# A Note on Practical Aspects of the Application of DIRDIF, a Procedure for Structure Elucidation When a Part of the Structure is Known 

By V. Parthasarathi,* Paul T. Beurskens $\dagger$ and H. J. Bruins Slot<br>Crystallography Laboratory, University of Nijmegen, Toernooiveld, 6525 ED Nijmegen, The Netherlands

(Received 16 May 1982; accepted 5 July 1983)

#### Abstract

The DIRDIF procedure (direct methods applied to difference structures) has been tested on a variety of structures. It is shown that errors in the atomic positions of approximately $0.3 \AA$ are acceptable, that the minimum size of the known molecular fragment is about $10 \%$ of the total scattering power, and that lack of knowledge about the unit-cell contents is not deleterious

## Introduction

When part of a structure is known, the DIRDIF method (Beurskens et al., 1982) can be effectively used to solve the unknown part of the structure. Although the various $D I R D I F$ procedures include unique features designed for solving enantiomorph and supersymmetry problems (see Prick, Beurskens \& Gould, 1983, and references therein), the general DIRDIF method has proved to be a very efficient tool for routine crystal-structure analyses, particularly if the known part is only barely sufficient to solve the structure. The automatic computer program uses observed structure amplitudes and positions of the known atoms as input to a structure-factor calculation and scaling routine. This is followed by a weighted tangent refinement of the difference structure factors, to yield a greatly improved electron density map.

[^0]0108-7673/83/060860-05\$01.50

To explore the effects of errors or lack of information, we pose the following questions:

Q1. How small may the known part be so that DIRDIF is still helpful?

Q2. How much error can be tolerated in the positional coordinates of the known atoms?

Q3. What are the effects of 'incorrect atoms' in an otherwise correct molecular fragment?

Q4. What is the effect of unknown chemical composition?
We investigated these aspects using a few known crystal structures as test cases. The results are summarized in this note.

## Calculations

All calculations were performed by the program DIRDIF using default executional parameters. A scaling procedure (Gould, Van den Hark \& Beurskens, 1975) leads to the determination of the scale factor, $S C, B_{p}$ the (overall) isotropic temperature parameter of the known part (heavy atom or 'partial structure'), and $B_{r}$ the (overall) isotropic temperature parameter of the unknown part of the structure ('rest structure').

The contribution of the known part to the total scattering power is defined by the a priori scattering fraction:

$$
p_{Z}^{2}=\sum_{p} Z_{p}^{2} / \sum_{l} Z_{l}^{2}
$$

where $Z$ is the atomic number, $\sum_{p}$ denotes summation over the known atoms, and $\sum_{l}$ denotes summation over all atoms in the unit cell.
© 1983 International Union of Crystallography

After the scaling procedure the scattering fraction is recalculated as

$$
p_{\text {exp }}^{2}=\sum_{h}\left|F_{p}\right|^{2} / \sum_{h}\left|F_{\text {obs }}\right|^{2},
$$

where $F_{p}$ is the partial structure factor, calculated with temperature parameter $B_{p}, F_{\text {obs }}$ is on an absolute scale, and $\sum_{h}$ denotes summation over all reflections.

Note that $p_{\text {exp }}^{2}$ depends on structural peculiarities as well as on the result of the scaling procedure.

Normalization of the difference structure factors,

$$
\Delta F_{1}=\left(\left|F_{\mathrm{obs}}\right|-\left|F_{p}\right|\right) \exp \left(i \varphi_{p}\right)
$$

gives $E_{1}$ values. $\left|E_{1}\right|$ is the lowest possible estimate for $\left|E_{r}\right|$ (the $|E|$ value of the unknown part of the structure). $E_{1}$ is 'phased' by the known atoms. It is the purpose of the DIRDIF procedure to transform $E_{1}$ values into $E_{r}$ values, by two or three cycles of weighted tangent refinement. The resulting $E_{r}$ values

are converted into $F_{r}$ values which are used as input to a Fourier synthesis and peak interpretation program.

The test structures are listed in Table 1; they are denoted by the code names MONOS, HEPTA and AU8P7.

MONOS is taken as an example of an organic molecule with one medium-heavy atom (sulphur). Structures of this type are usually solved by direct methods. We find it easier to obtain the sulphur position from a sharpened Patterson synthesis and to determine the remaining non-hydrogen atoms using DIRDIF. One interpretation of the Patterson synthesis of MONOS leads to a sulphur position with $x=0 \cdot 0$, which constitutes a centrosymmetric structure. This enantiomorph problem can be solved by DIRDIF (Prick, Beurskens \& Gould, 1983). In this note, however, we report the DIRDIF results for slightly shifted positions of the input sulphur atom. For this compound, questions Q2 and Q4 (see above) are answered by the results collected in Tables 2 and 3. An error of $0.5 \AA$ in the position of the sulphur atom is too much. An error of $0.4 \AA$ leads to an incomplete structure; the highest peak in the Fourier synthesis gives an improved position of the sulphur atom. For comparison, Table 2 also includes the results obtained by a Sim's (1960) weighted Fourier synthesis. As can be seen from Table 3, satisfactory results occur for widely varying cell contents.

