl-4-bromo-4-deoxy-2-*O*-

[a] 2,5-Di-*O*-benzoyl-3-bromo-3-deoxy-α-D-xylofuranosyl bromide.

methyl-α-L-xylopyranoside (*α8b*), m.p. 72–74 °C. Two recrystallizations from ether-pentane gave a product with m.p. 73–74 °C, $[\alpha]_D^{21}$ −76.2° (*c* 1.3, $CHCl_3$). (Found: C 48.87; H 5.07; Br 23.02). The structures of the two products were derived from their NMR spectra (Table 2).

Methyl-2,3-O-benzylidene-4-O-benzoyl-α-D-lyxopyranoside (3) (587 mg) gave two products. The fast moving material (351 mg, 49 %) was methyl 2,4-di-*O*-benzoyl-3-bromo-3-deoxy-α-D-lyxopyranoside (*α7a*) which was crystallized from ether–pentane, m.p. 103–105 °C, $[\alpha]_D^{25}$ −125.4° (*c* 1.3, $CHCl_3$). (Found: C 55.26; H 4.25; Br 18.25. Calc. for $C_{20}H_{19}BrO_6$: C 55.18; H 4.40; Br 18.36). The slower moving fraction (44 mg, 6 %) was identified, after rechromatography, through its NMR spectrum as impure methyl 2,3-di-*O*-benzoyl-4-bromo-4-deoxy-β-L-xylopyranoside (*β8a*).

Methyl 2,3-O-benzylidene-5-O-benzoyl-β-D-ribofuranoside (10) (576 mg) gave after treatment with triphenylmethyl fluoroborate followed by reaction with tetraethylammonium bromide and chromatography 521 mg (74 %) of methyl 2,5-di-*O*-benzoyl-3-bromo-3-deoxy-D-xylofuranoside as a mixture of anomers in an α:β ratio of 3:2, as seen from an NMR spectrum. Treatment with 30 % hydrogen bromide in glacial acetic acid and work up in the usual way gave 520 mg of 2,5-di-*O*-benzoyl-3-bromo-3-deoxy-α-D-xylofuranosyl bromide, characterized through its NMR spectrum. The bromide was stirred over night with silver carbonate (1.0 g) in methanol (10 ml) and the product thus obtained was benzoylated with benzoyl chloride (0.3 ml) in pyridine (10 ml). Preparative TLC (ether–pentane 1:2) gave 276 mg (60 %) of methyl 2,5-di-*O*-benzoyl-3-bromo-3-deoxy-β-D-xylofuranoside (*12*) as a syrup, $[\alpha]_D^{21}$ +31.8° (*c* 3.0, $CHCl_3$). (Found: C 55.02; H 4.47; Br 18.54. Calc. for $C_{20}H_{19}BrO_6$: C 55.18; H 4.40; Br 18.36). Besides, 68 mg (12 %) of a mixture of the anomeric 1,2,5-tri-*O*-benzoyl-3-bromo-3-deoxy-D-xylofuranoses was isolated. The products were characterized through their NMR spectra.

Microanalyses were performed by Dr. A. Bernhardt, Mikroanalytisches Laboratorium or by Novo Microanalytical Laboratory.

Effects of Salts on the Partition of Proteins in Aqueous Polymeric Biphasic Systems

GÖTE JOHANSSON

Department of Biochemistry, Umeå University, S-901 87 Umeå, Sweden

1. The influence of salts on the partition of ovalbumin and lysozyme in an aqueous biphasic system containing dextran and poly(ethylene glycol) has been studied. The logarithm of the partition coefficient of protein is almost linearly related to the net charge of the protein. The slope of the line varies with the salt included in the system.
2. The separatory capacity of this biphasic system has been characterized by comparing the partition of the two proteins. The separatory capacity varies markedly with the salt used and can be divided into two independent parts. One part depends on the difference in the net charge of the two proteins and is sensitive to cosolute electrolytes. The other part is determined by the solvation properties of the phases for proteins and is independent of the electrolytes in the system. The ions of the salt included in the system function independently in determining the charge-sensitive part of the separatory capacity.
3. The data on partition of a protein and of the salt that steers the protein partition conform to an earlier proposed model. According to this, the unequal affinity of the ions of the salt causes an interfacial potential which in turn affects the partition of charged macromolecules.
4. The interfacial potential has been experimentally determined by independent methods. Its value is in the range of 0 – 7 mV.

Biological materials such as proteins, nucleic acids, cell organelles, and even cells can be included, without changes in their biological activity, in the aqueous polymeric biphasic systems introduced by Albertsson.[1] Substances, depending on their molecular structure or surface characteristics, usually partition unequally between the two liquid phases of the system. The latter can therefore be used for separation of biomaterials. The partition behaviour of both biopolymers and particles is sensitive to the presence of salts in the system. It is further affected in different ways by salts which are chemically very similar, *e.g.* LiCl and NaCl.[1] Various alkali salts have been used to steer the partition of biomaterials in the biphasic system. It has been observed that salts also affect the resolving power of the systems.[2] In a previous communication[3] it was shown that alkali salts partition unequally between the two phases.

A theoretical model to describe the influence of salt on the partition of proteins has been formulated by Albertsson.[4] According to this model, the presence of several kinds of ions which differ in their relative affinity for the two liquid phases gives rise to an electrical potential across the interface between the phases. This proposed interfacial potential, ψ, that arises when the salt $A_{\nu_+}B_{\nu_-}$ is included in the system is given by

$$\psi = \frac{RT}{(\nu_+ + \nu_-)F} \ln \frac{K_-}{K_+} \qquad (1)$$

where R is the gas constant, T the absolute temperature and F the Faraday constant. K_+ and K_- respresent hypothetical partition coefficients which the positive and the negative ion, respectively, should have if every single ion could partition independently of other electrically charged species in the sytem. K_+ and K_- are related to the resultant partition coefficient of the salt, K_s, by

$$\ln K_s = \frac{1}{\nu_+ + \nu_-} \ln (K_+^{\nu_+} K_-^{\nu_-}) \qquad (2)$$

If a protein with the net charge Z is partitioned together with an excess of salt, the partition coefficient of the former, K_p, is given by

$$\ln K_p = \ln K_p^0 + \frac{Z}{\nu_+ + \nu_-} \ln \frac{K_-}{K_+} \quad (3)$$

where K_p^0 is the partition coefficient of the protein, when partitioned with an excess of a salt for which $K_- = K_+$, which means that $\psi = 0$.

The aim of the present work was to study the mechanism of the salt effect and to test the theoretical model. For this purpose two well known proteins, ovalbumin and lysozyme, for which the charge can be predicted from pH, have been partitioned in the biphasic systems.

The separatory effect of different salts included in the biphasic system has also been determined by comparing the partition of the two proteins under identical conditions, and the interfacial potential has been measured.

The results are in agreement with the model and the partition of proteins as regards the salt effect can therefore be explained and predicted in a rational way.

MATERIAL AND METHODS

Chemicals. Dextran T 500, mol. wt. 500 000, was supplied by Pharmacia Fine Chemicals, Uppsala, Sweden. Poly(ethylene glycol), mol. wt. 4000, was obtained from Union Carbide Chemicals Co., New York, as Carbowax 4000. Salts, acids, and bases were of analytical grade. Water was double distilled in quartz. Proteins were obtained from Sigma Chemical Co., St. Louis, Missouri: hen ovalbumin, grade V, and lysozyme from egg white, grade I.

Biphasic systems were obtained by mixing aqueous solutions of dextran, 20 % (w/w) and poly(ethylene glycol), 40 % (w/w) with protein and/or salt solutions in test tubes. The protein solutions, 5 g/l lysozyme or 10 g/l ovalbumin, were predialyzed against 5 mM potassium phosphate buffer, pH 6.8, at 3 °C overnight. The pH of the solutions of neutral salts was adjusted to 6.8 by adding minute amounts of HCl or NaOH solutions. Ammonium salts were adjusted to the same pH by adding dilute ammonia.

The biphasic systems were mixed and placed in a thermostat bath, 25 ± 0.2 °C. After attaining the bath temperature, the system was mixed by inverting 40 times and then left for one hour in the thermostat bath to separate. The pH measured directly in the upper phase by means of a glass electrode was close to 6.70.

Partition coefficient of a protein. The protein concentration in each phase was measured in terms of absorbance. From each phase an aliquot was withdrawn with a 500 µl constriction pipette. The phase was transferred to 2.000 ml water and the inside of the pipette was washed ten times with the diluted phase to remove all of the viscous solution. The same pipette was used for both phases to ensure equal volumes. The absorbance of the diluted phases was measured at 280 nm with a Zeiss spectrophotometer, PMQ II, using a blank prepared from a system containing no protein, but the same concentration of salt. The partition coefficient, K_p, was calculated as the ratio between the absorbance determined for the upper and lower phase, respectively.

The partition coefficient as function of the net charge of the protein was determined by preparing 20 g phase system containing protein and neutral salt but no buffer. The system was titrated with either NaOH, Tris, HCl or H_3PO_4 solution, 0.1 – 1.0 M, at constant temperature, 25 ± 0.2 °C. After each addition the system was shaken and two aliquots, 2 and 1 ml were withdrawn. The 2 ml portion was allowed to settle and the partition coefficient, K_p, was determined as above. The 1 ml portion was diluted with 1.5 ml water and pH of the diluted solution was measured using a pH-meter (Radiometer, pHM-26) equipped with a glass electrode (Radiometer GK 2026C).

The partition coefficients of salt, K_s, was determined for chlorides, bromides, iodides, and thiocyanates by potentiometric titration using a Radiometer titrigraph fitted with one silver and one Hg-Hg_2SO_4-electrode (Radiometer, type P4011 and K 601). 1.000 ml upper or lower phase was mixed with 5 ml water and titrated with 15 mM $AgNO_3$. Partition of fluoride, sulfate, nitrate, and perchlorate was determined by direct conductometric measurements. 2.000 ml of one phase was mixed with 2.000 ml of the opposite phase from a phase system containing no salt and with 10.00 ml water. The conductivity of the solution was measured at 25 °C with a Metrohm conductometer E 382. Corrections were made by subtracting the conductivity of a similarly diluted mixture of phases from a system without salt. The conductivity is assumed to be proportional to the salt concentration in these diluted solutions. To obtain equal volumes of the two phases the same method as described earlier for dilution of the phases was used.

Measurements of interfacial potential. The arrangement for measuring the difference in interfacial potential is shown in Fig. 1. The potential was measured with a Radiometer TTT2 titrator used as mV-meter and connected with a Servogor potentiometric recorder, type RE 520. The whole apparatus was kept in a thermostated room at 25 °C. The measured potential was corrected for the potential that appeared between two identical systems, both containing potassium chloride.

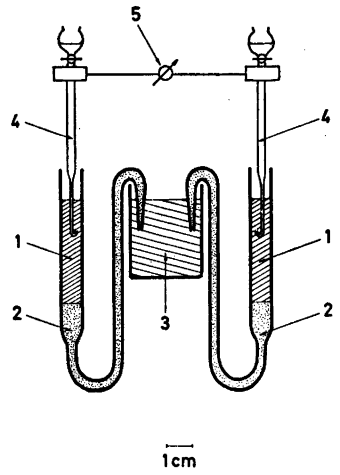

Fig. 1. Arrangement for measuring the interfacial potential difference between two biphasic systems containing different salts. Each U-tube-shaped vessel contains a single biphasic system where (1) is the upper phase and (2) the lower phase. The two lower phases are brought into electrical contact *via* a salt bridge consisting of 0.5 M NH_4NO_3 in 20 % (w/w) dextran solution (3). Calomel electrodes, Radiometer type K 100, (4), with open liquid junction and containing 12 % (w/w) poly(ethylene glycol) saturated with KCl are inserted in the upper phases. The potential difference between the two calomel electrodes is measured with the aid of a millivoltmeter (5).

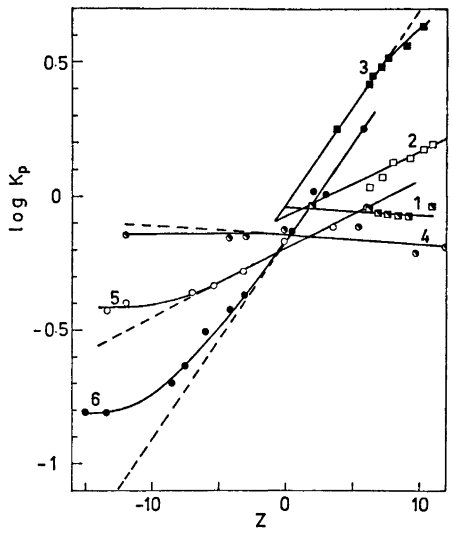

Fig. 2. Relationship between protein partition coefficient, K_p, and the net charge of the proteins, Z. The latter was obtained from titration curves and isoelectric points for the proteins. 1, lysozyme with 0.05 M K_2SO_4; 2, lysozyme with 0.1 M KF; 3, lysozyme with 0.1 M KBr; 4, ovalbumin with 0.05 M K_2SO_4; 5, ovalbumin with 0.1 M KF; and 6, ovalbumin with 0.1 M KBr, partitioned in systems containing 8 % (w/w) dextran and 8 % (w/w) poly(ethylene glycol) at 25 °C. The concentrations of protein were 1 g/l for lysozyme and 2 g/l for ovalbumin. Broken lines indicate linear extrapolations.

RESULTS AND DISCUSSION

Dependence of protein partition on the electrical charge of the protein. Ovalbumin or lysozyme were partitioned in a biphasic system containing either K_2SO_4, KF, or KBr. The variation of the protein partition coefficient with the protein net charge is shown in Fig. 2. The net charges were estimated from the measured pH values by using the titration curves of the proteins given by Tanford and Wagner [5] and Kenchington.[6] The logarithm of the partition coefficient of the protein is found to be linearly related to its net charge, Z. The slopes of the lines for the two proteins are almost identical when partition was carried out in the presence of a given salt. Some deviations from linearity are observed for ovalbumin when it is negatively charged. On the other hand, the slope of the line varies with the salt. This is in agreement with eqn. (3). For a single protein, the lines obtained when it is partitioned with different salts intersect where the net charge $Z = 0$. Albertsson *et al.*[7] have taken advantage of this fact and from the plot of log K_p *versus* pH estimated the isoelectrical points for a series of proteins.

The deviation from a straight line may indicate either a change in molecular weight of the protein due to association or dissociation, or changes in its effective charge due to interaction with ions other than H^+ and OH^-. The deviation could also be due to a difference in the extent of ionization of the protein in water as compared with that in polymer solutions. The effective Z may consequently differ from that calculated from titration curves in aqueous solutions. Deviations may also result from conformational changes which affect the K_p^0 in eqn. (3). Sasakawa and Walter [8] have shown that K_p at the isoelectric point. *i.e.* K_p^0, varies

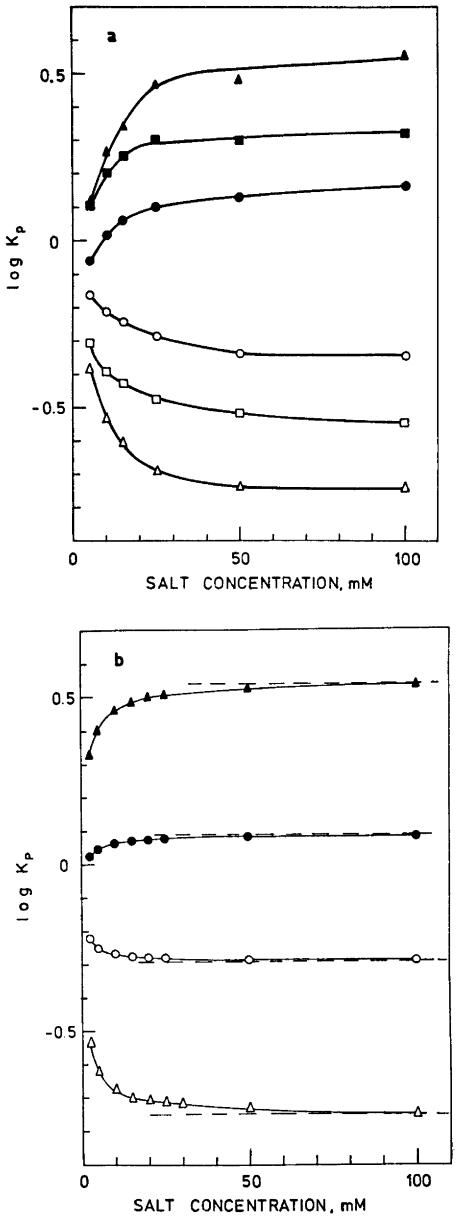

Fig. 3. Variation of protein partition coefficient, K_p, with salt concentration.
a. Lysozyme, 1 g/l (black spots) and ovalbumin, 2 g/l (white spots) were partitioned at 25 °C in a system containing 8 % (w/w) dextran, 8 % (w/w) poly(ethylene glycol), 1 mM sodium phosphate buffer, pH 6.8, and various concentrations of KF, ○; potassium acetate, □; and KBr, △.
b. Theoretical curves for lysozyme, black spots ($Z = 7.3$, $K_p^0 = 0.89$ and $C_p = 0.0705$ mM) and ovalbumin, white spots ($Z = -7.3$, $K_p^0 = 0.71$ and $C_p = 0.0445$ mM) when partitioned with KBr, △, or KF, ○. $K_+ = 0.828$ (K^+), $K_- = 1.202$ (Br^-) or 0.904 (F^-). The broken lines indicate the limit partition of the proteins at infinite salt concentration.

strongly with the protein and is also related to the molecular weight of the protein.

When K_2SO_4 is included in the system used here, the partition of a given protein is almost independent of Z. This salt therefore gives a system in which the interfacial potential is close to zero.

Dependence of protein partition on the concentration of salt. When ovalbumin and lysozyme are partitioned at very low salt concentrations their partition coefficients are close to one, but with increasing salt concentration K_p asymptotically approaches limiting values, Fig. 3a. At pH = 6.7 and at high salt concentration the positively charged lysozyme and the negatively charged ovalbumin have affinity for opposite phases.

The dependence of K_p on the salt concentration, according to the theoretical model, can be derived from eqn. (1), Fig. 3b, by combination with expressions for electroneutrality and mass balance which yields eqn. (4).

$$\frac{1 - 1/(1 + K_- y) + Z(2C_p - x)/2C_s}{Zx/2C_s + 1/(1 + K_- y)} = \frac{K_+}{y} \qquad (4)$$

where

$$y = [(2C_p - x)/xK_p^0]^{1/z}$$

C_p, and C_s are the respective molar concentrations of protein and salt in the system, and x is the molar concentration of protein in the lower phase. K_p^0, K_+ and K_- have been defined in connection with eqn. (1) – (3).

The validity of (4) is restricted to a system where the two phases have equal volume and the salt is a 1 – 1-electrolyte. Furthermore the protein must be negatively charged. Z is the *numerical* value of the protein net charge. Eqn. (4) was numerically scanned over a range of x values $0 < x < 2C_p$, with an increment of 0.0001 mM to obtain the value of x that best fitted the equation. This was done with aid of a Hewlett Packard electronic calculator 9100. K_p is related to x *via* eqn. (5).

$$K_p = (2C_p - x)/x \qquad (5)$$

The theoretical and experimental curves, Fig. 3, have the same shape. At very low salt concentrations the presence of 1 mM phosphate buffer will increasingly affect the partition of the protein as salt concentration decreases. This has not been corrected for in the calculations. The contribution of the protein to the interfacial potential will grow smaller and smaller as the concentration ratio between salt and protein increases. Therefore the partition of the protein will be increasingly determined by the partition of the salt ions when the concentration of the latter increases. The limiting partition coefficient for a protein in the presence of excess salt is given by eqn. (3). It is evident that to obtain the largest possible difference in the partition of the two proteins the salt concentration must be sufficiently high. In the present experiments the protein concentration in the systems was 2 g/l or less. When 25 mM 1 – 1-electrolyte is used, the difference in log K_p for the two proteins was about 90 % of the maximal one.

Above a minimum salt concentration the separation effect is almost independent of the salt concentration. This is in contrast to other separation methods which utilize charge differences between proteins, *e.g.* ion exchange chromatography or electrophoresis. In these separation procedures the ionic strength plays an important role in determining the separation. In partition, however, ionic strength can be chosen within a very wide range of values without affecting the degree of separation. Partition at high ionic strength may therefore be used for resolving proteins or subunits which otherwise interact strongly.

The separatory effect of various salts. The degree of separation of two substances by partition is measured by a separation factor, β. This is defined as the ratio between the partition coefficients of the two substances [9] and the order of the coefficients is chosen so that $\beta \geq 1$. It has here been found more suitable to use a logarithmic expression.

According to eqn. (3) the partition coefficient of a protein can be split into two parts; one, K_p^0, depending on the relative solvation of the protein in the two phases, the other part, $K_p^{el}[=(K_-/K_+)^{z/(\nu_+ + \nu_-)}]$, depending on the net charge of the protein. The difference in log K_p, Δ log K_p, of *two* proteins partitioned under equal conditions can be split up in the same way:

$$\Delta \log K_p = \Delta \log K_p^0 + \Delta \log K_p^{el} \quad (6)$$

where Δ log K_p^{el} depends on the difference in net charge between the two proteins. The value Δ log K_p is a measure of the separatory capacity of the biphasic systems and is related to the separation factor β, *via* log $\beta = |\Delta \log K_p|$. The part of the separatory capacity that depends

Table 1. The charge-dependent part of the separatory capacity, Δ log K_p^{el}, obtained when ovalbumin or lysozyme, respectively, was partitioned with different salts in a biphasic system containing 8 % (w/w) dextran and 8 % (w/w) poly(ethylene glycol) at 25 °C.

Salt	Salt concentration (mM)	Δ log K_p^{el}	Salt	Salt concentration (mM)	Δ log K_p^{el}
KF	25	−0.25	NaF	25	−0.23
KCl	25	−0.87	NaCl	25	−0.83
KBr	25	−1.06	NaBr	25	−1.04
KI	25	−1.36	NaI	25	−1.26
KSCN	25	−1.49	NaSCN	25	−1.36
K_2SO_4	20	0.04	Na_2SO_4	20	0.05
$KClO_4$	25	−1.73	$NaClO_4$	25	−1.58
NH_4F	25	0.04	LiF	20	0.29
NH_4Cl	25	−0.60	LiCl	25	−0.35
NH_4Br	25	−0.81	LiBr	25	−0.54
NH_4I	25	−1.14	LiI	25	−0.86
NH_4SCN	25	−1.21	LiSCN	25	−0.92
$(NH_4)_2SO_4$	20	0.22	Li_2SO_4	20	0.31
KNO_3	100	−0.81	$LiClO_4$	25	−1.15

on the net charges of the proteins should, according to the theory, be the difference between $\Delta \log K_p$ and $\Delta \log K_p^0$. $\Delta \log K_p$[$=\log K$ (ovalbumin) $-\log K$ (lysozyme)] for the protein pair ovalbumin and lysozyme (partitioned separately) at pH 6.7 has been determined using biphasic systems which contained different salts. $\Delta \log K_p^0 = 0.10$ for this pair of protein has been determined from Fig. 2, as the difference in $\log K_p$ at $Z=0$ when the proteins are partitioned in the presence of K_2SO_4. The resulting $\Delta \log K_p^{el}$ values are given in Table 1.

When the salt used is a 1 – 1-electrolyte, the $\Delta \log K_p^{el}$ values obtained, can be expressed as the sum of two constant terms, $\Delta \log K_C$ and $\Delta \log K_A$, which are characteristic for the cation and anion respectively,

$$\Delta \log K_p^{el} = \Delta \log K_C + \Delta \log K_A \quad (7)$$

Setting $\Delta \log K_C$ for the potassium ion arbitrarily equal to zero, $\Delta \log K_C$ will be 0.03 for Na^+; 0.28 for NH_4^+; and 0.53 for Li^+ and $\Delta \log K_A$ will be -0.25 for F^-, -0.87 for Cl^-, and -1.07 for Br^-. The maximum deviation for $\Delta \log K_A$ or $\Delta \log K_C$ calculated for an ion from data concerning different salts containing that ion is less than ± 0.02. The additivity holds less well for I^-, SCN^-, and ClO_4^-, for which $\Delta \log K_A$ is found to be -1.36 ± 0.07, -1.45 ± 0.06, and -1.67 ± 0.06, respectively.

If the negative ions are arranged in order of their $\Delta \log K_A$ values, the series obtained corresponds to the well-known Hofmeister's series. The most extreme charge-depending separatory effect is shown by salts containing chaotropic ions, SCN^- or ClO_4^-, which makes these salts attractive for enhancing the separatory capacity of the biphasic systems. However, such salts should be used with care, since high concentrations of the chaotropic ions may denature proteins.

By using salts for which $\Delta \log K_p^{el} = 0$ the pH-dependent separation effect can be nullified. In the system studied here and at the operating temperature NH_4F as well as K_2SO_4 have this property. Therefore in a system containing one of these salts the partition coefficient of a protein should be independent of the protein net charge and equal to K_p^0. Variations in K_p^0 with pH would indicate structural changes in the protein molecule.

Depending on the salt used, a small yet significant variation in K_p^0 has been noted. It is here assumed that the shift in $\log K_p^0$ is the same for the two proteins studied so that the difference $\Delta \log K_p^0$ is independent of salt. The good agreement between experiment and theory indicates that this is a valid approximation. The relative variation of K_p^0 with salt has been approximated by the change in the means of $\log K_p$ of ovalbumin and lysozyme. The increase in $\log K_p^0$ goes hand in hand with increasing partition coefficient of the salt, given in Table 2. The order of increasing K_p^0 is $F^- < Cl^- < Br^- < I^- < SCN^- < ClO_4^-$ and $K^+ < Na^+ < NH_4^+ < Li^+$. The shifts in $\log K_p^0$ seem to be unique for each ion and additive just as in the case of $\Delta \log K_p^{el}$.

The zero-potential partition of ions. By combining the partition coefficients for a salt and those for proteins partitioned with excess of this salt, the K_+ and K_- values for the ions of the salt can be calculated. Eqn. (3) yields

$$\log \frac{K_-}{K_+} = \frac{\nu_+ + \nu_-}{\Delta Z} \Delta \log K_p^{el} \times 1.11 \qquad (8)$$

where ΔZ is the difference in net charge of the two proteins. The correction factor 1.11 estimated from Fig. 3 is introduced since Δ log K_p at the salt concentration used is close to, but not identical with, the limiting value obtained with excess of salt. For 1 – 1-electrolytes eqn. (2) can be written as

$$\log (K_+ K_-) = 2 \log K_s \qquad (9)$$

K_+ and K_-, Table 3, column b, have been calculated for alkali, ammonium, and halide ions from (8) and (9) and using Δ log K_p^{el} and K_s from Tables 1 and 2. The charge difference, ΔZ, used in the calculations has been obtained from the titration curves and the isoelectric points. The latter were taken to be 4.75 for ovalbumin and 11.0 for lysozyme.[8]

On this basis, at pH 6.7, Z is −12.0 and 7.5 for ovalbumin and lysozyme, respectively, and therefore $\Delta Z = -19.5$.

A considerable variation is observed in the values of K_+ or K_- for a given ion. In addition, there is also a systematic variation in the values for the various counter ions. The K_+ and K_- have also been calculated *via* eqn. (9) solely from the partition coefficients of salts given in Table 2. This is possible because one of the salts, NH_4F, only gives rise to very small interfacial potential, as can be seen from the data given in Table 1. K_+ and K_- for the ions of this salt must therefore be almost equal to each other and also equal to the partition coefficient of the salt. From these two values, K_+ and K_- for the other ions have been calculated *via* (9) and are recorded in Table 3, column d. These K_+ and K_- differ considerably from the values obtained from Δ log K_p^{el}.

The K_- has also been directly estimated for chloride, bromide, and iodide by partition of salts containing these ions in a system containing K_2SO_4 in large excess. This salt gives only rise to a very low interfacial potential since Δ log K_p^{el} is close to zero, Table 1. These experimental K_- values, Table 3, column a, agree well with the values calculated on the basis of $K_+ = K_-$ for NH_4^+ and F^-, Table 3, column d. K_+ for the cations, Table 3, column e, has been calculated from the experimental values concerning Br^- and Cl^-.

The observed deviation of K_+ and K_- calculated from the Δ log K_p^{el} data when compared with the values obtained experimentally or

Table 3. Logarithms of partition coefficients (K_+ and K_-) of ions when interfacial potential is zero, in a biphasic system containing 8 % (w/w) dextran and 8 % (w/w) poly(ethylene glycol) at 25 °C. Salt concentration, 10 – 25 mM.
a, 10 mM halide in a system containing excess of K_2SO_4, 50 mM.
b, calculated from Δ log K_p^{el} and K_s using eqns. (8) and (9) with $\Delta Z = -19.5$.
c, calculated as in *b* but using $\Delta Z = -14.6$.
d, calculated from K_s *via* eqn. (9), assuming K_+ for ammonium to be equal to K_- for fluoride.
e, K_+ calculated from K_s *via* (9) using K_- for Cl^- and Br^- given under *a*. K_- for F^- is likewise calculated from K_+ so obtained.

Ion	Experimental log K_-	Calculated log K_+ or log K_-			
	a	b	c	d	e
K^+		−0.062 ± 0.016	−0.082 ± 0.004	−0.089	−0.084 ± 0.002

Cl^-	+0.051	+0.038 ± 0.006	+0.051 ± 0.004	+0.058	
F^-		−0.044 ± 0.006	−0.044 ± 0.004	−0.039	−0.040 ± 0.004

via the partition coefficients of the salts indicates that the estimated net charges for ovalbumin and lysozyme are not correct. By using eqn. (3) the net charges have been calculated from the partition data of the two proteins in a system containing KBr and assuming log K_p^0 to be −0.05 and −0.15 for lysozyme and ovalbumin, respectively. The net charge is found to be 7.3 for lysozyme and −7.3 for ovalbumin. The former is in good agreement with the value, 7.4, obtained from the titration curve, while the value for ovalbumin is considerably less than the titrimetrical one, −12.0. If the net charges, calculated *via* (3), are used for calculating K_+ and K_- from Δ log K_p^{el} the result, Table 3, column c, is in excellent agreement with the values obtained from the partition coefficients of the salts, Table 3, columns a, d, and e. The assumption of a smaller Z value for ovalbumin at pH = 6.7 is consistent with the data for this protein in Fig. 2. Ovalbumin shows a deviation from the linear dependence of Z when negatively charged. If, however, the net charge at pH = 6.7 is estimated by extrapolation to the assumed linear relation, one obtains $Z = -7.5$ in the case of KF and $Z = -8.0$ in the case of KBr.

In a biphasic system the ions of a salt would attain the partition coefficients K_+ and K_- if the demand of electroneutrality did not require that their actual partition coefficients are the same. Only in a thin layer around the interface may an unequal distribution of cation and anion exist, a so called Stern layer.[10] K_+ and K_- express the relative affinities of the ions for the two phases. The affinity of ammonium and alkali ions for the dextran-rich lower phase is greater than that for the PEG-rich upper phase; $K_+ < 1$. The affinity for the lower phase increases in the order $Li^+ < NH_4^+ < Na^+ < K^+$. The above finding indicates that these ions, especially K^+ and Na^+, form weak complexes with dextran in water solution. It has further been shown that the IR-spectra of dextran [11] in aqueous solution are influenced by potassium and sodium salts.

The halide ions except F^- have a greater affinity for the upper phase and this affinity increases in the order $Cl^- < Br^- < I^-$. This is in agreement with the electrophoretic mobility of PEG in salt solutions containing these ions.[2]

Effect of salt concentration on K_s. The partition coefficient of the studied salts are found to be independent of the salt concentration in the interval 2 − 100 mM.

Interfacial potential, ψ, was calculated using the following expression (10), obtained by combining (1), (3), and (6).

Table 4. Values of interfacial potential, ψ, in a biphasic system containing 8 % (w/w) dextran, 8 % (w/w) poly(ethylene glycol) and 20 mM alkali or ammonium halide at 25 °C.

[a] Measured relative to KCl and recalculated to absolute values by assuming the potential to be −4.0 mV in the case of KCl. [b] Calculated from Δ log K_p^{el}. [c] Calculated from K_+ and K_-.

$$\psi = \frac{RT}{F}\frac{1}{\Delta Z}\Delta \ln K_p^{el} \text{ (excess of salt)} \quad (10)$$

with $\Delta Z = -14.6$ and introducing the correction factor 1.11 mentioned earlier, in connection with (8), yields

$$\psi = -\frac{59.2}{14.6}\Delta \log K_p^{el} \times 1.11 \quad (11)$$

The interfacial potentials calculated for alkali and ammonium halides are given in Table 4.

The interfacial potential has also been measured relative to a system containing KCl. The results are presented in Table 4. For anions the potential varies in the expected sequence I^-, Br^-, Cl^-, F^-. For cations the sequence expected is K^+, Na^+, NH_4^+, Li^+, but that observed experimentally is K^+, NH_4^+, Na^+, Li^+. This deviation may be due to polarization phenomena at the contact surfaces in the electrical element, the so called junction potentials. These could perhaps be decreased by using another salt in the salt bridge between the two biphasic systems. NH_4NO_3, which has been used here, is ideal in water solution because of the equal transport number of the two ions. The same is not necessarily true in 20 % (w/w) dextran solution, used in these experiments. The experiments show, however, that the interfacial potential is of the predicted order.

Measurements of the interfacial potential in an aqueous biphasic system containing phosphate and chloride has recently been published by Reitherman *et al.*[12] The values of the potentials were of the same order as those here described.

CONCLUSIONS

The effect of electrolytes on the separatory capacity of the aqueous biphasic systems is due to a difference in the affinity of the constituent ions for the two phases.

This leads to the formation of an electrical double-layer and consequently an interfacial potential. When a biphasic system contains an excess of salts the induced interfacial potential depends only on the salt and this will affect the partition of proteins according to their charges.

The separatory capacity of a biphasic system for a given pair of proteins can be split into two parts. One part reflects the solvation of the proteins in the two phases and is almost independent of the presence of salts in the system. The other part is related to the difference in net charges of the two proteins. This charge-depending part of the separatory capacity is characteristically affected by the ions of the salt in the system. The effects of the ions are algebraically additive. By choosing a salt with ions having large effects on the separatory capacity it may be possible to resolve (even complex) protein mixtures by liquid-liquid extraction. Since the separatory capacity induced by a salt is constant throughout a considerably wide range of salt concentrations, separations can be carried out at a suitable ionic strength without any loss in the efficiency of separation.

The experimental data are in excellent agreement with the equations for interfacial potential put forward by Albertsson. They can therefore be used with confidence for quantitative predictions. Thus, partition studies can be used for determination of physico-chemical properties of proteins, *e.g.* net charge. It should also be possible to detect conformational changes, protein-protein associations and binding of low-molecular weight substances to proteins, from partition studies.

Periodate Oxidation of Phenols. XIV.* Oxidation of *p*-Hydroxybenzyl Alcohol with Periodate and Bismuthate

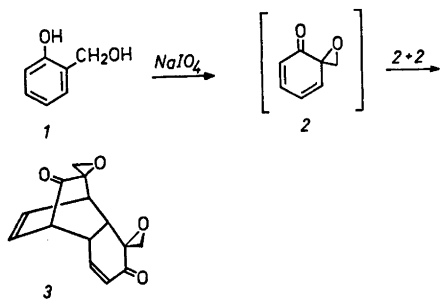
ERICH ADLER, KRISTER HOLMBERG and LARS-OLOF RYRFORS

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

Treatment of *p*-hydroxybenzyl alcohol with sodium metaperiodate in acetic acid-water gives, in addition to amorphous material, *p*-benzoquinone (23 %) and *p*-hydroxybenzaldehyde (4 %). If sodium bismuthate is used as oxidant, the yield of *p*-benzoquinone is only 5 % and a new product, 1-oxaspiro[2.5]octa-4,7-dien-6-one (*5*), is formed in a yield of 20 %.

It was observed several years ago that *p*-hydroxybenzyl alcohols on treatment with aqueous sodium metaperiodate give formaldehyde and the corresponding *p*-benzoquinone.[1] *o*-Hydroxybenzyl alcohols were later found to react with the same oxidant to give the Diels-Alder *endo* dimers of the initially formed spiro(oxirane-2,4-cyclohexadienones).[2,3] For instance, periodate oxidation of salicyl alcohol (*1*) (Scheme 1) afforded a dimer (*3*) of the intermediary 2,4-cyclohexadienone *2* in a yield of 74 %, with only 1 % of salicyl aldehyde being formed simultaneously.[2] Similar oxidation of *o*-hydroxybenzyl alcohols carrying at least one bulky ring substituent gave the corresponding monomeric spiro compounds which, due to steric hindrance, did not dimerize.[4]

The primary aim of the present study was to find conditions under which oxidation of *p*-hydroxybenzyl alcohols leads to the formation of spiro(oxirane-2,5-cyclohexadienones) rather than to the oxidative cleavage to the corresponding *p*-benzoquinone and formaldehyde. It has been possible to perform the first-mentioned reaction with 4-hydroxybenzyl alcohol.



Scheme 1.

From the reaction mixture obtained on treatment of 4-hydroxybenzyl alcohol (*4*) for 30 min with a solution of sodium metaperiodate in acetic acid-water (4:1) only *p*-benzoquinone (yield, 23 %) and *p*-hydroxybenzaldehyde (yield, 4 %) could be isolated. A similar experiment with sodium bismuthate as oxidant gave, in addition to minor amounts of *p*-benzoquinone (5 %) and *p*-hydroxybenzaldehyde (2 %), 20 % of a product $C_7H_6O_2$ (m.p. 51 – 52 °C) which was the desired spiro compound *5*. Its structural assignment is based on the chemical behaviour and the spectral properties described below.

In the reaction mixtures obtained in the periodate and bismuthate oxidation experiments no unreacted 4-hydroxybenzyl alcohol could be detected. The major part of the starting material had been converted into a dark-coloured product which was strongly adsorbed on the silica gel column used in the separation of the reaction products. If the oxidation with periodate was carried out in water or in a 10 %, rather than the above-mentioned 80 %, aqueous acetic acid solution, a dark-brown amorphous material deposited. It is most probable that the

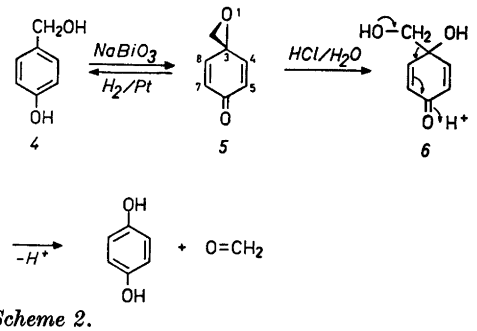
* Part XIII: Holmberg, K. *Acta Chem. Scand. B 28* (1974) 857.

formation of this material is mainly due to *ortho* oxidation of *4*, the resulting *o*-quinone alcohol being unstable under the conditions used, as shown in separate studies.[5] It has been reported earlier that periodate oxidation of 2,4-dimethylphenol, possessing a free *ortho* position, gives 3,5-dimethyl-1,2-benzoquinone [6] among other products.

Catalytic hydrogenation of *5* regenerated 4-hydroxybenzyl alcohol, as could be expected from the similar behaviour of spiro(oxirane-2,5-cyclohexadienones) carrying substituents in the six-membered ring.[7] Dilute aqueous hydrochloric acid caused rapid degradation of *5* to give formaldehyde and hydroquinone. It is assumed that, in this reaction, hydrolysis first gives the *p*-quinol *6* which in a rapid (proton-catalyzed) retro aldol condensation loses its hydroxymethyl group as formaldehyde, concomitant aromatization constituting a driving force (Scheme 2).

Similar loss of a 4-carbinol substituent takes place in 2,5-cyclohexadienone intermediates arising in certain modes of radical coupling involved in the biosynthesis of lignin,[8,9] in the oxidative degradation of *p*-hydroxybenzyl alcohols with dipotassium nitrosodisulfonate,[10] in the formation of oligomers of the polyphenylene oxide type from 3,5-disubstituted 4-hydroxybenzyl alcohols,[11,12] and in the colour reaction of 4-hydroxybenzyl alcohols with *N*-chloroquinone imide.[13]

The 60 MHz NMR spectrum of compound *5* in $CDCl_3$ exhibited two signals at δ 3.36 and 6.49, the ratio of their integrals being 1:2. The former signal can be ascribed to the protons of the oxirane ring. Since the plane of this ring is perpendicular to that of the dienone ring, the two oxirane protons are equivalent and the same is true for the vinyl protons H-4, H-8 and H-5, H-7, respectively. By a fortuitous shift coincidence the two last-mentioned pairs of protons give rise to a single signal.



Scheme 2.

The presence of a group of three peaks at 1665, 1635, and 1622 cm^{-1} in the IR spectrum of *5*, arising from the cross-conjugated carbonyl system is in accord with IR spectroscopic characteristics of other 2,5-cyclohexadienones. It may be noted, however, that in the spectrum of *5* these three bands are of high intensity, whereas in the spectra of previously investigated 2,5-cyclohexadienones the band of lowest frequency generally was rather weak.[14,15] A peak of medium strength at 3060 cm^{-1} can be attributed to the CH_2 group of the oxirane ring.[16]

In the UV spectrum of *5* (in ethanol), the maximum of the $\pi \rightarrow \pi^*$ absorption was found at λ 250 nm ($\log \varepsilon = 4.24$) and that of the $n \rightarrow \pi^*$ band at λ 336 nm ($\log \varepsilon = 1.47$). As can be seen from Table 1, the former maximum is located at a considerably higher wavelength than the corresponding maxima of *p*-toluquinol (*13*) [17] and of the spiro(oxolane-2,5-cyclohexadienone) *14*,[18] the positions of the two latter maxima being in accord with that calculated for a β-substituted enone system (227 nm). The deviation from the Woodward rules found for *5* seems to be due to a conjugative effect of the oxirane ring.

For comparison, Table 1 also includes the λ_{max} value of the spiro(cyclopropane-2,5-cyclohexadienone) *16*,[20] as well as those of the dimethyl dienone *15* and the spiro compound *17*.[19] The absorption maximum of *16* is found at a wavelength still higher than that of its oxa analogue *5*. It may further be noted that compound *17* absorbs at a higher wavelength than its oxa analogue *14* and the monocyclic compounds *13* and *15*.

As mentioned above, compound *5* is obtained on oxidation of *4* with bismuthate but seems not to be formed when periodate is used as oxidant. This is remarkable, since the two oxidants are generally considered equivalent as glycol-cleaving agents [21] and have been shown to act similarly in the oxidation of guaiacol to *o*-benzoquinone and methanol.[22] An attempt to rationalize the different action of bismuthate and periodate in the present case has been made in Scheme 3. The oxidation of *4* is believed to be initiated by nucleophilic attack by the phenolic

	13	5	14	15	16	17
λ_{max}, nm	227	250	228	227	274	242
log ε	4.25	4.24	4.08	4.1	4.34	4.20

Table 1. Ultraviolet maxima ($\pi \rightarrow \pi^*$ bands) of some 2,5-cyclohexadienones. Solvents: Ethanol for *13*,[17] *5*, *14* [18] and *17* [19]; methanol for *16* [20]. The λ_{max} value of *15* has been calculated by application of Woodward's rules; the log ε value is that of the 2-methyl derivative.[20]

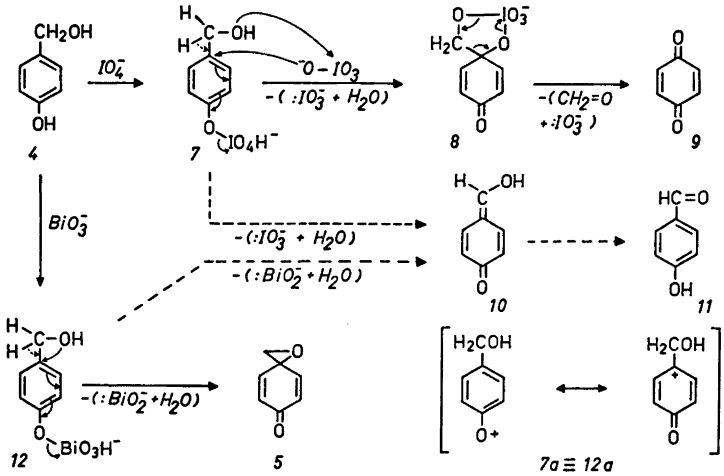
oxygen on the iodine and bismuth atoms of the oxidants, resulting in the formation of aryl esters *7* and *12*, respectively. In the bismuthate system, the formation of *5* is then assumed to proceed by a concerted reaction involving two-electron transfer to the bismuth atom with simultaneous nucleophilic attack by the alcoholic oxygen atom on the aromatic ring. In the periodate system, the oxygen of a second molecule of periodate rather than the alcoholic hydroxyl group may attack the ring, subsequent (or preceding) coordination of the latter group to the iodine atom giving intermediate *8*. This cyclic glycol periodic ester would decompose in the normal way [23] to give formaldehyde and *p*-benzoquinone (*9*).

The different behaviour of esters *7* and *12* can possibly be attributed to the fact that the concentration of bismuthate ions in 80 % acetic acid solution of *4* is low, most of the sodium bismuthate during the reaction being present as a solid, whereas the sodium periodate is completely dissolved.

The formation of small amounts of *p*-hydroxybenzaldehyde (*11*) in both systems may be understood as being due to the loss of a proton from the carbinol carbon atom in *7* and *12* giving the enol *10* which tautomerizes to *11* (see dashed line arrows in Scheme 3).

Instead of the one-step concerted reactions indicated in formulae *7* and *12*, one may as well assume two-step reactions, involving, in a first step, two-electron transfer to the periodate and bismuthate residue with formation of a resonance-stabilized phenoxonium ion (*7a*≡ *12a*), the latter reacting further to give the postulated intermediates *8* and *10*, as well as product *5*.

p-Benzoquinone (*9*) is also formed in the bismuthate oxidation system, although in considerably smaller amounts than in the periodate system, the yields obtained after a reaction time of 30 min being 5 and 23 %, respectively (*cf.* p. 883). Prolonged bismuthate oxidation slowly increased the yield of *9*, whereas the yield of *5* decreased, the total of *9* and *5* remain-



Scheme 3.

ing approximately constant. This indicates that, in the bismuthate system, the *p*-benzoquinone is formed *via* the spiro compound *5*. In fact, treatment of *5* with bismuthate in 80 % aqueous acetic acid for 30 min gave *p*-benzoquinone in a yield of 22 %, in addition to unreacted *5* (65 %).

The possibility of *5* being an intermediate in the formation of *p*-benzoquinone in the periodate system seems to be ruled out by the fact that only 28 % of compound *5* was converted to the quinone when treated with periodate in 80 % aqueous acetic acid for 30 min.

These conversions of *5* to *p*-benzoquinone must be due to hydrolytic opening of the oxirane ring followed by loss of formaldehyde, the resulting hydroquinone (*cf.* the similar hydrolysis by aqueous HCl, Scheme 2) being dehydrogenated by the oxidant present. The hydrolysis of *5* in 80 % aqueous acetic acid, in the absence of oxidant, was followed by UV spectrometry revealing a decrease in absorbance at 250 nm (λ_{max} of *5*) and an increase at 290 nm (λ_{max} of hydroquinone). Expectedly, hydrolysis in this solvent was much slower than that found in aqueous hydrochloric acid (*cf.* p. 884). After 24 h treatment of *5* with 80 % acetic acid, however, hydroquinone could be isolated in a yield of 82 %.

Compound *5* proved to be stable in an aqueous solution of $NaIO_4$, but was rapidly converted to formaldehyde and *p*-benzoquinone in aqueous H_5IO_6, acid hydrolysis of the oxirane ring again being the initial step.

Treatment with aqueous sodium hydrogen carbonate did not appreciably affect compound *5*; however, addition of aqueous NaOH caused immediate conversion into dark brown products. At room temperature, solid *5* slowly deteriorates, whereas it can be stored essentially unchanged for several months at −20 °C.

Some compounds with the basic structure *5* carrying substituents in the dienone ring have been reported earlier. They were prepared by the action of alkali upon 2,5-cyclohexadienones with a halohydrine grouping in the 4-position [24] or by the action of diazomethane on substituted *p*-quinones.[7] A tricyclic analogue of *5* carrying the spirooxirane ring in the 10-position of anthrone has also been described.[25]

EXPERIMENTAL

UV spectra were recorded on a Cary Model 14 spectrophotometer; IR and NMR spectra were obtained using Beckman 9A and Varian A-60 instruments, respectively. Chemical shifts are given in δ (ppm) units, TMS being used as internal standard.

Oxidation of 4-hydroxybenzyl alcohol (4) with sodium metaperiodate. A solution of $NaIO_4$ (0.06 mol) in a mixture of 100 ml of water and 80 ml of acetic acid was added to a solution of *4* (0.03 mol) in 320 ml of acetic acid. After 30 min at room temperature ethylene glycol (5 ml) was added in order to remove excess periodate and the dark red-brown solution was extracted with three 150 ml portions of dichloromethane. The combined extracts were washed twice with aqueous hydrogen carbonate and with water and, after being dried over anhydrous Na_2SO_4, were brought to dryness under vacuum, leaving a brown oil. The latter was chromatographed on a silica gel column (4 × 60 cm) using benzene-ethyl acetate (4:1) as eluent. The first eluted yellow fraction gave p-*benzoquinone* ($R_F = 0.39$) in a yield of 23 %. A following fraction provided 4-*hydroxybenzaldehyde* ($R_F = 0.21$); yield, 4 %. The products were identified by m.p. and mixed m.p. with authentic samples.

Oxidation of 4-hydroxybenzyl alcohol (4) with sodium bismuthate. A solution of *4* (0.03 mol) in 300 ml of an acetic acid-water (4:1) mixture was stirred for 30 min at room temperature with $NaBiO_3$ (0.06 mol). Unconsumed bismuthate was filtered off and the dark brown-red filtrate worked up as described above. Elution of the silica gel column gave:

(*a*) p-*Benzoquinone* ($R_F = 0.39$) in a yield of 5 %.

(*b*) *1-Oxaspiro[2.5]octa-4,7-dien-6-one (5)*, R_F = 0.33, colourless crystals of m.p. 51 – 52 °C after sublimation (40 °C, 1 mmHg); yield, 20 %. (Found: C 69.01; H 5.04. Calc. for $C_7H_6O_2$: C 68.84; H 4.95). UV, IR and NMR spectra, *cf.* p. 884.

(*c*) 4-*Hydroxybenzaldehyde* ($R_F = 0.21$); yield, 2 %.

Catalytic hydrogenation of 5. A solution of *5* (124 mg) in acetone (10 ml) was added to the suspension of prehydrogenated PtO_2 (30 mg) in acetone (5 ml). The mixture was stirred under hydrogen for 30 min after which time 1 mol of H_2 per mol of *5* had been consumed and further hydrogen uptake was slow. Removal of the solvent from the filtered solution and recrystallization of the crystalline residue from ether gave *4-hydroxybenzyl alcohol*, identical by m.p. and mixed m.p. with authentic material. Yield, 80 %.

Hydrolysis of 5 with 2 M aqueous hydrochloric acid. (a) A solution of *5* (110 mg) in 2 M aqueous HCl (25 ml) was kept at room temperature for 3 min and then extracted with three 100 ml portions of ether. The combined extracts were dried over anhydrous Na_2SO_4 and brought to dryness. The crystalline residue was recrystal-

lized from ether and was found to be identical to *hydroquinone* by m.p. (168–170 °C) and mixed m.p. Yield, 74 %. (b) Compound *5* (21.7 mg, 0.18 mmol) was dissolved in 2 M aqueous HCl. After 5 min, the solution was neutralized with aqueous NaOH. A 0.1 M NaOAc-HCl (2:1) buffer solution (300 ml) of pH 4.6 was added, followed by 30 ml of a saturated aqueous solution of dimedone (*cf.* Ref. 26). Filtration after 15 h gave *dimedone-formaldehyde compound*, m.p. 185–187 °C, identical by mixed m.p. with an authentic sample. Yield, 53.2 mg (100 %).

Hydrolysis of 5 with 80 % aqueous acetic acid. A solution of *5* (300 mg) in a 4:1 acetic acid-water mixture (50 ml) was kept at 25 °C for 24 h. The solution was then concentrated under vacuum to one third of its volume and extracted with 3 × 25 ml of chloroform. Removal of the solvent from the combined extracts gave an oily residue which crystallized on addition of a few milliliters of ether. The product after recrystallization from acetone had m.p. 170–171 °C and was identical by mixed m.p. with authentic *hydroquinone*. Yield, 82 %.

Treatment of 5 with $NaIO_4$ and $NaBiO_3$ in 80 % aqueous acetic acid. (a) Solutions of *5* (300 mg) in acetic acid (60 ml) and of $NaIO_4$ (920 mg) in 60 % aqueous acetic acid (60 ml) were mixed and after 30 min the mixture was extracted with chloroform (3 × 40 ml). The residue obtained on evaporation of the combined extracts was chromatographed (silica gel, benzene-ethyl acetate, 4:1) giving p-*benzoquinone* in a yield of 28 % and unreacted *5* (62 %). (b) $NaBiO_3$ (1.2 g) was added to a stirred solution of *5* (300 mg) in 80 % aqueous acetic acid (60 ml). After 30 min, the filtered solution was worked up as described under (*a*), affording p-*benzoquinone* (22 %) in addition to unreacted *5* (65 %).

Treatment of 5 with H_5IO_6 in aqueous solution. Aqueous solutions of *5* (300 mg, 15 ml) and H_5IO_6 (1.1 g, 80 ml) were mixed and the mixture was extracted after 17 h with 3 × 100 ml of chloroform. The combined extracts, after being dried and evaporated, gave a residue which was purified by sublimation (25 °C, 0.05 mmHg) to give p-*benzoquinone* in a yield of 85 %. In a separate experiment, formaldehyde present in the reaction mixture was converted into the dimedone compound; yield, 80 %.

Periodate Oxidation of Phenols. XV.* Oxidation of 3,5-Dimethyl- and 2,5-Dimethyl-4-hydroxybenzyl Alcohols

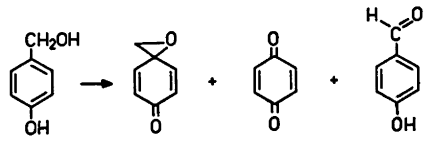
ERICH ADLER, KRISTER HOLMBERG and LARS-OLOF RYRFORS

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

Oxidation of 4-hydroxy-3,5-dimethylbenzyl alcohol (*5*) in aqueous acetic acid with periodate gave 2,6-dimethyl-1,4-benzoquinone (*6*), 4-hydroxy-3,5-dimethylbenzaldehyde (*7*), and 6-acetoxy-4-hydroxymethyl-2,6-dimethyl-2,4-cyclohexadienone (*8*), whereas only *6* and *7* were obtained when bismuthate was used as oxidant. Preferential *para* oxidation by the latter reagent was also observed when mesitol was used as substrate.

When *5* was oxidized with periodate in H_2O/EtOH (60:5), a Diels-Alder adduct (*20*) of *o*-quinol *21* with simultaneously formed *p*-quinone *6* was obtained, in addition to *o*-quinol dimer *22* and aldehyde *7*. Under similar conditions, 4-hydroxy-2,5-dimethylbenzyl alcohol (*25*) yielded the corresponding *p*-benzoquinone *26* and aldehyde *27*, as well as the dimeric *o*-quinol *29* which in the solid state had the structure of a cyclic hemiketal (*29a*).

In a preceding paper,[1] oxidation of 4-hydroxybenzyl alcohol (*1*) with sodium periodate in 80 % aqueous acetic acid was reported to give



1 *2* *3* *4*

p-benzoquinone (*3*) and 4-hydroxybenzaldehyde (*4*), as well as considerable amounts of polymeric material. If sodium bismuthate was used as oxidant, the spiro(oxirane-2,5-cyclohexadienone) *2* was formed in addition to *3* and *4*.

In the present study the behaviour of 4-hydroxy-3,5-dimethylbenzyl alcohol (*5*) towards the two oxidants has been examined using aqueous acetic acid as solvent. Unlike the unsubstituted 4-hydroxybenzyl alcohol, *5* failed to give a spiro compound on treatment with bismuthate, but certain differences in the ratio of *ortho* and *para* oxidation products formed by periodate and bismuthate, respectively, were observed. For comparison, the oxidation of 2,4,6-trimethylphenol (*15*) in the same solvent has been investigated. Furthermore, the oxidation of the 3,5- and 2,5-dimethyl derivatives of *1* with aqueous periodate, in the absence of acetic acid, has been studied.

Oxidation in aqueous acetic acid

4-Hydroxy-3,5-dimethylbenzyl alcohol (5) (Chart 1). Both periodate and bismuthate produced 2,6-dimethylbenzoquinone (*6*) and 4-hydroxy-3,5-dimethylbenzaldehyde (*7*), *i.e.*, the dimethyl homologues of the products (*3*, *4*) formed on similar oxidation of unsubstituted 4-hydroxybenzyl alcohol.[1] With periodate as oxidant a third product, *viz.* the *o*-quinol acetate *8*, was obtained. The total yields of identified products formed after a reaction time of 30 min, which was sufficient for the starting material (*5*) to be completely consumed, were considerably higher than those obtained from *1*, since in the latter case large amounts of amorphous material were formed.[1]

The spiro compound *11* could not be detected in the bismuthate reaction mixture, although

* Part XIV, see Ref. 1.

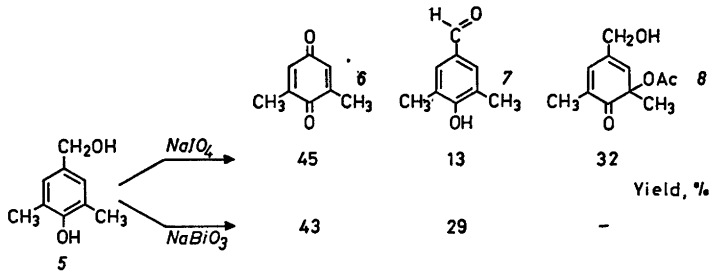


Chart 1.

its formation in the bismuthate system had been expected, since the parent compound *2* had been obtained from *1* in the same system.[1] The failure of the phenol alcohol *5* to give *11* may possibly be understood as shown in Chart 2.

Assuming that the initially formed aryl bismuthate *9* decomposes by two-electron transfer to give the phenoxonium ion *10*, the latter could undergo ring closure to provide the spiro-oxirane *11*. The same result would be obtained if *9* undergoes concerted ring closure and loss of a trivalent bismuth species (dashed line arrow). The unsubstituted analogue *2* of the spiro compound *11* has been found to be slowly hydrolyzed by 80 % aqueous acetic acid, the reaction being complete after about 24 h at room temperature.[1] In the present case, however, the two allylic methyl groups may stabilize the cation *10*, thus favouring reaction *11*→*10* and increasing the rate of hydrolysis. The resulting *p*-quinol *12* would lose formaldehyde to give 2,6-dimethylhydroquinone (*13*) which would be oxidized to the quinone *6* (*cf.* Ref. 1).

The second reaction product (*7*) can be assumed to arise by loss of a proton from the carbinol C-atom of *10* or by a corresponding concerted reaction of *9* (dotted line arrow) followed by rearrangement of the resulting enol *14*.

The fact that *o*-quinol acetate (*8*) is formed in the periodate system but not in the bismuthate system and, furthermore, the comparatively high yield of aldehyde *7* obtained with bismuthate (Chart 1) seemed to indicate that bismuthate preferentially acts as a *para*-oxidizing agent. With the aim of obtaining further support for this view, the following experiments with 2,4,6-trimethylphenol (mesitol) were carried out.

2,4,6-Trimethylphenol (15) (Chart 3). When treated in 80 % aqueous acetic acid with

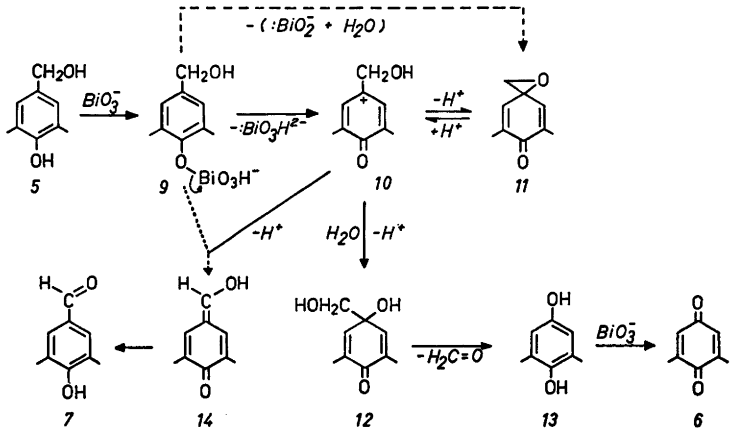

Chart 2.

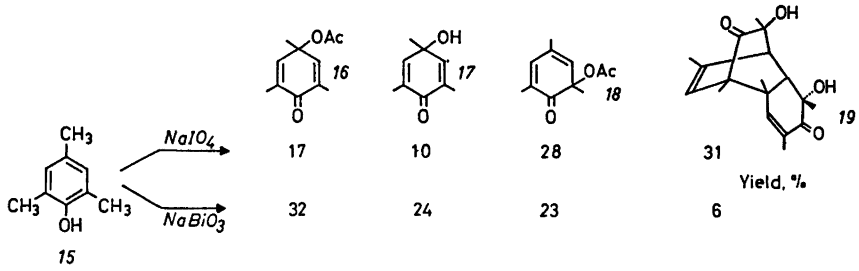

Chart 3.

periodate or bismuthate for 30 min, products *16* – *19* were obtained in either case. However, with periodate as oxidant, the ratio of *ortho*/*para* oxidation products was 59/27, whereas almost the inverse ratio (29/56) was found for the bismuthate system.

Oxidation in aqueous ethanol

In earlier work on the periodate oxidation of 2-methyl- and 2-hydroxymethyl-substituted phenols the reaction had been carried out in aqueous [2-4] or aqueous ethanolic [5] solution and therefore it was of interest to examine the behaviour of the 4-hydroxybenzyl alcohols *5* and *25* under similar conditions. The solvent mixture used in this study contained a small amount of ethanol which was sufficient to keep the starting material, as well as the reaction products, in solution.

4-Hydroxy-3,5-dimethylbenzyl alcohol (5) (Chart 4). Treatment of *5* with periodate gave, in addition to *p*-quinone *6* and aldehyde *7*, which also had been obtained when aqueous acetic acid was used as solvent, two compounds, $C_{17}H_{20}O_5$ and $C_{18}H_{24}O_6$, melting at 129 – 130 °C and 179 – 180 °C, respectively.

The lower-melting yellow compound, $C_{17}H_{20}O_5$, was assigned the structure of a Diels-Alder adduct (*20*) between *o*-quinol *21* and *p*-quinone *6*. This structure is based on the following spectral and chemical evidence.

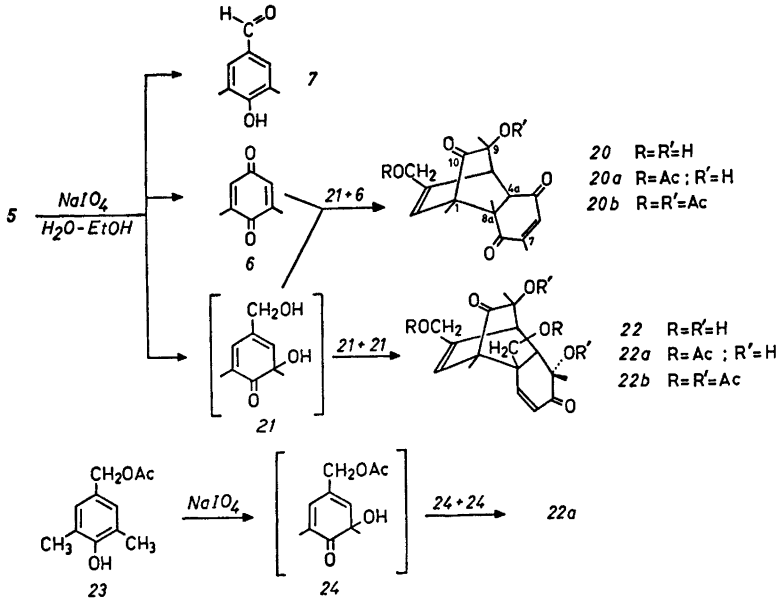

Chart 4. (*Note added in proof*: Formula *22* – *22b* should carry a CH_3 group in position 7.)

The ethanolic solution of *20* showed strong UV absorption with maxima at 215 and 234 nm, as well as low-intensity absorption at 305 nm (sh) and 375 nm. The absorption band at 215 nm can be attributed to transannular charge transfer between the 2,3-ethylenic bond and the C-10 keto group; strong absorption at a similar wavelength has previously been found to be characteristic of the β,γ-conjugated carbonyl system present in dimeric *o*-quinols.[5,6] The maxima at 234, 305, and 375 nm can be ascribed to the enedione system present in the dienophile moiety of the molecule; similar absorption has been reported to be typical of enediones.[7-9] In the IR spectrum of *20* the conjugated CO groups are reflected by an absorption band at 1660 cm^{-1}, whereas the isolated CO group gives rise to a peak at 1723 cm^{-1}.

The NMR spectrum of the compound was in full agreement with structure *20* (see Experimental).

Treatment of *20* with Ac_2O/pyridine, which does not acetylate tertiary hydroxyl groups, gave the monoacetate *20a*, whereas the diacetate *20b* was obtained with $Ac_2O/HClO_4$.[10]

The product $C_{18}H_{24}O_6$, m.p. 179–180 °C, was colourless and had the spectral properties expected for an *o*-quinol dimer of structure *22*. A diacetate (*22a*) was formed with Ac_2O/pyridine and a tetraacetate (*22b*) was obtained from either *22* or *22a* with $Ac_2O/HClO_4$, which is in accord with this structural assignment. Diacetate *22a* was also formed, *via* the intermediary *o*-quinol *24*, on periodate oxidation of 4-hydroxy-3,5-dimethylbenzyl acetate (*23*).

The dimeric *o*-quinol *22* was obtained in a yield of 14 % and the *o*-quinol-*p*-quinone adduct *20* in a yield of 33 %. The formation of these compounds at room temperature illustrates the high diene reactivity of *o*-quinols.

4-Hydroxy-2,5-dimethylbenzyl alcohol (*25*) (Chart 5). Periodate was consumed at a considerably lower rate by *25* than by its isomer *5*, which is in analogy with the exceptionally sluggish reaction of 2,5-dimethylphenol as compared with other phenols, such as 2,6-dimethylphenol.[4] Expectedly, *25* gave the *p*-benzoquinone *26* and the aldehyde *27*. In addition, a colourless compound of m.p. 203–204 °C was isolated. Its composition, $C_{18}H_{24}O_6$, seemed to indicate the compound to be a Diels-Alder dimer (*29*) of the intermediary *o*-quinol *28*. The IR spectrum of the substance (in KBr) revealed the presence of the conjugated keto group at C-6, but, surprisingly, the expected peak due to the keto group at C-10, which in dimeric *o*-quinols is found within the range of 1710–1725 cm^{-1}, was missing. It was supposed, therefore, that the latter keto group was masked by the formation of a hemiketal with the hy-

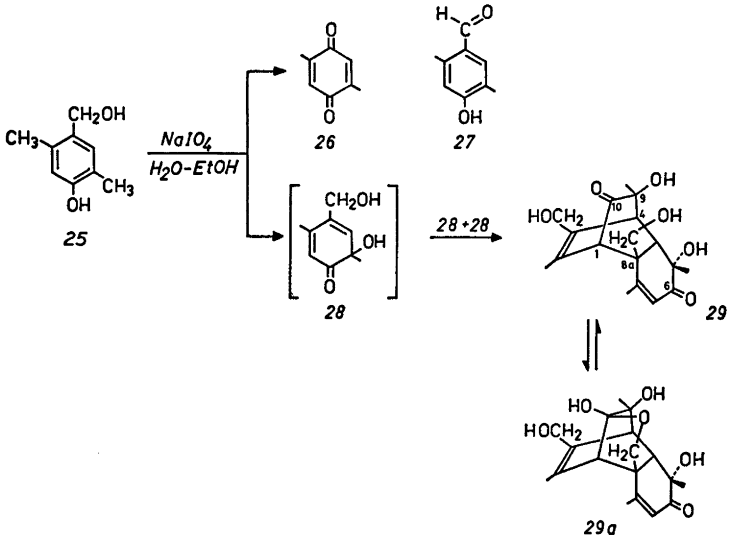

Chart 5.

droxyl group of the substituent at C-8a. In fact, the IR spectrum of the compound dissolved in DMSO, ethanol or dioxan showed peaks due to both the conjugated and the isolated keto groups. Structure *29a* is therefore ascribed to the compound in the solid state and the structure of a dimeric *o*-quinol (*29*) to the substance dissolved in a polar solvent ("ring-chain tautomerism").

No *o*-quinol-*p*-quinone adduct of type *20* was detected in the reaction mixture obtained from phenol *25*.

Structural and stereochemical orientation in dimers *22* and *29* and in adduct *20*

The structural and stereochemical specificity characteristic of the Diels-Alder dimerisation of 2,4-cyclohexadienones [4,6,11] is illustrated again by the fact that only a single *o*-quinol dimer (*22* and *29*, respectively) has been detected in the oxidation of each of the phenols *5* and *25*. Similarly, the Diels-Alder reaction *21*+*6* gives a single adduct (*20*).

The assignment of the structural orientation given in formulae *20* and *22* is based on the NMR spectra of these compounds. They showed the patterns required for coupling between the vicinal protons at C-4 and C-4a as well as between the protons at C-4 and C-2 (for *20*: $J_{4,4a}=2.2$ Hz, $J_{4,2}=2.0$ Hz; for *22*: $J_{4,4a}=2.1$ Hz, $J_{4,2}=2.0$ Hz. See also Experimental).

The dimers *22* and *29*, as well as adduct *20*, were stable towards periodate, in spite of the presence of the 9,10-hydroxyketone grouping. As discussed in Part XII,[6] this can be interpreted to be due to the steric orientation of the 9-OH group as shown in the formulae, in combination with the presence of the CH_2OH or the CH_3 substituent, respectively, at C-8a. Although there is no direct evidence for the configuration at C-5 to be that given in formulae *22* and *29*, its correctness is highly probable since it is favoured if steric approach control is operative in the dimerization and since it actually has been established for other dimeric *o*-quinols.[6,11]

The formation of hemiketal *29a* constitutes proof of the *endo* configuration of this dimer. *Endo* configuration has also been assumed above for dimer *22*, as well as for adduct *20*. This seems justified because the dimerization of *o*-quinols has been shown earlier to follow the *endo* addition rule.[4,11,12]

EXPERIMENTAL

UV spectra were recorded on a Cary Model 14 spectrophotometer; IR and NMR spectra were obtained using Beckman 9 A and Varian A-60 instruments, respectively. Chemical shifts are given in δ (ppm units, TMS being used as internal standard).

4-Hydroxy-3,5-dimethylbenzyl alcohol (*5*), the corresponding benzyl acetate (*23*), and 4-hydroxy-2,5-dimethylbenzyl alcohol (*25*) were prepared according to Refs. 13, 14, and 15, respectively.

Oxidation with periodate in aqueous acetic acid. A solution of phenols *5* or *15* (0.03 mol) in acetic acid (320 ml) was mixed with a solution of $NaIO_4$ (0.06 mol) in a mixture of acetic acid (80 ml) and water (100 ml). After 30 min (room temperature) ethylene glycol (5 ml) was added to remove excess periodate and the mixture was extracted with three 150 ml portions of dichloromethane. The combined extracts were washed with aqueous bicarbonate, dried over Na_2SO_4 and brought to dryness. The resulting residue was chromatographed on a silica gel column (4 × 60 cm) using benzene/ethyl acetate (4:1) as eluent.

Periodate oxidation products obtained from 4-hydroxy-3,5-dimethylbenzyl alcohol (5). The eluate fractions gave:

(a) 2,6-Dimethyl-1,4-benzoquinone (6), $R_F=0.43$; yield, 45 %. M.p., after sublimation, 69–71 °C (Lit.[16] 72–73 °C). The IR spectrum of the compound was in accord with that reported for *6*.[17]

(b) 6-Acetoxy-4-hydroxymethyl-2,6-dimethyl-2,4-cyclohexadienone (8). $R_F=0.38$, yellow oil. Yield, 32 %. (Found: *M*, by mass spectrometry, 210.0902. Calc. for $C_{11}H_{14}O_4$: *M* 210.0892.) IR (KBr): ν_{max}, cm^{-1} 1668 (conj. CO), 1740 (ester CO), 3460 (OH). NMR ($CDCl_3$): δ 1.36 (s, 3 H, CH_3), 1.95 (broad s, 3 H, olefinic CH_3), 2.07 (s, 3 H, CH_3COO), 4.20 (d, 2 H, CH_2), 5.33 (1 H, OH), 6.06 and 6.83 (multiplets, 1 H each, 2 olefinic H).

(c) 4-Hydroxy-3,5-dimethylbenzaldehyde (7), $R_F=0.29$; yield, 13 %. M.p., after recrystallization from benzene, 113–114 °C (Lit.[18] 114–115 °C). The IR spectrum of the compound was in accord with that reported for *7*.[19]

Periodate oxidation products obtained from mesitol (15). The eluate fractions gave:

(a) 6-Acetoxy-2,4,6-trimethyl-2,4-cyclohexadienone (18), $R_F=0.47$; yield, 28 %. Yellow crystals, m.p. 80–82 °C (Lit.[20] 82–84 °C)

(b) 4-Acetoxy-2,4,6-trimethyl-2,5-cyclohexadienone (16), $R_F=0.43$. Pale yellow oil;[20] yield, 17 %. NMR ($CDCl_3$): δ 1.51 (s, 3 H, CH_3-4),

1.89 (s, 6 H, CH_3-2 and CH_3-6), 2.00 (s, 3 H, CH_3COO), 6.69 (s, 2 H, H-3 and H-5).

(*c*) *4-Hydroxy-2,4,6-trimethyl-2,5-cyclohexadienone (17)*, $R_F = 0.14$; yield, 10 %. M.p. 45–46 °C (Lit.[21] 45.5–46 °C). The IR and NMR spectra of the compound were in agreement with those expected for structure *17*.

(*d*) *1,4a,5,8a-Tetrahydro-5,9-dihydroxy-1,3,5,7,8a,9-hexamethyl-1,4-ethanonaphthalene-6,10 (4H)-dione (19)*, $R_F = 0.09$, yield, 31 %. Identical by m.p. and mixed m.p. with an authentic sample.[5]

Oxidation with bismuthate in aqueous acetic acid. Sodium bismuthate ($NaBiO_3$, 0.06 mol) was added to a stirred solution of phenol *5* or *15* (0.03 mol) in 300 ml of acetic acid/water (4:1). After 30 min the mixture was filtered and the filtrate worked up as described for the periodate procedure.

Phenol *5* gave *2,6-dimethyl-1,4-benzoquinone (6)* in a yield of 43 % and *4-hydroxy-3,5-dimethylbenzaldehyde (7)* in a yield of 29 %.

Mesitol (*15*) gave o-*quinol acetate* 18 (23 %); p-*quinol acetate* 16 (32 %), p-*quinol* 17 (24 %) and *dimeric* o-*quinol* 19 (6 %).

Periodate oxidation of 4-hydroxy-3,5-dimethylbenzyl alcohol (5) in aqueous ethanol. A solution of $NaIO_4$ (3.84 g, 18 mmol) in water (150 ml) was added to a solution of *5* (1.80 g, 12 mmol) in 500 ml of ethanol-water (1:10). After 16 h (room temp.) the mixture was extracted with 3 × 200 ml of hexane. The combined extracts gave *2,6-dimethyl-1,4-benzoquinone (6)*; yield, 21 %.

The aqueous phase was extracted with 5 × 400 ml of ethyl acetate. The combined extracts were dried over Na_2SO_4 and evaporated, and the residue obtained was chromatographed on a silica gel column using acetone/hexane (2:1) as eluent. The eluate fractions gave:

(*a*) *4-Hydroxy-3,5-dimethylbenzaldehyde (7)*, $R_F = 0.60$; yield, 6 %.

(*b*) *1,4,4a,8a-Tetrahydro-9-hydroxy-3-hydroxymethyl-1,7,8a,9-tetramethyl-1,4-ethanonaphthalene-5,8,10-trione (20)*, $R_F = 0.53$; yield, 33 %. Yellow crystals, m.p. 129–130 °C (ethyl acetate/hexane). (Found: C 66.7; H 6.5. Calc. for $C_{17}H_{20}O_5$: C 67.1; H 6.6). UV (ethanol): λ_{max}, nm (log ε) 215 (4.05), 234 (4.05), 305 sh (2.70), 375 (2.12). IR (KBr): ν_{max}, cm^{-1} 1635 (C=C), 1660 (conj. CO), 1723 (CO), 3330, 3460 and 3540 (OH). NMR ($CDCl_3$): δ 1.37, 1.40 and 1.42 (singlets, 3 H each, 3 CH_3), 2.10 (d, 3 H, CH_3-7), 2.60 (broad, 2 H, 2 OH, exchangeable with D_2O), 3.31 (t, 1 H, H-4), 3.62 (d, 1 H, H-4a), 4.20 (d, 2 H, CH_2), 5.79 (m, 1 H, H-2), 6.71 (quartet, 1 H, H-6).

(*c*) *1,4a,5,8a-Tetrahydro-5,9-dihydroxy-3,8a-bis(hydroxymethyl)-1,5,7,9-tetramethyl-1,4-ethanonaphthalene-6,10(4H)-dione (22)*, $R_F = 0.42$; yield, 14 %. Colourless crystals, m.p. 179–180 °C (benzene). (Found: C 64.25; H 7.16. Calc. for $C_{18}H_{24}O_6$: C 64.28; H 7.19). UV (ethanol): λ_{max}, nm (log ε) 210 (3.94), 240 sh (3.78), 310 sh (2.48). IR (KBr): ν_{max}, cm^{-1} 1650 (C=C), 1690 (α,β-conj. CO), 1718 (CO), 3400 (broad, OH). NMR (DMSO-d_6): δ 1.09, 1.12 and 1.25 (singlets, 3 H each, 3 CH_3), 1.70 (s, 3 H, CH_3-7), 2.81 (d, 1 H, H-4a), 2.93 (t, 1 H, H-4), 3.50 and 3.83 (broad signals, 2 H each, 2 CH_2), 4.67 and 5.25 (broad signals, 1 H each, 2 prim. OH), 4.82 and 5.41 (singlets, 1 H each, 2 tert. OH), 5.02 (m, 1 H, H-2), 6.19 (broadened s, 1 H, H-8).

Monoacetate 20a. From *20* by treatment with Ac_2O/pyridine. The crude solid obtained was treated with a small amount of diethyl ether and the yellow crystalline product collected. M.p. 106–107 °C (ethyl acetate/hexane). (Found: C 65.67; H 6.53. Calc. for $C_{19}H_{22}O_6$: C 65.88; H 6.40). IR (KBr): ν_{max}, cm^{-1} 1644 (C=C), 1670 (conj. CO), 1722 (CO), 1740 (ester CO), 3450 (OH).

Diacetate 20b. From *20* by treatment with $Ac_2O/HClO_4$.[10] Yellow crystals of m.p. 115–116 °C (ethanol). (Found: C 64.97; H 6.08. Calc. for $C_{21}H_{24}O_7$: C 64.93; H 6.22). IR (KBr): ν_{max}, cm^{-1} 1626 (C=C), 1661 (conj. CO), 1722 (CO), 1740 (ester CO).

Diacetate 22a. (*a*) From *22* by treatment with Ac_2O/pyridine, m.p. 168–169 °C (methanol). (Found: C 62.98, H 6.83. Calc. for $C_{22}H_{28}O_8$: C 62.89; H 6.71). IR (KBr): ν_{max}, cm^{-1} 1638 (C=C), 1673 (α,β-conj. CO), 1728 (CO), 1746 (broad, ester CO), 3470 and 3530 (*tert.* OH).

(*b*) A solution of 4-hydroxy-3,5-dimethylbenzyl acetate (*23*) (2.91 g, 15 mmol) in a mixture of acetic acid (100 ml) and water (300 ml) was mixed with a solution of $NaIO_4$ (4.91 g, 23 mmol) in water (100 ml). After 90 min the solution was extracted with 5 × 75 ml of dichloromethane. The residue obtained from the combined extracts was treated with a few milliliters of ether. The crystalline product formed (yield, 34 %) was identical by m.p. and mixed m.p. with *22a* prepared according to (*a*).

Tetraacetate 22b. From *22* or *22a* by treatment with $Ac_2O/HClO_4$,[10] m.p. 166–167 °C (methanol). (Found: C 61.8; H 6.5. Calc. for $C_{26}H_{32}O_{10}$ C 61.9; H 6.4). IR (KBr): ν_{max}, cm^{-1} 1708 (α,β-conj. CO), 1732 (CO), 1748 (broad, ester CO).

Periodate oxidation of 4-hydroxy-2,5-dimethylbenzyl alcohol (25) in aqueous ethanol. A solution of $NaIO_4$ (10.3 g, 48 mmol) in water (300 ml) was added to a solution of *25* (1.80 g, 12 mmol) in a mixture of ethanol (400 ml) and water (1300 ml). After 72 h (room temp.) the solution was extracted with 3 × 300 ml of hexane. The combined hexane phases gave *2,5-dimethyl-1,4-benzoquinone (26)* in a yield of 22 %. After sublimation (0.05 mmHg, 30 °C) the compound melted at 121–122 °C (Lit.[16] 124–124.5 °C). The IR spectrum of the compound was in accord with that reported for *26*.[17]

The aqueous phase was further extracted with 5 × 400 ml of ethyl acetate. The combined extracts were dried over Na_2SO_4 and evaporated, leaving a dark-coloured oil which was dissolved

in a few milliliters of acetone. A crystalline product deposited, which was recrystallized from acetone to give the *hemiketal* 29a of *1,4a,5,8a-tetrahydro-5,9-dihydroxy-3,8a-bis(hydroxymethyl)-2,5,8,9-tetramethyl-1,4-ethanonaphthalene-6,10(4H)-dione (29)*, m.p. 203–204 °C. Yield, 14 %. (Found: C 64.34; H 7.20. Calc. for $C_{18}H_{24}O_6$: C 64.28; H 7.19). UV (ethanol): λ_{max}, nm (log ε) 210 (3.73), 236 (3.70), 312 sh (2.22). IR (KBr): ν_{max}, cm^{-1} 1630 (C=C); 1680 (α,β-conj. CO), 3400 (broad, OH). IR (DMSO-d_6): ν_{max}, cm^{-1} 1630 (C=C), 1684 (α,β-conj. CO), 1722 (CO). NMR (DMSO-d_6): δ 1.11, 1.40 and 1.43 (singlets, 3 H each, 3 CH_3), 1.96 (broadened s, 3 H, CH_3-8), 2.75 (s, 1 H, H-1), 2.91 and 3.21 (doublets, 1 H each, H-4 and H-4a), 3.62 and 3.74 (broad signals, 2 H each, 2 CH_2), 4.68 and 5.12 (broad signals, 1 H each, 2 prim. OH), 4.83 and 5.48 (singlets, 1 H each, 2 *tert.* OH), 5.84 (s, 1 H, H-7). $J_{4,4a}$ = 2.0 Hz.

The acetone filtrate was chromatographed on a silica gel column using benzene/ethyl acetate (4:1) as eluent. *4-Hydroxy-2,5-dimethylbenzaldehyde (27)*, R_F = 0.31, was isolated in a yield of 5 %. After recrystallization from benzene, m.p. 129–130 °C (Lit.[22] 132–133 °C).

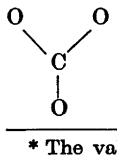
Non-bonded Oxygen—Oxygen Interactions in 2,4,10-Trioxaadamantane and 1,3,5,7,9-Pentoxecane

MARGRET MÅNSSON

Thermochemistry Laboratory, Chemical Center, University of Lund, S-220 07 Lund, Sweden

Enthalpies of combustion, utilizing a micro combustion calorimetric technique, and enthalpies of sublimation have been determined for 2,4,10-trioxaadamantane and 1,3,5,7,9-pentoxecane (pentoxane). Standard enthalpies of formation for the compounds in the gaseous state, ΔH_f°(g), have been derived and are $-(499.2 \pm 2.2)$ and $-(779.8 \pm 1.3)$ kJ mol^{-1}, respectively. The calculated stabilization energy due to next-nearest-neighbour oxygen-oxygen interaction in trioxaadamantane, relative to adamantane and aliphatic monoethers, is 53 kJ mol^{-1}. The gaseous enthalpy of formation per $-CH_2O-$ unit in pentoxane is very nearly the same as that in trioxane and tetroxane.

One pair of next-nearest-neighbour oxygen atoms in an aliphatic straight-chain compound gives rise to a stabilization energy as large as 17.$_6$ kJ mol^{-1} relative to monoethers,* whereas the stabilization in an $-O-CH_2-O-CH_2-O-$ arrangement, within experimental uncertainties, is twice that of one pair.[1] Addition of another $-CH_2-O-$ group likewise increases the total stabilization energy to three times that for a single pair.[1] This means that consecutive pairs of next-nearest-neighbour oxygens in straight-chain compounds give rise to the same stabilization energy per pair even though some of the oxygens are simultaneously engaged in two interactions. The orthoester arrangement



in 2,4,10-trioxaadamantane can similarly be looked upon as a three pair oxygen-oxygen next-nearest-neighbour interaction system. Does the fact that the interacting oxygens are all attached to the same carbon atom, and moreover rather rigidly locked into fixed positions, have a marked influence on the resulting stabilization energy in this tricyclic ortho ester?

In s-trioxane (1,3,5-trioxacyclohexane) the stabilization from the three pairs of oxygen atoms appears to be only 28 kJ mol^{-1}, when the aliphatic ether increment is used in the calculations.[1,3] However, if the ether increment is instead evaluated from the enthalpies of formation for gaseous cyclohexane and tetrahydropyran, the calculated stabilization energy in trioxane due to the oxygen-oxygen interactions becomes 42 kJ mol^{-1}. This is a good illustration of the importance of clearly defining the reference system in calculations and discussions of thermochemical stabilization or destabilization (strain) energies. In the study of trioxane and the formaldehyde tetramer tetroxane it was found that the gaseous enthalpies of formation per $-CH_2O-$ unit in the two compounds were not significantly different.[3]

In this paper energy of combustion and enthalpy of sublimation measurements are reported for 2,4,10-trioxaadamantane (2,4,10-trioxatricyclo[3.3.1.1^{3,7}]decane) and pentoxane (1,3,5,7,9-pentoxecane). A recently developed micro-bomb (4.5 cm^3) combustion calorimeter together with an ampoule technique for milligram quantities of material has been used in the combustion studies.[4]

* The value given in Ref. 1 is 16.9 kJ mol^{-1}. A recalculation with parameters for the ether increment taken from Ref. 2 yields 17.6 kJ mol^{-1}.

EXPERIMENTAL

Compounds. 2,4,10-Trioxaadamantane, a gift from Dr. Kjell Olsson, The Royal Agricultural College, Uppsala, Sweden, was synthesized from *cis,cis*-cyclohexane-1,3,5-triol and excess triethylformate in methanolic HCl.[5] The crude product was recrystallized from petroleum ether and the obtained crystals then sublimed at approximately 10 Torr * and 323 K to remove traces of solvent. A concentrated ether solution of purified material was analyzed by GLC on Apiezon, silicone (SE-30), and Carbowax columns. No trace of any impurity could be found. The above described material was used in series A. However, water analysis by a coulometric method[6] indicated 0.07_3 mass per cent of water. A second preparation of trioxaadamantane was therefore sublimed through activated molecular sieves. The dried material was handled in a small plastic glove bag, which had been flushed several times with dry nitrogen and which also housed a large dish with freshly activated molecular sieves. Pellets for the combustion experiments of series B were made inside the glove bag whereas when pellets for series A were prepared no real precautions to avoid moisture had been taken (relative humidity 25 – 30 %). However, the water content of the second preparation was determined to be 0.06_9 mass per cent. Evidently "dry conditions" have to be maintained much more rigorously when one wants to prevent contamination by water while working with milligram quantities of "slightly hygroscopic"[5] materials. A correction for $0.07_0 \pm 0.00_5$ mass per cent of water has been applied to the measured energy of combustion of trioxaadamantane.

The 1,3,5,7,9-pentoxecane (pentoxane) sample was a gift from Dr. Yasuhiko Miyake, Mitsui-Toatsu Chemicals, Inc., Japan. The melting point of the sample, determined on a Perkin-Elmer DSC-1B differential scanning calorimeter, was $335._3$ K; literature value 334 ± 1 K.[7] No impurities were found when a concentrated ether solution of pentoxane was carefully analyzed by GLC on silicone (SE-30) and Carbowax columns. The NMR and mass spectra were in good agreement with those reported in the literature.[8,9] Water analysis,[6] performed on a small sample that had been well exposed to laboratory air, indicated ≤ 0.01 mass per cent of water. No correction for water in pentoxane has been applied.

The Delrin ** (polyoxymethylene) ampoules used in this investigation were not manufactured from the same rod as those referred to in Ref. 4. A redetermination of the energy of combustion of this particular polyoxymethylene material was therefore required. The ampoules were cleaned and conditioned as described earlier.[4]

The benzoic acid used in calibration experiments was National Bureau of Standards SRM 39i.

Combustion calorimetry. The micro combustion calorimeter, the calorimetric and calculational procedures, and the ampoule technique have been described previously.[4] The amount of water initially in the bomb (internal bomb volume 4.50 cm^3) was 20 mm^3. The initial pressure of oxygen, $p^i(O_2)$, varied between 34.6 and 37.1 atm * in the trioxaadamantane experiments; for the pentoxane runs it varied from 35.9 to 37.5 atm. The oxygen was 99.995 % pure and in combination with an efficient flushing procedure, this resulted in negligible corrections for the formation of HNO_3 during combustions.[4] Electrical calibrations were performed after each combustion experiment.

In both series of measurements on trioxaadamantane ($p_{25} \sim 3 \times 10^{-2}$ Torr **) the compound was enclosed in thin-walled polyoxymethylene ampoules.[4] An unusually large number of failures was encountered in the combustions on trioxaadamantane, possibly due to air being trapped in the pellets. Four out of twelve runs were rejected because some trace of soot on the bomb wall indicated incomplete combustion. Five successful runs were performed in series A and three in series B.

Five combustions were performed with pentoxane ($p_{25} \sim 2 \times 10^{-2}$ Torr **) enclosed in ampoules; one was rejected. Four experiments were carried out where somewhat larger pellets of pentoxane were burned without protection. The mass loss of these pellets was determined as a function of time to allow an appropriate correction to be applied for material evaporated during assembly and closing of the bomb. 6 ± 1 μg evaporated in 10 min, while the time for mounting the crucible and closing the bomb was less than four min. In the pentoxane as well as in the trioxaadamantane series all the included successful runs were without any trace of soot.

The Delrin ampoules were weighed on a Sartorius type 4125 electronic micro balance, the linearity of which has been verified. The sensitivity was checked several times during a series of weighings. A Mettler M5 micro balance, carefully calibrated against standard weights,[4] was used when the pelleted samples were weighed either into closed ampoules or in the open crucible. The sensitivity of the Mettler balance was checked before and after each series of weighings.

All weighings have been reduced to masses and molar masses computed from the 1969 table of atomic weights.[10] The energy equiva-

* Torr = (101.325/760) kPa

lent, ε(calor), of the calorimetric system was calculated from the mean value of pertinent electrical calibrations, values of ε^i(cont) and the experimentally established relation between benzoic acid and electrical calibrations: ε(calor,b.a.) = ε(calor,el.) + (0.060 ± 0.070) J K^{-1}. The corrections to standard states, ΔU_Σ, were calculated using a computer program based on the procedure by Hubbard *et al.*[11] Some auxiliary quantities used in the calculations are listed in Table 1. The final overall precision of the ΔU_c° mean values was estimated as recommended by Rossini.[12] The reference temperature of the combustion experiments is 298.15 K.

Vaporization calorimetry. The enthalpies of sublimation at 298.15 K were measured using

the Morawetz calorimeter.[13] The trioxaadamantane sample was sublimed into the calorimeter. Four experiments were performed following the procedure described in Ref. 13 with around 6 mg evaporated per experiment. A molten sample of pentoxane was dropped from a heated pipette into the evaporation pan of the calorimeter. Seven experiments were performed with on the average 7 mg evaporated per experiment.

RESULTS AND DISCUSSION

In Table 2 detailed results for some typical combustion experiments are given, one from each of the four series of measurements. Values of $-\Delta u_c°$, referring to unit mass, for the individual runs are listed in Table 3. One of the trioxaadamantane values in series A has been discarded on statistical grounds. The calculated mean value for each series together with the standard deviation of the mean and the estimated final overall uncertainty are included in Table 3. No significant difference was found between the results from the two different series of measurements on each compound. Therefore the mean values were weighted proportionately to the inverse squares of their overall uncertainties. The obtained $\Delta u_c°$ values were $-(25.360_1 \pm 0.013_4)$ and $-(16.844_9 \pm 0.006_7)$ kJ g^{-1} for trioxaadamantane and pentoxane, respectively; the uncertainties are twice the final overall standard deviations of the mean. After correction for 0.07_0 mass per cent of water the trioxaadamantane value becomes -25.377_9 kJ g^{-1}. The $\Delta u_c°$ values refer to the idealized combustion reaction in which all reactants and products are in their thermodynamic standard states at 298.15 K. Table 4 gives the standard molar energies, $\Delta U_c°$, and enthalpies, $\Delta H_c°$, of combustion for the compounds in the crystalline state, together with the molar enthalpies of sublimation, ΔH_{subl}, and derived enthalpies of formation, $\Delta H_f°$, for the compounds in the crystalline and gaseous states, all at 298.15 K. The enthalpies of formation at 298.15 K for gaseous carbon dioxide and liquid water used in the calculations are from Ref. 14. No previous determinations of the enthalpies of formation of the compounds studied here have been found in the literature.

Unsubstituted adamantane forms the natural basis for a reference system in the evaluation of the non-bonded oxygen-oxygen interaction energy in trioxaadamantane. Three independent determinations of the energy of combustion of adamantane were published recently.[15–17] Two of these are in close agreement, whereas the third [15] differs by almost 9 kJ mol^{-1} from the others. The reason for this discrepancy has not yet been explained. Taking the average of the three reported determinations of the enthalpies of combustion and sublimation leads to a standard enthalpy of formation for gaseous adamantane equal to -131.6 kJ mol^{-1}. From this value and the aliphatic ether increment for the exchange of a $-CH_2-$ group by an ether oxygen $-O-$ (-104.8 kJ mol^{-1}), the predicted enthalpy of formation of gaseous 2,4,10-trioxaadamantane is -446.0 kJ mol^{-1}. The experimentally obtained value is -499.2 kJ mol^{-1} implying a stabilization energy of 53 kJ mol^{-1} in trioxaadamantane. If on the other hand the cyclohexane-tetrahydropyran based ether increment (-100.0 kJ mol^{-1}) is used, the calculated stabilization energy for the three pair oxygen-oxygen next-nearest-neighbour interaction system is 68 kJ mol^{-1} in the tricyclic ortho ester studied here.

Traditionally, adamantane was considered to be relatively free of strain, but recent calculations show that it is in fact appreciably

Table 4. Results and derived quantities at 298.15 K. The uncertainties given are twice the final overall standard deviation of the mean. cal = 4.184 J.

strained; *cf.* for instance Refs. 18 and 19. The exact nature of the strain, however, still seems to be a matter of some controversy. Schleyer *et al.*[18] account for the strain (~ 27 kJ mol^{-1}) in terms of angle strain and C···C non-bonded repulsions, whereas Allinger *et al.*[19] state that "the strain in adamantane is largely due to an excessive number of H···H repulsions." Since only the overall effect of strain and stabilization in a compound is discernible from thermochemical measurements, a simple calculation of the oxygen-oxygen interaction energy in trioxaadamantane may well be obscured by such changes in the "strain" in adamantane that are not taken care of in the choice of ether increment.

The stabilization due to next-nearest-neighbour oxygens in straight-chain compounds can be rationalized in terms of electrostatic interactions.[20] A simple calculational model of this kind correctly reproduces the additivity found for the stabilizing effect of consecutive pairs of oxygens in $-O-CH_2-O-CH_2-O-$ chains. With parameters calibrated by the 17.$_6$ kJ mol^{-1} interaction energy for a single pair, a value of 58 kJ mol^{-1} is predicted for the stabilization energy due to non-bonded oxygen-oxygen interaction in ortho esters.

Energy of combustion measurements on trimethyl- and triethylorthoformate have been published.[21] From these, and estimates of the enthalpies of vaporization, gaseous enthalpies of formation were derived.[21] The calculated stabilization energy in these compounds is 72 * and 69 kJ mol^{-1}, respectively.**

The gaseous enthalpies of formation per $-CH_2O-$ unit in trioxane, tetroxane, and pentoxane are $-(155.3 \pm 0.2)$, $-(155.1 \pm 0.2)$ and $-(156.0 \pm 0.3)$ kJ mol^{-1}, respectively, which means that the overall stabilization per $-O-CH_2-O-$ interaction is the same in these compounds.

Acknowledgements. I am very much indebted to Drs. Yasuhiko Miyake and Kjell Olsson for the generous gifts of samples, and to Mr. Ronald Karlsson, who kindly performed the water analysis. The excellent assistance of Miss Monica Andersson, who performed the combustion experiments, and of Mrs. Gunilla Gräntz, who made the vaporization measurements, is gratefully acknowledged.

Homogeneous Electron Exchange in Catalytic Polarographic Reduction

HENNING LUND,[a] MARIE-ANDRÉE MICHEL [a] and JACQUES SIMONET [b]

[a] Department of Organic Chemistry, University of Aarhus, 8000 Aarhus C, Denmark and [b] Department of Chemistry, University of Clermont-Ferrand, 63170 Aubière, France

Electron transfer reactions between an electrolytically generated anion radical $A\cdot^-$ and a more difficultly reducible compound (BX) forming an unstable anion radical has been studied by means of classical polarography. The rate of the reduction of BX by $A\cdot^-$, measured by the catalytic increase of the wave-height of A, is dependent on the difference in the reduction potentials of A and BX; the electron transfer reaction or the decomposition of $BX\cdot^-$ may be rate determining. Comparison of results from direct and indirect electrolytic reduction may throw light on the influence of the electrode on product distribution.

Polarographic "catalytic currents" are well-known (Fig. 1), especially in inorganic polarography, *e.g.* the hydrogen peroxide [1] or hydroxylamine [2] reoxidation of ferrous ions during the polarographic reduction of ferric ions, or the reoxidation of Ti^{3+} by hydroxylamine [3] during polarography of Ti^{4+}. A theory [4-6] for the connection between the ratio of the limiting current to the diffusion controlled current and the rate constant of the catalyzing reaction has been developed.

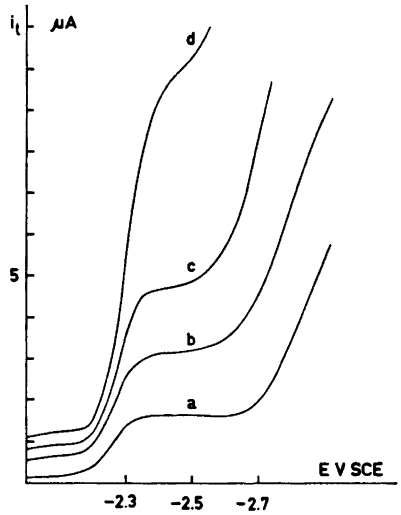

Fig. 1. Polarograms of chrysene (4×10^{-4} m) in DMF containing tetrabutylammonium iodide and (a) 0; (b) 5×10^{-4} m; (c) 1.5×10^{-3} m; (d) 4×10^{-3} m bromobenzene.

A similar increase of a polarographic current due to a regeneration of the depolarisator by electron exchange with another species seems not to have been investigated in detail for organic molecules.[7] The phenomenon seems, however, to be rather general provided certain requirements are met, and below is given a preliminary report on a number of such cases including examples of many different types of compounds. All the examples can be fitted into the general scheme

$$A + e^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A\cdot^- \quad (1)$$

$$A\cdot^- + BX \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} A + [BX]\cdot^- \quad (2)$$

$$[BX]\cdot^- \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} B\cdot + X^- \quad (3)$$

$$B\cdot + A\cdot^- \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} B^- + A \quad (4)$$

$$B^- + [H^+] \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} BH \quad (5)$$

$$A\cdot^- + A\cdot^- \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} A^{2-} + A \quad (6)$$

$$B\cdot + B\cdot \underset{k_{-7}}{\overset{k_7}{\rightleftharpoons}} B-B \quad (7)$$

$$B\cdot + A\cdot^- \underset{k_{-8}}{\overset{k_8}{\rightleftharpoons}} BA^- \quad (8)$$

$$B\cdot + HS \underset{k_{-9}}{\overset{k_9}{\rightleftharpoons}} BH + S\cdot \quad (9)$$

$$B\cdot + e^- \underset{k_{-10}}{\overset{k_{10}}{\rightleftharpoons}} B^- \quad (10)$$

$$A^{2-} + [H^+] \underset{k_{-11}}{\overset{k_{11}}{\rightleftharpoons}} AH^- \quad (11)$$

Scheme 1.

In this scheme A gives a polarographic wave at a less negative potential than that of BX; the radical anion $A\cdot^-$ produced in (1) should be stable measured on the time scale relevant here. The reoxidation of $A\cdot^-$ to A by BX (2) or by B· (4) gives rise to the observed catalytic current.

BX is a molecule, the anion radical of which is cleaved into the neutral radical B· and the stable ion X^-(3). The radical B· will in most cases, but not all, exchange an electron with $A\cdot^-$ (4), undergo dimerization (7), coupling (8), hydrogen abstraction (9), or direct reduction at the electrode (10) may occur. Usually (2) and (4) together result in the reoxidation of two $A\cdot^-$ for every BX reduced to BH and X^-. It may be noted, that the reoxidation of Fe^{2+} by hydrogen peroxide and hydroxylamine also fits into the scheme with these compounds acting as BX compounds where the first electron uptake is followed by a rapid cleavage to a neutral radical and a stable anion.

As A-compounds have been employed aromatic hydrocarbons, heterocyclic compounds, aromatic ketones, esters, nitriles, and nitro compounds, but other types may work as well. As BX-compounds have been used alcohols, esters, halides, sulphonamides, and azides.

In Table 1 are presented some of the results. In column 1 and 2 are the A and BX compounds, respectively; in the third column is given the difference ΔE between the half-wave potentials of A and BX, and in the fourth one the rate constant k calculated according to the

Koutecký equation.[6]

The results given in Table 1 will be discussed qualitatively on the basis of Scheme 1. The Koutecký equation gives a formal rate constant which could include many of the rate constants in the scheme, but the more significant ones would most likely be k_2 or k_3 or both.

If the most significant factor in k is k_2, and thus (3) and (4) very fast, k would, for a given BX, depend on the potential difference between $E°_A$ and $E°_{BX}$, the rates of the equilibria $A+A\cdot^- \rightleftharpoons A\cdot^- + A$ (12), and the corresponding one for $BX/BX\cdot^-$ (13). The rate constants for a number of equilibria of the type (12) have been measured from the broadening of the lines in the EPR spectra [8-12] and are generally [13] between 10^7 and 10^9 M^{-1} s^{-1}. The instability of the $BX\cdot^-$ makes it difficult to obtain data for (13), but it seems reasonable to assume, that the rate of electron exchange for aromatic BX compounds (13) is of the same magnitude as that of (12). The reported rate constant for (12) includes nitrobenzene [8] (3×10^7 M^{-1} s^{-1}) and benzonitrile [9] (2×10^8 M^{-1} s^{-1}), with benzene,[10] naphthalene,[11] and benzophenone [12] having rate constants between these limits. In this connection the results from the pulse radiolysis on the rate of electron transfer reactions in solution are of interest.[14-16]

From the equation [17] $k_{ABX}=(k_A k_{BX} K_{ABX} f)^{\frac{1}{2}}$, where k_{ABX}, k_A, and k_{BX} are the rate constants of (2), (12), and (13), respectively, K the equilibrium constant of (2), and f a factor which often is close to 1, the dependence of k_{ABX} on $\Delta E°$ can be estimated. The data for k_A [8-12] show only a moderate variation, and regarding k_A as constant is probably not more than a factor 5 off. This approximation would make it possible to predict a decrease in the observed rate constant (2) with a factor 10 for a given BX for an increase in $\Delta E°$ by 0.12 V.

In Fig. 2 is shown as ordinate the logarithm of rate constants k for several A, calculated from Koutecký equation,[5] in the presence of chlorobenzene as the BX-compound, and ΔE as abscissa. Instead of $\Delta E°$ is taken the difference in polarographic half-wave potential between that of A and that of chlorobenzene, as the reversible redox potential for chlorobenzene is difficult to obtain due to the instability of its anion radical. Extrapolation of the experimental values to $\Delta E=0$ suggests $k\sim5\times10^7$; the value,

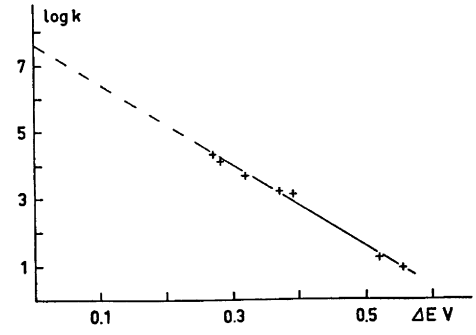

Fig. 2. Dependence on ΔE of the logarithm of the rate constants [5] of the chlorobenzene reoxidation of the following anion radicals (with increasing ΔE): biphenyl, 1-methylnaphthalene, naphthalene, 2-methylphenanthrene, phenanthrene, terphenyl, and benzonitrile.

which a.o. is dependent on how close $E°$ is to $E_{\frac{1}{2}}$ for chlorobenzene, is of the order expected for an electron exchange in solution, and for chlorobenzene the measured rate constant k may well be close to k_2.

When X forms an anion less stable than Cl^- or the reduction potential of BX becomes less negative,[18] the rate of (3) will diminish, and (3) may become the rate determining step, the rate thus being close to $k_3[BX]\cdot^-$. $BX\cdot^-$ could then be regarded as stable in this context and its approximate concentration deduced from a knowledge of the equilibrium constant of (2), which may be estimated from the difference in half-wave potentials between A and BX.[17,19] An increase in ΔE of 0.06 V would diminish K with a factor 10 and as $K<10^{-5}$ in the cases discussed here, $[A]\cdot^-$ and [BX] may be regarded as constant; $[A][BX]\cdot^-$ would then be diminished nearly 10 times and $[BX]\cdot^-$ approximately $10^{\frac{1}{2}}$. A similar dependence of k on ΔE would thus be expected regardless of whether (2) or (3) is the rate-controlling step.

On the basis of the available evidence it seems likely that the rate of the electron exchange between $A\cdot^-$ and BX is the limiting factor when $BX\cdot^-$ decomposes fast, but that the rate of the decomposition of $BX\cdot^-$ becomes more significant when X^- becomes a poorer leaving group. A quantitative analysis involving more data may illuminate these points.

The rate constant k_4 has been assumed to be high compared to k_7 and k_8, and (4) thus

contributing to k with a factor $\frac{1}{2}$. This assumption is valid, when the reduction potential of A is much more negative than that of B·; if this is not the case, k_7 or k_9 may be larger than k_4; k_9 may be larger than k_4 in the indirect reduction of iodobenzene and a number of compounds, where n has been found close to 1; cyclic voltammetric results point in the same direction.[18,20-23]

Electron transfer from a tight ion pair to a molecule is slower than from a loose ion pair or a free radical anion.[15] The rate of electron transfer from anthracene to 2-chloropyridine was nearly the same in DMF containing LiCl or tetrabutylammonium iodide; quinoxaline showed a slower exchange in LiCl than in TBAI; this, however, may be due to a complex formation between the base quinoxaline and the Lewis acid Li^+ prior to reduction so an ion pair is formed directly. In tetrahydrofuran an effect may possibly be found of ion pair formation even for aromatic hydrocarbons.

Sometimes the reduction (amalgam formation) of the supporting electrolyte hinders the reduction of a difficultly reducible substrate. It was found that electron transfer from anthracene anion radical to 2-chloropyridine was possible in the presence of Li^+ although the polarographic wave of Li^+ masks the reduction of 2-chloropyridine. This suggests the possibility of reduction of very difficultly reducible BX compounds, provided $BX\cdot^-$ decomposes faster than $R_4N\cdot$.

An anion radical transports only one electron at a time and delivers it to a molecule outside the electrical double layer where the electrode has no influence on the stereochemistry of the product; thus a possible controversy between a one-electron and a two-electron step and a possible stereochemical influence of the electrode may be resolved. The reduction of D,L and *meso* α,α′-dichlorobibenzyl (stilbene dichloride) to stilbene both by means of anion radicals and directly at the electrode suggests two one-electron steps. The cyclopropane formation by reduction of 1,3-dibromides may follow a similar pattern.

The presence of both a proton donor and a BX compound introduces a competition for the anion radical; addition of phenol to a solution containing naphthalene and chlorobenzene results in a decrease of the catalytic wave. A quantitative treatment of the height of the naphthalene wave in dependence of the concentration of chlorobenzene and phenol would correlate the reaction rates of the anion radical in electron exchange reactions and reactions with proton donors.

EXPERIMENTAL

The polarograph was a Radiometer PO4d Polariter. The *N*,*N*-dimethylformamide (DMF) was dried over molecular sieves A4; further drying with Al_2O_3 (Woelm Al_2O_3W200) directly in the polarographic cell did not change the rate constants found.

A measurement was made as follows: To a solution of tetrabutylammonium iodide in DMF at 25 °C was added the A compound, and the polarogram recorded; an amount of the BX compound was added and the polarogram recorded; more BX was added, a polarogram recorded, and so on until it was apparent from the polarogram that the BX-compound was present in a great excess.

The relative uncertainty of a rate determination is rather large, about 15 – 30 %, mainly due to the following two facts: When ΔE is small, the waves of A and BX become increasingly difficult to separate at higher concentrations of BX which makes the measurements of the wave-height of A less accurate; when ΔE becomes large, the increase in the wave-height of A is small, and the uncertainty in the relative increase is large.

Non-bonded Oxygen—Oxygen Interaction in Ethoxymethyl Propionate

MARGRET MÅNSSON

Thermochemistry Laboratory, Chemical Center, University of Lund, S-220 07 Lund, Sweden

The energy of combustion and enthalpy of vaporization at 298.15 K have been measured for ethoxymethyl propionate. Standard enthalpies of formation at 298.15 K have been derived for the compound in the liquid and gaseous states. The results are:

$\Delta H_f°(l) = -(667.2 \pm 1.1)$ kJ mol^{-1}
$\Delta H_f°(g) = -(617.4 \pm 1.1)$ kJ mol^{-1}

Ethoxymethyl propionate is shown to have an additional stabilization energy of 8 kJ mol^{-1} relative to the stabilization energy in ethyl propionate.

Next-nearest-neighbour oxygen atoms in an aliphatic straight-chain compound, $-O-CH_2-O-$, give rise to a stabilization energy of 17.$_6$ kJ mol^{-1}* relative to aliphatic monoethers,[1,3] whereas the next-next-nearest-neighbour arrangement brings about a 10 kJ mol^{-1} destabilization.[1] With three oxygens in "1,3,5"-positions, $-O-CH_2-O-CH_2-O-$, the total stabilization due to non-bonded oxygen-oxygen interaction, within experimental uncertainty, is twice that in the "1,3"-dioxa compound.[1] The stabilizing effect of an $-O-CH_2-O-$ arrangement can be rationalized in terms of electrostatic interactions.[4] The calculational model used so far correctly reproduces the additivity found for consecutive pairs of next-nearest-neighbour oxygens, but does not satisfactorily account for the large destabilizing oxygen-oxygen interaction in 3,6-dioxaoctane.

Gaseous enthalpies of formation for diethyl carbonate and ethyl propionate were used to estimate the stabilization ("resonance") energy of an alkyl carbonate relative to that of an alkyl ester.[5] The calculated stabilization energies were 129 and 80 kJ mol^{-1}, respectively. The possibility of a contribution to the calculated stabilization energy in diethyl carbonate due to oxygen-oxygen interaction of the same nature as that found in "1,3"-diethers is an interesting question which cannot be answered at the present time. However, a knowledge of the $-O-CH_2-O-$ interaction energy, if any, in an alkoxymethyl ester, $-O-CH_2-O-CO-$, might help in attempts to explain the nature and origin of the above mentioned non-bonded oxygen-oxygen interactions. In this paper energy of combustion and enthalpy of vaporization measurements on ethoxymethyl propionate are reported.

EXPERIMENTAL

Compounds. Ethoxymethyl propionate was synthesized essentially as described in Ref. 6. The chloromethyl ethyl ether was prepared from ethanol, s-trioxane and dry HCl, and after removal of water and excess HCl the crude ether product was reacted with (fused) sodium propionate under as moisture-free conditions as possible. The reacted material was distilled twice at reduced pressure through an all-glass column filled with helices, the main fractions of the second distillation boiling at ~339 K/40 Torr.* GLC analysis on this material showed the presence of three impurities, two of which were identified as ethanol and propionic acid, respectively. All of the observed impurities

* The value given in Ref. 1 is 16.9 kJ mol^{-1}. A recalculation with parameters for the aliphatic ether increment taken from Ref. 2 yields 17.6 kJ mol^{-1}.

* Torr = (101.325/760) kPa.

were removed by preparative GLC (Carbowax; 343 K). The identity of the purified compound was confirmed by the NMR and mass spectra. No additional impurities were found when the purified material was tested by GLC on polyethylene glycol (PEG 20M) and diethylene glycol succinate polyester columns. However, GLC analysis on an SE-30 silicone column indicated that about 0.5 % of yet another impurity was present. Unfortunately this particular type of column caused decomposition of the compound when the column and/or injector temperature was increased above ~340 K. Tests on a different silicone (OV-17) column showed no such decomposition, but again the impurity could not be separated from the main component at any of the conditions tried. In an attempt to remove this additional impurity the material was run through the preparative gas chromatograph on an SE-30 column with injector and column temperatures at 333 K. The amount of impurity could, however, only be reduced by about 50 % in this way and therefore its nature and concentration had to be established reasonably well to allow the appropriate correction to be applied to the measured energy of combustion. Mass spectrometric analysis, coupled with GLC, indicated a molecular weight of the impurity of 116. The fragmentation pattern gave several indications of the presence of an ethoxy group as well as strong support for two oxygens in the molecule.[7] The composition $C_6H_{12}O_3$ and the structure of ethoxymethyl ethyl ketone were in accord with the obtained mass spectrum, whereas for instance a structure such as that of ethyl butyrate could be ruled out.[8]

The response of the flame ionization detector, used in the GLC analysis, to 1 mol of impurity was estimated to be very nearly the same as that per mol of ethoxymethyl propionate.[9] From the measured areas under the GLC peaks the amount of impurity was calculated as 0.25 mass per cent with an assigned uncertainty of ±0.03 mass per cent.

Drying the material with molecular sieves before it was transferred to the vacuum line for the ampoule filling procedure caused no detectable change in the purity. The water content, determined by GLC[10] on the sample in one of the combustion ampoules, was 0.002_5 mass per cent. No correction for water has been applied. Densities at 293.15 and 298.15 K were 0.9642_7 and 0.9593_0 g cm^{-3}, respectively. $n_D^{25} = 1.3961$.

The paraffin oil, laboratory designation TKL-66, used as auxiliary material in the combustions, has been described.[11] The benzoic acid, used in the calibration experiments, was National Bureau of Standards SRM 39i.

Combustion calorimetry – apparatus and procedure. The rotating-bomb calorimeter TKL-3 was used with the platinum-lined bomb 3B;[12] internal bomb volume 0.2609 dm^3. All combustions were carried out with 0.79 cm^3 of water initially in the bomb that was flushed with oxygen (99.995 % pure; less than 10 ppm. of nitrogen) for three min before charging to the initial pressure of oxygen $p^i(\text{gas}) = 30.0$ atm* at 298.2 K. Calibrations were carried out under certificate conditions and the other experiments designed to give close to the same temperature rise. Further details of the calorimetric procedure have been given previously.[1] A Hewlett Packard HP-M40-2801A Quartz Thermometer with 2850D probes was used for the temperature measurements. It was used in the 100 s mode (resolution 10^{-5} K) with minimum time between readings. Fore-, main-, and after-periods were all of 20 min duration.

The dried sample was transferred in vacuum to the receiver containing the Pyrex glass ampoules to be filled for the combustion experiments.[13] The ampoule mass varied between 26 and 44 mg. Five combustions were carried out on ethoxymethyl propionate. In all experiments tests were made for carbon monoxide in the final bomb gases. The detection limit of the test is well below 1 ppm of CO in the bomb gas [14] corresponding to a correction of about 4 ppm of the total heat evolved in a combustion. No evidence of CO was found in any of the experiments. The almost negligible amount of nitric acid in the final bomb solution was determined spectrophotometrically [15] at wavelength $\lambda = 202$ nm.

All weighings were reduced to masses and molar masses computed from the 1969 table of atomic weights.[16] The corrected temperature rise, $\Delta\theta$, and the energy equivalent of the standard calorimetric system, ε°(calor), were calculated as outlined by Bjellerup.[17] ε°(calor) was recalculated to air density 1.2 g dm^{-3}, since variations in air density affect the amount of water in the calorimeter.

Vaporization calorimetry. The enthalpy of vaporization at 298.15 K of ethoxymethyl propionate was measured using the Wadsö calorimeter.[18] Five experiments were performed.

RESULTS AND DISCUSSION

All symbols used are those of Hubbard, Scott and Waddington.[19] The Washburn corrections, ΔU_Σ, were calculated using a computer program based on the procedure in Ref. 19. The energy of solution of carbon dioxide in water, $\Delta U_{\text{soln}}(CO_2)$, and the solubility constant, $K(CO_2)$, were taken as −17.09 kJ mol^{-1} and 0.03440 mol dm^{-3} atm^{-1}, respectively, at 298.15 K.[20] The $(\partial v/\partial T)_p$ value for ethoxymethyl propionate was calculated from measured densities, whereas the value used for the

* atm = 101.325 kPa.

specific heat capacity, $c_p = 1.8$ J K^{-1} g^{-1}, is an estimate. The final overall precision of the ΔU_c° mean value was estimated as recommended by Rossini.[21] The enthalpies of formation at 298.15 K for gaseous carbon dioxide and liquid water, used in the calculation of the enthalpy of formation, are from Ref. 22.

Using data from Ref. 2 the energy of combustion of liquid ethoxymethyl ethyl ketone, assumed to be the remaining impurity in the sample, was estimated as -3622 kJ mol^{-1}, equal to -31.18 kJ g^{-1}. An uncertainty of ± 0.5 kJ g^{-1} (58 kJ mol^{-1}) was assigned to this value to account for possible misjudgement of the identity of the impurity. Since it seems very unlikely that the impurity is an ester, the uncertainty does not fully cover the approximately 80 kJ mol^{-1} stabilization energy of an ester group.[5] The net correction to be applied to the measured Δu_c° value due to impurity is (13.5 ± 1.8) J g^{-1}, corresponding to (1.57 ± 0.21) kJ mol^{-1}, where the uncertainty also includes that assigned to the determination of the impurity concentration. This 1.8 J g^{-1} uncertainty has been taken into account in the calculation of the final overall precision of the ΔU_c° mean value.

Details of a typical combustion experiment are given in Table 1. The individual $-\Delta u_c^\circ$ values, referring to unit mass, are listed in Table 2, uncorrected for impurity. The corrected Δu_c° mean value is -25.7649 kJ g^{-1}. The ΔU_c° values refer to the idealized combustion reaction, where reactants and products are in their

thermodynamic standard states at 298.15 K. Table 3 gives the standard energy, ΔU_c°, and enthalpy, ΔH_c°, of combustion for the compound in the liquid state, together with the enthalpy of vaporization, ΔH_v, and the derived standard enthalpies of formation, ΔH_f°, for the liquid and gaseous states at 298.15 K.

No enthalpy of formation value for ethoxymethyl propionate or any other alkoxymethyl ester was found in the literature. The calculated gaseous enthalpy of formation increment for insertion of a $-CH_2-O-$ group in an alkane is -145.9 kJ mol^{-1}.[2] From this value and the enthalpy of formation of gaseous ethyl propionate, $-(463.6 \pm 0.7)$ kJ mol^{-1},[5] a value of -609.5 kJ mol^{-1} may be "predicted" for the enthalpy of formation of ethoxymethyl propionate. This "predicted" value rests on the assumption that the total stabilization energy in ethoxymethyl propionate is the same as that in ethyl propionate.* The experimentally derived enthalpy of formation value for the

* The reference system in all the calculations referred to here consists of n-alkanes, and aliphatic monoethers and ketones.

former compound is $-(617.4 \pm 1.1)$ kJ mol^{-1}, implying that there is an extra stabilization energy in ethoxymethyl propionate of (7.9 ± 1.3) kJ mol^{-1}, relative to ethyl propionate, due to interaction between the ether type oxygen and the alkoxy oxygen in the ester group. This is only half of the stabilizing effect, 17.6 kJ mol^{-1}, found for non-bonded interaction between the two oxygens in a "1,3"-dioxa alkane.

Acknowledgements. I am very much indebted to Mr. Tore Henricsson, who synthesized the compound. The valuable assistance of Miss Monica Andersson, who did the GLC work and performed the vaporization measurements, is gratefully acknowledged.

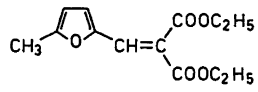
Reactions between Furfurylidenemalonic Esters and Grignard Reagents. III. Diethyl 5-Methylfurfurylidenemalonate. Isolation of a 1,6-Addition Product

GUST.-AD. HOLMBERG, LARS JALANDER, HÅKAN NORRGÅRD and BARBRO PETTERSSON

Institutionen för organisk kemi, Åbo Akademi, SF-20500 Åbo 50, Finland

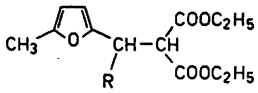
When methylmagnesium iodide and ethylmagnesium bromide react with diethyl 5-methylfurfurylidenemalonate, only 1,4-addition products are formed. Isopropylmagnesium bromide gives a small quantity of reduction product beside the 1,4-addition product. *t*-Butylmagnesium chloride gives reduction product, 1,4-addition product, and two 1,6-addition products. The last-mentioned compounds easily rearrange to diethyl 3-*t*-butyl-5-methylfurfurylmalonate, which was isolated by preparative gas chromatography.

Reactions between diethyl furfurylidenemalonate and different Grignard reagents have previously been studied in this laboratory.[1,2] 1,4-Additions were shown to be the principal reactions. Methylmagnesium iodide and ethylmagnesium bromide did not give any other reactions at all. Isopropylmagnesium bromide caused reduction of a small portion of the unsaturated ester to diethyl furfurylmalonate besides the 1,4-addition. Isobutylmagnesium chloride reacted in the same way but the reduced quantity was larger. *t*-Butylmagnesium chloride gave, in addition to these reactions, also 1,6- and 1,8-additions through extension of the conjugated double bond system to the furan nucleus. Apparently, the product of the last-mentioned reaction immediately rearranged to diethyl 5-*t*-butylfurfurylmalonate when the reaction mixture was brought into contact with water. The two 1,6-addition products were stabler but rearranged prototropically to one and the same product, diethyl 3-*t*-butylfurfurylmalonate, in acid solution.



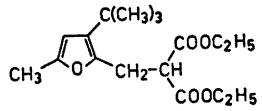
I

The reaction products could not, however, be isolated in the experiments with *t*-butylmagnesium chloride. The structures of the products were therefore deduced mainly from mass spectra taken with a combined gas chromatograph/mass spectrometer. An introduction of an alkyl group in position 5 of diethyl furfurylidenemalonate was expected to reduce the number of reaction products and in this way to facilitate separation and make ordinary structure determinations possible. *t*-Butylmagnesium chloride was therefore allowed to react with diethyl 5-methylfurfurylidenemalonate (I). A gas chromatographic analysis of the reaction products showed that four compounds were present. A fifth compound, probably a dimer, appeared secondarily after standing for some days. Two of the primary reaction products rearranged in acid solution to a new compound while the other two compounds did not react. After the number of products had been reduced in this way, the compounds were easily separated by preparative gas chromatography. The NMR spectra of the fractions obtained showed that the substances



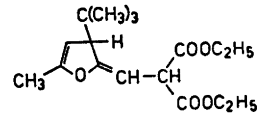
II

were diethyl 5-methylfurfurylmalonate (II; R = H), diethyl 2,2-dimethyl-1-(5′-methyl-2′-furyl)-propylmalonate [II; R = $(CH_3)_3C$], and diethyl 3-*t*-butyl-5-methylfurfurylmalonate (III). Because the last-mentioned compound had formed from two primary reaction products by prototropical rearrangement, it is quite clear that these compounds were the *cis* and *trans* isomers of diethyl 3-*t*-butyl-5-methyl-2,3-dihydro-2-furylidenemethylmalonate (IV).



III

These results show that *t*-butylmagnesium chloride gives reduction and 1,4- and 1,6-additions with diethyl 5-methylfurfurylidenemalonate. The molar ratio of the products of these reactions was 8:58:34 in the present experiments. It is remarkable that the possibilities of the two isomers of diethyl 3-*t*-butyl-5-methyl-2,3-dihydro-2-furylidenemethylmalonate being formed are not equal. The molar ratio of these was 25:9.



IV

A series of experiments was performed with methylmagnesium iodide, ethylmagnesium bromide, and isopropylmagnesium bromide in order to examine whether these Grignard reagents give rise to 1,6-additions beside reduction and 1,4-additions but the results in this respect were as negative as those with diethyl furfurylidenemalonate.[1] The reagents gave reduction and 1,4-addition in the same way as in these experiments. The only difference was that isopropylmagnesium bromide gave a smaller quantity of reduction product and a larger quantity of 1,4-addition product in the experiment with the methyl-substituted ester.

The structures of the reaction products of *t*-butylmagnesium chloride and diethyl furfurylidenemalonate had been deduced mainly from mass spectra. Consequently, the results might be called in question. However, a comparison of these spectra and those now obtained from substances whose structures are unquestionable reveals that the conclusions concerning the structures were correct.

EXPERIMENTAL

Diethyl 5-methylfurfurylidenemalonate (I) was prepared from 5-methylfurfural and diethyl malonate according to the general method for the preparation of α,β-unsaturated esters previously used in this laboratory.[1] The ester, b.p. 177 – 179 °C/12 mmHg, was purified by recrystallisation from ligroin. The yield of pure material, m.p. 56 – 57 °C, was 62 %. (Found: C 62.00; H 6.23. Calc. for $C_{13}H_{16}O_5$: C 61.90; H 6.39.) MS: *m/e*(r.a.) $M^{+\cdot}$ 252(63), calc. 252; $(M+1)^{+\cdot}$ (8.9, calc. 8.9); $(M+2)^{+\cdot}$ (2.0, calc. 1.3); $(M-C_2H_5)^+$ 223(26); $(M-OC_2H_5)^+$ 207 (71); $(M-COOC_2H_5)^+$ 179(100); $CH_3-C_3H_2O-CH=CH-CO^+$ 135(30); unidentified ions at 163(22); 152(15); 110(88). NMR spectrum: the furan proton H-3 at τ 3.41 coupled to H-4 at τ 3.98 ($J = 3.0$ Hz); methyl protons at τ 7.70 long-range coupled to H-4 ($J = 0.9$ Hz); methine proton in position β at τ 2.78 (singlet); methylene protons (ester) at τ 5.75 and 5.80 coupled to the methyl protons at τ 8.67 and 8.70 ($J = 7.1$ Hz).

5-Methylfurfural used in this synthesis was prepared according to Traynelis, Miskel Jr, and Sowa.[3] When a sample of 5-methylfurfural prepared according to Rinkes [4] from sugar was used, the ester obtained was not quite pure.

The reactions of diethyl 5-methylfurfurylidenemalonate with methylmagnesium iodide, ethylmagnesium bromide and isopropylmagnesium bromide were performed on semimicro and macro scales according to the method previously described.[1]

Diethyl 1-(5′-methyl-2′-furyl)ethylmalonate (II; R = CH_3), b.p. 140 – 142 °C/7 mmHg, was the only product in the experiments with methylmagnesium iodide. It was isolated by distillation under reduced pressure. (Found: C 62.46; H 7.30. Calc. for $C_{14}H_{20}O_5$: C 62.67; H 7.51.) The NMR spectrum of the compound shows a rather complex signal at τ 6.4 – 6.80 from the hydrogen atoms at the α and β carbon atoms. The complexity is a consequence of long-range coupling of the hydrogen atoms of the attached methyl group to the hydrogen in the α position. An almost identical signal is found in the spectra of the homologue, diethyl 1-(2′-furyl)ethylmalonate,[1] and α,β-dibromobutyric acid,[5] which contains the same structural element, $CH_3-CH-CH-C=O$, attached to negative atoms and groups. The present spectrum also shows the appropriate signals from the other hydrogen nuclei of the compound.

Diethyl 1-(5′-methyl-2′-furyl)propylmalonate (II; R = C_2H_5), b.p. 144 – 146 °C/18 mmHg, was the only reaction product in the experiment with ethylmagnesium bromide. It was isolated

by distillation under reduced pressure. (Found: C 63.72; H 7.75. Calc. for $C_{15}H_{22}O_5$: C 63.81; H 7.85.) The NMR spectrum shows the presence of an AB spin system with the shifts at τ 6.55 and 6.80 ($J = 9.6$ Hz) due to the hydrogen atoms in the α and β positions. The two signals of the latter atom are split into triplets as a consequence of coupling to the two hydrogen atoms of the attached methylene group. Appropriate signals from the other hydrogen atoms of the compound are found in the spectrum.

Isopropylmagnesium bromide gave diethyl 5-methylfurfurylmalonate (II; R = H; see below) and diethyl 2-methyl-1-(5′-methyl-2′-furyl)propylmalonate (II; R = $(CH_3)_2CH$). The ratio of the reaction products was about 1:100. The latter product was isolated by preparative gas chromatography (column 9 mm × 4.0 m; stationary phase 25 % SE-30 on Chromosorb W; helium flow 200 ml/min; initial temperature about 250 °C, slow programming to 300 °C; injected quantity 0.1 ml each time). (Found: C 64.64; H 7.99. Calc. for $C_{16}H_{24}O_5$: C 64.84; H 8.16.) The NMR spectrum shows the presence of an AB spin system with the shifts at τ 6.37 and 6.72 ($J = 11.0$ Hz) due to the hydrogen atoms in the α and β positions. The two signals from the latter atom are split into doublets as a consequence of coupling to the hydrogen atom of the methine group attached to the β carbon atom. In addition to these signals appropriate signals from the other hydrogen atoms are found in the spectrum.

The reactions of diethyl 5-methylfurfurylidenemalonate with t-*butylmagnesium chloride* were performed according to the method previously described. The reaction products were analysed by gas chromatography (column 3 mm × 1.5 m; stationary phase 3 % SE-30 on Chromosorb W; nitrogen flow about 28 ml/min; initial temperature 100 °C; temperature programming 10 °C/min). Four peaks with the relative retention times 1.00 (compound A), 1.37 (compound B), 1.68 (compound C), and 1.73 (compound D) were obtained when the analysis was carried out immediately after the experiment. When the analysis was repeated the following day, a fifth peak with the relative retention time 2.07 (compound E) appeared. A sample of the reaction products was dissolved in ethanol and the solution was acidified with a small quantity of sulfuric acid. The acid solution was poured into a sodium hydrogen carbonate solution after two days and the mixture was extracted with ether. The gas chromatogram of this ether solution showed four ordinary and two rather small peaks. The relative retention times of the larger peaks were 1.00 (compound A), 1.37 (compound B), 1.59 (compound F), and 2.05 (compound E) and those of the small peaks 1.76 and 1.93. The compounds in the latter reaction mixture were separated by preparative gas chromatography (*cf.* above).

Compound A was diethyl 5-methylfurfurylmalonate (II; R = H). (Found: C 61.69; H 7.05. Calc. for $C_{13}H_{18}O_5$: C 61.41; H 7.14.) The NMR spectrum shows an AB_2 peak system with the shifts at τ 5.56 and 6.99 ($J = 5.8$ Hz) due to the hydrogen atoms at the α and β carbon atoms. In addition to these signals, the spectrum contains the appropriate signals from the rest of the hydrogen atoms of the compound.

Compound B was identified as diethyl 2,2-dimethyl-1-(5′-methyl-2′-furyl)propylmalonate (II; R = $(CH_3)_3C$). (Found: C 66.04; H 8.35. Calc. for $C_{17}H_{26}O_5$: C 65.78; H 8.44.) The NMR spectrum shows a simple AB quartet with the shifts at τ 6.40 and 6.59 ($J = 9.1$ Hz) due to the hydrogen atoms in the α and β positions. The appropriate signals from the remaining hydrogen atoms are found in the spectrum.

Compound F was shown to be diethyl 3-*t*-butyl-5-methylfurfurylmalonate (III). (Found: C 65.54; H 8.24. Calc. for $C_{17}H_{26}O_5$: C 65.78; H 8.44.) The NMR spectrum contains an AB_2 peak system with the shifts at τ 6.41 and 6.86 ($J = 9.1$ Hz) due to the hydrogen atoms in the α and β positions. In addition to these signals and in contrast to the other NMR spectra in this paper, the spectrum of compound F contains only one furan signal, a singlet. The shift is at τ 4.38 and the signal is apparently due to H-4. Appropriate signals from the remaining hydrogen atoms are also found in this case in the spectrum.

The compounds C and D could not be separated by preparative gas chromatography.

Compound E was not isolated in its pure state. Its mass spectrum reveals that it might be a dimer.

The ratio of the peak areas of compounds A, B, C, D, and E is 10:100:42:16:10. The molar ratio of the compounds A, B, C, and D calculated from the above ratio and the structures of the compounds is 8:58:25:9. After treatment with sulfuric acid, the ratio of the compounds, A, B, and F is 8:57:35.

The mass spectra of the reaction products are collected in Table 1. No greater differences are observed between the spectra of the compounds of type II and those of the corresponding compounds without the methyl group in position 5.[1,2] Two fragmentation reactions dominate when R is hydrogen or a small alkyl group: (1) the cleavage of the bond between the α and β carbon atoms which gives rise to the ions $(M-159)^+$ and 2) the loss of a carbethoxy group and a hydrogen atom at the β carbon which results in the ions $(M-74)^{+\cdot}$. These ions finally lose an ethoxy radical, $\cdot OC_2H_5$, and are transformed into the ions $(M-119)^+$. With increasing size and degree of branching of group R, these reactions are suppressed by a third reaction: loss of a carbethoxy group and group R which results in the formation of the ions at *m/e* 180. Even these ions lose an ethoxy radical and are converted into the ions at *m/e* 135, $CH_3-C_4H_2O-CH=CH-CO^+$.

The spectra of the compounds C and D are

Table 1. Abundances of important ions in the mass spectra of the reaction products.

Mass of ion	R in formula II					Compound		
	H	CH_3	C_2H_5	i-C_3H_7	*t*-C_4H_7	C	D	F
M	19	6	9	14	8	3	4	18
M−45	8	1	2	39	4	–	–	–
M−74	40	17	21	13	–	–	–	27
M−89	–	–	–	–	–	–	–	10
M−102	19	6	[a]	–	2	4	7	3
M−119	27	13	11	6	–	–	–	3
M−146	18	10	7	3	2	–	–	4
M−159	100	100	100	100	35	7	3	100

253	–	–	3	3	29	25	40	–
180	[c]	–	38	44	43	50	42	4
135	[d]	6	18	98	100	100	100	42
122	–	[e]	7	7	–	2	2	3
95	[f]	–	9	22	26	23	19	7

[a] *cf.* *m/e* 180. [b] *cf.* M. [c] *cf.* M−74. [d] *cf.* M−119. [e] *cf.* M−146. [f] *cf.* M−159.

of the same type as those of the two isomers of diethyl 3-*t*-butyl-2,3-dihydro-2-furylidenemethylmalonate,[2] *i.e.* high abundances of the ions at *m/e* 135, $CH_3-C_4H_2O-CH=CH-CO^+$, and *m/e* 254, $(M-C_4H_8)^{+\cdot}$, and low abundances of the ions $(M-159)^+$. This fact and the rearrangement of the compounds into diethyl 3-*t*-butyl-5-methylfurfurylmalonate show that compounds C and D are the *cis* and *trans* isomers of diethyl 3-*t*-butyl-5-methyl-2,3-dihydro-2-furfurylidenemethylmalonate.

The spectrum of compound F, diethyl 3-*t*-butyl-5-methylfurfurylmalonate agrees well with that of its homologue without the methyl group in position 5.[2] The abundance of the ion $(M-159)^+$ is high and those of the ions $(M-74)^{+\cdot}$ and $(M-89)^+$ are higher than most of the other ions. The relatively high abundance of the ion at *m/e* 135, $CH_3-C_4H_2O-CH=CH-CO^+$, is as difficult to explain as the corresponding ion at *m/e* 121 in the mass spectrum of diethyl 3-*t*-butylfurfurylmalonate.

The elemental analyses were carried out by Mr. F. Sels, Janssen Pharmaceutica, Beerse, Belgium.

Diels-Alder Reactions of 2,4-Cyclohexadienones.* IV.** Addition of *o*-Quinols to *p*-Benzoquinones

KRISTER HOLMBERG, HANS KIRUDD and GERTRUD WESTIN

Department of Organic Chemistry, Chalmers University of Technology and University of Göteborg, Fack, S-402 20 Göteborg 5, Sweden

2,6-Dimethylphenol and mesitol were oxidized with aqueous periodate in the presence of an excess of *p*-benzoquinone, toluquinone, 2,6-dimethyl-*p*-benzoquinone or 2,3,5-trimethyl-*p*-benzoquinone. In all cases, the corresponding *o*-quinol-*p*-quinone Diels-Alder adduct was obtained and, in most cases, the *o*-quinol dimer was formed simultaneously. The ratio adduct/dimer was higher with mesitol than with 2,6-dimethylphenol as starting phenol. Furthermore, the yields of adduct increased with decreasing number of methyl substituents in the quinone. No *o*-quinol adducts were obtained with duroquinone.

In each case only one adduct was detected. Spectral and chemical evidence was provided to show that both stereochemical and structural orientation in the adducts were of the same type as previously found in the *o*-quinol dimers.

The adducts obtained with *p*-benzoquinone or toluquinone were slowly degraded to 1,4-naphthoquinones by treatment with periodate.

As described earlier,[1-3] periodate oxidation of 2,6-, 2,5-, and 2,4-dimethylphenol, as well as of mesitol, produces the corresponding 6-hydroxy-6-methyl-2,4-cyclohexadienones ("*o*-quinols", *1b – 1e*) which can not be isolated, however, since they undergo rapid self Diels-Alder reaction to give the *o*-quinol dimers *2b – 2e*. Similarly, the parent *o*-quinol *1a*, formed on acid hydrolysis of its acetate, spontaneously dimerizes to compound *2a*.[4]

In all cases, only one dimeric product has been obtained indicating a high degree of both regio- and stereoselectivity of the Diels-Alder dimerizations. All *o*-quinol dimers have the same basic structure involving *endo* configuration and the structural and steric orientation shown in formulae *2a – 2e*.[2,5,6]

In the present paper we wish to report the trapping of the monomeric *o*-quinols formed on periodate oxidation of 2,6-dimethylphenol and mesitol by *p*-benzoquinones added to the reaction mixture. It was of interest to examine whether the *o*-quinol-*p*-quinone addition reaction involves orientation specificity similar to that encountered in the dimerization of the *o*-quinols.

Formation of *o*-quinol-*p*-quinone adducts

In an attempt to investigate the dienophile character of 2,4-cyclohexadienones, Wessely *et al.*[8] treated an *o*-quinol acetate with typical

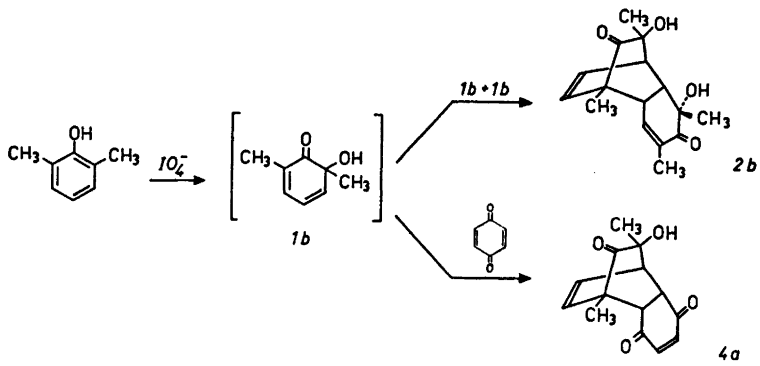

Scheme 1.

dienes, *viz.* butadiene and cyclopentadiene. However, in these systems the two last-mentioned compounds added as dienophiles to the *o*-quinol acetate, which acted as diene, indicating a comparatively low dienophile reactivity of the latter compound.

In connection with the present work it may be mentioned that the addition of an *o*-quinol to an *o*-quinone [8] as well as that of another *o*-quinol to a *p*-quinone [9] have been encountered earlier. In both cases the *o*-quinol dimer was formed in addition to the *o*-quinol-quinone adduct. This indicates that the *o*-quinols possessed a dienophile activity comparable to that of the quinones.

In the present work aqueous-ethanolic solutions of 2,6-dimethylphenol or mesitol were added to a solution containing a *p*-benzoquinone (see Table 1) and periodate (molar ratio, 1:1.5:1.1). The competing reactions expected to take place are illustrated in Scheme 1 for the system 2,6-dimethylphenol/*p*-benzoquinone.

The yields of *o*-quinol dimers (*2b*, *2e*) and *o*-quinol-*p*-quinone adducts (*4a*–*h*) formed are listed in Table 1. In each reaction, not more than one product of each type was detected, indicating a high degree of selectivity of both types of Diels-Alder reactions.

In addition to the dimers and the adducts shown in Table 1, the reactions with 2,6-dimethylphenol gave small amounts of 3,3′,5,5′-tetramethyldiphenoquinone [10] and 2,6-dimethyl-1,4-benzoquinone, whereas those with mesitol yielded minor amounts of 4-hydroxy-2,4,6-trimethyl-2,5-cyclohexadienone (*cf.* also Ref. 1).

The following two conclusions can be drawn from the results presented in Table 1.

(1) The yield of adduct is higher in the system mesitol/*p*-quinone than in the system 2,6-dimethylphenol/*p*-quinone. This may be understood as follows. Whereas the dienophilic

Table 1. Yields (based on the amount of phenol used) of adducts (*4a*–*4h*) and dimers (*2b*, *2e*) formed on periodate oxidation of 2,6-dimethylphenol and mesitol in the presence of a *p*-benzoquinone.

double bond, *i.e.* the γ,δ-double bond of the $\alpha,\beta,\gamma,\delta$-unsaturated carbonyl system, is unsubstituted in *o*-quinol *1b*, it possesses a methyl substituent in the γ-position in *o*-quinol *1e*. It is well-known that dienophile reactivity generally decreases with increasing electron density;[7] therefore, due to the electron-releasing effect of the γ-methyl group, *o*-quinol *1e* should be a poorer dienophile than *o*-quinol *1b*. Furthermore, the dimerization of *1e* may be slower than that of *1b* because of steric hindrance exerted by the γ-methyl group present in the former *o*-quinol. Both effects will favour the formation of adducts *4e*–*4h*.

The presence of a γ-methyl substituent has been found to be critical in the dimerization of *o*-quinol acetates. Whereas the *o*-quinol acetates corresponding to *o*-quinols *1a* and *1b* dimerize when heated at 120 °C to give the diacetates of *2a* [4] and *2b*,[1] respectively, the acetates derived from *o*-quinols *1d* and *1e*, possessing a γ-methyl group, proved to be stable even at 160 °C.

(2) The lower the number of methyl substituents in the *p*-benzoquinone, the higher the yield of adduct. This relationship can also be understood to be due to steric and electronic effects, the more heavily methyl substituted *p*-benzoquinone being the poorer dienophile.

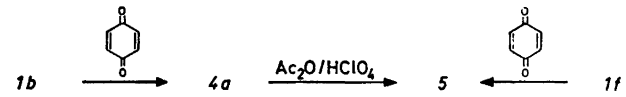
Contrary to the *o*-quinols, their acetates do not undergo Diels-Alder dimerization at room temperature. It was found, however, that a benzene solution of a mixture of *o*-quinol acetate *1f* and *p*-benzoquinone when kept for 10 d at room temperature gave adduct *5* (50 %) as the sole reaction product. Thus *p*-benzoquinone is a better dienophile than the *o*-quinol acetate. Adduct *5* was also obtained by acetylation of the *o*-quinol-*p*-quinone adduct *4a*, indicating analogous structures for the two adducts (Scheme 2).

p-Benzoquinone contains two dienophilic double bonds, and several examples of bis-adducts between *p*-benzoquinone and dienes have been reported.[11] It is known that the formation of the bis-adducts proceeds in two steps, the first diene molecule adding about one hundred times faster than the second one.[11] In the reactions between *p*-benzoquinones and *o*-quinols, however, no bis-adducts have been detected. Furthermore, an attempt to prepare a bis-adduct between *p*-benzoquinone and *o*-quinol *1e* by adding mesitol dropwise to a solution containing a mixture of adduct *4e* and sodium periodate was unsuccessful. The products obtained from the reaction mixture were the *o*-quinol dimer *2e* and unchanged adduct *4e*. Apparently, the adducts of type *4*, for steric reasons, cannot compete as dienophiles with *o*-quinols and *p*-quinones.

The structure of the *o*-quinol-*p*-quinone adducts

The following alternative possibilities regarding the structure of the adducts have to be considered. (*a*) Two structural orientations are conceivable for the adducts *4b*–*4d* and *4f*–*4h*, as exemplified by formulae *4b* and *4b'*. (*b*) The adducts may have *endo* or *exo* configuration. (*c*) The C-9 hydroxyl group may be *anti* and the C-9 methyl group *syn* to the ethylene bridge, or *vice versa*.

The NMR spectra (60 MHz, $CDCl_3$) of the adducts of 2,6-dimethyl- and 2,3,5-trimethyl-



Scheme 2.

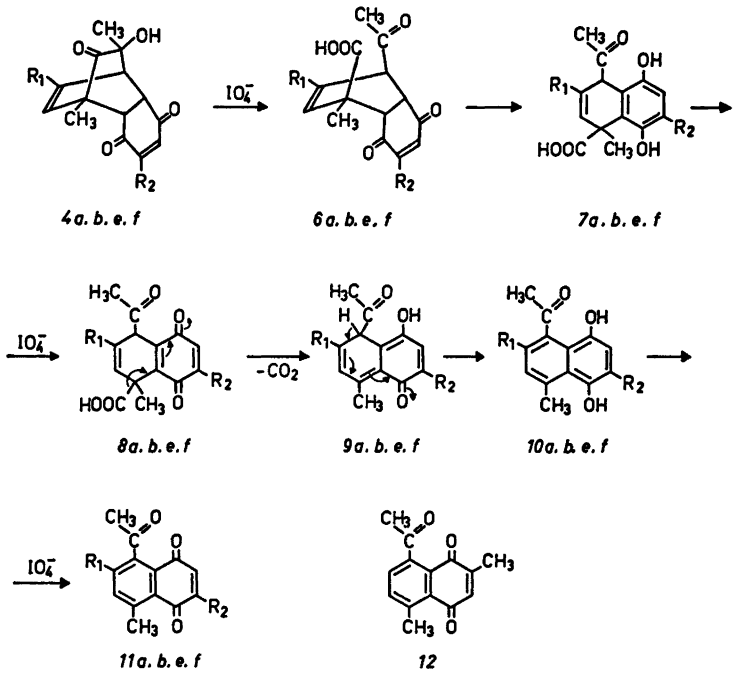
p-benzoquinone clearly showed vicinal coupling between the hydrogen atoms at positions 4 and 4a ($J_{4,4a}=2.0-3.0$ Hz), thus ascertaining the structural orientation of the diene and dienophile moieties to be those shown in the formulae above. In the alternative orientation, represented by formula *4b'*, these adducts would carry a methyl substituent at C-4a.

The structural orientation of the toluquinone adducts could not be clarified by simple NMR analysis. Degradation of the adduct between *o*-quinol *1b* and toluquinone with periodate (see p. 917) gave an acetyl-dimethyl-1,4-naphthoquinone, the m.p. of which (108 – 110 °C) differed from that (150 °C) of a naphthoquinone for which structure *12* has been proposed.[12,13] For this reason, the adduct is assumed to have structure *4b* rather than *4b'*.

By analogy, formula *4f* is assumed for the adduct between toluquinone and *o*-quinol *1e*.

It has been shown that, whereas *o*-quinol dimers *2a – 2c* slowly consume one mol of periodate with cleavage of the 9,10-ketol bridge, dimers *2d* and *2e* are stable towards this oxidant.[6] This has been explained by assuming that the configuration at C-9 is that given in formulae *2*, and that the methyl group at C-8a in dimers *2d* and *2e* prevents the formation of the cyclic periodic ester involving the carbonyl carbon atom at C-10 and the C-9 hydroxyl oxygen atom, which precedes the cleavage reaction. This reasoning, of course, requires *endo* configuration of the dimers.

Periodate oxidation of adducts *4a – 4h* gave the following results. The adducts possessing a methyl group in the 8a-position were stable towards the oxidant, whereas those lacking the angular methyl substituent underwent reaction. The products expected from ketol cleavage, *i.e.* acids *6a*, *6b*, *6e*, and *6f*, however, were



4a. 6a-11a $R_1=R_2=H$
4b. 6b-11b $R_1=H$; $R_2=CH_3$
4e. 6 -11e $R_1=CH_3$; $R_2=H$
4f. 6 -11f $R_1=R_2=CH_3$

Scheme 3.

not obtained from the reactions. Instead, methyl substituted 5-acetyl-1,4-naphthoquinones (*11a*, *11b*, *11e*, and *11f*) were isolated in yields between 52 and 78 % after 2 d reaction time.

A probable pathway for the formation of the naphthoquinones of type *11* is given in Scheme 3. The initial step is believed to be cleavage of the 9,10-ketol bridge of adducts *4* with the formation of carboxylic acids *6*. Aromatization of the enedione ring gives the hydroquinones *7*, which are rapidly oxidized by periodate or iodate to the corresponding *p*-benzoquinones *8*. The latter, being vinylogous β-keto acids, decarboxylate spontaneously to give, via compounds *9*, the 1,4-naphthodiols *10*. These, in turn, are oxidized by periodate or iodate to give the 1,4-naphthoquinones *11*. A similar mechanism has been proposed for the degradation of dimeric *o*-quinones by periodate to give 1,2-naphthoquinones.[14]

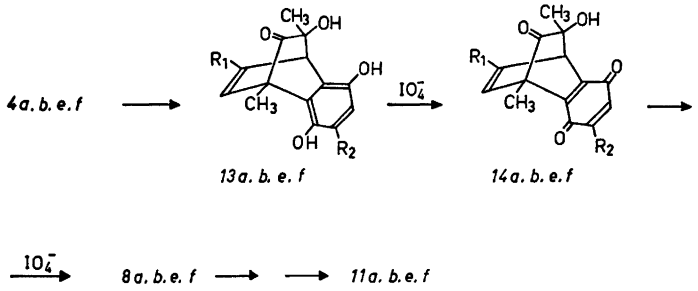
The behaviour of the adducts towards periodate permits the following structural conclusions.

(1) Cleavage of the ketol bridge of the adducts *4a*, *4b*, *4e*, and *4f* by periodate implies that these adducts have *endo* configuration, because an *exo* form of the adducts, similarly to the 8a-methyl substituted *o*-quinol dimers (*2d*, *2e*), would be assumed to be resistant to periodate. By analogy, *endo* configuration is also assigned to the adducts *4c*, *4d*, *4g*, and *4h*, although in these cases experimental evidence is lacking. The exclusive formation of *endo* adducts is in harmony with the behaviour of 2,4-cyclohexadienones in other Diels-Alder reactions.[11]

(2) The resistance to periodate of adducts *4c*, *4d*, *4g*, and *4h*, carrying angular methyl groups at C-8a, indicates that the C-9 hydroxyl group in these adducts is oriented *anti* to the ethylene bridge (compare the analogous behaviour of C-8a substituted *o*-quinol dimers.[6] See also p. 916). This high degree of selectivity regarding the steric orientation at C-9, earlier recognized in the dimerization of *o*-quinols,[6] can be ascribed to steric approach control,[11] the bulky methyl group being directed away from the reaction center. It then seems justified to assume the same steric arrangement at C-9 for adducts *4a*, *4b*, *4e*, and *4f*.

It might be argued that, instead of following pathway *A* presented in Scheme 3, the conversion *4*→*11* may proceed by the alternative route *B* shown in Scheme 4. The initial step of route *B* would be aromatization of the enedione ring of the adducts *4a*, *4b*, *4e*, and *4f* to give the hydroquinones *13*. Rapid oxidation to the *p*-quinones *14*, followed by periodate cleavage of the ketol bridge, would lead to the *p*-quinones *8*, which would be converted into naphthoquinones *11* by the mechanism given in Scheme 3.

If the conversion *4*→*11* proceeds by route *B*, it would not be possible to draw any conclusions regarding *endo* or *exo* configuration of the adducts, since both forms would give rise



Scheme 4.

to the same intermediate hydroquinones *13*.

The following observations, however, speak against pathway *B*.

Firstly, the acetate *5* of adduct *4a* would be expected to be stable towards periodate if ketol cleavage is the primary step (route *A*), but would be transformed into the acetate of *p*-benzoquinone *14a* (*via* the 9-acetyl derivative of hydroquinone *13a*) if *B* is the proper route. Route *A* was supported by the finding that acetate *5* remained unchanged on 2 d treatment with periodate.

Secondly, whereas adduct *4a*, similar to the behaviour of other enediones,[15,16] is smoothly converted into the hydroquinone *13a* by alkali, acid-induced aromatization, which would be involved in the primary step of mechanism *B* (Scheme 4), proceeds less readily. Adduct *4a* proved to be stable in glacial acetic acid and was only slowly transformed into hydroquinone *13a* by 10 % aqueous-ethanolic sulphuric acid, *13a* being obtained in a yield of only 20 % after two days treatment. It is not probable, therefore, that adducts *4* on treatment with aqueous-ethanolic $NaIO_4$ (pH 4 – 5), in a first reaction step, would undergo the aromatization to *13* shown in Scheme 4.

The isolated hydroquinone *13a*, when treated with excess periodate gave the naphthoquinone *11a*. Using a 1:1 ratio of *13a* and periodate, the *p*-benzoquinone *14a* could be isolated, and further oxidation of the latter compound produced the naphthoquinone *11a*. These results support the mechanism for the conversion *13a*→*11a* given in Scheme 4.

It is known that the ethylenic bond of the enedione system of *p*-benzoquinone adducts is easily hydrogenated with zinc/acetic acid.[16,17] The dihydroadduct *15*, obtained in this way from adduct *4a*, on treatment with periodate gave the carboxylic acid *16* (see Scheme 5). This finding lends further support to the assignment of *endo* configuration to adduct *4a*, since the *exo* form of *15* should presumably be resistant towards the oxidizing agent.

There is, however, a possibility for *15* to undergo *exo-endo* interconversion via the dienol. Such an isomerization by base has been reported for a similar adduct.[18] Considering the behaviour of the adducts of type *4* in the presence of acid (see above), however, it seems improbable that isomerization of *15* would take place in acetic acid or aqueous periodate solutions.

The NMR spectra of adducts *4a* – *4h* were in agreement with the assigned structures. As an example, the NMR signals given by *4a* are reported on p. 919. Similarly, the NMR spectra of the 1,4-naphthoquinones of type *11* have been exemplified by the spectrum of *11a* (p. 920), the spectra of the remaining naphthoquinones also being in accord with the proposed structures.

