Abstract

The title structure, HgSeO₃, is isomorphous with those of a series of perovskite-like *MSeO₃* compounds and contains corner-sharing HgO₆ octahedra, connecting to form a three-dimensional network, and Se⁴⁺ ions in the cavities of the structure. The octahedron is substantially distorted with Hg—O bond distances between 2.103 (11) and 2.641 (11) Å. The geometry of the selenite group

deviates significantly from those of the selenites of the isomorphous series.

Comment

Crystal structures of selenite compounds of mercury(II) have not been reported previously. In a study of the solubility of the system HgO—SeO₂—H₂O, two phases with compositions HgSeO₃ and 3HgSeO₃·H₂SeO₃ were reported to exist (Gospodinov & Barkov, 1991). The study further confirmed previous findings that HgSeO₃ crystallizes in two polymorphic forms of which one is stable at 298 K and the other at 373 K. The two forms are reported to be isomorphous with corresponding polymorphs of ZnSeO₃ and CdSeO₃ (Markovskii & Sapozhnikov, 1961; Gospodinov & Bogdanov, 1983; Micka, Uchytlova & Ebert, 1984).

Selenite forms an isomorphous series of distorted perovskite-like *MSeO₃* structures in space group *Pnma*, where *M* is Mg²⁺, Mn²⁺, Co²⁺, Ni²⁺, Cu²⁺ and Zn²⁺, as reported by Kohn, Inoue, Horie & Akimoto (1976). The metal in compounds of this series is octahedrally coordinated. Recently, Cd²⁺ was also found to form two polymorphous forms of selenite, one of which is isomorphous with the perovskite-like structures, while the other was found to be a monoclinic CdSeO₃ structure (Valkonen, 1994). In addition, the crystal structure of another polymorph of ZnSeO₃, in space group *Pbca*, has been reported, in which the Zn atom is five-coordinate (Bensch & Gunter, 1986). It seemed interesting to explore the crystallization of HgSeO₃ and compare the structure to the above different crystal forms.

HgSeO₃ (prepared in this study) crystallizes in space group *Pnma*, isomorphous with the series of perovskite-like *MSeO₃* structures. The structure can be depicted as composed of HgO₆ octahedra linked together at corners to form a three-dimensional network, with Se⁴⁺ ions in the cavities of this network. Alternatively, it can be considered as a structure in which the selenite group bridges six Hg²⁺ ions, with all selenite O atoms within bonding distance of two Hg²⁺ ions.

Within the Hg²⁺ coordination octahedron, three unequal pairs of metal–oxygen distances were found [2.103 (11), 2.593 (10) and 2.641 (11) Å] representing a substantial tetragonal flattening of the octahedron. Tetragonal flattening, although notably less marked, was also found in isomorphous ZnSeO₃, where the corresponding distances were 2.089, 2.177 and 2.223 Å, whereas in isomorphous CdSeO₃, the octahedron about the metal ion was rather regular with corresponding distances of 2.271, 2.348 and 2.357 Å. In isomorphous CuSeO₃, the difference between the smallest and largest metal–oxygen distance was even larger than that in the present compound (0.602 Å), but the octahedron was elongated, as is typical of six-coordinate copper (Kohn, Inoue, Horie & Akimoto, 1976; Valkonen, 1994).

The metal–oxygen distances in the present compound are rather typical of six-coordinate Hg^{2+} , as is the 2 + 4 coordination scheme. In HgHPO_4 , the bond range for the 2 + 4 distorted HgO_6 octahedron is 2.060 (9)–2.924 (10) Å and the sites of nine other distorted 2 + 4 octahedra (with either tetragonal elongation or flattening) were reported, having a short-bond range of 2.0–2.1 and a long-bond range of 2.6–2.8 Å (Dubler, Beck, Linowsky & Jameson, 1981).

The Se–O distances in HgSeO_3 are not similar to those in isomorphous ZnSeO_3 and CdSeO_3 . While in the latter compounds the bond lengths are 1.717 and 1.723 Å (2×), and 1.706 and 1.713 Å (2×), respectively, in the present compound they are 1.660 (17) and 1.734 (11) Å (2×). Also, the pyramidal shape of the selenite group in the present compound is flatter than usual, with the O–Se–O bond angles between 102.9 (6) and 103.2 (5)°, as compared to 95.4 and 104.1° for ZnSeO_3 , and 100.5 and 103.0° for CdSeO_3 (Kohn, Inoue, Horie & Akimoto, 1976; Valkonen, 1994).

