Disodium hexamanganese(II,III) germanate is the first aenigmatite-type compound with significant amounts of manganese. $\mathrm{Na}_{2}\left(\mathrm{Mn}_{5.26} \mathrm{Na}_{0.74}\right) \mathrm{Ge}_{6} \mathrm{O}_{20}$ is triclinic and contains two different Na positions, six Ge positions and 20 O positions (all with site symmetry 1 on general position $2 i$ of space group $P \overline{1}$ ). Five out of the seven $M$ positions are also on general position $2 i$, while the remaining two have site symmetry $\overline{1}$ (Wyckoff positions $1 f$ and $1 c$ ). The structure can be described in terms of two different layers, $A$ and $B$, stacked along the [011] direction. Layer $A$ contains pyroxene-like chains and isolated octahedra, while layer $B$ is built up by slabs of edgesharing octahedra connected to one another by bands of Na polyhedra. The $\mathrm{GeO}_{4}$ tetrahedra show slight polyhedral distortion and are among the most regular found so far in germanate compounds. The $M$ sites of layer $A$ are occupied by highly charged (trivalent) cations, while in layer $B$ a central pyroxene-like zigzag chain can be identified, which contains divalent (or low-charged) cations. This applies to the aenigmatite-type compounds in general and to the title compound in particular.

## Comment

Syntheses and crystal chemical investigations in the system of 1:3 Na and Li transition-metal germanate pyroxenes have shown that at ambient pressures pyroxene phases $\mathrm{Na} M^{3+} \mathrm{Ge}_{2} \mathrm{O}_{6}\left(M=\mathrm{Cr}, \mathrm{Fe}, \mathrm{Sc}\right.$ and In) and $\mathrm{Li} M^{3+} \mathrm{Ge}_{2} \mathrm{O}_{6}(M=$ $\mathrm{Al}, \mathrm{Ga}, \mathrm{Cr}, \mathrm{Fe}, \mathrm{Sc}$ and In ) can be grown as high-quality single crystals using high-temperature solution (flux) techniques (Redhammer et al., 2008). To extend the range of $M$-cationic substitution in clinopyroxene, the crystallization of $\mathrm{Mn}^{3+}$ bearing Na germanate pyroxenes was attempted, but it was found that the pyroxene structure is not stable; instead, crystals of a new aenigmatite-type phase have been formed, whose crystal structure is described here.

