to Fig. 3 (a) would account only for the maxima $A, B$ and $D$, but leave $C$ and $E$ unexplained, all these maxima would be expected on assuming a type of structure shown in Fig. 3 (b). On the other hand, no unobserved maxima could be derived on that basis, whereas Fig. $3(a)$ would demand maxima $F, G$ and $H$.

The existence of seven layers seems more likely than of five, for in the latter case the side chains or haem groups would have to be responsible for the extension of the molecule in the $c^{\prime}$ direction being at least 56 A . instead of about 42 A .-the width of the five layers. The outline of the model represented by Fig. 4 is actually based on the assumption of seven layers.

It is possible to tackle the problem of the shape of the molecule from a different angle, starting from the above-mentioned hypothesis that short-range forces are keeping the molecules in position in the crystals at all states of swelling or shrinkage. The experimental data to be explained on this basis are the varying lattice constants of the dry, partly wet, wet and expanded crystals, as measured by Boyes-Watson et al. (1947, Tables 1 and 3, p. 93). They would be consistent with a cross-section of the molecule like the one shown in Fig. 4 in the arrangements it would assume in the dry,
normal wet, and expanded crystal. But this is not the only model consistent with these data. It should only serve as an example which seems preferable to all models suggested up to the present, in so far as it would be in keeping with (i) the one-dimensional Fourier projection (on $c^{\prime}$ ) of the molecule, (ii) the Patterson projection (on the $b, c$ plane) of the normal wet crystal, and (iii) the lattice constants of the various stages of swelling and shrinkage explained on the basis of short-range forces only. Further experimental data will have to be used to reject or confirm the outline of this model and, perhaps, to refine it.

# The Crystal Structure of Hollandite, the Related Manganese Oxide Minerals, and $\alpha-\mathbf{M n O}_{2}$ 

By Anders Byström and Ann Marie Byström<br>Institute of General and Physical Chemistry, University of Stockholm, and Geological Survey of Sweden, Stockholm 50, Sweden

(Received 8 August 1949)
Hollandite, cryptomelane, coronadite and $\alpha-\mathrm{MnO}_{2}$ form an isostructural series of the general formula $A_{2-y} B_{8-z} X_{16}, A$ being large ions such as $\mathrm{Ba}^{2+}, \mathrm{Pb}^{2+}$, and $\mathrm{K}^{+}, B$ small and medium-sized ions such as $\mathrm{Mn}^{4+}, \mathrm{Fe}^{3+}, \mathrm{Mn}^{2+}$, and $X$ in the cases investigated $\mathrm{O}^{2-}$ and $\mathrm{OH}^{-}$ions. The unit cell, which contains one formula unit, is tetragonal or pseudotetragonal, in the latter case monoclinic. Approximate dimensions of the tetragonal unit cell are $a=9.8$ and $c=2.86 \mathrm{~A}$. When deformed the short axis will be the $b$ axis of the monoclinic cell. The deviation of $\beta$ from $90^{\circ}$ is $0.5-1.5^{\circ}$, and the difference $a-c$ is $0 \cdot 1-0 \cdot 2 \mathrm{~A}$. The space group of the tetragonal cell is $C_{4 h}^{5}-I 4 / \mathrm{m}$ and the atomic positions are

$$
\begin{gathered}
\left(0,0,0 ; \frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right)+\quad \begin{array}{l}
2-y A \text { in } 2(b): \quad 0,0, \frac{1}{2} ; \\
8-z B \text { in } 8(h): \\
8 X \text { in } 8(h): \quad x_{1}, y_{1}, 0 ; \bar{x}_{1}, \bar{y}_{1}, 0 ; \bar{y}_{1}, x_{1}, 0 ; y_{1}, \bar{x}_{1}, 0 ; \\
8 X \text { in } 8(h): \quad x_{3}, y_{3}, 0 ; \text { etc. }
\end{array} . \\
8
\end{gathered}
$$

For a hollandite specimen the parameters were calculated to be

$$
\begin{array}{lll}
x_{1}=0.348, & x_{2}=0.153, & x_{3}=0.542 \\
y_{1}=0.167, & y_{2}=0.180, & y_{3}=0.167
\end{array}
$$

The $A$ ion is surrounded by eight oxygen ions at a distance of 2.74 A . forming a cube and at a greater distance ( 3.31 A .) by four oxygen ions forming a square at the same $z$ level as the $A$ ion. The $B$ ion is surrounded by six oxygen ions forming an octahedron, and with a mean distance of $B-\mathrm{O}=1.98 \mathrm{~A}$.
In the cases investigated, the variable $y$ in the general formula varies from 0.8 to 1.3 and $z$ from $0 \cdot 1$ to $0 \cdot 5$.

## 1. Introduction

In the course of a study of manganese oxides, precipitates consisting of $\alpha-\mathrm{MnO}_{2}$ were obtained by the
reduction of a $\mathrm{KMnO}_{4}$ solution by various reagents, for instance, $\mathrm{H}_{2} \mathrm{O}_{2}$ and HCl . As has been stated previously (Cole, Wadsley \& Walkley, 1947), and as we could con-
firm, the X-ray powder photographs of these preparations showed that there must be a close structural similarity between $\alpha-\mathrm{MnO}_{2}$ and some of the manganese oxide minerals, namely, cryptomelane, hollandite and coronadite. The powder photographs of $\alpha-\mathrm{MnO}_{2}$ showed the characteristic broadening of the reflexions which is caused by very small crystallites. Heat-treated samples gave somewhat sharper reflexions, but it was impossible to obtain crystals large enough for rotation and Weissenberg methods. Hydrothermal syntheses also failed to produce such crystals. As no definite conclusions regarding the composition and structure of $\alpha-\mathrm{MnO}_{2}$ could be drawn from powder photographs alone, we determined to investigate also the above-mentioned manganese oxide minerals.

