The Crystal Structure of Proto-enstatite, MgSiO₃*

By J. V. Smith

Department of Mineralogy and Petrology, Division of Earth Sciences, The Pennsylvania State University, University Park, Pennsylvania, U.S.A.

(Received 5 November 1958)

Proto-enstatite, at room temperature, is orthorhombic with 8 units of MgSiO₃ in a cell of dimensions a = 9.25, b = 8.74, c = 5.32 Å, pseudo space group *Pbcn*. The atomic coordinates of the pseudo space group were determined from X-ray powder data. The SiO₃ chain is fully extended. One of the Mg atoms has an irregular coordination, which may be the reason for the instability of proto-enstatite at low temperature. The structure is very similar to that predicted by Atlas (1952).

Proto-enstatite is one of the five forms of MgSiO₃ that have so far been described (see Atlas, 1952 for literature survey). Only three of the five have been thought to have a field of stability-rhombic enstatite, clino-enstatite and proto-enstatite. Determination of the phase relations is difficult because of the sluggishness of the transformations between rhombic enstatite and the other two forms, and because of the ease of the inversion between the proto- and clinoforms. Whether clino- or proto-enstatite is the stable form at high temperature or whether both have a field of stability is still open to doubt, (Atlas, 1952; Foster, 1951; Boyd & Schairer, 1957), but it is certain that rhombic enstatite is the form stable at low temperatures and that proto-enstatite is unstable at the temperature of this structure determination. Protoenstatite changes into clino-enstatite upon heating at 1400 °C., upon long standing at room temperature, and upon grinding. Thus the structure of the two forms must be related and, indeed, Atlas has used this as a basis for predicting a crystal structure for protoenstatite.

This investigation has three objectives: establishing reliable crystallographic data for proto-enstatite, providing information on the atomic movements that occur during the phase transformations of $MgSiO_3$ and looking for a structural reason why stress can markedly effect the transformation for proto- to clinoenstatite. In this paper the first objective will be described: the second and third will be discussed later in collaboration with Dr N. Morimoto, who is currently engaged on a refinement of the structure of clino-enstatite.

The author is indebted to Dr F. R. Boyd of the Geophysical Laboratory, Washington, D.C. for attempting to grow large crystals of proto-enstatite. In spite of considerable labour, all attempts were unsuccessful and the structure determination has had, perforce, to be carried out on a powder sample. The conditions of crystallization were: treatment of an

 $MgSiO_3$ glass in a hydrothermal bomb at 1080 °C. for four days at 500 bars H_2O .

Crystallographic data

The X-ray powder diffraction pattern (Table 1) was indexed on an orthorhombic cell with

$$a = 9.25, b = 8.74, c = 5.32 \text{ Å} (\pm 0.005).$$

Atlas obtained values of 9.25, 8.92, 5.25 Å for a specimen inverted from an iron- and aluminium-bearing anthophyllite. All reflections but one, (210), would obey the rules for the space group *Pbcn*, although little reliance could be placed on this pseudo space group because of the low number of unequivocally indexed reflections in the principal zones. The axes x and y should be interchanged to conform to common usage: however, the above order of axes is given to show the relation to clino-enstatite whose 8.8 Å axis is the symmetry axis. The volume of the unit cell is 430 Å³ and the calculated specific gravity for 8 units of MgSiO₃ is 3.10.

Intensity data were obtained from powdered crystals smeared on a glass slide that was mounted on a diffractometer. Cu $K\alpha$ radiation and a proportional counter were used. The counter was moved at a rate of $0.1^{\circ} 2\theta$ per minute and the total number of counts printed out ten times per minute. A profile of each peak was plotted and the integrated intensity obtained. At low angles no difficulty was experienced in estimating the background level, but at angles greater than 2θ 30° the background was irregular, possibly because of the presence of peaks too small for recognition but sufficiently large for an upset of the background level. Above 2θ 70° the reflections were so irregular and difficult to index that no measurements were made. Divergence slits of 4° were used so that all the specimen was irradiated at all angles, permitting a simple correction for the Lorentz-polarization factor.

Measurements of lattice spacings and peak intensities (Table 1) for the X-ray Powder Data File were

^{*} Contribution No. 58-15, College of Mineral Industries.

