The Crystal Structure of ReCl₅

BY KENNETH MUCKER, GORDON S. SMITH AND QUINTIN JOHNSON

Lawrence Radiation Laboratory, University of California, Livermore, California, U.S.A.

(Received 10 July 1967)

ReCl₅ forms monoclinic crystals with lattice constants: $a=9.24$, $b=11.54$, $c=12.03$ Å; $\beta=109.1^\circ$. The space group is $P2_1/c$, and the unit cell contains eight ReCl₅ units. Full-matrix, least-squares refinement of diffractometrically measured X-ray diffraction data resulted in a final R of 9.3% (all reflections). The structure is based on a double-hexagonal closest packing of chlorine atoms, in which rhenium atoms occupy one-fifth of the octahedral holes. Two such octahedra share an edge to form a dimeric Re₂Cl₁₀ unit. The Re–Cl bond distances involving bridging Cl average to 2.465 ± 0.013 Å; the average bond length to nonbridging Cl is 2.244 ± 0.012 Å. Rhenium atoms in the Re₂Cl₁₀ units are each shifted by about 0.20 Å from the centers of the octahedra in directions away from one another. The packing mode of Cl in ReCl₅ contrasts with a hexagonal closest packing of Cl in TaCl₅ and a cubic closest packing of Cl in UCl₅. Of these, ReCl₅ exhibits both the highest density and the smallest interatomic distances.

Introduction

Four compounds in the rhenium–chlorine system are known (Colton, 1965): ReCl₃, ReCl₄, ReCl₅ and ReCl₆. The pentachloride is a dark brown to black material, melting at 220°C. It is moisture-sensitive and highly reactive; a few of its chemical reactions have recently been investigated (Cotton, Robinson & Walton, 1967).

Our interest in ReCl₅ stems from the variety of crystal structures assumed by the pentachlorides. Examples include: ionic structures – P^+Cl_4^- and P^-Cl_6^- in P^+Cl_5 (Powell, Clark & Wells, 1940); trigonal, bipyramidal molecules – SbCl₅ (Ohlberg, 1959); bridged M₂Cl₁₀ dimers – NbCl₅ (Zalkin & Sands, 1958); MoCl₅ (Sands & Zalkin, 1959); UCl₅ (Smith, Johnson & Elson, 1967); and infinite chains of edge-shared pentagonal bipyramids – PaCl₅ (Dodge, Smith, Johnson & Elson, 1967). Five-coordination, we note, is avoided in all except SbCl₅. The present investigation shows ReCl₅ to be of the bridged-dimer type, but of a different crystallographic variety.

Experimental

Our sample of ReCl₅ was kindly provided by Dr D. Brown of the Atomic Energy Research Establishment, Harwell, England. Dr Brown informed us that the material was prepared by the thermal decomposition

of ReCl₆ in a dry nitrogen atmosphere. Microscopic examination of the sample-tube showed a number of suitably sized crystals. The tube was opened in a dry-box and a half-dozen or so crystals were sealed off in thin-walled glass capillaries for X-ray examination. The reactive nature of ReCl₅ was evidenced by the fact that samples left open overnight in the dry-box developed traces of a brown liquid (possibly ReOCl₄).

Single-crystal diffraction photographs showed monoclinic symmetry; the systematic extinctions ($h0l$, $l=2n+1$; $0k0$, $k=2n+1$) are those uniquely characterizing the space group $P2_1/c$ (*International Tables for X-ray Crystallography*, 1952). Refined values of the lattice constants are (Mo $K\alpha=0.7107$ Å); $a=9.24$, $b=11.54$, $c=12.03$ Å; $\beta=109.1^\circ$ (probable errors estimated as about 0.3%). The density calculated for eight ReCl₅ units per unit cell is 3.98 g.cm⁻³.