The UV spectra of the adducts

The β,γ-enone system present in the adducts *4a* – *4h* is expected to give rise to a transannular charge transfer band around 210 nm.[6,19,20] However, such bands were visible above 200 nm only in the spectra of the adducts *4e* – *4h*, obtained from *o*-quinol *1e*.

The three further absorption bands can be ascribed to the enedione system.[16,21] The band around 290 nm (column 2) is enhanced by the overlapping $n\rightarrow\pi^*$ absorption of the β,γ-unsaturated carbonyl system.[1] Although the Woodward rules cannot be applied properly to enediones,[22] the position of the $\pi\rightarrow\pi^*$ bands (column 1) are within the expected range, increasing methyl substitution causing increasing batochromic shift.[15]

The position of the bands listed in columns 2 and 3 are in harmony with data given in the literature for similar enediones.[16,21] Both bands show a hypsochromic shift with increasing methyl substitution of the ethylenic bond. This

4g	213 (4.10) sh	235 (4.11)	288 (2.70) sh	374 (2.07)
4h	213 (4.05)	245 (4.06)	280 (3.20) sh	370 (2.06)

effect becomes clear also from the colours of the adducts, which change from bright yellow (*4a* and *4e*) via light yellow (*4b*, *4c*, *4f*, and *4g*) to almost colourless (*4d* and *4h*).

The transannular charge transfer bands of compounds *4e – 4h* are overlapped to some degree by the adjacent $\pi \rightarrow \pi^*$ bands of the enedione system, which affects their ε values. In the dihydroadduct *15*, where only the former band is present (λ_{max} 204 nm), the log ε value is 3.63, in agreement with values for similar compounds.[19]

EXPERIMENTAL

UV spectra were recorded on a Cary Model 14 spectrophotometer; IR and NMR spectra were obtained using Beckman 9A and Varian A-60 instruments, respectively. Chemical shifts are given in δ (ppm units with TMS used as internal standard).

o-Quinol-p-quinone adducts 4a – 4h. A solution of the phenol (2,6-dimethylphenol or mesitol, 0.010 mol) in ethanol-water 1:1 (20 ml) was added dropwise during a 10 min period to a solution of a mixture of sodium metaperiodate (0.011 mol) and the *p*-benzoquinone (*p*-benzoquinone, toluquinone, 2,6-dimethyl-*p*-benzoquinone, or 2,3,5-trimethyl-*p*-benzoquinone, 0.015 mol) in ethanol-water 1:2 (180 ml). After further 15 min excess periodate was destroyed by 4 ml of ethylene glycol. Red crystals of 3,3′,5,5′-tetramethyldiphenoquinone were filtered off from the oxidation mixtures of 2,6-dimethylphenol. Yield, 1 %; m.p. after recrystallization from chloroform 203 – 210 °C (lit.[19] 207 – 217 °C).

The solution was then extracted with three 40 ml portions of hexane, which removed the major part of the *p*-quinone, and subsequently with dichloromethane, and the latter extract was dried over anhydrous Na_2SO_4 and evaporated to dryness. The residue was chromatographed on a silica gel column using benzene-ethyl acetate (4:1). The R_F values of the *o*-quinol-*p*-quinone adducts were between 0.14 and 0.18 and those of the *o*-quinol dimers between 0.08 and 0.11. The products were recrystallized from ethanol. Yields, see Table 1. *o*-Quinol dimers *2b* and *2e* were shown to be identical by mixed m.p. with authentic samples.[1]

1,4,4a,8a-Tetrahydro-9-hydroxy-1,9-dimethyl-1,4-ethanonaphthalene-5,8,10-trione (4a). M.p. 162 – 163 °C. (Found: C 68.53; H 5.66. Calc. for $C_{14}H_{14}O_4$: C 68.28; H 5.73). UV, see Table 2. IR (KBr): ν_{max}, cm^{-1} 1612 (C=C), 1675 (conj. CO), 1730 (CO), 3410 (OH). NMR (DMSO-d_6): δ 1.08 and 1.17 (singlets, 3 H each, 2 CH_3), 2.95 (d, 1 H, H-8a), 3.28 (ddd, 1 H, H-4), 3.67 (dd, 1 H, H-4a), 5.81 (dd, 1 H, H-2), 5.91 (s, 1 H, OH), 6.37 (dd, 1 H, H-3), 6.79 (s, 2 H, H-6 and H-7). $J_{2,3}=8$ Hz, $J_{2,4}=2$ Hz, $J_{3,4}=6$ Hz, $J_{4,4a}=3$ Hz, $J_{4a,8a}=9$ Hz.

1,4,4a,8a-Tetrahydro-9-hydroxy-1,7,9-trimethyl-1,4-ethanonaphthalene-5,8,10-trione (4b). M.p. 171.5 – 172.5 °C. (Found: C 69.23; H 6.20. Calc. for $C_{15}H_{16}O_4$: C 69.21; H 6.20). UV, see Table 2. IR (KBr): ν_{max}, cm^{-1} 1625 (C=C), 1665 (conj. CO), 1715 (CO), 3420 (OH).

1,4,4a,8a-Tetrahydro-9-hydroxy-1,7,8a,9-tetramethyl-1,4-ethanonaphthalene-5,8,10-trione (4c). M.p. 146 – 147 °C. (Found: C 70.0; H 6.7. Calc. for $C_{16}H_{18}O_4$: C 70.1; H 6.6). UV, see Table 2. IR (KBr): ν_{max}, cm^{-1} 1620 (C=C), 1655 (conj. CO) 1730 (CO), 3400 (OH).

1,4,4a,8a-Tetrahydro-9-hydroxy-1,6,7,8a,9-pentamethyl-1,4-ethanonaphthalene-5,8,10-trione (4d). M.p. 148 – 149 °C. (Found: C 70.7; H 7.1. Calc. for $C_{17}H_{20}O_4$: C 70.8; H 7.0). UV, see Table 2. IR (KBr): ν_{max}, cm^{-1} 1630 (C=C), 1660 (conj. CO), 1720 (CO), 3410 (OH).

1,4,4a,8a-Tetrahydro-9-hydroxy-1,3,9-trimethyl-1,4-ethanonaphthalene-5,8,10-trione (4e). M.p. 110 – 111 °C. (Found: C 69.02; H 6.30. Calc. for $C_{15}H_{16}O_4$: C 69.21; H 6.20.) UV, see Table 2. IR (KBr): ν_{max}, cm^{-1} 1610 (C=C), 1665 (conj. CO), 1720 (CO), 3410 (OH).

1,4,4a,8a-Tetrahydro-9-hydroxy-1,3,7,9-tetra-

methyl-1,4-ethanonaphthalene-5,8,10-trione (4f). M.p. 165–166 °C. (Found: C 70.02; H 6.59. Calc. for $C_{16}H_{18}O_4$: C 70.05; H 6.61). UV, see Table 2. IR (KBr): ν_{max}, cm^{-1} 1625 (C=C), 1670 (conj. CO), 1725 (CO), 3380 (OH).

1,4,4a,8a-Tetrahydro-9-hydroxy-1,3,7,8a,9-pentamethyl-1,4-ethanonaphthalene-5,8,10-trione (4g). M.p. 170–171 °C (Found: C 70.70; H 7.01. Calc. for $C_{17}H_{20}O_4$: C 70.81; H 6.99). UV, see Table 2. IR (KBr): ν_{max}, cm^{-1} 1635 (C=C), 1660 (conj. CO), 1715 (CO), 3430 (OH).

1,4,4a,8a-Tetrahydro-9-hydroxy-1,3,6,7,8a,9-hexamethyl-1,4-ethanonaphthalene-5,8,10-trione (4h). M.p. 164–165 °C. (Found: C 71.08; H 7.26. Calc. for $C_{18}H_{22}O_4$: C 71.50; H 7.33). UV, see Table 2. IR (KBr): ν_{max}, cm^{-1} 1630 (C=C), 1670 (conj. CO), 1720 (CO), 3410 (OH).

Oxidation of 2,6-dimethylphenol and mesitol with periodate in the presence of duroquinone: A solution of the phenol (5.0 mmol) in ethanol-water 1:1 (10 ml) was added dropwise during a period of 10 min to a solution of sodium metaperiodate (5.5 mmol) and duroquinone (7.5 mmol) in ethanol-water 3:2 (225 ml). After an additional 15 min, ethylene glycol (2 ml) was added to reduce excess periodate. The reaction mixture was worked up as described above. Thin layer chromatography indicated that no adducts had been formed. The crude reaction products on treatment with acetone/hexane gave the *o*-quinol dimers *2b* and *2e*, respectively, identified by mixed m.p. with authentic samples.[1] Yields, see Table 1.

Acetate 5. (*a*) *By acetylation of adduct* 4a. The adduct was treated with the $Ac_2O/HClO_4$ reagent according to Ref. 23. M.p. 147–149 °C after recrystallization from ethanol. Yield, 72 %. (Found: C 66.3; H 5.5. Calc. for $C_{16}H_{16}O_5$: C 66.66; H 5.60). IR (KBr): ν_{max}, cm^{-1} 1612 (C=C), 1680 (conj. CO), 1740 (CO and ester CO). The NMR spectrum ($CDCl_3$) shows a singlet at δ 2.10 (3 H) due to the ester $-CH_3$.

(*b*) *From* o-*quinol acetate* 1f *and* p-*benzoquinone.* *p*-Benzoquinone (2.0 g) and *o*-quinol acetate *1f*[24] (2.0 g) were dissolved in 20 ml of dry benzene. The mixture was kept for 10 d in the dark at room temperature. The solvent was then removed and the residue treated with 40 ml of ether. The crystals deposited were recrystallized from ethanol. A 50 % yield of acetate *5* was obtained, identical with the product obtained according to (*a*) by mixed m.p. and spectroscopic data.

Naphthoquinones 11a, 11b, 11e, *and* 11f. A solution of 2.5 g of sodium metaperiodate in 100 ml of water was added to a solution of 1.0 g of the adduct (*4a*, *4b*, *4e*, or *4f*) in 750 ml of ethanol-water 1:2. After 2 d at room temperature the solution was extracted with dichloromethane. The extract was dried over anhydrous Na_2SO_4 and brought to dryness under vacuum. The residue, on treatment with ether, gave yellow crystals, which were recrystallized from ethanol.

5-Acetyl-8-methyl-1,4-naphthoquinone (11a). Yield, 78 %. M.p. 142–144 °C. (Found: C 72.59; H 4.73. Calc. for $C_{13}H_{10}O_3$: C 72.89; H 4.71). UV (ethanol): λ_{max}, nm (log ε) 240 (4.31), sh 323 (3.30), 351 (3.42). IR (KBr): ν_{max}, cm^{-1} 1550, 1585 and 1610 (arom. ring and C=C), 1660 and 1705 (CO). NMR ($CDCl_3$): δ 2.48 (s, 3 H, CH_3-8), 2.78 (s, 3 H, CH_3CO), 6.93 (s, 2 H, H-2 and H-3), 7.33 and 7.59 (doublets, 1 H each, H-6 and H-7, $J_{6,7}=8$ Hz).

5-Acetyl-2,8-dimethyl-1,4-naphthoquinone (11b). Yield, 68 %. M.p. 108–110 °C. (Found: C 73.78; H 5.31. Calc. for $C_{14}H_{12}O_3$: C 73.67; H 5.30). UV (ethanol): λ_{max}, nm (log ε) 248 (4.24), 353 (3.42). IR (KBr): ν_{max}, cm^{-1} 1550, 1590 and 1630 (arom. ring and C=C), 1660, 1695 and 1710 (CO).

5-Acetyl-6,8-dimethyl-1,4-naphthoquinone (11e). Yield, 63 %. M.p. 113–114 °C. (Found: C 73.7; H 5.3. Calc. for $C_{14}H_{12}O_3$: C 73.67; H 5.30). UV (ethanol): λ_{max}, nm (log ε) 250 (4.26), 356 (3.46). IR (KBr): ν_{max}, cm^{-1} 1542, 1586 and 1614 (arom. ring and C=C), 1660 and 1702 (CO).

5-Acetyl-2,6,8-trimethyl-1,4-naphthoquinone (11f). Yield, 52 %. M.p. 156–157 °C. (Found: C 74.2; H 5.8. Calc. for $C_{15}H_{14}O_3$: C 74.36; H 5.83). UV (ethanol): λ_{max}, nm (log ε) 253 (4.27), 358 (3.48). IR (KBr): ν_{max}, cm^{-1} 1549, 1591 and 1630 (arom. ring and C=C), 1658 and 1700 (CO).

1,4-Dihydro-5,8,9-trihydroxy-1,9-dimethyl-1,4-ethanonaphthalen-10-one (13a). (*a*) *By alkaline treatment of* 4a. A solution of 2.5 g of adduct *4a* in 150 ml of ethanol was added dropwise, in a nitrogen atmosphere, to ice-cold 1.25 M aqueous NaOH (125 ml). Twenty min after the addition had been completed, the mixture was neutralized with dil. HCl and then extracted with chloroform. The extract was dried over anhydrous Na_2SO_4 and evaporated. Recrystallization of the residue from ethanol gave a 76 % yield of *13a*, m.p. 290–292 °C. (Found: C 68.18; H 5.72. Calc. for $C_{14}H_{14}O_4$: C 68.28; H 5.73). UV (ethanol): λ_{max}, nm (log ε) sh 210 (4.18), sh 235 (3.79), 308 (3.59). IR (KBr): ν_{max}, cm^{-1} 1492, 1600, 1620 (arom. ring), 1708 (CO), 3250 and 3370 (OH). NMR (DMSO-d_6): δ 1.28 (s, 3 H, CH_3-9), 1.73 (s, 3 H, CH_3-1), 4.29 (dd, 1 H, H-4), 5.09 (s, 1 H, OH-9), 6.10 (dd, 1 H, H-2), 6.46 (s, 2 H, H-6 and H-7), 6.61 (dd, 1 H, H-3), 8.60 (s, 2 H, OH-5 and OH-8). $J_{2,3}=7.5$ Hz, $J_{2,4}=2$ Hz, $J_{3,4}=6.5$ Hz.

(*b*) *By acid treatment of* 4a. A solution of adduct *4a* (0.5 g) in 10 % ethanolic sulphuric acid (150 ml) was kept for 2 d at room temperature, then diluted with water and extracted with chloroform. Evaporation of the extract gave *13a* in a 20 % yield, identical with the product obtained according to (*a*) by mixed m.p. and spectroscopic data.

1,4-Dihydro-9-hydroxy-1,9-dimethyl-1,4-ethanonaphthalene-5,8,10-trione (14a). A solution of sodium metaperiodate (0.85 g, 4 mmol) in water (100 ml) was added to hydroquinone

13a (0.98 g, 4 mmol) in ethanol-water 2:5 (700 ml). After 5 min, excess periodate was removed by addition of 5 ml ethylene glycol, and the solution was extracted with chloroform. Removal of the solvent from the combined extracts gave a crystalline residue. Recrystallization from ethanol gave *14a*, m.p. 166–168 °C, in a 64 % yield. (Found: C 68.71; H 4.90. Calc. for $C_{14}H_{12}O_4$: C 68.84; H 4.95). UV (ethanol): λ_{max}, nm (log ε) sh 210 (4.13), 247 (4.19), sh 310 (2.97), 352 (2.95). IR (KBr): ν_{max}, cm^{-1} 1577 and 1605 (C=C), 1655 (conj. CO), 1722 (CO), 3460 (OH). NMR ($CDCl_3$): δ 1.43 (s, 3 H, CH_3-9), 1.85 (s, 3 H, CH_3-1), 2.85 (s, 1 H, OH), 4.53 (dd, 1 H, H-4), 6.14 (dd, 1 H, H-2), 6.52 (t, 1 H, H-3), 6.66 (s, 2 H, H-6 and H-7). $J_{2,3}=J_{3,4}=7$ Hz, $J_{2,4}=2$ Hz.

Naphthoquinone 11a. (*a*) *From* 13a. A solution of 2.0 g of sodium metaperiodate in 100 ml of water was added to 0.50 g of hydroquinone *13a* dissolved in 300 ml ethanol-water 1:2. After 24 h the solution was extracted with chloroform. Evaporation of the extract gave yellow crystals of *11a*, m.p. after recrystallization from ethanol 142–144 °C. Identical by mixed m.p. with the product obtained from periodate oxidation of adduct *4a*.

(*b*) *From* 14a. A mixture of 2.0 g of sodium metaperiodate and 0.50 g of *14a* dissolved in 400 ml of ethanol-water 1:2 was kept at room temperature for 24 h. Extraction with chloroform gave crystals of *11a*, m.p. after recrystallization from ethanol 142–144 °C. Identical by mixed m.p. with the product obtained according to (*a*).

1,4,4a,6,7,8a-Hexahydro-9-hydroxy-1,9-dimethyl-1,4-ethanonaphthalene-5,8,10-trione (15). Zinc powder (2.0 g) was added in portions to a stirred solution of 1.0 g of adduct *4a* in 40 ml acetic acid-water 2:1. After 20 min, the mixture was filtered and the filtrate concentrated to a volume of 10 ml. Water was added and the solution extracted with dichloromethane. The extract was dried over anhydrous Na_2SO_4 and evaporated, yielding almost colourless crystals. Recrystallization from benzene/hexane gave *15*, m.p. 109–110 °C, in a 66 % yield. (Found: C 67.75; H 6.50. Calc. for $C_{14}H_{16}O_4$: C 67.73; H 6.53). UV (ethanol): λ_{max}, nm (log ε) sh 204 (3.63), 306 (2.22). IR (KBr): ν_{max}, cm^{-1} 1655 (C=C), 1697 and 1720 (CO), 3390 (OH).

4-Acetyl-1,4,4a,6,7,8a-hexahydro-1-methyl-5,8-dioxo-1-naphthalenecarboxylic acid (16). A solution of sodium metaperiodate (1.0 g) in 75 ml water was added to a solution of dihydroadduct *15* (0.50 g) in 75 ml ethanol-water 2:3. After 16 h the solution was extracted with chloroform. The extract was dried over anhydrous Na_2SO_4 and concentrated to a volume of 10 ml. The crystals deposited were recrystallized from ethanol to give *16*, m.p. 167–168 °C, in a 80 % yield. (Found: C 63.9; H 6.1. Calc. for $C_{14}H_{16}O_5$: C 63.62; H 6.10). UV (ethanol): λ_{max}, nm (log ε) 283 (2.36). IR (KBr): ν_{max}, cm^{-1} 1710 (CO), 2300–3300 (COOH). The NMR spectrum (DMSO-d_6) shows a singlet at δ 2.22 (3 H) due to the CH_3CO group.

Resolution of Glutathione-linked Enzymes in Rat Liver and Evaluation of their Contribution to Disulfide Reduction *via* Thiol—Disulfide Interchange

STELLAN ERIKSSON, PER ASKELÖF, KENT AXELSSON, INGER CARLBERG, CLAES GUTHENBERG and BENGT MANNERVIK

Department of Biochemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

Glutathione-linked enzymes in the postmicrosomal fraction of rat liver were resolved and the contribution of these enzymes to disulfide reduction *via* thiol-disulfide interchange was evaluated. The mixed disulfide of cysteine and glutathione (CySSG)*, 5,5′-dithiobis(2-nitrobenzoate) (DTNB), and the mixed disulfide of 3-carboxy-4-nitrobenzenethiol and glutathione (ArSSG) were used as disulfide substrates and glutathione (GSH) was the thiol substrate. Thiol-disulfide interchange involving GSH was normally followed by coupling to glutathione reductase (EC 1.6.4.2), but the reaction between DNTB (or ArSSG) and GSH was measured directly without coupling.

CySSG-thioltransferase activity** (EC 1.8.4.1) was separated into two and DTNB-thioltransferase activity into several components. Glutathione reductase and glutathione *S*-aryltransferase (EC 2.5.1.13) behaved as one and two components, respectively. Aged rat liver preparations contained additional, more acidic species of all these activities except the aryltransferase.

NADPH-linked reduction of DTNB coincided with glutathione reductase activity after all purification steps. No significant contribution to the thiol-disulfide interchange activity in rat liver could be ascribed to glutathione reductase or glutathione *S*-aryltransferase.

The aromatic disulfide substrates, DTNB and ArSSG, are not suitable for the study of CySSG-thioltransferase in crude enzyme-preparations unless the effect of interfering activities can be evaluated.

Thiol-disulfide interchange was found to be the major route of DTNB reduction in rat liver. The NADPH-dependent reduction of DTNB described in the literature may be explained by the presence of GSH and glutathione reductase.

In our studies concerning the reduction of low molecular weight disulfides in biological systems the role of glutathione reductase in rat liver cytosol has been evaluated.[1] For disulfides other than glutathione disulfide the main route of enzymatic reduction is composed of thiol-disulfide interchange (eqns. 1, 2) coupled to reduction of GSSG by NADPH and glutathione reductase (eqn. 3).

$$R_1SSR_2 + GSH \rightleftharpoons R_1SSG + R_2SH \quad (1)$$

$$R_1SSG + GSH \rightleftharpoons GSSG + R_1SH \quad (2)$$

$$GSSG + NADPH + H^+ \rightleftharpoons 2GSH + NADP^+ \quad (3)$$

Glutathione (GSH) is the predominant thiol in living cells and probably the main thiol substrate for thioltransferase-catalyzed reactions *in vivo*. Several low molecular weight disulfides have been reported to be reduced enzymatically by GSH *via* a thiol-disulfide interchange, for instance the naturally occurring homocystine,[2] the mixed disulfide of CoA and GSH,[3–5] cystine,[1,3,6–9] the mixed disulfide of cysteine and GSH,[1,3] and others such as thiamine disulfide derivatives[10] and the nonbio-

* Unusual abbreviations: ArSSG, the mixed disulfide of glutathione and 3-carboxy-4-nitrobenzenethiol; CySSG, the mixed disulfide of glutathione and cysteine; $CySSO_3H$, *S*-sulfocysteine; DTNB, 5,5′-dithiobis(2-nitrobenzoate).

** Thioltransferase has recently been introduced as a name for enzymes catalyzing thiol-disulfide interchange.[12,26] These enzymes have earlier been referred to as transhydrogenases.[3]

logical disulfides 5,5′-dithiobis(2-nitrobenzoate) (DTNB) and the mixed disulfide of 3-carboxy-4-nitrobenzene thiol and GSH (ArSSG).[11] The purpose of using DTNB (denoted ArSSAr in eqn. 4 to emphasize its disulfide character) or ArSSG as the disulfide substrate was to obtain a convenient assay method of the thioltransferase activity based on direct spectrophotometric determination of ArSH released as shown in eqns. (4) and (5)

$$\mathrm{ArSSAr} + \mathrm{GSH} \rightleftharpoons \mathrm{ArSSG} + \mathrm{ArSH} \quad (4)$$

$$\mathrm{ArSSG} + \mathrm{GSH} \rightleftharpoons \mathrm{GSSG} + \mathrm{ArSH} \quad (5)$$

To determine whether DTNB could generally replace cystine derivatives in the determination of thioltransferase activity, the activity profiles with these different substrates obtained after column chromatography and isoelectric focusing have been compared.

It has previously been demonstrated that the essence of the enzymatic thiol-disulfide interchange is thiol transfer.[12] Glutathione reductase and glutathione *S*-aryltransferase also have an element of thiol transfer in their catalytic functions, and the present investigation was undertaken to clarify whether these enzymes contribute to the thioltransferase activity measured in rat liver preparations. The limitations of replacing the glutathione reductase-coupled assay of thioltransferase with direct spectrophotometric measurement using DTNB as substrate as well as the nature of the DTNB-thioltransferase activity are discussed. In addition, DTNB has previously been used to characterize NADPH-dependent reductases with protein disulfides and low molecular weight disulfides as substrates in crude preparations,[9,13–17] but in these studies possible interference by endogenous glutathione reductase, thioltransferase, and GSH, and by the thioredoxin system was not evaluated. It was therefore of interest to see whether NADPH-dependent reduction of DTNB could be explained by a combination of thiol-disulfide interchange according to eqns. (4) and (5) and the reduction of GSSG by NADPH mediated by glutathione reductase.

As regards glutathione *S*-aryltransferase, it has been suggested that this activity is responsible for the enzymatic reaction of GSH with disulfides,[18] and the relation of this enzyme to CySSG-thioltransferase has therefore also been examined. Preliminary results from this investigation have been previously reported.[19,20]

MATERIALS AND METHODS

The mixed disulfide of cysteine and glutathione was synthesized according to Eriksson and Eriksson,[21] *S*-sulfocysteine according to Segel and Johnson,[22] and the mixed disulfide of glutathione and 3-carboxy-4-nitrobenzenethiol according to Mannervik.[23] The homogeneity of the compounds in stock solutions was tested by paper electrophoresis [21] before use in the enzymatic experiments, and in no case were any impurities detected.

Glutathione reductase (yeast), NADPH, GSH, and GSSG were obtained from Sigma; 5,5′-dithiobis(2-nitrobenzoic acid) from Aldrich ;3,4-dichloro-1-nitrobenzene from Schuchardt; Ampholine carrier ampholytes from LKB; Sephadex G-25 Fine from Pharmacia Fine Chemicals; and CM-cellulose CM 32 from Whatman.

Separation of rat liver enzymes. Livers from male Sprague-Dawley rats were homogenized in 4 volumes of 0.25 M sucrose and the resulting homogenate was centrifuged at 105 000 *g* for 60 min. The supernatant was passed through a Sephadex G-25 Fine column which had a volume 5 times the volume of the supernatant. The gel was equilibrated with the eluent required in subsequent experiments. The protein fraction of the effluent was used in the isoelectric focusing and ion-exchange chromatography experiments.

Isoelectric focusing was carried out in a 110 ml column according to the instructions of the manufacturer (LKB). The ampholyte (1 %) covered a pH-range of 3 – 10 (Ampholine No. 8141) in a 0 – 50 % sucrose density gradient. The sample (50 – 100 mg of protein) was desalted on a Sephadex G-25 Fine column (equilibrated with water) and introduced into the middle of the gradient to avoid denaturation by contact with the electrolytes surrounding the electrodes. The isoelectric focusing was run at 4 °C for 36 h at 300 V. The contents of the column were collected in 1.0 – 1.5 ml fractions.

CM-cellulose chromatography was carried out in columns (2 × 10 cm) equilibrated with 10 mM sodium phosphate buffer, pH 6.1 (1 mM EDTA). After introduction of the sample, the column was washed with the phosphate buffer used for equilibration until no protein could be detected in the effluent. The elution was continued with a linear concentration gradient of 0 – 0.2 M NaCl (500 ml total volume) in the original buffer and fractions of 7 – 10 ml were collected.

The protein concentration was calculated on the basis of the absorbance at 260 and 280 nm.[24]

Assays of enzymatic activities. Glutathione reductase was assayed spectrophotometrically

by recording NADPH oxidation at 340 nm. The reaction system contained 1 mM GSSG, 0.1 mM NADPH, 0.17 M sodium phosphate buffer (pH 7.6), 1 mM EDTA, and enzyme (10 – 50 μl) in a total volume of 1 ml. The measurements were made on an LKB 8600 Reaction Rate Analyzer, which maintained the reaction mixture at 30 °C. Reductase activity demonstrable with DTNB as the disulfide substrate was determined in the same reaction system with the substitution of 0.5 mM DTNB for GSSG. The formation of 3-carboxy-4-nitrobenzenethiolate was followed at 412 nm with a recording spectrophotometer.

Glutathione *S*-aryltransferase activity was measured by spectrophotometric determination of *S*-2-chloro-4-nitrophenyl-glutathione using 3,4-dichloro-1-nitrobenzene and GSH as substrates (*cf.* Ref. 25). The determination was made on an LKB 8600 Reaction Rate Analyzer at 340 nm, using an extinction coefficient of 10 mM^{-1} cm^{-1}. The reaction system contained 5 mM GSH, 1 mM 3,4-dichloro-1-nitrobenzene (added as a 20 mM solution in ethanol), 0.17 M sodium carbonate buffer (pH 8.0), and enzyme (50 μl) in a final volume of 1 ml.

Assay of CySSG-thioltransferase was based on the use of GSH and CySSG or GSH and $CySSO_3H$ as substrates and determination of the GSSG formed (as shown in eqns. (6) and (7))

$$CySSO_3^- + GSH \rightleftharpoons CySSG + HSO_3^- \quad (6)$$

$$CySSG + GSH \rightleftharpoons GSSG + CySH \quad (7)$$

by coupling to glutathione reductase (eqn. 3). CySSG and $CySSO_3H$ are interchangeable in this assay system; it has previously been demonstrated by column chromatography and isoelectric focusing experiments that these substrates define the same enzymatic activity (as do, for example, *S*-sulfoglutathione and cystine).[19,20,26] $CySSO_3H$ has the advantage over CySSG of giving a three-fold lower non-enzymatic reaction rate when these substrates are used in the concentrations given below, which result in the same enzymatic reaction rate. The activity was determined spectrophotometrically at 340 nm using a Beckman DB-G spectrophotometer. The reaction system contained 0.5 mM GSH, 0.25 mM CySSG, 0.1 mM NADPH, 0.4 unit of yeast glutathione reductase, 0.125 M sodium phosphate buffer (pH 7.6), 1 mM EDTA, and enzyme (50 – 100 μl) in a final volume of 1 ml. The reaction was started by addition of CySSG (or $CySSO_3H$) 3 min after mixing of the other components.[1] The amount of yeast glutathione reductase used was sufficient to eliminate the influence on the thioltransferase assay of endogenous glutathione reductase in the sample tested. $CySSO_3H$ was used in a concentration of 2.5 mM, when substituted for CySSG. A correction for the spontaneous reaction was made by separate determination of thiol-disulfide interchange in the absence of thioltransferase. Boiled enzyme preparations had no catalytic effect on the reaction.

Measurement of thioltransferase activity using ArSSG or DTNB as the disulfide substrate (ArSSG- or DTNB-thioltransferase activity) was based on the formation of 3-carboxy-4-nitrobenzenethiolate, which was monitored spectrophotometrically at 412 nm (*cf.* Ref. 11). The reaction system contained 0.02 mM GSH, 0.1 mM ArSSG or 0.02 mM DTNB, 0.17 M sodium phosphate buffer (pH 5.5), 1 mM EDTA, and enzyme (50 μl). The reaction velocities were corrected for the contribution of the nonenzymatic reaction.

The formation of 1 μmol/min of product was designated as a unit of enzymatic activity.

RESULTS

Isoelectric focusing of thioltransferase from rat liver. To obtain an overall view of all enzymatic activities of interest in this investigation, a post-microsomal supernatant from homogenates of rat liver was subjected to isoelectric focusing in the pH range of 3 – 10. Fig. 1 shows an experiment with a supernatant dialyzed for 30 h against 1 % glycine (pH 7). Four major peaks of thioltransferase activity were demonstrated using $CySSO_3H$ and GSH as substrates. In other experiments following prolonged dialysis (70 h) only one acidic peak was obtained, apparently at the expense of the two basic components. Only the two basic components were observed when the enzyme sample was chromatographed on Sephadex G-25 before the isoelectric focusing.

Two components of glutathione reductase (not shown) and glutathione *S*-aryltransferase which did not coincide with each other or the other activities tested were detected. DTNB-thioltransferase activity gave four peaks (not shown), two of which partially overlapped the two basic peaks of CySSG-thioltransferase activity.

To test whether the activity obtained with DTNB as the disulfide substrate could be resolved further from the other enzyme activities tested, a more extensive separation of the enzyme activities was undertaken using ion exchange chromatography in combination with isoelectric focusing.

Chromatography of the cytosol fraction of rat liver on CM-cellulose. All enzyme activities studied in the cytosol fraction of fresh rat livers were adsorbed onto CM-cellulose equili-

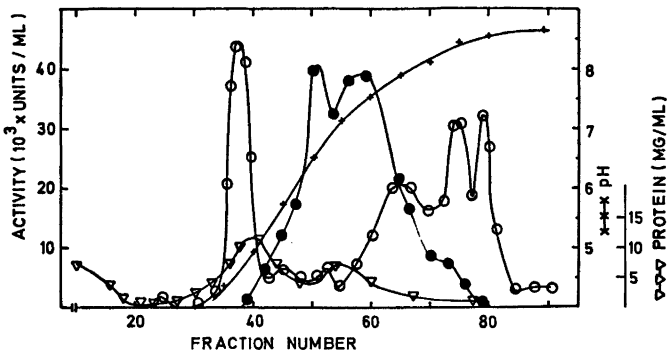

Fig. 1. Isoelectric focusing of the supernatant fraction from rat liver after dialysis for 30 h against 1 % glycine buffer, pH 7. The protein sample, 100 mg, was introduced into the middle of the 0 – 50 % sucrose gradient containing 1 % Ampholine (No. 8141), pH 3 – 10. Isoelectric focusing was carried out at 4 °C for 36 h at 300 V. The contents of the column were collected in 1.0 – 1.5 ml fractions. O, CySSG-thioltransferase; ●, GSH *S*-aryltransferase x 1:20.

brated with 10 mM sodium phosphate buffer, pH 6.1, containing 1 mM EDTA. Elution with a salt gradient resulted in two peaks of CySSG-thioltransferase activity (Fig. 2), the relative sizes of which were dependent on the experimental conditions. This variable elution pattern indicated that the two activities might be interconvertible forms of a single enzyme. This possibility was the subject of a separate investigation in which evidence for a GSH-dependent interconversion of the two forms was obtained [27] (see also Ref. 26). A similar variable elution pattern was not seen for any of the other activities studied. Aged preparations contained additional activities which were not retained by the column and which presumably were identical with the acidic degradation products observed in the isoelectric focusing experiments.

Glutathione reductase appeared as a single component which had its peak in a fraction containing the maximal activities of thioltransferase, measured with ArSSG and DTNB as disulfide substrates. The activities obtained with ArSSG and DTNB were usually distributed in three distinct peaks which essentially coincided for the two substrates. The major peaks of the two activities had shoulders which overlapped with fractions containing the maxima of the CySSG-thioltransferase activity. The glutathione *S*-aryltransferase activity had two peaks which partially coincided with the thioltransferase activity.

Isoelectric focusing of fractions obtained from CM-cellulose chromatography. Fractions 37 and 39 from the CM-cellulose chromatography depicted in Fig. 2 were subjected to isoelectric focusing in an attempt to resolve the different enzymatic activities. The resolution of fraction No. 37 is shown in Fig. 3. Glutathione reductase, glutathione *S*-aryltransferase, and CySSG-thioltransferase activities were clearly resolved. DTNB-thioltransferase activity is separated into three peaks coinciding with the peaks of glutathione reductase, glutathione *S*-aryltransferase, and CySSG-thioltransferase.

Isoelectric focusing of fraction No. 39, containing low CySSG-thioltransferase activity, is illustrated in Fig. 4. CySSG-thioltransferase activity is less stable than the other activities (see Refs. 6, 15, and 28) and could not be detected after the isoelectric focusing. Glutathione reductase appeared as a single component separated from the other activities. The glutathione *S*-aryltransferase activity appeared as one minor and two major components. The enzymatic activity demonstrated with DTNB as disulfide substrate was separated into one major and two minor peaks. The coincidence of glutathione *S*-aryltransferase and DTNB-thioltransferase activities (Figs. 3 and 4) will be considered further in the Discussion.

In a different series of experiments the fraction from the CM-cellulose column containing the second component of CySSG-thioltransferase (corresponding to fraction No. 41 in Fig. 2) was analyzed by isoelectric focusing (Fig. 5).

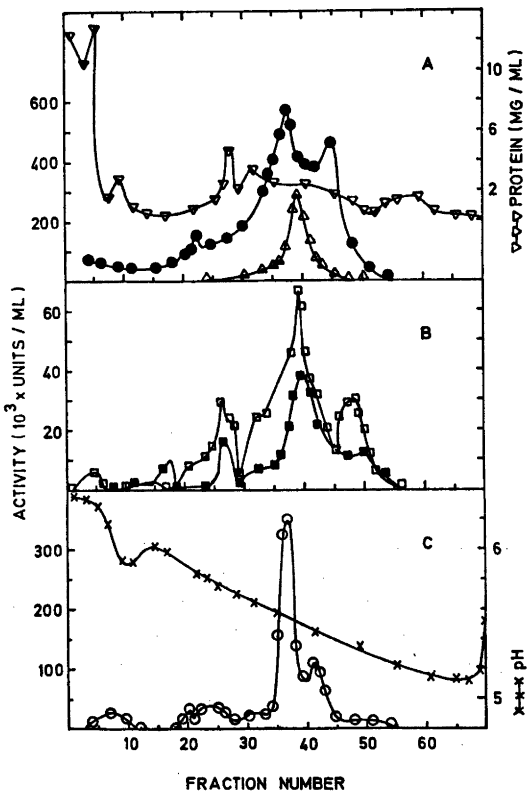

Fig. 2. Fractionation of the supernatant fraction from rat liver by CM-cellulose chromatography. To obtain the protein sample in the same buffer conditions prevailing in the equilibrated CM-cellulose, the supernatant was passed through five volumes of Sephadex G-25 equilibrated with 10 mM sodium phosphate buffer (pH 6.1), 1 mM EDTA. The protein effluent was applied to the CM-cellulose column (2 x 10 cm). The column was washed with the buffer used for equilibration till no protein was eluted. The elution was continued with a linear concentration gradient of 0 – 0.2 M NaCl (500 ml total volume) in the original buffer and fractions of 7 – 10 ml were collected. The enzymatic activities are: (A) ●, GSH *S*-aryltransferase; △, glutathione reductase (activity x 1:5); (B) □, DTNB-thioltransferase activity; ■, ArSSG-thioltransferase activity; (C) ○, CySSG-thioltransferase.

The results were essentially the same as those depicted in Fig. 3, but some of the CySSG-thioltransferase activity was found in the low pH-range of the gradient, indicating degradation due to prolonged dialysis before isoelectric focusing. Furthermore, the reductase activity obtained with DTNB and NADPH (in the absence of added thiols), which was not separated from glutathione reductase by CM-cellulose chromatography, coincided exactly with the glutathione reductase activity.

In addition, we investigated the possibility that thioltransferase activities with DTNB or ArSSG were catalyzed by the same proteins catalyzing the other activities tested. Isoelectric focusing of a fraction corresponding to No. 26 in Fig. 2, the first of the three major peaks containing DTNB-thioltransferase activity, showed high isoelectric points for the components of DTNB-thioltransferase, which were resolved from the other activities tested (Fig. 6). Furthermore, low activity was obtained when ArSSG was used as the substrate in assaying fractions containing high glutathione *S*-aryltransferase and CySSG-thioltransferase activities.

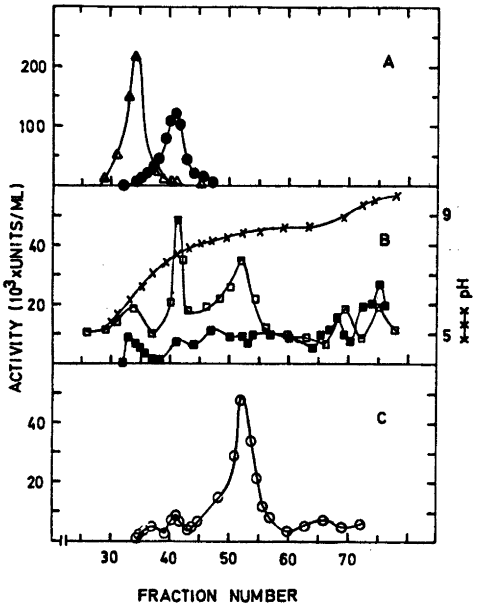

Fig. 3. Isoelectric focusing of fraction No. 37 from the CM-cellulose chromatography depicted in Fig. 2. The symbols for enzymatic activities are explained in the legend to Fig. 2. Further information is supplied in Fig. 1 and Materials and Methods.

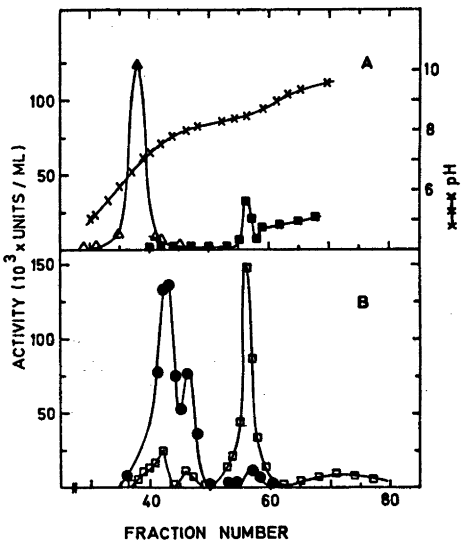

Fig. 4. Isoelectric focusing of fraction No. 39 from the CM-cellulose chromatography depicted in Fig. 2. The symbols are given in Fig. 2. Glutathione reductase (activity × 1:10). Further information is supplied in Fig. 1 and Materials and Methods.

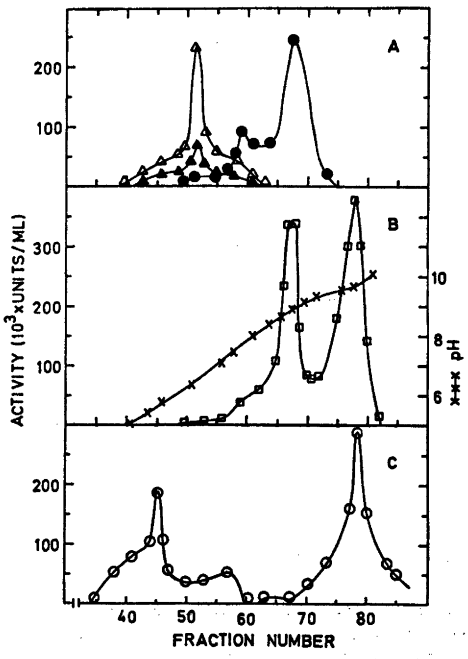

Fig. 5. Isoelectric focusing of a fraction from CM-cellulose chromatography corresponding to fraction No. 41 in Fig. 2. ▲, NADPH-DTNB oxidoreductase; △, glutathione reductase (activity × 1:40), ●, GSH-*S*-aryltransferase (activity × 1:4). The other symbols are given in Fig. 2. Further information is supplied in the legend to Fig. 1 and Materials and Methods.

DISCUSSION

The results of the present investigation demonstrate that the cytosol fraction of rat liver contains at least two forms of thioltransferase active with CySSG (or $CySSO_3H$). These components are distinguishable by chromatography on CM-cellulose columns or by isoelectric focusing. The two activities, after being separated by ion exchange chromatography, are essentially homogeneous in subsequent isoelectric focusing experiments (*cf.* Figs. 3 and 5). Upon aging of the supernatant, additional, more acidic forms appear. (For instance, the experiment demonstrated in Fig. 5 shows activity below pH 8 in the gradient presumably due to degradation of the sample during dialysis before the isoelectric focusing.) It could be established (*cf.* Figs. 3 and 5) that no significant contribution to the CySSG-thioltransferase activity could be ascribed either to glutathione reductase (*cf.*

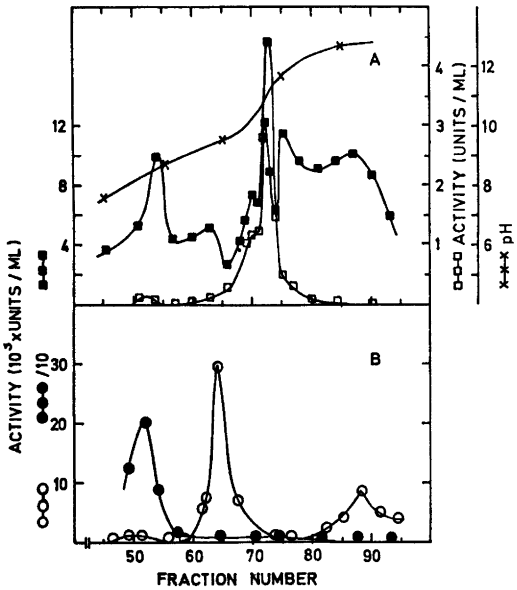

Fig. 6. Isoelectric focusing of a fraction from CM-cellulose chromatography corresponding to the first peak in Fig. 2 B containing fractions Nos. 20 – 29. The substrate concentrations used for measuring DTNB- and ArSSG-thioltransferase activities are: GSH, 50 μM; DTNB, 50 μM; and ArSSG, 135 μM. GSH *S*-aryltransferase (activity × 1:10). The symbols used are explained in the legend to Fig. 2. Further information is supplied in the legend to Fig. 1 and Materials and Methods.

Ref. 11) or to glutathione *S*-aryltransferase, which has been stated to be identical with an enzyme catalyzing the thiol-disulfide interchange involving GSH and thiamine disulfide.[18]

The fact that several different enzymes can use DTNB and GSH as substrates, in combination with the limited resolution of the enzyme activities, explains the unusual shape of the peaks of the DTNB activity profile depicted in Fig. 2.

The third peak of DTNB-dependent activity in Fig. 2 B was not characterized further, but is probably a separate activity, since the activities of all other enzymes examined were low in these fractions from the column. Thus, all three peaks of DTNB activity seemed to contain a component which was distinct from glutathione reductase, glutathione *S*-aryltransferase, and CySSG-thioltransferase. Three major peaks of DTNB-dependent activity have been seen in all experiments, and the first has been found to increase upon aging of the rat liver preparation.

It is obvious from Figs. 2 and 6 that the glutathione reductase-coupled system for determination of thioltransferase activity catalyzing thiol-disulfide interchange of cystine and glutathione derivatives cannot without restrictions be replaced by the assay method based on the thiolysis of DTNB [11] when a crude enzyme preparation is used. In conclusion, a number of protein components in the supernatant fraction from rat liver catalyze the reduction of non-biological aromatic disulfides by GSH.

Glutathione reductase normally appeared as a single component in chromatographic experiments. The reductase activity obtained with DTNB and NADPH as substrates coincided with the glutathione reductase activity in all experiments (*cf.* Fig. 5). This contrasts with the finding of Tietze that the DTNB- and GSSG-reducing activities can be separated by chromatography on DEAE-cellulose.[15]

The glutathione *S*-aryltransferase activity appeared as two components which are separable from the major components of the other activities tested (*cf.* Figs. 1, 2, 4 and Ref. 29). However, isoelectric focusing did not resolve overlapping peaks of glutathione *S*-aryltransferase and DTNB-thioltransferase activity (*cf.* Figs. 3, 4, and 5) or glutathione *S*-aryltransferase and ArSSG-thioltransferase activity (Fig. 6). This finding indicates that glutathione *S*-aryltransferase, which is known to have a broad substrate specificity,[25] can utilize DTNB and ArSSG as substrates. The nature of the reactions with these substrates has not been studied, and although the original assumption was that a thiol-disulfide interchange was measured, it cannot be excluded that arylation of GSH occurred. It is known that DTNB can arylate sulfhydryl groups nonenzymatically.[30]

The results in Fig. 4 also seem to indicate that the component showing the highest thioltransferase activity with DTNB and GSH as substrates is able to catalyze the arylation of GSH with 3,4-dichloro-1-nitrobenzene.

A general conclusion based on the present investigation is that assay of either glutathione reductase, glutathione *S*-aryltransferase, or CySSG-thioltransferase is not interfered with by

the other two enzymes. The glutathione *S*-aryltransferase (*cf.* Refs. 18 and 29) and the CySSG-thioltransferase activities are present in at least two separable forms. The different forms of both of these two enzyme activities seem to be capable of catalyzing the reaction of DTNB and ArSSG with GSH. DTNB-thioltransferase activity is also associated with several protein components distinct from the other enzyme activities measured (Figs. 2, 4, and 6). Before concluding definitely that these activities are thioltransferases, it is desirable to further characterize them, bearing in mind that DTNB is a compound not normally found *in vivo*.

The two components of the CySSG-thioltransferase activity are interconvertible, as is demonstrated in a following paper.[27] This finding indicates that these are different forms of a single enzyme. This activity is responsible for the enzymatic reduction in rat liver of a variety of low molecular weight disulfides (see Introduction), as well as for the reduction of *S*-sulfo-derivatives of, for example, cysteine or GSH.[26] CySSG-thioltransferase is present in the cytosol [1] and is clearly distinguishable from the enzyme ("GSH-insulin transhydrogenase") catalyzing thiol-disulfide interchange between GSH and insulin or other polypeptide disulfides.[31,32] The latter enzyme is also present in rat liver [33,34] and is probably localized in the microsomal fraction.[15,35,36] The conclusion that the two enzymes are different is further supported by the lack of activity of purified CySSG-thioltransferase with 0.25 mM GSH and 0.25 mM insulin or oxytocin in the glutathione reductase-coupled system (S. Eriksson, unpublished experiments). On the other hand, the CySSG-thioltransferase is probably identical with the thiol-disulfide "transhydrogenase" of rat tissues active with low molecular weight substrates.[3,7,15] This latter enzyme was originally described by Racker under the name of glutathione-homocystine transhydrogenase [2] and has subsequently also been purified from yeast.[6]

The enzyme-catalyzed reaction between GSH and DTNB has, with the exception of the activity observed with partially purified CySSG-thioltransferase,[11] not previously been described. It seems possible that the enzymatic activity observed with GSH and thiamine disulfides as substrates may be of a similar nature.[10,18] A partially purified preparation of the latter activity was not active with cystine, cystamine, or homocystine as substrates, which was taken as evidence that this activity is not identical with CySSG-thioltransferase.[10] The thioltransferase activities obtained with DTNB and that described for thiamine disulfides are similar in that some of the components separated by ion-exchange chromatography or isoelectric focusing coincide with peaks of glutathione *S*-aryltransferase activity (Figs. 3, 4, and 5; *cf.* Ref. 18).

It is clear that the high redox potential of DTNB makes it more reactive than alkyl disulfides. Therefore, it is not unexpected that several components of rat liver are able to catalyze the reaction between thiols and DTNB (*cf.* Figs. 3 and 5). Whether the activity demonstrated with DTNB has any physiological significance remains to be seen.

Pyridine nucleotide-dependent reduction of DTNB has previously been observed in several enzymatic systems. In bacteria and bacterial spores a reductase has been identified which is more active with DTNB than with any other disulfide (including GSSG) tested.[13,14] Multicomponent systems,[37,38] probably identical with the thioredoxin system,[39] capable of NADPH-dependent reduction of disulfides are also active with DTNB. A similar reduction of DTNB which may also be partially linked to thioredoxin has been detected in rat liver.[15–17] Furthermore, it is known that glutathione reductase can directly catalyze the reduction of DTNB, although this activity is relatively low.[40,41] In the present investigation the only NADPH-dependent activity detected after isoelectric focusing (Fig. 5) or CM-cellulose chromatography seems to be the latter activity; the thioredoxin system is probably not functional due to separation of thioredoxin and thioredoxin reductase. Finally, it should be observed that the discussion in the literature of the NADPH-dependent reduction of DTNB [9,15–17] has ignored the reactions between DTNB and GSH (eqns. 4, 5), which can be coupled to glutathione reductase (eqn. 3). The present investigation shows that this thiol-disulfide interchange is enzymatic. Failure to properly evaluate the contribution of corresponding thiol-disulfide interchange reactions has previously limited the understanding of the nature of "cystine reductase" [42–44] (*cf.*

Ref. 45), "*S*-sulfoglutathione reductase",[46,47] (*cf.* Ref. 48) and "coenzyme A-glutathione mixed disulfide reductase" [49–52] (*cf.* Refs. 5 and 26).

Evidence for a Glutathione-dependent Interconversion of Two Forms of a Thioltransferase from Rat Liver Catalyzing Thiol-Disulfide Interchange

STELLAN ERIKSSON, PER ASKELÖF, KENT AXELSSON and BENGT MANNERVIK

Department of Biochemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

In studies on rat liver two forms of a thioltransferase (EC 1.8.4.1), an enzyme catalyzing thiol-disulfide exchange, were separated by CM-cellulose chromatography and isoelectric focusing. Incubation with glutathione increased the activity of the more acidic form and caused a concomitant loss of the basic form. This effect could be reversed by dithioerythritol. Glutathione disulfide did not effect the conversion of one form of the enzyme into the other. Treatment of the basic component with [^{35}S]-GSH resulted in incorporation of radioactivity which was recovered in the acidic thioltransferase peak found upon repeating the chromatography on CM-cellulose. These experimental findings are consistent with a mechanism of interconversion involving thiol-disulfide interchange of GSH and a disulfide group of the enzyme.

In a previous paper we reported that two forms of a thioltransferase, an enzymatic activity in rat liver catalyzing thiol-disulfide interchange with glutathione (GSH) and the mixed disulfide of cysteine and glutathione (CySSG),* could be separated by CM-cellulose chromatography and isoelectric focusing.[1] These forms were distinct from similar activities observed in aged rat liver preparations. The ratios of the reaction velocities obtained with a variety of glutathione sulfenyl derivatives (such as CySSG, *S*-sulfoglutathione, and the mixed disulfide of coenzyme A and glutathione) as well as with other disulfides and thiosulfate esters were the same for both fractions of the CySSG-thioltransferase activity, indicating that these are different forms of the same enzyme.[2] The distribution of the total CySSG thioltransferase activity between its two different forms varied with experimental conditions in a way which suggested that the variations could be ascribed to dissociation or association phenomena. The present investigation was undertaken to further elucidate the mechanism of interconversion of the two forms of the enzyme.

* Unusual abbreviations: CySSG, the mixed disulfide of cysteine and glutathione; $CySSO_3H$, *S*-sulfocysteine; DTE, dithioerythritol.

MATERIALS AND METHODS

In addition to the materials and methods described in the previous paper,[1] dithioerythritol (DTE) (Sigma); Diaflo ultrafiltration membranes (Amicon); [^{35}S]-GSH (Schwarz/Mann), and Aquasol (NEN) have been used.

Pretreatment of homogenates from rat liver before CM-cellulose chromatography. Livers from male Sprague-Dawley rats (45 g) were homogenized shortly after removal in 4 volumes of 0.25 M sucrose and the resulting homogenate was centrifuged for 1 h at 145 000 *g*. The supernatant (134 ml) was adjusted to pH 8.0 and divided into three equal parts. One part served as a control in the subsequent CM-cellulose chromatography. The remaining two parts were incubated at pH 8.0 for 5 min with 2 mM GSH and one of these was afterwards treated with 1 mM dithioerythritol for another 5 min. The three preparations were then chromatographed on separate Sephadex G-25 columns of equal sizes to remove GSH and dithioerythritol and to change the solvent of the samples to the buffer used for equilibration of the CM-cellulose columns. The sample volume was 20 % of the Sephadex G-25 bed volume.

CM-cellulose chromatography. Fractionation of the three samples on CM-cellulose was carried out simultaneously under identical conditions, and the effluent was collected in 7 – 10

ml fractions. Three CM-cellulose columns (2 × 14 cm) were equilibrated with 10 mM sodium phosphate buffer – 1 mM EDTA (pH 6.2). Each sample was introduced into a separate column, which was then washed with the buffer used for equilibration until the UV absorption of the effluent vanished. Elution was carried out with a linear gradient formed from 250 ml 10 mM sodium phosphate – 1 mM EDTA (pH 6.2) in the mixing chamber and 250 ml 50 mM sodium phosphate – 1 mM EDTA 0.2 M NaCl (pH 6.2) in the reservoir.

[^{35}S]-GSH labelling of thioltransferase collected from CM-cellulose columns. Pooled fractions were concentrated two-fold on a PM 30 Diaflo membrane, adjusted to pH 8.0, and incubated for 10 min with 120 μM [^{35}S]-GSH (spec. act. 5 Ci/mol). The incubation mixture was desalted on Sephadex G-25 according to the procedure described above and subsequently rechromatographed on CM-cellulose to determine whether the basic form of the thioltransferase had incorporated [^{35}S]-GSH to give the acidic form. Radioactivity was determined by liquid scintillation counting of 1 ml samples in 10 ml Aquasol.

Ultrafiltration. The first and second peaks of the thioltransferase activity, obtained after CM-cellulose chromatography, were collected separately and each was subjected to a series of ultrafiltrations on membrane filters of increasing porosities. The collected material (37.5 ml) was first concentrated to a volume of 13.5 ml on a PM 30 membrane. This concentrate was then filtered on an XM 50 membrane until a volume of 4 ml remained in the cell. Finally, this remaining material was concentrated to 1 ml on an XM 100 membrane. Both peaks were treated in the same manner at 4 °C and the enzyme activities in both concentrates and filtrates were measured.

RESULTS AND DISCUSSION

Fig. 1 demonstrates a typical elution profile obtained after chromatography of the supernatant fraction from rat liver on a CM-cellulose column. Gradient elution separated the thioltransferase activity into two components. The distribution of the activity was dependent on the experimental conditions and varied from a distribution in which the first peak contained the major part of the activity (*cf.* Ref. 1, Fig. 2C) to a distribution in which the second peak dominated. The possibility was considered that the appearance of two peaks was an artifact produced by the steep rise in the pH of the effluent which coincided with the appearance of thioltransferase activity (Fig. 1). The initial decrease in the pH of the effluent is caused by

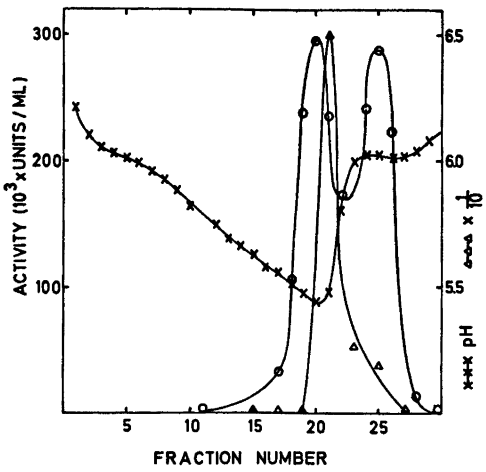

Fig. 1. CM-cellulose chromatography of the supernatant fraction from 30 g of rat liver after chromatography on Sephadex G-25. The sample was eluted with a linear salt gradient. The thioltransferase activity appears in two peaks of similar sizes if the sample volume is about 20 % of the volume of the Sephadex gel bed. (See Materials and methods). The enzymatic activities are: O, thioltransferase measured with $CySSO_3H$ and GSH as substrates; △, glutathione reductase.

substitution of sodium ions of the gradient for hydrogen ions of the ion-exchange matrix and the subsequent rise in pH indicates the establishment of new ionic equilibria. However, glutathione reductase, which appears in the same region of the elution profile, is not split into two components. Furthermore, the two peaks of thioltransferase activity were also obtained when a gradient having less buffering capacity was used, conditions which delay the pH rise (*cf.* Ref. 1, Fig. 2C). Finally, isoelectric focusing also established the existence of two separable components of thioltransferase activity and thus eliminated the possibility that the appearance of the two peaks was an artifact due to a particular separation technique.

It was discovered that the size of the column beds had a marked effect on the distribution of the thioltransferase activity between the two peaks. An increase of the second component at the expense of the more acidic one was correlated with an increase in the column bed size using a constant sample volume. This effect was most clearly observed with changes in the column bed size for gel filtration on Sephadex

G-25, which preceded the CM-cellulose chromatography, but also to a smaller extent in the latter separation. It is well known that Sephadex can retard substances by adsorption due to hydrophobic interactions,[3,4] and the possibility was therefore considered that non-covalently bound lipids could be removed from the enzyme, thereby causing conversion of the more acidic thioltransferase component into the other form.

That lipids are indeed separated from the protein fraction of rat liver supernatant by gel filtration is suggested by the appearance of a very slowly migrating yellowish zone, which causes the fractions it is eluted in to appear turbid. In order to test the possibility that lipids constitute the difference between the two peaks of thioltransferase activity, the supernatant fraction from rat liver was treated, after gel filtration and before ion-exchange chromatography, with the lipid fraction obtained from the Sephadex column. However, no difference between the treated sample and the untreated control could be detected with respect to the distribution of the thioltransferase activity (22 and 78 % of the total activity in the first and second peaks, respectively, for both samples). Treatment of the sample with different mixtures of purified lipids known to be present in rat liver did not change the relative amounts of the two components either.

The influence of the column bed size on the distribution pattern of thioltransferase activity can be explained by assuming that the two components are in a dissociation-association equilibrium. The dissociation could involve removal of a low-molecular weight compound, as in the hypothesis discussed above, or consist of an oligomer-monomer transition by a protein containing subunits. In order to test the latter possibility the two forms of thioltransferase obtained after CM-cellulose chromatography were compared with respect to their molecular weights by means of ultrafiltration on Diaflo filters of different porosities. Ultrafiltration was chosen as the method for molecular weight determination instead of gel filtration, because the latter procedure causes inactivation of thioltransferase activity and is known to remove, for example, GSH from the thioltransferase. A preliminary estimation by gel filtration on Sephadex G-50 of the molecular weight of the basic form of the thioltransferase indicated a value of about 50 000; and the molecular weight of the acidic form was therefore expected to be a multiple of this value, if dissociation and association of subunits would be the mechanism of the interconversion of the two enzyme forms. The results of ultrafiltration of the two forms are shown in Table 1. Care was taken to use membranes with pore sizes such that full and partial retention of the enzyme activity in the ultrafiltration cell were both obtained. This is essential, because both oligomer and monomer may be too large to penetrate the membrane filter or both may be too small to be retained at all. The extent of retention and penetration of the two components was not significantly different on membrane filters of the same porosity, thus excluding major differences in molecular weights. The retention characteristics of the membranes used would have revealed differences between the two components if the molecular weights were 50 000 and a multiple thereof. Consequently, these results seem to

Table 1. Activity distribution in concentrate and filtrate after ultrafiltration of the two thioltransferase components. The most acidic (peak I) and the most basic (peak II) components were separated by CM-cellulose chromatography and were subjected to ultrafiltration as described in Materials and methods.

Filter	Activity (10^3 × units/ml) Peak I Concentrate (C)	Filtrate (F)	$\frac{F}{C}$	Peak II Concentrate (C)	Filtrate (F)	$\frac{F}{C}$

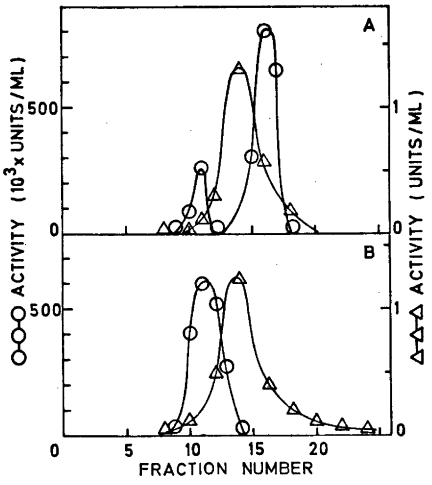

Fig. 2. CM-cellulose chromatography of (A) an untreated control and (B) a GSH-treated rat liver supernatant. The supernatant fraction from 30 g of rat liver was adjusted to pH 8.0 and divided into two parts. One of these was used as a control in the subsequent CM-cellulose chromatography. The second part was treated with 2 mM GSH for 5 min. Both parts were chromatographed simultaneously on separate Sephadex G-25 columns to change the solvent to that used in the subsequent CM-cellulose chromatography. The symbols for enzymatic activities are given in the legend to Fig. 1.

exclude an oligomer-monomer transition as the explanation for the two peaks of thioltransferase activity.

Glutathione, which is present in high concentration in rat liver,[5] is a substrate of the thioltransferase and has been found to activate aged preparations of the enzyme (Ref. 6 and unpublished results). Therefore, another explanation of the appearance of two thioltransferase components could be that the enzyme occurs in both a GSH-containing and a GSH-deficient form. Fig. 2 illustrates an attempt to explore this possibility. It is shown that after incubation with 2 mM GSH (see MATERIALS AND METHODS), the second component, after chromatographing on CM-cellulose had disappeared and the first component had increased. The first component was identified from its position in relation to that of glutathione reductase in the elution profile. The position of glutathione reductase in the elution profile was not affected by pretreatment with GSH, nor could any effect on the positions of the two peaks of aryltransferase be demonstrated (*cf.* Ref. 1). This conclusion was based on measurements of the pH, volume, and conductance of the effluent. Furthermore, the GSH-treated thioltransferase had a total activity corresponding to the sum of the activities of the two peaks obtained from the untreated control sample, which supported the interpretation that the second component was converted into the first one.

To obtain further evidence for this interpretation, the following experiment was carried out. A sample was divided into three equal parts, one of which served as an untreated control for CM-cellulose chromatography. The remaining two parts were treated with 2 mM GSH as in the experiment described above, and one of these was afterwards incubated with 1 mM DTE before the ion-exchange chromatography. The purpose of the experiment was to confirm the previous observation and to find out whether the effect of GSH could be reversed by DTE, which is a strong disulfide-reducing agent. The amount of DTE used was sufficiently small to prevent complete conversion of the first component into the second one. This precaution was taken to eliminate the possibil-

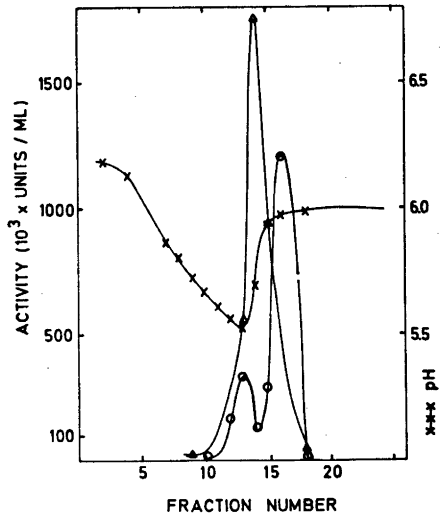

Fig. 3. The reversal by dithioerythritol (DTE) of the effect of GSH-treatment seen in Fig. 2. GSH-treated sample (see Materials and methods and Fig. 2) was incubated with 1 mM DTE for 5 min at pH 8.0 before the subsequent Sephadex G-25 and CM-cellulose chromatography. Thioltransferase (activity x 2). The symbols for enzymatic activities are given in the legend to Fig. 1.

ity that the effect of the DTE-treatment was a change in the relative positions of glutathione reductase and the first thioltransferase peak. The three different preparations were freed by gel filtration from the reagents used in the pretreatment and were chromatographed under identical conditions on CM-cellulose columns of equal sizes. The results of the chromatography of the untreated and GSH-treated samples were similar to those described in Fig. 2; and the result obtained with the DTE-treated preparation demonstrated a reappearance of the second thioltransferase peak (Fig. 3) such that this peak contained an even greater amount of the total thioltransferase activity than the second peak from the untreated control. The chromatographic properties of glutathione reductase were not affected by the DTE-treatment. Thus, this experiment demonstrates that the second component can be converted into the more acidic one by treatment with GSH and that the more acidic component can then be reconverted into the second one by incubation with DTE.

To obtain direct evidence that GSH was bound to the thioltransferase, [^{35}S]-GSH was incubated with different enzyme preparations Treatment of the supernatant fraction of rat liver with [^{35}S]-GSH resulted in only a small incorporation of radioactivity, because the concentration of endogenous GSH in the supernatant was approximately 1 mM, which was in large excess of the [^{35}S]-GSH added. Furthermore, extensive washing of the material adsorbed onto CM-cellulose released [^{35}S]-GSH in a large volume after the effluent containing the unadsorbed protein. This leakage may arise from dissociation of GSH from the enzyme-GSH complex. Consequently, no distinct peak of radioactivity was obtained on subsequent elution with a linear salt gradient.

However, the results were more definitive when the basic form of thioltransferase obtained by CM-cellulose chromatography was treated with radioactive GSH and rechromatographed on CM-cellulose in order to visualize [^{35}S]-GSH binding to thioltransferase. This treatment demonstrated the formation of an acidic thioltransferase which coincided with the peak of radioactivity in the elution profile (Fig. 4). Coincidence between enzyme activity and radioactivity is in itself not conclusive evidence for a

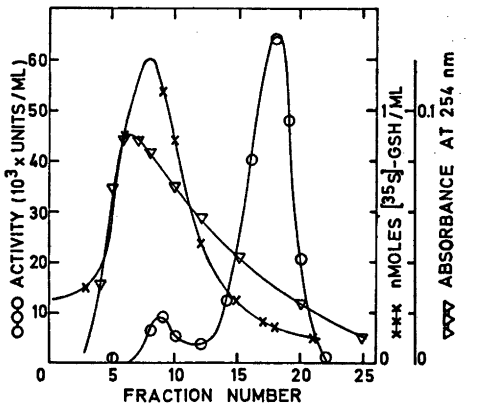

Fig. 4. Incorporation of [^{35}S]-GSH into the basic thioltransferase component. The basic component (22 ml, 1.64 mg protein per ml) obtained after CM-cellulose chromatography was adjusted to pH 8 and incubated with 120 μM [^{35}S]-GSH (spec. act. 5 Ci/mol). The incubation mixture was chromatographed on Sephadex G-25 and then chromatographed on a CM-cellulose column (2 x 4 cm). Unadsorbed proteins and free GSH were washed out before elution of the thioltransferase with a linear salt gradient. The gelfiltration removed 60 % of the original radioactivity, 7 % was recovered in the effluent (50 ml) preceding the gradient, and 0.5 % appeared in the fractions containing the acidic form of the thioltransferase. The symbols are: ∇, absorption at 254 nm; x, [^{35}S]-GSH; O, CySSG-thioltransferase.

GSH-enzyme complex, because the enzyme species in question is not pure enough. However, this evidence for the binding of [^{35}S]-GSH to thioltransferase is strengthened by the fact that incubation of the basic form of thioltransferase with radioactive GSH gives rise to an acidic enzyme form and a coincident peak of radioactivity.

These results support the hypothesis that the enzyme can exist in both a GSH-containing and a GSH-deficient form, as does the finding that the GSH-treatment gives rise to the most acidic thioltransferase component, which is expected due to the acidic properties of GSH. This explanation is also in accord with the results of the ultrafiltration experiments in which no significant difference in the molecular weights of the two components could be demonstrated.

It was also shown by equilibrium dialysis that GSH was bound to a partially purified thioltransferase preparation, but the possibility that the

binding measured was caused by components other than the thioltransferase could not be excluded.

It is assumed that GSH is covalently linked to the enzyme *via* a disulfide bond. If so, DTE-treatment of the native enzyme would be expected to increase the second component at the expense of the first one, a result which was in fact obtained experimentally. The binding of GSH to the enzyme could take place by thiol-disulfide interchange either between GSH and a disulfide group of the enzyme or between GSSG (formed by oxidation of GSH) and a sulfhydryl group of the protein. To test the latter possibility, the enzyme was treated with 1 mM GSSG before chromatography on CM-cellulose. This treatment gave no significant increase of the more acidic component, which lends support to the former mechanism of binding. According to this interpretation, GSH and a disulfide-containing form of the thioltransferase are in equilibrium with a mixed disulfide of GSH and the enzyme (Fig. 5). This scheme explains why the amount of the GSH-containing component decreases with the size of the chromatographic bed in the gel filtration experiments; removal of GSH shifts the equilibrium in favor of the GSH-deficient enzyme form. It should also be pointed out that the binding of GSH according to Fig. 5 may be a partial reaction of the catalytic mechanism of the enzyme.

It is noteworthy that glutathione *S*-epoxide transferase can also occur in multiple forms and that these forms are also interconvertible under the influence of GSH.[7] Furthermore, the GSH concentration influences the relative proportions of the three major components of glucose-6-phosphate dehydrogenase in rat liver.[8] Highly purified enzymes, such as glyceraldehyde-3-phosphate dehydrogenase[9] and acylphosphatase,[10] have been found to contain bound GSH, but in these cases the possibility exists that these enzyme forms are artifacts formed during purification. Data in the literature also suggest that enzymatic activities can be modulated by formation of mixed disulfides with low-molecular-weight compounds (*cf.* Refs. 11–13) and that GSH can be involved in such thiol-disulfide interchange reactions. This postulated physiological function receives support from the finding that a substantial proportion of the cellular GSH is bound to proteins.[14–16]

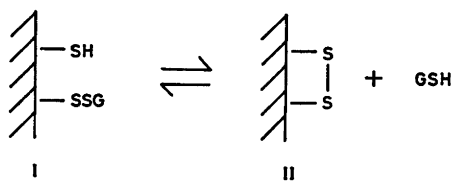

Fig. 5. The proposed equilibrium between GSH and CySSG-thioltransferase. The enzyme forms I and II correspond to the first (acidic) and second (basic) component, respectively, obtained after chromatography on CM-cellulose.

Interaction of Quinacrine Mustard with Whole and Partially Deproteinized Calf Thymus Deoxynucleoproteins

RITVA-KAJSA SELANDER

The Folkhälsan Institute of Genetics, P.O. Box 819, SF-00101 Helsinki 10, Finland

Spectrophotometric and fluorimetric studies were made on the binding of quinacrine mustard to whole and partially deproteinized calf thymus deoxynucleoproteins. Proteins were extracted from the deoxynucleoprotein with 0.2, 0.3, 0.4, 0.6, and 3 M NaCl in the presence of 6 M urea and 0.04 M sodium bisulfite. The proteins were further separated from the remaining deoxynucleoprotein on Bio-Gel A-50 columns. A decrease in the fluorescence intensity of quinacrine mustard was observed as the proteins were removed from the deoxynucleoprotein. The greatest decrease was obtained when most of the proteins (extraction with 0.6 or 3 M NaCl in 6 M urea and 0.04 M sodium bisulfite) were removed from the DNA core. At low dye-to-polymer ratios the removal of all the histones (NaCl concentrations above 0.4 M in 6 M urea and 0.04 M sodium bisulfite) caused a marked change in the fluorescence intensity of quinacrine mustard. Probably the proteins compete for the binding of the dye to deoxynucleoprotein. Natural and artificial deoxynucleoproteins reacted differently with quinacrine mustard. This probably reflects structural differences between the polymers. When quinacrine and quinacrine mustard were mixed with whole deoxynucleoprotein, differences occurred in the absorption and fluorescence properties of the two dyes. This suggests that the two dyes must interact in different ways with the polymer.

Studies on the chemical composition of chromosomes in eucaryotes show that several kinds of proteins, both basic (histones) and acidic (non-histones), as well as RNA, are bound to chromosomal DNA.[1] Various techniques have been used to investigate the structure of these chromosomal components.[2-4] The interaction between small molecules or dyes with macromolecules has also provided information about the molecular organization of chromosomes.

Dyes that have been found useful include acridine derivatives, such as acridine orange,[5-7] proflavine,[8-10] quinacrine and quinacrine mustard.[6,7,11-14] The interaction of other dyes such as azure A,[15] ethidium bromide,[16] and toluidine blue [17] with macromolecules has also been investigated.

A fair amount of evidence indicates that quinacrine and quinacrine mustard bind differentially to the bases in nucleic acids (see reviews above). An enhancement of the fluorescence intensity of these two dyes occurs with adenine residues, whereas guanine residues decrease the fluorescence intensity of the dyes in solution. Weisblum and de Haseth [7] postulated that the fluorescence intensity of bound quinacrine also reflects the pattern of base-repetition in the nucleic acid. The binding of the dye also depends on the strandedness of the nucleic acid.[14,18] Studies on the interaction between quinacrine mustard and proteins (histones) in solution showed that the dye-protein interaction depends on the physical state of the protein.[18]

This paper describes the absorption and fluorescence properties of quinacrine mustard bound to deoxynucleoproteins in solution. Parallel studies were made with the related dye, quinacrine. The data refer to staining of metaphase chromosomes *in situ* with fluorochromes.

EXPERIMENTAL

Deoxynucleoproteins. DNP* from calf thymus was isolated according to the method of Zubay and Doty.[19] The DNP was characterized by a low 320 nm to 260 nm ratio of absorbance (≤ 0.05) and by a protein to DNA ratio of

Table 1. Chemical characterization of DNA, whole DNP and partial DNP's from calf thymus. Extraction performed with urea, $NaHSO_3$, and increasing amounts of NaCl.

Sample	E_{260}[a] (10^{-3})	E_{260}/E_{280}	E_{260}/E_{230}	Protein/DNA ratio	% Protein remaining
DNP (whole)	7.7	1.16	0.71	1.62	100
DNP (extracted)					
0.2 M NaCl	7.1	1.23	0.83	0.68	43
0.3 M NaCl	7.1	1.52	1.13	0.60	32
0.4 M NaCl	7.0	1.53	1.31	0.50	23
0.6 M NaCl	6.8	1.62	1.27	0.37	14
3 M NaCl	6.8	1.62	1.27	0.19	7
DNA[b]	6.8	1.95	1.93	0.00	0

[a] Angerer and Moudrianakis.[16] [b] DNA from calf thymus was isolated as described elsewhere.[20]

approximately 1.6 (Table 1). The whole DNP was stored in 0.7×10^{-3} M potassium phosphate buffer, pH 8.0 at −20 °C.

Partial deoxynucleoproteins. Partial DNP's were prepared by selective dissociation of proteins with NaCl, urea, and sodium bisulfite.[21]

Freshly prepared chromatin was dialyzed against 6 M urea and placed in a buffer solution containing both 6 M urea and 0.04 M sodium bisulfite at pH 7.8 and with increasing amounts of NaCl. The final NaCl concentrations were 0.2, 0.3, 0.4, 0.6, and 3 M. The solutions were stored for 24 h at 4 °C before gel filtration in the same salt concentration. Bio-Gel A-50 (BIO-RAD Laboratories, U.S.A.) columns equilibrated at the same NaCl, urea, and $NaHSO_3$ concentrations were used to separate the dissociated proteins. Samples of 20 ml containing approximately 60 to 80 E_{260} units DNP were placed on these columns, 35 cm in length and 2.5 cm in diameter. The rate of elution at 4 °C was approximately 0.5 ml/min. The DNP peak separated off first followed by the protein peak (Fig. 1). The recovery of the DNP was approximately 75 % and that of the protein 60 to 70 %. The DNP was assayed at 260 nm. It was not possible to assay the proteins at 230 nm since $NaHSO_3$ absorbs strongly at this wavelength. The proteins were therefore assayed by measuring the turbidity at 400 nm after precipitation with trichloroacetic acid.[22] The partial DNP's were stored in 2×10^{-4} M EDTA, pH 6.2 and the proteins in 1 % acetic acid.

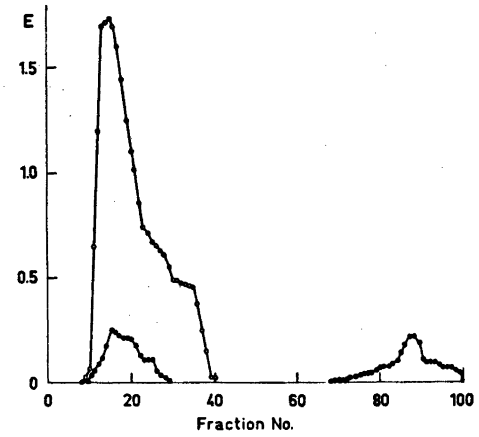

Fig. 1. Chromatography of deoxynucleoprotein on Bio-Gel A-50. The partially deproteinized DNP (*cf.* Experimental) in 0.6 M NaCl, 6 M urea and 0.04 M $NaHSO_3$ was applied to a Bio-Gel A-50 column and step-wise eluted (2.5 ml portions) with the same salt solution. The DNP (○) was estimated at 260 nm and the protein (●) at 400 nm according to Bonner *et al.*[22]

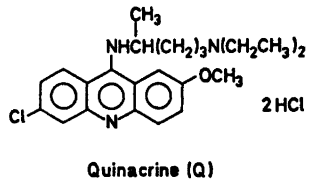
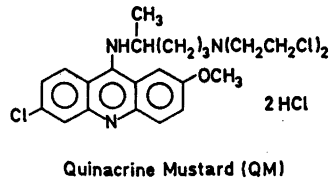
Dyes, The dyes Quinacrine and Quinacrine Mustard* were gifts from Sterling-Winthrop Research Institute, U.S.A. The structures of



Quinacrine (Q)



Quinacrine Mustard (QM)

(I)

* In this publication deoxynucleoprotein = DNP; Quinacrine = Q; Quinacrine Mustard = QM.

the two dyes are shown in (I). Spectral characteristics of QM have been reported earlier.[12] The absorption and fluorescence properties of Q were almost identical with those of QM. The absorption spectra of Q showed peaks at 280, 345, 424, and 435 nm. The molar extinction coefficient at 424 nm was 8.5×10^3.[23] With excitation at 436 nm a fluorescence peak was obtained at 514 nm.[19] The fluorescence intensity of Q was greatest at pH 11 to 12.

Proteins. Calf thymus histone fractions IIA (intermediate histone fraction), III (lysine-rich histones) and IV (arginine-rich histones) were purchased from Sigma Chemical, U.S.A.

Analysis. DNA content was determined by the absorption at 260 nm using the molar extinction coefficients for whole and partial DNP's in Table 1, and cross-checked with the diphenylamine reaction.[24] Proteins were determined by the method of Lowry *et al.*[25] calibrated against bovine serum albumin.

The methods of absorption and fluorescence measurements have been described elsewhere.[12] The fluorescence intensity was measured at 514 nm with excitation at 436 nm. Before any titration measurements the DNP samples were dialyzed against 0.7×10^{-3} M potassium phosphate buffer, pH 8.0 or against 0.05 M Tris solution, pH 7.5 (*cf.* Experimental). In absorption measurements an identical DNP sample without dye was used in the reference cell to eliminate any contribution to the absorption by DNP. DNP did not disturb the fluorescence measurements at 514 nm.

The fluorescence data were expressed as the percentage change (Δ %) relative to the intensity of the fluorescence intensity of the dye alone.

Reconstitution of proteins and DNA. Artificial DNP's were prepared according to the method described by Bonner *et al.*[22] In these experiments histone fractions IIA, III, and IV (Sigma) and calf thymus DNA were used. The histone-to-DNA mass ratios in the artificial nucleohistones were: DNA-IIA 1.24, DNA-III 1.22, and DNA-IV 0.96.

Analytical disc electrophoresis. Free proteins from the Bio-Gel A-50 runs were lyophilized and dissolved in 10 M urea, 0.9 M acetic acid. Histones were removed from whole and partial DNP's by acid extraction (0.2 M H_2SO_4) and dialyzed against 6 M urea, 0.9 M acetic acid. Disc electrophoresis was carried out using the method of Panyim and Chalkley.[26] The samples (50 – 150 μg) were applied on the gels (0.6 cm × 10 cm), which consisted of 15 % polyacrylamide in 2.5 M urea, 0.9 M acetic acid, pH 2.8, and were pre-electrophoresed for 2 h at 200 V. Electrophoreses were carried out at 200 V for 2 h. Both upper and lower buffers were 0.9 M acetic acid. The gels stained in Amido-Black (0.5 % Amido-Black in 50 % ethanol, 7 % acetic acid) for 4 h and destained by electrophoresis in 7 % acetic acid. Bovine serum albumin was added as a marker protein.

RESULTS

Composition of deoxynucleoprotein samples. Fig. 1 depicts a run on a Bio-Gel A-50 column with DNP extracted with 0.6 M NaCl, 6 M urea, and 0.04 M $NaHSO_3$. The DNP separated first (E_{260}) followed by the dissociated proteins (E_{400}).

The DNA and protein content in the various samples were analyzed spectrophotometrically and a summary of the results is shown in Table 1. The electrophoretic patterns for the different protein fractions are shown in Fig. 2. Fig. 2a depicts the pattern obtained when the histone fractions IIA, III, and IV (Sigma) were mixed together.

NaCl concentrations of 0.2 M and 0.3 M (urea, $NaHSO_3$) removed, respectively, 57 % and 68 % of the proteins from the DNA core (Table 1). These proteins were mostly lysine-rich histones, and almost no arginine-rich histones were extracted from the DNP at these low NaCl concentrations (Fig. 2b, c). At 0.4 M NaCl (urea, $NaHSO_3$) some arginine-rich histones could be extracted from the DNP although

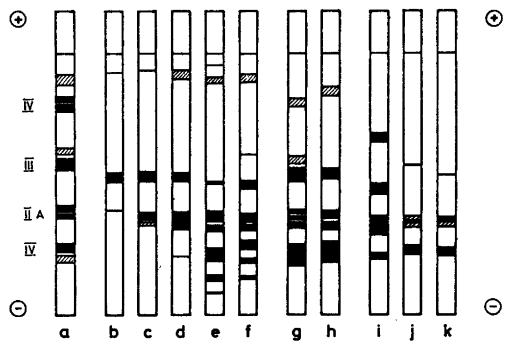


Fig. 2. Polyacrylamide gel electrophoresis. (a) Histones: IIA (intermediate histone fraction), II (lysine-rich), and IV (arginine-rich) from Sigma were dissolved in 10 M urea, 0.9 M acetic acid. (b – f) Bio-Gel A-50 separated free proteins in 10 M urea, 0.9 M acetic acid (*cf.* Experimental) extracted from whole DNP with 6 M urea, 0.04 M $NaHSO_3$ and increasing amounts of NaCl: (b) 0.2 M NaCl, (c) 0.3 M NaCl, (d) 0.4 M NaCl, (e) 0.6 M NaCl and (f) 3 M NaCl. (g – h) Histones extracted with acid from whole DNP in (g) 0.7×10^{-3} M potassium phosphate buffer, pH 8.0 and (h) 6 M urea. (i – k) Histones extracted with acid from partial DNP's, deproteinized with 6 M urea, 0.04 M $NaHSO_3$ and increasing amounts of NaCl: (i) 0.2 M NaCl, (j) 0.3 M NaCl, and (k) 0.4 M NaCl. The slowest moving band was bovine serum albumin.

the fraction still consisted mainly of lysine-rich histones and intermediate histones (Fig. 2d). The extraction with 0.6 M NaCl (urea, $NaHSO_3$) removed all the histones, even the arginine-rich ones (Fig. 2e), leaving 14 % proteins, probably the non-histones, on the DNA core (Table 1). Even after extraction with 3 M NaCl (urea, $NaHSO_3$) some of the proteins (7 %) remain on DNA (Table 1). Fig. 2f depicts the electrophoretic pattern of the histones dissociated at 3 M NaCl (urea, $NaHSO_3$).

The salt-dissociated protein fractions were compared electrophoretically with the histones which remain on partially deproteinized DNP's. The electrophoresis of histones removed by acid extraction from whole freshly prepared chromatin is shown in Fig. 2g. An almost identical electrophoretic pattern was obtained for histones removed from chromatin in 6 M urea (Fig. 2h). From this it is obvious that urea by itself does not remove histones from DNP.[21] The electrophoresis of the histones that remain on the partially deproteinized DNP's shows that an increased amount of histones was removed as the NaCl concentration in urea-$NaHSO_3$ solution was increased (Table 1 and Fig. 2 i-k). Lysine-rich and arginine-rich histones as well as intermediate histones remained on DNA after extraction with 0.2 M NaCl in urea–$NaHSO_3$ (Fig. 2i). An almost complete absence of lysine-rich histones was found on the DNA core after extraction with 0.3 M, respectively 0.4 M, NaCl in urea-$NaHSO_3$ (Fig. 2j and 2k). No histones remained on DNA after extraction with 0.6 or 3 M NaCl in urea-$NaHSO_3$ (not shown in the figure).

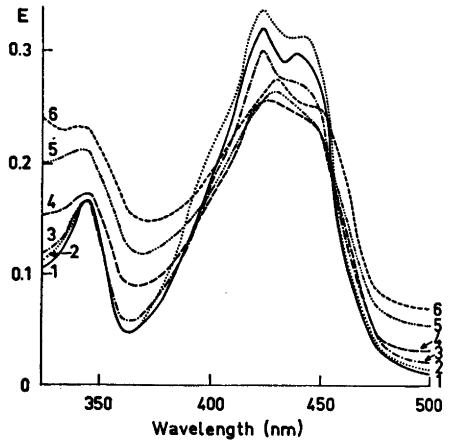

Fig. 3. Absorption spectra of quinacrine mustard mixed with whole deoxynucleoprotein. QM was mixed with different amounts of whole DNP in 0.7×10^{-3} M potassium phosphate buffer, pH 8.0. (1) 0.033 mg/ml QM alone, (2) 0.040 mg/ml DNP, (3) 0.072 mg/ml DNP, (4) 0.115 mg/ml DNP, (5) 0.150 mg/ml DNP and (6) 0.200 mg/ml DNP. (The values of concentration refer to DNA plus proteins).

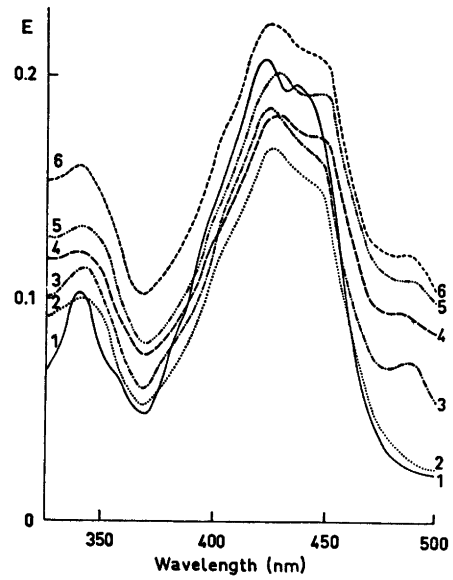

Fig. 4. Absorption spectra of quinacrine mustard bound to selectivity deproteinized deoxynucleoproteins. QM (0.013 mg/ml) was mixed with different partial DNP's (0.025 mg/ml) in 0.05 M Tris solution, pH 7.5. (1) QM alone, (2 – 6) partial DNP's from which the proteins were selectively removed by extraction with 6 M urea, 0.04 M $NaHSO_3$ and decreasing amounts of NaCl: (2) 3 M NaCl, (3) 0.6 M NaCl, (4) 0.4 M NaCl, (5) 0.3 M NaCl and (6) 0.2 M NaCl.

These data clearly show that the removal of the histones is complete at 0.6 M NaCl (urea, $NaHSO_3$) and that almost all lysine-rich histones are removed with 0.4 M NaCl (urea, $NaHSO_3$). These findings are in agreement with the results reported by Kleiman and Huang.[21]

The release of proteins from the DNP's is shown by an increase in the 260 nm to 280 nm ratio as well as in the 260 nm to 230 nm ratio (Table 1).

Absorption studies. The change in the absorption spectra of QM upon the addition of increasing amounts of whole DNP to the dye

solution is shown in Fig. 3. Similar absorption spectra have also been recorded for QM complexed to DNA.[14] At very low DNP-to-dye ratios, however, there was an overall increase in the absorption spectra (Fig. 3, curve 2). A similar enhancement was found in the fluorescence intensity of QM mixed with whole DNP (*cf.* below). The shift of the absorption maximum from 424 nm to higher wavelengths is similar to the shift found with DNA. This shift and a isosbestic point at 455 nm are indicative of the formation of specific complexes of the dye with macromolecules (Fig. 3, curves 3 – 5).[37] The absorption maximum at 345 nm is markedly increased. The fact that the isosbestic point is the same whether QM is bound to DNP or DNA suggests that the dye must interact in the same way with the two polymers. The step-by-step addition of polymers to other dyes in solution leads to similar changes in the absorption spectra of the dye tested.[16,17]

Similar changes occurred in the absorption spectra of QM with addition of partially deproteinized DNP's to the dye solution (Fig. 4). For DNP's from which the proteins have been removed with 0.3 M NaCl in urea-$NaHSO_3$ (mostly the lysine-rich histones, Fig. 2c) the absorption maximum at 424 nm was reduced. However, the DNP fraction extracted with 0.2 M NaCl (urea, $NaHSO_3$) gave an overall enhancement of the absorption spectra of QM

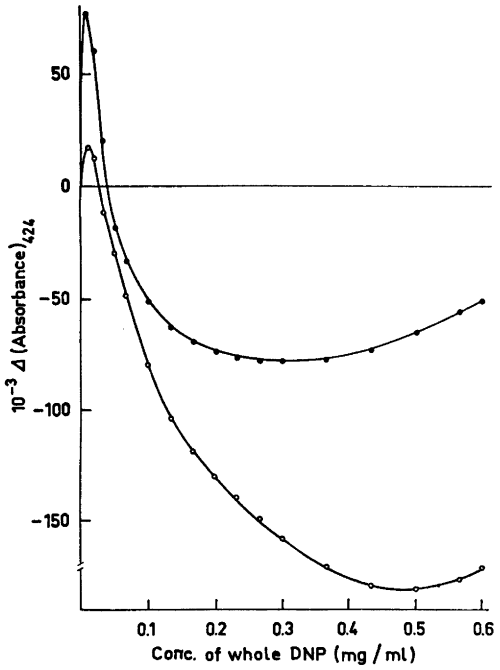

Fig. 6. Absorption properties of quinacrine and quinacrine mustard bound to whole deoxynucleoprotein. To a constant amount of Q and QM (0.033 mg/ml) were added increasing amounts of whole DNP in 0.7×10^{-3} M potassium phosphate buffer, pH 8.0, Differences in the absorption maximum at 424 nm for (O) Q and (●) QM were estimated.

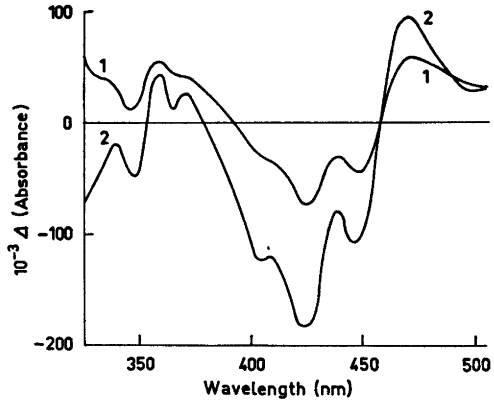

Fig. 5. Difference spectra of quinacrine and quinacrine mustard bound to whole deoxynucleoprotein. Whole DNP (0.115 mg/ml) was mixed with (1) 0.033 mg/ml QM and (2) the same amount of Q in 0.7×10^{-3} M potassium phosphate buffer, pH 8.0.

(Fig. 4, curve 6). The same enhancement was found with whole DNP (Fig. 3, curve 2). The absorption spectra of QM was reduced the most with the DNP fraction extracted with 3 M NaCl in urea-$NaHSO_3$ (all the histones were removed from the DNA core, Fig. 2f). When the amount of the proteins removed from the DNP increased (increased NaCl concentration in urea-$NaHSO_3$), a corresponding increase in the ratio of absorption at 424 and 365 nm was observed. For DNP extracted with 0.2 M NaCl (urea, $NaHSO_3$) the 424 to 365 nm ratio was 2.15 whereas the corresponding value for DNP extracted with 3 M NaCl (urea, $NaHSO_3$) was 3.11.

Whole DNP alters the absorption spectra of Q, too. However, the absorption spectra of bound Q differs from that of bound QM (Fig. 5). When equal amounts of Q and QM was used, the spectra of Q were more reduced upon the addition of whole DNP to the dye solution.

The differences between these two dyes was particularly marked at wavelengths around the absorption maximum at 424 nm (Fig. 5).

The step-by-step addition of whole DNP to Q or QM leads first to an enhancement of the absorption maximum at 424 nm (Fig. 6). However, DNP concentrations above 0.03 mg/ml give a continuous reduction of the absorption maximum at 424 nm. A much higher enhancement of the absorption maximum (424 nm) was recorded in the QM-DNP mixtures than in the Q-DNP mixtures. However, the decrease of the absorption maximum is greater in the Q-DNP system than in the QM-DNP system. A DNP concentration of 0.4 mg/ml was still effective in reducing the absorption maximum of Q. However, only DNP concentrations below 0.2 mg/ml reduce the absorption maximum of QM, and further additions of whole DNP to the dye solution did not change the absorption maximum of bound QM at 424 nm.

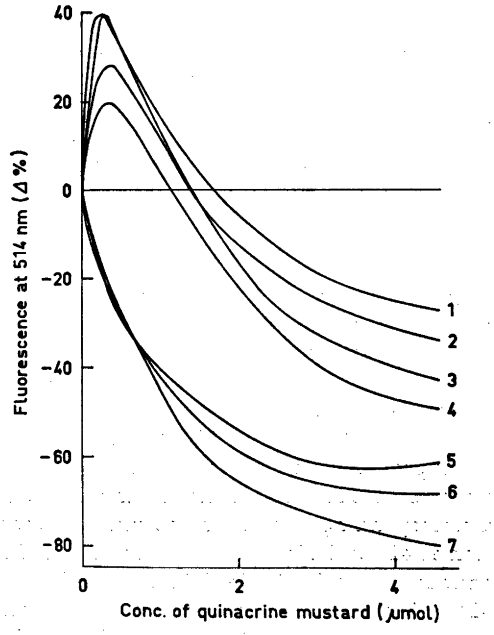

Fig. 7. Effect of DNA, whole and selectively deproteinized deoxynucleoproteins on the fluorescence intensity of quinacrine mustard. To a constant amount (0.025 mg/ml) of (1) whole DNP and partial DNP's extracted with (2) 0.2 M NaCl, (3) 0.3 M NaCl, (4) 0.4 M NaCl, (5) 0.6 M NaCl and (6) 3 M NaCl in 6 M urea, 0.04 M $NaHSO_3$, and (7) DNA, increasing amounts of QM in 0.05 M Tris solution, pH 7.5 were added.

At DNP concentrations above 0.35 mg/ml there was an increase in the absorption maximum of QM. These differences between the two dyes suggest that they must interact in different ways with the DNP. This is in line with the findings reported by Michelson *et al.*[11] They showed differences in the interaction of Q and QM with polynucleotides, particularly with poly(I), poly(dT), and poly(rU).

Fluorescence studies. The changes in the fluorescence intensity of QM bound to DNA, whole DNP, and partial DNP's are shown in Fig. 7. All the samples gave a net quench of the fluorescence intensity of the dye at high dye-to-polymer ratios. From the figure it is obvious that the samples can be divided into two separate groups. At high polymer-to-dye ratios, whole DNP and partial DNP's still containing arginine-rich histones (extraction with 0.2 to 0.4 M NaCl in urea-$NaHSO_3$, Fig. 2) enhanced the fluorescence intensity of the dye, whereas DNA and partial DNP's extracted with $\geq$0.6 M NaCl (urea, $NaHSO_3$) always quenched the fluorescence intensity of QM. It is evident that the proteins bound to DNA are able to

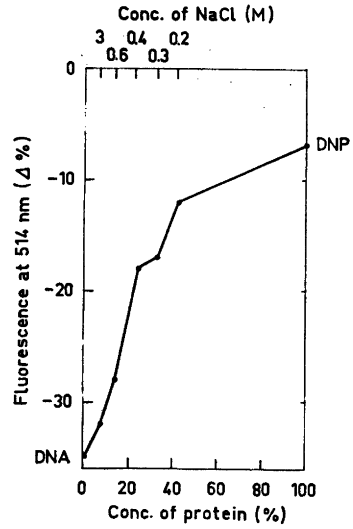

Fig. 8. Effect of selective removal of proteins from deoxynucleoprotein on the fluorescence intensity of quinacrine mustard. To a constant amount of polymer (0.030 mg/ml) was added QM (0.013 mg/ml) in 0.05 M Tris solution, pH 7.5. The proteins were selectively removed with 0.2, 0.3, 0.4, 0.6, and 3 M NaCl in 6 M urea and 0.04 M $NaHSO_3$ (*cf.* Experimental).

prevent the binding of the dye (steric hindrance). The histones are bound to the phosphate groups in DNA,[28] thus also limiting the external ionic binding of the dye to negative phosphate groups. When the dye concentration was increased, the fluorescence intensity of the solution decreased as compared with the solution containing the dye alone. This is probably due to an interaction between proteins and the dye as well as to an increased dye-to-dye interaction.[18,29]

The effect of the quantity of the proteins in the DNP on the fluorescence intensity of QM is shown in Fig. 8. The fluorescence intensity of the dye was directly proportional to the amount of protein in the DNP. The curve was almost rectilinear between 0 and 42 % protein in the DNP. The fluorescence intensity decreased by 75 % when all histones (86 % in the whole DNP, Table 1) were removed from the DNP (extraction with 0.6 M NaCl in urea-$NaHSO_3$). The extraction of the remaining proteins from the DNP (14 % in whole DNP, Table 1) accounts for the further decrease (25 %) of the fluorescence intensity of the dye. Thus the fluorescence intensity of nucleoprotein-bound QM mostly depends on the tightly bound proteins, probably the non-histones, in the DNP. The quenching effect of native DNA on the fluorescence intensity of the dye was 5 times greater than that of whole DNP.

When whole DNP was added step-by-step to QM there was first an enhancement of the fluorescence intensity of the dye (Fig. 9). At higher DNP concentrations (>0.4 mg/ml), however, there was a quenching of the fluorescence intensity of QM until a plateau was obtained (approximately at 0.2 mg/ml DNP in the solution).

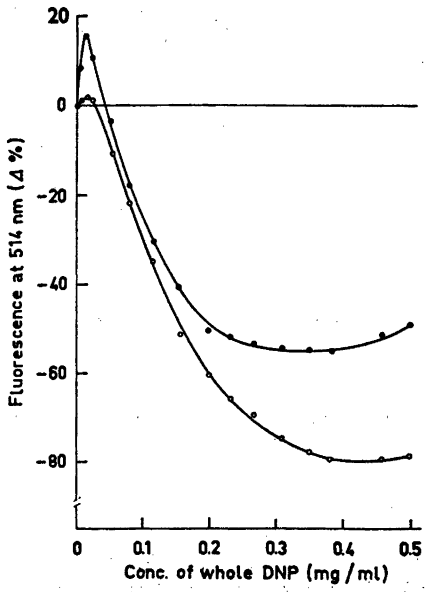

Fig. 9. Effect of whole deoxynucleoprotein on the fluorescence intensity of quinacrine and quinacrine mustard. To a constant amount of (0.033 mg/ml) Q (○) and QM (●) were added increasing amounts of whole DNP in 0.7×10^{-3} M potassium phosphate buffer, pH 8.0.

Whole DNP enhanced and quenched the fluorescence intensity of Q, too (Fig. 9). The

Table 2. Amount of quinacrine mustard bound to DNA, whole DNP and partial DNP's from calf thymus. Extraction performed with urea, $NaHSO_3$, and increasing amounts of NaCl.

Sample	Amount of bound quinacrine mustard at the end of the dialysis.[a] mg dye/mg DNA	%
DNP (whole)	0.12	44
DNP (extracted)		
0.2 M NaCl	0.15	56
0.3 M NaCl	0.17	63
0.4 M NaCl	0.18	67
0.6 M NaCl	0.20	74
3 M NaCl	0.21	78
DNA	0.27	100

[a] Non-equilibrium dialysis was performed in (5 ml) 0.05 M Tris solution, pH 7.5 4 °C for 48 h with 0.020 mg QM/ml and 0.025 mg polymer/ml.

Table 3. Effect of different protein fractions on the fluorescence intensity of quinacrine mustard in solution.[a] Protein fraction obtained by extraction with urea, $NaHSO_3$ and increasing amounts of NaCl.

0.2	+22	lysine-rich histones
0.3	+25	most lysine-rich and intermediate histones
0.4	+29	lysine-rich, intermediate and some arginine-rich histones
0.6	+35	all histones
3	+22	all histones and some tightly bound proteins (probably non-histones)

[a] Protein fractions (0.025 mg/ml) from partial DNP's were mixed with QM (0.007 mg/ml) in 1 % acetic acid solution.

quenching effect on the fluorescence intensity of Q was more marked than the effect on the fluorescence intensity of QM, particularly at high DNP-to-dye ratios (*cf.* Absorption studies). This probably indicates that more Q is bound to the DNP than QM. Difference in the type of binding between Q and QM have also been shown by Modest and Sengupta.[20] They reported that QM binds approximately 25 times strongly to DNA as does Q, but fewer QM molecules, however, bind per unit length of DNA.

Binding studies. Non-equilibrium dialysis[13] was used to estimate the amount of QM bound to DNA, whole DNP and partial DNP's (Table 2). The removal of the proteins from DNP led to an increase of approximately 50 % in the amount of available binding sites in the DNA. DNP binds 0.12 mg QM/mg DNA, while 1 mg DNA binds 0.27 mg dye. The greatest increase in the binding sites was found after the removal of proteins with 3 M NaCl (urea, $NaHSO_3$) from the DNA core (*cf.* Fig. 8). These findings are unlike the results reported for binding of ethidium bromide to partial DNP's.[16] The greatest effect on the interaction between ethidium bromide and DNP was found when the histone f1 was extracted. Differences in the type of binding between acridine dyes and ethidium bromide have also been shown earlier.[7]

Interaction with proteins. The effect of the selectively dissociated protein fractions on the fluorescence intensity of QM was also tested (Table 3). All the protein fractions enhanced the fluorescence intensity of the dye. The greatest enhancement was obtained with the protein fraction containing all the histones (extracted from DNP with 0.6 M NaCl in urea-$NaHSO_3$). When most of the proteins were extracted (extraction with 3 M NaCl in urea-$NaHSO_3$), the enhancement obtained was identical with that of the protein fraction containing only lysine-rich histones (extraction with 0.2 M NaCl in urea-$NaHSO_3$, Fig. 2). This indicates

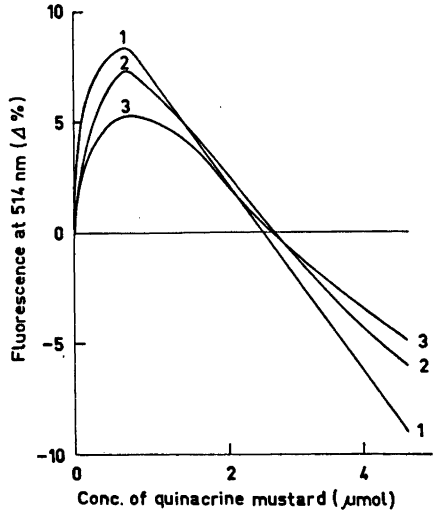

Fig. 10. Effect of artificial partial nucleohistones on the fluorescence intensity of quinacrine mustard. To a constant amount (0.025 mg/ml) of (1) DNA-IIA, (2) DNA-III and (3) DNA-IV were added increasing amounts of QM in 1 M NaCl solution (*cf.* Experimental).

that the proteins which are hard to remove (probably the non-histones) prevent the enhancing effect of the histones on the fluorescence intensity of the dye. The enhancement of the fluorescence intensity of QM with different histone fractions agrees well with previous findings.[13]

Artificial nucleohistones. The effect of artificial DNP's on the fluorescence intensity of QM is shown in Fig. 10. The greatest quench of the fluorescence intensity of the dye was obtained with an artificial DNP composed of DNA and of an intermediate histone fraction (DNA-IIA). A net enhancement of the fluorescence intensity of QM at low dye-to-polymer ratios was obtained with all three artificial DNP's. These curves differ from those obtained for natural DNP's (*cf.* Fig. 7); structural differences between natural and artificial DNP's may account for the differences.

DISCUSSION

Absorption and fluorescence studies. When whole DNP was mixed with Q or QM in solution an enhancement of the absorption maximum as well as of the fluorescence intensity of the two dyes was found. Several interpretations for this phenomenon are possible: (1) the binding mechanism between the dyes and the DNA core in the chromatin; (2) the interactions between the dyes and the proteins in the DNP samples; (3) the limiting of the ionic binding of the dyes by the proteins on the DNA core; (4) the blockade of the base specificity of the dyes by the proteins in the DNP.

The changes in the absorption and fluorescence properties of bound QM appear to be quite similar in DNA, whole DNP, and partial DNP's. This indicates that the binding processes are very similar for these different types of polymers. It is therefore possible that the first binding, at low dye-to-polymer ratios, is an intercalation of aromatic rings of the dye between the bases in the nucleohistone as first suggested with DNA.[31] The second process, at increased dye concentrations in the solution, is an electrostatic interaction between the positive groups in the dye and the negative groups in DNP. The titration curves obtained when different DNP samples were mixed with QM in solution indicate that the fluorescence intensity is determined by the concentration ratio of the dye and DNP. At low dye concentrations the intercalation is dominant and there is an enhancement of the fluorescence intensity of QM, whereas at high dye concentrations the ionic bindings dominate and the fluorescence intensity of QM is quenched.

In this paper it is shown that while all the major classes of chromosomal proteins inhibit the binding of QM to chromatin, the removal of the tightly bound proteins (extraction with 0.6 and 3 M NaCl in urea-$NaHSO_3$) has the greatest effect on the binding of the dye to chromatin. In an earlier paper an interaction between the dye QM and calf thymus histones in solution has been reported.[13] It is therefore likely that the dye also may be able to interact with proteins which cover the DNA core in the chromatin. Likely binding sites on the DNP are the carboxyl groups on the histones, since they are on the surface of the nucleoprotein complex.[28]

The binding sites for QM in whole DNP were reduced as compared to the binding sites for QM in native DNA. An increase of approximately 50 % in the amount of bound QM was found when all the proteins were removed from the DNA core. Clark and Felsenfeld [32] have shown that the proteins are not evenly distributed in the chromatin. They postulated that about half of the DNA is covered with proteins. Their conclusion corroborates other reports of dye-binding to chromatin. Klein and Szirmai [15] found with the dye, azure A, that about the half of the DNA in the chromatin reacted with the dye. A similar dye-binding capacity suggesting that approximately 50 % of the DNA is covered with proteins, has been reported by Angerer and Moudrianakis,[16] Miura and Ohba,[17] Ringertz and Bolund,[33] Bolund,[34] and Itzhaki.[35,36] According to Phillips [28] the negative charge of DNP is about 60 % of that of DNA, *i.e.* about half of the negative groups of DNA are able to combine with the positive groups on cationic dyes in the DNP. The proteins on the DNA core reduce the amount of binding sites for the dye because the positive residues on the histones are bound to the negative groups in DNP, thus limiting the ionic binding of the dye. Since the proteins on the DNA core reduce the ionic binding sites between the dye and DNA, the fluorescence intensity for a QM–DNP

mixture is higher than for a QM–DNA mixture.

The selective removal of proteins from whole DNP increases the quenching of the fluorescence intensity of QM in solution. However, at low dye-to-DNP ratios an enhancement of the fluorescence intensity of the dye was found with whole DNP and partially deproteinized DNP's still containing arginine-rich histones and other proteins (probably non-histones). These results indicate that the arginine-rich histones, which still covered the GC-rich regions in the DNA,[37] prevent the quenching effect of GC-rich regions on the fluorescence intensity of QM.[12] When all the histones were removed from the DNP, a net quench of the fluorescence intensity of the dye was found. The fluorescence intensity of QM as well as of Q is highly depending on the base content of the DNA.[6,7,10–12,14] When histones blockade bases in the DNA they are able to prevent the base specific interactions between the dyes and the bases in the DNA.

However, from the results in this paper it is not possible to say which one of the above given alternatives would explain why the absorption maximum or the fluorescence intensity was enhanced when the two dyes Q and QM were mixed with whole DNP. Probably the phenomenon is caused by the action of all the alternatives together.

Comparison between Q and QM. The main difference of the two dyes Q and QM is in the long aliphatic side chain at C-9. QM has an alkylating mustard group at the end of the side chain and is therefore able to bind chemically to polymers, whereas the binding of Q is only through intercalation or electrostatic (*cf.* the structure of the two dyes).

Differences in the absorption and fluorescence properties were obtained when equal amounts of Q and QM were mixed with whole DNP in solution. The absorption spectra of Q was more reduced and the quenching effect on the fluorescence intensity of Q was more marked upon the addition of whole DNP to the solution as compared with the effect of whole DNP on QM. These differences probably indicate that more Q is bound to whole DNP than QM. This is in agreement with the results reported by Modest and Sengupta.[30] When they compared the two dyes Q and QM they found that fewer QM molecules was bound to DNA.

Natural and artificial nucleohistones. A quite different picture emerged when artificial nucleohistones were mixed with QM in solution. Even arginine-rich complexes (the DNA-IV complex) were able to enhance the fluorescence intensity of the dye at low dye-to-polymer ratios. This reflects structural differences between natural and artificial nucleohistones. These differences might have resulted from the inability of the histones to interact properly with the DNA, *i.e.* the histones had assumed new positions on the DNA core.[38] During the reconstitution a rearrangement of the proteins may occur.[32] Angerer and Moudrianakis [16] reported that the association constant for binding of ethidium bromide to natural DNP differs from the constant for the binding of the dye to artificially reconstituted DNP.

The fluorescence of metaphase chromosomes in situ. With the *in situ* hybridization technique it has been possible to determine the composition of chromosomal DNA in some particular regions in eucaryotic chromosomes. AT-rich satellite DNA was found in the centromeric regions of the mouse chromosomes [38] and in the secondary constrictions of the human chromosomes 1, 9, and 16.[39] Saunders *et al.*[40] were able to show a GC-rich satellite DNA in the secondary constriction in No. 9. Moreover cytochemical experiments indicate that regions staining brightly with Q or QM contain AT-rich DNA, while regions with dull fluorescence contain GC-rich DNA.[41–44] The mouse centromers and the secondary constrictions of human chromosomes 1, 9, and 16, however, show dull fluorescence when stained with quinacrine derivatives. These contradictory results, AT-richness and dull fluorescence, might be explained from the results in this paper.

Methanol-acetic acid fixed metaphase chromosomes contain very little protein.[45] Comings *et al.*[45] showed that the fixative was not able to remove the non-histones. Therefore it can be assumed that the above mentioned chromosomal regions might be covered by non-histones which compete with the dye, thereby giving dull fluorescence. When metaphase slides were subjected to denaturation and reassociation and thereafter stained with QM, the centromeric regions of the mouse chromosomes as well as of the secondary constrictions in human chromosomes 1, 9, and 16 showed a bright fluorescence.[46]

This phenomenon can be explained by a possible extraction of proteins (non-histones) during the treatment in sodium hydroxide (denaturation) and the incubation in salt solution (reassociation).[45] Protein dissociation might uncover the AT-rich regions, resulting in an enhancement of the fluorescence. At all the dye-to-polymer ratios tested, a quenching of the fluorescence intensity of QM was seen with DNP from which only the histones were removed (*cf.* Results). The other proteins, probably the non-histones, therefore may be able to prevent the effect of the bases in DNA on the fluorescence intensity of the dye.

Comings *et al.*[45] proposed that the non-histone-DNA complexes contribute to the banding after C- and G-banding procedures.[47] On the other hand recent findings of Zirkin [48] showed an almost complete absence of non-histones in the heterochromatin in metaphase chromosomes from bovine kidney. It is therefore questionable whether bands reflect only the presence of non-histones. Secondary and tertiary configurations in the chromosomal macromolecules may also contribute to the bands. Moreover, the degree and pattern of the base repetition apperently contribute to the occurrence of brighter and duller regions along the metaphase chromosomes.[18]

In this paper it is shown that tightly bound proteins, probably the non-histones in the deoxynucleoprotein markedly affect the fluorescence intensity of QM in solution. The study of the effect of isolated non-histones in solution is underway in this laboratory.

Acknowledgements. I am very grateful to Dr. Albert de la Chapelle for valuable discussions and suggestions in connection with this work. Generous gifts of quinacrine and quinacrine mustard from the Sterling-Winthrop Research Institute are also acknowledged. This investigation was supported by grants from the Finnish National Research Council for Medical Sciences and the Sigrid Jusélius Foundation.

Algal Carotenoids. XIII.** Chemical Reactions of Allenic Carotenoids

JON EIGILL JOHANSEN and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway

The conversion of the allenic end group I to acetylenic (II) and chlorinated (presumably V) end groups on treatment with chloroformic hydrogen chloride is demonstrated.

Treatment with phosphorus oxychloride in pyridine of carotenoids with the allenic end group I also caused transformation to acetylenic products, in addition to previously reported allenic anhydro-products.

Facile dehydration and chlorine substitution of the secondary hydroxy group of peridinin (*1*) were observed.

Chlorinated carotenoids, identified by mass spectrometry, appear to be readily formed.

On the basis of electronic spectra and R_F-values alone Egger *et al.*[1] and Nitsche *et al.*[2,3] have claimed the conversion of carotenoids with the allenic end group I to carotenoids with the acetylenic end group II besides end group IV on treatment with chloroformic hydrogen chloride, Scheme 1B. More recently [3a] IR-evidence for the conversion of I (unacetylated) to II (unacetylated) has been published.

Such conversion was not observed on treating peridinin (*1*) with methanolic hydrogen chloride, and only products with the allenic end group intact were reported.[4,5]

Also lithium aluminium hydride treatment of carotenoids with end group I has been reported to give conversion to the acetylenic (ν_{max} 2150 cm^{-1}) end group II.[5a]

We now report further evidence on the reactions of carotenoids containing the allenic end group I in chloroformic hydrogen chloride and on treatment with phosphorus oxychloride, resulting in the formation of acetylenic and chlorinated derivatives.

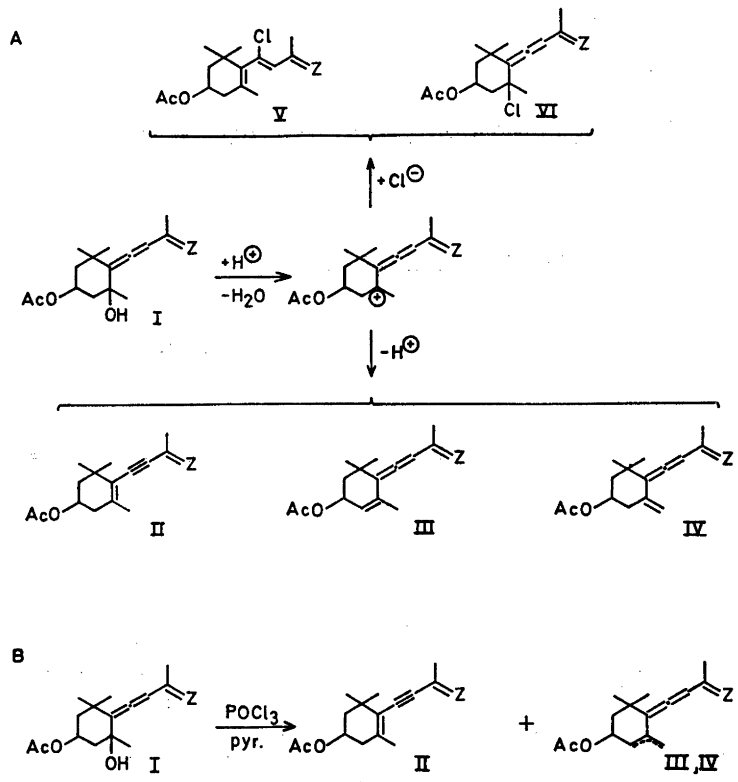
RESULTS AND DISCUSSION

Carotenoids containing the allenic end group I were on treatment with chloroformic hydrogen chloride converted to products with acetylenic (II) and chlorinated (probably V) end groups, whereas products with end groups III, IV, and VI were not observed, Scheme 1. Further evidence for the position of the chloro substituent in end group V will be presented.[5b]

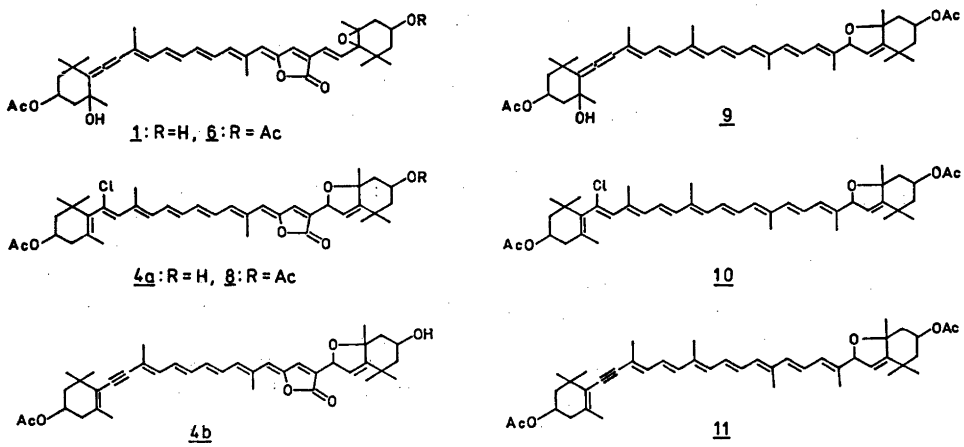
Thus peridinin (*1*, Scheme 2) on such treatment provided besides three minor products (*2**, *3**, and *5**) a major presumably mixed product (*4a*, *b*; Scheme 2) with highest mass number ion at *m/e* 648.3216 (calculated 648.3218 for $C_{39}H_{49}O_6{}^{35}Cl$) and with no allene, but a very weak acetylenic (2170 cm^{-1}) IR absorption. Asterisks indicate that the structural formulae are not given; numbers refer to compounds described in the Experimental part.

Likewise treatment of peridinin acetate (*6*) gave two major products (*7** and *8**) of similar polarity. The least polar product *7** had highest mass number ion at *m/e* 630 (consistent with $C_{39}H_{47}O_5{}^{35}Cl$, supported by ^{37}Cl isotope peak at *m/e* 632) compatible with the formation of end group V and elimination of acetic acid from one of the acetoxy groups. The more polar product *8** had molecular ion at *m/e* 690 and ^{37}Cl isotope peak at *m/e* 692 compatible with $C_{41}H_{51}O_7Cl$, again consistent with the formation of end group V.

** No. XII *Acta Chem. Scand. B 28* (1974) 485.



Scheme 1.



Scheme 2.

Small amounts of dinochrome acetate (*9* = neochrome diacetate [6]) were available. Treatment with chloroformic hydrogen chloride gave a product (*10*) with molecular ion at *m/e* 702 and ^{37}Cl isotope peak at *m/e* 704 (consistent with $C_{44}H_{59}O_5Cl$) and with a 4 nm bathochromic shift in the visible spectrum in acetone solution relative to *9*. The product was unseparable from diadinochrome diacetate (*11*) with the acetylenic end group II on kieselguhr paper.[1]

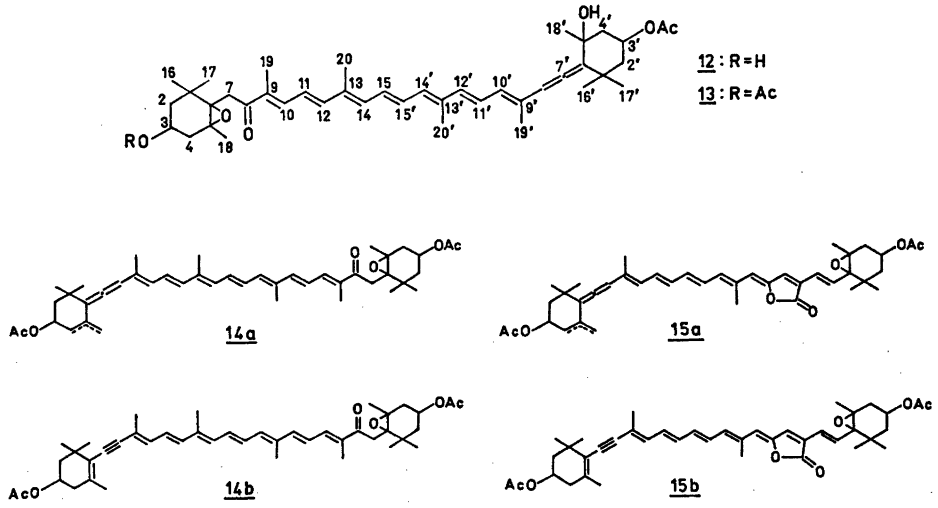
The mass spectra of the chlorinated products *2**, *4*, *5**, *7**, *8**, and *10* all showed strong M − 36 ions. This might be due to loss of HCl from the molecular ion, to the presence of carotenoids with end group II, or both of these possibilities.

Failure to effect chromatographic separation (TLC or paper) of the actylenic and chlorinated derivatives may partly be due to accompanying epoxide-furanoid rearrangement of the second end group in the carotenoids (*1* and *6*) studied, theoretically resulting in two epimeric furanoxides in each case.

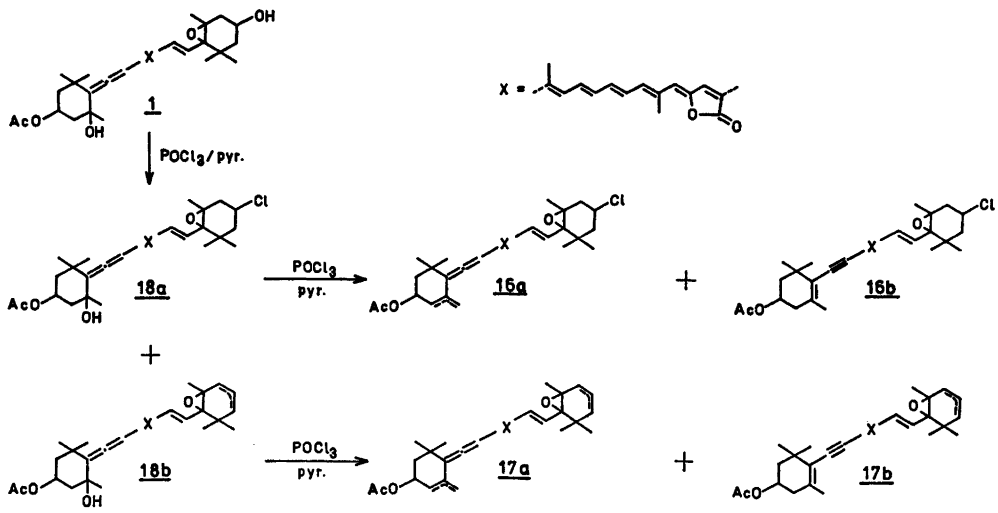
We further report the conversion of the allenic end group I to the acetylenic end group II on treatment with phosphorus oxychloride in pyridine, in addition to the transformation of I to III/IV previously reported by Bonnett *et al.*,[7] Scheme 1B.

Thus fucoxanthin acetate (*13*, prepared from fucoxanthin (*12*, Scheme 3) when treated with phosphorus oxychloride gave the mixed anhydro-products (*14a, b*) judged by visible-, IR-, NMR-, and mass spectra. Absorption in the IR region at 1920 and 2170 cm^{-1} were assigned to the allenic group in *14a* and the acetylenic group in *14b*, respectively. No absorption due to terminal methylene was observed in the IR- or NMR spectra of the mixed products (*14a, b*). Separation of *14a* and *14b* was not effected by TLC, but achieved by circular kieselguhr paper chromatography on the micro scale. The visible spectrum in hexane solution of the tentatively identified acetylenic *14b* showed less fine-structure and had absorption maximum at 1 nm longer wavelength than that of the tentatively allenic *14a*. The acetylenic product (*14b*) may previously have been overlooked.[7]

Likewise peridinin acetate (*6*) on similar treatment with phosphorus oxychloride gave the allenic anhydro-peridinin acetate (*15a*) and the acetylenic pyrrhoxanthin acetate (*15b*). Anhydro-peridinin acetate (*15a*) had absorption maximum in visible light at 1.5 nm longer wavelength than that of peridinin (*1*) in hexane solution, but exhibited the same spectral fine structure, whereas pyrrhoxanthin acetate (*15b*) had less fine structure and absorption maximum at 3 nm longer wavelength than that of peridinin (*1*). No absorption characteristic of terminal methylene was observed. Pyrrhoxanthin acetate (*15b*) was inseparable by co-



Scheme 3.



Scheme 4.

chromatography from authentic *15b* [6] on circular kieselguhr paper.

Peridinin (*1*) gave in the same reaction three main products [8] by TLC (*16*, *17*, and *18*, Scheme 4), each considered to represent mixtures. Product *16* had molecular ion at *m/e* 630.3109 (calculated 630.3112 for $C_{39}H_{47}O_5{}^{35}Cl$) in addition to ions at *m/e* 199.0883 (calculated 199.0890 for $C_{11}H_{16}O^{35}Cl$) and 201.0865 (calculated 201.0860 for $C_{11}H_{16}O^{35}Cl$), compatible with pyrylium ions [9] revealing that the 3′-hydroxy group was substituted by chlorine. Product *17* had molecular ion at *m/e* 594 and a fragment ion at *m/e* 163, demonstrating that the 3′-hydroxy group had been eliminated as water. Products *16* and *17* were each mixtures containing both the allenic (*16a*, *17a*) and acetylenic (*16b*, *17b*) end group as dicussed above for the dehydration of fucoxanthin acetate (*13*). Product *18* exhibited molecular ions at *m/e* 648 (*18a*) and 612 (*18b*). Fragment ions at *m/e* 223, 212, and 197 indicated that the allenic end group was intact.[5,10] Product *18* thus represented a mixture of products where the 3′-hydroxy group partly was substituted by chlorine (*18a*) and partly eliminated as water (*18b*).

In conclusion further evidence for the conversion of the allenic (I) to acetylenic end groups in carotenoids is here presented, in chloroformic hydrogen chloride as well as in phosphorus oxychloride/pyridine.

Under both conditions stable, chlorinated products were also observed. Without mass spectrometry such halogenated carotenoids would not be identified.

The facile dehydration and chlorine substitution of the secondary hydroxy group in peridinin (*1*) in phosphorus oxychloride/pyridine was unexpected.

EXPERIMENTAL

Materials and methods were as described elsewere.[11]

Acid treatment of allenic carotenoids

Peridinin (*1*, 15.7 mg, available from a previous study [6]) was kept in 0.02 M HCl–$CHCl_3$ (100 ml) for 4 h at room temp. The mixture was diluted with petroleum ether, the organic extract washed with water, solvents removed, and the residue dried under vacuum. Chromatography on kieselgel G (25 % acetone in petroleum ether = 25 % APE) gave several bands. The four major products (*2–5*, representing 36 % of starting material) were further investigated.

Product *2*, yield 0.08 mg (1 %), had R_F = 0.75 (Schleicher and Schüll paper No. 287 = SS287, 5 % APE); λ_{max}(hexane) *430.5* and 458.5 nm (the main maximum is given in italics); *m/e* 510.2531 (M, 48 %, calc. 510.2537 for $C_{31}H_{39}O_4{}^{35}Cl$), 474 (M–36, 17 %), 439 (8 %), 383 (11 %), 257 (12 %), 236 (16 %), 211 (10 %), 207 (13 %), 183 (23 %), 57 (100 %) and no *m/e* 181.

Product *3*, yield 1.2 mg (22 %), had R_F= 0.41 (broad, SS287, 5 % APE); λ_{max}(hexane) *437.5* and 464 nm; *m/e* 552.3237 (M?, 3 %, calc. 552.3240 for $C_{37}H_{44}O_4$) and 181 (53 %); ν_{max} (KBr) 3425 (OH), 3012–2870 (CH), 2170 (very weak, –C≡C–), 1730 (C=O), 1640, 1530, 1453 (CH_2), 1366 (CH_3), 1241, 1164, 1100, 1038 (C–O), 988 and *697* (*trans* –CH=CH–) and 783 cm^{-1}.

Product *4*, yield 4.0 mg (71 %), had R_F= 0.18 (broad, SS287, 5 % APE); λ_{max}(hexane) *435* and 462.5 nm; *m/e* 648.3216 (M, 46 %, calc. 648.3218 for $C_{39}H_{49}O_4{}^{35}Cl$), 612 (M–36, 29 %), 588 (M–60, 0.9 %), 570 (M–78, 1.0 %), 568 (M–80, 1.9 %), 556 (M–92, 2.2 %), 552 (M–60–36, 10 %), 460 (M–92–60–36, 8.2 %), 234 (58 %) and 181 (100 %); δ ($CDCl_3$) 0.93 (imp.), 1.07, 1.17, 1.21, 1.27 (imp.), 1.35, 1.67, 1.70, 1.83, 2.09 and 2.21. Product *4* was crystallized from acetone-petroleum ether, yield 1.8 mg; λ_{max} (hexane) 323, *435.5* and 462.5 nm; ν_{max}(KBr) 3420 (OH), 3013–2870 (CH), 2170 (weak, acetylene), 1740 (C=O), 1629, 1598, 1531, 1446 (CH_2), 1386, 1367, 1352 (CH_3), 1243, 1214, 1180, 1145, 1100, 1040 (C–O), 987, 974, 947, 908, 864, 837, 801, 782 (Cl?), 729 and 665 cm^{-1}.

Product *5*, yield 0.34 mg (6 %), had R_F= 0.78 (SS287, 20 % APE); λ_{max}(hexane) *436* and 459.5 nm; *m/e* 648 (M, 3.3 %), 612 (M–36, 2.5 %), 570 (M–78, 3.4 %), 552 (M–60–36, 3.5 %), 430 (70 %), 412 (34 %) and 181 (70 %).

Peridinin acetate (*6*, 1.5 mg) treated as above gave after chromatography on kieselgel G several products; the two major ones *7* and *8* were further investigated.

Product *7*, yield 0.12 mg (8 % of starting material) had λ_{max}(acetone) *440* and (458) nm; *m/e* 630 (M, 1.8 %, ^{37}Cl isotope peak at *m/e* 632), 594 (M–36, 13 %), 223 (18 %), 216 (12 %) and 181 (24 %).

Product *8*, yield 1.07 mg (70 % of starting material) had λ_{max}(acetone) *437.5* and (456) nm; *m/e* 690 (M, 22 %, ^{37}Cl isotope peak at *m/e* 692, 654 (M–36, 13 %), 630 (M–60, 0.8 %), 612 (M–78, 1.3 %), 610 (M–80, 2.0 %), 598 (M–92, 3.0 %), 594 (M–60–36, 9.8 %), 502 (7.5 %), 303 (5.3 %), 223 (22 %), 216 (30 %) and 163 (43 %).

Dinochrome acetate (*9*, 0.22 mg) treated as above for 2 h gave after chromatography on kieselgel G one main product (*10*, representing 70 % of reaction mixture); λ_{max}(acetone) 407, *428* and 454.5 nm; *m/e* 702 (M, 3.2 %, ^{37}Cl isotope at *m/e* 704), 666 (M–36, 3.7 %), 622 (M–80, 4.3 %, ^{37}Cl isotope at *m/e* 624), 223 (8.1 %) and 183 (11 %). Co-chromatography with diadinochrome diacetate (*11*) gave no separation on SS288 paper (R_F= 0.65, 10 % APE).

$POCl_3$/pyridine treatment of allenic carotenoids

Fucoxanthin acetate (*13*, 34.3 mg prepared from fucoxanthin (*12*) treated with $POCl_3$ (20 drops) in dry pyridine (5 ml) for 6 h at 40°C gave recovered fucoxanthin acetate (*13*, 1.3 mg, 4 % of starting material) and dehydrated fucoxanthin acetate (*14a, b*, 18.0 mg, 53 % of starting material). The mixed products *14a, b* had λ_{max}(acetone) *446* and 466 nm; ν_{max}(KBr) 3420 (H_2O), 3030 2958, 2920 and 2860 (CH), 2167 (–C≡C–), 1912 (>C=C=C<), 1735 (C=O), 1658, 1609, 1575, 1530, 1468 and 1452 (CH_2), 1364 (CH_3), 1242, 1200, 1154, 1130, 1030, (C–O), 968 (*trans* –CH=CH–), 919, 891, 836 (>C=CH–), 805, 735, 658 and 645 cm^{-1}; δ($CDCl_3$, for numbering see fucoxanthin acetate (*13*) in Scheme 3) 0.90 and 0.93 (imp.), 0.98 s (CH_3–1), 1.07 s (CH_3–1), 1.13, 1.17, 1.19 and 1.22 (CH_3–5,1′, 1′), 1.26 (imp.), 1.77 (CH_3–5′ in *14a*?), 1.85 (CH_3–9′ in *14a*?), 1.97 (CH_3–9 and CH_3–5′ in *14b*?), 1.99, 2.01, 2.04 and 2.06 (CH_3–9 in *14b*?, CH_3–13,13′ and CH_3– in OAc), 2.61 d(H–7, J=18 Hz), 3.71 (H–7, J= 18 Hz), 4.23 (H–4, J=6 Hz), *ca.* 4.89 (H–3) and 5.56 (H–3 in *14a*); *m/e* 682 (M, 16 %), 664 (M–18, 0.9 %), 638 (M–44, 0.1 %), 622 (M–60, 11 %), 604 (M–78, 4.1 %), 590 (M–92, 2.2 %) and 43 (100 %).

The mixed products (*14a, b*) gave three zones on paper chromatography (SS287, 2 % APE): Unassigned: R_F= 0.41 (5 %); λ_{max} (hexane) 263, 329, (425), *446.5* and 475 nm; % III/II = 28;[12] *14a* (tentatively): R_F= 0.38 (55 %); λ_{max}(hexane) 263, 329,427, *448.5* and 477.5 nm; % III/II = 35 [12] and *14b* (tentatively) R_F= 0.29 (40 %); λ_{max}(hexane) 277, 340, *449.5* and 477 nm; % III/II = 9.[12]

Peridinin acetate (*6*, 4.6 mg) treated with $POCl_3$ in dry pyridine as above gave after purification by TLC recovered peridinin acetate (*6*, 1.8 mg, 38 % of starting material) and dehydrated peridinin acetate (*15a, b*, 1.5 mg, 32 % of starting material). The mixed product *15a, b*, had λ_{max} (acetone) *459.5* and (475) nm; λ_{max} (KBr) 3020, 2958, 2960 and 2855 (CH), 2167 (–C≡C–), 1908 (>C=C=C<), 1754 and 1739 (C=O), 1640, 1524, 1449 (CH_2), 1364 (CH_3), 1243, 1181, 1166, 1126, 1032 (C–O), 985 (*trans* –CH=CH–), 943, 905, 819 (>C=CH–), 795, 768, 726 and 643 cm^{-1}; *m/e* 654 (M, 20 %), 594 (M–60, 24 %), 579 (M–75, 2.3 %), 574 (M–80, 0.6 %), 562 (M–92, 1.5 %), 478 (9.6 %), 443 (1.2 %), 431 (1.5 %), 343 (2.2 %), 285 (4.3 %) and 223 (19 %). Two zones were obtained by paper chromatography (SS287, 5 % APE): Anhydro-peridinin acetate (*15b*, tentatively); R_F= 0.50 (60 %); λ_{max} (hexane) 327, *456* and 486.5 nm: % D_B/D_{II} = 17;[12] % III/II = 72 [12] and pyrrhoxanthin acetate (*15a*, tentatively); R_F= 0.41 (40 %); λ_{max} (hexane) *458.5* and 488 nm; % D_B/D_{II}= 12,[12] % III/II = 44.[12] These were not inter-convertible by iodine catalyzed stereomutation.

Peridinin (1, 21.8 mg) treated as above gave 9.5 mg (44 %) recovery. Chromatography on kieselgel G ($CHCl_3$) gave three major products: *16*, *17* and *18* numbered from the solvent front.[8]

Product *16a*, *b*, yield 0.28 mg (4 %), had λ_{max} (hexane) *457* and 487 nm; *m/e* 630.3109 (M, 30 %, calc. 630.3112 for $C_{39}H_{47}O_5{}^{35}Cl$), 594 (M − 36, 0.3 %), 570 (M − 60, 40 %, ^{37}Cl isotope peak at *m/e* 572), 534 (M − 60 − 36, 10 %), 373 (14 %), 223 (20 %), 201.0865 (12 %, calc. 201.0860 for $C_{11}H_{16}O^{37}Cl$), 199.0883 (34 %, calc. 199.0890 for $C_{11}H_{16}O^{35}Cl$) and 183 (14 %). Product *16* gave two zones by paper chromatography (SS287, 5 % APE): *16a*; R_F = 0.77 (60 %); λ_{max}(hexane) 326, *458* and 488 nm; % III/II = 75,[12] % D_B/D_{II} = 22 [12] and *16b*; R_F = 0.64 (40 %; λ_{max} (hexane) (335), *461* and 490 nm; % III/II [12] = 28; % D_B/D_{II} [12] = 16.

Product *17a*, *b*, yield 2.5 mg (35 %), had λ_{max} (hexane) *455* and 484 nm; ν_{max} (KBr) 3022 − 2855 (CH), 2167 (−C≡C−), 1912 (>C=C=C<), 1740 (C=O), 1638, 1570, 1460 (CH_2), 1374 and 1360 (CH_3), 1240, 1180, 1144, 1124, 1074, 1047, 1023, 986, 944, 905, 870, 818, 769, 718, and 634 cm^{-1}; *m/e* 594 (M, 11 %), 534 (26 %) and 163 (26 %) and no *m/e* 181. Product *17a*, *b*, gave two zones by paper chromatography (SS287, 10 % APE): *17a*: R_F = 0.77 (60 %); λ_{max} (hexane) (307), 320.5, 334.5, *455* and 484.5 nm; % III/II = 72, [12] % D_B/D_{II} = 37 and *17b*: R_F = 0.64 (40 %); λ_{max} (hexane) (307), 320, 335.5, *458* and 487 nm; % III/II = 41; % D_B/D_{II} = 26.

Product *18a*, *b*, yield 4.0 mg (59 %), had λ_{max} (hexane) *455* and 484.5 nm; ν_{max} (KBr) 3400 (OH), 3022 − 2855 (CH), 1928 (allene), 1730 (C=O), 1640, 1520, 1455 (CH_2), 1366 (CH_3), 1247, 1182, 1162, 1124, 1071, 1025, 984, 956, 924, 903, 859, 820, 768, 718, and 633 cm^{-1}; *m/e* 648 (M_1, 5.1 %, ^{37}Cl isotope peak at *m/e* 650, 612 (M_2, 16 %), 594 (M_1 − 36, M_2 − 18, 50 %), 570 (M_1 − 60, 44 %), 534 (M_1 − 60 − 36, 28 %), 520 (M_2 − 92, 73 %), 223 (32 %), 212 (50 %), 201 (18 %), 199 (28 %), 197 (99 %), and 163 (100 %) and no *m/e* 181.

Separation of Sugars into Anomers by Partition Chromatography on Ion Exchange Resins

OLLE RAMNÄS and OLOF SAMUELSON

Department of Engineering Chemistry, Chalmers University of Technology, Fack, S-402 20 Göteborg 5, Sweden

Various mono- and disaccharides were separated into anomers by partition chromatography on an anion exchange resin (SO_4^{2-}) in aqueous ethanol at −10 °C. With most sugars two peaks representing the α- and β-pyranoses were recorded. For some saccharides anomerization interfered with the separation. The conformation of the sugars exerts a predominant influence on their chromatographic behaviour.

Reducing sugars can be well separated into α- and β-anomers by gas chromatography of their trimethylsilyl derivatives.[1] Separate peaks corresponding to the furanoid and pyranoid forms are often obtained. Efficient separations of methyl glycosides can be achieved by ion exchange chromatography on strongly basic anion exchange resins in their hydroxide form [2] and by partition chromatography on ion exchange resins in aqueous ethanol.[3] In separation of sugars by paper chromatography at room temperature only one spot is obtained for each sugar although two or more forms of each sugar are present in most systems.[4] In thin-layer chromatography single spots are obtained at 20 − 30 °C in contrast to the appearance of elongated or double spots at −18 °C.[5] Evidently, a partial separation of different forms occurs in favourable systems.

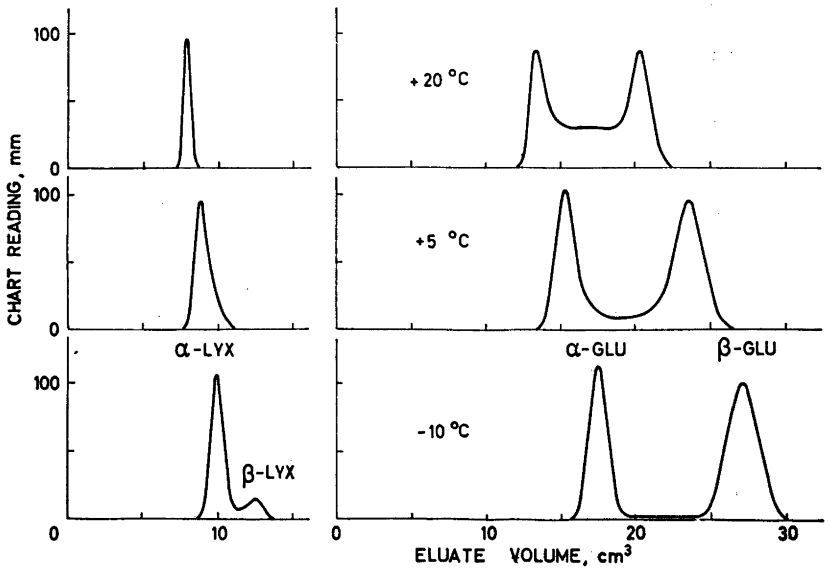

Fig. 1. Separation into anomers of D-lyxose, 20 μg (left diagrams), and D-glucose, 75 μg (right diagrams), at various temperatures.

We now report on the separation of sugars into anomers by partition chromatography on ion exchange resins in aqueous ethanol at low temperature. Separations at elevated temperature have previously been applied in analyses of complex mixtures of sugars.[6]

RESULTS AND DISCUSSION

When a mixture of α- and β-D-glucose dissolved in 75 % ethanol was eluted at 75 °C a sharp single peak was obtained. At 20 °C the mixture was resolved into two overlapping peaks [Fig. 1]. When the temperature was lowered, both peaks were eluted later which is in agreement with the earlier observation that the distribution coefficients of sugars increase with decreasing temperature.[7] At −10 °C the curve between the two peaks approached the baseline. Separate experiments with fresh solutions of α- and β-D-glucose gave sharp single peaks and showed that the first peak contained the α-anomer and the second peak the β-anomer. The retention time of the β-anomer at −10 °C was 6 h. The anomerization of the compounds was negligible at this temperature whereas at +5 °C the anomerization interfered with the separation. Evidently, the α- and β-forms can be separated by partition chromatography on ion exchange resins at low temperatures. Favourable aspects in this connection are that the mutarotation is slower in ethanol than in water [8] and that the low freezing point of the eluent permits separations at low temperature. A prerequisite for an efficient separation is that fine resin particles be used so that the sorption equilibrium can be approached during the chromatographic run. The volume distribution coefficients, D_v, of the anomers are given in Table 1.

Table 1. Volume distribution coefficients (D_v) of mono- and disaccharides in 75 % ethanol at various temperatures on an anion exchange resin (SO_4^{2-}).

Saccharide	−10 °C	+5 °C	+20 °C
D-Ribose I	4.6	–	–
D-Ribose II	5.3	4.2	3.6
α-D-Arabinose	9.1	7.1	6.3
β-D-Arabinose	4.9	4.1	4.1
α-D-Xylose	5.5	5.0	4.5
β-D-Xylose	9.4	8.2	7.0
α-D-Lyxose	5.6	4.9	4.4
β-D-Lyxose	7.0	–	–
α-D-Allose	6.2	–	–
β-D-Allose	10.8	–	–
α-D-Glucose	9.7	8.5	7.4
β-D-Glucose	15.1	13.1	11.3
α-D-Mannose	6.5	5.9	5.4
β-D-Mannose	10.9	9.3	7.8
α-D-Gulose	6.6	–	–
β-D-Gulose	10.6	–	–
α-D-Galactose	8.2	7.3	6.4
β-D-Galactose	15.1	13.2	11.1
α-D-Talose	4.7	–	–
β-D-Talose	7.1	–	–
β-D-Fructose	6.7	5.9	5.2
D-Fructose II	7.5		
α-L-Sorbose	9.2	7.3	6.7
α-Cellobiose	22.5	20.4	15.6
β-Cellobiose	34.7	30.6	22.2
α-Lactose	19.9	17.8	14.1
β-Lactose	30.4	25.5	20.6

Equally good resolution into two compounds was obtained at −10 °C with solutions of D-allose, D-mannose, and D-xylose. Aqueous ethanol solutions were kept at room temperature so that equilibrium was approached. One of the peaks was identified from the position of the single peak recorded in a separate run with a fresh solution of an authentic crystalline sample. The proportion of furanose forms of D-glucose, D-mannose, and D-xylose in equilibria in aqueous solutions is less than 1 % [9] which means that the two peaks recorded must represent the pyranose forms. The relative amounts of the anomers determined from the peak areas, were in good agreement with literature data.[9] The proportion of furanose of D-allose in aqueous solution is about 10 %,[9] but for unknown reasons no indication of its presence was obtained in the chromatograms.

D-Galactose as well as D- and L-arabinose gave rise to two well separated main peaks which were identified as α- and β-pyranose by the same technique. With both sugars a minor, seriously overlapping compound appeared after the first main peak. The experiments with D-galactose were repeated on an overloaded column to make it possible to isolate this compound. The eluate was analysed by both the orcinol and the periodate-formaldehyde methods. The results given in Fig. 2 show that the compound present in the distorted tail of the first peak gave a much stronger relative response in the periodate-formaldehyde channel

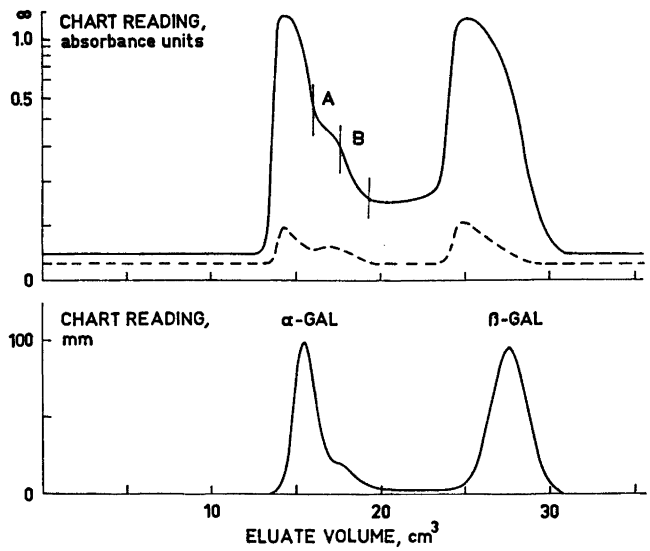

Fig. 2. Separation into anomers of D-galactose at −10 °C. Analysis by the orcinol method (full line) and periodate-formaldehyde method (broken line). Loading: 3500 μg (upper diagrams); 75 μg (lower diagram).

than the major compounds. This suggests that the compound is either a furanose or a ketohexose. D-Tagatose, which can be formed from D-galactose by isomerization, is eluted as a single peak at −10 °C at about the same position as the unknown compound. Since the elution volume of D-tagatose would probably be affected by the presence of large amounts of D-galactose, two fractions, A and B, were cut as indicated in the figure and rechromatographed on analytical columns at −10 °C and 75 °C. The chromatograms from the experiments at −10 °C could not be distinguished from that recorded with the original galactose sample [Fig. 2]. The eluate from the runs at 75 °C was analysed by the orcinol method at high amplification. The separation of D-tagatose from D-galactose is very favourable at this temperature. In addition to D-galactose only minor amounts of D-tagatose (totally in both fractions 0.5 % of the starting material) were detected. The concentration of D-tagatose in fraction B was about 5 times greater than in fraction A, which means that the unknown compound cannot be D-tagatose. The results indicate that one or both furanose forms of D-galactose were present in fraction A.

With D-gulose two well separated peaks were recorded. No crystals were available and an equilibrium mixture in aqueous ethanol was therefore analysed. The relative areas of the peaks obtained at −10 °C were in agreement with literature data.[9] The smaller peak was therefore ascribed to the α-pyranose form and the larger one to the β-pyranose form. No other compounds were recorded.

D-Talose, which is known to exist as both anomers of the furanose and pyranose forms and to give an extremely rapid mutarotation,[10] gave only two distinct peaks. The first of these was identified as the α-pyranose form by the study of an authentic sample. A large amount of the sugar was eluted between the peaks. This confirms that a rapid interconversion of various forms occurs with D-talose.

The chromatograms from the run with D-lyxose [Fig. 1] show tailing single peaks at +20 °C and +5 °C and two partially separated peaks at −10 °C. Authentic samples were available for both α-L- and β-D-lyxose and identification of the peaks was obtained as with D-glucose. In agreement with mutarotation data[10] the chromatograms showed that the anomers were rapidly interconverted.

With D-ribose which exhibits a very rapid mutarotation, appreciable amounts of the furanose forms are present together with the pyranoses.[9] Only two seriously overlapping

peaks were recorded at −10 °C. The resolution was much lower for solutions equilibrated at +80 °C and −20 °C after mixing with ethanol than in the experiments with D-ribose dissolved in 75 % ethanol (−20 °C) or first in water (+2 °C) followed by addition of ethanol (−20 °C) and chromatographed as soon as the sugar was dissolved. These results as well as the shape of the elution curves show that at least three forms were present at equilibrium.

Among the ketoses studied, D-fructose gave rise to two peaks which exhibited a severe overlapping at −10 °C. At +5 °C and +20 °C only one peak was recorded. L-Sorbose was the only sugar which gave a sharp single peak even at the low temperature. This was expected since it had previously been observed that L-sorbose exists almost exclusively in the α-pyranose form.[10]

The two disaccharides studied, cellobiose and lactose, can exist only in the pyranose forms and as expected, two sharp peaks were recorded at low temperature with each sugar. Negligible amounts were recorded between the peaks. The mutarotation was so slow that rough estimates of the distribution coefficients could be obtained even at +20 °C.

The results presented above show that the method is well suited to the separation at −10 °C of anomeric pyranoses both for analytical and preparative purposes. Separation at low temperature can also be of interest for identification of single sugars or simple mixtures when only trace amounts are available. With some sugars the interconversion of different anomers is so rapid at −10 °C that the resolution is poor.

A previous study of methyl pyranosides of D-glucose and D-xylose by partition chromatography on a sulfate resin at high temperature showed that the α- and β-forms were well separated and appeared in that order.[3] The results given in Table 1 show that for those sugars for which it was possible to determine the elution order of the anomeric pyranose forms, the α-anomer was eluted before the β-anomer, *i.e.* the elution order was the same as with the derivatives. This holds true for all disaccharides and monosaccharides with the exception of D-arabinose. The fact that D-arabinose constitutes an exception is not unexpected in regard to results from conformational studies.[11] They show that the $^1C_4$ conformation is favoured for α-D-arabinopyranose and to a lesser extent for β-D-arabinopyranose whereas with the other monosaccharides studied the $^4C_1$ conformer is favoured. A study of ethyl-α- and β-D-arabinopyranoside on a sulfate resin [92.4 % (w/w) ethanol] at 75 °C showed that for the α-form the D_v value was equal to 2.0 whereas for the β-form it was 1.5. Hence, the arabinosides were eluted in the same order as the arabinose anomers. The results show that the conformation of the sugars and sugar derivatives have a predominant influence on their chromatographic behaviour.

EXPERIMENTAL

The chromatographic equipment was the same as described earlier.[6] The eluate was automatically analysed by the orcinol method [12] and by the periodate-formaldehyde method at pH 2.[13] A strongly basic anion exchanger in its sulfate form (Technicon T5C, 10 − 17 μm) was used. The eluent (75 % aqueous ethanol, w/w) was cooled before entering the column. The volume of the resin bed decreased with decreasing temperature. The volume (143 × 4 mm) measured at −10 °C was used in the calculation of all D_v-values. Because of high pressure in the column, the flow rate was low, 0.6 cm min^{-1} (−10 °C), 1.1 cm min^{-1} (+5 °C) and 1.7 cm min^{-1} (+20 °C). The ethanol concentration in all sugar solutions was 75 %, w/w. All sugars were commercial samples except D-allose and D-gulose, which were kindly supplied by Dr. O. Theander (Stockholm) and Dr. W. Meyer zu Reckendorf (Münster).

Short Communications

The Role of H_2O_2 in the Reversible Inhibition of RNA Synthesis by Thiols in *E. coli*

L. EHRENBERG, I. FEDORCSÁK, M. HARMS-RINGDAHL and MARIA NÄSLUND

Dept. of Radiobiology, Wallenberg Laboratory, Stockholm University, S-104 05 Stockholm, Sweden

Cysteine has been shown by Roberts *et al.*[1] to inhibit the growth of *E. coli*. Vergroesen *et al.*[2] reported that thiols with $pK_a < 10$ were toxic at concentrations between 0.1 and 2.0 mM in human kidney tissue culture. Nagy *et al.*[3,4] demonstrated that cysteine had an inhibitory action on RNA and protein synthesis in *E. coli*. According to Kari *et al.*[5] 0.4 mM cysteine inhibits inducible synthesis of β-galactosidase, and at high concentrations cysteine as well as cysteamine give rise to energy depletion and inhibition of RNA synthesis by inhibiting membrane bound respiratory enzymes.

