Crystallization and preliminary crystallographic analysis of the Magnetospirillum magneticum AMB-1 and M. gryphiswaldense MSR-1 magnetosome-associated proteins MamA

MamA is a unique magnetosome-associated protein that is predicted to contain six sequential tetratricopeptide-repeat (TPR) motifs. The TPR structural motif serves as a template for protein–protein interactions and mediates the assembly of multi-protein complexes. Here, the crystallization and preliminary X-ray analysis of recombinant and purified Magnetospirillum magneticum and M. gryphiswaldense MamA are reported for the first time. M. gryphiswaldense MamA Δ 41 crystallized in the tetragonal space group $P_{12,12}$ or $P_{32,12}$, with unit-cell parameters $a = b = 58.88$, $c = 144.09$ Å. *M. magneticum* MamA Δ 41 crystallized in the orthorhombic space group $P2_12_12_1$, with unit-cell parameters $a = 44.75$, $b = 76.19$, $c = 105.05$ Å. X-ray diffraction data were collected to resolutions of 2.0 and 1.95 \AA , respectively.

1. Introduction

The tetratricopeptide repeat (TPR) is a structural motif that is found in a wide range of proteins as an independent fold or as a segment of a fold and serves as a template for protein–protein interactions that can mediate the assembly of multi-protein complexes (D'Andrea & Regan, 2003). TPRs are thus involved in many different processes in a eukaryotic cell, including synaptic vesicle fusion (Young et al., 2003), peroxisomal targeting and import (Brocard & Hartig, 2006; Fransen et al., 2008) and mitochondrial and chloroplast import (Baker et al., 2007; Mirus et al., 2009). In addition, TPRs are required for many bacterial pathways involving outer membrane assembly (Gatsos et al., 2008) and pathogenesis (Tiwari et al., 2009; Edqvist et al., 2006). One unique bacterial system that requires TPR proteins is the magnetosome of magnetotactic bacteria.

Magnetotactic bacteria comprise a diverse group of aquatic microorganisms that have the unique ability to navigate along geomagnetic fields, a behaviour that is believed to simplify their search for transition environments such as the oxic–anoxic transition zone (Faivre & Schuler, 2008). In these microorganisms, the biomineralization of iron takes place in the magnetosome, a specialized subcellular organelle that is assembled from a chain of bilayer lipid vesicles that each induce the deposition of, and enclose an \sim 50 nm crystal of, magnetite or its sulfide analogue greigite ($Fe₃S₄$). This organelle is characterized by its ability to essentially grow one magnetite crystal per vesicle under ambient conditions.

Magnetosome formation and magnetite biomineralization are controlled by a large set of proteins that includes unique soluble and integral membrane proteins (Schuler, 2008; Murat et al., 2010). Comparison of magnetospirillum species (i.e. Magnetospirillum magneticum AMB-1, M. magnetotacticum MS-1 and M. gryphiswaldense MSR-1) has shown that genes encoding magnetosome proteins are situated on a single genomic island that contains four main operons, termed mamAB, mamCD, mms6 and mamXY (Jogler, Kube et al., 2009). Deletion of the magnetosome-related genomic island from the genome results in loss of magnetic orientation (Bazylinski & Frankel, 2004; Komeili, 2007). Studies of magnetosome-forming genes have revealed that the biomineralization process is controlled by these four operons, with the mamAB operon being assumed to be involved in iron transport and magnetosome-vesicle alignment (Scheffel et al., 2008; Amemiya et al., 2007; Schuler, 2008; Komeili, 2007). Accordingly, the sequencing of additional magnetotactic bacterial genomes revealed a high degree of conservation within the mamAB operon (Schubbe et al., 2009; Matsunaga et al., 2009; Jogler, Kube et al., 2009; Jogler, Lin et al., 2009).