Intensity measurements were carried out on a General Electric XRD-5 diffractometer equipped with a goniostat. The crystal specimen was an irregularly shaped plate, approximately 0.22 mm in length and 0.14×0.07 mm in cross section. The stationary crystal-stationary counter technique (Furnas, 1957) was used; the radiation was Zr-filtered Mo $K\alpha$. A total of 1127 reflections were recorded up to a 2θ -cutoff of 40°. Because of the irregular shape of the crystal and a rather large linear absorption coefficient ($\mu=233$ cm⁻¹ for

Mo $K\alpha$), reflections at $\chi=90^\circ$ showed a pronounced variation of intensity with ϕ . For example, the overall variations of the 020 and 040 reflections were 4:1 and 6:1, respectively, lowest readings being obtained when the thickest parts of the crystal were presented to the X-ray beam. The intensity variation with ϕ of these two reflections provided corrective factors which were applied to all reflections. These corrections, admittedly approximate, nevertheless proved to be remarkably effective (see below). Finally, the intensities were converted to relative $|F|$'s through the application of Lorentz-polarization factors.

Determination of structure

The most reasonable calculated density (3.98 g.cm^{-3}) was for eight units of ReCl_5 per unit cell. A partial corroboration came from volume considerations. In closest-packing, each Cl atom requires about 34 \AA^3 . Division of this number into the cell volume indicated about 36 Cl atoms within the unit cell. The first nine largest peaks in the three-dimensional Patterson function were very satisfactorily accounted for by vector interactions between two fourfold Re atoms: Re(1) at $0.31, 1/8, 0.29$ and Re(2) at $-0.11, 1/8, 0.19$. A structure-factor calculation based on these two atoms gave an R -value of 29%; ten fourfold Cl atoms were readily located in a 'heavy-atom' electron-density synthesis. Individual isotropic temperature factors being employed, there are 49 parameters to be determined from the 1127 measured reflections.

The structure model was refined by the full-matrix, least-squares program of Gantzel, Sparks & Trueblood (ACA Program no. 317, unpublished). The atomic scattering factors used were those listed in *International*

Tables for X-ray Crystallography (1962) for neutral Re and singly-ionized Cl. The quantity minimized was $\sum w(|F_o| - 1/K|F_c|)^2$ where K is the scale factor relating $|F_o|$ and $|F_c|$ and the w 's are given by the following weighting scheme (Smith, Johnson & Nordine, 1965): $w = F_o^{1/4}, F_o < A$; $w = A^{5/4}F_o^{-1}, F_o > A$. When the structure factors were placed on an absolute scale, $A = 186$. Five cycles of refinement reduced the R index ($= \sum (K|F_o| - |F_c|) / \sum K|F_o|$) to 9.3% (all reflections). Changes in parameter values in the last cycle were ≤ 0.001 times the standard deviations.

There is some indication of extinction effects in the stronger reflections, and for the weaker reflections it appears that the background may have been generally slightly underestimated. In view of the approximate nature of the absorption corrections, these effects were not investigated further. Nevertheless the largest peak in a final difference synthesis amounted to only 1.0 e.\AA^{-3} . To test the effectiveness of the absorption corrections, a refinement series was carried out on the un-

Fig. 2. Sequence of networks along the b axis. Chlorine positions are based on a double-hexagonal closest packing arrangement; rhenium atoms at $y = \pm \frac{1}{4}$ and $\pm \frac{3}{4}$ occupy octahedral holes between layers. The various chlorine atoms are indicated by numbers. Re atoms at $\frac{1}{8}$ and $-\frac{1}{8}$ are indicated by \times and \otimes respectively; Re at $\frac{3}{8}$ and $-\frac{3}{8}$ by \oplus and \ominus respectively.

might be expected, *cf.* $\text{Re}^{\text{IV}}\text{-Cl}$ distances of (a) $2.35 \pm 0.02 \text{ \AA}$ in bis- $[p\text{-toluidinium}]$ hexachlororhenate (Adman & Margulis, 1967) and (b) $2.38 \pm 0.02 \text{ \AA}$ in $\text{K}_4[\text{ReOCl}_5]_2 \cdot \text{H}_2\text{O}$ (Morrow, 1962). In contradistinction, the present $\text{Re}\text{-Cl}$ distances involving nonbridging Cl are (reasonably enough) shorter than the $\text{Re}^{\text{IV}}\text{-Cl}$ distances cited above.