For the nomenclature of the manganese oxide minerals the rules recommended by Fleischer \& Richmond (1943) have been applied. Their description of the chemical and X-ray characteristics of the minerals can be summarized as follows: The general formula is probably $A R_{8} \mathrm{O}_{16}$ with $A=\mathrm{K}, \mathrm{Pb}$ and Ba , and $R=\mathrm{Mn}^{4+}$ chiefly. The minerals contain $0-5 \%$ non-essential water. The symmetry is tetragonal (cryptomelane) or pseudotetragonal (coronadite and hollandite), in which case probably triclinic.

The size of the unit cell of cryptomelane has been determined by Ramsdell (1942) to be $a=9 \cdot 82, c=2 \cdot 86 \mathrm{~A}$. and by Richmond \& Fleischer (1942) to be $a=9 \cdot 82$, $c=2.83 \mathrm{~A}$. The reflexions indicate a body-centred cell. Frondel \& Heinrich (1942) made unsuccessful efforts to index the powder patterns of coronadite and hollandite with this cell. However, they could index nearly all lines in terms of another body-centred tetragonal cell with $a=6.95, c=5.72 \mathrm{~A}$. for coronadite and $a=6.94$, $c=5.71 \mathrm{~A}$. for hollandite. For coronadite they suggested the formula $\mathrm{MnPbMn} \mathrm{O}_{6} \mathrm{O}_{14}$ or $\mathrm{MnPbMn}_{6} \mathrm{O}_{14} \mathrm{H}_{2} \mathrm{O}$. Hollandite was looked upon as the barium analogue of coronadite, perhaps ( MnFe ) $\mathrm{BaMn}_{6} \mathrm{O}_{14}$. As will be seen, there is a close relationship between the unit cell of cryptomelane and that suggested for hollandite and coronadite: $6.95 \sqrt{ } 2=9.82$ and $5 \cdot 72 / 2=2 \cdot 86$. Richmond \& Fleischer (1942) remark that the powder and Weissenberg photographs of cryptomelane and hollandite are nearly identical and suggest that the three minerals are isostructural. Gruner (1943) assumes a complicated general formula for the three minerals, namely,

$$
\begin{aligned}
& \mathrm{Mn}_{8-\left(\frac{1}{2} x+\frac{1}{2} y+\frac{1}{2} z\right)}^{4}\left(\mathrm{Mn}^{2}, R^{2}\right)_{x}(\mathrm{~K}, \mathrm{Na})_{y}(\mathrm{Ba}, \mathrm{~Pb})_{z} \\
& \mathrm{O}_{16}\left(\mathrm{H}_{2} \mathrm{O}\right)_{2-(y+z)} .
\end{aligned}
$$

## 2. Unit cell and formula of hollandite

During an investigation of Swedish manganese ores by Ödman (1947) a number of mineral specimens were collected, which, by X-ray powder photographs, were shown to belong to the hollandite-coronadite-cryptomelane isostructural series. From these specimens a number of prismatic crystals were selected, and rotation and Weissenberg photographs were taken with the
prism axis as rotation axis. All rotation photographs showed a period of about 2.85 A . in this direction.

However, the Weissenberg photographs differed considerably. For a crystal picked out from hollandite I (see below), the Weissenberg photographs showed the tetragonal Laue symmetry $C_{4 h}$ with $a \doteqdot 9.9 \mathrm{~A}$. The powder photographs could not be indexed with a tetragonal cell. Several reflexions were split, but this could be accounted for if a small monoclinic deformation was assumed with the tetragonal $c$ axis as $b$ axis in this monoclinic cell. In other cases, the Weissenberg photographs also showed the lower symmetry, but then the crystals always consisted, not of one individual only, but of two or more. In the case of hollandite ir, there appears a very weak reflexion in the powder photographs at a slightly larger glancing angle than 020 (Table 4). This reflexion cannot be indexed with the same cell as the other reflexions. It seems probable that it indicates the presence of another hollandite phase in this specimen with a slightly smaller $b$ axis ( 2.857 instead of 2.875 A.). For all reflexions with $k=1$ this difference in $b$ axis will make a very small difference in glancing angle ( 0.0020 in the value of $\sin ^{2} \theta$ ), and as all the reflexions in these photographs are broadened, a further splitting of the reflexions due to the presence of another phase will be impossible to recognize. However, from the relative intensities of the two 020 reflexions it seems that this other phase is present in an amount of about $10-20 \%$. For hollandite I and for the main constituent in hollandite ir the following cell dimensions are obtained from the powder photographs ( $\mathrm{Cr} K \alpha=2 \cdot 2909 \mathrm{~A}$.):

$$
\begin{array}{ll}
\text { Hollandite I (162/43) } & \text { Hollandite II (294/43) } \\
a=9.91 \pm 0.01 \mathrm{~A} . & a=10.00 \pm 0.01 \mathrm{~A} . \\
b=2 \cdot 872 \pm 0.003 \mathrm{~A} . & b=2.879 \pm 0.003 \mathrm{~A} . \\
c=9.75 \pm 0.01 \mathrm{~A} . & c=9.72 \pm 0.01 \mathrm{~A} . \\
\beta=90.6^{\circ} & \beta=91.1^{\circ} \\
V=278 \cdot 0 \mathrm{A.}^{3} & V=278.8 \mathrm{A.}^{3}
\end{array}
$$

The reflexions of the powder photographs are listed in Table 4.