One of the most highly conserved magnetosome-associated proteins is MamA (also known as Mms24 and Mam22). Copurification of MamA with magnetosome vesicles indicated that MamA accounts for \sim 10% of the magnetosome-associated proteins (Grunberg et al., 2004); while deletion of MamA does not affect vesicle formation, it does result in the appearance of shorter magnetosome chains, thereby limiting iron accumulation (Komeili et al., 2004). MamA is targeted to the magnetosomal matrix (Taoka et al., 2006). Moreover, complementation of a Δm amA mutant with greenfluorescent-protein-tagged MamA showed the protein to be localized to the magnetosome during the logarithmic but not the stationary phase of growth (Komeili et al., 2004). However, the role of MamA in magnetosome function remains unresolved.

To analyze the structure–function relationship of MamA and to elucidate structure-based differences between Magnetospirillum magnetotactic bacterial species, we have initiated crystallographic studies of the MamA protein from M. magneticum AMB-1 and M. gryphiswaldense MSR-1. Here, we report the crystallization and preliminary X-ray analysis of a truncated version of MamA $(MamA\Delta41)$.

2. Materials and methods

2.1. Expression of the $m a \Delta 41$ gene in Escherichia coli

The truncated $m a m A \Delta 41$ gene was amplified using the polymerase chain reaction (PCR) from the genomic DNA of two species of magnetotactic bacteria, i.e. M. magneticum AMB-1, using the primers AMB-1-f, 5'-GCATTACGCATATGGACGACATCCGCCAGGTG-3', and AMB-1-r, 5'-GCGCGGCAGCCATATGGCATACG-3', and M. gryphiswaldense MSR-1, using the primers MSR-1-f, 5'-GCAT-TACGCATATGGATGACATTCGTCAGGTGTATTACCG-3', and MSR-1-r, 5'-GCGCGGCAGCCATATGGCATACG-3'. The primers were designed to introduce an NcoI site at the initiation codon, ATG, followed by a glycine-encoding codon (GGA) to maintain the reading frame. The termination codon was replaced by an ScoI site. The fragments were digested with NcoI and SacI and cloned into the respective sites of plasmid $pET52b(+)$, giving rise to plasmids pET52bMamA Δ 41-MSR1 and pET52bMamA Δ 41-AMB1. In these constructs, the $m a m A \Delta 41$ genes were fused in-frame to express a $His₁₀$ tag at the C-terminus of the protein.

E. coli strain BL21 harbouring plasmid pET52bMamA∆41 were grown in auto-induction medium (Studier, 2005) containing ampicillin (50 mg ml⁻¹) at 310 K for 3 h. The cultivation temperature was then shifted from 310 to 300 K for a further 48 h. The cells were harvested by centrifugation at 5465g for 10 min at 277 K.

2.2. Purification of MamA Δ 41

MamA Δ 41-MSR-1-expressing cells were suspended in buffer A (20 mM Tris–HCl pH 8, 1 M NaCl, 20 mM imidazole) and incubated with DNase I (1 mg ml⁻¹) and EDTA-free protease-inhibitor cocktail (P8849, Sigma) for 20 min at 277 K. The cells were then disrupted by two cycles in a French press pressure cell at 172 MPa. Cell debris was separated by centrifugation at 270 000g for 1 h at 277 K and the soluble fraction was applied onto a home-made gravity Ni–NTA column (4 ml bed volume, 2.5 cm diameter; Econo-Column Chromatography Columns from Bio-Rad containing Ni–NTA His-Bind Resin, Lot M0063428 from Novagen) pre-equilibrated with buffer A. The protein was washed with 100 ml buffer $B(20 \text{ m})$ Tris–HCl pH 8, $1 M$ NaCl, 40 mM imidazole) and and eluted with buffer C (20 mM Tris–HCl pH 8, 5 mM NaCl and 500 mM imidazole). To remove the His₁₀ tag, bovine thrombin $(10 \text{ U ml}^{-1}$; 9002-04-4, Fisher Bio Reagents) was added to the eluted protein and the mixture was dialyzed against buffer D (10 mM Tris–HCl pH 8, 5 mM NaCl) for 16 h at 277 K. The protein was applied onto a MonoQ column (4.6/100 PE, GE Healthcare Biosciences) equilibrated with buffer E (10 m) Tris–HCl pH 8, 40 mM NaCl) and eluted with a linear gradient of 40–1000 mM NaCl in buffer C. The relevant protein peak was collected and dialyzed against buffer D for 4 h at 277 K. The protein was concentrated to a concentration of 8 mg ml^{-1} using a Vivaspin-4 (10 000 molecular-weight cutoff; Sartorius Stedim Biotech GmbH) and then applied onto a size-exclusion column (HiLoad 26/60 Superdex 200, GE Healthcare Biosciences) equilibrated with buffer D. Purified MamA Δ 41-MSR1 was then concentrated to 17.0 mg ml⁻¹ for crystallization, flash-frozen in liquid nitrogen and stored at 193 K. The sample purity at this stage was analyzed by SDS–PAGE and protein identification was confirmed by tandem mass spectroscopy. The purification of $MamA\Delta 41$ -AMB1 was similar to that of MamA Δ 41-MSR1 with small modifications to the NaCl concentrations, as described elsewhere (Zeytuni & Zarivach, 2010).