In the present communication we report some experiments carried out in order to clarify the mechanism of the RNA synthesis inhibiting action of thiols in cells of *E. coli*. Thiols (*e.g.* mercaptoethanol) are known not to affect RNA-polymerase *in vitro*. Therefore the inhibition *in vivo* appears to be caused by some reaction products of thiols. Possibly, cytotoxicity of thiols is due to the same products.

Materials and methods. Chemicals. (5-^{3}H)Uracil was purchased from Radiochemical Centre, Amersham, inorganic chemicals for analytical purpose were obtained from Merck, Darmstadt, and all other chemicals and biochemicals from Sigma Chemical Co.

Medium I. Phosphate buffer, pH 6.8, 60 mM; $MgSO_4$, 0.8 mM; 19 amino acids, 0.1 mM of each (except cysteine); cysteine, 0.05 mM; thymine, 0.015 mM; uracil, 0.02 mM; glycerol, 22.0 mM.

Medium II. Phosphate buffer, pH 6.8, 75 mM; $MgSO_4$, 1.0 mM; 19 amino acids, 0.125 mM of each, (except cysteine); thymine 0.01 mM; glycerol, 5 mM; (5-^{3}H)uracil, 2.5 μCi per ml, 500 mC per mol.

Washing medium. Phosphate buffer, pH 6.8, 60 mM; NaCl, 120 mM; $MgSO_4$, 0.5 mM.

RNA-SDS solution. 50 mg yeast RNA (Sigma, grade VI) and 5 g SDS dissolved in 100 ml distilled water and, to eliminate RNase contamination, incubated with 0.6 ml diethyl pyrocarbonate at 90 °C for 30 min.[6]

Cell suspension A. E. coli TAU⁻ CP 107 (rel+) cells (kindly provided by Dr. L. Alföldi, Biological Research Center, Hungarian Academy of Sciences, Szeged, Hungary) from an overnight culture on nutrient agar were suspended in saline to yield a cell suspension with a density equal to OD = 0.2, measured at 520 nm, in 1 cm cuvettes, with a Unicam model SP 600 spectrophotometer.

Cell suspension B. 0.5 ml Cell Suspension A was diluted 10 times with Medium I and the culture was aerated for about 3 h by shaking at 37 °C until a cell density equal to OD = 0.4 – 0.5 was reached. The cell suspension was cooled to 0 °C, the bacteria were collected and washed with Washing medium at 0 °C on Sartorius membrane filter (pore size 0.45 μm) and then suspended in Washing medium to yield a cell suspension with a cell density equal to OD = 0.2.

Assay for RNA synthesis. 0.1 ml Cell Suspension B was added to 0.4 ml prewarmed Medium II and the suspension was incubated by shaking at 37 °C. At given times 0.1 ml RNA-SDS solution was added and after 5 min incubation at 37 °C the lyzed cells were chilled and mixed with 5 ml 5 % cold trichloroacetic acid. The precipitate was collected on Sartorius membrane filter (pore size 0.45 μm) and washed with cold 5 % TCA. The filters were placed into scintillation vials and nucleic acids were hydrolyzed with 0.2 ml 5 % TCA at 60 °C for 30 min. The filters were then dissolved in 5 ml methyl cellosolve, and the radioactivity was measured after the addition of 10 ml scintillation liquid (0.5 % PPO and 0.005 % POPOP in toluene) in a Liquid Scintillation Counter Intertechnique SL 30 with an efficiency of 29 %.

Results and discussion. The action of cysteine, cysteamine, and 2-mercaptoethanol on the RNA synthesis is summarized in Fig. 1. The time curve of RNA synthesis in control and in cysteine-inhibited cells is shown in Fig. 2. Catalase or a peptide, called Fraction V (FV) isolated from Red Kidney beans,[7,8] completely counteracted the inhibitory effect of cysteine (heat inactivated catalase was inactive). Inhibition of RNA synthesis by cysteine in *E. coli* was reversible by catalase, as demonstrated by adding catalase after preincubation with cysteine for 20 min (Fig. 2). RNA synthesis started 10 min after the addition of catalase and proceeded with the same rate as in the control cells.

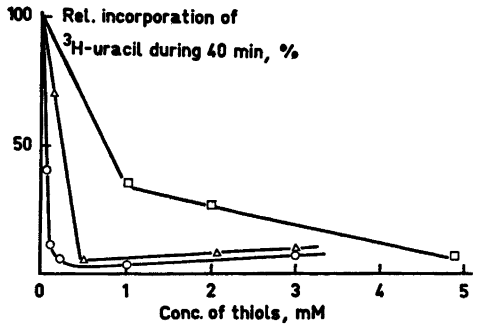

Fig. 1. The effect of cysteine (○), cysteamine (△) and 2-mercaptoethanol (□) on the RNA synthesis. (100 % corresponds to 3.3×10^5 cpm incorporated into *E. coli* TAU⁻ CP 107 (rel⁺) cells during 40 min incubation in the absence of thiols, *cf.* control in Figs. 2 and 3).

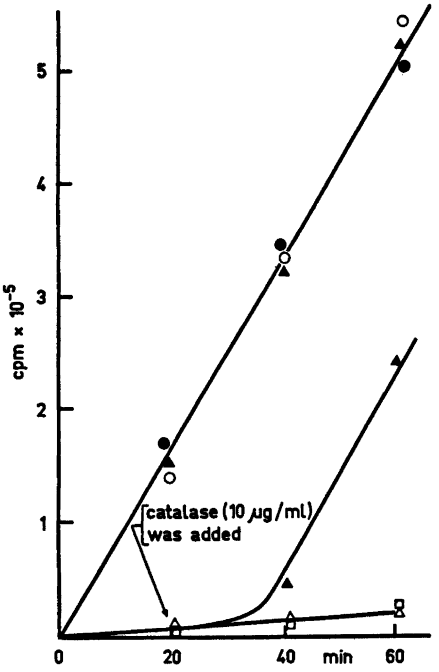

Fig. 2. The effect of catalase and FV on the inhibition of RNA synthesis caused by cysteine. Control (○); cysteine, 0.1 mM (△); cysteine, 0.1 mM plus catalase, 10 μg/ml (▲); cysteine, 0.1 mM plus heat inactivated catalase, 10 μg/ml (□); cysteine, 0.1 mM plus FV, 50 μg/ml (●), Catalase (Sigma C-100 40 000 units/mg) was added either at 0 or at 20 min.

Catalase did not reduce the concentration of cysteine.[9] From the fact that in the presence of catalase RNA synthesis was found to be unaffected by thiols, we conclude that peroxide formed during the oxidation of thiols rather than thiols as such was responsible for the inhibition of RNA synthesis. Indeed, we found that H_2O_2 inhibited RNA synthesis in *E. coli* cells and that this inhibition could be reversed by catalase in the same way as the inhibition caused by thiols (Fig. 3).

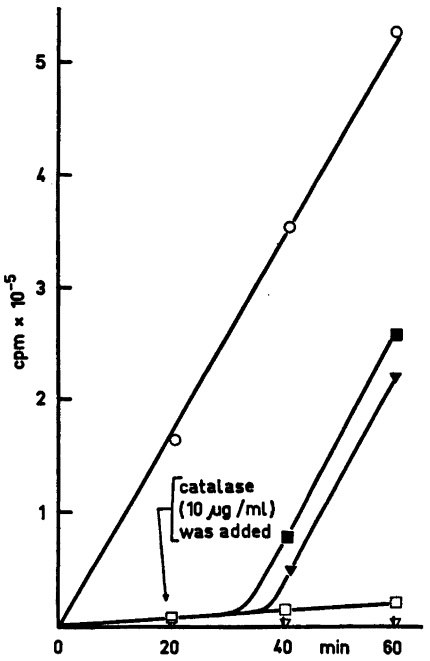

Fig. 3. The effect of H_2O_2 and catalase on the RNA synthesis. Control (○); H_2O_2 0.1 mM (□); H_2O_2, 1.0 mM (▽); H_2O_2, 0.1 mM plus catalase, 10 μg/ml (■); H_2O_2, 1.0 mM plus catalase, 10 μg/ml, (▼). Catalase (Sigma C-100 40 000 units/mg) was added at 20 min.

The concentration of H_2O_2 in aerobic systems containing thiols seems to be low, because H_2O_2 generated according to eqn. (1) is continuously eliminated according to eqn. (2).[10]

$$2RSH + O_2 \rightarrow RSSR + H_2O_2 \quad (1)$$

$$H_2O_2 + 2RSH \rightarrow 2H_2O + RSSR \quad (2)$$

From rate constants determined for reactions (1) and (2) the steady concentration of H_2O_2 in a 1 mM aerated cysteamine solution was estimated to be 0.01 – 0.1 mM.[9] In this concentration range H_2O_2 clearly inhibits RNA

synthesis. Additional experiments show that the cytotoxic action of thiols is also due to peroxide.[9] Evidently, some cell constituent(s) are highly sensitive towards H_2O_2. Therefore, H_2O_2 should always be considered as a potential cytotoxic agent and/or as an efficient inhibitor of RNA synthesis in aerobic biochemical and biological systems containing thiols or other autoxidable materials. These effects can be prevented by catalase or by peptide FV. Catalase rapidly decomposes H_2O_2 formed in reaction (1). FV has no H_2O_2 decomposing activity [9] but prevents the formation of H_2O_2 by inhibiting reaction (1). Reaction (1) requires trace amounts of metal catalyst. FV was found to bind metal ions, especially copper, and by doing so to inhibit generation of H_2O_2 and aerobic oxidation of thiols.[9] This peptide has also been shown to counteract the inhibition of RNA synthesis caused by thiols in lymphocytes.[11]

The Absolute Configuration of α-(Benzotriazolyl-1)propionic Acid. Synthesis of α-(4,5,6,7-Tetrahydrohydrobenzotriazolyl-1)propionic Acid

HÅKAN GUSTAFSSON and ARNE FREDGA

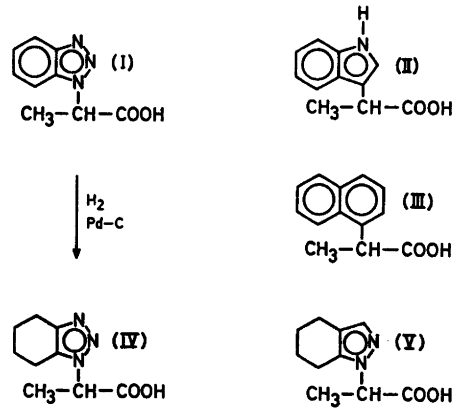
Department of Organic Chemistry, Institute of Chemistry, University of Uppsala, Box 531, S-751 21 Uppsala 1, Sweden

α-(Benzotriazolyl-1)propionic acid (I) has been resolved by Fredga and Lindgren.[1] Its absolute configuration has now been determined by X-ray powder photogram studies and CD measurements.

Attempts were first made to correlate I with α-(indolyl-3)propionic acid (II) of known configuration [2] by the quasi-racemate method.[3] However, neither melting-point diagrams nor X-ray powder photograms gave any indication of formation of quasi-racemates or solid solutions.

The acid I was then tested against α-(naphthyl-1)propionic acid (III).[4] Here the great difference in melting-point (~120 °C) is not favourable for thermal analysis. X-Ray powder photograms showed no quasi-racemate, but (+)-I and *S*-(+)-III gave solid solutions indicating the same absolute configuration. Thus (+)-I has *R*-configuration.

(−)-I was also hydrogenated yielding (−)-α-(4,5,6,7-tetrahydrobenzotriazolyl-1)propionic acid (−IV) (Scheme 1). The CD-spectrum of



Scheme 1.

(−)-IV was compared with that of *S*-(+)-α-(4,5,6,7-tetrahydroindazolyl-1)propionic acid (+V), whose absolute configuration is known.[5] (−)-IV and *S*-(+)-V give the same type of CD-curves (Fig. 1). This is also the case for (+)-I

synthesis. Additional experiments show that the cytotoxic action of thiols is also due to peroxide.[9] Evidently, some cell constituent(s) are highly sensitive towards H_2O_2. Therefore, H_2O_2 should always be considered as a potential cytotoxic agent and/or as an efficient inhibitor of RNA synthesis in aerobic biochemical and biological systems containing thiols or other autoxidable materials. These effects can be prevented by catalase or by peptide FV. Catalase rapidly decomposes H_2O_2 formed in reaction (1). FV has no H_2O_2 decomposing activity [9] but prevents the formation of H_2O_2 by inhibiting reaction (1). Reaction (1) requires trace amounts of metal catalyst. FV was found to bind metal ions, especially copper, and by doing so to inhibit generation of H_2O_2 and aerobic oxidation of thiols.[9] This peptide has also been shown to counteract the inhibition of RNA synthesis caused by thiols in lymphocytes.[11]

The Absolute Configuration of α-(Benzotriazolyl-1)propionic Acid. Synthesis of α-(4,5,6,7-Tetrahydrohydrobenzotriazolyl-1)propionic Acid

HÅKAN GUSTAFSSON and ARNE FREDGA

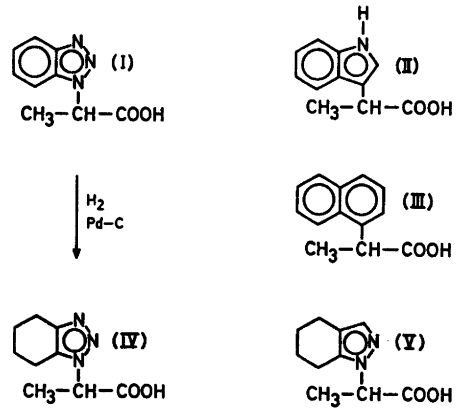
Department of Organic Chemistry, Institute of Chemistry, University of Uppsala, Box 531, S-751 21 Uppsala 1, Sweden

α-(Benzotriazolyl-1)propionic acid (I) has been resolved by Fredga and Lindgren.[1] Its absolute configuration has now been determined by X-ray powder photogram studies and CD measurements.

Attempts were first made to correlate I with α-(indolyl-3)propionic acid (II) of known configuration [2] by the quasi-racemate method.[3] However, neither melting-point diagrams nor X-ray powder photograms gave any indication of formation of quasi-racemates or solid solutions.

The acid I was then tested against α-(naphthyl-1)propionic acid (III).[4] Here the great difference in melting-point (~120 °C) is not favourable for thermal analysis. X-Ray powder photograms showed no quasi-racemate, but (+)-I and *S*-(+)-III gave solid solutions indicating the same absolute configuration. Thus (+)-I has *R*-configuration.

(−)-I was also hydrogenated yielding (−)-α-(4,5,6,7-tetrahydrobenzotriazolyl-1)propionic acid (−IV) (Scheme 1). The CD-spectrum of



Scheme 1.

(−)-IV was compared with that of *S*-(+)-α-(4,5,6,7-tetrahydroindazolyl-1)propionic acid (+V), whose absolute configuration is known.[5] (−)-IV and *S*-(+)-V give the same type of CD-curves (Fig. 1). This is also the case for (+)-I

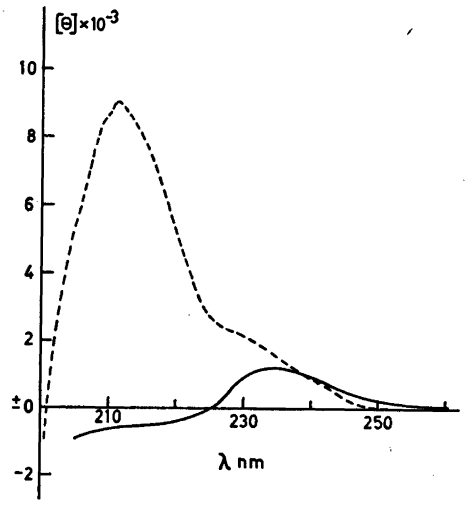


Fig. 1. CD spectra of *S*-(−)-IV (− − −, $c = 3.26 \times 10^{-2}$ g/100 ml) and *S*-(+)-V (———, $= 4.04 \times 10^{-2}$ g/100 ml) in methanol.

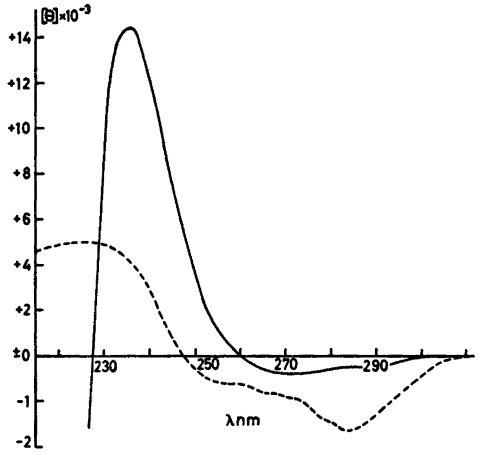

Fig. 2. CD spectra of *R*-(+)-I (− − −, $c = 3.52 \times 10^{-2}$ g/100 ml) and *S*-(+)-II (———, $c = 3.30 \times 10^{-2}$ g/100 ml) in methanol.

and *S*-(+)-II (Fig. 2). We have here additional evidence for the *R*-configuration of (+)-I.

Experimental. The UV spectra were recorded on a Bausch-Lomb Spectronic 505 spectrophotometer and the IR spectra on a Perkin-Elmer 157 spectrophotometer in KBr pellets. The ^{1}H NMR spectra were recorded on a Varian A-60 instrument using sample solutions of about 10 % and tetramethylsilane as internal standard. The optical activity was measured with a Perkin-Elmer 141 spectropolarimeter in micro cells of 10 cm length. The CD curves were recorded in 1 ml cells in methanol solutions with a Cary 60 spectropolarimeter equipped with a CD accessory and the mass spectra recorded at 70 eV with an LKB 9000 instrument. The X-ray powder photograms were taken with a Guinier-Hägg camera using Cr$K\alpha_1$ radiation.

The thin layer chromatograms were run in 20 % acetic acid − benzene on non-activated plates (E. Merck) coated with silica gel F 254 with a nominal thickness of 0.25 mm. The chromatograms were examined under UV light or developed with iodine vapour.

The melting points were determined with a hot stage microscope and are uncorrected. The micro analyses were carried out in the analytical department of the institute.

R,S-α-*(4,5,6,7-Tetrahydrobenzotriazolyl-1)propionic acid (IV).* 0.40 g *R,S*-I was dissolved in 4.0 ml 96 % ethanol and 0.80 g 10 % palladium-on-charcoal was added. Hydrogenation was carried out in an autoclave at a hydrogen gas pressure of 90 atm for 22 h at 75 °C with shaking. The catalyst was then filtered off and washed with a small amount of 96 % ethanol. The solvent was evaporated and the residue tested by thin layer chromatography. In addition to IV ($R_F = 0.53$) a small amount of I ($R_F = 0.63$) was indicated. A small spot at $R_F = 0.75$ was probably the ester of IV.

The product was dissolved in a small amount of warm 96 % ethanol and warm ligroin (b.p. 60 − 71 °C) was added. After cooling 0.045 g pure IV was obtained. M.p. 197 − 198 °C. ^{1}H NMR (DMSO-d_6): δ 1.70 (m and d, $-CH_2-$ and CH_3-), δ 2.52 (complex m, $-CH_2-\underset{|}{C}=$), δ 5.28 (q, α-H). λ_{CO} 5.8 μm. UV: λ_{max} 230 nm (log ε 3.67).

[Found (195.2, MS): C 55.31; H 6.73; N 21.29. Calc. for $C_9H_{13}N_3O_2$ (195.2): C 55.37; H 6.71; N 21.53.]

S-(−)α-(4,5,6,7-Tetrahydrobenzotriazolyl-1)-propionic acid (−IV). 0.20 g (−)-I was dissolved in 4.0 ml 96 % ethanol and hydrogenated in the same way as described above with 0.40 g 10 % palladium-on-charcoal as catalyst. 0.053 g (−)-IV was obtained after two recrystallizations. M.p. 187.5 − 188 °C. $[\alpha]_D^{25} = -19.9°$, $[\alpha]_{365}^{25} = -56.7°$ (*c* 0.1410, 96 % ethanol). The acid was chromatographically pure.

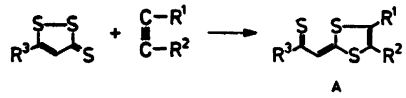
Mass Spectrometric Studies of α-(1,3-Dithiol-2-ylidene)-thioketones and Thioaldehydes

CARL TH. PEDERSEN,[a] HUBERT DAVY,[b] JØRGEN MØLLER[c,*] and JEAN VIALLE[b]

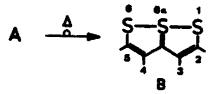
[a] Department of Chemistry, Odense University, DK-5000 Odense, Denmark, [b] Département de Chimie, Université de Caen, F-14032 Caen Cedex, France and [c] Physical Laboratory II, H. C. Ørsted Institute, Universitetsparken 5, DK-2100 Copenhagen Ø, Denmark

The reactions of 1,2-dithiol-3-thiones with activated acetylenes such as phenylacetylene, benzoylacetylene, acetylene dicarboxylic acid ester, and phenylacetylene carboxylic acid esters result in compounds which can be formulated as α-(1,3-dithiol-2-ylidene)thioketones and thiolaldehydes (A).[1-3]



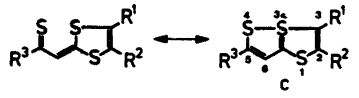
A

The compounds readily rearrange at high temperature in the presence of sulfur containing compounds such as phosphorus pentasulfide, thioacetamide and sulfur to the isomeric 1,6,6aλ^4-trithiapentalenes (B).[1,4,5]



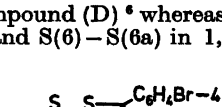
B

The close relationship to the 1,6,6aλ^4-trithiapentalenes has resulted in the formulation of analogous bicyclic canonical forms such as (C) for these compounds, (C) is a 1,3aλ^4,4-trithiapentalene. However, X-ray investigations



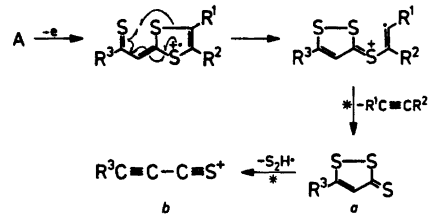
C

have shown, that the distance S(3a)–S(4) is 2.91 Å in compound (D) [6] whereas the distances S(1)–S(6a) and S(6)–S(6a) in 1,6,6aλ^4-trithiapentalene fall in the range 2.23–2.51 Å.[7] This seems to indicate that these compounds are most correctly described by structure (A); this assumptions is in accordance with the electron impact induced fragmentation of the compounds. The loss of a hydrogen atom from the aromatic bicyclic 1,6,6aλ^4-trithiapentalenes and loss of substituents from the aryl substituted 1,6,6aλ^4-trithiapentalenes were found to be a characteristic feature in the mass spectra of the latter,[8] whereas the corresponding processes are insignificant here.



D

The mass spectra of VI and IX have recently been published by one of us.[9] In both cases the predominant fragmentation was loss of phenylacetylene from the molecular ions probably under formation of 5-substituted-1,2-dithiol-3-thiones. We now report this fragmentation to be a general process for compounds of this type *cf.* Table 1. A probable mechanism is suggested in scheme 1.



Scheme 1.

This fragmentation mode accounts for most of the significant ions. One exception is the $[C_6H_5CO]^+$ ion found in the spectra of IX to XII (this ion gives rise to the base peak in XII). Another ion which was found in some abundance when both R^1 and R^2 are aromatic substituents is the $[R^1C{\equiv}CR^2]^{+\cdot}$ ion. The peak corresponding to $[R^3CS]^+$ is remarkably small when compared with $[C_6H_5CS]^+$ in the mass spectra of 5-phenyl substituted 1,6,6aλ^4-trithiapentalenes.[8] The same ion is present in the mass spectra of phenyl substituted 1,2-dithiol-3-thiones [10] in which case it appears in approximately the same abundance as in I to XII. However, it cannot be excluded that the $[R^3CS]^+$ ion in these cases also is formed directly from the molecular ion. The mass spectrum of VIII (Fig. 1) indicates that also a $[R^1CS]^+$ ion is formed (*m/e* 121) (in this case in the same abundance as $[R^3CS]^+$, *m/e* 151). The ion at *m/e* 132 corresponds to $[R^3C{\equiv}CH]^{+\cdot}$ which is a typical fragment in the spectra of 1,2-dithiol-3-thiones.[10]

Small peaks from doubly-charged ions corresponding to M^{2+} are present in all cases and to $[M-CS]^{2+}$ in the spectra of II to VIII. In the spectra of III and VIII the latter ion appears in relatively high abundance (*cf.* Fig. 1). If R^3 is a *p*-methoxy-phenyl group the methoxy

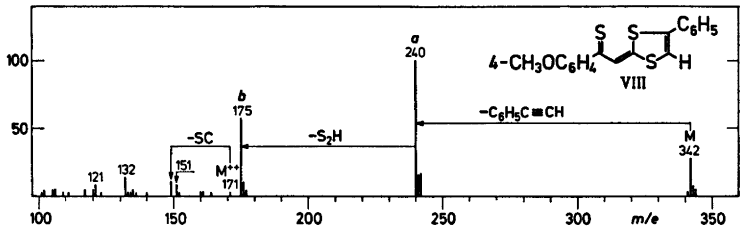

Fig. 1.

group may allow further stabilization of $[M-CS]^{2+}$ as important factors for stabilization of doubly charged ions are separation of charges and a possible formation of a conjugated system in the ion.[11] Loss of CS from the singly charged molecular ions in no cases gave rise to discernible ions.

Experimental. Mass spectra were obtained on a MS 902 spectrometer using the direct sample insertion system and the lowest feasible ion source temperature. 70 eV electrons were used. Peaks corresponding to doubly-charged ions appearing at half mass numbers and peaks of abundance lower than 2 % were omitted. When necessary the elemental composition of an ion was determined by accurate mass measurements (± 10 ppm).

α-(1,3-Dithiol-2-ylidene)thioketones and thioaldehydes were prepared by reacting the appropriate 1,2-dithiole-3-thiones with acetylenes.[12]

A Method of Studying the Competitive Binding of Small Molecules to Macromolecules in the Gel State by High Resolution ^{1}H NMR Spectroscopy. Solvent Effects in Polyuronide Gels

H. GRASDALEN,[a] I. SVARE [a] and O. SMIDSRØD [b]

[a] Department of Physics and [b] Institute of Marine Biochemistry, University of Trondheim, N-7034 Trondheim-NTH, Norway

It has been known for some time that it is possible to prepare stable, rigid, voluminous, and highly transparent gels of calcium alginate in organic solvents.[1,2] The state of solvation of the macromolecules in these gel systems, as well as of macromolecular gels in general, is far from completely understood. The main object here is to describe a method by which high resolution ^{1}H NMR-spectroscopy can be used for studying the solvation of macromolecules bound in gel matrices.

Gels were prepared by dialysing solutions of sodium alginate (*Laminaria hyperborea*, stipe, M/G = 0.57) contained in standard 5 mm thin wall NMR-tubes against 0.1 M aqueous $Ca(NO_3)_2$, and then against a large volume of water to remove excess $Ca(NO_3)_2$. The gels formed had a regular cylindrical shape with a diameter about 3 mm and could be removed from the NMR-tube and placed in large volumes of different liquids for solvent exchange, and then reinserted into a heavy wall NMR-tube (inner diameter ~3 mm) for recording of spectra (VARIAN A-60A at about 39 °C).

The exchange of H_2O for EtOH occurred with a permanent slight contraction of the gels, which for a 5 % w/v water gel was found to be 8 % (v/v) and 13 % at 95 % and ~100 % EtOH, respectively, after 2 d of dialysis, after which time no further volume contraction occurred. The significant shrinkage observed at very low water content suggests that the macromolecules are preferably associated with water molecules.

The ^{1}H NMR spectra of ethanol in the gels were found to be highly dependent on the content of water in the ethanol. The spectra from gels containing 95 % EtOH had almost as narrow lines as in pure ethanol solution, while the spectra from gels containing ~100 % EtOH had very broad lines, suggesting more interaction between ethanol and the polyuronide chains in the latter case. Since the small amount of water in 95 % EtOH had such an immense effect on the ethanol spectrum, it was thought that a more systematic perturbation of the ethanol spectrum by dialyzing the gels against EtOH containing different solutes might yield information on their solvation relative to ethanol.

In order to determine the time needed for a complete exchange of solvent in each case some information on the mobility of the solvent in the gels was needed. The mobility of solvents in macromolecular gels is in general fairly high as evidence by self-diffusion coefficient measurements.[3-5] The time for the EtOH/H_2O solvent exchange in the gels used here was found to be about 3 min for hydroxyl and water protons and about 6 min for ethanol molecules as reflected by ^{1}H NMR line intensities in the external solution. The exchange times were almost independent of the alginate concentration in the range up to 10 % and comparable to the self-diffusion times in free solvents.[6] This is also to be expected because of the relative wide pores in alginate gels (mean diameter 200 – 500 Å as judged from electron micrographs).[7-8] Based upon these experiments a standard time of 10 min was used for equilibration of the gels against large excess of solvent mixtures. Attempts were also made to determine the corresponding equilibrium composition in the gels for the EtOH/H_2O system by measuring the release of water by dialysis against ~100 % EtOH. It was found that the gels in general contained more water than the external solution. A gel equilibrated aginst 98 % EtOH had for example about 20 % higher H_2O/EtOH-ratio than the external solution. Due to the

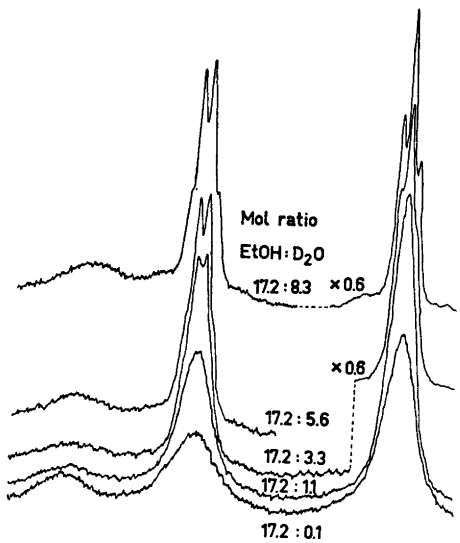

Fig. 1. ^{1}H NMR spectra of EtOH in a 10 % w/v calcium alginate gel at ~39 °C with successive addition of D_2O. The "100 % EtOH" used in the experiment was found by analysis by gas chromatography to contain less than 0.2 % water.

small volume of the gels, *ca.* 0.15 cm³, this ratio could not be determined with high accuracy, and we will at this stage relate the spectra to the composition of the external solutions.

The striking effect of water in narrowing the ethyl lines of EtOH in a 10 % alginate gel is demonstrated in Fig. 1. The behaviour can be interpreted in terms of a two-phase model for the binding of ethanol to alginate.[9] In pure ethanol a minor fraction of the solvent molecules may be restricted in their movements by interaction with the macromolecules leading to increased relaxation rates and broad ^{1}H NMR lines for their protons. If a rapid molecular exchange occurs between the interacting molecules and the bulk solvent, population-weighted average line widths are obtained. In support of this model is the observations that in pure ethanol the line widths increase with increasing concentration of alginate in the gels, and an observed difference in the line width of the CH_2 and the CH_3 lines in the ethanol-signal. In a 10 % gel in pure EtOH the CH_2 lines were 35 Hz wide and the CH_3 lines about 20 Hz wide. This difference is expected if some ethanol molecules are bound by hydrogen bonds to the alginate chains, because the CH_3-group then will be less restricted in its movement through rotation around one extra bond. The high resolution spectra obtained after addition of relative small amounts of water (corresponding to about 4 water molecules per monomer residue) indicate that no appreciable solvation of EtOH occurs under these conditions. This result strongly indicate that the water molecules bind more strongly to the alginate chains, and thereby hinder their solvation by ethanol.

In Fig. 2 the effect of water is compared with that of methanol, acetone, and cyclohexane. By assuming that the spin-spin coupling in the $-CH_2-CH_3$ group was unaffected by the broadening mechanism, the full line width at half maximum could be obtained by computer simulation, and the width of the CH_3 lines is plotted against the mol fraction of ethanol in the external solution. The results indicate a very marked difference in the solvation of the four solutes relative to ethanol with decreasing solvation in the order water > methanol > ethanol > acetone ≥ cyclohexane. This was also supported by the relative line widths of the solutes at a mol fraction of 0.3. They decreased in the order water > MeOH > acetone (10 Hz) > cyclohexane (4 Hz). The series are expected except for the lacking effect of acetone in perturbating the ethanol spectrum. Acetone could be thought to bind to the hydroxyl groups of the alginate, and it is most interesting that this seems not to be the case. This result suggests that alginate is more effective in forming hydrogen bonds as a hydrogen acceptor than as a hydrogen donor, which agrees with current ideas concerning the solvation of carbohydrates in general.[10]

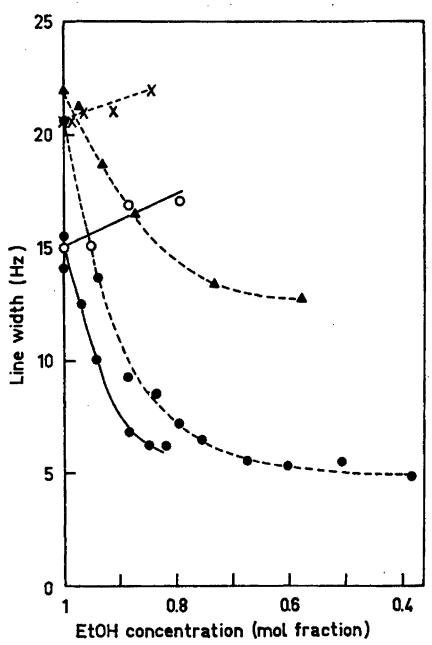

Fig. 2. The width of EtOH methyl ^{1}H NMR lines in calcium alginate gels at ~39 °C as a function of mol fraction of EtOH in the solvent. – – –, 10 % gel; ——— 5 % gel; ●, EtOH/H_2O; ▲, EtOH/MeOH; ○, EtOH/cyclohexane; ×, EtOH/acetone.

Whatever the molecular mechanism for the differences are, the effects shown in Fig. 2 are large and easy to detect, indicating that the technique may prove valuable in solvation studies on macromolecular gels. A more detailed study involving more model solutes will now be undertaken in our laboratories.

Another interesting aspect of the method is that the solvent binding capacity of the macromolecules must depend on the degree of junction formation of the chains. Crosslinking will probably reduce the macromolecular surface available for solvent interaction. Evidence for this is seen in Fig. 2 where the CH_3 lines in dry EtOH gels increase somewhat less than proportional to the concentration of alginate. This is also the case for the H_2O line in pure water gels. A study involving alginate gels of different composition and concentration may therefore shed more light on the chain structure of these gels.

Acknowledgement. Dr. T. Painter is thanked for valuable discussions.

Studies on the Possible Effects of Adsorption on the Product Distribution of Organic Electrode Reactions. IV. Anodic Acetoxylation of 2-Methylindan, 2,2-Dimethylindan, 5,6-Dimethoxy-2-methylindan and Neopentylbenzene

HANS STERNERUP

Division of Organic Chemistry, University of Lund, Chemical Center, P.O.B. 740, S-220 07 Lund 7, Sweden

2-Methylindan, 2,2-dimethylindan, 5,6-dimethoxy-2-methylindan and neopentylbenzene have been anodically oxidized in an acetic acid/sodium acetate medium with different anode materials. The stereochemistry of the products was analyzed with special attention to the possible steric influence of the electrode surface on product distribution. Further, the influence of pulsing the anode potential has been investigated.

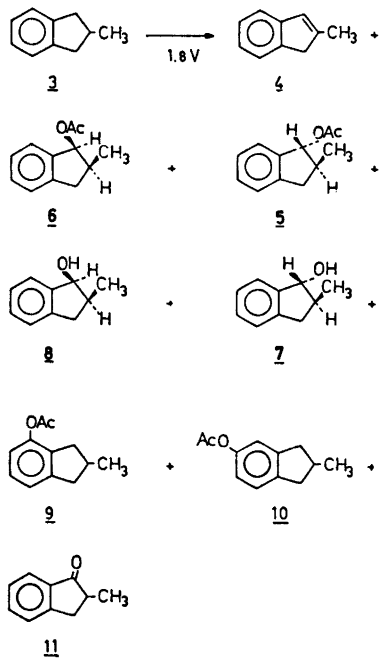
Previous papers in this series have dealt with the possible stereochemical consequences of adsorption in the anodic oxidation of 2-*t*-butylindan (*1*) and 1-*t*-butylacenaphthene (*2*) in HOAc/NaOAc.[1] By introducing a sterically demanding substituent on one side of the plane defined by the ring plane it was hoped that adsorption with the less hindered side toward the electrode surface would result in an increased *cis-trans* ratio in the side-chain substitution product. To some extent this hypothesis was substantiated: the *cis-trans* ratio of the α-acetates from *1* was 16:84, as compared to < 2:98 in a related homogeneous reaction. On the other hand, the behaviour of *2* did not show any unambiguous preference for the formation of the *cis* isomer (*cis-trans* ratio 3:97; no related homogeneous reaction could be studied due to experimental difficulties.)

The substrates *1* and *2* might, however, not be quite ideal for studying the problem at hand. NMR data for several 1,2-disubstituted *t*-butylindan derivatives indicated that the *t*-butyl group does not exert the kind of clearcut steric hindrance of one side of the molecule that might be expected from studies of molecular models. On the contrary, there is evidence that the *t*-butyl group points out in an "equatorial" manner from the saturated ring, due to hydrogen-π-orbital repulsion.[2] This means that the tertiary carbon atom of the *t*-butyl group is situated almost in the plane of the aromatic ring and thus presents steric hindrance on both sides of the molecule, even if not to the same extent. By instead using 2-methylindan as a substrate, this possibly exaggerated effect should be eliminated. The ratio of the diameters of the rotation bodies swept out by the van der Waals radii of the two substituents is approximately 2:1 as measured perpendicular to the C_2-R bond. Other investigators have reported chemically non-equivalent aromatic faces in homogeneous solution, due to alkyl-aromatic π-electron interaction.[3]

This paper reports the stereochemical outcome of the anodic oxidation of 2-methylindan in glacial acetic acid/anhydrous sodium acetate. In addition 2,2-dimethylindan, 5,6-dimethoxy-2-methylindan, and neopentylbenzene were examined under the same conditions.

RESULTS

Products formed in the anodic oxidation of 2-methylindan (*3*) in HOAc/1 M NaOAc are 4 – 11 (Scheme 1).



Scheme 1.

The major products were the side-chain acetates *5* and *6* which made up 80 % of the total product mixture. The *cis-trans* ratio was 51:49 as measured from the NMR integrals of the proton α to the acetoxy group; for *5* δ 5.84 ppm, *J* 4.3 Hz; and for *6* δ 6.06, *J* 5.6 Hz. For details of the product distribution see Table 1.

The products were identified in the following manner. The side-chain alcohols *7* and *8* were known from previous work (*trans* isomer, m.p. 88 – 89 °C; *cis* isomer, m.p. 50 – 51 °C).[4] In the present study, the trans isomer *7* was prepared by hydration of *4* according to a literature method using lithium aluminium hydride and boron trifluoride etherate in diethyl ether,[5] m.p. 88 °C (NMR for α-H of *7*: δ 4.51, *J* 6.8 Hz) after recrystallization from petroleum ether. The crude product contained about 5 % of the *cis* isomer. Lithium aluminium hydride, sodium borohydride, and aluminium isopropoxide reduction of *11* according to standard procedures gave mixtures of *8*:*7* in the ratios of 33:67, 20:80, and 15:85, respectively. From these mixtures, the necessary spectral characteristics (NMR, mass spectrum) of *8* could be obtained (NMR for α-H: δ 4.78, *J* 6.0 Hz). The mixture of side-chain alcohols *7* and *8* was treated with acetic anhydride and pyridine, which gave acetates *5* and *6* in the same ratio (NMR: *5* δ 5.85, *J* 4.3 Hz, *6* δ 6.06, *J* 5.6 Hz).

The nuclear acetates were prepared according to the reaction sequence in Scheme 2. The isomers *9* and *10* were formed in the ratio of 45:55, and *10* was considered to be the major product on the basis of earlier studies of the indan system.[6] 2-Methylindene was prepared

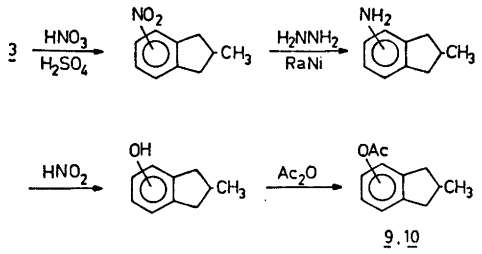
$Co(OAc)_3$ oxidation	traces	51.4	17.2	–	31.4		37:63
Solvolysis							43:57

[a] In this case no sodium acetate was present.

from the mixture of *7* and *8* by acid-catalyzed elimination.



Scheme 2.

As seen by inspection of Table 1, the products from the anodic oxidation of *3* using Bu_4NBF_4 as supporting electrolyte instead of sodium acetate are the same as above, except for the nuclear acetates *9* and *10* which are not expected to be formed in this case.[7] Two runs were made with water added, 5 and 10 %, respectively. This increased the amount of *7* and *8* formed (*cis-trans* ratio 34:66) so that with 10 % water added it almost equalled the amount of side-chain acetates. This is in accordance with the accepted reaction mechanism.[8] The *cis-trans* ratio for the acetates *5* and *6* was in this case 52:48.

No significant influence of the electrode material on the ratio between *5* and *6* could be detected. Table 1 shows the *cis-trans* ratio for the electrode materials used. Cobalt(III) acetate oxidation of 2-methylindan and solvolysis of *trans*-1-(*p*-nitrobenzoyloxy)-2-methylindan were used as homogeneous reference reactions. The mechanism of cobalt(III) acetate oxidation is known to be of the electron transfer type and in the last few years studies have been reported of the oxidation of a number of hydrocarbons,[9] where one of the main reaction modes has been acetoxylation in benzylic positions. The cobalt(III) oxidation of *3* gave *5* and *6* as the main products with a *cis-trans* ratio of 37:63.

For the solvolysis experiment the pure *trans* isomer of 1-(*p*-nitrobenzoyloxy)-2-methylindan was prepared by treating the 85:15 mixture of *7* and *8* with *p*-nitrobenzoyl chloride and recrystallization of the product from ethanol. No trace of the α proton from *cis*-1-(*p*-nitrobenzoyloxy)-2-methylindan was evident in the NMR spectrum of the *trans* form, not even when the signal from the α proton of the *trans* isomer (δ 6.04, J 4.0 Hz) was several times off scale. Solvolysis for 24 h in HOAc/1 M NaOAc at 75 °C produced the side-chain acetates *5* and *6* in a *cis-trans* ratio of 43:57.

If two oxidizable substrates with different adsorption properties are present in the electrolyte, the competition factor between them can be changed by pulsing the electrode potential.[10] For 2-substituted indans the two possible modes of adsorption (with the substituent pointing towards and away from the electrode surface, respectively) could be regarded in the same way as two different substrates. As before, the orientation with the substituent pointing away from the electrode surface is expected to be energetically favoured. Pulsing the anode potential should then change the ratio between *5* and *6*. As is seen from the results in Table 2, no difference in the *cis-trans* ratio for the side-chain acetates between pulse and constant potential electrolysis can be detected.

Another possibility to change the *cis-trans* ratio of the side-chain acetates, was tried with 2-*t*-butylindan as a substrate, and the results are shown at the last entry of Table 2. It is known that adsorption on electrodes reaches a maximum value at the potential of

Table 2. Results from pulse experiments with 2-methylindan and 2-*t*-butylindan in acetic acid/1 M sodium acetate.

Substrate	Duration of A pulse	B pulse	*cis-trans* Ratio for side-chain acetates
2-Methylindan	2.5 ms/0.2 V	7.5 ms/1.8 V	46:54

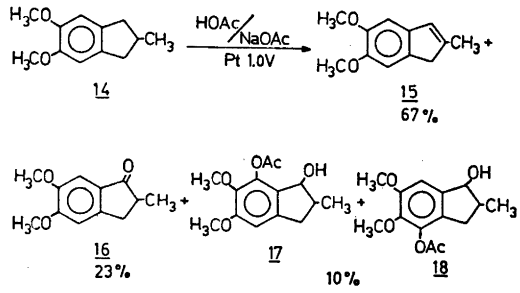
12	Pt	73.4	–	–	26.6	–	–
12	$Co(OAc)_3$ ox.	24.6	–	–	75.4	–	–

[a] See Table 6. [b] This compound has a mass spectrum *m/e* (%) 218(0.6) 176(8) 161(8) 133(10) 118 (100) 90(30) 43(8). [c] Carried out as for 2-methylindan but at 90 °C.

zero charge and diminishes as the electrode potential is changed toward both negative and positive potentials.[11] In this experiment the anode was kept at a potential where no current passed through the cell, 0.50 V *vs.* SCE, for three seconds to allow an adsorption equilibrium to be established, and then the adsorbed material was oxidized by a short (0.3 s at 1.8 V) pulse. The *cis-trans* ratio, 15:85, for 1-acetoxy-2-*t*-butylindan, does not differ from the value obtained in constant potential electrolysis.

The oxidation of neopentylbenzene (*12*) in HOAc/1 M NaOAc gave a somewhat unexpected result. No products were formed (product integral in GLC less than 0.5 % of recovered starting material). Changing the anode material did not alter this behaviour. On the other hand, with Bu_4NBF_4 as a supporting electrolyte side-chain acetoxylation took place as expected (Table 3). In order to see if the anomalous oxidation behaviour of neopentylbenzene was shown also by its "back-bonded" analogue 2,2-dimethylindan (*13*), this compound was prepared and oxidized. Here the side-chain acetate was formed predominantly. For details of the product distribution, see Table 3. Product identification from neopentylbenzene oxidation was carried out by comparison of mass spectra and GLC retention times with authentic samples. For 2,2-dimethylindan the products were identified by mass spectral analysis.

In order to find out whether the presence of polarizable groups in the molecule would enhance adsorption and thus influence product distribution, 5,6-dimethoxy-2-methylindan (*14*) was oxidized in HOAc/1 M NaOAc. The preparative run (to 25 % of a 2e transfer) was made at 1.0 V *vs.* SCE. GLC analysis showed four major product peaks corresponding to the elimination product *15*, ketone *16* and side-chain alcohol acetoxylated in the nucleus, *17* and *18*. The product distribution (mol % of total products) was as given in Scheme 3.



Scheme 3.

The products were identified on the basis of their mass spectra and, in addition, for compound *16*, the GLC retention time.

DISCUSSION

The stereochemistry of the anodic oxidation of 2-methylindan in glacial acetic acid/sodium acetate does not give any evidence for a preferential adsorption mode of the substrate. Thus the expectation that there would be a

more distinct difference between the two faces of this molecule than in the case of 2-*t*-butylindan has not been fulfilled.

2-*t*-Butylindan shows a significant difference between anodic and comparable homogeneous reactions [1] which is not the case for 2-methylindan, as can be seen from Table 1. This study is based on the idea of different reactivities of the two sides of the molecule defined by the plane of the aromatic ring. This in turn invokes a kind of selection process where molecules with the "right" side toward the electrode are preferred for reaction. For 2-*t*-butylindan this selection process appears to be operating to some extent. For 2-methylindan the result might be explained by the assumption that the energy difference between the two modes of adsorption, with the methyl group pointing toward and away from the electrode surface, respectively, is so small that it is not sufficient to cause any preferred orientation at the electrode surface once the molecule has arrived there. (This would require an extra desorption-absorption sequence.)

Here it is interesting to note the special stereochemical features of neopentylbenzene. The side-chain of this molecule has rotational freedom around the two bonds connecting the *t*-butyl group with the aromatic nucleus. This makes it possible for the side-chain to orient itself out from the electrode surface at the same time as the molecule is adsorbed at the aromatic ring. This would explain why no α substitution product is formed from neopentylbenzene. In 2,2-dimethylindan, which can be considered as a neopentylbenzene without free rotation, normal product formation takes place. One objection against this kind of reasoning is clearly that 2,2-dimethylindan formally is a dialkylsubstituted aromatic hydrocarbon and consequently should be easier to oxidize than a monosubstituted one.[12]

The differing ease of oxidation of 2-methyl- and 2,2-dimethylindan on the one hand and neopentylbenzene on the other is evident from the voltammograms of the compounds (Figs. 1 – 4). These have been recorded at the beginning of the experiments. The current-potential curve for the solvent-supporting electrolyte was recorded first, measuring the current at each tenth of volt of anode potential in the range 0 to +3 V *vs.* SCE. The substrate was

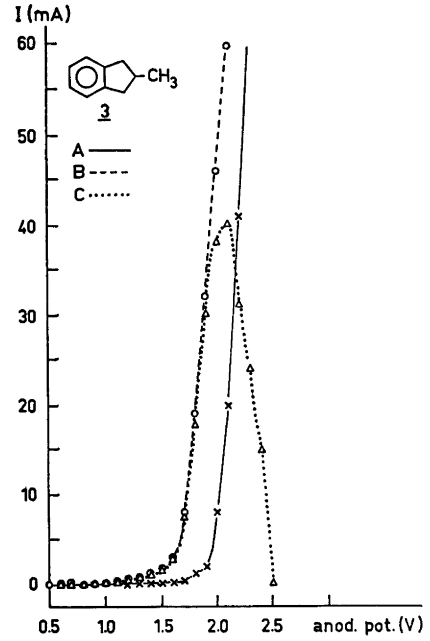


Fig. 1. Voltammogram for compound *3* in HOAc/1 M NaOAc. Curve A: Background current. Curve B: Current with 5 mmol of substrate added. Curve C: Shows the difference between B and A.

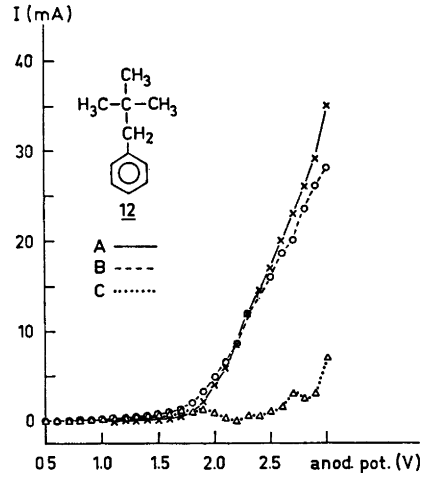

Fig. 2. Voltammogram for compound *12* in HOAc/1 M NaOAc. Curve A: Background current. Curve B: Current with 5 mmol of substrate added. Curve C: Shows the difference between B and A.

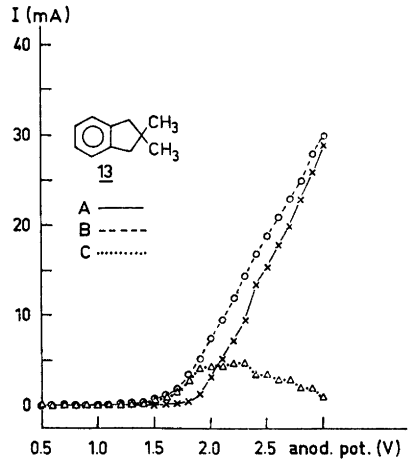

Fig. 3. Voltammogram for compound *13* in HOAc/1 M NaOAc. Curve A: Background current. Curve B: Current with 5 mmol of substrate added. Curve C: Shows the difference between B and A.

then added and the procedure repeated. Thus voltammetric curves and product analyses relate to the same single experiment.

In the pulse experiments, the goal has been to maximize adsorption. At mercury electrodes, it has been shown that substrate adsorption reaches a maximum value at the potential of zero charge. The same behaviour is exhibited by solid electrodes, even if data are relatively scarce in such systems.[11,13] It is considered that the potential of zero charge (p.z.c.) at platinum lies in the range of 0.20 – 0.5 V *vs.* SCE. Accordingly, the possibility of revealing any preferential orientation in adsorption should be most favourable at p.z.c. However, neither varying the pulse frequency nor keeping the anode at p.z.c. and using short oxidation pulses, give any results in support of such a behaviour of the substrates used here (2-methylindan and 2-*t*-butylindan). These facts cannot be explained at the present time. In one pulse experiment an attempt was made to increase the yield of the elimination product, 2-methylindene, by expelling the intermediate carbonium ion from the electrode surface. Experimentally this was done by applying a positive pulse at + 1.8 V *vs.* SCE for two seconds and a negative pulse at − 1.8 V for one second. However, the amount of *4* did not increase. It is interesting to note that the side-chain acetates *5* and *6* made up 88 % of the products in this experiment, the highest value obtained in any experiment with *3*. This may have synthetic implications, since the pulse sequence used corresponds to changing polarity over the cell.

In a recent investigation on oxidative coupling of an isoquinoline derivative, the authors found stereospecific behaviour of an electrode process but not of an analogous homogeneous reaction.[14] They explained this behaviour with adsorption of the substrate at the electrode surface. Since the isoquinoline substrate used contained polarizable groups, 5,6-dimethoxy-2-methylindan was oxidized to trace if the presence of such groups in the systems pertinent to this work would enhance adsorption. Unfortunately no side-chain acetates were formed and thus no information regarding this aspect was obtained.

In some experiments using 2-methylindan as a substrate water was added to the electrolysis solution (see Table 1). This increased the

amount of side-chain alcohols formed. The addition of water might have given stereochemical information, since if acetate ions are preferentially adsorbed at the electrode surface, as is known from studies on the Kolbe reaction,[15] a substrate molecule which reacts not on, but in close vicinity of the electrode surface, should have different concentrations of the two nucleophiles on each side of the symmetry plane. If the substrate shows any preferred orientation this should be revealed in the *8:7* ratio. The result (*8:7* = 34:66) is, however, almost equal to the *cis-trans* ratio obtained in the homogeneous Co(III) oxidation.

EXPERIMENTAL

Materials. Analytical grade acetic acid (Merck AG, Germany) was frozen out twice. Anhydrous sodium acetate (analytical grade) was used as purchased (Merck AG, Germany). Tetrabutylammonium tetrafluoroborate was prepared as described previously.[16]

Electrolysis experiments. The electrolyses were carried out in a water-jacketed vessel, volume 55 ml. The upper part was ground planar to fit a "Quickfit" cover; catalogue number MAFo/50, with five B 10 necks. A saturated calomel electrode (Radiometer K 401 or K 4016) was used as reference electrode.

Electrode arrangement. In the case of platinum two parallel foils, 20 by 30 mm and 0.1 mm thick, at a distance of 15 mm from each other were freely immersed in the solution. When using carbon or lead dioxide anodes, one platinum foil was exchanged for a graphite plate, 20 by 30 mm and 5 mm thick, or a lead dioxide plated (see below) graphite plate of the same dimensions. The electrode distance was the same as above. The porous tip of the reference electrode was placed between the electrodes as close to the anode as possible.

Efficient stirring was achieved with a magnetic stirrer. In all electrolysis experiments the temperature was kept at 25 ± 0.5 °C. The potentiostat was the TR.70/2 A type, equipped with an RB 1 type waveform generator, both from Chemical Electronics Co., Newcastle upon Tyne, England. The time calibration of the pulse length was performed with a Philips PM 3220 0 – 10 MHz oscilloscope. The amount of charge passed through the cell was measured by a 60 mV electronic integrator built by the electronic workshop, Chemical Center, Lund. The integrator was fed over a variable resistor.

Procedure for plating lead dioxide upon graphite. An acidic lead nitrate (200 g $Pb(NO_3)_2$/l, 10 g $Cu(NO_3)_2$/l, 4 g HNO_3/l, 1 g NaF/l) solution was placed in a two-compartment cell with a liquid junction. A copper wire was placed in the cathode compartment. The piece of graphite to be plated was then rotated in the anode compartment with a speed of half a revolution per second. Sand was added to the anode compartment and stirred by a magnetic stirrer to puncture gas bubbles formed during plating in order to prevent the formation of holes in the lead dioxide layer. The current density was kept at 40 mA/cm^2.

Analytical procedures. GLC analysis was carried out using a Perkin-Elmer 880 gas chromatograph, equipped with a Perkin-Elmer Model D-26 Integrator. A 4 m 3 % OV-25 on Chromosorb W column was used for all analyses. Mass spectra were recorded by an LKB 9 000 mass spectrometer and NMR spectra by a Varian A-60 NMR spectrometer. Deuteriochloroform was used as solvent.

2-Methylindan was prepared by catalytic hydrogenation of 2-methylindanone-1.[17] 2-Methylindanone-1 (31 g) in acetic acid (93 ml) was shaken with 10 % palladium on carbon (1.5 g) in a Parr low pressure hydrogenation apparatus. The pressure had dropped to a constant value after 2 h. The solution was poured into water (400 ml). Potassium hydroxide (98 g) was used to neutralize the acid. After extraction three times with ether, the extracts were washed twice with water. After drying with anhydrous $MgSO_4$, the ether was evaporated and the residue distilled through a 20 cm Vigreux column, giving 19.9 g (72 %) of 2-methylindan, b.p. 66 – 68 °C/11 mmHg. NMR: δ 1.07 (d, J 5.5 Hz, 3, methyl protons), 2.16 – 3.16 (m, 5, aliphatic side-chain protons), 7.03 (s, 4, aromatic protons).

4- and 5-Nitro-2-methylindan. 2-Methylindan (6.6 g) was cooled in an ice-bath. A cold (< 10 °C) solution of 5 ml concentrated nitric acid (68 %) in 6 ml of concentrated sulphuric acid was added dropwise with stirring. The temperature was kept at 5 – 10 °C. After the addition of acid the reaction mixture was stirred for another 20 min with cooling and then the temperature was allowed to rise to ambient for 3 h. The reaction mixture was poured into ice water (200 ml) and stirred for 15 min. After extraction three times with ether the ether solution was washed with water, $NaHCO_3$ solution and water again. Anhydrous $MgSO_4$ was used for drying the ethereal solution. The solvent was evaporated and the residue, 7.2 g, was distilled *in vacuo* through a 5 cm Vigreux column giving 5.45 g (62 %) of 4- and 5-nitro-2-methylindan, b.p. 94 – 98 °C/0.3 mmHg. The isomers were formed in a 37:63 ratio, as determined by GLC, the major product being assigned the 5-structure [6] MS, see Table 4). NMR: δ 1.13 (d, J 6 Hz, 3, methyl protons) 2.30 – 3.70 (m, 5, aliphatic protons), 7.05 – 7.55 and 7.66 – 8.02 (m, 3, aromatic protons).

4- and 5-Amino-2-methylindan. The above mixture of 4- and 5-nitro-2-methylindan (5.2 g) was dissolved in ethanol (50 ml). Hydrazine hydrate, (100 %, 3.7 g) was added and the

Table 4. Retention times and mass spectral data for 2-methylindan and derivatives. Analysis carried out on a 3 % OV-25, on Chromosorb W column (4 m × 0.3 mm), temperature 80 – 250 °C, 6 °C/min, initial period 6 min.

Compound	Retention time, min	Mass spectrum, *m/e* (% of base peak)

4-Nitro-2-methylindan	22.6	178(3) 177(35) 160(100) 130(30) 129(24) 116(17) 115(53) 91(18)
5-Nitro-2-methylindan	23.6	178(10) 177(100) 160(27) 131(34) 130(32) 116(41) 115(48) 91(45)
4- and 5-Amino-2-methylindan	20.6	148(10) 147(100) 146(43) 133(12) 132(86) 131(17) 130(17)
4- and 5-Hydroxy-2-methylindan	20.4	149(6) 148(67) 147(16) 133(100) 131(16) 105(17)

solution warmed to 40 °C. Freshly prepared Raney nickel (0.25 g), suspended in a few ml of ethanol, was added in portions. When no further gas was evolved on adding the catalyst, the reaction was refluxed for one hour. The catalyst was filtered off. After evaporating the solvent *in vacuo*, the residue was distilled through a 5 cm Vigreux column giving 2.68 g (62 %) of 4- and 5-amino-2-methylindan, b.p. 72 – 74 °C/0.3 mmHg. The two isomers could not be separated by GLC, (MS, see Table 4). NMR: δ 1.10 (d, J 5 Hz, 3, methyl protons) 2.0 – 3.2 (m, 5, broadened aliphatic side-chain and amine protons) and 6.22 – 7.10 (m, 3, aromatic protons).

4- and 5-Hydroxy-2-methylindan.[18] To the above mixture of 4- and 5-amino-2-methylindan (2.36 g) was added concentrated sulfuric acid (4.7 g), water (2.7 g) and acetic acid (5 ml). Sodium nitrite (1.11 g) in water (6.5 ml) was then added dropwise, the temperature of the reaction mixture being kept below 5 °C. The reaction solution was then stirred at 0 °C for 30 min and at 100 °C for another 30 min. The ether solution was dried with $MgSO_4$ and the solvent removed in a rotating film evaporator. The residue was distilled yielding 1.04 g (44 %) of 4- and 5-hydroxy-2-methylindan, b.p. 72 – 74 °C/0.2 mmHg (MS, see Table 4). NMR: δ 1.13 (d, J 5.5 Hz, 3, methyl protons), 2.13 – 3.25 (m, 5, aliphatic side-chain protons), 5.18 (s, broadened, 1, hydroxylic proton), 6.43 – 7.23 (six discrete bands, with a strong singlet at δ 6.63, 3, aromatic protons).

4- and 5-Acetoxy-2-methylindan. The above mixture of 4- and 5-hydroxy-2-methylindan (0.9 g) was dissolved in acetic anhydride (30 ml). Two drops of pyridine were added and the solution refluxed overnight. After cooling, water (60 ml) was added. The mixture was allowed to stand with occasional shaking for 4 h. The water phase was extracted with ether. After drying with $MgSO_4$, the ether was removed in a rotating film evaporator. GLC of the residue showed two components in the ratio 44:56, (MS, see Table 4). NMR: δ 1.12 (d, J 6 Hz, 3, methyl protons in 2-position), 2.07 – 3.35 (m, 5, aliphatic side-chain), 2.22 (s, 3, methyl protons in acetoxy group), 6.63 – 7.20 (m, 3, aromatic protons, strong bands at 6.83 and 7.02).

Hydration of 2-methylindane.[5] Lithium aluminium hydride (0.2 g) in dry ether (15 ml), boron trifluoride etherate (0.9 g) and 2-methylindene (1.5 g) in dry ether (25 ml) were reacted according to Ref. 5. *trans*-2-Methylindanol-1 (1.49 g, 87 %) was isolated as crude product. NMR analysis showed traces of the *cis* form (appr. 5 %). Recrystallization from petroleum ether gave a sample melting at 88 °C. For NMR and MS, see below.

Reduction of 2-methylindanone-1 by aluminium isopropoxide. Aluminium isopropoxide (0.13 mol) in dry isopropyl alcohol (67 ml) was heated to reflux in a distilling flask connected. to a column of 7 – 8 theoretical plates 2-Methylindanone-1 (19.3 g) dissolved in dry isopropyl alcohol (40 ml) was added dropwise. Simul-

taneously with the addition of ketone, distillate was taken out from the still head at a rate of four drops a minute. When the addition of ketone was completed the distillation was continued until the temperature in the still head was 82.5 °C. The solution was allowed to cool and then poured onto ice (400 g). Hydrochloric acid (6 M) was added until acidic reaction was shown on indicator paper. The organic product was extracted with ether and the solution then washed with water and $NaHCO_3$ solution. After drying with $MgSO_4$ the ether was evaporated. Distillation of the white solid residue gave 15.7 g (80 %) of 1-hydroxy-2-methylindan, b.p. 116 – 117 °C/ 11 mmHg (MS, see Table 4). NMR: δ 1.16 (d, J 6 Hz, 3, $-CH_3$) 2.0 – 3.30 (m, 4, –OH proton at 2.55), 4.51 (d, J 6.8 Hz, α-H in *trans* form), 4.78 (d, J 6.0 Hz, α-H in *cis* form, *cis- trans* = 15:85) and 6.97 (m, 4 aromatic protons).

Reduction of 2-methylindanone-1 by lithium aluminium hydride. 2-Methylindanone-1 (2.92 g) dissolved in dry ether (10 ml) was added dropwise to lithium aluminium hydride (0.84 g) in dry ether (25 ml). After the addition of ketone, the solution was refluxed for 20 min. The excess of hydride was destroyed by water. After acidification, the water phase was extracted with ether. The ether solution was dried with $MgSO_4$. Evaporation of the ether gave a white solid residue of 1-hydroxy-2-methylindan (2.30 g, 78 %). NMR: as for reduction by aluminium isopropoxide, *cis-trans* = 33:66.

Reduction of 2-methylindanone-1 by sodium borohydride. 2-Methylindanone-1 (25 g) was dissolved in ethanol (99.5 %, 250 ml). Sodium borohydride (25 g) was added. The solution was stirred for 2 h. Additional sodium borohydride was added (12.5 g) and the solution stirred overnight. After addition of water (1 l) the reaction was extracted with ether. The ether solution was washed with water and dried with $MgSO_4$. Evaporation of the ether gave 11.2 g of 2-methylindanol-1 (44 %). GLC analysis showed no trace of the starting material. NMR analysis gave a *cis-trans* ratio of 20:80. For details of NMR spectrum, see above.

cis- and trans-*1-Acetoxy-2-methylindan.* A sample of 1-hydroxy-2-methylindan (0.4 g) (*cis-trans* ratio 15:85) was dissolved in acetic anhydride (5 ml) with a drop of pyridine added. The solution was refluxed overnight. The work-up procedure was the same as for the nuclear acetatets. NMR: δ 1.15 (d, J 6.5 Hz, 3, methyl protons), 2.05 (s, 3, methyl protons of the acetoxy group), *cis* and *trans* isomers not resolved due to the low intensity of the signal due to the *cis* isomer), 2.15 – 3.50 (m, 3, aliphatic protons in the side-chain), 5.84 (d, J 4.3 Hz, α-H to acetoxy group in the *trans* isomer), 6.06 (d, J 5.6 Hz, α-H to the acetoxy group in the *cis* isomer. The integral over the doublets corresponded to 1 H; *cis-trans* ratio = 15:85), 7.06 – 7.44 (m, 4 H, aromatic protons).

2-Methylindene.[19] 2-Methylindanol-1 (3.0 g, 85 % *trans* isomer) and phosphoric acid (1.5 g) were warmed slowly under reduced pressure to 130 – 140 °C. A lime coloured fluid (0.86 g) distilled over at a temperature of 80 °C in the still head. The distillate was taken up in ether, treated with $NaHCO_3$ solution and dried. The ether evaporated. NMR: δ 2.02 (s, 3, methyl protons), 3.10 (s. 2, $-CH_2-$ in aliphatic ring), 6.33 (unresolved quartet, 1, vinylic proton), 6.86 – 7.39 (m, 4, aromatic protons).

trans-1-(p-*Nitrobenzoyloxy)-2-methylindan.* 1-Hydroxy-2-methylindan (3 g, 85 % *trans* isomer) was dissolved in pyridine (35 ml). *p*-Nitrobenzoyl chloride (12 g) was added with cooling in an ice-bath. Thereafter, the reaction mixture was heated on a water-bath at 100 °C for 30 min. The reaction mixture was cooled to room temperature, poured on ice and acidified with concentrated hydrochloric acid. After suction and washing of the precipitate it was stirred in 0.05 M sodium hydroxide solution with addition of solid sodium hydroxide until the water remained alkaline to remove excess *p*-nitrobenzoic acid. After filtering, the product was air dried, giving 6.8 g of crude material. Recrystallization from ethanol, gave 2.4 g of *trans*-1-(*p*-nitrobenzoyloxy)2-methylindan, m.p. 81 – 82 °C. NMR: δ 1.23 (d, J = 6.8 Hz, 3, methyl protons), 2.26 – 3.65 (m, 3, aliphatic protons in side-chain), 6.04 (d, J = 4.0 Hz, 1, α-H to acyloxy group). No trace of the signal from the α proton of the *cis* isomer could be seen even when increasing the amplitude ten times, 7.25 (s, 4, aromatic protons in indan ring), 8.11 (s, 4, aromatic protons in *p*-nitrophenyl ring).

Solvolysis of trans-*1-*(p-*nitrobenzoyloxy)-2-methylindan.* The ester (1.0 g) was dissolved in glacial acetic acid (20 ml), 1 M in anhydrous sodium acetate and the solution kept at 75 ± 1 °C for 24 h. The acetic acid was neutralized in a $NaHCO_3$ slurry and the organic material extracted with ether. After washing and drying, the ether was evaporated. The NMR spectrum for the residue showed that the solvolysis had only run to approximately 60 %. The *cis-trans* ratio for side-chain acetates was 43:57 as measured from the integral of the α protons corrected for remaining *p*-nitrobenzoate. No significant amount of the elimination product, 2-methylindene, was detected. In an attempt to complete the solvolysis, the reaction time was extended to 3 d. The solvolysis still did not go to completion. Besides 12 % starting material, elimination now accounted for 22 % of the product.

Oxidation of 2-methylindan by cobalt(III) acetate. 2-Methylindan (645 mg) was dissolved in glacial acetic acid (50 ml) and cobaltic acetate [290 mg, 20 % in Co(III)][20] was added. The dark green homogeneous solution was kept at 70 ± 1 °C for 20 h. The work-up procedure was the same as for the electrolysis

Table 5. Retention times and mass spectral data for neopentylbenzene and derivatives. Analysis carried out on a 3 % OV-25 on Chromosorb W column (4 m × 0.3 mm), temperature 80 – 250 °C, 6 °C/min, initial period 6 min.

experiments. NMR analysis showed a *cis-trans* ratio of 37:63. GLC, see Table 1.

Neopentylbenzene was prepared according to a literature method,[21] yield 43 % (lit. 30 %), b.p. 63–67 °C/14 mmHg (MS, see Table 5). NMR: δ 0.89 (s, 9, *t*-butyl protons), 2.47 (s, 2, $-CH_2-$) and 7.13 (s, 5, aromatic protons).

1-Phenyl-2,2-dimethylpropanol-1. Pivalophenone (2.5 g), dissolved in dry ether (10 ml), was dropped onto lithium aluminium hydride (340 mg) in dry ether (25 ml) and the mixture stirred under reflux for 4 h. Water was then added dropwise. When no more hydrogen evolved, sulphuric acid (10 %, 40 ml) was added to dissolve the aluminium hydroxide. The organic material was collected by extraction with ether. The combined ether extracts were washed with $NaHCO_3$ solution and water, and then dried with $MgSO_4$. After evaporation of the solvent, distillation gave 0.67 g of product, b.p. 92–94 °C/12 mmHg (MS, see Table 5). NMR: δ 0.88 (s, 9, *t*-butyl), 2.16 (s, 1, $-OH$), 4.30 (s, 1, $-CH-$) and 7.22 (s, 5, aromatic protons).

1-Phenyl-2,2-dimethyl-1-propyl acetate. 1-Phenyl-2,2-dimethylpropanol-1 (0.48 g) was dissolved in acetic anhydride (5 ml), one drop of pyridine was added and the solution refluxed overnight. Working-up as for 4- and 5-acetoxy-2-methylindan gave a sample for NMR and mass spectral analysis (MS, see Table 5). NMR: δ 0.91 (s, 9, *t*-butyl), 2.00 (s, 3, $-OC-CH_3$), 5.47 (s, 1, $-CH-$ proton α to acetoxy group) and 7.20 (s, 5, aromatic protons).

Oxidation of neopentylbenzene with cobalt(III) acetate. Neopentylbenzene (776 mg) was dissolved in glacial acetic acid (50 ml). Cobaltic acetate [20 % $Co(OAc)_3$, 307 mg], was added and the solution kept at 110 °C for 20 h, after which the colour of the solution had turned pink. For product distribution, see Table 3.

2,2-Dimethylindanone-1.[22] 2-Methylindanone-1 (7.3 g) and methyl iodide (17.8 g) was dissolved in dry ether (125 ml). Potassium *t*-butoxide (14 g) was added in portions with stirring. After half a minute a vivid reaction started. The remaining base was added at such a rate that the solvent kept boiling. Addition completed, the reaction mixture was stirred under reflux for 2 h. Water (150 ml) was added and the phases separated. The water phase was extracted with ether. The combined ether solutions were washed with $NaHCO_3$ solution and very diluted sulphuric acid was added dropwise until gas evolution started. After drying and evaporation as earlier 8.3 g of 2,2-dimethylindan remained. GLC showed only one peak and the product was used without further purification (MS, see Table 5). NMR: δ 1.22 (s, 6, methyl protons), 2.98 (s, 2, methylene protons) and 7.23–7.85 (m, 4, aromatic protons).

2,2-Dimethylindan.[22] 2,2-Dimethylindanone-1 (8.3 g) was dissolved in glacial acetic acid (20 ml). Palladium on carbon (10 %, 0.8 g) was added as a catalyst. Hydrogenation and work-up procedure as for 2-methylindan. Distillation gave 2,2-dimethylindan (2.53 g), b.p. 65–66 °C/11 mmHg. NMR: δ 1.13 (s, 6, methyl protons), 2.68 (s, 4, methylene protons) and 7.07 (s, 4, aromatic protons).

Electrolysis experiments. The solvent-supporting electrolyte (50 ml) was poured into the electrolysis vessel. A background voltammogram was taken up measuring a stable current at each 0.1 V anode potential from 0 to +3 V *vs.* SCE. Then approximately 5 mmol of substrate was added. A new voltammogram was taken up and thereafter a preparative run was made until 25 % of the calculated charge for a 2e transfer process had passed. With platinum electrodes the anode potential was pulsed when necessary in order to diminish passivation of the electrodes which otherwise drastically lowered the current (2.9 s at working potential, 0.1 s at 0 V).

Work-up procedure. A sample of 5 ml was withdrawn from the electrolysis solution for determining current yield. Naphthalene (30–50 mg) was added as an internal standard and this solution was taken up in methylene chloride (25 ml). This solution was shaken with water (25 ml) and then with $NaHCO_3$ solution. After drying with anhydrous $MgSO_4$ the analysis was made by GLC. The remaining 45 ml of the electrolysis solution was diluted with methylene chloride (100 ml) and shaken with water (150 ml). The water phase was shaken with further methylene chloride (25 ml) and the combined organic extracts were then shaken with $NaHCO_3$ solution until no more gas evolved. After separation of the phases, the organic layer was dried and the solvent evaporated. The residue was used for product analysis, NMR and MS.

Acknowledgements. The author gratefully acknowledges valuable discussions with Professor Lennart Eberson and Docent Klas Nyberg. Fil. kand. Lars Cedheim has kindly provided compound *14*, the preparation of which will be published elsewhere. This work was supported by grants from the Swedish Natural Science Research Council, the Carl Trygger Foundation, the Royal Physiographic Society of Lund and the Faculty of Science, University of Lund. Part of the cost for the analytical equipment was defrayed by a grant from the Knut and Alice Wallenberg Foundation.

On the Reaction of 2,5-Dihalothiophenes with Tetracyanoethylene Oxide

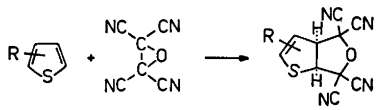
SALO GRONOWITZ and BENGT UPPSTRÖM*

Division of Organic Chemistry 1, Chemical Center, Box 740, S-220 07 Lund 7, Sweden

The reaction between 2,5-dihalothiophenes or 2,5-dihaloselenophenes and tetracyanoethylene oxide leads to 2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (IIIa) and 2,5-bis(dicyanomethylene)-2,5-dihydroselenophenes (IIId), respectively. Possible reaction paths are discussed.

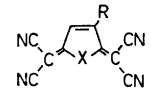
The reaction of 2,5-bis(dicyanomethylene)-3-bromo-2,5-dihydrothiophene (IIIb), obtained from 2,3,5-tribromothiophene and tetracyanoethylene oxide, with thiophenol gave 2,5-bis-(dicyanomethylene)-3-phenylthio-2,5-dihydrothiophene (VII).

Linn and coworkers [1,2] have shown that tetracyanoethylene oxide (I) adds to olefins and also to aromatic systems like benzene and thiophene in a stereospecific manner to give derivatives of tetracyanotetrahydrofurans. In connection with our general study of this cycloaddition reaction in the thiophene series, we made attempts to rearomatize the 1,1,3,3-tetracyano-1,3,3a,6a-tetrahydrothieno [2,3-c]-furans (II) formed and in this way open a new route to 2,3-disubstituted thiophenes.



I II

Our rearomatization attempts have hitherto failed. One of our hopes was that this could be achieved by adding I to 2,4- or 2,5-dibromothiophene followed by elimination of hydrogen bromide. 2,4-Dibromothiophene did not react. When 2,5-dibromothiophene was heated with I in ethylene bromide solution a red liquid started to reflux after a few hours. This liquid was distilled off and boiled at 60 – 65 °C and was identified as carbonyl cyanide by its reaction with *N*,*N*-dimethylaniline, yielding bis(*p*-dimethylaminophenyl)dicyanomethane.[3] From the reaction mixture, which contained 2,3,5-tribromothiophene and tetrabromothiophene (identified by combined VPC-MS analyses), an intense yellow compound could be isolated which by elemental analysis and mass spectrometry was shown to have the composition $C_{10}H_2N_4S$. The IR spectrum of this compound was unusually simple, showing only a few peaks, but indicated the presence of sp^2-hybridized C – H bonds and of nitrile groups. The ^1H NMR spectrum showed only one sharp peak at δ 7.33. The structure of this product was determined by X-ray crystallography and shown to be 2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (IIIa).[4]



III

a X = S, R = H
b X = S, R = Br
c X = S, R = Cl
d X = Se, R = H
e X = Se, R = Br

From the products formed in this reaction, the following stoichiometry seems reasonable:

* Taken in part from the Ph.D. thesis of Bengt Uppström, University of Lund, 1973.

The molecular bromine which is formed reacts immediately with the excess of 2,5-dibromothiophene to give 2,3,5-tribromothiophene and tetrabromothiophene. We checked of course that these compounds were not formed upon refluxing 2,5-dibromothiophene in ethylene bromide. Nor could we detect any appreciable amounts of carbonyl cyanide upon refluxing only I in ethylene dibromide. Based upon the above mentioned stoichiometry, the yield of IIIa calculated on I was as high as 70 %.

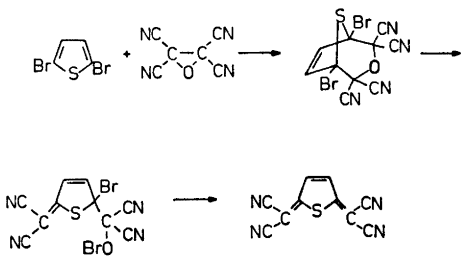
As we could find no precedent for this reaction in the literature, we were interested in studying its scope. We found that 2,3,5-tribromothiophene reacted similarly, yielding a compound $C_{10}HBrN_4S$ (IIIb), which was hydrogenolysed to IIIa over Pd on carbon. Also 2,3,5-trichlorothiophene, 2,5-dibromo- and 2,3,5-tribromoselenophene reacted similarly to give 3-chloro-2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (IIIc), 2,5-bis(dicyanomethylene)-2,5-dihydroselenophene (IIId), and 3-bromo-2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (IIIe). The yields, however, were in these cases much lower: 16, 26 and 38 %, respectively. Removal of carbonyl cyanide during the reaction by distillation, which in the reaction between 2,5-dibromothiophene and I doubled the yield, had no effect in these cases.

The reaction most probably also occurred with 2,3,5-triiodothiophene, but due to separation difficulties the product was not obtained pure. In the reaction of 2,5-dibromo-3-methyl thiophene with I only traces of the expected product were obtained.

In spite of several changes in the experimental conditions the yields could unfortunately not be increased. The long initiation period before carbonyl cyanide appeared in the reaction mixture led us to believe that the reaction was perhaps radical in nature. However, the addition of benzoyl peroxide had no effect on the reaction rate.

The mechanism of the reaction must be rather complex. The formation of carbonyl cyanide obviously makes the simple mechanism indicated in Scheme 1 less likely, if it is assumed that IIIa and carbonyl cyanide are formed in the same reactions.

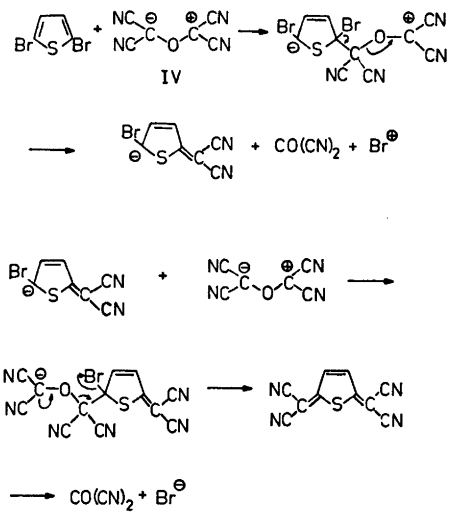
In this mechanism, it is assumed that I adds over the 2,5-position instead of the normal cycloaddition over the 2,3-bond. The bicyclic



Scheme 1.

adducts open and after complex elimination of Br_2O, IIIa is obtained. However, this path does not explain the formation of carbonyl cyanide.

In the normal cycloadditions of I to olefins and aromatics a 1,3-dipolar form of I (IV) has been assumed to be the reactive intermediate.[5] The following complex mechanism, shown in Scheme 2, can therefore be envisaged.

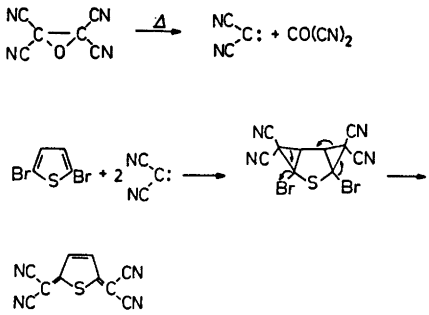


Scheme 2.

It is assumed that the 1,3-dipolar form of I first reacts as a nucleophile and the second molecule as an electrophile.

The opposite orders of attack are of course also possible, but appear even less likely than the reaction path indicated in Scheme 2. An important objection to this mechanism is the sluggishness with which non-activated halothiophenes undergo nucleophilic aromatic substitution.

Linn and coworkers [6,7] found that I was very susceptible to nucleophilic attack, which formally led to cleavage into the elements of carbonyl cyanide and dicyanomethylene. It is therefore not unlikely that by thermal dissociation or induced by nucleophilic species small amounts of dicyanomethylene are in equilibrium with I and that IIIa is formed as indicated in Scheme 3.



Scheme 3.

Schemes 2 and 3 are both in accordance with the products obtained.

We tried to obtain support for the mechanism in Scheme 3 by reacting 2,5-dibromothiophene with dicyanomethylene in the absence of carbonyl cyanide. Streith and Cassel,[8] through photolysis of pyridinium dicyanomethylide,[7] generated dicyanomethylene which added to benzene.

However, both photolytic and thermal attempts to obtain IIIa from 2,5-dibromothiophene and pyridinium dicyanomethylide failed. Dicyanomethylene has also been obtained from dicyanodiazomethane,[9] but due to the explosive nature of this precursor no experiments were undertaken with it.

A weak support for the mechanism indicated in Scheme 3 stems from the fact that in a few experiments tetracyanoethylene was observed as a minor by-product. This could possibly have been formed through dimerization of dicyanomethylene. The mechanism indicated in Scheme 1 could be disproven (or proven) by the use of ^{13}C labelled I.

The mass spectra of III show very little fragmentation. The total intensity of all other ions is 15 % of that of the molecular ion, indicating the stability of these compounds. The two unsubstituted derivatives primarily lose HCN from the molecular ion, and this is also true for the 3-methyl derivative. The halogen-substituted compounds first lose the halogen atom and the HCN.

Compounds III are analogues of the interesting tetracyanoquinodimethane (V). This compound can easily be reduced to *p*-phenylenedimalononitrile (VI) by reagents such as thiophenol, mercaptoacetic acid or hydroiodic acid.[10] Compound IIIa was, however, decomposed by hydroiodic acid and with thiophenol the starting material was recovered. IIIb on the other hand yielded with thiophenol in acetic acid a beautifully red, difficultly soluble compound, m.p. 215 – 216 °C, which according to mass spectrum and elemental analyses had the composition $C_{16}H_6N_4S_2$. Its NMR spectrum, which due to its difficult solubility had to be recorded in trifluoroacetic acid, shows two peaks at δ 7.08 and δ 6.64 with the relative intensities 5:1. These facts indicate that the compound is 3-phenylthio-2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (VII) and that nucleophilic substitution of the olefinic bromine had occurred.

EXPERIMENTAL

2,5-Bis(dicyanomethylene)-2,5-dihydrothiophene (IIIa). A solution of 24.0 g (0.10 mol) of 2,5-dibromothiophene and 5.0 g (0.035 mol) of tetracyanoethylene oxide [11] in 50 ml of 1,2-dibromoethane was heated with stirring in an oil-bath at 160 °C, in an apparatus arranged for distillation. After 3 h carbonyl cyanide started to distill of, b.p. 60 – 65 °C. After heating for an additional 2 h, 1.8 g (65 %) of carbonyl cyanide was obtained, characterized through reaction with *N,N*-dimethylaniline, yielding bis(*p*-dimethylaminophenyl)dicyanomethane, m.p. 193 – 194 °C; literature value,[3] m.p. 192 – 193 °C. The reaction mixture was cooled, carbon tetrachloride added, the precipitate filtered off and recrystallized, yielding 2.5 g (70 %) of the

title compound, m.p. 182–183 °C. The first filtrate was distilled and the high-boiling distillation residue (1.8 g) consisted according to VPC (column OV-17 (3 %) on gaschrom Q, 3 m × 3 mm) of 70 % 2,3,5-tribromothiophene and 30 % of tetrabromothiophene. NMR (CD_3COCD_3): δ 7.33. IR (KBr): 3120, 3100, 3050, 2220, 1550, 810, and 700 cm^{-1}. Mass spectrum (*m/e*, %): 212, 7; 211, 14; 210, 100; 185, 5; 183, 6; 121, 8; 118, 6; 108, 13; 94, 15; 83, 5; 82, 10; 76, 8; 75, 15; 70, 11; 69, 13; 64, 6; 63, 6; 62, 6; 57, 8; 55, 7; 45, 15; 43, 12; 41, 6; 40, 5; 38, 8; 37, 5; 32, 5; 28, 5; 27, 5. [Found: C 58.02; H 1.11; N 25.72; S 15.41. Calc. for $C_{10}H_2N_4S$: C 57.14; H 0.96; N 26.65; S 15.25.]

3-Bromo-2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (IIIb). A solution of 10.0 g (0.070 mol) of tetracyanoethylene oxide and 64.0 g (0.20 mol) of 2,3,5-tribromothiophene in 100 ml of 1,2-dibromoethane was refluxed for 24 h and filtered hot. After 2 d a black tarry product was isolated which was extracted with benzene in a Soxhlet apparatus. Evaporation yielded 2.8 g (28 %) of the title compound, m.p. 173–175 °C after recrystallization from benzene or chloroform. NMR (CD_3COCD_3): δ 8.22. IR (KBr): 3090, 2220, 1545, 1520, and 810 cm^{-1}. Mass spectrum (*m/e*, %): 292, 7; 291, 15; 290, 100; 289, 14; 288, 99; 265, 5; 263, 5; 210, 17; 209, 17; 199, 6; 165, 8; 157, 6; 145, 10; 144, 6; 138, 5; 124, 10; 121, 5; 120, 10; 119, 5; 118, 15; 113, 6; 108, 15; 106, 10; 101, 13; 100, 15; 98, 5; 94, 15; 93, 5; 92, 5; 89, 10; 88, 5; 87, 7; 86, 12; 82, 15; 81, 5; 80, 5; 79, 8; 76, 10; 75, 15; 74, 5; 70, 15; 69, 15; 68, 5; 64, 12; 63, 18; 62, 15; 61, 5; 60, 5; 49, 10; 45, 13; 44, 12; 38, 13; 37, 12; 32, 10. [Found: C 41.6; H 0.52; Br 27,7; N 19.1; S 10.9. Calc. for $C_{10}HBrN_4S$: C 41.5; H 0.35; Br 27.6; N 19.4; S 11.1.]

Hydrogenolysis of 3-bromo-2,5-bis(dicyanomethylene)-2,5-dihydrothiophene. In a Parr hydrogenation apparatus, 200 ml of peroxide-free dioxane, and 1.16 g of 3-bromo-2,5-bis(dicyanomethylene)-2,5-dihydrothiophene were placed. The mixture was hydrogenated at 5 atm. for 24 h, the catalyst filtered off and the dioxane removed *in vacuo*. The tarry residue was extracted with benzene, the benzene solution evaporated to a small volume, and then chromatographed on a silica gel column using benzene as eluent. 0.3 g (36 %) of 2,5-bis(dicyanomethylene)-2,5-dihydrothiophene, having the spectral properties as the sample described above was obtained.

3-Chloro-2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (IIIc). A solution of 18.7 g (0.10 mol) of 2,3,5-trichlorothiophene, 7.0 g (0.049 mol) of tetracyanoethylene oxide in 50 ml of 1,2-dibromoethane was refluxed for 48 h. The solution was filtered hot and evaporated to a volume of about 10 ml. The tarry product was filtered off and recrystallized from benzene (charcoal) to give 0.90 g (16 %) of the title compound, m.p. 180–181 °C. NMR (CD_3COCD_3) δ 8.15. IR (KBr): 3090, 2220, 1550, 920, and 865 cm^{-1}. Mass spectrum (*m/e*, %): 247, 5; 246, 40; 245, 15; 244, 100; 209, 8; 118, 8; 94, 10. [Found: C 49.1; H 0.55; Cl 14.35; N 22.95; S 13.00. Calc. for $C_{10}HClN_4S$ (244.7): C 49.09; H 0.41; Cl 14.49; N 22.90; S 13.11.]

2,5-Bis(dicyanomethylene)-2,5-dihydroselenophene (IIId). A solution of 28.9 g (0.10 mol) of 2,5-dibromoselenophene,[12] 5.0 g (0.035 mol) of tetracyanoethylene oxide in 50 ml of 1,2-dibromoethane was refluxed for 48 h. After filtration, evaporation and recrystallization from benzene, 1.2 g (26 %) of the title compound, m.p. 199–201 °C, was obtained. NMR (CD_3COCD_3): δ 7.93. IR (KBr): 3120, 3050, 2220, 1545, and 810 cm^{-1}. Mass spectrum (*m/e*, %): 259, 12; 258, 100; 257, 8; 256, 50; 255, 16; 231, 6; 178, 5; 142, 11; 140, 5; 125, 6; 124, 5; 118, 5; 101, 5; 100, 5; 93, 5; 80, 16; 78, 8; 76, 6; 75, 12; 63, 5; 62, 5. [Found: C 47.56; H 1.20; N 21.48 Calc. for $C_{10}H_2SeN_4$ (257.1): C 46.71; H 0.79; N 21.79.]

3-Bromo-2,5-bis(dicyanomethylene)-2,5-dihydroselenophene (IIIe). A solution of 36.8 g (0.10 mol) of 2,3,5-tribromoselenophene[12] and 5.0 g (0.035 mol) of tetracyanoethylene oxide in 50 ml of 1,2-dibromoethane was refluxed for 48 h. After filtration and evaporation, the residue was chromatographed on silica gel using benzene as eluent, yielding 2.2 g (38 %) of the title compound, m.p. 165–166 °C. NMR (CD_3COCD_3): δ 8.28. IR (KBr): 3080, 2215, 1535, and 750 cm^{-1}. Mass spectrum (*m/e*, %): 340, 12; 339, 10; 338, 78; 337, 12; 336, 100; 335, 16; 334, 45; 333, 12; 332, 14; 330, 11; 258, 5; 257, 16; 255, 6; 168, 11; 166, 10; 161, 12; 157, 6; 150, 8; 141, 12; 140, 5; 130, 5; 124, 16; 101, 16; 100, 12; 98, 5; 86, 7; 80, 21; 78, 6; 75, 18; 62, 7. [Found: C 35.64; H 0.56; Br 23.73; N 16.64; Se 23.40. Calc. for $C_{10}HBrN_4Se$ (336.0): C 35.75; H 0.30; Br 23.78; N 16.67; Se 23.50.]

3-Phenylthio-2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (VII). To a solution of 1.0 g (0.0035 mol) of 3-bromo-2,5-bis(dicyanomethylene)-2,5-dihydrothiophene in 100 ml of acetic acid, 0.55 g (0.0050 mol) of thiophenol was added and the acetic acid evaporated over night. The solid residue was washed with a little ether and chromatographed on silica gel using chloroform-ether (4:1) as eluent, yielding 0.60 g (54 %) of the title compound, m.p. 215–216 °C. NMR (CF_3COOH): $\delta_{C_6H_5}$ 7.08, δ_4 6.64. IR (KBr): 3070, 2230, 2210, 1538, 1490, 830, and 740 cm^{-1}. Mass spectrum (*m/e*, %): 320, 5; 318, 100; 293, 5; 292, 5; 291, 77; 261, 5; 260, 5; 259, 5; 254, 5; 253, 5; 233, 5; 210, 5; 110, 5; 109, 5; 108, 5; 94, 5; 89, 5; 84, 5; 83, 5; 77, 43; 75, 5; 69, 5; 66, 5; 65, 5; 51, 52; 50, 5; 45, 5; 39, 5. [Found: C 59.58; H 2.09; N 16.79; S 20.53. Calc. for $C_{16}H_6N_4S_2$ (318.4): C 60.30; H 1.90; N 17.60; S 20.14.]

IR spectra were recorded on a Perkin-Elmer 257 Grating Infrared Spectrophotometer, NMR spectra on a Varian A-60 spectrometer and mass spectra on an LKB 9000 mass spectrometer. The gas chromatographic analyses were

performed with a Perkin-Elmer 900 gas chromatograph.

Ionisation Potentials in Structure Analysis of Gaseous Hydroxypyridine 1-Oxides*

TRULS GRÖNNEBERG, TORGEIR HURUM and KJELL UNDHEIM

Department of Chemistry, University of Oslo, Oslo 3, Norway

The 3- and 4-isomers of the tautomeric hydroxypyridine 1-oxides exist predominantly in the hydroxy form in the gaseous state in the mass spectrometer. Internal hydrogen bonding in a pseudo-ring structure is suggested for the 2-isomer. The conclusions are based on comparisons of ionisation potential data.

Extensive physical measurements on the tautomerism of hydroxypyridine 1-oxides in solution and solid state have been carried out.[2] We wish to report studies of hydroxypyridine 1-oxides in the gaseous state by the determination of ionisation potentials (IP). IP determinations have recently been found very useful in structure analysis of gaseous molecules;[3-4] such data for the tautomeric hydroxy and amino pyridines have been interpreted in favour of the hydroxy and amino forms.[3,4]

Interpretation of the IP data for the hydroxypyridine 1-oxides (*1*—*3*) required corresponding data for the phenolic ethers (*4*—*6*) and the 1-methoxy analogues (*7*—*9*). These derivatives correspond to fixing the hydroxypyridine 1-oxides in either tautomeric form. The IP values were obtained by the semi-log plot method with xenon as reference gas.[6]

The influence of a substituent on the ease of ionisation depends on the nature of other substituents as well as on the ring system and relative position;[4,7] generally an electron releasing substituent decreases the IP. In the methoxypyridine 1-oxides the IP value (*4*—*6*) is increased by 0.2 eV from the 2- to the 3-isomer, but decreased by 0.4 eV from the 3- to the 4-isomer. The IP decrease of a methyl group relative to that of a hydrogen atom on a phenolic oxygen in simple systems is of the order 0.2—0.3 eV. This corresponds to the observed difference (0.2 eV) between the 3-methoxy isomer (*5*) and the 3-hydroxy isomer (*2*). The latter can be assumed to be present in the gas phase as such rather than as its tautomeric 1-hydroxy zwitterion. The charge separation introduced in the zwitterionic form will reduce the volatility compared to that of the non-charged 3-hydroxy form; furthermore, structures with charge separation should be disfavoured in the gas phase because at 10^{-6} Torr the charges cannot be dispersed by solvation or other intermolecular interactions. The IP for the 4-methoxy isomer (*6*) is also about

Table 1. Ionisation potentials.

[M−31]				–	11	5	3	1

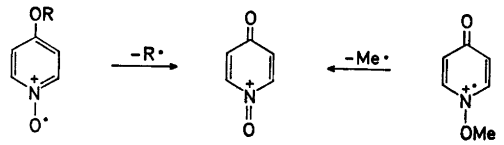
[a] [M−1]; [b] *m/e* 78 base peak; [c] *m/e* 39 base peak.

0.2 eV lower than for the 4-hydroxy isomer (*3*) which supports the hydroxy formulation for the latter. The difference (0.6 − 0.7 eV) between the 2-isomers (*1* and *4*), however, is too large to be inherent in the methyl group. Nor can the difference be explained by the molecule being in the form of 1-hydroxypyrid-2-one as IP of the model 1-methoxy derivative (*7*) is about 0.6 eV below that of (*1*); the effect of the *O*-methyl group is assumed to be of the same order as discussed above. It is well established, however, that *1* forms strong intramolecular hydrogen bonding.[2,8] A major part of the observed IP difference in the 2-series is therefore attributed to ground state destabilisation on *O*-alkylation which prevents intramolecular hydrogen bonding. Presumably the 2-hydroxy isomer, therefore, is present in the gas phase as a strongly hydrogen bonded molecule with structure in between those of the two tautomeric forms.

A further comparison of the IP data for the 4-isomers (*6* and *9*) supports the hydroxy formulation for *3*. Assuming similar effect from the methyl groups (0.2 eV) the estimated IP's for 4-hydroxypyridine 1-oxide and 1-hydroxypyrid-4-one are 8.2 and 8.7 eV, respectively; the former is in agreement with the observed value (8.18 eV).

The reproducibility of IP for the betaine (*8*) was poor; the value also appears higher than expected for a pyridinium betaine, and $[M-O]^+$ is a major fragment in its spectrum. The data are consistent with a large degree of transmethylation to the 3-methoxy derivative (*5*) before evaporation.

To verify that the gaseous molecules studied have not undergone structural rearrangements their characteristic primary fragmentations are summarised in Table 2. The mass spectra of heteroaromatic *N*-oxides are characterised by the $[M-O]^+$ and $[M-OH]^+$ fragments; the latter is the more important if a hydrogen can readily be abstracted from an α-substituent.[9,10] In the present series the molecular ion is the base peak except for the 2-isomers. The near absence of $[M-OH]^+$ in the spectrum of *2*, which has $[M-O]^+$ as base peak, shows that hydrogen abstraction is unfavourable when the hydrogen is situated on an electronegative atom such as oxygen. The $[M-OH]^+$ fragment is important, however, for the 2-methoxy derivative (*4*), presumably because of hydrogen abstraction from the *O*-methyl group. The isomeric 1-methoxypyrid-2-one (*7*) is characterised by the $[M-CH_2O]^{+\cdot}$ fragment. An interesting feature for the 4-isomers is loss of the substituent on the oxygen atom (Scheme 1). The driving force may be preferable charge stabilisation on the nitrogen atom with formation of a quinonoid structure.



3 R = H
6 R = Me

Scheme 1.

EXPERIMENTAL

The mass spectra were recorded on an AEI MS-902 mass spectrometer attached to an AEI DS30 data system. The electron energy was 70 eV and the ionising current 100 μA. During recording of the ionisation efficiency curves the repeller was at cage potential and the ionising

current 20 μA. Xenon was the reference compound. The IE-curves were interpreted by the semi-log plot method. The recorded IP values are the average of three determinations, the deviation being ± 0.05 eV except for compound *8* as discussed above. The compounds *1*, *7* and *4*, *5*, *9* were introduced by the indirect insertion system at 100 and 150 °C, respectively, and the remaining compounds by the direct insertion probe. The source temperature was 220 °C.

The compounds used were prepared according to the literature;[8,11,12] the reactive betaine (*8*) was isolated from its $MeHSO_4$-salt by freeze-drying of the eluate from an Amberlite IRA-400 (OH^-) column.

The Crystal Structure of 7-Hydroxy-6-methyl-7,6-borazarothieno[3,2-*c*]pyridine, $C_6H_7N_2BSO$

BENGT AURIVILLIUS and IRENE LÖFVING

Division of Inorganic Chemistry 2, Chemical Center, University of Lund, P.O.B. 740, S-220 07 Lund 7, Sweden

The crystal and molecular structure of 7-hydroxy-6-methyl-7,6-borazarothieno[3,2-*c*]-pyridine has been studied by the aid of three-dimensional X-ray integrated film data. The symmetry is monoclinic, space group $P2_1/c$. The unit cell contains 4 molecules $C_6H_7N_2BSO$ and the cell dimensions are $a=7.732(4)$, $b=10.059(4)$, $c=11.946(6)$ Å, $\beta=124.56(6)°$. The structure has been refined to an R-value of 0.080 (1135 independent reflections). The fused rings, C_5H_2BS, are approximately planar. Neglecting the substituents, the largest deviation from the best plane is 0.03 Å. The average of the various distances within the pyridine-like skeleton C_3N_2B is close to 1.40 Å.

Gronowitz and coworkers [1] have investigated several organoboron compounds from physicochemical and synthetic points of view. The aim of the present study was to investigate the planarity of the borazaropyridine ring which is isoelectronic with the pyridine ring, and also to determine its bond lengths. The substance chosen for this investigation was the compound 7-hydroxy-6-methyl-7,6-borazarothieno[3,2-*c*]pyridine. A study of the crystal structure of a related monocyclic compound, *e.g.* 5-ethyl-3-hydroxy-3,2-borazaropyridine,[2] would have been more appropriate for our purposes, but we have hitherto not succeeded in protecting these single crystals from deteriorating during the X-ray work.

7-Hydroxy-6-methyl-7,6-borazarothieno[3,2-*c*]pyridine, $C_6H_7N_2BSO$, was first synthesized by Gronowitz and Namtvedt.[3] Single crystals suitable for this study were kindly supplied by Dr. A. Maltesson. X-Ray powder diffraction photographs were recorded in a Guinier-Hägg focusing camera with Cu$K\alpha_1$ radiation and potassium chloride ($a=6.2909$ Å) added as an internal standard. The following lattice parameters were obtained with the aid of least-squares calculations: $a=7.732(4)$, $b=10.059(4)$, $c=11.946(6)$ Å, $\beta=124.56(6)°$, $V=768$ Å^3. The density observed by flotation methods was 1.40 g cm^{-3}. Assuming 4 formula units $C_6H_7N_2BSO$ per unit cell, the calculated density is 1.43 g cm^{-3}. The needle-shaped single crystals used for the X-ray work were enclosed in a Lindemann capillary over a saturated solution of the substance in water. The reason is that the substance decomposes in air of normal relative humidity. The capillary was mounted on an integrating Weissenberg camera, in such a way that the needle axis [001] was parallel to the rotation axis. The layers $hk0$ to $hk10$ were registered with Cu$K\alpha$ radiation. The multiple film technique was used, and the intensities of the reflections were measured with the aid of a Nonius Mark II micro densitometer. The following conditions limiting possible reflections were found: hkl, no conditions; $h0l$, $l=2n$; $0k0$, $k=2n$. These extinctions are characteristic of the space group $P2_1/c$ (No. 14). The intensities were corrected for Lorentz and polarization effects, but not for the absorption effects ($\mu=31.3$ cm^{-1}).

The crystal structure was solved by means of symbolic addition methods, using the program GAASA.[4] The program worked automatically, and peaks corresponding to the 11 non-hydrogen atoms in the asymmetric part of the unit cell could be recognized in the first E-map. The positions thus obtained were refined by means of least-squares calculations

using anisotropic temperature factors for all atoms. Difference Fourier maps revealed the positions of all hydrogen atoms except the one attached to the oxygen atom. A final refinement including all atoms but one hydrogen atom gave a conventional R value of 0.080 for all observed 1135 reflections. The R value for the 1121 reflections actually used in the refinement was 0.068. The reflections given non-zero weight in the refinement had $|F_o|$ values according to $0.5 \leq |F_o|/|F_c| \leq 2.0$. Cruickshank's weighting scheme with $A=1.5$, $C=0.17$ and $D=0$ was used. The S value (goodness of fit) was 0.17, and thus deviated heavily from 1, which is not unusual using film data. The final weighting scheme gave for ten $|F_o|$ intervals values of $\overline{w\Delta^2}$ between 0.6 and 1.6. The final positional and thermal parameters of the atoms are given in Table 1. Lists of observed and calculated $|F|$ values can be obtained on request from the Division of Inorganic Chemistry 2, Lund.

Table 1. Final positional and thermal parameters for 7-hydroxy-6-methyl-7,6-borazarothieno[3,2-c] pyridine. Standard deviations are given in parentheses. The anisotropic thermal parameters are based on the expression: exp $[-(h^2\beta_{11}+k^2\beta_{22}+l^2\beta_{33}+2hk\beta_{12}+2hl\beta_{13}+2kl\beta_{23})]$.

DISCUSSION OF THE STRUCTURE

Intramolecular distances. One molecule of 7-hydroxy-6-methyl-7,6-borazarothieno[3,2-c]-pyridine is projected on its best plane in Figs. 1a – 1c, where distances, angles, and deviations from the best plane are given. *E.s.d.*'s for distances between non-hydrogen atoms are 0.004 Å for carbon-sulfur interactions and

0.005 – 0.006 Å for other distances. *E.s.d.*'s for carbon-ring hydrogen bond lengths are 0.04 – 0.05 Å, and for carbon-methyl hydrogen distances 0.05 – 0.09 Å. *E.s.d.*'s for angles between non-hydrogen atoms are 0.2 – 0.3° and for angles involving only one hydrogen atom 3 – 5°.

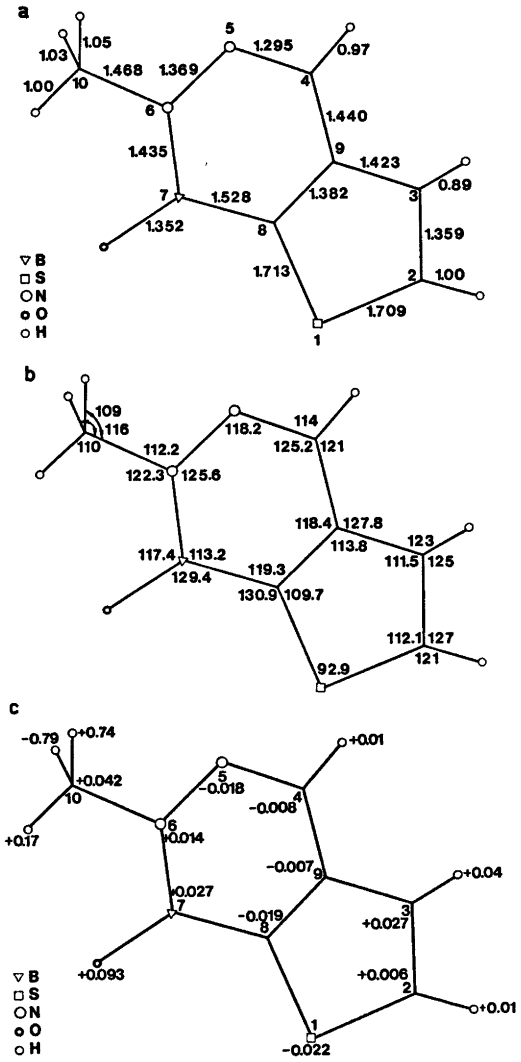

Fig. 1. Projection of one molecule of 7-hydroxy-6-methyl-7,6-borazarothieno[3,2-*c*]pyridine on its best plane. Fig. 1a shows the numbering of the atoms together with the intermolecular distances, Fig. 1b gives pertinent angles within the molecule, and Fig. 1c gives the deviations (Å) of the various atoms from a best plane calculated using only the nine ring atoms.

The various distances within the pyridine-like skeleton C_3N_2B differ significantly, but as expected their average is close to 1.40 Å. The C(4) – N(5) distance of 1.295(5) Å corresponds to a partial double bond and according to the curve given by Donohue, Lavine and Rollett [5] the π bond order is 0.67. The N(5) – N(6) distance of 1.369(4) Å is shorter than a single bond N – N and its length corresponds to π bond order of 0.45 according to calculations made by Sabesan and Ventkatesan.[6] The B(7) – N(6) distance of 1.435(5) Å is about the same as the B – N distance 1.424(1) Å found in hexachloroborazine in a recent refinement.[7] The B(7) – C(8) distance of 1.528(5) Å may be compared to the B – C distances in derivatives of the pyridine-like compound borin, C_5H_5B. Thus Huttner, Krieg and Gartzke,[8] in their paper on π complexes between cobolt(0) and two substituted borins, found an average B – C (ring) distance of 1.519(5) Å. The B – OH distance in the present compound is 1.352(5) Å. It is appreciably shorter than the value 1.395(7) Å given for a boron-ether oxygen distance in Ref. 8 but agrees fairly well with the value of 1.366 Å given for a formal single bond between three-coordinated boron and oxygen in a number of borates.[9] One noteworthy thing about the angles in the pyridine-like skeleton C_3BN_2 is that those around boron deviate appreciably from 120°. The distances and angles within the thiophene ring are normal. The fused rings C_5N_2BS are approximately planar. Neglecting the substituents, the best plane was calculated for the nine atoms of the ring skeleton. The largest deviations of the ring atoms from the plane occurred for the B(7) and C(3) atoms and amounted to +0.03 Å in both cases. The substituents O and C(10) were at distances of +0.09 and +0.04 Å, respectively, from the best plane (*cf.* Fig. 1c). The dihedral angle between the thiophene ring and the borazaropyridine ring is 178(6)° and does thus not deviate significantly from zero. The respective least-squares planes were calculated using only ring atoms. It may also be noted that one of the methyl hydrogen atoms is situated nearly in the ring plane, whereas the other two hydrogen atoms of the same group are situated at equal distances above and below the best plane.

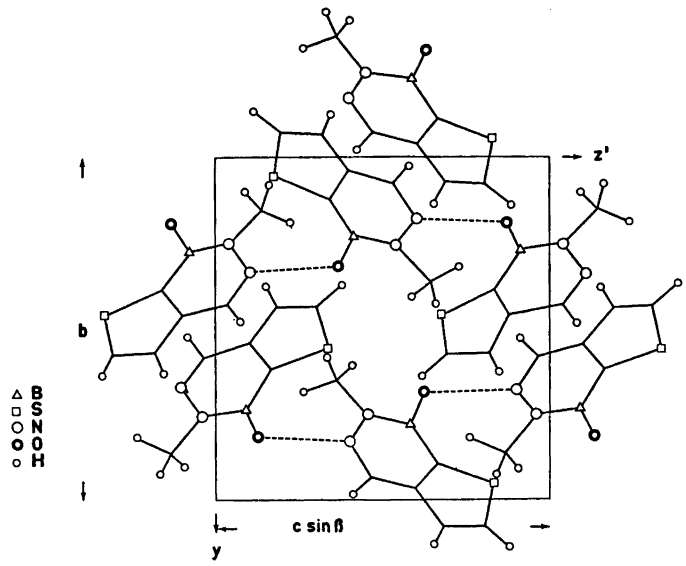

Fig. 2. Projection of the structure on a plane perpendicular to the *a*-axis.

Intermolecular distances. Fig. 2 shows the projection of the crystal structure on a plane perpendicular to the *a* axis. The molecules are joined by O–H···N hydrogen bonds to two chains, identical by centrosymmetry. The corresponding O–N distances are 2.789(4) Å.

A final difference map showed a peak corresponding to 0.24 of the height of a hydrogen atom at the expected position of the H(OH) atom. However, the map also revealed peaks and pits, which measured in the same scale amounted to 0.3 and 0.6 units, respectively.

Except for the hydrogen bond just mentioned no other intermolecular distances shorter than the corresponding sums of the van der Waals radii occur.

These studies form part of a research program financially supported by the Swedish Natural Science Research Council.

A New Preparative Method for *trans* Alkenols*

ALF CLAESSON

Department of Organic Chemistry, Faculty of Pharmacy, University of Uppsala, Box 574, S-751 23 Uppsala, Sweden

Four 4-alken-1-ols (*3b–f*) have been prepared in a new stereoselective mode, which involves treatment of 5-(tetrahydro-2-pyranyloxy)-3-penten-1-ols and the corresponding 5-alkoxy derivatives (*2b–f*) with lithium aluminium hydride in refluxing dioxane. The method is an extension of a reported analogous reaction of 4-alkoxy-2-buten-1-ols, which gives rise to 3-alken-1-ols. 3-Penten-1-ol is prepared here using this latter method. Disubstituted olefinic alcohols are formed in a minimum *trans:cis* ratio of 97:3. The reaction is proposed to have a transition state with strong carbanion character.

According to our recent publication,[1] 3-alken-1-ols can be prepared in good yields using readily available acetylenes as key intermediates (*cf.* Scheme 1, $n=0$). Furthermore, this reaction is stereoselective as shown by the formation of 3-hepten-1-ol in a *trans:cis* ratio of 97:3 and ~100 % pure 2-methyl-*trans*-4-octen-2-ol. In the present paper we have included the preparation of *trans*-3-penten-1-ol, to further verify the high stereoselectivity in the formation of 3-alken-1-ols. Trisubstituted olefins, however, are formed with poor stereoselectivity, the ratio of *trans:cis* beeing 3:2 in the typical case.

We here wish to report on an extension of this new synthetic method to the stereoselective preparation of *trans*-4-alken-1-ols starting with the acetylenic derivatives *1b–f* (*cf.* Scheme 1, $n=1$, and Table 1).

RESULTS

The starting acetylenes *1a–f* were obtained using standard procedures. Their preparation has been described elsewhere.[8,23]

The preparations of *trans*-3-penten-1-ol (*3a*) and the 4-alkenols *3b–f* from the acetylenes *1a–f* were carried out as described for 3-alkenols in our previous work [1] (*cf.* Scheme 1 and Table 1). Partial hydrogenation of *1a–f* in hexane gave the corresponding alkoxy- or Thp-oxy-alkenols (*2a–f*) which without prior

purification were allowed to react with lithium aluminium hydride (LAH) in refluxing dioxane.

The *cis:trans* ratios of the so obtained alkenols *3a–e* were determined on GLC using 3 or 6 m long columns containing 20 % Carbowax 20 M or SE-30. In all cases, except that of *3e*, the corresponding *cis* alkenols were prepared independently to allow a correct assignment of the *cis:trans* ratios. *cis*-4-Hexen-1-ol,[2] *cis*-3-penten-1-ol,[3] and *cis*-4-octen-1-ol were obtained through partial hydrogenation of the corresponding 4-alkyn-1-ols.[2-4]

The *cis* and *trans*-4-hexen-1-ols separated on a 6 m Carbowax 20 M column with a ratio of retention times *cis:trans* = 1.09 at 25 min. Other authors have reported clean separation on PEG-1500.[5] In contrast, the isomers of 4-octen-1-ol could not be completely separated on a 6 m Carbowax column and there was no separation on a 3 m SE-30 column. The ratio of retention times for the *cis* and *trans* isomers was 1.06 at 25 min on Carbowax. However, the separation attained allowed an estimation accurate enough to establish the maximum content of the *cis* isomer indicated in the Table 1. No difference in the *cis:trans* ratios of 4-octen-1-ol from different starting materials (*1c* and *1d*) could be detected.

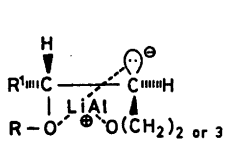
The tertiary alcohol *3e* was homogeneous on all the above columns even at retention times of about 1 h.

3-Penten-1-ol (*3a*) contained 3 % of the *cis* isomer, which is the same percentage, that we have reported [1] for 3-hepten-1-ol prepared in the same way. (R_t *cis*: R_t *trans* = 1.14 at 22 min on a 3 m Carbowax column).

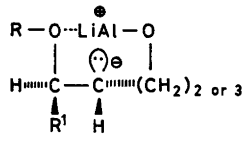
We have made use of the different chemical shifts in NMR of *cis* and *trans* methyl groups in trisubstituted olefins [6] in determining the isomer composition of some 4-methyl-3-alken-1-ols.[1] From the 100 MHz NMR spectrum of *3f*, it could be estimated that the *trans:cis* ratio was 3:2, in spite of some interference from methylene protons at δ 1.50.

DISCUSSION

The above formations of 3- and 4-alkenols formally constitute a type of allylic rearrangement (S_N2' reaction). However, mechanistically the question arises as to what degree the attack by hydride on the double bond and the expulsion of alkoxide are concerted.



4



5

There are essentially two main reaction mechanisms. (*i*) The first is a normal concerted reaction with a more or less synchronous attack by hydride and allylic rearrangement in the transition state. (*ii*) The reaction may also, in the extreme case, proceed in two steps *via* carbanions, that might be pictured as *4* or *5*, both of them affording *trans* olefins upon decomposition.

When considering the most likely mechanism one should have in mind that the double bond of allylic alcohols having a carbanion stabilizing group at C-3 is easily reduced by LAH with formation of an organometallic bond at this position. The cinnamyl alcohol system is particularly well investigated.[7]

Therefore, in the present case it seems reasonable to assume that attack by hydride on the double bond is well ahead of the expulsion of the alkoxide group, leading to a transition state having strong carbanion character. The reaction might possibly proceed *via* organometallic intermediates, which then is especially conceivable, when the poorly leaving *t*-butoxy group is substituted.

We have not been able to detect a hydrolysis product derived from carbanions such as *4* and *5*, which is not surprising in view of their expected instability. In an analogous reaction we have allowed acetylenic derivatives of type *1b–f* to react with LAH in tetrahydrofurane.[8] In contrast, this reaction proceeds *via* clearly detectable vinylic organometallic intermediates to β-allenic alcohols.

For a hypothetical organometallic intermediate there should be two possible modes of elimination, which are depicted as *4* and *5* and which are suggestive of the *anti* and *syn* modes of β-elimination [9-12] respectively, terms which, however, refer to the relative positions of groups, when they are eliminated from a stable molecule.

Drawings, such as *4* and *5*, also give a clear indication why the reaction is stereoselective, though they cannot explain the reason why the formation of 4-alken-1-ols is more stereoselective than that of 3-alken-1-ols (*cf.* *3a* and *3b*).

When speculating about the mechanism it is interesting to note the resemblance of the above new *trans* alkenol synthesis to some other more or less stereoselective formations of these products, which also proceed *via* elimination of an alkoxy group from an organometallic intermediate or *via* carbanionic transition states.[2,13–22]

One example of the reaction dealt with in this paper has actually been reported by other authors but was not applied to stereoselective synthesis. LAH reduction of 3,4-diphenyl-4-methoxy-2-cyclopenten-1-one gave 3,4-diphenyl-3-cyclopenten-1-ol in good yield.[22]

As indicated in Table 1 the yields of 4-alken-1-ols in the above reactions of 5-alkoxy-3-penten-1-ols with LAH are variable and they are also poorly reproducible (±15 % yield). However, because of the high stereoselectivity of the reaction it can be concluded that it should in some cases be useful for preparing *trans* 4-alken-1-ols.

EXPERIMENTAL

Infrared spectra were recorded on a Perkin-Elmer 15G spectrophotometer as a film between NaCl discs. NMR spectra were taken on solutions in $CDCl_3$ with tetramethylsilane as an internal standard, using a Perkin-Elmer R 12 B or a Varian HA 100 D spectrometer.

All reactions with Grignard reagents and $LiAlH_4$ were performed under nitrogen.

4-Alken-1-ols (3b–f) and 3-penten-1-ol (3a). General procedure. The acetylenes (*1a–f*) (0.02 mol) were hydrogenated in hexane over Lindlar catalyst (Fluka) at atmospheric pressure until the calculated volumes of hydrogen were adsorbed(1 – 3h) to give the corresponding olefinic alcohols (*2a–f*). The catalyst was filtered off and the solvent evaporated. The residue was dissolved in 15 ml of dioxane and slowly added dropwise to a stirred suspension of $LiAlH_4$ (0.03 mol) in dioxane. *Note:* It is important to allow complete alcoholate formation between $LiAlH_4$ and the alcohol before heating is started as otherwise a violent reaction may occur. After refluxing the reaction mixture was cautiously poured on ice and ether. The alcohol was taken up in ether, which was washed once with a saturated ammonium chloride solution and dried over potassium carbonate. Microdistillation or preparative GLC yielded the title compounds in states of purity exceeding 96 % on GLC.

2-Methyl-trans-5-octen-2-ol (3e) was isolated by preparative GLC (Carbowax 20 M). IR: 965 cm^{-1} (HC=CH, *trans*). NMR: δ 5.60 – 5.40 (m, 2 H), 2.30 – 1.75 (m, 5 H), 1.50 (t, 2 H), 1.20 (s, 6 H), 0.97 (t, 3 H). (Found: C 75.7; H 12.6. Calc. for $C_9H_{18}O$: C 76.02; H 12.76).

6-Methyl-5-octen-2-ol (3f) was isolated by microdistillation at an oil-bath temperature of 95 °C and a pressure of 11 mmHg. NMR: δ 5.35 – 5.05 (m, 1 H), 3.80 (sextet, 1 H), 2.80 (s, 1 H), 2.30 – 1.75 (m, 4 H), 1.65 (m, 3 H), 1.50 (q, 2 H), 1.20 (d, 3 H) and 0.96 (t, 3 H). The multiplet at δ 1.65 could be resolved at 100 MHz into a downfield multiplet and an upfield singlet, the latter interfering with the methylene quartet. Rel. areas ~2:3. (Found: C 75.9; H 12.7. Calc. for $C_9H_{18}O$: C 76.02; H 12.76).

Acknowledgement. I wish to thank Dr. Conny Bogentoft for valuable discussions and most stimulating co-operation, Professors Bruce Rickborn and Manfred Schlosser for their courtesy of making important comments. Furthermore, I am indebted to Professor Bengt Danielsson for commenting upon the manuscript, to my co-worker Dr. Lars-Inge Olsson for preparing some of the starting acetylenes and to Mr. Rolf Andersson, Agricultural College of Sweden, for recording the 100 MHz NMR spectrum. This work has been supported financially by the Swedish Natural Science Research Council.

X-Ray Crystallographic Studies on Cycloheptadithiophene Compounds and Similar Systems. II. The Crystal Structure of Bis(4-dithieno[3,2;2′,3′-*f*]borepinyl) Ether, $(C_{10}H_6BS_2)_2O$

BENGT AURIVILLIUS

Division of Inorganic Chemistry 2, Chemical Center, University of Lund, P.O.B. 740, S-220 07 Lund 7, Sweden

The crystal and molecular structure of bis(4-dithieno[3,2;2′,3′-*f*]borepinyl) ether has been studied by the aid of three-dimensional X-ray diffraction data. The symmetry is monoclinic, space group $C2/c$. The unit cell contains 4 molecules $(C_{10}H_6BS_2)_2O$ and the cell dimensions are: $a = 23.101(9)$ $b = 6.819(2)$, $c = 11.991(4)$ Å and $\beta = 97.79(3)°$. The structure has been refined to an R-value of 0.059 for 1896 reflections. Each $C_{10}H_6BS_2$ part is approximately planar. The largest deviation from the best plane occurs for the boron atom and amounts to 0.09 Å. A twofold axis passes through the ether oxygen atom and the whole molecule has a propeller form. The two non-equivalent B – C distances have equal lengths, 1.533(3) Å.

The present investigation is part of a more general study on the aromaticity of a number of cycloheptadithiophene compounds and dithienoborepines by Gronowitz and coworkers.[1,2] The crystal structure of dithieno[2,1-*b*;4,5-*b*′]-tropylium perchlorate[3] has previously been discussed by Gronowitz *et al.*,[4] who pointed out that the tropylium cations in the compound are essentially planar, the largest deviations from the planes being about 0.05 Å. Besides the approximate planarity of the molecule, the crystal structure determination[3] gave as a result that the sulfur to tropylium carbon atom distances were slightly longer than the purely thiophenic sulfur-carbon distances.

X-RAY WORK

The compound bis(4-dithieno[3,2;2′,3′-*f*]-borepinyl) ether, $(C_{10}H_6BS_2)_2O$, was first synthesized by Gronowitz, Gassne and Yom-Tov.[1] Later on Jeffries[5] described another route to the synthesis of the compound. Single crystals for the present work were kindly supplied by Dr Jeffries. X-Ray powder diffraction photographs were recorded in a Guinier-Hägg focusing camera with Cu$K\alpha_1$ radiation and potassium chloride (a = 6.2909 Å) added as an internal standard. The following lattice parameters were obtained with the aid of least-squares calculations: a = 23.101(9) Å, b = 6.819(2) Å, c = 11.991(4) Å, β = 97.79(3)°, V = 1871 Å^3. The density 1.47 g cm^{-3} was obtained by flotation methods. Assuming 4 formula units $(C_{10}H_6BS_2)_2O$ per unit cell, the calculated density is 1.48 g cm^{-3}. The single crystal used for the structure determination had the form of a nearly rhombic prism with the basal lengths 0.21 mm and the height 0.074 mm. The acute angle of the rhomb was 75°. The monoclinic b axis extended along the short basal diagonal and the c axis approximately along the long one. The a axis was perpendicular to the basal plane. Intensity data (graphite-monochromatized Cu$K\alpha_1$ radiation) were collected for 1896 reflections with an Enraf-Nonius single crystal diffractometer using the $\omega - 2\theta$ scan technique with a scan interval $\Delta\omega = (0.90 + 0.50 \tan\theta)$. The background was measured by extending the scan interval by ¼ at each end. Out of the 1896 reflections 127 are not above the background by giving net counts less than 10 in a fast prescan of approximately 13 s. On data reduction another 320 reflections, although considered

Table 1. Positional and thermal parameters of the atoms of $(C_{10}H_6BS_2)_2O$. Estimated standard deviations are given in parentheses. The anisotropic thermal parameters are based on the expression: $\exp[-(h^2\beta_{11}+k^2\beta_{22}+l^2\beta_{33}+2hk\beta_{12}+2hl\beta_{13}+2kl\beta_{23})]$.

above the background during the prescan, were found to be weaker than $3\sigma(I)$, where I is the intensity and $\sigma(I)$ its standard deviation. The intensities were corrected for Lorentz, polarization and absorption effects. The linear absorption coefficient used for the crystal was 44.6 cm^{-1}. Systematically absent reflections were hkl with $h+k=2n+1$ and $h0l$ with $l=2n+1$, indicating either the space group Cc (No. 9) or $C2/c$ (No. 15). As a reasonable structure was obtained assuming space group $C2/c$, the space group Cc was not further considered.

The positions of the sulfur atoms were derived from the three-dimensional Patterson function and the positions of all other atoms from successive difference Fourier maps. The positions of all atoms were refined using a full-matrix least-squares computer program. At this refinement all non-zero 1769 reflections were used, but reflections outside the limits $0.5 \leq |F_o|/|F_c| \leq 2.0$ were given zero weight. The number of zero-weighted reflections was 97, and all but one had initial I values less than $3\sigma(I)$. The weight factor used was $w_i = (\sigma^2(F_o) + 0.002 \cdot F_o^2 + 0.067)^{-1}$. Anisotropic temperature factors were used for the non-hydrogen and isotropic ones for the hydrogen atoms. The final R_1 values, $\sum|\Delta F|/\sum|F_o|$, were 0.0592 for all 1896 reflections and 0.0469 for 1672 reflections. The weighted factor $R_2 = (\sum w_i(\Delta F)^2/\sum w_i(F_o)^2)^{1/2}$ was 0.0592 for the 1672 reflections. The value of S (goodness of fit) was 1.00. The final weighting scheme gave the following $\overline{w_i\Delta^2}$ values for the ten $|F_o|$ intervals: 0.34 for the $|F_o|$ interval 0.0 – 1.8 and 0.91 to 1.17 for the rest of the intervals. The isotropic formal equivalents of the anisotropic temperature factors for the non-hydrogen atoms varied between 2.88 and 5.07 Å^2. Final positional and thermal parameters of the atoms are given in Table 1. Lists of observed and calculated structure factors are available on request from the Division of Inorganic Chemistry 2, Lund.

DISCUSSION OF THE STRUCTURE

Intramolecular distances and angles. Pertinent distances and angles for the present compound are given in Fig. 1. *E.s.d.*'s for distances between non-hydrogen atoms vary between 0.002 and 0.004 Å, and corresponding values for angles between 0.1 and 0.2°. *E.s.d.*'s for

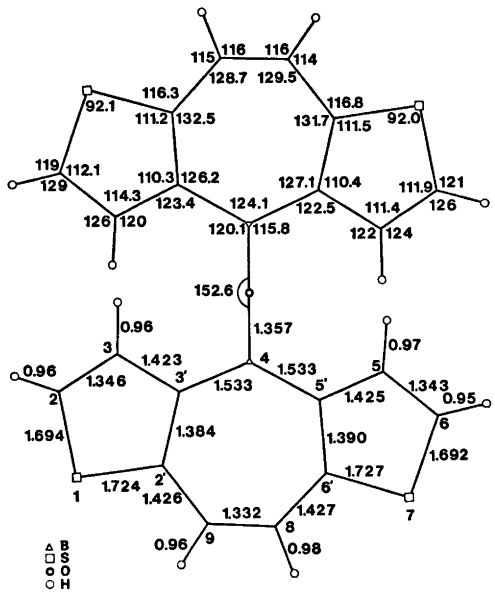

Fig. 1. Pertinent distances and angles in one $(C_{10}H_6BS_2)_2O$ molecule. Each $C_{10}H_6BS_2$ part is projected on its best plane. The carbon atoms are numbered but not marked.

carbon-hydrogen distances vary between 0.03 and 0.04 Å, and are about 2° for the S – C – H and C – C – H angles.

A twofold axis passes through the ether oxygen atom, and the whole molecule has a propeller form (Fig. 2). The two dithienoborepinyl parts form an acute angle of 63.2(7)°. As seen from Fig. 1, each $C_{10}H_6BS_2$ part of the molecule has an approximative symmetry plane passing through the boron atom B(4) and the midpoint of the line C(8) – C(9). The borepinyl ring is, however, not quite symmetrical; the corresponding angles within the ring differ at levels $(3.0 \pm 0.3)\sigma$. The difference between the external angles O – B(4) – C(3′) and O – B(4) – C(5′) is strongly significant, $\Delta/\sigma(\Delta)$ being 16. The two thiophene groups of the asymmetric part of the unit cell do not differ significantly with respect to the distances and angles. Each of the sulfur-borepinyl carbon distances [S(1) – C(2′); S(7) – C(6′)] is significantly longer than the purely thiophenic sulfur-carbon distances [S(1) – C(2); S(7) – C(6)], $\Delta/\sigma(\Delta)$ being 8 and 10 in the two cases. The same tendency was found for the sulfur-carbon distances in dithienotropylium perchlorate,[3]

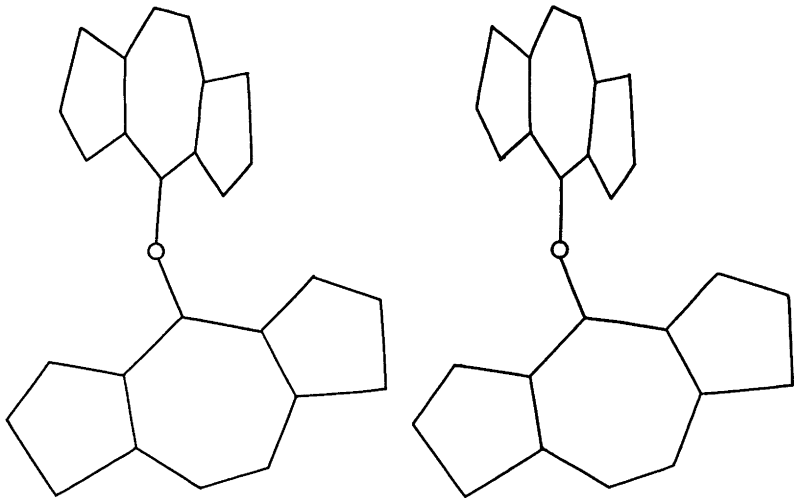

Fig. 2. A stereoscopic view of one $(C_{10}H_6BS_2)_2O$ molecule. Only non-hydrogen atoms are shown. The crystallographic y axis points towards the reader. The ether oxygen atom is marked by a small ring.

and the corresponding sulfur-carbon distances compare quite well in the two compounds. Similar disparities of C–S bonds in thiophene derivatives have been discussed by, *e.g.*, Goldberg and Shmueli,[6] who suggest that the longer sulfur-carbon bond is the one connecting sulfur to the carbon atom more actively engaged in the π delocalization (*e.g.* the borepinyl carbon atoms in the present compound). The fused double bonds C(2′)–C(3′) and C(5′)–C(6′) (Fig. 1) in the thiophene groups of the present borepinyl compound are significantly longer than the thiophenic ones, $\Delta/\sigma(\Delta)$ being 8 and 9, respectively.

The same situation was indicated in the crystal structure of dithienotropylium perchlorate.[3] The differences in the C–S and C–C distances may tend to support the view that the borepinyl ring, and probably also the tropylium ring, have aromatic properties.

The boron atoms are three-coordinated to two carbon atoms and one oxygen atom in a planar arrangement. The B–C distances are 1.533(3) Å. These distances are slightly longer, or perhaps equal to, the bond length 1.519(5) Å obtained for the B–C distances in the borin (C_5H_5B) skeleton.[7] It may also be mentioned that similar short B–C distances, 1.528(5) Å, have also been found in 7-hydroxy-6-methyl-7,6-borazarothieno(3,2-*c*) pyridine.[8] The short B–C distances now obtained seem reasonable since the boron atom takes part in a borepinyl ring. Another consequence of this participation is that the C(3′)–B(4)–C(5′) angle is larger than 120°. The boron-ether oxygen distance, 1.357(2), is shorter than the B–O distance of 1.395(7) Å found by Huttner, Krieg and Gartzke[7] in bis(1-methoxyborinato)cobolt(0). It is also shorter than the mean value of the B–O distances, 1.372 Å, obtained for the crystal structure of B_2O_3 *I*, where boron is three-coordinated,[9] although individual bond lengths in this compound are as short as 1.34(2) Å. Thus the boron and oxygen atoms in the present compound are partially double bonded. However, the B–O distance, 1.357Å, compares well to the B–OH distance of 1.352(5) Å found in the borazaro compound,[8] discussed above. As mentioned previously, the boron atom has a planar coordination in the present structure. The angles around boron deviate significantly from 120°. The same situation is encountered in other compounds with three-coordinated boron, *e.g.* $Na_2B_4O_7$.[10] The B–O–B angle of 152.6(3)° (Fig. 1) is essentially larger than is usually found for boron-oxygen compounds. According to Krogh-Moe,[11] values of 123–138° are normal for intergroup B–O–B

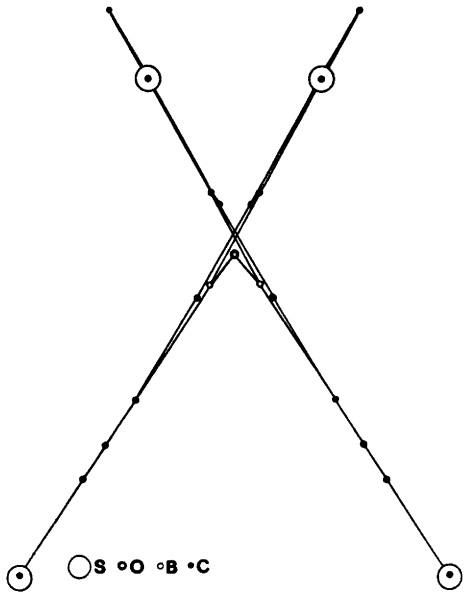

Fig. 3. Projection of one molecule of $(C_{10}H_6BS_2)_2O$ on a plane perpendicular to the line of intersection between the best planes of the $C_{10}H_6BS_2$ parts. Only non-hydrogen atoms are shown. Carbon atoms overlap sulfur atoms in four cases in the projection.

angles in complex borates.

Planarity of the different rings. The best plane through the $C_{10}H_6BS_2$ part was calculated using only the positions of the 13 non-hydrogen atoms, giving them all unit weight. The largest deviation from the plane occurred for the boron atom, amounting to 0.09 Å, whereas the deviations of the sulfur atoms were 0.04–0.05 Å. As mentioned in Ref. 3, the same calculations were made for the dithienotropylium cation, where deviations of 0.04 – 0.05 Å were found for the sulfur atoms, while all other atoms were closer to the best plane. Similar least-squares calculations were performed for the borepinyl ring only, using the positions of the 7 non-hydrogen atoms, and giving them unit weight. The largest departure from planarity, 0.038 Å, was found for the boron atom and the smallest one, 0.015 Å, for C(8). Calculations of the same kind for the tropylium ring[3] showed that no atom was more distant from the plane than 0.015 Å. Considering the *e.s.d.*'s of the atomic positions, it is concluded that neither the dithienoborepinyl parts, $C_{10}H_6BS_2$, nor the borepinyl parts, C_6B, of the present compound $(C_{10}H_6BS_2)_2O$, are planar from a statistical point of view. It also seems probable that the 7- and 13-membered rings of the borepinyl compound are less planar than the corresponding rings in the dithienotropylium cation.[3]

A projection of one molecule $(C_{10}H_6BS_2)_2O$ on a plane perpendicular to the common line to the best planes of the $C_{10}H_6BS_2$ parts is given in Fig. 3, which shows that the dithienoborepinyl parts have boat forms. However, the best planes were calculated for the two thiophene rings separately and the angle between the normals to these planes was found to be 4(2)°. Thus the boat form has no statistical significance.

Intermolecular distances. No intermolecular distances occurring in the crystal structure are shorter than the respective sums of the van der Waals radii. The shortest hydrogen-hydrogen interaction is 2.6 Å.

These studies form part of a research program financially supported by the Swedish Natural Science Research Council.

Studies on the Heterogeneity of Commercial Pronase-P Based on a Preparative Separation Method Using Sephadex G-75 Superfine

BO LÖFQVIST AND JAN-ERIK KLEVHAG

Biochemistry 1, Chemical Center, University of Lund, P.O.B. 740, S-220 07 Lund 7, Sweden

A highly improved separation method for Pronase-P was developed by gel chromatography on a specially selected more uniform fraction of the commercial superfine Sephadex G-75 beads under suitable packing and running conditions. A 10 × 90 cm bed capable of separating 1300 mg of Pronase was packed for preparative purposes and found to have better resolving efficiency than smaller columns. The enzymatically active material in Pronase was by this chromatography method separated into seven fractions with molecular weights ranging from 15 000 to 50 000 dalton. Thus Pronase components are far more heterogeneous in molecular size than had earlier been appreciated. Complete resolution was obtained between components of an estimated difference in molecular weight as small as 2000 – 3000 dalton. The possibility of intrinsic proteolysis causing specific digestion of some of the Pronase components was also demonstrated using the gel chromatography method. The results confirmed the extensive heterogeneity of Pronase earlier found using polyacrylamide gel electrophoresis, thus indicating the presence of at least 14 different enzymatically active components.

Pronase was first isolated by Nomoto and Narahashi [1] from the culture broth of *Streptomyces griseus* strain K1, and characterized as a homogeneous proteolytic enzyme with a broad substrate specificity. [2,3] Further characterization [4,5] revealed the presence of several proteolytically active components in Pronase. The most extensive analysis of the heterogeneity of Pronase to date was performed by Löfqvist and Sjöberg [6] using polyacrylamide gel electrophoresis. By this technique 14 different bands were resolved, of which 13 showed enzymatic activity using casein or LNA* as substrates. On the other hand Jurášek *et al.* [7] were able to separate only 6 different components using CM-Sephadex at pH 5 and a Ca^{2+} free medium. Since the electrophoretic separation method [6] permitted separation only on an analytical scale and further characterization of the heterogeneity of Pronase and the Pronase components required larger amounts of material, a preparative separation method had to be developed.

Already Nomoto *et al.*, [3] however, observed that the presence of Ca^{2+} ions was crucial to stabilize Pronase against autodigestion. In proceeding investigations [8] it has also been shown that different buffer-anions as well as pH have a marked influence on the stability of the Pronase components. Because of these restrictions in composition of the medium the number of suitable preparative separation techniques available was limited. In preliminary investigations the use of preparative polyacrylamide gel electrophoresis [9] was examined, but the resolution obtained was inferior to the separation of Pronase on analytical gels under similar conditions.

Since the resolution of gel chromatography is independent of the composition of the elution buffer, this technique was also considered suitable. The separation medium could thus be selected due to the stability demands of the Pronase components. Earlier reports [10,11] indi-

* *Non-standard abbreviations.* *N*-Benzoyl-L-arginine methyl ester.HCl, BAME; L-leucine-β-naphthylamide.HCl, LNA; Pronase-P lot No. 511324, Pronase I: Pronase-P lot No. 592045, Pronase IV.

cated that the molecular weights of four of the Pronase components were between 15 000 and 27 000 dalton. A preparative separation, using Sephadex G-75, therefore seemed possible. The present report describes the optimization of such a method based on a specially prepared Sephadex G-75 Superfine, and the application of this method to the examination of the heterogeneity and stability of Pronase-P.

MATERIALS AND METHODS

Pronase-P was purchased from Kaken Chemical Company, Tokyo, (lot No. 511324 and 592045, abbreviated Pronase I and IV). In the present investigation Pronase IV was used, while Pronase I was used only as a reference to the work of Löfqvist and Sjöberg.[6]

Sephadex G-75 (particle diameter in the dry state 40 – 120 μ), and Sephadex G-50, G-75, and G-100 Superfine (particle diameter in the dry state 10 – 40 μ) were obtained from Pharmacia Fine Chemicals. Several lots of G-75 Superfine, differing in resolving capacity, were used.

For the analysis of enzymatic activity were used L-leucine-β-naphthylamide.HCl, *N*-benzoyl-L-arginine methyl ester.HCl, ammonium sulfonate, N(1-naphthyl)-ethylenediamine dihydrochloride purchased from Sigma Chem. Co., and casein of Hammarsten grade from Merck AG. Acrylamide, *N,N'*-methylene-bisacrylamide and *N,N,N',N'*-tetramethylene diamine were obtained from Eastman Organic Chem. The staining of analytical gels was performed with Coomassie Blue (Sigma Chem. Co.).

Highly purified, crystallized samples of bovine serum albumin, soybean trypsin inhibitor, and lysozyme from Sigma Chem. Co., ovalbumin, β-lactoglobulin, and chymotrypsinogen from Calbiochem AG, and whale myoglobin from Schwartz were used for the estimation of the molecular weights of the Pronase components. All other reagents were of analytical grade.

Column chromatography. The columns used were, if nothing else is indicated, of the hydrodynamic precision type K 25/45 (bed size 2.5 × 40 cm), K 25/100 (bed size 2.5 × 90 cm), and K 100/100 (bed size 10 × 90 cm). (Pharmacia Fine Chemicals). UV-monitor and fraction collector for the eluate was from LKB-Products.

Gel swelling. The Sephadex beads were swelled for 24 h in standard buffer (30 mM boric acid – NaOH, pH 7.5; 30 mM $CaCl_2$; and 3 mM NaN_3). The same buffer was used for the separations, which were performed at 25 ± 0.5 °C.

Gel sieving. To obtain more defined beads the swelled gels were sieved on nylon nets allowing particles of maximum 40 μ to pass. During this procedure the small beads were washed through the net by buffer. The distribution in particle size in the obtained fractions was examined in a light microscope. As illustrated in Fig. 1, the sieving procedure gave a sharp cut in particle size between the beads, which stayed on the net, and those, which were washed through. In one case the beads that passed the 40 μ-net were also sieved on a 28 μ-net. The diameter of the beads, which were removed through the 40 μ- and 28 μ-net corresponded to 20 and 14 μ, respectively, in dry state.

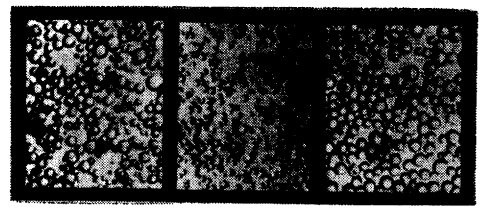

Fig. 1. The distribution in particle size of: (a) the beads of commercial Sephadex G-75 Superfine: (b) the beads removed by wet sieving on a 40 μ nylon net: (c) the residual beads after sieving.

Gel packing and sample application. In order to pack the Sephadex Superfine beads into a separating bed with good flow characteristics a special packing procedure had to be developed. A cylindrical perspex extention tube with the same inner diameter as the column was mounted on top of the column. The column was filled with buffer to a height of 5 cm above the bottom net (28 μ). The swelled gel was diluted to 1.5 – 1.6 bed volumes and filled into the center of the column along a glass rod. The lower end of the glass rod was kept below the liquid surface in the column. A 40 cm hydrostatic pressure was maintained during the packing procedure. Two or three bed volumes (V_t) of buffer were passed through the column before its flow properties were tested. The column K 100/100 had to be packed by a special procedure which will be reported separately as well as further details concerning optimal conditions for gel packing.

A solution (2 mg/ml) of Blue Dextran 2000 (Pharmacia Fine Chemicals) was used for control of the flow characteristics of the packed bed, and for determination of the void volume (V_0).

Pronase-P was dissolved in standard buffer at a concentration of 80 mg/ml. Samples were applied to columns within 2 min in order to reduce the intrinsic proteolysis of the Pronase components. The sample load was usually kept at 16 mg per cm^2 gel area. For all columns, except for K 100/100, the sample was applied by means of a syringe beneath the buffer surface on the top of the column.

Elution. The operating pressure was kept at

about 40 cm and regulated by a Mariotte flask to get a constant flow rate. The obtained flow rates for most beds were from 2 to 3 ml/cm² h. The smallest beads (diameter 14 – 20 μ in the dry state), and the K 100/100 column produced flow rates of 1.6 – 2.0 ml/cm² h. The collected fractions were stored at +4 °C.

Enzyme assays. Caseinolytic activity at pH 7.5 and 10 was measured according to the method of Kunitz, [12] activity towards BAME was determined using the method of Schwert *et al.* [13] and leucine aminopeptidase activity was measured using LNA by the method of Goldbarg and Ruthenburg, [14] all modified according to Löfqvist and Sjöberg.[6]

Analytical polyacrylamide gel electrophoresis was performed [6] in order to explore the heterogeneity of the gel chromatography peaks. Samples of either 20 or 50 μl of the column eluates were applied to the gels without prior concentration. The buffer used was 0.38 M Boric acid – 0.01 M CaO, pH 6.8.

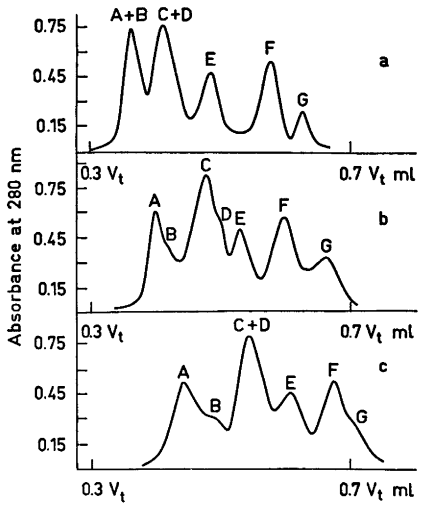

Fig. 3. The high molecular weight components of Pronase IV separated on a 2.5 × 40 cm bed of: (a) Sephadex G-50 Superfine: (b) Sephadex G-75 Superfine: (c) Sephadex G-100 Superfine. The flow rates were 2 – 3 ml/cm² h and the amount of sample applied was 16 mg/cm².

RESULTS

Conditions for preparative chromatography on Sephadex G-75 Superfine

The molecular weights determined for the Pronase components characterized so far [10,11] indicated that the pore size of Sephadex G-75 ought to be suitable for separation of Pronase. A 1.5 × 60 cm bed of Sephadex G-75 (particle diameter 40 – 120 μ in the dry state) was packed in a column of simple construction and examined for its resolving capacity on Pronase. A result similar to that of Narahashi *et al.*[15] was obtained (Fig. 2a). Two broad regions of A_{280}-absorbing material were eluted. The first region was poorly resolved into three fractions, which showed protease and peptidase activity using casein and LNA as substrates. The other region emerged close to V_t and contained components with a molecular weight below 5 000 dalton and without enzymatic activity. In order to examine whether a better resolution of the Pronase components could be obtained the column was repacked with Sephadex G-75 Superfine, particle size 10 – 40 μ in the dry state. (Usually these small beads are difficult to pack into separating beds with good flow characteristics and are therefore seldom used in column chromatography.) When Pronase was chromatographed on this bed (Fig. 2b) a better resolution than with G-75 was obtained of both the high and low molecular weight material. Five peaks could be distinguished in the high molecular weight region, and three peaks were indicated in the low molecular weight region. In order to further improve the separation results the packing procedure described in Materials and Methods was introduced along with the use of hydrodynamically more optimal columns (Pharmacia K 25/45). At the same time the separation on Sephadex G-50, G-75, and G-100 (all Superfine) were compared (Fig. 3) to establish the optimal pore size for

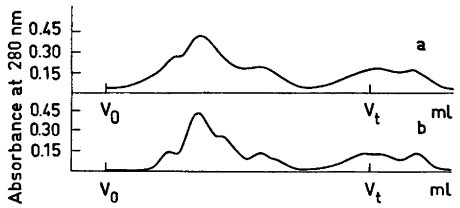

Fig. 2. The effect of bead size on the resolution of Pronase IV on a 1.5 × 60 cm gel chromatography bed of: (a) Sephadex G-75; (b) Sephadex G-75 Superfine. The rates of elution were 2.5 ml/cm² h and the amount of sample applied was 12 mg/cm².

the resolution of the Pronase components. Using Sephadex G-75 Superfine a remarkable improvement of the separation was noted on this bed compared to the results obtained on the earlier 1.5 × 60 cm bed (Fig. 2b). Thus seven different high molecular weight peaks (labelled A – G) were discerned, and five of these peaks were well separated from the other material. Using Sephadex G-50 Superfine a better resolution of F and G was achieved than with G-75 Superfine (Fig. 3a), while there was a poorer separation in the A – D region. As expected, the reverse was true, when Sephadex G-100 Superfine was used (Fig. 3c). With this material a better resolution of peaks A and B was obtained, while F and G separated poorly. Thus Sephadex G-75 Superfine was the most suitable for studies of the heterogeneity of Pronase, when an optimal separation of all the Pronase components was desired.

In order to improve the resolution of the Pronase components in peaks A – G a 2.5 × 90 cm bed was packed. For that purpose a new lot of Sephadex had to be used. The packing performance as well as the resolution of this lot of Sephadex G-75 Superfine was, however, not as good as expected. Therefore a number of different lots were tested. A considerable variation in the resolution power between the lots was found. The best lot was selected and packed in a K 25/100 column. The elution profile for Pronase fractions from this column is shown in Fig. 4a. The resolution was, however, still not complete between any of the peaks, and each peak eluted in a rather large volume. It was assumed that the variations in performance between different batches of Sephadex were due to inhomogeneities in particle size. Therefore, in an attempt to further improve the separation properties of the gel, the swelled Sephadex G-75 Superfine particles were sieved on a nylon net. About 10 % of the gel particles were in wet state smaller than 40 μ and passed through the net and were removed. The separation of Pronase-P on a bed (2.5 × 90 cm) packed with the sieved and more homogeneous gel material (Fig. 4b) resulted in an improved resolution compared to the unsieved gel (Fig. 4a). No new peaks were resolved but the elution volume for each peak was markedly reduced, clearly indicated by comparison of the elution volume of peak E in the two elution diagrams,

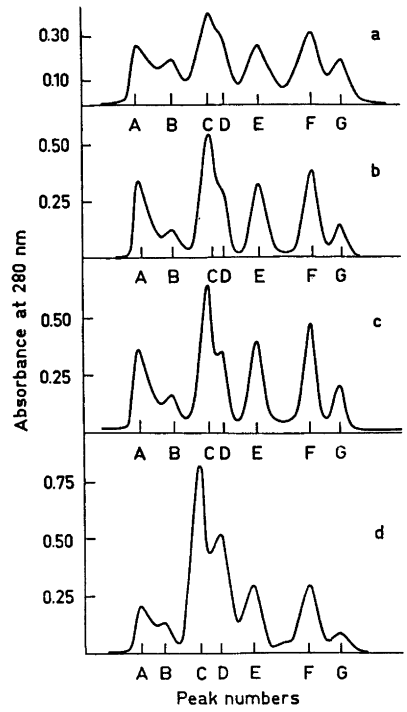

Fig. 4. The elution diagrams of the high molecular weight components in Pronase IV separated: (a) on a 2.5 × 90 cm bed of Sephadex G-75 Superfine (particle size 10 – 40 μ in the dry state): (b) on a 2.5 × 90 cm bed of sieved Sephadex G-75 Superfine (particle size 20 – 40 μ in the dry state): (c) on a 10 × 90 cm bed of sieved Sephadex G-75 Superfine (particle size 20 – 40 μ in the dry state). In (d) is shown the elution diagram of Pronase I on the same bed as used in (b). The flow rates were 1.6 – 3 ml/cm² h. The amount of sample applied was 16 mg/cm².

and a more complete separation of the peaks was thus obtained.

The same sieving procedure was also applied to batches with poor original resolving power in order to examine if their quality could be improved. This was, however, only possible to a limited extent, and it can for these batches be concluded that other factors than inhomogeneities in particle size are responsible for the poor separation characteristics. In accordance with the theory of gel chromatography [11] the smallest beads, which in wet state passed the 40 μ sieving net, should give a further improved resolution of the Pronase components. To facilitate the packing of this material it was

sieved further, and the smallest particles, which passed a 28 μ net, were removed. In spite of this fractionation it was not possible to pack the residual beads (particle diameter 14 – 20 μ in the dry state) into a separating bed with acceptable flow characteristics. Nevertheless a remarkably small zone spreading could be observed on the best packed bed, indicating that a further resolution could be achieved, provided a bed with good flow characteristics could be packed.

The applied amount of Pronase on the 2.5 × 90 cm bed (Fig. 4b) was 80 mg. With increased amounts of protein applied the resolution between the peaks declined considerably. Only a few mg of each component could therefore be obtained in each run. Consequently it was desirable to scale up the separation. A K 100/100 column was therefore packed, which with the same load per area would allow 16 times as much material to be separated. The separation obtained (Fig. 4c), where thus 1300 mg Pronase was chromatographed, was even better than that obtained when the K 25/100 column was used.

Investigation of Pronase heterogeneity

Qualitative and quantitative differences in the composition of different Pronase preparations. In all the separations presented so far Pronase IV was used. The elution diagram of Pronase I, the preparation used in earlier investigations,[6] is presented in Fig. 4d. A comparison of the K_{av} values for the peaks in Fig 4b and 4d (Table 2) indicated only small differences in the qualitative composition of the two Pronase preparations. Certain divergences were, however noted. Thus the K_{av} for peak A and D was substantially lower for Pronase IV than for Pronase I. The separation between peak D and E was also incomplete in the elution diagram of Pronase I. These differences were significant and reproducible, and indicate that the two analyzed Pronase preparations might contain different components.

The quantitative differences between the two Pronase preparations were more pronounced judged from the amount of A_{280}-absorbing material found in different peaks (Table 1). Thus peak A is proportionally larger in Pronase IV, while in Pronase I peaks C and D are more predominant. The amount of enzymatically inactive low-molecular A_{280}-absorbing material is about 30 % in both the Pronase batches tested.