Analyses on carefully selected material were carried out by A. Bygdén. The coarse material was washed with $\mathrm{SO}_{2}$ water and dilute HCl (room temperature) to dissolve the pyrolusite from the surface of the material used for analyses, whereafter particles with a specific gravity less than 3.94 were separated with Clerici solution. These particles amounted to about $0 \cdot 15 \%$ of the original sample. The analyses are given in Table 1. In Table 2 the number of atoms are calculated with the assumption of 16 oxygen ions + hydroxyl ions in the unit cell.

For the chief metal components the following ionic radii are valid:
$\begin{array}{llll}\mathrm{Mn}^{4+} & 0.50 \mathrm{~A} . & \mathrm{Fe}^{3^{+}} & 0.60 \mathrm{~A} .\end{array} \quad \mathrm{Na}^{+} 0.95 \mathrm{~A} . \quad \begin{array}{ll}\mathrm{Ba}^{2+} & 1.35 \mathrm{~A} . \\ \mathrm{Al}^{3+} & 0.50 \mathrm{~A} .\end{array} \mathrm{Mn}^{2+} 0.80 \mathrm{~A} . \quad \mathrm{K}^{+} \quad 1.33 \mathrm{~A} . \quad \mathrm{Pb}^{2+} \mathrm{l} .21 \mathrm{~A}$.
Apparently the true oxidation state of the elements in the minerals cannot be deduced from the analyses. From
the fact that hollandite and coronadite are isostructural, it seems safe to deduce that the lead is present as $\mathrm{Pb}^{2+}$ ions. It seems reasonable to assume that in a mineral with $\mathrm{Mn}^{4+}$ as dominating component, iron is present as $\mathrm{Fe}^{3+}$ ions. The manganese atoms are given as $\mathrm{Mn}^{4+}$ ions and $\mathrm{Mn}^{2+}$ ions. This is obviously quite arbitrary; they could as well be divided into $\mathrm{Mn}^{4+}$ and $\mathrm{Mn}^{3^{+}}$ions, the

latter with an ionic radius of 0.62 A . If the ions are divided into three groups, small, medium-sized, and large ions, the following formulas for the cell contents are obtained:

Hollandite I:
$\left(\mathrm{Mn}^{4+}, \mathrm{Al}, \mathrm{Si}_{6} \cdot 776 \text { ( } \mathrm{Fe}, \mathrm{Mn}^{2+}\right)_{1 \cdot 113}(\mathrm{Ba}, \mathrm{K}, \mathrm{Pb}, \mathrm{Na})_{1 \cdot 02} \mathrm{O}(\mathrm{OH})_{16}$. Hollandite II:
$\left(\mathrm{Mn}^{4+}, \mathrm{Al}, \mathrm{Si}\right)_{5 \cdot 977}\left(\mathrm{Fe}, \mathrm{Mn}^{2+}, \mathrm{Ti}\right)_{1 \cdot 835}(\mathrm{Ba}, \mathrm{Pb}, \mathrm{K}, \mathrm{Na})_{0 \cdot 979} \mathrm{O}(\mathrm{OH})_{16}$.
With these cell contents, the specific gravities were calculated to be 4.721 and 4.884 respectively, as compared with the experimental values of $4 \cdot 705$ and $4 \cdot 964$.

## 3. Symmetry, space group and structure of hollandite

As was mentioned previously, some Weissenberg photographs showed the tetragonal symmetry $C_{4 h}$, whereas others indicated a monoclinic unit cell. In the following, indices referring to a tetragonal cell are denoted with the subscript $t$, and those referring to a monoclinic cell with the subscript $m$. The axis of the two cells are related in the following way:

$$
a_{t}=a_{m}, \quad b_{t}=c_{m} \quad \text { and } \quad c_{t}=b_{m}
$$

In all the Weissenberg photographs only reflexions with $h+k+l=2 n$ appeared. No special space-group criteria were valid. Possible space groups in the tetragonal system are $C_{4 n}^{5}-I 4 / m, C_{4}^{5}-I 4$ and $S_{4}^{2-I \overline{4}}$, and in the monoclinic system $C_{2 h}^{3}-I 2 / m, C_{2}^{3}-I 2$ and $C_{s}^{3}-I m$. The monoclinic deformation is very small, and therefore it is justified to assume the same atomic arrangement as

Hollandite r and Hollandite n , see Table 1 this paper.
Coronadite 5 from Bou Tazoult, Morocco. Analysis from paper by Lindgren (1933). Cell dimensions determined from powder photographs with focusing cameras from a specimen presented to the Mineralogical Institute of the University of Stockholm by Muséum National d'Histoire Naturelle, France.

Cryptomelane 1 from Tombstone, Arizona. Analysis from a paper by Richmond \& Fleischer (1942). Cell dimensions are determined from a specimen presented to the Geological Survey of Sweden by Mr Fleischer.

The numbers 5 for coronadite and 1 for cryptomelane are retained for comparison of the same minerals in papers by Frondel \& Heinrich, and Gruner respectively.
in the tetragonal cell, which gives the following intensity relations:

$$
I\left(h_{m} k_{m} l_{m}\right)=I\left(\bar{l}_{m} k_{m} h_{m}\right), \text { and } I\left(h_{m} k_{m} \bar{l}_{m}\right)=I\left(l_{m} k_{m} h_{m}\right)
$$

In fact, a very well-exposed zero-layer line of a monoclinic crystal showed only small deviations from these intensity relations.

The intensities used for the structure determination were taken from Weissenberg photographs (Cr $K$ radiation) of a crystal picked out from the specimen hollandite I (see Tables I and 2). In spite of the fact that the powder photographs showed a monoclinic deformation of the unit cell, the Weissenberg photographs did not show any deviation from tetragonal symmetry, and the precision of the camera was certainly sufficient to show the difference of length between $a_{m}$ and $c_{m}$. However, weak additional reflexions indicate the presence of the monoclinic phase, and in view of the fact that the reflexions from both have the same relative intensity, the analysis used is assumed to be valid for either.