2.3. Crystallization

MamA Δ 41 was crystallized using the sitting-drop vapour-diffusion method at 286 K. 0.5 µl MamA Δ 41 (AMB-1, 20 mg ml⁻¹; MSR-1, 17 mg ml⁻¹) and 0.5 µl reservoir solution were mixed to form the drop. The initial crystallization conditions were examined using commercial screening kits from Hampton Research (Crystal Screen 1, Crystal Screen 2, Index and PEG/Ion Screen), Emerald BioSystems (Cryo I and Wizard I and II) and Molecular Dimensions (Structure Screen I and II and ProPlex).

2.4. Diffraction data collection

Crystals were harvested and flash-cooled in liquid nitrogen without addition of cryoprotecting solution. Diffraction data were collected on beamline ID14-2 of the ESRF (Grenoble, France), which is equipped with an ADSC Q4 CCD detector. Data collection was performed at 100 K. For the MamA Δ 41 (MSR-1) data set, a total of 360 frames were collected with an oscillation range of 1° and an exposure time of 8 s per image. The crystal-to-detector distance was 155 mm. For the Mam $A\Delta 41$ (AMB-1) data set, a total of 180 frames were collected with an oscillation range of 1° and an exposure time of 8 s per image. The crystal-to-detector distance was 160 mm. The data were processed using MOSFLM (Leslie, 2003), POINTLESS (Evans, 2006) and SCALA from the CCP4 program suite (Collaborative Computational Project, Number 4, 1994).

3. Results and discussion

The secondary-structure model suggested by Okuda & Fukumori (2001) for AMB-1 MamA shows that the putative TPR motif in the N-terminal region of the protein contains amphiphilic residues. We have constructed a secondary-structure and sequence alignment based on protein-homology models found using the HH-Pred server (http://toolkit.tuebingen.mpg.de/hhpred). The final models were built according to the top seven previously determined structures. Although these templates are highly similar in secondary structure

Figure 1

Micrographs of (a) the MamA Δ 41 MSR-1 and (b) the MamA Δ 41 AMB-1 crystals.

Table 1

Diffraction data and processing statistics.

Values in parentheses are for the highest resolution shell.

† $R_{\text{merge}} = \sum_{hkl} \sum_i |I_i(hkl) - \langle I(hkl) \rangle| / \sum_{hkl} \sum_i I_i(hkl)$, where $I_i(hkl)$ is the observed intensity of an individual reflection and $\langle \overline{I(hkl)} \rangle$ is the mean intensity of that reflection.