The triclinic aenigmatite group of compounds can be summarized with the general formula $A_{2} B_{6} T_{6} \mathrm{O}_{20}$, where $A=$ Na or Ca in six-to-eightfold coordination, $B$ is octahedrally coordinated $\mathrm{Fe}^{2+}, \mathrm{Fe}^{3+}, \mathrm{Mg}, \mathrm{Al}, \mathrm{Cr}, \mathrm{Ti}^{4+}$ or $\mathrm{Sb}^{5+}$, and $T$ is tetrahedrally coordinated $\mathrm{Si}, \mathrm{Al}, \mathrm{B}$ or Be . The mineral group comprises several naturally occurring minerals, such as aenigmatite itself, $\mathrm{Na}_{2} \mathrm{Fe}_{5} \mathrm{TiSi}_{6} \mathrm{O}_{20}$ (Cannillo et al., 1971), wilkinsonite, $\mathrm{Na}_{2} \mathrm{Fe}_{4}{ }^{2+} \mathrm{Fe}_{2}{ }^{3+} \mathrm{Si}_{6} \mathrm{O}_{20}$ (Burt et al., 2007), krinovite, $\mathrm{Na}_{2} \mathrm{Mg}_{4} \mathrm{Cr}_{2} \mathrm{Si}_{6} \mathrm{O}_{20}$ (Merlino, 1972; Bonaccorsi et al., 1989), rhönite, $\mathrm{Ca}_{2}\left(\mathrm{Mg}, \mathrm{Fe}, \mathrm{Ti}_{6}\right)_{6} \mathrm{Si}_{6} \mathrm{O}_{20}$ (Bonaccorsi et al., 1990), or sapphirine-1Tc, $(\mathrm{MgAl})_{8} \mathrm{Si}_{6} \mathrm{O}_{20}$ (Merlino, 1980); a detailed review of the aenigmatite group is given by Kunzmann (1999). Additionally, the crystal structures of several Be-containing minerals, closely related to the aenigmatite group, have been refined recently, among them surinamite, $\left(\mathrm{Mg}, \mathrm{Fe}^{2+}\right)_{3} \mathrm{Al}_{4^{-}}$ $\mathrm{BeSi}_{3} \mathrm{O}_{16}$ (Barbier et al., 2002), makarochinite, $\mathrm{Ca}_{2} \mathrm{Fe}_{4}{ }^{2+} \mathrm{Fe}^{3+}$ $\mathrm{TiSi}_{6} \mathrm{O}_{20}$ (Grew et al., 2005), and welshite, $\mathrm{Ca}_{2} \mathrm{Mg}_{4} \mathrm{Fe}^{3+} \mathrm{Sb}^{5+}-$ $\mathrm{Si}_{4} \mathrm{Be}_{2} \mathrm{O}_{20}$ (Grew et al., 2007). Besides the naturally occurring species, Barbier (1995) reported the synthetic aenigmatite analog germanate, $\mathrm{Na}_{2}(\mathrm{Mg}, \mathrm{Fe})_{6}(\mathrm{Ge}, \mathrm{Fe})_{6} \mathrm{O}_{18} \mathrm{O}_{2}$, while Yang \& Konzett (2000) describe $\mathrm{Na}_{2} \mathrm{Mg}_{6} \mathrm{Si}_{6} \mathrm{O}_{18}(\mathrm{OH})_{2}$ and Gasparik et al. (1999) report $\mathrm{Na}_{2}\left(\mathrm{Mg}_{4.31} \mathrm{Si}_{0.39} \mathrm{Fe}_{1.3}\right) \mathrm{Si}_{6} \mathrm{O}_{20}$. The title compound is of special interest as it is the first aenigmatitetype material containing Mn as the dominant octahedral cation.

The structure of $\mathrm{Na}_{2}\left(\mathrm{Mn}_{5.26} \mathrm{Na}_{0.74}\right) \mathrm{Ge}_{6} \mathrm{O}_{20}$ contains six distinct octahedrally coordinated $M(M=\mathrm{Mn}$ and Na$)$ sites,

Figure 1
A view of the asymmetric unit and some symmetry-related atoms of the title compound, showing $95 \%$ probability displacement ellipsoids and the atomic numbering scheme. [Symmetry codes: (i) $x+1, y, z$; (ii) $-x,-y+1$, $-z+2$; (iii) $-x+1,-y+1,-z+1$; (iv) $-x+1,-y+1,-z+2$; (v) $x, y$, $z+1$; (vi) $-x+1,-y+2,-z+1$; (viii) $x+1, y, z-1$; (ix) $x, y, z-1$; (x) $-x,-y+2,-z+1$.]
two different sevenfold-coordinated Na sites, six distinct Ge sites and 20 O -atom positions. An anisotropic displacement plot, containing the atomic nomenclature, is given in Fig. 1. The structural topology is described in terms of two layers stacked alternately along the [011] direction (Fig. 2). The first layer, labelled layer $A$ from here on, contains pyroxene-like chains (Ge1-Ge4) extending in the [100] direction with two additional corner-sharing $\mathrm{GeO}_{4}$ tetrahedra attached laterally (Fig. 3a). Within this layer, the tetrahedral chains are connected by isolated octahedra ( Mn 1 and Mn 2 ). The second layer (layer $B$ ) is formed by infinite slabs of edge-sharing octahedra extending along $a$ (M3-M7). These slabs are linked by 'bands' of Na polyhedra (Fig. 3b).