The rhenium atoms are both shifted by about 0.20 \AA from the centers of the octahedra in directions away from one another, *i.e.* along the line joining $\text{Re}(1)$ and $\text{Re}(2)$ (Fig. 1). Again, displacements of a similar magnitude are observed in the other bridged-dimer pentahalides, and suggest a strong repulsion, presumably of a coulombic nature, between metal atoms. As a result of this distortion, bond angles within the octahedra deviate noticeably from 90° , although the $\text{Cl}\cdots\text{Cl}$ distances outlining the octahedra are rather constant at $3.27 \pm 0.05 \text{ \AA}$. The angles deviating most drastically from 90° are $\text{Cl}(1)\text{-Re}(1)\text{-Cl}(6) = 80.8^\circ$ and $\text{Cl}(1)\text{-Re}(2)\text{-Cl}(6) = 81.9^\circ$.

The crystal structure as a whole is based on a double-hexagonal closest packing (d.h.c.p.) of Cl atoms, in which Re atoms occupy one-fifth of the octahedral holes. This arrangement is illustrated in Fig. 2 where the four hexagonal nets characteristic of d.h.c.p. are shown. The stacking sequence of these nets along the b axis is $ABAC\dots$. For the present arrangement of Re atoms and for the idealized case of exact d.h.c.p. of Cl atoms, simple geometrical considerations require that the repeat distance along the b axis be $4\sqrt{8/3}R$, (R =the packing radius of Cl). Similarly, the a - and c -axis repeat distances are related to distances within the hexagonal nets as follows: $a = 2\sqrt{7}R$, $c = 4\sqrt{3}R$; the monoclinic angle is $90 + (\sqrt{3}/2\sqrt{7})$ ($= 109.1^\circ$). Numerical values for $R = 1.75 \text{ \AA}$ are: $a = 9.26$, $b = 11.43$ and $c = 12.12 \text{ \AA}$, compared with experimental values of $a = 9.24$, $b = 11.54$ and $c = 12.03$; $\beta = 109.1^\circ$. The use of a more conventional value of $R = 1.80 \text{ \AA}$ (Pauling,

1960) leads to predicted repeat-distances which are 2–4% larger than observed. As mentioned earlier, the intra-octahedral $\text{Cl}\cdots\text{Cl}$ distances average well below 3.60 \AA , so that a smaller overall Cl packing radius is to be expected.

This d.h.c.p. packing of Cl in ReCl_5 provides an interesting comparison with the behavior of Cl in the other bridged-dimer pentachlorides. In NbCl_5 , MoCl_5 and TaCl_5 , the Cl are in hexagonal closest packing (h.c.p.), and in UCl_5 the Cl are in cubic closest packing (c.c.p.). Thus, ReCl_5 , NbCl_5 and UCl_5 represent three crystallographically distinct ways of forming M_2Cl_{10} dimers in the solid state. We note further that examples of these three packing modes are found in crystal structures of the rare-earth metals (Pauling, 1960). Samarium forms a still more complicated closest-packing arrangement which repeats after nine layers (Daane, Rundle, Smith & Spedding, 1954). It is inviting to speculate whether some of the pentahalides might display a halide atom arrangement of the Sm type.

It is relevant also to speculate on the possibility of the pentachlorides undergoing polymorphic transformations from one type of Cl packing to another. In the case of the rare-earth metals, Jayaraman & Sherwood (1964) indicate that with increasing pressure the transitions proceed in the order: h.c.p. \rightarrow Sm-type \rightarrow d.h.c.p. \rightarrow f.c.c. There is no change in the number of nearest neighbors, but each step is accompanied by a small increase in density, or equivalently, a small decrease in the atomic volume. It is conceivable that this order originates from more favorable relations of second (and more distant) nearest neighbors, and that the sequence will be retained in other close-packed compounds. However, a comparison of structural data for TaCl_5 , ReCl_5 and UCl_5 (Table 4) shows ReCl_5 to possess far and away the highest density and lowest value of V_{Cl} (volume of unit cell/number of Cl atoms within the unit cell). In this respect the effect of Re