HEPTA is taken as an example of an equal-atom structure. The two independent molecules consist of fused hexagons. Such structures often lead to $E$ maps in which hexagonal patterns are found ('chicken wire'). Here, we report the DIRDIF results for fragments of different size and quality, at approximately correct position and orientation. (For the application of DIRDIF translation functions to misplaced fragments, see Doesburg \& Beurskens, 1983). For the fragments, which are defined in Table 4, the answers to the questions $Q 1, Q 2$ and $Q 3$ are given in Tables 5, 6 and 7 , respectively. The results for different fragments show large variations, related to the nature of the fragments. For instance, the fragment $F 6 a$ constitutes a hexagon, which is not a unique feature in this structure, while $F 6 c$ constitutes a connected chain of six carbon atoms belonging to different hexagons. As can be seen in Table 5, all fragments but $F 6 a$ give satisfactory results. The answer to $Q 2$ depends on the size of the fragment:

Table 4. Description of fragments of HEPTA

| $F 10 a$ | 0.21 | 29 | 55 |
| $F 12 a$ | 0.24 | 30 | 60 |

[^1]Table 6 shows that the atomic positions of a 12 -atom fragment may have standard deviations up to $0.4 \AA$, while the smaller fragments only give satisfactory results with more accurate positions. The six-atom fragment $F 6 b$ with a standard deviation of $0 \cdot 20 \AA$ (which implies larger deviations for two or three atoms) is only marginally sufficient for the elucidation of the structure. In Tables 5 and 6 it is shown that for small or poor fragments, which do not lead to the determination of the complete structure, the first thirty peaks include a relatively large number of correct atomic positions. Table 7 gives the results for some fragments to which 1, 2 or 3 'wrong atoms' were added at

$\ddagger N_{\mathrm{g}}$ : number of gold atoms located in the DIRDIF Fourier synthesis (maximum: 8).
incorrect though chemically reasonable positions, extending the hexagonal pattern. There is a strong tendency for the 'wrong atoms' not to appear within the list of the highest peaks.

Au8P7 is taken as an example of a troublesome heavy-atom structure. In this type of gold cluster compound the composition and the skeleton geometry are often not known. We have solved several cluster compounds by finding a few gold atoms from partial interpretation of a Patterson synthesis, and locating the remaining heavy atoms using $D I R D I F$. The questions $Q 2, Q 3$ and $Q 4$ are answered in Tables 8 and 9. A known fragment consisting of three Au atoms revealed in all cases the positions of the remaining Au atoms, except when all positions were wrong. An error in the cell contents up to $75 \%$ has little effect on the DIRDIF results, as Table 9 shows: all Au atoms were located.

## Discussion of the results

From these experiments, it may be concluded that errors in the atomic positions of approximately $0.3 \AA$ are acceptable (Tables 2, 6 and 8 ), that 'wrong atoms'
in the peak list are de-emphasized (Table 7), that the minimum size of the known fragment is about $10 \%$ of the total scattering power (Tables 5 and 6), and that errors in the cell contents have little effect (Tables 3 and 9).

These results cannot be generalized quantitatively, since structures of different complexities and with different structural peculiarities may behave differently in a given situation. However, they are consistent with our many practical applications of DIRDIF to the solution of unknown structures.

When $D I R D I F$ fails to reveal the structure, valuable information about the nature of the problem is given by various statistical quantities, some of which are collected in the tables.

Tables 2 and 6 show that a bad partial structure (large errors in the positions of the input atoms) leads to large values of $B_{p}$. (An incorrect input model is 'blown up' by the scaling procedure.) $B_{r}$ is not that much affected by the model. (For a small fragment $B_{r}$ is largely determined by the overall temperature parameter.)

The effect of varying cell contents is minimized by the scaling procedure. The resulting temperature factor $B_{p}$ is a function of the assumed relative scattering power of the input fragment. (Table 3).

The a priori calculated scattering power of the known fragment, $p_{z}^{2}$, depends on the number and the type of atoms only; the experimental scattering fraction, $p_{\text {exp }}^{2}$, depends on the quality of the model, on structural peculiarities, and also on the result of the scaling procedure. Therefore, $B_{p}$ and $p_{\text {exp }}^{2}$ are strongly correlated. Nevertheless, we find it useful to observe the results for $p_{\text {exp }}^{2}$ : its value decreases if the model is bad.