Table 1. Powder data

Values of I are the peak intensities measured with a Geiger counter diffractometer with specimen fully irradiated at all angles. pF^2 values were determined from the integrated intensities given by a proportional counter, after correction for the Lp factor. 1, 2, 3: three principal lines in order of peak intensity. Resolution of doublet begins at 32 degrees.

made with a Geiger-counter diffractometer using the same geometry as for the collection of integrated intensities. To calibrate the diffractometer, a separate smear mount of pure silicon of similar thickness to that of proto-enstatite was used, and the cell dimension a 5.4306 Å was assumed for the silicon. Tests have shown that this calibration method, if carefully applied, results in errors not greater than 0.02° in 2θ . The three strongest peaks of clino-enstatite were observed, indicating a proportion of about 5–10%. The I and pF^2 values in Table 1 differ for several reasons: rounding-off of the I values, Lorentz-polarization factor, peak versus integrated character, and random error.

Structure determination

It was obvious that when only one reflection did not obey the indicated pseudo space group, it would be necessary to ignore it and develop the average structure for the pseudo space group. Furthermore some simplifying assumptions had to be made in the adjustment of the atomic coordinates, for the customary process of automatic refinement by F-series was not possible. In many respects the structure determination was analogous to those carried out in the early nineteen-thirties.

The first simplifying assumption arose from a comparison of the repeat unit c with that for a chain of silicon-oxygen tetrahedra. By analogy with the other forms of MgSiO₃ it was obvious that an $(SiO_3)_{\infty}$ chain of the pyroxene type lay along the c-axis. Fortunately, it was possible to deduce that the chain in proto-enstatite was fully extended, for the length 5.32 Å, is actually slightly greater than that to be expected for a fully extended chain with the usual Si-O distances. For a regular tetrahedron the Si-O distance that corresponds to the 5.32 Å chain repeat is 1.63 Å, somewhat larger than the value of 1.60 Å, found in framework structures (Smith, 1954). Probably the tetrahedron is slightly distorted because of the unsymmetrical coordination.

The second simplifying assumption concerned the shape of the tetrahedron. As adjustment of the atomic coordinates, based on structure factor calculation, could not be expected to go beyond 0.1 Å, more accurate coordinates could be obtained by assuming a regular shape for the silicon-oxygen tetrahedra and using the standard distances which would be expected to be accurate to 0.03 Å. From this and the first assumption, the position of the chain could be specified by only three coordinates, if the space group were *Pbcn*. As the Mg atoms could either lie in one 8-fold position with three parameters or two 4-fold positions with one parameter each, this left only five or six variable parameters.

A few trials using *Pbcn* soon gave the coordinates for proto-enstatite (Table 2). Adjustment of the coordinates was as follows: the x and y coordinates were adjusted by use of the hk0 reflections. Four paraTable 2. Effect on structure factors of the Mg_1 atom

	y =	= 0.265

The F_o values differ slightly because a different scaling factor has been used to make $\Sigma F_c = \Sigma F_o$.

meters are involved: the y coordinates of the two Mg atoms, and the two coordinates which specify the position of the chain. The position of the Mg_I atom is crucial to the discussion of the stability of the structure, so the effect of varying its position is shown in Table 2. Change of the y-coordinate from 0.265 to 0.29 has a marked effect on the agreement between the calculated and observed structure factors and it seems safe to say that the y-coordinate is less than 0.29. The only remaining coordinate that required adjustment is the z-coordinate of the chain. Significant discrepancies developed when the z-coordinate was changed from 0.07 to 0.05 or 0.09 and these are regarded as the limits of error.

Assessment of the accuracy of the coordinates is not easy. The value of $\Sigma(F_o^2 - F_c^2)/\Sigma F_o^2$ is 0.36 corresponding to an *R*-value of about 0.2. This is quite satisfactory for a structure with pseudo-symmetry but provides little basis for assessing accuracy. It is thought that the distances Mg–O and O–O are probably accurate to 0.1 Å and unlikely to be wrong by more than 0.2 Å.

Discussion

The structure displayed in Figs. 1, 2 and 3 is almost identical with that proposed but not proved by Atlas, testifying to the excellent use made by him of qualitative considerations. Only in one respect is his description of the structure in error: his structure like the one described here has symmetry *Pbcn* not the *Pbc2* listed in his paper.