Molecular weights of the Pronase components. The bed used for chromatography in Fig. 4b and 4d was calibrated with a number of proteins of known molecular weights. When the logarithm of their molecular weights were plotted against the determined V_e/V_0 (Fig. 5) a straight line was obtained. The V_e/V_0 values for the peaks of Pronase IV are also indicated in Fig. 5. and show that the approximate molecular weights of the Pronase components vary between 15 000 and 50 000 dalton. Thus the Pronase components exhibit a much larger variation in molecular size than was suggested by the ultracentrifugation studies of Narahashi *et al.*,[15] where a single peak corresponding to a molecular weight of 20 000 dalton was obtained. The

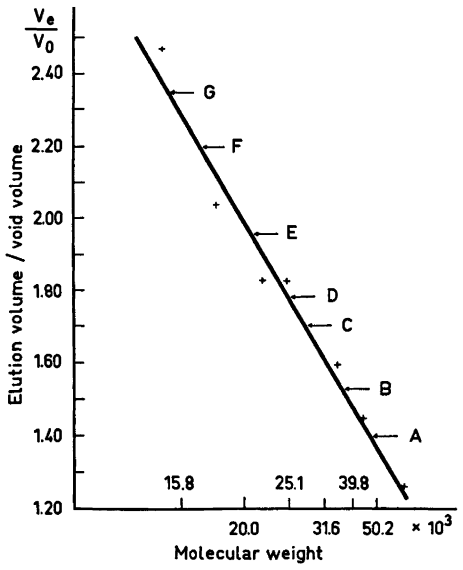

Fig. 5. The elution volume/void volume (V_e/V_0) of a series of standard proteins (see Materials and Methods) *versus* their molecular weights. V_e/V_0 values for the chromatographically separated peaks A – G are indicated by arrows.

molecular weight of peak G (15 000 dalton) corresponds well to the value (17 750 dalton) calculated by Bauer and Löfqvist [16] from the amino acid composition. On the other hand peak A with an apparent molecular weight of 50 000 dalton shows a molecular weight twice as high as previously reported for any Pronase component.[10,11]

Electrophoretic analysis of the different gel chromatography peaks. In order to identify the Pronase components present in the different peaks in terms of the electrophoretic bands identified by Löfqvist and Sjöberg [6] analytical polyacrylamide gel electrophoreses were run on each of the seven peaks in the elution diagrams presented in Fig. 4b and 4d. The content of electrophoretic bands in the two Pronase preparations are given in Table 2. All the major bands of Pronase I,[6] except band 11, which could not be examined in the buffer system used, were identified in the chromatography peaks. This further establishes that the heterogeneity of Pronase is actually as extensive as earlier shown [6] and not caused by intrinsic proteolysis during the separation. Most of the major electrophoretic bands of Pronase I were also identified in the corresponding peaks of Pronase IV (Table 2). A few interesting differences were, however, observed. Thus Pronase IV contained two components (one electrophoretic band 9 in peak A and one electrophoretic band 10 in peak CD), which were earlier not found in Pronase I.[6] On the other hand the major bands 2 and 5 occurring in peak F and the tailing edge of peak D of Pronase I were hardly detected or lacking in Pronase IV.

In addition to the major components minor bands appeared in most of the peaks of the elution diagrams. They only occupied a small fraction (less than 10 %) of the material in each peak and have either been regarded as

Table 2. The heterogeneity of the chromatography peaks A – G in terms of components found by analytical polyacrylamide gel electrophoresis.

Peak	Major electrophoretic bands[a] present in Both Pronase I and IV	Pronase IV only	Pronase I only	Minor electrophoretic bands present in Pronase I or IV
A	8	9	13 – 14[b]	–
B	6, 7	–	13 – 14[b]	8
C	12, 13 – 14[b]	–	–	4, 10, 9
D	13 – 14b, 10, 9	10[c]	5	4, 7, 12
E	4	–	–	7
F	1	–	2	3, 2
G	3	–	–	1

[a] The numbering of the bands refer to the earlier results by Löfqvist and Sjöberg.[6] [b] Band 13 and 14 were not separated in the system used for the electrophoretic analysis. [c] Band 10 appeared as a double band in Pronase IV.

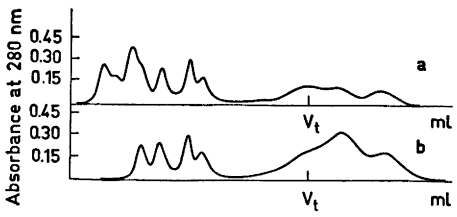

Fig. 6. The elution diagrams of Pronase IV in 30 mM ammonium acetate buffer, pH 4.8 (a) in the presence of 30 mM $CaCl_2$, (b) without $CaCl_2$ on a 2.5 × 90 cm bed of Sephadex G-75 Superfine. The flow rates were 5 ml/cm² h, and the sample loads were 16 mg/cm².

contaminants from a neighbouring peak or as impurities of less importance at this stage of investigation.

Stability of the Pronase components. The potential risk for intrinsic proteolysis of the Pronase components during the separation was considered as a critical factor in this investigation of the heterogeneity of Pronase. Since the resolving power of a Sephadex bed, however, is not influenced by the composition of the eluting medium used, the stability of the separated components in various media could be studied by comparing the elution profiles obtained in different buffers. This advantage of gel chromatography was used to investigate the stability of the Pronase components under the conditions used by Jurášek *et al.*[7] These investigators were able to identify 6 Pronase components after dialysis of Pronase against Ca^{2+} -free acetate buffer pH 5 and separation on a CM-Sephadex column. They thus concluded that "Pronase appears to be a less complex mixture of proteolytic enzymes than had previously been appreciated". When we separated Pronase on a 2.5 × 90 cm Sephadex G-75 Superfine bed equilibrated with a Ca^{2+}-free acetate buffer at pH 4.8 (Fig. 6b), peaks A, B and C were found to be completely digested into low molecular weight fragments. The protective effect of 30 mM Ca^{2+} under in other respects similar conditions is shown in Fig. 6a. The stability of peaks A, B, and C is remarkably increased but still not as good as that at pH 7.5 as judged by the amount of enzymatically inactive low molecular weight components produced. At pH 4.8 these occupy 40 % instead of the at pH 7.5 normally found 30 % of the A_{280}-absorbing material. This sign of increased intrinsic proteolysis was, however, not correlated with the disappearance of any particular peak in the elution diagram.

The stability of Pronase IV was further examined by analysis of the recovery of enzymatic activity after gel chromatography at pH 7.5 in the presence of Ca^{2+}. The residual enzymatic activities for a parallel sample of unfractionated Pronase IV stored beneath the Sephadex column (80 mg/ml) (Table 3) were also measured. A substantial loss in activity towards casein when analyzed at pH 7.5 and a small loss in activity towards BAME occurred both in the chromatographed Pronase sample and in the sample stored unfractionated. The activities towards casein at pH 10 and LNA were largely unaltered.

Table 3. Residual activity after separation of Pronase IV on Sephadex G-75 Superfine or preincubation at different concentrations in standard buffer.

Pronase IV dissolved in standard buffer at a concentration of	% Residual activity Casein at pH 7.5	Casein at pH 10	LNA	BAME
1.5 mg/ml	100	100	100	100
80 mg/ml, chromatographed and pooled before analysis	65	96	98	86
80 mg/ml, stored 36 h before analysis	61	90	97	87
80 mg/ml, diluted to 1.6 mg/ml after 2 min and analyzed	86	101	99	100

From Table 3 it can also be seen that the loss in activity is highly dependent on the concentration of Pronase in the solution. After 2 min of incubation a 15 % loss in enzymatic activity towards casein analyzed at pH 7.5 was observed at a Pronase concentration of 80 mg/ml. It thus appears that the presence of calcium ions was particularly important for the stability of the components that exhibited only neutral protease activity.

DISCUSSION

The resolution obtained by gel chromatography is highly dependent on the amount of sample applied. This fact is not always considered in practical separation work. Thus overloading especially in the case of complex samples often leads to a poor resolution. In the work of Narahashi *et al.* [15] and Awad *et al.*[10] 4 – 10 times as much Pronase was applied to Sephadex G-75 or G-100 columns as was used in the present report. Consequently this might be one reason, why these investigators were only able to partially separate two fractions and get weak indications of one additional component.

There are, however, several other parameters that have to be regarded in order to achieve good separation results on gel chromatography. The theory of gel chromatography gives the relation of these parameters to each other as well as their contribution to the separation efficiency.[17] The applicability of the theory in practical separational work is, however, limited by restrictions like packing performance of the gel, uniformity of the beads and obtainable flow properties of a packed bed, and these factors have to be examined and optimized in experimental work.

The effect of packing procedure but also to some extent column design on the separation result is illustrated by comparison of Figs. 2b and 3b. The superfine beads were found to be more difficult to pack and thus the in theory predicted advantage of using small beads was limited by the poorer packability of these beads. By modification of the packing procedure it was, however, possible to obtain a separating bed giving account for the larger resolving capacity expected from superfine beads. Further improvement of the separation results was also achieved, when a more uniform preparation of superfine beads (particle diameter in the dry state 20 – 40 μ instead of the normal 10 – 40 μ) was used. This was most likely due to improved packing performance of the gel with the more uniform particle distribution. The differences in resolving efficiency from one batch of Sephadex G-75 Superfine to another also indicated the presence of other hitherto not described variations in the uniformity of the Sephadex beads. Investigations in progress show that the separation efficiency can be further improved by partial elimination of such variations. The improved gel chromatography method on Sephadex G-75 Superfine columns, as described in the present paper showed, however, that the Pronase components were far more heterogeneous in molecular size than had earlier been appreciated. Thus Pronase was separated into seven peaks with molecular weights ranging from 15 000 to 50 000 dalton and with complete resolution between components of an estimated difference in molecular weight as small as 2000 – 3000 dalton.

Through analysis of each of the gel chromatography peaks by polyacrylamide gel electrophoresis the qualitative nature of the Pronase heterogeneity was investigated. From the result thereby obtained and the enzymatic activities observed for the different electrophoretic bands [6] it can be concluded that chromatography peaks A – D contain neutral proteases as well as leucine aminopeptidases. In the absence of Ca^{2+} ions at pH 4.8 these components are found to be highly susceptible to autodigestion and peaks A, B, and C are completely digested already during the course of separation. These results explain the findings of Jurášek *et al.* [7] that "Pronase appears to be a less complex mixture of proteolytic enzymes than had previously been appreciated", and that it does not contain any neutral proteases. The conditions used by Jurášek *et al.* [7] simply caused a total digestion of several of the Pronase components, and these investigators were only able to detect the most stable ones. A certain loss in neutral protease activity also occurred under the conditions used for the separations presented in this paper. This was probably caused by intrinsic proteolysis. The nature of the resulting products, however, has not been investigated, and the possibility that any of

the components originally present in Pronase are completely digested also under the conditions applied to this investigation cannot be excluded. However, this seems unlikely and is not supported by any results obtained by analysis of Pronase in various media on either gel chromatography or gel electrophoresis,[6] and we thus believe that the found heterogeneity gives a complete picture of the heterogeneity present in the investigated Pronase preparations.

Since the most pronounced heterogeneity is found in the region (A–D), where the neutral proteases are eluted and since both qualitative and quantitative variations (Tables 1 and 2) in the heterogeneity between different Pronase preparations also are found in this region, it can be questioned to which extent the found heterogeneity represents enzymes originally produced by the microorganism and to which extent the heterogeneity is caused by intrinsic proteolysis of the originally produced enzymes occurring during the fermentation and isolation processes. Further attention to the question of the originality of the identified Pronase components will be given in a separate paper.[18] At this stage, however, the fate of two of the Pronase components in the A–D region will be discussed in some detail.

Firstly peak D of Pronase I was found to contain electrophoretic band 5, not visible in Pronase IV. Peak D in Pronase I also showed a higher K_{av} than that of peak D in Pronase IV, causing a poor resolution between peak D and E. The component equivalent to electrophoretic band 5 thus seems to be eluted as the smallest component in peak D. In the investigation by Löfqvist and Sjöberg [6] band 5 was the only component, which was not active towards any of the substrates tested. Later studies have shown that this component is active towards *N*-carbobenzoxy-L-glycyl-L-leucine and thus corresponds to the carboxypeptidase in Pronase,[15] The molecular weight can be estimated at around 23 000 dalton.

Secondly Pronase IV was found to contain two components with the same electrophoretic mobility. Thus both peak A and D produced a major band in position 9. In Pronase I, however, band 9 was only found in peak D. In the earlier investigation [6] this band also showed activity towards casein at pH 10. The molecular weight of the components in peak D was found to be 25 000 dalton. Band 9 in peak D thus seems to correspond well with the subtilisin-like alkaline protease with a molecular weight of 28 000 dalton isolated by Gertler and Trop [11] and Awad *et al.*[10] The other band 9, which was only found in peak A of Pronase IV, seems to be responsible for the lower K_{av} obtained for that peak in Pronase IV and would thus have the largest molecular weight, 50 000 dalton, of the Pronase components.

The heterogeneity of the remaining peaks E, F, and G is less complex. In the case of Pronase IV only one main component is found in each peak. The K_{av} values as well as the amounts of A_{280}-absorbing material of the two Pronase preparations also agreed well, thus indicating a higher stability of these components. From the activities earlier observed for the electrophoretic bands [6] it can be concluded that peak E contains the trypsin-like enzyme in Pronase, further characterized by Jurášek and Smillie [19] and peak F the elastase-like enzyme III, described by Gertler and Trop. [11] Peak G finally contains an enzyme with broad substrate specificity, showing similarities to both elastase and chymotrypsin.[16,20]

Acknowledgements. We wish to express our gratitude to Professor Gösta Ehrensvärd for his continuous interest in our work, and to Miss Ylva Persson for her skilful technical assistance. We also like to thank Drs. B. Jergil and C.-A. Bauer for many valuable discussions.

Zinc Enzymes in Commercial Pronase-P. Further Characterization of the Heterogeneity of the Proteolytic Enzymes of the K-1 Strain of *Streptomyces griseus*

BO LÖFQVIST

Biochemistry 1, Chemical Center, University of Lund, P.O.B. 740, S-220 07 Lund 7, Sweden

Pronase has been shown to contain both zinc endopeptidases and zinc aminopeptidases. The zinc atom could be reversibly removed by pentaethylenehexamine in presence of 30 mM Ca^{2+}. A considerable heterogeneity was found within both groups of enzymes by separation on gel electrophoresis and gel chromatography, and it was concluded that limited proteolysis had occurred during the fermentation or isolation procedures of Pronase. Consequently it is uncertain to which extent the zinc enzymes present in Pronase are identical to the ones produced by the actinomycete. A minimum number of genuine enzymes, which could account for the observed heterogeneity, was suggested. This included two zinc endopeptidases and two zinc exopeptidases. In addition to these enzymes it was concluded that the K1 Strain of *Streptomyces* also produced one carboxypeptidase and four different serine endopeptidases. The catalytic mechanism of the carboxypeptidase was not conclusively elucidated. It was, however, proposed to be a metallo enzyme with a most firmly bound prosthetic ion.

Pronase, which was first isolated and characterized as a homogeneous extracellular enzyme produced by *Streptomyces griseus* Strain K1,[1] has been shown to be an extremely complex mixture of proteolytically active components.[2-4] Due to substrate analysis evidence has also been presented indicating that Pronase contains various groups of proteinases, namely neutral and alkaline proteases, aminopeptidases, and carboxypeptidases.[2,4-6] The heterogeneity of the alkaline proteinases is well established and four different enzymes have been identified. One of these is described as subtilisin-like,[7] while two show similarities to the mammalian proteinases from pancreas.[7,8] These three alkaline proteinases are thus found to be serine enzymes. The fourth component with alkaline proteinase activity has so far only been found in one particular batch of Pronase-P [4] and has not been further characterized. Further one serine proteinase, described as trypsin-like,[8,9] is present in Pronase, which hence is found to contain four or maybe five serine proteinases.

The other groups of proteinases in Pronase are less well-known and have so far not been subject to any extensive characterization. Narahashi *et al.*[10] observed that EDTA inhibits the amino- and carboxypeptidase activity as well as 65 % of the neutral proteinase activity. Although Ca^{2+} ions are known to be essential for the stability of Pronase,[11] it is not clear whether the inactivation caused by EDTA is due to destabilization of the tertiary structures of Pronase components by removal of the Ca^{2+} ions [12] or to inhibition of enzymatic activity of metallo enzymes by removal of prosthetic metal ions.

In a preceding paper [13] Löfqvist and Klevhag described the separation of Pronase into seven enzymatically active peaks by chromatography on Sephadex G-75 Superfine, as well as the heterogeneity of each peak on polyacrylamide gel electrophoresis. In this paper these different Pronase peaks are characterized further with respect to their metal ion requirement and enzymatic activity in order to elucidate the nature of the observed heterogeneity of Pronase.

EXPERIMENTAL

Materials. Enzyme: Pronase-P (lot No. 592 045, in the preceding paper[13] abbreviated Pronase IV) was obtained from the Kaken Chemical Company, Tokyo.

Inhibitors: Diisopropylfluorophosphate, pentaethylenehexamine, and 1,10-phenantrolin were products of Fluka AG.

Enzyme substrates: Casein of Hammarsten grade and glutaryl-L-phenylalanine-*p*-nitroanilide were obtained from Merck AG, L-leucine-β-naphthylamide.HCl and *N*-benzoyl-L-arginine methyl ester.HCl from Sigma, *N*-carbobenzoxy-L-glycyl-L-leucine and 4-phenylazobenzyloxycarbonyl-L-prolyl-L-leucyl-L-glycyl-L-prolyl-D arginine.$2H_2O$ from Fluka AG. All other low molecular weight substrates were purchased from Cyclo Chemical Co.

Separation methods. Preparative gel chromatography was performed on a 2.5 × 90 cm bed of Sephadex G-75 Superfine prepared according to Löfqvist and Klevhag.[13] The protein fractions were stored at 4 °C.

Preparative polyacrylamide gel electrophoresis: 1.4 mg Pronase or 100 μl of the eluate in peak F from the gel chromatography separation was applied in sucrose stabilized 0.38 M boric acid − 0.01 M CaO buffer, pH 6.8, to preflushed 1 × 10 cm gels and analyzed for enzymatic activity according to Löfqvist and Sjöberg.[4]

Analytical gel chromatography: A 2.5 + 90 cm Sephadex G-75 Superfine bed was used for analytical purposes by applying only 1 mg Pronase. An improved resolution was thereby obtained, but due to the low amount of A_{280} nm absorbing material the eluted Pronase components had to be identified by their enzymatic activity.

Determination of metal content. The metal content in Pronase was determined by atomic absorption spectrometry of suitable amounts dissolved in nitric and perchloric acid. Zinc was also determined directly in the eluted fractions from the gel chromatography column. Corrections for blanc values were made.

Inhibition procedures. Inhibition by both DFP* and penten was, unless otherwise specified, carried out directly on the eluate by incubation for 30 min in presence of at least 100 mol excess of the inhibitor. The zinc enzymes were reactivated by addition of $ZnCl_2$ in 20 % excess amounts compared to the concentration of penten. In case of the carboxypeptidases 5 ml of the fractions from the gel chromatography column were dialyzed towards 1 000 ml of 5×10^{-4} M EDTA or penten in standard buffer for 24 h at 4 °C.

Determination of enzymatic activity. Enzymatic activity towards casein, LNA and BAME was determined as described in the preceding paper.[13] Activity towards GPNA was measured at 40 °C according to the method of Erlanger *et al.* [14] as described by Bauer and Löfqvist.[15] Collagenolytic activity was determined at 40 °C according to the method of Wünsch and Heidrich.[16] Enzymatic activity towards all other substrates was assayed at 40 °C by the ninhydrin method.[17]

RESULTS

In order to examine if other metal ions than Ca^{2+} were present in Pronase an analysis using atomic absorption spectrometry was performed. The results obtained are collected in Table 1. The only metal ions found in substantial amounts except calcium were zinc and magnesium. Other ions like Co, Cu, and Cd were found only in trace amounts and were assumed insignificant for the enzymatic activity of the Pronase components.

Since no requirement for magnesium ions has been reported for proteolytic enzymes, these ions in Pronase were regarded as a residue from the culture medium of the actinomycete and their functional role was thus not further investigated. Zinc, however, has been observed as prosthetic metal ion in several proteinases of microbial origin [18,19] Assuming an average molecular weight of 30 000 dalton [13] for the Pronase components, the zinc content corresponded to one zinc atom for every fourth protein molecule. It was thus of interest to further investigate the role of zinc in Pronase.

Table 1. The amounts of metal ions (in ppm) found in commercial Pronase-P.

Calcium	99 000
Magnesium	720
Zinc	310
Cobalt	8
Nickel	9
Manganese	12
Cadmium	2
Copper	23
Lead	12

This has to be done in presence of calcium ions, since these were reported to stabilize the Pronase components. Consequently EDTA, which chelates both zinc and calcium ions, could not be used to remove the zinc ions. The addition of 10^2 molar excess of 1,10-phenantrolin, a commonly used chelating agent for zinc, gave only a slight inhibition of the activity of Pronase. Pentaethylenehexamine (penten) on the other hand was found to be more potent as a chelating agent for zinc.

Pronase (1 mg/ml) dissolved in a buffer containing 30 mM Ca^{2+} was treated with 1 mM penten and 1 mM DFP. After incubation for half an hour at room temperature no residual activity towards LNA, BAME or casein at neutral or alkaline pH could be observed. By addition of zinc to a final concentration of 1.2 mM approximately 65 % of the activity towards casein when analyzed at pH 7.5 and the leucineaminopeptidase activity were restored. No activity towards BAME or casein at pH 10 could, however, be detected under these conditions. These inhibition studies indicated that Pronase contained enzymes with two entirely different types of catalytic mechanisms, namely zinc proteinases and serine proteinases.

In order to investigate if zinc ions were bound to various Pronase components, Pronase was separated by gel chromatography on Sephadex G-75 Superfine,[13] and each fraction was analyzed for its zinc content by atomic absorption spectrometry (Fig. 1). It is seen that zinc is bound to Pronase components eluted in the first four peaks (A – D) of the elution diagram. No significant amount of zinc was detected in the remaining peaks E – G. In total, 65 % of the zinc present in the Pronase-P preparation was recovered in peaks A – D. The ratio of zinc content to A_{280} absorbance differed from peak to peak (Fig. 1). In peaks A and C the zinc content was low, around 1 ppm per unit of OD_{280} nm, while in peaks B and D it was around 2.5 times higher. These results thus show that there are zinc proteinases present in Pronase, and that these components are eluted in the first four peaks (A – D) from the gel chromatography column.

Zinc endopeptidases. The various zinc-containing Pronase components present in peaks A – D were further investigated as to substrate specificity. Thus aliquot of the fractions collected from the separation shown in Fig. 1 were treated with DFP in order to inhibit the serine proteinases and analyzed for activity towards casein at pH 7.5 and collagenase substrate A. Enzymatic activity towards both these substrates was found in the two peaks A and C (Fig. 2). A substantial tailing was found for peak A, but no indications for

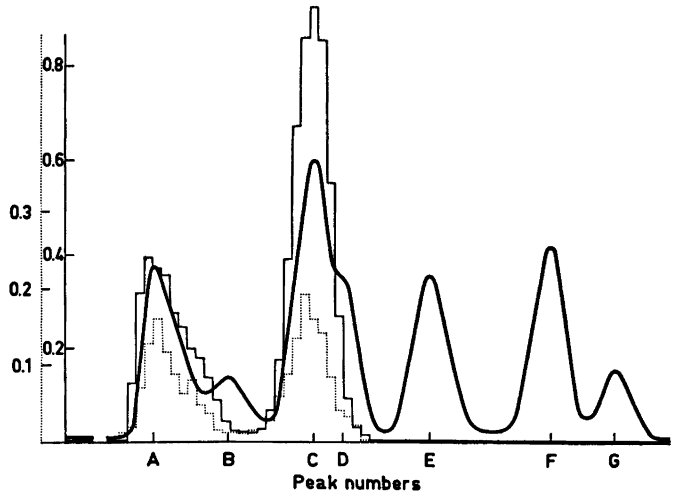

Fig. 2. Zinc endopeptidases found in Pronase-P after separation of 80 mg by gel chromatography on a 2.5 × 90 cm Sephadex G-75 Superfine bed. Fig. 3. Zinc aminopeptidases found in Pronase-P after separation of 80 mg by gel chromatography on a 2.5 × 90 cm Sephadex G-75 Superfine bed. The enzymatic activities were measured against LNA and pro-tyr and calculated as optical density per ml eluate and minute. — · —, LNA activity OD_{560} nm/min ml eluate; - - -, pro-tyr activity OD_{570} nm/min ml eluate.

heterogeneity in substrate specificity between different Pronase components within either one of peaks A and C [13] was found. Activity was also observed towards a number of other substrates, CBZ-gly-phe-NH_2, CBZ-gly-tyr-NH_2, CBZ-gly-leu-NH_2, CBZ-trp-leu-NH_2, and Ac-phe-tyr-NH_2, but also these substrates failed to indicate any differences in substrate specificity between the Pronase components in each of peaks A and C.

The DFP-treated fractions of peaks A–D were also made 1 mM with respect to penten

and tested for activity towards casein at pH 7.5 and collagenase substrate A. No residual enzymatic activity was found. The activity could, however, be completely restored by addition of zinc in excess amounts (1.2 mM). It was thus concluded that Pronase components eluted in peak A and C could be classified as zinc endopeptidases with neutral proteinase and collagenase activity.

Peaks A and C were found to contain low amounts of zinc compared to peaks B and D (Fig. 1), and it was questioned if the zinc endopeptidases had been depleted of zinc during the separation of Pronase on the gel chromatography column. This, however, did not seem to be the case to any substantial degree, since the enzymatic activity measured for the endopeptidases after reactivation with excess amounts of zinc was only 5 – 10 % higher than that observed prior to the penten inhibition.

Zinc aminopeptidases. Each fraction from the elution diagram shown in Fig. 1 was also tested for aminopeptidase activity using LNA and pro-tyr as substrates. The observed activities (Fig. 3) show that all the aminopeptidase activity in Pronase was present in peaks B and D. A complete inactivation of the LNA active fractions was observed by the addition of penten to a final concentration of 1 mM. The activity was restored by addition of excess amounts (1.2 mM) of zinc, as was the case for the zinc endopeptidases. Consequently it can be concluded that the aminopeptidases in Pronase are zinc exopeptidases.

Carboxypeptidases. A third category of enzymes found in Pronase are the carboxypeptidases, which have been described to have a substrate specificity similar to the mammalian carboxypeptidase A (E.C. 3.4.2.1) [2] using CBZ-gly-leu as substrate. Carboxypeptidase activity was found in peaks A, C, D and in the region between peaks D and E (Fig. 4). The activity in peaks A and C showed exactly the same elution profile as the zinc endopeptidases. Thus CBZ-gly-leu did not seem to be completely selective as a substrate in searching for carboxypeptidases in Pronase. The activity found in peak D and in the region between peak D and E, however, did not show any endopeptidase activity and thus seemed to correspond to components with true carboxypeptidase activity. Other substrates like CBZ-glu-tyr, CBZ-gly-phe and Ac-phe-tyr were also hydrolyzed by these carboxypeptidases.

In contrast to the zinc endopeptidases and the aminopeptidases the carboxypeptidase activity in peak D and in the region between

The enzymatic activities were measured against casein at pH 7.5 and 10, BAME and GPNA on fractions preincubated with 1 mM penten for 30 min and calculated as optical density per ml eluate and minute. I, Caseinolytic activity (pH 7.5) OD_{280} nm/min ml eluate; II, BAME activity OD_{253} nm/min ml eluate; III, caseinolytic activity (pH 10) OD_{280} nm/min ml eluate; IV, GPNA activity OD_{410} nm/min ml eluate. Roman numerals refer to the various enzymatic activities.

peaks D and E was not inhibited by 1 mM penten. Not even 10 mM penten followed by filtration on Sephadex G-25 or dialysis towards 0.5 mM penten or EDTA had any effect on the activity. Nor did 1 mM DFP show any effect on the carboxypeptidase activity. When the fractions were made 1 mM with respect to $HgCl_2$, however, the components were irreversibly inactivated.

Since the total amount of carboxypeptidase activity in the investigated batch of Pronase-P was found to be much lower than could be expected from the results of Narahashi *et al.*,[2] several other batches of Pronase were also analyzed for this activity. Large variations between different batches were found, and the Pronase I [4,18] for example contained 20 times more activity than the batch used in this investigation. The carboxypeptidase in Pronase thus seemed to be rather instable during the isolation procedure used for Pronase-P.

Serine endopeptidases. Another aliquot of each of the fractions from the elution diagram shown in Fig. 1 was made 1 mM with respect to penten to inhibit the zinc enzymes. A residual activity towards casein at neutral pH was found in peaks D, E, F, and G as shown in Fig. 5. The original activity in E, F, and G was unaffected by penten. Although the residual activity in peak D was found in the same fractions as the collagenase activity presented in Fig. 2. no activity was found when tested against collagenase substrate A or LNA in the presence of penten.

Subsequent incubation with DFP of these fractions showing neutral proteinase activity gave a complete inactivation, and no activity towards casein at pH 7.5 or pH 10, BAME or GPNA could be detected. This further established the presence of at least four different serine proteinases in Pronase.

Further examinations concerning the substrate specificity of the serine enzymes in peaks D – G were performed. Activity towards casein at pH 10 was found in peaks D, F, and G, while no such activity was found in peak E. On the other hand peak E was the only peak showing activity towards BAME and thus corresponded to the trypsin-like enzyme found in Pronase.[5,9]

Peaks D – G were also tested towards the chymotrypsin substrate GPNA. Activity was mainly found in peak G, as has already been reported by Bauer and Löfqvist,[15] but a small amount of activity was also present in peak F. Minor activities towards CBZ-glu-tyr, CBZ-gly-phe and Ac-phe-tyr were also found in peak F. These activities were not inhibited by 1 mM DFP or 1 mM penten. Dialysis towards 0.5 mM penten was, however, sufficient to cause an inactivation. The activities could then also be restored by the addition of excess

amounts of Zn^{2+}. By preparative polyacrylamide gel electrophoresis of the eluate in peak F it was possible to distinguish along with the main component in band position 1, also two minor bands in position 2 and 3. No neutral proteinase activity could be detected in these minor bands. They contained, however, all the carboxypeptidase activity found in peak F. It is thus likely that the weak band in position 2 observed in peak F of Pronase IV by Löfqvist and Klevhag [13] is not equivalent to the alkaline proteinase found in band position 2 in Pronase I.

Among the substrates tested CBZ-ala-val-OMe was found to be rather specific for the serine proteinase present in peak D. This enzyme was also active towards casein at pH 10, which further strengthened the suggestion [13] that the subtilisin-like component [7] in Pronase is found in this peak.

DISCUSSION

By use of the gel chromatography separation method of Löfqvist and Klevhag [13] Pronase has been found to be a mixture of mainly zinc- and serine-proteinases. The zinc enzymes are found in the first four peaks (A–D) of the elution diagram. Along with the zinc proteinases peak D also contained carboxypeptidase activity as well as a serine proteinase. The additional serine proteinases were eluted in peaks E, F, and G. The zinc enzymes were according to their substrate specificity divided into endo- and exopeptidases.

Zinc endopeptidases. Zinc has been found to be essential for the enzymatic activity of the endopeptidases eluted in peak A and C and could be exchanged reversibly in presence of 30 mM Ca^{2+}. It was thus concluded that these enzymes are zinc proteinases. The content of zinc corresponds to 0.8 and 0.5 zinc atoms per mol enzyme in peak A and C, respectively, as calculated from the molecular weights (50 000 and 28 000 dalton) [13] and an assumed ε(1 %, 1 cm) at 280 nm of 10. A considerable heterogeneity of the material eluted in peak A and C was found [13] by analysis on polyacrylamide gel electrophoresis and in accordance with the above calculated low zinc values it was questioned to which extent the components present in peak A and C were active enzymes. In the earlier separation of Pronase on polyacrylamide gel electrophoresis at pH 6.8 for 9 h [4] it is, for example, observed that one of the components in peak A (Band 8) was enzymatically inactive. A separation of Pronase on preparative polyacrylamide gel electrophoresis was thus performed in order to examine, whether the various components found within peak A and C were enzymatically active. As

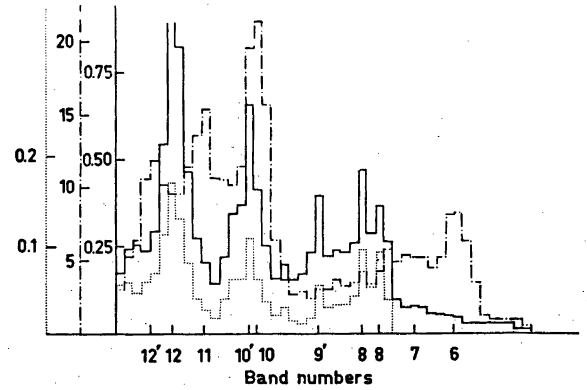

Fig. 6. Histogram showing the enzymatic activities of Pronase-P found in the different gel fractions of a small (1 × 10 cm) preparative polyacrylamide gel after 6 h electrophoresis (cathodic migration) in 0.38 M boric acid – 0.01 M CaO buffer. The gel fractions (0.5 mm thick) were extracted at pH 7.5 with standard buffer, incubated for half an hour with 1 mM DFP and tested for activity towards casein at pH 7.5 and 10 as well as LNA. The activities found are given in optical density per ml extract and hour. Band numbers are given as suggested by Löfqvist and Sjöberg [4] from the staining found in a duplicate run. —, Caseinolytic activity (pH 7.5) OD_{280} nm/h ml eluate; . . ., collagenase activity OD_{410} nm/h ml eluate; — · —, LNA activity OD_{560} nm/h ml eluate.

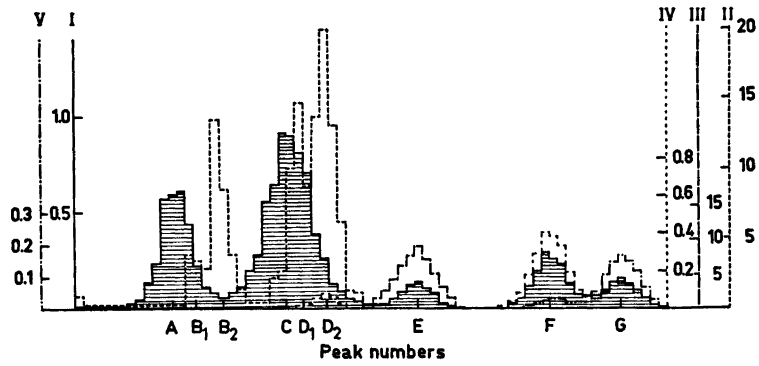

Fig. 7. Analysis of the heterogeneity of Pronase-P due to molecular size by separation of 1 mg on a 2.5 × 90 cm Sephadex G-75 Superfine bed. The separated components were identified by their enzymatic activities towards casein at pH 7.5 and 10, LNA, BAME and GPNA. The amount of activity found is calculated as optical density per ml eluate and hour. I, Caseinolytic activity (pH 7.5) OD_{280} nm/h ml eluate; II, LNA activity OD_{560} nm/h ml eluate; III, BAME activity OD_{253} nm/h ml eluate; IV, caseinolytic activity (pH 10) OD_{280} nm/h ml eluate; V, GPNA activity OD_{410} nm/h ml eluate. Roman numerals refer to the various enzymatic activities.

shown in Fig. 6 each component was active towards both casein at pH 7.5 and collagenase substrate A. Consequently no indications were obtained for the presence of any zinc-free components in peak A or C.

Since a considerable loss in neutral proteinase activity was reported when high concentrations of Pronase (80 mg/ml) were separated on gel chromatography [13] and much more stable conditions were obtained at lower concentrations (1.5 mg/ml), it was also of interest to investigate if a less pronounced heterogeneity might occur at low enzyme concentrations. Thus a separation on a 2.5 × 90 cm Sephadex G-75 Superfine bed was performed purely for analytical purposes (Fig. 7). Considering the improved resolution, which could be expected at this low sample load (and demonstrated by the separation results obtained for the leucine aminopeptidases), peak A was eluted less heterogeneous than in the 80 mg separations. The board elution profile of peak C, however, indicated that this material was heterogeneous even after separation at these more stable conditions. Consequently it was concluded that the poor stability of the zinc endopeptidases in Pronase during the gel chromatography separations [13] could not explain the observed heterogeneity. This seemed to be the result of unstable conditions during the fermentation and isolation of Pronase.

Since peaks A and C were distinctly separated and no intermediate sized components were found, it was, however, considered likely that the components in each of the peaks represented genuine endopeptidases produced by the actinomycete. The molecular weights of these two endopeptidases would thus be 50 000 and 28 000 dalton, respectively. Their content of zinc calculated per mol of enzyme also differed with a factor of about two. The possibility that the larger endopeptidase is a dimer of the smaller one can thus not be excluded. In that case the Kl Strain of *Streptomyces griseus* would only have produced one zinc endopeptidase. Further investigations are in progress to examine the identity of the zinc endopeptidases in Pronase.

Zinc aminopeptidases. The aminopeptidases in Pronase are in this investigation found to contain approximately one zinc atom per mol enzyme assuming an ε (1 %, 1 cm) at 280 nm of 10. Furtheron it is shown that zinc is essential for the enzymatic activity and that the zinc ion can be reversibly removed from the aminopeptidases in a medium containing 30 mM Ca^{2+}. It is thus concluded that zinc is the original prosthetic metal ion of the aminopeptidases. Recently, however, Vosbeck *et al.*[6] found calcium or strontium "as the preferred metal ion" of two aminopeptidases isolated

from Pronase. By dialysis of Pronase against different metal ions calcium was earlier [10] shown to be essential for the aminopeptidase activity. Calcium as well as zinc thus seems to be essential for the activity of the aminopeptidases in Pronase. It is, however, most likely that calcium plays a different role from that of zinc, and in analogy to the findings on thermolysin,[12,20] another zinc- and calcium-dependent proteinase, it is assumed that the calcium ions act as stabilizers, contributing to a stable and enzymatically active tertiary structure of the enzyme molecules by formation of internal salt linkages between carboxyl groups present in different parts of their polypeptide chains. The results on thermolysine also showed that this enzyme is rapidly autolyzed in calcium-free solutions. This gives a possible explanation to the "inhibitory" effect of Zn^{2+} noted by Narahashi and Yanagita [10] for the aminopeptidases in Pronase, and it is most likely that the aminopeptidases in Pronase are calcium-stabilized zinc enzymes.

The aminopeptidases in Pronase were on gel chromatography eluted in two different peaks (B and D). Peak B was not completely separated from peak A and thus pure aminopeptidase activity is only obtained in the later part of peak B. In the case of peak D the alkaline proteinase (Band 9) as well as the carboxypeptidase (Band 5) are eluted together with the aminopeptidase activity, and no part of the peak contained pure aminopeptidase activity.

From the molecular weights estimated for the components in peak B and D, 37 000 and 25 000 dalton respectively,[13] and the absence of LNA-active components with intermediate molecular weights, it is most likely that at least two different zinc aminopeptidases are produced by the actinomycete.

A considerable heterogeneity was, however, observed within both peak B and D and 4–6 components with LNA-activity were found by analytical gel chromatography (Fig. 7), and gel electrophoresis (Fig. 6). No major differences in functional properties were, however, indicated between these components (4, 6, 13), and at this stage of investigation they are assumed to be products of limited proteolysis of the aminopeptidases originally produced by the actinomycete. The favourable stability of the aminopeptidases during the course of separation [13] also indicates that this limited proteolysis has occurred during the fermentation or isolation procedure of Pronase. It is thus uncertain to which extent the zinc aminopeptidases present in Pronase are identical to the ones originally produced by the actinomycete.

Carboxypeptidases. The carboxypeptidases in peak D and in the region between peak D and E could not be inhibited by either penten or EDTA in presence of 30 mM Ca^{2+}. In calcium-free media, however, Narahashi and Yanagita [10] observed inactivation of the CBZ-gly-leu activity by EDTA. It thus seems likely that also the components with carboxypeptidase activity in Pronase need calcium ions as stabilizers of their tertiary structure and the observed heterogeneity is probably due to limited proteolysis. Thus it is likely that only one carboxypeptidase is produced by the Kl Strain of *Streptomyces griseus*.

The nature of the active site of this carboxypeptidase could, however, not be revealed by inhibition experiments. In other carboxypeptidases with similar properties,[22] however, zinc was found to be so firmly bound so it could not be released even by prolonged dialysis against strong chelating agents. It can thus not be excluded that also the carboxypeptidase in Pronase is a metallo enzyme. Indications for this were indirectly obtained by examination of two minor components with true carboxypeptidase activity found in peak F. These components were, due to their substrate specificity and the poor stability indicated for the Pronase carboxypeptidase assumed to be partly digested products of the original carboxypeptidase and they were found to contain a firmly bound zinc atom as prosthetic metal ion. It is thus proposed that the carboxypeptidase in peak D or the region between D and E also is a zinc enzyme.

Serine endopeptidases. Four serine endopeptidases were as expected found in Pronase. They were eluted in chromatography peaks D, E, F, and G, respectively. From recent investigations [15,22] it can also be concluded that they do represent different gene products, out of which one is described as a subtilisin-like enzyme, one as a trypsin-like enzyme, while the remaining two show properties similar to both

Table 2. The heterogeneity of Pronase in terms of components identified on gel chromatography and gel electrophoresis and the corresponding number of original enzymes produced by *Streptomyces griseus* Strain Kl.

	Zinc endopeptidases	Zinc aminopeptidases	Carboxypeptidase	Serine endopeptidases	
A	8, 9′	–	–	–	1
B	–	6, 7	–	–	1
C	10′, 12, 13	–	–	–	1
D	–	10, 11, 12′, 14	5	9	3
E	–	–	–	4	1
F	–	–	–	1, (2)	1
G	–	–	–	3	1

[a] The components are numbered as in Ref. 13. [b] Each component has in case of incomplete separation between different peaks only been assigned to the peak in which its main activity is found.

chymotrypsin and elastase. Together with the main components each peak was also found to contain minor constituents.[13] These minor constituents in peak F were further examined and found to have a substrate specificity completely different from the main component. This further stresses the need for thorough purification control of the Pronase enzymes before detailed characterization of their properties is carried out.[15]

The summarized results of the heterogeneity found for the different categories of proteolytic enzymes in Pronase are given in Table 2. The assumed number of original enzymes produced by the *Streptomyces griseus* Strain Kl is 9, out of which 4 are serine enzymes and at least 4 are zinc enzymes. Further 9 zinc-depending major components are found in the particular batch of Pronase investigated. There is, however, so far no evidence indicating that these components should represent original enzymes. At this stage of investigation it is therefore most relevant to classify them as products of limited proteolysis.

Acknowledgements. I wish to express my gratitude to Professor G. Ehrensvärd for his continuous interest in this work. I also like to thank Mrs. Y. Skoog and Miss A.-M. Dahl for their most skilful technical assistance. Thanks are also due to Mrs. G. Norén and K. Löfqvist for their assistance in editing the manuscript. I am also indebted to Drs. C.-A. Bauer and B. Jergil for valuable advice and discussions.

Dioxolanylium Ions Derived from Carbohydrates. II

STEFFEN JACOBSEN and CHRISTIAN PEDERSEN

Department of Organic Chemistry, Technical University of Denmark, DK-2800 Lyngby, Denmark

Reaction of methyl 2,3:4,6-di-*O*-benzylidene-α-D-mannopyranoside with triphenylmethyl fluoroborate gave the 2,3-benzoxonium ion (*2*); the 4,6-benzylidene group did not react. A similar treatment of 3-*O*-benzoyl-5,6-*O*-benzylidene-1,2-*O*-isopropylidene-α-D-glucofuranose gave the 5,6-benzoxonium ion (*5*), and 1,2:3,4-di-*O*-benzylidene-β-D-arabinopyranose yielded the 3,4-benzoxonium ion (*11*). In the latter case no hydride abstraction took place from the 1,2-benzylidene group. A study of a number of compounds showed that 4,6-, 3,5-, and 1,2-*O*-benzylidene groups, attached to pyranose or furanose rings, did not undergo hydride abstraction with triphenylmethyl fluoroborate. The reactions of the ions *2*, *5*, and *11* with water and with bromide ions were studied.

In the preceding paper[1] it was shown that benzoxonium ions could be generated by reaction of benzylidene derivatives with triphenylmethyl fluoroborate in acetonitrile solution. The dioxolanylium ring was shown to undergo *cis*-opening when hydrolysed whereas reaction with bromide ions lead to *trans*-opening and formation of bromo-deoxy sugars. In the present paper further examples of these reactions are described, mainly in the hexose series, and the behaviour of various types of benzylidene compounds towards triphenylmethyl fluoroborate has been investigated.

Treatment of methyl 2,3:4,6-di-*O*-benzylidene-α-D-mannopyranoside (*1*) with triphenylmethyl fluoroborate in acetonitrile gave the 2,3-benzoxonium ion (*2*) in quantitative yield after 16 h. The ion was quite stable and its NMR spectrum could be measured in deuterioacetonitrile (Table 1). On prolonged reaction with triphenylmethyl fluoroborate a slow decomposition took place, but no hydride abstraction from the 4,6-*O*-benzylidene group was observed. Lack of reactivity of certain types of benzylidene derivatives was found in a number of other cases. Thus the following compounds could not be induced to react with triphenylmethyl fluoroborate in acetonitrile: methyl 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside, methyl 2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-α-D-galactopyranoside, 3,5-*O*-benzylidene-6-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-glucofuranose, 1,2:4,6-di-*O*-benzylidene-3-*O*-benzoyl-α-D-glucopyranose, and 1,2:3,5-di-*O*-benzylidene-6-*O*-benzoyl-α-D-glucofuranose. From these results it appears that benzoxonium ions with 6-membered rings cannot be formed under the conditions used; the latter two examples furthermore show that 1,2-benzoxonium ions are not formed. However, while 1,2-*O*-benzylidene groups were isomerized by triphenylmethyl fluoroborate to mixtures of *endo* and *exo* isomers 4,6-*O*-benzylidene groups were completely unaffected. This was further confirmed by treating 1,2:3,4-di-*O*-benzylidene-β-D-arabinopyranose (*10*) with triphenylmethyl fluoroborate which gave the 3,4-benzoxonium ion (*11*) as the sole product. NMR spectra of the two diastereomers of *11* are shown in Table 1. The dibenzoxonium ion which could be formed by hydride abstraction from *11* was not detected. It is known to be stable in anhydrous hydrogen fluoride solution.[2]

Treatment of 3-*O*-benzoyl-5,6-*O*-benzylidene-1,2-O-isopropylidene-α-D-glucofuranose (*4*) with triphenylmethyl fluoroborate rapidly gave the benzoxonium ion (*5*) as seen from its NMR spectrum in deuterioacetonitrile (Table 1). The corresponding 3-*O*-mesylated ion was obtained by Hanessian and Staub.[3] Barton *et al.*[4] have shown that isopropylidene groups will react with triphenylmethyl fluoroborate. This reac-

Table 1. Proton NMR spectra of benzoxonium ions and products prepared from them. Chemical shifts are in ppm relative to tetramethylsilane, coupling constants in Hz.

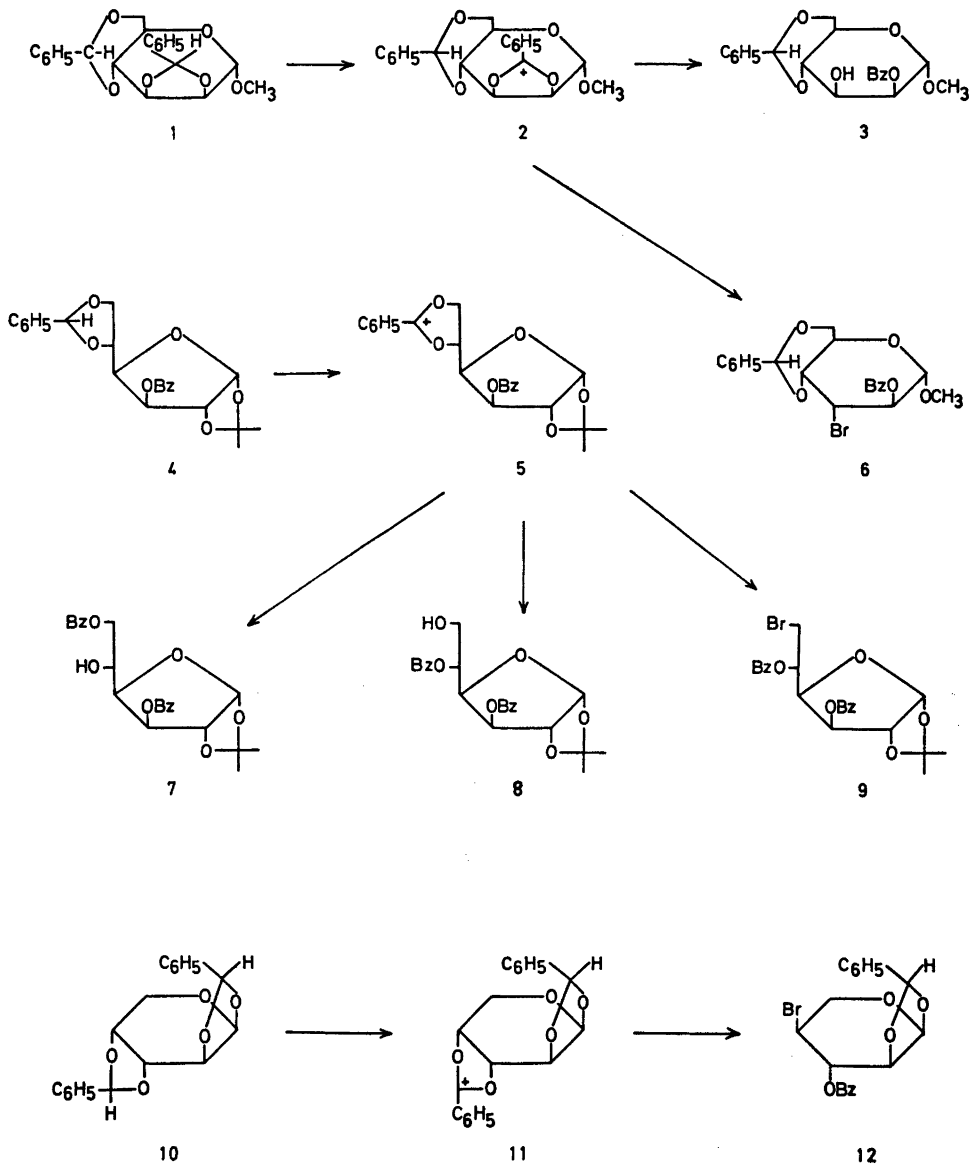
[a] Assignment of structure is based on the chemical shift of the benzylidene proton.[14]



tion is, however, slower than the reaction with benzylidene groups and it was not observed. When the benzoxonium ion (*5*) was kept in acetonitrile solution in the presence of excess triphenylmethyl fluoroborate for several days a slow decomposition took place.

The benzoxonium ions were reacted with water and with bromide ions as in the preceding paper.[1] Treatment of *2* with water gave the 2-*O*-benzoate (*3*), with an axial *O*-benzoyl group, as the sole product, in agreement with the results of King and Allbutt.[5] The 5,6-benzoxonium ion (*5*) gave a mixture of the 6-*O*-benzoate (*7*) and the 5-*O*-benzoate (*8*) on hydrolysis.

Reaction of *2* with bromide ions lead to *trans*-opening of the dioxolanylium ring and gave the 3-bromo-3-deoxy-altroside (*6*) as the only product. The formation of the *trans*-diaxial product is in agreement with the results

that King and Allbutt [6] found for nucleophilic opening of dioxolanylium rings fused to bicyclic systems. The 5,6-benzoxonium ion (*5*) gave only the 6-bromo-derivative (*9*) on reaction with bromide ions.[3] Finally, the benzoxonium ion (*11*) when treated with bromide ions gave the 4-bromo-4-deoxy-L-xylose derivative (*12*) as a mixture of the two diastereomers.

EXPERIMENTAL

For details of chromatography and NMR spectroscopy see the preceding paper.[1]

Methyl 2,3:4,6-di-O-benzylidene-α-D-mannopyranoside (1). Methyl α-D-mannopyranoside (9.7 g) and benzaldehyde (11.5 g) were boiled for 10 h with *p*-toluenesulfonic acid (100 mg) in chloroform (200 ml) with a Soxhlet extractor containing 50 g of 4 Å molecular sieves. The solution was then washed with aqueous sodium hydrogencarbonate and water, dried and evaporated. The residue was crystallized from ethanol–chloroform to give 8.5 g of *1*. The mother liquor was evaporated and the residue was dissolved in chloroform and boiled for 1 h with *p*-toluenesulfonic acid (100 mg). Work up as described above gave 3.4 g of *1*. After an additional equilibration the total yield of *1* was 13.7 g, m.p. 160–175 °C. One recrystallization from ethanol-chloroform gave 11.9 g of a product with m.p. 176–177 °C (reported [7] m.p. 180–181 °C).

Conversion of benzylidene derivatives to hydroxy-benzoates

The benzoxonium ions were prepared by reaction of the benzylidene derivatives with a 10–25 % molar excess of triphenylmethyl fluoroborate in dry acetonitrile at room temp. Hydrolysis and chromatography was performed as described in the preceding paper.[1]

Methyl 2,3:4,6-di-O-benzylidene-α-D-mannopyranoside (1) (520 mg) gave the benzoxonium ion (*2*) after reaction with triphenylmethyl fluoroborate for 16 h. Hydrolysis and chromatography yielded 364 mg (67 %) of methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-mannopyranoside (*3*) as a syrup, $[\alpha]_D^{21}$ −33.8° (*c* 1.3, $CHCl_3$). (Found: C 65.13; H 5.82. Calc. for $C_{21}H_{22}O_7$: C 65.27; H 5.74). An NMR spectrum (Table 1) proved the structure. Debenzoylation with sodium methoxide in methanol and recrystallization from ethanol-water gave methyl 4,6-*O*-benzylidene-α-D-mannopyranoside, m.p. 145–145.5 °C (reported [7] m.p. 146–147 °C). A mixed m.p. with an authentic sample gave no depression.

3-O-Benzoyl-5,6-O-benzylidene-1,2-O-isopropylidene-α-D-glucofuranose (4) [8] (533 mg) gave the benzoxonium ion (*5*) after reaction with triphenylmethyl fluoroborate for 1 h. Hydrolysis and chromatography yielded two products. The fast moving fraction (183 mg, 33 %) was 3,6-di-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-glucofuranose (*7*), m.p. 108–110 °C, $[\alpha]_D^{20}$ −4.4° (*c* 1.7, $CHCl_3$), (reported [9] m.p. 108–109 °C, $[\alpha]_D$ −4.6°). The slow moving fraction (213 mg, 38 %) was the 3,5-di-*O*-benzoate (*8*) as a syrup, $[\alpha]_D^{21}$ −111.3° (*c* 1.6, $CHCl_3$). (Found: C 64.34; H 5.77. Calc. for $C_{23}H_{24}O_8$: C 64.48; H 5.65). Benzoylation of (*8*) with benzoyl chloride in pyridine gave 3,5,6-tri-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-glucofuranose, m.p. 118–120 °C (reported [10] m.p. 119–120 °C). A mixed m.p. with an authentic sample gave no depression.

Conversion of benzylidene derivatives to bromo-deoxy-benzoates

The benzoxonium ions were prepared as described above and treated with dry tetraethylammonium bromide (3 molar equiv.) in acetonitrile for 2 h. Work up and chromatography as described in the preceding [1] paper gave the products.

Methyl 2,3:4,6-di-O-benzylidene-α-D-mannopyranoside (*1*) (552 mg) gave 388 mg (50 %) of methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-3-bromo-3-deoxy-α-D-altropyranoside (*6*). Crystallization from ethyl acetate–pentane gave the pure product, m.p. 134–136 °C. (Found: C 56.25; H 4.62; Br 17.91. Calc. for $C_{21}H_{21}BrO_6$: C 56.13; H 4.71; Br 17.79). The product was identical with a sample prepared by benzoylation of methyl 4,6-*O*-benzylidene-3-bromo-3-deoxy-α-D-altropyranoside,[11] m.p. 136.5–137.5 °C, $[\alpha]_D^{21}$ +1.6° (*c* 1.5, $CHCl_3$). A mixed m.p. gave no depression.

In a separate experiment 3.3 g of *1* was converted to the 2,3-benzoxonium ion (*2*) which was treated with tetraethylammonium bromide to give the bromo-compound (*6*) in acetonitrile solution. Stirring with saturated aqueous sodium hydrogencarbonate (50 ml) for 30 min gave a crystalline precipitate which was filtered off and washed with water. Extraction with pentane (3 × 50 ml) removed most of the triphenylmethane. The product was then dissolved in ethyl acetate (50 ml) and treated with activated carbon. Evaporation of the ethyl acetate to *ca.* 10 ml and addition of pentane (40 ml) precipitated 1.75 g (43 %) of *6*, m.p. 135–137 °C. One recrystallization from ethyl acetate–pentane gave 1.60 g, m.p. 136–138 °C, $[\alpha]_D^{20}$ +1.2° (*c* 1.2, $CHCl_3$).

3-O-Benzoyl-5,6-O-benzylidene-1,2-O-isopropylidene-α-D-glucofuranose (4) (454 mg) gave after chromatography 427 mg (79 %) of 3,5-di-*O*-benzoyl-6-bromo-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose (*9*) as a syrup, $[\alpha]_D^{21}$ −114.5° (*c* 1.2, $CHCl_3$). (Found. C 56.41; H 4.78; Br 16.13. Calc. for $C_{23}H_{23}O_7Br$: C 56.22;

H 4.72; Br 16.26). A product obtained by benzoylation of 5-*O*-benzoyl-6-bromo-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose [12] had $[\alpha]_D^{21}$ −119.8° (*c* 1.4, $CHCl_3$). NMR spectra of the two products were identical.

1,2:3,4-Di-O-*benzylidene-β*-D-*arabinopyranose* [13] (10) (508 mg) gave the 3,4-benzoxonium ion (*11*) after treatment with triphenylmethyl fluoroborate for 4 h in acetonitrile solution. Reaction with tetraethylammonium bromide and work up as described above yielded 324 mg (51 %) of a mixture of the diastereomeric 3-*O*-benzoyl-1,2-*O*-benzylidene-4-bromo-4-deoxy-α-L-xylopyranoses (*12*). Crystallization from ethyl acetate (3 ml)-pentane (10 ml) gave 102 mg, m.p. 124–125 °C. Recrystallization gave the pure *endo*-H isomer, m.p. 125–126 °C, $[\alpha]_D^{21}$ −43.3° (*c* 1.7, $CHCl_3$). (Found: C 56.43; H 4.31; Br 19.72. Calc. for $C_{19}H_{17}BrO_5$: C 56.31; H 4.22; Br 19.72). The *exo*-H isomer could not be obtained pure, but preparative TLC (benzene) gave a product which contained 80 % *exo*-H isomer, allowing it to be identified through its NMR spectrum (Table 1).

Microanalyses were performed by Dr. A. Bernhardt, Mikroanalytisches Laboratorium or by Novo Microanalytical Laboratories.

On the Occurrence of 1-*O*-Alkylglycerols and 1-*O*-(2-Methoxyalkyl)glycerols* in Human Colostrum, Human Milk, Cow's Milk, Sheep's Milk, Human Red Bone Marrow, Red Cells, Blood Plasma and a Uterine Carcinoma

BO HALLGREN, ANITA NIKLASSON, GUNNEL STÄLLBERG and HANS THORIN

Research Laboratories, Astra Nutrition AB, S-431 20 Mölndal 1, Sweden

1-*O*-Alkylglycerols and 1-*O*-(2-methoxyalkyl)-glycerols were isolated from the neutral lipids and phospholipids of human colostrum, human milk, cow's milk, sheep's milk, human red bone marrow, red cells, blood plasma, and a uterine carcinoma. Human colostrum has a higher content of unsubstituted glycerol ethers in the neutral lipids than human milk. Human milk contains nearly 10 times more unsubstituted glycerol ethers than cow's milk and twice as much as sheep's milk. The highest percentage of unsubstituted glycerol ethers in neutral lipids was found in the human red bone marrow and the uterine carcinoma. The methoxy-substituted glycerol ethers were found both in the neutral lipids and in the phospholipids of all the tissues studied but only in trace quantities. Glycerol ethers with 16 and 18 carbon atoms in the long hydrocarbon chains are the principal components of both the unsubstituted and the 2-methoxy-substitued glycerol ethers. A poly-unsaturated methoxy-substituted glycerol ether, 1-*O*-(2-methoxydocosahexaenyl)glycerol, was found in the neutral lipids and phospholipids of red blood cells.

The physiological effect of the glycerol ethers that is best documented is the stimulation of the bone marrow. Sandler [1] reported that batyl alcohol (1-octadecylglycerol) had a stimulatory effect on the erythrocyte count of both normal rats and those poisoned with benzene. It was confirmed by several investigators that both optically active and racemic batyl alcohol stimulated erythropoesis, thrombopoesis and granulopoesis.[2–10] Chimyl alcohol also has a stimulatory effect on haemopoesis [9] but selachyl alcohol (*cis*-9-octadecenylglycerol) has no haemopoetic activity.[7,10]

The glycerol ethers occur in the tissues in the form of diesters [11,12] and alkyl acyl phosphatides.[13–17] A high level of glycerol ether lipids was found in a variety of transplantable tumours in animals [18–19] and in human tumours.[20]

2-Methoxy-substituted glycerol ethers have been isolated from Greenland shark liver oil.[21] These substituted glycerol ethers have antibiotic activity and also inhibited the dissemination and growth of several experimental tumours in mice.[22,23] The aim of the present investigation was to study methoxy-substituted as well as ordinary, unsubstituted glycerol ethers in human milk, red bone marrow, red blood corpuscles, and blood plasma. A human uterine tumour has also been studied. Milk from two ruminant species, cow and sheep, is included for comparison with human milk. The composition of the two groups of glycerol ethers has also been determined.

MATERIAL AND METHODS

Material. The human milk was pooled milk from a milk bank at Sahlgren's hospital, Gothenburg. Colostrum was collected during the first two days after delivery, "transition milk" during days 3 – 7 and the third sample of milk was from lactating women 8 days to 3 months

* "Alkyl" also includes unsaturated carbon chains except those with a double bond adjacent to the glycerol ether oxygen.

after delivery. The cow's milk was fresh pasteurized milk and the sheep's milk was fresh but unpasteurized.

Red blood cells and plasma were obtained by centrifugation of blood from blood donor bottles. The cells were washed twice with one volume of 0.9 % NaCl. The red bone marrow was collected from the long bones of several autopsy cases free from any blood diseases.

The uterine carcinoma was obtained from the Department of Gynecology, Sahlgren's hospital. The tumour could not be dissected out from the part of the uterus obtained. The large tumour analyzed thus included some normal uterine tissue.

Extraction of lipids. The blood plasma and the milk were freeze-dried before the extraction of the lipids. The red bone marrow, the red cells and the uterine carcinoma were extracted directly. One part by weight of the freeze-dried or the fresh material was extracted with 12 volumes of a chloroform – methanol mixture, 2:1 (v/v) or a mixture of chloroform – ethanol, 2:1 (v/v). The mixture was boiled under reflux for 90 min. After cooling at room temperature, it was filtered. The residue was boiled for another 90 min in chloroform – methanol or chloroform – ethanol. The extract was evaporated to half its volume and then partitioned against one-fifth volume of 0.1 % NaCl. After separation of the chloroform phase, the NaCl solution was extracted 3 times with chloroform. The solvents were evaporated from the lipid extract and the residue was dried under a stream of nitrogen.

Separation of neutral lipids, phospholipids, glycerol ethers, and isopropylidene derivatives of glycerol ethers. 10 g of lipid material was dissolved in chloroform and applied to a column of 1350 g of silicic acid (silicic acid for lipid chromatography, Bio-Rad Lab., Richmond, Calif.). The neutral lipid fraction was eluted with chloroform and chloroform – methanol 9:1 (or chloroform – ethanol 9:1). The main phospholipid fraction was eluted with chloroform – methanol 1:1 (or chloroform – ethanol 1:1) but due to tailing the last parts had to be eluted with methanol (or ethanol).

The neutral lipid fraction was saponified by boiling in 1 M KOH in ethanol for 1 h. The phospholipids were treated according to Thompson and Lee.[24] The material was refluxed with acetic acid – acetic anhydride 3:2 for 8 h. The mixture was made alkaline with 6 M KOH in ethanol and refluxed for a further 2 h. The non-saponifiable material was extracted into ether. Fatty acid salts remaining in the material were removed by treatment with a small amount of lithium aluminium hydride in ether solution. In a few cases the lipid fraction was directly treated with lithium aluminium hydride to cleave the ester bonds. After acidification of the reduction mixture with hydrochloric acid, the organic material was extracted into ether. The material was chromatographed on silicic acid columns. Hydrocarbons, sterols and alcohols were eluted with a mixture of light petroleum (b.p. 60 – 80 °C) and ethyl ether (19:1 v/v). The unsubstituted and methoxy-substituted glycerol ethers were then eluted with ethyl ether. The column chromatography was checked by thin-layer chromatography (Silica gel G, Merck. Developing solvent: trimethylpentane/ethyl acetate/methanol, 50:40:5). To transform the glycerol ethers into their isopropylidene derivatives the material from the fractions containing glycerol ethers was treated with acetone in the presence of perchloric acid.[25] The crude mixture of isopropylidene derivatives was purified by chromatography on silicic acid columns (and checked by TLC). The isopropylidene derivatives of the unsubstituted glycerol ethers were eluted with a mixture of 1 % ether in light petroleum (b.p. 60 – 80 °C) and those of the methoxy-substituted glycerol ethers with a mixture of 5 % ether in light petroleum. The amounts of unsubstituted and methoxy-substituted glycerol ethers were determined by weighing the fractions after evaporation of the solvents under a stream of nitrogen. In some cases with very small amounts of material available, preparative thin-layer chromatography was used (Silica gel G, layer 0.5 – 1 mm). When trimethylpentane/ethyl acetate, 70:20, was used as developing solvent, the isopropylidene derivatives of the unsubstituted and the methoxy-substituted glycerol ethers were obtained from the bands with $R_F \approx 0.6$ and $R_F \approx 0.3$, respectively. The isopropylidene derivatives were used for determination of the compositions by means of gas chromatography and mass spectrometry.

Gas-liquid chromatography. The gas chromatography was performed with a Perkin-Elmer F 11 instrument equipped with a flame ionization detector. A 180 cm × 2 mm i.d. stainless steel column, packed with Gas Chrom Q 80 – 100 mesh containing 1 % Apiezon L was used. The column temperature was in most cases 220 °C. The flow was 30 ml helium/min.

Gas-liquid chromatography-mass spectrometry. The GLC – MS was carried out with the LKB 9000 combination instrument. The operating conditions of the mass spectrometer were: electron energy 70 eV, ion source temperature 270 °C, trap current 60 μA and accelerating voltage 3.5 kV.

The gas chromatography on the combined instrument was carried out at 220 °C using a 300 cm × 2 mm i.d. glass column packed with Gas Chrom Q 80 – 100 mesh, containing 1 % Apiezon L.

RESULTS AND DISCUSSION

The quantitative data on the amounts of glycerol ethers in the lipids are given in Table 1. The content of lipids in human colostrum as

Table 1. The content of unsubstituted and methoxy-substituted glycerol ethers in neutral lipids and in phospholipids isolated from human colostrum, human milk, cow's milk, sheep's milk, human red bone marrow, human red cells, human blood plasma, and a human uterine carcinoma.

Material	Lipids % (w/w)	Neutral lipids (N) and phospholipids (P) in total lipids % (w/w)		Unsubstituted glycerol ethers in N and P [a] % (w/w)		Methoxy-substituted glycerol ethers in N and P % (w/w)	
		N	P	N	P	N	P
Human colostrum, 1–2 days	2.9	96.4	3.6	0.19	0.16	trace	trace

[a] The figures should be multiplied by a factor of about 2.0–2.5 to get the content of the original glycerol ether lipids in the lipid fractions.

well as in transition milk and milk collected from 8 days to 3 months after delivery is about the same. The percentage of phospholipids in the lipids decreases from 3.6 % in the colostrum to 1.0 % in the milk from the second week of lactation and onwards. The content of glycerol ethers in the phospholipids is about the same, 0.2 %, in the tree types of human milk, whereas the glycerol ether content in the neutral lipids is highest in colostrum, 0.19 %, and decreases to 0.14 % during the first week and then to 0.10 %. The neutral lipids of cow's milk and sheep's milk contain 0.01 and 0.02 % glycerol ethers, respectively. A comparison of human milk with cow's and sheep's milk shows that human milk per volume contains nearly 10 times more glycerol ethers than cow's milk and twice the amount found in sheep's milk. Trace quantitites of (2-methoxyalkyl)glycerols were found in the neutral lipids as well as in the phospholipids in all the samples of milk studied.

The phospholipids of human red bone marrow, red blood cells and blood plasma are fairly rich in alkylglycerols. The highest figure, 2 %, was found for the red bone marrow. The neutral lipids of the bone marrow are also rich in glycerol ethers in contrast to the neutral lipids of the red blood cells and the blood plasma. In both the neutral lipids and the phospholipids of the uterine carcinoma high levels of glycerol ethers were found. Minute amounts of 1-*O*-(2-methoxyalkyl)glycerols were found in both the neutral lipids and the phospholipids of all tissues investigated.

Composition of the glycerol ethers. The composition of the unsubstituted glycerol ethers of the neutral lipids and of the phospholipids is given in Table 2. The compounds with even-numbered, long chains are predominant; the compounds with odd-numbered chains usually constitute less than 5 % of the whole mixture. The unsubstituted glycerol ethers in the neutral lipids of cow's milk and sheep's milk contain somewhat more odd-numbered, long chains than human milk and also branched alkyl chains. The glycerol ethers with 16 and 18 carbon atoms in the long chains (16:0 chimyl, 18:0 batyl, and 18:1 selachyl alcohol) are the principal components. The compounds with 16 carbon atoms in the long chains are mainly

Table 3. Percentage of saturated components in the glycerol ethers of neutral lipids and phospholipids from various human material.

	Sat. % Neutral lipids	Sat. % Phospholipids
Colostrum	61	58
"Transition milk", 3–7 days	53	55
Milk, 8 days – 3 months	51	51
Red bone marrow	67	55
Red blood cells	42	72
Blood plasma	39	65
Uterine carcinoma	51	52

saturated. The degree of unsaturation increases with the chain length and the compounds with 24 carbon atoms are mainly unsaturated. The proportion of saturated glycerol ethers in the neutral lipids is higher in the colostrum than in other human milk samples. The red bone marrow has a higher proportion of saturated lipids than other human tissues studied (see Table 3). Only the saturated glycerol ethers, chimyl and batyl alcohol, have been found to stimulate the formation of blood cells.[1–10] The glycerol ethers of the neutral lipids in the bone marrow might be precursors to the glycerol ether phospholipids in the blood cells. It is interesting to note that the phospholipids of the red cells are relatively saturated (Table 3).

The composition of the methoxy-substituted glycerol ethers occurring in neutral lipids and phospholipids is demonstrated in Table 4. As the methoxy-substituted glycerol ethers are found only in minute quantities it was difficult to isolate them in a pure form. The principal components are 2-methoxy-substituted hexadecyl-, hexadecenyl-, and octadecenyl glycerol ethers. A characteristic feature of the methoxy-substituted glycerol ethers is the high content of ethers with 16 carbon atoms in the long alkyl chain. A poly-unsaturated methoxy-substituted glycerol ether with 6 double bonds, 1-*O*-(2-methoxydocosahexaenyl)glycerol was found in both the neutral lipids and the phospholipids of red blood cells. This poly-unsaturated glycerol ether was first found in Greenland shark liver oil.[26]

In the present study we have thus demonstrated that 2-methoxy-substituted glycerol ethers are of common occurrence but in minute

quantities. In some experiments the isolation of the glycerol ethers has been performed using ethanol instead of methanol to allay any suspicion that the methoxy-substituted glycerol ethers could be artefacts from methanol treatment.

The physiological functions of the two types of glycerol ethers, the unsubstituted and the 2-methoxy-substituted ones, have not been clarified. The chimyl and batyl alcohols stimulate blood cell formation [1-10] and the 2-methoxy-substituted glycerol ethers have inhibitory effects on tumour growth and dissemination of metastases.[22,23] Further studies to elucidate the metabolism and physiological functions of the methoxy-substituted as well as of the unsubstituted, ordinary glycerol ethers are therefore indicated.

On the Occurrence of 1-*O*-(2-Methoxyalkyl)glycerols and 1-*O*-Phytanylglycerol in Marine Animals

BO HALLGREN, ANITA NIKLASSON, GUNNEL STÄLLBERG and HANS THORIN

Research Laboratories, Astra Nutrition AB, S-431 20 Mölndal 1, Sweden

1-*O*-(2-Methoxyalkyl)glycerols were isolated from the lipids of herring fillets, Baltic herring fillets, mackerel fillets, marine crayfish, fresh-water crayfish, shrimps, sea mussels, and cod liver oil. They were found both in the neutral lipids and in the phospholipids in considerably higher amounts than in mammalian tissues. The methoxy-substituted glycerol ethers had a high content of ethers with 16 carbon atoms in the long alkyl chains. The compounds with 16 and 18 carbon atoms together usually constituted over 90 %. The composition is roughly similar in the neutral lipids and in the phospholipids. A poly-unsaturated compound, 1-*O*-(2-methoxydocosahexaenyl)glycerol was found in the neutral lipids of mackerel fillets and cod liver oil and in the phospholipids of shrimps. A glycerol ether with a phytanyl chain was isolated from the liver oil of cod caught in the Baltic sea. The content and composition of the unsubstituted glycerol ethers have been determined for comparison.

2-Methoxy-substituted glycerol ethers were first isolated from Greenland shark liver oil.[1] They were also found in human milk, cow's milk, sheep's milk, and different human tissues, *viz.* red bone marrow, red cells, blood plasma, and in a uterine carcinoma.[2] The methoxy-substituted glycerol ethers had antibiotic activity and inhibited the dissemination and growth of several experimental tumours in mice.[3,4] As they occur in a relatively high concentration in shark liver oil compared to the minute amounts found in the mammalian tissues studied, it was of interest to determine the content of 2-methoxy-substituted glycerol ethers in different marine animals. The distribution of the compounds between the neutral lipids and the phospholipids was also studied.

MATERIAL AND METHODS

The material studied were fillets from herring (*Clupea harengus*), Baltic herring (*Clupea harengus*), mackerel (*Scomber scomber*), marine crayfish (*Nephrops norvegicus*), fresh-water crayfish (*Astacus fluviatilis*), shrimps (*Pandalus borealis*), and sea mussels (*Mytilus edulis*). Only the edible parts of the crayfishes, shrimps and sea mussels were included in the samples investigated. Both a commercial sample of cod liver oil and liver oil from cod caught in the Baltic sea were analyzed.

The extraction of the lipids, the separation of neutral lipids and phospholipids, the isolation of glycerol ethers and their isopropylidene derivatives, gas chromatography and mass spectrometry were performed as earlier described.[2] As before,[2] ethanol was used instead of methanol in some experiments in order to exclude the possibility of artefacts from methanol treatment.

RESULTS AND DISCUSSIONS

The methoxy-substituted glycerol ethers like the unsubstituted ones occur both in the neutral lipids and in the phospholipids (Table 1). The percentage of both groups of glycerol ethers is usually much higher in the phospholipids than in the neutral lipids. Due to the large proportion of neutral lipids in herring, Baltic herring, and mackerel, about the same quantities of glycerol ethers are found in the two lipid fractions of these species.

The content of methoxy-substituted glycerol ethers is higher in the neutral lipids and especi-

Table 1. The content of unsubstituted and methoxy-substituted glycerol ethers in the neutral lipids (N) and the phospholipids (P) isolated from marine animals.

Material	Lipids	Neutral lipids (N) and phospholipids (P) in total lipids		Unsubstituted glycerol ethers [a] in N and P		Methoxy-substituted glycerol ethers [a] in N and P	
	% (w/w)	% (w/w)		% (w/w)		% (w/w)	
		N	P	N	P	N	P
Herring fillets	17.3	94.4	5.6	0.05	0.57	0.02	0.14
Baltic herring fillets	10.4	91.4	8.6	0.07	0.54	0.01	0.14
Mackerel fillets	20.7	95.5	4.5	0.06	1.10	0.02	0.22
Marine crayfish	2.3	53.9	46.1	1.20	1.30	0.17	0.35
Fresh-water crayfish	4.3	69.6	30.4	0.65	1.70	0.07	0.06
Shrimps	2.8	47.6	52.4	1.20	1.70	0.08	0.19
Sea mussels	2.1	54.9	45.1	1.10	1.90	0.08	0.47
Cod liver oil, commercial sample	100	100		0.05		0.03	
Liver oil from cod caught in the Baltic sea	100	100		0.05 [b]		0.02	

[a] The figures should be multiplied by a factor of about 2.0–2.5 to get the content of the original glycerol ether lipids in the lipid fractions. [b] In addition this cod liver oil contained 0.03 % phytanyl glycerol ethers.

ally in the phospholipids of the marine animals studied than in the lipids of the mammalian tissues investigated.[2] The principal components of the methoxy-substituted glycerol ethers are the same in the marine animals as in the mammalian tissues. The compounds with 16 and 18 carbon atoms in the long hydrocarbon chains amount to over 90 % of the methoxy-substituted glycerol ethers of both the neutral lipids and the phospholipids (Table 2). The compounds with C_{16} chains, especially, are usually found in high concentrations. Only small amounts of methoxy-substituted glycerol ethers with less than 16 carbon atoms in the long alkyl chains are found. A poly-unsaturated methoxy glycerol ether, 1-*O*-(2-methoxydocosahexaenyl)glycerol, was found in the neutral lipids of mackerel fillets, in the liver oil from the cod caught in the Baltic sea, and in the phospholipids of shrimps. Such a poly-unsaturated methoxy-substituted glycerol ether was first isolated from Greenland shark liver oil [5] and has also been found in the lipids of human red blood cells.[2]

The content of unsubstituted glycerol ethers in the lipids of the herring, Baltic herring and mackerel fillets (Table 1) is comparable with the amounts of these glycerol ethers found in the mammalian tissues.[2] A somewhat higher content of unsubstituted glycerol ethers was found in the crayfish, shrimps, and mussels. Cod liver oil contains small quantities of glycerol ethers compared to the large amounts found in shark liver oil.[1,6] The composition of the unsubstituted glycerol ethers of the neutral lipids and of the phospholipids is roughly similar (Table 3). The compounds with even-numbered long hydrocarbon chains are the principal components and among them those with 16 and 18 carbon atoms dominate. The unsubstituted glycerol ethers of the neutral lipids of herring fillets, mackerel fillets, crayfish, shrimps, and sea mussels contain more saturated C_{16} and C_{18} components than cod liver oil. Fairly large amounts of C_{14} compounds are present in the unsubstituted glycerol ethers of both the neutral lipids and the phospholipids of herring and mackerel fillets.

[a] Phytanyl 33.3.

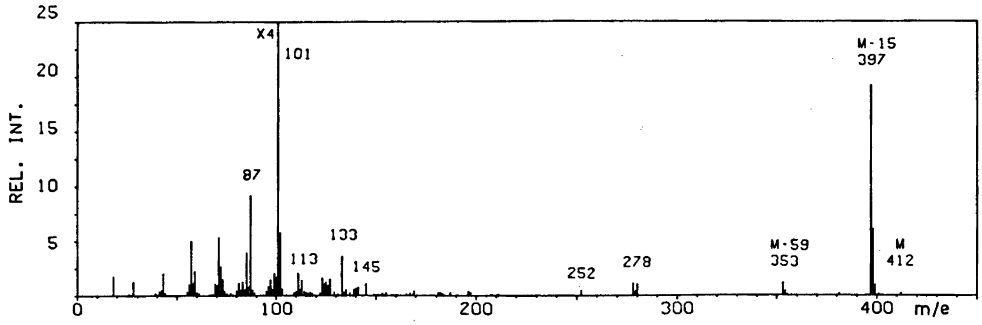

Fig. 1. Mass spectrum of the isopropylidene derivative of phytanylglycerol, isolated from cod liver oil.

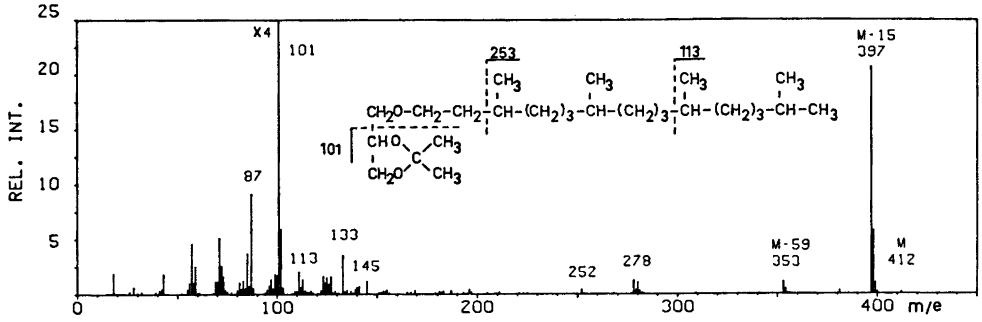

Fig. 2. Mass spectrum of synthetic 1-*O*-phytanyl-2,3-*O*-isopropylideneglycerol.

In the liver oil from cod caught in the Baltic sea a glycerol ether with a phytanyl chain was found. The phytanyl glycerol ether amounted to about a third of the whole glycerol ether mixture. A somewhat higher R_F-value in thin-layer chromatography (TLC) than for batyl alcohol both before and after acetonation indicated that the compound could be a glycerol ether with a branched hydrocarbon chain. This was supported by the IR spectrum of the compound, which showed strong bands at about 3450 (OH), 2960 (CH_3), 1365 – 1375 doublet ($C(CH_3)_2$), and 1100 cm^{-1} (C – O – C).[7] The mass spectrum indicated a molecular weight of 412 for the isopropylidene derivative. For comparison 1-*O*-phytanyl-2,3-*O*-isopropylideneglycerol and 1-*O*-phytanylglycerol were synthesized from dihydrophytol and isopropylideneglycerol in the same manner as earlier described.[8] The IR spectra of the synthesized compounds were identical with those of the compounds from cod liver oil, both as free glycerol ethers and as isopropylidene derivatives. The R_F-values in TLC were also identical. Analyses by GLC – MS of the isopropylidene derivatives gave the same retention times and identical mass spectra (Figs. 1 and 2).

A diphytanyl glycerol ether isolated from *Halobacterium cutirubrum* has been studied in detail by Joo *et al.*[7] They found that the diether had the unusual L-configuration. They also found small amounts of α-monophytanylglycerol ($[\alpha]_D - 0.95°$) which, however, had been formed from the diether during acid hydrolysis.[9] Unfortunately the amount of the phytanyl ether isolated from cod liver oil was not enough for determination of the optical rotation.

The phytanyl chain probably originates from chlorophyll. The composition of the glycerol ethers is thus obviously dependent on the diet of the animals. The glycerol ethers of the freshwater crayfish are somewhat more saturated than those of the marine crayfish. This is also true for Baltic herring fillets compared to the herring fillets. These differences might be related to different dietary intake or other environmental factors, *e.g.* water temperature.

Reaction of Acetylated Methyl Glycosides with Hydrogen Bromide

KLAUS BOCK and CHRISTIAN PEDERSEN

Department of Organic Chemistry, Technical University of Denmark, DK-2800 Lyngby, Denmark

Treatment of acetylated methyl glycopyranosides with hydrogen bromide in acetic acid gave, in addition to the expected pyranosyl bromides, large amounts of furanosyl bromides. The reaction was studied with a number of methyl hexopyranosides and pentopyranosides and in almost all cases furanosyl bromides were found to be the major products. Methyl tri-*O*-acetyl-β-D-ribopyranoside was almost completely converted into a mixture of the anomeric tri-*O*-acetyl-D-ribofuranosyl bromides by treatment with hydrogen bromide in acetic acid for 2 h.

It was reported previously that treatment of methyl tri-*O*-acetyl-β-D-arabinopyranoside with hydrogen bromide lead to formation of tri-*O*-acetyl-D-arabinofuranosyl bromide in addition to the expected pyranosyl bromide. A mechanism for the ring-contraction was proposed, and it was shown that the benzoylated arabinoside did not undergo ring-contraction with hydrogen bromide.[1]

In the present paper the behaviour of a number of acetylated glycosides towards hydrogen bromide in acetic acid is described. In most cases the reactions were studied by NMR spectroscopy only. In these experiments the acetylated glycosides were dissolved in a solution of 30 % hydrogen bromide in glacial acetic acid in an NMR sample tube and kept at room temperature. NMR spectra were then run at intervals at 90 MHz until no further changes were observed. In Table 1 are given the results of a number of such experiments.

The products formed were identified from the chemical shifts of the anomeric protons of the glycosyl bromides, which were the final products. The relative amounts of products were calculated from the integrated spectra. Authentic spectra of the products shown in Table 1 were obtained from fully acetylated pyranoses and furanoses under the same conditions. Fully acetylated sugars form glycosyl bromides rapidly and ring-changes do not take place, even on prolonged treatment with hydrogen bromide.

The results obtained from these experiments show that when the reactions of acetylated methyl pyranosides with hydrogen bromide are completed furanosyl bromides are the main product in almost all cases (Table 1). Methyl tri-*O*-acetyl-β-D-arabinopyranoside, which was investigated previously,[1] undergoes ring-contraction to a smaller extent than any of the other methyl glycopyranosides investigated. Methyl tri-*O*-acetyl-β-D-ribopyranoside is almost completely converted into a mixture of the anomeric tri-*O*-acetyl-D-ribofuranosyl bromides.

In some cases signals, which could not be ascribed to pyranosyl or furanosyl bromides, were observed. These are probably due to the formation of open-chain, *aldehydo*-derivatives. Only in the case of methyl tri-*O*-acetyl-α-D-lyxopyranoside was such a compound formed in larger amounts; it probably has the structure (*11*). The formation of open-chain derivatives by acetolysis of acetylated methyl glycosides is well known.[2,3]

Acetylated methyl α-D-mannofuranoside and ethyl β-D-galactofuranoside underwent ring-expansion to some extent to give pyranosyl bromides when treated with hydrogen bromide (Table 1). This was also the case with methyl tri-*O*-acetyl-α-D-arabinofuranoside.[1] According to the proposed mechanism [1] ring-changes take place with the methyl glycosides and not with glycosyl bromides. Since methyl furanosides give glycosyl bromides more rapidly

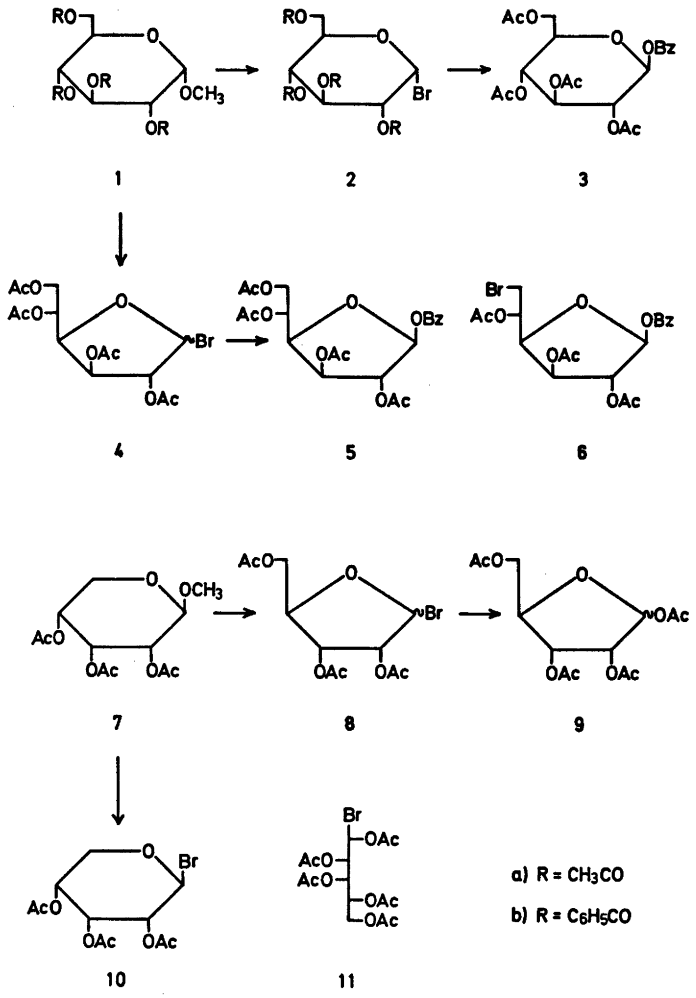
than pyranosides (Table 1) it is understandable that they undergo ring-expansion to a small extent only.

Phenyl tetra-*O*-acetyl-β-D-galactopyranoside gave only a small amount of furanosyl bromide when treated with hydrogen bromide. 2,3,4-Tri-*O*-acetyl-D-xylopyranose gave considerable amounts of furanosyl bromides, but not as much as the corresponding methyl xylopyranosides.

In order to confirm the results shown in Table 1 products were isolated and characterized in two cases. Treatment of methyl tetra-*O*-acetyl-α-D-glucopyranoside (*1a*) with hydrogen bromide in acetic acid for 20 h gave a mixture of glycosyl bromides (*2a*) and (*4*) which were very unstable. They were therefore treated with silver benzoate to give 1-*O*-benzoates. From this product the pyranose (*3*) and the furanose (*5*) were isolated. Besides, 2,3,5,6-tetra-*O*-acetyl-D-glucofuranose was obtained, probably resulting from hydrolysis of the bromide (*4*). A small amount of the 6-bromo-6-deoxy-glucofuranose derivative (*6*) was



also isolated. Thus the reaction of (*1a*) with hydrogen bromide gives a complicated mixture of products, and it is understable that Zemplén [4] could not isolate acetobromoglucose from this reaction.

Treatment of the tetrabenzoate (*1b*) with hydrogen bromide gave a good yield of tetra-*O*-benzoyl-α-D-glucopyranosyl bromide (*2b*).

Methyl tri-*O*-acetyl-β-D-ribopyranoside (*7*) is almost completely converted into a mixture of the anomeric furanosyl bromides (*8*) when treated with hydrogen bromide (Table 1). Since these bromides are unstable the reaction mixture was treated with acetic anhydride and zinc bromide in order to convert them into the tetraacetates (9) which could then be isolated in 58 % yield.

EXPERIMENTAL

Melting points are uncorrected. NMR spectra were recorded on a Bruker HX-90E instrument. The spectra shown in Table 1 were measured on solutions which contained *ca.* 10 % carbohydrate in 30 % HBr/HOAc. The chemical shifts were measured relative to internal chloroform. Thin layer chromatography (TLC) was performed on silica gel PF_{254} (Merck): for preparative work 1 mm layers on 20 × 40 cm plates were used. Spots were visualized with UV light or by charring with a hot wire.

*Methyl tetra-*O*-acetyl-α-*D*-glucopyranoside (1a)* (1.0 g) was dissolved in 4 ml of 30 % HBr/HOAc and the solution was kept at room temp. for 20 h. It was then diluted with dichloromethane, washed with water and aqueous $NaHCO_3$, dried ($MgSO_4$) and evaporated. The crude product (1.15 g) was dissolved in dry acetonitrile (25 ml) and stirred over night with silver benzoate (3.0 g). The mixture was filtered through carbon and the solvent was evaporated. The residue was dissolved in dichloromethane and washed with aqueous $NaHCO_3$, dried and evaporated. The syrupy product was separated into several fractions by preparative TLC using diethyl ether – pentane (2:1) as eluent.

The fastest moving fraction gave 77 mg (6 %) of 2,3,5-tri-*O*-acetyl-1-*O*-benzoyl-6-bromo-6-deoxy-β-D-glucofuranose (*6*) as a syrup, $[\alpha]_D^{20}$ −64.7° (*c* 2.1, $CHCl_3$). (Found: C 48.34; H 4.60; Br 17.12. Calc. for $C_{19}H_{21}BrO_9$: C 48.22; H 4.47; Br 16.89). A 100 MHz NMR spectrum gave the following δ-values and coupling constants (Hz): H1 6.43; H2 5.30; H3 5.55; H4 4.69; H5 5.25; H6 3.67; H6′ 3.76. J_{12} ~0; J_{13} 0.3; J_{23} 0.8; J_{34} 4.7; J_{45} 9.4; J_{56} 3.2; $J_{56'}$ 4.0; $J_{66'}$ −11.8.

The next two fractions could not be identified. The fourth fraction gave 351 mg (28 %) of a mixture of (*3*) and (*5*) in a ratio of 4:1 as seen from an NMR spectrum. Crystallization and recrystallization from ethanol gave tetra-*O*-acetyl-1-*O*-benzoyl-β-D-glucopyranose (*3*), m.p. 140 – 141 °C, $[\alpha]_D^{20}$ −25.5° (*c* 2.9, $CHCl_3$) (reported [5] m.p. 143 – 145°, $[\alpha]_D$ −26.6°). 1-*O*-Benzoyl-tetra-*O*-acetyl-β-D-glucofuranose (*5*) was identified in the mother liquor from (*3*) by comparing its NMR spectrum with that of an authentic sample.[6]

The last fraction gave 140 mg (14.5 %) of a product which consisted mainly of 2,3,5,6-tetra-*O*-acetyl-D-glucofuranose as seen from an NMR spectrum. Acetylation gave a mixture of the anomeric penta-*O*-acetyl-D-glucofuranoses the NMR spectra of which were identical with those previously reported.[7]

*Methyl tetra-*O*-benzoyl-α-*D*-glucopyranoside (1b)* (1.0 g) was dissolved in dichloromethane (1.0 ml) and HBr/HOAc (5.0 ml) was added. The solution was kept for 3 days at room temp. and worked up as described above. The product was crystallized from ether to give 705 mg (65 %) of tetra-*O*-benzoyl-α-D-glucopyranosyl bromide (*2b*), m.p. 122 – 124 °C. One recrystallization gave the pure product, m.p. 125 – 125.5 °C, $[\alpha]_D^{20}$ +123.1° (*c* 1.4, $CHCl_3$) (reported [8] m.p. 129 – 130 °C (corr.), $[\alpha]_D$ +124°). The material in the mother liquor consisted of the same bromide and *ca.* 10 % unreacted (*1b*) as seen from an NMR spectrum. No furanosyl bromide could be detected.

*Methyl tri-*O*-acetyl-β-*D*-ribopyranoside (7)* (2.19 g) was kept in HBr/HOAc (6.0 ml) for 1.5 h at room temp. Acetic anhydride (35 ml) and anhydrous zinc bromide (100 mg) were then added and the mixture was stirred for 15 min. It was then poured on ice and stirred for 3 h. The product was extracted with chloroform; the solution was washed with water and aqueous $NaHCO_3$, dried and evaporated. The product (2.31 g) consisted mainly of a mixture of the anomeric tetra-*O*-acetyl-D-ribofuranoses (9) in an α:β ratio of 1:3 as seen from an NMR spectrum. Crystallization from ethanol gave 510 mg (21 %) of the β-anomer (*β9*), m.p. 55 – 58 °C. Preparative TLC of the material in the mother liquor gave 892 mg (37 %) of α,β-mixture. Crystallization of this from ethanol gave 300 mg of (*β9*), m.p. 56 – 58 °C. Recrystallization from ethanol gave a product with m.p. 57 – 59 °C, $[\alpha]_D^{20}$ −12.7° (*c* 4.5, $CHCl_3$). This is the low melting form of tetra-*O*-acetyl-β-D-ribofuranose;[9] we have not been able to obtain the high melting form.[10] An NMR spectrum was in agreement with the structure and showed no impurities.

Microanalyses were performed by Dr. A. Bernhard Mikroanalytisches Laboratorium.

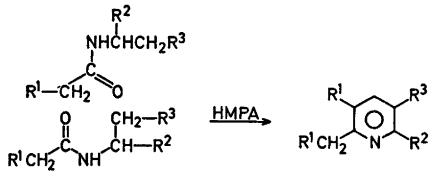
Studies on Organophosphorus Compounds. IX.* Hexamethylphosphoric Triamide (HMPA) as Reagent in a New Quinoline Synthesis

E. B. PEDERSEN** and S.-O. LAWESSON

Department of Organic Chemistry, Chemical Institute, University of Aarhus, 8000 Aarhus C, Denmark

Acetanilides, refluxed in DMF and HMPA, produce 2-dimethylamino-quinolines in 40 – 76 %. For other anilides the yields decreased when the size of the acyl-group increased. A mechanism is suggested in which the anilide first produces the corresponding *N*,*N*-dimethyl-amidine, which by further reaction with DMF gives the quinoline. The kinetics of the formation of the amidines showed that the reactions were autocatalyzed by $(Me_2N)_3P(O)OH$. Also it was found that acetanilide, when refluxed in HMPA and acetic acid derivatives such as phenylacetate and *N*,*N*-dimethyl-acetamide, gave the corresponding 2-dimethylamino-4-methyl-quinoline. Furthermore 23 – 54 % yield of 2-dimethylamino-4-methyl-quinolines were formed when anilines were refluxed in acetic acid and HMPA.

In an earlier investigation [1] it was demonstrated that gentle reflux of secondary carboxamides (RCONHR′, where R or/and R′ is aromatic) in hexamethylphosphoric triamide (HMPA) produced the corresponding *N*,*N*-dimethyl-amidines in fair yields. However, if R or R′ were able to form sufficiently stable carbonium ions fragmentation reactions [2] were found. It was also found that gentle reflux of aliphatic secondary carboxamides produced pyridines,[3] eqn. 1, and it was suggested that the pyridine was formed by the reaction of two different carboxamide molecules. This was confirmed by the observation that a mixture of acetanilide and *N*-isopropylpivaloamide heated in HMPA formed 2-*t*-butyl-6-methylpyridine. In a similar experiment it was attempted to prepare 5,6,7,8-tetrahydroquinoline from acetanilide and *N*-cyclohexyl-formamide by heating in HMPA. Quite unexpectedly the formamide reacted in a different way with acetanilide and instead 2-dimethylamino-quinoline was obtained in 51 % yield. As this new quinoline synthesis was very promising – easy available starting materials, simple reaction conditions, fair yield *etc.* – a thorough investigation was made on this reaction and this paper describes the results of that.



(1)

RESULTS AND DISCUSSION

In the reaction of acetanilide and *N*-cyclohexylformamide with HMPA at reflux temperature cyclohexylamine is split off and 2-dimethylamino-quinoline is produced. It was therefore expected that dimethylformamide (DMF) should undergo a similar reaction and that was indeed found, (Table 1).

Furthermore DMF is a very convenient reagent as side reactions, shown in eqn. 1, are excluded in this quinoline synthesis. The substituents R on the aromatic ring of the acetanilide give no systematic variations of the yields of the quinolines, which are in the order of

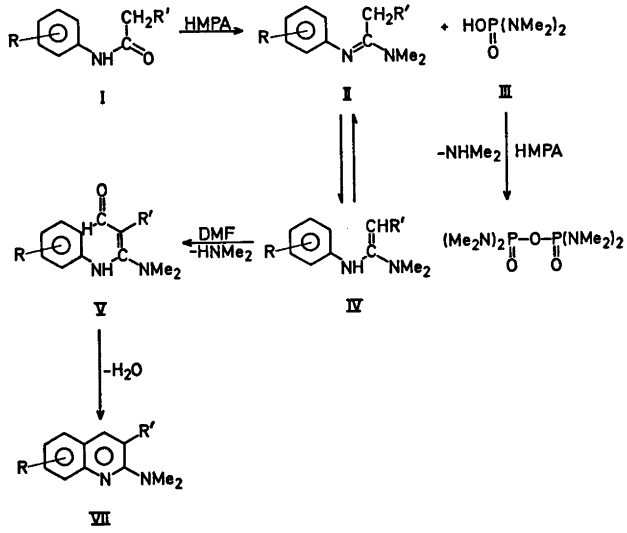
H	i-Pr	0	22

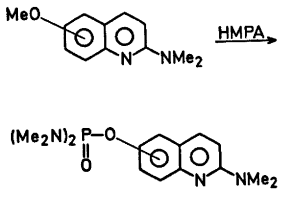
40 – 76 %. However, the substituents R′ had a marked influence on the yields, which decreased from 72 % to 0 %, when hydrogen was replaced by the isopropyl group, (Table 1).

Concerning the mechanism (Scheme 1) it is suggested that the first step is the formation of the corresponding *N*,*N*-dimethyl-amidine II, which is a known reaction when acetanilide is heated in HMPA.[1] In fact, when *N*,*N*-dimethyl-*N*′-phenyl-acetamidine is refluxed (as the corresponding anilide) in DMF and HMPA, 2-dimethylaminoquinoline was obtained in 60 % yield. The amidine II is then assumed to be in a tautomeric equilibrium with the highly reactive enamine IV, which undergoes a reaction with DMF to form V. The intermediate V then tautomerizes to its enol-form VI, which subsequently undergoes a ring closure reaction followed by elimination of water to form the quinoline VII. It might be possible that the hydroxyl group of the enol VI is replaced by a dimethylamino group as ketones are known to produce the corresponding *N*,*N*-dimethyl-enamines by heating in HMPA.[4] If this is the case, a ring closure reaction followed by elimination of dimethylamine also can give the quinoline VII. Octamethylpyrophosphoramide, OMPA, was isolated in the reaction of *p*-methyl- and *p*-methoxy-acetanilide with DMF and HMPA. Its presence in the reaction mixture is best explained by the reaction of primarily formed phosphoric acid derivative III with HMPA, (Scheme 1).

Furthermore, support of the suggested mechanism was also provided by the generation of dimethylamine, which easily could be followed during the reaction by the colour change of silica gel (light blue→dark blue) placed in a drying tube on top of the reflux-condenser. In the synthesis of 6- and 8-methoxy-2-dimethylamino-quinolines the yields were slightly reduced because of further reaction of the methoxy-group with HMPA, (eqn. 2).

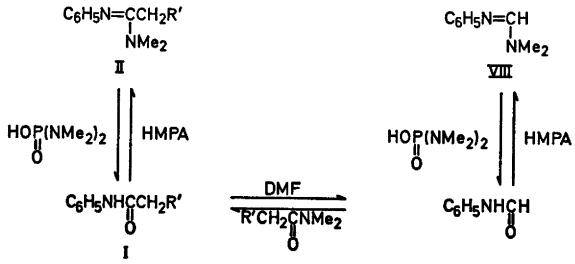


Scheme 1.

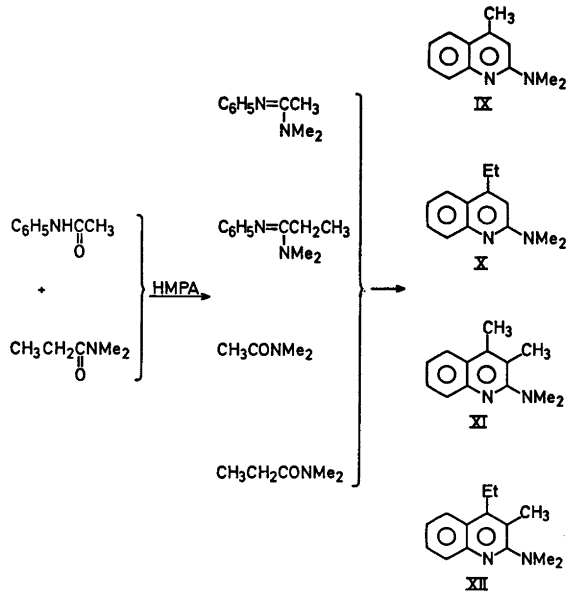


(2)

In the reaction of isovaleranilide no quinoline VII was isolated, but instead II (R′=i-Pr), VIII and *N*,*N*-dimethylvaleramide were found besides some starting material. As III is likely to be present in the reaction mixture (Scheme 2) the suggested equilibrium is quite appropriate. This equilibrium is shifted from VIII towards II as the amidine II is used up in the quinoline syntheses. This was further substantiated in the reaction of acetanilide with HMPA and DMF where only 1 % of VIII was isolated and the yield of the quinoline VII was as high as 72 % whereas the yields of VIII and VII in the reaction of valeramide were 22 % and 0 %, respectively, (Table 1). Equilibria as suggested in Scheme 2 can also produce a very complex reaction mixture in other cases. Thus the quinolines, IX – XII are found in the reaction of acetanilide with *N*,*N*-dimethyl-propionamide and HMPA, (Scheme 3). If the above equilibria were of minor importance, only the quinoline X should be formed by analogy to the formation of the quinoline VII (Scheme 1). It is quite obvious that, if *p*-methyl-acetanilide is refluxed in *N*,*N*-dimethyl-acetamide and HMPA, transacylation reactions cannot interfere with the quinoline synthesis and a high yield is obtained of the corresponding quinoline, (Table 2). Also phenyl acetate can be used in the reaction with acetanilide and HMPA and

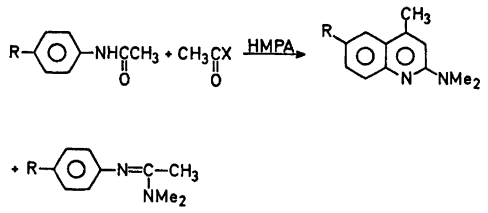


Scheme 2.



Scheme 3.

Table 2.



R	X	Quinoline (%)	Amidine (%)
CH_3	NMe_2	46	
H	OC_6H_5	52	
CH_3	p-CH_3-C_6H_4NH	18	44
CH_3O	p-CH_3O-C_6H_4NH	6	76
Cl	p-Cl-C_6H_4NH		64

the corresponding 2-dimethylamino-4-methyl-quinoline was obtained. In this reaction phenol should be produced in a similar way as dimethylamine did in the reaction of DMF with IV, (Scheme 1). In fact phenol was produced, but it reacted with HMPA as it has been shown recently [5] and $C_6H_5OPO(NMe_2)_2$ and $(C_6H_5O)_2$-$PO(NMe_2)$ were found in the reaction mixture. Furthermore in the synthesis of *N*-aryl-*N'*,*N'*-dimethylacetamidines from acetanilides in some cases the corresponding 2-dimethylamino-4-methyl-quinolines were obtained as by-products (Table 2). These by-products are produced by the reaction of the formed amidine with the starting material and clearly demonstrate that 2-dimethylamino-quinolines may be formed whenever an acetic acid derivative is heated together with an acetanilide in HMPA.

2-Dimethylamino-4-methyl-quinolines are formed when anilines are refluxed in acetic acid and HMPA (Table 3). The mechanism of this reaction is easily understood as it is known that acetic acid by heating in HMPA produces *N*,*N*-dimethyl-acetamide.[6] The so formed acetamide then undergoes transacylation reaction with the anilines to form acetanilides, which then produce the quinoline by reaction with the acetamide. By refluxing aniline in propionic acid and HMPA the corresponding quinoline, XII, was obtained in 17 %. The relatively low yield is not surprising as the size of the acyl group also has a profound influence on the yield in the reaction of the carboxamides I with DMF and HMPA (Table 1).

KINETICS

The reaction given in eqn. 3, which is observed when no DMF is added, is also the first step in the quinoline synthesis, Scheme 1.

$$\underset{\text{I}}{p\text{-R}-C_6H_4NHCOCH_3} \xrightarrow{\text{HMPA}} p\text{-R}-C_6H_4N=\underset{\text{NMe}_2}{\underset{|}{C}}CH_3 + \underset{\text{O}}{\underset{\|}{HOP}}(NMe_2)_2 \qquad (3)$$

II III

The conversion of the amide I to the amidine II in HMPA can easily be followed by NMR when no DMF is added as the *ortho*-protons to the amido-group in the aromatic ring of the acetanilides fall at a different field in NMR than all other aromatic protons of I and II. It

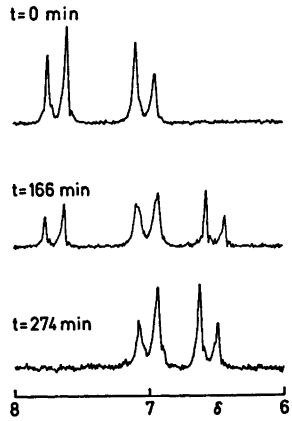

Fig. 1. Reaction of *p*-acetotoluidide with HMPA followed by NMR of aromatic hydrogen atoms.

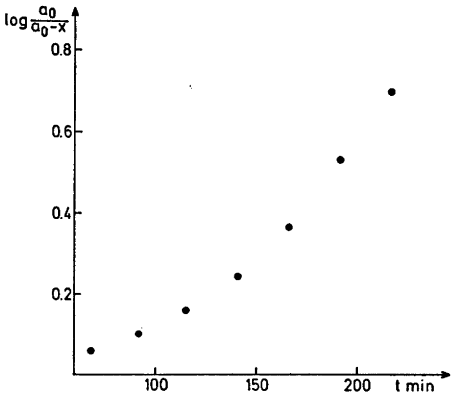

Fig. 2. Log $a_0/(a_0-x)$ *versus* t. 1.000 mol kg^{-1} *p*-acetotoluidide in HMPA.

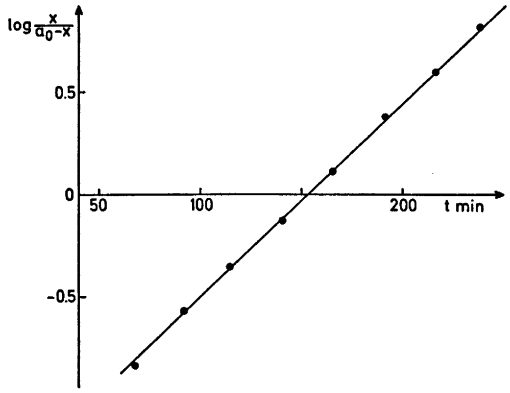

Fig. 3. Log $x/(a_0-x)$ *versus* t. 1.000 mol kg^{-1} *p*-acetotoluidide in HMPA.

should be noted that the number of aromatic hydrogens is constant during the reaction. An example is given in Fig. 1 for the reaction of *p*-acetotoluidide with HMPA at 210 °C. At this temperature only traces of dimethylamine could be detected. This indicates that almost no OMPA is formed by the reaction of III with HMPA at this temperature as dimethylamine is produced in this reaction, (Scheme 1).

The most simple approach to the kinetics of the reaction given in eqn. 3 is to assume that the reaction is pseudo first order with regard to the amide I if excess of HMPA is used. However, if log $a_0/(a_0-x)$, where a_0 is starting concentration of I and x the consumption of I, is plotted against the time, (Fig. 2), this reaction order is easily ruled out as no linear correlation is found. Instead if it is assumed that the reaction is autocatalysed the rate equations will be as follows:

$$d(a_0-x)/dt = -k(a_0-x)(x+c_0) \quad (4)$$

or

$$[1/(a_0+c_0)] \ln (x+c_0)/(a_0-x) = kt+K \quad (5)$$

where a_0 is initial concentration of I, x consumption of I as well as concentration of the catalyst produced during the reaction, c_0 is initial concentration of the catalyst, k rate constant, t time, and K constant. For *p*-acetotoluidide heated in HMPA, $c_0 = 0$, at 210 °C there is then found an excellent linear correlation when log $x/(a_0-x)$ is plotted against t, (Fig. 3).

At the start of the reaction where no catalyst is present this correlation is obviously not found. An induction period of 50 – 60 min was needed to produce the amount of catalyst, about 0.1 equivalent, necessary for the good linear correlation.

The rate constants for the reaction of *para* substituted acetanilides with HMPA at 210 °C were calculated by the least squares method (*para*-substituent, rate constant mol^{-1} kg min^{-1} given): Cl, 2.28×10^{-2}; H, 2.31×10^{-2}; CH_3, 2.22×10^{-2}; OCH_3, 2.11×10^{-2}. These rate constants can be correlated with σ_p^+ values but the found Hammett ϱ-value is so close to zero as 0.05 that no reasonable conclusion about the mechanism can be drawn.

In order to find out if III was the catalyst in the reaction it was prepared *in situ*

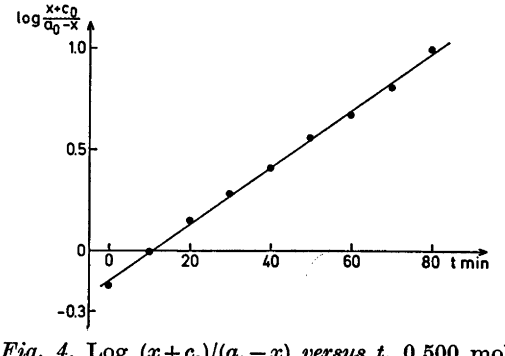

Fig. 4. Log $(x+c_0)/(a_0-x)$ *versus* t. 0.500 mol kg^{-1} NaOH, 0.500 mol kg^{-1} $(Me_2N)_2P(O)Cl$ and 1.000 mol kg^{-1} *p*-acetotoluidide in HMPA.

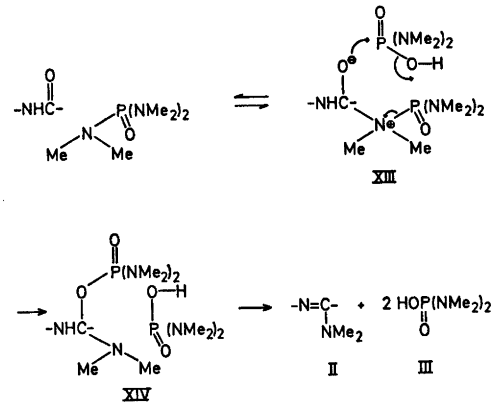
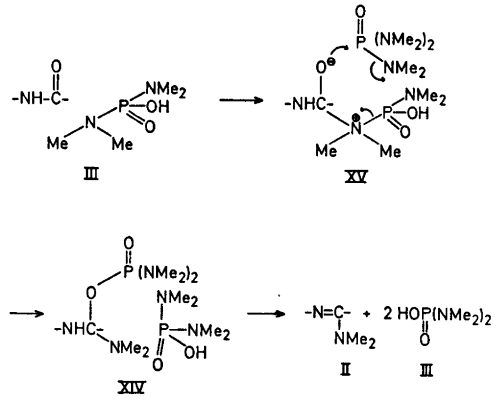
from $(Me_2N)_2P(O)Cl$ and powdered NaOH (1:1) in HMPA and then combined with *p*-acetotoluidide and heated. In fact if the reaction was followed by NMR and c_0 was assumed to be equal to the initial concentration of $(Me_2N)_2P(O)Cl$ and NaOH in eqn. 5, a linear correlation was obtained between log $(x+c_0)/(a_0-x)$ and t, (Fig. 4). Furthermore the rate constant, 2.19×10^{-2} mol^{-1} kg min^{-1} calculated by the least squares method was very close to the one obtained when no catalyst was added. Interestingly when the catalyst was added no induction periode was needed, instead 10 % of *p*-acetotoluidide was converted to the corresponding amidine even before the reaction temperature of 210 °C was reached. As the kinetics shows that the phosphoric acid derivative III is formed and also acts as a catalyst in the reaction of secondary carboxamides with HMPA, two mechanisms can easily be set up for the formation of the amidines; Schemes 4 and 5. In the first HMPA and the carboxamide are in equilibrium with the additions complex XIII, which in the rate determining step reacts with III to give XIV and III is then recovered. Compound XIV then produces the amidine II by an elimination reaction. In the other mechanism the carboxamide by reaction with III forms the additions complex XV, which by reaction with HMPA also produces XIV and III. The last step is then the same as above. The phosphoric acid derivative III is probably partly deprotonated by the amidine formed during the reaction or by HMPA. The nucleophilicity of the dimethylamino-groups of III is then increased compared to those of HMPA. As the first step in both mechanisms depends on the nucleophilicity of a dimethylamino-group in HMPA and III, respectively, the latter mechanism seems to be the most probable one.



Scheme 4.



Scheme 5.

CONCLUSION

2-Dimethylamino-quinoline has earlier been prepared from a variety of quinoline derivatives [7–12] and thus from not easily available starting materials. Also manystep-ring-closure reactions have been used for the synthesis of, *e.g.* 2-dimethylamino-4-methyl-quinolines.[13] In this paper a method is presented giving the same types of quinolines as mentioned above [7–13] but with easily available, simple and cheap starting materials and with a one-pot reaction. We thus strongly feel, that the dimethylamino-quinoline synthesis presented here seems to be the method of choice and, to the best of our knowledge and judgement, superior to all known procedures.

EXPERIMENTAL

In all experiments commercial HMPA dried over molecular sieves (3A) was used. NMR spectra were recorded on a Varian A-60 spectrometer (s = singlet, d = doublet, t = triplet, q = quartet and m = multiplet). The microanalyses were performed by Løvens Kemiske Fabrik, Copenhagen.

2-Dimethylamino-quinoline. Acetanilide (13.5 g), 10 ml DMF and 50 HMPA were heated on a silicon-oil bath (250 °C) for 16 h. The reflux temperature increased during this time from 205 °C to 240 °C. The reaction mixture was

allowed to cool to 100 °C and was then poured into 400 ml 2 M NaOH and extracted with 3 × 200 ml diethyl ether. The organic phase was washed with 2 × 100 ml H_2O, dried over K_2CO_3 and the ether was stripped off. Distillation 95 – 110 °C/0.1 mmHg followed by recrystallization from light petroleum (60 – 80 °C) gave 11.5 g (67 %) of the title compound, m.p. 70 – 71 °C, lit.[11] m.p. 70 – 71 °C. Preparative TLC of the mother liquid using silica gel as the supporting material and elution with ether – light petroleum (1:4) gave further 0.93 g (5 %) of the title compound, $R_F = 0.18$, and 0.1 g (< 1 %) of *N,N*-dimethyl-*N'*-phenyl-formamidine, $R_F = 0.06$.

2-Dimethylamino-8-methyl-quinoline. *o*-Acetotoluidide (14.9 g), 10 ml DMF and 50 ml HMPA were heated as above and worked up as above. Distillation 100 – 110 °C/0.07 mmHg gave a fraction, which was chromatographed on a silica gel column. Using ether – light petroleum (1:10) for elution 14.1 g (76 %) of the title compound was obtained; b.p. 94 – 96 °C/0.05 mmHg; $n_D^{23} = 1.6367$; NMR δ ($CDCl_3$): 2.65 (s, 3 H), 3.08(s, 6 H), 6.72(d, $J = 9$ Hz, 1 H), 6.9 – 7.5(m, 3 H), 7.73(d, $J = 9$ Hz, 1 H); IR(Film): 1610 cm^{-1} (strong); UV (C_6H_{12}): $\lambda_{max} = 251$ nm (log $\varepsilon = 4.55$) and 354 nm (log $\varepsilon = 3.80$). (Found: C 77.34; H 7.54; N 15.07. $C_{12}H_{14}N_2$ requires: C 77.38; H 7.58; N 15.04). Further elution with ether gave 0.43 g (3 %) of *N,N*-dimethyl-*N'*-*o*-tolyl-formamidine; b.p. 128 – 130 °C/12 mmHg; $n_D^{21} = 1.5772$; NMR δ ($CDCl_3$): 2.26 (s, 3 H), 2.93(s, 6 H), 6.4 – 7.2(m, 4 H), 7.38(s, 1 H); IR(Film): 1640 cm^{-1} (strong). (Found: C 73.98; H 8.65; N 16.81. $C_{10}H_{14}N_2$ requires: C 74.03; H 8.70; N 17.27).

2-Dimethylamino-6-methyl-quinoline. *p*-Acetotoluidide (14.9 g), 10 ml DMF and 50 ml HMPA were heated as above. The reaction mixture was allowed to cool to 100 °C and was then poured into 400 ml 2 M NaOH and extracted with 3 × 200 ml ether. The combined ether phases were washed with 2 × 100 ml water, dried over K_2CO_3 and the ether was stripped off. Distillation 118 – 122 °C/0.3 mmHg and subsequent recrystallization from light petroleum (60 – 80 °C) gave 11.3 g (61 %) of the title compound; m.p. 78 – 79 °C; NMR δ ($CDCl_3$): 2.38(s, 3 H), 3.10(s, 6 H). 6.72(d, $J = 9$ Hz, 1 H), 7.1 – 7.8(m, 4 H); IR(CCl_4): 1610 cm^{-1} (strong); UV (C_6H_{12}): $\lambda_{max} = 250$ nm (log $\varepsilon = 4.54$), 357 nm (log $\varepsilon = 3.77$). (Found: C 77.50; H 7.64; N 15.06. $C_{12}H_{14}N_2$ requires: C 77.38; H 7.58; N 15.04). The combined water phases were then extracted with 3 × 100 ml $CHCl_3$ and distillation 112 – 118 °C/0.1 mmHg gave 5.2 g OMPA.

2-Dimethylamino-6-methoxy-quinoline. *p*-Acetanisidide (16.5 g), 10 ml DMF and 50 ml HMPA were heated as above for 16 h and worked up in a similar way. The ether extract gave by distillation at 134 – 142 °C/0.1 mmHg and subsequent recrystallization from light petroleum (60 – 80 °C) 10.3 g (51 %) of the title compound; m.p. 71 – 72 °C; NMR δ ($CDCl_3$): 3.11(s, 6 H), 3.60(s, 3 H), 6.7 – 7.9(m, 5 H); IR(CCl_4): 1615 cm^{-1} (strong); UV (C_6H_{12}): $\lambda_{max} = 243$ nm (log $\varepsilon = 4.54$) and 366 nm (log $\varepsilon = 3.76$). (Found: C 71.23; H 7.02; N 13.97. $C_{12}H_{14}N_2O$ requires: C 71.26; H 6.98; N 13.85). Preparative TLC of the distillation residue using silica gel as supporting material and ether for elution gave 1.46 g (5 %) of 6-bis(dimethylamino)-phosphinyloxy-2-dimethylaminoquinoline; m.p. 80 – 82 °C; NMR δ ($CDCl_3$): 2.72(d, $J = 10$ Hz, 12 H), 3.15(s, 6 H), 6.85(d, $J = 9$ Hz, 1 H), 7.2 – 7.9(m, 4 H); IR(KBr): 1620 cm^{-1} (strong). (Found: H 7.01; N 17.10. $C_{15}H_{23}N_4O_2P$ requires: H 7.19; N 17.38). From the $CHCl_3$ extract there was obtained 3.5 g OMPA by distillation 118 – 122 °C/0.2 mmHg.

2-Dimethylamino-8-methoxy-quinoline. *o*-Acetanisidide (16.5 g), 10 ml DMF and 50 ml HMPA were heated as above for 16 h. Work up as for 2-dimethylamino-quinoline followed by distillation 130 – 140 °C/0.1 mmHg and subsequent recrystallization from light petroleum (60 – 80 °C) gave 8.0 g (40 %) of the title compound; m.p. 105 – 107 °C; NMR δ ($CDCl_3$): 3.17(s, 6 H), 3.97(s, 3 H), 6.7 – 7.3(m, 4 H), 7.78(d, $J = 9$ Hz, 1 H); IR(CCl_4): 1610 cm^{-1} (strong); UV (C_6H_{12}): $\lambda_{max} = 270$ nm (log $\varepsilon = 4.43$) and 356 nm (log $\varepsilon = 3.59$). (Found: C 71.12; H 6.93; N 13.86. $C_{12}H_{14}N_2O$ requires: C 71.26; H 6.98; N 13.85). Preparative TLC of the distillation residue using silica gel as supporting material and acetone – $CHCl_3$ (1:9) for elution gave 1.77 g (5 %) of 8-bis(dimethylamino)phosphinyloxy-2-dimethylamino-quinoline; NMR δ ($CDCl_3$): 2.78(d, $J = 10$ Hz, 12 H), 3.17(s, 6 H), 6.85(d, $J = 9$ Hz, 1 H), 7.0 – 7.7(m, 3 H), 7.80(d, $J = 9$ Hz, 1 H); IR(CCl_4): 1620 and 1630 cm^{-1} (strong); UV (C_6H_{12}): $\lambda_{max} = 260$ nm (log $\varepsilon = 4.46$) and 353 nm (log $\varepsilon = 3.68$). (Found: C 55.63; H 7.38; N 17.12. $C_{15}H_{23}N_4O_2P$ requires: C 55.89; H 7.19; N 17.38).

2-Dimethylamino-benzo[h]quinoline. *N*-α-Naphthylacetamide (18.5 g), 10 ml DMF and 50 ml HMPA were heated as above for 16 h. Work up as for 2-dimethylamino-quinoline and followed by recrystallization gave 13.0 g (59 %) of the title compound; m.p. 92 – 93 °C; NMR δ ($CDCl_3$): 3.12(s, 6 H), 6.68(d, $J = 9$ Hz, 1 H), 7.4 – 7.9 (m, 6 H), 9.17(m, 1 H); IR(CCl_4): 1610 cm^{-1} (strong); UV (C_6H_{12}): $\lambda_{max} = 241$ nm (log $\varepsilon = 4.72$), 2.91 nm (log $\varepsilon = 4.26$), 321 nm (log $\varepsilon = 3.05$), 363 nm (log $\varepsilon = 3.81$) and 382 nm (log $\varepsilon = 3.81$). (Found: C 81.02; H 6.35; N 12.57. $C_{15}H_{14}N_2$ requires: C 81.05; H 6.35; N 12.60).

2-Dimethylamino-3-methyl-quinoline. *N*-Phenylpropionamide (14.9 g), 10 ml DMF and 50 ml HMPA were heated as above for 25 h. Work up as above gave by distillation 86 – 110 °C/0.15 mmHg a fraction, which was subjected to chromatography on a silica gel column. Elution with ether – light petroleum (40 – 60 °C) (1:1) gave 9.8 g (53 %) of the title compound; b.p. 158 – 160 °C/11 mmHg; $n_D^{26} = 1.6161$; NMR δ

($CDCl_3$): 2.35(d, $J=1.0$ Hz, 3 H), 2.95(s, 6 H), 7.1 – 8.0 (m, 5 H); IR(CCl_4): 1615 cm^{-1} (strong), 1635 cm^{-1} (strong); UV (C_6H_{12}): 253 nm (log $\varepsilon=4.33$) and 333 nm (log $\varepsilon=3.72$). (Found: C 77.21; H 7.72; N 15.09. $C_{12}H_{14}N_2$ requires: C 77.38; H 7.58; N 15.09). Further elution with ether gave 0.94 g (5 %) of *N,N*-dimethyl-*N'*-phenylformamidine.

2-Dimethylamino-3-ethyl-quinoline. *N*-Phenylbutyramide (8.15 g), 5 ml DMF and 25 ml HMPA were heated as above for 12 h. Work up as above gave by distillation a fraction 60 – 100 °C/0.07 mmHg which was subjected to chromatography on a silica gel column. Elution with ether – light petroleum (40 – 60 °C) (1:1) gave 2.6 g (26 %) of the title compound; b.p. 167 – 169 °C/14 mmHg; $n_D^{24}=1.6132$; NMR δ ($CDCl_3$): 1.28 (t, $J=7$ Hz, 3 H), 2.78 (q, $J=7$ Hz, 2 H), 2.93 (s, 6 H), 7.1 – 8.0 (m, 5 H); IR(CCl_4): 1610 cm^{-1} (strong), 1630 cm^{-1} (strong); UV (C_6H_{12}): 253 nm (log $\varepsilon=4.34$), 333 nm (log $\varepsilon=3.74$). (Found: C 77.64; H 8.20; N 13.97. $C_{13}H_{16}N_2$ requires: C 77.96; H 8.05; N 13.99). Further elution with ether gave 3.7 g of a fraction which was estimated by NMR and GLC to contain about 50 % *N,N*-dimethyl-*N'*-phenyl-formamidine, corresponding to ~10 % yield.

Attempted preparation of 2-dimethylamino-3-isopropylquinoline. *N*-Phenyl-isovaleramide (17.7 g), 10 ml DMF and 50 ml HMPA were heated as above for 18 h. The reaction mixture was taken up in 400 ml 2 M NaOH and extracted with 3 × 200 ml ether. The combined ether phases were washed with 2 × 100 ml H_2O, dried over K_2CO_3 and the ether stripped off. Light petroleum was added and 3.6 g (20 %) of the starting material precipitated. Fractionated distillation of the mother liquid gave 1.5 g (11 %) *N,N*-dimethyl-isovaleramide, b.p. 78 – 80 °C/12 mmHg, $n_D^{20}=1.4421$, lit.[14] b.p. 72 – 74 °C/8 mmHg, $n_D^{20}=1.4412$. Further distillation 130 – 160 °C/11 gave a mixture of 3.2 g (22 %) *N,N*-dimethyl-*N'*-phenyl-formamidine and 3.0 g (15 %) *N,N*-dimethyl-*N'*-phenyl-isovaleramidine (estimated by NMR), the latter compound was purified by preparative TLC using silica gel as supporting material and CH_3CN-MeOH-acetone (1:1:1) for elution, NMR δ ($CDCl_3$): 0.78 (d, $J=6$ Hz, 6 H), ~1.7 (m, 1 H), 2.25 (d, $J=7$ Hz, 2 H), 2.98 (s, 6 H), 6.5 – 7.4(m, 5 H); IR(CCl_4): 1630 cm^{-1} (strong); UV (C_6H_{12}): 245 nm (log $\varepsilon=4.08$). Further distillation 100 – 135 °C/0.08 mmHg and subsequent washing with light petroleum gave 2.1 g 12 % of starting material.

2-Dimethylamino-4-methyl-quinoline. Aniline (4.7 g), acetic acid (10 g) and 50 ml HMPA were heated on a silicone-oil bath (250 °C) for 18 h. The reaction mixture was allowed to cool to 100 °C and was then taken up in 400 ml 2 M NaOH and extracted 3 × 200 ml ether. The combined ether-phases were washed with 2 × 100 ml H_2O, dried over K_2CO_3 and the ether stripped off. Distillation at 90 – 120 °C/0.1 mmHg, and subsequent recrystallization from light petroleum gave 3.6 g (39 %) of the title compound, m.p. 47 – 48 °C, lit.[13] m.p. 47 – 50 °C.

2-Dimethylamino-4,6-dimethyl-quinoline. *p*-Toluidine (5.4 g), acetic acid (10 g) and 50 ml HMPA were heated as above. Work up as above gave after distillation 100 – 140 °C/0.1 mmHg and subsequent recrystallization from light petroleum 5.4 g (54 %) of the title compound m.p. 85 – 87 °C; NMR δ ($CDCl_3$): 2.43 (s, 3 H), 2.50 (d, $J=1.0$ Hz, 3 H), 3.11 (s, 6 H), 6.68 (q, $J=1.0$ Hz, 1 H), 7.1 – 7.8(m, 3 H); IR(CCl_4): 1620 cm^{-1} (strong); UV (C_6H_{12}): 254 nm (log $\varepsilon=4.50$), 356 nm (log $\varepsilon=3.78$). (Found: C 78.08; H 8.21; N 14.00. $C_{13}H_{16}N_2$ requires: C 77.96; H 8.05; N 13.99).

2-Dimethylamino-4,8-dimethyl-quinoline. *o*-Toluidine (5.4 g) acetic acid (10 g) and 50 ml HMPA were heated as above for 16 h. Work up as above gave after distillation 80 – 130 °C/0.05 mmHg and subsequent recrystallization from light petroleum 3.5 g (35 %) of the title compound; m.p. 58 – 60 °C, lit.[13] m.p. 60 – 62 °C.

6-Chloro-2-dimethylamino-4-methyl-quinoline. *p*-Chloroaniline (6.4 g) acetic acid (10 g) and 50 ml HMPA were heated as above for 16 h. Work up as above gave after distillation 110 – 150 °C/0.15 mmHg and subsequent recrystallization from light petroleum 4.4 g (40 %) of the title compound; m.p. 81 – 83 °C; NMR δ ($CDCl_3$): 2.43(d, $J=1.0$ Hz, 3 H), 3.12(s, 6 H), 6.65(q, $J=1.0$ Hz, 1 H), 7.2 – 7.8(m, 3 H); IR(CCl_4): 1620 cm^{-1} (strong); UV (C_6H_{12}): 252 nm (log $\varepsilon=4.53$), 280 nm (log $\varepsilon=4.23$), 288 nm (log $\varepsilon=4.10$), 359 nm (log $\varepsilon=3.82$). (Found: C 65.28; H 5.94; N 12.68. $C_{12}H_{13}ClN_2$ requires: C 65.30; H 5.94; N 12.69).

2-Dimethylamino-6-methoxy-4-methyl-quinoline. *p*-Anisidine (6.2 g) acetic acid (10 g) and 50 ml HMPA were heated as above. Work up as above gave after distillation 130 – 180 °C/0.2 mmHg and subsequent recrystallization from light petroleum 2.5 g (23 %) of the title compound m.p. 84 °C lit.[13] m.p. 87 – 89 °C.

2-Dimethylamino-4-ethyl-3-methyl-quinoline. Aniline (4.7 g) propionic acid (12.6 g) and 50 ml HMPA were heated as above. Work up as above gave the title compound, which was purified on a silica gel column using ether – light petroleum (1:4) for elution to give 1.78 g (17 %) of pure title compound; b.p. 154 – 156 °C/2 mmHg; $n_D^{24}=1.6085$; NMR δ ($CDCl_3$): 1.20 (t, $J=8$ Hz, 3 H), 2.37 (s, 3 H), 2.90 (s, 6 H), 3.00 (q, $J=8$ Hz, 2 H), 7.1 – 8.0 (m, 4 H); IR(CCl_4): 1595 cm^{-1} (strong); UV (C_6H_{12}): 252 nm (log $\varepsilon=4.37$), 333 cm^{-1} (log $\varepsilon=3.70$). (Found: C 78.67; H 8.49; N 12.96. $C_{14}H_{18}N_2$ requires: C 78.46; H 8.47; N 13.07).

N,N-Dimethyl-N'-p-tolyl-acetamidine. *p*-Acetotoluidide (29.8 g) and 100 ml HMPA were heated at 230 °C for 6 h. Work up as for 2-dimethylaminoquinoline and subsequent fractionated distillation gave: *1.* 15.6 g (44 %) of

the title compound, b.p. 80 – 82 °C/0.05 mmHg, $n_D = 1.5670$; NMR δ ($CDCl_3$): 1.82 (s, 3 H), 2.27 (s, 3 H), 2.97 (s, 6 H), 6.3 – 6.7 (m, 2 H), 6.8 – 7.2(m, 2 H); IR(CCl_4): 1625 cm^{-1} (strong); UV (C_6H_{12}): 241 nm (log $\varepsilon = 4.14$). (Found: C 74.98; H 9.22; N 16.02. $C_{11}H_{16}N_2$ requires: C 74.95; H 9.15; N 15.90). *2.* 3.6 g (18 %) 2-dimethylamino-4,6-dimethyl-quinoline b.p. 129 – 131 °C/0.1 mmHg.

N,N-*Dimethyl-N'-(p-methoxyphenyl)-acetamidine.* Acetanisidide 33 g and 100 ml HMPA were heated at 225 °C for 4 h. and the reaction mixture was worked up as above. Distillation 105 – 110 °C/0.2 mmHg gave 29 g, 76 % of the title compound, $n_D^{24} = 1.5717$; NMR δ ($CDCl_3$): 1.82 (s, 3 H), 2.87 (s, 6 H), 3.73 (s, 3 H), 6.5 – 6.9 (m, 4 H). IR(CCl_4): 1620 cm^{-1} (strong): UV (C_6H_{12}): 241 nm (log $\varepsilon = 4.14$). (Found: C 68.95; H 8.44; N 14.56. $C_{11}H_{16}N_2O$ requires: C 68.72; H 8.39; N 14.56). Further distillation 160 – 170 °C/0.5 mmHg and subsequent recrystallization from light petroleum gave 1.38 g (6 %) 2-dimethylamino-6-methoxy-4-methylquinoline.

N'-*(p-Chlorophenyl)*-N,N-dimethyl-*acetamidine. p*-Chloroacetanisidide (30 g) and 100 ml HMPA were heated at 225 °C for 5 h and the reaction mixture was worked up as above. Distillation 90 – 100 °C/0.05 mmHg gave 22.3 g (64 %) of the title compound, $n_D^{24} = 1.5859$; NMR δ ($CDCl_3$): 1.83 (s, 3 H), 2.98 (s, 6 H), 6.4 – 6.7 (m, 2 H), 7.0 – 7.3 (m, 2 H); IR(CCl_4): 1620 cm^{-1} (strong); UV (C_6H_{12}): 248 nm (log $\varepsilon = 4.14$). (Found: C 61.27; H 6.75; N 14.13. $C_{10}H_{13}ClN_2$ requires: C 61.06; H 6.66; N 14.24).

p-*Acetotoluidide (14.9 g)* + N,N-*dimethyl-acetamide (12 g)* and 50 ml HMPA were heated on a silicone-oil (250 °C) bath for 16 h and the reaction mixture was worked up as above. Distillation 120 – 160 °C/ 0.3 mmHg and subsequent recrystallization from light petroleum gave 9.2 g (46 %) of 2-dimethylamino-4,6-dimethyl-quinoline.

Acetanilide (13.5 g) + *phenylacetate (16 g)* and 50 ml HMPA were treated as above for 16 h. The cooled reaction mixture is poured into 400 ml 2 M NaOH and extracted with 4 × 200 ml ether. To the combined ether phases (ether phase 1) was added 150 ml 2 M HCl. The precipitate was filtered off and the ether phase 1 was separated. The precipitate was taken up in the acidic water phase, which then was made alkaline and extracted with ether. This ether phase was dried over Na_2SO_4, and distillation at 110 – 120 °C/0.2 mmHg and subsequent recrystallization from light petroleum gave 9.7 g (52 %) 2-dimethylamino-4-methyl-quinoline. The ether phase 1 was dried over Na_2SO_4 and by distillation at 100 – 150 °C/0.05 mmHg a fraction was obtained, which was subjected to column chromatography using silica gel as the supporting material. Elution with ether gave 1.67 g dimethylamidodiphenyl phosphate; b.p. 137 – 140 °C/0.05 mmHg, lit.[5] b.p. 154 °C/0.2 mmHg; $n_D^{26} = 1.5402$, lit./ $n_D^{25} = 1.5407$. Further elution with MeOH gave 3.36 g bis(dimethylamido)phenyl phosphate; b.p. 160 – 161 °C/10 mmHg, lit.[5] b.p. 154 – 155 °C/9 mmHg; $n_D^{25} = 1.5061$, lit.[5] $n_D^{25} = 1.5037$.

N,N-*Dimethylpropionamide* + *acetanilide.* To a solution of *N,N*-dimethylpropionamide in HMPA (prepared by heating propionic acid (5.7 g) in HMPA (50 ml) at reflux temperature for 2 h)[6] acetanilide (6.75 g) was added. The mixture was heated for 17 h on a silicon oil-bath (250 °C), poured into 400 ml 2 M NaOH and extracted with 4 × 200 ml ether. The combined ether phases were washed with 2 × 100 ml H_2O and dried over K_2CO_3. Distillation 86 – 150 °C/0.05 mmHg gave a fraction which was subjected to column chromatography using silica gel as the supporting material.

1. Elution with ether – light petroleum (1:4) gave 1.9 g of a mixture of XI and XII (1:1) which could be separated by preparative GLC (Perkin-Elmer F 21, 5 % Se 30). 3,4-Dimethyl-2-dimethylamino-quinoline (XI), NMR ($CDCl_3$): 2.35 (s, 3 H), 2.50 (s, 3 H), 2.90 (s, 6 H), 7.1 – 8.0(m, 4 H); IR(CCl_4): 1610 cm^{-1} (strong); UV (C_6H_{12}): 250 nm (log $\varepsilon = 4.38$), 334 nm (log $\varepsilon = 3.68$).

2. Further elution with ether – light petroleum (2:3) gave 3.2 g of a mixture of IX and X (1:3) which could be separated by preparative GLC as above. 2-Dimethylamino-4-ethyl-quinoline (X), NMR ($CDCl_3$): 1.31 (t, $J = 7$ Hz, 3 H), 2.93 (q, $J = 7$ Hz, 2 H), 3.15 (s, 6 H), 6.70 (s, 1 H), 7.0 – 7.9 (m, 4 H); IR(CCl_4): 1620 cm^{-1} (strong), UV (C/H_{12}): 250 nm (log $\varepsilon = 4.55$), 350 nm (log $\varepsilon = 3.77$).

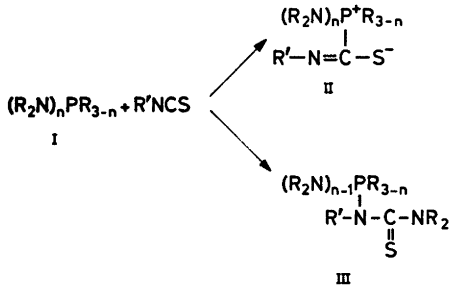
Reactions of Aminophosphines with Isothiocyanates. Dipolar Ionic Products

LARS ENGELS [a] and OTTO DAHL [b]

[a] The Royal Danish School of Educational Studies, Department of Chemistry, Emdrupborg, DK-2400 Copenhagen, Denmark and [b] Department of General and Organic Chemistry, University of Copenhagen, The H. C. Ørsted Institute, DK-2100 Copenhagen, Denmark

The reactions of three methyl substituted aminophosphines with methyl- and phenylisothiocyanate have been studied. The products are shown by ^1H and ^{31}P NMR spectroscopy to be dipolar ions, and analogous to those formed by trialkylphosphines. The dipolar ionic compounds derived from trimethylphosphine and methiodides of all dipolar ionic compounds have been prepared for comparison.

Aminophosphines (I) have been claimed by Oertel *et al.*[1] to react with isothiocyanates to give insertion products (III). They were formulated as insertion products because they (i) gave thioureas on hydrolysis and (ii) displayed an IR band at 1490 cm^{-1} "characteristic of thioureas". The alternative structure II, which is analogous to that of the known trialkylphosphine isothiocyanate adducts,[2,3] was not considered. We have reinvestigated the reaction and present evidence that product structure corresponds to II.



The investigation has been limited to the reaction of I, R = CH_3, $n = 1,2,3$ with methyl- and phenylisothiocyanate. A crystalline precipitate was generally formed upon mixing the aminophosphine and the isothiocyanate in ether or pentane at −20 °C. Ethyl- and isopropylisothiocyanate react similarly, but no compound could be isolated from *tert*-butylisothiocyanate. Also, we were unable to isolate any reaction product when the aminophosphine was *P*-phenyl substituted. Yields, melting points, and microanalyses of the compounds prepared and their methiodides IV are given in Table 1. Two of the compounds (IIa and IIb) are, judging from their melting points, identical to products obtained by Oertel *et al.* and described as insertion compounds.[1]

Assignment of structure. The adducts are assigned structure II on the basis of their ^1H and ^{31}P NMR spectra (Table 2): (i) Each compound, regardless of the number of amino groups, displays only one $(CH_3)_2N$ doublet with a rather large coupling constant (9.3 − 10.8 Hz). Since this is a coupling to phosphorus,* its magnitude and the fact that all R_2N groups are equivalent indicate that no R_2N group is separated from phosphorus by insertion of RNCS in a P−N bond. (ii) Dissociation to I and isothiocyanate is evident for several of the adducts as observed from their ^1H NMR spectra in $CDCl_3$. This is most unlikely for compounds with structure III. (iii) The ^{31}P chemical shifts are in the range expected for phosphonium compounds (general chemical shift range for phosphonium compounds containing R_2N groups −65 to −25 ppm).[4] The chemical shifts

* All couplings in Table 2 are shown by ^{31}P decoupling to be P···H couplings.

Table 1. Reaction products of aminophosphines with isothiocyanates. Dipolar ionic compounds and their methiodides.

No.	Compound	Yield, %	M.p., °C	Analyses (C, H, N, S)

[a] 1–5 % solutions in $CDCl_3$ at *ca.* 35 °C. Chemical shifts in ppm, $\delta(^1H)$ from TMS, $\delta(^{31}P)$ from external 85 % H_3PO_4, coupling constants J in Hz.

of III are expected to be much closer to those of I. (iv) The coupling constants J_{PCH} in the products are larger than those in I in agreement with the formulation of the compounds as phosphonium compounds.[5] (v) The ^1H chemical shifts are close to those found for similar phosphonium compounds [6] and agree with a deshielding of the protons by P^+, relative to the protons of I.

Methylation of the compounds II results in a further NMR deshielding of all protons and phosphorus in accord with a reduced electron density in the methiodides IV (Table 2). Apart from the deshielding and the doublet (due to coupling to phosphorus) from the S-CH_3 group the spectra of II and IV are very much alike, as expected for compounds with similar structures.

For comparison we have included the analogous compounds (II, $n=0$) derived from trimethylphosphine (I, $n=0$) in the investigation. The NMR spectra of these (Table 2) are very similar to those of the compounds described above. Since tertiary phosphines are not able to give insertion compounds analogous to III, but are known to give dipolar ionic compounds

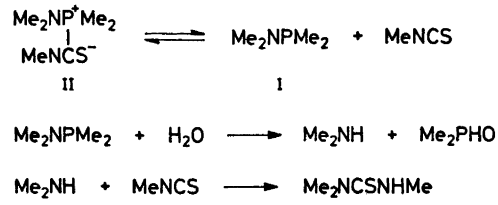
with isothiocyanates,[2,3] this similarity of the NMR spectra support the evidence given above for the dipolar ions structure of the aminophosphine adducts.

Compounds II and IV are expected to exist as mixtures of *E* and *Z* isomers due to restricted rotation about the C=N bond.

IVZ IVE

However, we were in no case able to observe more than one set of ^{1}H NMR signals at temperatures down to −50 °C in $CDCl_3$. These results indicate that II and IV exist mainly as one of the *E*−*Z* isomers, and we suggest that to be the *Z* isomer for the following reasons. (i) The rather large J_{PCNCH} coupling constant in I and IV (R′=CH_3) indicate a *trans* configuration for P^+ and CH_3 about the C=N bond. (ii) The *Z* isomer is probably the most stable isomer for both steric ($-P^+$ is larger than S^- and probably also SCH_3) and electronic reasons (the lonepair of nitrogen being closer to $-P^+$).

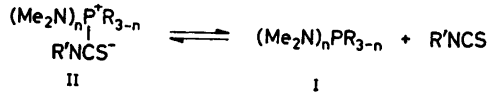
Properties of adducts II. The compounds are colourless to yellow solids which are easily hydrolysed by moist air. The hydrolysis products are thioureas, as found by Oertel *et al.*,[1] and various phosphorus acids. These hydrolysis products are explained by the fact that II is reversibly dissociated to I and isothiocyanate. Hydrolysis of I, a fast process, gives Me_2NH which subsequently combines with the isothiocyanate to give a thiourea, *e.g.*



The dissociation of II to I and isothiocyanate is perceptible from the smell of the solid II, and in most cases is also observable by ^{1}H NMR in $CDCl_3$ solution (Table 3). The values in Table 3 show that dissociation occurs more readily in the order of R′: Me < Ph < Bu^t. This variation is probably due to increasing steric hindrance in II with larger R′. The steric hindrance is expected to be largest for $(Me_2N)_3P$ and smallest for PMe_3, in accordance with the values which show a larger variation with R′ in the former case. An increase in the dissociation of II is also seen with decreasing number of amino groups (decreasing *n*). This variation shows that dimethylamino groups stabilize II relative to I + R′NCS, probably by stabilizing the phosphonium centre by $p\pi$-$d\pi$ overlap.[6] The values in the last column show that substituting a Me group on phosphorus for a Ph group strongly increases the dissociation of II. This is expected from the well-known reduced nucleophilicity of tertiary phosphines when phenyl groups are introduced.[7]

The compounds II are thermally rather un-

Table 3. Degree of dissociation of II to I and R′NCS [100 × mol I/(mol I + mol II) at equilibrium, starting solutions 2.0×10^{-1} M of II in $CDCl_3$, *t ca.* 35 °C, calculated from ^{1}H NMR integral values].



R′NCS	I $(Me_2N)_3P$	$(Me_2N)_2PMe$	Me_2NPMe_2	PMe_3	$(Me_2N)_2PPh$
MeNCS	< 1	< 1	3	27	*ca.* 97 [a]

Bu^{t}NCS	> 95 [a]				

[a] 2.0×10^{-1} M in aminophosphine and isothiocyanate.

stable. Although stable for several months at −20 °C, they decompose within a few days at room temperature. From the ^{1}H NMR spectra of the decomposing compounds in $CDCl_3$ it seems that II is first transformed into two new compounds. These subsequently decompose, and the presence of at least three new compounds is established by ^{31}P decoupling experiments. Likewise we obtained mixtures upon attempts to distil the compounds following Oertel *et al.* who isolated some of their products by distillation. One of the compounds in the mixtures may have the structure III, but it seems unlikely that the products obtained by Oertel *et al.* in any case were pure III. The thermal decomposition of II is under further investigation in our laboratories.

The IR spectra of II showed a strong band at 1475−1515 cm^{-1} (KBr). This band is assigned (mainly) to a C=N stretching vibration because a band is found in the same range in the IR spectra of IIg and IIh, and because the band is shifted to higher wavenumbers in the methiodides IV. Although thioamides and thioureas have a band in the same region (the B-band [8]), it is nevertheless not solely characteristic of thioureas, as implied by Oertel *et al.*

EXPERIMENTAL

Microanalyses were carried out at the Microanalysis Department of Department of General and Organic Chemistry, the H. C. Ørsted Institute. ^{1}H and ^{31}P NMR spectra were obtained on a Bruker HX 90E spectrometer. Tris(dimethylamino)-phosphine and dimethylaminodimethylphosphine were prepared according to the literature.[9] Trimethylphosphine was obtained from its silver iodide complex [10] by pyrolysis. All preparations were performed in a nitrogen atmosphere.

Bis(dimethylamino)methylphosphine. To a stirred solution of $(Me_2N)_2PCl$ [11] (12.4 g) in dry ethyl ether (75 ml), kept at −78 °C, was added MeLi (1.6 M in ether, 50 ml). After 2 h at 20 °C the reaction mixture was set aside for LiCl to precipitate, the solution decanted and the solvent evaporated under reduced pressure. Vacuum distillation through a 15 cm Vigreux column gave $(Me_2N)_2MeP$ (5.4 g, 50 %), b.p. 37−39 °C/13 mmHg (lit.[12] 64−67 °C/49−50 mmHg). According to its ^{1}H NMR spectrum the product contained a small amount of $(Me_2N)_3P$ (3−6 %), but was otherwise pure.

Dipolar ionic compounds (II). The phosphine (4 mmol) in dry ether or pentane (5−10 ml) was cooled to −78 °C and methyl- or phenylisothiocyanate (6 mmol) added with stirring. After 24 h at −20 °C (−78 °C in case of IIc) the colourless or yellow crystals were filtered off, washed with cold ether or pentane and dried 5 min *in vacuo* at 20 °C. The crude compounds were analytically pure except those for which solvents of crystallisation are given in Table 1.

Methiodides (IV). To a methylene chloride or acetone solution of II was added the corresponding isothiocyanate (*ca.* mol:mol) in order to suppress dissociation, and then excess methyl iodide at −78 °C. After 1 h at 20 °C the solvent was evaporated and the residue recrystallized from the solvent given in Table 1.

Acknowledgements. Financial support from the Danish Scientific Research Foundation for purchase of the Bruker NMR apparatus is greatly acknowledged. Dr. O. Larsen has kindly delivered samples of IIg and IIh.

Bromination of Enamines from Methyl Isopropyl Ketone. A Possible Route to Bromomethyl Isopropyl Ketone

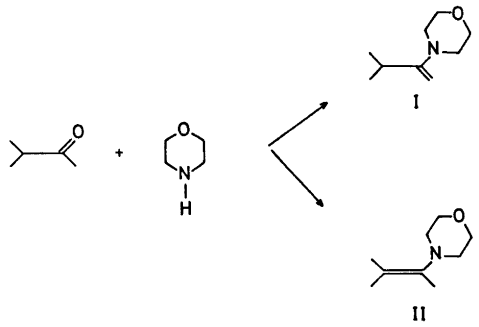
ROLF CARLSON and CHRISTOFFER RAPPE

Department of Organic Chemistry, University of Umeå, S-901 87 Umeå, Sweden

The relative amounts of the various bromo ketones obtained by reacting the morpholine enamines of methyl isopropyl ketone with bromine under different conditions were determined. Mechanistic details of the reaction are briefly discussed. A convenient method of preparing bromomethyl isopropyl ketone *via* the morpholine enamine is described and the optimum conditions for this reaction are presented.

Enamines react with elementary halogens to form α-haloimmonium salts, which on hydrolysis yield the corresponding α-halocarbonyl compounds.[1–7] It has also been reported that certain imines from methyl ketones react with *N*-halosuccinimides to yield halomethyl ketones involving enamine intermediates.[8,9]

When an unsymmetric ketone with α- and α′-hydrogens, *e.g.* methyl isopropyl ketone, is converted to the corresponding tertiary enamine using a secondary amine, *e.g.* morpholine, two isomeric tertiary enamine products are possible, I and II (Scheme 1). The isomers I and II are interconvertible and the equilibrium ratio of I:II is 29:71 at room temperature. However the equilibration is a rather slow process in absence of heat and/or acid, and the isolation of I and II in pure state has been reported.[10]



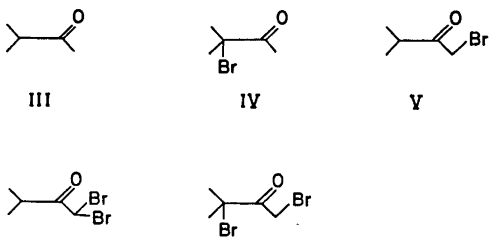
Scheme 1.

α-Halogenation of ketones occurs in the enolized ketone. When unsymmetric ketones are halogenated, mixtures of isomeric haloketones are usually obtained, due to formation of isomeric enols. In some cases a 1:1 ratio of isomeric α-haloketones is reported.[11] It is difficult to prepare halomethyl ketones by direct halogenation of ketones. However, Gaudry and Marquet have reported that bromination of a number of methyl ketones in carbon tetrachloride containing a few percent of methanol affords high yields of the bromomethyl ketone.[12]

No reports of halogenation of tautomerizable tertiary enamines have been found in the literature. The purpose of the present investigation is to ascertain whether or not transformation of a ketone to the corresponding tertiary enamine offers a means of overcoming difficulties encountered by direct halogenation of the ketone. We wish to report some results obtained by bromination of the morpholine enamines from methyl isopropyl ketone. Results from the bromination of the corresponding dimethylamino and pyrrolidino enamines will be reported later, due to the fact that these experiments led to a negative product balance, and the reason for this is not yet fully understood. Control experiments showed that the recovery of ketone was 92 % and of bromine 96 % when the morpholine enamine I was treated with one equivalent of bromine and subsequently hydrolyzed. The recovery of ketone in experiments with dimethylamino and

pyrrolidino enamines was considerably lower.

The enamines I, II as well as I+II in equilibrium mixture were allowed to react with 0.5, 1.0, and 2.0 equivalents of bromine in methylene chloride at −78 °C and room temperature. The reaction between the enamines and bromine is instantaneous and the reaction mixture was quenched with water after one minute followed by removal and analysis (GLC) of the organic layer. The ketones III−VII (Scheme 2) were identified and the results of these experiments are summarized in Table 1.



Scheme 2.

These results may be interpreted in the following way. At −78 °C the enamines are rapidly converted to the corresponding α-bromoimmonium salts, which are relatively stable towards further bromination. Consequently the yields of dibromoketones are low in these experiments. At room temperature the α-bromoimmonium salts which constitute the primary products undergo further reaction prior to hydrolysis. The yield of the dibromo ketone VII is rather high when one equivalent of bromine is used and this has led us to propose the intermediates VIII and IX (Scheme 3).

It should be noted that the yield of V far exceeds the amount of the corresponding enamine I present in the equilibrium mixture and as much as *ca.* 14 % of V is found when a pure sample of the other isomer II is brominated. This unexpected result is explained by the reaction sequence in Scheme 3. The dibromoimmonium salt IX is debrominated to the bromo enamine X which is then protonated or brominated on the nitrogen atom. These cationic species are not prone to react with the electrophile bromine.

This explanation is further supported by time interval measurements carried out on the reaction between the enamines and bromine at room temperature (see Table 2). One equivalent of bromine was used throughout. The table

Table 1. Product distribution obtained by bromination of the enamines under conditions given in the text.

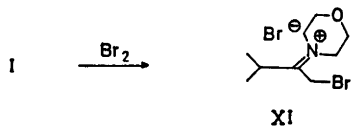
clearly shows that for the dibrominated product the bromination is reversible under these conditions.

When two equivalents of bromine are used the yields of dibrominated ketones are low which might be explained by rapid *N*-bromination of the bromo enamines formed in the reaction mixture when the primarily formed monobromo immonium salts are deprotonated. This indicates that bromination of the nitrogen atom proceeds more rapidly than bromination of the β-carbon in bromo enamines. Excess bromine enables *N*-bromination go almost to completion and consequently the concentration of free bromo enamine susceptible to attack of bromine on the β-carbon is low.