Other statistical quantities, such as the expectation value of $\left|E_{r}\right|$, have been discussed previously (Beurskens, Prick, Doesburg \& Gould, 1979).

Tables 5 and 6 show that in cases in which the known fragment is only barely sufficient to solve the structure (very small fragment and/or large errors in the atomic positions), the input model is obtained from the $D I R D I F$ Fourier synthesis with improved positions, and that some new atomic positions may be selected from the list of the largest peaks. Also, Table 7 shows that possible 'wrong atoms' will sink to the bottom of the peak list. One may therefore use selected output positions as input to another $D I R D I F$ run, while considering the following:

- If a well defined structure is found in the DIRDIF Fourier map, and only a few atoms are missing, a conventional Fourier synthesis may be used to locate the missing atoms. (At this stage the difference structure factors are largely determined by errors in the model and errors in the observed intensities; tangent refinement now is not advisable; the program $D I R D I F$ automatically bypasses the refinement, and produces a conventional Fourier synthesis).
- If the complete structure is recognized, but of poor quality, a conventional Fourier synthesis may be used to obtain refined parameters.
- If only a fragment is recognized (say less than $60 \%$ of the total scattering power), this fragment may be used as input to DIRDIF.
- If the structure is not recognized, one should pay attention to the printed statistical quantities, and examine the input model. Large $B_{p}$ and small $p_{\text {exp }}^{2}$ indicate a bad model. Too large or too small $B_{r}$ values or an $\left|E_{r}\right|^{2}$ average which deviates too much from unity are often related to scaling problems: in this case the user may supply reasonable values for $B_{p}$ and $B_{r}$ and rerun $D I R D I F$ with a severe $\sin \theta / \lambda$ cut-off. The following rerun options may be considered:
* If the model consists of one or more heavy atoms, which appear to be shifted by more than $0.1 \AA$, the new positions may be used as input.
* For a light-atom fragment the same option can be applied and one may also reject the atoms that return low in the peak list, and include some higher peaks.
* If the input fragment completely returns in the $D I R D I F$ Fourier, with atomic shifts less than $0.1 \AA$, we suggest adding a number of high peaks to the known fragment: this number may be $10,20 \%$ of the total number of non-hydrogen atoms, or $50 \%$ of the number of atoms of the input model, depending on the problem at hand.

The investigations were supported (in part) by the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organization for the Advancement of Pure Research (ZWO).

# General Lattice Factor of the Ideal Paracrystal 

By W. Wilke<br>Abteilung Experimentelle Physik, Universität Ulm, Oberer Eselsberg, D-7900 Ulm, Federal Republic of Germany

(Received 5 May' 1983; accepted 29 June 1983)

#### Abstract

The lattice factor of a paracrystalline lattice with oblique axes and with general orientation of the fluctuation tensor ellipsoid is calculated. Directly applicable formulas for the special case of a monoclinic (macro) lattice, which is of interest in connexion with the small-angle scattering of oriented semicrystalline polymers, are given.

## 1. Introduction

The ideal paracrystal is a model of a statistical distorted crystal lattice or macro lattice (Hosemann \&

0108-7673/83/060864-04\$01.50

Bagchi, 1962). The distortions are described by the cell-edge statistics $H_{k}(\mathbf{x})(k=1,2,3)$ and the mean cell-edge vectors are

$$
\begin{equation*}
\mathbf{a}_{k}=\int \mathbf{x} H_{k}(\mathbf{x}) \mathrm{d}^{3} \mathbf{x} \tag{1}
\end{equation*}
$$

For statistics $H_{k}(\mathbf{x})$ having a center of symmetry, the statistical amplitude $F_{K}(\mathbf{b})$, the Fourier transform, . $F\left\{H_{k}(\mathbf{x})\right\}$, can be expressed in the form

$$
\begin{equation*}
\left.F_{k}(\mathbf{b})=\left|F_{k}(\mathbf{b})\right| \exp \mid-2 \pi i \mathbf{b} \cdot \mathbf{a}_{k}\right] \tag{2}
\end{equation*}
$$

where, for statistics $H_{k}(\mathbf{x})$ Gaussian (otherwise as an approximation),

$$
\begin{equation*}
\left.\left|F_{k}(\mathbf{b})\right|=\exp \mid-2 \pi^{2} \mathbf{b} \cdot \mathbf{T}(k) \cdot \mathbf{b}\right] \tag{3}
\end{equation*}
$$