Possibly the most informative diagram is Fig. 3 where the familiar trapezium-shaped cross-sections of the pyroxene chain are visible in the xy projection. Each Mg atom lies in a polyhedron of six oxygen atoms arising from four different chains. In Fig. 1 the chains are seen lengthways on in the familiar position with the vertices pointing upwards (or downwards). The packing of the oxygen atoms shows up

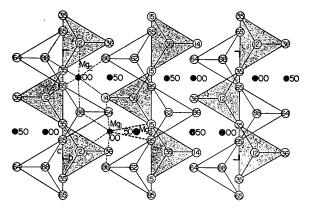

Fig. 1. *a*-axis projection: open circles, oxygen atoms; solid circles, magnesium atoms; silicon atoms omitted. Half of the $(SiO_3)_{oo}$ chains are stippled. The two longer distances in the Mg₁-O polyhedron are shown by heavy dashed lines: all other Mg-O bonds by light dashed lines. The numbers give the *x* parameters in hundredths.

very neatly in this projection. The oxygen atoms lie closely on four levels $z \simeq 0.15$, 0.35, 0.65, and 0.85, such that each level contains the 'basal' oxygen atoms of one chain and the 'vertical' oxygen atoms of another chain. The Mg atoms lie at 0.00 and 0.50 in octahedra, three of whose oxygen atoms come from one layer and three from another layer. For the Mg₂ atom the oxygen atoms fall closely at the corners of an octahedron, but for the Mg, atom the arrangement is quite distorted. The third projection (Fig. 2) gives another view of the length of the chain. The symmetrical arrangement of the chains is especially well displayed in this projection, as is the way in which the coordination of the Mg₂ atom depends on the stagger between the chains in the upper and lower halves of the unit cell.

Probably the most interesting aspect of the struc-

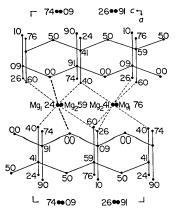

Fig. 2. b-axis projection: small solid circles, oxygen and silicon atoms; large solid circles, magnesium atoms. For clarity, the adjacent $(SiO_3)_{\infty}$ chains and the adjacent Mg atoms have been moved slightly apart. The two longer distances in the Mg₁-O polyhedron are shown by heavy dashed lines, all other Mg-O bonds by light dashed lines. The corners of the unit cell are shown, and the y-coordinates in hundredths of the cell edge.

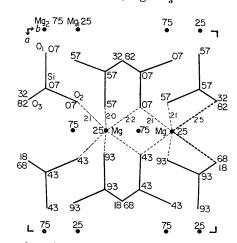

Fig. 3. c-axis projection. The silicon and oxygen atoms lie at the ends and intersections of the heavy lines, which act as skeletons for the familiar trapesium-shaped cross-sections of pyroxene chains. In the upper left one set of Si and O atoms are labelled. Magnesium atoms are shown by solid circles and the bonds to oxygen atoms by broken lines. The Mg-O distances are given in Å, the longer ones being emphasized by the heavier broken lines. The z-coordinates of all the atoms are shown, and the corners of the unit cell depicted.

ture is the coordination of the Mg atoms. That of the Mg₂ atom is almost perfectly octahedral with distances Mg-O two each of 2.0, 2.1, 2.2 Å, in agreement with the standard value. That of the Mg₁ atom is quite different and is thought to be the weak spot, the Achilles heel, of the structure. The nature of the coordination is most easily seen from Fig. 1. The Mg,

Table 3. Atomic coordinates

	Mg_1	Mg_2	Si	0 ₁	O_2	03
x	0.000	0.000	0.292	0.118	0.359	0.348
$y \\ z$	$\begin{array}{c} 0.265 \\ 0.250 \end{array}$	$0.087 \\ 0.250$	0·091 0·07	0·097 0·07	0∙259 0∙07	0∙000 0•32

atom at height 0.00 lies below three oxygen atoms at a height of 0.14 of thereabouts and above three atoms at a height of 0.86 or thereabouts. For regular octahedral coordination the oxygen atoms would have to lie alternately up and down as a circuit of the Mg atom were made, a condition not obeyed by the Mg₁ atom. Four of the Mg₁-O distances are 2.1 Å, in agreement with the expected value for an Mg octahedron, but the other two are 2.5 Å. Reference was made earlier to the importance of the y coordinate of the Mg₁ atom. It may be seen from Fig. 3 that the long Mg-O distance is largely dependent on only one

Table 4. Interatomic distances (Å)