In the estimation of the intensities the relation $I_{\alpha} / I_{\beta}=7$ was used. The intensity of 440 was arbitrarily taken as 100 . From the estimated values of $I,|F|_{\text {obs }}$ was calculated by the formula $|F|_{\text {obs. }}=\left\{I \sin \gamma \frac{2}{\cos ^{2} 2 \theta}\right\}^{\frac{1}{2}}$ (Kaan \& Cole, 1949). All the $|F|_{\text {obs. }}$ values were then multiplied by a constant to make the sum of the positive and negative values of $|F|_{\text {obs. }}-|F|_{\text {calc. }}$ close to zero. No attempt at timing the photographs of different levels was made. As barium and manganese are the main constituents, the scattering factors of the other metallic elements were recalculated in terms of $f_{\mathrm{Ra}}$ and $f_{\mathrm{Mn}}$ respectively.

From the formula of hollandite I (see above) it appears that there are 8.9 metal ions and 16 oxygen + hydroxyl ions to place in the unit cell. As the structure is bodycentred there must be an even number of atomic sites in the cell, and it seems most probable that the metal ions are distributed over ten sites. In $C_{4 h}^{5}-I 4 / m$ there are two ways of combining the positions to give ten sites, either one twofold position + two fourfold positions or one twofold + one eightfold position. Only the possibilities $2(a)$ or $2(b)+8(h)$ lead to reasonable interatomic distances.

Now it seems more probable that $\mathrm{Ba}^{2+}, \mathrm{K}^{+}, \mathrm{Na}^{+}$and $\mathrm{Pb}^{2+}$ ions-in all 1.02 in the cell-are placed in $2(a)$ or $2(b)$ and the rest of the metal ions-in all $7 \cdot 86$-in $8(h)$, than to fill up $2(a)$ or $2(b)$ with $\mathrm{Mn}^{2+}$ or $\mathrm{Fe}^{3+}$ and place the rest of the ions- $6 \cdot 88$-in $8(h)$, as the difference in size between $\mathrm{Ba}^{2+}$ and $\mathrm{Mn}^{2+}$ (the largest of the medium-sized ions) is nearly twice the difference between $\mathrm{Mn}^{2+}$ and $\mathrm{Mn}^{4+}$. The following arrangement of the metal ions is then arrived at:
$\left(0,0,0 ; \frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right)+$
$1 \cdot 02(\mathrm{Ba}, \mathrm{K}, \mathrm{Na}, \mathrm{Pb})$ in $2(a)$ or $2(b): 0,0,0$ or $0,0, \frac{1}{2}$;
$7 \cdot 86(\mathrm{Mn}, \mathrm{Fe}, \mathrm{Al}, \mathrm{Si})$ in $8(h): x, y, 0 ; \bar{x}, \bar{y}, 0 ; \bar{y}, x, 0 ; y, \bar{x}, 0$.

A rough variation of the parameters showed that with $2 \pi x_{1}=115-125^{\circ}$ and $2 \pi y_{1}=55-65^{\circ}$. and the large atoms in $2(b)$, most of the calculated $F$ values agreed with those observed (compare columns 1 and 2 in Table 5). The other two possible tetragonal space groups $C_{4}^{5}-I 4$ and $S_{4}^{2}-I \overline{4}$ gave no further alternative for the arrangement of the metal ions in the $x, y$ plane. However, there appear some rather large discrepancies: the calculated $F$ value of 330 is very much too high and that of 301 too low, 420 should be weaker than 240 but is stronger, and 820 should be weaker than 280 and not stronger as calculated; but the oxygen atoms can be expected to have a rather large influence on the $F$ values.

An inspection of the available space shows that the 16 oxygen + hydroxyl ions can be arranged in two fundamentally different ways, either in planes at $z=\frac{1}{4}$ and $z=\frac{3}{4}$ forming a three-dimensional tetrahedron framework around the ions in $8(h)$, or at $z=0$ and $z=\frac{1}{2}$ forming a three-dimensional octahedron framework. With the former alternative $F(002)=77$ and with the latter $F(002)=192$. From a Weissenberg photograph of the $h h l$ reflexions it appeared that 002 was one of the strongest reflexions, much stronger than 660 with $F \doteqdot 100$, and that speaks definitely in favour of the alternative with octahedron framework, corresponding in $C_{4 h}^{5}$ to an arrangement with 16 oxygen + hydroxyl ions in $2.8(h)$ with the approximate parameters $2 \pi x_{2} \doteqdot 60^{\circ}, 2 \pi y_{2} \doteqdot 60^{\circ}, 2 \pi x_{3} \doteqdot 180^{\circ}$ and $2 \pi y_{3} \doteqdot 60^{\circ} . \mathrm{A}$ careful variation of all the parameters around the approximate values leads to the following structure:

$$
\text { Space group } C_{4 h}^{5}-I 4 / m
$$

$1.02(\mathrm{Ba}, \mathrm{Pb}, \mathrm{K}, \mathrm{Na})$ in $2(\mathrm{~b})$.
$7.86(\mathrm{Mn}, \mathrm{Fe}, \mathrm{Al}, \mathrm{Si})$ in $8(h):$

$$
\begin{array}{ll}
2 \pi x_{1}=125^{\circ} \pm 2^{\circ}, & x_{1}=0.348 \pm 0.005 \\
2 \pi y_{1}=60^{\circ} \pm 2^{\circ}, & y_{1}=0.167 \pm 0.005
\end{array}
$$