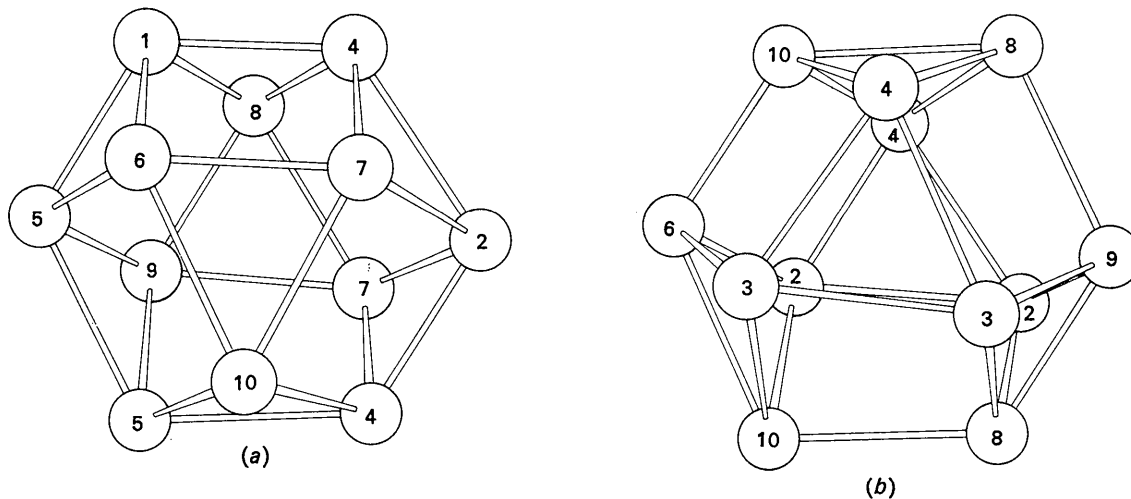

Fig. 3. Illustration of the two types of coordination polyhedra about Cl atoms: (a) neighbors of $\text{Cl}(2)$ as in cubic closest packing, and (b) neighbors of $\text{Cl}(7)$ as in hexagonal closest packing. Central atoms and rhenium neighbors omitted for the sake of clarity.

is to cause a net compression of the Cl framework. This would seem analogous to an external mechanical pressure. The higher density for UCl_5 than for TaCl_5 reflects a heavier mass; actually of the three, UCl_5 has the most open structure. The data in Table 4 therefore suggest that UCl_5 or TaCl_5 may transform under pressure to the d.h.c.p. arrangement; conversely at higher temperatures ReCl_5 or TaCl_5 may transform to the c.c.p. arrangement.

Table 4. Comparison of structural data for the bridged-dimer pentachlorides

V_{Cl} = volume of unit cell/number of Cl atoms within unit cell.

	TaCl_5	ReCl_5	UCl_5
Packing of Cl	h.c.p.	d.h.c.p.	c.c.p.
Density, g.cm^{-3}	3.68	3.98	3.81
V_{Cl} (\AA^3)	32.3	30.3	36.2
M-Cl (bridge) (\AA)	2.56*	2.47	2.69
M-Cl (nonbridge) (\AA)	2.28*	2.24	2.44
M...M (dimer) (\AA)	3.95*	3.74	4.17

* Estimated from positional parameters for NbCl_5 .

In ReCl_5 , half of the Cl atoms [Cl(1) through Cl(5)] have their 12 Cl neighbors arranged as in c.c.p., and the other half [Cl(6) through Cl(10)] have their neighbors arranged as in h.c.p. The polyhedra are not in general regular, since contacts between Cl atoms within the same octahedron are smaller than contacts between Cl in different dimers. In addition to having 12 Cl neighbors, every Cl atom is bonded to at least one Re;

Cl(1) and Cl(6) are bonded to two Re atoms. A complete list of nearest neighbor Cl...Cl distances is given in Table 5. A typical coordination polyhedron of each type is illustrated in Fig. 3; the others can be constructed by overlaying the networks of Fig. 2.

As pointed out previously for UCl_5 (Smith, Johnson & Elson, 1967), a description of the structure in terms of a closest-packed array leaves open the question whether the M_2Cl_{10} dimers have an independent existence as discrete molecules. We know of no information relating to whether or not the $\text{Re}_2\text{Cl}_{10}$ dimers are retained in the liquid or vapor phase or upon dissolution of ReCl_5 in an inert solvent.

We are indebted to Dr A. Zalkin for furnishing copies of the several IBM-7094 programs used in the calculations. We thank Dr C. K. Johnson for supplying a copy of his ORTEP program. We also acknowledge with gratitude the aid of Mr D. H. Wood in the dry-box manipulations of the ReCl_5 sample. This work was performed under the auspices of the U.S. Atomic Energy Commission.