The average $\mathrm{Ge}-\mathrm{O}$ bond lengths within the tetrahedral chain of layer $A$ are similar ( $\sim 1.741-1.747 \AA$ ), except for the Ge3 site, where the average is somewhat smaller (Table 1). This is due to a very small Ge3-O8 bond length [1.699 (5) Å]. Atom O 8 is common to the Ge 3 , the $M 5$ and two $M 6$ polyhedra. The $M 6$ sites, hosting $\mathrm{Na}^{+}$cations, exhibit a low valence sum (Brese \& O'Keeffe, 1991) of 1.47 valence units (v.u.) and are only weakly bound to atom O 8 ; they contribute 0.34 and 0.22 v.u to the valence sum of atom O8. Thus, the remaining two bonds of O 8 to Ge 3 and $M 5$ are expected to be stronger and thus shorter. The Ge1 and Ge4 tetrahedra have two GeO bridging (br) bonds, the $\mathrm{Ge}-\mathrm{O}_{\mathrm{br}}$ distance being typically longer than the nonbridging ( nbr ) $\mathrm{Ge}-\mathrm{O}_{\mathrm{nbr}}$ distances. This is most evident for the Ge 1 tetrahedron, with two short $[\langle\mathrm{Ge}-$ $\left.\mathrm{O}_{\mathrm{nbr}}\right\rangle=1.723$ (5) $\AA$ ] and two long $\left[\left\langle\mathrm{Ge}-\mathrm{O}_{\mathrm{br}}\right\rangle=1.772\right.$ (5) $\AA$ ] bonds. The Ge 2 and Ge 3 tetrahedra have three bridging bonds with neighboring tetrahedra, with $\left\langle\mathrm{Ge}-\mathrm{O}_{\mathrm{br}}\right\rangle$ distances of 1.753 (5) and 1.744 (5) $\AA$, respectively; the difference $\Delta_{b r}=$ $\left\langle\mathrm{Ge}-\mathrm{O}_{\mathrm{br}}\right\rangle-\left\langle\mathrm{Ge}-\mathrm{O}_{\mathrm{nbr}}\right\rangle$ is 0.047 and $0.045 \AA$ for Ge 2 and Ge 3 , respectively.

Synthetic $\mathrm{Na}_{2}\left(\mathrm{Mg}_{3.6} \mathrm{Fe}_{2.4}\right)\left[\left(\mathrm{Ge}_{5.6} \mathrm{Fe}_{0.4}\right) \mathrm{O}_{18}\right] \mathrm{O}_{2}$ shows a more uniform distribution of individual $\mathrm{Ge}-\mathrm{O}$ bond lengths, ranging between 1.722 (2) and 1.781 (2) $\AA$ (Barbier, 1995). The $\langle\mathrm{Ge}-\mathrm{O}\rangle_{\text {br }}$ values are comparable to those in the title