$16(\mathrm{O}+\mathrm{OH})$ in $2 \cdot 8(h):$
$2 \pi x_{2}=55^{\circ} \pm 3.5^{\circ}, \quad x_{2}=0.153 \pm 0.010$,
$2 \pi y_{2}=65^{\circ} \pm 3.5^{\circ}, \quad y_{2}=0.180 \pm 0.010$,
$2 \pi x_{3}=195^{\circ} \pm 3.5^{\circ}, \quad x_{3}=0.542 \pm 0.010$,
$2 \pi y_{3}=60^{\circ} \pm 3.5^{\circ}, \quad y_{3}=0.167 \pm 0.010$.
As will be seen from Table 5, the agreement between observed and calculated intensities is very satisfactory. The correctness of the oxygen positions is proved both by the disappearance of all the discrepancies mentioned above and by the fact that the quotient

$$
\frac{\Sigma\left||F|_{\text {obs. }}-|F|_{\text {calc. }}\right|}{\Sigma|F|_{\text {obs. }}}
$$

is decreased from 0.29 to $0 \cdot 19$ when reckoning with the oxygen atoms.

## 4. Discussion of the structure

With the above-mentioned parameter values the following interatomic distances are obtained. (In these calculations the dimensions from the Weissenberg photo-
graphs $a_{t}=9 \cdot 96 \pm 0.05$ and $c_{t}=2 \cdot 86 \pm 0.01 \mathrm{~A}$. were used):

$$
\begin{array}{ll}
\text { In the same plane } & \text { In different planes } \\
4\left(\mathrm{Ba}-\mathrm{O}_{2}\right)=3.31 \mathrm{~A} . & 8\left(\mathrm{Ba}-\mathrm{O}_{1}\right)=2.74 \mathrm{~A} . \\
1\left(\mathrm{Mn}-\mathrm{O}_{1}\right)=1.94 \mathrm{~A} . & 2\left(\mathrm{Mn}-\mathrm{O}_{1}\right)=2 \cdot 12 \mathrm{~A} . \\
1\left(\mathrm{Mn}-\mathrm{O}_{2}\right)=1.93 \mathrm{~A} . & 2\left(\mathrm{Mn}-\mathrm{O}_{2}\right)=1.90 \mathrm{~A} . \\
1\left(\mathrm{O}_{1}-\mathrm{O}_{1}\right)=3.33 \mathrm{~A} . & 2\left(\mathrm{O}_{1}-\mathrm{O}_{1}\right)=2.88 \mathrm{~A} . \\
1\left(\mathrm{O}_{2}-\mathrm{O}_{2}\right)=3.44 \mathrm{~A} . & 2\left(\mathrm{O}_{2}-\mathrm{O}_{2}\right)=2.81 \mathrm{~A} . \\
1\left(\mathrm{O}_{1}-\mathrm{O}_{2}\right)=3.88 \mathrm{~A} . & 2\left(\mathrm{O}_{2}-\mathrm{O}_{1}\right)=2.61 \mathrm{~A} . \\
1\left(\mathrm{O}_{2}-\mathrm{O}_{1}\right)=2.77 \mathrm{~A} . & 2(\mathrm{Mn}-\mathrm{Mn})=2.93 \mathrm{~A} .
\end{array}
$$

Further, there are the distances $\mathrm{Ba}-\mathrm{Ba}, \mathrm{Mn}-\mathrm{Mn}, \mathrm{O}-\mathrm{O}$ equal to $c(=2 \cdot 86$ A.).

As will be seen from Fig. 1, the oxygen and hydroxyl ions form octahedra around the manganese ions. As in ramsdellite (Byström, 1949) these octahedra are linked together to form double strings running in the $c$ direction, the octahedra in one string sharing an edge with two consecutive octahedra from the other string. In each string the octahedra share opposite edges in the $c$ direction. The double strings are combined to a threedimensional framework by sharing corners. The large ions at $0,0, \frac{1}{2}$ and $\frac{1}{2}, \frac{1}{2}, 0$ are surrounded by eight $\mathrm{O}_{1}$ ions, situated at the corners of a slightly distorted cube with $M-\mathrm{O}=2.74 \mathrm{~A}$., and four $\mathrm{O}_{2}$ ions at 3.31 A ., the latter at the corners of a square, which is perpendicular to the $c$ axis and bisects the sides of the cube. The sum of the bond strengths is 2.0 for the $\mathrm{O}_{1}$ ions and 1.9 for the $\mathrm{O}_{2}$ ions, in very good agreement with expected values.

Fig. 1. The structure of hollandite projected on (001). Open circles denote ions at the level $z=0$ and filled circles ions at the level $z=\frac{1}{2}$.

The mean distance $\mathrm{Mn}-0$ is 1.98 A . In the two modifications of $\mathrm{MnO}_{2}$ whose structures have hitherto been determined, pyrolusite and ramsdellite, the $\mathrm{Mn}-\mathrm{O}$ distances are slightly shorter, being 1.88 A . for pyrolusite and 1.89 A . for ramsdellite, but then the amount of lower-valency ions in hollandite ( $\mathrm{Fe}^{3+}, \mathrm{Mn}^{2+}$ ) must cause an increase of these distances. The increase is larger than expected, but this may be owing to parameter errors.