Si-O1	1.61	Mg_1-O_1	2.07	0 ₁ -0''	3.12
$Si-O_2$	1.59	$Mg_1 - O_2$	2.15	$O_1 - O_2$	2.80
$Si-O_3$	1.63	$Mg_1 - O_3$	2.52	$0_{1}^{1} - 0_{2}^{7}$	2.96
$0_{1} - 0_{2}$	2.64	$Mg_2 - O_1$	2.02	$O_1^{1} - O_3^{2}$	3.24
$0_{1} - 0_{3}$	2.65	$Mg_2 - O_1'$	2.17	$O_{3}^{1} - O_{3}^{2}'$	2.91
$O_2 - O_3$	2.63	Mg ₂ -O ₂	2.11	$Mg_1 - Mg_2$	3.08
$O_{3}-O'_{3}$	2.66	$O_1 - O_1'$	3.14	$Mg_1 - Mg_2'$	3.08

parameter, the y coordinate of the Mg₁ atom. Calculations show (Table 2) that increase of the y coordinate from 0.265 to 0.29 gives a significant worsening of the agreement between the observed and calculated structure factors. This change of the coordinate reduces the distance Mg_1-O_3 only from 2.5 to 2.3 Å, still leaving a value greater than the 2.1 Å value for all the other Mg-O distances. Thus it is taken that this distance is genuinely much longer than the other ones around the Mg₁ atom. The long distance goes to the O_3 atom, which is already bonded to two silicon atoms and which, on a strict interpretation of the valence bond rule, should already be satisfied by the bonding to the silicon atoms. Thus it is not surprising to find the Mg_1 atom further away from the O_3 atoms than from the O_1 and O_2 atoms. Nevertheless the coordination is very irregular, especially as the two long distances are adjacent in the Mg₁ polyhedron, and is regarded as the weak point of the structure.

Clino-enstatite, the monoclinic form of $MgSiO_3$, also shows pseudo-symmetry, the true lattice being primitive and the pseudo-lattice C face-centered. Although a detailed analysis of the pseudo-symmetry of clino-enstatite must await the completion of the structure refinement by Dr N. Morimoto, it seems safe to say that the pseudo-symmetry arises from a slight collapse and twisting of the silicon-oxygen chains about the relatively small Mg ions. In diopside, the type structure of monoclinic pyroxenes, the Ca ions are sufficiently large to hold the structure in the more symmetrical arrangement. The irregular shape of the Mg_1 polyhedron of proto-enstatite in which the Mg_1-O_3 distances are greater than normal indicates that the pseudo-symmetries of both proto- and clinoenstatite arise from the relative smallness of the Mg ion.

At higher temperatures, where proto-enstatite may be the stable form of $MgSiO_3$, the Mg_2 atom along with other atoms will be vibrating considerably more and should fill the cavity more effectively. Furthermore, the known increase of solid solution with higher temperatures for many compounds shows that structural tolerance for valence mis-balance and size discrepancy is generally greater. For these two reasons, it is thought that the poor coordination of the Mg_1 atom will become of lesser importance at higher temperature, allowing proto-enstatite to become more stable.

The cooperation of Drs F. R. Boyd, N. Morimoto and J. F. Schairer of the Geophysical Laboratory was most valuable. This investigation forms part of a programme of fundamental research on the pyroxenes, supported by the National Science Foundation.

The Crystal Structure of Sr₄PtO₆ and Two Related Compounds*

BY JOHN J. RANDALL, JR. AND LEWIS KATZ

Department of Chemistry, The University of Connecticut, Storrs, Connecticut, U.S.A.

(Received 30 October 1958 and in revised form 5 January 1959)

The crystal structure of Sr_4PtO_6 has been determined by a trial and error method. The crystals are trigonal with space group $R\bar{3}c$; the triply primitive hexagonal cell dimensions are a = 9.74, c = 11.90 Å. The platinum ions are octahedrally coordinated with oxygen and are linked in the c direction through strontium ions surrounded by trigonal prisms of oxygens. These strings of coordination polyhedra are connected laterally by strontiums in eight fold coordination with oxygen. This structure is of the same type as that reported for K_4CdCl_6 . The isolation of one PtO_6 group from the next is postulated as a reason for the ease of hydrolysis of the compound. Sr_4IrO_6 and Sr_4RhO_6 have the same structure.

Introduction

In the course of an investigation of the interaction of the alkaline earth oxides with platinum metal oxides, we have prepared and studied compounds with the formulas Sr_4PtO_6 , Sr_4IrO_6 , and Sr_4RhO_6 .[†] Powder photographs indicated that these compounds had essentially the same structure. In contrast to the behavior of most ternary oxides, these compounds