Figure 2
A polyhedral representation of the aenigmatite-type structure, viewed down the [100] direction, displaying the structure of stacked $A$ and $B$ layers.
compound; however, the $\Delta_{\mathrm{br}}$ values are approximately half of the value found here, i.e. the bond-length distortion (Renner \& Lehmann, 1986) is smaller for the title compound (Table 1). The Ge3 tetrahedron [equivalent to $T 4$ in Barbier (1995)] is much more regular and does not display a short $\mathrm{Ge}-\mathrm{O}$ bond pointing towards the $M$-site layer as found in the title compound. However, the trioctahedral unit of Mn6-Mn6 ${ }^{\mathrm{i}}$ Mn5 sites, to which atom O 8 is bonded besides $\mathrm{Ge} 3^{\mathrm{ii}}$ [symmetry codes: (i) $-x+1,-y+2,-z$; (ii) $x, y, z-1$ ], exhibits a less uniform charge distribution in $\mathrm{Na}_{2}\left(\mathrm{Mn}_{5.26}{ }^{-}\right.$ $\left.\mathrm{Na}_{0.74}\right) \mathrm{Ge}_{6} \mathrm{O}_{20}$ than in the Barbier (1995) sample $\mathrm{Na}_{2}\left(\mathrm{Mg}_{3.6}-\right.$ $\left.\mathrm{Fe}_{2.4}\right)\left[\left(\mathrm{Ge}_{5.6} \mathrm{Fe}_{0.4}\right) \mathrm{O}_{18}\right] \mathrm{O}_{2}$. Here $M 6$ is exclusively occupied by $\mathrm{Mg}^{2+}$ and $M 5$ has an $\mathrm{Mg}_{0.74}{ }^{2+} \mathrm{Fe}_{0.26}{ }^{3+}$ composition, while the title compound has - on the basis of bond-valence calculations (Brese \& O'Keeffe, 1991) - an $\mathrm{Na}_{0.74}{ }^{+} \mathrm{Mn}_{0.26}{ }^{2+}$ and $\mathrm{Mn}_{0.32}{ }^{2+} \mathrm{Mn}_{0.68}{ }^{3+}$ composition for $M 6$ and $M 5$, respectively.

Generally, the $\mathrm{GeO}_{4}$ tetrahedra are remarkably regular in the title compound. Both the tetrahedral angle variance (TAV) and the tetrahedral quadratic elongation (TQE) parameters (Robinson et al., 1971) are low, the Ge5 and Ge6 tetrahedra being somewhat more regular than those within the tetrahedral chain. For comparison, distortion parameters found in other germanates are most frequently found in the ranges between 40 and $100^{\circ}$ for TAV, and 1.01 and 1.02 for TQE (Redhammer \& Roth, 2004a, 2006; Redhammer et al., 2005, 2006, 2007a,b,c; Redhammer, Merz et al., 2007). The most regular $\mathrm{GeO}_{4}$ tetrahedra found so far are realized in $\mathrm{Cu}_{2} \mathrm{Fe}_{2} \mathrm{Ge}_{4} \mathrm{O}_{13}$ (the Ge3 site with TAV and TQE values of $1.6^{\circ}$ and 1.0005; Redhammer, Merz et al., 2007) and in $\mathrm{Cu}\left(\mathrm{Cu}_{0.44} \mathrm{Cr}_{4.58}\right) \mathrm{Ge}_{2} \mathrm{O}_{12}$ (with TAV and TQE values of $5.32^{\circ}$ and 1.0013, respectively; Redhammer et al., 2007a). The bondvalence sums of the Ge sites in the title compound are close to the expected value, the $\mathrm{GeO}_{4}$ tetrahedra within the chain being slightly overbonded, while the 'attached' tetrahedra are somewhat underbonded.

The chain of Ge1-Ge4 tetrahedra is distinctly kinked in $\mathrm{Na}_{2}\left(\mathrm{Mn}_{5.26} \mathrm{Na}_{0.74}\right) \mathrm{Ge}_{6} \mathrm{O}_{20}$; the average $\mathrm{O}-\mathrm{O}-\mathrm{O}$ tetrahedral bridging angle is $146.4(1)^{\circ}$, with the individual values ranging between 140.9 (1) and 152.1 (1) $)^{\circ}$ (Table 1). A similar average kinking angle of $143.3^{\circ}$ was found by Barbier (1995) for the $\mathrm{Na}-\mathrm{Mg}-\mathrm{Fe}$ germanate. These $\mathrm{O}-\mathrm{O}-\mathrm{O}$ angles compare well with the tetrahedral bridging angle in germanate clinopyroxenes, e.g. in synthetic $\mathrm{LiFeGe}_{2} \mathrm{O}_{6}$ [137.6 (1) and 151.1 (1) ${ }^{\circ}$ for the $A$ and $B$ chain in the $P 2_{1} / c$ phase at 298 K ; Redhammer et al., 2008] or in $\mathrm{CaCuGe}_{2} \mathrm{O}_{6}$ [with the $A$ and $B$ chains kinked by 139.3 (1) and $179.9(1)^{\circ}$ in the $P 2_{1} / c$ phase at $\sim 720 \mathrm{~K}$, while the bridging angle is 159.4 (1) $)^{\circ}$ in the $C 2 / c$ phase at $\sim 800 \mathrm{~K}$ (Redhammer et al., 2005)]. The aenigmatite-type silicate minerals show bridging angles that are larger by $\sim 10-12^{\circ}$. The average $T-\mathrm{O}$ bond lengths in aenigmatite-type compounds are positively correlated with the average tetrahedral radius of the individual $T$ sites (Table 1); however, no systematic variation is found for any polyhedral distortion parameter. This indicates that the distortional geometry of the tetrahedra is dominated by the geometry of the neighboring polyhedra, especially by the $M$-site cations and by the way in which O atoms are shared between neighbouring sites.