However, the most peculiar feature in the hollandite structure is doubtless the short $\mathrm{Ba}-\mathrm{Ba}$ distances of 2.86 A., i.e. only a little more than twice the ionic radius of the $\mathrm{Ba}^{2+}$ ion. Now it is true that the position $2(b)$ is only filled to $50 \%$, but there is still a possibility of $25 \%$ for Ba ions in adjacent positions. It seems that an arrangement with half as many atomic sites but all
filled in a larger unit cell would be preferable. This is possible in a primitive cell with the $c$ axis $2 \times 2.86$ A., but in none of the rotation photographs of different hollandites is there any indication of an extra layer line nor any reflexions with $h+k+l=2 n+1$. Thus it can be stated that the former arrangement with short $\mathrm{Ba}-\mathrm{Ba}$ distances statistically in every fourth cell is preferable. These short $\mathrm{Ba}-\mathrm{Ba}$ distances may be one of the reasons why the hollandite structure always seems to have a tendency to disorder, manifested by the fact that the reflexions in the powder photographs are broadened, which is also the case for cryptomelane. Only for coronadite with somewhat smaller $\mathrm{Pb}^{2+}$ ions are powder photographs of normal sharpness obtained. That the large ions are loosely bound is also demonstrated by the fact that the $\alpha-\mathrm{MnO}_{2}$ preparations show cation exchange like the zeolite minerals (Gruner, 1943). This will be discussed in a later section.

Besides the positions occupied by the barium and manganese ions in hollandite there are possible metal atom sites at $0, \frac{1}{2}, z$ and $\frac{1}{2}, 0, \bar{z}$. With $z=\frac{1}{4}$ these positions are surrounded tetrahedrally by four oxygen ions at 1.8 A. (There are such holes at both $z=\frac{1}{4}$ and $z=\frac{3}{4}$, but the $M-M$ distance would be only $\frac{1}{2} c=1 \cdot 43 \mathrm{~A}$., which seems improbably short.) The distance to adjacent Mn ions would be $2 \cdot 2$ A., a rather short distance, but not impossible. However, careful intensity calculations indicate that these positions are not occupied in hollandite.

## 5. The monoclinic cell of hollandite

As was shown above, the powder photographs indicate that the unit cell of hollandite is often slightly deformed to monoclinic symmetry. The structure can be described in $C_{2 h}^{3}-I 2 / m$ with the barium ions in $2(b)$ and the manganese ions and the oxygen ions in $4(i)$. Because of the small deviation from tetragonal symmetry (see above), it is possible to give correct signs to nearly all the structure factors. A Fourier analysis can then be carried out to show how the parameters should be adjusted. This will be discussed in a later paper.

## 6. Cryptomelane and coronadite

Powder photographs of cryptomelane from Tombstone, Arizona, and coronadite from Bou Tazoult, Morocco, showed no deviations from tetragonal symmetry. The cell dimensions were calculated to be

$$
a=9.84, \quad c=2 \cdot 858 \text { A. for cryptomelane }
$$

and $a=9.89, \quad c=2.862 \mathrm{~A}$. for coronadite.
As will be seen from Table 2 the agreement between observed densities and those calculatedwith $16(\mathrm{O}+\mathrm{OH})$ ions in the cell is very good. The statement that these specimens are both tetragonal is obviously true within the limits of the resolving power of the powder cameras. The photographs were taken with focusing cameras of Phragmén type. The maximum difference in length between $a_{t}$ and $b_{t}$ (or rather $a_{m}$ and $c_{m}$ if a difference
really exists) is for cryptomelane about 0.02 A . and for coronadite $0.005-0.01 \mathrm{~A}$. The deviation of the angle from $90^{\circ}$ is in the former case $\leqslant 0 \cdot 3^{\circ}$ and in the latter case $\leqslant 0 \cdot 1^{\circ}$.

## 7. The general formula of the minerals

The general formula $A_{2-y} B_{8-z} X_{16}$, is apparently sug. gested by the structure.* $A$ represents large ions ( $\mathrm{Ba}^{2+}, \mathrm{Pb}^{2+}, \mathrm{K}^{+}, \mathrm{Na}^{+}$chiefly) and $B$ small ions, chiefly $\mathrm{Mn}^{4+}$, which to balance the formula is substituted by ions like $\mathrm{Fe}^{3+}, \mathrm{Mn}^{2+}$ (or $\mathrm{Mn}^{3+}$ ), $\mathrm{Zn}^{2+} . y$ is always approximately unity in the minerals hitherto investigated, and must probably be so at least in the barium and potassium compounds because of the short $A-A$ distances (see above). In the four minerals discussed here, $z$ falls within the limits $0 \cdot 1-0 \cdot 5$. $X$ represents anions which are O or OH in the minerals of this series here investigated, the amount of OH ranging from 5 to $12 \%$ in the minerals hitherto discussed. Of other anions $\mathbf{F}$ is of the size to be accommodated in these positions.

From Gruner's general formula it follows that there are sixteen oxygen ions in the cell and that the number of water molecules + number of $\mathrm{Ba}, \mathrm{Pb}, \mathrm{K}, \mathrm{Na}$ ions is two, thus indicating that the water molecules (the $\mathrm{H}_{2} \mathrm{O}^{+}$ water in the analyses) and the large ions together occupy a twofold position. This assumption leads to a different formula for the minerals (Table 2), but the difference is too small to affect the intensities measurably. However, $\mathrm{H}_{2} \mathrm{O}$ molecules in the same position as the barium atoms in hollandite would give eight $\mathrm{O}-\mathrm{H}_{2} \mathrm{O}$ distances of 2.74 A. These short distances must imply hydrogen bonding, but there are only two hydrogen atoms, which thus must be distributed among eight bonds. It seems that in such a case longer $\mathrm{O}-\mathrm{H}-\mathrm{O}$ distances would be expected, as the $\mathrm{O}-\mathrm{H}-\mathrm{O}$ distance in diaspore (Ewing, 1935), with one bond per hydrogen atom, is 2.65 A ., thus only slightly shorter, whereas in ramsdellite (Byström, 1949), without hydrogen bonds, but with the same structure, the $0-0$ distance is increased to about $3 \cdot 3$ A. It may also be pointed out that in the zeolites (according to Gruner the water in cryptomelane is of zeolitic nature) the water molecules are surrounded by only two oxygen ions or other water molecules and one or two positive ions (Bragg, 1937).