(overall E value of $>1 \times 10^{-30}$), their sequence identity to MamA Δ 41 is significantly lower, in the range 20–30%. These seven templates were PDB entries 3cv0 (peroxisomal targeting signal 1 receptor PEX5; Sampathkumar et al., 2008), 1fch (peroxisomal targeting signal 1 receptor; Gatto et al., 2000), 2q7f (YrrB protein; Han et al., 2007), 2pl2 (hypothetical conserved protein TTC0263; Lim et al., 2007), 2ho1 (type 4 fimbrial biogenesis protein, PilF; J. Koo, L. Sampaleanu, P. Yip, S.-Y. Ku, D. Neculai, A. Yu, L. L. Burrows & P. L. Howell, unpublished work), 1w3b (O-linked GlcNAc transferase; Jinek et al., 2004) and 2gw1 (mitochondrial precursor protein import receptor; Wu & Sha, 2006). These models also suggest that MamA contains six sequential TPR motifs which create a superhelix-like structure. Furthermore, a general search of the PDB revealed that TPRcontaining proteins were only able to crystallize after deletion of the N-terminal extensions. Taking these findings into consideration, we decided to delete the putative TPR repeat corresponding to the first 40 amino acids. Subsequently, we were able to purify and crystallize MamA∆41 from both species (Fig. 1).

 $MamA\Delta 41$ from both species was expressed in $E.$ coli and purified to homogeneity, with a yield of approximately 60 mg purified protein from 60 g bacterial culture. MamA Δ 41 (MSR-1) crystals appeared using Index condition No. 5 (2 M ammonium sulfate, 0.1 M HEPES pH 7.5). These conditions were further refined and resulted in MamA Δ 41 (MSR-1) crystals that were grown with altered reservoir conditions (1.65 M ammonium sulfate, 0.1 M HEPES pH 8.2, 0.1 mM NaCl). MamA Δ 41 (AMB-1) crystals appeared using Index condition

 (b)

No. 85 [0.2 M magnesium chloride, 0.1 M Tris–HCl pH 8.5, 25%(w/v) PEG 3350]. These conditions were further refined and $MamA\Delta41$ (AMB-1) crystals were grown with altered reservoir conditions [0.1 *M* magnesium chloride, 0.1 *M* Tris–HCl pH 8.5, 25%(w/v) PEG 3350].

Crystals of Mam $A\Delta 41$ (MSR-1) were reproducibly obtained in space group $P4_12_12$ or $P4_32_12$, which are enantiomorphic space groups that both fulfil the systematic absence rules. Further validation of the chosen space groups was perform by POINTLESS, which indicated that the space-group choices were correct, with a symmetryabsence probability of 0.885 each. The unit-cell parameters were $a = b = 58.88$, $c = 144.09$ Å (Table 1), with diffraction to a resolution of 2.0 Å. Assuming the presence of one monomer per asymmetric unit, the calculated V_M value (Matthews, 1968) and solvent content were $3.12 \text{ Å}^3 \text{ Da}^{-1}$ and 60.59%, respectively, both of which are within the normal range of values observed for soluble protein crystals. Crystals of MamA Δ 41 (AMB-1) were reproducibly obtained in space group $P2_12_12_1$ (POINTLESS symmetry-absence probability of 0.908 and total probability of 0.898), with unit-cell parameters $a = 44.75$, $b = 76.19$, $c = 105.05$ Å (Table 1), with diffraction to a resolution of 1.95 Å. Assuming the presence of two monomers per asymmetric unit, the calculated V_M value (Matthews, 1968) and solvent content are 2.24 \AA ³ Da⁻¹ and 45.06%, respectively.

MamA is the first magnetosome-associated protein as well as the first TPR-containing protein from magnetotactic bacteria to be crystallized and will lead to the determination of the first magnetosome-associated protein structure. These crystals should be sufficient for structural determination, as they diffracted to high resolution and yielded data sets with a low R_{merge} and high redundancy. To determine the structure and to differentiate between the two possible tetragonal space groups, molecular-replacement methodologies will be applied. For this protocol, the constructed homology models and TPR-containing protein structures will be used. Such molecularreplacement experiments are ongoing.