The $M 1$ and $M 2$ octahedra connect individual chains of $\mathrm{GeO}_{4}$ tetrahedra with each other along the $c$ direction. Thereby, the apices of the tetrahedra alternate 'up' and 'down' (Figs. 2 and $3 a$ ). The isolated $M 1$ and $M 2$ sites are characterized by a small $\langle M-\mathrm{O}\rangle$ bond length and are preferentially filled by trivalent or highly charged cations in the aenigmatitetype compounds. In krinovite, $\mathrm{Na}_{2} \mathrm{Mg}_{4} \mathrm{Cr}_{2} \mathrm{Si}_{6} \mathrm{O}_{20}$, these two sites exclusively host $\mathrm{Cr}^{3+}$ (Bonaccorsi et al., 1989), while in rhönite, $\mathrm{Ca}_{2}(\mathrm{Mg}, \mathrm{Fe}, \mathrm{Ti})_{6} \mathrm{Si}_{6} \mathrm{O}_{20}, M 1$ and $M 2$ are characterized by high amounts of $\mathrm{Ti}^{4+}$ (Bonaccorsi et al., 1990). On the basis of bond-valence considerations, Burt et al. (2007) state that M1 and $M 2$ are filled by 84 and $70 \% \mathrm{Fe}^{3+}$ in wilkinsonite, $\mathrm{Na}_{2} \mathrm{Fe}_{6} \mathrm{Si}_{6} \mathrm{O}_{20}$. Finally, $\mathrm{Fe}^{3+}$ clearly dominates $\mathrm{Mg}^{2+}$ in $\mathrm{Na}_{2}(\mathrm{MgFe})\left[(\mathrm{GeFe}) \mathrm{O}_{18}\right] \mathrm{O}_{2}$, having an occupation of $80 \%$ in $M 1$ and M2. In most of the aenigmatite-type compounds, the average $\langle M 1-\mathrm{O}\rangle$ and $\langle M 2-\mathrm{O}\rangle$ distances are - together with $\langle M 7-\mathrm{O}\rangle$ - the smallest of all $\langle M-\mathrm{O}\rangle$ bond lengths. This is also true for the title compound. On the basis of bond-valence calculations, the small $\langle M 1-\mathrm{O}\rangle$ and $\langle M 2-\mathrm{O}\rangle$ values of 2.037 (6) and 2.047 (5) $\AA$ indicate that Mn is almost exclusively in the trivalent state on these two sites. The $M 1$ and $M 2$ polyhedra connect the tetrahedral ' $A$ ' layer with two neighboring ' $B$ ' layers, by sharing four of their edges with the M5 and $M 7$ octahedra (two edges each for the layer above and below the ' $A$ ' layer). In comparison to other aenigmatite-type compounds, it is evident that $\mathrm{Mn}^{3+}$ with its $3 d^{4}$ electronic
configuration causes a distinct distortion to the $M 1$ and $M 2$ sites, expressed by a large BLD value but also by large octahedral angle variance and quadratic octahedral elongation parameters (Table 1). In the silicate aenigmatite-type minerals, these two polyhedra appear to be much more regular (Table 1); the $\mathrm{Na}-\mathrm{Mg}-\mathrm{Fe}$ germanate of Barbier (1995) also exhibits less polyhedral distortion.