Gruner has shown that his formula gives fairly good agreement between observed and calculated densities. In these calculations he has, however, omitted the water in the analyses, in spite of the fact that he declares that only a small part of it can be adsorbed. We have recalculated the densities with his formula, including the water, and the results are shown in Tables 2 and 3. The

[^0]difference $\left\{\left(d_{\text {calc. }}-d_{\text {obs. }}\right) / d_{\text {obs. }}\right\} \times 100$ is shown below for the two alternatives:

|  |  | Hollandite I | Hollandite II |
| :---: | :---: | :---: | :---: |
| Diff.Gruner Diff.Byström | (\%) | $3 \cdot 1$ | $2 \cdot 1$ |
|  | (\%) | $0 \cdot 3$ | $-1.7$ |
|  |  | Coronadite | Cryptomelane 1 |
| Diff.gruner | (\%) | $5 \cdot 2$ | $5 \cdot 3$ |
| Diff. Bystrom | (\%) | -0.4 | $-1.4$ |

For the specimens in Table 3 we have not, because of lack of material, been able to control the cell dimensions, but have taken values from comparable minerals with the following results:

| Diff. Gruner Diff. Byatröm | $\begin{aligned} & (\%) \\ & (\%) \end{aligned}$ | Hollandite (Kajlidongri) |  | Coronadite |
| :---: | :---: | :---: | :---: | :---: |
|  |  |  |  | 7 |
|  |  |  |  | $3 \cdot 4$ |
|  |  | Cryptomelane |  |  |
|  |  | 2 | 3 | 4 |
| Diff.Gruner | (\%) | 1.8 | $2 \cdot 7$ | $7 \cdot 7$ |
| Diff. ${ }_{\text {Byatröm }}$ | (\%) | $-2.3$ | -6 | $-3 \cdot 1$ |

As will be seen, Gruner's formula leads to a larger difference between observed and calculated densities in six out of nine cases and to better agreement in only one case. As also structural reasons make Gruner's hypothesis for the water distribution suspicious, it seems that our suggestion with the water as hydroxyl ions among the oxygen ions is the correct one. However, it is possible that in several cases (those with larger observed than calculated densities) part of the water present is adsorbed, which would lead to higher calculated densities.

Just those specimens for which the differences $d_{\text {calc. }}-d_{\text {obs. }}$ are negative and large, are optically isotropic and give broadened X-ray reflexions. This hints that the crystallites are of the dimensions $<(1000)^{3} \mathrm{A.}^{3}$. If we assume that one water molecule can be adsorbed by each ion on the surface of the crystallites $\left(\mathrm{H}_{2} \mathrm{O}\right.$ being a dipole), the amount of the adsorbed water for $V \sim 1000^{3} \mathrm{~A} .^{3}$ will be approximately $1 \%$. If the crystallites are only $500^{3} \mathrm{~A}^{3}{ }^{3}$, approximately $2 \% \mathrm{H}_{2} \mathrm{O}$ can be adsorbed. The calculated densities agree with those observed for cryptomelane 2,3 and 4 if we assume that 50,70 and $40 \%$ respectively of the water $\left(\mathrm{H}_{2} \mathrm{O}^{+}\right)$is present as adsorbed water, corresponding in weight percentages to $0.9,2.3$ and $1.3 \%$. As will be seen, the crystallites in the specimen cryptomelane 2 must be very small to allow such an adsorption. Apparently, the presence of such an adsorbed layer of water on the surfaces of the crystallites does not prevent the specimens from looking massive and compact. Included water may influence the results, but it seems that water of that type must be driven off at temperatures below $110^{\circ} \mathrm{C}$., and here only $\mathrm{H}_{2} \mathrm{O}^{+}$water is discussed.

As is shown in Table 3, the sum of numbers of Al, Mn and Fe ions in the hollandite from Kajlidongri is larger than eight $(8 \cdot 46)$. It is rather improbable that the surplus of these ions would occupy the vacant sites in

Table 3. Calculated atomic contents and densities of unit cells based on (a) ( $\mathrm{O}+\mathrm{OH}=16$ ) and (b) $\mathrm{O}=16$

[^1]$2(b)$. This specimen is also remarkable, because of the fact that no water is present. As the analysis was carried out in a tent, it seems that the values are not quite reliable, and a new analysis is desirable.

Gruner also gives other reasons why the 0 of the water differs structurally from the other oxygen ions in the compound. None of his reasons, however, is in contradiction to the formula suggested by us. The fact that practically all the water can be driven off without collapse of the structure indicates that at the same time part of the bivalent (or tervalent) Mn ions are oxidized to tetravalent Mn , and thus the number of anions in the unit cell is maintained. For some of the specimens listed in Tables 2 and 3, the $\mathrm{Mn}^{2+}$ content is lower than this explanation would imply (cryptomelane 1 in Table 2 and cryptomelane 3 and 4 in Table 3). It is, however, just those specimens where the adsorption probably is great. A study of the change of cell dimensions and densities after driving off the water would be desirable, and if we can obtain material for such an investigation it will be made.

However, if Gruner's assumption that the water is of zeolitic nature is correct, the water should be regained as easily as it is driven off, and all or practically all of it should be readsorbed, which is not the case, as is evident from Gruner's own experiment. The behaviour of the specimen from Romanèche is just what would be expected if our explanation is valid.