Yields of the 1,1-dibromoketone VI are very low in all experiments. However, spiking experiments showed that this is not due to a rearrangement of VI to VII during hydrolysis and work up. The low yields of dibromoketones from the bromination of I can probably be explained on the basis of a more rapid proton transfer from the methyl group in the immonium salt VIII, than from the bromomethyl group or from the isopropyl group in XI (Scheme 4). Therefore



Scheme 4.

we assign the amounts of VII as coming from the minor amounts of II present in the starting enamine. The proton is transferred to an unbrominated enamine which is consequently withdrawn from further bromination by this protonation. The amounts of III are somewhat too small to account for this proton transfer, but some parent ketone is apparently lost during hydrolysis and work up. The slower proton transfer from XI than from VIII is probably due to steric hindrance in the base attack.

Table 1 shows that it is possible to prepare bromomethyl isopropyl ketone V in a high yield by the reaction of the least substituted enamine I with bromine. The experiments accounted for in Table 1 were performed on a 10 mmolar scale and we have also tried to discover the optimum conditions for synthesis on a larger scale. In this context some experimental findings are of importance. In the experiments listed in Tables 1 and 2 the enamine was added to a stirred solution of bromine. The reverse addition procedure is unsuitable since it leads to considerable amounts, approximately 40 %, of unbrominated ketone, in addition to a rather high yield of the dibromomethyl ketone VI. This can be explained by a proton transfer from the monobromo immonium salt to an unbrominated enamine, followed by a second bromination of the bromo enamine thus formed. This can be avoided by the addition of enamine to bromine. A direct scale-up also yielded rather large amounts of dibromo ketones, and it is possible that this may be caused by heat evolved during the reaction.

The enamine I is the kinetically controlled product when it is prepared according to the method described by White and Weingarten.[13] In this reaction hydrocarbons are preferred as solvents, and using pentane we attempted a direct bromination of the crude enamine. However, it was found to give rise to practical difficulties. The bromo immonium salts formed precipitated as a sticky mass which made stirring impossible. However, methylene chloride is known to be a good solvent for ion pairs [14] and we found it to be a more favourable solvent. Use of low concentrations of reactants (< 1 M) gave a homogeneous reaction mixture. Therefore the most suitable procedure for bromination of the enamine I to the bromomethyl ketone V was to use a type of "flow" reactor described below.

The yield of V determined by NMR analysis of the distilled crude product was 57 % calculated from the amount of starting enamine. A disadvantage is that the yield of the enamine when prepared according to Ref. 13 is only 60 – 70 % and use of more forced conditions in the synthesis of the enamine results in mixtures of tautomeric enamines. Thus the actual yield of the bromoketone calculated from the starting ketone is 30 – 40 %. A considerable advantage is that the product contains only trace amounts of the isomeric monobromo ketone IV. The desired bromomethyl ketone can easily be separated from unbrominated and dibrominated ketones by distillation.

EXPERIMENTAL

The enamines were prepared according to White and Weingarten.[13] Separation of the isomers was conducted according to Pocar *et al.*[10] NMR-spectra were recorded on a Varian A-60A or a JEOL C-60 HL spectrometer.

Procedure for the experiments in Table 1. 10 mmol of the enamine in 20 ml of methylene chloride was added in one portion with vigorous stirring to a solution of the calculated amount of bromine in 20 ml of methylene chloride. After one minute the reaction was quenched with 20 ml of water and the mixture subsequently stirred for 1 h to complete the hydrolysis. The organic layer was separated and washed with 10 ml of 2 % $NaHSO_3$-solution and 2 × 10 ml of water and then dried over anhydrous magnesium sulphate. The filtered solution was analyzed by GLC, using a PYE M 64 Gas Chromatograph with a FID and 270 cm × 6 mm, 12 % QF-1 column at 120 °C. Chromatogrammes were recorded on a Philips recorder with a Disc integrator, and the relative amounts of the various ketones were determined from the integrals. Corrections were made for different FID responses of the various ketones. The peaks in the chromatogrammes were well resolved. The figures in Table 1 are the average values of three GLC determinations and the accuracy is within ± 1 %. The identities of the ketones were determined by means of GLC-MS, using a PYE M 84 Gas Chromatograph with a FID and an LKB 9000 Mass Spectrometer. Mass spectral analysis was aided by comparison with authentic sample spectra.

Procedure for the experiments in Table 2. 10 mmol of the enamine in 10 ml of methylene chloride was added to a stirred solution of 10

mmol of bromine in 90 ml of methylene chloride. 5 ml aliquots were hydrolyzed with 5 ml of water and analyzed by GLC.

Preparation of bromomethyl isopropyl ketone. A typical procedure was: 39.0 g (0.454 mol) of methyl isopropyl ketone and 120 ml of morpholine were dissolved in 1000 ml of isopentane. The mixture was cooled to −5 °C and a solution of 25 ml (0.227 mol) of titanium tetrachloride in 100 ml of isopentane was added with stirring. The reaction mixture was stirred at −5 °C overnight and filtered. Evaporation of the solvent at reduced pressure afforded the crude enamine *I* almost free of the other isomer. The yield of the enamine was 44.9 g (64 %) estimated from the NMR spectrum. The crude enamine was dissolved in 500 ml of methylene chloride and transferred to a graduated dropping funnel. An equivalent amount of bromine was dissolved in 500 ml of methylene chloride and subsequently transferred to a second graduated dropping funnel. The reagents were mixid in the following way. The two dropping funnels were mounted on a 250 ml fournecked flask fitted with a mechanical stirrer, drying tube and an outlet stopcock from the bottom of the flask. The flask was cooled with dry ice-ethanol. (The cooling device was actually a plastic bag tied around the bottom outlet pipe with copper wire, the plastic bag being supported by a polystyrene foam beaker, cut into two halves and reassembled around the bag). The bromine solution was added as 25 ml aliquots to the reaction flask with stirring and cooling. Each addition was followed by a rapid addition of a 25 ml portion of enamine solution. The resulting mixture was stirred for an additional 30−40 s. Thereafter it was tapped off *via* the bottom outlet pipe into a 2 l threenecked flask, fitted with a stirrer, where it was quenched with a 25 ml portion of water. A small amount of approximately 10 % $NaHSO_3$-solution was added portionwise to the hydrolysate to destroy excess of bromine. After the reaction was complete, stirring with water was continued for another 40 min. The organic layer was separated and the aqueous layer extracted with 100 ml of methylene chloride. The combined organic layers were then washed three times with 200 ml of water and dried over anhydrous magnesium sulphate. The solvent was evaporated at reduced pressure, and the residue was distilled "bulb to bulb" at a reduced pressure. A final fractionation with a Vidmer column afforded 22.0 g of pure (> 95 %) bromomethyl isopropyl ketone, 46 % yield calculated on the starting enamine.

Preparation of Sepharose*-bound α-Ketosides of *N*-Acetylneuraminic Acid and their Interaction with *Vibrio cholerae* Neuraminidase

LEIF HOLMQUIST

Research Institute of National Defence, Department 4, S-172 04 Sundbyberg 4, Sweden

The 2-aminoethyl and the 2-aminoethylaminocarbonylmethyl α-ketosides of *N*-acetylneuraminic acid and the 2-aminoethylamide of the 2-hydroxyethyl α-ketoside of *N*-acetylneuraminic acid have been synthesized and coupled to cyanogen bromide activated Sepharose. In the resulting polymers, the *N*-acetylneuraminic acid groups are bound to the matrix by means of α-ketoside (*N*-acetylneuraminic acid-Sepharose) and amide (*N*-acetylneuraminamide-Sepharose) linkages, respectively. Columns of *N*-acetylneuraminic acid-Sepharose equilibrated with buffers of pH 5.5 or 9 adsorbed *Vibrio cholerae* neuraminidase very strongly. The enzyme was effectively desorbed in high yield from the polymer by addition of the benzyl α-ketoside of *N*-acetylneuraminic acid to the eluent. The transformation of the *N*-acetylneuraminic acid-Sepharose to the 7-carbon analogue of *N*-acetylneuraminic acid-Sepharose resulted in a polymer having a slightly weaker affinity for the enzyme. *N*-Acetylneuraminamide-Sepharose did not significantly adsorb the neutraminidase.

Previous studies on the specificity of neuraminidase,[1-3] have revealed that the carboxyl group in the glyconic part of neuraminidase labile α-ketosides of *N*-acetylneuraminic acid, seems essential for the enzymatic cleavage of the α-ketosidic bond. It has also been demonstrated [4-5] that *Vibrio cholerae* neuraminidase is activated by divalent cations such as calcium and manganese, which presumably in conjunction with the carboxyl group in the substrate are essential for the formation of the enzyme-substrate complex.[5] In order to study further the interaction of *N*-acetylneuraminic acid derivatives and neuraminidase, attempts were made to prepare matrix-bound α-ketosides of *N*-acetylneuraminic acid. The enzyme-substrate binding properties have previously been utilized in the purification of *Vibrio cholerae* neuraminidase using erythrocyte stromata.[4]

The present paper reports the coupling of the 2-aminoethylamide of the 2-hydroxyethyl α-ketoside of *N*-acetylneuraminic acid and of the 2-aminoethyl and the 2-aminoethylaminocarbonylmethyl α-ketosides of *N*-acetylneuraminic acid to cyanogen bromide activated Sepharose and some properties of the polymers. In addition, the transformation of matrix-bound *N*-acetylneuraminic acid to its 7-carbon analogue will be described.

The synthesis of the 2-aminoethylaminocarbonylmethyl α-ketoside of *N*-acetylneuraminic acid was conveniently performed by treatment of the previously reported butoxycarbonyl α-ketoside of tetra-*O*-acetyl-*N*-acetylneuraminic acid [2] with anhydrous ethylene diamine. The purification of the nonulosaminic acid derivative, was facilated by the fact that it was not adsorbed by Amberlite IRC 50 (H^+). The 2-aminoethylamide of the 2-hydroxyethyl α-ketoside of *N*-acetylneuraminic acid, having a hydrophilic aglycone, was similarly prepared by treatment of the corresponding methyl ester with ethylene diamine.

The coupling of the 2-aminoethyl [3] and the 2-aminoethylaminocarbonylmethyl α-ketosides of *N*-acetylneuraminic acid and of the 2-aminoethylamide of the 2-hydroxyethyl α-ketoside of *N*-acetylneuraminic acid to Sepharose was per-

* Sepharose is the commercial name for beaded agarose from Pharmacia Fine Chemicals, Sweden.

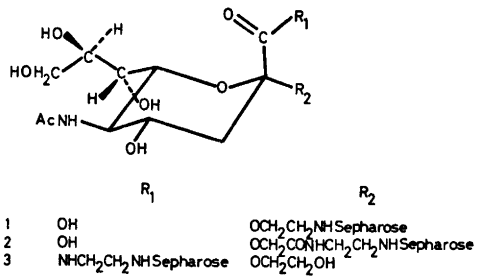

Fig. 1. Sepharose-bound 2-aminoethyl α-ketoside (1) 2-aminoethylaminocarbonylmethyl α-ketoside (2) and 2-aminoethylamide of the 2-hydroxyethyl α-ketoside (3) of *N*-acetylneuraminic acid.

formed as previously described,[6-7] resulting in polymers having the *N*-acetylneuraminic acid groups fixed to the matrix by means of α-ketoside (*N*-acetylneuraminic acid-Sepharose) and amide (*N*-acetylneuraminamide-Sepharose) linkages, respectively (Fig. 1).

Oxidation of the matrix-bound nonulosaminic acid with periodic acid and reduction of the resulting formyl derivative with sodium borohydride afforded the Sepharose-bound 7-carbon analogues of *N*-acetylneuraminic acid. The polymer beads were not destroyed when treated with periodic acid and sodium borohydride. Further, the beaded form remained unaffected when the Sepharose derivatives were freeze dried or treated with boiling water. On assaying *N*-acetylneuraminic acid-Sepharose at 37 °C with neuraminidase, free *N*-acetylneuraminic acid was released. In contrast the *N*-acetylneuraminamide-Sepharose was resistant to the hydrolytic action of the neuraminidase as well as to 0.05 M hydrochloric acid. By treatment with 0.5 M sulfuric acid at 80 °C, however, the amide linkage could be hydrolyzed and the resulting nonulosaminic acid determined. Under these hydrolyzing conditions, the released acid is probably partly destroyed resulting in an underestimate of the bound *N*-acetylneuraminic acid. Table 1 shows the amounts of *N*-acetylneuraminic acid in different Sepharose conjugates.

All of the *N*-acetylneuraminic acid-Sepharose preparations adsorbed *Vibrio cholerae* neuraminidase very strongly, type V showing a high enzyme binding capacity. Sodium acetate buffer pH 5.5 which according to Mohr and Schramm,[4] is effective in eluting neuraminidase adsorbed to erythrocyte stromata, eluted the enzyme from columns of the Sepharose derivatives only very slowly. The 7-carbon analogue of *N*-acetylneuraminic acid-Sepharose, prepared by periodic acid oxidation and sodium borohydride reduction of the matrix-bound *N*-acetylneuraminic acid, showed a slightly weaker affinity for the enzyme. Attempts to elute the neutraminidase

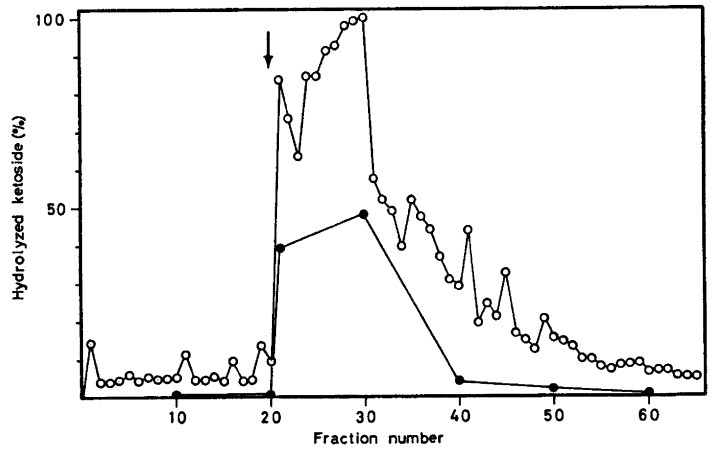

Fig. 2. Activity of *Vibrio cholerae* neuraminidase in the effluent from a column of *N*-acetylneuraminic acid-Sepharose (type V). The enzyme was eluted with 0.1 M sodium acetate buffer pH 5.5, 0.05 M with respect to calcium chloride, containing 200 μg benzyl α-ketoside of *N*-acetylneuraminic acid per ml buffer. The arrow denotes the start of the addition of the benzyl α-ketoside. Incubation was performed for 30 min (●) and 20 h (○). For further details see text.

with sodium borate buffer pH 9 were also unsuccessful. With either of the aforementioned buffers, serum albumin was eluted in a volume corresponding to that of the column. By means of sodium acetate buffer pH 5.5 containing 200 μg benzyl α-ketoside of *N*-acetylneuraminic acid per ml, however, the neuraminidase was desorbed in high yield from columns of *N*-acetylneuraminic acid-Sepharose, demonstrating a specific adsorption of the enzyme to the polymer (Fig. 2).

Vibrio cholerae neuraminidase, when applied to a column of *N*-acetylneuraminamide-Sepharose and eluted with sodium acetate or sodium borate buffer pH 5.5 or 9.0, respectively, was eluted with the total bed volume. In accordance with previous findings,[1-3] the carboxyl group in the glyconic part of the substrate seems to play a dominant role in the formation of the enzyme-substrate complex.

The present results demonstrate that *N*-acetylneuraminic acid-Sepharose and its derivatives, being water insoluble substrates of *Vibrio cholerae* neuraminidase, should be useful for enzyme-substrate binding studies and for the purification of neuraminidases from other sources, as well as for studies on virus and bacteria.

EXPERIMENTAL

Material and methods. The same general methods were used as previously reported.[1-3] Neuraminidase from *Vibrio cholerae* (glycoprotein *N*-acetylneuraminyl-hydrolase, EC 3.2.1.18) was purchased from Behring-Werke, Marburg; 1 ml containing 500 units (producer's specification). The 2-aminoethyl α-ketoside and the benzyl α-ketoside of *N*-acetylneuraminic acid were prepared as previously described.[3,1,8]

Syntheses. 2-Benzyloxyethyl α-ketoside of tetra-O-acetyl-N-acetylneuraminic acid. Peracetylated *N*-acetylneuraminic acid (1 g) was transformed to its 2-chloro derivative as described by Meindl and Tuppy [8] and condensed with 2-benzyloxyethanol (5 g) in the presence of silver carbonate (0.5 g) and pulverized Drierite (2 g). After reacting overnight, the mixture was treated as previously described for the preparation of the butoxycarbonylmethyl α-ketoside of *N*-acetylneuraminic acid.[2] The product obtained from the chloroform layer was crystallized from water. The yield was 280 mg (24 %) m.p. 165–169 °C (decomp.), $[\alpha]_D^{25}$ −12° (*c* 1.0; methanol) Found: C 55.06; H 6.13; N 2.24. $C_{28}H_{37}NO_{14}$ requires C 54.99; H 6.10; N 2.29).

2-Hydroxyethyl α-ketoside of methyl tetra-O-acetyl-N-acetylneuraminate. The peracetylated benzyloxyethyl α-ketoside of *N*-acetylneuraminic acid was transformed to its methyl ester with diazomethane. A solution of the ester (200 mg) in ethanol–water (1:1, 20 ml) was added to palladium oxide (100 mg) in ethanol–water and hydrogenated overnight at room temperature. Removal of catalyst and evaporation of solvent resulted in a chromatographically pure product which was dissolved in water and freeze-dried. The yield was 150 mg (88 %). $[\alpha]_D^{25}$ −20° (*c* 1.0; chloroform). (Found: C 48.50; H 5.95; N 2.55. $C_{21}H_{32}NO_{14}$ requires C 48.27; H 6.17; N 2.68).

2-Aminoethylamide of 2-hydroxyethyl α-ketoside of N-acetylneuraminic acid. The 2-hydroxyethyl α-ketoside of the methyl tetra-*O*-acetyl-*N*-acetylneuraminate (20 mg) was dissolved in anhydrous ethylene diamine (0.2 ml). After being left overnight at room temperature, the reaction mixture was concentrated to dryness and the residue dried for several hours over diphosphorus pentoxide in vacuum at room temperature, dissolved in methanol and precipitated with ethyl ether. The resulting chromatographically homogeneous product (10 mg) was dissolved in 0.1 M sodium carbonate buffer pH 10.2 (2 ml). This solutions was used in the coupling procedure.

2-Aminoethylaminocarbonylmethyl α-ketoside of N-acetylneuraminic acid. A solution of crystalline butoxycarbonyl α-ketoside of tetra-*O*-acetyl-*N*-acetylneuraminic acid [2] (100 mg) in anhydrous ethylene diamine (0.5 ml) was left overnight at room temperature. After evaporation of solvent, the residue was taken up in water and the solution put on a 1 × 5 cm Amberlite IRC 50 (H^+) column. Elution with water resulted in a chromatographically pure α-ketoside. After freeze-drying, the yield was 55 mg (76 %). $[\alpha]_D^{25}$ −19 °(*c* 1.0; water) (Found: C 41.99; H 6.74; N 9.68. $C_{15}H_{27}N_3O_{10}.H_2O$ requires C 42.15; H 6.84; N 9.83).

Periodate oxidation. The matrix-bound *N*-acetylneuraminic acid (0.4 ml) was treated with a solution of periodic acid (20 mg) in water (1 ml) for 30 min at room temperature. The resulting 6-formylhexulosonic acid derivative was filtered off and washed with water, 0.1 M hydrochloric acid, and water.

Sodium borohydride reduction. Sepharose-bound α-ketoside of *N*-acetylneuraminic acid (0.2 ml) after periodate oxidation was treated with sodium borohydride (20 mg) in water (1 ml). After 60 min at room temperature, the resulting 7-carbon analogue of the *N*-acetylneuraminic acid derivative was filtered off and washed as above.

Preparations of columns. Activation of Sepharose (2 ml) with cyanogen bromide was performed as previously described.[6-7] The pH of the reaction mixture was held at 11 by means of 0.1 or 2 M sodium hydroxide. After 30 to 60 min at room temperature, crushed ice was added to the reaction mixture. The acti-

Table 1. Amounts of *N*-acetylneuraminic acid, released from different Sepharose conjugates by treatment with neuraminidase or acid.

α-Ketoside of *N*-acetylneuraminic acid	Type of Sepharose	Cyanogen bromide used for activation (mg/ml wet gel)	Released *N*-acetylneuraminic acid (μmol/ml wet gel) with neuraminidase	with 0.05 M hydrochloric acid	Type
2-aminoethyl	2 B	300	0.3	0.6	I
2-aminoethyl	2 B	50	0.04	0.1	II
2-aminoethylamino-carbonylmethyl	2 B	50	0.04	0.1	III
2-aminoethylamino-carbonylmethyl	4 B	50	0.7	1.6	IV

2-aminoethylamide of 2-hydroxyethyl	4 B	300	–	0.2[a]	VI

[a] Hydrolysis with 0.5 M sulfuric acid. See text.

vated Sepharose was rapidly filtered off and washed cold 0.1 M sodium carbonate buffer pH 10.2 (20 ml). The *N*-acetylneuraminic acid derivative having a free primary amino group (10 mg), dissolved in the same buffer as above (2 ml), was added to the polymer and the mixture was left overnight at 5 °C. The mixture was filtered, the filtrate being saved for further couplings, and the polymer was washed with 0.1 M sodium hydroxide, 0.1 M hydrochloric acid and distilled water. Columns of the Sepharose derivatives were equilibrated with the appropriate buffer and the column experiments were performed at *ca.* 0 °C.

The enzyme labile fraction of the bound *N*-acetylneuraminic acid was determined by incubation of the Sepharose derivative (0.2 ml) with neuraminidase (100 μl) for 24 h at 37 °C in 0.05 M Tris-maleate buffer pH 6.40, (0.005 M with respect to calcium chloride) in a total volume of 0.60 ml. Acid hydrolysis of α-ketosidically bound *N*-acetylneuraminic acid was performed by heating the Sepharose derivative (0.2 ml) in 0.1 M hydrochloric acid (0.2 ml) for 60 min at 60 °C. Samples of 200 μl were analyzed according to Warren.[9] The amount of *N*-acetylneuraminic acid, bound as amide was estimated by treatment of the polymer (0.2 ml) with 1 M sulfuric acid (0.2 ml) at 80 °C for 60 min and samples of 200 μl were treated as above. The results from the couplings are shown in Table 1.

Column experiments. The neuraminidase (0.5 ml) was applied to 5 × 5 mm Sepharose columns which, after 15 min, were washed with 0.1 M sodium acetate buffer pH 5.5 and sodium borate buffer pH 9, both being 0.01 M with respect to calcium chloride. Fractions (2 ml) were collected and a flow rate of about 0.2–0.3 ml/min was used. To each fraction was added a solution of benzyl α-ketoside of *N*-acetylneuraminic acid (400 μg) in buffer (50 μl). After incubation for 30 min and 20 h at 37 °C, aliquots of 200 μl were removed from each fraction and released *N*-acetylneuraminic acid analyzed as above. When using sodium borate buffer pH 9, the effluent was adjusted to pH 7 with 0.1 M ice-cold hydrochloric acid prior to the incubation with benzyl α-ketoside of *N*-acetylneuraminic acid.

Desorption of neuraminidase from the columns was performed with 0.1 M sodium acetate buffer pH 5.5, 0.01 M with respect to calcium chloride, containing 200 μg of the benzyl α-ketoside of *N*-acetylneuraminic acid per ml buffer. The effluent was directly incubated for 30 min and 20 h at 37 °C and aliquots (200 μl) from the 2 ml fractions were analyzed as above. In all experiments the temperature of the Sepharose columns was kept at *ca.* 0 °C.

Some New α-(Cyclopolymethylenepyrazolyl-2)propionic Acids. Resolution of α-(Cycloheptapyrazolyl-2)propionic Acid and Determination of its Absolute Configuration

HÅKAN GUSTAFSSON, HANS ERICSSON and SIGRID LINDQVIST

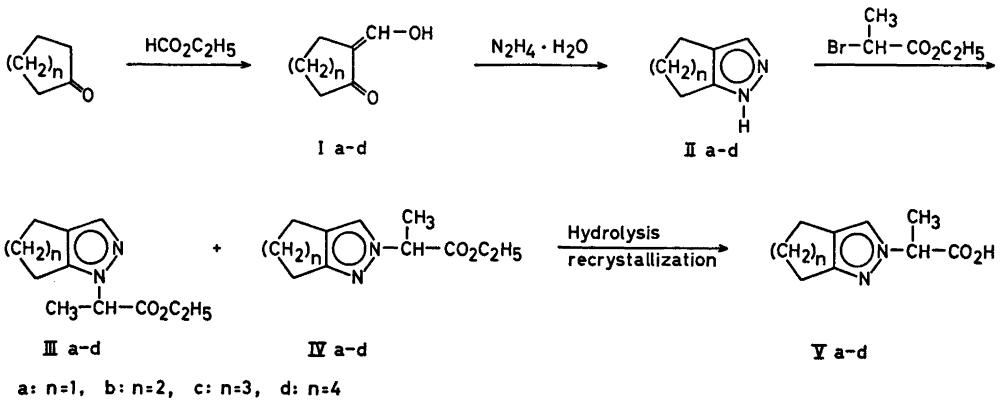
Department of Organic Chemistry, Institute of Chemistry, University of Uppsala, S-751 21 Uppsala, Sweden

α-(Cyclopentapyrazolyl-2)propionic acid (Va), α-(cycloheptapyrazolyl-2)propionic acid (Vc), and α-(cyclooctapyrazolyl-2)propionic acid (Vd) have been synthesized from the corresponding cyclomethylenepyrazoles and ethyl α-bromopropionate by hydrolysis of the ester product. The reaction of cyclopentapyrazole (IIa) or 4,5,6,7-tetrahydroindazole (IIb) with ethyl α-bromopropionate in alcoholic sodium ethoxide solution gave a ratio of 1-ester to 2-ester of about 40:60. Alkylation of IIa with ethyl α-bromopropionate and without base yielded an ester ratio of 70:30, while IIb yielded the ratio 31:69. The acid Vc was resolved into its optical antipodes by fractional crystallization of its (−)-α-(β-naphthyl)ethylamine and (−)-ephedrine salts giving acids with $[\alpha]_D^{25} = +46.9$ and −46.5°, respectively, in chloroform. The absolute configuration of Vc was determined by means of circular dichroism measurements.

Some α-propionic acid derivatives of benzotriazole,[1,2] indazole,[3] and 4,5,6,7-tetrahydroindazole [4] have been synthesized earlier for stereochemical studies and studies of synthetic plant hormones. Three α-(cyclomethylenepyrazolyl-2)propionic acids have now been synthesized. The compounds are under examination with regard to auxin activity [5] and antimalarial action.[6]

The title compounds were synthesized from the corresponding cycloalkanones according to Scheme 1.

The cycloalkanones were formylated with ethyl formate in ether solution with sodium methoxide as base to give the α-hydroxymethylenecycloalkanones, which were then reacted



Scheme 1.

with hydrazine monohydrate under formation of the cyclopolymethylenepyrazoles IIa–d. The method used was, with slight modification, that of Ainsworth [7] for synthesis of 4,5,6,7-tetrahydroindazole. A higher yield of the cyclomethylenepyrazoles (IIa–c) was obtained by adding 99 % hydrazine hydrate directly to the dried ether solution of Ia–c.

The alkylation with alkylhalides of unsymmetrically substituted pyrazoles with unsubstituted nitrogen generally gives a mixture of isomers due to the ambident character of the pyrazole nucleus.[8] No rules have been established for predicting the course of reaction from the nature of the substituents in the pyrazole nucleus. The entering position is also influenced by the alkylating agent and the experimental conditions.[9]

The reaction between IIa–d and ethyl α-bromopropionate without solvent at 120° C gave both 1- and 2-ester. The ratio between 1-ester and 2-ester was dependent on the pyrazole used. IIa–c formed esters in the ratio 70:30, 31:69, and 19:81, respectively. A considerable amount of II remained unreacted. The analysis of the reaction products was done after neutralization with potassium carbonate solution and extraction with ether. The acid obtained after hydrolysis and recrystallization from ethanol-water was pure Va–d. Both IIa and IIb gave an ester ratio of about 40:60 on reaction with ethyl α-bromopropionate in alcoholic sodium ethoxide solution at room temperature.

The chemical shifts in DMSO-d_6 for the vinyl protons in II and the corresponding III and IV are well separated. The isomeric composition of the reaction mixture and the amount of unreacted IIa–d were determined from the peak areas of the different vinyl protons in the ^{1}H NMR spectra by cutting out and weighing the peaks and by GLC analysis. The position of the α-propionic acid group in Va–d was established by ^{1}H NMR spectroscopy according to Gustafsson.[10]

PRELIMINARY TESTS ON RESOLUTION

Preliminary tests for resolving Vc were done with the common alkaloids and some synthetic bases. Crystalline salts were formed with (–)-ephedrine, (+)-α-(β-naphthyl)ethylamine, dehydroabietylamine and (–)-α-phenethylamine in ethyl acetate giving levorotatory acid. The cinchonidine salt formed in ethyl acetate yielded dextrorotatory acid. Oils were obtained with cinchonine and brucine in ethyl acetate. On the basis of these results the resolution was performed with (–)-ephedrine and (–)-α-(β-naphthyl)ethylamine with ethyl acetate as solvent.

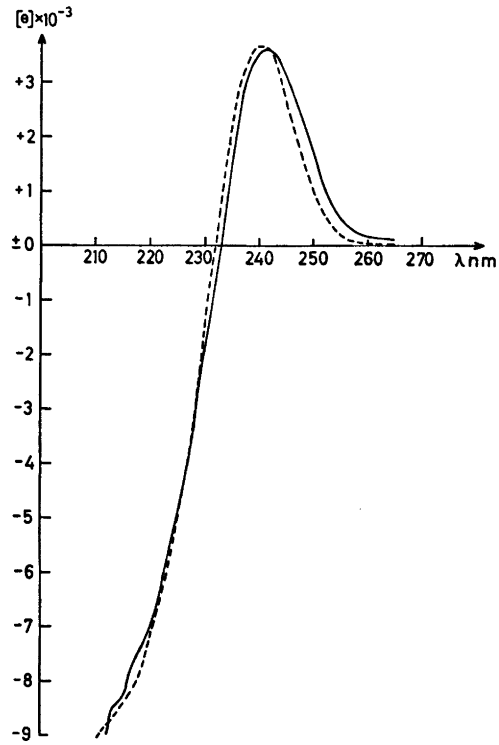


Fig. 1. CD spectra of D(–)Vb (——, $c = 3.96 \times 10^{-3}$ g/100 ml) and (–)Vc (- - -, $c = 3.88 \times 10^{-3}$ g/100 ml) in methanol.

DETERMINATION OF THE ABSOLUTE CONFIGURATION

The circular dichroism (CD) curves of D(–)Vb and (–)Vc were examined for configurational correlations. Fig. 1 clearly shows that (–)Vc has the D(*R*)-configuration. The absolute configuration of L(+)Vb was unequivocally established by direct synthesis *via* L(+)alanine.[11]

EXPERIMENTAL

The optical activity was measured with a Perkin-Elmer 141 spectropolarimeter in 1 ml micro cells of 10 cm length and with chloroform as solvent. The circular dichroism (CD) curves were recorded at 27 °C in 1 mm cells on a Cary 60 spectropolarimeter, equipped with a circular dichroism accessory. The IR spectra were recorded on a Perkin-Elmer 157 spectrophotometer and the UV spectra on a Spectronic 505 spectrophotometer. The ^{1}H NMR spectra were recorded on a Varian A-60 spectrometer in DMSO-d_6 solutions of about 15 % concentration with TMS as internal standard.

Gas-liquid chromatography (GLC) was performed on a Perkin-Elmer 990 gas chromatograph fitted with a flame ionization detector. Column temperature 150 °C, injection port temperature 240 °C and detector temperature 240 °C. Nitrogen carrier gas, flow rate 47 ml/min. Column: Chromosorb W, AW, DMCS-treated, 100 – 200 mesh, coated with 7.5 % UCON 50LB 550X, packed in a 3.0 m glass column AW, DMCS-treated, I.D. 3.5 mm. The column was conditioned at 200 °C before use. The mass spectra were recorded on an LKB 9000 A gas chromatograph-mass spectrometer operating at 70 eV. The melting points were determined with a hot stage microscope and are uncorrected. The microanalyses were carried out at the Analytical Department, Institute of Chemistry, University of Uppsala.

(+)-Ephedrine was isolated from its hydrochloride (Fluka AG $[\alpha]_{546}^{20} = +39 \pm 2°$ (*c* 11.5; water) by addition of 2 M sodium hydroxide and subsequent extraction with ether. The ether solution was dried over magnesium sulphate, the ether evaporated and the residue distilled. B.p.$_{0.2}$ 115 – 116 °C.

α-Hydroxymethylenecyclopentanone (Ia). A mixture of 84.0 g (1.0 mol) cyclopentanone distilled and dried over magnesium sulphate and 110 g (1.5 mol) dried ethyl formate was added with stirring at 15 °C to 54.0 g (1.0 mol) sodium methoxide in 2.0 l dry diethyl ether in a 5 l three-necked flask equipped with condenser, stirrer, dropping funnel, and drying tubes. The mixture was stirred at room temperature for 6 h, and allowed to stand overnight, after which 200 ml water was added and the mixture stirred until a solution was obtained. The ether phase was washed with 20 ml water. The combined water phase was acidified with 165 ml 6 M hydrochloric acid and extracted three times with 80 ml portions of ether. The ether solution was washed with a saturated aqueous solution of sodium chloride and then dried over anhydrous sodium sulphate. The boiling point from an earlier run was 67 – 73 °C at 1 mm torr (lit.[12,13] B.p.$_{11}$ 90 – 95 °C).

α-Hydroxymethylenecycloheptanone (Ic). A dry ether solution of α-hydroxymethylenecycloheptanone (Ic) was prepared in the same way from 44.5 g (0.40 mol) dried and distilled cycloheptanone, 44.4 g (0.60 mol) dried ethyl formate and 21.6 g (0.40 mol) sodium methoxide.

α-Hydroxymethylenecyclooctanone (Id). α-Hydroxymethylenecyclooctanone (Id) was prepared in the same way from 50.0 g (0.40 mol) cyclooctanone, 44.4 g (0.60 mol) ethyl formate and 21.6 g (0.40 mol) sodium methoxide in 1.0 l dried ether. 32.2 g (53 %) Id was obtained as a colourless viscous oil with b.p.$_{12}$ 104 – 106 °C and n_D^{22} 1.5154 (lit.[14] B.p.$_{0.1}$ 70 – 71 °C).

Cyclpolyomethylenepyrazoles (II). A slight excess of 99 % hydrazine hydrate (based on the amount of cycloalkanone used in the formylation step) was added dropwise with stirring to the ether solution of I in an ice bath. After standing at room temperature overnight the ether solution was concentrated in a rotary evaporator and the residue fractionated at reduced pressure. Distillation gave the corresponding cyclopolymethylenepyrazole as a clear viscous oil which crystallized to a white solid on standing at room temperature.

Cyclopentapyrazole (IIa). The ether solution of Ia previously described was reacted with 52.0 g (1.04 mol) 99 % hydrazine hydrate. Yield 50.2 g (46 % based on the amount of cyclopentanone used). B.p.$_{30}$ 165 °C. M.p. 57 °C (lit.[15] M.p. 57 – 59 °C). ^{1}H NMR (DMSO-d_6): δ 2.48 (m, $-CH_2-$), δ 7.15 (s, $-CH=$).

Cycloheptapyrazole (IIc). Cycloheptapyrazole was obtained from the ether solution of Ic and 21.0 g (0.42 mol) 99 % hydrazine hydrate. Yield 40.6 g (75 % based on the amount of cycloheptanone used). B. p.$_{1.2}$ 125 – 128 °C (lit.$_{0.5}$ [16,17] 118 – 120 °C) ^{1}H NMR (DMSO-d_6): δ 1.65 (m, $-CH_2-$), δ 2.50 (m, $-CH_2-C=$), δ 7.11 (s, $-CH=$).

Cyclooctapyrazole (IId). Cyclooctapyrazole was synthesized from 32.2 g (0.21 mol) of Id and 11.0 g (0.22 mol) 99 % hydrazine hydrate in 150 ml dry ether.

Yield 26.6 g (85 %). B.p.$_{1.5}$ 160 – 165 °C. M.p. 45 °C (lit.[18] M.p. 45 °C) ^{1}H NMR (DMSO-d_6): δ 1.42 (broad, $-CH_2-$), δ 2.54 (m, $-CH_2-C=$), δ 7.10 (s. $-CH=$).

D,L-α-*(Cyclopentapyrazolyl-2)propionic acid (Va).* 54.0 g (0.50 mol) of IIa and 108.6 g (0.60 mol) ethyl α-propionate were warmed at 120 °C for 4 h. After cooling, 100 ml water was added and the mixture was extracted three times with 100 ml portions of ether. The ether phase was washed with water and dried over magnesium sulphate. A GLC test showed that the ether solution contained 1-ester and 2-ester in the ratio 70:30. The ether was distilled off in a rotary evaporator and the residue was fractionated at reduced pressure. 34.1 g product with b.p.$_{0.5}$ 134 – 136° C was obtained. 20 % of IIa remained unreacted. ^{1}H NMR (DMSO-d_6): δ 6.95 (s, $-CH=$; IIIa), δ 7.21 (s, $-CH=$; IVa).

10.0 g of the product was hydrolyzed with

50 ml 2 M sodium hydroxide at 100 °C for 2 h. After cooling, the hydrolysate was extracted with ether. The water phase was then acidified with concentrated hydrochloric acid to pH 3.5 and placed in a refrigerator. 6.0 g product was obtained containing both 1-acid and 2-acid. After recrystallization twice from ethanol-water (2:1) and once from ethanol, no 1-isomer was found by ^{1}H NMR analysis. M.p. 170–171 °C. ^{1}H NMR (DMSO-d_6): δ 1.57 (d, 3 H, CH_3-), δ 2.46 (complex m, 6 H, $-CH_2-$), δ 4.89 (q, 1 H, α-H), δ 7.21 (s, 1 H, $-CH=$). IR (KBr), C=O 5.8 μ. UV, λ_{max} 233.4 nm (log ε 3.82). [Found (179.4, titration): C 59.87; H 8.73; N 15.65. Calc. for $C_9H_{12}N_2O_2$ (180.2): C 59.99;H 6.71; N 15.54].

D,L-α-*(Cycloheptapyrazolyl-2)propionic acid (Vc).* The acid Vc was synthesized in the same way from 40.0 g (0.29 mol) cycloheptapyrazole and 63.4 g (0.35 mol) ethyl α-bromopropionate. 33.8 g product was obtained after distillation. B.p. $_{0,1-0.2}$ 126–134 °C. Hydrolysis and recrystallization once from ethanol-water and twice from ethyl acetate yielded 18.5 g of Vc. M.p. 154–159 °C. IR (KBr) C=O 5.8 μ. UV λ_{max} 231.2 nm (log ε 3.83). ^{1}H NMR (DMSO-d_6): δ 1.55 (complex m and d, 9 H, $-CH_2-$ and CH_3-), δ 2.50 (complex m, 4 H, $-CH_2-\underset{|}{C}=$), δ 4.82 (q, 1 H, α-H), δ 7.28 (s, 1 H, $-CH=$). [Found (208.2, MS): C 63.36; H 7.64; N 13.54. Calc. for $C_{11}H_{16}N_2O_2$ (208.2): C 63.45; H 7.73; N 13.45].

D,L-α-*(Cyclooctapyrazolyl-2)propionic acid (Vd).* 58.6 g (0.39 mol) cyclooctapyrazole was reacted with 81.5 g (0.45 mol) of ethyl α-bromopropionate in the same way. 33.5 g product was obtained with b.p.$_{0.8}$ 153–156 °C. Hydrolysis and recrystallization from ethanol-water (2:1) yielded 16.2 g of Vd. M.p. 107 °C. IR (KBr) C=O 5.8 μ. UV λ_{max} 231.5 nm (log ε 3.76). ^{1}H NMR (DMSO-d_6): δ 1.57 (complex m and d, 11 H, $-CH_2-$ and CH_3-), δ 2.54 (complex m, 4 H, $-CH_2-\underset{|}{C}=$), δ 4.93 (q, 1 H, α-H), δ 7.36 (s, 1 H, $-CH=$). [Found (222.2, MS): C 64.61; H 8.19; N 12.43. Calc. for $C_{12}H_{18}N_2O_2$ (222.3): C 64.82; H 8.16; N 12.60].

Alkylation of cyclopentapyrazole and 4,5,6,7-tetrahydroindazole with ethyl α-bromopropionate in alkaline medium. 1.0 g (9 mmol) of IIa was dissolved in a sodium ethoxide solution made from 0.30 g (13 mmol) sodium in 7 ml 99 % ethanol. 5.0 g (22 mmol) ethyl α-bromopropionate was the added with stirring for a few minutes. The temperature increased to 52 °C and a white precipitate of sodium bromide was formed. After 25 min the reaction mixture became neutral. The mixture was concentrated in a rotary evaporator, and 5 ml of water was added to the residue. The mixture was extracted with three 10 ml portions of ether, the organic layer was dried, and the ether was distilled off. A ^{1}H NMR analysis of the mixture showed that 70 % of IIa was transformed into an ester mixture consisting of 42 % IIIa and 58 % IVa.

Alkylation of IIb in the same way gave 41 % IIIb and 59 % IVb of the total amount of ester formed. A good analytical separation of IIb, IIIb, and IVb by GLC was obtained with retention times 54, 93, and 102.5 min., respectively. The retention times for IIa, IIIa, and IVa were 27, 45, and 53 min.

9	50	3.2	−45

Preliminary tests on resolution of α-(cycloheptapyrazolyl-2)propionic acid (Vc). Preliminary experiments on resolution were performed with common alkaloids and some synthetic bases. 1 mmol of Vc and 1 mmol base were dissolved in a small amount of solvent and the salt obtained was filtered off and dried. The acid was liberated by adding 2 M sodium hydroxide. The organic base was removed by extraction several times with chloroform. The water solution was then acidified with 2 M hydrochloric acid to pH 3.5. The acid was filtered off and dried, and, the optical activity was determined in chloroform.

D*(R) (−)α-(Cycloheptapyrazolyl-2)propionic acid.* 12.5 g (0.060 mol) of Vc and 10.0 g (0.060 mol) (−)-ephedrine were dissolved in 780 ml of boiling ethyl acetate. After one night in a refrigerator the salt was filtered off and recrystallized several times from ethyl acetate. Acid was liberated from 0.10 g salt after each recrystallization and the optical activity was determined in chloroform. The results are given in Table 1.

The acid was liberated from its (−)-ephedrine salt by adding 2 M sodium hydroxide. After extraction with chloroform the water phase was acidified to pH 3.5 with concentrated hydrochloric acid. The product was recrystallized from ethanol–water (2:1) and dried over phosphorus pentoxide in vacuum. 1.1 g of Vc was obtained with m.p. 177–178.5 °C. The optical activity of (−)Vc in some different solvents is given in Table 2.

L(+)-α-*(Cycloheptapyrazolyl-2) propionic acid.* The mother liquor from the first crystallization

9	210	1.3	+42

was evaporated to dryness. 10.5 g salt was isolated from which the acid was liberated as described earlier. 4.6 g acid with $[\alpha]_D^{25} = +17°$ was obtained. This acid (0.022 mol) and 3.77 g (0.022 mol) (−)-α-(β-naphthyl)ethylamine [19] were dissolved in 130 ml of boiling ethyl acetate and the salt allowed to crystallize in a refrigerator. After nine recrystallizations the optical activity remained constant. The course of the resolution is given in Table 3. The acid was then liberated and recrystallized from ethanol–water (2:1). 0.50 g acid in white glistening crystals was obtained with m.p. 178–180 °C. $[\alpha]_D^{25} = +46.9°$ (*c* 0.398).

Acknowledgements. We wish to express our sincere gratitude to Professors A. Fredga and G. Bergson for their kind interest in this work and for all facilities put at our disposal. We are also indebted to Docent R. Håkansson at the University of Lund for assistance with the circular dichroism spectra. A grant from the Faculty of Mathematics and Natural Sciences, University of Uppsala is gratefully acknowledged.

1-*O*-(2-Hydroxyalkyl)glycerols Isolated from Greenland Shark Liver Oil

BO HALLGREN and GUNNEL STÄLLBERG

Research Laboratories, Astra Nutrition AB, S-431 20 Mölndal 1, Sweden

2-Hydroxy-substituted glycerol ethers with 14, 16, and 18 carbon atoms in the long carbon chains have been found in the unsaponifiable fraction of Greenland shark liver oil. The mass spectrum of the isopropylidene derivative of the predominant 16:1 hydroxy compound from shark liver oil and that of synthetically prepared 1-*O*-(2-hydroxy-4-hexadecenyl)-2,3-*O*-isopropylideneglycerol were identical.

Methoxy-substituted glycerol ethers with 16:0 16:1, and 18:1 * as the predominating carbon chains have been isolated from shark liver oil.[1] They have also been found in trace quantities in the lipids from other marine animals [2] and from mammals including man.[3] In isolating larger quantities of methoxy-substituted glycerol ethers from other lipids in the unsaponifiable fraction of Greenland shark liver oil, the enrichment steps were checked by thin-layer chromatography (TLC). A small spot with an R_F-value lower than that of the methoxy glycerol ethers was observed. By a series of concentration steps the unknown compounds were obtained in milligram quantities. The R_F-values, compared with those of the unsubstituted and the methoxy-substituted glycerol ethers and their isopropylidene derivatives and later also with synthetically prepared 1-*O*-(2-hydroxyhexadecyl)glycerol [4] and 1-*O*-(2-hydroxyhexadecenyl)glycerol, indicated that the unknown compounds could be hydroxy-substituted glycerol ethers. This was also supported by the gas chromatographic – mass spectrometric (GLC–MS) analysis. The retention time and the mass spectrum of the compound, corresponding to the predominant peak of the gas chromatogram, were identical with the retention time and the mass spectrum of synthetically prepared 1-*O*-(2-hydroxy-4-hexadecenyl)-2,3-*O*-isopropylideneglycerol (Figs. 1 and 2). Hydroxy-substituted tetradecyl, tetradecenyl, hexadecyl, and octadecenyl glycerol ethers were also indicated. It is not likely that the position of the double bond differs from that in the methoxy-substituted glycerol ethers.[1] Therefore the compounds found would be 1-*O*-(2-hydroxytetradecyl)glycerol, 1-*O*-(2-hydroxy-4-tetradecenyl)glycerol, 1-*O*-(2-hydroxyhexadecyl)glycerol,[4,5] 1-*O*-(2-hydroxy-4-hexadecenyl)glycerol, and 1-*O*-(2-hydroxy-4-octadecenyl)glycerol.

In investigations on the biosyntheses of alk-1-enyl glycerol ethers from the corresponding alkyl compounds Blank *et al.*[6] and Snyder *et al.*[7] found an unidentified compound that behaved similarly to a β-hydroxy-*O*-alkylglycerol. It has been proposed [7] that a glycerol ether compound with a substituent such as hydroxy in the 2-position of the alkyl chain could be an intermediate in the biosynthesis of the alk-1-enyl lipids from the alkyl ones. However, in experiments by Muramatsu and Schmid,[8] labelled 1-*O*-(2-hydroxyheptadecyl)-glycerol, which had been formed in rat brain after administration of 1,2-heptadecanediol-2-^{14}C, did not form observable amounts of labelled *O*-alk-1-enyl ether.

* The first figure denotes the number of carbon atoms in the long carbon chain (the methoxy group excluded) and the figure after the colon the number of double bonds.

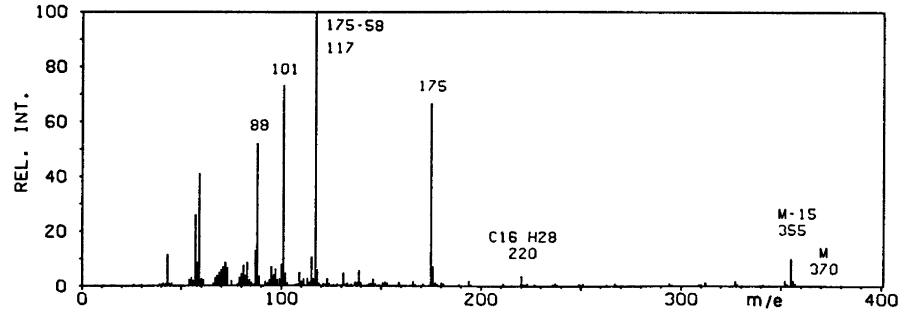

Fig. 1. Mass spectrum of the isopropylidene derivative of 1-*O*-(2-hydroxyhexadecenyl)glycerol, isolated from Greenland shark liver oil.

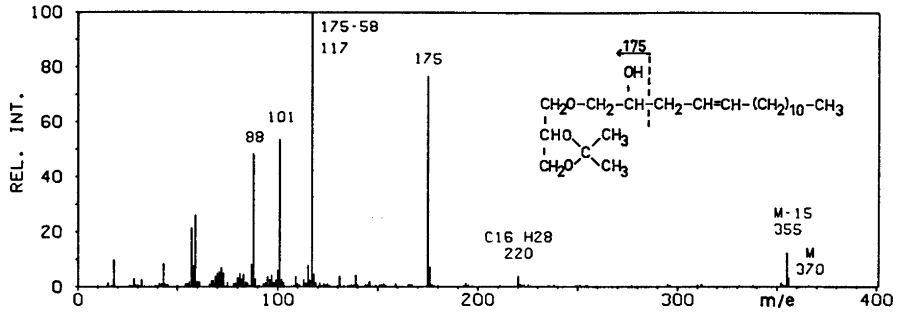

Fig. 2. Mass spectrum of synthetic 1-*O*-(2-hydroxy-4-*cis*-hexadecenyl)-2,3-*O*-isopropylideneglycerol.

EXPERIMENTAL

Enrichment of hydroxy-substituted glycerol ethers from the unsaponifiable fraction of the liver oil from Greenland shark * (*Somniosus microcephalus*) was performed by the following procedure. The unsaponifiable fraction (13 g), obtained after hydrolysis of the liver oil in 1 M ethanolic KOH, was freed from some less polar material by crystallization from acetone (120 ml) at −18 °C. The material (4.0 g) from the filtrate was dissolved in 81 % methanol (125 ml) and extracted continuously with light petroleum, b.p. 40−60 °C, (in an extractor with a sintered disc distributor). The lipids (2.3 g) obtained from the methanol−water phase were chromatographed on a silicic acid (75 g) column (Bio-Sil HA minus 325 mesh, Bio-Rad Laboratories, Richmond Calif). After eluting less polar components with ether, the more polar ones were eluted with methanol. TLC (silica gel G, Merck, developing solvent: trimethylpentane − ethyl acetate − methanol, 50:40:10) showed that the unknown compounds were enriched in the first fractions of the methanol eluate. This material (10 mg) was treated with acetone in the presence of 10^{-2} M $HClO_4$.[9] TLC (developing solvent: trimethylpentane−ethyl acetate, 60:30) indicated that some compounds in the mixture had been transformed to isopropylidene derivatives. Preparative TLC gave 1.4 mg of a material, which was subjected to gas chromatographic-mass spectrometric analysis.

The GLC−MS analysis was performed on a LKB 9000 combination instrument under the following operating conditions: electron energy 70 eV, ion accelerating voltage 3.5 kV, trap current 60 μA, and ion source temperature 270 °C. The gas chromatographic separation was carried out at 210 °C using a 3 m × 3 mm i.d. glass column packed with Gas Chrom Q 80−100 mesh, containing 1 % Apiezon L. The flow was 30 ml helium/min.

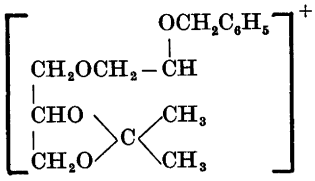
Synthesis of 1-*O*-(2-hydroxy-4-*cis*-hexadecenyl)-2,3-*O*-isopropylideneglycerol

2-Benzyloxy-4-hexadecynyl p-toluenesulfonate and methanesulfonate. Reduction of methyl 2-benzyloxy-4-hexadecynoate [10] (2.95 g) with lithium aluminium hydride gave 2.7 g of crude 2-benzyloxy-4-hexadecyn-1-ol, which by treat-

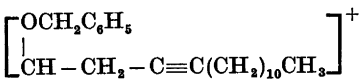
* The liver oil was supplied by A/S Johan C. Martens and Co., Bergen, Norway.

ment with *p*-toluenesulfonyl chloride (2.0 g) in the presence of dry pyridine [11] gave 3.9 g of almost pure (as shown by TLC) 2-benzyloxy-4-hexadecynyl *p*-toluenesulfonate. The corresponding methanesulfonate was obtained by treatment of the alcohol with methanesulfonyl chloride in the manner described by Baumann and Mangold.[12]

1-O-(2-Benzyloxy-4-hexadecynyl)-2,3-O-isopropylideneglycerol was prepared according to the procedure described by Gupta and Kummerow.[13] Potassium (0.45 g) was granulated by stirring in refluxing dry benzene (25 ml). Isopropylideneglycerol (4.0 g) was slowly added during 15 min. After 1 h, when no more potassium could be observed in the flask, a solution of 2-benzyloxy-4-hexadecynyl *p*-toluenesulfonate (3.9 g) in dry benzene (5 ml) was added. The mixture was refluxed for 5 h. After cooling, ether was added. The benzene–ether solution was washed with water and dried over anhydrous sodium sulfate. The crude product was purified by silicic acid chromatography, yielding 1.57 g (41 %) of almost pure (as shown by TLC) acetonide of 2-benzyloxyhexadecynylglycerol. (On storage the acetonide slowly decomposed into several compounds). The 1-*O*-(2-benzyloxyhexadecynyl)-2,3-*O*-isopropylideneglycerol was also prepared from the methanesulfonate. Tetrahydrofuran was used as solvent instead of benzene. The yield of purified acetonide was 56 % of the calculated amount. The mass spectrum of the acetonide [4] shows a molecular ion peak at $m/e = 458$. The base peak at $m/e = 91$ is probably due to tropylium ions, formed from the benzyl group. Prominent peaks at $m/e = 265$ and $m/e = 313$ correspond to the fragments



and



*1-O-(2-Hydroxy-4-*cis*-hexadecenyl)-2,3-O-isopropylideneglycerol.* Selective hydrogenation [14] of 1-*O*-(2-benzyloxy-4-hexadecynyl)-2,3-*O*-isopropylideneglycerol (660 mg) in pyridine solution (5 ml) and with 5 % palladium on barium sulfate (70 mg) as catalyst gave a mixture of benzyloxy- and hydroxy-substituted hexadecenyl compounds (in the proportions 9:1). Chromatography on a silicic acid column (eluent: light petroleum – ether, 9:1) gave 60 mg of 1-*O*-(2-hydroxy-4-hexadecenyl)-2,3-*O*-isopropylideneglycerol (MS in Fig. 2). Hydrolysis of the acetonide in a mixture of ether and concentrated hydrochloric acid [15] and purification by chromatography on a silicic acid column (eluent: ether-methanol, 99:1) gave the free glycerol ether (pure as shown by TLC) as a colourless transparent jelly, which after crystallization at −18 °C melted at about 34 °C (probably polymorphism). The IR spectra of the 1-*O*-(2-hydroxy-4-hexadecenyl)glycerol and of 1-*O*-(2-hydroxyhexadecyl)glycerol were almost identical except in the ranges of the double bond absorptions (≈3010, 1635 and 700 cm^{-1}). The *cis* form of the unsaturated compound was confirmed by the bands at 1635 and 700 cm^{-1}.

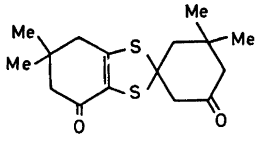
Enethiols. VIII.* 3-Mercapto-5,5-dimethyl-2-cyclohexen-1-one ("Thiodimedone") and Derivatives. Thermal and Photochemical Rearrangements

L. DALGAARD and S.-O. LAWESSON

Department of Organic Chemistry, Chemical Institute, Aarhus University, DK-8000 Aarhus C, Denmark

Reaction of 3-chloro-5,5-dimethyl-2-cyclohexen-1-one with Na_2S gave 3-mercapto-5,5-dimethyl-2-cyclohexen-1-one (RSH). Subsequent alkylation of RSH (Na^+ salt) gave the sulfides RSR′ (R′ = CH_3-, $CH_2=CHCH_2-$, $CH_3CH=CHCH_2-$, and CH_3COCH_2-). Similarly RSH (Tl^+ salt) yielded RSR′ (R′ = $HC\equiv CCH_2-$) while RSH (Bu_4N^+ salt) gave (R′ = $H_2C=C=CH-$) by alkylation with $HC\equiv CCH_2Br$. Allylic sulfides (RSR′) underwent thio-Claisen rearrangement and cyclization at about 140 °C in quinoline to 2,6,6-trimethyl-4-oxo-2,3,4,5,6,7-hexahydrobenzothiophene (when R′ = $CH_2=CHCH_2-$) and 2,3,6,6-tetramethyl-4-oxo-2,3,4,5,6,7-hexahydrobenzothiophene (when R′ = $CH_3CH=CHCH_2-$). Rearrangement in acetic anhydride gave 3-acetylthio-2-allyl-5,5-dimethyl-2-cyclohexen-1-one (when R′ = $CH_2=CHCH_2-$). Photolysis of RSR′ (R′ = $CH_2=CHCH_2-$, $CH_3CH=CHCH_2-$, $PhCH_2-$, $CH_3C(O)-$, and $H-$) gave RSSR and a 1,3-dithiole:



This product was obtained in 79 % yield by photolysis of RSSR. Photolysis of RSR′ (R′ = phenyl) gave 3,3-dimethyl-5-oxo-2,3,4,5-tetrahydrodibenzothiophene.

In previous papers dealing with the thermal [1-5] and photochemical [1] behaviour ($Z-E$ isomerization [1,2] and thio-Claisen rearrangements [1-5]) of α,β-unsaturated sulfides, open chain compounds were investigated. As part of this study it seemed desirable to investigate enethiols and sulfides having the corresponding mercapto- and alkylthio group placed in the β-position of an α-β-unsaturated carbonyl compound, but in which intramolecular H-bonding of the enethiol is excluded. Thiodimedone (3-mercapto-5,5-dimethyl-2-cyclohexen-1-one) and the 3-alkylthio derivatives were thought to be suitable representatives of such compounds. 3-Mercapto-5,5-dimethyl-2-cyclohexen-1-one and most of its derivatives were conveniently prepared from the 3-chloro-2-cyclohexen-1-one (for relevant literature, see Refs. 6 – 15). Results on synthesis, thermolysis, and photolysis of these compounds are the subject of the present work.

Synthesis of 3-mercapto-5,5-dimethyl-2-cyclohexen-1-one (thiodimedone) and derivatives (Fig. 1). Dimedone *1*, when treated with PCl_3 gave *2*,[16] which by further reaction with Na_2S gave *3* and small amounts of *4*. Acidification, alkylation or oxidation of the water solution of *3* yielded thiodimedone *5*, the sulfides *6* – *9*, or the disulfide *13*, respectively. Preparation of the unsoluble thallium(I) salt of *5* suspended in HMPA followed by alkylation with 2-propynyl bromide resulted in the formation of the 2-propynyl sulfide *10*. When alkylation was performed in a homogeneous mixture, consisting of the tetrabutylammonium salt of *5* dissolved in CH_2Cl_2 and 2-propynyl bromide, the allenyl sulfide *11* was formed. The acetyl derivative *12* was prepared from acetyl chloride and *5* dissolved in pyridine. Treatment of *1*

* Part VII. See Ref. 1.

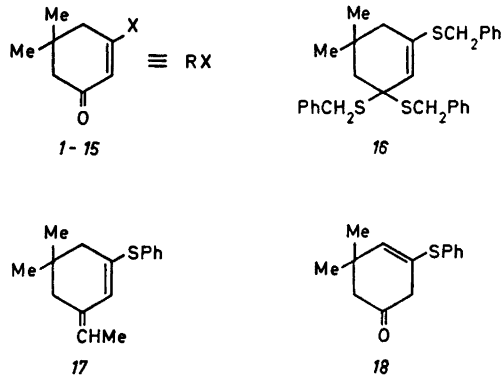


Fig. 1. Compounds *1-18*. 1 (ROH), *2* (RCl), 3 ($RS^{\ominus}$), *4* (RSR), *5* (RSH), *6* ($RSCH_3$), *7* ($RSCH_2CH=CH_2$), *8* ($RSCH_2CH=CHCH_3$), *9* ($RSCH_2COCH_3$), *10* ($RSCH_2C{\equiv}CH$), *11* ($RSCH=C=CH_2$), *12* ($RSCOCH_3$), *13* (RSSR), *14* (RSPh), *15* ($RSCH_2Ph$).

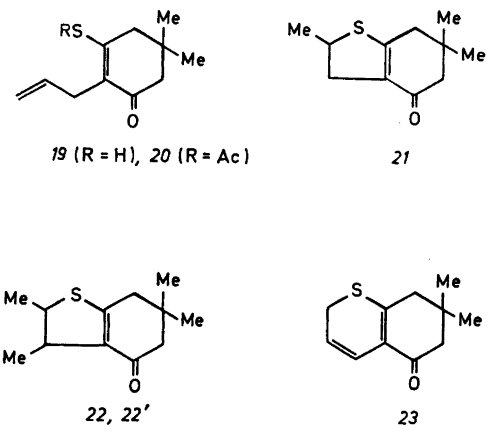

Fig. 2. Compounds *19-23*.

with the appropriate thioles gave the sulfides *14* [7] and *15* [7] together with the thioacetal *16*. When *14* was reacted with ethyllithium a 1,2-addition followed by elimination took place resulting in the formation of *17*, while treatment of *14* with $LiNH_2/NH_3$ gave partly isomerization to *18* (see also Refs. 17, 18).

Thermal rearrangements of allylic derivatives. 3-Allyloxy-2-cyclohexen-1-one has been shown [19] to undergo Claisen rearrangement at 190-210 °C. Similarly the 3-allylthio analogues do undergo thio-Claisen rearrangement. Rearrangement in the presence of *p*-toluenesulfonic acid resulted in the formation of 2-allyl-3-mercapto-5,5-dimethyl-2-cyclohexen-1-one *19*, which cyclisized partly during distillation. When the reaction was performed in boiling acetic anhydride, 3-acetylthio-2-allyl-5,5-dimethyl-2-cyclohexen-1-one *20* was isolated. Rearrangement in quinoline at 160 °C yielded the hexahydrobenzothiophene *20*. The 2-butenyl derivative rearranged to *21* somewhat slower under similar conditions. Heating of the 2-propynyl (*10*) and the allenyl (*11*) sulfides in quinoline or pyridine resulted mostly in tarry material However, the 2H-thiapyran *23* could be isolated in a reasonably pure state by rearrangement of *10*.

Photolysis of 3-mercapto-5,5-dimethyl-2-cyclohexen-1-one and sulfide derivatives. Photolysis of the compounds *5*, *7*, *8*, *12*, and *15* (Table 1) did not yield the expected [23-24] 2+2 cycloadducts. Irradiation of the enethiol *5* gave the disulfide *13* which is an ordinary type of product in photolysis of thiols,[25] the 1,3-dithiole *24* and the 1,4-dithiane *25*. The allyl *7*, 2-butenyl *8*, and the benzyl *15* derivatives gave *13* and *24* in variable ratios. In one experiment when *15* was irradiated traces of PhCHO arising from the benzyl group were detected along with *13*. The acetyl derivative *12* yielded *13* and *24* together with EtOAc upon photolysis in EtOH. As might be expected the phenyl derivative *14* did not undergo cleavage reaction at the R-S bond, but instead an intramolecular cyclization-oxidation reaction (eqn. 1) took place, giving the tetrahydrodibenzothiophene *26* in poor yields. Similar reactions have been observed for other types of divinyl sulfides.[26,27] In

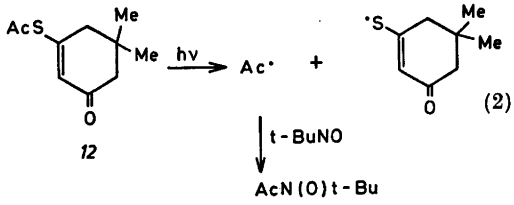
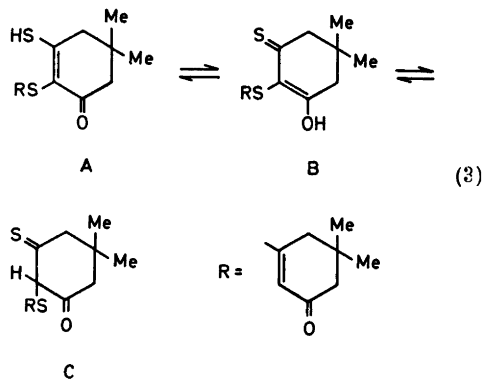
order to find out if *24* could be formed from *13* this compound was irradiated at 254 nm in ethanol. It turned out [28] that *24* was produced in high yields (79 %) and crystallized directly from the solvent. Also sunlight caused this conversion (*13*→*24*) in solution, while in the solid state *13* was quite stable. The possibility that the rearrangement was thermally induced was ruled out, as no conversion was observed when *13* was boiled in ethanol in the dark. More severe conditions (*i.e.* heating in HMPA in the presence of $KHSO_4$)[29,30] which have brought about 3,3-sigmatropic rearrangements of other divinyl-disulfides,[29–32] gave only tar.

Various methods were used in order to determine the mechanisms of the observed photochemical reactions. A hexane solution of the acetyl derivative *12* and 2-methyl-2-nitrosopropane was irradiated at 254 – 300 nm in the ESR spectrograph. The formation of *N*-acetyl-*N*-(*t*-butyl)nitroxide ($a_N = 8$ gauss) [33] indicated that the primary photochemical process was a cleavage of *12* into acetyl and thiyl radicals (eqn. 2). However, no well defined signal from the thiyl radical or trapped thiyl radical could be observed. Also attempts to trap radicals by photolysis of the disulfide *13* were fruitless. The conversion of *13* irradiated with monochromatic light (254 and 300 nm) was measured by the change of the UV spectrum. The change of the UV spectrum obtained in ethanol differed



(2)

clearly from that obtained in $CHCl_3$. In both solvents the absorption at 277 nm disappeared with about equal rates. However, in ethanol an absorption at 350 nm appeared quickly, reached a maximum and then faded out. In $CHCl_3$ only comparatively weak absorption at 350 nm was found. It is believed that different tautomers (eqn. 3) of the same intermediate are formed when the solvent is changed, thus giving rise to different UV-spectra. For comparison, it should be pointed out that *5* showed a behaviour similar to the intermediate in eqn. 3 as *5* revealed absorption at 342 nm in ethanol and DMSO, while in $CHCl_3$ this band was comparatively weak. The suggested intermediate (M) represented by structure A, B, and C in eqn. 3 might be formed by a radical chain process initiated by light (eqn. 4). The propagation step (eqn. 5) consists of a thiyl radical attack on C-2 of *13* (RSSR), giving M and another thiyl radical. This means that the rate of disappearance of *13* is dependent on the concentration of *13*. Measurement of the quantum yield ($\Phi = 0.1$) for disappearance of *13* showed no such dependence on [RSSR], and it seems therefore reasonable to suggest another mechanism. The reaction could proceed through reactions in which two thiyl radicals combine to give M either as free radicals or in a solvent cage (eqn. 7). Finally a concerted [1,3]-sigmatropic process could be suggested (eqn. 8). The conversion of M to *24* might be a thermal cyclisation reaction, but more likely a photochemical process, because it explains the change of the UV spectrum in EtOH. The absorption at 350 nm, ascribed to M, did not change on standing in the dark, while irradiation caused a change as described above.



(3)

Initiation:

$$RSSR \rightarrow RSSR^* \rightarrow 2\ RS\cdot \quad (4)$$

Propagation:

$$RS\cdot + RSSR \xrightarrow{k_1} M + RS\cdot \quad (5)$$

$$\Phi I = -dC/dt = k_1[RS\cdot][RSSR] \quad (6)$$

$$2\ RS\cdot \rightarrow M \quad (7)$$

$$RSSR \rightarrow RSSR^* \rightarrow M \quad (8)$$

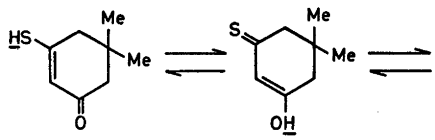
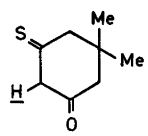
SPECTROSCOPY

Tautomerism of thiodimedone. In principle thiodimedone *5* can exist as the monomeric keto-enethiol (D), thioketo-enol (E), and the ketothioketo (F) structures (eqn. 10). In concentrated solutions or neat also dimer structures



5 (D) 5 (E)

(10)



5 (F)

analogous to the findings for 1,3-cyclohexandione and dimedone should be considered likely.[36,37] The IR spectrum of thiodimedone showed absorption at 2520 cm^{-1} and a broad band at 1680 cm^{-1} assigned, respectively, to the mercapto and the α,β-unsaturated keto group of the keto-enethiol (D). This was the only tautomer detectable by NMR. The signal at δ 6.05 was assigned to the vinyl proton, as an allylic coupling to the protons on C-4 was observed. The broad signal at δ 4.23 could be attributed to a mercapto proton, excluding an enolic proton, which was expected to reveal a signal at lower field (δ 9 – 13). The broadening of this signal was ascribed to proton exchange. Contrary to what is often found for enethiols, no coupling between the proton of the mercapto group on C-3 and the protons on C-4 was present. The structural requirement for a maximum coupling is that the bondings between the hydrogens obtain a planar zig-zag framework, as found for enethiols possessing an intramolecular chelated structure.[38] As only energetical less important intermolecular hydrogen bonding can occur in thiodimedone, the rotation about the C – S bond is less restricted, and the coupling decreases to zero. The UV spectrum of thiodimedone obtained in hexane showed absorption at 268 nm, ascribed to the $\pi - \pi^*$ transition of the α,β-unsaturated keto chromophore, present in the keto-enethiol (A). When the solvent was changed to EtOH or DMSO absorption maxima at 282 and 340 nm were observed. On going from an α,β-unsaturated ketone to the thione the $\pi - \pi^*$ absorption is shifted about 80 nm.[39–42] The strong absorption of 340 nm must therefore arise from structure *5*E. The structure *5*F cannot be excluded because saturated thioketones have only weak absorption above 300 nm and the observed one is strong.

Identification of other compounds. The spectroscopic data of 3-alkylthio derivatives of thiodimedone are shown in Table 3 (NMR) and Table 4 (IR and UV). These compounds gave rise to an IR absorption in the range of 1650 – 1680 cm^{-1} due to an α,β-unsaturated carbonyl group and a band at 1570 – 1595 cm^{-1} corresponding to a carbon-carbon double bond. The UV spectra of compounds *7* – *10*, *15* showed

Table 2. Rate of disappearance ($-\Delta C/\Delta t$) of compound *13*, measured by the change in UV absorbance (ΔAbs) for various concentrations (C) of *13*.

$C \times 10^7$ mol/cm³	ΔAbs	$-\Delta C \times 10$/[a] mol/cm³	Δt (s)	$-\frac{\Delta C}{\Delta t} \times 10^{11}$ mol/cm³ s
0.645	0.29	1.45	180	8.06
1.30	0.23	2.30	300	7.67
1.94	0.25	3.45	420	8.23
3.23	0.21	5.25	720	7.23
3.87	0.23	6.90	900	7.67
6.45	0.29	14.50	1800	8.05

[a] ΔC corresponds to 16–23 % conversion of *13*. $\Delta C = \Delta\text{Abs}/\Delta\varepsilon$, where $\Delta\varepsilon$ is the difference between the molar absorbance of compound *13* ($\varepsilon = 21\,400$) and that of compound *24* ($\varepsilon = 1400$) at 277 nm.

Table 3. ^{1}H NMR chemical shift (δ values) and coupling constants (J Hz) of 3-mercapto-5,5-dimethyl-2-cyclohexen-1-one and derivatives. The solvent is CCl_4.

[a] The solvent is EtOH, unless otherwise stated. [b] Solvent: Hexane, [c] ether, [d] DMSO, [e] MeCN, [f] $CHCl_3$.

absorption at 287–292 nm which is ascribed to a $\pi-\pi^*$ transition of the conjugated system. The compounds *4*, *11*, *14* which were further conjugated with an additional carbon-carbon double bond showed a $\pi-\pi^*$ transition at somewhat longer wavelength *i.e.* in the range of 294–313 nm. The disulfide *13* and the acetyl *12* derivatives absorbed at shorter wavelength, namely at 277 nm, than the above mentioned compounds. The spectroscopic data of the products obtained by rearrangement of 3-allylthio and 3-(2-butenyl) derivatives are shown in Table 5 (NMR) and Table 6 (IR and UV). The UV absorptions of the hexahydrobenzothiophenes were found at 312 nm which are about 25 nm higher than the corresponding bands of the starting materials. This is in agreement with the bathochromic effect exhibited by an α-substituent on α,β-unsaturated carbonyl chromophore.

The composition and the molecular weight of the 1,3-dithiole *24* were determined to be $C_{16}H_{22}O_2S_2$ (M = 310) from the elemental analysis and the mass spectrum, respectively. The ^1H NMR spectrum showed signals at δ 1.05–1.15 δ 2.25–2.48, and δ 3.02 with the relative intensity of 1:4:6, while the IR spectrum showed strong bands at 1705, 1660, and 1560 cm^{-1}. Several structures, which were compatible with these data, could be drawn. Among the most plausible suggestions are those, which maintain the carbon skeleton and the positions of substituents of the starting material. However, an unambiguous choice could be made from the ^{13}C-noise decoupled and the off resonance NMR spectra, which are shown in Table 6. The assignment of the signals was based on the data given for the chemical shifts and C–H coupling constants of cyclohexanone [43] and cyclohexenone.[44] Approximate values of the C–H coupling constants were determined from the residual splittings, using the expression given by Ernst,[45] and shown to be of the same size as for methylene groups of cyclohexane.[45]

Compound *25* was shown to have the composition $C_{16}H_{24}O_2S_2$ (molecular weight 312)

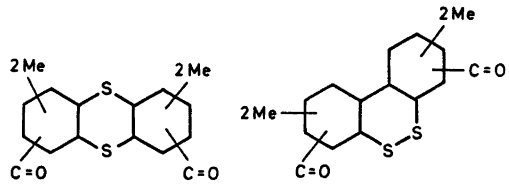

Fig. 3. Possible structures for the photo-dimer *25*.

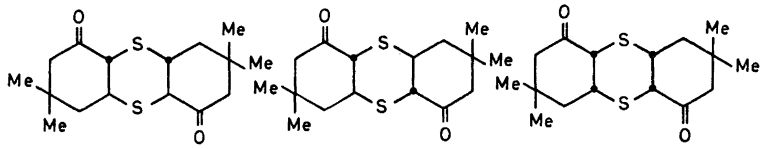
as determined by the mass spectrum. The noise decoupled ^{13}C NMR spectrum showed 8 signals (Table 7) from the 16 carbon atoms, indicating magnetic equivalent pairs of carbon atoms. The off resonance decoupled spectrum showed the presence of methyl methylene and methine carbon atoms. It was assumed that the carbon skeleton of thiodimedone *5* was maintained in the photo-dimer *25*, which might then have one of the 1,2- or 1,4-dithiane structures shown in Fig. 3. However, the 1,2-dithiane structure was unlikely, as it did not account for the ^1H NMR multiplet signal at δ 3.6 – 4.1 assigned to a pair of equivalent methine protons. The signals due to the methine protons in the α-position to the carbonyl group of the 1,2-dithiane would be found at higher field, *i.e.* at about δ 3. The most probable structures are therefore those represented in Fig. 4, which could not be distinguished based on ground of the available data.

EXPERIMENTAL

^1H NMR spectra were recorded at 60 MHz on a Varian A-60 spectrometer. The temperature of the 15 – 20 % solutions (w/w) were 33 ± 1 °C. TMS was used as internal reference standard and the chemical shifts are expressed in δ-values and are correct within ± 0.02 ppm. ^{13}C spectra were recorded on a Varian XL-100-15 spectrometer operating in the c.w. mode at 25.2 MHz. Internal field-frequency lock was provided by the ^2H resonance of $CDCl_3$ as solvent. Carbon line positions were measured relative to the carbon resonance of internal TMS. Noise-modulated and single-frequency proton decoupling experiments were performed by means of the Varian Gyrocode spin decoupler. The sample solution was contained in a 12 mm tube. 70 eV mass spectra were obtained on a Bell and Howell CEC 21 – 104 single focussing mass spectrometer. The IR spectra were recorded as 5 % solutions, film,



25

Fig. 4. Compound *25*.

or as KBr pellets on a Perkin-Elmer infracord 137 and the UV spectra on a Bausch & Lomb Spectronic 505 spectrophotometer with EtOH as solvent. B.p's are uncorrected. Analyses were made by Novo Industri A/S, Copenhagen.

General procedure for the preparation of the sodium salt of 3-mercapto-5,5-dimethyl-2-cyclohexen-1-one. An amount of 16 g (0.1 mol) 3-chloro-5,5-dimethyl-2-cyclohexen-1-one, *2*, was dropped to a solution of 25 g (0.1 mol) $Na_2S.9H_2O$ in 25 ml water during 2 h. The mixture was kept at about 60 °C until it became homogeneous after further 2 h. This solution was then extracted with diethyl ether (2 × 10 ml), which after drying and evaporation gave small amounts of bis(5,5-dimethyl-2-cyclohexen-3-yl-1-one)sulfide, *4*. The water solution was then used for further reactions.

3-Mercapto-5,5-dimethyl-2-cyclohexen-1-one, 5. Acidification (0.1 mol) of the solution of the sodium salt of *5* with cold 4 M HCl, extraction with ether, drying and evaporation of the ether gave the crude product, which amounted to 14.8 g (95 %). The yield decreased considerably by distillation at 98 °C/0.1 mmHg; $n_D^{25} = 1.5690$. (Found: C 61.49; H 7.79; S 19.47. $C_8H_{12}OS$ requires: C 61.52; H 7.75; S 20.49).

Bis(5,5-dimethyl-2-cyclohexen-1-on-3-yl)-sulfide, 4. Ether extraction of the water solution of the sodium salt of *5* prepared by the general procedure gave after drying and evaporation 0.656 g (5 %) of m.p. 176–177 °C. (Found: C 68.84; H 7.98; S 11.46 $C_{16}H_{22}O_2S$ requires: C 69.04; H 7.97; S 11.50). MS, *m/e* (%): 280(9), 279(38), 278(51), 264(5), 263(23), 207(8), 196(5,) 195(11), 194(57), 156(9), 155(47), 152(14), 151(16), 141(9), 139(9), 138(15), 137(24), 123(9), 112(11), 111(12), 110(77), 95(9), 93(8), 91(8), 79(23), 77(15), 71(17), 68(100), 56(8), 55(22), 53(22).

Bis-(5,5-dimethyl-2-cyclohexen-1-on-3-yl)-disulfide, 13. To a water solution of 0.1 mol of the sodium salt of *5* prepared by the general method were added (excess) 20 g (0.079 mol) of iodine dissolved in 50 ml THF. After about 2 h at room temp. a saturated solution of $Na_2S_2O_3$ was added until the dark colour disappeared, and the mixture was extracted with CH_2Cl_2. This was then stripped off and the residue treated with ether and water. The ether was dried and evaporated giving 14.1 g (91 %) of crystalline product. M.p. 91 °C (ether). (Found: C 61.95; H 7.16; S 20.21. $C_{16}H_{22}O_2S_2$ requires: C 61.92; H 7.15; S 20.6). MS, *m/e* (%): 310(26), 295(9.2), 279(11), 278(37), 277(100), 255(9.2), 254(39), 253(56), 247(7.4), 246(45), 254(19), 220(11), 212(35), 156(26), 155(33), 100(56), 83(56), 71(32), 67(65), 55(37).

5,5-Dimethyl-3-methylthio-2-cyclohexen-1-one, 6. To the solution prepared by the general method were added 16 g (0.11 mol) MeI. The temp. was kept at about 30 °C. The mixture was then allowed to stir overnight. Extraction with ether, drying evaporation of the solvent yielded 15.1 g (89 %) of crystalline compound, m.p. 35 °C (lit. m.p.[6] 34–37 °C).

3-Allylthio-5,5-dimethyl-2-cyclohexen-1-one, 7. An amount of 15 g (0.12 mol) allyl bromide in 25 ml DMSO was added to the water solution of the 0.1 mol sodium salt of *5*. The temp. was allowed to rise to 45 °C. After 2 h the mixture was cooled and extracted with 15 ml ether, which was then evaporated. Extraction with water of the residue dissolved in light petroleum was repeated. Drying and evaporation and distillation gave 18 g (92 %); b.p. 65 °C/10^{-4} mmHg, $n_D^{25} = 1.5520$. (Found: C 67.34; H 8.21; S 16.11. $C_{11}H_{16}OS$ requires: C 67.32; H 8.22; S 16.31).

3-(2-Butenylthio)-5,5-dimethyl-2-cyclohexen-1-one, 8. An amount of 8 g (0.059 mol) of 2-butenyl bromide was added to 0.05 mol of the water solution of the sodium salt of *5*. Stirring overnight, followed by extraction with ether, drying and evaporation of the ether gave 8.7 g (83 %); b.p. 114–116 °C/0.1 mmHg; m.p. 33–34 °C. (Found; C 68.61; H 8.64; S 15.11. $C_{12}H_{18}OS$ requires: C 68.54; H 8.63; S 15.22).

5,5-Dimethyl-3-(propan-2-on-1-ylthio)-2-cyclohexen-1-one, 9. A water solution of 0.1 mol of the sodium salt of *5* was treated with 11 g (0.12 mol) chloroacetone. The exothermal process was finished within ½ h. Extraction with 50 ml of ether, drying, and evaporation of the solvent gave 14.5 g (68 %) of crystalline product; m.p. 65 °C (ether–light petroleum 1/1). (Found: C 62.47: H 7.74; S 15.21 $C_{11}H_{16}O_2S$ requires: C 62.25; H 7.60; S 15.08).

5,5-Dimethyl-3-(2-propynylthio)-2-cyclohexen-1-one, 10. An amount of 1.80 g (11.5 mmol) of *5* was dropped to 3.0 g (12 mmol) of thallium(I) ethoxide dissolved in 25 ml benzene. The solid product was filtered off and washed with benzene and ether, giving an mount of 3.9 g (95 %). Then 3.59 g (10 mmol) of this salt were suspended in 15 ml HMPA and 1.5 g (12.6 mmol) of 2-propynyl bromide were added. The mixture was stirred overnight and extracted with ether and water. The ether was stripped off and extraction was repeated with light petroleum and water. Drying and evaporation of the solvent yielded 1.77 g (89 %) which were distilled quantitatively. B.p. 80 °C/10^{-4} mmHg; $n_D^{25} = 1.5608$; (Found: C 68.23; H 7.04; S 16.23. $C_{11}H_{14}OS$ requires: C 68.02; H 7.27; S 16.5).

3-Allenylthio-5,5-dimethyl-2-cyclohexen-1-one, 11. An amount of 4.62 g (29.5 mmol) of *5* dissolved in 30 ml CH_2Cl_2 was added to 10.5 g (31.0 mmol) of tetrabutylammonium hydrogensulfate and 3 g (75 mmol) of NaOH in 30 ml water. Then 4 g (34 mmol) of 2-propynyl bromide were added and the mixture stirred for 18 h. The CH_2Cl_2 phase was evaporated and the residue was treated with ether and water. Drying and evaporation yielded 4.9 g (86 %) of *11*. However, the yield decreased considerably by distillation which gave 1.58 g of b.p. 70 °C/10^{-4} mmHg; $n_D^{25} = 1.5705$. (Found: C 67.94;

H 7.14; S 15.95. $C_{11}H_{14}OS$ requires: C 68.02; H 7.27; S 16.5).

3-Acetylthio-5,5-dimethyl-cyclohexen-1-one, 12. Acidification and work up (without distillation) of a solution prepared by the general method gave *5* which was then treated with 10 g pyridine and 100 ml ether. An amount of 9 g (0.115 mol) acetyl chloride was dropped to the mixture and after 1 h the pyridinium hydrochloride was filtered off and the residue washed with water. The ether was dried over $NaHCO_3$. Evaporation gave 19 g and distillation yielded 15.82 g (75 %); b.p. 96 °C/0.05 mmHg; $n_D^{25} = 1.5314$. (Found: C 60.79; H 7.13; S 15.80. $C_{10}H_{14}O_2S$ requires; C 60.59; H 7.12; S 16.15).

1,3,3-Tribenzylthio-5,5-dimethyl-1-cyclohexene, 16, and 3-benzylthio-5,5-dimethyl-2-cyclohexen-1-one, 15. Preparation by the method of Campaigne.[7] An amount of 14 g (0.1 mol) of dimedone, *1*, and 24.8 g (0.2 mol) of phenylmethanethiol were mixed in 200 ml ethanol. The solution was saturated with HCl gas. A precipitate of 1.16 g (3.6 %) of *16* was formed (theoretical yield 31.9 g). M.p. 77–82 °C. (Found: C 72.73; H 6.68; S 19.88. $C_{29}H_{32}S_3$ requires: C 73.09; H 6.77; S 20.14). NMR (CCl_4): δ 0.96 (6 H, s), 1.83 (4 H, br.s), 3.53 (2 H, s), 3.70 (4 H, s), 5.18 (1 H, s), 7.22 (15 H, s). IR ν_{max}(KBr) (cm^{-1}) 1590. UV (EtOH) λ_{max} (log ε): 212 (4.46), 252 nm (4.07). The alcohol solution was poured into 300 ml water in which 150 g Na_2CO_3 was dissolved. A precipitate was filtered, and then dissolved, dried and the solvent evaporated, giving 5.5 g (22 %) of *15*. M.p. 84–85 °C. (Found: C 73.11; H 7.29; S 13.11. $C_{15}H_{18}OS$ requires: C 73.14; H 7.37; S 12.99).

Treatment of 3-alkylthio-5,5-dimethyl-2-cyclohexen-1-ones with nucleophiles

3-Ethyliden-5,5-dimethyl-1-phenylthio-cyclohexene, 17. An amount of 11.6 g (0.05 mol) of *14* dissolved in 50 ml THF was treated with 0.05 mol EtLi in 50 ml THF solution at −10 °C. After about 1 h, 15 g (0.106 mol) MeI were added and the mixture allowed to stir for 1 h. The solvent was stripped off and extracted with ether and water. The ether phase was dried and evaporated, giving 12.0 g of a liquid. After a short time it became milky and separated into two layers. The mixture was treated with ether again, dried and the solvent evaporated. Distillation yielded 9.4 g (77 %) of b.p. 123–124 °C/0.2 mmHg; $n_D^{25} = 1.5909$. IR ν_{max}(film) (cm^{-1}) 3050(m), 2900(s), 1570(m). NMR (CCl_4): δ 0.89 and 0.92 (6 H, s), 1.70 (3 H, br. d, 7), 2.02 (4 H, br. s), 5.1–5.5 (1 H, m), 6.24 and 6.56 (1 H, br.s), 7.28 (5 H, br.s.). (Found: C 78.24; H 8.00; S 13.17. $C_{16}H_{20}S$ requires: C 78.65; H 8.25; S 13.1).

5,5-Dimethyl-3-phenylthio-3-cyclohexen-1-one, 18. An amount of 2.32 g (0.01 mol) of *15* dissolved in 10 ml of dry ether was dropped to a suspension of $LiNH_2$ in liq. NH_3 (prepared from 400 mg Li). The NH_3 was evaporated and the residue acidified with H_2O and NH_4Cl. Extraction with ether drying and evaporation of the solvent gave 2.05 g of crude product, which was fractionated on a column, giving 1.85 g (80 %) of starting material and 0.19 g (8 %) of *19*. IR ν_{max}(film) (cm^{-1}) 1710(s). MS, *m/e* (%): 232(56), 219(6), 218(16), 217(100), 189(14), 176(6), 164(10), 156(6), 113(10), 111(12), 110(26), 109(26), 107(56), 95(8), 93(6), 91(8), 81(15), 80(12), 79(68), 78(10), 77(43), 69(10), 67(17), 66(8), 65(15), 55(12), 53(19).

Rearrangement of 7

2-Allyl-3-mercapto-5,5-dimethyl-2-cyclohexen-1-one, 19. Traces of *p*-toluenesulfonic acid were added to 5.3 g (27 mmol) of *7* and kept at 100 C for 4½ h in a Vigreaux distillation apparatus. Distillation gave 3 fractions, which consisted of compounds *19* and *21*, as shown by the NMR and IR spectra.

3-Acetylthio-2-allyl-5,5-dimethyl-2-cyclohexen-1-one, 20. An amount of 2.68 g (13.7 mmol) of *7* in 10 ml acetic anhydride was boiled at 140 °C for 2 h. The acetic anhydride was stripped off and the residue dissolved in ether, which was then extracted with 2 M aqueous Na_2CO_3. Drying and evaporation of the ether yielded 2.87 g crude product. 1.40 of this was purified with PLC yielding 0.5 g (38 %) of *20* and 0.26 g of an unidentified mixture. B.p. of *20* 60° C/10^{-4} mmHg; $n_D^{25} = 1.5290$; (Found: C 65.09; H 7.51; S 13.41 $C_{13}H_{18}O_2S$ requires: C 65.53; H 7.61; S 13.41).

2,6,6-Trimethyl-4-oxo-2,3,4,5,6,7-hexahydrobenzothiophene. 21. An amount of 2.05 g (10.4 mmol) of *7* in 5 ml quinoline was heated to 140 °C. After 3 h the starting material was converted. The mixture was extracted with ether and 4 M HCl. The ether layer was dried and evaporated. Crude product amounted to 1.78 g. Distillation gave 0.73 g (36 %) of b.p. 100 °C/0.01 mmHg; $n_D^{25} = 1.5535$; (Found: C 67.26; H 7.92; S 15.99. $C_{11}H_{16}OS$ requires: C 67.32; H 8.22; S 16.31).

Rearrangement of 8

2,3,6,6-Tetramethyl-4-oxo-2,3,4,5,6,7-hexahydrobenzothiophene, 22. An amount of 1.77 g (8.3 mmol) of *8* in 3 ml quinoline was heated for 5 h. Extraction with 4 M HCl and ether gave after drying and evaporation of the ether 1.40 g, which was distilled. B.p. 100 °C/0.01 mmHg, giving 1.17 g of a mixture of 27 % starting material and 73 % product. The experiment was repeated with 0.585 g of this mixture at a temp. of 160 °C and a reaction time of 3 h. Work up as above gave 0.348 g (yield 39 %) of b.p.

100 °C/0.01 mmHg; $n_D^{25} = 1.5420$; (Found: C 67.79; H 8.42; S 14.99. $C_{12}H_{18}OS$ requires C 68.54; H 8.63; S 15.22).

Rearrangement of *10*

7,7-Dimethyl-5-oxo-2,5,6,7,8-pentahydrobenzothiopyran, 23. An amount of 1.19 g (6.2 mmol) of *10* was boiled in 4 ml pyridine for 3½ h. The solvent was evaporated and the residue distilled. B.p. 100 °C/0.01 mmHg; $n_D^{25} = 1.5796$.

General procedure by photolysis of 3-alkylthio- and 3-arylthio-5,5-dimethyl-2-cyclohexen-1-ones. A solution of the compound was irradiated in a "Rayonet RS" photoreactor (for details see Table 1). A flow of dry and oxygen-free N_2 through the solution was maintained during the photolysis. The reaction was followed by UV spectroscopy and TLC. The solvent was evaporated and the residue was fractionated on a silica gel column or plate (about 100 g silica gel/g of product) with benzene – ethyl acetate = 4:1 (w/w) as eluent. However, the mixture obtained by photolysis of *14* was worked up using ether – light petroleum = 1:1 (w/w) as eluent.

The 1,3-dithiole, 24. M.p. 167 – 169 °C; (Found: C 61.90; H 7.12; S 20.63. $C_{16}H_{22}O_2S_2$ requires: C 61.92; H 7.15; S 20.6). NMR ($CDCl_3$): δ 1.05 – 1.15(12 H, 3 s); 2.25 – 2.48 (8 H, br. singlets and AB splittings); 3.02 (2 H, br.s). IR ν_{max}($CHCl_3$) (cm^{-1}), 1710(m-s); 1660(s); 1560(m.) UV ($CHCl_3$) λ_{max} (log ε), 250 (3.71), 350 nm (3.71). MS, *m/e* (%): 310(33), 308(5), 277(5) 256(8), 255(21), 254(68), 253(100), 239(32), 214(8), 213(16), 212(72), 178(20), 156(11), 155(8), 83(48), 55(54).

The 1,4-dithiane, 25. M.p. 172 – 174 °C; NMR ($CDCl_3$): δ 0.93 – 1.1(12 H, br.s); 1.7 – 2.7 (8 H, m); 3.1 – 3.3(2 H, m); 3.6 – 4.1 (2 H, m). IR $\nu_{max}CHCl_3$(cm^{-1}): 1705. MS, *m/e* (%): 312(2), 311(9), 310(4), 309(6), 308(8), 297(18), 282(12), 281(56), 280(40), 279(30), 278(10), 277(17), 263(16), 261(14), 260(75), 248(20), 247(100), 246(14), 245(10), 206(22), 195(40), 181(20), 157(23), 156(67), 155(8), 141(25), 125(77), 97(38), 91(22), 83(56), 55(46), 43(26), 41(53).

3,3-Dimethyl-5-oxo-2,3,4,5-tetrahydrodibenzothiophene, 26. M.p. 100 – 102 °C (Found: C 73.88; H 6.16; S 13.86. $C_{14}H_{14}OS$ requires: C 73.02; H 6.13; S 13.90). NMR (CCl_4): δ 1.15 (6 H, s), 2.36 (2 H, s), 2.90 (2 H, s), 7.1 (3, H, m), 8.50 – 8.65 (1 H, m). IR ν_{max}(KBr) (cm^{-1}) 1650. UV (EtOH): λ_{max} (log ε): 220 (4.08), 243 (3.70), 303 nm (3.48).

Aclnowledgement. A grant from Statens Naturvidenskabelige Forskningsråd is greatly acknowledged. Drs. H. J. Jakobsen, T. Bundgård, and N. Jacobsen of this Institute are thanked for advice concerning ^{13}C NMR spectroscopy, LAOCOON III, and ESR spectroscopy, respectively.

Derivatives of Hydrazine. XII. Rotational Isomerism of Methyl Dithiocarbamates and Dithiocarbazates

BRITTA MYNSTER DAHL and PER HALFDAN NIELSEN

Department of General and Organic Chemistry, University of Copenhagen, The H. C Ørsted Institute, DK-2100 Copenhagen, Denmark

The ^{1}H NMR spectra have been recorded for a series of methyl dithiocarbamates and dithiocarbazates carrying one or more *N*-alkyl substituents. Signals attributed to the occurrence of *Z* and *E* isomers have been observed. The multiplicity, position, and solvent shifts at −20 °C are tabulated. The assignment of the *Z* and *E* isomers is based upon comparison of the spectral data with those of two cyclic dithiocarbazates which are necessarily *Z* isomers. The assignment is in harmony with results obtained for methyl diselenocarbamates and diselenocarbazates and furthermore support Bauman's interpretation of the ^{1}H NMR spectra of thionocarbamate esters.

A study of the variable temperature ^{1}H NMR spectra in a series of *Se*-methyl N^2-methyldiselenocarbazates and -carbamates [1] has demonstrated the occurrence of hindered rotation around the N^2-C bond (Fig. 1, Y = Se). Based on these results three deductions were possible. (1) The N^2-CH_3 group *cis* to the C=Y group always gives rise to a signal at lower field than the same group *trans* to the C=Y group. (2) In nitrobenzene solution, the low-field N^2-methyl resonance is shifted downfield relative to $CDCl_3$ solution while the high-field *N*-methyl resonance is shifted upfield. (3) In CCl_4 solution, the signal from the N^2-CH_3 group in the *Z* isomer is displaced towards higher field relative to the position in $CDCl_3$ solution, while the signal from the N^2-CH_3 group in the *E* isomer is almost unaffected by this change in solvent.

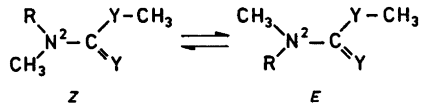

Fig. 1.

Compound	R	Compound	R
1	NH_2	*4*	CH_3
2	$NHCH_3$	*5*	CH_3CH_2
3	$N(CH_3)_2$	*6*	$(CH_3)_2CH$

The generalisations (1) and (3) have been found to be valid for the corresponding sulfur compounds. In order to obtain well-resolved signals from the *Z* and *E* isomers it was necessary to work below the m.p. of nitrobenzene (6 °C) and accordingly the validity of the generalisation (2) could not be tested. Holloway and Gitlitz [2] showed that hindered rotation of dithiocarbamate esters leads to the appearance of signals assigned to *E* and *Z* forms by low temperature ^{1}H NMR spectroscopy. This has also been demonstrated in the case of *N,N*-diisopropyldithiocarbazic esters [3] and *O*-phenyl *N,N*-diisopropylthiocarbazate,[4] but in the two last cases the occurrence of additional dipolar forms represented an extra complication. Since these can only occur in carbazates containing the unsubstituted N^2-H group, we chose for the present study the dithiocarbazates *1*—*3* (Fig. 1, Y = S). The well-known isomerism [2,5] of methyl dimethyldithiocarbamate (*4*) was reinvestigated. Methyl *N*-ethyl-*N*-methyldithiocarbamate (*5*) and methyl *N*-isopropyl-*N*-methyldithiocarbamate (*6*) were included for steric comparison with *2* and *3*.

When the ^{1}H NMR spectra of *1*—*6* were recorded at *ca.* 40 °C each type of protons exhibits only one signal (singlet or multiplet). This reflects the state of rapid interconversion on the NMR time scale between the possible

Table 1. ^{1}H NMR chemical shifts (δ) of 3 % solutions of *N*-alkyl substituted methyl dithiocarbazates and dithiocarbamates at −20 °C and 1,3,4-thiadiazolidine-2-thiones at 40 °C in CCl_4, $CDCl_3$, CD_3NO_2, and C_6D_5Br.

Abbreviations: s = singlet, d = doublet, t = triplet, q = quartet, and sep = septuplet. Center of multiplet is given.

[a] The N^3-CH_3 doublet collapsed on strong irradiation at the resonance frequency of the N^3−H proton. [b] Poorly resolved doublet. [c] The signal was absent in the spectrum of the corresponding S−CD_3 ester. [d] The solubility in CCl_4 was too low for recording the spectrum at −20 °C. [e] Necessarily identical for *Z* and *E* positions. [f] The signals from the ethyl group are ($CDCl_3$): CH_3 (*Z*) 1.30t, (*E*) 1.27t, CH_2 (Z) 3.88q, (*E*) 4.18q. A considerable solvent shift is observed in C_6D_5Br: CH_3 (*Z*) 0.91t, (*E*) 0.97t, CH_2 (*Z*) 3.42q, (*E*) 3.86q. [g] The signals from the isopropyl group are ($CDCl_3$): CH_3 (*Z*) 1.28d, (*E*) 1.22d, CH (*Z*) 4.92sep, (*E*) 6.00sep. A considerable solvent shift is observed in C_6D_5Br: CH_3 (*Z* and *E*) 0.85d, CH (*Z*) 4.67sep, (*E*) 5.98sep. [h] Average values from at least two measurements. The estimated error is 3 %.

rotamers. However, on cooling the signals are broadened. At −20 °C all the compounds *1*, *2*, and *4*−*6* exhibit well-resolved separate signals from the two isomers. As observed in the case of the corresponding selenium compound [1] the dithiocarbazate *3* failed to show the expected splitting of the signals at temperatures down to −40 °C. Since the rotational barriers are expected to be of the same magnitude in compounds *1*−*3* this result is taken to indicate that the population of one of the isomers of *3* is very low. The chemical shift data and the isomer ratios in four solvents are tabulated in Table 1.

In all cases the NMR spectra can be explained by assuming an equilibrium composed of the *Z* and the *E* isomers shown in Fig. 1 (Y=S). In principle, a barrier to rotation exists around both the N^2-C bond and the C−S bond. However, recent CNDO/2 calculations indicate [6] that (i) the energy barrier to rotation around the C−S bond is one order of magnitude lower than that around the C−N bond, and (ii) hindered rotation around the C−S bond leads to only one energetically favourable isomer in the case of compounds such as *1*−*6*. Empirically, a reliable indication of isomerism around the C−S bond has not been observed. In the present case the *Z*/*E* isomer ratio varies with changes in solvent, concentration, and temperature, allowing a clear separation of the signals in two groups, each arising from one isomer. When possible, this was confirmed by spin decoupling experiments and in the case of *2* by recording the spectrum of the *S*-trideuteriomethyl ester.

In order to decide which signals arise from the *Z* and which from the *E* isomer, we chose as model compounds the cyclic dithiocarbazates shown at the top of Table 1. By virtue of their cyclic structures they of necessity have the N^2-CH_3 groups situated in the *Z* position. In accordance with generalisation (3) mentioned above for the corresponding selenium compounds, the signal from this group is displaced towards higher field in CCl_4 solution relative to $CDCl_3$ solution. However, in order to obtain a more firm basis for the assignment the solvent shift was determined in the four solvents $CDCl_3$, CD_3NO_2, CCl_4, and C_6D_5Br. Since the solvent shifts of the N^2-CH_3 group of the *Z* and the *E* forms in these solvents are quite different, it was possible to use this as a criterion for assigning the isomers. Furthermore, generalisation (1) stated above also applies to methyl substituted thioureas,[7] monothiocarbazic esters,[8] and thioamides.[9] The assignment given in Table 1 is in complete accordance with this rule. Finally, if the NMR spectra of the sulfur and selenium compounds corresponding to Fig. 1 are compared they show a striking resemblance in their solvent, concentration and temperature dependence. This is taken to indicate that similar factors are operative within both classes of compounds in determining the *Z*−*E* isomer ratios.

Our results can be compared with those reported by Bauman [10] for thiocarbamate esters. In the case of *O*-methyl *N*-methylthiocarbamate it was demonstrated that *E*−*Z* isomerism gives rise to signal splitting at temperatures below 36 °C. The assignment of *Z* and *E* isomers was based primarily on the generalization (1) mentioned above. This assignment has recently been confirmed by Bauman [11] by using the ability of tris(dipivalomethanato)europium(III) to form complex compounds selectively with the *E* form. It was furthermore shown [10] that the benzene-induced shift (*i.e.* $\delta_{CDCl_3}-\delta_{C_6D_6}$) is greater for the $N-CH_3$ signal from the *E* form than from the *Z* form. This empirical result has also been found to apply in the case of thioamides [12] and thioureas [13] and it is easily seen from Table 1 that it is in agreement with the bromobenzene shifts ($\delta_{CDCl_3}-\delta_{C_6D_5Br}$) observed for the dithiocarbamates *4*−*6*. In our opinion, therefore, the assignment given by Rao *et al.*[14,15] for *O*-methyl *N*-methylthiocarbamate and related compounds should be changed to agree with the assignment given by Bauman. Similarly, the present results suggest that the assignment made by Holloway and Gitlitz [2] for dithiocarbamates should be reversed.

The *Z*−*E* isomer ratios for *1*−*3*, *5* and *6* are qualitatively the same for the corresponding sulfur and selenium compounds.[1] Both dithio- and diselenocarbamates show a small but definite tendency for the larger *N*-alkyl group to occupy a *trans* relationship to $C-SCH_3$ and $C-SeCH_3$, respectively. This trend is more marked in the case of *N*-isopropyl than in the case of *N*-ethyl groups. Since dilution experiments indicate that intermolecular forces can be neglected to a first approximation, this must

be due either to an inductive or to a steric effect. The present results allow no distinction between these possibilities. However, it has been shown [6] that the steric requirements of the $SCH_3/SeCH_3$ groups are much larger than those of the double-bonded sulfur/selenium provided that rotation around the C–S/C–Se bonds is not strongly restricted. In our opinion this is the most likely explanation for the observed trend. In the dithiocarbazates the *Z* forms predominate. This can be explained by invoking intramolecular compensation of the local dipoles in the same way as for diselenocarbazates.[1]

The coalescence temperatures for the *Z*–*E* splitting have in all cases been found to lie between 10 and 40 °C ($CDCl_3$) while those of the selenium analogues [1] are somewhat higher (*e.g. Se*-methyl N^2,N^3-dimethyldiselenocarbazate in C_6H_5Br at *ca.* 70 °C). In agreement with earlier results [2,16] Yoder *et al.*[17] have determined the coalescence temperature for *4* to be 33 °C with a $\Delta G_a^{\ddagger}$ of 15 kcal/mol, while the barrier in the selenoesters has not been determined though it is undoubtedly somewhat higher. By analogy with thioamides and selenoamides [18] (*cf.* Walter [19]) a higher rotational barrier for the central N^2–C bond of the diselenoesters can be explained by a more extensive electron delocalisation of the NCSe group.

Tin(IV) complexes of *N*,*N*-dimethylthio, dithio-, seleno-, diseleno-, and thioselenocarbamates have been described by Tanaka *et al.*[20–23] In the ^1H NMR spectra of the tin(IV) compounds with the mixed ligands Me_2NCOSe- and Me_2NCSSe-, the methyl groups gave rise to a doublet in which one of the signals was observed to be smaller in height and broader than the other. This was explained as due to *trans* coupling probably of 1–2 Hz in those molecules containing the natural abundance of ^{77}Se. In order to test the possibility of broadening of lines by coupling to selenium, the spectra of *4* and the selenium analogue $Me_2NC(Se)SeMe$ were compared in $CDCl_3$ at −40 °C in approximately identical concentrations. Within experimental error identical half-band widths were found for CH_3–N signals in both compounds (1.2 Hz) suggesting the coupling with ^{77}Se to be too small to give rise to the suggested broadening of the lines.

The infrared spectra of the compounds *1*–*6* are remarkably similar to those of the corresponding selenium compounds in the range 1200–4000 cm^{-1}. Below this region the change from CSS to CSeSe is followed by the systematic shift of several strong bands towards lower wave numbers. Especially prominent are peaks in the range 900–1100 cm^{-1}. Normal coordinate analyses for the dimethyldithiocarbamate [24] and the dimethyldiselenocarbamate ions [25] have shown, that bands in this region originate in highly mixed vibrations, so location of the bands with major CS/CSe stretching contributions has not been attempted. The deformational vibration of the CH_3 group bonded to sulfur was established by replacement with the CD_3 group. It occurs around 1430 cm^{-1} and when bonded to selenium around 1415 cm^{-1} in agreement with published evidence.[26] In the deuterated compounds the corresponding bands were observed in the 1000–1030 cm^{-1} range.

EXPERIMENTAL

Conditions and equipment used for the physical measurements were those described in part XI of this series.[1]

Methyl 2,3-dimethyldithiocarbazate (2). An ethanolic solution (4 ml) of methyl iodide (10^{-3} mol) was added to a filtered aqueous solution (5 ml) of potassium 2,3-dimethyldithiocarbazate [27] (10^{-3} mol). The reaction mixture was stirred for 5–10 min at room temperature and the solvent evaporated *in vacuo* with gentle heating until a volume of ½–1 ml was reached. This residue was extracted with benzene, dried, and taken to dryness. The crude product was purified by dissolution in ether and reprecipitation with pentane (−80 °C). The yield was 75 % of colourless crystals, m.p. 16.5–18 °C. (Found: C 31.91; H 6.57; N 18.70. Calc. for $C_4H_{10}N_2S_2$: C 32.00; H 6.71; N 18.66).

Methyl 2-methyl-2-ethyldithiocarbamate (5). Methylethylammonium chloride (40 mmol) was added to powdered potassium hydroxide (40 mmol) in dioxane (15 ml) and the mixture was stirred for 30 min. The resulting amine solution was dried (KOH pellets) and then added to a suspension of powdered KOH (40 mmol) in dioxan (40 ml). Carbon disulfide (40 mmol) in dioxan was added to the vigorously stirred solution over a period of 1 h. At the end potassium methylethyldithiocarbamate was filtered off, washed with dioxane and dry ether and dried *in vacuo*. The reaction with methyl iodide proceeded as described above for *2*. The compound was purified by dissolution in the minimum amount of pentane and cooling to *ca.* −80 °C with scratching. The solid that separated

was quickly collected by centrifugation, washed with a small amount of cold pentane and dried *in vacuo*. The melting point was well below room temperature. Yield 60 %. (Found: C 39.49; H 7.26; N 9.82. Calc. for $C_5H_{11}NS_2$: C 40.24; H 7.43; N 9.38). Though the analysis was not quite satisfactory, the impurities were not discernible in the NMR spectrum.

Methyl 2-methyl-2-isopropyldithiocarbamate (6). The compound was prepared as was the previous compound, except that it was found necessary to add a small amount of water during the generation of the amine. Yield 50 % of a colourless oil, which solidified by immersion in a bath cooled to *ca.* −80 °C. (Found: C 44.30; H 8.20; N 8.56. Calc. for $C_6H_{13}NS_2$: C 44.13; H 8.02; N 8.58).

The preparation of the cyclic dithiocarbazates has been described in a previous communication.[28] The structures have been established by comparison of the spectral properties with those of the corresponding selenium compounds.[29]

Short Communications

Bacterial Carotenoids. XLV.* Synthesis of Lycopen-20-al and Rhodopin-20(20′)-al

OLE PUNTERVOLD and
SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim, Norway

In the carotenoid field *N*-bromosuccinimide (NBS) has been frequently used for the introduction of carbon-carbon double bonds.[1,2] Although no brominated carotenoid intermediates have been isolated, it is assumed that the reaction proceeds *via* allylic bromides, *cf.* Ref. 3. Thus allylic acetates or ethers are obtained in the presence of acetic acid or alcohol, respectively.[4,5] A remarkable dehydrogenation is reported for canthaxanthin (*1*, Scheme 1), which provided the 15,15′-didehydro derivative with central triple bond.[6,7]

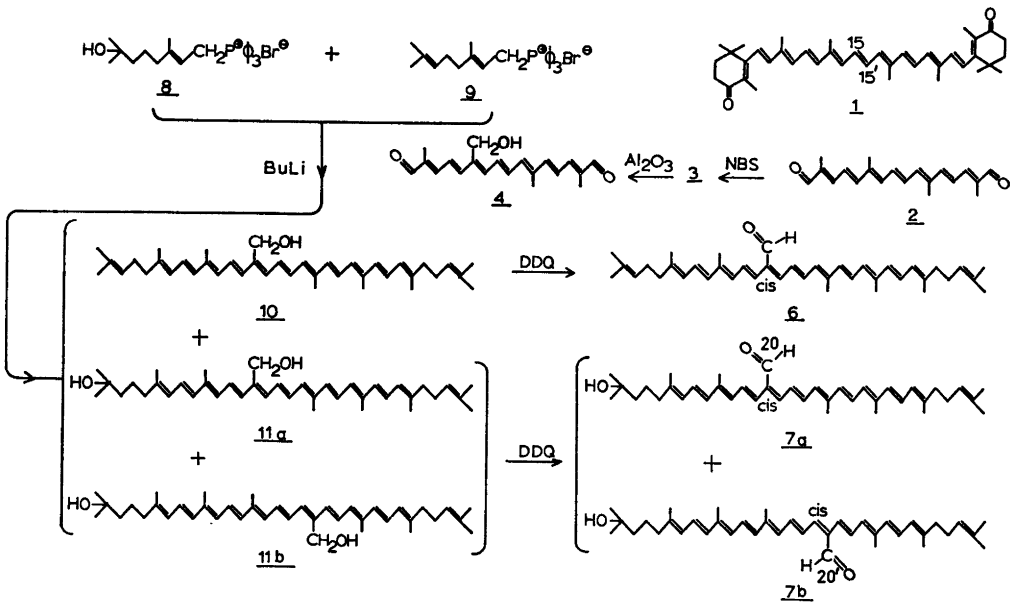
On the basis of this experience NBS-treatment of crocetindial (*2*) was expected to give either the acetylenic analogue or result in allylic substitution.

Under particular conditions NBS-treatment of crocetindial (*2*) resulted in allylic substitution of one of the central methyl groups. After chromatography of the product *3* on alumina, the allylic alcohol *4* was isolated. Characterization of *3* and *4* and a general study of the reaction between NBS and diapocarotenals are published separately.[8]

The dial *4*, containing the desired hydroxy substituent, was used for the synthesis of lycopen-20-al (*6*) and an expected mixture of rhodopin-20-al (*7a*) and rhodopin-20′-al (*7b*), Scheme 1.

The hydroxy-dial *4* (9 mg) was reacted with the ylids of a mixed phosphonium salt (24 % *8* and 76 % *9*, *cf.* Ref. 9) by a general procedure [10] providing in good yield lycopen-20-ol (*10*, 75 % of recovered carotenoid) and a presumed mix-

* No. XLIV *Acta Chem. Scand. B. In press.*



Scheme 1.

ture of rhodopin-20-ol and rhodopin-20′-ol (*11a* and *11b*; 20 % of recovered carotenoid).

Lycopen-20-ol (*10*, 5.4 mg), purified by TLC (kieselgel; 15 % acetone in petroleum ether) had λ_{max} (acetone) for the *trans* isomer (51 % of the stereoisomeric mixture) 345, 363, 450, 471 and 500 nm, for neo U (27 %) 345, 362, 442, 466 and 496 nm and for neo V (23 %) 345, 363, (446), 467 and 495 nm; ν_{max} (KBr) 3300 and 1000 (OH) and 950 cm^{-1} (*trans* CH=CH); *m/e* 552 (M), M−16, M−18, M−69, M−92, M−106, M−108, M−122, M−158, M−174.

Rhodopin-20(20′)-ol (*11a* and *11b*) which could not be separated, had λ_{max} (acetone) 345, 363, 440, 469 and 495 nm (*cis* and *trans*); *m/e* 570 (M), M−2, M−16, M−18, M−92, M−106, M−108, M−158, M−174 and was inseparable from natural rhodopinol (*ex. Thiocystis* sp.[11]) on alumina paper. On electron impact both *10* and *11* showed the elimination of 108, 122 and 174 mass units characteristic of aliphatic carotenoids with in-chain hydroxymethyl groups.[12]

Allylic oxidation of lycopen-20-ol (*10*), best achieved with DDQ [13,14] in dry ether at 0 °C, gave lycopen-20-al (*6*), but only in 7 % yield. Previous attempts to oxidize such allylic alcohols have met with the same difficulties.[14] The synthetic lycopen-20-al (*6*) was obtained as two stereoisomers with λ_{max} (acetone) 363, 502 (very broad) nm and 368, 492 (very broad) nm and *m/e* 550 (M), M−2, M−16, M−18, M−69, M−92, M−106, M−120, M−158, M−172, which could not be separated from those of authentic rhodopinal *ex. Thiocystis* sp.[11]

Allylic oxidation of rhodopin-20(20′)-ol (*11a* and *11b*), effected with DDQ, gave a presumed mixture of *7a* and *7b* in 2 % yield. The cross-conjugated aldehyde (*7a* and *7b*) had λ_{max} (acetone) *ca.* 490 (very broad), *m/e* 568 (M), M−2, M−18, M−73, M−69−18, M−106, M−120, M−120−18, M−158, M−172 and could not be separated from rhodopinal *ex. Thiocystis* sp.[12]

Rhodopin-20-al (*7a*) and lycopen-20-al (*6*) have been isolated from several *Thiorhodaceae* spp.[11,14,15] Also the corresponding allylic alcohols rhodopin-20-ol (*11a*) and lycopen-20-ol (*10*) are naturally occurring.[12,14,15] Structural studies led to derivatives of rhodopin and lycopene with one of the in-chain methyl groups oxidized.[14] Subsequent mass-spectrometric analysis was consistent with structures *7a*, *6*, *11a* and *10*.[21]

The present small scale synthesis of lycopen-20-al (*6*) and lycopen-20-ol (*10*) confirms the structures previously assigned to these carotenoids.

The properties of the mixed rhodopinals (*7a* and *7b*) confirm the previous chromophore assignment, but add no proof for 20- rather than 20′-substitution.

The same exceptional instability, failure to crystallize,[14] characteristic broad electronic spectra with strong absorption in the *cis*-peak region,[14] and the typical fragmentation pattern on electron impact,[12] as well as identical chromatographic properties,[12,14,15] were recorded for both the natural and synthetic pigments.

The synthetic use of the hydroxy-dial *4* for the preparation of other, more stable cross-conjugated carotenals is being pursued.[16]

The Use of Ethylene Maleic Anhydride for the Preparation of a Water-soluble Polyanionic Derivative of Pepsin. Preparation and Properties

HENNING LØWENSTEIN

The Protein Laboratory, University of Copenhagen, 34 Sigurdsgade, DK-2200 Copenhagen, Denmark

The pH-activity profile for several enzymes covalently bound to polyanionic or polycationic carriers, may be shifted towards alkaline or acidic pH values, respectively, when compared with the corresponding profile of the native enzyme.[1] It has been shown that the pH-activity profile of pepsin (EC 3.4.23.1) may also be shifted, when coupled to polyelectrolytes as glass and probably agarose and cellulose.[2-4] However, all these modifications give rise to insoluble derivatives. Furthermore, most of the coupling reactions proceed at optimum rate at alkaline pH, where pepsin is rapidly and irreversibly denatured. Ethylene maleic anhydride copolymer (EMA) which is an example of a polyanion may be coupled to proteins [5,6] even at pH values lower than 6.[7] The aim of this work was to determine whether porcine pepsin covalently bound to a soluble polyanionic carrier could be used to catalyse the clotting of milk in the pH range 6 – 6.5 where native porcine pepsin is rapidly inactivated.

In the present paper the preparation of a catalytically active and watersoluble polyanionic enzyme (EMA-pepsin) is described. The coupling was undertaken at pH 5.8. The activity against macromolecular substrates (Haemoglobin and reconstituted skim milk) of EMA-pepsin was measured. The change in activity relative to native pepsin reflected the influence of the electrostatic field, induced by the attached polyelectrolyte chain. A marked enchancement of stability in the pH range above pH 6 was demonstrated in the EMA-modified pepsin.

Pepsin (2 × crystallized porcine pepsin) was purchased from Worthington Biochem. Corp., Freehold, N.Y., U.S.A. Bovine haemoglobin (cryodialyzed) was a gift from Børge Thing, Finseninstitutet, Copenhagen, Denmark. Nonfat low-heat spray-dried milk powder was from West Comp., Fon du Lac, Wisc., U.S.A. Chymosin (Rennin) was a gift from Chr. Hansen's Laboratorium Ltd., Copenhagen, Denmark. Linear ethylene maleic anhydride copolymer (EMA grade 11) was generously provided by Monsanta Ltd., La Salle, Quebec, Canada. The molecular weight was about 20 000 Dalton as determined by sedimentation equilibrium in the ultracentrifuge.[7] Formaldehyde (35 % W/W solution) and sodium borohydride was from Merck, Darmstadt, Germany. 2,4,6-Trinitrobenzenesulfonic acid (TNBS) was from Sigma, St. Louis, U.S.A.

200 mg pepsin was dissolved and 400 mg EMA 11 was suspended in 20 ml 0.05 M sodium phosphate buffer pH 5.8. The reaction was carried out at 30 °C for about 20 h in a pH-stat, equipped with a thermostated reaction vessel (25 ml) (Radiometer, Copenhagen, Denmark). During the reaction the pH was kept constantly at 5.8 by addition of 2 M sodium hydroxide. EMA-pepsin and EMA were precipitated with dilute hydrochloric acid (final pH 2.2) and ultracentrifuged for 20 min at 17 000 *g*. The centrifugation was repeated 4 times with intermittent washing of the precipitate with potassium chloride/hydrochloric acid buffer pH 2.2, ionic strength 0.1. Finally the precipitate was redissolved in 0.5 M sodium phosphate, and the pH was adjusted to 5.8. The modified enzyme was stored at −20 °C. The final volume was 10 ml.

Determination of pepsin contents in the precipitate and the supernatants was performed by amino acid analysis [9] for aspartic and glumatic acids, threonine, serine, glycine, and valine and comparison with the contents of these amino acids found in a pepsin solution with known concentration.

The average number of EMA-molecules bound per pepsin molecule was calculated from the number of residual free amino groups. These were determined by the TNBS method according to Fields [8] and by amino acid analysis [9] after reductive methylation with formaldehyde and sodium borohydride according to Means and Feeney.[10]

The rate of proteolysis of reconstituted milk was determined as described by Foltmann [11] with the following modification: Ten ml of reconstituted skim milk and one ml of 0.05 M sodium phosphate buffer pH 6.0, 6.3, or 6.5 were placed in one branch and the enzyme solution (not more than 100 µl) in the other branch of a bifurcated glass tube. Reconstituted milk with pH-values of 6.0, 6.3, and 6.5 at 20 °C was obtained by dissolving the dry skim milk powder in 0.04, 0.01, and 0.001 M calcium chloride, respectively.

For stability measurements, the enzyme was stored in 0.05 M phosphate buffer of pH 6.3 and 6.5 at 30 °C, for varying length of time before determination of the proteolytic activity. The time of coagulation was in all cases between 4 and 5 min.

Measurements of the proteolysis of haemoglobin was carried out according to Kassell and Meitner [12] using 1.25 % haemoglobin solutions, ionic strength 1.0 and 0.010 and pH between 4 and 6, as substrates. Agarose gel electrophoresis was performed according to Ref. 13.

Coupling of EMA to pepsin by the method described here gave yields of about 30 %. Estimates of the yield based on the different amino acids were in good agreement and the

method was reproducible. (Coupling experiments performed at low temperature in acetone-water mixtures according to Centeno,[6] but at pH 5.8 in stead of 7 showed only negligible conjugation). In dilute HCl the EMA-pepsin and free EMA were selectively precipitated, leaving unmodified pepsin in the supernatant. The recovery of EMA-pepsin was 95 % of the yield after four washings and the amount of pepsin in the last wash less than 2 % of the amount in the initial reaction mixture. Isolated EMA-pepsin was stable during storage at 5 °C for at least two months at pH 5.8, and ionic strength about 1.0. Agarose gel electrophoresis of the reaction mixture showed two distinct protein bands, whereas pepsin only gave one.

The pepsin molecule contains only one ε-amino group and one α-amino group. Amino acid analysis after reductive methylation of EMA-pepsin was performed. It was demonstrated that nearly 100 % of the lysine was modified. Modification of the residual free N-terminal α-amino group in pepsin cannot be detected by this method. However, a determination of the residual free primary amino groups of the isolated EMA-pepsin using the TNBS method showed that 50 % of these groups were modified. This makes it reasonable to suggest that mainly lysine was modified with EMA under the selected conditions. Binding of two or more pepsin molecules to the same EMA molecule might be excluded as the agarose gel electrophoresis only showed two bands.

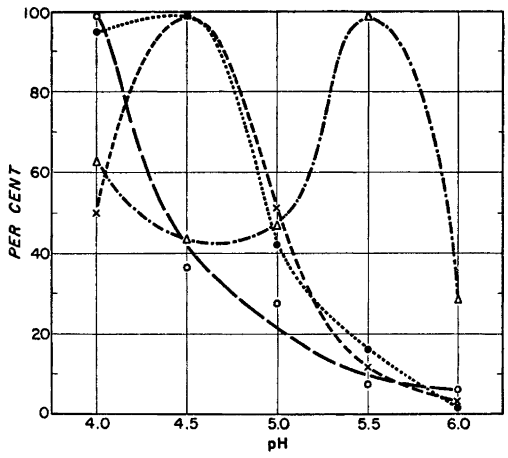

Fig. 1. pH-Activity profiles for pepsin and EMA-pepsin measured at different ionic strength using haemoglobin as substrate. The individual activities were calculated as the mean of four measurements (range ± 5 to 15 %) and expressed as the percentage of the activity at pH-optimum. ●, pepsin ($\Gamma/2 = 1.0$); ○, pepsin ($\Gamma/2 = 0.010$); ×, EMA-pepsin ($\Gamma/2 = 1.0$), △, EMA-pepsin ($\Gamma/2 = 0.010$).

pH-activity profiles of pepsin and EMA-pepsin measured in the pH-range 4 – 6 using haemoglobin as substrates are shown in Fig. 1. The profiles of the polyanionic derivatives of pepsin are displaced towards more alkaline pH-values by 1.5 pH units at low ionic strength ($\Gamma/2 = 0.010$) as compared with the native enzyme. The displacements are less pronounced at higher ionic strength ($\Gamma/2 = 1.0$). The enzymatic activity at 30 °C is expressed as percentage of the maximum activity obtained. The pH-activity profile shift could be attributed to a lowered intrinsic pH arising from a polyanion near the domain of the active site of the enzyme. The theoretical aspects of the electrostatical field prevailing in the microenvironment of polyanionic enzymes are discussed in several papers.[1,14] Another explanation of the pH-shift might be decreasing solubility of EMA-pepsin at pH below 4. However, turbidometric measurement shows that EMA-pepsin is soluble even at pH 3, ionic strength 0.01 and 1, respectively.

Comparison between the activity of pepsin and EMA-pepsin against reconstituted milk is shown in Table 1. The low activity of EMA-pepsin compared with that of pepsin may reflect steric hindrance due to the bulky EMA-group which will reduce the contact between the active centre of the enzyme and a macromolecular substrate. Also interaction between

Table 1. Proteolytic activity of EMA-pepsin relative to unmodified pepsin at different pH-values measured on reconstituted milk.[11]

pH	% Activity
6.0	8.2 (±.7)
6.3	11.6 (±.1)
6.5	14.8 (±.05)

Table 2. Half-lives for proteolytic activity of pepsin and EMA-pepsin at pH 6.3 and 6.5. Half-lives were calculated from the time dependent decrease in proteolytic activity against reconstituted milk. The activity was defined to be 100 % at time zero, and the kinetics of inactivation to be of first order. The coefficient of the correlation found by first order kinetic plots are given in brackets.

pH	Pepsin $t_{1/2}$(min)	EMA-pepsin $t_{1/2}$(min)
6.3	70 (−0.98)	180 (−0.95)
6.5	30 (−1.00)	150 (−1.00)

positively charged substrate groups and EMA might prevent catalysis.

The stability of pepsin and EMA-pepsin in the pH-range above 6.0 was determined using calf chymosin as internal standard. The activity was measured relatively to pepsin at 30 °C. The results are given in Table 2 as half-lives. It is seen that the stability against the irreversible denaturation is three–five times better for EMA-pepsin than for unmodified pepsin.

For pepsin an electrostatic expansion of the negatively charged polypeptide chain may lead to denaturation at pH-values higher than 6. The enchanced stability of EMA-pepsin relative to pepsin may be attributed to different micro-environmental states of the two enzymes.

Tritium—Protium Exchange in Dextran at 25 °C

N. V. B. MARSDEN

Institute of Physiology and Medical Biophysics, Uppsala University, Biomedical Center, Box 572, S-751 23 Uppsala, Sweden

In the dextran (Sephadex®) gels the cross-links are connected by ether linkages to the anhydroglucose residues of the dextran chains. Thus, at each point of attachment of a cross-link an hydroxyl hydrogen is lost and the concentration of hydroxyl groups remaining after cross-linking provides valuable information about the cross-linking structure. Since hydroxyl hydrogens will exchange with deuterium (D) or tritium (T) [1] provided they are accessible, tritium exchange can, thus, be used, giving information about the fraction of accessible groups, to determine the hydroxyl concentration.

The degree of accessibility of the Sephadex hydroxyls is, as yet, unknown. As regards other polysaccharides all the hydroxyls of amylose and starch, notwithstanding some degree of crystallinity in the latter, were reported to exchange with deuterium of deuterated water.[2] The 1,6-linked polysaccharides, *e.g.* dextran, are conformationally very flexible with an extended structure [3] and inaccessibility is unlikely but should be tested for. The lack of crystallinity in a dry sample of the most highly cross-linked Sephadex gel,[4] G-10, while not proof of accessibility, is strongly suggestive of it.

This communication reports an attempt to measure the tritium exchange constant of the parent polymer dextran as a model for the dextran gels. The exchange reaction between tritiated water (HTO) and the gel hydroxyls is

$$\mathrm{HTO} + \mathrm{Gel-OH} \rightleftharpoons \mathrm{Gel-OT} + \mathrm{H_2O}$$

Because of the relatively large difference in their vibrational zero point energies,[5,6] the bond dissociation energies of the different hydrogen isotopes differ sufficiently for the exchange constants to deviate considerably from unity in many systems; the T/H value usually diverging more than the D/H.

Experimental. Dextran® ($\overline{M}_w = 250\,000$; $\overline{M}_n = 113\,000$) was dissolved, without predrying, in double quartz-distilled water to a concentration of approximately 40 %. The concentration (weight fraction of dextran = 0.3604) was then calculated from the polarimetry [7] (Na D line 589 nm) of triplicate gravimetric dilutions (~2 % solutions).

About 15 ml of the 36 % dextran solution were placed in one compartment of a double glass flange (FG 25, Quickfit, Great Britain) chamber and were separated from 15 ml water containing HTO (1 mCi/ml) in the other compartment by a hydrophobic polyvinylidene

positively charged substrate groups and EMA might prevent catalysis.

Tritium—Protium Exchange in Dextran at 25 °C

N. V. B. MARSDEN

Institute of Physiology and Medical Biophysics, Uppsala University, Biomedical Center, Box 572, S-751 23 Uppsala, Sweden

In the dextran (Sephadex®) gels the cross-links are connected by ether linkages to the anhydroglucose residues of the dextran chains. Thus, at each point of attachment of a cross-link an hydroxyl hydrogen is lost and the concentration of hydroxyl groups remaining after cross-linking provides valuable information about the cross-linking structure. Since hydroxyl hydrogens will exchange with deuterium (D) or tritium (T) [1] provided they are accessible, tritium exchange can, thus, be used, giving information about the fraction of accessible groups, to determine the hydroxyl concentration.

The degree of accessibility of the Sephadex hydroxyls is, as yet, unknown. As regards other polysaccharides all the hydroxyls of amylose and starch, notwithstanding some degree of crystallinity in the latter, were reported to exchange with deuterium of deuterated water.[2] The 1,6-linked polysaccharides, *e.g.* dextran, are conformationally very flexible with an extended structure [3] and inaccessibility is unlikely but should be tested for. The lack of crystallinity in a dry sample of the most highly cross-linked Sephadex gel,[4] G-10, while not proof of accessibility, is strongly suggestive of it.

This communication reports an attempt to measure the tritium exchange constant of the parent polymer dextran as a model for the dextran gels. The exchange reaction between tritiated water (HTO) and the gel hydroxyls is

$$\mathrm{HTO} + \mathrm{Gel-OH} \rightleftharpoons \mathrm{Gel-OT} + \mathrm{H_2O}$$

Because of the relatively large difference in their vibrational zero point energies,[5,6] the bond dissociation energies of the different hydrogen isotopes differ sufficiently for the exchange constants to deviate considerably from unity in many systems; the T/H value usually diverging more than the D/H.

Experimental. Dextran® ($\overline{M}_w = 250\,000$; $\overline{M}_n = 113\,000$) was dissolved, without predrying, in double quartz-distilled water to a concentration of approximately 40 %. The concentration (weight fraction of dextran = 0.3604) was then calculated from the polarimetry [7] (Na D line 589 nm) of triplicate gravimetric dilutions (~2 % solutions).

About 15 ml of the 36 % dextran solution were placed in one compartment of a double glass flange (FG 25, Quickfit, Great Britain) chamber and were separated from 15 ml water containing HTO (1 mCi/ml) in the other compartment by a hydrophobic polyvinylidene

fluoride 0.45 μm pore membrane (VF 6, GELMAN, Ann Arbor, Mich., U.S.A.).

The compartments were not stirred because of the high viscosity of the dextran solution. Kel-F grease (3 M, St. Paul, Minn., U.S.A.) was used to seal the membrane to the two flanges which were then held together by clamping the double chamber in a special holder which also served to support the chamber submerged in a water bath kept at 25 ± 0.05 °C.

This membrane has the useful property that although it allowed a rapid exchange of water molecules (the half-time for HTO or $H_2{}^{18}O$ exchange was about 24 h) there was no net water transport for up to 15 days with concentration differences (sucrose) across the membrane of up to 0.2 M.[8] As the dextran concentration used had an osmotic pressure corresponding to about 0.2 M,[9] there should thus be no, or very little, net water transport. There was, in fact, a little, the dextran fraction decreasing from $f_d = 0.3604$ to $f_d = 0.3069$ after 13 weeks. This was due to influx of water from the "water" side since dextran was not detected chemically on the latter side at the end of the experiment.

Duplicate samples were taken from both compartments, suitably diluted (about 500×) and the tritium activities in ten 0.1 ml samples of the dilutions were measured. All samples and dilutions were weighed. The high dilutions ensured that the dextran concentration introduced into the scintillation fluid (Aquasol, NEN. Boston, U.S.A.) was not more than 0.006 %, a concentration which did not affect the tritium counting rate significantly.

Samples taken after 3 weeks had not quite reached equilibrium (estimated > 95 %). Second samples were therefore taken 10 weeks later when equilibrium was assumed; the differences at 3 and 13 weeks were less than 5 %.

The exchange constant $K^{T/H}$ was calculated from the ratio (R) between the tritium activities in the two compartments, *i.e.*,

$$R = \frac{(3/162)K^{T/H}f_d + (2/18)(1-f_d)}{(2/18)}$$

where f_d is the final dextran concentration and $K^{T/H}$ the T/H exchange constant; the figures refer to the numbers of exchange sites on the anhydroglucose residues (3) and water (2) and to the rounded molecular weights of the residues (162) and water (18).

The value of the exchange constant ± the estimated error of the estimate was,

$$K^{T/H} = 1.20 \pm 0.06.$$

The above constant is calculated assuming complete accessibility, which with regard to the structure of dextran and known properties of other related oligosaccharides seems reasonable.

Whether dextran is a satisfactory model for a cross-linked Sephadex is another question. In the 1,4-β-linked cellulose there is a marked tendency for inter-chain coupling to occur when hydroxyls of different chains approach sufficiently closely to form hydrogen bonds [10] which make the groups inaccessible to exchange. In Sephadex, particularly with the more highly cross-linked types where there may be considerable restriction in chain movement, this may also occur and requires further study.

Data on the T/H equilibrium exchange constant are apparently conflicting. In cellulose limited accessibility introduces considerable uncertainty into the calculation of the constant as indeed is the case with most biological macromolecules. Lang and Mason, [1] however, concluded that for cellulose the equilibrium T/H probably exceeded unity. In the open-chain peptides poly D,L-alanine and poly D,L-lysine, T/H and T/D were reported to be 1.21 and 1.09, respectively, [11] compared with the corresponding ratios in the solvent. The T/H ratios were also of a similar order in myoglobin [12] and oxidised ribonuclease [13] although some uncertainty exists in these closed-chain peptides due to the question of accessibility. Lobunez and Karush [14] in a study of the distribution of tritium between gaseous ammonia and dry protein found that the latter was preferred.

The absence of a significant equilibrium isotope effect between tritium and deuterium has been reported in bovine plasma albumin [15] and several other workers have found small or absent isotope effects.[16]

The problem in interpreting the data is much simpler in a polysaccharide such as dextran, where there is only one type of exchange group, and whose random conformation should promote accessibility. It is thus more comparable to the simpler homogeneous open-chain peptide than to a natural peptide constrained in a native protein and the close agreement of the $K^{T/H}$ value reported here with that of the open-chain peptides probably reflects this.

I want to thank Miss Birgitta Klang for skilful technical help and the Swedish Natural Science Research Council (Grant No. 2944) for financial aid.

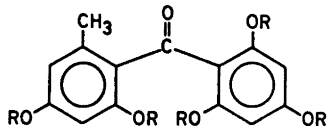
Synthesis of 2,2′,4,4′,6′-Pentahydroxy-6-methylbenzophenone*

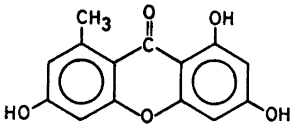
GÖRAN SUNDHOLM

Institute of Chemistry, Organic Department, University of Uppsala, Box 531, S-751 21 Uppsala, Sweden

2,2′,4,4′,6′-Pentahydroxy-6-methylbenzophenone (I) has often been postulated as a precursor of certain polyketides in lower plants, *viz.* xanthones [1] and griseofulvin.[1,2]



I R=H
II R=CH_3
III R=$CH_2C_6H_5$



IV

For biosynthetic studies on lichen xanthones (all of which are related to norlichexanthone, IV) [3] I was needed. There appears, however, to be no record of its synthesis in the literature.

In an attempt to synthesize I, *O,O*-dimethylorsellinoyl chloride was reacted with 2,4,6-trimethoxyphenyl lithium in diethyl ether [4] to give the methylated benzophenone II in ~50 % yield. During demethylation of II with boron tribromide in dichloromethane, I was formed (15 %) together with partially demethylated benzophenones and xanthones.

In another synthesis, *O,O,O*-tribenzylphloroglucinol carboxylic acid was condensed with *O,O*-dibenzylorcinol using trifluoroacetic anhydride in dichloromethane [5] to give the benzylated benzophenone III in high yield. 2,2′,4,4′-Tetrabenzyloxy-6,6′-dimethylbenzophenone was formed as a by-product. Hydrogenolysis of III afforded I quantitatively.

The spectral data (NMR, UV, IR, MS) are in agreement with the pentahydroxy benzophenone I structure. (Cooling of the KBr disc prevented thermally induced formation of IV during the registrating of the IR spectrum of I. When recording the mass spectrum of I, the main part of the sample dehydrated to IV in the direct inlet system before evaporation; however peaks at *m/e* 276, 151, and 153 were present).

The compound is sensitive to moisture even at room temperature. Other 2,2′,6′-hydroxylated benzophenones are known to dehydrate fairly easily under alkaline conditions, even as the methyl ethers.[2]

Because of its great instability, it would be difficult to demonstrate the presence of I in plant material even if appreciable amounts should occur.

Experimental. All melting points are uncorrected. Elemental analyses were performed by the Analytical Department, Institute of Chemistry, Uppsala. All solvents used were of analytical grade. Petroleum ether refers to the fraction boiling at 43 – 55 °C. Column chromatography was done using Merck Silica Gel 60 (70 – 230 mesh); TLC was carried out using Merck's precoated silica gel plates. IR spectra were recorded with a Perkin-Elmer 157. NMR-spectra were recorded on a Varian A-60D, using TMS as the internal standard. UV-spectra were recorded on a Unicam SP 1800.

O,O-Dimethylorsellinoyl chloride.[6] *O,O*-Dimethylorsellinic acid [7] (7.2 g) in dry benzene (20 ml) was reacted with oxalyl chloride (3.5 ml) under nitrogen and left overnight at room temperature. Distillation (b.p. 123 – 128 °C/2 mmHg) gave 6.7 g (79 %) product which was extremely sensitive to moisture. NMR (CCl_4): δ 2.28 (s 3 H), 3.71 (s 3 H), 3.79 (s 3 H), 6.17 (s 2 H); IR ν_{max} (CCl_4) 1785 cm^{-1} (C=O).

2,2′,4,4′,6′-Pentamethoxy-6-methylbenzophenone (II). 1,3,5-Trimethoxybenzene (3.60 g) [8] in ether (25 ml) was treated with butyl lithium (14.3 ml, 16.7 mmol/ml in hexane) under nitrogen at room temperature (1 h). The slurry was slowly added to an ethereal solution (20

O,O-Dimethylorsellinoyl chloride.[6] *O,O*-Dimethylorsellinic acid [7] (7.2 g) in dry benzene (20 ml) was reacted with oxalyl chloride (3.5 ml) under nitrogen and left overnight at room temperature. Distillation (b.p. 123 – 128 °C/2 mmHg) gave 6.7 g (79 %) product which was extremely sensitive to moisture. NMR (CCl_4): δ 2.28 (s 3 H), 3.71 (s 3 H), 3.79 (s 3 H), 6.17 (s 2 H); IR ν_{max} (CCl_4) 1785 cm^{-1} (C=O).

2,2′,4,4′,6′-Pentamethoxy-6-methylbenzophenone (II). 1,3,5-Trimethoxybenzene (3.60 g) [8] in ether (25 ml) was treated with butyl lithium (14.3 ml, 16.7 mmol/ml in hexane) under nitrogen at room temperature (1 h). The slurry was slowly added to an ethereal solution (20

* Part 33 of the series Chemical Studies on Lichens. Part 32 in press.

ml) of *O,O*-dimethylorsellinoyl chloride during 40 min at 0 °C under nitrogen. Water (20 ml) was added, the precipitate dissolved in benzene, washed with water, dried ($MgSO_4$), and evaporated to give a pale yellow oil. Recrystallization from benzene/petroleum ether afforded 2.8 g (47 %) of colourless needles, m.p. 126.5–127 °C. R_F 0.7 [silica gel, dichloromethane-acetone (4:1)]. NMR ($CDCl_3$): δ 2.32 (t 3 H, $J = 0.5$ Hz), 3.54 (s 3 H), 3.64 (s 6 H), 3.78 (s 3 H), 3.80 (s 3 H), 6.07 (s 2 H), 6.31 (m 2 H, $J = 2.2$ Hz, $J = 0.5$ Hz). IR, ν_{max}(KBr) 1667 cm^{-1} (C=O). (Found C 65.6; H 6.4; MW (MS) 346. $C_{19}H_{22}O_6$ requires C 65.8; H 6.4).

Demethylation of benzophenone II. Boron tribromide (750 mg, 6 equiv.) in dichloromethane (7 ml) was added dropwise during 15 min to a stirred solution of II (173 mg, 0.5 mmol) in dichloromethane (6 ml) at room temperature. After 1.5 h an orange product precipitated and the reaction was continued for 6.5 h. Additional boron tribromide (750 mg) was added and stirring continued overnight. Water (50 ml) was added at 0 °C with stirring. After work-up the crude material was separated by TLC [silica gel 0.5 mm, dichloromethane–acetone (4:1) to yield I (R_F 0.10, 20 mg, 15 %; identical with I prepared by hydrogenation of III, see below). IV (R_F 0.28, 35 mg, 27 %), and griseoxanthone C[2] (R_F 0.45, 15 mg, 11 %)]. The identities of the xanthones were confirmed by comparison with authentic samples. The other bands contained mono-, di-, and trimethoxybenzophenones.

Benzyl-O,O,O-tribenzylphloroglucinol carboxylate. To a solution of anhydrous phloroglucinolcarboxylic acid (2 g)[9] and benzyl bromide (8.5 g) in acetone (50 ml) was added freshly roasted K_2CO_3 (13.8 g). The mixture was stirred at room temperature (48 h). After pouring into ether-water, the ether layer was washed with water, dried and evaporated. The product crystallized from hexane/tetrahydrofuran to give colourless needles (3.1 g, 50 %) m.p. 102–103 °C. NMR (C_3D_6O): δ 5.08 (s 2 H), 5.10 (s 4 H), 5.26 (s 2 H), 6.44 (s 2 H), 7.10–7.55 (m 20 H); IR ν_{max}(KBr) 1725 cm^{-1} (C=O). (Found C 79.3; H 5.7; MW (MS) 530. $C_{35}H_{30}O_5$ requires C 79.3; H 5.6).

O,O,O-Tribenzylphloroglucinol carboxylic acid. Benzyl-*O,O,O*-tribenzylphloroglucinol carboxylate (0.53 g) was added to a solution of KOH (1.2 g in 2 ml water) and ethylene glycol (12 ml) and the mixture refluxed (48 h). Water (25 ml) was then added, the solution extracted with ether and the ether layer washed with water. The aqueous extracts were combined, acidified (pH ~2) with 2 M hydrochloric acid, extracted with ether, washed, dried and evaporated. Recrystallization from benzene/petroleum ether gave colourless needles (0.39 g, 89 %); m.p. 134–35 °C. NMR (C_3D_6O): δ 5.12 (s 2 H), 5.16 (s 4 H), 6.47 (s 2 H), 7.12–7.62 (m 15 H); IR ν_{max}(KBr) 3560–2210 (OH), 1700 (sh), and 1690 cm^{-1} (C=O). (Found C 76.3; H 5.5; MW (MS) 440. $C_{28}H_{24}O_5$ requires C 76.4; H 5.5).

2,2',4,4',6'-Pentabenzyloxy-6-methylbenzophenone (III). *O,O,O*-Tribenzylphloroglucinol carboxylic acid (1.32 g) and *O,O*-dibenzylorcinol (4.56 g)[5] were dissolved in dry dichloromethane (25 ml) and freshly distilled trifluoroacetic anhydride (1.5 ml) was dropwise added. After 10 min, the mixture was evaporated and chromatographed on silica gel (750 g, petroleum ether-ether (2:1)) to give unreacted *O,O*-dibenzylorcinol (3.67 g), 2,2',4,4'-tetrabenzyloxy-6,6'-dimethylbenzophenone [170 mg, recrystallized from benzene/petroleum ether to give colourless needles (50 mg); m.p. 124–125 °C (lit. 116–120 °C)[5]], and pentabenzyloxybenzophenone (III) (1.81 g, 83 %, recrystallized from methanol, filtered at −20 °C, dried over P_2O_5 to give 1.44 g of a glassy product that starts melting at 33 °C). NMR (C_3D_6O): δ 2.14 (s 3 H), 4.78 (s 2 H), 4.80 (s 4 H), 5.11 (s 4 H), 6.30 (s 2 H), 6.45 (q 2 H, $J = 1.8$ Hz), 6.85–7.50 (m 25 H); IR ν_{max}(CCl_4) 1665 cm^{-1} (C=O). (Found C 80.8; H 5.8; MW (MS) 726. $C_{49}H_{42}O_6$ requires C 81.0; H 5.8).

2,2',4,4',6'-Pentahydroxy-6-methylbenzophenone (I). The benzophenone III (73 mg) was hydrogenated at room temperature in ethyl acetate over 10 % palladium-carbon (20 mg) at atmospheric pressure until hydrogen uptake ceased. Filtration, evaporation and trituration with petroleum ether yielded I (28 mg, ~100 %) as a pale yellow powder. NMR (C_3D_6O): δ 2.12 (t 3 H, $J = 0.6$ Hz), 5.91 (s 2 H), 6.28 (t 2 H, $J = 0.6$ Hz), 3.5 (broad 2 H), and 10.8 (broad 3 H); IR ν_{max}(KBr) 3900–2900 (strong, OH), 1625 (sh), and 1605 cm^{-1} (C=O); UV (MeOH) ν_{max} 300 (ε 15 000), 310 nm (ε 6 300).

Acknowledgements. I wish to thank my teacher Dr. Johan Santesson for many stimulating and helpful discussions. The costs of this investigation were defrayed by a grant from the Swedish Natural Science Research Council to Dr. Gerd Bendz at this Institute.

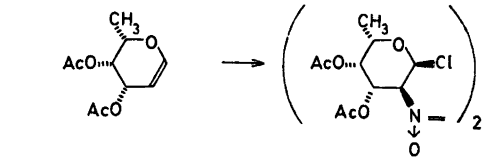
A Synthesis of a 2-Acetamido-2,6-dideoxy-L-galactose Derivative

PER J. GAREGG, BENGT LINDBERG and THOMAS NORBERG

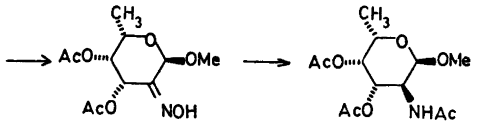
Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

In connection with studies of bacterial polysaccharides, 2-acetamido-2,6-dideoxy-L-galactose (*N*-acetyl-L-fucosamine) was needed. Different syntheses of this sugar, and of its enantiomer, have been described,[1-3] and the synthesis of this sugar *via* the corresponding acetylated glycal, a procedure devised by Serfontein,[4] Lemieux [5-7] and their coworkers, is now reported. The advantage of this procedure is that the desired epimer predominates in the final product and that it is simple.

3,4-Di-*O*-acetyl-1,2,6-trideoxy-L-*lyxo*-hex-1-enopyranose [8] (3,4-di-*O*-acetyl-L-fucal, I) and nitrosyl chloride gave the dimeric nitroso compound (II) in 86 % yield. Treatment of II



I II



III IV

with methanol and pyridine in tetrahydrofuran yielded the glycoside oxime (III) which, without purification, was treated with lithium aluminium hydride and acetylated. GLC of the product revealed the presence of two components (7:3), presumably the methyl 2-acetamido-3,4-di-*O*-acetyl-2,6-dideoxy-α-hexopyranosides with the L-*galacto*- and L-*talo*-configurations. The major component crystallized (20 % yield from II), m.p. 150 °C, $[\alpha]_D$ −144° (chloroform) and NMR spectroscopy in the presence of tris-(dipivaloylmethanoato)europium demonstrated that this was the *galacto*-isomer (IV). The spectral assignments of ring protons shown in Table 1 were confirmed by spin decoupling experiments.

Table 1. ^{1}H NMR data for methyl 2-acetamido-3,4-di-*O*-acetyl-2,6-dideoxy-α-L-*galacto*-hexoside (IV). δ values in ppm from tetramethylsilane (internal) in deuteriochloroform, coupling constants in Hz.

NH*Ac* or OAc	2.12 1.97 1.98	

[a] 0.2 mol Eu(DPM)$_3$/mol IV. [b] Unresolved at δ 4.4−5.4.

Experimental. Melting points are corrected. Concentrations were performed at reduced pressure. Optical rotations were recorded at room temperature (20−22 °C) using a Perkin-Elmer 141 instrument. NMR spectra were recorded for all new compounds using a Varian A60-A instrument and were invariably in agreement with the postulated structures. TLC was performed on silica gel F_{254} (Merck). Gas liquid chromatography was performed on a Perkin-Elmer Model 990 instrument at a nitrogen flow of 20 ml/min on an ECNSS column (3 % on Gas-Chrom Q).

Dimeric-3,4-di-O-acetyl-2,6-dideoxy-2-nitroso-α-L-galacto-hexopyranosyl chloride (II). 3,4-Di-*O*-acetyl-1,2,6-trideoxy-L-*lyxo*-hex-1-enopyranose (I) ("di-*O*-acetyl-L-fucal") was obtained in a 52 % yield from L-fucose essentially as described by Iselin and Reichstein [8] who report a 30 % yield for this transformation. The higher yield in the present synthesis may be due to the lower temperature (−10 to −20 °C) used in the reductive 1,2-elimination, the shorter reaction time (1 h against 3 h) or the use of extremely finely powdered zinc. The glycal I (1.42 g, m.p. 48−50 °C, in agreement with the literature value) in ethyl acetate (60 ml) was cooled to −40 °C with stirring while air in the reaction vessel was displaced with nitrogen. Nitrosyl chloride was then passed through the solution at −40 °C for about 20 min. Excess nitrosyl chloride was displaced by nitrogen and the solution was allowed to attain room temperature. Concentration and recrystallization from

chloroform – hexane gave 1.60 g of II, m.p. 147 °C (decomp.), $[\alpha]_D$ −183° (*c* 0.5, in chloroform). (Found: C 42.8; H 4.94; N 4.88; O 34.4; Cl 12.9. $C_{10}H_{14}NO_6Cl$ requires C 42.9; H 5.05; N 5.01; O 34.3; Cl 12.7.)

*Methyl 2-acetamido-3,4-di-*O*-acetyl-2,6-dideoxy-α-*L*-galacto-hexoside (IV).* The above nitrosyl chloride adduct II (1.40 g) was refluxed with methanol (0.32 g) and pyridine (0.79 g) in dry tetrahydrofuran (40 ml) for 1 h and concentrated. The residue was taken up in chloroform and the chloroform solution shaken with water, dried over magnesium sulfate, filtered and concentrated to yield III as a colourless syrup (1.38 g) which was used directly in the next step. The oxime III (1.38 g) in tetrahydrofuran (35 ml) was refluxed under nitrogen with lithium aluminium hydride (0.66 g) for 3 h. Excess hydride was decomposed by adding, in turn, ethyl acetate and 50 % aqueous methanol (135 ml). The mixture was filtered, the filtrate was neutralized (HCl) to pH 4.5, low-boiling solvents were removed by evaporation and the residual water solution was freeze-dried. The product was acetylated overnight at room temperature with acetic anhydride (8 ml) and pyridine (20 ml). The solution was poured into ice-water and the mixture extracted with chloroform. The combined chloroform phases were washed with ice-cold 1 M sulfuric acid, saturated aqueous sodium hydrogen carbonate and finally water, dried over magnesium sulfate, filtered and concentrated to yield 1.44 g of crude product. GLC at 200 °C showed the presence of two components in an approximate ratio of 7:3. The major component crystallized from diethyl ether – hexane to yield 0.31 g of IV, m.p. 150 °C, $[\alpha]_D$ −144° (*c* 0.25, chloroform). (Found: C 51.7; H 6.91; N 4.82. $C_{13}H_{21}NO_7$ requires C 51.5; H 6.98; N 4.62.)

Synthesis of 3-Deuterio-2,3-diphospho-D-glyceric Acid

BERTIL ERBING, PER J. GAREGG and BENGT LINDBERG

Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

2,3-Diphospho-D-glyceric acid, labelled with deuterium at C-3, was required for NMR studies of its association with hemoglobin [1] and the present paper describes the synthesis of this substance. The key intermediate, 2,3:4,5-di-*O*-cyclohexylidene-D-*manno*-hexodialdose (III) was obtained in a manner similar to that described by Angyal and Hoskinson for the synthesis of 2,3:4,5-di-*O*-isopropylidene-L-*manno*-hexodialdose, an intermediate in the synthesis of L-mannitol from quebrachitol.[2]

D-*chiro*-Inositol (I), obtained by demethylation of pinitol, was converted into the 1,2:5,6-dicyclohexylidene derivative (II) as described by Angyal and co-workers for the enantiomer.[3]

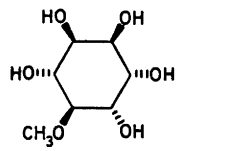
Synthesis of 3-Deuterio-2,3-diphospho-D-glyceric Acid

BERTIL ERBING, PER J. GAREGG and BENGT LINDBERG

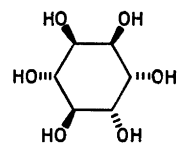
Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

2,3-Diphospho-D-glyceric acid, labelled with deuterium at C-3, was required for NMR studies of its association with hemoglobin [1] and the present paper describes the synthesis of this substance. The key intermediate, 2,3:4,5-di-*O*-cyclohexylidene-D-*manno*-hexodialdose (III) was obtained in a manner similar to that described by Angyal and Hoskinson for the synthesis of 2,3:4,5-di-*O*-isopropylidene-L-*manno*-hexodialdose, an intermediate in the synthesis of L-mannitol from quebrachitol.[2]

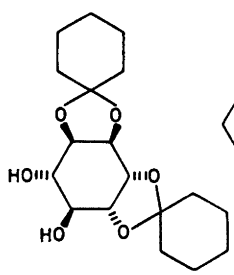
D-*chiro*-Inositol (I), obtained by demethylation of pinitol, was converted into the 1,2:5,6-dicyclohexylidene derivative (II) as described by Angyal and co-workers for the enantiomer.[3]



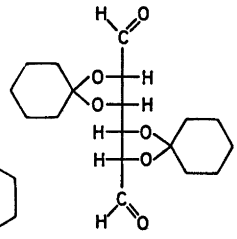
Pinitol



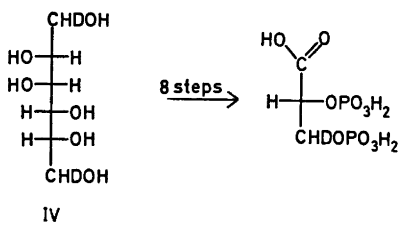
I



II



III



IV

Periodate oxidation afforded the hexodialdo derivative III which, without purification, was converted into 1,6-dideuterio-D-mannitol (IV). The deuterium labelling was confirmed by NMR and by GLC-MS of its hexaacetate. 1,6-Dideuterio-D-mannitol was converted into the title compound by established procedures previously described for unlabelled 2,3-diphospho-D-glyceric acid.[4-6] The various intermediates were characterized by NMR and, when appropriate, by GLC-MS.