The slab of $M$ sites, which is the main building unit of the ' $B$ ' layer in the aenigmatite structure (Figs. 2 and $3 b$ ), hosts the $M 3-M 7$ octahedra. The average $M-\mathrm{O}$ bond lengths range between 2.054 (5) and 2.321 (5) $\AA$, reflecting the mixed occupation with $\mathrm{Mn}^{2+}, \mathrm{Mn}^{3+}$ and $\mathrm{Na}^{+}$. All three cations rarely occupy the $M$ sites in aenigmatite-type compounds known so far. Thus, the $M-\mathrm{O}$ bond lengths in the title compound are amongst the largest reported. Using bond-valence analysis (Brese \& O'Keeffe, 1991), $\mathrm{Mn}^{2+} / \mathrm{Mn}^{3+}$ ratios on the different $M$ sites have been determined in a manner similar to that described by Burt et al. (2007), giving $\mathrm{Mn}^{3+}$ percentages of, respectively, $38 \%$ on $M 3,0 \%$ on $M 4,32 \%$ on $M 5,0 \%$ on $M 6$ and $79 \%$ on $M 7 ; M 1$ and $M 2$ are occupied by $100 \% \mathrm{Mn}^{3+}$, while for $M 6$ the site occupancy is given as $\mathrm{Na}_{0.74} \mathrm{Mn}_{0.26}{ }^{2+}$. Using these $\mathrm{Mn}^{2+} / \mathrm{Mn}^{3+}$ ratios to calculate average cationic radii $\left\langle r_{M}\right\rangle$, a well defined positive correlation is valid between $\langle M-\mathrm{O}\rangle$ and $\left\langle r_{M}\right\rangle$. This trend is well met by data from several other aenigmatite-type compounds (Fig. 4). All ' $B$ '-layer octahedra are connected to each other by corner sharing.

Figure 3
A polyhedral representation of the aenigmatite-type structure, viewed down the [111] direction, depicting (a) the Ge1-Ge6 ' $A$ ' layer and ( $b$ ) the slabs of the $M$-site ' $B$ ' layers.

Along the $a$ direction, a four-octahedron unit, consisting of two $M 3$ and two $M 4$ octahedra, alternates with a six-octahedron unit of two M5, two M6 and two M7 octahedra. The M6 polyhedron thereby is the only one that shares six of its edges with neighboring $M$ polyhedra and shows - by far - the largest average $M-\mathrm{O}$ bond length. This is due to the presence of $\mathrm{Na}^{+}$at $M 6$, a feature not reported so far for the aenigmatite structure type, but also due to the intense edge sharing with the neighboring sites. Among all $M$ sites, the $M 6$ octahedron is the most distorted; the value found for the title compound thereby is the largest reported so far for aenigmatite-type compounds. Generally, the M6 site deviates most from ideal octahedral geometry in the aenigmatite structure (Table 1). A rough positive correlation can be found between average cationic radius $\left\langle r_{M}\right\rangle$ and polyhedral distortion parameters, e.g. between $\left\langle r_{M}\right\rangle$ and OAV for some $M$ sites; this is most evident for the $M 3$ and $M 5$ sites, while the polyhedral distortion of the $M 1, M 2$ and $M 7$ octahedra appears to be independent of $\left\langle r_{M}\right\rangle$ and is dominated by geometric constraints from their neighboring sites. The $M 4$ site displays the second largest $\langle M-\mathrm{O}\rangle$ bond length, reflecting the fact - corroborated by the bondvalence sum - that this site is occupied by $\mathrm{Mn}^{2+}$ exclusively. It is this site which is the most regular in terms of bond length and angular distortion (Table 1). This can be regarded as additional evidence that $M 4$ is occupied only by $\mathrm{Mn}^{2+}$ with its closed-shell $3 d^{5}$ electronic configuration. In most aenigmatitetype compounds, except rhönite, the $M 4$ site is occupied by divalent cations only. In contrast, the $M 7$ site, sharing a common edge with the $M 1$ site of the ' A ' layer, preferentially accommodates highly charged cations, e.g. $\mathrm{Fe}^{3+}$ only in synthetic $\mathrm{Na}_{2}(\mathrm{Mg}, \mathrm{Fe})_{6}(\mathrm{Ge}, \mathrm{Fe})_{6} \mathrm{O}_{18} \mathrm{O}_{2}$ (Barbier 1995), or $\mathrm{Cr}^{3+}$ in krinovite. From this charge distribution, it is evident that, within the ' $B$ '-layer $M 3-M 7$ octahedral slab, a central pyroxene-like zigzag chain of edge-sharing $M 4-M 4-M 6-M 6-$ $M 4 \cdots$ octahedra can be identified which preferentially contains divalent cations or, more generally, cations with low charge, while the $M 3, M 5$ and $M 7$ octahedra, attached to this chain, host - additionally or exclusively - trivalent or higher valent cations. This zigzag chain, which is closely related to the