## 8. $\alpha-\mathrm{MnO}_{2}$

Evidently from the isostructural relationship between $\alpha-\mathrm{MnO}_{2}$ and hollandite, it follows that $\alpha-\mathrm{MnO}_{2}$ must hold some large ions, as, for example, $\mathrm{K}^{+}$, to prevent the structure from collapsing. The necessity of $\mathrm{K}^{+}$ions for the formation of $\alpha-\mathrm{MnO}_{2}$ has been pointed out by Cole et al. (1947).
Gruner's experiment on the cation exchange of $\alpha-\mathrm{MnO}_{2}$ shows that $\mathrm{Ag}^{+}$ions enter the structure more readily than the larger $\mathrm{Pb}^{2+}$ and $\mathrm{Ba}^{2+}$ ions. This is evidently what is to be expected from the structure, as the short $A-A$ distances of about 2.8 A . must lead to a certain instability of the structure, because of strong repulsive forces between the cations, and these forces must apparently be less for the smaller ions. In accordance with this the twofold position can be filled to a larger extent with a larger number of adjacent $A$ ions, when these ions are smaller and of less valency, i.e. as is the case for $\mathrm{Ag}^{+}$compared with $\mathrm{Pb}^{2+}$ and $\mathrm{Ba}^{2+}$.

## 9. A comparison of the structures of $\alpha-\mathrm{MnO}_{2}$, $\beta-\mathrm{MnO}_{2}, \gamma-\mathrm{MnO}_{2}$ and ramsdellite

As will be seen from Fig. 3, the network of oxygen octahedra is principally the same in $\beta-\mathrm{MnO}_{2}$ (pyrolusite) and ramsdellite. In $\beta-\mathrm{MnO}_{2}$ every other octahedron is occupied by a Mn ion both in the $a$ and $b$ directions. However, in ramsdellite there are pairs of occupied and unoccupied octahedra in the $b$ direction, but in the $a$
direction every other octahedron is filled. Obviously, in $\alpha-\mathrm{MnO}_{2}$ the $a$ and $b$ directions of pyrolusite and ramsdellite corresponds to [110] and [110] (Fig. 2). Some of the oxygen atoms in the network are substituted with $\mathrm{K}^{+}$ions, but if octahedron chains are considered, in which the $\mathrm{K}^{+}$ions do not take part, we find in both the [110] and [110] directions pairs of occupied and unoccupied octahedra, as in the $b$ direction in ramsdellite.

Fig. 2. The network of oxygen octahedra in hollandite projected on (001).

Fig. 3. The network of oxygen octahedra in pyrolusite (to the left) and ramsdellite (to the right) projected on (001). The circles denote Mn ions.

There is also a close similarity in the corresponding spacings. Along [110] in $\alpha-\mathrm{MnO}_{2}$ we find six octahedra and along [010] in ramsdellite four. The length of [110] is $\sqrt{ } 2 \times 9 \cdot 8 \mathrm{~A}$., and recalculated on four octahedra this corresponds to $\frac{4}{6} \sqrt{ } 2 \times 9 \cdot 8=9 \cdot 2$ A., to be compared with $9 \cdot 27 \mathrm{~A}$. for the $b$ axis in ramsdellite.
The structure of $\gamma-\mathrm{MnO}_{2}$ has not been definitely established (Cole et al. 1947; Byström, 1949), but it seems that the structure is partly disordered, and possibly the arrangement of the Mn ions changes from ramsdellite to pyrolusite at random.* The cell dimen-

sions of $\gamma-\mathrm{MnO}_{2}$ indicate that the ramsdellite arrangement dominates. Attempts will be made to calculate the percentage of each arrangement from the intensity and broadening of the reflexions.

A large number of syntheses shows that by the precipitation of manganese dioxide, either $\alpha-\mathrm{MnO}_{2}$ or $\gamma-\mathrm{MnO}_{2}$ is obtained. A possible explanation is that the primary product by these precipitations is the double strings, which are common for the $\alpha-\mathrm{MnO}_{2}$ and ramsdellite structures. If large ions are present, the double strings cluster together around these in the $\alpha-\mathrm{MnO}_{2}$ manner. These precipitates, after annealing at low temperature or after hydrothermal treatment, show the reflexions of an undeformed hollandite structure. If no large ions are present (or if the concentration is too low), the double strings are knitted together to a rams-dellite-like arrangement. However, by the annealing of these precipitates by boiling with water, there is a tendency for the Mn ions to change positions to those of pyrolusite, and thus a partly disordered structure results. If the annealing temperature is $\operatorname{high}\left(300^{\circ} \mathrm{C}\right.$.), a complete transformation to pyrolusite occurs.

The investigation forms part of a work on metallic
oxides, financially supported by the Swedish Natural Science Research Council. One of the authors (A. B.) is indebted to the Fund Lars Hiertas Minne for a grant.

[^0]:    * An extension of the general formula is possible if the tetrahedral atomic sites discussed in the previous section are filled. If $C$ represents small ions with radius 0.4 A ., the formula will be: $A_{2-y} B_{8-z} C_{2-u} X_{16}$.

[^1]:    v.w. = very weak, w. = weak, $m .=$ moderately strong, st. = strong, v.st. = very strong, br. = broadened.

[^2]:    * In a recent paper McMurdie (1948) concludes from powder photographs that $\gamma-\mathrm{MnO}_{2}$ must have a disordered pyrolusite structure. However, from the spacings it is obvious that the substance which he has called $\gamma-\mathrm{MnO}_{2}$ is not identical with the oxide called $\gamma-\mathrm{MnO}_{2}$ by Cole et al. (1947) and by Byström (1949), but is rather a poor $\beta-\mathrm{MnO}_{2}$ preparation.