Some stereoselectivity during the reduction of the hexodialdo derivative III with sodium borodeuteride, due to asymmetric induction, is not excluded and has been observed in related reactions.[7,8]

Experimental. Concentrations were performed under reduced pressure. Precoated plates with Silica Gel F_{254} (Merck) were used for TLC and Silica Gel 60 (> 230 mesh, Merck) for column chromatography. Light petroleum refers to a fraction with b.p. 60 – 71 °C. NMR spectra were recorded with a Varian A 60-A instrument and were invariably in agreement with the postulated structures. Mass spectra were recorded with a Perkin-Elmer 270 instrument and optical rotations with a Perkin-Elmer 141 polarimeter. GLC was performed with a Perkin Elmer model 900 instrument using a column packed with ECNSS-M (3 %) on Gas-Chrom Q.

1,2:5,6-Di-O-cyclohexylidene-D-chiro-inositol (II). D-*chiro*-Inositol (11 g), cyclohexanone (275 ml), benzene (165 ml), and *p*-toluenesulfonic acid (0.55 g) were heated under reflux using a Dean and Stark separator. When, after 5 h, codistillation of water ceased, aqueous 10 % potassium carbonate (200 ml) was added and the excess reagent was removed by steam distillation. The crystals which formed on cooling the residue were filtered off. TLC (ethyl acetate – light petroleum 3:1) indicated the presence of both di- and tri-cyclohexylidene-D-*chiro*-inositol. The product was taken up in benzene – ethanol 10:1 (60 ml) and treated with acetic acid saturated with hydrogen bromide (0.6 ml) for 45 min at room temperature. The crystals which had separated were filtered off and washed with light petroleum. Recrystallization from ethanol afforded II (10 g) m.p. 208 – 209 °C $[\alpha]_{578}$ +18° (*c* 0.4, chloroform) in agreement with the values reported for its enantiomer. (Found: C 63.7; H 8.3. $C_{18}H_{28}O_6$ requires: C 63.5; H 8.3.)

1,6-Dideuterio-D-mannitol. The dicyclohexylidene-D-*chiro*-inositol (4.1 g), in methanol (800 ml) was treated with sodium metaperiodate (4.1 g) in water (80 ml) for 4 h with stirring at room temperature in the dark. Ethylene glycol (0.3 g) was added and the stirring continued for another 15 min. Precipitated sodium iodate was removed by filtration and the filtrate diluted with water (400 ml) and then extracted with chloroform. The combined chloroform extracts were washed with water, dried over sodium sulfate and concentrated to a syrup (crude III). This was dissolved in dioxane – methanol 3:1 (100 ml) and treated with sodium borodeuteride (0.4 g). The solution was kept at room temperature for 18 h. Excess deuteride was decomposed by adding acetic acid and the solution was concentrated. Boric acid was removed by repeated codistillations with methanol and the product purified by chromatography on a silica gel column using ethyl acetate and light petroleum (3:2) as eluent. The chromatographically pure product was hydrolyzed with aqueous acetic acid (60 %) at 100 °C for 5 h, cooled and concentrated. The resulting syrup was taken up in water (150 ml) and washed with chloroform. The water solution was concentrated to yield crystalline IV (2.0 g) m.p. 165 – 166 °C.

3-Deuterio-2,3-diphospho-D-glyceric acid was obtained from IV as described by Baer and Fischer[4-6] for unlabelled D-mannitol and purified as its barium salt. (Found: C 5.95; H 1.44 (recalculated for D_2H_{10}); Ba 54.5; P 9.59. $(C_3H_3DO_{10}P_2)_2Ba_5.3H_2O$ requires C 5.70; D + H 1.12; Ba 54.3; P 9.80.)

Intermolecular Hydride Transfer Reactions. I. Electrophilic Aromatic Substitution with 2,6-Dimethoxycarbonylpyrylium Cation

EILIF TERJE ØSTENSEN

Organic Chemistry Laboratories, The Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway

The reaction of the 2,6-dimethoxycarbonylpyrylium cation with monosubstituted benzene derivatives to 4-substituted-4*H*-pyrans has been studied. Intermolecular hydride transfer between the pyrylium cation and the 4*H*-pyrans may occur, whereby the more stabilized pyrylium ion is formed.

It has previously been shown that 2,6-didimethoxycarbonylpyrylium perchlorate (*1*) reacted with carbonylactivated methyl groups to yield 4-substituted 4*H*-pyrans, and moreover that intermolecular hydride transfer between *1* and 4-alkyl substituted 4*H*-pyrans took place forming the more substituted pyrylium cations.[1]

The present work deals with the reaction of *1* with monosubstituted benzene derivatives (*2*).

Equimolecular amounts of *1* and anisole in acetonitrile solution were allowed to react for 24 h. Treatment with ether deposited a crystalline product for which elemental analysis and ^{1}H NMR data were consistent with the pyrylium salt *3* (R = OCH_3). Formation of the 4*H*-pyran *4*, which has been synthesized earlier,[2] was verified from ^{1}H NMR analysis of the concentrated etheral solution after removing of *3* (R = OCH_3). Reactions leading to *3* and *4* are depicted in Scheme 1.

It is likely that the first step of the process is an electrophilic substitution reaction to form the 4*H*-pyran *5* (R = OCH_3), which is subsequently oxidized by another molecule of *1* to yield *3* (R = OCH_3). The reduction of *1* by intermolecular hydride transfer explains the formation of *4*.

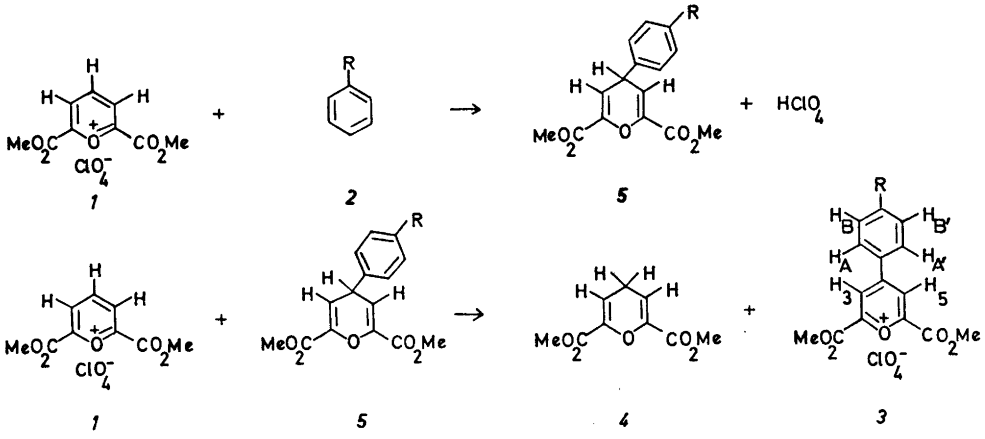
The reaction was repeated in trideuterioacetonitrile solution. The 4*H*-pyran *5* (R = OCH_3) was not formed in detectable amounts as shown by the ^{1}H NMR spectrum of the reaction mixture. The presence of nearly equimolecular amounts of unreacted anisole, the pyrylium cation *3* (R = OCH_3) and the 4*H*-pyran *4* showed that the stoichiometry of the reaction was according to the equation:

$$2(1) + (2) = (3) + (4) + HClO_4$$

The reaction between equimolecular amounts of *1* and dimethylaniline in acetonitrile solution also resulted in isolation of a salt. The product, however, was not the expected pyrylium salt *3* [R = $N(CH_3)_2$], but the hydroperchlorate of the amine *5* [R = $N(CH_3)_2$] in 85 % yield. The reaction was repeated with two molar equivalents of *1* and this yielded the pyrylium salt *3* [R = $N(CH_3)_2$] in 75 % yield and the 4*H*-pyran *4*.

The reaction of *1* with toluene (molar ratio; 2:1) in trifluoroacetic acid solution was carried out in the ^{1}H NMR sample tube. The result as shown by ^{1}H NMR spectra was analogous to that obtained in the reaction of *1* with anisole. Only formation of *3* (R = CH_3) and *4* in equal amounts and the simultaneous disappearance of *1* and toluene were observed. The pyrylium salt *3* (R = CH_3) was isolated when the reaction was quantitative.

These experiments demonstrate that the 4-unsubstituted pyrylium nucleus *1* is a very reactive cation, which readily takes part in both electrophilic aromatic substitution and hydride transfer reactions. Kinetic studies have not been carried out. The results, however, indicate that intermolecular hydride transfer is much faster than substitution in the reaction of *1* with



Scheme 1.

Table 1. The ^1H NMR spectra (δ values) of pyrylium salts *3* recorded in trifluoroacetic acid solution

R	H_3,H_5	$O-CH_3$	$H_A,H_{A'}$	$H_B,H_{B'}$	R	$J_{AB}=J_{A'B'}$ Hz
CH_3	9.23	4.30	8.38	7.68	2.65	10
OCH_3	9.00	4.27	8.50	7.38	4.17	10
$N(CH_3)_2$	8.52	4.22	8.22	7.38	3.57	10

equimolecular amounts of anisole. On the other hand, the inverse is presumably the case in the reaction of *1* with dimethyaniline. It seems likely that the explanation is an increased rate of substitution due to the dimethylamino group and furthermore a decreased rate of hydride transfer due to the formation of the hydroperchlorate of the amine *5* ([R = $N(CH_3)_2$]).

The ^1H NMR shift values of the pyrylium salts *3* are listed in Table 1.

The increased stabilizing effect of substituent R on the pyrylium cation through the series Me, OMe, $N(CH_3)_2$ is reflected in chemical shift positions of the heterocyclic ring protons. The upfield shifts of these protons are in agreement with a decreased positive charge of the pyrylium nucleus.

Experimental. The ^1H NMR spectra were recorded on a Varian A-60A instrument with TMS as internal standard.

*2,6-Dimethoxycarbonyl-4-*p*-methoxyphenylpyrylium perchlorate* (*3*, *R* = *OCH*$_3$). To a solution of 2,6-dimethoxycarbonylpyrylium perchlorate [2] (1.48 g, 0.005 mol) in dry acetonitrile (5 ml) was added anisole (0.540 g, 0.005 mol) at 20 °C with stirring. After 24 h anh. ether (75 ml) was added. The precipitated material was filtered off and recrystallized from acetic acid. The yield was 93 % (0.930 g), m.p. 212–215 °C (decomp.). (Found: C 47.75; H 3.84; Cl 8.76. Calc. for $C_{16}H_{15}O_{10}Cl$: C 47.71; H 3.73; Cl 8.82). ^1H NMR spectrum see Table 1. The filtrate after removal of *3* (R = OCH_3) was concentrated under reduced pressure and the residual material was redissolved in $CDCl_3$. ^1H NMR spectrum of this solution showed signals due to 2,6-dimethoxycarbonyl-4*H*-pyran (*4*) and anisole. ^1H NMR spectrum of 2,6-dimethoxycarbonyl-4*H*-pyran in $CDCl_3$ (δ): 3.05 (triplet; $2H_4$, $J_{3,4}=4$ Hz), 3.81 (singlet; OCH_3) 6.05 (triplet; H_3H_5).

*2,6-Dimethoxycarbonyl-4-*p*-dimethylaminophenyl-4H-pyran*, [*5*, *R* = *N(CH*$_3$)$_2$] *hydroperchlorate.* To a solution of 2,6-dimethoxycarbonylpyrylium perchlorate (0.60 g, 0.002 mol) dissolved in dry acetonitrile (5 ml) was added dimethylaniline (0.24 g, 0.002 mol) at 20 °C with stirring. After 24 h the title compound was filtered off (0.4 g). The filtrate was diluted with ether and additional 0.32 g was collected.

The yield was 85 % (0.720 g), m.p. 224–227 °C (decomp.) (CH_3CN). (Found: C 48.85; H 4.79; N 3.53; Cl 8.53. Calc. for $C_{17}H_{20}O_9ClN$: C 48.87; H 4.79; N 3.35; Cl 8.50). ^1H NMR spectrum in TFA (δ); 3.50 (doublet; $^+NH(CH_3)_2$, $J=5$ Hz), 4.0 (singlet; OCH_3), 4.58 (triplet; H_4, $J_{3,4}=4.0$ Hz), 6.32 (doublet; H_3H_5). The aromatic protons form an AA'BB' system centered at δ 7.67 with a small chemical shift difference between H_A and H_B.

*2,6-Dimethoxycarbonyl-4-*p*-dimethylaminophenylpyrylium perchlorate* [*3*, *R* = *N(CH*$_3$)$_2$] was prepared as *5* [R = $N(CH_3)_2$] from 0.004 mol of pyryliumsalt and 0.002 mol of dimethylaniline. The reaction mixture was left standing for one week. The yield was 75 %, m.p. 280–285 °C (decomp.). (Found: C 49.16; H 4.47; N 3.27; Cl 8.46. Calc. for $C_{17}H_{18}O_9ClN$: C 49.10; H 4.33; N 3.37; Cl 8.54). ^1H NMR spectrum see Table 1. The filtrate, after removal of the title compound, was concentrated under reduced pressure and the residual material was redissolved in $CDCl_3$. ^1H NMR spectrum of this solution showed signals due to the 2,6-dimethoxycarbonyl-4*H*-pyran (*4*).

*2,6-Dimethoxycarbonyl-4-*p*-methylphenylpyrylium perchlorate* (*3*, *R* = *CH*$_3$). 2,6-Dimethoxycarbonylpyrylium perchlorate (0.06 g, 2×10^{-4} mol) and toluene (0.01 g, 10^{-4} mol) was dissolved in trifluoroacetic acid (0.3 ml). The solution was transferred into a ^1H NMR sample tube and left standing at 20 °C. Spectra were recorded regularly and after 12 days the signals due to the added pyrylium salt were undetectable. The solution was diluted with ether and the title compound was collected by filtration: m.p. 195–197 °C (decomp.). (Found: C 49.65; H 4.01. Calc. for $C_{16}H_{15}O_9Cl$; C 49.67, H 3.88). ^1H NMR spectrum see Table 1.

The Crystal Structure of Two Polarized Ethylenes

SIXTEN ABRAHAMSSON,[a] GUNNAR REHNBERG,[a] TOMMY LILJEFORS[b] and JAN SANDSTRÖM[b]

[a] Crystallography Group, Swedish Medical Research Council Unit for Molecular Structure Analysis, University of Göteborg, P.O.B., S-400 33 Göteborg 33, Sweden and [b] Division of Organic Chemistry, University of Lund, Chemical Centre, P.O.B. 740, S-220 07 Lund 7, Sweden

The structures of 1,1-bis-methylthio-2-*p*-bromobenzoyl-2-cyanoethylene and 1,3-dimethyl-2-[*p*-bromobenzoyl-cyanomethylene]-imidazolidine have been determined by X-ray crystallography.

The length of the carbon-carbon double bond in the first compound, 1.369 Å, indicates only a moderate ground state polarization. The second compound shows a twist of 41° between the imidazolidine and O(1)=C(7)−C(8)−C(12)−N(1) planes, and a C=C bond length of 1.448 Å, indicating a strong steric effect.

The observed bond lengths are discussed in their relation to PPP calculations and experimental rotation barriers.

In recent years several investigators have found by NMR lineshape methods that ethylenes with push-pull substituents (polarized ethylenes) have free energies of activation ($\Delta G^{\ddagger}$) to rotation around the double bond lower than 25 kcal/mol, in some cases even lower than 6−7 kcal/mol, which is the practical lower limit for most NMR spectrometers (see Ref. 1 for a recent review).

These barriers should be compared to $\Delta H^{\ddagger}$ = 62.2 kcal/mol for 1,2-dideuterioethylene [2] and 60.0 kcal/mol for *cis*-2-butene.[3] It is a popular concept that low torsional barriers are due to low π-bond orders of the bonds concerned. However, this is not necessarily true, since the barriers measure the energy differences between the ground and transition states, whereas the bond order is a function of the electron interaction in the ground state alone. In polarized ethylenes the transition state energy is determined by the capacity of the two parts of the molecule to stabilize respectively a positive and a negative charge. It is therefore of interest to study the relation between bond lengths and torsional barriers in polarized ethylenes. Some bond lengths resulting from X-ray crystallographic studies of similar compounds have recently been published. The double bond joining the cyclopropene and cyclopentadiene rings in 1,2,3,4-tetrachloro-5,6-dipropylcalicene is 1.37 Å,[4] and the corresponding bond in 1,2,3,4-tetrachloro-5,6-diphenylcalicene is 1.36 Å.[5] No torsional barriers are known for these calicenes, but Kende *et al.*[6] have found barriers in the range 18.0−19.4 kcal/mol for 1-formyl-5,6-dipropylcalicene in different solvents, and Prinzbach [7] has observed temperature dependent NMR spectra of 1,3-di-*tert*-butyl-5,6-dimethylcalicene, from which free energy barriers of 17.8 kcal/mol (in C_6D_6) and 14.4 kcal/mol (in CCl_4) can be calculated. The exocyclic double bond in 6,6-ethylenedithiofulvene is 1.37 Å,[8] as compared to 1.346 Å in 6,6-dimethylfulvene, by an electron diffraction study.[9]

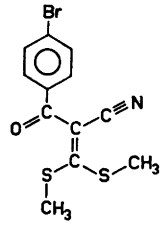
In 2-formyl-6-dimethylaminofulvene the exocyclic double bond is 1.389 Å.[10] The barrier to rotation around this bond could not be measured, probably due to unfavourable conformer distribution, but it is probably lower than the 22.1 kcal/mol barrier found for the simple 6-dimethylaminofulvene.[11]

More recently, Shmueli *et al.*[12] have studied the crystal structure of 1-dimethylamino-2,2-biscarbomethoxyethylene, for which the length of the double bond was found to be 1.380 Å and the free energy barrier to rotation around this bond 15.6 kcal/mol.

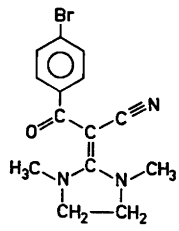
The purpose of the present investigation has been to study the molecular structure of an ethylene with push-pull substituents, for which

the barrier to rotation around the carbon-carbon double bond is known, in order to increase the knowledge of relations between barriers and bond lengths. For this purpose, 1,1-bismethylthio-2-*p*-bromobenzoyl-2-cyanoethylene (TCE) was chosen. The barrier of the bromine-free analogue has been studied by the complete lineshape method, and $\Delta H^{\ddagger} = 13.8$ kcal/mol, $\Delta S^{\ddagger} = -17.3$ e.u. and $\Delta G^{\ddagger}_{300} = 19.0$ kcal/mol were found.[13] From the rate of rotation at the coalescence temperature and assuming the same entropy of activation, TCE has $\Delta H^{\ddagger} = 13.9$ kcal/mol and $\Delta G^{\ddagger}_{300} = 19.1$ kcal/mol.

Furthermore, this study includes the structure of a polarized ethylene, 1,3-dimethyl-2-[*p*-bromobenzoyl-cyanomethylene]-imidazolidine (ICE) (II), for which the NMR spectrum indicates a twisted double bond in solution.[14] The barrier in ICE cannot be studied, but the bromine-free 1,3-dibenzyl analogue has $\Delta G^{\ddagger} = 9.5$ kcal/mol with the planar state as transition state.



I



II

EXPERIMENTAL

The preparation of TCE [15] and the bromine-free analogue of ICE [16] has been described previously. ICE was prepared similarly and was obtained in 82 % yield as pale yellow prisms, m.p. 183.5 – 185 °C after recrystallization from toluene. (Found: C 52.5; H 4.36; Br 25.1; N 13.1; O 4.94. $C_{14}H_{14}BrN_3O$ (320.19) requires C 52.5; H 4.41; Br 25.0; N 13.1; O 5.00).

X-Ray single crystal data for the two compounds were collected on a Picker FACS I automatic diffractometer using graphite monochromated Cu$K\alpha$ radiation. Reflexions up to $2\theta = 124°$ were measured with a 2.0 degree $\theta - 2\theta$ scan. The scanning speed was 1 degree min^{-1}. The background level was determined from 10 second counts on each side of the reflexion.

Lorentz and polarization factors were applied, but no correction was made for extinction or absorption. Atomic scattering factors were taken from the International Tables for X-Ray Crystallography [17] except for hydrogen in which case the values of Stewart, Davidson and Simpson [18] were used. All calculations were performed on a Datasaab D21 – PDP15 dual computer system with programs developed at the Crystallography Group.

STRUCTURE DETERMINATION AND REFINEMENT

TCE. In total 1177 independent reflexions were measured of which 1164 were more than two standard deviations above background and used in the structure analysis. The non-hydrogen atom positions were found from successive electron density series starting with the phases of the bromine atom. The hydrogen atoms were included at their expected positions which were compatible with the peaks in a difference synthesis. In the final least-squares treatment using the full matrix all positional parameters were refined. Anisotropic temperature factors were used except for the hydrogen atoms which were given isotropic temperature factors corresponding to those of their parent atoms. The B-values were not refined. At an R-value of 0.037 no further improvement occurred and the refinement was terminated.

Table 1. Fractional positional coordinates in TCE and temperature factors for the hydrogen atoms. The standard deviations (within brackets) are multiplied by 10^4 and 10^3 for the hydrogen atoms.

The weight assigned to each observation in the refinement [19] was

$$w = 1 + [(|F_o| - 1.67|F_{min}|)/1.67|F_{min}|]^2$$

Corrections for anomalous dispersion were applied for bromine and sulfur.

ICE. The intensities of 2442 reflexions were recorded of which 2127 were more than 2σ above background and used in the analysis. The structure determination procedure was analogous to that for TCE except that it was not possible to refine the hydrogen positions. The final R-value was 0.043. The weighting scheme used was

$$w = 1 + [(|F_o| - 10.4|F_{min}|)/15.5|F_{min}|]^2$$

DISCUSSION

The final atomic parameters are given in Tables 1–4. Structure factor lists can be obtained on request from the Crystallography Group. Distances and angles are given in Figs. 1 and 2 which also show the atomic numbering and in Tables 5 and 6 where the standard deviations are included. Least-squares planes through various parts of the molecules are given in Tables 7 and 8. Stereoscopic pairs of the molecules are shown in Figs. 3 and 4.

The dimensions of the two bromobenzene groups are normal. The mean value of the C–C bond is 1.388 Å in TCE and 1.384 Å in ICE. The average angle is 120.0° in both structures. In both cases C(7) is about 0.1 Å out of

Table 4. Anisotropic thermal parameters for the non-hydrogen atoms of ICE in the form $\exp[-2\pi^2(h^2a^{*2}U_{11}+k^2b^{*2}U_{22}+l^2c^{*2}U_{33}+2hka^*b^*U_{12}+2klb^*c^*U_{23}+2hla^*c^*U_{13})]$. The standard deviations (within brackets) have been multiplied by 10^4.

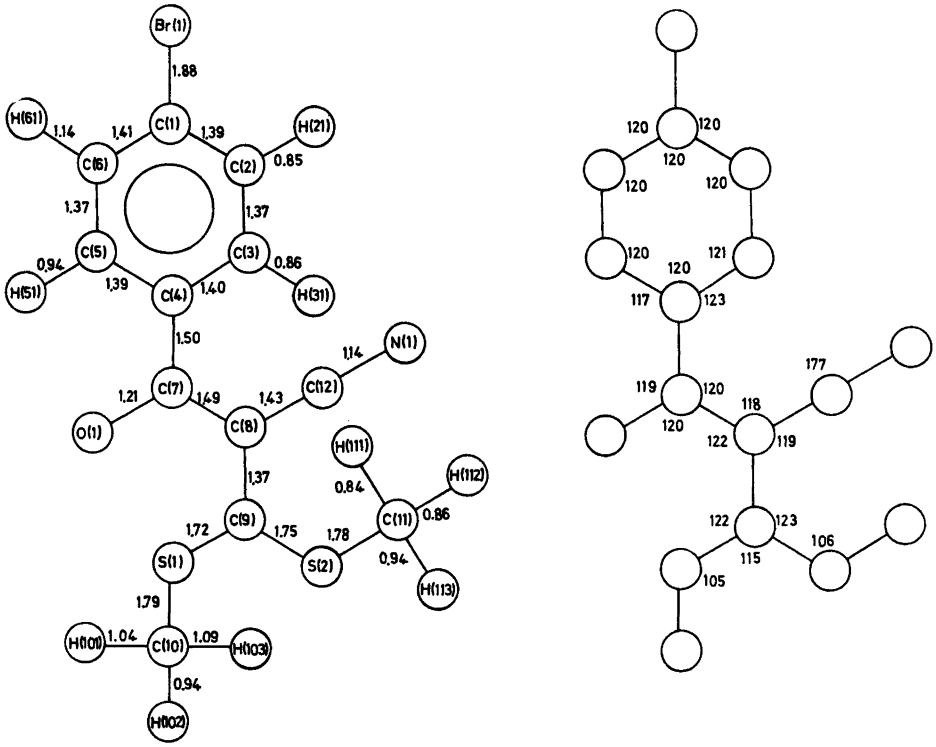

Fig. 1. Bond distances and angles in TCE.

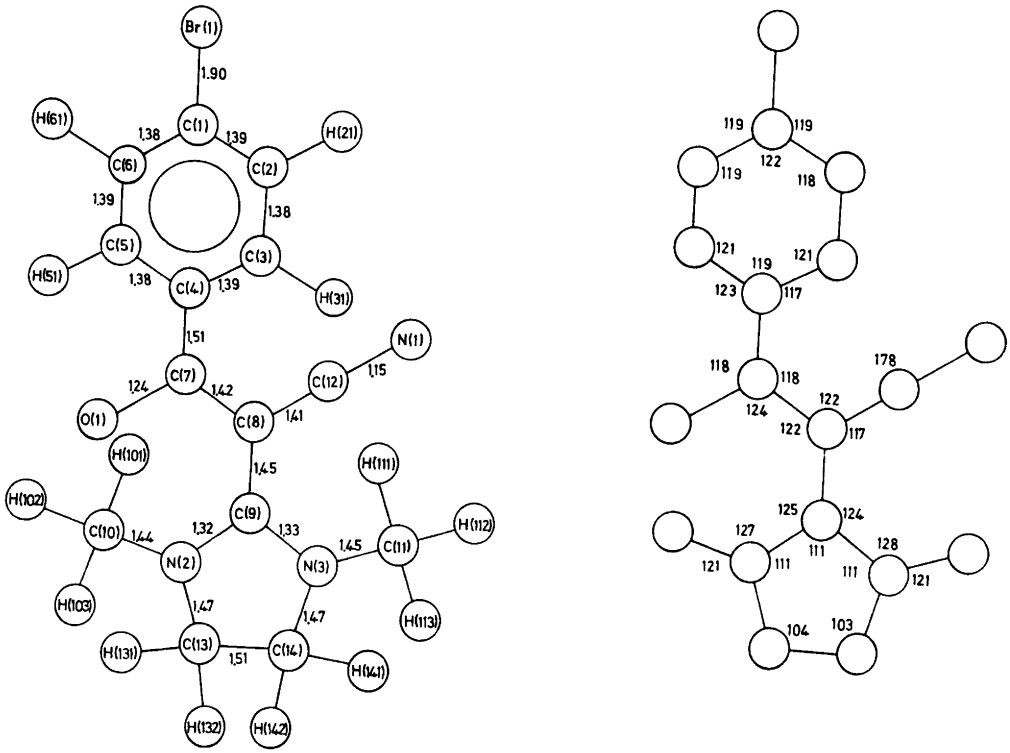

Fig. 2. Bond distances and angles in ICE.

the plane of the ring at the same time as the carbonyl group is twisted 32.1° (TCE) and 60.7° (ICE) from the plane. Whereas in ICE O(1) is near the plane through C(7), C(8) and C(12), it is 0.35 Å off the corresponding plane in TCE. The calculated twist [angle between planes through C(7), C(8), C(12) and C(9), N(2), N(3) and C(9), S(1), S(2) respectively] around the double bond is 15.2° in TCE and 41.1° in ICE. In TCE most of the effect appears to be due to the change in direction of the C(9) – S(1) bond.

The double bond in ethylene is given lengths between 1.332 and 1.339 Å.[20] Using 1.337 Å for this bond, and 1.517 Å for a $C(sp^2)-C(sp^2)$ bond with zero π-bond order and zero rotational barrier,[21] direct proportionality between barriers and bond orders (and a linear relation (4) between bond orders and bond lengths) should have given a C(8) – C(9) bond length of 1.477 Å. The experimental value for this bond, 1.369 Å, shows that no barrier-bond order proportionality exists. To obtain a general idea of electron distribution and bond lengths in TCE, calculations have been performed by the PPP method modified according to Roos and Skancke.[22] The modified matrix elements are given by (1) and (2), where ν refers to atoms directly bonded to μ, and λ to all atoms except μ. Alkyl groups were not taken into account.

$$F_{\mu\mu} = H_{\mu\mu}^{\text{core}} - 1/2 q_\mu \gamma_{\mu\mu} + \sum_{\lambda \neq \mu} q_\lambda \gamma_{\mu\lambda} \quad (1a)$$

$$H_{\mu\mu}^{\text{core}} = W_{\mu\mu} - (n_\mu - 1)\gamma_{\mu\mu} - \sum_{\lambda \neq \mu} n_\lambda \gamma_{\mu\lambda} \quad (1b)$$

$$W_{\mu\mu} = W_{\mu\mu}^\circ + \sum_\nu \Delta W_{\mu\nu} \quad (1c)$$

$$\Delta W_{\mu\nu} = \Delta W_{\mu\nu}^\circ + \delta_{\mu\nu}{}^W (R_{\mu\nu} - R_0) \quad (1d)$$

$$F_{\mu\nu} = \beta_{\mu\nu} - \tfrac{1}{2} p_{\mu\nu} \gamma_{\mu\nu} \quad (2a)$$

$$\beta_{\mu\nu} = \beta_{\mu\nu}^\circ + \delta_{\mu\nu}{}^\beta (R_{\mu\nu} - R_0) \quad (2b)$$

Repulsion integrals between nearest neighbours are given by (3). Other two-centre repulsion integrals are calculated by the

$$\gamma_{\mu\lambda} = \gamma_{\mu\lambda}^\circ + \delta_{\mu\lambda}{}^\gamma (R_{\mu\nu} - R_0) \quad (3)$$

hard sphere approximation of Parr.[23] The parameters W_0, ΔW_0, β_0, and the different δ values are taken from the work of the Stockholm School and are collected together with the pertinent references in Table 9. The cyano group has not been parametrized, and instead the parameters for pyridine nitrogen have been employed here. The bond lengths were calculated by an iterative procedure according to Sundbom.[24] An idealized geometry was used in the first calculations, assuming a planar molecule with single and double bond lengths taken from similar systems. The imidazolidine ring in ICE was regarded as a regular pentagon, and all other bond angles were assumed to be 120°. Using the π-bond orders from the first calcula-

tion, new bond lengths were calculated by (4), where $R_{\mu\nu}°$ is a standard bond length,

$$R_{\mu\nu} = R_{\mu\nu}° - 0.18\, p_{\mu\nu} \quad (4)$$

1.517 Å for a C–C bond, 1.458 Å for a C–N bond, 1.365 Å for a C–O bond, and 1.773 Å for a C–S bond. The C–Br and C≡N bonds were not iterated. The calculations were repeated until self-consistent bond lengths were obtained, which only required a few cycles. The results are given in Table 10 together with the starting bond lengths and the experimental bond lengths. The agreement between the calculated and the experimental C=C bond length in TCE is quite satisfactory, and the same can also be said about the C–S bonds, for which even the difference in bond length is correctly reproduced. The too large calculated C(8)–C(12) bond length can be ascribed to the use of $R_{\mu\nu}° = 1.517$ Å for this bond, though C(12) is *sp*-hybridized. The too low calculated value for the C(4)–C(7) bond can at least partly be explained by the observed twisting of the benzene ring out of the plane through C(8), C(7), and O(1) of 32.1°. The twisting of the S(1)–C(9)–S(2) group (15.2°) is probably too small to affect the bond lengths significantly. With the adopted conformation the S(1)–O(1) contact distance is 2.673 Å (van der Waals distance 3.25 Å) and C(11)–N(1) is 3.44 Å. H(111) is 2.54 Å from C(12) and 2.55 Å from N(1). Very short non-bonded interactions between sulfur and oxygen have been found earlier, *e.g.* 2.64 Å in two 2-acyl-methylene-1,3-dithietans,[25,26]

2.41 Å in a 3-acetylmethylene-1,2-dithiole [27] and 2.78 Å in *o*-carboxyphenyl methyl sulfoxide.[28] The nature of this attractive force has been discussed by Kapecki and Baldwin [29] in terms of EHT calculations, and by Pfister-Guillouzo *et al.*[30] in terms of CNDO/2 calculations. The EHT calculations give no conclusive result, and the latter authors conclude that introduction of *d* orbitals in the basis set is necessary to get a proper description of the O···S interaction.

In the benzene ring H(31) is 2.56 Å from C(12) but 2.91 Å from N(1). Whereas thus C(12) has the same hydrogen packing contacts from two sides, the surrounding of N(1) is less symmetrical. This might explain the observed deviation of the C(8)−C(12)−N(1) angle from 180°. H(51) is 2.52 Å (van der Waals distance 2.72 Å) from O(1).

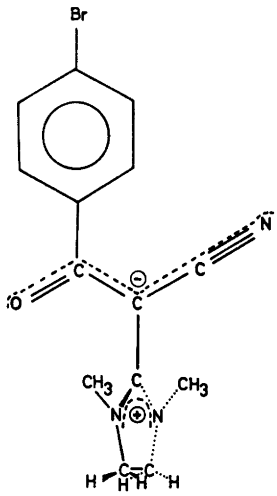

Fig. 5. ICE in the 90° twisted state.

For ICE, the C=C bond length calculated for a planar molecule is 1.388 Å. The difference between this and the experimental value of 1.448 Å must largely be ascribed to a steric interference between the N-methyl groups on one side and the carbonyl and cyano groups on the other causing a considerable twist (41.1°) of the molecule around the double bond. The C(10)−O(1) distance is 2.90 Å compared with the van der Waals distance 3.22 Å, and the C(11)−N(1) distance is 3.46 Å. The shortest O(1)···H distance is 2.27 Å and the shortest N(1)···H distance 2.67 Å. Evidently the interaction with the carbonyl group is the most important one. A case of a twisted double bond, which is only slightly stretched (to 1.345 Å), has recently been reported [31] but this bond is a member of a polycyclic ring system, which may well restrict its expansion.

The experimental C(9)−N(2) and C(9)−N(3) bonds are considerably shorter than those calculated for the planar molecule. This can be ascribed to the twist and reflects the greater contribution in the actual molecule of the amidinium ion structure, which is postulated to stabilize the 90° twisted molecule [14] (Fig. 5). This is compatible with the almost planar arrangement of O(1), C(7), C(8), C(12), and N(1). The imidazolidine group is also nearly planar whereas it for instance in 1-(4-chlorobenzyl)-1-nitroso-2-(4,5-dihydro-2-imidazolyl)hydrazine [32] is considerably puckered. A larger polarization in ICE than in TCE is shown both by experimental and calculated bond lengths in the electron attracting part of the molecule (Table 10). Similarly, ICE shows a more extensive charge separation in the calculated π-electron distribution (see Fig. 6 for the distribution of

Table 10. Bond lengths (Å).

H(141)	H(112^{i})	(1, 1, 1)	2.81
H(141)	H(142^{i})	(1, 1, 1)	3.00
H(142)	H(111^{i})	(1, 1, 1)	2.54

From Table 11 it is evident that the most important intermolecular contacts of TCE involve the methyl hydrogens. There are thus no hydrogen packing distances less than 3 Å between benzene rings.

Table 12 gives the shortest intermolecular distances in ICE. Here the hydrogen atoms of one benzene ring are in packing contact with those of other benzene rings as well as with those of CH_2- and CH_3-groups. O(1) has apart from the intramolecular interaction with H(103) of 2.27 Å also other very short distances to H(21) (2.36 Å) and H(142) (2.36 Å).

Composition of the Essential Oil of Sweet Marjoram Obtained by Distillation with Steam and by Extraction and Distillation with Alcohol—Water Mixture

JYRKI TASKINEN

Research Laboratories of the State Alcohol Monopoly (Alko), Box 350, SF-00101 Helsinki 10, Finland

The steam distilled oil of sweet marjoram (*Majorana hortensis* Moench) and an alcoholic distillate of this herb used for flavouring liqueurs were analysed by gas chromatography, infra-red spectrophotometry, nuclear magnetic resonance and mass spectrometry. 11 monoterpene hydrocarbons, 8 sesquiterpene hydrocarbons, 10 monoterpene alcohols, 5 esters of monoterpene alcohols and 4 other compounds were identified. Additionally, 6 ethyl ethers of monoterpene alcohols and 9 ethyl esters of long-chain fatty acids were found in the alcoholic distillate. Of the 53 components identified in the sweet marjoram aroma concentrates in the present study, 35 are reported for the first time.

Sweet marjoram is obtained from *Majorana hortensis* Moench (*Origanum majorana* L.), which has for centuries been cultivated in the Mediterranean countries and nowadays in the Northern Temperate Zone as well. The commercially available herb is prepared from the dried leaves and flowers. The content of volatile oil varies between 0.5 and 3.5 % depending on the origin of the herb and many other factors.[1]

The composition of sweet marjoram oil was first investigated at the turn of the century, when Biltz [2] found it to consist of 40 % monoterpene hydrocarbons, mostly terpinene. Somewhat later, Wallach [3,4] showed that sweet marjoram contains terpinenol-4 and α-terpineol. After that no further investigations into the aroma compounds of sweet marjoram were published until the sixties. Nicoletti and Baiocchi [5] found that the oil of sweet marjoram contains monoterpene hydrocarbons, terpinenol-4, α-terpineol, linalool, linalyl acetate and *cis*-sabinene hydrate, which had not previously been identified in natural oils. Lossner [6] found *trans*-sabinene hydrate as well, and identified 6 monoterpene hydrocarbons. In the same study, gas chromatographic analysis showed that the oils of sweet marjoram originating from seven different countries were all much the same. Lossner's analysis showed that the German oil contained 1 % α-pinene, 9 % myrcene, 8 % α-terpinene + limonene, 20 % γ-terpinene, 7 % terpinolene, 9 % linalool + *trans*-sabinene hydrate, 3 % linalyl acetate, 13 % *cis*-sabinene hydrate, 23 % terpinenol-4, and 5 % α-terpineol. Ikeda *et al.*[7] analysed the monoterpene hydrocarbons in the sweet marjoram oil by gas chromatography and, in addition to those above, identified α-thujene, camphene, β-pinene, sabinene, α-phellandrene, β-phellandrene, and ocimene by their retention times.

The volatile oil from sweet marjoram grown in India differs substantially in both physical characteristics and chemical composition from that of European and American origin.[1] The following compounds have been identified in the Indian oil: carvacrol,[8] eugenol,[8,9] chavicol,[8] methylchavicol,[8] linalool,[8,9] α-terpineol,[8,9] terpinenol-4,[9] geraniol,[9] and caryophyllene.[8]

The volatile oil is commonly separated by steam distillation; the oil of sweet marjoram produced by this method is used in the flavour industry, pharmacy *etc.* In the production of alcoholic beverages, however, it is considered that a finer quality aroma is obtained if the volatile components are separated by percolation and distillation with an alcohol-water mix-

ture. This work investigates both oil separated by steam distillation and the aroma concentrate used in the preparation of herbal liqueurs. The aims of the study were to identify the aroma compounds from sweet marjoram and to investigate the effect of the different methods of separation on the aroma concentrates.

EXPERIMENTAL

Apparatus. A Hewlett-Packard 7620 A gas chromatograph fitted with a TC detector was used for analysis. The temperature of the injection block and the detector was 240 °C. Four pairs of 6 mm × 3 m stainless steel columns were packed with: 10 % FFAP on 60/80 mesh Chromosorb W AW, 5 % SE-30 on 60/80 mesh Chromosorb G, 15 % Apiezon L on 60/80 mesh Chromosorb W AW, and 5 % LAC-2R-446 on 70/80 mesh Chromosorb G AW DMCS. Peak areas were measured by an Infotronics CRS-11 HSB/42 Integrator. For the preparative work the fractions eluting at the TCD exhaust were collected in 1 mm × 20 cm glass tubes cooled with dry ice.

The IR spectra were measured with samples between plates of KBr on a Perkin-Elmer 521 spectrophotometer equipped with a beam condenser. The mass spectra were measured on a Varian CH 7 combined GLC-MS connected with a Spectro System 100 MS computer. The ionisation energy used was 70 eV, and a 2 mm I.D. × 2 m glass column packed with FFAP or SE-30 was used in the GLC.

The NMR spectra were measured on a Varian A 60 model using carbon tetrachloride as solvent and tetramethylsilane as internal standard.

Materials and procedure. The alcoholic distillate of sweet marjoram used in the investigation was produced in Alko's flavour distillery from East-European plants. The herb is percolated for three weeks with a 55 % ethanol water mixture as the first stage in the preparation of the alcoholic distillate. The percolate is distilled under reduced pressure and a fraction with the desired aroma is collected. For the analysis, the aroma compounds were separated from the alcoholic distillate by extraction into pentane. 500 ml lots of the distillate were diluted with water to 50 % alcohol, saturated with NaCl and shaken in a separating funnel with pentane. The extract was dried over Na_2SO_4 and the pentane distilled off.

The volatile oil was separated from 200 g of sweet marjoram (from the same batch of herb as that used in the preparation of the alcoholic distillate) by 2 h steam distillation. The oil was extracted from the distillate with pentane, the exract dried over Na_2SO_4, and the pentane distilled off to leave 2.2 g oil.

The sweet marjoram oil obtained by steam distillation and the pentane extract from the alcoholic distillate were first fractionated by preparative GLC on a FFAP column, and the fractions collected were in most cases further separated on a second column so that pure compounds could be collected for determining the spectra. The combined GLC-MS analysis using an SE-30 column was made directly from fractions obtained with the FFAP column.

Before analysing the sesquiterpene hydrocarbons by GLC, the steam distilled oil and the pentane extract from the alcoholic distillate were each fractionated by column chromatography. 200 μl samples were added to a 1 cm × 15 cm silica gel column (Kieselgel, 0.2 – 0.5 mm, from Merck) and the hydrocarbons were eluted with 200 ml pentane.

The components were identified by comparing their GLC retention times and spectra with those of authentic samples or with published spectra or, when reference materials were unavailable, by interpreting the spectral data.

Ledene was synthesized by dehydrating ledol with 5 % H_2SO_4, as described by Kiryalov.[10]

RESULTS AND DISCUSSION

The gas chromatogram of the steam distilled sweet marjoram oil on FFAP column is presented in Fig. 1, and that of the pentane extract from the alcoholic distillate in Fig. 2. The compounds identified are shown in Table 1 with their percentage contribution as calculated from the peak areas and identification methods.

The monoterpene hydrocarbons constituted about 30 % of the oil separated by steam distillation and about 44 % of the aroma from the alcoholic distillate. The main components, γ-terpinene and α-terpinene, were separated from the steam distilled oil by preparative gas chromatography. A direct analysis of sweet marjoram oil by combined GLC-MS using a FFAP column identified α-pinene, β-pinene, sabinene, myrcene, α-phellandrene, β-phellandrene, limonene, and terpinolene by comparing retention times and mass spectra with those of authentic samples and α-thujene using a published mass spectrum.[11] Gas chromatographic analysis of the pentane extract of the alcoholic distillate showed that the same compounds were present and in approximately the same relative proportions.

The sesquiterpene hydrocarbons formed less than 3 % of the steam distilled oil and 7.5 % of the aroma fraction of the alcoholic distillate. The same two main components dominated in

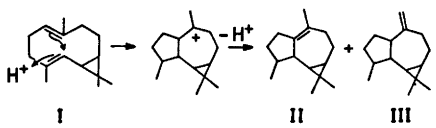
[a] Spectrum of an authentic sample.

both samples. The larger of these was identified as caryophyllene. The other was tentatively identified as bicyclogermacrene. Its mass spectrum gave a molecular weight of 204. The IR spectrum had absorption bands at 3010, 1650, and 829 cm^{-1}, corresponding to a trisubstituted double bond. The NMR spectrum is identical with that reported by Nishimura *et al.*[12] for bicyclogermacrene in other respects, although it was not possible to resolve with certainty the cyclopropane ring multiplet from the background noise because of the small sample size available. The same minor components, ledene, α-humulene, α-copaene, β-farnesene, γ-elemene, and alloaromadendrene, were found in the hydrocarbon fractions from both samples. Ledene (II) was identified by comparing its IR spectrum with that of a sample synthesized by the dehydration of ledol.

Ledene (II) has not previously been reported to occur in natural oils. Its occurence, and that of alloaromadendrene (III), together with bicyclogermacrene (I) in the oil of sweet marjoram is in agreement with the suggestion by Nishimura [12] that bicyclogermacrene could be the biogenetic precursor of aromadendrane-type compounds. It is also possible, however, that ledene and alloaromadendrene have been formed from bicyclogermacrene during the isolation or analysis of the volatile oil.



Scheme 1.

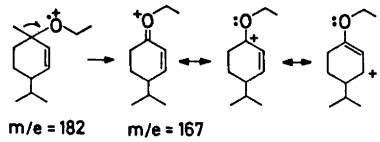
Monoterpene alcohols constituted about 65 % of the steam distilled oil and about 25 % of the aroma fraction from the alcoholic distillate. Ten alcohols were identified in the steam distilled oil: terpinenol-4, α-terpineol, linalool, geraniol, *cis*- and *trans*-sabinene hydrate, *cis*- and *trans*-piperitol, and *cis*- and *trans*-2-*p*-menthen-1-ol. Six of these alcohols, terpinenol-4, α-terpineol, linalool, *cis*- and *trans*-sabinene hydrate, and *cis*-2-*p*-menthen-1-ol were also found in the alcoholic distillate.

In the chromatogram of the pentane extract from the alcoholic distillate there was a group of peaks between the monoterpene hydrocarbons (peaks 1 – 10) and the monoterpene alcohols (starting at peak 16), all of which were absent from the chromatogram of the steam distilled oil. IR, NMR, and MS analysis showed that the peaks represented ethyl ethers of monoterpene alcohols, obviously formed during the preparation of the flavour distillate. These ethers made up about 15 % of the aroma fraction, comparable to the 25 % of the monoterpene alcohols.

The first of this group of components eluted from the FFAP column in peak 8 together with γ-terpinene, from which it could be separated using the SE-30 column. The mass spectrum revealed a molecular weight of 182 and fragments typical of monoterpenes at *m/e* 136, 121, 93. The IR spectrum exhibited the characteristic absorption of the C – H stretching of the cyclopropane ring at 3050 cm^{-1}, the typical double absorption of the *gem*-dimethyl group at 1382 and 1368 cm^{-1}, and the strong absorption band at 1070 cm^{-1} of the ether bond. The NMR spectrum contained two unsymmetrical doublet signals centered at δ 0.88 and 0.96 (each 3 H, $J = 6$ Hz) corresponding to the methyls of an isopropyl group, a 3 H singlet at δ 1.20 ($CH_3 - C - O -$), and a triplet centered at δ 1.10 (3 H, $J = 7$ Hz) and a quartet centered at δ 3.40 (2 H, $J = 7$ Hz) from an ethoxy group. The multiplet appearing at δ 0.1 – 0.5 is clearly caused by the methylene protons of the cyclopropane ring. An ether of ethanol and sabinene hydrate (4-ethoxy-thujane) would fit these data. The spectra from component 11 closely resemble those of the ether in peak 8, the main difference in NMR spectrum being that the signal from one of the methylene protons of the cyclopropane ring appears at lower field strength (δ 0.5 – 0.7) in the spectrum of component 11. It is reasonable that this proton would be less shielded if the ethoxy group were *cis* to the cyclopropane ring. Accordingly, the ether in peak 8 is tentatively identified as *trans*-4-ethoxy-thujane and peak 11 as the corresponding *cis* compound.

The absorption bands at 3020, 1635, and 730 cm^{-1} in the IR spectrum of compound 12 indicate the presence of a double bond, which is most probably *cis* disubstituted. The absorptions at 1380 and 1360 cm^{-1} reveal the typical double peak of the *gem*-dimethyl group. The molecular peak appears in the mass spectrum at *m/e* 182. A structure derived from 2-*p*-

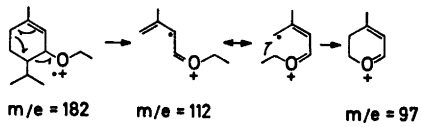
menthene is compatible with these data. The base peak in the mass spectrum is *m/e* 167 (M − 15). With the methyl and ethoxy groups on the same carbon, cleavage at the bond *β* to oxygen would result in a stable (M − 15) ion.



Scheme 2.

The (M − 45) peak too is larger (29 %) here than in the spectra of the other ethers found is sweet marjoram oil. The suggested structure favours this fragmentation as well, since cleavage of the ethoxy group would lead to the formation of a tertiary allylic carbonium ion.

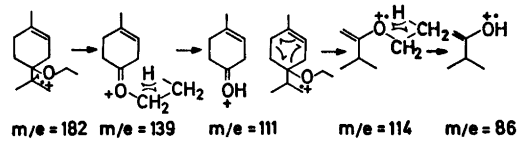
The IR spectrum of compound 13 displayed absorptions at 3010, 830, 1375, 1360 and 1080 cm^{-1}, corresponding to a trisubstituted double bond, a *gem*-dimethyl group, and a C − O bond. The mass spectrum showed the molecular ion peak at *m/e* 182 and the base peak at *m/e* 112. Considering only those ethyl ethers derived from the alcohols already identified in the aroma of sweet marjoram, the ethyl ether of piperitol has the most likely structure to accomodate these data. Cleavage of the ring at the bonds *β* to oxygen and the double bond would lead to the formation of the resonance stabilized *m/e* 112 ion. The base peak in the mass spectrum of piperitol is at *m/e* 84, which have been shown to occur by a corresponding mechanism.[13] Loss of a methyl group from the *m/e* 112 ion would produce a fragment of *m/e* 97, which is in fact the second most abundant ion (45 %) in the spectrum.



Scheme 3.

The IR and mass spectra of compound 15 closely resemble those of compound 13. According to the gas chromatographic behaviour of corresponding alcohols, peak 13 was tentatively identified as the ethyl ether of *trans*-piperitol (*trans*-3-ethoxy-1-*p*-menthene) and peak 15 as the *cis*-compound.

The mass spectrum of component 14 revealed that its molecular weight is also 182. Absorptions in the IR spectrum at 3010, 835, 790, 1385, 1365 and 1070 cm^{-1} were characteristic for a trisubstituted double bond, a *gem*-dimethyl group, and a C − O bond. The NMR spectrum of component 14 had a doublet centered at *δ* 0.87 (6 H, $J = 6.5$ Hz) corresponding to an isopropyl group, a signal at *δ* 1.64 caused by methyl adjacent to a double bond, a multiplet centered at *δ* 5.18 from a proton of the double bond, a triplet centered at *δ* 1.08 (3 H, $J = 7$ Hz) and a quartet centered at *δ* 3.28 (2 H, $J = 7$ Hz) corresponding to an ethoxy group. These data suggest a structure derived from 1-*p*-menthene. The (M − 15) peak in the mass spectrum is only 3 %, while the (M − 43) peak is 52 %. Attachment of the ethoxy group to C-4 would facilitate elimination of the isopropyl group. The *α*-cleavage and rearrangement of hydrogen after *β*-cleavage, which is usual for ethers,[14] would also rationalize the formation of the fragment *m/e* 111 (30 %) as well as the fragments *m/e* 114 (29 %) and 86 (64 %), when the ring cleaves at the bonds *β* to the double bond. The peaks *m/e* = 111 and 86 are also prominent in the mass spectrum of terpinenol-4. Accordingly, component 14 was identified as 4-ethoxy-1-*p*-menthene.



Scheme 4.

The following five monoterpene alcohol acetates were identified in the pentane extract from the alcoholic distillate of sweet marjoram by comparing their retention times and IR spectra with those of authentic samples: linalyl acetate, terpinenyl-4 acetate, *α*-terpinyl acetate, neryl acetate and geranyl acetate. Together these esters made up less than 5 % of the aroma fraction, with linalyl acetate making the largest contribution. The amount of esters found in the steam distilled oil was very low, although linalyl acetate, neryl acetate and geranyl acetate could be identified by GLC.

The only carbonyl compound found in sweet marjoram oil was carvone, which constituted

about a quarter of peak 28. The carvone from the alcoholic distillate formed only a small part of peak 28, but still lent its characteristic odour to this fraction.

The aromatic compounds *p*-cymen-8-ol, *p*-cymene and anethol were found as minor components in the steam distilled oil.

Nine long-chain fatty acid ethyl esters were found in the alcoholic distillate of sweet marjoram. Together they constituted less than 2 % of the aroma fraction of this distillate, and were completely absent from the steam distilled oil. Ethyl caprate, laurate, myristate, palmitate, oleate, linoleate, and linolenate were identified by comparing their retention times, IR and mass spectra with those of authentic samples. The IR spectrum of compound 33 is very similar to those of other unsaturated ethyl esters except that it exhibits the additional feature of the absorption band at 965 cm^{-1}, which is characteristic for a *trans*-disubstituted double bond. The molecular peak in the mass spectrum appears at $m/e = 282$ and the base peak at $m/e = 88$, the latter being characteristically formed in the fragmentation of ethyl esters as a consequence of the McLafferty rearrangement. This implies that components 33 is an ethyl *trans*-hexadecenoate isomer. The position of the double bond could not be settled by the available data.

Clearly the ethyl esters were formed by the action of the ethanol on the herb during the preparation of the alcoholic distillate, and their occurrence suggests the presence of the corresponding acids in sweet marjoram.

The results show that there are marked differences in the composition of the aroma between the sweet marjoram oil obtained by steam distillation and that produced by alcoholic distillation. With the exception of *cis*- and *trans*-sabinene hydrate, the proportion of monoterpene alcohols is clearly lower in the alcoholic distillate than in the steam distilled oil. Lossner [6] claims that *cis*-sabinene hydrate is especially important in the aroma of sweet marjoram. The proportion of mono and sesquiterpene hydrocarbons and esters of monoterpene alcohols is higher in the alcoholic distillate than in the steam distilled oil.

More interesting than these quantitative differences is the formation of new aroma compounds, such as ethyl ethers of monoterpene alcohols and ethyl esters of long-chain fatty acids, during the preparation of the alcoholic distillate. The newly-formed esters are present at quite a low concentration and have a relatively high odour threshold,[15] so that their contribution to the aroma of the alcoholic distillate is slight. The ethyl ethers of the monoterpene alcohols, however, made up about 15 % of the aroma fraction, and by smelling the aroma components as they eluted from the gas chromatograph it was found that many of these ethers had a relatively strong odour, which differed from that of the corresponding alcohols. It is probable, therefore, that the ethers contribute to the aroma of the alcoholic distillate from sweet marjoram.

Lignin Chromophores. Part II.* The Behaviour of 2,4′- and 4,4′-Dihydroxystilbene Structures towards Oxygen—Alkali**

JOSEF GIERER, INGEGERD PETTERSSON and ILONA SZABO-LIN***

Swedish Forest Products Research Laboratory, Chemistry Department, Box 5604, S-114 86 Stockholm, Sweden

The oxidation of 2,4′- and 4,4′-dihydroxystilbene structures, formed in lignins during alkaline delignification processes, has been studied by reacting appropriate model compounds with oxygen in alkaline media. The formation of the different reaction products is outlined in Scheme 1, which shows quinonemethide radicals as common intermediates, arising by a one-electron oxidation step. Quinonemethide radicals from 2,4′-dihydroxystilbenes (VIIIb) undergo ring closure to give 2-arylcoumaran-3-yl radicals (IX, XI) which dimerise (X) or are oxidised to 2-arylcoumarones (XII). Quinonemethide radicals from 4,4′-dihydroxystilbenes (XVb), however, undergo a further one-electron oxidation yielding 4,4′-stilbenequinones (XVI). The latter are subsequently oxidised to benzils (XIV). The significance of hydroxystilbene structures as potential chromophoric systems in alkali and sulfate lignins is briefly discussed.

In Part I of this series [1] the formation of 2,4′- and 4,4′-dihydroxystilbene structures in lignins during pulping has been summarised. Depending on the conditions employed, these stilbene groupings may constitute intermediate or final structures.[2]

Some years ago, it was reported that 2,4′-dihydroxystilbenes during alkaline pulping in the presence of oxygen are extensively converted into 2-arylcoumarones.[2] Recently,[3] this conversion has been interpreted in terms of a two-stage oxidation, proceeding *via* radicals of the quinonemethide type (*cf.* also Ref. 4).

The aim of the present work was to elucidate the action of oxygen in alkali on 2,4′-dihydroxystilbene structures and on the 4,4′-dihydroxy isomers.

RESULTS AND DISCUSSION

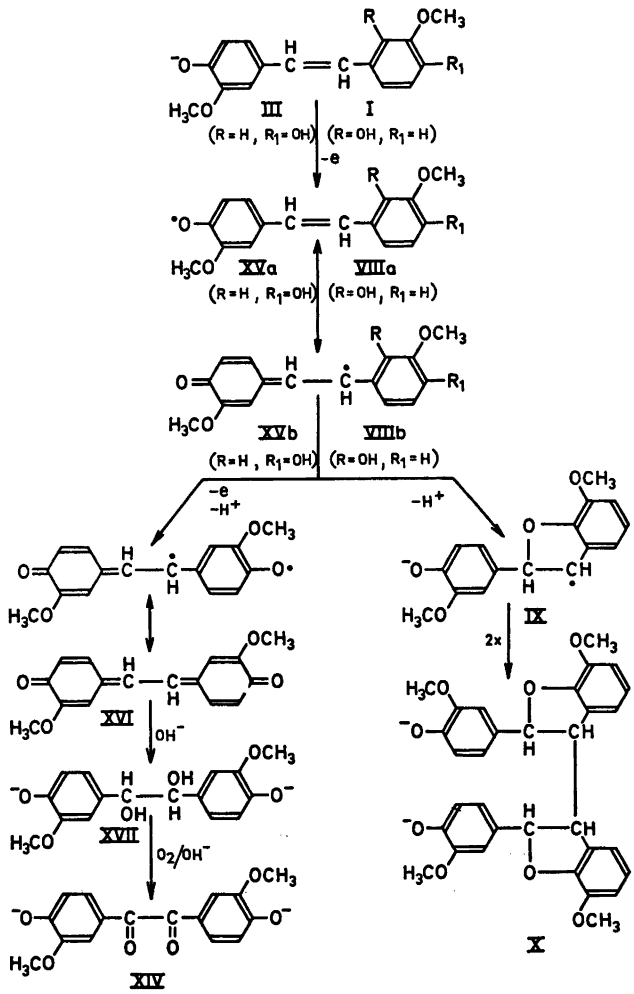
The suggested course of oxidation of the two types of dihydroxystilbenes is outlined in Scheme 1.

Oxidation of 2,4′-dihydroxy-3,3′-dimethoxystilbene. After treatment of the diacetate of stilbene I (II) with 2 M sodium hydroxide at 100 °C in the presence of oxygen for 3 h, acetylation of the resulting reaction mixture and separation of the components by column chromatography (see Experimental), the main reaction product was obtained in a crystalline state, m.p. 185–187 °C. The NMR-spectrum, the molecular ion (*m/e* 626) and the mass spectral fragmentation were in accordance with the data for the diacetate of the dimer X. It is suggested that compound X arises by the following route (see Scheme 1): Oxidation of I, formed from II by alkaline hydrolysis, gives the 4′-phenoxy radical (VIIIa). This radical, in its mesomeric quinonemethide form VIIIb, undergoes ring closure to give the 2-arylcoumaran-3-yl radical IX (*cf.* Ref. 3). The latter finally dimerises yielding compound X. Alternatively, the quinonemethide radical

* Part I, see Ref. 1.

** A preliminary report on the results of this work has been given (by J. G.) at the "Chromophore Seminar", Raleigh, N. C., April 17–19, 1972.

*** Present address: Medical University of South Carolina, Charleston, USA.



Scheme 1. Oxidation of 2,4′- and 4,4′-dihydroxystilbenes with oxygen in alkali.

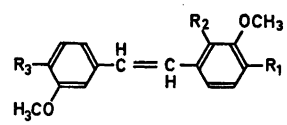
VIIIb dimerises first to give a *bis*-quinonemethide which then by twofold ring closure yields compound X. The formation of *bis*-quinonemethides by oxidation of appropriate hydroxystilbenes (*e.g.* VII) with one-electron oxidants (*e.g.* dichloro-dicyanobenzoquinone, DDQ) has been reported earlier.[5]

It is worthy of note that under similar conditions radical XI behaves differently from radical IX, the former being oxidised to an arylcoumarone derivative (XII).[3] Dimerisation of XI appears to be excluded presumably owing to the steric hindrance caused by the *trans*-arrangement[6] of the methyl and aryl substituents on the coumaran ring in XI.

The reaction sequence proposed for the formation of compound X is based on the following experimental evidence:

The intermediacy of 4′-phenoxy radicals was supported by treating compound VI, in which formation of this type of radical is blocked by etherification of the 4′-hydroxyl group, under similar oxidative conditions. No dimeric product was formed and the starting material was recovered in almost quantitative yield in two stereoisomeric forms (TLC, NMR and mass spectra).

The intermediate formation of radical IX



I $R_1 = H$, $R_2 = R_3 = OH$

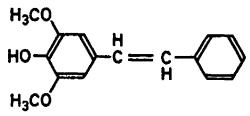
II $R_1 = H$, $R_2 = R_3 = OOCCH_3$

III $R_1 = R_3 = OH$, $R_2 = H$

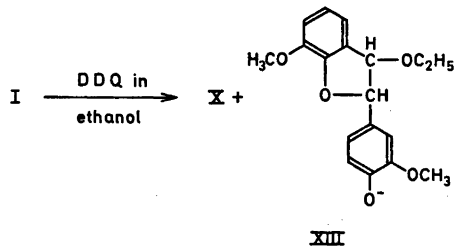
IV $R_1 = R_3 = OOCCH_3$, $R_2 = H$

V $R_1 = H$, $R_2 = OH$, $R_3 = OCH_3$

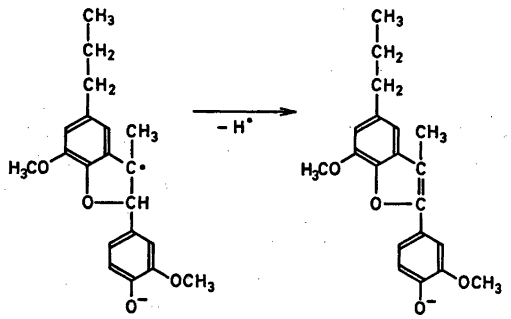
VI $R_1 = H$, $R_2 = OOCCH_3$, $R_3 = OCH_3$



VII



XIII



XI XII

and/or VIIIb during oxidation was demonstrated as follows: The 2,4′-dihydroxystilbene derivative I, when oxidised with an equimolar amount of DDQ in ethanol for 30 min, gave, in addition to compound X, isolated as the diacetate (62 %), another major product (about 12 %) which was identified as the ethoxy-substituted arylcoumaran derivative XIII. It is, thus, concluded that formation of the latter, either by combination of radical IX or its quinonemethide precursor VIIIb with a solvent radical, or by addition of ethanol to the appropriate carbonium ion of the quinonemethide type, competes with dimerisation.

In addition to the dimer (X), small amounts of vanillin, guaiacol, and of three further (unidentified) compounds were detected in the form of their acetates by GLC-MS (*cf.* also Ref. 3).

Oxidation of 4,4′-dihydroxy-3,3′-dimethoxystilbene. Similar oxidative treatment of compound IV and working-up of the resulting reaction mixture gave the acetates of the following compounds: vanillil (XIV, main product), vanillin, guaiacol and acetoguaiacone, as well as a polymeric fraction. The acetates were identified by their melting points, NMR- and mass spectra.

It is suggested that the main product, vanillil (XIV), is formed as shown in Scheme 1.

In the first one-electron oxidation step, a stilbene semiquinone (phenoxy radical XVa and its mesomeric form, the quinonemethide radical XVb) is generated. This step is common to the oxidation of both types of dihydroxystilbenes investigated here. However, whereas the quinonemethide radical VIIIb derived from the 2,4′-dihydroxystilbene I cyclises (formation of IX) and dimerises (formation of X), the radical (XVb) derived from the 4,4′-dihydroxyisomer (III) undergoes a second one-electron oxidation, giving rise to the 4,4′-stilbenequinone XVI. Addition of hydroxyl ions to this *bis*-quinonemethide results in the formation of the anion of hydrovanilloin (XVII) which is then oxidised to vanillil (XIV).

The proposed intermediacy of stilbenequinone XVI and hydrovanilloin (XVII) in the formation of vanillil (XIV) was supported by the fact that XVI and XVII, when treated under similar conditions as used for the reaction of III, afforded XIV in high yields. Treatment of hydrovanilloin (XVII) with alkali in an atmosphere of nitrogen did not yield any XIV.

Vanillil (XIV) was found many years ago [7] in the reaction mixture obtained after oxidation of lignosulfonates by cupric oxide. The

compound was considered to arise from $C_\alpha - C_\alpha$ linked lignin units by oxidative cleavage of the rest of the side chains.[7-9] However, the 1,2-diarylpropane-1,3-dihydroxy structures, shown to be present in lignins.[10-12] constitute a more likely source of vanillil.[13] Their conversion into 4,4'-dihydroxy-3,3'-dimethoxystilbene (III) by the action of alkali has been previously [11,12] illustrated in model experiments and the oxidation of this stilbene with oxygen in alkali *via* the corresponding stilbenequinone to vanillil (*cf.* Ref. 14) has now been demonstrated. In contrast to its behaviour towards cupric oxide and alkali,[7-9] vanillil when treated with oxygen-alkali under the aforementioned conditions does not undergo benzilic rearrangement and oxidative decarboxylation.

Vanillin, the other product formed in appreciable amounts (29 %) from compound IV on the oxidative treatment, presumably arises mainly by oxidative cleavage of the stilbene double bond.[15] However, the formation of guaiacol and acetoguaiacone in minor amounts (3 and 4 %, respectively) indicates that alkaline (non-oxidative) fragmentation may also operate (*cf.* the behaviour of compound II and Ref. 3)

CONCLUSIONS

From the results of the model experiments reported in this work, it may be concluded that hydroxystilbene structures generated in lignins during various pulping processes [2,3] are extensively oxidised by oxygen in alkaline media. Thus, 2,4'-dihydroxystilbene structures yield either arylcoumaran structures by coupling of the intermediate β-radicals with each other or with other radical species, or arylcoumarone structures by oxidation of the β-radical intermediates. 4,4'-Dihydroxystilbene structures are converted to benzil structures by oxidation of the β-radical and stilbenequinone intermediates.

These conversions of dihydroxystilbenes in alkaline media require the presence of oxygen. If air (oxygen) is replaced by nitrogen or if the treatment is carried out in aqueous alkali containing sulfide ions ("white liquor"),* the unchanged dihydroxystilbene can be recovered in a high yield. The isolation of the arylcoumarone XII after treatment of dihydrodehydro-diisoeugenol with white liquor reported previously [3] could only be reproduced if a sufficient amount of oxygen was present in the solution during the treatment.

The results imply that the oxidation of the hydroxystilbene structures formed in lignins during various pulping processes will be extensive during alkali pulping and, particularly, during oxygen-alkali pulping. During sulfate pulping, however, the cooking liquor usually does not contain sufficient oxygen (*cf.* also Refs. 16 and 17) to bring about extensive oxidation of hydroxystilbene structures. The latter may therefore be expected to survive this pulping treatment. Assuming phenoxy- and β-radicals are formed in the first oxidation step by the action of oxidants other than oxygen (*e.g.* quinonoid structures [18]), they would presumably be reduced to the initial hydroxystilbene structures by the reducing sulfur compounds present in the white liquor. In fact, spectrophotometric data indicating the presence of hydroxystilbene structures in lignins from sulfate spent liquors have been reported [18,19] and stilbene III has recently [20] been isolated from a sulfate spent liquor.

The products of oxidation in alkaline media identified in the present work do not include stilbenequinones regarded as possible contributors to the color of sulfite pulps [21] and bisulfite pulps.[22] During the oxidation of 4,4'-dihydroxystilbenes in alkaline solution, stilbenequinone chromophores only appear as intermediates, whereas similar oxidation of 2,4'-dihydroxystilbenes does not even proceed *via* stilbenequinones (*cf.* also Ref. 4). For all these reasons it seems doubtful whether hydroxystilbene structures are converted to chromophoric systems of the stilbenequinone type during the sulfate cook. If such chromophoric systems actually are present in the residual lignins of sulfate pulps or in lignins obtained from sulfate spent liquors, they probably have been formed by autoxidation of the isolated products rather than by oxidation during the pulping process.

Sulfate pulps and sulfate lignins are light-yellow immediately after isolation from the pulping liquor. On exposure to air a rapid

* The term "white liquor" refers to a solution of NaOH (3.5 g) and $Na_2S.9H_2O$ (3.1 g) in water (100 ml).

discolouration takes place, the products assuming the well-known brown colour. Pulps and lignins produced by treatment of wood with oxygen-alkali are significantly lighter in colour than technical kraft pulps and lignins compared at the same degree of delignification. This difference in colour could be explained, at least partly, by the presence of dihydroxystilbene intermediates. Such structures would remain unaffected during sulfate pulping and afford stilbenequinone chromophores on subsequent exposure to air, whereas treatment with oxygen-alkali would remove them by oxidation to arylcoumaran, arylcoumarone and benzil structures.

These oxidation products, like the parent dihydroxystilbenes, do not constitute chromophoric systems *per se*. However, hydroxy-substituted stilbene, arylcoumarone and benzil structures could possibly explain part of the absorption of alkali and sulfate lignins in the near ultraviolet region (*cf.* Refs. 18 and 19). The conjugated double bond in the first two structures and the carbonyl groups in the last structures may function as efficient sensitising groups during the light-induced discoloration and degradation of pulps.[23,24]

EXPERIMENTAL

Melting points are corrected. Evaporations were carried out under reduced pressure.

Thin-layer (TLC) and column chromatography. The reaction mixtures and the various fractions from the column chromatographic separations were investigated by thin-layer chromatography using silica gel HF_{254} (E. Merck, Darmstadt) as adsorbant and light petroleum – ethyl acetate (2:1) as solvent system. Vanillin dissolved in conc. sulfuric acid served as developer. The preparative separations were carried out by column chromatography on silicic acid (Merck 60, 120 – 230 mesh) using the same solvent system.

NMR spectra were recorded on a Perkin-Elmer R-12 spectrometer using deuteriochloroform as solvent and tetramethylsilane (TMS) as internal standard. Chemical shifts (δ values) are given in ppm downfield from TMS.

Mass spectra (MS) were run on a Perkin-Elmer 270 instrument at 20 eV using the direct inlet system or the combination with a gas-liquid chromatograph (GLC); column: silicon OV-1 (3 %) on Gas Chrom Q washed with conc. hydrochloric acid and treated with dimethyldichlorosilane. The temperature of the probe heater was between 110 and 230 °C; detector: 280 °C; injector: 180 °C.

UV spectra were recorded on a DK-2 Beckman spectrophotometer.

Model compounds

The hydroxystilbenes I, III, V and acetoxystilbenes II, IV, and VI used in this study were prepared as described in Part I [1] of this series. Stilbenequinone XVI was obtained by oxidation of stilbene III with DDQ [5] (see below). Hydrovanilloin (XVII) was prepared by electrolytic reduction of vanillin according to Ref. 25.

Treatment of the model compounds with oxygen-alkali. The model compound in the form of the acetate (100 – 300 mg) was heated in 2 M sodium hydroxide (3 – 10 ml) in the presence of oxygen for 3 h at the temperatures given below. After neutralisation with carbon dioxide, the solution was repeatedly extracted with ethyl acetate. The combined extracts were dried (Na_2SO_4) and evaporated. The residue was acetylated with acetic anhydride-pyridine and the resulting mixture of acetylated compounds was separated into its components by preparative column chromatography and/or gas-liquid chromatography. The acetates were identified by their melting points, elemental analyses, NMR and mass spectra.

Compound II (300 mg, *trans*-form, m.p. 138 – 139 °C), in 2 M sodium hydroxide (10 ml), was heated at 100 °C (steam bath) for 3 h, a slow stream of oxygen passing through the solution. The reaction mixture was worked up and separated as described above. The following fractions were obtained from the column:

(1) Monomeric acetylated phenols (15 mg), consisting mainly of vanillin acetate and guaiacol acetate (GLC-MS).

(2) A crystalline fraction (183 mg, 61 %) which after recrystallization from methanol was identified as *bis-[2-(4'-acetoxy-3'-methoxyphenyl)-7-methoxycoumaran-3]-yl* (diacetate of X), m.p. 185 – 187 °C. (Found: C 68.87; H 5.54; O 25.47. $C_{36}H_{34}O_{10}$ (626.36) requires: C 69.03; H 5.43; O 25.54). NMR: δ 7.00 – 6.10 (m, 12 H, arom. H), 5.45 (d, 2 H, 2 H_α), 4.30 – 3.65 (m, 2 H, 2 H_β), 3.89 (s, 6 H, 2 arom. OCH_3), 3.58 (s, 6 H, 2 arom. OCH_3), 2.20 (s. 6 H, 2 arom. $OCCH_3$). MS: 626 (10, M^+), 584 (5), 313 (20), 271 (100), 243 (15).

(3) Mixture containing the diacetate of X and unknown reaction products (26 mg).

(4) Polymeric fraction (about 70 mg).

Compound VI (300 mg, *trans*-form, m.p. 103 – 104 °C) similarly treated gave a mixture of the two stereoisomers of the starting material, indicating isomerisation *via* the *o*-quinonemethide radical or the *o*-quinonemethide carbanion. One of the isomers was obtained in crystalline form. (Found: C 69.48; H 6.06;

O 24.42. $C_{19}H_{20}O_5$ (328.19) requires: C 69.53, H 6.09, O 24.38). The two forms exhibited almost identical mass spectra MS: 328 (24, M+), 286 (100), 271 (20) but migrated at sufficiently different rates to allow separation of the mixture by TLC and preparative column chromatography. The crystalline isomer turns blue and the amorphous greyish-brown on spraying with vanillin – conc. sulfuric acid, followed by heating.

Investigation of the crude acetylated reaction mixture by GLC-MS revealed the presence of traces of the acetates of vanillin, acetoguaiacone and guaiacol.

Compound IV (300 mg, *trans*-form, m.p. 228 – 229 °C) in oxygen-saturated 2 M sodium hydroxide (10 ml) was heated in an autoclave at 180 °C. Column chromatography of the acetylated reaction mixture afforded in the order given: (1) guaiacol acetate (6.9 mg, 3 %); (2) vanillin acetate (67.3 mg, 29 %); (3) acetoguaiacone acetate (9.3 mg, 4 %); (4) *4,4'-diacetoxy-3,3'-dimethoxybenzil* (vanillil diacetate, diacetate of XIV); 116 mg, 50 %; m.p. 138 – 139 °C. NMR: δ 7.76 – 6.96 (m, 6 H, arom. H), 3.87 (s, 6 H, 2 arom. OCH_3), 2.28 (s, 6 H, 2 arom. $OCCH_3$); λ_{max} (methanol) 262 nm (ε, 25.700) and 318 nm (shoulder) (ε, 15 700); (5) Polymeric material (32.5 mg, 14 %).

After treatment of compound IV (150 mg) with white liquor (10 ml) at 180 °C and usual working-up, starting material (100 mg, m.p. 224 – 227 °C) was recovered. GLC-MS analysis of the acetylation mixture after removal of the starting material showed the presence of small amounts of catechol diacetate, guaiacol acetate and of an unknown compound (M+ 306).

Compound II and the 2,4'-dihydroxystilbene derivative obtained from dihydro-dehydro-diisoeugenol [26] were likewise resistent to treatment with white liquor.

3,3'-Dimethoxy-4,4'-stilbenequinone (XVI) (50 mg) and *hydrovanilloin* (XVII) (50 mg) were similarly treated with oxygen-saturated 2 M sodium hydroxide (6 ml) at 180 °C. In both cases, usual working-up provided high yields (about 90 %) of the diacetate of vanillil (XVI), identical by m.p. (137 – 138 °C) as well as NMR and mass spectra with the product obtained from compound IV.

Treatment of XVII with nitrogen-saturated 2 M sodium hydroxide gave a mixture of phenolic substances which did not contain any detectable amount of compound XIV (TLC).

Oxidation of hydroxystilbenes with DDQ

Compound I [1,4] (m.p. 133.5 – 134.5 °C) (100 mg) was dissolved in anhydrous ethanol (5 ml). An equimolar amount of DDQ (85.2 mg, 0.37 mmol) was added to the solution at room temperature with stirring. After 30 min, the solution was evaporated and the resulting oily residue (210 mg) was chromatographed on a column of silica gel. The first fraction gave an amorphous product which on the basis of its NMR- and mass spectra was identified as *2-(4'-hydroxy-3'-methoxyphenyl)-3-ethoxy-7-methoxycoumaran* (XIII) NMR: δ 6.92 – 6.70 (m, 6 H), 5.47 (d, 1 H), 4.98 (d, 1 H), 3.97 – 3.52 (q, 2 H) 3.83 (s, 3 H), 3.75 (s, 3 H), 1.22 (t, 3 H). MS: 316 (32, M+), 287 (14), 285 (15), 270 (100, M – C_2H_5OH).

The second fraction contained compound X, identical with the main product of oxidation from compound II using oxygen in alkali as oxidant. It was characterised as the diacetate by m.p., NMR and mass spectra (see above).

Compound III (400 mg), dissolved in anhydrous ethanol (20 ml), was similarly oxidised with DDQ [5] (341 mg). The red crystalline precipitate formed was centrifuged off and washed with small portions of ethanol. The *3,3'-dimethoxy-4,4'-stilbenequinone* (*XVI*) thus obtained (300 mg, 75 %) did not have a sharp melting point (182 – 185 °C) (lit. 195 – 205 °C and 202 – 206 °C) [5] but was chromatographically pure.

1,3,5-Trineopentylbenzene. VII.* Friedel-Crafts Reactions of 1,3,5-Trineopentylbenzene with Acyl Chlorides and Preparations of Some Chloro Derivatives of 1,3,5-Trineopentylbenzene

ERIK DAHLBERG, PER MARTINSON** and KÅRE OLSSON

Department of Organic Chemistry, University of Göteborg and Chalmers University of Technology, Fack, S-402 20 Göteborg 5, Sweden

2-Acetyl-1,3,5-trineopentylbenzene, 2-propanoyl-1,3,5-trineopentylbenzene, 2-benzoyl-1,3,5-trineopentylbenzene, 2-(2-methylpropanoyl)-1,3,5-trineopentylbenzene, and 2,4,6-trineopentylbenzenecarboxylic acid have been prepared by Friedel-Crafts acylation of 1,3,5-trineopentylbenzene with acyl chlorides and aluminum chloride in carbon disulfide. NMR, IR, and mass spectra are reported for these novel compounds.

Ring-chlorinated products were formed when 1,3,5-trineopentylbenzene was treated with antimony(V) chloride in carbon disulfide, and thus 1,3,5-trichloro-2,4,6-trineopentylbenzene could be prepared in good yield.

In the present investigation, larger and larger acyl groups were introduced into the ring of 1,3,5-trineopentylbenzene. In some cases, introduction of such groups into polyalkylbenzenes brings about migration [2–5] or removal [6] of alkyl groups, possibly due to steric strain,[7] and it was considered of interest to study acylation reactions of the sterically hindered 1,3,5-trineopentylbenzene.

RESULTS

Dermer *et al.*[8] have examined a series of metal chlorides to determine their relative efficiencies as Friedel-Crafts catalysts. For the acetylation of toluene, the efficiency was found to decrease in the series: aluminum chloride > antimony(V) chloride > iron(III) chloride > tellurium(II) chloride > tin(IV) chloride. For the preparation of 2-acetyl, 2-propanoyl, 2-benzoyl, and 2-(2-methylpropanoyl)-1,3,5-trineopentylbenzene, and 2,4,6-trineopentylbenzenecarboxylic acid (I)–(V) in the present work, aluminum chloride, iron(III) chloride, and tin(IV) chloride were employed as catalysts, and carbon disulfide, dichloromethane, and nitrobenzene as solvents.

Freshly sublimed aluminum chloride caused dealkylation of 1,3,5-trineopentylbenzene to form 1,3-dineopentylbenzene, neopentylbenzene, and 2-methylbutane. The latter product was probably formed by rearrangement of neopentyl groups which had been removed from the 1,3,5-trineopentylbenzene. 1,3-Dineopentylbenzene was formed as the major product by treating 1,3,5-trineopentylbenzene with freshly sublimed aluminum chloride in carbon disulfide for 24 h at room temperature.

It has been reported that the use of acyl halides as acylating agents causes some complications. Acyl halides often decarbonylate in the presence of Friedel-Crafts catalysts, and alkyl cations are formed, which, in some cases, act as alkylating agents.[9,10] In the present case, freshly sublimed aluminum chloride caused

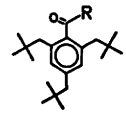

Fig. 1. R = methyl (I), ethyl (II), phenyl (III), isopropyl (IV), or hydroxyl (V).

* Part VI: see Ref. 1. ** Present address: Department of Pharmacology, University of Göteborg, Fack, S-400 33 Göteborg 33, Sweden.

decomposition of the acyl chlorides. This reaction was most significant when 2-methylpropanoyl chloride was used.

The dealkylation of 1,3,5-trineopentylbenzene and the decomposition of the acyl chlorides were minimized when commercial aluminum chloride was used without further sublimation. As has been reported for similar reactions, the improvement of the acylation reaction when commercial aluminum chloride was used may be due to trace amounts of iron(III) chloride [11,12] or products of hydrolysis.[13]

It has been demonstrated [14] that the yield of product often decreases rapidly when the amount of catalyst exceeds the molar amount of the aromatic substrate. In the present case, however, an excess of catalyst improved the acylation reaction in accordance with what was reported by Dermer *et al.*[8]

When 1,3,5-trineopentylbenzene was treated with acetyl chloride and iron(III) chloride in carbon disulfide, 2-chloro-1,3,5-trineopentylbenzene was formed as the major product. Treatment of 1,3,5-trineopentylbenzene with iron(III) chloride in carbon disulfide for 20 h at room temperature gave 40 % of 2-chloro-1,3,5-trineopentylbenzene as the only product.

This can be compared with the report that mesitylene was found to react with iron(III) chloride at room temperature in an aromatic solvent to yield 12 – 19 % of 2,2′,4,4′,6,6′-hexamethylbiphenyl in addition to 24 – 36 % of 2-chloromesitylene.[15] Moreover, an increase in yield of biaryl-type product was found in the order toluene < *m*-xylene < mesitylene, which was correlated with an increase in steric hindrance, basicity, and opportunity for hyperconjugative stabilization of the σ-complex.[16] However, recent studies by Nyberg indicate that the biaryl formation is a cation radical reaction.[17] The absence of biaryl products in the case of 1,3,5-trineopentylbenzene may be explained by the much larger steric demands of *tert*-butyl groups. It can be noted that in the treatment of 1,3,5-trineopentylbenzene with freshly sublimed aluminum chloride (see above) no biaryl or chloro-substituted compounds were formed.

When tin(IV) chloride was used, no acetylation or chlorination took place.

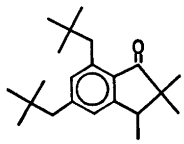
Carbon disulfide was preferred to dichloromethane and nitrobenzene as solvent in the acylation reaction. When 1,3,5-trineopentylbenzene was treated with acetyl chloride and aluminum chloride for 20 h at room temperature in carbon disulfide, dichloromethane, or nitrobenzene, the yields of 2-acetyl-1,3,5-trineopentylbenzene were 80, 30, and 5 %, respectively.

With commercial aluminum chloride as catalyst and carbon disulfide as solvent, compounds (I), (II), and (III) could be prepared in good yields without any side reactions. In the preparation of (IV), under the same conditions, some minor side reactions occurred. If the 2,2-dimethylpropanoylation reaction was interrupted before completion, the only side reaction was the formation of a small amount of 2-chloro-1,3,5-trineopentylbenzene. Attempts to force the reaction toward completion failed because of decomposition of the product (IV).

Compound (V) could be prepared by treating 1,3,5-trineopentylbenzene with oxalyl chloride and aluminum chloride in carbon disulfide.

Attempts to prepare 2-(2,2-dimethylpropanoyl)-1,3,5-trineopentylbenzene *via* acylation failed. The above-mentioned solvents and catalysts, including antimony(V) chloride, were employed. The combination commercial aluminum chloride-dichloromethane was preferred since the main product [*i.e.* (*VI*)] was formed in the highest yield with this combination. The decomposition of 2,2-dimethylpropanoyl chloride was considerable. The main product was formed in about 40 % yield in addition to about 30 different by-products. When the reaction was carried out in carbon disulfide instead of dichloromethane, the yield of the main product decreased and the number of by-products increased. The main product was not 2-(2,2-dimethylpropanoyl)-1,3,5-trineopentylbenzene, however, and none of the other products observed on the gas chromatograms had the same retention time as this compound, which has recently been prepared [18] by a lithium organic reaction. The main product has been identified as 2,2,3-trimethyl-5,7-dineopentyl-1-indanone (*VI*).[19] In this connection, it is interesting to note that successful introduction of the 2,2-dimethylpropanoyl group in mesitylene and a number of polymethylbenzenes has been reported.[7]

It has been reported that aromatic compounds can be chlorinated by antimony(V) chloride,[16] and that chlorinated compounds are formed as by-products when antimony(V) chloride is used



VI

as a Friedel-Crafts catalyst.[8] In the present case, only chlorinated compounds were formed when antimony(V) chloride was used in the presence or absence of an acyl component. 1,3,5-Trineopentylbenzene thus yielded mono-, di- and trichloro-1,3,5-trineopentylbenzene with antimony(V) chloride, parallelling the behavior of mesitylene.[20]

2-Chloro-1,3,5-trineopentylbenzene, 2,4-dichloro-1,3,5-trineopentylbenzene, and 1,3,5-trichloro-2,4,6-trineopentylbenzene were orginally prepared by Márton and Martinson [21] using chlorine gas and iron as a catalyst. In their preparation of 1,3,5-trichloro-2,4,6-trineopentylbenzene, chlorodealkylation occurred and a complex mixture of compounds was formed. In the present case, no side reactions took place, and 1,3,5-trichloro-2,4,6-trineopentylbenzene could be prepared in good yield with antimony(V) chloride as the chlorinating agent.

EXPERIMENTAL

Measurements. Gas chromatographic (GLC) analyses were carried out on a Perkin-Elmer 900 gas chromatograph fitted with a flame ionization detector. The inner diameter of the columns used was 2 mm and the length 2 m. The stationary phase was 3 % of SE-30 silicon gum rubber on Gaschrom Q 100 – 200 mesh. The areas of the peaks on the gas chromatograms were measured by triangulation.

The IR spectra were recorded on a Beckman IR 9 spectrophotometer using potassium bromide pellets. The absorption maxima are reported in cm^{-1} and the intensities are characterized as weak (w), medium (m), strong (s), or very strong (vs).

The NMR spectra were recorded on a Varian A 60 spectrometer. About 10 % by weight solutions in carbon tetrachloride were used. The probe temperature was 35 °C. The chemical shifts are reported in ppm downfield from tetramethylsilane as internal standard. The multiplicities of the peaks are reported as singlet (s), doublet (d), triplet (t), quartet (q), heptet (h) and multiplet (m).

The mass spectra (MS) were determined (at the Department of Medical Biochemistry, University of Göteborg) on an AEI MS 902 mass spectrometer under the following conditions: electron energy 70 eV, accelerating voltage 8 kV and emission 100 μA, or (at the Department of Medical Chemistry, University of Göteborg) on an LKB 9000 mass spectrometer with an electron energy of 70 eV. The latter mass spectrometer was connected to a gas chromatograph with a column containing 3 % of OV-1. The intensities of the peaks are reported in parenthesis as percentages of the base peak. Only the most abundant peaks are reported, together with the parent peaks and the isotope peaks corresponding to the latter.

The melting points were determined on a Kofler micro hot stage.

Materials. Acyl chlorides: Fluka (*purum*). Aluminum chloride: Kistner (*puriss.*). Antimony(V) chloride: Riedel-De Haën (anhydrous, fuming). Silica gel; Merck (neutral, less than 0.08 mm, for column chromatography). Carbon disulfide: Kistner (*purum*). Dichloromethane: Fisher (*p.a.*). The above chemicals were used without further purification, with the exception of aluminum chloride which was sublimed before it was used in some reactions. 1,3,5-Trineopentylbenzene was prepared as described by Martinson and Márton.[22]

Acylations

2-Acetyl-1,3,5-trineopentylbenzene (I). a. With aluminum chloride as catalyst and carbon disulfide as solvent. In a two-necked flask equipped with a magnetic stirrer, a drying tube, and a dropping funnel, 13.9 g (104.1 mmol) of finely powdered aluminum chloride was covered with 50 ml of carbon disulfide, and the flask was then cooled with ice water. The mixture was magnetically stirred and 7.4 ml (104.1 mmol) of acetyl chloride was added. After 15 min 10.0 g (34.7 mmol) of 1,3,5-trineopentylbenzene, dissolved in 20 ml of carbon disulfide, was added dropwise over a period of 30 min. After this addition, the mixture was stirred at room temperature. At regular time intervals small aliquots were withdrawn and analyzed by GLC. The reaction was found to be complete after 15 h, and the flask was then cooled with ice water and the excess of aluminum chloride and acetyl chloride was destroyed with crushed ice. The organic and aqueous layers did not separate well, and therefore the carbon disulfide was evaporated and the aqueous layer was extracted five times with 20 ml portions of hexane. The combined hexane extracts were dried over magnesium sulfate. After evaporation of the solvent, the product was decolorized by adsorption chromatography (alumina, hexane). Recrystallization several times from ethanol (water was cautiously added to the hot solution until turbidity appeared) gave 10.2 g (89 %) of a white crystalline product. *M.p.*: 63 – 65 °C. *IR*: 2962vs, 2910m, 2870m, 1694vs, 1604m, 1565w, 1481s, 1427w, 1396w, 1366s, 1352m, 1280w,

1245s, 1204w, 1148m, 1054m, 980m, 882m, 874m, 780w, 756w, 700w, 607w, 584w, 546w. MS: *m/e* (%) *MS*: 29(13), 41(15), 43(12), 57(41), 147(15), 162(100), 163(13), 219(9), 247(8), 315(20), 330(6.9), 331(1.8), 332(0.2). *NMR*: δ 0.88 (s, 18 H, *tert*-butyl), 0.93 (s, 9 H, *tert*-butyl) 2.28 (s, 3 H, methyl), 2.38 (s, 4 H, methylene), 2.43 (s, 2 H, methylene), 6.75 (s, 2 H, aromatic).

When the acetylation reaction was carried out in 10 ml of carbon disulfide with 1 % of the above-mentioned molar amounts, 2-acetyl-1,3,5-trineopentylbenzene was formed in about 80 % yield after 20 h.

b. With iron(III) chloride as catalyst. The reaction was carried out in 10 ml of carbon disulfide at room temperature with the same molar amounts as in the last experiment described under *a*, but the aluminum chloride was exchanged for iron(III) chloride. A GLC analysis of the mixture after 20 h showed that two products had been formed. 2-Acetyl-1,3,5-trineopentylbenzene had been formed in about 10 % yield, and the other product, which was formed in about 22 % yield, was identified as 2-chloro-1,3,5-trineopentylbenzene.

c. With tin(V) chloride as catalyst. The reaction was carried out at room temperature with the same molar amounts as in *b* but the iron(III) chloride was exchanged for tin(IV) chloride. No products could be detected in the mixture after 20 h (GLC).

d. With dichloromethane as solvent. The reaction was carried out in 10 ml of dichloromethane at room temperature with the same molar amounts as in the last experiment described under *a*. After 20 h, 2-acetyl-1,3,5-trineopentylbenzene had been formed in about 30 % yield (GLC).

e. With nitrobenzene as solvent. The reaction was carried out in 10 ml of nitrobenzene at room temperature with the same amounts of reactants as in *d*. After 20 h, 2-acetyl-1,3,5-trineopentylbenzene had been formed in about 5 % yield (GLC).

2-Propanoyl-1,3,5-trineopentylbenzene (II). The same molar amounts as in the first experiment described under *a* were used, but the acetyl chloride was exchanged for propanoyl chloride. The reaction, which was carried out at room temperature, was found to be complete after 34 h (GLC), and the final yield was 10.1 g (85 %) of white crystals. *M.p.*: 42 – 44 °C. *IR*: 2960vs, 2910m, 2868m, 1705vs, 1609m, 1569w, 1478s, 1465w, 1428w, 1413w, 1395m, 1367s, 1340m, 1228w, 1238s, 1223m, 1202m, 1166w, 1142m, 1076m, 1008w, 948s, 932w, 924w, 882s, 872w, 799w, 790m, 753w, 731w, 656w, 523w. *MS*: 29(19), 41(21), 43(15), 57(49), 71(8), 147(9), 176(13), 204(100), 205(16), 233(18), 260(47), 261(9), 290(6), 315(84), 316(22), 330(27), 331(6), 344(14.6), 345(3.8), 346(0.5). *NMR*: 0.87 (s, 18 H, *tert*-butyl), 0.93 (s, 9 H, *tert*-butyl), 1.11 (t, 3 H, methyl, $J = 7$ Hz), 2.30 (s, 4 H, methylene), 2.43 (s, 2 H, methylene), 2.45 (q, 2 H, methylene, $J = 7$ Hz), 6.76 (s, 2 H, aromatic).

2-Benzoyl-1,3,5-trineopentylbenzene (III). The same molar amounts as in the first experiment described under *a* were used, but the acetyl chloride was exchanged for benzoyl chloride. The reaction, which was carried out at room temperature, was found to be complete after 20 h (GLC). A hexane solution of the crude product was washed several times with 10 % aqueous sodium hydroxide solution to remove the benzoic acid from the organic layer. The organic layer was then washed with water, with dilute hydrochloric acid, and finally again with water. After the solution was dried over magnesium sulfate, the hexane was evaporated, and the product was decolorized by adsorption chromatography (alumina, hexane). Several recrystallizations (ethanol – water) gave 9.2 g (69 %) of crystalline product. *M.p.*: 90 – 92 °C. *IR*: 3062w, 2970vs, 2910m, 2859s, 1675vs, 1603m, 1582w, 1567w, 1477s, 1448m, 1424w, 1393m, 1362s, 1312m, 1288m, 1264s, 1236m, 1199w, 1170m, 1156w, 1116w, 1070w, 1024w, 926s, 897w, 879m, 870w, 797w, 790w, 750w, 706vs, 683m, 648w, 550w. *MS*: 29(39), 39(12), 41(59) 43(26), 57(100), 71(14), 77(14), 91(11), 105(39), 149(18), 209(13), 224(16), 262(16), 265(13), 279(26), 280(33), 335(61), 336(72), 337(18), 377(16), 392(0.9), 393(0.3). *NMR*: 0.82 (s, 18 H, *tert*-butyl), 0.97 (s, 9 H, *tert*-butyl), 2.27 (s, 4 H, methylene), 2.50 (s, 2 H, methylene), 6.87 (s, 2 H, aromatic), 7.1 – 7.7 (m, 5 H, aromatic).

2-(2-Methylpropanoyl)-1,3,5-trineopentylbenzene (IV). The same molar amounts as in the first experiment described under *a* were used, but the acetyl chloride was exchanged for 2-methylpropanoyl chloride. To minimize the decomposition of this acyl chloride, the flask was cooled to – 10 °C before the acyl chloride was added. After this addition and the addition of 1,3,5-trineopentylbenzene, the temperature of the flask was slowly raised to room temperature and the acylation reaction begun. A small amount of gas evolved during the reaction. After 15 h a main product, which was later identified as 2-(2-methylpropanoyl)-1,3,5-trineopentylbenzene, had been formed in about 91 % yield (GLC), and a by-product, which was later identified as 2-chloro-1,3,5-trineopentylbenzene, had been formed in about 1 % yield (GLC). The work-up procedure described for 2-benzoyl-1,3,5-trineopentylbenzene was then applied. The two products and the unreacted 1,3,5-trineopentylbenzene were separated on a column of silica gel. With hexane as eluent, 1,3,5-trineopentylbenzene was eluted, followed by 2-chloro-1,3,5-trineopentylbenzene. 2-(2-Methylpropanoyl)-1,3,5-trineopentylbenzene was eluted with diethyl ether. Several recrystallizations (ethanol – water) of 2-(2-methylpropanoyl)-1,3,5-trineopentylbenzene gave 9.4 g (76 %) of white crystals. *M.p.*: 56 – 58 °C. *IR*: 2968vs, 2910m,

2868m, 1700vs, 1605m, 1567w, 1480s, 1470w, 1426w, 1396m, 1384w, 1366s, 1332w, 1289w, 1239s, 1221m, 1202w, 1135m, 1085w, 990w, 972s, 961w, 917w, 885m, 862w, 796m, 756w, 713w, 647w, 528w. *MS*: 29(6), 41(10), 43(14), 57(19), 71(7), 259(11), 315(100), 316(25), 343(10), 358(0.7), 359(0.2). *NMR*: 0.86 (s, 18 H, *tert*-butyl), 0.93 (s, 9 H, *tert*-butyl), 1.05 (d, 6 H, methyl, $J = 7$ Hz), 2.30 (s, 4 H, methylene), 2.44 (s, 2 H, methylene), 2.64 (h, 1 H, methine, $J = 7$ Hz), 6.77 (s, 2 H, aromatic).

2,4,6-Trineopentylbenzenecarboxylic acid (V). Aluminum chloride (2.53 g, 19.0 mmol) was covered with 20 ml of carbon disulfide and the flask cooled in an ice bath. Oxalyl chloride (1.62 ml, 19.0 mmol) was slowly added, and the mixture was stirred for 15 min before a solution of 4.9 g (17.0 mmol) of 1,3,5-trineopentylbenzene in 10 ml of carbon disulfide was added dropwise over a period of 30 min with continued stirring. The mixture was then reflux for 7 h before being poured into a mixture of 35 g of ice and 5 ml of concentrated hydrochloric acid. The organic layer was separated off, and the aqueous layer was extracted with three 10 ml portions of carbon disulfide. The combined organic layers were washed with two 10 ml portions of water and were then extracted with 20 ml of ice-cold 10 % sodium hydroxide solution. Acidification of the extract with 6 M hydrochloric acid liberated the 2,4,6-trineopentylbenzenecarboxylic acid which soon precipitated. The precipitate was collected and washed with water on a filter and was then dried in a desiccator. The tan-colored crude product (2.3 g) was recrystallized first from acetone and then from carbon tetrachloride to yield 1.9 g (34 %) of white crystals. *M.p.*: 164.5–165.5 °C. *IR*: 2955vs, 2907s, 2870s, 2655m, 2550m, 1688vs, 1606m, 1561w, 1480s, 1451m, 1427m, 1393m, 1364s, 1298s, 1279m, 1261m, 1237m, 1202w, 1182w, 1153w, 1094m, 930w(broad), 879w, 779w, 749w. *MS*: 29(20), 41(25), 43(9), 57(84), 71(5), 164(100), 165(11), 220(38), 221(6), 276(6), 317(10), 332(2.4), 333(0.7). *NMR*: 0.94 (s, 27 H, *tert*-butyl), 2.48 (s, 2 H, methylene), 2.81 (s, 4 H, methylene), 6.87 (s, 2 H, aromatic), 12.27 s, 1 H, carboxylic).

Attempts to prepare 2-(2,2-dimethylpropanoyl)-1,3,5-trineopentylbenzene. 1. With aluminum chloride as catalyst. The reaction was carried out in 30 ml of dichloromethane using 50 % of the molar amounts used in the first experiment described in *a* under the heading 2-acetyl-1,3,5-trineopentylbenzene, but the acetyl chloride was exchanged for 2,2-dimethylpropanoyl chloride. To minimize the decomposition of this acyl chloride, the flask was cooled to −35 °C before the acyl chloride was added. After this addition and the addition of 1,3,5-trineopentylbenzene the temperature of the flask was slowly raised to room temperature, and products started to form. Gases evolved during the reaction. After 10 h the mixture was worked up as described for 2-benzoyl-1,3,5-trineopentylbenzene. The resulting oil was shown by GLC to consist of about 40 % of a main product and about 60 % of a complex mixture of about 30 compounds. The main product has been identified as 2,2,3-trimethyl-5,7-dineopentyl-1-indanone.[19]

2. With antimony(V) chlorine as catalyst. A solution of antimony(V) chloride (1.33 ml, 10.41 mmol) in 20 ml of carbon disulfide was cooled with ice water, and 2,2-dimethylpropanoyl chloride (1.28 ml, 10.41 mmol) was added After 15 min 1,3,5-trineopentylbenzene (1.0 g, 3.47 mmol), dissolved in 10 ml of carbon disulfide, was added over a period of 30 min. The reaction mixture was then stirred at room temperature. After 12 h the reaction mixture was worked up as described for 2-benzoyl-1,3,5-trineopentylbenzene. The crystalline product was shown by GLC to consist of two product. The minor product (3 %) was identified as 2-chloro-1,3,5-trineopentylbenzene and the other one as 2,4-dichloro-1,3,5-trineopentylbenzene. The products were separated on a column of silica gel. With hexane as eluent, 2,4-dichloro-1,3,5-trineopentylbenzene was eluted, followed by 2-chloro-1,3,5-trineopentylbenzene. Yields: 2-chloro-1,3,5-trineopentylbenzene, 12 mg (1 %), 2,4-dichloro-1,3,5-trineopentylbenzene, 1.0 g (80 %). *MS*: The masses of the molecules were determined by high-resolution mass spectrometry. For 2-chloro-1,3,5-trineopentylbenzene the value 322.243 ± 0.005 u was found. The value [23] for $C_{21}H_{35}{}^{35}Cl$ is 322.243 u. 29(15), 41(23), 43(15), 57(100), 71(8), 154(42), 155(6), 156(17), 210(31), 211(6), 212(10), 265(13), 266(10), 307(8), 322(8.5), 323(2.1), 324(3.1), 325(0.8). For 2,4-dichloro-1,3,5-trineopentylbenzene the value 356.202 ± 0.005 u was found for the mass of the molecule. The value [23] for $C_{21}H_{34}{}^{35}Cl_2$ is 356.204 u. 29(10), 41(24), 43(12), 57(100), 71(7), 188(34), 190(22), 244(16), 246(10), 299(10), 300(7), 301(7), 341(4), 356(2.9), 357(0.7), 358(1.9), 359(0.5), 360(0.4). The m.p. and NMR and IR spectra were identical with those reported [21] for the two compounds.

Treatments of 1,3,5-trineopentylbenzene with Friedel-Crafts catalysts. a. With freshly sublimed aluminum chloride. Freshly sublimed aluminum chloride (0.69 g, 5.19 mmol) was covered with 15 ml of carbon disulfide, and a solution of 0.50 g (1.73 mmol) of 1,3,5-trineopentylbenzene in 5 ml of carbon disulfide was added. The mixture was then stirred at room temperature, and after 24 h the composition of the mixture was determined by GLC. Three products were detected, in addition to unreacted 1,3,5-trineopentylbenzene. The mixture was investigated with an LKB 9000 mass spectrometer which was connected to a gas chromatograph, before it was worked up as described for 2-acetyl-1,3,5-trineopentylbenzene. The total yield, including the remaining reactant was 0.40 g, and the products were separated on a column of silica gel with hexane as eluent. The products were identified as 1,3-dineopentylbenzene, neo-

pentylbenzene, and 2-methylbutane. The ratios of the amounts of 1,3,5-trineopentylbenzene, 1,3-dineopentylbenzene, and neopentylbenzene were 0.5:1:0.6, as estimated from the gas chromatogram. *MS*: 1,3-Dineopentylbenzene. 29(16), 41(23), 57(99), 71(5), 77(5), 91(14), 103(5), 104(7), 105(17), 106(100), 107(86), 115(5), 131(5), 161(13), 162(13), 203(14), 218(13.6), 219(2.6), 220(0.1). *NMR*: 1,3-Dineopentylbenzene. 0.92 (s, 18 H, *tert*-butyl), 2.44 (s, 4 H, methylene), 6.6 – 7.2 (m, 4 H, aromatic). The aromatic part of the spectrum clearly indicated that the compound was the *meta* isomer. *MS*: Neopentylbenzene. 29(12), 39(11), 41(24), 51(6), 57(85), 65(15), 91(64), 92(100), 93(7), 105(8), 115(5), 133(12), 148(18.3), 149(2.3), 150(0.1). These values are in accordance with those reported for neopentylbenzene.[24a] *MS*: 2-Methylbutane. 27(25), 29(30), 39(19), 41(73), 42(95), 43(100), 55(7), 56(25), 57(73), 72(11), 73(0.5). These values are in accordance with those reported for 2-methylbutane.[24b]

b. With commercial aluminum chloride. Commercial aluminum chloride (0.28 g, 2.07 mmol) was covered with 10 ml of carbon disulfide. A solution of 0.20 g (0.69 mmol) of 1,3,5-trineopentylbenzene in 5 ml of carbon disulfide was then added dropwise and the mixture was stirred at room temperature. A GLC analysis of the mixture after 20 h showed that only small amounts (altogether < 1 % of the above-mentioned aromatic substrate) of dealkylated products had been formed. No other products could be detected.

c. With iron(III) chloride. The reaction was carried out at room temperature with the same molar amounts as in *b*, but the aluminum chloride was exchanged for iron(III) chloride. A GLC analysis of the mixture after 20 h showed that one product had been formed in about 40 % yield. This product was identified as 2-chloro-1,3,5-trineopentylbenzene. No other products could be detected.

d. With tin(IV) chloride. The same molar amounts as in *b* were used. A GLC analysis of the mixture after 20 h at room temperature showed only starting material.

e. With antimony(V) chloride. The reaction was carried out at room temperature in 30 ml of carbon disulfide with twice the molar amounts used in *a*, but the aluminum chloride was exchanged for antimony(V) chloride. Two products which were later identified as 2,4-dichloro-1,3,5-trineopentylbenzene and 1,3,5-trichloro-2,4,6-trineopentylbenzene were formed. The composition of the mixture changed as follows (GLC): 1 h, 94 % of 2,-4-dichloro-1,3,5-trineopentylbenzene and 6 % of 1,3,5-trichloro-2,4,6-trineopentylbenzene; 2 h, 40 and 60 %, respectively; 4 h, 20 and 80 %, respectively. After 4 h the reaction mixture was worked up as described for 2-acetyl-1,3,5-trineopentylbenzene. The two products were separated on a column of silica gel. With hexane as eluent, 1,3,5-trichloro-2,4,6-trineopentylbenzene was eluted, followed by 2,4-dichloro-1,3,5-trineopentylbenzene. Yields: 2,4-dichloro-1,3,5-trineopentylbenzene 0.15 g (13 %), 1,3,5-trichloro-2,4,6-trineopentylbenzene 0.95 g (70 %). The physical properties of the products were in accordance with those reported.[20]

Synthesis and Proton Magnetic Resonance Studies of 2,2,3-Trimethyl-5,7-dineopentyl-1-indanone and the Corresponding Indanol and Indan

ERIK DAHLBERG, PER MARTINSON* and KÅRE OLSSON

Department of Organic Chemistry, University of Göteborg and Chalmers University of Technology, Fack, S-402 20 Göteborg 5, Sweden

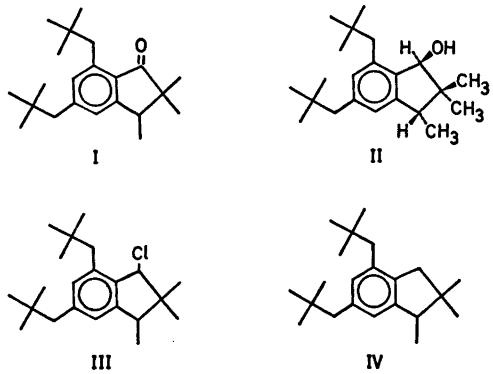
2,2,3-Trimethyl-5,7-dineopentyl-1-indanone was formed by a ring-closure reaction when 1,3,5-trineopentylbenzene was treated with 2,2-dimethylpropanoyl chloride or carbon monoxide under Friedel-Crafts conditions. Its structure was determined by means of several spectroscopic methods including the europium-shift NMR technique. 60 MHz NMR studies showed that the 7-methylene group formed an AB spectrum due to the inherent assymmetry in the five-membered ring. Stepwise reduction of 2,2,3-trimethyl-5,7-dineopentyl-1-indanone to the corresponding indanol and indan gave further evidence for the structure. NMR studies of the indanol showed that the configuration of the hydroxyl group at carbon 1 and the methyl group at carbon 3 was *trans*.

In an earlier publication[1] an unsuccessful attempt to prepare 2-(2,2-dimethylpropanoyl)-1,3,5-trineopentylbenzene is described. The main product was isolated from the complex reaction mixture and has now been identified as 2,2,3-trimethyl-5,7-dineopentyl-1-indanone (I). The present paper deals with the preparation and identification of this particular compound and some of its derivatives.

The compound (I) has been prepared in two ways. The first one is by treatment of 1,3,5-trineopentylbenzene with 2,2-dimethylpropanoyl chloride and aluminum chloride in dichloromethane. The second one consists of a reaction between 1,3,5-trineopentylbenzene and carbon monoxide in dichloromethane with aluminum chloride as catalyst.

* Present address: Department of Pharmacology, University of Göteborg, Fack, S-400 33 Göteborg 33, Sweden.

The assigned structure of I is based on the following observations. High-resolution mass spectrometry gave the mass 314.261 ± 0.002 u, which gives the molecular formula $C_{23}H_{34}O$. The presence of two *tert*-butyl groups was indicated by the mass spectrum. The IR spectrum had an absorption at the same wavenumber (1710 cm^{-1}) as the carbonyl stretching of indanone.[2] From the NMR spectrum, it could be concluded that the molecule contains two *meta*-coupled ($J = 1$ Hz) aromatic protons (δ 6.83 and 7.02), two *tert*-butyl groups with different chemical shift values (δ 0.91 and 0.95), two isolated methyl groups with different chemical shift values (δ 1.01 and 1.17), a methyl-methine grouping (δ 1.26 and 3.03, $J = 8$ Hz), a methylene group with magnetically equivalent protons (δ 2.58), and a methylene group in which the protons are nonequivalent (δ 3.09, $J = 12$ Hz).



I II III IV

The 2,2,3-trimethyl-1-indanone structure could be assigned to I, in preference to the 2,3,3-trimethyl-1-indanone structure, on the basis of the chemical shifts. The methine and methyl resonances of 2,2,3-trimethyl-1-indanone have been reported to be δ 3.05 (quartet), 1.03 (singlet), 1.20 (singlet), and 1.28 (doublet), respectively, in deuteriochloroform.[3] A comparision can also be made with the methyl (δ 1.05) and methine (δ 2.64) resonances of the isopropyl group in 2-(2-methylpropanoyl)-1,3,5-trineopentylbenzene,[1] whereas in 1,3,5-triisopropylbenzene the methine protons absorb at δ 2.84.

To get further information on the pattern of substitution in the alicyclic ring, I was reduced by lithium tetrahydridoaluminate to the indanol (II). This resulted in changes in the NMR resonance frequencies, but induced no additional splitting of the methine resonance. This indicates that the methyl groups are in the 2,2,3-positions.

The indanol (II) was converted to the corresponding indan (IV) by treatment with sulfinyl chloride to form the chloro-substituted compound III, followed by treatment with lithium in liquid ammonia. The NMR spectrum of (IV) showed *tert*-butyl, 3-methylene and aromatic resonance at δ 0.91, 2.60, and 6.60, respectively. These values are in close agreement with those in 2,2-dimethyl-4,6-dineopentylindan (δ 0.90 and 0.92, 2.65, 6.60 and 6.69).[4]

The chemical shifts of the aromatic hydrogens and the neopentyl groups in the NMR spectrum of I lead us to suggest that the neopentyl groups are in positions 5 and 7 rather than 4 and 6. The hydrogen in the peri-position in 9-fluorenone absorbs at δ 7.58[5] and the *ortho* hydrogens in acetophenone absorb at δ 7.95.[6] The aromatic hydrogens of I absorb at δ 6.83 and 7.02, which is taken as evidence that they are in the 4 and 6 positions. In addition, the large down-field shift of the magnetically nonequivalent methylene hydrogens in one of the neopentyl groups of I indicates that this group is in the 7 position, deshielded by the carbonyl group.

In an attempt to further confirm the structural assignements above, the effect of $Eu(fod)_3$-d_{27}[7] on the NMR spectrum of I was studied. The paramagnetic pseudocontact shift, Δ_{Eu},[8] for the different hydrogens was estimated from the NMR data and is tabulated in Table 1. From these data it can be found that all the signals shifted in the manner that could be expected for the suggested structure. A plot of the Δ_{Eu}-values *vs.* $(3\cos^2\theta-1)/r^3$ according to the McConnel-Robertson equation[9] gave a good linear correlation (see Fig. 1) if the Eu-ion was placed at a distance of 3.0 Å from the carboxyl oxygen on a straight line connecting the carbon and oxygen atoms of the carbonyl group. The distances r and the angles θ were estimated from a Dreiding molecular model in which the aromatic and five-membered ring and the carbonyl group were coplanar. The suggested non-coplanarity of I (see below) is probably of no importance for these estimations. Much poorer correlation was found with the alternative structure discussed above (see Fig. 2).

Table 1. Δ_{Eu}-values for compound (I). For the designation of the hydrogens see Fig. 1.

Protons	Δ_{Eu} (ppm)
a	0.9
b	1.1
c	1.7
d	1.7
e	1.9
f	2.1
g	4.0
h	5.1
i	5.3
j	5.3

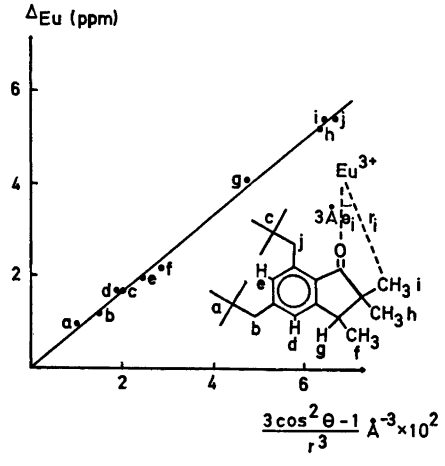


Fig. 1. Plot of Δ_{Eu}-values *vs.* $(3\cos^2\theta-1)/r^3$ for compound (I).

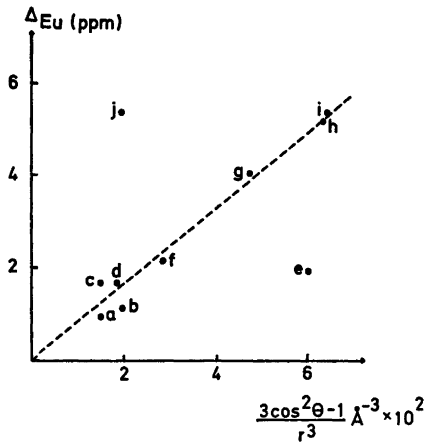

Fig. 2. Plot of Δ_{Eu}-values *vs.* $(3\cos^2\theta-1)/r^3$ for the hypotetical alternative structure 2,2,3-trimethyl-4,6-dineopentyl-1-indanone. The 5- and 7-aromatic hydrogens are designated d and e, respectively. The hydrogens of the methylene groups of the 4- and 6-neopentyl groups are designated b and j, respectively, and the hydrogens of the *tert*-butyl groups of the 4- and 6-neopentyl groups are designated a and c, respectively. For the designation of the other hydrogens see Fig. 1.

The methylene protons of the neopentyl group at carbon 7 of the indanone (I) are magnetically nonequivalent, but those of the neopentyl group at carbon 5 are magnetically equivalent. Heating I to 200 °C in deuteriobromoform caused only a slight decrease of the relative chemical shifts between the two methylene protons of the 7-neopentyl group. If the nonequivalence were due to restricted rotation in the molecule, the barrier to internal rotation, $\Delta G^{\ddagger}$, should have to be at least as high as 23 kcal/mol ($\Delta G^{\ddagger}$(200 °C) = 23.7 kcal/mol), which is considered less probable.

In order to rationalize this nonequivalence, we suggest that the carbonyl group is noncoplanar with the benzene ring in the predominant conformation of I, due to the unsymmetrical pattern of substitution in the five-membered ring. The nonequivalence of the methylene protons of the 7-neopentyl group would thus mainly be induced by the large magnetic field from the carbonyl group.

The distance between the carbonyl group and the methylene protons of the 5-neopentyl group is too large for the asymmetric field from the carbonyl group to be of importance, and thus these protons appear as a singlet.

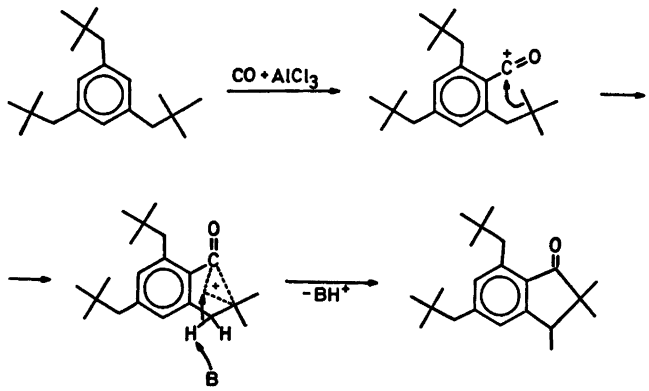
It is interesting to note that 1,2,2-trimethyl-4,6-dineopentylindan (IV) does not show magnetic nonequivalence in the methylene groups. This is explained by the absence of the field from the carbonyl group.

2,2,3-Trimethyl-5,7-dineopentyl-1-indanol (II) has two centers of chirality. Of the two possible (diastereomeric) pairs of enantiomers, only one seems to have been formed in the reduction of I with lithium tetrahydridoaluminate. The close similarity of the shifts of the geminal 2-methyl groups (δ 1.00 and 1.03) indicates that the 1-hydroxyl group and the 3-methyl group are situated on different sides of the plane of the five-membered ring. In contrast it has been reported [3] that the product of sodium tetrahydridoborate-reduction of 2,2,3-trimethyl-1-indanone showed NMR resonances at 0.68 and 1.18 ppm for the geminal 2-methyl groups and a structure with the 1-hydroxyl and the 3-methyl group on the same side of the ring plane was there assigned.

The stereoisomeric difference between II and 2,2,3-trimethyl-1-indanol [3] may be explained by the difference in the reducing agents [10] and/or in steric hindrance.

The suggested mechanism of formation of I with carbon monoxide is outlined in Scheme 1. It is suggested that the same mechanism is valid for the alternative synthesis, including 2,2-dimethylpropanoyl chloride, since this acyl chloride is known to decarbonylate easily under Friedel-Crafts conditions.[11] 1,3,5-Trineopentylbenzene is carbonylated to form an acylium cation, which undergoes an intramolecular reaction between the electron-deficient carbon and a carbon-carbon bond of one of the neighboring *tert*-butyl groups. The methyl group at the two-electron, three-center bond then effects an electrophilic substitution of one of the hydrogens of the methylene group to form the final product. An interesting feature of this mechanism would be that the formation of the three-center bond occurs between the electron-deficient carbon and a carbon-carbon bond and not a carbon-hydrogen bond of a methyl group. The latter mechanism has been suggested for a formation of 1,1-dimethyl-4,6-di-*tert*-butylindan from 2,4,6-tri-*tert*-butylbenzyl alcohol.[12]

We have rejected, as less possible, a mecha-



Scheme 1. Tentative mechanism of formation of 2,2,3-trimethyl-5,7-dineopentyl-1-indanone (I).

nism involving benzylic hydride ion abstraction from 1,3,5-trineopentylbenzene, followed by a 1,2-methyl shift and a carbonylation of the cation thus formed with concomitant ring closure, *cf.* Ref. 13. In a separate study [1] it was shown that commercial aluminum chloride had no effect on 1,3,5-trineopentylbenzene. This is in accordance with the known resistance to oxidation of an aromatic neopentyl group.[14]

EXPERIMENTAL

Measurements. Gas chromatographic (GLC) analyses were carried out on a Perkin-Elmer 900 gas chromatograph fitted with a flame ionization detector. The inner diameter of the columns used was 2 mm and the length 2 m. The stationary phase was 3 % of SE-30 silicon gum rubber on Gaschrom Q 100 – 200 mesh. The areas of the peaks on the gas chromatograms were measured by triangulation.

The IR spectra were recorded on a Beckman IR 9 spectrophotometer using potassium bromide pellets or a potassium bromide cell. The absorption maxima are reported in cm^{-1} and the intensities are characterized as weak (w), medium (m), strong (s), or very strong (vs).

The NMR spectra were recorded on a Varian A 60 spectrometer. About 10 % by weight solutions in carbon tetrachloride were used. The probe temperature was 35 °C. The chemical shifts are reported in ppm downfield from tetramethylsilane as internal standard. The multiplicities of the peaks are reported as singlet (s), doublet (d), and quartet (q). The spectrum of 2,2,3-trimethyl-5,7-dineopentyl-1-indanone (I) was also determined in deuteriochloroform with successive additions of tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-d_6-4,6-octanedione-d_3)europium(III), [Eu(fod)$_3$-d_{27}]. The chemical shift values found for each protons or group of protons for each addition of europium(III) were plotted as functions of the molar ratios X = [Eu(fod)$_3$]/[Compound (I)] and linear correlations were made. The Δ_{Eu}-values were then defined for each proton or group of protons as the difference in the extrapolated chemical shifts for $X = 1$ and the actual chemical shifts for $X = 0$.

The mass spectra (MS) were determined (at the Department of Medical Biochemistry, University of Göteborg) on an AEI 902 mass spectrometer under the following conditions: electron energy 70 eV, accelerating voltage 8 kV and emission 100 μA, or (at the Department of Medical Chemistry, University of Göteborg) on an LKB 9000 mass spectrometer with an electron energy of 70 eV. The latter mass spectrometer was connected to a gas chromatograph with a column containing 3 % of OV-1. The intensities of the peaks are reported in parenthesis as percentages of the base peak. Only the most abundant peaks are reported, together with the parent peaks and the isotope peaks corresponding to the latter.

Materials. Aluminum chloride: Kistner (*puriss*). Dichloromethane: Fisher (*p.a.*). Lithium tetrahydridoaluminate: Metallgesellshaft AG, Frankfurt a. M. Hexane: Fisher (*p.a.*). Sulfinyl chloride: Kistner (*puriss*). 1,3,5-Trineopentylbenzene was prepared as described by Martinson and Márton.[15]

2,2,3-Trimethyl-5,7-dineopentyl-1-indanone (I). a. A stirred suspension of aluminum chloride (7.0 g, 52.2 mmol) in 20 ml of dichloromethane was cooled to −35 °C and 2,2-dimethylpropanoyl chloride (6.7 ml, 52.2 mmol) was added. After 15 min, 1,3,5-trineopentylbenzene (5.0 g, 17.4 mmol) dissolved in 10 ml of dichloromethane, was added dropwise. The temperature of the flask was then slowly raised to room temperature and products started to form. Gases evolved during the reaction, and after 10 h the excess of aluminum chloride and 2,2-dimethylpropanoyl chloride was destroyed with

water. The aqueous layer was then extracted several times with hexane, and the combined dichloromethane and hexane layers were washed with 10 % aqueous sodium hydroxide solution, then with water, then with dilute hydrochloric acid and finally again with water. The organic layer was dried over magnesium sulfate, and the solvent was evaporated. The resulting oil was shown, by GLC, to consist of about 40 % of a main product and about 60 % of a complex mixture of about 30 compounds. Partial separation was performed on a column of silica gel. Unreacted 1,3,5-trineopentylbenzene and about 10 products were eluted with hexane. The main product was eluted with benzene and collected together with some other products. The column chromatography (silica gel, benzene) was repeated several times to give 2,2,3-trimethyl-5,7-dineopentyl-1-indanone of 97 % purity (GLC). The yield was 1.5 g (27 %) of an oil. *IR:* 2960vs, 2910m, 2865s, 1710vs, 1607vs, 1587s, 1480vs, 1427w, 1394m, 1367vs, 1304s, 1237s, 1202s, 1192s, 1160w, 1133m, 1095w, 992m, 974s, 918m, 890s, 873s, 746m. *MS:* 29(18), 41(27), 43(8), 57(7), 173(8), 187(18), 188(8), 202(100), 203(16), 243(13), 258(32), 299(14), 314(15.6), 315(3.9), 316(0.5). The mass of the molecule was determined by high-resolution mass spectrometry, and the value 314.261 ± 0.002 u was found. The value [16] for $C_{22}H_{34}O$ is 314.261 u. *NMR:* δ 0.91 (s, 9 H, *tert*-butyl), 0.95 (s, 9 H, *tert*-butyl), 1.01 (s, 3 H, methyl), 1.17 (s, 3 H, methyl), 1.26 (d, 3 H, methyl, $J = 8$ Hz), 2.58 (s, 2 H, methylene), 3.03 (q, 1 H, methine, $J = 8$ Hz), 3.09 (q, 2 H, methylene, $J = 12$ Hz, $\Delta\nu_{AB} = 11$ Hz), 6.83 (d, 1 H, aromatic, $J = 1$ Hz), 7.02 (d, 1 H, aromatic, $J = 1$ Hz).

b. To a suspension of 210 mg (1.58 mmol) of aluminum chloride in 5 ml of dichloromethane, a solution of 150 mg (0.52 mmol) of 1,3,5-trineopentylbenzene in 5 ml of dichloromethane was added, and a slow stream of carbon monoxide was bubbled into the mixture. A GLC analysis of the mixture after 24 h showed that a main product had been formed in about 60 % yield together with about 15 minor products. The work-up procedure described in *a* was then applied, and the total yield was 163 mg of an oil. The oil was investigated with an LKB 9000 mass spectrometer connected to a gas chromatograph. The MS of the main product was identical with that reported in *a* for 2,2,3-trimethyl-5,7-dineopentyl-1-indanone.

2,2,3-Trimethyl-5,7-dineopentyl-1-indanol (II). 2,2,3-Trimethyl-5,7-dineopentyl-1-indanone (0.2 g, 0.64 mmol) in 5 ml of diethyl ether was added to a suspension of 0.24 g (6.4 mmol) of lithium tetrahydridoaluminate in 20 ml of diethyl ether. The mixture was refluxed overnigt, and the reaction was then found to be complete (GLC). The flask was cooled and the excess of lithium tetrahydridoaluminate was destroyed with water. The mixture was filtered and the precipitate was washed several times with diethyl ether. The organic and aqueous layers were separated, and the organic layer was dried over magnesium sulfate. After evaporation of the solvent, the product was recrystallized from ethanol-water. The yield was 0.16 g (80 %) of white crystals which, according to GLC, were more than 98 % pure. *IR:* 3390vs, 2950vs, 2902s, 2862s, 1610m, 1591m, 1478s, 1414m, 1392m, 1384w, 1362s, 1235s, 1200m, 1039s, 1025s, 989m, 902w, 875s, 836m, 771m, 749w, 685m. *MS*: 29(26), 41(36), 43(34), 55(9), 57(100), 69(8), 71(23), 132(8), 171(16), 185(30), 186(77), 187(17), 188(17), 189(28), 203(11), 204(36), 227(10), 241(23), 242(94), 243(28), 254(23), 259(13), 260(47), 261(10), 283(11), 298(15), 301(15), 316(55.5), 317(13.6), 318(1.8). The mass of the molecule was determined by high-resolution mass spectrometry, and the value 316.277 ± 0.002 u was found. The value [16] for $C_{22}H_{36}O$ is 316.277 u. *NMR*: δ 0.91 (s, 9 H, *tert*-butyl), 0.94 (s, 9 H, *tert*-butyl), 1.00 (s, 3 H, methyl), 1.03 (s, 3 H, methyl), 1.21 (d, 3 H, methyl, $J = 7$ Hz), 1.35 (d, 1 H, hydroxylic, $J = 7$ Hz), 2.46 (s, 2 H, methylene), 2.65 (q, 1 H, methine, $J = 7$ Hz), 2.72 (q, 2 H, methylene, $J = 13$ Hz, $\Delta\nu_{AB} = 37$ Hz), 4.70 (d, 1 H, methine, $J = 7$ Hz), 6.76 (d, 1 H, aromatic, $J = 1$ Hz), 6.79 (d, 1 H, aromatic, $J = 1$ Hz). After addition of a small amount of water the coupling between the hydroxylic proton (δ 1.35) and the methine proton (δ 4.70) disappeared.

3-Chloro-1,2,2-trimethyl-4,6-dineopentylindan (III). 2,2,3-Trimethyl-5,7-dineopentyl-1-indanol (120 mg, 0.38 mmol) was dissolved in 5 ml of hexane, and 0.1 ml (1.3 mmol) of freshly distilled sulfinyl chloride was added. The mixture was stirred overnight at room temperature, and the reaction was then found to be complete according to GLC. The solvent and the excess of sulfinyl chloride were evaporated. The yield was 127 mg (100 %) of a crystalline product which was used directly in the next step.

1,2,2-Trimethyl-4,6-dineopentylindan (IV). 3-Chloro-1,2,2-trimethyl-4,6-dineopentylidane (127 mg, non-purified product from the above reaction) was dissolved in 3 ml of hexane and added to a solution of 26.6 mg (3.8 mmol) of lithium in 15 ml of liquid ammonia. The mixture was stirred for 2 h. The excess of lithium was then destroyed with water, and the mixture was neutralized with 6 M hydrochloric acid. The aqueous layer was extracted several times with hexane, and the combined hexane extracts were dried over magnesium sulfate. After evaporation of the solvent, the product was decolorized by adsorption chromatography (silica gel, hexane). The yield was 110 mg (96 %, computed on the indanol) of an oil which, according to GLC, was more than 98 % pure. *IR*: 2950vs, 2900w, 2860m, 2840w, 2710w, 1614w, 1588m, 1478s, 1465m, 1391m, 1285w, 1236s, 1200m, 1169w, 1115w, 1044w, 875s, 750m, 645w, 420m. *MS*: 29(10), 41(21), 43(16), 57(31), 71(9), 143(7), 157(9), 173(21), 187(29), 188(73), 189(11), 143(100), 244(53), 285(10), 300(20.1), 301(4.9), 302(0.6). *NMR*: δ 0.82 (s, 3 H, methyl), 0.91

(s, 18 H, *tert*-butyl), 1.12 (d, 3 H, methyl, $J=7$ Hz), 1.16 (s, 3 H, methyl), 2.41 (s, 4 H, methylene), 2.60 (s, 2 H, methylene), 2.74 (q, 1 H, methine, $J=7$ Hz), 6.60 (s, 2 H, aromatic).

Acknowledgements. We thank Professor Lars Melander for his interest in this work and for his constructive criticism during the course of preparation of the manuscript. We also thank Dr. Johanna Andersson for her linguistic corrections. This work has been supported by the Swedish Natural Science Research Council.

Three-dimensional Structure of Usnic Acid

ROLF NORRESTAM,[a] MARIANNE von GLEHN[a] and CARL AXEL WACHTMEISTER[b]

[a] Department of Structural Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden and [b] Wallenberg Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

The three-dimensional structure of the very common lichen substance usnic acid, $C_{18}H_{16}O_7$, has been determined. By the use of single crystal *X*-ray diffraction data collected at −110 °C it was possible to determine the positional parameters of both the 50 nonhydrogen atoms and the 32 hydrogens of the asymmetric unit. The two molecules in the asymmetric unit have almost identical conformations. The six oxygens of each molecule are all involved in intramolecular hydrogen bonds of different strengths giving O···O distances ranging from 2.40 to 2.69 Å. Some information on possible racemization mechanisms can be gained from the present study.

Usnic acid, $C_{18}H_{16}O_7$, is one of the most common lichen substances. Up to 20 % of the dry weight of some lichens consist of this yellow acidic enol. Usnic acid, which is toxic to higher animals and exerts hypermetabolic activity, has to some extent been used as an uncoupler of oxidative phosphorylation in studies of the mechanism of this process. The now accepted structural formula, shown in Fig. 1, has been confirmed through total synthesis.[1] The structural formula implies several possibilities for formation of intramolecular hydrogen bonds. The existence of such hydrogen bonds is indicated by the fact that usnic acid, in spite of its high content of proper hydrogen bond donors and acceptors has pronounced lipophilic properties. Spectroscopic studies on usnic acid, using infrared and proton magnetic resonance techniques, have indicated the existence of three hydrogen bonds of markedly different strengths.[2,3] It has been shown [4,5] from determinations of unit cell parameters, space group symmetry and density, that usnic acid crystallizes with two formula units per asymmetric unit. Thus, the existence of strong intermolecular interactions like, *e.g.*, hydrogen bonds leading to a dimerization and a further complication of the hydrogen bond scheme cannot be ruled out. On the other hand the spectroscopical investigations [2] suggested that all of the three hydrogen bonds indicated are intramolecular.

The X-ray structural investigation of usnic acid, reported in the present paper, has been carried out to obtain the three-dimensional structure, and thereby also clarify the hydrogen bond scheme and the nature of the intermolecular interactions. The crystalline specimen used

Fig. 1. Proposed bond schemes for the two most plausible tautomers of usnic acid.

Table 1. Unit cell dimensions (Å) for usnic acid. (Space group: $P2_12_12_1$. Composition of asymmetric unit: $C_{36}H_{32}O_{14}$).

	Jones and Palmer[4]	This study 22 °C	−110 °C
a	8.09	8.069	8.042
b	19.10	19.058	18.890
c	20.39	20.326	20.264

was obtained by evaporation of a chloroform solution of (−)-usnic acid.

The space group $P2_12_12_1$ was confirmed by X-ray investigations with precession and De Jong-Bouman techniques using Mo$K\alpha$ radiation. In order to be able to locate not only the 50 independent nonhydrogens atoms, but also the 32 hydrogens, it was decided to collect single crystal X-ray diffraction data at low temperature. Thus, the diffraction data were collected at about −110 °C on a single crystal diffractometer using monochromatized Cu$K\alpha$ radiation. In all, 2405 reflections significantly above the background were observed. The cell dimensions determined are given in Table 1.

The structure was solved by the application of direct methods using the variance-weighted phase-sum formulae for phase determination and refinement.[6] Of the 31 highest peaks in the obtained electron density map, 28 were chemically meaningful and were used in the subsequent difference electron density maps and least-squares refinements to locate the remaining 22 nonhydrogen and 32 hydrogen atoms. After least-squares refinement of the structural model, allowing all the nonhydrogens to vibrate anisotropically and using fixed isotropic temperature factors for all hydrogens, the *R* value became 0.04. No attempts to determine the absolute

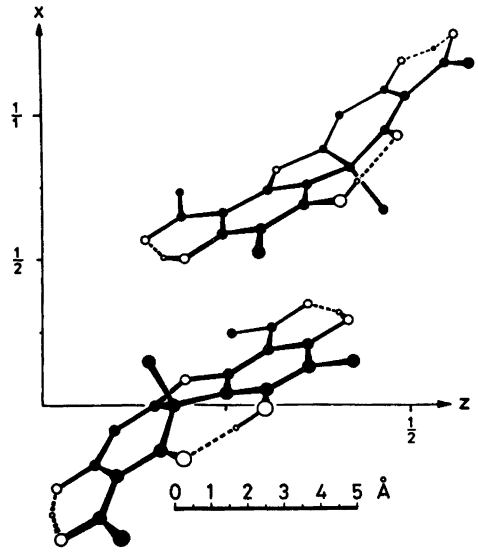

Fig. 2. The molecular geometries of the two molecules of the asymmetric unit. The figures refer to fractional coordinates.

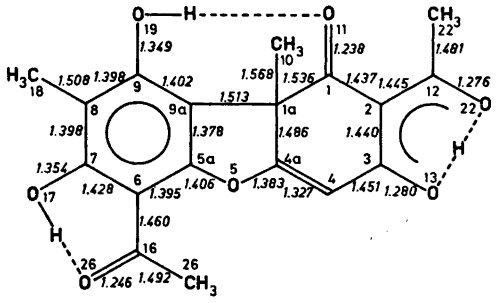

Fig. 3. The obtained intramolecular bond distances averaged over the two molecules of the asymmetric unit.

Table 2. Hydrogen bond distances (Å) and angles (°) in the two independent molecules.

Hydrogen bond	O···O	O−H	H···O	∠O−H···O
O(19)−H···O(11)	2.66	0.99	1.69	166
	2.69	0.84	1.86	170
O(17)−H···O(26)	2.54	0.88	1.69	163
	2.53	1.00	1.58	156
O(13)···H···O(22)	2.40	1.27	1.16	164
	2.41	1.07	1.38	158

configuration from the diffraction data have been made.

The observed molecular geometries and intramolecular distances are shown in Figs. 2 and 3 together with the atomic labels used in this study. As seen, the two molecules have almost identical conformations, they both adopt a kind of butterfly conformation. No short intermolecular distances indicating intermolecular hydrogen bonds were found. The three hydroxyl hydrogens in each molecule are all involved in strong intramolecular hydrogen bonds, giving O···O distances ranging from 2.4 to 2.7 Å. The hydrogen bond distances and angles, listed in Table 2, indicate that the bond strength increases in the order O(19)–H···O(11), O(17)–H···O(26) and O(13)···H···O(22) in consistence with the interpretation of the NMR and IR spectra reported by Forsén *et al.*[8] The very short O···O distance of 2.40 Å in the chelated O(13)···H···O(22) hydrogen bond is significantly shorter than those found in, *e.g.*, the dibenzoylmethanes [7] where a similar intramolecular hydrogen bond situation leads to O···O distances of about 2.47 Å. Distances of about 2.40 Å appears actually to represent the lower limit of O···O distances in hydrogen bonds found sofar.[8] The oxygen-hydrogen distances in the O(13)···H···O(22) hydrogen bond (*cf.* Table 2) suggests that the hydrogen is attached to different oxygen atoms in the two independent molecules in the crystal structure. This would be in agreement with the infrared spectroscopical studies on acetylacetones [9], which indicate that strong but unsymmetrical intramolecular hydrogen bonds would be a general feature of β-diketones. The existence of two different enolic tautomers, due to the differences of the O(13)···H···O(22) hydrogen bonds, would also be an explanation for the two molecules per asymmetric unit in the crystal structure. However, the standard deviations of the oxygen–hydrogen distances, 0.05 Å, and the expected systematic errors when locating hydrogens by X-ray diffraction techniques [10] does not permit any definitive decisions between the alternatives, symmetrical or unsymmetrical hydrogen bonds between O(13) and O(22). Further studies using single crystal neutron diffraction techniques have been initiated.

Fig. 3 shows the intramolecular bond scheme drawn in accordance with the observed bond distances. This bond scheme agrees largely with one of the tautomers of the earlier proposed bond scheme (Fig. 1a) and excludes the other tautomer (Fig. 1b). The only major difference being the complete delocalization of the double bonds over the region O(13)–C(3)–C(2)–C(12)–O(22), which leads to C–O bond lengths of 1.28 Å and C–C bond lengths of 1.44 Å.

Usnic acid of natural origin is represented by both its enantiomers which differ by the configuration around the quaternary carbon atom, C(1a), and is furthermore known to easily undergo thermal racemization in, *e.g.*, boiling xylene solution. The hitherto most widely accepted racemization mechanism is the one suggested by Stork [11] and involves a homolytic loosening of the C(1a)–C(1) bond to form a resonance stabilized diradical. Other suggestions,[12] on the other hand, include a homolytic loosening of the C(1a)–C(9a) bond. A striking support to any of these suggested mechanisms would of course be to observe a correspondingly elongated bond length, due to a weakened C–C bond, in the crystal structure. A certain support for Stork's mechanism might be gained from this study since the bond lengths obtained for the four bonds C(1a)–C(1), C(1a)–C(4a), C(1a)–C(9a), and C(1a)–C(10) around the quaternary carbon atom C(1a) are 1.54, 1.49, 1.51, and 1.57 Å, respectively. Thus, the C(1a)–C(1) distance of 1.54 Å is somewhat larger than the usual C(sp^3)–C(sp^2) bond distance [13] of 1.516 Å. No easy connection between the long (1.57 Å) C(1a)–C(10) distance and a racemization reaction can be formulated. It is noteworthy that the hydrogen bond O(19)–H···O(11), although the weakest of the three intramolecular hydrogen bonds, is of decisive importance for the thermal stability of usnic acid. Thus, the activation energy for racemization of (–)-usnic acid in decalin or toluene is some 4 kcal higher than in typical electron donor solvents as dioxane or tetrahydropyran, which evidently can break the O(19)–H···O(11) bond.[12,14] On the other hand, acetylation of (–)-usnic acid at the hydroxyl group containing O(19) gives a monoacetate [2] for which the corresponding low activation energy is largely independent of solvent type.[14]

This investigation is part of a research program with financial support from the Swedish Natural Science Research Council.

Kinetics and Other Characteristics of Diamine Oxidase of Pea Seedlings

ULF NYLÉN and PETER SZYBEK

Biokemi 1, Kemicentrum, P.O.B. 740, S-220 07 Lund 7, Sweden

1. Spectrophotometric titration with phenylhydrazine has given evidence that diamine oxidase of pea seedlings contains one mol of reactive carbonyl groups per mol of enzyme.

2. The effect of variation in concentration of five amine substrates and oxygen, on the steady-state kinetic behaviour, have been studied in detail. The kinetics are found to conform to a Dalziel rate equation without ϕ_{12} term, and thus the enzymatic reactions are proposed to follow a ping-pong mechanism. Investigation of the pH dependence of the enzyme has given strong indication that for good binding the amine group in the substrate, which participates in the oxidation, must be uncharged, while the other amine group ought to be positively charged.

3. Electron paramagnetic resonance spectra showed that the protein-bound copper is not significantly reduced in the presence of substrate under anaerobic conditions, but a distinct shift in the signal gives evidence for a change in the way that the copper is bound.

Diamine oxidase of pea seedlings, like kidney diamine oxidase and plasma amine oxidase (benzylamine oxidase), contains copper [1–4] and a functional carbonyl group, which in the case of the last two enzymes is almost certainly pyridoxal phosphate.[5–6] However, attempts to demonstrate pyridoxal phosphate in pea seedling diamine oxidase have been unsuccessful.[7]

The presence and requirement of Cu^{2+} in the enzyme is well established,[1–4] but its function is not understood. Cupric ions are required to activate copper-free oxidase of pea seedlings,[4] bovine plasma,[8] and pig kidney.[9] Electron paramagnetic resonance studies have provided strong evidence that no change in valence state of copper occurs in benzylamine oxidase of blood plasma during catalysis.[10] The situation in the case of pig kidney diamine oxidase is more obscure, and evidence for reduction of copper has been reported.[11] The present investigation gives evidence for no reduction of copper in diamine oxidase of pea seedlings in the presence of substrate under anaerobic conditions.

The catalytic mechanism for the enzyme has not been well clarified. For some other amine oxidases strong evidence has been given for a ping-pong mechanism.[12–14] The present study attempts to clarify some characteristic kinetic behaviour of pea seedling diamine oxidase, and to see whether a mechanism similar to that found with other amine oxidases can be applied to this enzyme with its much higher specific activity.

MATERIALS AND METHODS

Diamine oxidase was prepared from pea seedling as described by Hill and Mann,[4] followed by column chromatography on Sephadex G-200. The enzyme thus obtained was 80 – 90 % pure according to specific activity tests, and was used for most of the experiments. For determination of the amino acid composition, the enzyme was further purified by analytical gel electrophoresis at pH 7.8. Preparations thus obtained had a specific activity of 85 U based on protein estimations with the Folin-Ciocalteau method as modified by Lowry *et al.*[15] and oxygen consumption measurements with a Clark electrode combined to an Eschweiler Combi-analysator U. The electrophoretically purified enzyme was used as a reference for almost pure enzyme. The specific activity was well above that reported by Hill and Mann [4] for an almost pure enzyme preparation. However, they used somewhat different

estimation procedures which may account for the discrepancy.

Other chemicals used in this investigation were of highest available purity. ^{14}C-Putrescine was obtained from Amersham, and catalase (2 times crystallized from bovine liver) was obtained from Sigma.

Titration with phenylhydrazine. Titrimetric experiments with phenylhydrazine at pH 7.2 in 0.2 M phosphate buffer were carried out according to methods previously described.[16] The concentration of the inhibitor hydrazine was such that 2 – 6 portions were required to reach the equivalence point. The enzyme selected for these experiments was more than 85 % pure according to specific activity determinations. In contrast to what has been found with other hydrazines,[4,17] the equilibration between phenylhydrazine and enzyme was very rapid. However, to ensure that equilibrium was attained, the reaction was allowed to proceed for 2 min after each addition of phenylhydrazine before measurements were made. 15 μl of this enzyme suspension were then assayed in the presence of 4 mM putrescine.

Steady-state kinetic methods. The enzymatic activity of diamine oxidase of pea seedlings was determined from the initial oxygen consumption at various concentrations of oxygen and amine substrate. The 2.5 ml reaction vessel contained enzyme, substrate and 50 μg catalase in 0.2 M potassium phosphate buffer. Above pH 8.0, 0.15 M potassium phosphate and 0.05 M potassium borate was used as the buffer. Estimations of initial activity were not possible at very low oxygen concentration. However, as the product inhibition is very low with all the substrates examined, except tryptamine, the kinetics at various oxygen concentrations could be determined by following oxygen consumption continuously until all the oxygen was consumed. The same procedure was used with tryptamine as substrate, but initial activity estimations were made down to an oxygen concentration of 5 μM, so that the product formed never exceeded 10 μM and the product inhibition could be neglected.

Transient-state kinetic methods. Transient-state kinetic experiments were performed in the Aminco-Morrow stopped-flow apparatus described by Lindström *et al.*[10] Anaerobic conditions were attained by the pumping-flushing technique described by Carrico *et al.*[18]

Electron paramagnetic resonance spectra of diamine oxidase. EPR spectra of diamine oxidase (about 80 % pure) were recorded at pH 8.0 in a Varian E-3 spectrometer at 77 K and 9.2 GHz. Spectra of the substrate-reduced form of the enzyme were determined in presence of 4 mM putrescine. The substrate was added as a solution directly into the EPR tube in an amount that diluted the enzyme by 20 %, and made the enzyme completely reduced and the solution anaerobic within a few seconds.

Table 1. Amino acid composition found in acid hydrolysate from electrophoretically purified diamine oxidase of pea seedling. Values are expressed as mol of amino acid per mol of methionine found in the hydrolysate.

Aspartic acid	16.8
Threonine [a]	9.2
Serine [a]	26.5
Glutamic acid	24.3
Proline	Not determined because of interference
Glycine	22.1
Alanine	11.2
Half-cystine	–
Valine	7.6
Methionine	1.0
Isoleucine	7.0
Leucine	8.2
Tyrosine	4.3
Phenylalanine	4.9
Histidine	4.7
Lysine	6.6
Tryptophan	–
Arginine	4.5
Ornithine	5.8

[a] Compensated for degradation during 24 h hydrolysis in 6 M HCl.

RESULTS

General properties. The general properties of the enzyme preparations used in the present investigation agree in all essential features with those reported by Hill and Mann.[2,4,20] The amino acid composition of the electrophoretically purified enzyme (Table 1) shows an unusually high content of ornithine, and as no half-cystine was observed, sulfur bridges seem to be absent in the enzyme.

Active site titration with phenylhydrazine. Pea seedling diamine oxidase like amine oxidase from pig kidney [9] and blood plasma,[19] shows a broad and fairly weak absorption in the visible region. On addition of phenylhydrazine the enzyme solution turns yellow due to the formation of an absorption band centered around 435 nm. Equilibrium is rapid and essentially completed within 15 s after each addition of phenylhydrazine at an enzyme concentration of 15 μM. No further change in absorption could be observed after addition of a threefold excess of phenylhydrazine, but the enzyme still showed

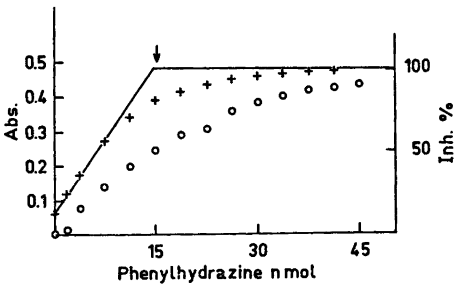

Fig. 1. Spectrophotometric titration of pea seedling diamine oxidase with phenylhydrazine. (+) shows the titration of 15.0 nmol enzyme in 1 ml 0.1 M phosphate buffer, pH 7.0, with 5 μl or 10 μl portions of 375 μM phenylhydrazine. measured at 435 nm; (O) shows the inhibition found simultaneously. Absorbancies and inhibitions have been corrected for dilution effects, and refer to a volume of 1 ml. Arrow indicates point of equimolar amounts of enzyme and inhibitor.

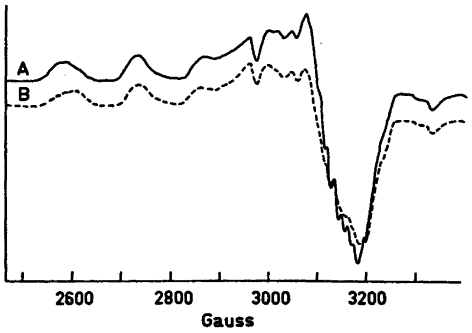

Fig. 2. Electron-paramagnetic-resonance spectra of 80 % pure diamine oxidase at 77 K and 9.2 GHz. Spectra were recorded at pH 8.0 in 0.4 ml aerobic 0.2 M phosphate buffer (A) and in an anaerobic solution after addition of 80 μl of a 24 mM solution of putrescine (B).

a low activity if measured in the presence of 4 mM putrescine (Fig. 1). The residual activity may be explained by the competition between substrate and hydrazine, as has been found with other hydrazines.[17] From Fig. 1, the number of active sites per molecule of enzyme is estimated graphically to be close to one, assuming a molecular weight of 96 000.[4] In an attempt to provide evidence for the presence of pyridoxal phosphate, indicated by the binding of hydrazines, the enzyme was reacted with ^{14}C-putrescine in an anaerobic solution, and reduced with $NaBH_4$, as described by Buffoni.[5] The treatment led to a significant incorporation of radioactivity into the protein, but no product which would indicate pyridoxal phosphate in the native enzyme was identified from paper electrophoresis at pH 3.6 after acid hydrolysis.

Electron paramagnetic resonance spectra of the enzyme. Fig. 2A shows the EPR spectrum of an 80 % pure preparation of pea seedling diamine oxidase as such, and Fig. 2B shows the spectrum recorded after reduction of the enzyme with an excess of substrate. The main features of the spectra indicate that the EPR signal arises largely from protein-bound Cu^{2+}. However, the contribution from an overlapping signal is possible on the basis of comparison with the EPR spectra reported for pig kidney diamine oxidase[11] and benzylamine oxidase.[10] This might be related to the presence of small amounts of Mn^{2+}, which has been reported as an impurity in pea seedling diamine oxidase preparations which are not homogeneous.[20] Integration of the spectra in Fig. 2 showed that there is no reduction of copper in the presence of a large excess of substrate, but the minor shifts observed for the two low-field hyperfine lines indicate a significant change in the binding situation of copper.

Kinetic experiments. Several amine oxidases have been reported to conform to a ping-pong mechanism.[12,14] As for pea seedling diamine oxidase, the ping-pong mechanism has been proposed from kinetic experiments with tryptamine by Yamasaki *et al.*[17] Attempts to verify their results showed that the strong product inhibition observed with tryptamine as substrate could substantially affect the results. The investigations described in this paper are therefore necessary for a more careful evaluation of the mechanism.

Preliminary experiments with different substrates showed that the apparent K_m for O_2 was always very low and was dependent on the nature and the concentration of the amine substrate. With poor substrates such as benzylamine the apparent affinity for oxygen was too high for a determination of the apparent K_m for O_2 (< 1 μM). Detailed kinetic studies of steady-state rate behaviour of the enzyme were carried out using the substrates: putrescine, cadaverine, histamine, tryptamine, and lysine. Each substrate was found to give linear and

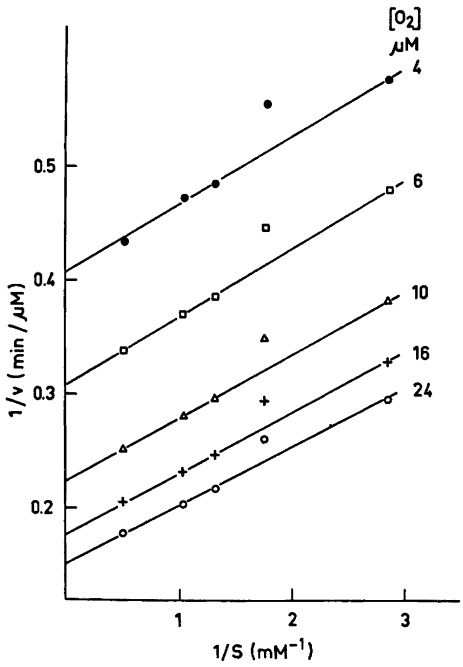

Fig. 3. Lineweaver-Burke plots of the effect of putrescine concentration on the rate of oxidation at different fixed concentrations of oxygen. Reaction solutions contained the diamine oxidase, catalase, and the substrates at 25 °C in 0.2 M phosphate buffer, pH 7.0.

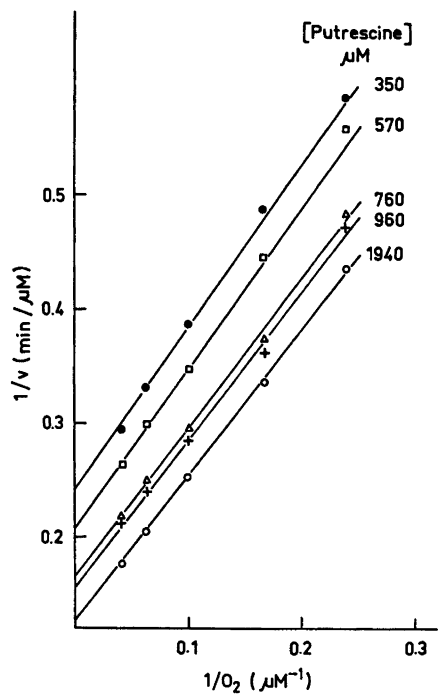

Fig. 4. Lineweaver-Burke plots of the effect of oxygen concentration on the rate of oxidation at various fixed concentrations of putrescine. Conditions as in Fig. 3.

parallel reciprocal plots when the oxygen concentration was varied at different constant substrate concentrations or *vice versa*, as is exemplified with putrescine (Figs. 3 and 4) and histamine (Figs. 5 and 6) at pH's 7.0 and 7.2, respectively. These data are consistent with the rate equation:

$$C_e/v = \phi_0 + \phi_1/\phi_2 + \phi_2/S \qquad (1)$$

As can be seen from Fig. 7 estimates of ϕ_1 obtained for the different substrates, except histamine, exhibit no significant variation with pH over the range 6 – 9. In reality the small variation observed may be ascribed to limitations in the function of the pO_2 apparatus at oxygen concentrations below 3 μM. Figs. 8 and 9 show that both ϕ_0 and ϕ_2 are strongly dependent on pH and vary in magnitude for the different substrates. Slopes of the straight lines obtained in plots of log ϕ_2 *vs* pH (Fig. 8) are essentially independent of the substrate, but the magnitude of ϕ_2 is obviously quite dependent on the nature of the substrate. ϕ_0 shows a minimum between pH 7.5 and 8.3 for all the substrates except histamine. Thus histamine deviates markedly in the behaviour of both ϕ_0 and ϕ_1 compared with the other substrates. In order to exclude the possibility that histamine reacts with a second active site in the enzyme or with some other enzyme present in the preparation, the influence of histamine on oxygen consumption was determined in the presence of cadaverine. The Lineweaver-Burke plots in Fig. 10 show that there is a strict competition between the two substrates for the same site in the enzyme.