Figure 4
The correlation between average ionic radius $\left\langle r_{M}\right\rangle$ and $\langle M-\mathrm{O}\rangle$ for the different $M$ sites in different aenigmatite-type compounds.

M1 chain of the clinopyroxene structure, reveals the very same interconnection with the chain of Ge1-Ge4 tetrahedra as is realized in the clinopyroxenes (Fig. 3b). Thus, an alternative description of the aenigmatite-type structure addresses pyroxene-like slabs, which alternate with spinel-like slabs (Barbier, 1995; Yang \& Konzett, 2000).

A major difference between the title compound and other aenigmatite-type compounds lies in the coordination geometry of the $\mathrm{Na}^{+}(A)$ cation. In the title compound, Na exhibits a ( $6+1$ )-fold coordination for both $A$ sites, with six $\mathrm{Na}-\mathrm{O}$ bonds between 2.346 (6) and 2.553 (6) $\AA$, the seventh being 2.805 (6) and 2.793 (6) $\AA$ apart. The next nearest O atoms to Na 1 and Na 2 are 3.249 (6) and 3.234 (6) $\AA$ away and are regarded as nonbonding. A similar observation was made by Barbier (1995) for the synthetic NaMg germanate. These longest coordinating $A-\mathrm{O}$ bond lengths are distinctly shorter in the germanate compounds than in the silicate aenigmatites of Table 1, where the longest $A-\mathrm{O}$ bonds range between 2.95 and $3.06 \AA$. Barbier (1995) states that this $(6+1)$-fold coordination of the Na sites is intermediate between the $(7+1)$-fold coordination as found in, for example, aenigmatite (Cannillo et al., 1971) and the sapphirine structure with the corresponding sixfold-coordinated Mg -rich sites (Barbier, 1995). The coordination of the $A$-site cations is directly related to the conformation state of the pyroxene-like tetrahedral chains. Silicate aenigmatite minerals with their (7+1)-coordination have average tetrahedal kinking angles above $150^{\circ}$, in the synthetic germanates the average kinking angles are 143.3 and $146.3^{\circ}$, while sappirine with the sixfold-coordinated Mg sites shows small tetrahedral kinking angles of $130.3^{\circ}$ only. A well defined negative correlation is valid between the conformation state of the tetrahedral chain and the long distant $A-\mathrm{O}$ bonds, i.e. the more the tetrahedral chains are stretched, the closer the long distant O atoms are moved towards the $A$ cations; in aenigmatite and wilkinsonite with the largest $\langle\mathrm{O}-$ $\mathrm{O}-\mathrm{O}\rangle$ angles, the eighth O atoms in the coordination polyhedron are $\sim 2.95 \AA$ apart and have to be regarded as bonding O atoms leading to the $(7+1)$-fold coordination (Table 1). In the clinopyroxenes, the principal mechanism is similar but reversed: as the tetrahedral chain becomes stretched, the respective O atom corresponding to the largest distance moves out of the coordination environment of the $M 2$ sites, most instructively displayed by the low-temperature behaviour upon the $C 2 / c-P 2_{1} / c$ phase transitions in Li clinopyroxenes (Redhammer et al., 2002, 2004b).