Experimental

The title compound was crystallized from an aqueous solution of SeO_2 with solid HgSO_4 by allowing the suspension to stand at temperatures between 330 and 370 K for one to two weeks.

Polytypism of CuFe₂(OH)₂(AsO₄)₂: the Triclinic Modification

H. EFFENBERGER

Institut für Mineralogie und Kristallographie, Universität Wien, Dr Karl Lueger-Ring 1, A-1010 Wien, Austria

(Received 20 July 1994; accepted 13 December 1994)

Abstract

The triclinic modification of dimorphic CuFe₂(OH)₂(AsO₄)₂ is presented. The O atoms are cubic close packed; between succeeding layers only alternate octahedral or tetrahedral positions are occupied. Within the 'octahedral sheets', Cu^[4+2](O_h)₂O₄ and Fe^[6](O_h)₂O₄ (O_h = hydroxyl O atom) polyhedra are edge-connected

to form bands; 2/5 of the positions are vacant. These □O₆ octahedra each share one face with an AsO₄ anion of the 'tetrahedral sheet'; bifurcated hydrogen bonds link neighbouring octahedral sheets.

Comment

A number of structure types for compounds with the general formula $M^{2+}M_2^{3+}(\text{OH})_2(\text{XO}_4)_2$ ($X = \text{P, As}$) have been described. The most prominent is the monoclinic lazulite-type known from several minerals: lazulite, MgAl₂(OH)₂(PO₄)₂ (Giuseppetti & Tadini, 1983), scorzalite, (Fe,Mg)Al₂(OH)₂(PO₄)₂ (Lindberg & Christ, 1959), barbosalite, Fe₃(OH)₂(PO₄)₂ (Lindberg & Christ, 1959), and hentschelite, CuFe₂(OH)₂(PO₄)₂ (Sieber, Tillmanns & Hofmeister, 1987). Even the substitution of M^{3+} by M^{2+} combined with the incorporation of a protonated XO₃OH group has been described: Co₃(OH)₂(PO₃OH)₂ (Effenberger, 1992). Lazulite-type arsenates are unknown.

With cations of larger atomic radii and, therefore, higher coordination numbers, the structure type changes, e.g. jagowerite, BaAl₂(OH)₂(PO₄)₂ (Meagher, Gibbons & Trotter, 1974), and carminite, PbFe₂(OH)₂(AsO₄)₂ (Finney, 1963). Moreover, Fe₃(OH)₂(PO₄)₂ forms a tetragonal polytype (lipscombit; Vencato, Mattievich & Mascarenhas, 1989).

The orthorhombic modification of CuFe₂(OH)₂(AsO₄)₂ (Effenberger, 1988) is closely related to the lazulite structure type: one $M^{2+}(\text{O}_h)_2\text{O}_4$ and two $M^{3+}(\text{O}_h)_2\text{O}_4$ octahedra share faces to form $M^{2+}M_2^{3+}(\text{O}_h)_4\text{O}_8$ trimers. The $M^{3+}(\text{O}_h)_2\text{O}_4$ octahedra are linked via O_h atoms into chains. As a result, corrugated sheets are formed with the undulations in the two phases being different. The layers are interconnected by XO₄ tetrahedra and by hydrogen bonds.

In triclinic CuFe₂(OH)₂(AsO₄)₂ (Fig. 1), the modes of coordination are as usual. The Cu^{II} atom has site symmetry $\bar{1}$ and is [4 + 2] coordinated to form an elongated octahedron, showing characteristic Jahn–Teller distortions due to the d^9 electronic configuration (Norrestam, 1994). The two Cu—O_h bonds are the shortest bonds within this polyhedron; the average bond length within the square formed by the four nearest neighbours is 1.957 Å. The additional bonds are almost 2.50 Å in length, indicating only weak interactions. The Fe(O_h)₂O₄ octahedron is less distorted. The longest bonds are to the O_h atoms. Contrary to the orthorhombic polytype the O_h atoms are in a *cis* arrangement. The average Fe—L bond length of 2.017 Å is in accordance with expectations for the trivalent oxidation state (L is an unspecified ligand belonging either to the arsenate group or to the hydroxyl group). The arsenate tetrahedron has an average As—O bond length of 1.687 Å. As a result of face-to-face connection, orthorhombic CuFe₂(OH)₂(AsO₄)₂ shows stronger distortion of the coordination polyhedra.