Anaerobic-transient-state-kinetic experiments. If diamine oxidase of pea seedling is reduced by substrate under anaerobic conditions, the absorption band centered around 500 nm is replaced by bands with maxima at 466, 437.5, and 350 nm.[4] The formation of these bands and the disappearance of the 550 nm band was found to be very fast in the presence of 2 mM

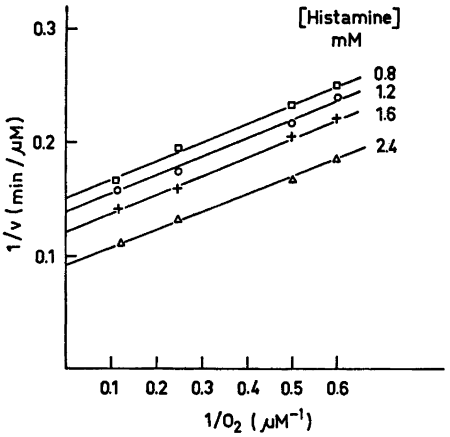

Fig. 5. Lineweaver-Burke plots of the effect of oxygen concentration on the rate of oxidation at various fixed concentrations of histamine. Conditions as in Fig. 3 except that pH was 7.2.

histamine. At 25 °C and pH 7, most of the absorption changes were within the dead-time (5 ms) of the instrument, but from what was registered all the chromophore changes seemed to be simultaneous.

DISCUSSION

Pea seedling diamine oxidase, pig kidney diamine oxidase and benzylamine oxidase are closely related in many respects. All these enzymes catalyze the oxidation of various amines

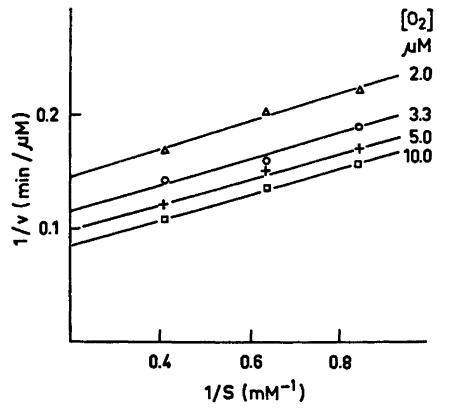

Fig. 6. Lineweaver-Burke plots of the effect of histamine concentration on the rate of oxidation at various fixed concentrations of oxygen. Conditions as in Fig. 5.

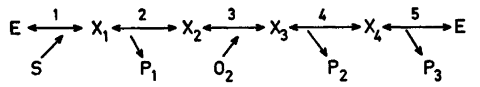
by molecular oxygen with the formation of the corresponding aldehydes, ammonia, and hydrogen peroxide. In this paper evidence is given that diamine oxidase of pea seedlings, like two other amine oxidases, conform to the rate equation (1), which for the other enzymes, has been taken as evidence for a ping-pong mechanism.[12,14] The results in this paper are in accordance with the mechanism in Scheme 1, suggested for benzylamine oxidase by Taylor *et al.*[14] The kinetic investigation cannot, however, provide any information as to the order in which the different products are released. If the kinetics are estimated under circumstances where no product inhibition is observed, steps 2, 4, and 5 can be regarded as irreversible, and thus:
$\phi_0 = 1/k_2 + 1/k_4 + 1/k_5$, $\phi_1 = (k_{-3} + k_4)/k_3k_4$, and $\phi_2 = (k_{-1} + k_2)/k_1k_2$. An examination of the different ϕ_i terms (Figs. 7, 8, and 9) shows that,



Scheme 1. The ping-pong mechanism suggested by Taylor *et al.*[14] for reactions catalyzed by benzylamine oxidase. S stands for amine substrate and P_i for the formed products. X_i denotes intermediately formed enzymatic species.

contrary to what is found with benzylamine oxidase,[10] the maximum activity under physiological conditions is largely independent of the oxygen concentration (ϕ_1).

For benzylamine oxidase a mechanism has been proposed, where the unprotonated amine is the real substrate.[21,22] A similar situation seems very likely for diamine oxidase of pea seedlings, as log (ϕ_2) decreases almost linearly with pH. All the substrates give slopes close to -1 (-0.6 to -0.9), which would be expected if only the substrates with uncharged amine groups can be oxidized by the enzyme, as the amine groups that participate in the oxidation always have pK_a's above 9.5. If this assumption is taken into account, the linear decreases of log (ϕ_2) *vs.* pH would largely reflect the increasing substrate concentration with increasing pH. The magnitude of ϕ_2, and most likely the binding of the substrate to the enzyme is, however, strongly dependent on the structure and the ionization of the substrate. All substrates of pea seedling diamine oxidase have one primary amine group which participates in the oxidation procedure, one hydrophobic region in the middle, and one specific region at the other end of the molecule. According to the nature of the specific region, the substrates can be divided into three main groups, which are characterized by different ϕ_2 values. Low ϕ_2 values are found in the first group, which contains substrates with a positively charged primary amine in the specific part of the substrate. Substrates in the second group are mainly uncharged in the specific part and are characterized by intermediate ϕ_2 values. High ϕ_2 values are found in the third group, which contains substrates with both a positively and negatively charged group in the specific part of the substrate.

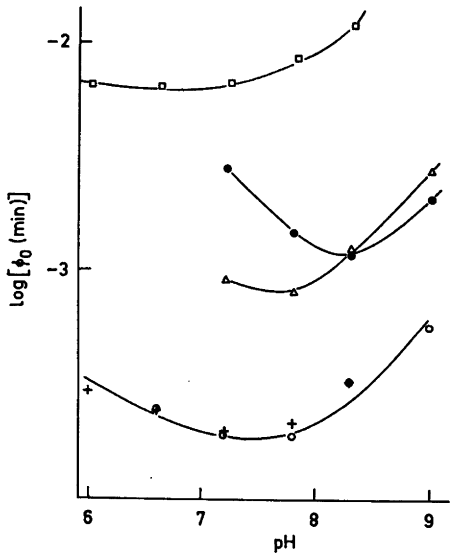


Fig. 9. Logarithmic plots of ϕ_0 for various substrates *vs.* pH. Symbols and conditions as in Fig. 7.

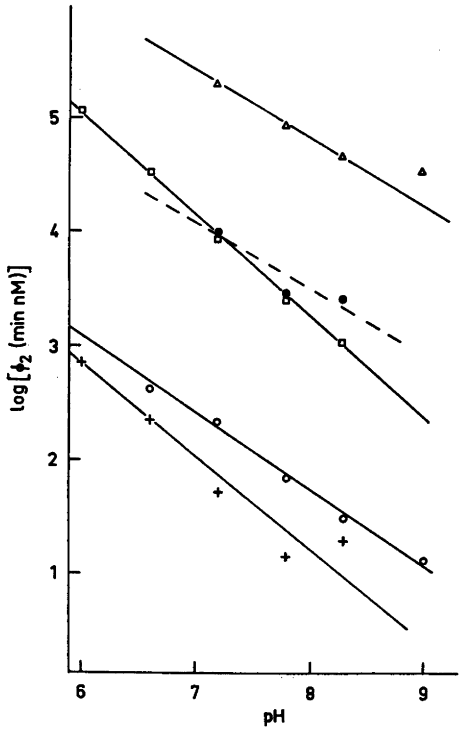

Fig. 8. Logarithmic plots of ϕ_2 for various substrates *vs.* pH. Symbols and conditions as Fig. 7.

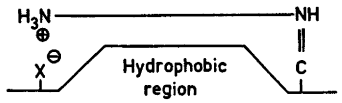
The mode of enzyme-substrate interaction may, according to the discussion above, be described as in Scheme 2, proposed for pig kidney diamine oxidase.[22] The negatively charged group of the enzyme proposed in Scheme 2 is most likely a carboxyl group. Preliminary experiments in this laboratory have shown, that modification of carboxyl groups with carbodiimide causes strong inhibition of pea seedling diamine oxidase activity. This inhibition may



Scheme 2. The binding situation proposed for enzyme-substrate interaction with pig kidney diamine oxidase by Barsley *et al.*[22] (X) stands for a negatively charged group in the enzyme.

be due to modification of the negatively charged group proposed in Scheme 2.

From Figs. 7 and 9 it is clear that the behaviour of ϕ_0 and ϕ_1 differs markedly between histamine and all the other substrates used. The difference in ϕ_0 can be explained by the low pK_a for the imidazole moiety in histamine, which causes deprotonization mainly between pH 6 and 7, thus resulting in a poorer binding situation at high pH. The cause of the much higher ϕ_1 obtained with histamine is more difficult to explain but might reflect a negative co-operation between the imidazole moiety of the substrate and a group of the enzyme which participates in the binding of oxygen.

A valence change of copper could not be detected after reaction of diamine oxidase and substrate in an anaerobic solution. This does not exclude the possibility that reduction of copper may be an obligatory step in the catalytic mechanism, as has been pointed out by Mondovi *et al.*[11] A rapid redox equilibration between certain enzymatic species, favouring those containing copper in the oxidized state, would result in less than stoichiometric reduction of the electron paramagnetic resonance signal by substrate under anaerobic conditions. If such a situation exists in the case of diamine oxidase of pea seedlings, it may be concluded that the anaerobic equilibrium concentration of enzyme species containing copper in the reduced state is less than 5 % of the total enzyme concentration. The present investigation does not, however, give any indication of a valence change of copper during catalysis.

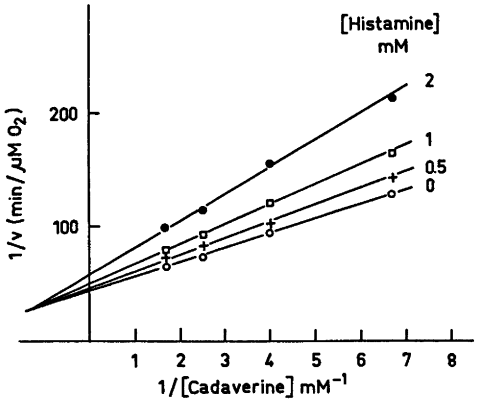


Fig. 10. Lineweaver-Burke plots of the effect of cadaverine concentrations on the rate of oxidation at various fixed concentrations of histamine. Conditions as in Fig. 3 except that pH was 7.2.

From this investigation it is clear that diamine oxidase of pea seedlings is closely related to other amine oxidases in many respects. Thus, all amine oxidases investigated show ping-pong mechanism. However, contrary to benzylamine oxidase,[10] the rate determining steps in catalysis with pea seedling diamine oxidase are independent of the oxygen concentration under physiological conditions. The function of copper must be quite similar for all the enzymes, even if it is doubtful that the cofactor is pyridoxal phosphate in pea seedling diamine oxidase.

Refinement of the Crystal Structure of L-DOPA Hydrochloride and a Comment on the Structure of α-Amino Acids

ARVID MOSTAD and CHRISTIAN RØMMING

Department of Chemistry, University of Oslo, Oslo 3, Norway

The crystal structure of L-DOPA hydrochloride has been refined by X-ray crystallographic methods using 2122 observed reflections with $0.3 < \sin\theta/\lambda < 0.8$. The final conventional R-factor is 0.030, standard deviations in bond lengths are less than 0.002 Å and in angles about 0.1°. The conformation of the carboxyl group has been shown to deviate from what is usually found in that the carbonyl oxygen atom is in *anti* position relative to the nitrogen atom about the $C-C_\alpha$ bond. The geometry of this particular conformation in α-amino acids is discussed.

The crystal structure determination of L-mimosine sulfate hydrate [1] demonstrated the presence of a conformation of the carboxylic group not commonly found in α-amino acids, *i.e.* an *anti*-planar arrangement of the atoms in the N−C−C=O group. A brief search in the literature yielded only one further example of this conformation in protonized α-amino acids, namely histidine hydrochloride,[2] although more examples may be found in some peptides and in other types of carboxylic acids. However, an indication of the same conformation was found in the report on the structure of L-DOPA hydrochloride.[3] We have undertaken the refinement of the structure of the latter compound to an accuracy sufficient for establishing the geometry of the amino acid group.

EXPERIMENTAL AND REFINEMENT

Crystals of L-DOPA hydrochloride were formed by evaporation of a solution of the compound in hydrochloric acid. A single crystal ground to a sphere (radius 0.18 mm) was used in the X-ray experiments.

Unit cell dimensions were determined from diffractometer measurements of 12 general reflections using MoK_α radiation ($\lambda = 0.71069$ Å). In good agreement with the data given by Jandacek and Earle [3] they were found to be: $a = 6.271(0.002)$ Å; $b = 5.835(0.001)$ Å; $c = 15.660(0.003)$ Å; $\beta = 112.65(0.02)°$. The space group is $P2_1$.

Intensity data were recorded with the use of an automatic Picker diffractometer using graphite crystal monochromated MoK-radiation. The take-off angle was 4° and the temperature was 18 ± 1 °C during the data collection. The $\omega - 2\theta$ scan technique was used with a 2θ scan speed of 1° min^{-1} through the scan range from 0.6° below $2\theta(\alpha_1)$ to 0.6° above $2\theta(\alpha_2)$. Background counts were taken for 30 s at each of the scan range limits. The intensities of three standard reflections were measured at intervals during the intensity data measurements; they showed no systematic variations. The standard deviations were taken as $\sigma(I) = (C_T + (0.02C_N)^2)^{\frac{1}{2}}$ where C_T is the total number of counts and C_N the scan count minus background count. The measurements included 2408 unique reflections with $\sin\theta/\lambda$ less than 0.8. Of these 2265 had net intensity larger than 2.5 $\sigma(I)$ and were regarded as observed reflections whereas the remaining reflections were excluded from the further calculations.

The intensity data were corrected for Lorentz, polarization, and absorption ($\mu = 0.4$ mm^{-1}) effects.

Atomic form factors used were those of Doyle and Turner [4] for the chloride ion and oxygen, nitrogen, and carbon atoms, and of Stewart, Davidson and Simpson [5] for hydrogen. A description of the computer programs employed during the refinement procedure is given in Ref. 6.

The first attempt to refine the structure on the basis of the coordinates given by Jandacek and Earle was without success as it turned out that all negative signs for positional parameters were left out of their paper. The structure was redetermined using the position of the chlorine

Table 1. Fractional coordinates ($\times 10^5$ for heavy atoms and $\times 10^3$ for hydrogen atoms) and thermal parameters ($\times 10^5$ for heavy atoms, the temperature factor is given by $\exp-(B11h^2+B22k^2+B33l^2+B12hk+B13hl+B23kl)$). Standard deviations (in parentheses) apply to the least significant figures.

atom as the heavy atom, and the model was refined by the usual methods. The full-matrix least-squares refinement program applied minimizes $\sum w(F_o-F_c)^2$ where w is the inverse of the variance of the structure factor. The parameters varied were all positional coordinates (except for one origin defining y coordinate), anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms. The latter were constrained to be equal for groups of hydrogen atoms with presumably equal vibrations, *i.e.* hydrogen

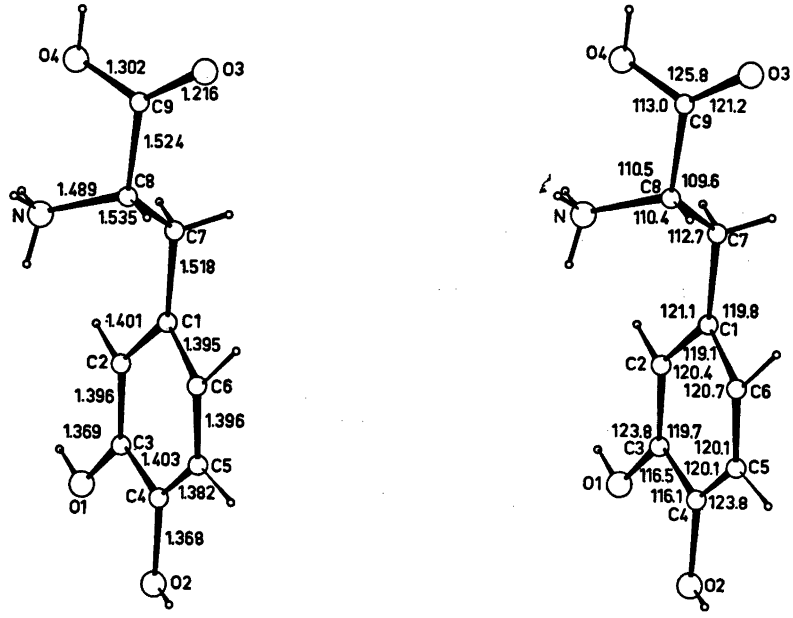

Fig. 1. a. Bond lengths (Å); b. bond angles (°) in L-DOPA hydrochloride.

Table 2. Observed and calculated structure factors (× 10).

atoms bonded to the benzene nucleus, those bonded to the carbon atoms of the side chain, those bonded to nitrogen, and the hydroxyl hydrogen atoms.

The analyses of $w\Delta^2$ as functions of F_o and of sin θ/λ showed that the variances of the structure factors had been underestimated at low scattering angles; thus, during the last stages of the least-squares refinement structure factors with sin θ/λ less than 0.3 were ignored, leaving 2122 observations for the determination of 175 parameters. The refinement converged with a conventional R-factor of 0.030 for the data actually utilized (0.032 for the total data set), the final R_w was 0.035.

The atomic parameters and their standard

deviations are given in Table 1, observed and calculated structure factors are listed in Table 2.

A rigid-body analysis showed that the thermal motion of the molecule to a fair approximation could be interpreted in terms of translational and librational oscillations; bond lengths were corrected for thermal libration.

Standard deviations in interatomic distances and bond angles were calculated from the correlation matrix ignoring uncertainties in unit cell parameters. Standard deviations in distances between non-hydrogen atoms are 0.002 Å and in angles 0.1°. If a hydrogen atom is involved the figures are 0.05 Å and 3–5°, respectively.

DISCUSSION

Bond lengths and angles are given in Table 3 and in Fig. 1, *a* and *b*. The numbering of the atoms is not the same as that given by Jandacek and Earle [3] but corresponds to that given for L-DOPA.[7] Compared to the original structure determination of L-DOPA. HCl the standard deviations of the present refinement are improved by factors between 7 and 10.

The geometry of the L-DOPA ion is nearly identical to that of the L-DOPA molecule as found in the crystals of the pure compound,[7] the obvious deviation being that of the alanine moiety which contains a carboxylate group in L-DOPA and a carboxyl group in the hydrochloride. The similarities apply to both bond lengths and angles as well as to the conformation.

The C8−C9 bond is slightly shorter in the protonized group than in the carboxylate group. The difference is highly significant even if no such difference exists between the mean value of the corresponding bond length (1.527 Å) in α-amino acids given by Marsh and Donohue [8] as compared to the value for protonized α-amino acids (1.524 Å) given by Sundaralingam and Putkey [9] (*cf.* Fig. 2).

The main reason for taking up the present refinement was to determine the structure of the carboxyl group with this special conformation about the C−Cα bond. As pointed out by several authors (*e.g.* Refs. 9, 10, 11) the conformation about this bond in α-substituted carboxylic acids is such as to bring the carbonyl oxygen atom in a *syn* planar arrangement with respect to the α-substituent. As far as α-amino acids are concerned no exception to this rule has been reported until recently. However, in the present structure it is the hydroxyl group which is found *syn* relative to the nitrogen atom; the dihedral angle N−C−C−O(H) is equal to −13.3°. The same conformation has been found in mimosine sulfate [1] (dihedral angle 5.6°) and in histidine hydrochloride.[2]

The structural data for the α-amino acid group (not corrected for thermal motion) for the three compounds found to have this uncommon conformation are given in Table 4. The weighted mean values are given in Fig. 2 together with the corresponding values given by Marsh and Donohue [8] for a zwitterionic group and those given by Sundaralingam and Putkey [9] for protonized α-amino acids with the carbonyl group in the *syn*-planar conformation.

From the data given in Fig. 2 it appears that the 180° rotation about the C−Cα bond has only a small, if any, influence on the Cα−C−O angles. However, Table 4 indicates a consistent variation of the C−C−O angles with the torsion angle N−C8−C9−O as would be expected if a repulsion between the carboxyl oxygen atoms and the substituents on the Cα carbon atom is postulated. Mean values such as those given in Fig. 2 should thus be used with caution.

The packing of ions in the crystals of L-DOPA hydrochloride has been discussed in detail by Jandacek and Earle.[3] The hydrogen bond lengths found in the present refinement are listed in Table 3; they are in good agreement with those given in the original paper. It was

suggested, however, that the chlorine ion is hydrogen acceptor in *four* hydrogen bonds in a way involving a set of bifurcated hydrogen bonds. After having localized the hydrogen atoms of the ammonium group we believe that only *three* of the interactions referred to may be described as proper hydrogen bonds; the remaining short N – Cl contact is 3.171 Å, whereas the hydrogen atoms bonded to this nitrogen atom are situated 2.80 Å or more from the chlorine ion. This short contact is thus better classified as a short van der Waals contact rather than a weak hydrogen bond, in which case the bifurcated hydrogen bonds reduce to one normal N – H···Cl hydrogen bond.

Isolation of ^{32}P-Labeled Phosphorylserine and Phosphorylthreonine from Ehrlich Mouse Ascites Tumor Cells Suspended in Different Isotonic Media Containing ^{32}P-Labeled Adenosine Triphosphate

GUNNAR RONQUIST and GUNNAR ÅGREN

Institute of Medical Chemistry, Biomedical Centre, The University of Uppsala, P.O. Box 575, S-751 23 Uppsala, Sweden

Intact Ehrlich tumor ascites cells were handled under physiological conditions and incubated for short periods with [^{32}P]ATP in isotonic media of varying cationic composition. Labeled phosphorylserine, phosphorylthreonine as well as three additional labeled fractions were isolated from a partial hydrolysate of the phosphoproteins in the outer layer of the plasma membrane.

The specific ^{32}P radioactivity was about the same for the phosphorylserine and the phosphorylthreonine fractions as well as for an additional one (peak 1, Fig. 1).

A complete amino acid analysis was carried out on the five fractions. As expected serine and threonine were most abundant in the corresponding phosphorylated fractions. Surprisingly, a high amount of proline was found in the sample corresponding to peak 1, having the same high specific radioactivity as found for phosphorylserine and phosphorylthreonine.

Cyclic AMP even in as high a concentration as 1×10^{-4} M did not stimulate a further phosphorylation. Maximal incorporation occurred in the presence of both Na^+ and K^+ as well as Mg^{2+}. If Mg^{2+} was stoichiometrically exchanged for Ca^{2+}, the incorporating activity decreased by more than 80 %. If half the amount of Mg^{2+} was excanged for Ca^{2+}, the corresponding activity was 50 % lower. With only Mg^{2+} and a monovalent cation present choline stimulated more than Na^+, which in its turn was more stimulatory than K^+. Possible functions of the labeled phosphoproteins are discussed.

Previous work from this laboratory has shown that [^{32}P]-labeled phosphorylserine as well as phosphorylthreonine can be isolated from Ehrlich mouse ascites tumor cells incubated under isotonic conditions with [γ^{32}P]ATP or [γ^{32}P]GTP. The extent of phosphorylation is much lower when either of these two nucleotides is replaced by CTP, UTP or pyrophosphate and is negligible when replaced by [^{32}P] orthophosphate. [1–3] It was concluded that the reaction between [γ^{32}P]ATP and the cells took place at the cell surface because ATP does not penetrate the intact cell membrane [4] and the cells remained intact throughout the experiments.

The labeled phosphoryl groups in the two phosphorylated amino acid residues represented only a small fraction of the total amounts of labeled orthophosphate liberated from [γ^{32}P] ATP at the cell surface. This type of phosphorylation may represent either an intermediary phosphorylation of an enzyme or a regulatory phosphorylation of a protein in the membrane. The latter type of reaction is catalyzed by a protein kinase. Furthermore, an intracellular protein kinase has been shown to be sensitive to cyclic AMP stimulation.[5,6]

In the present investigation, we have studied the effect of adding cyclic AMP to the incubation medium and of varying the cationic composition of the isotonic medium on the transfer of phosphate from external ATP to seryl- and threonyl residues of proteins presumably located at the cell surface.

MATERIAL AND METHODS

The Ehrlich mouse ascites tumor cells were grown for 7 – 8 d in 5 week old Swiss albino

mice obtained from the Anticimex breeding farm, Norrviken, Stockholm. The tumor cells were separated by centrifugation of the ascitic fluid, which had been diluted without delay several-fold with icecold Krebs-Ringer bicarbonate medium in order to diminish the tendency of cell agglutination. The cells were washed once in the Krebs-Ringer bicarbonate medium and the final washing was carried out in a medium with the same buffer and cationic composition as the incubation medium. The [γ^{32}P]ATP used was prepared as previously described.[3]

The cells were incubated in a medium containing either 130 mM sodium chloride and 25 mM potassium chloride or 155 mM of one single cationic salt (NaCl, KCl, choline Cl) to maintain isotonicity. The incubation procedure as well as the isolation of the phosphorylated amino acid residues have been described earlier.[1,2] The Schneider protein fraction was isolated from the cell [7] and partially hydrolyzed according to Lipmann. [8] Radioactivity was determined in a Nuclear Chicago Scintillation counter by measuring the Cherenkov radiation.

RESULTS

Fig. 1 illustrates the elution pattern from a typical experiment where 500 mg of a partial hydrolysate of the Schneider protein from incubated Ehrlich cells was separated on a Dowex 50 column. Five peaks can be distinguished. The two main peaks contain [^{32}P] phosphorylserine and [^{32}P]phosphorylthreonine residues. In addition three smaller labeled peaks are distinguished, the first in position

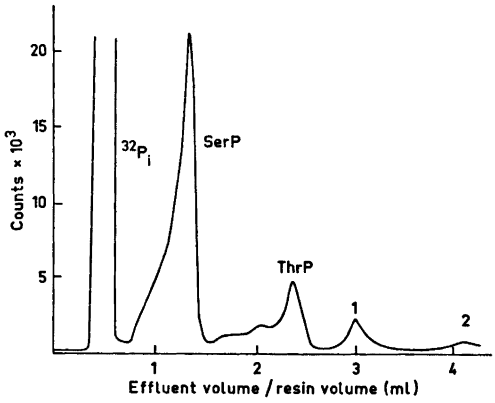

Fig. 1. Elution curve from a partial hydrolysate of the Schneider protein from incubated intact Ehrlich cells. Chromatography was performed on a 50 ml Dowex 50 (8 % DVB) column with 0.01 M HCl as eluent.

Table 1. Total radioactivity of the five fractions collected during chromatography on Dowex 50 (Fig. 1) together with their relative specific activities.

Fraction obtained[a]	Total ^{32}P-radio-activity[b]	Fraction weight[c]	Specific ^{32}P-radio-activity[d]
SerP	8 317	12	100
Peak between SerP and ThrP	630	6	15
ThrP	2 384	3	115
Peak 1	674	1	97
Peak 2	177	3	8

[a] Peak 3, occasionally found, is not included because of its very low specific activity. [b] Activity expressed in counts per min. [c] Schneider protein, mg [d] Expressed as percentage of the specific activity of SerP.

between phosphorylserine and phosphorylthreonine and the other two after the phosphorylthreonine peak. Occasionally a third peak after phosphorylthreonine could be observed.

Table 1 summarizes the total amount of material corresponding to each peak as well as total ^{32}P-activity. It is evident from the table that the specific activity of the [γ^{32}P]-phosphoryl group of ATP incorporated into the five fractions was about the same for the phosphorylserine and phosphorylthreonine fractions and the first fraction after phosphorylthreonine while it was significantly lower for the two other peaks.

Each fraction collected from the column was submitted to total acid hydrolysis and the amino acid content was analyzed. The amino acid content of each of the five fractions are given in Table 2. Serine residues were predominant in the [^{32}P]phosphorylserine fraction as is seen in the table.

Only slight amounts of threonine were detected in that fraction. Glutamic acid was present in a higher amount than any other amino acids with the exception of serine. Likewise, in the small fraction eluted between phosphorylserine and phosphorylthreonine, glutamic acid and serine were predominant.

The threonine content of the phosphorylthreonine fraction was high compared with the amount of serine. Even here as was the case for the phosphorylserine fraction glutamic

Table 2. Amino acid composition of the five radioactive fractions collected during chromatography on Dowex 50 of the partially hydrolyzed Schneider protein from Ehrlich cells.

Amino acid composition	Serine[a]	Threonine	Glutamic acid	Leucine	Isoleucine	Proline	Glycine	Valine	Aspartic acid	Alanine	Cystine	Phenylalanine[c]
SerP	216[b]	5	39	12	13	5	10	6	6	5	<5	<5
Peak between SerP and ThrP	30	9	34	8	5	11	9	12	<5	7	<5	5
ThrP	8	27	17	<5	<5	12	7	<5	<5	<5	<5	<5
Peak 1	13	5	24	8	10	126	6	14	<5	<5	5	6
Peak 2	9	<5	11	5	5	5	5	<5	<5	<5	<5	<5

[a] Amino acid analysis was carried out according to Stein and Moore using a Biocal BC 200 analysator. [b] Figures denote nmol per 100 mg Schneider protein from Ehrlich cells. [c] Tyrosine, methionine, arginine, histidine, and lysine were all less than 5 nmol per 100 mg Schneider protein in all fractions.

Table 3. Incubation of Ehrlich cells for 30 s at 37 °C with [γ^{32}P]ATP in a medium made isotonic by 130 mM NaCl, 25 mM KCl, and 2 mM $MgCl_2$.

Medium[a]	SerP	ThrP	Peak 1
1. Na^+, K^+, Mg^{2+}	100[b]	100	100
2. As in 1 plus 3′,5′-AMP (10^{-4} M)	90	90	84
3. As in 1 plus 3′,5′-AMP (10^{-6} M)	87	92	83

[a] Unlabeled orthophosphate concentration was 1×10^{-3} M in all media. The incubation was terminated with trichloroacetic acid giving a final conc of 5 %. [^{32}P]phosphorylserine (SerP), [^{32}P]phosphorylthreonine (ThrP), and [^{32}P]-labeled peptide material (Peak 1) were isolated from the acid insoluble material as described in Methods. [b] The figures given denote percentage values of phosphoryl group incorporation obtained in a medium containing Na^+, K^+ and Mg^{2+} but lacking 3′,5′-AMP. All figures are average values from two experiments.

acid was present in a comparatively high amount. The fraction corresponding to peak No. 1, Fig. 1, contained both serine and threonine in a relationship of 2.6 to 1. The amounts of glutamic acid in this fraction were again relatively high. Proline, however, was the predominant amino acid of this fraction exceeding by nearly ten times the amount of serine.

In order to elucidate the effect of cyclic AMP on the phosphorylation of the different membraneous protein fractions, experiments with [γ^{32}P]-labeled ATP were carried out with the addition of two different concentrations of cyclic AMP (10^{-6} M and 10^{-4} M, respectively) to the isotonic medium. As is seen in Table 3 cyclic AMP, even at the higher concentration, does not stimulate the phosphorylation by [γ^{32}P]ATP.

The effects of different cations on the phosphorylation of the phosphorylserine and phosphorylthreonine residues are given in Table 4.

Table 4. Incubation of Ehrlich cells for 1 min at 37 °C with [γ^{32}P]ATP in an isotonic medium with variation of the cationic composition.

Medium[a]	SerP	ThrP	Peak 1	Preak 2
1. Na^+, K^+, Mg^{2+}[b]	401.6[c] (100)[d]	100.9 (100)	31.2 (100)	13.8 (100)
2. Na^+, K^+, Mg^{2+}, Ca^{2+}	210.3 (52.4)	39.3 (39.9)	11.4 (36.5)	0
3. Na^+, K^+, Ca^{2+}	71.2 (17.7)	14.0 (13.9)	0	0
4. Na^+, Mg^{2+}	189.8 (47.3)	47.8 (47.4)	14.7 (47.1)	5.4 (39.5)
5. K^+, Mg^{2+}	142.2 (35.4)	32.0 (31.7)	12.2 (39.2)	0
6. $Choline^+$, Mg^{2+}	293.3 (73.0)	69.1 (68.5)	21.7 (69.7)	0

[a] Unlabeled orthophosphate concentration was 1×10^{-3} M in all media. The incubation was terminated with trichloroacetic acid giving a final conc of 5 %. [^{32}P]Phosphorylserine (SerP), [^{32}P]phosphorylthreonine (ThrP) and [^{32}P]-labeled peptide material (Peak 1 and Peak 2) were isolated from the acid insoluble material as described in Methods. [b] 1. 130 mM Na^+, 25 mM K^+ and 2 mM Mg^{2+}; 2. Na^+ and K^+ as in 1, with 1 mM Mg^{2+} and 1 mM Ca^{2+}; 3. Na^+ and K^+ as in 1 with 2 mM Ca^{2+}; 4. 155 mM Na^+ and 2 mM Mg^{2+}; 5. 155 mM K^+ and 2 mM Mg^{2+}; 6. 155 mM $choline^+$ and 2 mM Mg^{2+}. [c] Figures denote [^{32}P]phosphoryl groups incorporated in pmol per 100 mg Schneider protein from Ehrlich cells. [d] Figures in brackets denote percentage value of that obtained under standard incubation conditions (1. Na^+, K^+, Mg^{2+}).

When the Mg^{2+} concentration and the ATP/-Mg^{2+} ratio are kept constant, the phosphorylation is greatest when both Na^+ (130 mM) and K^+ (25 mM) are present. If all Mg^{2+} is replaced stoichiometrically by Ca^{2+} under otherwise similar experimental conditions the phosphorylation observed represents only 18 % of the maximum phosphorylation. This phosphorylation can be increased by replacing half the amount of Ca^{2+} by Mg^{2+}.

Experiments were also made in the presence of Mg^{2+} and [γ^{32}P]ATP as described above, but in the presence of only *one* monovalent cation (155 mM). The monovalent cations tested were: sodium, potassium, and choline. Most phosphorylation was obtained with choline (73 % of maximum value), whilst with sodium and potassium phosphorylation proceeded to the extent of 47 % and 35 %, respectively, of the maximum value.

The amount of labeled phosphorylthreonine residue was in all experiments 4 – 5 times smaller than that of the phosphorylserine residue [3] regardless of extracellular ionic conditions.

DISCUSSION

The time interval between the removal of the tumor cells from the donor animals and the incubation never exceeded 50 min. In addition, the cells were handled in a physiological buffer at 4 °C during preparation. We therefore have every reason to believe that the cells were intact during the incubation. In addition, no macroscopic signs of cell damage, *e.g.* any tendency of agglutination, were observed during the incubation. Since [γ^{32}P]ATP does not penetrate an intact plasma membrane [4] we conclude that the phosphorylation reactions observed occur at the cell surface.

Phosphorylserine and phosphorylthreonine residues from a protein hydrolysate are indicative of either an intermediate phosphorylation of certain enzymes [9,10] or a regulatory phosphorylation catalyzed by protein kinase.[6]

Alkaline phosphatase, an enzyme forming an intermediate which is phosphorylated at a phosphorylserine residue,[3] has been shown by de Thé [11] to be associated with the outer surface of the plasma membrane of thymomas of leukemic mice. Thus, alkaline phosphatase activity might also be associated with the outer surface of the plasma membrane of Ehrlich tumor cells. However, Engström [8] has shown that alkaline phosphatase is also phosphorylated with [^{32}P]orthophosphate as substrate. But since [^{32}P]orthophosphate does not act as a phosphoryl donor at the Ehrlich cell surface [3] and labeled phosphorylthreonine has never been isolated from alkaline phosphatase (Engström, personal communication 1974), we consider it unlikely that the observed labeling involves an alkaline phosphatase on the cell surface. In addition, although the experimental conditions have been varied as regards substrates,[3] ionic composition of the incubation medium as well as the incubation time the ratio between phosphorylserine and phosphorylthreonine has remained constant. This fact favors the view that one single entity of protein(s) is phosphorylated with [γ^{32}P]ATP.

Other enzymes (*e.g.* phosphoglucomutase) are probably also phosphorylated exclusively at a serine residue in the active centre. The hypothesis of an intermediate enzymatic phosphorylation would therefore appear untenable.

The phosphorylation studied here might well represent a regulatory phosphorylation catalyzed by one or more protein kinases localized at the surface of the plasma membrane. In this connection it may be mentioned that Matsumura and Takedo [12] have observed that a phosphorylation probably representing a regulatory function occurs in the cytosol of rat liver cells. Furthermore, they were able to separate two main fractions one catalyzing mainly the phosphorylation of a seryl residue, the other mainly a threonyl residue. The importance of the phosphorylation of the threonyl residue in our study is emphasized by the fact that the specific activities of the phosphorylserine and phosphorylthreonine residues were about the same (Table 1).

We made the interesting observation that cyclic AMP even at high concentrations (1×10^{-4} M) did not stimulate the assumed protein kinase reaction. This does not exclude the possible existence of a regulatory phosphorylation system localized at the surface of the cell membrane. This behavior might reflect an adaptation to the physiological conditions existing in the plasma membrane architecture when adenyl cyclase is believed to be located

on the inner surface of the plasma membrane.[13] Adenyl cyclase activity has never been possible to demonstrate at the outer surface of several types of tumor cells.[14] The possible existence of external ATP as a substrate in a "membraneous metabolic pool" has been discussed earlier.[15] Recent reports concerning the effects of *extracellular* ATP on different cells [16–19] might be explained by protein kinase action at the outer surface of the cell.

Our results demonstrate the presence of metabolically active proteins on the outside of the plasma membrane. In accordance with this observation it is interesting to note the recent finding of the occurrence of surface peptides on intact Ehrlich cells.[20]

Acknowledgements. We are indebted to Ing. S. Eklund, Mr. C. Wernstedt and Miss H. Grundberg for skilful technical assistance. We also thank Professor J. Sjöquist of this institute for kindly carrying out the amino acid analyses.

This investigation was supported by a grant from the Swedish Medical Research Council (project B73-13X-228-10B).

Studies on Orchidaceae Alkaloids. XL.* Biosynthetic Studies of (−)-Cryptostyline I in *Cryptostylis erythroglossa* Hayata

STIG AGURELL,[a] INGRID GRANELLI,[b] KURT LEANDER[b] and JAN ROSENBLOM[b]

[a] Astra Läkemedel, S-151 85 Södertälje, Sweden and [b] Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-104 05 Stockholm, Sweden

The biosynthesis of (−)-cryptostyline I (I) has been studied using radioactive precursors, the position of the radiolabel being determined by subsequent degradation.

The biosynthetic results show that 3,4-dimethoxyphenethylamine, *N*-(3-hydroxy-4-methoxybenzyl)-3-hydroxy-4-methoxyphenethylamine (XI) and 1-(3,4-methylenedioxyphenyl)-6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium bromide (II) are specifically incorporated. Preliminary results indicate that dopamine is a precursor of the 1-phenyl group and the C-1 carbon atom. Vanillin is shown to be better incorporated than isovanillin.

* For number XXXIX, see Ref. 1.

In a previous report [1] we showed that tyrosine and 3,4-dihydroxyphenylalanine as well as tyramine and dopamine are specifically incorporated into the phenethylamine portion of (−)-cryptostyline I (I). It was also evident that 3-hydroxy-4-methoxyphenethylamine was incorporated to a greater degree than 4-hydroxy-3-methoxyphenethylamine. We now report further experiments on the biosynthesis of (−)-cryptostyline I (I). The specificity of the incorporation of the precursors into (−)-cryptostyline I (I) has been established by degradation studies (Table 1 and Fig. 1).

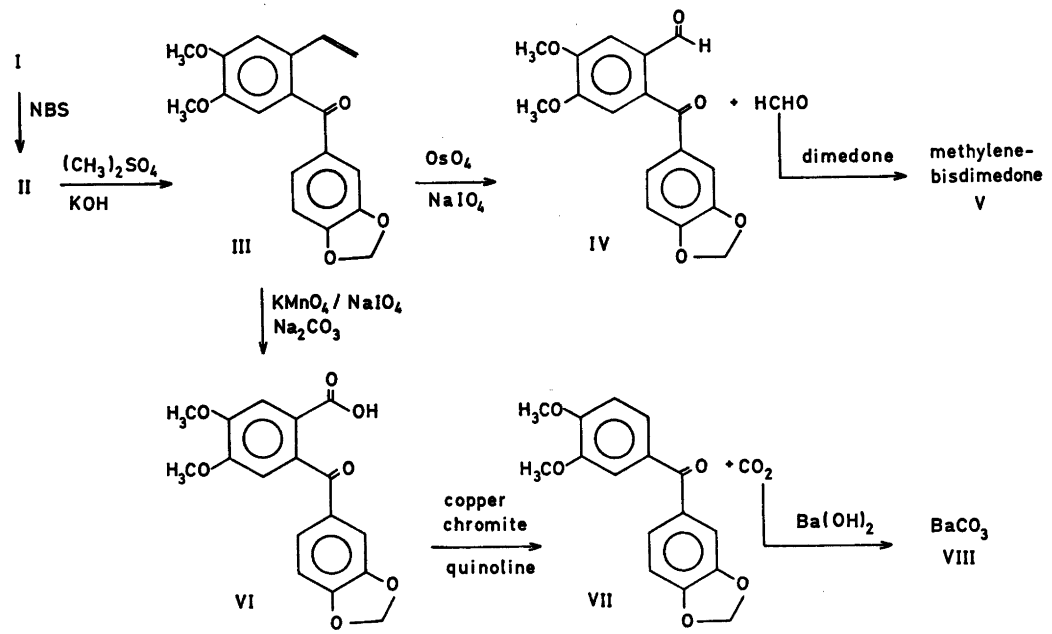

Fig. 1. Degradation of cryptostyline I.

Table 1.

Labelled compounds	Amount fed		Isolated (−)-cryptostyline I	Added carrier
	mg	μCi	mg	mg
Dopamine-β-^{14}C	0.26	100	60	240
3,4-Dimethoxyphenethylamine-α-^{14}C	2.4	100	30	60
N-(3-Hydroxy-4-methoxy-1′-^{3}H-benzyl)-3-hydroxy-4-methoxyphenethylamine-α-β-^{3}H (XI)[a]	5	325	55	40
1-(3,4-Methylenedioxyphenyl)-6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium bromide-^{3}H	5	24	25	25
Vanillin-^{3}H	5	105	35	30
Isovanillin-^{3}H	5	150	40	35

Spec. act. in isol. (−)-cryptostyline I μCi/mmol × 10^{-3}	Recovered radioactivity % × 10^{-3}	Radioactivity % I	II	III	IV	V	VI	VII	VIII
77.0	14.0	100					96	57	35
1.7	0.16	100		98	12	91			
5.7	0.29	100[b]	81[b]				16[b]		
4700	1500	100[c]							
2.3	0.23	100[c]							
0.36	0.029	100[c]							

[a] The tritium-ratio between the C_1 and C_3-C_4 positions was 2.7 asuming non-exchange during debenzylation.

[b] The tritium-ratio between the C_1 and C_3-C_4 positions was 0.29. This figure was calculated by dividing the 19 % label shown by degradation to have occurred at the C_1 position by 65 % calculated by substracting the 16 % label in VI from the 81 % present in compound II. On the assumption that the losses of tritium and hydrogen at C-1 during the cyclization to (−)-cryptostyline I (I) are equal the ratio 0.29 in I should be doubled when I is compared with the precursor XI.

[c] Boiling with concentrated hydrochloric acid gave an unlabelled (−)-cryptostyline I (I).

As shown in Table 1, 3,4-dimethoxyphenethylamine is incorporated into (−)-cryptostyline I (I) but considerably less efficiently than dopamine. The latter was, however, administered in smaller amounts. It therefore appears probable that 3,4-dimethoxyphenethylamine is demethylated to the known precursor 3-hydroxy-4-methoxyphenethylamine before incorporation into I. An analogous reaction is known [2] for cactus species, where 3,4-dimethoxyphenethylamine was demethylated to 4-hydroxy-3-methoxyphenethylamine before further biosynthetic reactions.

Dopamine, labelled in the β-carbon, was administered to the plants to elucidate whether it is a progenitor of only one or of both the aromatic rings in I. The results suggest that dopamine is a precursor of both the aromatic parts of the molecule, since only about half of the radioactivity from dopamine-β-^{14}C was located at carbon C-4 of (−)-cryptostyline I (I). We have previously shown [1] that dopamine-α-^{14}C is incorporated into (−)-cryptostyline I (I) with only a slight scrambling of label and hence, it seems likely that the remaining label is present at C-1.

The origin of the 1-phenyl group was further investigated. Vanillin (Table 1) was decidedly better incorporated into I than was isovanillin. Incorporation rates were low but due to their minimal water solubilities both aldehydes had to be applied to the leaves as solutions in poly-

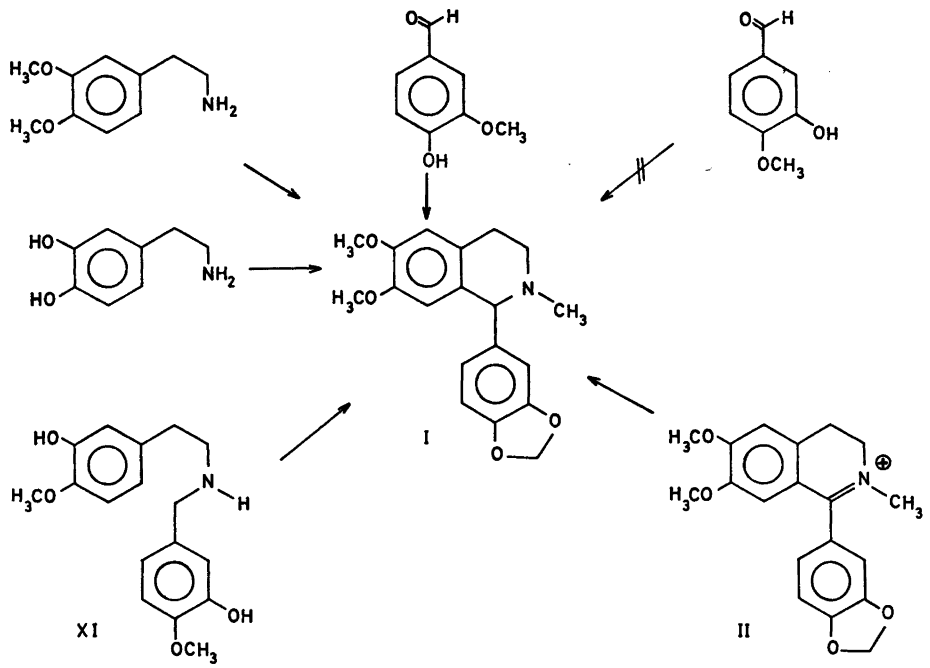

Fig. 2. Suggested precursors for the biosynthesis of (−)-cryptostyline I.

ethyleneglycol and thus may not be available for biosynthesis to the same extent as the amines. Barton *et al.*[3] have earlier found that isovanillin is poorly utilized in the biosynthesis of alkaloids owing to its poor absorption. We have not established which aromatic moiety became labelled from the aldehyde. The C_6-C_1 unit in some Amaryllidaceae alkaloids has previously been shown to be derived from protocatechualdehyde.[4]

N-(3-Hydroxy-4-methoxybenzyl)-3-hydroxy-4-methoxyphenethylamine (XI), labelled in both parts of the molecule, was incorporated in low yield. If we assume that XI, with the exception of the methyl groups, is incorporated intact into I it is clear from Table 1 that there has been a considerable loss of tritium from the position in XI which later appears at C_1 in (−)-cryptostyline I (I). The original tritium-ratio between the C_1 and the C_3-C_4 positions, which was 2.7 in XI, has decreased to 0.58 in I, as discussed in the footnotes to Table 1. This may be due to loss of tritium during passage through an intermediate such as the immonium salt of I (II). The indication that II is a main intermediate is supported by the efficient incorporation of II into (−)-cryptostyline I (I). Alternative explanations include metabolic degradation of XI to smaller fragments followed by re-incorporation. It should be noted that in XI the isovanillin substitution pattern is present in the 1-phenyl ring. In view of the results with vanillin and isovanillin it seems more probable that the isomer of XI, *N*-(4-hydroxy-3-methoxybenzyl)-3-hydroxy-4-methoxyphenethylamine, is the true precursor of II and (−)-cryptostyline I (I).

EXPERIMENTAL

The general methods described in Ref. 1 were used. 3,4-Dimethoxyphenethylamine-1-^{14}C and dopamine-2-^{14}C were obtained from the Radiochemical Centre, Amersham, UK and New England Nuclear Corp., Boston, USA, respectively.

Feeding experiments. The labelled amines were dissolved in small amounts of dilute acetic acid and the solutions were injected into the leaves of *C. erythroglossa.* The labelled vanillin and isovanillin were dissolved in small amounts of polyethyleneglycol and the solutions were applied to the leaves of the plants. (−)-Cryptostyline I (I) was isolated as described earlier.[1]

Unlabelled carrier was added to the isolated alkaloid in amounts specified in Table 1.

3,4-Dimethoxy-3',4'-methylenedioxybenzophenone (VII). A mixture of 2-(3,4-methylenedioxybenzoyl)-4,5-dimethoxybenzoic acid (VI, 70 mg), quinoline (1 ml) and copper chromite (20 mg) was refluxed for 10 min. Chloroform (10 ml) was added and the copper chromite filtered off. The chloroform phase was washed with hydrochloric acid (2 %) until all quinoline was removed, dried (Na_2SO_4) and concentrated. The residue was chromatographed on a silica gel column (2 × 5 cm) using chloroform as eluent. The fraction containing VII was further purified by preparative thin-layer chromatography on silica gel using chloroform as eluent ($R_F = 0.5$). Recrystallization from toluene gave VII (40 mg), m.p. 164–165 °C (Lit.[9] m.p. 164–165 °C). The carbon dioxide formed in the reaction was trapped in a saturated aqueous solution of barium hydroxide. The precipitate was filtered off and immediately dried under a high vacuum to give barium carbonate (VIII, 20 mg).

Vanillin labelled in the aromatic ring. Concentrated hydrochloric acid (0.03 ml) and tritiated water (0.04 ml, 0.2 Ci) were added to a solution of vanillin (46 mg) in dioxane (0.10 ml). The solution was heated in a sealed ampoule at 115 °C. After 3 h, water (4 ml) was added and the aqueous solution extracted with chloroform (4 × 5 ml). The combined chloroform solutions were dried (Na_2SO_4) and evaporated to dryness. The residue was dissolved in methanol and the solvent evaporated. This procedure was repeated five times. The residue was dissolved in chloroform and filtered through a short silica gel column. Evaporation of the eluate to dryness and recrystallization of the residue from toluene gave the tritiated vanillin, m.p. 80–81 °C (Lit.[5] m.p. 83–84 °C) with a specific activity of 3.2 mCi/mmol.

Tritiated isovanillin was prepared as described for vanillin, m.p. 116–117 °C (Lit.[6] m.p. 114–116 °C) with a specific activity of 4.6 mCi/mmol.

(±)-Cryptostyline I labelled with tritium in the aromatic rings was obtained by heating (±)-cryptostyline I (I, 34 mg) dissolved in dioxane (0.1 ml) with concentrated hydrochloric acid (0.03 ml) and tritiated water (0.05 ml, 0.25 Ci) in a sealed ampoule at 120 °C for 5 h. Water was added (2.5 ml) and the aqueous solution was washed with ether (5 ml), made alkaline (pH 13) with sodium hydroxide (1 M) and extracted with ether (2 × 5 ml). The combined ether solutions were dried (Na_2SO_4) and evaporated to dryness. Recrystallization of the residue from ether gave (±)-cryptostyline I (I, 21 mg), m.p. 117–118 °C (Lit.[7] m.p. 117–118 °C) with a specific activity of 2.1 mCi/mmol. Oxidation of this sample with *N*-bromosuccinimide [1] gave 1-(3,4-methylenedioxyphenyl)-6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium bromide with a specific activity of 1.9 mCi/mmol.

N-(3-Benzyloxy-4-methoxy-1'-^{3}H-benzyl)-3-benzyloxy-4-methoxy-α,β-^{3}H-phenethylamine hydrochloride (X). 3-Benzyloxy-4-methoxybenzaldehyde (96 mg) and 3-benzyloxy-4-methoxy-α,β-^{3}H-phenethylamine [8] (103 mg, 5.38 mCi/mmol) were dissolved in ether (20 ml) and the solution was allowed to stand for 20 h at room temperature. Evaporation of the solvent gave the crude imine IX, which was dissolved in dioxane:methanol 3:1 (27 ml) and reduced with sodium borotriteride (11.8 mg, 62 mCi). After

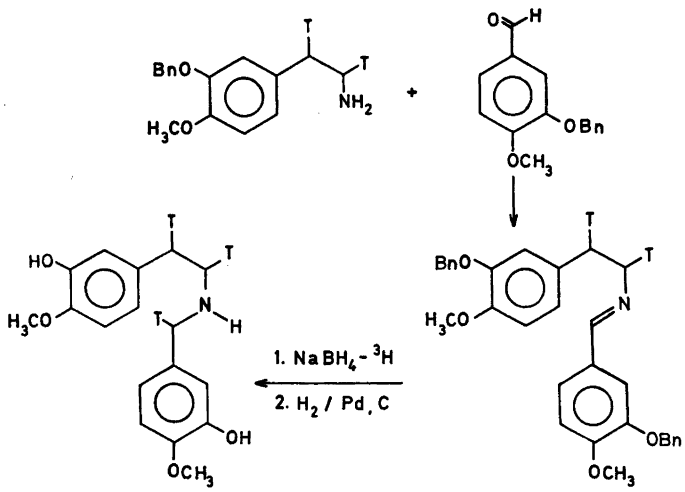

Fig. 3. Synthesis of the labelled compound XI.

stirring for 1.5 h an excess of sodium borohydride (120 mg) was added and the stirring continued for 2 h. The solution was diluted with water (25 ml) and extracted with ether (4 × 40 ml). The combined ether solutions were dried (Na_2SO_4) and evaporated to dryness leaving the crude phenethylamine derivative, which was converted to the corresponding hydrochloride. Recrystallization from ethanol gave X in the form of needles (150 mg), m.p. 148–150 °C. (Found: C 71.6; H 6.6; N 2.6. Calc. for $C_{31}H_{34}NO_4$: C 71.6; H 6.6; N 2.7.) UV spectrum, nm (ε): λ_{max} (ethanol) 279 (5600), 231 (16 900). NMR spectrum ($CDCl_3$): δ 2.98 (m, 4 H), 3.68 (s, 3 H), 3.78 (s, 3 H), 3.92 (s, 2 H), 5.05 (s, 2 H), 5.24 (s, 2 H), 6.65–7.65 (m, 16 H).

N-(3-Hydroxy-4-methoxy-1'-^{3}H-benzyl)-3-hydroxy-4-methoxy-α,β-^{3}H-phenethylamine (IX). A solution of X (150 mg) in acetic acid (15 ml) was hydrogenated over palladium on carbon (10 %, 10 mg) at room temperature and atmospheric pressure. When the theoretical amount of hydrogen had been consumed (40 min) the catalyst was filtered off and water (50 ml) was added. After washing with ether (2 × 25 ml) the pH of the solution was adjusted to 8.0–8.5 with sodium hydroxide (1 M) and extracted with ether (5 × 40 ml). The combined ether extracts were dried (Na_2SO_4) and the solvent evaporated. The residue was recrystallized from ethanol giving XI, m.p. 140–143 °C. (Found: C 66.8; H 6.5; N 4.4. Calc. for $C_{17}H_{21}NO_4$: C 67.3; H 7.0; N 4.6). NMR spectrum (pyridine-d_5): δ 2.92 (m, 4 H), 3.73 (s, 6 H), 3.84 (s, 2 H), 6.10–7.45 (m, 9 H). Specific activity: 19.7 mCi/mmol.

Acknowledgement. We thank Dr. Björn Lüning for his interest in this work and Mrs. Birgit Dittmer for measuring the radioactivities. This study was supported by the Swedish Natural Science Research Council.

Studies on the Smith Degradation

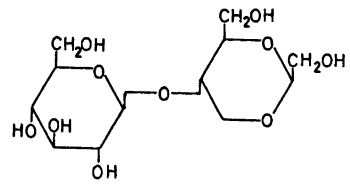
BERTIL ERBING, BENGT LINDBERG and SIGFRID SVENSSON

Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, Fack, S-104 05 Stockholm, Sweden

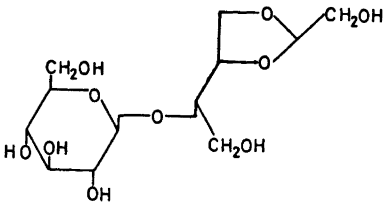
Two oligosaccharide derivatives, methyl 6-*O*-(β-D-glucopyranosyl)- 3-*O*-methyl-α-D- glucopyranoside (III) and *O*-α-D-mannopyranosyl-(1→3)-*O*-α-D-galactopyranosyl-(1→2)-glycerol (IV) have been subjected to the Smith degradation. Only the normal degradation products, methyl 3-*O*-methyl-α-D-glucopyranoside (IX) and 2-*O*-α-D-galactopyranosyl-glycerol (X), respectively, were obtained. The results indicate that acetal migration with the formation of cyclic acetals involving sugar moieties is insignificant in the Smith degradation.

Following Smith degradation of polysaccharides,[1] that is periodate oxidation, borohydride reduction, and mild acid treatment, glycosidic linkages of unoxidized sugar residues are not hydrolyzed while non-cyclic acetals in modified sugar residues are cleaved. Investigation of the resultant products, therefore, reveals structural features of the original polysaccharide.

One complication, observed by Smith and his coworkers,[1] is acetal migration during the mild acid treatment. Cyclic acetals formed by such migration are considerably more stable to acid hydrolysis than the non-cyclic acetals; consequently compounds containing cyclic acetal structures may be present in the product. Thus on Smith degradation of oat glycan,[1] not only 2-*O*-β-D-glucopyranosyl-D-erythritol but also 1,3-*O*-(2-hydroxyethylidene)-2-*O*-β-D-glucopyranosyl-D-erythritol (I) was obtained. Gorin and Spencer [2] observed that smaller amounts of analogous 3,4-*O*-(2-hydroxyethylidene)-2-glycopyranosyl derivatives of erythritol (*e.g.* II) were also formed from polysaccharides containing β-(1→4)-linked D-glucose or D-mannose residues. Such acetals became the main byproducts when polysaccharides containing



I



II

Fig. 1.

α-(1→4)-linked D-glucose or D-mannose residues were degraded.

It seemed possible that cyclic acetals, involving sugar moieties of the degraded product, could also be formed by acetal migration during the Smith degradation. This possibility has now been investigated, using suitable model substances.

RESULTS AND DISCUSSION

Two model substances were investigated. One, methyl 6-*O*-(β-D-glucopyranosyl)-3-*O*-methyl-α-D-glucopyranoside (III), was prepared by conventional methods from 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide and methyl 2,4-di-*O*-acetyl-3-*O*-methyl-α-D-glucopyranoside. Fully trideuteriomethylated III gave the ex-

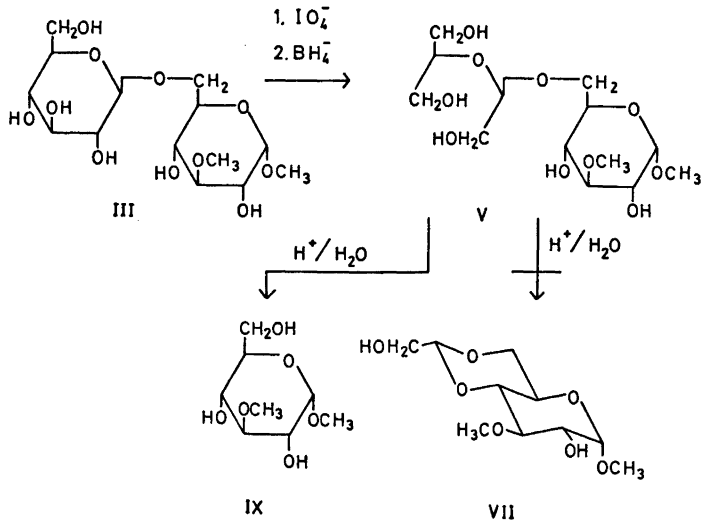


Fig. 2.

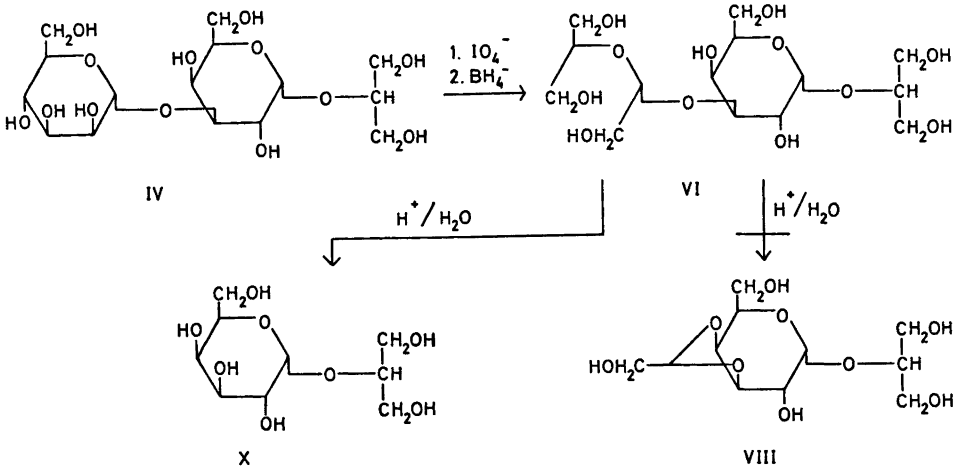

Fig. 3.

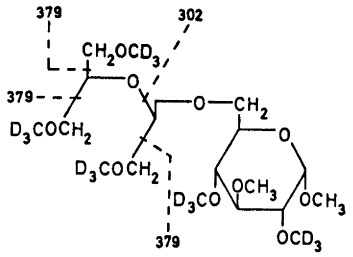
pected mass spectrum.[3] The other substance *O*-α-D-mannopyranosyl-(1→3)-*O*-α-D-galactopyranosyl-(1→2)-glycerol (IV) was previously isolated from the marine red alga *Furcellaria fastigiata*.[4] It seemed possible that the polyalcohols (V, VI) obtained from these should yield some 4,6- and 3,4-(2-hydroxyethylidene)-acetal (VII and VIII), respectively, on mild acid treatment.

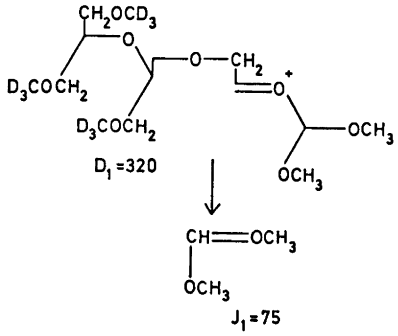
Each disaccharide derivative (III and IV) was oxidized with sodium metaperiodate in aqueous methanol and reduced with sodium borohydride. The product was isolated by chromatography on Sephadex G25 and its purity checked by TLC and, after permethylation, by GLC. From III a single product was obtained. The MS of its pertrideuteriomethylated derivative (XI) was in agreement with the postulated structure. The origins of some major fragments are indicated in the formula.

Two components were obtained from IV, probably due to preferential cleavage between

C-2 and C-3 and formation of a cyclic hemiacetal in equilibrium with the open structure, whereby further oxidation is slowed down. By subjecting the product to borohydride reduction and a second oxidation reduction, a single component was obtained. The MS of the permethylated derivative (XII) of polyalcohol VI indicated

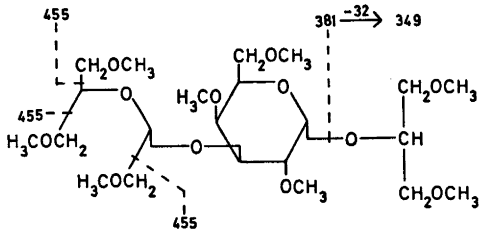


XI Mw 427



that it was the expected product. The origins of some major fragments are indicated in the formula.

The polyalcohols V and VI were hydrolysed at different temperatures. The rate constants



XII Mw 500

Table 1. Rate constants and activation energies for the acid hydrolysis of the mixed acetals V, VI, and XIII.[5]

Compound	Temp. °C	$k \times 10^4$ s^{-1}	E kJ/mol
	20	0.25	
V	30	0.99	114.0
	40	4.9	
	20	0.47	
VI	30	2.2	108.5
	40	8.1	
	20	0.89	
XIII	30	3.62	98.5
	40	11.30	

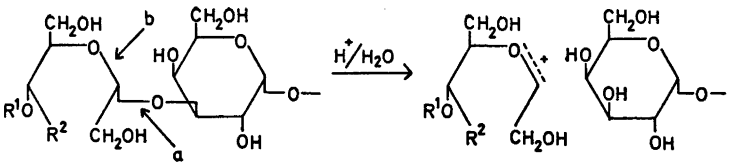
were of the same order of magnitude as those for XIII,[5] obtained on oxidation-reduction of methyl α-D-glucopyranoside (Table 1).

During the hydrolyses of V and VI, samples were withdrawn, borohydride reduced, and analysed by TLC and, after permethylation, by GLC. Only unchanged starting material and the expected degradation product, methyl 3-*O*-methyl-α-D-glucopyranoside (IX) and 2-*O*-α-D-galactopyranosyl-glycerol (X), respectively, were observed and not even traces of cyclic acetals, such as VII and VIII. The results of the present study therefore indicate that the formation of cyclic acetals involving unoxidized sugar residues is insignificant during Smith degradation. One explanation for the findings that cyclic acetals involving erythritol occur, but those involving sugar residues do not, is that the first linkage cleaved when the non-cyclic acetal (*e.g.* XIV) is hydrolysed is the one to the sugar residue (a) and not the other linkage to the alditol residue (b).

Although an explanation is not obvious, perhaps there is strain due to crowding of substituents in the solvated ion formed by protonation of the oxygen at *b*, which should precede the fission, and less strain in the corresponding ion formed by protonation at *a*, and that this is responsible for the observed effect.

EXPERIMENTAL

General methods. Melting points are corrected. Concentrations were performed at reduced pressure at a bath temperature not exceeding 40 °C. Optical rotations were determined using a Perkin-Elmer 141 instrument. GLC was per-



XIV

R^1 = H, sugar residue
R^2 = H, CH_2OH

Fig. 4.

formed using a column (0.15 × 180 cm) of 3 % OV 1 on Gaschrom Q at 210 °C and a Perkin-Elmer 900 instrument. Permethylated melibiitol ($T_M = 1$) was used as standard. GLC-MS was performed using Perkin-Elmer 270 and Varian Mat 311 instruments. TLC was performed on precoated plates with Silica Gel 60 F_{254} (Merck), 0.25 mm.

Methyl 3-O-methyl-α-D-glycopyranoside was obtained together with the 2-*O*-methyl derivative by partial methylation of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (7.6 g), fractionation of the product by silicic acid chromatography and catalytic hydrogenation, as previously described.[5] Methyl 4,6-*O*-benzylidene-3-*O*-methyl-α-D-glucoside (2.1 g) was eluted as the second component and showed, after crystallization from ethanol, m.p. 149–150 °C and $[\alpha]_{578}^{20}$ +116° (*c* 1.0, $CHCl_3$), in good agreement with published values. The title compound was obtained as a chromatographically pure syrup (1.25 g). The MS of the permethylated (CD_3I) product agreed with the postulated structure.[3]

Methyl 2,4-di-O-acetyl-3-O-methyl-6-trityl-α-D-glucopyranoside. Triphenylmethyl chloride (3.9 g) was added to a solution of methyl 3-*O*-methyl-α-D-glucopyranoside (3.0 g) in dry pyridine (100 ml). The solution was heated on a steam bath for 20 min, acetic anhydride (80 ml) was added and the heating continued for further 20 min. The solution was cooled and poured into a mixture of ice (300 g) and water (100 ml), which was then extracted with chloroform (4 × 100 ml). The chloroform solution was washed with 8 % aqueous sodium hydrogen carbonate (4 × 100 ml) and water (3 × 100 ml), dried (Na_2SO_4) and concentrated. The product (3.5 g) crystallized from ethanol and showed m.p. 158–159 °C and $[\alpha]_{578}^{20}$ +90° (*c* 1.9, $CHCl_3$). (Found: C 69.8; H 6.23. $C_{31}H_{34}O_8$ requires: C 69.7; H 6.41).

Methyl 2,4-di-O-acetyl-3-O-methyl-α-D-glucopyranoside. A saturated (at 0 °C) solution (1.5 g) of hydrogen bromide in acetic acid was added to a solution of the above trityl compound (3.0 g) in acetic acid (12 ml), kept at 10 °C. The mixture was shaken for 60 s and then rapidly filtered into ice and water (50 g). The trityl bromide was washed with acetic acid (10 ml) and the combined filtrate and washings extracted with chloroform (4 × 20 ml). The chloroform solution was washed with ice-water (4 × 20 ml) and dried (Na_2SO_4). Concentration of the solution yielded a syrup (1.4 g), used without further purification in the following step.

Methyl 6-O-β-D-glucopyranosyl-3-O-methyl-α-D-glucopyranoside (III). The above syrup (0.8 g), silver oxide (0.7 g), Drierite (2.5 g) and dry ethanol-free chloroform (10 ml) were stirred in the dark for 1 h and iodine (0.2 g) was added. A solution of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (1.0 g) in chloroform (10 ml) was added in 1 ml portions over 2 h and stirring continued for further 24 h. The mixture was filtered, concentrated and fractionated on a silica gel column (5 × 40 cm), using chloroform – acetone (5:1) as irrigant. The fractions were investigated polarimetrically and by TLC. The main component was obtained as a syrup (1.0 g) that crystallized from ethanol, m.p. 126–128 °C, $[\alpha]_{578}^{20}$ +49° (*c* 0.4, $CHCl_3$). (Found: C 50.1; H 6.09. $C_{26}H_{38}O_{17}$ requires: C 50.2; H 6.15). This product (0.9 g) was dissolved in methanol (10 ml) and methanol saturated (room temperature) with ammonia (50 ml) was added. The solution was kept overnight at room temperature, concentrated and the resulting syrup (0.5 g) purified by chromatography on a Sephadex G25 column to give the title compound as a chromatographically pure syrup.

α-D-Mannopyranosyl-(1→3)-α-D-galactopyranosyl-(1→2)-glycerol. The nonaacetate of the title compound was deacetylated and the product purified as above, yielding a chromatographically pure syrup.

The mixed acetal V. To the disaccharide glycoside III (0.2 g) in methanol (20 ml) was added 0.23 g sodium metaperiodate in water (5 ml). The mixture was stirred for 2 h at room temperature in the dark, ethylene glycol (0.1 g) was added and stirring continued for 15 min. Methanol (30 ml) was then added and the mixture filtered, concentrated and dissolved in water (10 ml). Sodium borohydride (0.2 g) was added, the solution kept at room temperature

for 12 h, excess borohydride was decomposed by addition of acetic acid and the solution was concentrated. Boric acid was removed by codistillations with methanol and the product purified by chromatography on Sephadex G25, $[\alpha]_{578} \simeq +117°$. TLC (ethanol—chloroform—water, 15:5:1) and GLC after permethylation ($T_M = 0.54$) showed that the product (0.15 g) was pure. The MS of the permethylated (CD_3I) product showed, *inter alia*, the following peaks (relative intensities in brackets): 48(100), 74(39), 75(21), 76(10), 91(51), 92(12), 104(9), 107(14), 109(12), 134(8), 151(2), 176(1.5), 179(1.6), 193(2.4), 211(1.2), 225(1.8), 301(0.6), 302(0.1), 320(0.2), 321(0.1), 357(0.1), 379(0.6).

The mixed acetal VI, $[\alpha]_{578} \simeq +94°$ was prepared as described above for V, except that the oxidation-reduction had to be repeated. The permethylated product showed $T_M = 1.23$, compared to $T_M = 1.89$ for the component that disappeared after the second oxidation-reduction. MS of the former showed, *inter alia*, the following peaks: 45(100), 71(41), 73(10), 101(12), 103(14), 127(6.1), 145(2.9), 159(2.0), 163(1.3), 177(3.0), 187(1.2), 207(0.4), 215(0.4), 233(0.4), 247(0.2), 275(0.2), 349(0.1), 380(0.1), 381(0.2), 455(0.1).

Acid hydrolysis studies. The mixed acetal (V or VI) (about 10 mg) in 0.125 M sulfuric acid (1 ml) was transferred to a jacketed polarimeter tub (10 mm) maintained at the required temperature. The optical rotation, at 365 nm, was determined at intervals and the reaction constant calculated, assuming first order kinetics. Samples from a parallel experiment were withdrawn at intervals, borohydride reduced and analysed by TLC and, after permethylation, by GLC and GLC-MS. In addition to unchanged starting material, methyl 3-*O*-methyl-α-D-glucopyranoside (T_M too low to be determined accurately) and 2-*O*-α-D-galactopyranosyl-glycerol ($T_M = 0.24$), respectively, were observed but no components indicative of acetal migration.

Thermolytic Fragmentation of 3-Alkylthio- and 3-Arylthio-1,2-dithiolylium Iodides in the Ion Source of the Mass Spectrometer

CARL TH. PEDERSEN,[a] NICANOR LOAYZA HUAMAN[a] and JØRGEN MØLLER[b],*

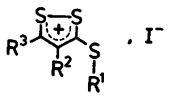
[a] Department of Chemistry, Odense University, DK-5000 Odense, Denmark and [b] Physical Laboratory II, H. C. Ørsted Institute Universitetsparken 5, DK-2100 Copenhagen Ø, Denmark

A series of 3-alkylthio- and 3-arylthio-1,2-dithiolylium iodides have been thermolysed in the ion source of the mass spectrometer. The mass spectra obtained from the thermolysis products of the alkylthio substituted compounds can be rationalized by assuming the primary formation of a 1,2-dithiolyl radical. The radical may stabilize either by loss of the thioalkyl alkyl group or by loss of a hydrogen atom.

The 3-arylthio substituted compounds form a tetrathiafulvalene, probably by dimerization of an intermediately formed carbene.

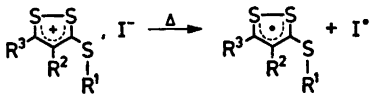
A mass spectrometric study of the thermolysis products of alkyl- and aryl substituted 1,2-dithiolylium salts has recently been reported.[1] Although some of the thermolysis products are not stable enough to be isolated, they are sufficiently long lived to allow ionization by electron impact when formed directly in the ionization chamber. Thus mass spectra obtained in this way make it possible to study the primary thermolysis products or the primary rearrangements products.

In this investigation salts of the type (A) (Table 1) were studied under the same conditions as before.[1]

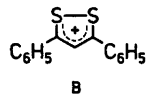


A

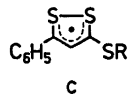
The mass spectra of the various thermolysis products may be rationalized by assuming the primary formation of a 1,2-dithiolyl radical by a sort of homolytic cleavage (I – XIII).



An analogous process was proposed as the primary process in the thermolysis of alkyl- and aryl substituted 1,2-dithiolylium salts,[1] where the thermolysis in some cases, *e.g.* 3,5-diphenyl-1,2-dithiolylium bromide, gave rise to the formation of stable radicals. Subsequent ionization then yielded the stable aromatic 1,2-dithiolylium cation (B) as the very abundant parent ion in the mass spectrum.



B



C

Similar abundant ions corresponding to radicals as (C) are not observed in any of the mass spectra from the salts studied in this investigation. However, the spectra from alkylthio dithiolylium salts bearing an aromatic substituent (IX – XIII) exhibit, besides the spectrum of the thermolysis product, an ion of low abundance (0.1 – 2 %) at a *m/e* value corresponding to the appropriate radical. Such peaks could not be detected in the spectra of I to VIII since the M + 1 isotope peaks of the abundant molecular

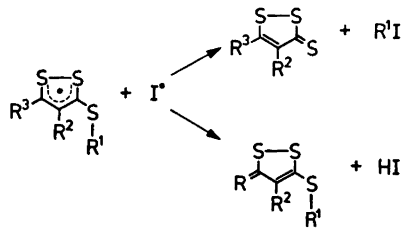
[a] All compounds melt with decomposition.

ion of the decomposition product appear at the same nominal mass number.

The observations described above are in accordance with the electrochemical behaviour of the two groups of salts. The 3,5-diphenyl-1,2-dithiolylium perchlorate gave reversible electrochemistry at room temperature and the corresponding stable radical was characterized by means of ESR spectroscopy.[2] 3-Methylthio-5-phenyl-1,2-dithiolylium methosulfate showed reversible electrochemistry only at −70 °C [3] indicating the lower stability of the radical.

The primary rearrangement process of the radicals initially formed from the alkylthio substituted salts could proceed in two different ways as suggested in Scheme 1.



Scheme 1.

Loss of the thioalkyl group R^1

The mass spectra exhibited by IX to XIII show abundant molecular ions corresponding to alkyl iodides and the appropriate 1,2-dithiol-3-thiones. The fragmentation patterns of the latter are virtually identical with those previously reported for these compounds.[4] This process accounts for all significant peaks observed in the spectra.

Loss of the alkyl group R^1 is also observed in the spectra of I to VIII, but to a much smaller extent.

Loss of a hydrogen atom

The major rearrangement process of the initially formed radicals in the case of compounds I to VIII corresponds to the initial loss of a hydrogen atom (Scheme 2). The mass spectra show the resulting $[HI]^{+\cdot}$ ion and abundant molecular ions corresponding to loss of hydrogen iodide from the parent salt (*cf.* Figs. 1 and 2). The hydrogen atom involved in this process do not originate from the alkylthio group R^1, as demonstrated by the spectra obtained from the deuterated salts II, VI, and VIII. In these cases all labelled hydrogens are retained in the molecular ions.

The mass spectrum exhibited by VII is shown in Fig. 1. A reasonable structure for the molecular ion appearing at *m/e* 202 may be *a*. This is in accordance with the structure proposed for the thermolysis product obtained from 3-methyl-4,5-tetramethylene-1,2-dithiolylium bromide.[1] Similarly the [M−H] ion is

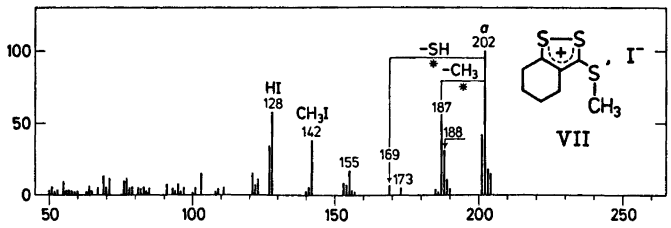


Fig. 1.

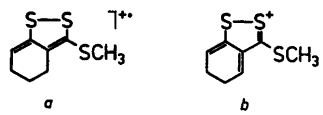


a *b*

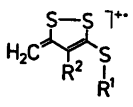
designated structure *b*, which is consistent with the spectrum of the deuterium labelled compound VIII.

The ion corresponding to the loss of $\cdot CH_3$ from the molecular ion gives rise to the abundant peak at *m/e* 187. Loss of methyl from the condensed ring system leading to a ring contraction as suggested for 3-methyl-4,5-tetramethylene-1,2-dithiolylium bromide [1] may also take place here. However, the alkyl group R^1 is lost preferentially, since in the spectrum of VIII the peak corresponding to the loss of CD_3 is five times as abundant as that corresponding to the loss of CH_3.

The hydrogen atom involved in the ·SH loss preferentially originates from the condensed system.

The peak at *m/e* 188 corresponds to the molecular ion of 4,5-tetramethylene-1,2-dithiol-3-thione most likely formed by loss of the alkyl group R^1 from the primary radical, Scheme 1. Loss of $\cdot CH_3$ and ·SH from *m/e* 188 give rise to the ions at *m/e* 173 and 155, respectively, as was also observed for an authentic sample of 4,5-tetramethylene-1,2-dithiol-3-thione.[5]

The structure of the molecular ion observed in the mass spectra obtained from I to IV corresponds to the loss of a hydrogen atom from the methyl group in the 5 position of the initially formed radical. This process yielding *c* is analogous to the formation of *a*, and is in



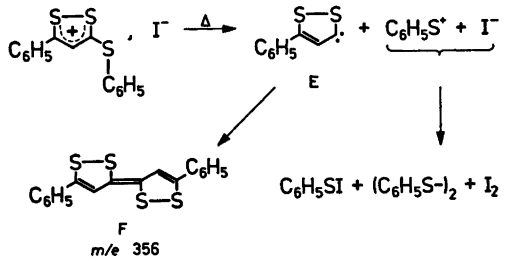
c

accordance with calculations of the spin densities in the dithiolyl radical.[6,7] These calculations suggest a high spin density in the 3 and 5 positions which will facilitate the loss of a hydrogen atom from the methyl group in the 5 position.

The mass spectrum of compound I is typical for this group and is shown in Fig. 2. Loss of R^1 and SR^1 from the molecular ion are characteristic processes. If the salt is unsubstituted in the 4 position, *e.g.* I, the molecular ion shows the loss of $\cdot S_2H$ whereas III and IV with a methyl group in the 4 position expel ·SH from the molecular ions. These differences in fragmentation are the same as found for 4-methyl-1,2-dithiol-3-thione and 5-methyl-1,2-dithiol-3-thione.[4] The peaks at *m/e* 83 and 71 are due to the loss of S_2 and CS_2, respectively, from the $[M-R^1]$ ion. Corresponding peaks are found in the other cases too.

The mass spectrum of the phenylthio compound XIV indicates a somewhat different thermolytic behaviour than that observed for the alkylthio substituted compounds.

The spectrum of XIV exhibits the base peak at *m/e* 109, which corresponds to C_6H_5S. This fragment is probably formed by a heterolytic cleavage (Scheme 2) and before ionization C_6H_5SI and $C_6H_5S-SC_6H_5$ are formed by nu-



Scheme 2.

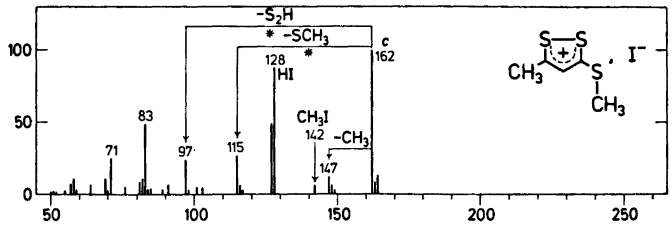


Fig. 2.

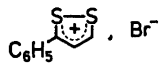
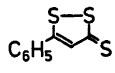
cleophilic attack of the iodide ion on $C_6H_5S^+$ and by reduction of this ion by I^-. The phenyl sulfenyl iodide and the diphenyl disulfide give rise to intense peaks at *m/e* 236 and *m/e* 218, respectively. Intense peaks corresponding to $[I]^{+\cdot}$, $[HI]^+$, and $[I_2]^{+\cdot}$ are also present.

The carbene formed by loss of $C_6H_5S^+$ dimerize prior to ionization accompanied by the formation of the tetrathiafulvalene (F). This behaviour is analogous to that previously reported for 5-phenyl-1,2-dithiolylium bromide (G),[1] and the spectra obtained from XIV and (G) are very similar (apart from the iodine and C_6H_5S containing ions).

The fragmentation pattern of 5-phenyl-1,2-dithiol-3-thione (H) gives rise to abundant peaks in the spectrum of XIV. (H) may arise by a mechanism analogous to that depicted for the formation of 1,2-dithiol-3-thiones in Scheme 1. However, since no peak corresponding to $[C_6H_5I]^{+\cdot}$ is observed, a thermal mechanism similar to that proposed in the case of (G) [1] is considered to be more likely.



G



H

EXPERIMENTAL

The mass spectra were obtained on a MS 902 mass spectrometer using the direct sample insertion system with a sample probe of pyrophylite and the lowest feasible ion source temperature (120 – 250 °C). 70eV electrons were used. Peaks corresponding to doubly charged ions appearing at half mass numbers and peaks of abundance lower than 2 % were omitted in the spectra shown.

*3-Alkylthio-1,2-dithiolylium iodides** were prepared from the appropriate 1,2-dithiol-3-thiones and methyl iodide either in refluxing butyl acetate [8] or in chloroform at room temperature.[9]

*3-Phenylthio-1,2-dithiolylium iodide** was prepared as described by Faust *et al.*[10]

Chlorinated Long-chain Fatty Acids. Their Properties and Reactions. VIII. The Kinetics and Stereochemistry of the Alkaline Dehydrochlorination of Diastereoisomeric Sodium 9,10-Dichlorooctadecanoates

KALEVI PIHLAJA* and MARTTI KETOLA

Department of Chemistry, University of Turku, SF-20500 Turku 50, Finland

The base-promoted removal of the first chlorine of sodium *erythro*-9,10-dichlorooctadecanoate in aqueous ethylene glycol was found to produce sodium 9(10)-chloro-*cis*-octadecenoate. The corresponding *threo* isomer gave 9(10)-chloro-*trans*-9-octadecenoate by a 2.5 times higher rate (363 K) in identical circumstances.

When kept in aqueous alkaline ethylene glycol (5.4 wt. % of water) at 418 K *threo*-dichloride lost all of its chlorine within 24 h, whereas *erythro*-dichloride lost only 68 % of its chlorine content within 825 h in agreement with the fact that intermediate vinylic *cis*-monochlorides react much slower than the corresponding *trans*-monochlorides.

Stereochemically the first reaction step is a *trans*-elimination process in which the different reaction rates of the diastereoisomers were shown to be mainly due to the differences in the ground state energies of their reactive conformations [$k_{threo}/k_{erythro} = 5.0$ (obs.) and 6.5 (calc.) at 298 K].

Diastereoisomeric compounds, such as *threo*- and *erythro*-isomers, may have different reaction rates.[1] For example, the base-promoted dehydrochlorinations of sodium *threo*- and *erythro*-9(10)-chloro-10(9)-hydroxyoctadecanoates have been found to occur at different rates.[2]

The kinetics and mechanisms of the removal of HCl from sodium *threo*-9,10-dichlorooctadecanoate have been studied earlier.[3,4] To complete these studies and to clarify the stereochemical course of the reaction, sodium *erythro*-9,10-dichlorooctadecanoate (*1*) was also prepared and subjected to alkaline dehydrochlorination.

EXPERIMENTAL

GLC analyses were carried out on a Perkin Elmer F 11 gas chromatograph equipped with a hydrogen flame ionization detector. The stainless steel columns were packed with Chromosorb G (60/80 mesh) coated with a polar (5 % XE-60, 200 cm × 3 mm) or non-polar silicone grease (3 % SE-30, 300 cm × 3 mm). The chromatograms were run under isothermal conditions at 160 °C with the former column and at 210 °C with the latter. Before analyses the acids were esterified with diazomethane in diethyl ether containing 10 % of methanol (v/v). The methyl esters of stearic (C18), arachidic (C20), 9-octadecynoic (C18) and 9(10)-chloro-*trans*-9-octadecenoic acids were used as reference compounds.

Proton resonance spectra were recorded on a Perkin Elmer R10 spectrometer (60 MHz) using CCl_4 as solvent and tetramethyl silane (TMS) as internal reference. The sample concentrations varied from 5 to 10 % (w/w). A Perkin Elmer Model 180 spectrophotometer was used to record IR absorption spectra using a thin film of sample between KBr windows. UV absorption spectra were run on a Unicam SP 800 spectrophotometer using absolute ethanol (the State Alcohol Monopoly, Grade AaS, for Spectrophotometry) as solvent. Mass spectra of the prepared methyl esters of the acids were determined with GLC-MS [0.9 m × 3 mm stainless steel column filled with silicone oil OV-17 (2 %; on Chromosorb G 60/80 mesh; 220 °C) connected to a Perkin Elmer M 270 mass spectrometer (ionizing potential 70 eV)].

The chlorine contents of *erythro*-9,10-dichlorooctadecanoic acid and its dehydrochlorination products were determined by the method described previously.[5]

Kinetic measurements and calculation of the reaction rate coefficients were accomplished as shown earlier.[3,4]

Syntheses. Elaidic acid was prepared by isomerization of oleic acid (Fluka AG, 96 % by GLC) by nitrogen oxide.[6] Its melting point after consecutive recrystallizations from diethyl ether and acetone at −17 °C was 42.5 °C (lit.[6] 43−44 °C).

erythro-9,10-Dichlorooctadecanoic acid was obtained by chlorination of elaidic acid (12 g) in CCl_4 solution (150 ml) saturated with chlorine.[5] After evaporation of solvent and excess chlorine the oily residue was treated with urea (12 g) in 100 ml of chloroform containing 10 ml of methanol to remove saturated acids present as impurities in the starting material. The mixture was stirred at 22 °C for 44 h. The excess urea and its fatty acid complexes were then filtered off. Recrystallization of the crude dichloride (about 17 g, after removal of solvent) twice from hexane (4 g of acid per 1 ml of solvent) at −17 °C yielded 7.2 g of acid, m.p. 44.5−45.5 °C (lit.[7] 47.5 °C). The chlorine content based on six determinations was 20.39±0.11 % (calc. 20.07 %). ^{1}H NMR (CCl_4): δ 0.89 (CH_3-), 1.33 [$-(CH_2)_n-$], 2.22−2.31 ($-CH_2COOH$), 1.86 ($-CH_2CHCl-$), 3.9 [$-CH(Cl)-$], and 12.1 ($COOH$). IR, ν_{max}: 1710 (COOH) and 646 cm^{-1} (C−Cl). The acid was converted to its sodium salt (*1*) by methanolic alkali.

Separation of the reaction products. The products formed in the first dehydrochlorination step were obtained by keeping a sample of sodium *erythro*-9,10-dichlorooctadecanoate (*1*) in aqueous alkaline ethylene glycol at 110 °C for 100 min. For the further removal of HCl from the vinylic monochloride formed from *1* more drastic conditions were used: the reaction vessel was kept at 145 °C for 343 and 825 h. The reaction mixture included 1.5 g of *1* and 0.3 mol of NaOH in 400 g of ethylene glycol, which contained 5.4 % of water by weight. The dehydrochlorination products were separated from the reaction mixtures by extraction with CCl_4 as described in an earlier paper.[8] The amount of the viscous residues was about 1 g in each case.

RESULTS AND DISCUSSION

Analyses of the reaction products. After esterification with diazomethane the dehydrochlorination products of *1* separated from the reaction mixtures were analyzed by GLC, NMR, IR, UV, and mass spectroscopy.

The product, after the first dehydrochlorination step, contained 10.1 % of chlorine (10.0 % in theory). IR ν_{max}: 3030 (CH=), 1710 (COOH), 1650 (CH=CCl) and 650 cm^{-1} (C−Cl), ^{1}H NMR (CCl_4): δ 0.89 (CH_3-), 1.96 ($-CH_2CH=$), 2.08 ($-CH_2CCl=$ or $-CH_2C=$), and 5.51 ($-CH=CCl-$; a triplet; J=7.5 Hz). The weak signal at about δ 3.6 may be due to $-CH(OR)-$, where R may be H or the anion of ethylene glycol, or to the alkoxy protons of $-CH(OCH_2CH_2OH)=CH-$. These systems may be formed through the addition of water or ethylene glycol to a double or triple bond. The UV spectrum of the first-step product had a maximum at 218 nm and an inflexion at 232 nm, which may be due to the formation of some conjugated dienes.

Because of the low reactivity of vinylic chloride formed in the first dehydrochlorination step of *1* the removal of the second mol of HCl required more vigorous reaction conditions: a sample of *1* was treated with alkaline reagent for 343 and 825 h at 145 °C. The dehydrochlorination products separated contained 8.3 and 6.4 % of chlorine, respectively. The IR spectrum of the product obtained after the shorter dehydrochlorination period had a new band at 1960 cm^{-1} (C=C=C), which is weakened by the prolonged alkali treatment. The product after 825 h showed also a weak IR band at 2280 cm^{-1} (C≡C). The presence of the allene group is confirmed by a multiplet at δ 5.0 in the NMR spectra of the dehydrochlorination products separated after 343 and 825 h. The product after 343 h had UV maxima at 228 and 255 nm, but after 825 h, only at 255 nm.

The GLC data relative to methyl stearate for the 'methylated' dehydrochlorination products of *1* are collected in Table 1. The results show, that on the polar XE-60 column, the main component (peak 2) of the first dehydrochlorination product is eluted after methyl 9(10)-chloro-*trans*-9-octadecenoate (peak 11). On the non-polar SE-30 column these compounds (peaks 2 and 11) have similar relative retention times. These results are in accordance with those of Stein [9] and Gunstone [10] for the corresponding bromo derivatives, methyl 9(10)-bromo-*cis*-9- and 9(10)-bromo-*trans*-9-octadecenoates. The mass spectrum of peak 2 showed the parent peak (M^+) at *m/e* 331 in agreement with the molecular weight (330.9) of $C_{19}H_{35}O_2Cl$ and the fragment peaks at *m/e* 299, 294, and 263, probably due to $[M-CH_3OH]^+$, $[M-HCl]^+$, and $[M-CH_3OH-HCl]^+$, respectively. Thus the principal product

Table 1. Gas chromatographic retention data for some model compounds and for dehydrochlorination products of sodium *erythro*-9,10-dichlorooctadecanoate (*1*). Retention times are given relative to the retention times for methyl stearate [1.00≡5.24 min (XE-60) and 1.00≡ 6.5 min (SE-30)].

11	9(10)-Chloro-*trans*-9-octadecenoic acid	2.36	1.61

[a] The major peak in the chromatogram.

in the first dehydrochlorination step seems to be sodium 9(10)-chloro-*cis*-9-octadecenoate.

Two compounds formed after the further dehydrochlorination (peaks 3 and 4 in Table 1) gave the molecular ion peaks at *m/e* 294 indicating the presence of dienic, allenic, or ynoic esters with the molecular weight (294.4) of $C_{19}H_{34}O_2$. According to the GLC data peak 4 may be an acetylenic ester since its relative retention time on the XE-60 column is equal to that of an authentic sample of methyl 9-octadecynoate (peak 9). Gunstone *et al.*[10] observed that on a polar column the long-chain allenic C_{18}-ester was eluted before the corresponding acetylenic one. Thus the relative retention times 1.1 (peak 3) and 1.2 (peak 4) may also indicate that the former is an allenic intermediate. Moreover, after 343 h the area of the peak of the allenic ester (peak 3 in Table 1) was larger than that of the ynoic ester (peak 4), while after the dehydrochlorination for 825 h, the order was reversed.

GLC and UV spectroscopy pointed out that the first-step dehydrochlorination product contained only small amounts of conjugated dienes, which moreover, were not among the products formed during the further dehydrochlorination of *1*. In the latter case the equilibrium reached was in favour of allenes and acetylenes, but not of conjugated dienes (Scheme 1).

Kinetics and mechanisms of dehydrochlorination. The values of the rate coefficients at five temperatures are collected in Table 2 and the values of thermodynamic functions of activation obtained from them by the method of least squares, in Table 3. Accordingly, the first chlorine from sodium *erythro*-9,10-dichlorooctadecanoate (*1*) is removed as HCl rather easily, although the rate of this reaction is about 2.5 times higher for the corresponding *threo* isomer under identical conditions (Table 3). This observation is in accordance with that reported by Gunstone *et al.*[10] for the corresponding dibromooctadecanoates. The removal of HCl from the vinylic *cis*-monochloride under the conditions used was too slow for determination. By heating of *1* with alkali for 825 h at 145 °C 36 % of the second chlorine was reacted,

Table 2. Rate coefficients for the first dehydrochlorination step of sodium *erythro*-9,10-dichlorooctadecanoate in aqueous alkaline ethylene glycol ($x_{H_2O}=0.165$) at different temperatures.[a]

Temperature °C	10^5k (s^{-1})	10^5k_{OH} (kg mol^{-1} s^{-1})
80	7.02 ± 0.09[b]	4.54 ± 0.06[b]
90	20.5 ± 0.3	13.3 ± 0.2
90	19.9 ± 0.3	12.9 ± 0.2
95	32.4 ± 0.3	20.5 ± 0.2
100	51.0 ± 0.6	33.0 ± 0.4
100	48.0 ± 0.6	31.1 ± 0.4

[a] The substrate concentration was 0.01 mol per kg of solvent, sodium hydroxide concentration was 0.773 mol per kg of solvent. [b] Standard deviation.

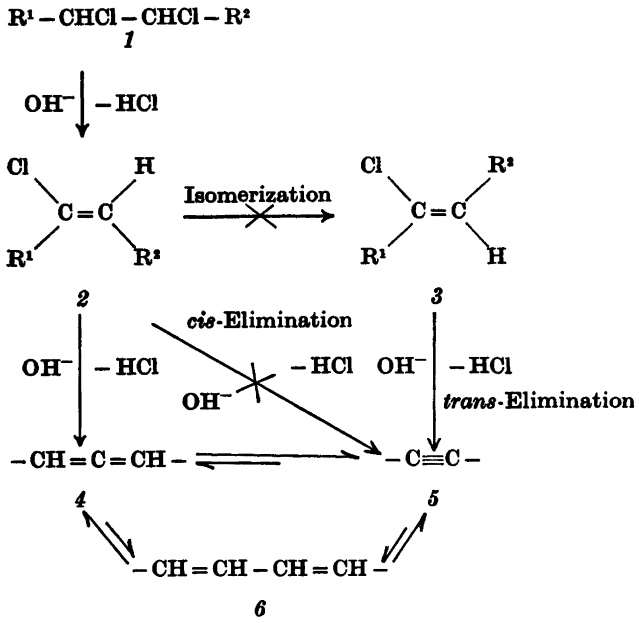
Table 3. Values of the thermodynamic functions of activation and relative rates at 90 °C for the alkaline dehydrochlorination of sodium *threo*- and *erythro*-9,10-dichlorooctadecanoates in aqueous alkaline ethylene glycol containing 16.5 mol % of water.

	Reaction step	$\Delta H^{\ddagger}$ kJ mol^{-1}	$\Delta S^{\ddagger}$ J mol^{-1} K^{-1}	$\Delta G^{\ddagger}$ kJ mol^{-1}	Rel. rate
erythro	I	103.2 ± 2.4[a]	-36.9 ± 6.6[a]	116.6 ± 0.05[a]	140
threo [b]	I	93.8 ± 0.4	-55.3 ± 1.2	113.9 ± 0.02	340
	II	108.1 ± 1.8	-64.3 ± 4.3	131.5 ± 0.2	1

[a] Standard deviation. [b] Refs. 3, 4.

whereas from *threo*-9,10-dichlorooctadecanoate all chlorines were removed after 24 h at 145 °C. This result confirms that the dehydrochlorination of *1* also occurs through *trans*(*anti*)-elimination (E2) where 9(10)-chloro-*cis*-9-octadecenoate is the first step product. The difficulty of the further dehydrochlorination of this *cis*-monochloro-ene (*2*) is mainly due to the great steric hindrance for the *cis*-(*syn*)-elimination.

According to Staley and Doherty [11] the formation of allene from 4-bromo-*cis*-4-octene is very much faster than that of the triple bond through *cis*(*syn*)-elimination. Their results show also that *trans*(*anti*)-elimination of HBr from 4-bromo-*trans*-4-octene yields the triple bond about forty times faster than the corresponding *cis*-isomer forms the allene. Thus the rates of dehydrobromination of monobromooctenes decrease in the sequence $k_{anti} > k_{allene} > k_{syn}$. Vigorous treatment of *1* with alkali yielded acetylenic and allenic intermediates but very little, or no conjugated dienes in accordance with the above results and those of Gunstone



$R^1 = CH_3(CH_2)_7 -$
$R^2 = -(CH_2)_7COONa$

Scheme 1. The possible reaction pathways in the alkaline dehydrochlorination of *1*.

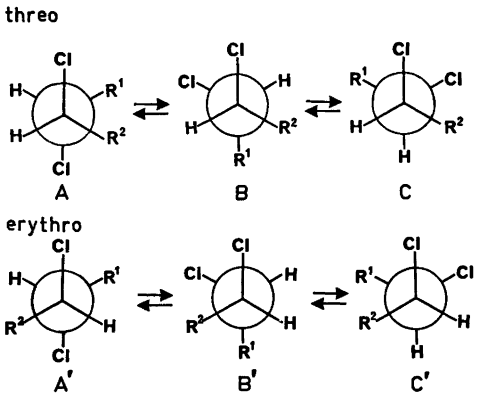


Fig. 1. The minimum energy conformations of sodium *threo*-(A – C) and *erythro*-9,10-dichlorooctadecanoates (A′ – C′).

et al.[10] for the corresponding bromo octadecanoates. Consequently, the base-promoted dehydrochlorination of *1* may be proposed to occur through the following steps (Scheme 1): in the first reaction step *trans*(*anti*)-elimination produces 9(10)-chloro-*cis*-9-octadecenoate (*2*) which during prolonged dehydrochlorination gives allenic intermediates (*4*) and octadecynoates (*5*) both of which are in equilibrium with dienic derivatives (*6*). The formation of *5* through *cis*(*syn*)-elimination or through isomerisation of *2* to *trans*-chloro-ene (*3*) followed by *trans* (*anti*)-elimination is only of minor importance. Secondary isomerizations of *4* and *5* may, of course, give other allenic and acetylenic derivatives,[12,13] which may also be formed from the vinylic *cis*-chloro alkene *2* (Scheme 1) through elimination of HCl preceded by a double bond shift.

Stereochemistry of the first dehydrochlorination step. The basepromoted dehydrochlorination proceeds under the conditions used by E2 mechanism.[14] A stereochemical requirement for this mechanism is that the leaving groups H and Cl are in an *anti* (or *trans*) periplanar conformation.[3,4,14,15]

Both sodium *threo*- and sodium *erythro*-9,10-dichlorooctadecanoates have three minimum energy conformations (Fig. 1) from which only C (*threo* isomer) and B′ and C′ (*erythro* isomer) can undergo the E2 elimination.

The rate of a given reaction of a conformationally heterogeneous system may be presented by the relation [15]

$$k = \sum x_i k_i$$

where x_i is the mol fraction and k_i the rate coefficient of the reaction studied for the ith conformation. Hence the total rates for the first dehydrochlorination steps of sodium *threo* (k_t) and *erythro*-9,10-dichlorooctadecanoates (k_e) may be written

$$k_t = k_A x_A + k_B x_B + k_C x_C$$

$$k_e = k_{A'} x_{A'} + k_{B'} x_{B'} + k_{C'} x_{C'}$$

If the dehydrochlorination reaction occurs predominantly as an *anti*-elimination $k_C \gg k_A \approx k_B \approx 0$ and $k_{C'} \approx k_{B'} \gg k_{A'} \approx 0$. Accordingly,

$$k_t \approx k_C x_C \text{ and}$$

$$k_e = k_{B'} x_{B'} + k_{C'} x_{C'}$$

Moreover, it is reasonable to assume that $k_C = 2k_{B'} = 2k_{C'}$ and $x_{B'} = x_{C'}$ where the factor two is due to the double *anti*-arrangement of the conformation C.[14] Consequently,

$$k_t/k_e = x_C/x_{C'}$$

If the *gauche* interactions due to the groupings R^1 and R^2 do not differ essentially from those of a methyl group the mol fraction of the different conformations may be estimated using the following values (in kJ mol^{-1}) for the various *gauche* interactions at 298 K: $R^1 - R^2$ (Me – Me) [16] + 2.7, Cl – Cl [17] + 5.0, and R^1 – Cl or R^2 – Cl (Me – Cl) [17] – 0.2.

The estimated interaction energies for the conformations of *threo*- and *erythro*-9,10-dichlorooctadecanoates are then (Fig. 1)

A + 2.3	B + 7.7	C + 4.6
A′ – 0.4	B′ + 7.5	C′ + 7.5

Since [15] $x_i/x_{i+1} = \exp\ [(H_i - H_{i+1})/RT]$ and $\sum x_i = 1$ we can estimate that $x_C \simeq 0.26$ and $x_{C'} = 0.04$ and thus $k_t/k_e \simeq x_C/x_{C'} \simeq 6.5$ at 298 K. Experimentally, the rate ratio for the *threo*- and *erythro*-9,10-dichlorooctadecanoates was found to be 2.5 at 363 K and 5.0 at 298 K.[14]

The calculated and experimental results being very close to each other support the postulation that the reaction is really preponderantly *trans*-elimination (E2) and that the difference in the reaction rates is mainly due to the different ground state energies of the reactive conformations of the *threo* and *erythro* isomers.

Crystalline Leghemoglobin. XV. Effect of Urea on the Conformation of the Slow Component (Lb*a*)

NILS ELLFOLK, GUNNEL SIEVERS and AIMO HARMOINEN

Department of Biochemistry, University of Helsinki, SF-00170 Helsinki 17, Finland

Soybean ferrileghemoglobin is reversibly unfolded by urea in phosphate buffer, pH 6.5. The unfolding is accompanied by extensive changes in the ultraviolet and visible spectra of the protein, which have been utilized in investigating the equilibrium and kinetics of the unfolding process at 25 °C. The studies were performed on component *a*, Lb*a*, of soybean leghemoglobin and, for comparison, on sperm whale myoglobin. The equilibrium denaturation data showed that the 50 % denaturation point is at 5.15 M urea for leghemoglobin and 7.60 M for sperm whale myoglobin.

The spectrum of denatured leghemoglobin (8.8 M urea) shows an increase in its low spin character, which is assumed to indicate that the heme group is still attached to the denatured protein in the protein concentrations used in this study. The denaturation of ferrileghemoglobin at high urea concentrations was found to be largely reversible upon diluting the reaction mixture. The kinetics of the unfolding reaction for leghemoglobin and for sperm whale myoglobin at pH 6.5 were investigated in the Soret band region. These studies indicate that leghemoglobin is a considerably less stable molecule than sperm whale myoglobin.

Urea denaturation has been extensively used to investigate the forces that maintain the protein molecule in its native form.[1-3] The effect of urea on myoglobin has recently received attention. Schlechter and Epstein [4] have reported a study of the denaturation equilibria of both whale and horse metmyoglobins, and Cann observations on the kinetics of the urea denaturation of metmyoglobin.[5-7] This investigation reports the effect of urea on the slow component of soybean leghemoglobin (Lb*a*). For comparison, some studies were also made on the effect of urea on sperm whale myoglobin.

MATERIALS AND METHODS

Leghemoglobin. The two main components (Lb*a* and Lbc) of soybean leghemoglobin were prepared as described previously.[8]

Sperm whale myoglobin was a commercial preparation (Type II) from Sigma Chemical Company (St. Louis, U.S.A.).

Urea, pure, from E. Merck AG (Darmstadt, Germany) was used. It was twice recrystallized from ethanol at 4 °C. Crystals were collected and washed with cold absolute ethanol, dried *in vacuo* and stored *in vacuo* over $CaCl_2$ and $CaSO_4$. Urea solutions were deionized immediately before use by passing the solutions through two ion exchange columns (2 × 8 cm containing 25 ml of Dowex 1 × 2 and 25 ml of Dowex 50 × 2, respectively).

Measurements of absorption spectra. Most of the spectra were measured using a Cary 15 recording spectrophotometer equipped with a jacketed cell holder through which circulated water from a constant temperature bath.

For the absorption spectra measurements at a fixed wavelength a Beckman DU-2 instrument was used without recording attachment.

Procedure for measuring kinetics. A cell containing the buffered urea solution (2.475 ml) was placed in the sample compartment of a Cary 15 recording spectrophotometer. 25 µl of a concentrated solution of Lb*a* or Mb was added to the cell using a cuvette-add-a-mixer. The change in absorption at the Soret band was monitored using the synchronous drive attachment of the spectrophotometer. The denaturation was followed until a very slow linear decline was obtained.

Circular dichroism measurements. Circular dichroism (CD) data for Lb*a* solutions were obtained using a Cary 61 recording spectropolarimeter, which was calibrated with D-10-camphorsulfonic acid. The circular dichroism data were reduced to mean residue ellipticities, $[\theta']_\lambda$, using the following formula:

$$[\theta']_\lambda = M_0[\theta]/10lc$$

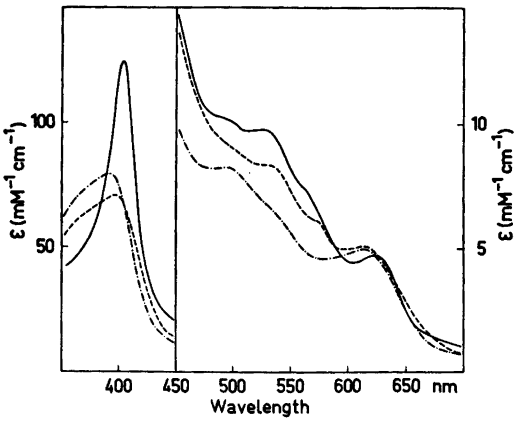

Fig. 1. Absorption spectra of soybean ferrileghemoglobin, Lb*a*, in 0.05 M sodium phosphate buffer, pH 6.5 at 25 °C. (———) native Lb*a*, (– – –) Lb*a* in 8.8 M. For comparison, the spectrum of protohemin IX (– · –) in 8.8 M urea and the same buffer is shown. The actual concentration of Lb*a* and of free protohemin were 7.2×10^{-5} M.

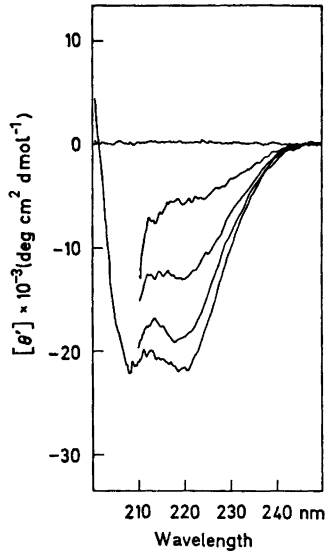

Fig. 2. The effect of urea on circular dichroism spectra of soybean ferrileghemoglobin, Lb*a*, in the spectral region below 250 nm. The measurements were made in 0.05 M sodium phosphate buffer, pH 6.5 at 25 °C, using a silica cell with 1 mm light path. Urea concentrations: 0, 5.0, 6.0, and 8.0 M. The value of mean residue ellipticity increases with increasing urea concentration. The actual protein concentration was 1.02×10^{-5} M.

where M_0, l, c are the mean residue weight, the length of the light path in cm, and concentration of the protein in g/ml, respectively. $[\theta]$ is the ellipticity in degrees recorded on the chart paper. The above formula gives the $[\theta']$ value, expressed in degree cm²/decimol of residues, which satisfies the relationship

$$[\theta]_\lambda = 2.303\ (4.500/\pi)(\varepsilon_L - \varepsilon_R)$$
$$= 3.300(\varepsilon_L - \varepsilon_R)$$

where $(\varepsilon_L - \varepsilon_R)$ is the difference in the molar extinction coefficients for left and right polarized light. The mean residue weight employed for Lb*a* was 106.5.[9]

Pyridine hemochrome was determined according to Paul *et al.*[10]

pH Measurements were carried out at 20 °C with a Radiometer PHM 3 pH-meter, which had been standardized against phthalate and borate buffers. The pH-values given in the experimental section refer to the pH-values of the original buffer.

RESULTS

The absorption spectrum of native Lb*a* and that of the protein in 8.8 M urea at pH 6.5 are shown in Fig. 1. At high urea concentrations spectral changes occur indicating conformational changes at the heme site. The typical ferrihemochrome spectrum with maxima at 530 nm and 565 nm shows that the low spin character of Lb*a* has increased in 8.8 M urea compared to that of protohemin IX in 8.8 M urea (Fig. 1). This is assumed to indicate that the heme moiety is not dissociated, but is attached to the denatured protein to a great extent at the protein concentrations used in this study.

CD spectra of Lb*a* in urea solutions were also measured in the ultraviolet region, as shown in Fig. 2. An increase of the ellipticity in the region of 200 – 250 nm at 8.0 M urea indicates extensive unfolding of the α-helix. It is evident that concomitant changes in the absorption and CD spectra occur with the denaturation by urea. Fig. 3 shows a plot of the fractional absorbance change at the Soret maximum as a function of the urea concentration.

The duration of incubation was found to have an influence on the extinction values; the largest decrease occurred within 30 s at the beginning of the incubation with the values

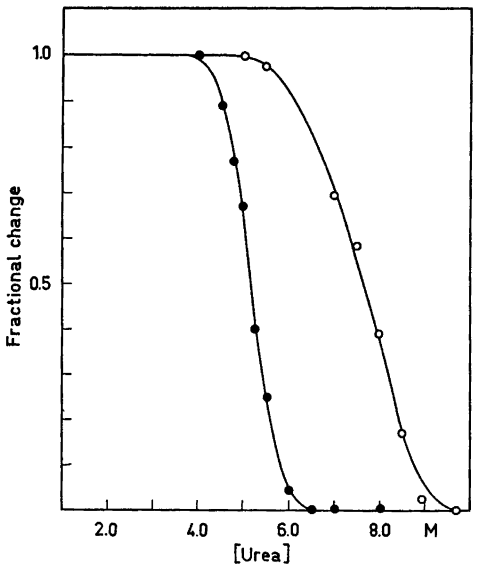

Fig. 3. Fractional absorption change at Soret maximum that occurs on denaturation of soybean ferrileghemoglobin, Lb*a*, (●), and sperm whale ferrimyoglobin, Mb, (○) at different urea concentrations in 0.05 M sodium phosphate buffer, pH 6.5 at 25 °C. The wavelengths used were 403.5 nm (Lb*a*) and 409.5 nm (Mb). The fractional change is equal to $(A_U - A_D)/(A_N - A_D)$, where A_N denotes the absorbance of the native protein, A_D that of the totally denatured protein, and A_U the absorbance at a given urea concentration. The actual protein concentration was 3.34×10^{-6} M.

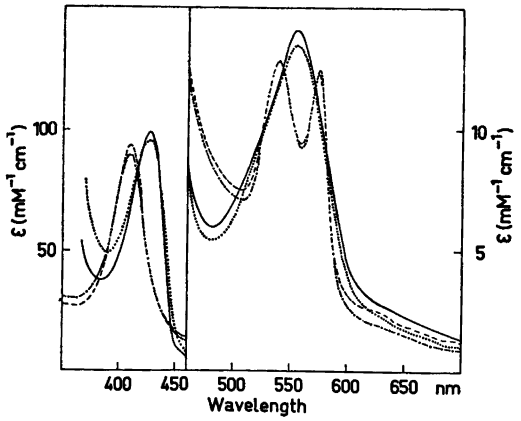

Fig. 4. Spectral properties of soybean leghemoglobin, Lb*a*, after reversal of the denaturation. FerriLb*a* (14.4×10^{-5} M) was denatured at 25 °C for 30 min in 0.05 M sodium phosphate buffer, pH 6.5, containing 8.0 M urea, after which the urea was diluted to 4.0 M with same buffer. (····) shows the spectrum of the reduced form (ferroLb*a*) produced by the addition of a small amount of dithionite. (— · —) represents the spectrum of the oxygen complex, obtained by bubbling air through the solution of the renatured ferroLb*a*. For comparison, the spectra of the native ferroLb*a* (———) and the oxygen complex of the native ferroLb*a* (— — —) in 0.05 M sodium phosphate buffer, pH 6.5, are shown.

decreasing more slowly thereafter. In the case of myoglobin the fast period in the beginning lasted about 10 min. The 50 % denaturation point of Lb*a* was found to be at 5.15 M urea and that of sperm whale myoglobin at 7.60 M urea.

The spectral changes accompanying denaturation of Lb*a* in urea were found to be largely reversible when the urea concentration was reduced by dilution. The recovery of the visible spectrum following denaturation is shown in Fig. 4 for Lb*a* incubated in 8.0 M urea for 1 h prior to dilution to 4.0 M urea. The recovery of the reduced form of Lb*a* was not limited to the return of a native-like spectrum only, the oxygen binding capability of the reduced form was also recovered. This is a strong indication that Lb*a* must have returned to a conformation closely resembling that of the biologically active native form.

The recovery of the intensity of the Soret band upon dilution was found to depend on the length of time a solution was kept in 8.0 M urea before diluting to the lower concentration. If the heme group is dissociated from the denatured protein, the irreversibility may be associated with nonspecific binding to the renatured globin.

These results indicate that an equilibrium exists between the native and unfolded states of ferrileghemoglobin in urea solutions, with the heme groups attached to both forms. It is known to be difficult to distinguish between a simple "two-state" unfolded equilibrium and a more complex, or "multi-state", one. We assume, therefore, a "two-state" mechanism in this particular case, for which the observed transition is

$$[NH] \rightleftharpoons [DH]$$

where [NH] and [DH] represent the heme-

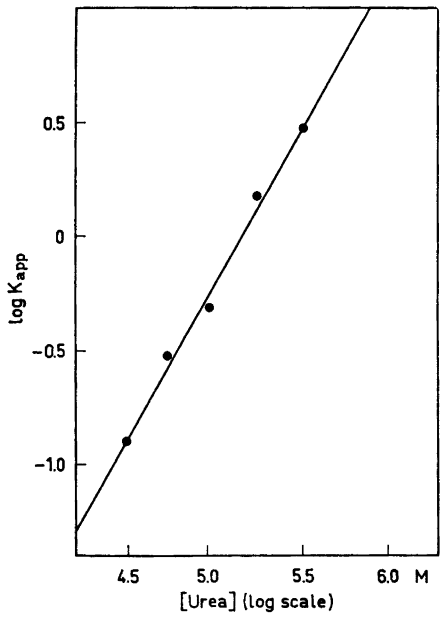

Fig. 5. Plot of log K_{app} *versus* logarithm of the urea concentration. The urea concentration when K_{app} is equal to unity is 5.15 M, and the slope of the line is about 16. The experimental conditions are identical to those in Fig. 3.

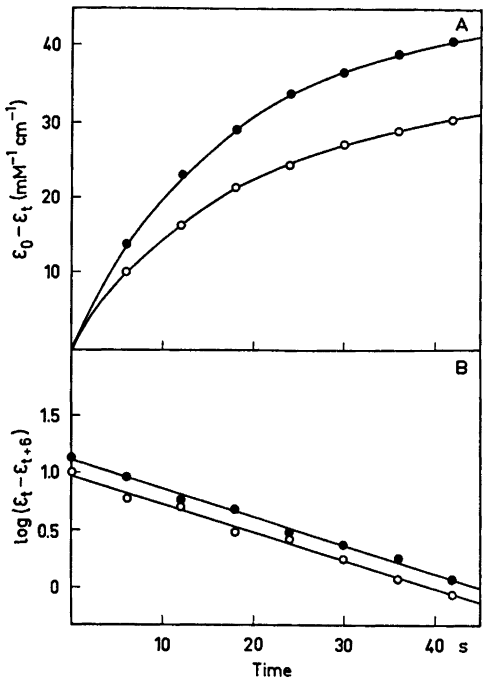

Fig. 6. The denaturation kinetics of soybean ferrileghemoglobin at urea concentrations of 5.25 and 5.50 M measured at 403.5 nm. The experimental conditions were identical to those in Fig. 3. *A*. The kinetics, recorded as differences between the extinction coefficients at zero time, and at the time t, (○) at 5.25 M and (●) at 5.50 M urea. *B*. Guggenheim plots for the denaturation kinetics. The ordinate refers to the logarithm of the difference between extinction coefficients separated by a constant time interval of 6 s, (○) at 5.25 M and (●) at 5.50 M urea.

protein complex in the native and denatured form, respectively. The equilibrium constant for the denaturation reaction is

$$K_D = [DH]/[NH]$$

and an apparent equilibrium constant can be calculated using an equation of the form [3]

$$K_{app} = A[U]^{\nu}$$

where [U] is the urea concentration and A and ν are constants. A plot of log K_{app} against log [U] is given in Fig. 5. The midpoint of the transition, which occurs when K_{app} is equal to unity, is found to be at 5.15 M urea. The slope was calculated to be about 16.

The effect of urea concentration on the course of denaturation was studied for Lb*a* and, for comparison, sperm whale myoglobin. In Fig. 6A the difference between the extinction coefficient at 403.5 nm at zero time and at time t is plotted against time. Fig. 7A shows a similar plot for myoglobin measured at 409.5 nm. It can be seen that the rate of denaturation of Lb*a* is much faster than that of myoglobin under the same conditions. Fig. 6B shows a plot according to the Guggenheim method,[11] which eliminates the need for a final absorbance value. The expression used is

$$\ln (A_t - A_{t+\Delta t}) = -(k_{+1} + k_{-1})t + \text{constant}$$

where A_t and $A_{t+\Delta t}$ are absorption values at a time t and $t+\Delta t$, respectively. A Δt of 6 s was chosen. It can be seen that the kinetics at the given urea concentrations are first order as for myoglobin (Fig. 7B).

DISCUSSION

The denaturation behaviour of soybean leghemoglobin (Lb*a*) was studied in urea solutions.

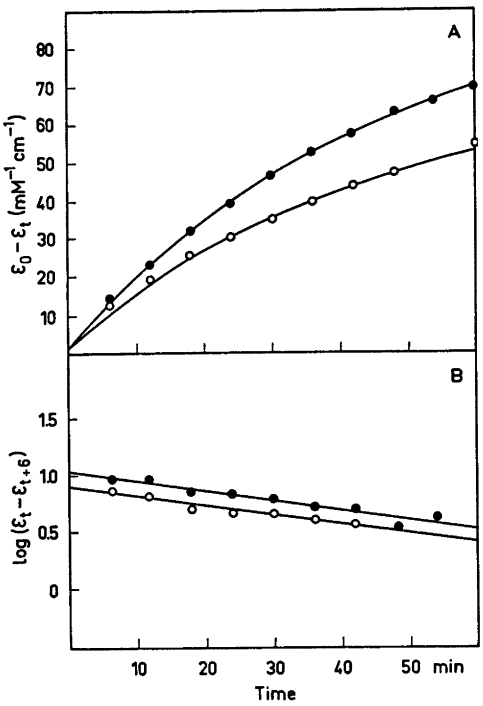

Fig. 7. The reaction kinetics of sperm whale ferrimyoglobin at urea concentrations of 7.5 and 8.0 M measured at 409.5 nm. The experimental conditions were identical to those in Fig. 3. *A.* The kinetics, recorded as differences between the extinction coefficients at zero time and at the time *t*, (○) at 7.5 M and (●) at 8.0 M urea. *B.* Guggenheim plots for the denaturation kinetics. The ordinate refers to the logarithm of the difference between extinction coefficients separated by a constant time interval of 6 min, (○) at 7.5 M and (●) at 8.0 M urea.

Comparative studies have also been performed on sperm whale myoglobin. The equilibrium denaturation data showed that the 50 % denaturation point is at 5.15 M urea for soybean leghemoglobin and 7.60 M urea for sperm whale myoglobin, the latter being close to the values reported in earlier studies.[4,12] The denaturation of the two proteins was found to be reversed by diluting the reaction mixture. It was shown that changes in the absorption spectra and circular dichroism accompanied the denaturation of Lb*a* by urea, but whether this reflects the same structural changes as those responsible for the changes in the heme absorption, or whether it concerns different areas of the molecule, is uncertain.

In the case of heme proteins, including leghemoglobin, the conformational properties of the globin are largely dependent upon the presence of the heme, the globin structure corresponding to a more unfolded state than the heme-complex.[13–17] It is therefore not surprising, that some detachment of the heme groups may accompany denaturation of the protein. However, with the present experimental conditions, it is assumed that no heme dissociation occurs to any large extent during the urea denaturation of leghemoglobin. It is evident that the renaturation of the denatured Lb*a* proceeds more completely when the heme moiety remains attached to the denatured protein. This additionally supports the belief that the heme group has an important role in maintaining the secondary and tertiary structures of the molecule.

Phloroglucinol Derivatives of *Hagenia abyssinica*. II.* The Structure Determination of Kosotoxin and Protokosin**

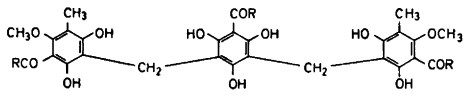
MAURI LOUNASMAA,[a] C.-J. WIDÉN [b] and AARRE HUHTIKANGAS [b]

[a] State Institute for Technical Research, Chemical Laboratory, SF-02150 Otaniemi, Finland and [b] Department of Pharmacognosy, University of Helsinki, SF-00170 Helsinki 17, Finland

Phloroglucinol derivatives (kosins) from *Hagenia abyssinica* (Bruce) Gmel. have been reinvestigated. On the basis of reductive alkaline cleavages and spectroscopic evidence the structures (II) and (III) are proposed for kosotoxin and protokosin, respectively. The so-called β-kosin proved to consist of a mixture of isobutyryl (iB), isovaleryl (iV), and 2-methylbutyryl (2-MeB) side chain homologues of methylene-bis-pseudo-aspidinol (IV).

Les dérives phloroglucinoliques (kosines) isolés d'*Hagenia abyssinica* (Bruce) Gmel. ont été réexaminés. Sur la base des données des clivages réductifs alcalins et des preuves spectrales les structures (II) et (III) sont proposées pour la kosotoxine et la protokosine, respectivement. La prétendue β-kosine est en fait un mélange des homologues isobutyryles (iB), isovaléryles (iV) et méthyl-2 butyryles (2-MeB) des chaînes latérales du méthylène-bis-pseudo-aspidinol (IV).

In a recent publication [1] we reported the isolation of four phloroglucinol derivatives (kosins), designated K1 – 4, from kousso flowers (*Flos koso*).*** For one of these (K1), apparently identical with the earlier known kosidin,[2] we proposed the structure (I). Owing to its close structural similarity to the *Dryopteris* phloroglucinols, however, we preferred to give to kosidin the new name trispseudo-aspidinol.



(I)

We also isolated [1] substances with the properties recorded for kosotoxin (K2) [3,4] and protokosin (K3 and/or K4).[3,5,6] All kosins proved to be mixtures of isobutyryl (iB), isovaleryl (iV), and 2-methylbutyryl (2-MeB) side-chain homologues. Because of the small amounts isolated, the structures of kosotoxin (K2) and protokosin (K3 and/or K4) could not be fully elucidated. Through the kind cooperation of Professor T. Reichstein of Basle, however, we obtained a further commercial sample of Flos koso. As a result of extensive spectral analyses and examinations of degradative products, the structures (II) and (III) are now proposed for kosotoxin (K2) and protokosin (K4), respectively.†, ††

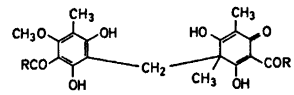
* Part I, Ref. 1.

** Part of this work was presented at the 4th Scandinavian Natural Products Chemistry Symposium held at Koli, Finland, June 12 – 17, 1973.

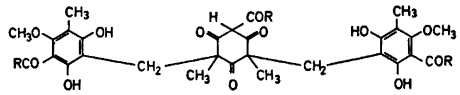
*** The dried female flowers (Flos koso) of *Hagenia abyssinica* (Bruce) Gmel. are known unde there names "kousso", "kosso" or "kusso" especially in Africa and the Near East. The kosins are presumably located in typical glandular hairs occurring on the epidermis.

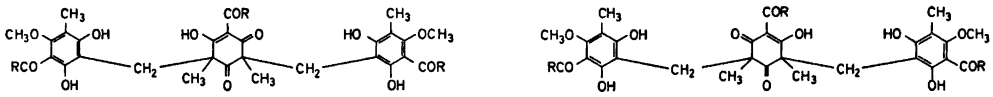
† It is plausible that even kosotoxin (II), for which only one formula is presented, can exist in several tautomeric forms.

†† K3, for which similar chemical and physical properties to those of K4 (protokosin) were reported,[1] proved to consist mainly of K4. The differences in their mass spectra turned out to be due to the fact that protokosin, at high temperatures, is transformed in the ionization chamber of the mass spectrometer to a mixture of compounds corresponding to $C_{41}H_{50}O_{11}$, $C_{40}H_{48}O_{11}$, $C_{39}H_{46}O_{11}$, and $C_{38}H_{44}O_{11}$.



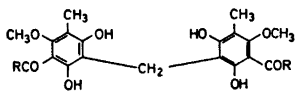
(II)



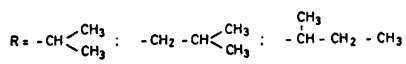


(III)

Moreover, we studied the so-called kosin, that is formed from kousso constituents by the action of alkali.[2–7] This "kosin", which was earlier considered to be a mixture of two isomeric dimethyl ethers of methylene-bis-methylphloroisobutyrophenone, assigned as "α-" and "β-kosin",[6,8] proved to be a mixture of compounds differing only in their acyl side chains. Thus, they all have the same "skeletal structure" as the earlier known "α-kosin" [IV, R = $-CH(CH_3)_2$]. Moreover, the acyl side chains proved to be the same as those found in the above mentioned naturally occurring phloroglucinol constituents of kousso: isobutyryl (iB), isovaleryl (iV), and 2-methylbutyryl (2-MeB). For the same reasons as advanced for trispseudo-aspidinol (I),[1] the name methylene-bis-pseudo-aspidinol is proposed for this mixture of "kosin" homologues (IV). Analogously, the earlier designated "α-kosin" [IV, R = $-CH(CH_3)_2$] should be called methylene-bis-pseudo-aspidinol iBiB.



(IV)



STRUCTURE DETERMINATIONS

Trispseudo-aspidinol (kosidin) (I). This tricyclic phloroglucinol derivative, for which the structure (I) was proposed earlier [1] and which was obtained as yellowish plates, m.p. 167 – 169 °C (methanol),[1] was not isolated in crystalline form in connection with the present work. According to semiquantitative TLC (*cf.* Ref. 1) it is a minor component (< 5 %) in the phloroglucinol mixture of kousso (crude kosin).

The mass spectrum of trispseudo-aspidinol (I) (Fig. 1) shows molecular peaks at *m/e* 710, 696, 682, and 668, corresponding to $C_{39}H_{50}O_{12}$, $C_{38}H_{48}O_{12}$, $C_{37}H_{46}O_{12}$, and $C_{36}H_{44}O_{12}$, respectively. These four peaks, as well as the peaks at *m/e* 653, 639, and 625, which can be assigned to the cleavages of C_4H_9- and C_3H_7- side chain units from the molecular ions, are in good agreement with the results of alkaline cleavages [1] and confirm that trispseudo-aspidinol (I) is a mixture of side chain homologues. The general fragmentation of trispseudo-aspidinol (I) is analogous to that found earlier for polycyclic *Dryopteris* phloroglucinols [9–11] and supports the proposed structure (I).

The NMR spectrum ($CDCl_3$) of trispseudo-aspidinol also supports the structure (I), in agreement with the NMR data reported earlier,[1]

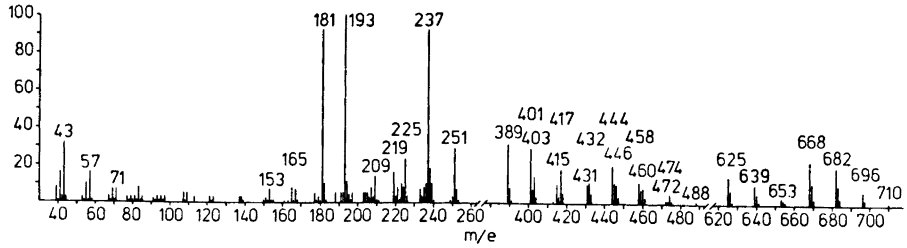


Fig. 1. Mass spectrum (70 eV) (*T* 200 °C) of trispseudoaspidinol (I).

showing the following signals:* δ 1.18 [18 H, d, *J* 7 Hz, mainly 3 $-CO-CH(CH_3)_2$], 2.12 (6 H, s, 2 CH_3-Ar), 3.72 (6 H, s, 2 CH_3O-Ar), 3.82 (4 H, s, 2 $-CH_2-$), ~3.9** [3 H, m, mainly 3 $-CO-CH(CH_3)_2$], 9.56 (2 H, s, 2 OH), 10.72 (2 H, s, 2 OH), 15.46 (1 H, s, OH), 15.56 (1 H, s, OH), 15.80 (1 H, br s, OH).

Kosotoxin (II). This bicyclic phloroglucinol derivative was isolated according to previously reported methods.[1] Repeated recrystallizations from hexane of the chromatographic fractions rich in kosotoxin gave yellowish plates, m.p. 119–122 °C (lit.[1] m.p. 110–112 °C). Kosotoxin is the main component (> 50 %) in the phloroglucinol mixture of kousso. The optical activity of kosotoxin (*cf.* Experimental Section) is in agreement with the asymmetric structure proposed (II). For the products obtained by reductive alkaline cleavage, which support well the structure (II); see Ref. 1 and Part III.

The mass spectrum of kosotoxin (II) (Fig. 2) shows molecular peaks at *m/e* 488, 474 and 460, corresponding to $C_{27}H_{36}O_8$, $C_{26}H_{34}O_8$ and $C_{25}H_{32}O_8$, respectively. The peaks at *m/e* 431 and 417 support the assumption that kosotoxin is a mixture of C_4H_9- and C_3H_7- side chain homologues and confirm the results of the alkaline cleavages. The general fragmentation pattern is similar to that found earlier for polycyclic *Dryopteris* phloroglucinols [9–11] and supports the proposed structure II.

The NMR spectrum ($CDCl_3$) of kosotoxin also supports the structure II, the following signals are shown: δ 1.12 [6 H, d, *J* 7 Hz, mainly $-CO-CH(CH_3)_2$], 1.18 (6 H, d, *J* 7 Hz, mainly $-CO-CH(CH_3)_2$), 1.28 (3 H, s, $CH_3-C\lesssim$), 1.92 (3 H, s, $CH_3-C\lesssim$), 2.20 (3 H, s, CH_3-Ar), 3.04 (2 H, br, s, $-CH_2-$), 3.76 (3 H, s, CH_3O-Ar), ~ 3.9 [2 H, m, mainly 2 $-CO-CH(CH_3)_2$], 9.66 (1 H, s, OH), 11.06 (1 H, s, OH), 15.54 (1 H, s, OH) 19.18 (1 H, s, OH).

Protokosin (III). This tricyclic phloroglucinol derivative was isolated as described previously,[1] crystallized from acetone, and obtained in the form of colourless needles, m.p. 181–183 °C (lit. m.p. 174–176 °C,[1] 176 °C,[2,3] 182 °C,[2,5]). Protokosin proved to be a major component (*ca.* 30–40 %) in the phloroglucinol mixture of kousso. Its optical activity (*cf.* Experimental Section) supports the asymmetric structure proposed (III). For the products obtained by reductive alkaline cleavage, which are in agreement with the structure III, see Ref. 1 and Part III.

The mass spectrum of protokosin (III) (Fig. 3) presents molecular peaks at *m/e* 738 (weak), 724, 710, and 696, corresponding to $C_{41}H_{54}O_{12}$, $C_{40}H_{52}O_{12}$, $C_{39}H_{50}O_{12}$, and $C_{38}H_{48}O_{12}$, respectively. The peaks at *m/e* 681, 667, and 653 support the assumption that protokosin is a mixture of C_4H_9- and C_3H_7-side chain homologues and confirm the results of the alkaline cleavages. The general fragmentation pattern is similar to that found earlier for polycyclic *Dryopteris* phloroglucinols [9–11] and supports the proposed structure (III). However, the very

* The signals assigned to the OH groups in the NMR spectra of trispseudo-aspidinol (I), kosotoxin (II), protokosin (III), "kosin" (IV) (m.p. 148–150 °C), and pseudo-aspidinol (VIII) (m.p. 65–66 °C) disappear after treatment with D_2O. The intensities given for acyl side chain proton signals should be regarded as approximative since trispseudo-aspidinol, kosotoxin, protokosin, and in smaller amount "kosin" (m.p. 148–150 °C) and pseudo-aspidinol (m.p. 65–66 °C) are mixtures of isobutyryl, isovaleryl, and 2-methylbutyryl side chain homologues. The weak signals due to protons in the isovaleryl side chains and γ-protons and secondary β-protons in the 2-methylbutyryl side chains are omitted.

** Owing to a typing error this signal was earlier reported as 3.0.[1]

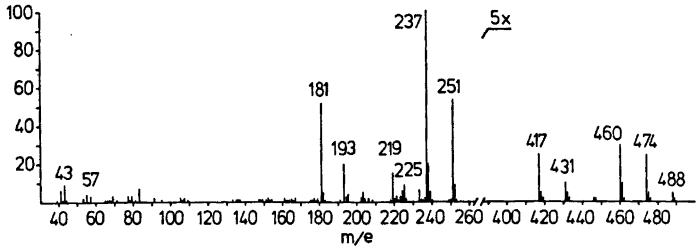

Fig. 2. Mass spectrum (70 eV) (*T* 150 °C) of kosotoxin (II).

weak intensities of the molecular peaks in the mass spectrum (Fig. 3) of protokosin are noteworthy.

The thermal rottlerone change, found earlier in connection with polycyclic *Dryopteris* phloroglucinols [9–11] and which takes place in the ionization chamber of the mass spectrometer, has to be taken into consideration in the interpretation of the fragmentation patterns of kousso constituents. In the case of protokosin, this phenomenon is clear, and among the compounds formed by this procedure, the "kosin" homologues are probably the most characteristic. They are partly responsible for example, for the formation of the ions assigned to *m/e* 488, 474, 460, 431, and 417.

The NMR spectrum ($CDCl_3$) of protokosin also supports the structure III showing the following signals: δ 1.16 [18 H, m, mainly 3 $-CO-CH(CH_3)_2$], 1.66 (6 H, br s, 2 $CH_3-C\leqslant$), 2.20 (6 H, s, 2 CH_3-Ar), 3.64 (4 H, s, 2 $\geqslant C-CH_2-C\leqslant$), 3.76 (6 H, s, 2 CH_3O-Ar), ~3.9 [3 H, m, mainly 3 $-CO-CH(CH_3)_2$], 6.02 (1 H, br s, OH), 10.40 (1 H, s, OH), 13.14 (1 H, s, OH), 14.56 (1, H br s, OH), 19.02 (1 H, s, OH). The intensities given for the signals should be regarded as approximate, owing to the existence of protokosin in several tautomeric forms and to the fact that protokosin is a mixture of isobutyryl, isovaleryl, and 2-methylbutyryl side chain homologues. The spectrum shows a weak signal at δ 3.46 which is probably due to the proton attached to the central ring in the fully ketonic form.

Methylene-bis-pseudo-aspidinol ("kosin") (pseudo-aspidin) (IV). In 1901 Lobeck [8] claimed that the commercial "kosin" of E. Merck (Darmstadt), apparently the first crystalline product isolated from kousso flowers, was a mixture of two closely related compounds, which he called "α-" and "β-kosin". Each of these compounds proved to contain two methoxyl groups. In 1952 Birch and Todd [6] suggested the formulae V and VI for "α-" and "β-kosin", respectively. On the basis of extensive synthetic work, Orth and Riedl [8] later rejected the proposed structures. As their synthetic 5,5′-methylene-bis-(3-methyl-phloroisobutyrophenone-2-methylether) [IV R = $-CH(CH_3)_2$] proved to be identical with the "α-kosin" of Birch and Todd,[6] the structure of "α-kosin" was settled. Moreover, Orth and Riedl [8] showed that "β-kosin" was not identical either with compound (VI) or any other synthetical dimethyl ether of 5,5′-methylene-bis-(3-methyl-phloroisobutyropheno-

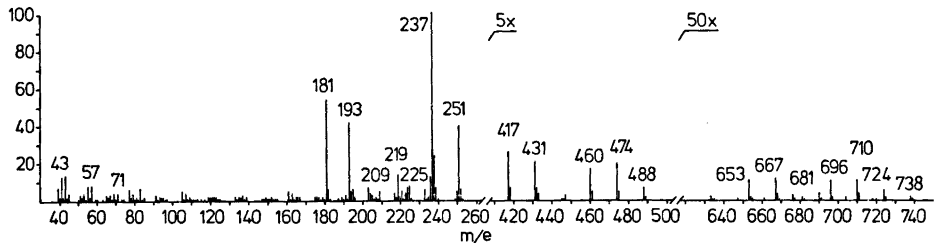

Fig. 3. Mass spectrum (70 eV) (*T* 220 °C) of protokosin (III).

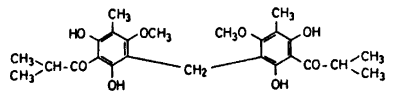
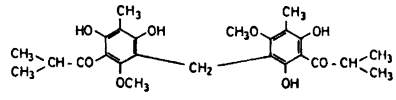
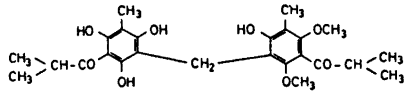


(V)



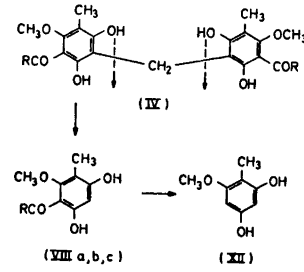
(VI)



(VII)

ne) containing the two methoxyl groups in different rings. Therefore, they proposed for "β-kosin" the tentative formula VII, where the two methoxyl groups are in the same ring.

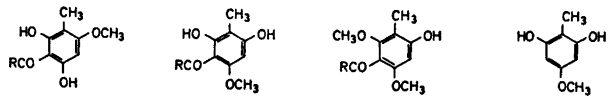
In the present work several "kosin" preparations with slightly varying melting points and crystalline forms * were isolated by column chromatography after treatment of crude kosin, kosotoxin (II), or protokosin (III) with alkali. In agreement with previous findings,[2-6] these "kosin" preparations proved to be very resistant against further break-down with alkali. "Kosin" was detected by TLC in the reaction mixture even after 24 h heating in 15 % NaOH on a water bath.** The sole decomposition products observed consisted of pseudo-aspidinols iB, iV, and 2-MeB (VIIIa, b, and c) (Scheme 1). As in our earlier work,[1] isomeric aspidinols such as (IX) and (X), were not detected by PC or TLC. Nor was there any sign of 3-methylphloroisobutyrophenone-2,6-dimethyl ether (XI) or other isomeric dimethyl ethers, which could be expected to appear among the decomposition products of (VII) or its isomer. On the other hand, some methylphloroglucinol-2-methyl ether (XII), resulting from the reductive alkaline cleavage of the acyl side chains of (VIIIa, b, and c), was recognized by TLC (Scheme 1). The same ether (XII) has previously been isolated by Lobeck [2] after strong reductive alkaline cleavage of his "α-kosin". Notably, no sign of methylphloroglucinol-4-monomethyl ether (XIII), which could be expected to be formed from compound X, was detected.



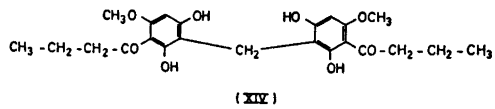
(IV) (VIII a,b,c) (XII)

R = -CH(CH3)2 (a), -CH2-CH(CH3)2 (b), -CH(CH3)-CH2-CH3 (c)

Scheme 1. Reductive alkaline cleavage of "kosin" (methylene-bis-pseudo-aspidinol) (IV)



(IX) (X) (XI) (XIII)



(XIV)

* According to Hems and Todd [5] "α-kosin" forms yellow needles, m.p. 158 °C, and "β-kosin" yellow prisms, m.p. 120 °C, when recrystallized from methanol.

** Even methylene-bis-pseudo-aspidinol BB (IV, R = $-CH_2-CH_2-CH_3$) (*cf.* Part III) and methylene-bis-*o*-desaspidinol BB (XIV), both of which contain methoxyl groups in *ortho* position to the acyl groups, are known to be very alkali stable compounds.[12,13]

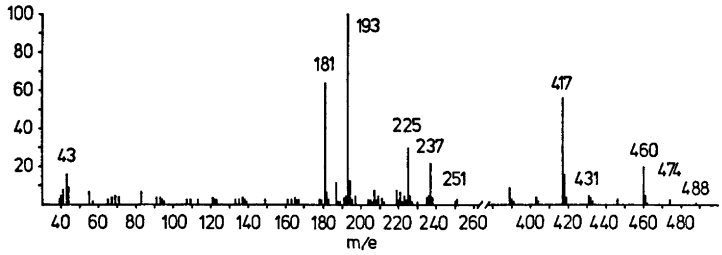


Fig. 4. Mass spectrum (70 eV) (*T* 130 °C) of "kosin" (methylene-bis-pseudo-aspidinol) (IV) (M.p. 148 – 150 °C).

In the light of these facts, it seems very probable that "α-" and "β-kosin" simply differ in their side chains, which consist of isobutyryl (iB), isovaleryl (iV), and 2-methylbutyryl (2-MeB) groups in different ratios.

The mass spectra of different "kosin" fractions (*cf.* Figs. 4 and 5) show molecular peaks at *m/e* 488, 474, and 460 corresponding to $C_{27}H_{36}O_8$, $C_{26}H_{34}O_8$, and $C_{25}H_{32}O_8$, respectively. The peaks at *m/e* 431 and 417 support the assumption that "kosin" fractions are mixtures of C_4H_9- and C_3H_7-side chain homologues and confirm the results of the alkaline cleavages. The general fragmentation pattern is similar to that found earlier for polycyclic *Dryopteris* phloroglucinols [9–11] and in agreement with the proposed structures (IV). The relative intensities of the molecular peaks in these spectra are in good agreement with the conclusion that "α-" and "β-kosin" differ only in their side chains. Thus the fraction melting at 148 – 150 °C shows a relatively strong molecular peak at *m/e* 460 and weak molecular peaks at *m/e* 474 and 488, supporting our conclusion that the "α-kosin" contains mainly isobutyryl side chains. On the other hand, the relative intensities of the molecular peaks at *m/e* 474 and 488 increase as the melting points of the different "kosin" fractions decrease, approaching the indicated melting point of "β-kosin" (m.p. 120 °C). Such changes point to the growing contribution of isovaleryl and 2-methylbutyryl side chains in the fractions.

The NMR spectrum (60 MHz) ($CDCl_3$) of the "kosin" fraction melting at 148 – 150 °C supports the structure (IV), showing the following signals: δ 1.18 [12 H, d, *J* 7 Hz, mainly 2 $-CO-CH(CH_3)_2$], 2.12 (6 H, s, 2 CH_3-Ar), 3.72 (6 H, s, 2 CH_3O-Ar), 3.84 (2 H, s, $-CH_2-$), ~3.9 [2 H, m, mainly 2 $-CO-CH(CH_3)_2$], 9.56 (2 H, s, 2 OH), 15.46 (1 H, s, OH) and 15.56 (1 H, s, OH).

The stereochemistry of both kosotoxin (II) and protokosin (III) has not yet been determined. However, it seems evident to us from the presence of optical activity, that the two chiral centres at positions 1 and 3 of the central ring of protokosin (III) (considered in the "triketonic" form) should have a like spatial arrangement of the groups. In this case the carbon atom at position 5 would not be asymmetric.

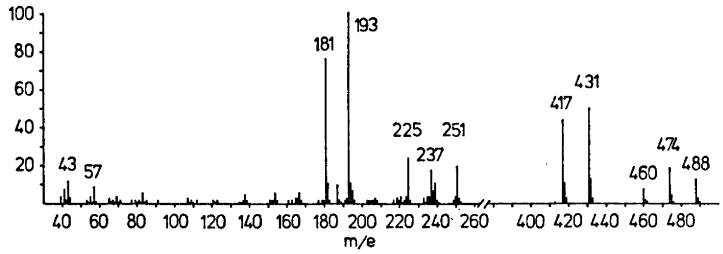

Fig. 5. Mass spectrum (70 eV) (*T* 130 °C) of "kosin" (methylene-bis-pseudo-aspidinol) (IV) (M.p. 125 – 127 °C).

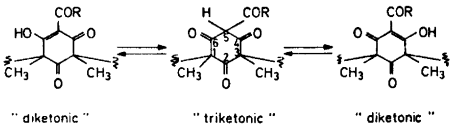

If the two carbons at positions 1 and 3 should have an opposite spatial arrangement of the groups the whole molecule would have a plane of symmetry, the carbon atom at position 5 would be pseudo-asymmetric, and the compound would show no optical activity ("meso form").*

TLC of the kosins. The thin-layer chromatographic behaviour of the kosins was investigated on thin silica gel layers buffered to pH 4 – 8 using the gradient technique (Fig. 6).[14] Methylene-bis-pseudo-aspidinol (IV) and trispseudo-aspidinol (I) are easily separated at pH 4 – 7, but at pH 7 – 8 hardly at all. With increasing pH the R_F-value of methylene-bis-pseudo-aspidinol (IV) decreases, whereas that of trispseudo-aspidinol (I) increases. Protokosin (III) and kosotoxin (II) advance together at every pH examined, the former being a little faster than the latter. There is no distinct influence of the pH on the TLC-behaviour of these two substances. No separation of the different homologues of the different kosins was achieved by TLC.

EXPERIMENTAL

General. The UV spectra were measured with a Beckman DB-G grating spectrophotometer and the IR spectra with a Beckman IR-8 spectrophotometer. The NMR spectra have been taken with a Varian A-60 instrument using TMS as internal standard. The mass spectra of the natural products (I, II, and III) have been recorded on an A.E.I. MS-9 double-focusing mass spectrometer (70 eV) at the Institut de Chimie des Substances Naturelles, Gif-sur-Yvette, France, through the courtesy of Dr. B. C. Das. The other mass spectra have been taken on a Perkin-Elmer 270 mass spectrometer. The optical rotations were measured on a Perkin-Elmer 141 Polarimeter. The melting points have been determined on a Reichert micro hot stage and are uncorrected. The thin-layer chromatographic methods were those previously reported.[1,14,15]

Material investigated. A 5 kg commercial sample of Flos koso "Siegfried" of unknown age and origin was investigated. By TLC it was shown to contain the same phloroglucinol derivatives as the material previously investigated (*cf.* Part I).[1]

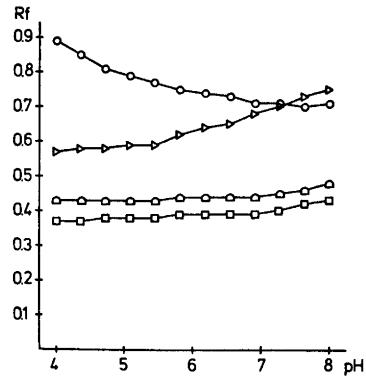

Fig. 6. Gradient TLC of trispseudo-aspidinol (I) (○, red), kosotoxin (II) (□, yellow), protokosin (III) (⌂, pale brown), and "kosin" (methylene-bis-pseudo-aspidinol) (IV) (△, pale brown) at pH 4 – 8. Chromatographed 3×. Solvent: hexane – chloroform 50:50. Colours with Fast Blue Salt B in parenthesis.

Preparation of ether extract and crude kosins. Preparations were made according to previously described methods.[1] The yields are listed in Table 1.

Column chromatography of crude Mg-kosin. Crude kosin (26.8 g) was suspended in benzene and chromatographed on 700 g of silica gel (Merck, particle size 0.05 – 0.2 mm) as previously described.[15] According to TLC, all fractions (10 ml each) were mixtures containing kosotoxin (II) and protokosin (III) in different ratios. The first fractions also contained some trispseudo-aspidinol (I). The four combined fractions (Table 2) were evaporated to dryness and separately dissolved in hot methanol, from which protokosin (III) started to crystallize as soon as cooling began. Kosotoxin (II), although present in large amounts (TLC), remained in solutions. After about one week, the mother liquors, containing only small amounts of protokosin (III),

Table 1. Yields of diethyl ether extract and crude kosins from Flos koso.

Flos koso (kg)	5.0
Material in diethyl ether extract (g)	324
(%)	6.5
Crude kosins MgO(g)	54
MgO(%)	1.1
$Ba(OH)_2$ (g)	70
$Ba(OH)_2$ (%)	1.4

* The 2-methylbutyryl group, which is one of the side chains present, has a chiral centre and this of course should cause some rotation.

Table 2. Melting points and yields of protokosin (III) from different fractions.

Fraction No. (10 ml each)	M.p. (°C)	Amount (mg)
1 – 32 (C_6H_6)	160 – 163	228
33 – 110 (C_6H_6)	166 – 171	1312
111 – 137 (C_6H_6)	171 – 175	593
138 – 410 (C_6H_6, C_6H_6-$CHCl_3$, 1:1)	175 – 178 [a]	870
Total		3003

[a] The melting point of the protokosin (III) of this fraction was raised to 181 – 183 °C by recrystallization from acetone.

were evaporated to dryness and the residues dissolved in hot hexane. The hexane solutions of the residues from fractions 33 – 410 (Table 3), which showed very similar TLC behaviour, were combined. On standing kosotoxin (II) slowly separated from the hexane solutions in several portions with slightly different melting points (Table 3). According to TLC the mother liquors still contained relatively large amounts of kosotoxin (II), which were not isolated in crystalline form.

Preparation of "kosins" (methylene-bis-pseudo-aspidinols) (IV), pseudo-aspidinols (VIIIa, b, c), and methylphloroglucinol-2-methyl ether (XII)

1. Mild reductive alkaline cleavage. Crude Ba-kosin (3.6 g) was mixed with 7.2 g of zinc powder, 50 ml of 5 % KOH was added, and the mixture heated on a water bath for 5 min. For details, see Part III, Cleavage A. The resulting product (3.6 g) was suspended in benzene and chromatographed on 100 g of silica gel. The fractions 1 – 7 (10 ml each) (benzene) gave 48.1 mg of "kosin" (IV) which, after crystallization from methanol, melted at 125 – 127 °C. The fractions 8 – 97 (benzene, benzene – chloroform, 1:1) gave another crop of "kosin" (IV) which, after crystallization from hexane, melted at 148 – 150 °C. The fractions 98 – 210 (chloroform) contained (TLC) pseudo-aspidinols (iB, IV, and 2-MeB acyl derivatives) (VIIIa, b, c) as well as some other compounds, the structures of which were not determined.

Table 3. Melting points and yields of kosotoxin (II) from the residues of different fractions.

Fraction No.	M.p. (°C)	Amount (mg)
1 – 32	100 – 110	315
	115 – 118	399
33 – 410	116 – 120	249
	119 – 122	121
	107 – 115	37
Total		1121

2. Strong reductive alkaline cleavage. Crude Ba-kosin (10 g) was mixed with 20 g of zinc powder, 100 ml of 15 % KOH was added and the mixture heated on a water bath for 24 h. For details, see Part III, Cleavage D. Part of the resulting product was used for determination of the organic acids formed. For details, see Part I. They consisted of isobutyric, isovaleric, and 2-methylbutyric acids in agreement with previous findings.[1] Another part of the resulting product (2.8 g) was used for column chromatography of the phloroglucinol derivatives formed. The fractions 1 – 12 (10 ml each) (benzene) gave 92 mg of "kosin" (IV), which, after crystallization from methanol, melted at 116 – 120 °C. The fractions 13 – 57 (benzene, benzene – chloroform, 1:1) contained only some unknown compounds, the structures of which were not determined. The fractions 58 – 112 (benzene – chloroform, 1:1, chloroform) contained some unknown compounds, as well as large amounts of pseudo-aspidinols (VIIIa, b, c). No crystalline compounds were obtained from hexane. Therefore, these fractions were rechromatographed on silica gel (hexane-benzene, 1:1). Seven fractions (50 ml each), containing pseudo-aspidinols (VIIIa, b, c), were collected and evaporated to dryness. These fractions, when combined and crystallized from hexane, gave three successive crystallizates of pseudo-aspidinols (VIIIa, b, c) (m.p. 59 – 61 °C, 275 mg), (m.p. 65 – 66 °C, 119 mg), (m.p. 62 – 65 °C, 98 mg). NMR ($CDCl_3$) (Fraction melting at 65 – 66 °C) : δ 1.18 [6 H, d, J 7 Hz, mainly $-CO-CH(CH_3)_2$], 2.12 (3 H, s, CH_3-Ar), 3.74 (3 H, s, CH_3-OAr), 3.86 [1 H, heptet, J 7 Hz, mainly $-CO-CH(CH_3)_2$] 6.22 (1 H, s, arom. H), 6.30 (1 H, s, OH), 13.06 and 13.12 (1 H, each s, OH). MS (fraction melting at 65 – 66 °C): M^+ at m/e 224 and 238 (weak) corresponding to $C_{12}H_{16}O_4$ and $C_{13}H_{18}O_4$. The fractions 113 – 127 (chloroform – ethanol, 95:5) gave 54 mg of methylphloroglucinol-2-methyl ether (XII), which, after crystallization from water, melted at 112 – 116 °C (lit.[12] 114 – 116 °C). MS: M^+ at m/e 154 corresponding to $C_8H_{10}O_3$.