## Experimental

As part of our crystal chemical investigations of $(\mathrm{Na}, \mathrm{Li}) \mathrm{MGe}_{2} \mathrm{O}_{6} 1: 3$ germanate clinopyroxene compounds (Redhammer et al., 2008), the title compound was obtained accidentally during attempts to synthesize $\mathrm{NaMnGe} 2_{2} \mathrm{O}_{6}$ using flux growth methods. A finely ground and homogenized mixture of $\mathrm{Na}_{2} \mathrm{CO}_{3}, \mathrm{Mn}_{2} \mathrm{O}_{3}$ and $\mathrm{GeO}_{2}$ in the stoichiometry $\mathrm{NaMnGe}_{2} \mathrm{O}_{6}$ was added to the high-temperature solvent ( $80 \mathrm{wt} \% \mathrm{Li}_{2} \mathrm{MoO}_{4}$ and $20 \mathrm{wt} \% \mathrm{LiVO}_{3}$ ) in a ratio of educt to flux of $1 \mathrm{~g}: 10 \mathrm{~g}$. This starting material was placed in a platinum crucible, covered with a lid and heated in a chamber furnace to 1473 K , held for 24 h at this temperature, and cooled to 973 K at a

## inorganic compounds

rate of $1.8 \mathrm{~K} \mathrm{~h}^{-1}$. After dissolution of the flux in hot distilled water, dark-brown-to-black needle-like crystals were obtained. Chemical analysis was performed on three different grains using an electron microprobe, indicating $7.60 \% \mathrm{Na}_{2} \mathrm{O}, 33.62 \% \mathrm{MnO}$ and $56.42 \mathrm{GeO}_{2}$ by weight; no other elements are present in the sample, as proved by energy dispersive X-ray analysis. On the basis of 20 O atoms and the $\mathrm{Mn}^{2+} / \mathrm{Mn}^{3+}$ ratio extracted from bond-valence calculations, this gives rise to the structural formula $\mathrm{Na}_{2.73 \text { (2) }} \mathrm{Mn}_{5.28 \text { (1) }} \mathrm{Ge}_{6.01 \text { (2) }} \mathrm{O}_{20}$, which is identical to the formula derived from structure refinement within experimental error.

Structure solution using Patterson methods (Sheldrick, 1997) yielded the Ge and Mn positions; O atoms and Na atoms were localized from difference Fourier map analysis. After full anisotropic refinement against $F^{2}$ with all the $M$ sites filled with Mn , it became evident that the Mn6 site is partly empty or partly substituted. Allowing the site-occupation factor of Mn6 to refine freely yielded an occupation of 0.43 Mn , significantly below the expected value of 1 , and a drop of the $R 1$ value by nearly $4 \%$. As chemical analysis showed an Na content above the expected 2.0 formula units, a mixed occupation of $M 6$ with Mn and Na was tested. The refinement converged to an occupation very close to that expected from chemical analysis.

Data collection: SMART-Plus (Bruker, 2001); cell refinement: SAINT-Plus (Bruker, 2001); data reduction: SAINT-Plus; program(s) used to solve structure: SHELXS97 (Sheldrick, 2008); program(s) used to refine structure: SHELXL97 (Sheldrick, 2008); molecular graphics: DIAMOND (Version 3.0; Brandenburg \& Berndt, 1999);
software used to prepare material for publication: WinGX (Version 1.70.01; Farrugia, 1999).