Physical data of the identified natural products, as well as those of methylene-bis-pseudo-aspidinol ("kosin") (IV) obtained by the alkaline treatment of the crude kosins

1. Trispseudo-aspidinol (kosidin) (I.). Yellowish plates, m.p. 167 – 169 °C (methanol).

UV (cyclohexane) (ε values calculated on $C_{36}H_{44}O_{12}$):λ_{max} 229 (ε 39 000), 284 (ε 39 500) nm. λ_{min} 250 nm. IR (KBr): λ 3.06 (m), 3.34 (m), 3.38 (m), 3.46 (w), 6.22 (s), 6.90 (s), 7.10 (s), 7.24 (m), 7.38 (m), 7.60 (sh), 7.88 (s), 8.44 (s), 8.68 (s), 9.02 (s), 9.42 (w), 9.70 (w), 10.02 (w), 10.18 (w), 10.36 (w), 10.64 (w), 10.80 (w), 11.06 (w), 12.50 (w) μ. NMR ($CDCl_3$): See theoretical section. MS: See theoretical section.

2. Kosotoxin (II). Yellowish plates, m.p. 119–122 °C (hexane). $[\alpha]_D^{25} + 11.9 \pm 0.2°$ (*c* 2.335, $CHCl_3$). UV (cyclohexane) (ε values calculated on $C_{25}H_{32}O_8$): λ_{max} 226 (ε 19 700), 283 (ε 24 000) nm. λ_{min} 251 nm. Phloroglucinol Derivatives of *Hagenia abyssinica*. III.* Reductive Alkaline Cleavages of Kosotoxin and Protokosin, and of Aspidin BB (*Dryopteris assimilis*)

MAURI LOUNASMAA,[a] C.-J. WIDÉN [b] and AARRE HUHTIKANGAS [b]

[a] State Institute for Technical Research, Chemical Laboratory, SF-02150 Otaniemi, Finland and [b] Department of Pharmacognosy, University of Helsinki, SF-00170 Helsinki 17, Finland

Products formed from kosotoxin (II), protokosin (III), and aspidin BB (VII) by reductive alkaline cleavages in different experimental conditions have been investigated. In all three cases, pseudo-aspidinol (IV), 3-methylfilicinic acid (X), methylphloroglucinol-2-monomethyl ether (XV), and methylene-bis-pseudoaspidinol (XVIII) were detected among the reaction products. Moreover, in the case of aspidin BB (VII), butyrylfilicinic acid (VIIIb), filicinic acid (IX), 3-methylbutyrylfilicinic acid (Vd), and albaspidine BB (XVII) were found.

Les produits formés à partir de la kosotoxine (II), de la protokosine (III) et de l'aspidine BB (VII) par clivages réductifs alcalins dans des conditions différentes expérimentales, ont été examinés. Dans les trois cas, le pseudo-aspidinol (IV), l'acide méthyl-3 filicinique (X), l'éther monométhylique-2 du méthylphloroglucinol (XV) et le méthylène-bis-pseudo-aspidinol (XVIII) ont été détectés parmi les produits réactionnels. De plus, dans le cas de l'aspidine BB (VII) l'acide butyrylfilicinique (VIIIb), l'acide filicinique (IX), l'acide méthyl-3 butyrylfilicinique (V d) et l'albaspidine BB (XVII) ont été trouvés.

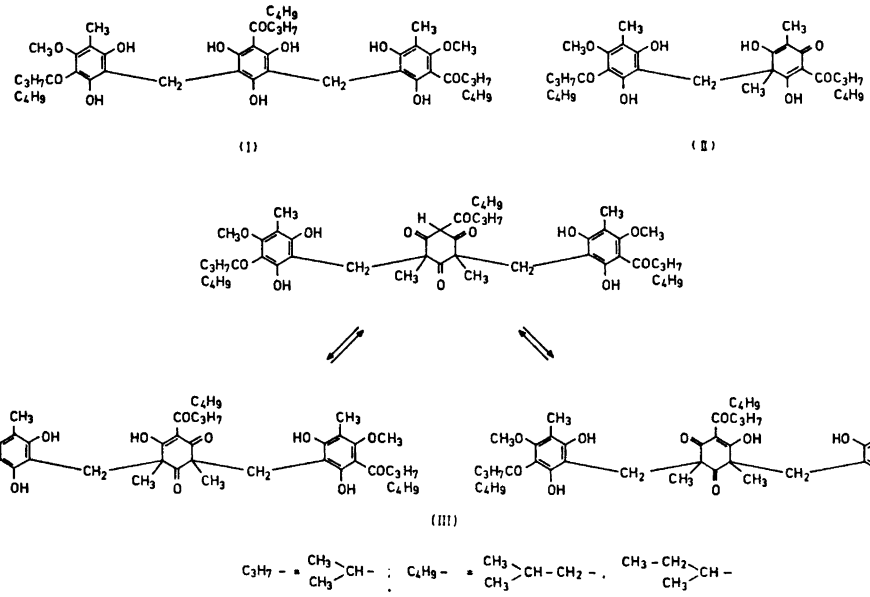
In previous papers [1,2] we have described the isolation and structure determination of three phloroglucinol derivatives (kosins) from female flowers of *Hagenia abyssinica* (Bruce) Gmelin. These are trispseudo-aspidinol (kosidin) (I), kosotoxin (II), and protokosin (III), each consisting of mixtures of isobutyryl (iB), isovaleryl (iV), and 2-methylbutyryl (2-MeB) acyl side chain homologues. The structure of trispseudo-aspidinol (I) was partly solved through an investigation of the monocyclic acylphloroglucinols formed by mild reductive alkaline cleavage of the molecule in the presence of metallic zinc.[1] This elegant cleavage method, originally reported by Boehm [3] and much used by him and later workers [4–6] for structure determinations of *Dryopteris* and *Hagenia* phloroglucinol derivatives, is here applied to the study of kosotoxin (II) and protokosin (III). Using the method in its original form, we were able to detect only the homologous pseudo-aspidinols iB, iV, and 2-MeB (IVa, b, and c) both from kosotoxin (II) and protokosin (III). No sign of 3-methylisobutyrylfilicinic acid (Va) or its iV (Vb) or 2-MeB (Vc) homologues was detected. Nor were 3,3-dimethylisobutyryl-filicinic acid (flavesone) (VIa), 3,3-dimethyl-isovalerylfilicinic acid (leptospermone) (VIb) or 3,3-dimethyl-(2-methylbutyryl)-filicinic acid (VIc) to be found among the products of protokosin (III).**

These results, as well as the absence of 3-methyl-butyrylfilicinic acid (fraginol ***) (Vd) from the decomposition products of *Dryopteris* phloroglucinol derivatives,[4,5,7] persuaded us to examine the products of reductive alkaline cleavage of kosotoxin (II) and protokosin (III) in more detail. Thereby, aspidin BB (VII)

* Part II, Ref. 2.

** Flavesone (VIa) and leptospermone (VIb) are known as naturally occurring compounds in the essential oils of certain *Leptospermum*, *Xanthostemon*, and *Eucalyptus* species (Myrtaceae).[8,9]

*** Fraginol (Vd) is reported as a naturally occurring compound in *Dryopteris fragrans* (L.) Schott.[10,11]



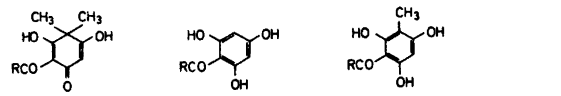
(I) (II)

(III)

(*Dryopteris assimilis* S. Walker) was used as a model compound. This phloroglucinol derivative, which frequently occurs in ferns of the *D. dilatata* complex,[11] is closely related to kosotoxin (II) in its chemical structure: *i.e.* the geminal dimethyl group found in aspidin BB (VII) is partly involved in the methylene bridge of kosotoxin (II).

Syntheses of isobutyrylfilicinic acid (VIIIa), 3-methylisobutyrylfilicinic acid (Va), and 3,3-dimethylisobutyrylfilicinic acid (VIa), and of their deacylated analogues (IX), (X), and (XI). For the examination of the decomposition products of kosotoxin (II) and protokosin (III) several synthetic model compounds were needed. Among these 3-methylisobutyrylfilicinic acid (Va), 3,3-dimethylisobutyrylfilicinic acid (VIa) and their deacylated analogues (X) and (XI) (syncarpic acid *) were of vital importance. The geminally substituted acylphloroglucinol derivatives were prepared in good yields by the C-methylation of isobutyrylphloroglucinol (XIIa), according to the methods of Riedl *et al.*[12,13] In all cases the resulting products were mixtures, containing isobutyrylfilicinic acid (VIIIa), 3-methylisobutyrylfilicinic acid (Va) and 3,3-dimethylisobutyrylfilicinic acid (VIa) in different ratios. In addition small amounts of substances such as unreacted isobutyrylphloroglucinol (XIIa), methylisobutyrylphloroglucinol (XIII), and their methyl ethers were also present. For the separation of isobutyrylfilicinic acid (VIIIa). 3-methylisobutyrylfilicinic acid (Va), and 3,3-dimethylisobutyrylfilicinic acid (VIa), obtained from the so-called carbonate fractions (see Refs. 12, 13), column chromatography on silica gel, with hexane – benzene in different ratios as eluent proved suitable. The first fractions consisted of mixtures of 3,3-dimethylisobutyrylfilicinic acid (VIa) and 3-methylisobutyrylfilicinic acid (Va),

* Syncarpic acid (XI) has been isolated from *Syncarpia laurifolia* Tenn. (Myrtaceae).[14]



(VIIIa) R = -CH(CH3)2 (XIIa) R = -CH(CH3)2 (XIII) R = -CH2-CH2-CH3

(XIIb) R = -CH2-CH2-CH3

Table 1. Products obtained by reductive alkaline cleavage of aspidin BB (VII) in different conditions (Cleavages A–C).

Compound	Cleavage A	B	C	R_F-values TLC [a]	PC [b]	Colour [c]
Aspidin BB (VII)	++	+	–	0.70	0.84 [d]	yellow
Albaspidin BB (XVII)	+	–	–	0.75	0.92 [d]	red
Methylene-bis-pseudo-aspidinol BB (XVIII)	+? [e]	+? [e]	+	0.73	0.92 [d]	pale brown
Pseudo-aspidinol B (IVd)	++	++	++	0.30	0.56 [d]	pale brown
Butyrylfilicinic acid (VIIIb)	++	++	++	0.23	0.41 [f]	red
3-Methylbutyrylfilicinic acid (Vd)	–	+	–	0.20	0.47 [f]	yellow
Filicinic acid (IX)	–	+	+	0.11	n.s.	blue
3-Methylfilicinic acid (X)	–	+	+	0.14	n.s.	orange yellow
Methylphloroglucinol-2-methyl ether (XV)	–	+	+	0.08	n.s.	dark brown

–, not detected; +, detected in traces or small amounts; ++, detected in large amounts; n.s., not studied. [a] At pH 6.0 in hexane–chloroform–ethanol 47.5:47.5:5.0.[1,5] [b] In cyclohexane–chloroform 1:1.[23] [c] Colour with Fast Blue Salt B. [d] At pH 8.6. [e] Could not be detected owing to overlapping of aspidin BB (VII) and albaspidin BB (XVII). [f] At pH 4.0.

from which the latter (Va) was separated by crystallization from ether. The subsequent fractions consisted of practically pure isobutyrylfilicinic acid (VIIIa).

The corresponding butyrylderivatives butyrylfilicinic acid (VIIIb) and 3-methylbutyrylfilicinic acid (Vd) were prepared by analogous procedures.[12]

The geminally substituted deacylated phloroglucinol derivatives (IX), (X), and (XI) were prepared by reductive alkaline cleavage of the corresponding isobutyryl compounds (VIIIa), (Va), and (VIa), respectively.

The thin-layer and paper chromatographic properties of the synthetically prepared acylfilicinic acids as well as their deacylated homologues appear in Tables 1 and 2. All other compounds except 3-methylisobutyrylfilicinic acid (Va) and 3,3-dimethylisobutyrylfilicinic acid (VIa) were easily separated in the chromatographic systems used.

Reductive alkaline cleavage of aspidin BB (VII). Aspidin BB (VII) was subjected to three different cleavages, A, B, and C, all being modifications of the original method of Boehm [3] (for details, see the Experimental section). The products isolated by column chromatography or detected by TLC and PC are listed in Table 1. The decomposition of aspidin BB (VII) is further depicted in Scheme 1.

The first step in the decomposition of aspidin BB (VII) by the reductive alkaline treatment is the cleavage of the methylene bridge, resulting in large amounts of pseudo-aspidinol B (IVd) and butyrylfilicinic acid (VIIIb). These are the main reaction products in all three cleavages (Cleavage A, B, and C). Of the other possible products, 3-methylbutyrylfilicinic acid (Vd) was detected in trace amounts, but only after cleavage B. On the other hand, no 3-methyl-pseudoaspidinol B (XIVd) could be found.

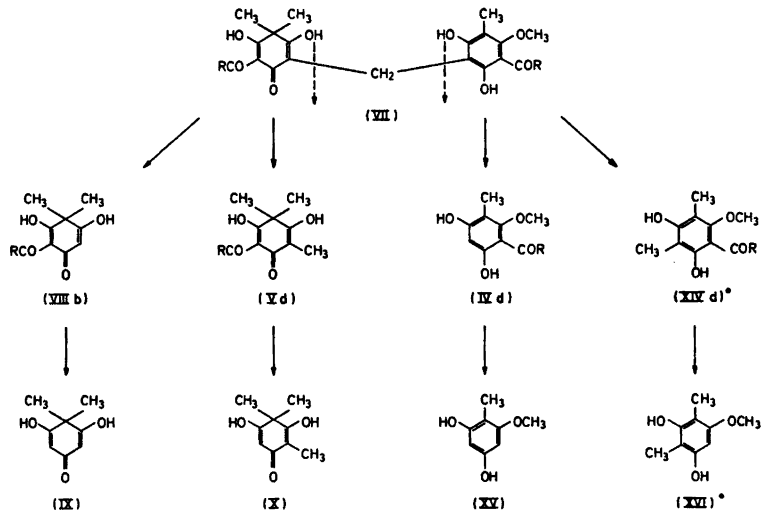
The second step in the decomposition of aspidin BB (VII) is the cleavage of the acyl side chains from the initially formed monocyclic compounds.* This second step, which leads mainly to the formation of filicinic acid (IX) and methylphloroglucinol-2-monomethyl ether (XV), is detectable after cleavage B and more clearly after cleavage C. In both cases, some 3-methylfilicinic acid (X) could also be de-

* To some extent, of course, the acyl side chain cleavage takes place directly from aspidin BB (VII).

Table 2. Products obtained by reductive alkaline cleavages of kosotoxin (II) and protokosin (III) in different conditions (Cleavages A – D).

Compound	Cleavage A	B	C	D	R_F-values in TLC [a]	in PC [b]	Colour [c]
Kosotoxin (II)	–	–	–	–	0.73	0.84 [e]	yellow
Protokosin (III)	–	–	–	–	0.73	0.84 [e]	pale brown
Methylene-bis-pseudo-aspidinol (XVIII)	+	+	+	+	0.75	0.92 [e]	pale brown
Pseudo-aspidinol (IV)	+ +	+ +	+ +	+ +	0.30	0.69 [e] 0.56	pale brown
Isobutyrylfilicinic acid (VIII a)	–	–	–	–	0.23	0.45 [f]	red
3-Methylisobutyrylfilicinic acid (Va)	–	–	–	–	0.20	0.50 [f]	yellow
3,3-Dimethylisobutyrylfilicinic acid (VIa)	–	–	–	–	0.20	0.50 [f]	yellow
3-Methylfilicinic acid (X)	–	–	–	+	0.14	n.s.	orange yellow
3,3-Dimethylfilicinic acid (XI)	–	–	–	+ ?[d]	0.20	n.s.	orange yellow
Methylphloroglucinol-2-methyl ether (XV) [g]	–	–	–	+	0.08	n.s.	dark brown

[a] At pH 6.0 in hexane – chloroform – ethanol 47.5:47.5:5.0.[1,5] [b] In cyclohexane – chloroform 1:1.[23] [c] Colour with Fast Blue Salt B. [d] From protokosin only. [e] At pH 8.6. The pseudo-aspidinol obtained from kousso constituents (see Experimental) separated in two spots, R_F 0.69 and 0.56. The latter was pseudo-aspidinol iB and the former a mixture of the pseudo-aspidinols iV and 2-MeB (see Ref. 1). [f] At pH 4.0. [g] Methylphloroglucinol-4-methyl ether (XXI) formed an orange spot with the R_F-value of 0.10.



Scheme 1. Reductive alkaline cleavage of aspidin BB (VII).

tected. 1,3-Dimethylphloroglucinol-4-monomethyl ether (XVI) was not found. We are the first to report the presence of 3-methylbutyrylfilicinic acid (Vd) among the decomposition products of aspidin BB (VII) (*cf.* Ref. 15–18). However, only traces were found, even here. 3-Methylfilicinic acid (X) on the other hand, was long ago isolated in small amounts by Boehm.[16] Earlier failures to detect 3-methylbutyrylfilicinic acid (Vd) or its acyl side chain homologues among the products of reductive alkaline cleavage of geminally disubstituted *Dryopteris* phloroglucinols, is possibly explained by the great instability of these products in the reaction conditions used (*cf.* also Riedl and Risse [7] and Aho [19]).

An alternative route in the decomposition of aspidin BB (VII) (*cf.* Ref. 17) leading to the formation of albaspidin BB (XVII) and methylene-bis-pseudo-aspidinol BB (XVIII $R = -CH_2-CH_2-CH_3$) is the so-called rottlerone change. This reaction, which proceeds according to the scheme

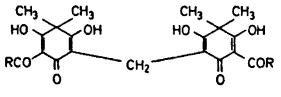
$$2R-CH_2-R' \rightleftharpoons R-CH_2-R + R'-CH_2-R'$$

is typical of the behaviour of methylene-bis-polyhydroxyphenols (polyhydroxydiphenylmethanes).[20] The formation of albaspidin BB (XVII) after cleavage A is clearly detected in its characteristic red spot (fast blue salt B) on TLC. The lightbrown spot corresponding to the other possible product, methylene-bis-pseudo-aspidinol BB (XVIII, $R = -CH_2-CH_2-CH_3$), cannot be detected with certainty because in the chromatographic systems used its R_F-values are very similar to those of the red spot of albaspidin BB (XVII) and the yellow spot of unreacted aspidin BB (VII). After more drastic reaction conditions, corresponding to cleavage B, there is no albaspidin BB (XVII) left, although the reaction mixture still contains some unreacted aspidin BB (VII). After cleavage C – the most drastic of the three variants used – the only of the bicyclic compounds present is methylene-bis-pseudo-aspidinol BB (XVIII, $R = -CH_2-CH_2-CH_3$), which is known to be a very alkali-stable substance.[18]

Reductive alkaline cleavage of kosotoxin (II) and protokosin (III). This was performed in the same three ways, as in the case of aspidin BB (VII). The products isolated by column chromatography or detected by TLC and PC are listed in Table 2, while decomposition is depicted in Schemes 2 and 3.

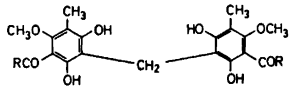
The first step in the decomposition of kosotoxin (II) and protokosin (III) is the cleavage of the methylene bridges, resulting in large amounts of pseudo-aspidinol iB, iV, and 2-MeB (IVa, b, c) in all three cases (cleavage A, B, and C). Although expected, no 3-methylisobutyrylfilicinic acid (Va), 1,3-dimethyl-5-isobutyrylphloroglucinol (XIX), or 3-methylpseudo-aspidinol iB (XIVa) or its isovaleryl or 2-methylbutyryl homologues were detected by TLC or PC. Neither were 3,3-dimethylisobutyrylfilicinic acid (VIa) or its isovaleryl and 2-methylbutyryl homologues observed in the case of protokosin (III).

The second step in the decomposition of both kosotoxin (II) and protokosin (III) could be expected to lead to 3-methylfilicinic acid (X), methylphloroglucinol-2-monomethyl ether (XV), 1,3-dimethylphloroglucinol-4-monomethyl ether (XVI), and 1,3-dimethylphloroglucinol (XX). Also some 3,3-dimethylfilicinic acid (XI) could be expected to be formed in the case of protokosin (III). However, none of these second step decomposition products were found after cleavage according to procedures A, B, or C. Rather, in all three cases, compounds of unknown structure were detected. Some of these showed R_F-values very similar to those of synthetical standards, but the colouration (fast blue salt B) was different. Owing to the presence of these unknown compounds in the reaction mixtures we tried a fourth, much more drastic variant of the reductive alkaline

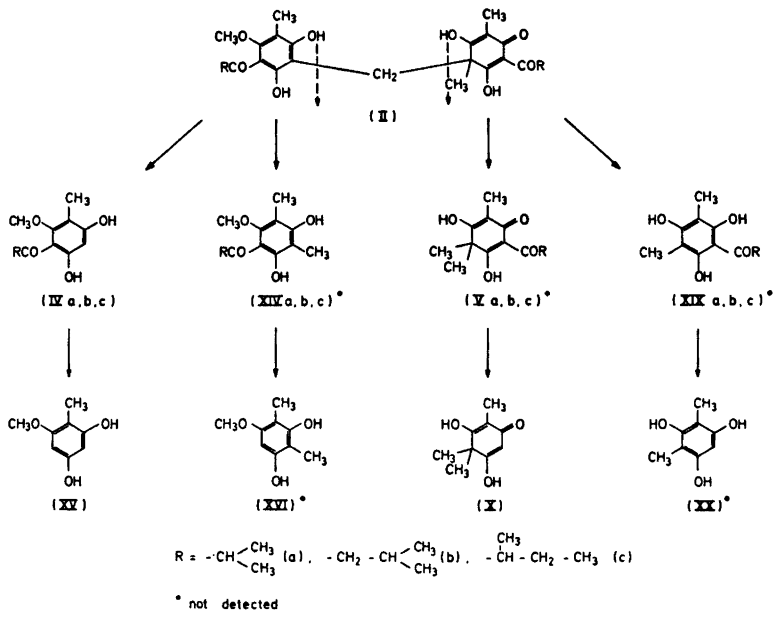


(XVII)

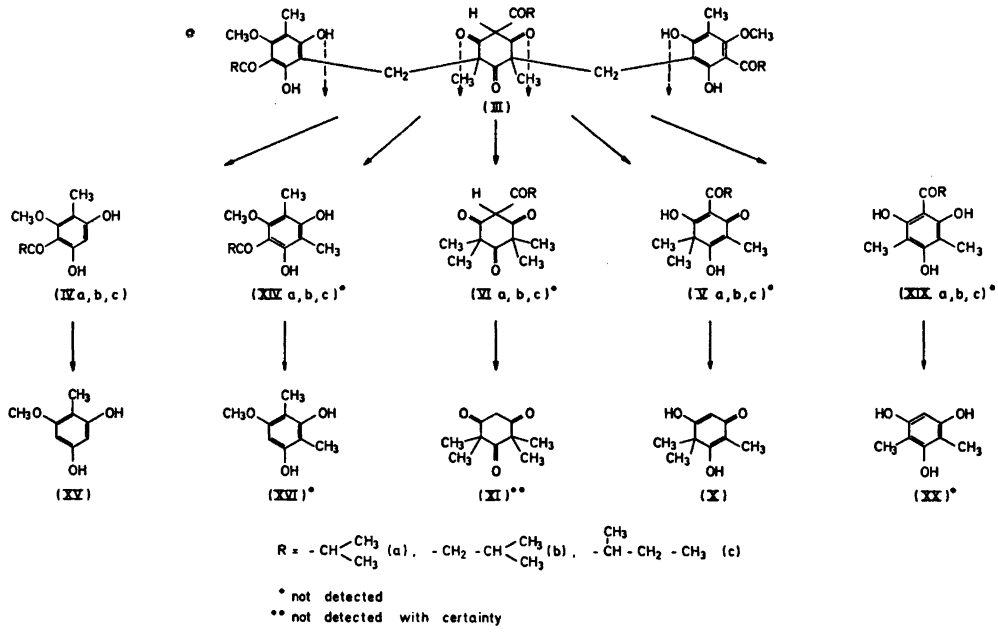
R = -CH2 - CH2 - CH3



(XVIII)

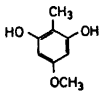


Scheme 2. Reductive alkaline cleavage of kosotoxin (II).



Scheme 3. Reductive alkaline cleavage of protokosin (III).

cleavage, called cleavage D (see the Experimental section). This time the unknown compounds were decomposed and large quantities of methylphloroglucinol-2-monomethyl ether (XV) * and trace amounts of 3-methylfilicinic acid (X) could be detected in the reaction mixture. The former was previously found by Lobeck [21] after reductive alkaline cleavage of kosotoxin (II) and "kosin" (XVIII).** However, the key degradation product expected from protokosin (III), 3,3-dimethylfilicinic acid (XI),*** could not be detected with certainty (*cf.* Table 2).



(XXI)

An alternative route in the decomposition of both kosotoxin (II) and protokosin (III) is the formation of iB, iV, and 2-MeB homologues of methylene-bis-pseudo-aspidinol ("kosin") (XVIII) ** by the rottlerone change. These products have been isolated earlier after reductive alkaline treatment of both kosotoxin (II) and protokosin (III), and they are known to be very alkali stable, as is the corresponding butyryl homologue (pseudo-aspidin BB) (XVIII R = $-CH_2-CH_2-CH_3$). Methylene-bis-pseudo-aspidinol ("kosin") (XVIII) ** could be detected after all three initial cleavage procedures (cleavage A, B, and C), but other products expected to be formed by the rottlerone change could not.

The structural similarity we have proposed here between aspidin BB (VII), kosotoxin (II), and protokosin (III) is supported by the fact that similar decomposition products, including methylene-bis-pseudo-aspidinol (XVIII),** pseudo-aspidinol (IV), methylphloroglucinol-2-monomethyl ether (XV), and 3-methylfilicinic acid (X), were obtained in all three cases.

EXPERIMENTAL

General. The IR spectrum was measured with a Beckman IR-8 spectrophotometer. The NMR spectra have been taken with a Varian A-60 instrument using TMS as internal standard. The mass spectra have been recorded on a Perkin-Elmer 270 mass spectrometer. The melting points have been determined on a Reichert micro hot stage and are uncorrected. The thin-layer chromatographic methods were those previously reported.[1,5] The paper chromatographic method was that of Penttilä and Sundman.[23]

Reference substances

1. Isobutyrylphloroglucinol.$2H_2O$ (XIIa) was prepared from phloroglucinol by the method of Riedl.[24] Colourless plates, m.p. 71–74 °C/134–136 °C (water) (lit.[24] m.p. 70 °C/138 °C). MS: M+ at *m/e* 196 corresponding to $C_{10}H_{12}O_4$. IR: C=O 6.24 μ.

2. Isobutyrylfilicinic acid (VIIIa) was obtained as a by-product in the synthesis of 3-methylisobutyrylfilicinic acid (Va) according to Riedl and Risse.[12] Slightly brownish plates, m.p. 152–154 °C (hexane) (lit.[23] m.p. 153–154 °C). MS: M+ at *m/e* 224 corresponding to $C_{12}H_{16}O_4$. NMR ($CDCl_3$): δ 1.16 [6 H, d, *J* 7 Hz, $-CO-CH(CH_3)_2$], 1.40 and 1.50 (6 H, each s, gem. dimethyl group of the ring), 3.96 [1 H, heptet, *J* 7 Hz, $-CO-CH(CH_3)_2$] and 5.54 (1 H, s, vinyl H only partly). The signals of OH-groups are omitted.

3. 3-Methylisobutyrylfilicinic acid (Va) † was prepared from isobutyrylphloroglucinol (XIIa) by the method of Riedl and Risse.[12] Colourless plates, m.p. 100–103 °C (ether). MS: M+ at *m/e* 238 corresponding to $C_{13}H_{18}O_4$. NMR ($CDCl_3$): δ 1.14 [6 H, d, *J* 7 Hz, $-CO-CH(CH_3)_2$], 1.42 and 1.50 (6 H, each s, gem. dimethyl group of the ring), 1.90 (3 H, s, $CH_3-C\ll$), 3.96 [1 H, heptet, *J* 7 Hz, $-CO-CH(CH_3)_2$] 7.40 (1 H, s, OH), and 18.30 (1 H, s, OH).

4. 3,3-Dimethylisobutyrylfilicinic acid (flavesone) (VIa) † was prepared from isobutyrylphloroglucinol (XIIa) by the method of Riedl and Risse.[12] Pale yellow oil (lit.[9] b.p. 134 °C/10 mmHg). MS: M+ at *m/e* 252 corresponding to

---

* Noteworthy, no methylphloroglucinol-4-monomethyl ether (XXI) could be found.

** R = $-CH(CH_3)_2$; $-CH_2-CH(CH_3)_2$; $-CH(CH_3)-CH_2-CH_3$.

*** Recently Kashman *et al.*[22] have isolated from *Myrtus communis* L. (Myrtaceae) two new acylphloroglucinol derivatives which they called myrtucummulone A and B, and from which they were able to prepare 3,3-dimethylfilicinic acid (syncarpic acid) (XI) by alkaline treatment. However, owing to the fact that all four methyl groups in 3,3-dimethylfilicinic acid (XI) are already present as such in myrtucummulone A and B, and not partly involved in the methylene bridges as in protokosin (III), the cases are not quite analogous.

† 3-Methylisobutyrylfilinic (Va), and 3-3-dimethylisobutyrylfilicinic acid (VIa) decomposing almost completely after few months storage, are unstable substances compared with isobutyrylfilicinic acid (VIIIa).

$C_{14}H_{20}O_4$. NMR ($CDCl_3$): δ 1.16 (6 H, d, J 7 Hz, $-CO-CH(CH_3)_2$, 1.36 and 1.46 (12 H, each s, 2 gem. dimethyl groups of the ring), 3.80 (1 H, heptet, J 7 Hz $-CO-CH(CH_3)_2$, and 17.80 (1 H, s, OH) (*cf.* Ref. 9).

5. Filicinic acid (IX) was obtained from isobutyrylfilicinic acid (VIIIa) by the method of Riedl and Risse.[12] Colourless plates m.p. 215 °C (ethanol) (lit.[12] m.p. 214–215 °C). MS: M+ at *m/e* 154 corresponding to $C_8H_{10}O_3$. NMR (DMSO-d_6): δ 1.20 and 1.26 (6 H, each s, gem. dimethyl group), 5.20 and 5.48 (weak) (< 2 H, each s, vinyl H's only partly). The signals of OH-groups are omitted.

6. Butyrylfilicinic acid (VIIIb) was prepared by acylation of filicinic acid (IX).[7] Slightly brownish plates, m.p. 98–100 °C (hexane) (lit.[28] m.p. 98–99 °C). MS: M+ at *m/e* 224 corresponding to $C_{12}H_{16}O_4$. NMR ($CDCl_3$): δ 1.01 (3 H, t, J 7 Hz, $-CO-CH_2-CH_2-CH_3$), 1.40 and 1.50 (6 H, each s, gem. dimethyl group), 1.74 (2 H, m, $-CO-CH_2-CH_2-CH_2-CH_3$), 3.02 (2 H, t, J 7 Hz, $-CO-CH_2-CH_2-CH_3$) and 5.54 (< 1 H, s, vinyl H only partly). The signals of OH-groups are omitted (*cf.* Ref. 10).

7. 3-Methylbutyrylfilicinic acid (Vd) ** was prepared from butyrylphloroglucinol (XIIb) by the method of Riedl and Risse.[12] Colourless plates, m.p. 78–79 °C (ether) (lit.[7] m.p. 87 °C). MS: M+ at *m/e* 238 corresponding to $C_{13}H_{18}O_4$. NMR ($CDCl_3$): δ 0.98 (3 H, t, J 7 Hz, $-CO-CH_2-CH_2-CH_3$), 1.40 and 1.50 (weak) (6 H, each s, gem. dimethyl group), 1.68 (2 H, m, $-CO-CH_2-CH_2-CH_2-CH_3$), 1.90 (3 H, s. $CH_3-C\langle$) and 3.00 (2 H, t, J 7 Hz, $-CO-CH_2-CH_2-CH_3$). The signals of OH-groups are omitted (*cf.* Ref. 10).

8. 3-Methylfilicinic acid (X) was obtained by reductive alkaline cleavage of 3-methylisobutyrylfilicinic acid (Va).[12] Yellowish plates, m.p. 178 °C (benzene) (lit.[12] m.p. 179–180 °C). MS: M+ at *m/e* 168 corresponding to $C_9H_{12}O_3$. NMR: (DMSO-d_6): δ 1.22 and 1.30 (6 H, each s, gem. dimethyl group), 1.68 (3 H, s, $CH_3-C\langle$) and 5.36 (< 1 H, s, vinyl H only partly). The signals of OH-groups are omitted.

9. 3,3-Dimethylfilicinic acid (XI) was prepared by reductive alkaline cleavage of 3,3-dimethylisobutyrylfilicinic acid (VIa).[12] Colourless needles, m.p. 186–189 °C (benzene (lit.[12] m.p. 187–190 °C). MS: M+ at *m/e* 182 corresponding to $C_{10}H_{14}O_3$. NMR: (DMSO-d_6). δ 1.20 (weak) and 1.30 (12 H, each s, 2 gem. dimethyl groups) and 5.28 (1 H, s, vinyl H). The signal of OH-group is omitted.

10. Pseudo-aspidinol B (IVd) was prepared by alkaline treatment (Cleavage A) of aspidin BB (VII) according to the method of Aebi *et al.*[17] Colourless plates, m.p. 70–72 °C (hexane) (lit.[17] m.p. 70–72 °C). MS: M+ at *m/e* 224 corresponding to $C_8H_{10}O_3$. NMR ($CDCl_3$): δ 0.98 (3 H, t, J 7 Hz, $-CO-CH_2-CH_2-CH_3$), 1.74 (2 H, m, $-CO-CH_2-CH_2-CH_2-CH_3$) 2.10 (3 H, s, CH_3-Ar), 3.04 (2 H, t, J 7 Hz, $-CO-CH_2-CH_2-CH_3$), 3.74 (3 H, s, CH_3O-), 6.20 (2 H, two superposable s, OH and aromatic H) and 13.20 (1 H, s, OH) (*cf.* Ref. 25).

11. Methylphloroglucinol-4-monomethyl ether (XXI) was prepared by the method of Weidel.[26] Slightly brownish needles, m.p. 124 °C (xylene) (lit.[26] m.p. 124 °C). MS: M+ at *m/e* 154 corresponding to $C_8H_{10}O_3$.

12. Methylene-bis-pseudo-aspidinol BB (XVIII R = $-CH_2-CH_2-CH_2$) was prepared by alkaline treatment (Cleavage C) of aspidin BB (VII) according to the method of Aebi *et al.*[18] Colourless needles, m.p. 140–141 °C (acetone) (lit.[18] m.p. 141–143 °C) MS: M+ at *m/e* 460 corresponding to $C_{25}H_{32}O_8$.

13. For the preparation of methylphloroglucinol-2-monomethyl ether (XV) and for the isolation of kosotoxin (II) and protokosin (III), see Part II.[2]

14. Aspidin BB (VII), m.p. 124–125 °C, consisted of an old sample isolated from *D. assimilis* S. Walker.[27]

** This is an unstable substance, like its corresponding isobutyryl isomer (Va).

Reductive alkaline cleavages

1. Aspidin BB (VII). Cleavage A. 1.2 g of aspidin BB (VII) was thoroughly mixed with 2.4 g of zinc dust, and 100 ml of 5 % NaOH solution was added. The mixture was kept on a boiling water bath for 5 min. The warm green-yellow solution was then separated from Zn by filtering, and the filter paper was washed with water. After cooling, the solution was acidified (pH 2) with 33 % H_2SO_4, whereupon a yellow precipitate was formed. The acidic solution was shaken three times with 50 ml ether and the combined ether solutions were shaken twice with 50 ml of distilled water and dried over Na_2SO_4. The filtered ether solution was evaporated *in vacuo*, whereupon 1.2 g of an oil was obtained. The phloroglucinols contained in this oil were separated by column chromatography on 30 g of silica gel. The fractions 1–14 (10 ml each) (benzene-light petroleum 1:1) contained, according to TLC, a mixture of albaspidin BB (XVII) and aspidin BB (VII), that did not separate. The fractions 15–40 (benzene-light petroleum 1:1) gave on crystallization from hexane 44 mg of aspidin BB (VII), m.p. 121–123 °C. The fractions 41–67 (benzene) contained only traces of aspidin BB (VII) and the fractions 68–83 gave by crystallization from hexane 40 mg of pseudo-aspidinol B (IVd), m.p. 70–72 °C. The fractions 84–140 (benzene–ether 9:1) contained only butyrylfilicinic acid (VIIIb), which was obtained as an oil.

Cleavage B. A 100 mg sample of aspidin BB (VII) was mixed with 200 mg of zinc dust and 20 ml of 5 % NaOH solution was added. The mixture was boiled for 5 min over a bunsen flame and the phloroglucinols were

separated as explained above for cleavage A and investigated by TLC (*cf.* theoretical section).

Cleavage C. A 1.0 g sample of aspidin BB (VII) was mixed with 2.0 g of zinc dust and 100 ml of a 15 % solution of NaOH was added. The mixture was boiled for 5 min on a Bunsen flame and processed according to Cleavage A. Crystallization of the resulting oil (1.0 g) from acetone gave 20 mg of methylene-bis-pseudo-aspidinol BB (XVIII R= $-CH_2-CH_2-CH_3$), m.p. 140–141 °C. No further uniform compounds were obtained.

2. *Kosotoxin (II). Cleavage A.* 1.0 g of kosotoxin (II) was subjected to reductive alkaline cleavage in the same way as described for aspidin BB (VII). The phloroglucinols of the reaction mixture (1.0 g) were separated by column chromatography on 30 g of silica gel. The fractions 1–12 (10 ml each) (benzene) were crystallized from methanol to give 41 mg of "kosin" (XVIII),* m.p. 128–132 °C. The melting point of these crystals was raised to 148–150 °C by recrystallization from hexane. The fractions 13–32 (benzene, benzene–chloroform 1:1) failed to give crystalline compounds from methanol. The fractions 33–43 (benzene–chloroform 1:1) contained (TLC) pseudo-aspidinols (IVa, b, c) as well as one compound of unknown structure. No crystals were obtained from hexane. The fractions 44–52 (benzene-chloroform 1:1), which contained the same compounds as the fractions 33–43, were dissolved in ether and extracted 4 times with 10 % $NaHCO_3$ solution. The ether solution was evaporated, and the residue dissolved in hexane, whereupon 20.4 mg of pseudo-aspidinol (IVa, b, c,) m.p. 60–61 °C was obtained.

Cleavages B and C were performed as described for aspidin BB (VII) and the resulting products investigated by TLC.

Cleavages D. 100 mg of kosotoxin (II) was mixed with 200 mg of zinc dust and added to 20 ml of a 15 % solution of NaOH. The mixture was warmed for 24 h on a water bath and processed as described for aspidin BB (VII), and then investigated by TLC.

3. Protokosin (III). Cleavage A. 1.06 g of protokosin (III) was subjected to reductive alkaline cleavage as described for aspidin BB (VII). The resulting phloroglucinols (1.06 g) were chromatographed on 32 g of silica gel. The fractions 1–22 (10 ml each) benzene) gave 77.9 mg of "kosin" (XVIII),* m.p. 127–129 °C, when crystallized from hexane. Fractions 23–32 (benzene) contained an unknown compound, the structure of which was not determined.

Fractions 33–92 (benzene, benzene–chloroform 1:1) contained pseudo-aspidinols (IVa, b, c). The residue after evaporation of the solvents was dissolved in ether and extracted four times with a solution of $NaHCO_3$. The evaporated ether solution was dissolved in hexane, giving 27.6 mg of pseudo-aspidinols (IVa, b, c), m.p. 58–61 °C. Fractions 93–190 (benzene-chloroform 1:1, chloroform) gave only mixed crystals of pseudo-aspidinols (IVa, b, c) and unknown compounds which were not further separated.

Cleavages B, C and D were performed as described for aspidin BB (VII) and kosotoxin (II), and resulting products were investigated by TLC.

The authors thank Miss Leena Karppi for skillful technical assistance.

* R= $-CH(CH_3)_2$; $-CH_2-CH(CH_3)_2$; $-CH(CH_3)-CH_2-CH_3$.

Bacterial Carotenoids. XLIV.* Zeaxanthin Mono- and Dirhamnoside

GERD NYBRAATEN and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim, Norway

The isolation of zeaxanthin (*1a*, 2 % of total carotenoid), zeaxanthin monorhamnoside (*3a*, 18 %) and zeaxanthin dirhamnoside (*2a*, 80 %) from a coryneform hydrogen bacterium strain 14 g (Institute of Microbiology, University of Göttingen) is reported.

The partial structures of these first, secondary, non-allylic, remarkably stable, carotenoid glycosides (*2a* and *3a*) were established by spectroscopic (visible light, IR, ^{1}H NMR and mass spectra) and chemical evidence. Acid hydrolysis provided rhamnose and strong alkaline hydrolysis zeaxanthin (*1a*) and modified dehydroaglycones.

The isolation and structure elucidation of carotenoid glycosides have recently been reviewed.[1] Also carotenoid glycosides subsequently isolated [2–5] belong to the same type of prim./sec. allylic or tert. glycosides.

We now report the first isolation of secondary, non-allylic carotenoid glycosides with remarkable stability.

The source of these rhamnosides is a yellow coryneform hydrogen bacterium strain 14 g under current investigation [6,7] at Institute of Microbiology, University of Göttingen.

RESULTS AND DISCUSSION

Strain 14 g contained *ca.* 0.074 % carotenoid per dry weight, comprising zeaxanthin (*1a*, 2 %), zeaxanthin dirhamnoside (*2a*, 80 %), and zeaxanthin monorhamnoside (*3a*, 18 %). Solubility properties, impurities and low recovery on acetylation of crude extracts complicated the isolation of the rhamnosides. Best results were obtained by purification of the free glycosides on acetylated polyamide columns.[3,4]

Zeaxanthin (*1a*, available 0.5 mg) exhibited visible spectrum and mass spectrum consistent with structure *1a*, was inseparable from authentic zeaxanthin (*1a*), and more polar than the 2,2′- or 4,4′-dihydroxy analogues.[8] Its diacetate *1b* was inseparable from authentic zeaxanthin diacetate (*1b*) and different from isozeaxanthin diacetate.

The major carotenoid (*2a*, available *ca.* 18 mg) had, according to the electronic spectrum, the same bicyclic chromophore as zeaxanthin (*1a*). Polarity and mass spectrometric data indicated its glycosidic character. The molecular ion of *2a* [*m/e* 860, consistent with $C_{40}H_{54}O_2(C_6H_{11}O_4)_2$] was shifted to *m/e* 1112 on peracetylation to *2b* and to *m/e* 944 on permethylation to *2c*, demonstrating the presence of six hydroxy groups. Molecular ions were generally supported by M − 79, M − 92, M − 106 and M − 158 ions caused by common in-chain fragmentations.[9]

At least one glycosidically bound methylpentose followed from the fragmentation pattern on electron impact. Thus *2a* itself had characteristic fragment ions M − 164, M − 163, M − 146 and *m/e* 147 and the hexaacetate *2b* diagnostically important M − 290, M − 289, M − 288, M − 272 and *m/e* 273 and 169 ions, typical of methylpentosides.[10,11] Corresponding fragment ions were also observed for the hexamethyl ether *2c*: M − 206, M − 188, *m/e* 189 and 167.[10] An *m/e* 331.1025 ($C_{14}H_{19}O_9$) ion of varying intensity in spectra of the hexaacetate *2b*, consistent with the tetraacetyl oxonium ion of a hexose,[10] could by other criteria (molecular ion

Scheme 1.

and glycoside hydrolysis) not be explained by a mixed hexoside, *cf.* Refs. 11–13. Contamination with an acetylated glucose polymer may offer an explanation, since this bacterium is known to produce polyglucose.[14] However, at this stage acetyl transfer within a disaccharide was also considered.

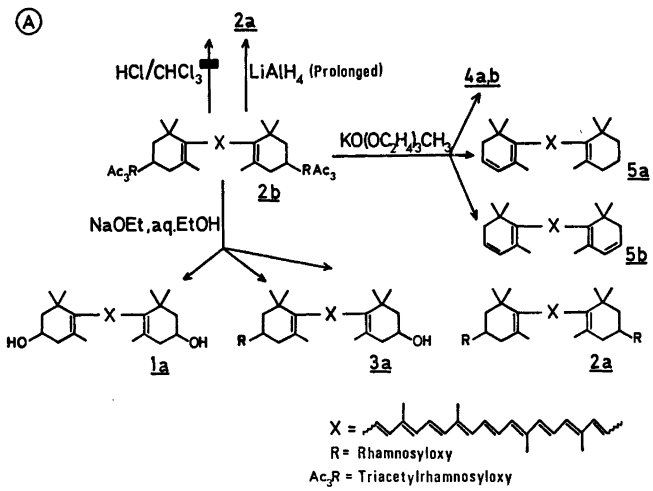
Methanolysis, followed by hydrolysis of the methyl glycosides thus formed gave no reducing sugars under conditions effective for secondary, allylic carotenoid glycosides.[11,12] Methanolysis under more vigorous conditions gave rhamnose as the only reducing sugar seen by paper chromatography. The identification was further confirmed by GLC of the derived rhamnose tetraacetate and rhamnitol pentaacetate in direct comparison with authentic standards. Evidence that zeaxanthin is the aglycone involved is given below, and it may therefore be concluded that the glycoside in question is a zeaxanthin dirhamnoside.

The possibility of the two rhamnose units being present in a disaccharide rather than separately bound to the diol aglycone *1a* was ruled out by ^{1}H NMR data: In the symmetrical zeaxanthin dimethyl ether (*1c*) the 18- and 18′-methyl groups cause one signal in deuteriopyridine at τ 8.24. In the monorhamnoside *3a* discussed below, two separate signals at τ 8.24 (18–Me) and τ 8.17 (18′–Me) are observed. The occurrence of only one signal at τ 8.24 (18,18′–Me) in the dirhamnoside therefore demonstrated the symmetrical nature of *2a*.

Evidence leading to identification of the aglycone will now be considered. The ^{1}H NMR spectrum of the dirhamnoside hexaacetate (*2b*, Scheme 1, including assignments) suggested that the aglycone involved was a β,β-carotenediol derivative.[9] Contrary to secondary, allylic carotenoid glycosides [11,12] the present rhamnoside gave no modified aglycones on treatment with $HCl/CHCl_3$ or on prolonged $LiAlH_4$ reduction.

Others [15,16] have reported that the aglycone and dehydroaglycone may be obtained from tertiary carotenoid glycosides on base treatment. The hexaacetate *2b* gave on treatment with sodium ethoxide in aqueous ethanol zeaxanthin (*1a*, 5 %) and the monorhamnoside (*3a*, 45 %) in addition to the dirhamnoside (*2a*), thus proving that zeaxanthin (*1a*) is the aglycone involved, Scheme 2. The hexamethyl ether *2c* suffered no such hydrolysis, indicating that the free glycoside is required as an intermediate.

Treatment of the hexaacetate *2b* with potassium methoxytriethyleneglycolate [17] in dioxane gave unidentified modified aglycone products



Scheme 2.

(*4a,b*, *5a,b*) with electronic and mass spectra compatible with 3,4(3′,4′)-dehydrogenation, Scheme 2.

These alkaline degradations are not well understood, although possible analogies have been considered.[18–22]

Turning now to the stereochemistry of zeaxanthin dirhamnoside (*2a*), the all-*trans* isomer was the predominant geometrical isomer. The chirality of the aglycone was not established. Zeaxanthin from other sources is known to have 3*R*,3′*R*-configuration.[23,24] Rhamnose sufficient for rotation measurements could not be isolated; L-rhamnosides are most common.[25–28] Regarding the stereochemistry of the glycosidic linkage no definite conclusions can be made from the available evidence. The preference for α-L-rhamnopyranoside [22] (Scheme 1) is tentative.

Zeaxanthin monorhamnoside (*3a*, available 4 mg) exhibited the same electronic spectrum as *1a* and *2a* and had intermediate polarity. Its molecular ion at *m/e* 714 (consistent with $C_{40}H_{55}O_2(C_6H_{11}O_4)$ shifted to *m/e* 882 on acetylation, demonstrating the formation of a tetraacetate *3b*. The monorhamnoside *3a* and its tetraacetate *3b* exhibited the same prominent fragment ions as the dirhamnoside (*2a* and *2b*) on electron impact and showed an *m/e* 331 ion in agreement with the methylpentoside formulation. The ^{1}H NMR spectrum was consistent with structure *3a* and zeaxanthin (*1a*) was obtained as 13 % of the recovered carotenoid on alkaline hydrolysis with sodium ethoxide.

EXPERIMENTAL PART

Biological material. Strain 14 g of a yellow, coryneform hydrogen bacterium, Institute of Microbiology, University of Göttingen, was cultivated in Göttingen (Batch 1) and in the Department of Biochemistry of this University (Batch 2) in a Na-lactate medium as described in detail elsewhere;[22] available *ca.* 2.5 kg fresh cells.

General methods and instruments used were those generally employed.[29] When not otherwise stated R_F-values refer to Schleicher & Schüll No. 287 circular kieselguhr paper, acetone in petroleum ether (APE). TLC refers to kieselgel G.

Isolation. Several chromatographic systems and isolation procedures were investigated,[22] two being referred here: A. Most satisfactory was extraction of centrifuged cells with acetone at room temperature, followed by transfer of the concentrated pigment extract to ether with 5 % aqueous NaCl, drying of the pigment by azeotropic distillation with benzene and chromatography on acetylated polyamide.[3,4] The crude pigment, insoluble in petroleum ether, ether, acetone, chloroform, benzene, methanol, and CS_2, but soluble in pyridine or benzene-methanol (*ca.* 1:1) was dissolved in the latter system and diluted with benzene for chromatography. *1a* required benzene, *3a* 2 % methanol in benzene, and *2a* 6 % methanol in benzene for elution from acetylated polyamide; pigment recovery 79 %.

B. Partition of the crude pigment, dissolved in pyridine, between petroleum ether and 80 %

aqueous methanol resulted in precipitation of the pigments in the aqueous phase; 92 % recovery. Standard acetylation and TLC (40 % APE) gave the acetates *1b*, *3b*, and *2b*; 59 % recovery. If partition was omitted acetylation of the crude pigment gave only 5 – 30 % recovery.

Batch 1, *ca.* 2 kg wet weight, provided 325 mg [E(1 %, 1 cm) = 1900] extracted pigment; 0.074 % of the dry extracted residue, purified by procedure B. Batch 2 gave 27 mg pigment, purified by procedure A.

Zeaxanthin (*1a*)

Characterization. 1a available 0.5 mg, purified by standard saponification and TLC; λ_{max} (acetone) 429, 451 and 474 nm, % III/II [30] = 29; *m/e* 568 (M), 550 (M – 18), 489 (M – 79), 476 (M – 92), 462 (M – 106), 422 (M – 146), 410 (M – 158), was inseparable from authentic *1a* and more strongly adsorbed than isozeaxanthin in direct comparison.

Zeaxanthin diacetate (1b). Standard acetylation of *1a* (0.2 mg) gave *1b*; *m/e* 652 (M), 592 (M – 60), 560 (M – 92) 546 (M – 106), 532 (M – 60 – 60), 500 (M – 60 – 92), 494 (M – 158), 486 (M – 60 – 106), inseparable from authentic *2a*.

Zeaxanthin dirhamnoside (*2a*)

Characterization. 2a (Batch 2), repeatedly crystallized from petroleum ether-methanol and pyridine-petroleum ether-acetone gave a semi-crystalline material, m.p. 216 – 218 °C; R_F = 0.16, TLC 35 % APE; λ_{max} (acetone) 428, 452, and 480 nm, % III/II = 27, λ_{max} (benzene-methanol 1:1) 436, 461 (ε = 75 700, compared with ε = 130 000 for authentic *1a* in acetone) and 488 nm; *m/e* (230 °C) 860 (M), 842 (M – 18), 824 (M – 18 – 18), 781 (M – 79), 768 (M – 92), 754 (M – 106), 734 (M – 126), 714 (M – 146), 702 (M – 158), 697 (M – 163), 696 (M – 164), 678 (M – 18 – 18 – 146), 622 (M – 92 – 146), 608 (M – 106 – 146), 604 (M – 18 – 92 – 146), 602 (M – 258), 568 (M – 146 – 146), 565, 550, 508, 472, 339, 264, 147; τ (deuteriopyridine) 8.85 (*gem.* Me), 8.73 (lipid imp.), 8.34 (*d*, J = 5.5 Hz, Me in rhamnose), 8.24 (18,18′-Me), 7.96 (in-chain Me).

For comparison L-rhamnose had C-5 methyl signals at τ 8.36 (β, d, J = 6 Hz) and 8.40 (α, d, J = 6 Hz). Authentic zeaxanthin dimethyl ether *1c* had τ 8.85 (*gem.* Me), 8.22 (18,18′-Me), 8.01 and 7.97 (in-chain Me) and 6.62 (OMe).

Glycoside hydrolysis. Methanolysis [11] of *2a* in 0.15 N dry HCl for 20 h, 22 °C, was not effected; pigment recovery 75 % and no reducing sugars formed after hydrolysis.[11,31] Methanolysis of *2a* (15 mg) in 0.2 N HCl for 5 h, 65 °C, followed by hydrolysis [11,31] with aqueous polystyrene sulfonic acid and ascending chromatography,[22] followed by development with aniline-phthalic acid, showed presence of rhamnose ($R_{glucose}$ = 1.44) only in co-chromatography tests with saccarose (0.45), mannose (0.65), galactose (0.81), glucose (1.00) rhamnose (1.44), and fucose (2.02).

An aliquot of the hydrolysate was acetylated and submitted to GLC (Perkin Elmer F11, silicon XE-60/ethyleneglycol succinate, 157 – 218 °C, 1 °/min) provided two peaks with retention time 20.4 min (75 %) and 22.9 min (25 %). Peracetylated α,β-L-rhamnose showed the same retention times and a ratio of 90:10.

Remaining tetraacetyl rhamnose was saponified and reduced with $NaBH_4$ in water. The rhamnitol, thus prepared, was acetylated and submitted to GLC as above and found identical (retention time 24.5 min) in direct comparison with authentic L-rhamnitol pentaacetate prepared from L-rhamnose.

Zeaxanthin dirhamnoside hexaacetate. (2b). Standard acetylation of *2a* (12 mg) gave *2b* (90 % yield), purified by TLC: λ_{max} as for *2a*; *m/e* 1112 (M), 1070 (M – 42), 1068 (M – 44), 1033 (M – 79), 1020 (M – 92), 1006 (M – 106), 992 (M – 60 – 60), 980 (M – 132), 976 (M – 44 – 92), 968 (M – 144), 956 (M – 156), 954 (M – 158), 868 (M – 244), 840 (M – 272), 824 (M – 288), 823 (M – 289), 822 (M – 290), 731 (M – 92 – 289), 717 (M – 106 – 289), 687 (M – 44 – 92 – 289), 568, 381, 351, 331.1025 ($C_{14}H_{19}O_9$), 273, 169, ν_{max} (KBr) 2925, 2855, 1752, 1445, 1370, 1225, 1180, 1150, 1135, 1050, 977, 910, 890, 840, 790 and 685 cm^{-1}; τ ($CDCl_3$), *cf. 2b*, Scheme 1, 8.91, 8.82 (*gem.* Me, *ca.* 12 H); 8.77 (*Me*–CH?); 8.28 (Me – 18,18′, *ca.* 6 H); 8.03 (in-chain Me, *ca.* 12 H); 8.01, 7.95, 7.85 (acetate Me, *ca.* 18 H); 7.38 (allylic CH_2); 4.0 – 6.0 (CH in rhamnose moiety); 3.0 – 4.0 (olefinic H), stepwise addition of Eu(dpm)$_3$ [32] until 3.1 mol/mol *2b* caused no shift of the aglycone methyl groups, 55 Hz downfield shift of allylic CH_2 and 30 – 19 Hz downfield shifts of CH_3 and $CH_3C{=}O$ of the rhamnose moiety; R_F = 0.65 in 10 % APE.

An acetylated compound more polar than *2b* by TLC and representing 4 % of *2b* was, from electronic spectrum (% III/II = 0), mass spectrum (as *2b*), and reversibility tests, shown to be a *cis* isomer of *2b*.

$LiAlH_4$-reduction of the hexaacetate 2b. Treatment of *2b* (0.5 mg) with $LiAlH_4$ in dry ether for 5 min – 24 h [11,12] gave no modified aglycone but only the free rhamnoside *2a*; pigment recovery 30 – 50 %.

Attempted allylic elimination of the hexaacetate 2b. 2b (0.3 mg) treated with 0.03 – 0.2 N dry HCl in ethanol-free chloroform for 2 – 15 min gave no new, coloured products.

Alkaline hydrolysis of the hexaacetate 2b. 2b (0.75 mg), in 2.5 N NaOEt in 96 % ethanol (10 ml) was kept for 3 h at 50 – 60 °C. The pigments were transferred to ether on dilution with water after acidification to pH 4; pigment recovery 42 %. Paper chromatography revealed the formation of zeaxanthin (*1a*). Acetylation of the products gave zeaxanthin diacetate (*1b*, 5 %, *m/e* 652 = M), zeaxanthin monorhamnoside tetraacetate (*3b*, 45 %, *m/e* 882 = M) and zeaxanthin dirhamnoside hexaacetate (*2b*, 50 %) with electronic spectra and R_F-values as authentic samples.

Treatment with potassium methoxytriethyleneglycolate [17] at room temperature was carried out with the hexaacetate (*2b*, 1.5 mg) in dioxane (1.4 ml, chromatographed on alumina and distilled under N_2) and potassium methoxytriethyleneglycolate (0.6 ml, *ca.* 0.5 N) added. The mixture was stirred mechanically for 1.5 h and worked up as above; pigment recovery 30 %. TLC gave two major zones, presumably comprising four products: *4a, b* (70 %, $R_F = 0.18$, TLC, 5 % APE), λ_{max} (acetone) 460 nm (round), *m/e* 548 (M_a, consistent with $C_{40}H_{52}O$), 546 (M_b, $C_{40}H_{50}O$?, 80 % of *m/e* 548), 456 ($M_a - 92$), 454 ($M_b - 92$), 442 ($M_a - 106$), 440 ($M_b - 106$) and *5a, b* (25 %, $R_F = 0.60$ in above system), λ_{max} (acetone) 442, 461, and (483) nm, *m/e* 534 (M_a, $C_{40}H_{54}$), 532 (M_b, $C_{40}H_{52}$, 50 % of *m/e* 534), 442 ($M_a - 92$,) 440 ($M_b - 92$), 428 ($M_a - 106$).

Zeaxanthin dirhamnoside hexamethyl ether (2c). Methylation of *2a* (9 mg) by the modified Kuhn procedure [33] gave *2c*; 40 % pigment recovery, quantitative conversion. Compound *2c* had λ_{max} as *2a*; *m/e* 944 (M), 942 (M − 2), 912 (M − 32), 883 (M − 61), 852 (M − 92), 850 (M − 2 − 92), 838 (M − 106), 830 (M − 114), 814 (M − 130), 812 (M − 132), 800 (M − 144), 786 (M − 158), 784 (M − 160), 770 (M − 174), 762 (M − 182), 756 (M − 188), 738 (M − 206), 694 (M − 92 − 158), 692 (M − 92 − 160), 664 (M − 92 − 188), 189, 157; $R_F = 0.90$, 10 % APE.

Alkali treatment with 2.5 % NaOEt as for *2b* caused no reaction.

Zeaxanthin monorhamnoside (*3a*)

Characterization. 3a, precipitated from methanol-benzene-petroleum ether, available 4 mg, m.p. 149 − 150 °C had μ_{max} (methanol-benzene 1:1) 436, 460 and 487 nm, % III/II = 23; *m/e* (220 °C) 714 (M), 696 (M − 18), 680 (M − 34), 672 (M − 42), 635 (M − 79), 622 (M − 92), 608 (M − 106), 602 (M − 112), 596 (M − 118), 588 (M − 34 − 92), 582 (M − 132), 568 (M − 146), 558 (M − 156), 556 (M − 158), 551 (M − 163), 550 (M − 164), 516 (M − 92 − 106), 508 (M − 206), 504 (M − 210), 476 (M − 92 − 146), 462 (M − 106 − 146), 339, 264, 163; τ (deuteriopyridine) 8.82 (*gem.* Me), 8.70 (lipid imp.), 8.34 (d, $J = 5.5$ Hz, Me in rhamnose), 8.24 (18 − Me), 8.17 (18′ − Me) and 7.95 (in-chain Me); $R_F = 0.50$, 35 % APE.

Zeaxanthin monorhamnoside tetraacetate (3b). 3a (0.4 mg) was quantitatively acetylated to *3b* λ_{max} as *3a*; *m/e* 882 (M), 840 (M − 42), 838 (M − 44), 822 (M − 60), 803 (M − 79), 790 (M − 92), 776 (M − 106), 748 (M − 42 − 92), 730 (M − 60 − 92), 726 (M − 156), 724 (M − 158), 716 (M − 60 − 106), 666 (M − 60 − 156), 664 (M − 60 − 158), 638 (M − 244), 610 (M − 272), 594 (M − 288), 593 (M − 289), 331 (15 % of *m/e* 273), 273, 153, (100 %); $R_F = 0.54$, 5 % APE.

Alkaline hydrolysis of tetraacetate 3b. 3b (0.5 mg) was treated with 2.5 % NaOEt as described above for *2b*; pigment recovery 40 %. Zeaxanthin (*1a*) was identified by paper chromatography. Acetylation of the product, followed by TLC gave zeaxanthin diacetate (*1b*, 13 %, inseparable from authentic *1b*) and *3b* (87 %, inseparable from the starting material *3b*).

Acknowledgement. The cultivation of the biological material was kindly carried out in Göttingen by the courtesy of Professor H. G. Schlegel and in Trondheim through Dosent K. E. Eimhjellen.

Dr. J. D. Surmatis, Hoffmann-La Roche, Nutley, New Jersey, provided synthetic zeaxanthin dimethyl ether.

GN was supported partly by a personal grant from The Norwegian Institute of Technology and partly by a grant from Hoffmann-La Roche, Basel, to SLJ.

On the Structure of Rapidly Labeled Rat Liver RNA

POVEL N. PAUS*

Department of Microbiology, University of Oslo, Blindern, Oslo 3, Norway

Rat liver total RNA, extracted by three phenol methods relying upon 4-aminosalicylate, naphthalene-1,5-disulfonate, and heat, respectively, gave different migration patterns, most pronounced for rapid label. The difference could not be attributed to differential extraction.

By the 4-aminosalicylate method, large amounts of rapidly labeled structures sedimenting up to 20 000 S were isolated. These structures, consisting of aggregates of heterogeneous RNA, were examined in the present report. They complied with most of the criteria used to classify giant heterogeneous nucleoplasmic RNA as a separate entity of covalent molecules, but they were not resistant to treatment with dimethyl sulfoxide or to heating in low-ionic-strength acetate buffers or in formaldehyde.

When such disaggregating treatment was performed on the RNAs extracted by the different methods, the rapidly labeled RNA >45 S disappeared, and several additional UV-absorbing constituents appeared in the cold-extracted RNAs. This caused a resemblance in the migration and sedimentation patterns of the different RNAs. Radioactive markers added to the extraction buffers prior to homogenization of the livers did not reveal any degradation during extraction or analysis. The results suggest that giant heterogeneous nucleoplasmic RNA from rat liver could essentially be an artifact of extraction.

The presence of giant heterogeneous nucleoplasmic RNA (giant hnRNA) (10 – 200 S) in eucaryotic cells has been established by many authors (review by Darnell [1]). It was identified in rat liver by Schütz *et al.*[2] A precursor relationship to cytoplasmic messenger RNA (mRNA) (6 – 30 S) [3,4] is widely accepted. However, conclusive evidence for specific cleavage has not been found. A remarkably reproducible base composition has been reported, with uridine content in excess of the corresponding DNA, and in excess of that of the cytoplasmic mRNA of the same cells.[3,5–8] Its biological role is thus still uncertain.

The existence of covalent molecules of corresponding size was questioned by Mayo and de Kloet [9] who showed that formaldehyde treatment converted rapidly sedimenting rapidly labeled RNA (rlRNA) to structures sedimenting as mRNA. Recent reports, using different disaggregating treatments, and different methods for analysis of the treated RNA, have been contradictory.[10–15] Even if such a conversion could be found to be accompanied by a corresponding change in the electrophoretic pattern, the possibility of giant size transcription with later conversion to smaller molecules could not be excluded.

In an examination of different methods for extraction of rat liver total RNA [16] large variations were found in the rapidly sedimenting rlRNA. These could not be attributed to differential extraction of the rapidly labeled molecules. Preliminary experiments showed that the amount and size of such molecules, when extracted by a 4-aminosalicylate method, were out of proportion to what could reasonably be expected to represent an *in vivo* state. The present study was undertaken to see whether these structures were consistent with the criteria of giant hnRNA. If so, such molecules could be mere artifacts of extraction, and not necessarily expression of giant size transcription. Besides, the criteria used to classify giant hnRNA as a separate entity of covalent molecules could be evaluated.

The results showed that the extracted aggregates met many of the criteria used for giant hnRNA, and that several of the disag-

* Present address: Department of Anesthesiology, Rikshospitalet, Pilestredet 32, Oslo 1, Norway.

gregating treatments previously used to establish the covalency of this class of molecules in fact did not disaggregate them. However, they could be disaggregated by heating in low-ionic-strength acetate buffer at 50 °C, or by treatment with dimethyl sulfoxide (DMSO). When such treatment was applied to materials extracted by different methods, evidence was obtained that emphasized the tendency of newly synthesized RNA to aggregate during extraction. To exclude the possibility of RNA degradation, controls using both homogeneous and heterogeneous markers were included.

MATERIALS AND METHODS

Animals. Male 250 g CD*F inbred rats (Charles River Breeding Laboratories, Wilmington, Mass.) were used.

Cell fractionation procedures. Liver nuclei were prepared by homogenizing the liver in 13 ml 1.5 M sucrose containing 2 mg/ml bentonite (treated according to Fraenkel-Conrat *et al.*[17]). The homogenate was filtered through gauze and layered on a 35 ml linear 1.5 – 2.25 M sucrose gradient, using a 10 ml 2.3 M sucrose cushion. All sucrose solutions were made up in buffer (Tris 0.05 M, KCl 0.025 M, $CaCl_2$ 3.3 mM; pH 7.1) containing 0.1 mg/ml dextran sulfate. Centrifugation was performed in a Spinco SW 25.2 rotor for 45 min at 25 000 rpm and 5 °C. The pellet was collected.

Polysomes were prepared after homogenization of the liver in two volumes chilled 0.25 M sucrose in TKM-buffer (Tris 0.05 M, KCl 0.025 M, $MgCl_2$ 2.5 mM; pH 7.0), containing 2 mg/ml bentonite. The homogenate was then centrifuged at 15 000 *g* for 10 min at 2 °C, and the supernatant made 0.4 % w/v with respect to deoxycholate. 15 ml was applied on top of two layers of sucrose in TKM-buffer, 10 ml 0.5 M sucrose and 5 ml 1.0 M sucrose. Centrifugation was performed in a Spinco SW 25.1 rotor for 3 h at 25 000 rpm and 2 °C. The pellet was used as polysome source.

Extraction procedures. Method 1 was a cold-phenol method based on the 4-aminosalicylate method of Parish and Kirby.[18] Method 2 was modified from the cold-phenol naphthalene-1,5-disulfonate method of Attardi *et al.*[5] Method 3 was modified from the hot-phenol method of Warner *et al.*[19] Details have been given previously.[16]

Preparation of E. coli *16 S (10 S) rRNA marker. Escherichia coli* K12 cells were grown logarithmically for 2 h in 500 ml of a minimal salt medium containing 0.4 % w/v glucose and 200 μCi ^{3}H-uridine. Ribosomal RNA (rRNA) was extracted by a modified Method 3, extracting at 4 °C, and the 16 S rRNA purified by repeated ultracentrifugations. After DMSO-treatment, the peak was recovered as a 10 S peak.

Chemical analysis. Protein was determined by the method of Lowry *et al.*[20] DNA was determined by a diphenylamine reaction.[21]

Ultracentrifugation. Sucrose gradient analysis and sedimentation coefficient determinations have been described previously.[16] The very high *s* values (≥ 2000 S) were determined by examining pellet material after short runs at reduced speed (10 000 rpm), taking the sedimentation during the acceleration and deceleration of the rotor into consideration. The possibility that the pelleting could be due to irregular sedimentation, was excluded by running in a sector-formed partition cell in a Spinco model E analytical ultracentrifuge.

Before density equilibrium centrifugation, RNA was fixed at 4 °C in 0.05 M sodium phosphate – citrate pH 7.0, containing 5 – 8 % w/v formaldehyde. Cesium chloride gradients were run in a Spinco SW 65 rotor for 66 h at 25 °C. Mixed cesium chloride : cesium sulfate 4:1 v/v (equal densities) gradients were run in a Spinco 65 fixed angle rotor at 30 °C and 61 000 rpm. All solutions contained 1.5 % w/v formaldehyde and 0.05 M sodium phosphate-citrate pH 7.0.

Polyacrylamide gel electrophoresis was performed as described previously.[16]

^{32}P Base composition analysis. Sucrose gradient fractions were pooled according to the UV-pattern, precipitated after addition of carrier RNA, and hydrolyzed in 0.3 M potassium hydroxide at 37 °C for 17 h. The nucleotides were separated by high voltage electrophoresis, using Whatman No. 1 paper as support.

Treatment with disaggregating agents. Formaldehyde treatment was performed by heating RNA in 0.01 M sodium acetate pH 6.0, containing 7.5 % w/v formaldehyde, at 63 °C for 15 min before chilling. RNA samples to be treated with DMSO were dissolved in DMSO containing 0.01 M LiCl and 1 mM EDTA.[22]

RESULTS AND DISCUSSION

Aggregate characteristics

Physical state. $rlRNA_1$,* isolated 20 min after administration of radioactive orotic acid, sedimented heterogeneously with 3 % of the radioactivity at 2000 S or faster, and 1 % at 20 000 S or faster.

No DNA was found in material ≥ 140 S. The protein content was 5 – 30 μg per mg total RNA_1, all sedimenting at *s* values ≥ 140 S. A reduction in protein content upon re-extraction with phenol with no change in RNA-pattern,

* Subscript $_1$, $_2$, or $_3$: That which pertains to Extraction Method 1, 2, or 3.

as well as cesium salt density gradient centrifugations, indicated that this protein was merely co-sedimenting. The sedimentation patterns were also unaffected by treatment of the isolated RNA with the lipid solvents ethanol, ethyl-ether, or methanol-chloroform 1:2 v/v, or exposure to pronase, DNAase, or amylase. RNAase treatment caused both rapid label and optical density to be confined exclusively to the top fractions of the gradients. The rapidly sedimenting substances therefore appear to consist of RNA without other macromolecules. Their conversion to slower sedimenting, faster migrating structures on moderate heating in a low-ionic-strength acetate buffer or by DMSO-treatment (see below), indicates that they consist of hydrogen-bonded aggregates.

Origin. By separate extraction of RNA from nuclei and polysomes, rlRNA$_1$ sedimenting at *s* values comparable to those obtained by extracting whole liver tissue could be demonstrated only in the nuclear fraction. Polysomal rlRNA sedimented in the region 5 – 35 S.

Kinetics. All RNA sedimenting faster than 65 S had identical labeling kinetics. Except for the growing polynucleotide chains,[16] it was labeled faster than any other fraction. The absolute amount of radioactivity ≥ 140 S was maximal about 20 min after administration of radioactive orotic acid (Fig. 1a). Its relative specific activity

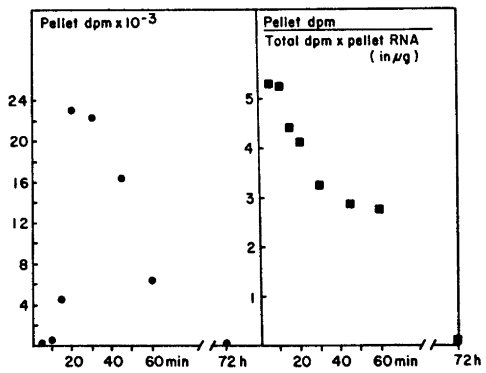

Fig. 1. Kinetics of labeling of apparent giant hnRNA$_1$. RNA$_1$ was isolated at different intervals after injection of 50 μCi ^{14}C-orotic acid. 1 mg RNA was subjected to ultracentrifugation (10 – 40 % w/w sucrose in 0.1 M sodium acetate pH 6.0, Spinco SW 25.1, 24 000 rpm, 5 °C, 14 h). The pellet (≥ 140 S) was eluted, and the amount of RNA and of radioactivity determined.

showed a steady decline with time (Fig. 1b), demonstrating the high turnover of the fast sedimenting RNA$_1$, and indicating that newly synthesized or even incomplete RNA strands are especially liable to aggregation.

Apparent base composition. Base composition analysis of RNA$_1$ isolated 1 h after intraperitoneal injection of ^{32}P$_i$ showed varying composition of the RNA in the heavy parts of the gradient. Even runs of the same material on parallel gradients showed considerable differences in base composition at the same gradient level. (Repeated analysis of material from the same hydrolysis tube showed identical results). However, the RNA in the regions > 65 S had adenine + uracil/guanine + cytosine ratios ≥ 1. With references to the polyadenylic sequences in nuclear and cytoplasmic mRNA, a relatively high adenine content, ranging from 25 to 31 mol per cent, was noteworthy. No substantial participation of rRNA/pre-rRNA could be detected.

Susceptibility to disaggregating conditions. Exposure to low ionic strength at room temperature [23] did not affect the rapidly sedimenting rlRNA$_1$, but retarded the 10 – 45 S rlRNA (Fig. 2a, b). This retardation was reversible (Fig. 2c), indicating a mere conformational change.

Heating at 50 °C for 3 min in the presence of 0.1 M sodium chloride left the rapid label pattern almost unaffected (Fig. 2d). When such heating was performed in 0.1 M sodium acetate, a substantial amount of rapidly sedimenting radioactivity was converted to material sedimenting in the 5 – 28 S region, and after heating in low-ionic-strength acetate buffer, nearly all radioactive material sedimented in the 5 – 35 S region (Fig. 2e). A parallel conversion was seen by gel electrophoresis (Fig. 5a, d). No specific release of material from the aggregates was found corresponding to rRNA or tRNA (Fig. 2f). Molecules without a firm secondary structure therefore seem to aggregate most readily. Local concentrations in the cell might also be of importance.

Five mM magnesium prevented any change during heating at 50 °C for 5 min. Concentrations of RNA above 1 mg/ml stabilized the original structures somewhat, increasing with greater concentrations. Treatment at room temperature with 1 % w/v SDS, 3 – 8 M urea or ethylurea and/or 1 – 10 mM EDTA did not

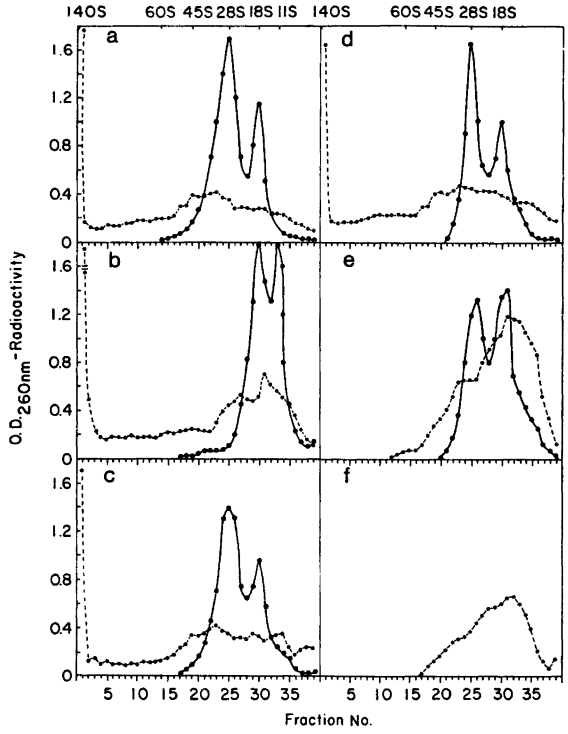

Fig. 2. The effects of low ionic strength and of elevated temperatures on the sedimentation pattern of RNA_1. (a–e) 1 mg RNA, extracted 10 min after administration of 300 μCi ^{3}H-orotic acid, was examined after incubation under the following conditions: (a) Control. No incubation. (b) In 5 mM EDTA-tris pH 7.0, at 25 °C for 1 h. (c) As under (b), with sodium acetate added to 0.1 M before chilling. (d) In 0.01 M sodium acetate containing 0.1 M sodium chloride and 1 mM EDTA at 50 °C for 3 min. (e) In 0.01 M sodium acetate pH 6.0 containing 1 mM EDTA, at 50 °C for 3 min before addition of acetate to 0.1 M. (f) rlRNA $\geq$140 S from an animal labeled for 30 min with 50 μCi ^{14}C-orotic acid was heated as under (e), and recentrifuged.

10–40 % w/w sucrose, Spinco SW 25.1, 24 000 rpm, 5 °C, 14 h, gradient buffer: (a,c–f) 0.1 M sodium acetate pH 6.0, (b) 5 mM EDTA-tris pH 7.0. ———, $OD_{260\ nm}$; (a–e) - - -, ^{3}H-dpm × 10^{-3}; (f) - - - ,^{14}C-dpm × 5 × 10^{-4}.

affect the gradient patterns, but abolished the adsorption of rlRNA to the centrifuge tubes.

After treatment with formaldehyde, the changes were more pronounced than after heating in low-ionic-strength buffer, but some fast-sedimenting, rapidly labeled structures persisted (Fig. 3a). The 28 S rRNA was then partly excluded from the gels, indicating a severe derangement of the molecular conformation, possibly also formation of intermolecular methylene bridges.[24] DMSO-treatment caused essentially the same changes as heating in buffer but some rlRNA, less than after formaldehyde-treatment, still sedimented at 2000 S or more (Fig. 3b).

Aggregate formation. When 20 min labeled RNA_1 >80 S was collected, dissociated by heating, and added to the aqueous phase before unlabeled rat liver total RNA was extracted, aggregation could directly be demonstrated, although to a less extent than observed after *in vivo* labeling (Fig. 4a, b). After re-dissociation, the radioactivity maximum sedimented as after the first dissociation (Fig. 4c).

Relationship to giant hnRNA. The rapidly sedimenting $rlRNA_1$ possesses several of the characteristics reported for giant hnRNA. It is the most rapidly labeled fraction found, except for the growing polynucleotide chains. It consists of pure RNA, and can be demonstrated

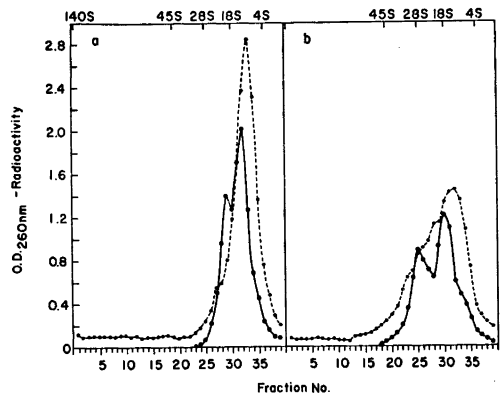

Fig. 3. Dissociation of rat liver RNA. RNA labeled for 10 min was examined by sucrose gradient centrifugation after treatment with (a) formaldehyde, (b) DMSO. The material had been stored for four years between the experiments reported in Fig. 2a–e and the experiments reported in this figure. Legend otherwise as in Fig. 2a.

only in the nuclear fraction. Its sedimentation pattern is fairly reproducible with 25–35 % of the total radioactivity sedimenting ≥140 S after a 20 min pulse. It resists treatment with 3–8 M urea or ethylurea, 1–2 % SDS, 1–10 mM EDTA, or low ionic strength at room temperature. It is also unaffected by heating at 50–60 °C in 0.1 M sodium chloride for 3–5 min. In spite of this, it is obviously an artifact of extraction, because it sediments at *s* values up to 20 000 S, and aggregation can directly be demonstrated.

To be designated as covalent, RNA molecules should be completely resistant to treatment with DMSO or to heating in low-ionic-strength acetate buffer containing 1 mM EDTA for removal of divalent ions. The difference between sodium chloride and sodium acetate is not understood, but Tal [25] noticed that potassium acetate depressed the melting temperature of rRNA. Parallel examination by ultracentrifugation and gel electrophoresis should be performed to determine whether changes in charge or in conformation *versus* aggregation/disaggregation have taken place. Because formaldehyde-treated RNA is partly excluded from acrylamide gels, the use of this denaturing agent is not advocated.

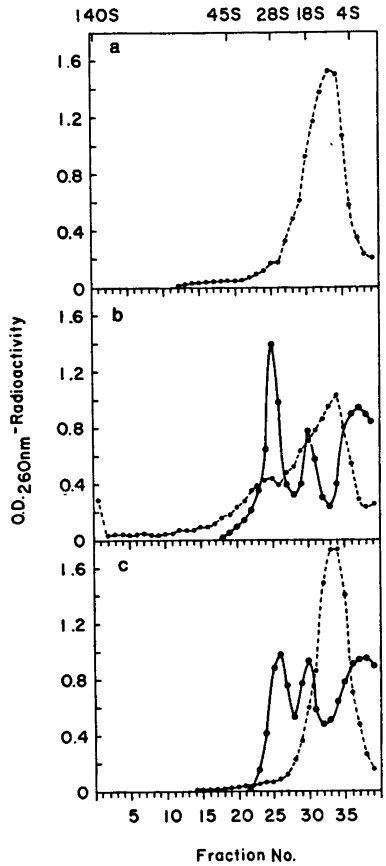

Fig. 4. Aggregation/disaggregation of rlRNA$_1$. (a) 20 min labeled RNA, originally sedimenting ≥80 S, was collected and dissociated by heating at 57 °C for 7 min in 0.01 M sodium acetate pH 6.0. The dissociated material was added to aqueous solution$_1$ before extraction of unlabeled rat liver total RNA. The extracted material was then dissociated by heating. (a) Dissociated rlRNA before addition to aqueous solution$_1$. (b) Total RNA after extraction. (c) Total RNA after dissociation.

10–40 % w/w sucrose in 0.1 M sodium acetate pH 6.0, Spinco SW 25.1, 24 000 rpm, 5 °C, 14 h. ———, OD $_{265\ nm}$; ----, ^{14}C-dpm × 10^{-2}.

Although DNA-like with respect to a high adenine + uracil content, our apparent giant hnRNA$_1$ did not have the high uracil content reported for giant hnRNAs. A specific base composition would suggest a separate molecular species, but determinations made by phosphorus-32 nearest neighbor technique must be regarded with caution.

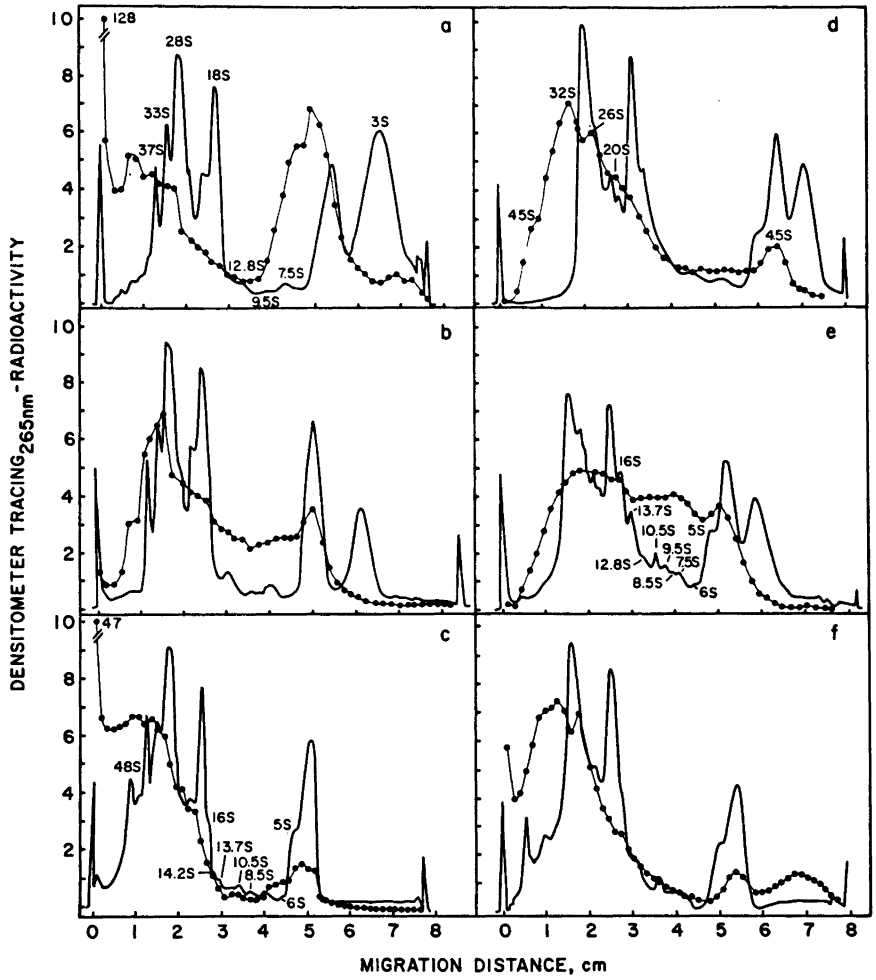

Fig. 5. Disaggregation of rat liver total RNA extracted according to three methods. RNA, extracted 20 min after administration of 50 μCi ^{14}C-orotic acid, heated in 0.01 M sodium acetate pH 6.0 at 50 °C for 3 min prior to electrophoresis. (a) RNA_1, (b) RNA_2, and (c) RNA_3: Unheated, run in magnesium-buffer. (d) RNA_1, (e) RNA_2, and (f) RNA_3: After heating, run in EDTA-buffer. 2.6 % w/v acrylamide, 12 mA/tube, 20 °C, 2 3/4 h. ———, densitometer tracing$_{265\ nm}$; ●, ^{14}C-dpm/mg gel.

Disaggregation patterns

When materials extracted by the 3 different methods were examined after heating in low-ionic-strength acetate buffer, it was found that the aggregates of $rRNA_3$ at 48, 37, and 33 S were harder to dissociate than those obtained by the other methods (Fig. 5a–f). The 28 S peak of RNA_1 and RNA_2 became reduced, while the 18 S peak remained unaffected. Additional peaks between the ribosomal peaks and in the 4–18 S region made the UV-patterns of RNA_1 and RNA_2 approach that of RNA_3, demonstrating which components of RNA_3 that could be attributed to heating during extraction. A comparison of the UV-patterns of unheated RNA with those obtained after heating (Fig. 5) indicates that the 25 S, 21.5 S, and 20 S peaks as well as the 12.8 S, 9.5 S, and 7.5 S peaks may represent *in vivo* existing separate molecules.

Heating at 50 °C for 3 min in 0.01 M sodium acetate usually made all $rlRNA_1$ enter the gels, with only traces of radioactivity migrating slower than the 45 S component, and with a main peak at 32 S (Fig. 5d). The amount of $rlRNA_3$ on top of the gels was reduced, but some radioactivity usually persisted (Fig. 5f), unless all aggregates of rRNA were dissociated. Such heating made these radioactivity patterns approach that of unheated $rlRNA_2$. However, parallel heating of $rlRNA_2$ also altered the migration patterns of this rlRNA species, with a decrease in the amount of radioactivity in the region > 18 S, and an increase in the 4 – 18 S region. Some label still migrated as a shoulder at 45 S (Fig. 5e). Heating of $rlRNA_1$ and $rlRNA_3$ at higher temperatures (> 60 °C) caused a further conversion in their patterns towards that of heated $rlRNA_2$.

After heating at 50 °C, similarity in the patterns of the different rlRNAs was in general found when materials with labeling times ≤ 10 min were investigated, and the UV-absorbing rRNA aggregates were dissociated. In these materials the amount of radioactivity in pre-rRNA/rRNA was negligible. Increase in the incubation times from 3 – 5 min to 1 h did not affect the patterns significantly. A further conversion was seen on increased heating, occurring in a parallel fashion for the different materials.

The conversion of the isolated giant hnRNAs to slower sedimenting, faster migrating structures demonstrates their aggregate nature, and supports the findings of Mayo and de Kloet.[9] All phenol methods examined caused aggregation of RNA. The preferential aggregation of newly synthesized RNA probably reflects a less firm secondary and tertiary structure of these molecules. The tendency towards aggregate formation varies according to the extraction method,[16] as does the dissociation temperature of the formed aggregates. One cannot exclude a transcription giving giant molecules which are immediately cleaved without dissociation of the fragments. However, hard evidence for the *in vivo* existence of rlRNA molecules larger than corresponding to 45 – 50 S cannot be found.

The rapid label in the 45 S and 36 S regions became reduced on heating, and the radioactivity accumulated as a 32 S peak. Convincing evidence has been obtained by electron microscopy (review by Bush and Smetana [26]) and by disaggregating experiments [9,27] to demonstrate the transcription of 45 S pre-rRNA as a single polynucleotide chain. The possibility exists, however, that the molecules do not immediately dissociate after scission. Possible co-migration of other rlRNA species in our experiments necessitates the use of subcellular fractionation to settle the question.

After heat treatment, rlRNA peaks were observed at 28 – 32 S, 26 S, 20 S and 4.5 S. Long label (24 – 48 h) followed the UV-pattern closely.

The possibility of RNA degradation

The size of the rat liver rlRNA molecules seemed smaller than could be expected from most previous reports. It was therefore imperative to exclude the possibility of degradation of the molecules during their extraction, storage or analysis.

RNAase activity during the extraction seemed unlikely: The ice-cold homogenized livers were mixed with phenol within 1 min after decapitation of the animals, and RNAase inhibitors were used throughout. Removal of DNA and glycogen by chemical [18] instead of enzymatic methods did not influence the dissociation. The sedimentation pattern of dissociated heterogeneous rlRNA seemed unaffected by passage of the rlRNA through the extraction procedure (Fig. 4a, c). Also unaffected was the migration pattern of a homogeneous marker, 16 S (10 S) rRNA from *E. coli* (Fig. 6a – c). As these molecules were partly unfolded by the DMSO-treatment during their purification, their sensitivity towards degradation should be increased. These results, therefore, strongly argue against any degradation during the extraction.

Degradation during storage could be excluded, as the dissociation patterns were unchanged, even after 4 years of storage.

The changes found on dissociation by heating at 50 °C could not be attributed to degradation during the incubation: Parallel changes were observed after treatment with DMSO at room temperature, which obviates both RNAase activity and thermal scissions,[28] and no further changes were found when the incubation was increased from 5 min to 1 h. At temperatures ≥ 60 °C, the patterns were not as stable,

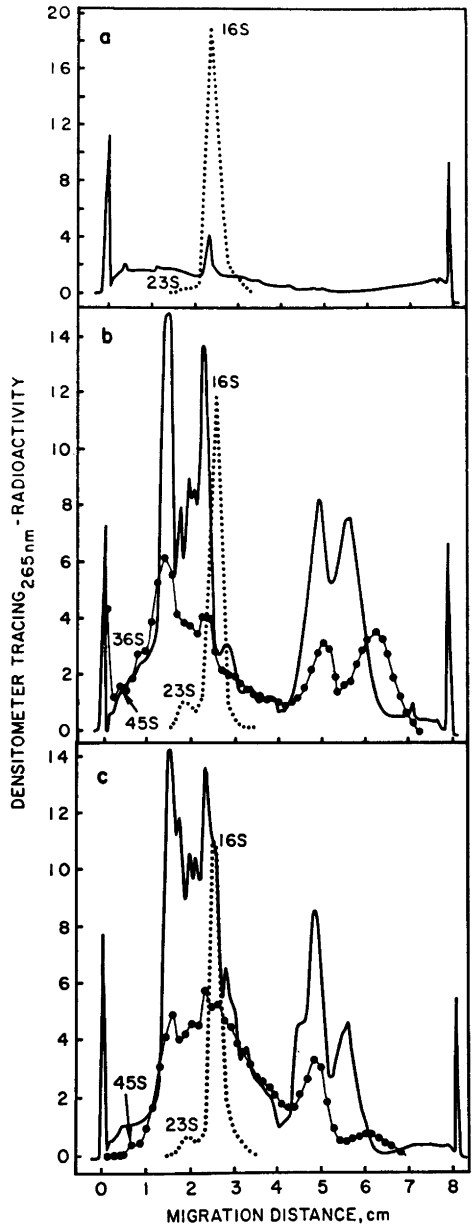

Fig. 6. Disaggregation of rat liver total RNA_2, extracted with *E. coli* 16 S (10 S) rRNA marker. The marker was prepared as described under Materials and Methods. Traces of 23 S rRNA were present. The purified ^3H-labeled marker was added to aqueous solution$_2$, before the chopped liver from a rat labeled for 45 min with 50 μCi ^{14}C-orotic acid was added, homogenized, and extracted. Disaggregation was performed by heating at 50 °C in 0.01 M sodium acetate pH 6.0 for 3 min. (a) Purified disaggregated marker material (25 μg). (b) Extracted total RNA (300 μg). (c) Extracted total RNA after disaggregation.

2.6 % w/v acrylamide, EDTA-buffer, 12 mA/tube, 20 °C, 3 h. ———, densitometer tracing$_{265\ nm}$; · · · ·, ^3H-dpm × 10^{-2}/mg gel; ●, ^{14}C-dpm/mg gel.

indicating a possible contribution from hydrolytic/thermal scissions.

As degradation could not be detected during extraction or analysis of the RNA, only trace amounts – if any – of the rat liver RNA molecules can be larger than corresponding to about 45 S. The strong tendency to aggregation of the rapidly labeled molecules should be considered whenever their structure, or factors affecting their turnover, are discussed.

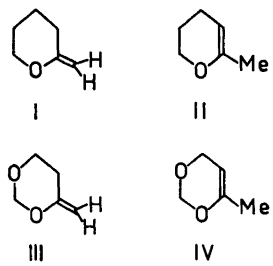
Thermodynamics of Vinyl Ethers. IX.* The Relative Stabilities of 4-Methylene-1,3-dioxane and 4-Methyl-1,3-dioxene-(4)

ESKO TASKINEN

Department of Chemistry, University of Turku, SF-20500 Turku 50, Finland

Equilibrium concentrations of the title compounds in cyclohexane solution at various temperatures have been determined. The following results were obtained for the isomerization of 4-methylene-1,3-dioxane to 4-methyl-1,3-dioxene-(4) at 298.15 K: $\Delta G° = -19.9 \pm 0.2$ kJ mol^{-1}, $\Delta H° = -16.1 \pm 0.8$ kJ mol^{-1} and $\Delta S° = 12.8 \pm 2.3$ J K^{-1} mol^{-1}. In the gas phase at 298.15 K, the values of $\Delta H°$ and $\Delta S°$ were obtained as -18.3 ± 0.9 kJ mol^{-1} and 10.2 ± 2.4 J K^{-1} mol^{-1}, respectively.

In a recent work by this author,[1] thermodynamics of the *exo*→*endo* isomerization of a number of five- and six-membered unsaturated heterocyclic ethers, such as 2-methylenetetrahydropyran (I) and 6-methyl-3,4-dihydro-2*H*-pyran (II), were investigated. In diethyl ether



Scheme 1.

solution at 298.15 K, the standard Gibbs free energy change for I→II was obtained to be -21.8 kJ mol^{-1}. The corresponding value for the isomerization of 4-methylene-1,3-dioxane (III) to 4-methyl-1,3-dioxene-(4) (IV) has been reported to be about -12.2 kJ mol^{-1},[2] which appeared amazing, since it is difficult to see any factor which could give rise to such a large difference between the values of $\Delta G°$ for the two similar isomerization reactions. Hence it was considered necessary to make a reinvestigation of the relative stabilities of III and IV.

EXPERIMENTAL

4-Chloromethyl-1,3-dioxane was prepared from paraformaldehyde (200 g), allyl chloride (320 cm^3) and concentrated sulfuric acid (120 cm^3) as described by Price and Krishnamutri.[3] The yield was 90 g (17 %), boiling temperature 352 to 356 K at 2.1 kPa. The product was distilled from an excess of potassium hydroxide to give a mixture of water and III, which was collected over potassium carbonate. The organic layer was separated, dried (K_2CO_3), and distilled. The yield of III, boiling temperature 337 to 338 K at 15.6 kPa, was 55 %. The product was converted into IV (boiling temperature 381 K at 101.3 kPa) by slow distillation at atmospheric pressure.

The *NMR spectra* were taken in CCl_4 solution with TMS as internal standard. III: τ 5.05 (O$-$CH$_2-$O), 6.13 (O$-$CH$_2-$C), 7.77 (C$-$CH$_2-$C), 5.60 (H *trans* to O), 5.42 (H *cis* to O); IV: τ 5.05 (O$-$CH$_2-$O), 5.87 (O$-$CH$_2-$C), 5.87 (C=C$-$H), 8.26 (CH$_3$).

Determination of normal boiling temperatures.[4] Reference curve (compound, normal b.t., relative retention time): isobutylidene ethyl ether, 366.7 K, 0.312; 1-methoxycyclopentene, 387.0 K, 0.511; 1-methoxycyclohexene, 417.1 K, 1.000. The relative retention times of III and IV were 0.597 and 0.443, respectively, corresponding to normal boiling temperatures of about 395.0 (III) and 380.9 K (IV).

Procedure. The equilibrations were carried out in cyclohexane with iodine as catalyst. Substrate concentration was about 4 mol dm^{-3} and catalyst concentration 0.01 mol dm^{-3}. Two initial mixtures were available for the equilibra-

* Part VIII: Taskinen, E. *Acta Chem. Scand. B 28* (1974) 357.

tions: "pure" III and "pure" IV; although the concentration of III in the latter was less than 1 %, it exceeded the equilibrium concentration of III, and hence the position of equilibrium was always approached from the side of the *exo* isomer (III). To be sure that the true equilibrium had been achieved, the progress of isomerization was followed over sufficiently extended periods of time (several times the time necessary for the isomer ratio to become constant). The column used in the gaschromatographic analyses was an 8 m column containing 10 % Carbowax 20 M on Chromosorb G. The compounds were eluted in the order IV, III. After the first isomer had been eluted through the column, the attenuation of the detector was decreased by a nominal factor of 250 to get a peak of detectable size for the less stable isomer (III). The real change of attenuation was found to be 218 ± 2 by a procedure described previously.[1] The relative peak areas were determined by the cut-and-weigh method, and the area ratio, A_{IV}/A_{III}, was multiplied by 218 to get the true mol ratio at equilibrium. The practical performance of the equilibrations has been described in more detail previously.[4]

RESULTS

Table 1 shows the values of the mean equilibrium constant K and its standard error at various temperatures. The values of the thermodynamic functions of isomerization at 298.15 K were obtained by a linear least-squares treatment of ΔG° against temperature T. The results are: $\Delta G^\circ = -19.9 \pm 0.2$ kJ mol^{-1}, $\Delta H^\circ = -16.1 \pm 0.8$ kJ mol^{-1} and $\Delta S^\circ = 12.8 \pm 2.3$ J K^{-1} mol^{-1} for the isomerization of III to IV in cyclohexane solution at 298.15 K (the errors are twice the standard errors). The values of ΔH°(g) and ΔS°(g) were evaluated to be -18.3 ± 0.9 kJ mol^{-1} and 10.2 ± 2.4 J K^{-1} mol^{-1}, respectively, from the liquid phase data and the normal boiling temperatures.[4]

Table 1. Values of the mean equilibrium constant K and its standard error for the reaction 4-methylene-1,3-dioxolane ⇌ 4-methyl-1,3-dioxene-(4) in cyclohexane solution at various temperatures; n denotes the number of independent determinations.

DISCUSSION

According to the results of this study, the difference (-19.9 kJ mol^{-1}) in the standard Gibbs free energy between IV and III is close to that (-21.8 kJ mol^{-1}, Ref. 1) between II and I. Interestingly, the corresponding difference between 1-methylcyclohexene (VI) and methylenecyclohexane (V) is -13.2 kJ mol^{-1}.[5] Herling *et al.*[5] have shown that the value of ΔS°(g) in V→VI is about 13 J K^{-1} mol^{-1}, which, within experimental error, is equal to that in III→IV, 10.2 ± 2.4 J K^{-1} mol^{-1}. The value of ΔS°(l) in diethyl ether for I = II has been obtained to be 28 ± 13 J K^{-1} mol^{-1} (the error quoted here is twice the standard error),[1] but it is evident that the high value of ΔS° in the latter case is due to solvation, since the values of ΔS° for other similar reactions studied in the same work [1] were considerably less positive if hexane was used as solvent in the equilibrations (for instance, ΔS°(l) for (*Z*)-2-ethylidenetetrahydropyran → 6-ethyl-3,4-dihydro-2*H*-pyran was obtained to be about 17 J K^{-1} mol^{-1} in diethyl ether but only about 9 J K^{-1} mol^{-1} in hexane). Thus it is likely that the entropy changes in the reactions I→II, III→IV, and V→VI are quite similar, and the differences in the values of ΔG° are due to enthalpy differences. It is remarkable that the difference in the standard Gibbs free energy between V and VI is *smaller* than that between I and II (or between III and IV). In the case of the five-membered analogues of V and VI, methylenecyclopentane and 1-methylcyclopentene, respectively, the value of ΔG°(l, 298.15 K) in *exo*→*endo* is -17.3 kJ mol^{-1},[5] while that for the reaction between the five-membered analogues of I and II, 2-methylenetetrahydrofuran and 5-methyl-2,3-dihydrofuran, respectively, is -7.1 kJ mol^{-1}.[1] The latter result is "natural" in the sense that on going from *exo* to *endo*, the number of alkyl groups attached to the double bond increases by one, and since alkyl groups do not stabilize the double bond of a

vinyl ether as effectively as they do an "ordinary" olefinic double bond,[1,6] the value of $\Delta G°$ (and that of $\Delta H°$, too, since entropy changes are be similar in both reactions) ought to be less negative in the latter reaction, in accord with experiment. Clearly, the situation is more complicated in the six-membered ring compounds. In a previous study,[1] the low thermodynamic stability of the *exo*-cyclic member of the *exo-endo* pair, I and II, was assumed to be due to an unfavorable orientation of the *p*-orbitals of the lone-pair electrons of the oxygen atom for an effective conjugation with the π-orbital of the double bond in the *exo*-cyclic isomer (I), which was assumed to have a chair conformation. Support for decreased conjugation in the *exo* compounds I and III is obtained from their NMR spectra: in most acyclic alkyl vinyl ethers, the chemical shifts of the terminal hydrogen atoms of the vinyl group are located about 1 ppm upfield from the corresponding shifts in simple olefins, or at about τ 6.2. On the other hand, the hydrogen atoms of the *exo*-cyclic methylene groups of I and III absorb at about τ 5.9 (Ref. 1) and τ 5.5, respectively. For comparison, the corresponding signals of 2-methylenetetrahydrofuran and 4-methylene-1,3-dioxolane are found at τ 6.1 (Ref. 1) and τ 5.9,[7] respectively. Hence the lower τ-values of the signals due to the protons of the *exo*-cyclic methylene group in the six-membered heterocycles indicate increased double-bond character of the ethylenic linkage resulting from the reduced resonance interaction between the lone-pair electrons of the oxygen atom and the π-electrons of the double bond.[8–10]

The chair conformation (a) is not the only imaginable conformation for III (and for I), since it is possible that an energetically more favorable spatial structure might be the half-chair conformation (b), where effective conjugation between the lone-pair electrons and π-electrons seems more likely. This aspect is in accordance with the probable conformations of unsubstituted δ-lactones (c) and 4-oxo-1,3-dioxanes (d),[11–13] but as stated above, the NMR shift data suggest that conjugation is weak in the *exo* forms I and III, which is best interpretable in terms of the chair structure.

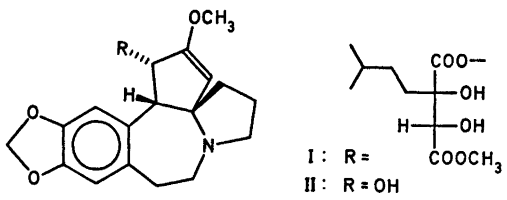
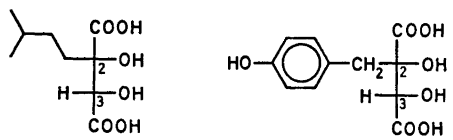
Isoharringtonine (I) is one of the alkaloids isolated from *Cephalotaxus harringtonia* which show antileukemia activity.[1] The alkaloid I is an ester of an amino alcohol, cephalotaxine (II) with a monomethyl ester of an optically active



diacid, 2,3-dihydroxy-2-isopentylbutanedioic acid (III). The absolute configuration of cephalotaxine has been determined in an X-ray investigation.[2] The relative configuration of the natural diacid III has been shown to be *erythro*,[3] but its absolute configuration has not been determined.

We here report that the absolute configuration of III is 2*R*, 3*S*, as found by comparison between the CD spectra of molybdate com-



III IV

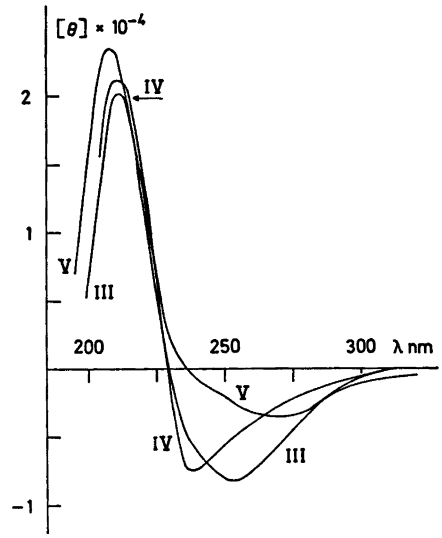


Fig. 1. CD spectra of molybdate complexes of the acid from isoharringtonine (III), piscidic acid (IV), and the hexahydro derivative of piscidic acid (V). The solutions had pH 2.9, 2.9, and 3.1, respectively.

plexes[4] of III and piscidic acid (IV). Acid IV is of natural origin and has a known absolute configuration (2*R*, 3*S*).[5] (In this paper[5] the reversed numbering is used.) The similarity between the CD spectra of the molybdate complexes (Fig. 1), taken together with the known *erythro* configuration[3] of III gave its absolute stereochemistry as 2*R*, 3*S*, thereby completing the knowledge about the configuration of isoharringtonine.

Other alkyltartaric acids of natural origin than the two ones mentioned above are known. The methyl homologue has been detected in wine,[6] and the isobutyl homologue has been found as a component of a glucoside from *Orchis militaris*.[7] Fukiic acid, the 3,4-dihydroxyphenyl analogue of piscidic acid, is also of natural origin.[8]

Experimental. The dimethyl esters of III and IV were hydrolysed with 4 M hydrochloric acid (reflux, 4 days), and excess hydrochloric acid was evaporated under diminished pressure. The crude acids so obtained were used directly in

preparation of CD solutions, which were 3.0 mM with respect to hydroxy acid and 2.7 mM with respect to sodium molybdate. Hydrochloric acid and sodium hydroxide solution were added until pH 2.9 – 3.1 was reached. Measurements of the CD spectra were carried out in a 0.5 mm cell using a Cary 60 spectropolarimeter (a Jasco J-40 instrument was used for the measurement on the hexahydro derivative of IV) five days after the solutions had been prepared.

The hexahydro derivative of IV was prepared by hydrogenation (1 atm, 23 °C, 24 h) of the dimethyl ester of IV (3.5 mg) in methanol (3 ml) using 5 % rhodium on alumina as catalyst (16 mg) followed by hydrolysis. The starting material was contaminated by approximately 5 % of an unknown compound, and after hydrogenation one further compound, probably dimethyl (cyclohexylmethyl)tartrate (GLC-MS), contaminated the desired hydrogenation product to the extent of about 5 %. Hydrolysis of the ester and preparation of the molybdate complex were performed as described above.

Acknowledgements. We thank Professor S. Sakamura, Hokkaido University, Sapporo, for a gift of the dimethyl ester of IV and Dr. Björn Lüning for his interest in this work. We thank Professor S. Gronowitz, Kemicentrum, Lund, for the spectropolarimetry facilities placed at our disposal, and Mr. Jan Glans and Dr. Rolf Håkansson for the measurement of CD spectra. Strained Heterocyclic Compounds. 7. Preparation of α-Phthalimido-β-lactams from α-Halo-β-lactams

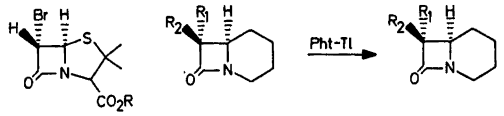
BJÖRN ÅKERMARK, INGER LAGERLUND and JOANNA LEWANDOWSKA

Department of Organic Chemistry, Royal Institute of Technology, S-100 44 Stockholm 70, Sweden

For some time we have been trying to develop a general synthesis of penicillins. In particular we are interested in synthesizing penicillin analogues containing a modified nucleus. In one approach carbene insertion has been used to produce halo-β-lactams of the types *1* and *2*.[1]



1

2a R_1=Br, R_2=H
2b R_1=H, R_2=Br
2c R_1=Cl, R_2=H

3a R_1=H, R_2=Pht
3b R_1=Pht, R_2=H
(Pht=Phthalimido)

As expected, these cyclizations yield predominantly the more stable *trans*-halo-β-lactams, *e.g. 1*, *2a*, and *2c*. Nucleophilic displacement of the halogen with an amine function should therefore yield amino-β-lactams with the *cis*-configuration characteristic for the penicillins and cephalosporins. Simple amines were found to destroy the β-lactams *2a* – *2c*, which were used as model compounds. Likewise, the use of metal amides were of no success.[2] Nor was it possible to use sodium azide which has been used for an unfused halo-β-lactam.[3] Therefore, we turned our attention to phthalimide salts. Potassium phthalimide reacted with the halo-β-lactams *2a* and *2c* to give a very low yield of phthalimido-β-lactam *3a*. The major part of the starting material was decomposed. On the other hand mercury(II) and silver(I) phthalimides were completely unreactive towards α-bromo-β-lactams. (In fact, silver phthalimide reacts reluctantly even with dilute HCl.)

In the search for compounds of intermediate reactivity we have now found that thallium(I) phthalimide reacts fairly readily in dimethyl sulfoxide at 150 °C with the bromo-β-lactams *2a* and *2b* to give phthalimido-β-lactams. The *trans*-compound *2a* gave the *cis*-7-phthalimido-8-oxo-1-azabicyclo[4.2.0]octane *3a* (55 % yield, 90 % stereoselectivity as determined by NMR and TLC), while the *cis*-compound *2b* gave *trans*-7-phthalimido-8-oxo-1-azabicyclo[4.2.0]-octane *3b* (24 % yield) with nearly complete stereospecificity. Since the halo-β-lactams isomerize slowly at 150 °C, the 10 % *trans*-phthalimido-β-lactam obtained from *trans*-bromo-β-

preparation of CD solutions, which were 3.0 mM with respect to hydroxy acid and 2.7 mM with respect to sodium molybdate. Hydrochloric acid and sodium hydroxide solution were added until pH 2.9 – 3.1 was reached. Measurements of the CD spectra were carried out in a 0.5 mm cell using a Cary 60 spectropolarimeter (a Jasco J-40 instrument was used for the measurement on the hexahydro derivative of IV) five days after the solutions had been prepared.

The hexahydro derivative of IV was prepared by hydrogenation (1 atm, 23 °C, 24 h) of the dimethyl ester of IV (3.5 mg) in methanol (3 ml) using 5 % rhodium on alumina as catalyst (16 mg) followed by hydrolysis. The starting material was contaminated by approximately 5 % of an unknown compound, and after hydrogenation one further compound, probably dimethyl (cyclohexylmethyl)tartrate (GLC-MS), contaminated the desired hydrogenation product to the extent of about 5 %. Strained Heterocyclic Compounds. 7. Preparation of α-Phthalimido-β-lactams from α-Halo-β-lactams

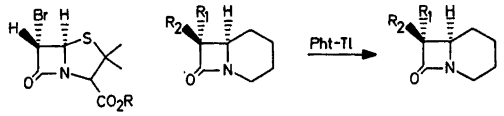
BJÖRN ÅKERMARK, INGER LAGERLUND and JOANNA LEWANDOWSKA

Department of Organic Chemistry, Royal Institute of Technology, S-100 44 Stockholm 70, Sweden

For some time we have been trying to develop a general synthesis of penicillins. In particular we are interested in synthesizing penicillin analogues containing a modified nucleus. In one approach carbene insertion has been used to produce halo-β-lactams of the types *1* and *2*.[1]



1

2a R_1=Br, R_2=H
2b R_1=H, R_2=Br
2c R_1=Cl, R_2=H

3a R_1=H, R_2=Pht
3b R_1=Pht, R_2=H
(Pht=Phthalimido)

As expected, these cyclizations yield predominantly the more stable *trans*-halo-β-lactams, *e.g. 1*, *2a*, and *2c*. Nucleophilic displacement of the halogen with an amine function should therefore yield amino-β-lactams with the *cis*-configuration characteristic for the penicillins and cephalosporins. Simple amines were found to destroy the β-lactams *2a* – *2c*, which were used as model compounds. Likewise, the use of metal amides were of no success.[2] Nor was it possible to use sodium azide which has been used for an unfused halo-β-lactam.[3] Therefore, we turned our attention to phthalimide salts. Potassium phthalimide reacted with the halo-β-lactams *2a* and *2c* to give a very low yield of phthalimido-β-lactam *3a*. The major part of the starting material was decomposed. On the other hand mercury(II) and silver(I) phthalimides were completely unreactive towards α-bromo-β-lactams. (In fact, silver phthalimide reacts reluctantly even with dilute HCl.)

In the search for compounds of intermediate reactivity we have now found that thallium(I) phthalimide reacts fairly readily in dimethyl sulfoxide at 150 °C with the bromo-β-lactams *2a* and *2b* to give phthalimido-β-lactams. The *trans*-compound *2a* gave the *cis*-7-phthalimido-8-oxo-1-azabicyclo[4.2.0]octane *3a* (55 % yield, 90 % stereoselectivity as determined by NMR and TLC), while the *cis*-compound *2b* gave *trans*-7-phthalimido-8-oxo-1-azabicyclo[4.2.0]-octane *3b* (24 % yield) with nearly complete stereospecificity. Since the halo-β-lactams isomerize slowly at 150 °C, the 10 % *trans*-phthalimido-β-lactam obtained from *trans*-bromo-β-

lactam probably arises from isomerization rather than from lack of stereospecificity in the displacement reaction. Also the chloro-β-lactam *2c* reacts with thallium phthalimide, but the reaction is sluggish and only low yields of the product *3a* have so far been realized (5 %).

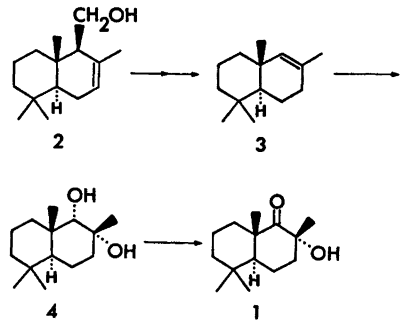
Tobacco Chemistry. 30. The Absolute Configuration of 11-Nor-8-hydroxy-9-drimanone, a Constituent of Greek *Nicotiana tabacum* L.

ARNE J. AASEN and CURT R. ENZELL*

Research Department, Swedish Tobacco Co., Box 17 007, S-104 62 Stockholm 17, Sweden

Schumacher and Vestal [1] have recently reported 11-nor-8-hydroxy-9-drimanone** (*1*) as a new constituent of Turkish tobacco leaves but without elaborating on the chirality of its three asymmetric centres. The gross structure of this ketol indicates a genetic relationship with tobacco terpenoids of the drimane/labdane group or, although less likely, of the carotenoid group.[2] Since all tobacco terpenoids of the labdane/drimane group possess the "normal" stereochemistry at the A/B-ring junction (5α-H, 10β-CH_3) and this would not be expected in the case of carotenoid derived tobacco nor-isoprenoids, elucidation of the absolute configuration of the ketol (*1*), now isolated from Greek tobacco, would indicate the nature of its precursor(s).

** Nomenclature and stereochemistry as defined in Ref. 3.



The absolute configuration of drimenol (*2*) has been determined through correlation with oleanolic and abietic acid,[3] and it was envisaged that a stereospecific conversion of drimenol to 11-nor-8-hydroxy-9-drimanone (*1*) would unravel the chirality of the three asymmetric centres of the latter compound. This was accomplished using as starting material the olefin *3*, which was prepared from drimenol (*2*) as previously described [4] by catalytic hydrogenation followed by oxidation to the corresponding saturated acid and subsequent decarboxylation using lead tetraacetate. Preferential attack by osmium tetroxide from the less hindered α-side of the olefin (*3*) furnished the *cis*-diol (*4*) in good yield. Subsequent mild oxidation employing chromic acid in a two-phase system [5] gave the desired product, 11-nor-8-hydroxy-9-drimanone (*1*), which possesses a cedar-like, woody fragrance.[1] The synthetic and natural materials were found indistinguishable when comparing NMR, IR, MS and retention times on a capillary column (co-injection), and they exhibited rotatory powers of the same sign and magnitude. Since several syntheses of drimenol have been accomplished,[6–10] its conversion, portrayed above, to 11-nor-8-hydroxy-9-drimanone (*1*) formally represents a total synthesis of the latter.

Possessing the same absolute configuration as the previously detected tobacco terpenoids of the drimane/labdane group,[2] it seems highly probable that the ketol (*1*) is derived from representatives of this group, *e.g.* from 8,11-drimandiol [11] by a route similar to the present synthetic one or by direct oxidation of 9,11-didehydronorambreinolide.[1]

Experimental. NMR, IR, UV, and mass spectra were recorded on Varian XL-100, Digilab FTS-14, Beckman DB-2A and LKB 9000 instruments, respectively. Rotations were measured on a Perkin-Elmer 141 instrument.

11-Nor-8-hydroxy-9-drimanone (*1*, 4 mg) was isolated from a volatile, neutral fraction (B 5) of an extract obtained from 295 kg sun-cured Greek *Nicotiana tabacum* L.[12] The separation of this fraction will be described elsewhere.[13] $[\alpha]^{20}$ +39.5° (589 mn), +41° (578), +50.5° (546), +124° (436), +337° (365) (*c* 0.29, $CHCl_3$);

lactam probably arises from isomerization rather than from lack of stereospecificity in the displacement reaction. Also the chloro-β-lactam *2c* reacts with thallium phthalimide, but the reaction is sluggish and only low yields of the product *3a* have so far been realized (5 %).

11-Nor-8,9α-drimandiol (4). 11-Nor-8-drimene (*3*, 100 mg) [4] dissolved in dry pyridine (10 ml) was added to a cooled (−30 °C) solution of osmium tetroxide (150 mg) in pyridine (10 ml) and the mixture stirred for 3 h while the disappearance of the hydrocarbon was monitored by TLC. A solution of $NaHSO_3$ (1.8 g) in water (30 ml)/pyridine (20 ml) was added and the solution stirred at room temperature for 20 min after which the mixture was diluted with water and extracted with CH_2Cl_2. The extract was washed with H_2SO_4 (5 %), water, brine, dried, and evaporated leaving a slightly coloured oil. Chromatography on silica gel furnished 11-nor-8,9α-drimandiol (*4*, 87 mg) which crystallized on standing at 5 °C; m.p. 58−59 °C; MS: *m/e* 226 ($M^{+\cdot}$ 12), 43 (100), 95 (86), 41 (84), 69 (81), 123 (73), 81 (72), 138 (65), 82 (64), 71 (60), 137 (50), 55 (49), 109 (39), 67 (33), 96 (28), 84 (28), 83 (23), 57 (20), 196 (20), 177 (19); ν_{max}(KBr): 3478 (shoulder), 3400 (broad), 2949 (s), 2874 (s), 1456 (m), 1377 (m), 1360 (w), 1124 (w), 1092 (w), 1072 (w), 1056 (m), 1026 (w), 1012 (w), 994 (w), 978 (w), 960 (w), 955 (w), 942 (w), 895 (w), 876 (w), 828 (w), 728 (w); $[\alpha]^{20}$ −11.6° (589 nm), −18° (578), −19.5° (546), −27.4° (436), −46° (365) (*c* 0.38, $CHCl_3$); $\delta(CDCl_3)$: 0.81 (3 H, s), 0.89 (3 H, s), 0.97 (3 H, s), 1.37 (3 H, s), 2.30 (OH, broad s), 2.74 (OH, d, *J* 2.5 Hz), 2.94 (1 H, d, *J ca.* 2.5 Hz), the signals at δ 2.30 and 2.74 disappeared and the resonance at δ 2.94 collapsed to a singlet on addition of D_2O.

11-Nor-8-hydroxy-9-drimanone (1). To a cooled (ice-bath) solution of the diol *4* (43 mg) in ether (10 ml) was added ten drops of the CrO_3-solution described by Brown *et al.*[5] After stirring for 30 min water was added and the mixture extracted with ether which was washed with $NaHCO_3$, water, brine, dried, and evaporated leaving an oil (38 mg). Chromatography on silica gel yielded pure 11-nor-8-hydroxy-9-drimanone (*1*, 17 mg) which was indistinguishable from the natural ketol *1* (NMR, IR, MS, retention time, when co-injected on a capillary GC-column). MS: *m/e* 224 ($M^{+\cdot}$ 22) 43 (100), 69 (86), 123 (72), 41 (64), 55 (50), 95 (50), 82 (49), 109 (48), 67 (46), 81 (44), 71 (43), 83 (42), 163 (42), 125 (40), 68 (37), 196 (25); minor intensity-differences were observed when compared with the spectrum recorded by Dr. Schumacher;[14] ν_{max}(film): 3485 (broad), 2932(s), 2870 (s), 1696 (s), 1466 (m), 1393 (m), 1380 (m), 1371 (m), 1343 (w), 1245 (m), 1175 (m), 1163 (m), 1142 (m), 1114 (w), 1100 (w), 1064 (w), 1026 (w), 1012 (w), 992 (s), 976 (m), 949 (m), 918 (w), 843 (w), 842, (w), 693 (w); lit.[1] ν_{max}(film): 3475, 1690, 1242 1160, 990; $[\alpha]^{20}$ +46° (589 nm), +49.3° (578), +59° (546), +142° (436), +395° (365) (*c* 0.3, $CHCl_3$); $\delta(CDCl_3)$: 0.93 (6 H, s), 1.18 (3 H, s), 1.41 (3 H, s), 2.00−2.35 (1 H, m); lit.[1] $\delta(CDCl_3)$: 0.93 (6 H), 1.16 (3 H), 1.40 (3 H).

Note added in proof. Dr. J. N. Schumacher (private communication) has confirmed our results by degrading 9,11-didehydronorambreinolide to 11-nor-8,9-drimandiol which exhibited the same optical activity as the corresponding diol derived from natural 11-nor-8-hydroxy-9-drimanone (*1*) by $LiAlH_4$ reduction.

The Direct Observation of Intermediates during the Oxidative Cyclization of Phenol Ethers

V. D. PARKER,[a] U. PALMQUIST[b] and A. RONLÁN[b]

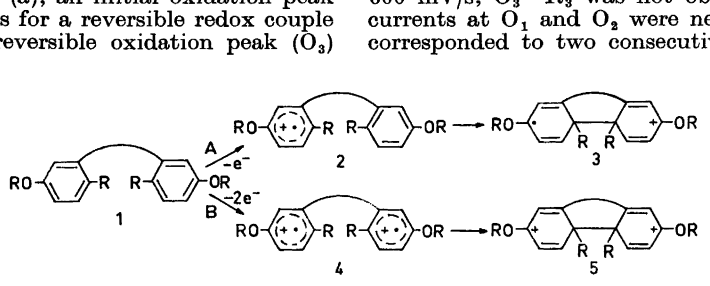
[a]Department of General and Organic Chemistry, The H.C. Ørsted Institute, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark and [b]Organic Chemistry 2, The Lund Institute of Technology, Chemical Center, P.O. Box 740, S-220 07 Lund 7, Sweden

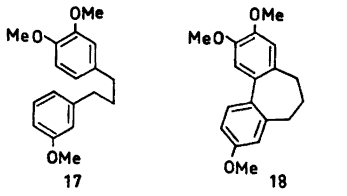
The oxidative cyclization of phenyl ethers is a topic of great current interest to organic chemists due to the importance of such coupling reactions in natural systems.[1-5] Various mechanisms, such as attack of a cation radical moiety upon an unoxidized aromatic ring (path A)[4] or initial oxidation to a dication diradical followed by coupling (path B)[2] have been proposed. The only mechanistic evidence that has been presented is voltammetric evidence for path B.[2] We now present conclusive evidence for the occurrence of path A during the oxidative cyclization of 1-(3,4-dimethoxyphenyl)-3-(4-methoxyphenyl)-propane (*6*).

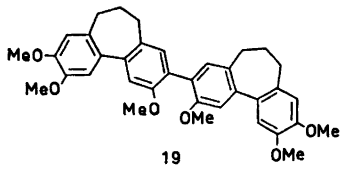
Anodic oxidation of *6* in dichloromethane-trifluoroacetic acid (TFA) (3:1) resulted in the formation of *11* which was isolated in 71 % yield. (Found: C 75.9; H 7.1. Calc. for $C_{18}H_{20}O_3$: C 76.1; H 7.0). The NMR assignment of the aromatic protons are as follows; H_A 7.14 (d, $J_{AB}=8.1$ Hz), H_B 6.79 (d,d, $J_{AB}=8.1$ Hz, $J_{BC}=2.8$ Hz), H_C 6.93 (d, $J_{BC}=2.8$ Hz), H_D 6.93 (s), and H_E 6.76 (s). Shifts are in δ values and the subscripts are those used in structure *11*. The remaining protons gave signals at δ: 3.85 (3 H, methoxy), 3.91 (3 H, methoxy), 3.93 (3 H, methoxy), 2.41 (t, 4 H, aliphatic) and 2.12 (q, 2 H, aliphatic). *M/e* 284 (M^+). An isomer of *11* was prepared by the oxidation of *17*. The isomer (*18*) showed a different NMR spectrum and did not form a dimer while *11* with an unsubstituted position *para* to the biphenyl linkage gave *19* upon further oxidation (V. D. Parker and A. Ronlán, unpublished results).

Cyclic voltammograms of *6* in the same solvent are shown in Fig. 1. At a voltage sweep rate of 31 mV/s (a), an initial oxidation peak (O_1), small peaks for a reversible redox couple (O_2-R_2), an irreversible oxidation peak (O_3) and a reduction peak (R_4) were observed on a complete cycle. The peaks O_3 and R_4 matched those observed during cyclic voltammetry of the product, *11*. The height of O_3 indicated that substrate was being oxidized nearly quantitatively to *11* at that voltage sweep rate. The effect of increasing the sweep rate is illustrated in (b) and (c).

The redox couple (O_2-R_2) became more pronounced with increasing sweep rate while the relative current at O_3 was diminished. A reduction peak (R_3) corresponding to O_3 was also observed. At 310 mV/s O_3-R_3 was very small (c). At voltage sweep rates greater than 600 mV/s, O_3-R_3 was not observed and the currents at O_1 and O_2 were nearly equal and corresponded to two consecutive one electron







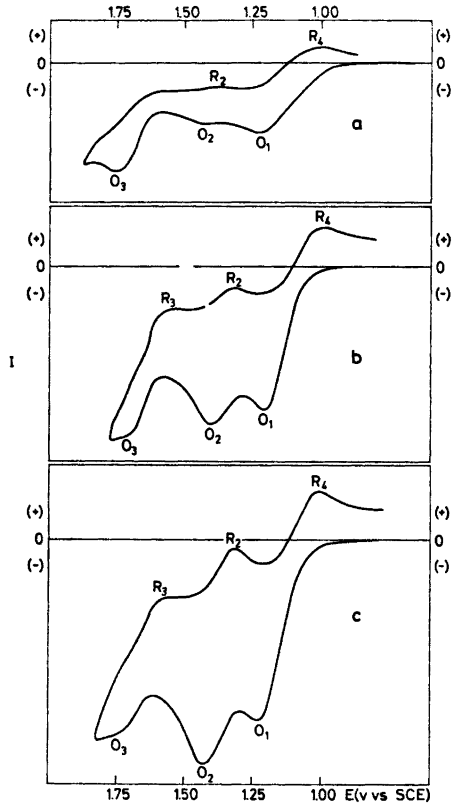


Fig. 1. Cyclic voltammograms for the oxidative cyclization of *6* in dichloromethane-TFA (3:1) containing Bu_4NBF_4 (0.2 M). Voltage sweep rate: (a) 31 mV/s, (b) 151 mV/s, (c) 310 mV/s.

transfers. Thus, it is clear that O_2-R_2 is a reversible redox couple of a short lived intermediate formed during oxidation of *6* to *11* which has a lifetime of the order of 1 s in dichloromethane-TFA (3:1) at room temperature. The reduction peak (R_4) was observed even at high sweep rates which indicates that under those conditions it corresponds to a further reduction of the species formed at R_2. Voltammetry in acetonitrile gave similar results with the height of O_2 showing a marked sweep rate dependence. On the other hand, R_2 was not observed under any conditions in acetonitrile indicating that the intermediate formed at O_2 was consumed in a rapid chemical reaction.

The sweep rate dependence for the observation of the reversible couple (O_2-R_2) suggested that the intermediate oxidized at O_2 undergoes a relatively slow chemical reaction which is outrun as the voltage sweep rate is increased. The latter suggested that it might be possible to observe different products if the chemical step was precluded by carrying out the oxidation at a potential greater than O_2. In fact, in acetonitrile *11* was formed in nearly quantitative yield when the reaction was carried out at a potential of + 1.25 V and the unrearranged dienone (*14*) was the exlusive product when the reaction was conducted at potentials greater than + 1.60 V.*

The intermediate undergoing oxidation at O_2 is a one electron oxidation product of (*6*) which reacts slow enough to be detected by slow sweep cyclic voltammetry. Mechanism B requires that the intermediate be the cation radical of *6* which is further oxidized to the dication diradical at O_2 (+ 1.42 V *vs.* SCE). We can rule out the latter mechanism on the basis that the dication diradical would not form at such a low potential** and would be a very reactive species. Mechanism A suggests that the intermediate could be a cation radical in which the cationic center and the unpaired electron are in different rings separated by saturated carbon (*8*) or the radical (*15*). On the basis of the data, we cannot definitively choose between *8* and *15* as the intermediate (Scheme). However, if *15* were the intermediate, O_2-R_2 would correspond to the couple, *15*⇌*13*. We have found that *14* oxidizes about 100 mV more easily than O_2 and this must involve oxidation of the ring containing two methoxy groups. It seems almost inconceivable that *15* should be more difficult to oxidize than *14*. Furthermore, the only product formed at potentials below O_2 is *11* which forms *via* a dienone phenol rearrangement of the intermediate and it seems much

* Compound (*14*) was isolated in 91 % yield and identified by comparison of the NMR, mass and IR spectra with that of the authentic compound prepared by either chemical [6] or electrochemical [7] oxidation of the corresponding phenol.

** The ring containing only one methoxy group in *6* would not be expected to oxidize more easily than anisole, + 1.7 V.

more likely that the cation radical (*8*) is the rearranging species rather than *15*. Two additional points favor *8* over *15* for the intermediate: At high sweep rates the cyclic voltammogram of *6* shows R_4 which must be due to reduction of the intermediate. The radical *15* would reduce at negative potentials. Also R_2 is not observed in acetonitrile, most likely due to rapid deprotonation of *12*. Thus, we favor the reaction pathway involving the cation radical (*8*) for the reactions producing both *11* and *14*.

Non-enzymic Oxidation of Lower Aliphatic Alcohols by Ascorbic Acid in Tissue Extracts

HELMUTH W. SIPPEL and
OLOF A. FORSANDER

Research Laboratories of the State Alcohol Monopoly (Alko), Box 350, SF-00101 Helsinki 10, Finland

It has been shown that ethanol is oxidized to acetaldehyde by ascorbic acid,[1] and since it is not oxidized further, the aldehyde accumulates. The ascorbic acid content of different tissues can vary considerably,[2] so that it can be assumed that the reaction proceeds at different speeds in different tissue extracts. As far as is known, no reports have been published on the non enzymic oxidation of other alcohols than ethanol.

Only small amounts of formaldehyde were formed from methanol when 20 mM alcohol was incubated in a citrate buffer, pH 4.0, containing 2.0 mM ascorbic acid (Table 1). The other normal and iso alcohols tested all formed more than 100 nmol aldehyde in a reaction mixture of 1 ml. With the exception of methanol the oxidation rate decreased with increasing chain length.

Table 1. Oxidation of some aliphatic alcohols by ascorbic acid. Alcohols (20 mM) in 0.1 M citrate buffer, pH 4.0, containing 2.0 mM ascorbic acid was incubated for 60 min at 65 °C. The aldehydes formed except formaldehyde were estimated gas chromatographically.[10] Formaldehyde was estimated spectrophotometrically by the Eegriwes' method.[11] The values given are the means of two experiments.

Alcohol added	Aldehyde formed	(μM)
Methanol	Formaldehyde	< 100
Ethanol	Acetaldehyde	530
Propanol	Propionaldehyde	310
Isobutanol	Isobutyraldehyde	230
Butanol	Butyraldehyde	220
Isopentanol	Isovaleraldehyde	120
Pentanol	Valeraldehyde	110

Extracts contained only a part of the ascorbic acid found in the intact tissue because of the dilution with perchloric acid (Table 2). Bovine liver has been reported to contain 1.7 mmol ascorbic acid/kg, kidney 0.7 mmol/kg, heart 0.3 mmol/kg and blood 0.1 mmol/kg.[2] Of the four tissue extracts examined the liver contained

more likely that the cation radical (*8*) is the rearranging species rather than *15*. Two additional points favor *8* over *15* for the intermediate: At high sweep rates the cyclic voltammogram of *6* shows R_4 which must be due to reduction of the intermediate. The radical *15* would reduce at negative potentials. Also R_2 is not observed in acetonitrile, most likely due to rapid deprotonation of *12*. Thus, we favor the reaction pathway involving the cation radical (*8*) for the reactions producing both *11* and *14*.

Non-enzymic Oxidation of Lower Aliphatic Alcohols by Ascorbic Acid in Tissue Extracts

HELMUTH W. SIPPEL and
OLOF A. FORSANDER

Research Laboratories of the State Alcohol Monopoly (Alko), Box 350, SF-00101 Helsinki 10, Finland

It has been shown that ethanol is oxidized to acetaldehyde by ascorbic acid,[1] and since it is not oxidized further, the aldehyde accumulates. The ascorbic acid content of different tissues can vary considerably,[2] so that it can be assumed that the reaction proceeds at different speeds in different tissue extracts. As far as is known, no reports have been published on the non enzymic oxidation of other alcohols than ethanol.

Only small amounts of formaldehyde were formed from methanol when 20 mM alcohol was incubated in a citrate buffer, pH 4.0, containing 2.0 mM ascorbic acid (Table 1). The other normal and iso alcohols tested all formed more than 100 nmol aldehyde in a reaction mixture of 1 ml. With the exception of methanol the oxidation rate decreased with increasing chain length.

Table 1. Oxidation of some aliphatic alcohols by ascorbic acid. Alcohols (20 mM) in 0.1 M citrate buffer, pH 4.0, containing 2.0 mM ascorbic acid was incubated for 60 min at 65 °C. The aldehydes formed except formaldehyde were estimated gas chromatographically.[10] Formaldehyde was estimated spectrophotometrically by the Eegriwes' method.[11] The values given are the means of two experiments.

Alcohol added	Aldehyde formed	(μM)
Methanol	Formaldehyde	< 100
Ethanol	Acetaldehyde	530
Propanol	Propionaldehyde	310
Isobutanol	Isobutyraldehyde	230
Butanol	Butyraldehyde	220
Isopentanol	Isovaleraldehyde	120
Pentanol	Valeraldehyde	110

Extracts contained only a part of the ascorbic acid found in the intact tissue because of the dilution with perchloric acid (Table 2). Bovine liver has been reported to contain 1.7 mmol ascorbic acid/kg, kidney 0.7 mmol/kg, heart 0.3 mmol/kg and blood 0.1 mmol/kg.[2] Of the four tissue extracts examined the liver contained

Table 2. Formation of acetaldehyde from ethanol in tissue extracts. Ethanol 20 mM in PCA-precipitated tissue extracts, pH 4.0, was incubated for 60 min at 45 °C both without and with addition of ascorbic acid. The acetaldehyde formed was estimated gas chromatographically.[10] The values given are the means of two experiments.

Tissue extract	Without ascorbic acid addition		Ascorbic acid added	
	Ascorbic acid (mM)	Acetaldehyde produced (μM)	Ascorbic acid (mM)	Acetaldehyde produced (μM)
Liver	0.34	41.0	1.0	75.6
Kidney	0.15	65.9	0.91	97.9
Heart	0.03	9.0	0.94	108.4
Blood	0	3.4	0.89	66.4

the highest amount of ascorbic acid (Table 2). The kidney extract contained less than half the ascorbic acid present in the liver extract, but nevertheless formed the greatest amount of acetaldehyde from ethanol. Heart and blood extracts contained little ascorbic acid, and the non-enzymic aldehyde formation was low. The ascorbic acid content in the blood extract was so low that it could not be measured. The addition of a similar quantity of ascorbic acid to each of the extracts increased the formation of acetaldehyde in each case, but by an amount dependent on the tissue type (Table 2). This could be explained by the presence of varying amounts of substances in the extracts which can modify the rate of the oxidation. It has been assumed [1] that ethanol is oxidized by a semidehydroascorbate peroxy radical produced in the incubation solution when ascorbic acid is oxidized. Thiols and disulfides strongly inhibit this reaction by acting as free radical acceptors.[3,4] Liver is the tissue richest in thiols and disulfides, while their content in heart muscle and blood is rather low.[5,6]

The non-enzymic oxidation rate of other aliphatic alcohols in tissue extracts containing

Table 3. Formation of aldehydes from some aliphatic alcohols in tissue extracts. Aliphatic alcohols (20mM) were incubated in PCA-precipitated tissue extracts, pH 4.0, for 60 min at 45 °C after addition of ascorbic acid. The ascorbic acid content in the incubation solution after addition was 0.93 ± 0.04 mM. The aldehydes formed were estimated gas chromatographically.[10] The values given are the means of two experiments.

Alcohol added	Aldehyde produced (μM)			
	Liver	Kidney	Heart	Blood
Propanol	50.6	30.4	73.6	47.2
Butanol	31.2	38.6	46.7	24.3
Isobutanol	51.6	31.3	54.2	53.3
Pentanol	22.7	8.6	17.0	22.3
Isopentanol	11.2	10.9	21.8	25.7

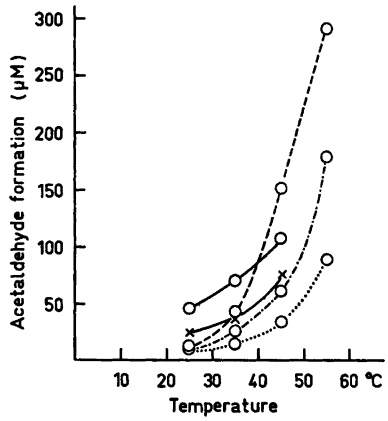

Fig. 1. Formation of acetaldehyde from ethanol at different temperatures and with different amounts of ascorbic acid. Ethanol (20 mM) in 0.1 M citrate buffer, pH 4.0, containing different amounts of ascorbic acid, and in liver and heart extracts (pH 4.0) to which ascorbic acid had been added, was incubated for 60 min at different temperatures. The acetaldehyde formed was estimated gas chromatographically.[10] Every point represents the mean value obtained from two experiments. - - - 2.0 mM, — · — 1.0 mM and ··· 0.5 mM ascorbic acid in citrate buffer; × liver extract containing 1.0 mM ascorbic acid, — heart extract containing 1.0 mM ascorbic acid.

0.9 mM ascorbic acid was lower than that of ethanol (Table 3). Propanol and isobutanol were oxidized at the same rate, while pentanol and isopentanol were oxidized slowly.

The acetaldehyde formed from a given amount of ethanol increased with increasing amounts of ascorbic acid (Fig. 1). With 20 mM ethanol and 1 – 2 mM ascorbic acid in citrate buffer, pH 4.0, rather much acetaldehyde was formed at 55 °C. At 37 °C, however, the aldehyde formation was low, especially at low ascorbic acid concentrations.

As shown in Fig. 1, more acetaldehyde was formed in tissue extract incubated at 25 °C than in ascorbic acid solution. An explanation for this may be that tissue extracts usually contain activators like Cu^{2+} and Fe^{3+} which catalyse the autoxidation of ascorbic acid, especially at low temperatures.[7] At physiological pH, however, the formation of acetaldehyde is much less since the reaction becomes much slower as the pH rises over 5.[1] In addition, ascorbic acid-rich tissues also contain a relatively high amount of SH groups,[8,6,5] which inhibit the non-enzymic oxidation *in vitro*.[1] It can be assumed, therefore, that aliphatic alcohols cannot be oxidized to aldehydes by ascorbic acid *in vivo* at such a speed that the products would produce harmful effects.

Experimental. Bovine liver, kidney, heart and blood were separately homogenized in 0.6 N perchloric acid (PCA) (35 g tissue/100 ml) and the homogenates filtered. Before use, the pH of the acidic filtrate was adjusted to 4.0 by adding 1.25 ml of 5 M KOH and 1 M citrate buffer (pH 4.0) to 10 ml of the filtrate. The samples were incubated for 60 min in a thermostated water bath in the presence of different aliphatic alcohols. After the incubation thiourea was added to prevent alcohol oxidation during the subsequent analysis of the aldehydes. Thiourea was added to the control samples before incubation. In two experiments 0.1 M citrate buffer, pH 4.0, containing different amounts of ascorbic acid was used instead of tissue extract. The ascorbic acid content was estimated by the method described by Roe.[9] The alcohols and aldehydes except formaldehyde were estimated on a Perkin-Elmer F 40 head-space gas liquid chromatograph, as reported previously.[10] Formaldehyde was estimated spectrophotometrically by the violet color which develops on heating with chromotropic acid (1,8-dihydroxynaphthalene-3,6-disulfonic acid) in the presence of strong sulfuric acid. The absorbance was measured at 570 nm.[11]

The analytical procedure was standardized with samples of diluted formaldehyde, acetaldehyde, propionaldehyde, butyraldehyde, isobutyraldehyde, valeraldehyde, isovaleraldehyde, methanol, ethanol, propanol, butanol, isobutanol, pentanol, and isopentanol of analytical grade. Standard and unknown samples were determined by identical procedures.

Correction of the Amino Acid Sequence of Soybean Leghemoglobin *a*

NILS ELLFOLK and GUNNEL SIEVERS

Department of Biochemistry, University of Helsinki, Unioninkatu 35, SF-00170 Helsinki 17, Finland

A comparison of the sequence of soybean leghemoglobin *a* (Lb*a*) [1,2] with the sequence of soybean leghemoglobin *c* (*to be published*) and kidney bean leghemoglobin *a* [3] revealed a genetically inexplicable difference at the site 50 – 54 in the leghemoglobin *a* chain. The order of these amino acids in both soybean leghemoglobin *c* and kidney bean leghemoglobin *a* is *Gly-Val-Asp-Pro-Thr*, whereas *Pro-Thr-Asp-Gly-Val* was proposed for leghemoglobin *a* from soybean. This

As shown in Fig. 1, more acetaldehyde was formed in tissue extract incubated at 25 °C than in ascorbic acid solution. An explanation for this may be that tissue extracts usually contain activators like Cu^{2+} and Fe^{3+} which catalyse the autoxidation of ascorbic acid, especially at low temperatures.[7] At physiological pH, however, the formation of acetaldehyde is much less since the reaction becomes much slower as the pH rises over 5.[1] In addition, ascorbic acid-rich tissues also contain a relatively high amount of SH groups,[8,6,5] which inhibit the non-enzymic oxidation *in vitro*.[1] It can be assumed, therefore, that aliphatic alcohols cannot be oxidized to aldehydes by ascorbic acid *in vivo* at such a speed that the products would produce harmful effects.

Experimental. Bovine liver, kidney, heart and blood were separately homogenized in 0.6 N perchloric acid (PCA) (35 g tissue/100 ml) and the homogenates filtered. Before use, the pH of the acidic filtrate was adjusted to 4.0 by adding 1.25 ml of 5 M KOH and 1 M citrate buffer (pH 4.0) to 10 ml of the filtrate. The samples were incubated for 60 min in a thermostated water bath in the presence of different aliphatic alcohols. After the incubation thiourea was added to prevent alcohol oxidation during the subsequent analysis of the aldehydes. Thiourea was added to the control samples before incubation. In two experiments 0.1 M citrate buffer, pH 4.0, containing different amounts of ascorbic acid was used instead of tissue extract. The ascorbic acid content was estimated by the method described by Roe.[9] The alcohols and aldehydes except formaldehyde were estimated on a Perkin-Elmer F 40 head-space gas liquid chromatograph, as reported previously.[10] Formaldehyde was estimated spectrophotometrically by the violet color which develops on heating with chromotropic acid (1,8-dihydroxynaphthalene-3,6-disulfonic acid) in the presence of strong sulfuric acid. The absorbance was measured at 570 nm.[11]

The analytical procedure was standardized with samples of diluted formaldehyde, acetaldehyde, propionaldehyde, butyraldehyde, isobutyraldehyde, valeraldehyde, isovaleraldehyde, methanol, ethanol, propanol, butanol, isobutanol, pentanol, and isopentanol of analytical grade. Standard and unknown samples were determined by identical procedures.

Table 1. Amino acid compositions of substilopeptidase A peptides from the tryptic peptide *a*T14.

Amino acid	S1	S2	S3	S4	S5
Aspartic acid	1.13	1.02		2.06	0.89
Threonine				0.97	
Serine			0.94		
Proline				1.90	
Glycine				0.53	
Alanine		1.13			1.11
Valine				1.07	
Leucine	0.94	0.86			
Phenylalanine	0.92		1.06		
Lysine				1.02	
E_{asp}	0.52	neutr.	neutr.	neutr.	neutr.

prompted us to re-investigate the sequence of the tryptic peptide *a*T14.

Materials and methods. The methods used were mainly those described previously.[2] Peptide *a*T14 was isolated from the tryptic hydrolysate of apoLb*a* using high voltage electrophoresis at pH 6.5, pH 1.9, and paper chromatography. Peptide *a*T14 was digested with subtilopeptidase A (Sigma Chemical Company, St. Louis, USA), and the peptides were isolated as described previously. The amino acid composition of the peptides was determined on a modified Beckman/Spinco 120 amino acid analyzer. The sequence of the partial peptides was determined by the dansyl-Edman method.[4] The dansyl amino acids were identified by high voltage electrophoresis on silica gel plates.[5] or by miniature thin layer chromatography on polyamide sheets (3 × 3 cm).[6]

Results and discussion The amino acid contents of the subtilopeptidase A peptides (denoted by S) are presented in Table 1. The low glycine content of peptide S4 indicates that it is a mixture of two peptides. The only difference between the peptides is at the amino end, at which the *N*-terminal glycine is missing from the smaller one (Fig. 1). This minor difference makes it impossible to separate the peptides by conventional means.

In the previous determination of the sequence of *a*T14, the subtilopeptidase A peptides were obtained in very low yield and, apparently contaminated by impurities, which led to an incorrect deduction of the sequence. The chymotryptic [7] and thermolytic [8] hydrolysates of apoLb*a* also yield peptides covering this portion of the Lb*a* chain. However, these peptides, *a*C18 and *a*Th10, respectively, were investigated only to elucidate the bridges between the tryptic peptides and were therefore not completely sequenced. Consequently the misinterpretation of the data was not observed. The correct sequence of peptide *a*T14 is given in Fig. 1.

Animal Carotenoids. 9*. Trikentriorhodin

MARTHA AGUILAR-MARTINEZ and SYNNØVE LIAAEN-JENSEN

Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim, Norway

In his thesis Smith [1] described the quantitative distribution pattern of carotenoids in the marine sponge *Trikentrion helium* Dickinson (family Cyamonidae) and a partial characterization of the individual carotenoids. The structure of a major carotenoid P474, now called trikentriorhodin, occurring both in esterified and unesterified form [1] has been further studied in our laboratory.

The work was complicated by the presence of much lipid contaminants. Esterified trikentriorhodin (26 % of total carotenoids) on saponification gave free trikentriorhodin (*1*), identical with naturally occurring trikentriorhodin (comprising 21 % of total carotenoids). The structural assignment is based on the following evidence; the position of the hydroxy group in the cyclopentane end group being tentative. Formally trikentriorhodin (*1*) is 3-hydroxy-$\varkappa,\chi$-caroten-6,8-dione. Trikentriorhodin (*1*) exhibited a round-shaped absorption spectrum in all solvents with λ_{max} 518 mn in CS_2; 497 nm in pyridine; (468), 488 and (520) nm in petroleum ether, 478 nm in acetone and 475 nm in diethyl ether, bathochromically displaced relative to astaxanthin [2] and hypsochromically shifted relative to rhodoxanthin,[3] caused by a so far unknown chromophore.

The molecular formula $C_{40}H_{52}O_3$ (*m/e* 580.3908, calc. 580.3917) was established by high precision mass spectrometry.

Fragment ions at M − 92 and M − 106 [4] confirm this assignment. The occurrence of trikentriorhodin as an ester and a prominent M − 18 ion in the mass spectrum of the hydrolyzed pigment indicated the presence of hydroxyl. Trikentriorhodin (*1*) was destroyed under standard conditions for silylation [5] or acetylation,[5] although a monoacetate *1b* (*m/e* 622 = M, M − 60) with unchanged electronic spectrum was obtained in low yield. Attempted methylation of allylic hydroxyl with HCl-MeOH [6] gave 60 % recovery of *1* and no methyl ether, under conditions where lutein gave the monomethyl ether [7] in high yield. Treatment with NaH/MeI [8,9] caused complete decomposition and gave no methyl ether. Attempted allylic oxidation with I_2/O_2 [10] or DDQ [11] again caused decomposition and provided no oxidation products. Trikentriorhodin (*1*) thus appeared to contain a non-allylic hydroxy group, the localization of which was further indicated from the mass spectrum with diagnostically useful fragment ions at M − 127 and *m/e* 127 (*a*, 22 % of base peak) and base peak *m/e* 109.1013 (calc. 109.1017 for $C_8H_{13} = b$, consistent with $b = a - 18$), compatible with a hydroxylated $\varkappa$ [12] end group,[13] Scheme 1.

Careful $LiAlH_4$-reduction gave more polar products with hypsochromically displaced electronic spectra, see below, demonstrating the presence of conjugated carbonyl. IR-absorption at 1610, 1568 cm^{-1} of trikentriorhodin compatible with enolized α- or β-diketone,[14] suggested an end group similar to that recently established by Khare *et al.* in mytiloxanthin (*2*).[15] Support was derived from an M − 155 peak [15] in the mass spectrum of *1*, attributed to α-cleavage, and ^1H NMR signals ($CDCl_3$) at δ 5.83 s (1 H) [15] and methyl singlets at δ 0.85, 1.20 and 1.34 [15,16] compatible with the $\varkappa$ end

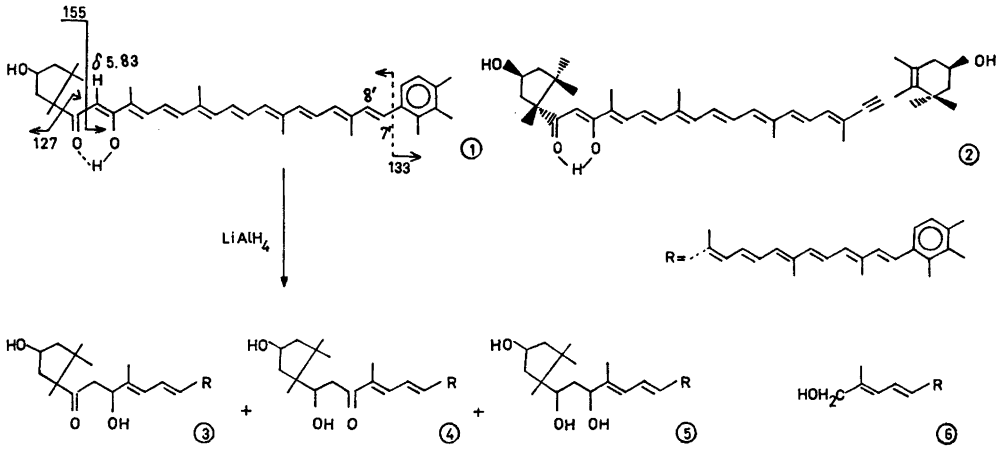

Scheme 1.

group. Weak acidic properties of the enolized β-diketone was consistent with irreversible adsorption of trikentriorhodin (*1*) on alumina, although less evident from partition tests without and in the presence of alkali.

Having now accounted for all oxygen functions, consideration of the chromophore and the remaining double bond equivalences, require that the second end group should be a trimethylphenyl end group. Confirmation was obtained from a broad, unresolved ^{1}H NMR-signal at δ 1.8–2.3 compatible with in-chain methyl and aromatic methyl.[4] Absence of M – 133 and *m/e* ions in the mass spectrum of *1* is ascribed to other preferred cleavages. Preference for 1,2,3-trimethyl substitution follows from the electronic spectrum of trikentriorhodin (*1*) and derivatives to be discussed next.

Micro scale $LiAlH_4$-reduction of *1* gave products with spectral properties compatible with the conjugated ketone *4* [λ_{max} in ether 456, (482) nm], the unconjugated ketone *3* (*m/e* 582 = M, M – 18); λ_{max} in ether 335, 351, 441, 468 nm), and the allylic alcohol *5* (λ_{max} in ether 335, 350, 441 and 465 nm; *m/e* 584 = M, M – 18, M – 18 – 18, M – 106 – 18, M – 158).

Direct comparison of the electronic spectra in diethyl ether of the triol *5* (λ_{max} 441, 468 nm) with that of renierol (*6*, λ_{max} 439, 465 nm), prepared by $LiAlH_4$-reduction of renieral, require 1,2,3- rather than 1,2,5-trimethyl substitution of the aryl ring; *cf.* Ref. 18. Consideration of the absorption maximum of mytiloxanthin (*2*) [15] at lower wavelength than that of trikentriorhodin (*1*) leads to the same conclusion. Evidence obtained by Smith [1] suggests the presence of β-isorenieratene with a 1,2,3-trimethylphenyl end group in *T. helium*.

Experimental. Methods were as commonly employed in this laboratory.[19,5] The isolation involved extraction with acetone, removal of colourless contaminants by deep-freezing, followed by filtration of the concentrated acetone extract, repeated TLC (silica gel G, 1 mm, 5 % acetone in petroleum ether), standard saponification of individual fractions, again followed by repeated TLC of saponified pigments. The carotenoid composition of *T. helium* studied here corresponded to that found by Smith;[1] available *ca.* 7 mg, purified *1*.

R_F-values on Schleicher and Schüll No. 287 kieselguhr paper in acetone-petroleum ether (APE) were: β-carotene 1.00 (0 % APE), *1* 0.29 (5 % APE), *1*-esters 0.27, 0.31 (0 % APE). Relative polarity on silica gel G plates (20 % APE) were *7* < *1* < *3* < *4* < *5*.

Acknowledgement. We thank Dr. V. E. Smith for passing this problem over to us and him and Professor D. L. Fox, Scripps Institution of Oceanography, La Jolla, California, for arranging collection of the biological material used in the present study. M. A.-M. was supported by a NORAD fellowship.
